a) 0.25 mm-thick cellulose plate; dioxane–water (15: 4 v/v). For details see the Experimental section.

acid and 4-methylaniline-*N*,2-disulfonic acid were soluble in non-polar solvents such as chloroform and carbon tetrachloride as well as in polar solvents. This solubility behavior is in marked contrast with that of the corresponding alkylammonium and metal salts. Furthermore, it is noteworthy that the phosphonium salts were remarkably stable toward hydrolysis, being comparable to the metal salts; that is, no hydrolysis was observed even after 0.5 h boiling of each saturated aqueous solution. This is in accord with the view that the amidosulfate ion ($R^1R^2NSO_3^-$) is indeed the unreactive species in the hydrolysis of the salts of amidosulfuric acid and its *N*-substituted derivatives, while the zwitterion ($R^1R^2NH^+SO_3^-$) is most probably the reactive species.[9]

Reaction of Butylammonium Butylamidosulfate (1) with 4-Methylaniline (6). When **1** was heated with **6** for 8 h under atmospheric pressure at different temperatures ranging from 120 to 180 °C, transsulfonation proceeded remarkably slowly. Thus, even after 8 h at 180 °C transsulfonation occurred only to the extent of 50%, to give (4-methylphenyl)amidosulfate (**9**) (40%) and 4-methylaniline-2-sulfonate (**12**) (6%) (Fig. 1). In marked contrast, the reaction was fast under reduced pressure. After 8 h at 150 °C **9** reached its maximum (80%) yield. At higher temperatures 4-methylaniline-2,6-disulfonate (**15**) as well as **12** were also formed at the expense of **9** (Fig. 1).

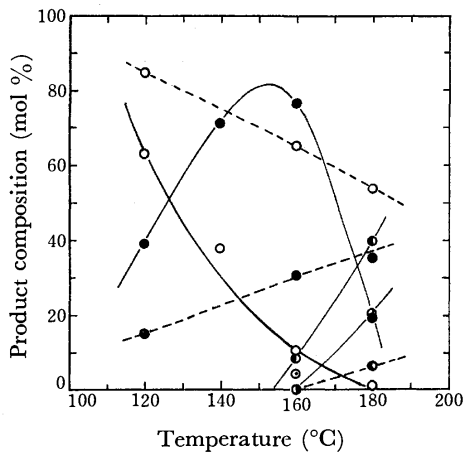

Fig. 1. Reaction of butylammonium butylamidosulfate with 4-methylaniline under atmospheric (----) and reduced (——) pressure.
Molar ratio 1: 1.1—1: 1.3, reaction time 8.5 h.
○: $BuNHSO_3^-$, ●: $MeC_6H_4NHSO_3^-$, ◐: $MeC_6H_3(SO_3^-)NH_2$, ⊙: $MeC_6H_3(SO_3^-)NHSO_3^-$, ◑: $MeC_6H_2(SO_3^-)_2NH_2$. The same symbols are used in all figures.

In order to gain a better understanding of the reaction path, the variation of product distribution with reaction time was followed (Fig. 2). In the first stage **1** was consumed rapidly and **9** was correspondingly formed. Two hours after the start of the reaction, the maximum (68%) yield of **9** was obtained. Beyond this point, **9** also decreased monotonically and **12** was formed instead. After 8.5 h **1** disappeared almost completely. **12** and **15** were the major products.

It is worthwhile noting the formation of 4-methylaniline-*N*,2-disulfonate (**13**), because the intermediacy of aniline-*N*,2- and *N*,4-disulfonic acids in the sulfonation of aniline with concentrated or fuming sulfuric acid has recently been discussed.[10] Although the formation of such compounds has already been reported,[7] no isolation was achieved. We isolated **13** successfully by preparative liquid chromatography.

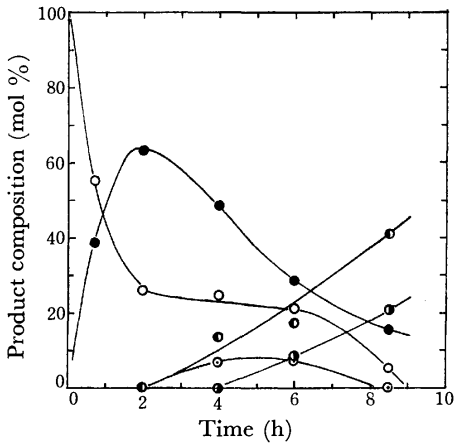

Fig. 2. Variation of product composition with reaction time in the reaction of butylammonium butylamidosulfate with 4-methylaniline at 180 °C under reduced pressure. Molar ratio 1: 1.1—1: 1.3.

Reaction of 4-Methylanilinium Butylamidosulfate (5). If the initial step both in the transsulfonation[13] and in the rearrangement[13] involves the dissociation into the free amidosulfuric acid (the reactive species) and the amine, it is to be expected that the rates of transsulfonation and rearrangement should increase with a decrease in the basicity of the salt-forming amine (to be discussed later).

As expected, transsulfonation of **5** was fast as compared with the reaction between **1** and **6**. Thus, the reaction

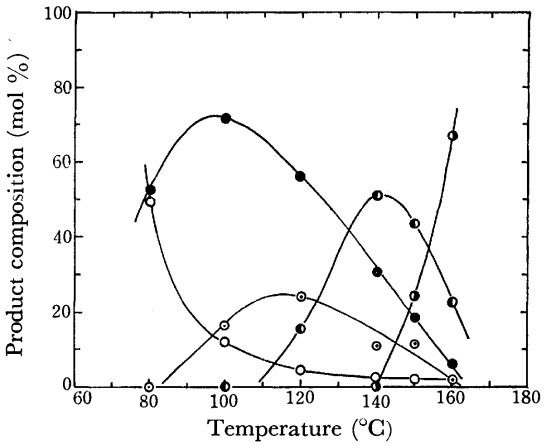

Fig. 3. Thermal reaction of 4-methylanilinium butylamidosulfate under reduced pressure. Reaction time 8.5 h.

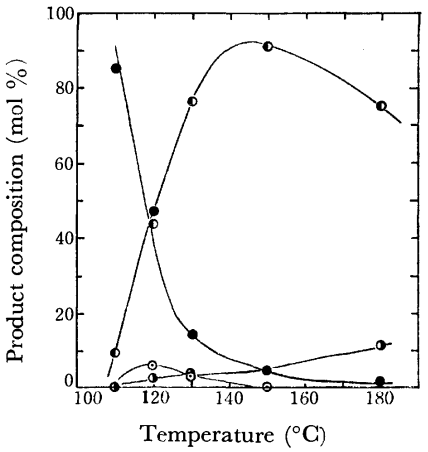

Fig. 5. Thermal reaction of 4-methylanilinium (4-methylphenyl)amidosulfate in *o*-dichlorobenzene. Reaction time 4 h. The reaction at 180 °C was conducted without solvent under reduced pressure.

of **5** at 80 °C for 8.5 h led to 52% conversion of **5** into **9**, and after 8.5 h at 120 °C **5** had disappeared almost completely (Fig. 3). It should be noted here that the reaction at 100 °C gave rise to the formation of **13** (17%), while no **12** was detected in the product mixture (TLC).

Thermal Rearrangement of Butylammonium (4-Methylphenyl)amidosulfate (9). **9** was heated for 8.5 h under reduced pressure in the temperature range 120—160 °C. The variation of product composition with reaction temperature is illustrated in Fig. 4. The rearrangement occurred only at temperatures above 120 °C, whereas with **5** the rearrangement to the ring sulfonate **13** took place far below 120 °C.

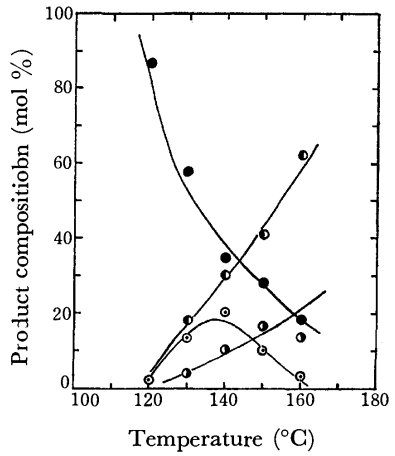

Fig. 4. Thermal reaction of butylammonium (4-methylphenyl)amidosulfate under reduced pressure. Reaction time 8.5 h.

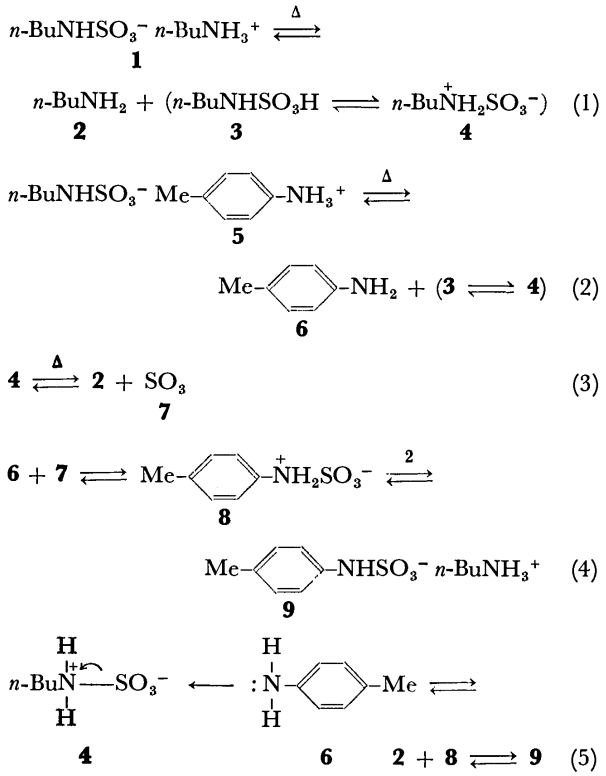
12 and **15** increased with an increase in temperature. The total yield of **12** plus **15** amounted to 80% at 160 °C. **13** was also formed up to 20%.

Thermal Rearrangement of 4-Methylanilinium (4-Methylphenyl)amidosulfate (11). The rearrangement of **11** was very rapid as compared with that of **9** (Fig. 5); after 4 h at 120 and 130 °C **11** rearranged to the extents of 45 and 85% respectively, yielding **12** (main product) along with **13** and **15**. A maximum yield of **12** was obtained from the reaction at 150 °C for 4 h. At 180 °C, a considerable amount (11%) of **15** was formed. Shortening of the reaction period to 35 min improved the yield of **12** (95%); only a trace of **15** was formed. This fact suggests that **15** can be formed not only by direct sulfonation of **12** with **8** (Eq. 16), but also by disproportionation of **12** (Eq. 17).[7]

Mechanistic Considerations. It is well known[14] that anhydrous metal salts of amidosulfuric acid and its *N*-substituted derivatives are much less reactive[4,14-16] than the corresponding ammonium salts[4] and the free acids[3-5,11,17] towards nucleophilic N–S bond cleavage (sulfonation, sulfamation, sulfation, hydrolysis, *etc*). Striking differences in reactivity of the N–S bond between the ammonium or amine salts and the metal salts can be explained in terms of the thermal dissociation of the former salts into the free amidosulfuric acid and the base. For the latter salts such type of dissociation is impossible. However, if a proton donor such as anilinium chloride, water, or a mineral acid is added in the reaction system,[7,15,18] then metal salts can also undergo the N–S bond cleavage. It has been proved that the salts of amidosulfuric acids exist as the true amidosulfate ions ($R^1R^2NSO_3^-M^+$),[19a,b] whereas the corresponding free acids exist as the zwitterions ($R^1R^2NH^+SO_3^-$).[19a,b,d]

All these results strongly suggest that an amidosulfate ion as such is more or less stable, although its stability is dependent on the nature of the *N*-substituent, whereas its *N*-protonated form (the zwitterion) is most probably the reactive species in acid-catalyzed hydrolysis,[9] solvolysis,[20] and transsulfonation.[4,18] Undoubtedly the heterolysis of the N–S bond of the zwitterion should be facilitated by the positive charge on the amido-nitrogen atom, because R^1R^2NH (neutral molecule) is a much better leaving group than $R^1R^2N^-$ (amide ion).

The initial step in both the transsulfonation and the rearrangement of the amine salts of the amidosulfuric



Scheme 1.

acids is presumably the dissociation of the salt into the amidosulfuric acid[21] and the salt-forming base (Eqs. 1, 2, 6, and 7). Support for this assertion was provided by the following observations: (1) in most of the runs carried out under reduced pressure, boiling of the reaction mixture and refluxing of **6** were observed immediately after the reaction had started; (2) under reduced pressure, transfer of the *N*-sulfonate group from **1** to **6** occurred much faster than it did under atmospheric pressure (Fig. 1); (3) the rates of transsulfonation and rearrangement increased with an increase in the acidity of the conjugate acid of the salt-forming base (compare Fig. 1 with Fig. 3, and Fig. 4 with Fig. 5).

Two possible types of mechanisms for the transsulfonation may be considered: (1) a dissociative mechanism (Eqs. 3 and 4) and (2) a bimolecular nucleophilic substitution (Eq. 5). It should be noted here that the transsulfonation with **5** occurred at such a low temperature that zwitterion **4** was quite stable. For example, at 100 °C for 8.5 h, **5** underwent transsulfonation to the extent of 80% to give **9** (72%) and **13** (16%).

Thermal decomposition of amidosulfuric acid[22] occurs only above its melting point (*i.e.*, at 210—220 °C). The most probable reaction has been considered to involve a chain condensation followed by cyclization to polysulfimide.[22] Cleavage of the N–S bond in this thermolysis probably takes place only through the hydrolysis with the water molecules released on the condensation and not through a pyrolytic process.

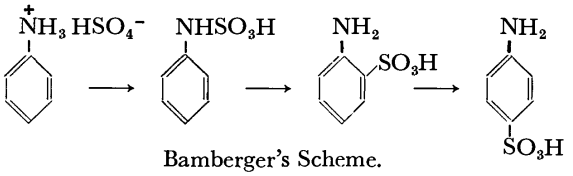
$$n\mathrm{NH_2SO_3H} \longrightarrow \mathrm{NH_2(SO_2NH)_{n-1}SO_3H} + (n-1)\mathrm{H_2O}$$
$$\longrightarrow (\mathrm{NHSO_2})_n + n\mathrm{H_2O}$$
$$\mathrm{NH_2SO_3H} + \mathrm{H_2O} \longrightarrow \mathrm{NH_4HSO_4}$$

The gas-phase reaction of sulfur trioxide with an amine such as trimethylamine is extremely exothermic.[23] Therefore, the N–S bond energy of $\mathrm{R^1R^2R^3N^+}$–$\mathrm{SO_3^-}$ must be very high. Accordingly the dissociative process seems to be unlikely.

On the other hand, it is well documented[20] that amidosulfuric acid and its *N*-substituted derivatives undergo cleavage of the N–S bond in a polar aprotic solvent such as pyridine, dioxane, DMF, *etc.* under mild conditions. It is, therefore, reasonable to assume that the transsulfonation proceeds through the latter process.

The rearrangement of phenylamidosulfuric acid to the ring sulfonic acid(s) has been performed by use of its salts under a variety of reaction conditions.[10] However, only a few papers have been published on the mechanism of thermal rearrangement of *neat* arylamidosulfates.[7]

Three possibilities may be considered for the mechanism of the rearrangement. The first possible mechanism is the intramolecular pathway postulated originally by Bamberger and Kunz[24] for the sulfonation of aniline. This scheme was later disproved experimentally.[25]



Bamberger's Scheme.

Furthermore, the formation of 2,6-dimethylaniline-4-sulfonate in the thermal rearrangement of 2,6-dimethylanilinium butylamidosulfate[26] cannot be explained by the intramolecular mechanism.

The second mechanism is an intermolecular process which involves thermal dissociation of **8** to **6** and **7**, followed by ring sulfonation of **6** with **7** (Eq. 8).

In view of the hydrolytic and thermal instability of **10**[11,14] thermal cleavage of the N–S bond may take place.

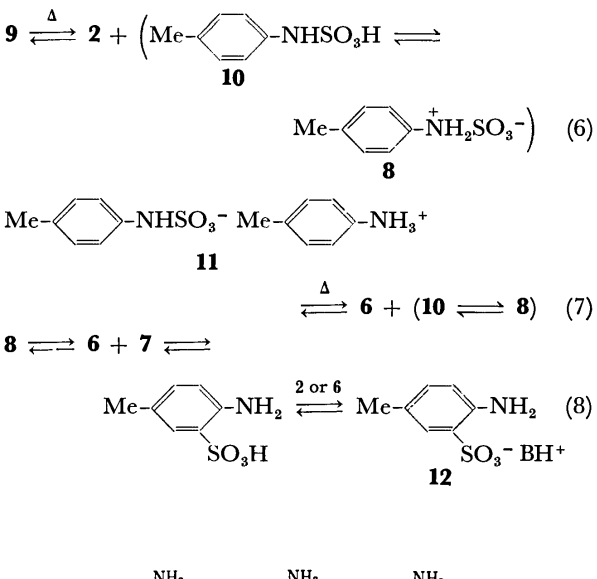
The third possible mechanism involves a bimolecular substitution at the sulfur atom (Eqs. 9 and 10). Since no traces of 4-methylaniline-3-sulfonate (*m*-sulfonation) could be detected (TLC) in the product mixture in any of our experiments, the free amine **6** and/or **10** but not the *N*-protonated species **8** must be the receptor of a rearranging *N*-sulfonate group.

Comparison of the data for the thermal rearrangment of **5** (Fig. 3) and **9** (Fig. 4) shows that conversion of **5** into **12** is much faster than that of **9** into **12**; thus, reaction of **5** at 120 °C for 8 h led to the formation of the rearrangement products **12** (16%) and **13** (24%), in addition to **9** (56%).[28] On the other hand reaction of **9** did not give **12** under the same conditions, and even after 8 h at 160 °C, 18% of **9** remained unchanged.

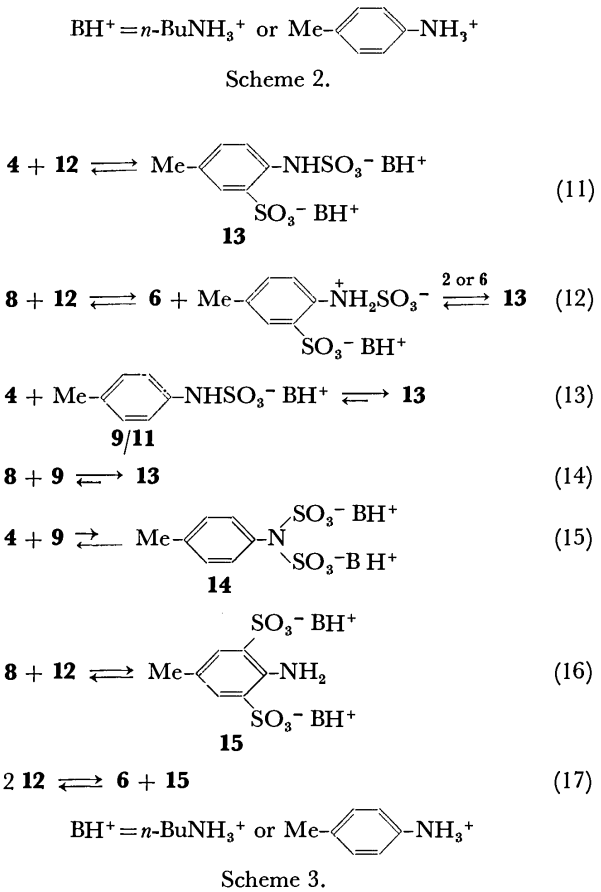
These results cannot be interpreted on the basis of the widely accepted sequence:[2c,3]

$$\mathrm{ArNH_2} + \mathrm{\overset{+}{N}H_3SO_3^-} \longrightarrow \mathrm{NH_2SO_3^-}\,\mathrm{ArNH_3^+} \longrightarrow$$
$$\mathrm{ArNHSO_3^-}\,\mathrm{NH_4^+} \longrightarrow o\text{- and/or } p\text{-Arenesulfonic acid}$$

A probable explanation involves concurrent pathways: The *N*-sulfonation of **6** with **4** to give **9** (Eq. 5) and the direct ring-sulfonation of **6** with **4** (Eq. 10) followed by sulfonate-group transfer from **4** and/or **8** to **12**



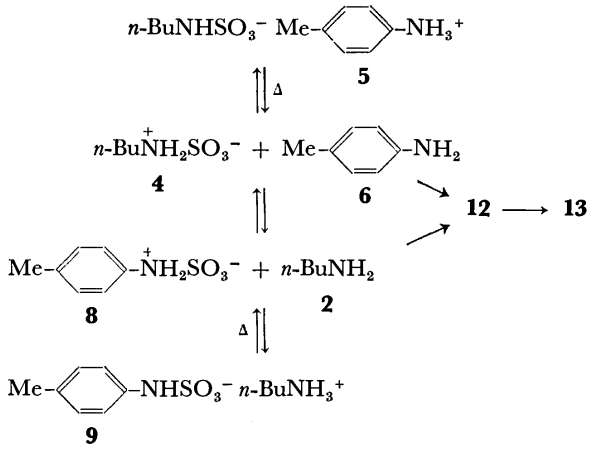
Scheme 2.



Scheme 3.

(Eqs. 11 and 12).

A dissociation equilibrium between the amidosulfate ion and the zwitterion should depend greatly on the acidity of the conjugate acid of the salt-forming amine; namely, this equilibrium shifts toward the zwitterionic form as the acidity of the conjugate acid of the amine increases[29] and thus the differences in reactivity between **5** and **9** can be accounted for by the following scheme:



On the other hand, the strength of the N–S bond of an *N*-substituted amidosulfuric acid is expected to increase as the basicity of the parent amine increases. The considerable differences in the rate of rearrangement between **5** and **11** (Figs. 3 and 4) can be explained in terms of the differences in reactivity between the reactive species **4** and **8**.

Several pathways for the formation of **13** may be considered. However, it seems most probable that **13** is formed by reaction(s) between **4** and **12**, and/or between **8** and **12** (Eqs. 11 and 12), since it has been well known that, in the presence of a proton donor such as anilinium chloride, the *N*-sulfonate group on an aromatic amine is transferred readily to another aromatic amino-nitrogen.[7,18]

Ring sulfonation of **9** (Eqs. 13 and 14) at as low as 100 °C seems less probable, since **9** should be much less reactive than **12**. This process may, however, operate at higher temperatures.[27]

(4-Methylphenyl)imidobis(sulfate) (**14**) could neither be isolated nor detected. This can be accounted for in terms of the great degree of steric strain due to the over-crowding around the imido-nitrogen atom.[30]

Experimental

All the melting points were measured in sealed capillaries and uncorrected. The dioxane was of chromatographic grade. The butylamine and 4-methylaniline were guaranteed reagents and used as received. The IR spectra were recorded for KBr discs on a JASCO IR-S spectrophotometer. DEAE-cellulose (Serva, hydrochloride form) was suspended in deionized water and allowed to stand for 20—40 min, and the supernatant was discarded; this process was repeated several times. The exchanger was then suspended in 3M NaCl, packed in a column, and washed with water. Thin-layer chromatography was performed on 0.25 mm-thick cellulose plates (cellulose mikrokristallin, E. Merck) by use of a dioxane–water (15:4 v/v) solvent system. Components were located by inspection under UV light or by placing the plate in a container filled with nitrous gases, followed by spraying with 1-naphthol-4-sulfonic acid and subsequent exposure to ammonia gas.

Reaction Runs. In a test tube (150×14 mm) equipped with a stopcock was placed a weighed amount of a substrate (2 mmol). The test tube was evacuated (*ca.* 20 Torr) with a water aspirator for a very short period (*ca.* 10 s) and the stopcock was closed. The test tube was then heated in a thermostated oil bath. After the reaction was complete, the product mixture was cooled and dissolved in a dilute sodium hydroxide solution. The solution was extracted three times with 2-ml portions of benzene to remove the unreacted 4-methylaniline. The aqueous solution was evaporated *in vacuo*. The residual solid was dissolved in deionized water and the solution was passed through a column (180×9 mm i.d.) of Dowex 50WX4 (Na^+ form). The eluate was collected into a volumetric flask and diluted accurately up to 100 ml. Aliquots of this stock solution were employed for the following product analyses.

Determination of Product Composition. The quantities of each component (**A**—**F**) were calculated from the determinations given below: *n*-$BuNHSO_3Na$ (**A**), 4-$MeC_6H_4NHSO_3Na$ (**B**), 2-SO_3Na-4-$MeC_6H_3NHSO_3Na$ (**C**), 2-SO_3Na-4-$MeC_6H_3NH_2$ (**D**), 2,6-$(SO_3Na)_2$-4-$MeC_6H_2NH_2$ (**E**), Na_2SO_4 (**F**).

Butylamidosulfate and (4-Methylphenyl)amidosulfate: An aliquot (5 or 10 ml) was pipetted on a column (164×13 mm i.d.) of DEAE-cellulose. The column was rinsed with 0.5 ml of distilled water and then eluted with 0.15 M NaCl at a flow rate of 0.25—0.3 ml/min. The first fraction containing **A** was eluted at 30—37 ml and the second fraction containing **B** at 42—48 ml. Each fraction was treated with 3 M HCl (1 ml) and 6 M $NaNO_2$ (0.2 ml). Sulfate ion thus formed was precipitated with 0.01 M $BaCl_2$ (10 or 20 ml) and the excess of barium ion was back-titrated with 0.01 M EDTA; (**A** and **B**).

Total Sulfonate-group Bound to Aromatic Amino-nitrogen: To an aliquot (5 or 10 ml) was added 0.01 M $BaCl_2$ (10 or 20 ml). The volume of the solution was adjusted to *ca.* 20 ml by dilution or evaporation. 3 M HCl (1 ml) was then added and the solution was boiled for 20 min and cooled.[31] The barium sulfate was filtered off and the excess of barium ions in the filtrate titrated; (**B**+**C**+**F**).

Total N-Sulfonate Group: To an aliquot (5 or 10 ml) were added successively 3 M HCl (1 ml), 0.01 M $BaCl_2$ (10 or 20 ml), and 6 M $NaNO_2$ (0.2 ml). After the solution had been left for 1 h, urea (*ca.* 0.1 g) was added. The solution was left again for 1 h, and then heated for 30 min; the precipitate was removed by filtration; the excess of barium ion was titrated; (**A**+**B**+**C**+**F**).

Sulfate Ion Formed in the Reaction: To an aliquot (10 ml) 0.01 M $BaCl_2$ (10 ml) and 3 M HCl (1 ml) were added at room temperature. The solution was filtered directly into an Erlenmeyer flask containing 0.1 M Zn-EDTA (10 ml) and ammonium chloride buffer solution (pH 10) (1 ml). The excess of barium ion was titrated with 0.01 M EDTA; (**F**).

4-Methylaniline-N,2-disulfonate plus 4-Methylaniline-2-sulfonate and 4-Methylaniline-2,6-disulfonate: The remainder of the stock solution after the above analyses was concentrated to *ca.* 20 ml. After addition of 3 M HCl (2 ml), the mixture was boiled for 20 min, cooled, and evaporated *in vacuo*. The residue was dissolved in hot water (20 ml). Barium hydroxide was then added in a slight excess in order to remove sulfate ions. After filtration, the filtrate was passed through a cation-exchange column (Amberlite IR 120 H^+-form) and the eluate was evaporated to dryness. Trituration of the residue with a minimum volume of ethanol gave 4-methylaniline-2-sulfonic acid (**C**+**D**); evaporation of the ethanol solution gave 4-methylaniline-2,6-disulfonic acid (**E**). The 2- and 2,6-acids were then titrated with 0.05 M NaOH.

Material. Butylamidosulfuric Acid: This compound was prepared by the action of butylamine on chlorosulfuric acid in 1,2-dichloroethane at −10—0 °C; mp 173.5—174.5 °C (decomposed with effervescence) (lit,[32] 177—178 °C). IR: 3125 (N-H, br, s), 1527 (NH_2^+, m), 1299 (NH_2^+-SO_3^-, s), 1246 (NH_2^+-SO_3^-, s), 1080 (SO_3^-, m), 1066 (SO_3^-, m), 835 (m), 770 (m), and 715 cm^{-1} (S-N, m). Found: N, 9.12; S, 21.04%. Calcd for $C_4H_{11}O_3NS$: N, 9.14; S, 20.93%.

Butylammonium Butylamidosulfate (1): This was prepared by neutralization of the free acid with butylamine in methanol. After recrystallization from ethyl methyl ketone, it melted at 125.5—127 °C (lit,[32] 127—128 °C). IR: 2950 (NH_2^+, m), 1465 (m), 1186 (SO_3^-, s), 1041 (SO_3^-, s), 910 (w), and 740 cm^{-1} (br, w). Found: N, 12.36; S, 14.13%. Calcd for $C_8H_{22}O_3N_2S$: N, 12.38; S, 14.16%.

4-Methylanilinium Butylamidosulfate (5): A slight excess of 4-methylaniline was added to a solution of butylamidosulfuric acid in methanol. The mixture was evaporated *in vacuo* and the residual solid was washed three times with benzene and dried in a desiccator. Colorless *crystals;* the melting point depended on the rate of heating. IR: 3260 (N-H, w), 2930 (NH_2^+, br, s), 1187 (SO_3^-, s), 1043 (SO_3^-, br, s), and 817 cm^{-1} (2H, m). Found: N, 10.68; S, 12.35%. Calcd for $C_{11}H_{20}N_2O_3S$: N, 10.76; S, 12.31%.

Barium (4-Methylphenyl)amidosulfate: 4-Methylanilinium amidosulfate (30 g), prepared by neutralization of amidosulfuric acid with 4-methylaniline in methanol, was heated with 4-methylaniline (45 g) at 100 °C for 3.5 h. After cooling, benzene (50 ml) was added. The solid was collected, washed with benzene, and recrystallized from water to give the pure *ammonium salt*. This was dissolved in hot water and treated with a slurry of barium hydroxide. The mixture was filtered and the residue was washed repeatedly with hot water. The filtrate and washings were combined and evaporated to dryness *in vacuo*. The residual solid was dissolved again in hot water (500 ml) and carbon dioxide was passed through the solution to remove the excess of barium hydroxide. The filtered solution was left overnight at room temperature. The *product* separated out as needles, which were filtered and washed twice with cold water, yield 22.7 g. IR: 3200 (N-H, m), 1218 (SO_3^-, s), 1180 (SO_3^-, s), 1058 (SO_3^-, s), and 816 cm^{-1} (1,4-, w—m).

Butylammonium (4-Methylphenyl)amidosulfate (9): An aqueous solution of ammonium (4-methylphenyl)amidosulfate was passed through a column of Dowex 50W×4 (butylammonium form) and the eluate was evaporated to a small volume, giving colorless *crystals*. These were filtered, washed with cold water, and dried. IR: 1512 (m), 1185 (SO_3^-, s), 1041 (SO_3^-, s), 895 (m), 820 (1, 4-, m), and 696 cm^{-1} (br, m). Found: N, 10.67; S, 12.23%. Calcd for $C_{11}H_{20}O_3N_2S$: N, 10.76; S, 12.31%.

4-Methylanilinium (4-Methylphenyl)amidosulfate (11): An aqueous solution of bis(4-methylanilinium) sulfate was added slowly to a stirred solution of barium (4-methylphenyl)amidosulfate (4.35 g) in water (50 ml) until no more precipitate was formed. After stirring for a short period, the precipitate was filtered and the filtrate was evaporated to dryness. The *product* was washed repeatedly with ether and dried in a desiccator over silica gel; glistening flakes. IR: 2915 (NH_3^+, br, m), 1517 (m), 1205 (SO_3^-, s), 1050 (SO_3^-, s), 897 (w), and 815 cm^{-1} (1,4-, m). Found: N, 9.49; S, 10.77%. Calcd for $C_{14}H_{18}N_2O_3S$: N, 9.52; S, 10.89%. Mp: 168—169.5 °C (depended on the rate of heating).

Tetraphenylphosphonium Chloride (16): This salt was prepared according to the procedure of Horner *et al.*[33] with a slight modification. IR: 1620 (w), 1583 (w), 1480 (w,) 1434 ($C_6H_5P^+$, m), 1311 (w), 1107 ($C_6H_5P^+$, s), 998 (m), 763

(m), 722 (s), and 688 cm^{-1} (m). Found: Cl, 9.42; P, 8.18%. Calcd for $C_{24}H_{20}ClP$: Cl, 9.46; P, 8.26%.

Preparation of Authentic Compounds. Sodium (4-Methylphenyl)amidosulfate: The sodium salt was obtained from the foregoing ammonium salt by passing through a cation-exchanger (Na^+ form) column. Recrystallization from methanol gave the pure *salt*. IR: 3260 (N–H, m), 1512 (m), 1198 (SO_3^-, s), 1061 (SO_3^-, s), 910 (m), and 810 cm^{-1} (1,4-, m). Found: N, 6.78; S, 15.00%. Calcd for $C_7H_8O_3NNaS$: N, 6.70; S, 15.33%.

Tetraphenylphosphonium (4-Methylphenyl)amidosulfate: A hot solution of **16** (550 mg) in 20 ml of water was added to a stirred solution of sodium (4-methylphenyl)amidosulfate (300 mg). The mixture was boiled for a short time and cooled slowly. The phosphonium salt was collected by filtration. Repeated recrystallization from water furnished a pure *sample*. Found: N, 2.67; P, 5.75; S, 6.25%. Calcd for $C_{31}H_{28}O_3PS$: N, 2.67; P, 5.89; S, 6.10%. IR: 3225 (N–H, w), 1440 ($C_6H_5P^+$, m), 1395 (w), 1224 (SO_3^-, s), 1205 (SO_3^-, s), 1103 ($C_6H_5P^+$, s), 1033 (SO_3^-, s), 881 (m), 827 (2H, m), 761 (m), 722 (s), and 686 cm^{-1} (br, m).

4-Methylaniline-2,6-disulfonic Acid and Its Salts: 4-Methylaniline-2-sulfonic acid (commercial reagent) (5.00 g) and freshly distilled chlorosulfuric acid (2.4 g) were mixed and the mixture was heated at 120 °C for 2 h and then at 140 °C (for 2 h) until the evolution of hydrogen chloride had subsided. After cooling, cracked ice was added carefully to the reaction mass. The resulting solution was neutralized with slurries of barium hydroxide, heated to boiling, and filtered while hot; the precipitate was washed repeatedly with hot water. The combined filtrate and washings were evaporated to dryness. The solid was recrystallized twice from hot water, yielding the pure *barium salt*. This was then converted to the corresponding free acid by passing through a column of Amberlite IR-120B (H^+ form); the eluate was neutralized with aqueous sodium hydroxide. The neutralized solution was then concentrated to a small volume (*ca.* 12 ml). 3 M HCl (7.0 ml) and hot alcohol (10 ml) were added with stirring while hot. The mixture was left overnight at room temperature. *Monosodium 4-methylaniline-2,6-disulfonate* separated out as white glistening crystals. IR: 1500 (w), 1460 (w), 1235 (SO_3^-, s), 1180 (SO_3^-, s), 1122 (w), 1045 (SO_3^-, s), 882 (1H, w), and 805 cm^{-1} (m). Found: N, 4.25; S, 19.72%. Calcd for $C_7H_8O_6NNaS \cdot 2H_2O$: N, 4.31; S, 19.71%.

The *bis(hexylammonium) salt* was prepared by neutralization of the free acid with hexylamine. Recrystallization from ethyl acetate–isopropyl alcohol (5 : 2 v/v) gave a pure *specimen*; mp: 185—186 °C. IR: 1470 (m), 1210—1175 (br, s), 1028 (s), 886 (w), 802 (m), and 752 cm^{-1} (w). Found: N, 8.90; S, 13.68%. Calcd for $C_{19}H_{39}O_6N_3S_2$: N, 8.95; S, 13.65%.

4-Methylaniline-2,5-disulfonic Acid and Its Salts: This acid was prepared by the reaction between 4-methylaniline-3-sulfonic acid and chlorosulfuric acid. The product was isolated as the *barium salt* and purified by recrystallization from water.

The barium salt was converted into the sodium and bis(hexylammonium) salts by the same procedure as above *Monosodium salt*; IR: 1513 (w), 1483 (m), 1382 (w), 1225—1193 (SO_3^-, br, s), 1130 (s), 1030 (SO_3^-, s), 780 (w), and 650 cm^{-1} (s). Found: N, 4.28; S, 19.07%. Calcd for $C_7H_8NNaS_2 \cdot 2H_2O$: N, 4.31; S, 19.17%. *Bis(hexylammonium) salt*; mp: 195—196 °C. IR: 1480 (m), 1399 (m), 1202 (s), 1176 (s), 1118 (w), 1014 cm^{-1} (s). Found: N, 8.86; S, 13.34%.

Dipotassium, Disodium, and Bis(tetraphenylphosphonium) Salts of 4-Methylaniline-N,2-disulfonic Acid: Sulfur trioxide (2.14 g, 26.7 mmol) was dissolved in dry 1,2-dichloroethane (10 ml) and cooled in an ice–water bath. Dry 2-methylpyridine (3.0 ml) was added, drop by drop, with cooling and vigorous stirring. After stirring for 30 min, the solvent was removed *in vacuo* to give colorless crystals of 2-methylpyridine-sulfur trioxide adduct.

To the adduct was added in one portion an ice-cold solution of 4-methylaniline-2-sulfonic acid (4.60 g, 24.6 mmol) and potassium carbonate (3.70 g, 26.8 mmol) dissolved in water (40 ml). The mixture was allowed to warm to room temperature. Potassium carbonate (0.50 g, 3.6 mmol) was then added. After stirring at 35—40 °C for 30 min, the mixture was evaporated *in vacuo*, giving the solid. Recrystallization from 90% aqueous methanol gave the *potassium salt*. IR: 1485 (m), 1375 (w), 1281 (m), 1197 (SO_3^-, s), 1092 (s), 1047 (SO_3^-, s), 1027 (SO_3^-, s), 900 (w), 873 (w), 840 (w), and 706 cm^{-1} (m). Found: N, 3.50; S, 17.08%. Calcd for $C_7H_7O_6K_2NS_2 \cdot 2H_2O$: N, 3.69; S, 16.90%.

The dipotassium salt was converted to the disodium salt by cation-exchange. Recrystallization from aqueous ethanol yielded the pure *sodium salt*.[34] Found: N, 4.20; S, 19.47%. Calcd for $C_7H_7O_6NNa_2S_2 \cdot H_2O$: N, 4.25; S, 19.47%.

A solution of **16** (400 mg) in water (20 ml) was added to a stirred solution of the foregoing potassium salt (200 mg) in water and the mixture was boiled for a few minutes. After cooling, the crystals were filtered, washed with water, and recrystallized from water to give the pure *phosphonium salt* (340 mg); mp 210—211 °C (dec) (immersed in a bath preheated at 204 °C). IR: 1485 (m), 1439 ($C_6H_5P^+$, s), 1210 (SO_3^-, s), 1106 ($C_6H_5P^+$, s), 1036 (SO_3^-, s), 1019 (m), 898 (w), 847 (w), 834 (w), 762 (m), 721 (s), and 688 cm^{-1} (m). Found: P, 6.76; S, 6.81%. Calcd for $C_{55}H_{47}O_6NP_2S_2$: P, 6.56; S, 6.79%.

Isolation and Identification of the Reaction Products. Tetraphenylphosphonium (4-Methylphenyl)amidosulfate: The product mixture from the reaction of **8** at 100 °C for 17 h was dissolved in water (10—20 ml).[35] To the filtered solution was added **16** (200 mg) and the mixture was boiled for a short time. The clear solution was allowed to cool slowly[36] and left overnight at room temperature. The crystals which separated were collected by filtration and washed three times with cold water. Repeated recrystallization from water gave the pure *phosphonium salt*. The IR spectrum was entirely in accord with that of an authentic sample. Found: N, 2.58; P, 5.78; S, 6.26%. Calcd for $C_{31}H_{28}O_3NPS$: N, 2.67; P, 5.89; S, 6.10%.

Bis(tetraphenylphosphonium) 4-Methylaniline-N,2-disulfonate: Disodium 4-methylaniline-*N*,2-disulfonate[37] was isolated by liquid chromatography from the reaction of **5** at 130 °C for 8.5 h. To the filtered solution (20 ml) of this salt (0.205 g) was added **16** (0.504 g) and the mixture was boiled for a short period and allowed to cool slowly. The crystallized phosphonium salt was purified by repeated recrystallization from water; mp 210—211 °C. The mixed mp with an authentic specimen was not depressed. The IR spectrum agreed entirely with that of authentic material.

4-Methylaniline-2-sulfonic Acid and Its Hexylammonoum Salt: The sodium salt was separated by liquid chromatography from the product mixtures. To a hot solution (*ca.* 5 ml) of this salt (0.350 g) was added 3 M HCl (2 ml). The mixture was boiled for 20 min and cooled. The *free acid* separated out as colorless needles (hemihydrate). IR: 1550 (NH_3^+, w), 1498 (m), 1270—1290 (s, br), 1262 (w), 1092 (m), 1020 (s), 829 (m), and 698 cm^{-1} (m). Found: N, 7.12; S, 16.33%. Calcd for $C_7H_9O_3NS \cdot 1/2H_2O$: N, 7.14; S, 16.34%.

The free acid was neutralized with a methanolic solution of hexylamine. The solution was evaporated to dryness and the solid was recrystallized from EtOH–AcOEt (1 : 1 v/v) to

give the pure *hexylammonium salt*: mp 208—209 °C, mixed mp 208—208.5 °C. The IR spectrum agreed entirely with that of an authentic sample.

Bis(hexylammonium) 4-Methylaniline-2,6-disulfonate: The crude disodium salt (0.30 g) was dissolved in water and the solution was passed through a column of Dowex 50WX4 (H^+ form). The eluate was neutralized with a methanolic solution of hexylamine. After evaporation, the solid was recrystallized from *i*-PrOH–AcOEt (1: 5 v/v) to give the *bis-(hexylammonium) salt* as fine needles; mp 185—186 °C, mixed mp with an authentic sample: 185.5—186 °C. The IR spectrum was in agreement with that of an authentic specimen.

26) To be published in a later paper.

27) It is expected that the electron-donating effect of the sulfamino group is much smaller than that of the amino group.

28) The formation of **13** can be accounted for in terms of the deficiency of **6** in the reaction mixture, *i.e.* $\mathbf{6}/SO_3 < 1$) caused by partial deposition of **6** on the cool wall of the reaction vessel.

29) The position of this equilibrium is, of course, dependent on the steric factors. 2,6-Dimethylanilinium salt of butylamidosulfuric acid, for example, is unstable and dissociates into the acid and 2,6-dimethylaniline even at room temperature. Accordingly, this salt undergoes trans-sulfonation and rearrangement to 2,6-dimethylaniline-4-sulfonic acid far more readily than **5**. See a later paper.

30) We succeeded, however, in isolating (2,4,6-trimethylphenyl)imidobis(sulfate) from the thermal reaction of 2,4,6-trimethylanilinium butylamidosulfate; see a later paper.

31) It was confirmed that both butylamidosulfate ion and the ring sulfonate group are not hydrolyzed under these conditions.

32) G. E. McCasland, *J. Am. Chem. Soc.*, **73**, 5507 (1951).

33) L. Horner, G. Mummenthey, H. Moser, and P. Beck, *Chem. Ber.*, **99**, 2782 (1966).

34) W. M. Lauer, M. M. Sprung, and C. M. Langkammerer, *J. Am. Chem. Soc.*, **58**, 225 (1936).

35) If the solution is acidic, it should be neutralized with 1 M ammonia.

36) If the phosphonium sulfonate tends to separate as an oil, sufficient water should be used for the crystallization and the solution should be seeded while hot.

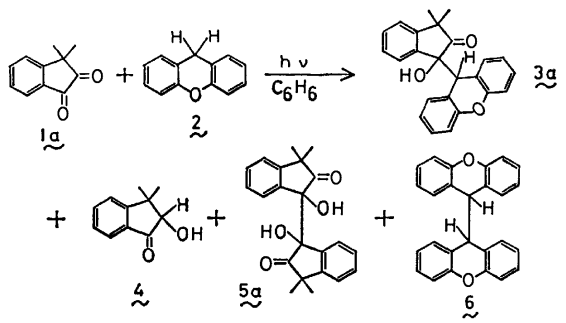
37) This compound gave 4-methylaniline-2-sulfonic acid on acid hydrolysis.

Photochemical Reaction of 3,3-Dimethyl-1,2-indanedione with Xanthene

Kazuhiro MARUYAMA,* Atsuhiro OSUKA, and Yoshinori NARUTA
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received April 22, 1978)

The photochemical reaction of 3,3-dimethyl-1,2-indanedione (DMID) with xanthene was investigated in detail. The products are 1-hydroxy-3,3-dimethyl-1-(9-xanthenyl)-2-indanone (**3a**) (49%), 2-hydroxy-3,3-dimethyl-1-indanone (13%), 1,1′-dihydroxy-3,3,3′,3′-tetramethyl-1,1′-biindan-2,2′-dione (**5a**) (23%), and 9,9′-bixanthenyl (**6**) (49%). The reaction proceeds *via* hydrogen abstraction by $^3(n\pi)^*$ of DMID leading to triplet radical pair composed of its semidione radical and 9-xanthenyl radical. The product **3a** is a combination product from the radical pair, while **5a** and **6** are escaping products from it. The hydrogen abstraction occurs at C-1 carbonyl group of DMID in a fairly efficient quantum yield ($\Phi=0.71$). Behavior of the DMID semidione radical is rather resemble those of open-chain semidione radicals than those of sterically hindered semidione radicals.

The photochemical reactions of a number of α-diketones in which the carbonyl groups are held in a somewhat rigid *cis*-configuration have been studied under various conditions.[1] *s-cis*-α-Diketone has been shown to undergo photo-hydrogen abstraction reaction in the presence of a hydrogen donor, and the resulting products can almost invariably be rationalized by taking into consideration a mechanistic pathway involving the initial hydrogen abstraction by photoexcited α-diketone *via* $^3(n\pi)^*$ excitation. For example, camphorquinone in methanol or in 2-propanol gives products derived from the initial hydrogen abstraction reaction from the solvent.[2] When 9,10-phenanthrenequinone is irradiated in hydrogen donating solvents, it yields 1,2-adduct or 1,4-adduct corresponding to the structures of the solvents.[3] In these light-induced reactions of camphorquinone and 9,10-phenanthrenequinone, intermediate radical pairs have been successfully detected by using CIDNP technique.[4] The light-induced hydrogen abstraction reactions of 3,3-dimethyl-1,2-indanedione (DMID), which is a nonenolizable aromatic α-diketone, have been investigated from the standpoint of comparing the photoreactivity with those of open-chain α-diketones.[5] The qualitative behaviors of photoexcited DMID in 2-propanol, diethyl ether, and toluene were reported by Rigaudy,[6] but the quantitative investigation has not been accomplished yet. In this investigation we have found that photoexcited DMID shows such a high reactivity to hydrogen donors as that of benzil.



Scheme 1

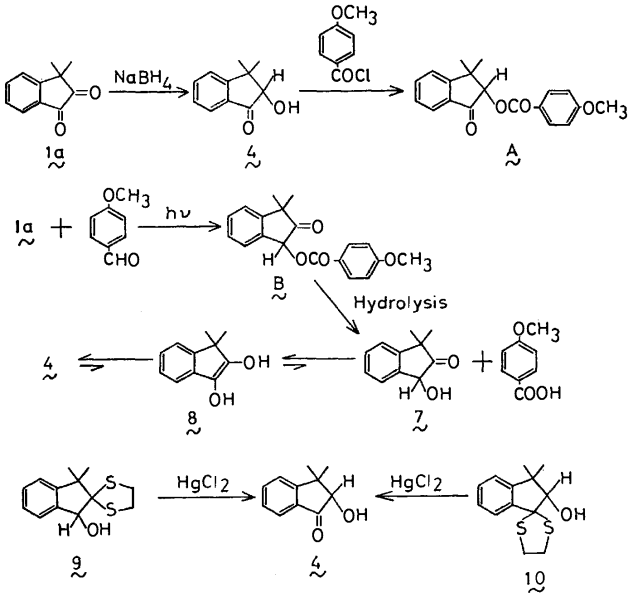
Results and Discussion

a) Reaction Products. A degassed solution of DMID **1a** (0.04 M) and equimolar xanthene **2**, a good hydrogen donor, in benzene was irradiated for an hour, using a 300 W high-pressure mercury lamp. Separation of the products by column chromatography and preparative TLC gave 1-hydroxy-3,3-dimethyl-1-(9-xanthenyl)-2-indanone **3a** (49%), 2-hydroxy-3,3-dimethyl-1-indanone **4** (13%), and 9,9′-bixanthenyl **6** (46%). On the other hand, the ^{1}H NMR spectrum of this reaction mixture showed two characteristic signals at δ 0.92 and 1.26 corresponding to the dimethyl protons of 1,1′-dihydroxy-3,3,3′,3′-tetramethyl-1,1′-biindan-2,2′-dione **5a** (pinacol), indicating its yield of 23% besides those of photoreaction products mentioned above (Scheme 1). When silica gel chromatography was applied for the product separation, **5a** was not isolated owing to its high susceptibility to autoxidation on silica gel. The structures of these products were determined by their IR, UV, ^{1}H NMR, elemental analyses and chemical reactions.

The IR spectrum of **3a** showed characteristic bands at 3420 (hydroxy) and 1746 cm^{-1} (nonconjugated five membered ring ketone), the ^{1}H NMR spectrum ($CDCl_2$) showed signals at δ 0.40 (s, 3H), 1.18 (s, 3H), 2.70 (broad, 1H), 4.40 (s, 1H) and 6.60—7.75 (m, 12H), in agreement with the structure of **3a**.

The IR spectrum of **4** showed two characteristic absorptions of a hydroxyl group (3500 cm^{-1}) and a conjugated five membered ring ketone (1726 cm^{-1}). The ^{1}H NMR spectrum (CCl_4) of **4** showed signals at δ 1.13 (s, 3H), 1.54 (s, 3H), 4.17 (s, 1H), 4.10 (broad 1H) and 7.20—7.26 (m, 4H). The hydroxy ketone **4** was independently prepared by reduction of DMID with sodium borohydride, and compared with the photoreduction product. It is an interesting problem which one of two carbonyl groups is reduced in the photoreaction or in the hydride reduction. The problem was solved in the following way. Esterification of **4** with *p*-anisoyl chloride gave ester **A**, and its IR spectrum showed two characteristic bands at 1721 and 1757 cm^{-1} corresponding to the ester of a five membered ring ketone. On the other hand, irradiation of DMID with *p*-anisaldehyde in benzene gave a small amount (4%) of ester **B** besides various other products. The IR spectrum of the ester **B** showed two characteristic bands at 1723 and 1774 cm^{-1} corresponding to the ester of a five membered ring ketone, but clearly different from **A**; the esters, **A** and **B**, are regioisomers each other. Comparison of the IR spectra of these two isomers led

to a conclusion that **B** might have a nonconjugated carbonyl group and **A** a conjugated one. Surprisingly the alkaline hydrolysis of **B** gave a mixture of **4** and *p*-anisic acid as well as the hydrolysis of **A** (Scheme 2). The result observed in the hydrolysis of **B** was explained in terms of a series of equilibria involving a indenediol **8** as a common intermediate. The equilibria might favor rather **4** because of the stability of the conjugated ketone. This was confirmed in the oxidative hydrolysis of both 1-hydroxy-3,3-dimethylspiro(indan-2,2′-[1,3]-dithiolane) **9** and 2-hydroxy-3,3-dimethylspiro(indan-1,2′-[1,3]dithiolane) **10** with mercury(II) chloride; namely, both isomers gave only **4**.



Scheme 2.

Irradiation of a degassed solution of 3,3-dimethyl-6-nitro-1,2-indanedione **1b** (NO_2–DMID) and xanthene for 6 h gave 1-hydroxy-3,3-dimethyl-6-nitro-1-(9-xanthenyl)-2-indanone **3b** in 70% yield and 1,1′-dihydroxy-3,3,3′,3′-tetramethyl-6-nitro-1,1′-biindan-2,2′-dione **5b** in 13% yield.

b) Reaction Mechanism. To investigate the reaction mechanism, we examined the photochemical reactions of DMID with xanthene in detail, changing the reaction conditions (Table 1).

Run 3 reveals that the pinacol **5a** photochemically decomposes to give two semidione radicals, which would regenerate **5a** by coupling or give DMID and hydroxy ketone by disproportionation. On irradiation, DMID thus formed would abstract a hydrogen atom from xanthene, giving **3a** and **6**. Run 4 shows obviously an occurrence of homolytic cleavage of photoexcited **3a**, yielding a semidione radical and 9-xanthenyl radical. However, exposure of a degassed solution of **5a** and **3a** in benzene to light of wavelength longer than 400 nm resulted in the nearly complete recovery of the starting materials (run 5 in the Table 1). When a solution of DMID and xanthene in benzene was irradiated with light of wavelength longer than 400 nm, DMID changed to give only **3a** and **5a** in yields of 13 and 27%, respectively, and **6** was formed in a yield of 29% (Run 2 in the Table 1).

The absence of hydroxy ketone in the reaction mixture of Run 2 might be ascribed to the much slower rate of disproportionation of the semidione radical than that of coupling of it. If **7** once would be produced from the semidione radical by disproportionation, **4** could be formed *via* the equilibria between **7** and **4** (Scheme 2).

In their stabilizing modes, the semidione radicals derived from α-diketones can be classified into two groups;[7] namely those derived from rigidly cis, sterically hindered α-diketones, which decay by disproportionation, and those derived from flexible α-diketones such as benzil or anisil, which terminate by coupling in rather faster decay rates. It is noteworthy that the *free* DMID semidione radical decays predominantly by coupling, resulting in the formation of **5a** in spite of its rigidly *cis*-fixed configuration.

c) Radical Pair as an Intermediate. The fact that DMID changes to give only **3a** and **5a** upon irradiation with light of wavelength longer than 400 nm is of value for examining the behaviors of the radical pair. That is, **3a** is a combination product of the semidione radical and 9-xanthenyl radical, whereas **5a** and **6** are escaping products from the initial solvent cage. We examined the effects of the concentration of xanthene and reaction temperature on the product distribution (Table 2). At three different temperature the ratio of **5a** to **3a** was

Table 1. Photochemical reaction of DMID **1a**, xanthene adduct **3a** and pinacol **5a** with xanthene in benzene. Photoreaction product distribution under various conditions

Run	Starting material	Irradiation condition	Products (%)				
			1	**3a**	**4**	**5a**	**6**
1	**1a**+**2**	A(1)	12	43	11	20	41
2	**1a**+**2**	B(3)	52	13	—	27	29
3	**5a**+**2**	A(6)	8	22	57	2	35
4	**3a**	A(6)	16	42	23	4	50
5	**3a**+**5a**	B(6)	—	98	—	96	—

A; usual irradiation, using high-pressure Hg lamp from outside. B; irradiation with light of wavelength longer than 400 nm. Yields were determined by ^{1}H NMR using durene as an internal standard.

Table 2. Photochemical reaction of DMID **1a** and xanthene **2** upon irradiation with light of wavelength (λ>400 nm). Effects of concentration of DMID and reaction temperature on the ratio of [**5a**]/[**3a**]

Temperature	5—7 °C		20—23 °C		30—34 °C	
[**2**]/[**1a**]	conv.	[**5a**]/[**3a**]	conv.	[**5a**]/[**3a**]	conv.	[**5a**]/[**3a**]
0.5	45(%)	1.2	47(%)	1.6	52(%)	2.3
1	48	1.2	48	1.8	43	2.4
3	56	1.4	46	1.9	42	2.1
5	68	1.0	53	2.0	58	2 0

a) Irradiation time is 2 h. b) [DMID]=9.83×10^{-3} M. c) Yields were determined by ^{1}H NMR with durene as an internal standard.

independent of the concentration of xanthene. This result suggests that neither the semidione radical nor 9-xanthenyl radical reacted with xanthene. In contrast, the ratio of **5a** to **3a** gradually increased with increasing reaction temperature. The increasing yield of the combination product **3a** with decreasing reaction temperature provides us a powerful support for the concept on the geminate combination of initially formed radical pair.

d) CIDNP Examination. Light-induced reactions of DMID and NO_2–DMID with xanthene were examined by means of CIDNP. As shown in Figure 1b, the methine proton of xanthenyl moiety of **3a** appeared at δ 4.40 as enhanced absorption signal 4, the dimethyl protons of DMID moiety of **3a** appeared at δ 0.40 and 1.18 as moderately enhanced absorption signals 1 and 2, and in addition the dimethyl protons of DMID appeared at δ 1.14 as enhanced emission signal 3. We can rationalized these polarized signals in terms of the initially formed triplet radical pair composed of the semidione radical **11a** and 9-xanthenyl radical **12**. The geminate combination of **11a** and **12** produces **3a**. On the other hand, **11a** escaping from the initial triplet radical pair reproduces DMID by donating a hydrogen atom to another DMID. The Kaptein's equation[8] (Eq. 1) allows us to predict the net effect of polarization, Γ_{ne}.

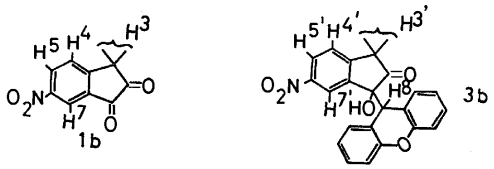
$$\Gamma_{ne} = \Delta g \varepsilon \mu A_i \quad (1)$$

if, $\Gamma_{ne}=+$, then absorption polarized signal,
$\Gamma_{ne}=-$, then emission polarized signal.

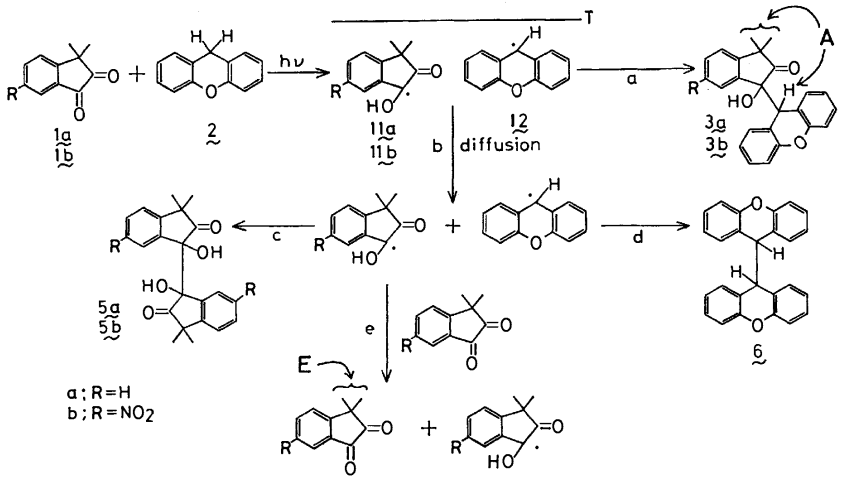
These parameters have their usual meanings. As to the enhanced absorption signal 4 in Fig. 1b, $\Delta g=-$, $\varepsilon=+$, and $A_i=-$ are to be considered, because **3a** is the geminate combination product, g-value of semidione radical is in general larger than that of carbon radical without exception, and the sign of hyperfine coupling constant A_i of α-hydrogen of carbon radical is assumed to be negative on the basis of the preceding reaction mechanism.[9] Thus, in Eq. 1, $+=-\cdot+\cdot\mu\cdot-$, then μ will be positive and the triplet radical pair was indicated.

The A_i sign of the dimethyl protons of **11a** was deduced to be positive from the direction of polarization of signals 1 and 2. Then, the observed enhanced emission signal 3 due to DMID itself led us to a conclusion that DMID was reproduced as the escaping product from the initial triplet radical pair. The hydrogen transfer process as designated e in Scheme 3 was similarly proposed in the photolysis of benzaldehyde[10] and the photochemical reaction of benzophenone in 2-propanol.[11]

In addition to the assigned polarized signals 1, 2, 3, and 4 observed in aliphatic region, other polarized signals in aromatic region remain unassigned in the reaction of DMID with xanthene due to their complicated spin-spin coupling. Photolysis of a solution of NO_2–DMID and xanthene provides us an invaluable information on this point. Figures 2a and 2b show the spectra of a solution of NO_2–DMID and xanthene in $CDCl_3$ before and during irradiation, respectively. The patterns of ^1H NMR signals in aromatic region of both NO_2–DMID and the xanthene-adduct **3b** are rather resemble each other. Thus, from comparison of their chemical shifts and coupling patterns each proton of these compounds was assigned as follows; H^3, δ 1.55



(s, 6H); H^4, 7.80 (d, J=8 Hz, 1H); H^5, 8.60 (dd, J=2 and 8 Hz, 1H); H^7, 8.66 (J=2 Hz, 1H) in **1b**, and $H^{3'}$, 0.46 (s, 3H) and 1.21 (s, 3H); $H^{4'}$, hidden in the signals of aromatic protons of xanthenyl moiety; $H^{5'}$, 8.18 (dd, J=2 and 8 Hz, 1H); $H^{7'}$, 7.76 (d, J=2 Hz, 1H); H^8, 4.46 (s, 1H). Based on these observation, we assigned polarized signals 1, 2, 4, 5, and 7 to $H^{3'}$, $H^{3'}$, H^8, $H^{7'}$, and $H^{5'}$, respectively, and polarized signals 3, 6, 8, and 9 to H^3, H^4, H^5, and H^7, respectively. Similar to the case of DMID, it was concluded according to Eq. 1 that **3b** was the geminate combination product from the initial triplet radical pair, and that there was reproduction of NO_2–DMID *via* the escaping semidione radical. Furthermore, consulting to Eq. 1 we can

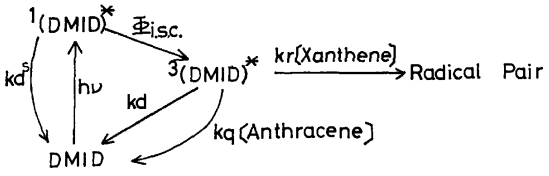


Scheme 3.

conclude from the direction of the polarized signals in aromatic region that the A_i signs of aromatic protons in the semidione radical **11b** were negative for the proton at C-7, negative for the proton at C-5, and positive for the proton at C-4, respectively.

e) Quantum Yield and Reaction Rate. The quantum yield for the disappearance of DMID in the presence of xanthene upon irradiation with light of 450 nm in a carefully degassed benzene solution was determined to be 0.71. The value of the quantum yield is significantly higher than the value of 0.07 ± 0.01 reported for the hydrogen abstraction reaction of camphorquinone with *p*-xylene,[2] but is nearly equal to the value of 0.7 reported for the reaction of benzil with toluene.[12] Although the carbonyl groups of DMID are rigidly fixed in a five membered ring, the C-1 carbonyl group is not suffering from such a high steric hindrance as the C-2 carbonyl group. Since in addition the C-1 carbonyl group is conjugated with the phenyl group, the π^* orbital of the C-1 carbonyl group in alkyl phenyl diketone may be stabilized by mixing with the benzene π^* orbitals and therefore contributes more to the lowest diketone π^* orbital.[13] Thus, the hydrogen abstraction of DMID could occur predominantly at the C-1 carbonyl group.

The lowest triplet $(n\pi)^*$ energy of DMID has been measured to be about 52 kcal/mol.[14] The photoreaction of DMID with xanthene was not quenched by phenanthrene (E_T=62 kcal/mol), but quenched by anthracene (E_T=42 kcal/mol) upon irradiation with 450 nm monochromatic light. There are some spectroscopic evidences[15] that the abstracting state is the lowest $^3(n\pi)^*$.



Scheme 4.

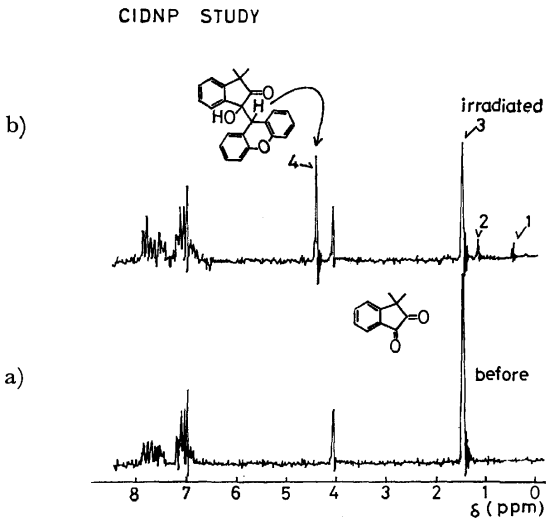


Fig. 1. ^{1}H NMR spectra observed in the photochemical reaction of DMID with xanthene in $CDCl_3$; a) before irradiation, b) during irradiation.

The possible reaction mechanism is described in Scheme 4, DMID in its ground state is excited to its $^3(n\pi)^*$ in the rate of $I\cdot\Phi_{isc}$: I; light intensity, Φ_{isc}; intersystem crossing yield. The ^{3}(DMID)* is consumed through two paths. The one is *via* self-decaying path (rate constant; k_d) involving both thermal and light emission, and the other is *via* hydrogen abstraction reaction from xanthene (rate constant; k_r). The hydrogen transfer process from the semidione radical to DMID can be neglected in Scheme 4, because there is no net change in the concentration of DMID. From the linear Stern-Volmer plots of Φ_d^{-1} *vs.* [xanthene]$^{-1}$ and Φ_d^{-1} *vs.* [anthracene], the quantum yield of

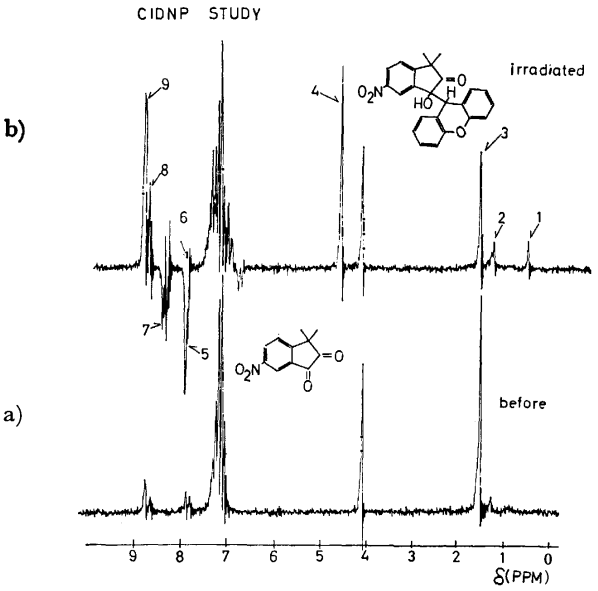

Fig. 2. ^{1}H NMR spectra observed in the photochemical reaction of NO_2–DMID with xanthene in $CDCl_3$; a) before irradiation, b) during irradiation.

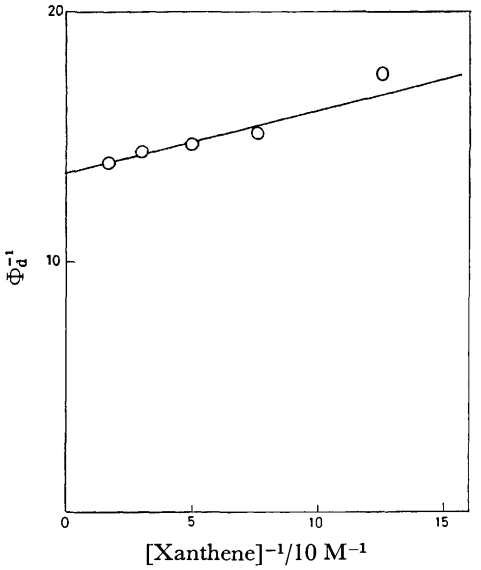

Fig. 3. Stern-Volmer plot of Φ_d^{-1} *vs.* [xanthene]$^{-1}$ in the photochemical reaction of DMID with xanthene.

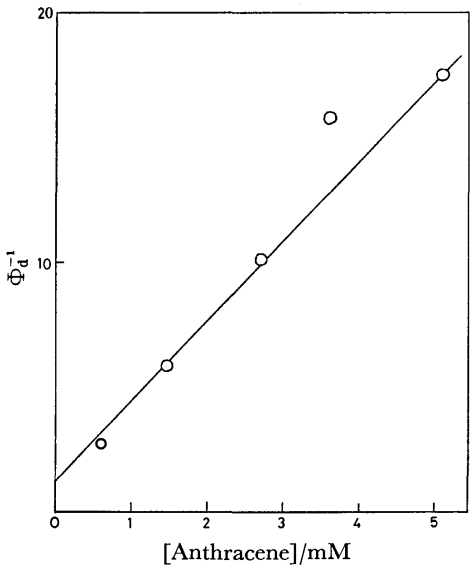

Fig. 4. Stern-Volmer quenching of the photochemical reaction of DMID and xanthene by anthracene.

intersystem crossing (Φ_{isc}) and the reaction rate constant (k_r) were estimated to $\Phi_{isc}=0.75$ and $k_r=5.7\times10^7$ M^{-1} s^{-1}, respectively.[16]

In conclusion, the hydrogen abstraction reaction of DMID with xanthene is a cosiderably fast process. The ^{3}(DMID)* shows high reactivity in the hydrogen abstraction reaction and behaves as one of aromatic α-diketones such as benzil rather than one of sterically hindered α-diketones.

Experimental

Apparatus. The melting points were measured with a Yanagimoto micro melting point apparatus and are uncorrected. Micro analyses were performed by the Micro analytical Laboratory of Kyoto University. IR spectra were recorded with a JASCO DS-402G spectrometer, and ^{1}H NMR spectra were taken with a JEOL PS-100 spectrometer with use of tetramethylsilane as an internal standard and the chemical shifts are expressed in δ value. UV irradiations were carried in a Pyrex glass tube at room temperature, using an Eikosha 300-W high-pressure mercury lamp.

Materials. 3,3-Dimethyl-1,2-indanedione (mp 104—105 °C) and 3,3-dimethyl-6-nitro-1,2-indanedione (mp 172—174 °C) were prepared by the method of Koelsh.[17] 1,1′-Dihydroxy-3,3,3′,3′-tetramethyl-2,2′-dioxo-1,1′-biindanyl (mp 123—125 °C) was prepared by the photoreduction of DMID in 2-propanol.

Photochemical Reaction of DMID with Xanthene. A degassed solution of DMID (1 mmol) and xanthene (1.2 mmol) in 30 ml of benzene was irradiated for an hour in a Pyrex glass tube, using a 300-W high-pressure mercury lamp from outside. After removal of the solvent, the residual oil was chromatographed on silica gel (Wakogel C-100). Elution with light petroleum ether (1%) gave colorless crystals of 9,9′-bixanthenyl **6** (46%). The isolated **6** was identified by comparison of IR and ^{1}H NMR spectra with those of the authentic sample. Elution with light petroleum ether (5%) gave colorless prisms of 1-hydroxy-3,3-dimethyl-1-(9-xanthenyl)-2-indanone **3a** (49%); mp 133—134 °C. Found: C, 80.72; H, 5.53%. Calcd for $C_{24}H_{20}O_3$: C, 80.86; H, 5.67%. Elution with light petroleum ether (10%) gave colorless oil of 2-hydroxy-3,3-dimethyl-1-indanone **4** (12%). Found: C, 74.72; H, 6.99% Calcd for $C_{11}H_{12}O_2$: C, 74.98; H, 6.86%. The hydroxy ketone **4** was also prepared by the reduction of DMID with $NaBH_4$ in ethanol in a yield of 68%.

Photochemical Reaction of 3,3-Dimethyl-6-nitro-1,2-indanedione. A degassed solution of **1b** (1 mmol) and xanthene (2 mmol) in 30 ml of benzene was irradiated for 6 houres in a Pyrex tube. White crystals were deposited and then filtered off (15%). The substance showed characteristic absorptions at 3500 (OH) and 1749 cm^{-1} (C=O), and changed to the starting **1b** on heating. The mass spectrum of it showed *m/e* at 219 and 221 corresponding to the molecular ions of NO_2–DMID and the hydroxy ketone, respectively, probably produced by disproportionation of the semidione cation radical. Therefore, the crystals were determined to be 1,1′-dihydroxy-3,3,3′,3′-tetramethyl-6,6′-dinitro-1,1′-biindan-2,2′-dione **5b** (pinacol). After removal of the solvent, the residual oil was chromatographed on silica gel column (Wakogel C-100). In addition to 9,9′-bixanthenyl **6** (75%), 1-hydroxy-3,3-dimethyl-6-nitro-1-(9-xanthenyl)-2-indanone **3b** (70%) was obtained. Colorless prisms; mp 170—171 °C; IR (KBr) 3520 (OH), 1725 (C=O), 1515 and 1250 cm^{-1}. Found: C, 71.80; H, 4.70; N, 3.52%. Calcd for $C_{24}H_{19}O_5$: C, 71.81; H, 4.77; N, 3.49%.

2-Anisoyloxyl-3,3-dimethyl-1-indanone; Ester A. A solution of **4** (1 mmol) in benzene (30 mL) was added *p*-anisoylchloride (1.1 mmol) at room temperature. The mixture was stirred for an hour, poured into water, and neutralized with $NaHCO_3$. Extraction with ether followed by drying (Na_2SO_4) and evaporation of the solvent afforded yellow oil. Separation on silica gel chromatography gave ester **A** (56%). Colorless needles; mp 98 °C; IR (KBr) 1757 (C=O), 1721 (ester), 1255 and 1032 cm^{-1}: ^{1}H NMR 1.24 (s, 3H), 1.64 (s, 3H), 3.38 (s, 3H), 5.56 (s, 1H), and 6.90—8.12 (m, 8H). Found: C, 73.45; H, 5.79%. Calcd for $C_{19}H_{18}O_4$: C, 73.53; H, 5.85%.

Photochemical Reaction of DMID with p-*Anisaldehyde.* A degassed solution of DMID (1 mmol) and *p*-anisaldehyde (1 mmol) in 30 ml of benzene was irradiated for 8 hours in a Pyrex tube. After removal of the solvent, the residual oil was chromatographed on silica gel (Wakogel C-200). 1-Anisoyloxy-3,3-dimethyl-2-indanone; ester **B** was obtained in 4% yield. Colorless oil; IR (CCl_4) 1774 (C=O), 1723 (ester), 1252 and 1034 cm^{-1}: ^{1}H NMR (CCl_4) 1.40 (s, 3H), 1.48 (s, 3H), 3.82 (s, 3H), 6.23 (s, 1H), and 6.78—8.01 (m, 8H). Found: C, 73.61; H, 5.89%. Calcd for $C_{19}H_{18}O_4$: C, 73.53; H, 5.85%.

Hydrolysis of Ester A and B. A solution of **A** or **B** (30 mg) in aqueous 50% ethanol was added to a solution of 0.1 N KOH (5 ml), neutralized with $NaHCO_3$, extracted with ether, dried, and chromatographed on preparative TLC. In addition to *p*-anisic acid (80%), the hydroxy ketone **4** was obtained in 60% and 56% yields in the reaction of the ester **A** and **B**, respectively.

3,3-Dimethylspiro(indan-1,2′-[1,3]dithiolan)-2-one ***13*** *and 3,3-Dimethylspiro(indan-2,2′-[1,3]dithiolan)-1-one* ***14***. A solution of DMID (1.0 mmol) and 1,2-ethanedithiol (1.1 mmol) in 20 ml of acetic acid was cooled at 0 °C and boron trifluoride etherate (1.1 mmol) was added with stirring. The mixture was allowed to stand 30 minutes at room temperature and was poured into water, and neutralized with $NaHCO_3$. Extraction with ether followed by drying with Na_2SO_4 and evaporation of the solvent afforded yellow semisolid oil. Separation on silica gel column chromatography gave **13** (67%); mp 77—78 °C: pale yellow needles. IR (KBr) 2970, 1774

(C=O), 1473, 1270, and 1047 cm^{-1}; ^1H NMR (CCl_4) 1.42 (s, 6H), 3.40—3.84 (m, 4H), and 7.04—7,32 and 7.48—7.64 (m, 4H). Found: C, 62.31; H, 5.60; S, 25.61%. Calcd for $C_{13}H_{14}OS_2$: C, 62.36; H, 5.64; S, 25.61%. And **14** (24%); pale yellow oil. IR (CCl_4) 2970, 1727 (C=O), 1608, 1543, 1255, and 1212 cm^{-1}; ^1H NMR (CCl_4) 1.54 (s, 6H), 3.12—3.60 (m, 4H), and 7.20—7.76 (m, 4H); Found: C, 62.45; H, 5.58; S, 25.75.%. Calcd for $C_{13}H_{14}OS_2$: C, 62.36 H, 5.64; S, 25.61%. The structures of these two regioisomers were determined by comparison of the characteristic bands due to the carbonyl group of **13** with that of **14**; namely, phenyl conjugated ketone **14** shows an absorption at smaller wave number compared with nonconjugated ketone **13.**

*2-Hydroxy-3,3-dimethylspiro(indan-1,2'-[1,3]dithiolane) **10** and 1-Hydroxy-3,3-dimethylspiro(indan-1,2'-[1,3]dithiolane) **9**.*
Both **13** and **14** were reduced with sodium borohydride in ethanol to give **10** (90%) and **9** (89%), respectively. Alcohol **10**; colorless needles; mp 72 °C; IR (KBr) 3490 (OH), 2990, 1545, 1133, and 1087 cm^{-1}: ^1H NMR (CCl_4) 1.08 (s, 3H), 1.33 (s, 3H), 2.86 (mobile, 1H), 3.30—3.41 (m, 4H), 4.12 (s, 1H), and 6.98—7.30 and 7.44—7.60 (m, total 4H). Found: C, 61.89; H, 6.65; S, 25.46%. Calcd for $C_{13}H_{16}OS_2$: C, 61.86; H, 6.39; S, 25.41%. Alcohol **9**; colorless oil: IR (CCl_4) 3490 (OH), 2990, 1547, and 1135 cm^{-1}: ^1H NMR (CCl_4) 1.31 (s, 3H), 1.51 (s, 3H), 3.02 (mobile, 1H), 2.09—3.40 (m, 4H), 5.18 (s, 1H), and 6.39—7.40 (m, 4H). Found: C, 62.53; H, 6.20; S, 25.09%. Calcd for $C_{13}H_{16}OS_2$: C, 61.86; H, 6.39; S, 25.41%.

*Oxidative Hydrolysis of **9** and **10**.* Both **9** and **10** were hydrolyzed with mercury(II) chloride by the method of Corey.[18] The hydroxy ketone **4** was obtained in 55% and 68% yields in the oxidative hydrolysis of **9** and **10**, respectively.

CIDNP Examination. PS-100 type NMR instruments equipped with ^1H NMR probe for irradiation (manufactured by JEOL) were used in CIDNP examinations. For irradiation, 1 kW super-high-pressure Xe lamp was applied.

Measurement of Quantum Yield. The absolute value of quantum yield for the disappearance of DMID in the reaction with xanthene was measured using 450 nm monochromatic light with application of both VY 42 and 45 KL filters (Toshiba). Disappearance of DMID in a carefully degassed benzene solution was measured at 505.7 nm. Light intensity was measured by means of tris(oxalato)ferrate(III) actinometry. In Stern-Volmer examination, we plotted the value calculated from relative quantum yields to the standard solution, using a merry-go-round.

Macrocyclic Formals. IV. Macrocyclic Formals as Complexing Agents

Yuhsuke KAWAKAMI,* Tomiya SUGIURA, and Yuya YAMASHITA
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Nagoya 464
(Received May 1, 1978)

Eleven to twenty membered macrocyclic formals have been synthesized from the corresponding polyethylene glycols and paraformaldehyde. Their activating efficiency has been measured in nucleophilic substitution reactions with alkali metal ions as counter ions. These macrocyclic formals were not as good complexing agents as crown ethers, but were much better than open chain polyethers which had the same number of oxygen atoms. In the reaction of butyl bromide with alkali metal acetate, 1,3,6,9,12,15-hexaoxacycloheptadecane was several times more effective than pentaethylene glycol dimethyl ether.

Macrocyclic compounds, such as crown ethers and cryptands, have been extensively studied in recent years as powerful complexing agents specially for alkali metal ions.[1–12] The authors have been interested in the polymerization reaction of macrocyclic formals having ether oxygens besides acetal oxygens. Macrocyclic oligomers were formed in the early stage, then high polymers were formed in the polymerization of macrocyclic formals.[13–17] There might be the possibility that the propagating cationic species was activated by macrocyclic oligomers already formed in the system through complexing in order to propagate. Thus, interest has been shown in the complexing ability of such macrocyclic formals with cations.

Macrocyclic formals from polyethylene glycols have the structure in which one of the ethylene groups of the crown ethers is replaced by a methylene group. They can be easily synthesized from the corresponding polyethylene glycols and paraformaldehyde by condensation and depolymerization at elevated temperatures in the presence of an acid *e.g.* *p*-toluenesulfonic acid. One of the advantages for macrocyclic formals as complexing agents is that they can be easily decomposed by mineral acids and can be separated from the products by simple extraction. From such a viewpoint, the effectiveness of crown ethers, macrocyclic formals and glymes as complexing agents were compared in a nucleophilic substitution reaction.

In this paper, complexing agents have been abbreviated according to the common crown ether nomenclature. For instance, 11-CF-4 stands for a 11-membered macrocyclic formal having four oxygen

crown ether
3*m*-CR-*m*

macrocyclic formal
(3*n*−1)-CF-*n*

glyme
3*p*-GL-*p*

atoms and 18-GL-6 stands for a glyme consisting of 18 skeltal atoms including 6 ether oxygen atoms, namely, pentaethylene glycol dimethyl ether.

Experimental

Synthesis of Complexing Agents. 1,3,6,9-Tetraoxacycloundecane (11-CF-4), 1,3,6,9,12-pentaoxacyclotetradecane (14-CF-5), and 1,3,6,9,12,15-hexaoxacycloheptadecane (17-CF-6) were synthesized according to the reported methods.[16,18] The crude products were purified by fractional distillation over lithium aluminum hydride. Since, 1,3,6,9,12,15,18-heptaoxacycloeicosane could not be synthesized by a similar method, the method of ether linkage formation was used.

A 500 ml three-necked flask equipped with a mechanical stirrer, reflux condenser and addition funnel was charged with tetraethylene glycol (50 g, 0.26 mol) and tetrahydrofuran (200 ml). Stirring was commenced and aqueous potassium hydroxide (60%, 60 ml) solution was added and the solution was heated at 60 °C for one and a half hours. A solution of formaldehyde bis(2-chloroethyl) acetal[19] (44.6 g, 0.26 mol) in tetrahydrofuran (34 ml) was then added in a stream after which the solution was refluxed and stirred vigorously for 7 days. The solution was allowed to cool and the bulk of the tetrahydrofuran was evaporated on a rotary evaporator. The resulting slurry was diluted with dichloromethane (170 ml). The upper organic layer was separated and washed with water (40 ml) in order to remove unreacted tetraethylene glycol. This water layer (40 ml) was extracted twice with dichloromethane (10 ml) and the extract was combined with the organic layer. The combined organic solution was dried with calcium chloride and the solvent was evaporated off. The residue was distilled under reduced pressure to give 7.8 g of a crude product (152—165 °C/0.2 mmHg). The crude product was redistilled over lithium aluminum hydride.

20-CF-7: bp 142—144 °C/0.2 mmHg yield 3.4 g, 4.5%. IR (NaCl, cm^{-1}) 2930, 2870, 1460, 1360, 1300, 1255, 1180, 1120, 1030, 940, 850. NMR ($CDCl_3$, δ ppm) 4.80 (s, 2H, $-OC\underline{H}_2O-$), 3.78 (s, 8H, $-OC\underline{H}_2C\underline{H}_2OC\underline{H}_2O-$), 3.70 (s, 16H, $-OC\underline{H}_2-C\underline{H}_2O-$).

Found: C, 52.96; H, 8.22%. Calcd for $C_{13}H_{26}O_7$: C, 53.05; H, 8.90%. *M. W.* (VPO) 294.34 (302).

12-Crown-4 was synthesized from 1,8-dichloro-3,6-dioxaoctane and ethylene glycol according to the literature[20] and 2,5,8,11 14,17-hexaoxaoctadecane (18-GL-6) by the condensation between 1-chloro-3,6-dioxaheptane and triethylene glycol monomethyl ether sodium salt.

18-GL-6: bp 149—151 °C/2.5 mmHg. IR (NaCl, cm^{-1}) 2880, 1460, 1355, 1200, 1110. NMR ($CDCl_3$, δ ppm) 3.68 (s, 16H, $-C\underline{H}_2-O-C\underline{H}_2-$), 3.62 (broad s, 4H, $CH_3OC\underline{H}_2-$), 3.40 (s, 6H, $C\underline{H}_3O-$)

Found: C, 54.35; H, 9.56%. Calcd for $C_{12}H_{26}O_6$: C, 54.07; H, 9.84%. Other complexing agents, 15-CR-5, 18-CR-6, 12-GL-4, and 15-GL-5 were commercially supplied.

Determination of Reaction Rate in the Presence of Complexing Agent. A 20 ml round bottomed flask equipped with a reflux condenser was charged with alkali metal acetate (metal: K, Na, Li) (0.01 mol), butyl bromide (0.01 mol) a complexing agent (0.01 mol), toluene (1.0 ml) as internal standard for GLC and benzene (9 ml). The mixture was heated to reflux at a bath temperature of 90 °C. At a

given time interval, a small portion of the reaction system was extracted with a syringe and analyzed by GLC. The conversion of the reaction was determined by use of a calibration curve using toluene as an internal standard. The gas chromatograph was a Hitachi model K 23 connected with 2 m of stainless steel columns packed with 15% Apiezon grease M on Chromosorb. It was operated at 80 °C with 17 ml/min helium as the carrier gas.

Determination of Cation Binding Efficiency of Complexing Agents. The cation binding efficiency of the complexing agents was determined by measuring the extraction equilibrium of alkali metal picrate between dichloromethane and water. Twenty five ml of 0.1 M alkaline solution containing 8×10^{-5} mol of picric acid was extracted with 25 ml of dichloromethane and the system left to reach equilibrium. The concentration of picrate species present in the organic phase and water phase was determined by measuring the UV absorption of each phase at equilibrium using λ_{max} 357 nm (ε 15000) in water, λ_{max} 378 nm (ε 18000) in CH_2Cl_2.[21] The UV spectrophotometer used was a Hitachi Perkin Elmer model 139 using quartz cells.

Results and Discussion

Effect of Complexing Agents on the Reaction Rate. The effect of complexing agents in accelerating Reaction 1 was examined.

$$CH_3CO_2M + n\text{-}C_4H_9Br \xrightarrow[\text{Benzene reflux}]{\text{Complexing agent}} CH_3CO_2n\text{-}C_4H_9 + MBr \quad (1)$$

(M=K, Na, Li)

The conversion of butyl bromide or the yield of butyl acetate determined by GLC was plotted against time. A typical result has been shown in Figure 1. The conversion and the yield coincide with each other very well. The initial slope of the curve was taken as the initial rate V_0 of the reaction and the initial rates in the presence of various complexing agents have been shown in Table 1. Crown ethers were the best activating complexing agents for the reactions of potassium or sodium acetate. The initial rates decreased in the order of crown ethers, macrocyclic formals and glymes. In the case of lithium acetate, only 15-CR-5 slightly activated the reaction.

It is generally considered that the complexing agents

15-GL-5	1.0	0.0	0.0
12-GL-4	0.25	0.0	0.0

Metal acetate 0.01 mol, *n*-BuBr 0.01 mol, complexing agent 0.01 mol, toluene 1.0 ml, benzene 9.0 ml, 90 °C.

activate the reaction by complexing with the counter cation and separating the cation from the anion species. It is also well recognized that crown ethers have specific ring sizes to fit specific cations, for instance, 18-CR-6 has a specific size for the potassium cation. In the case of macrocyclic formals, 20-CF-7 appeared to be a much better activating agent than 17-CF-6 for the reaction with potassium as the counter cation. Moreover, 17-CF-6 was a better activating agent than 14-CF-5 or 20-CF-7 for the reaction with sodium as the counter cation. Thus, in case of macrocyclic formals, the specific ring size to fit an alkali metal cation might be one ethyleneoxy unit larger than that in case of crown ethers.

Thus, in comparing the effectiveness of complexing agents in accelerating Reaction 1, it would be reasonable to compare 20-CF-7 with 18-CR-6 and 18-GL-6 and 17-CF-6 with 15-CR-5 and 15-GL-5. For the potassium cation, the ratio of the initial rates among 18-CR-6, 20-CF-7, and 18-GL-6 was 46: 1.0: 0.046 and for the sodium cation, it was 31: 1.0: 0.21. The ratio among 15-CR-5, 17-CF-6, and 15-GL-5 was 52: 1.0: 0.067 for the potassium cation and 5.7: 1.0: 0.00 for the sodium cation. It was shown that the macrocyclic formals were not as good activating agents as the crown ethers, however, they were much better than the glymes. The difference in initial rate V_0 would reflect the effective concentration of the activated anion with its counter cation complexed. In order to clarify the difference in the effectiveness among complexing agents, the complexing agents' efficiency in the extraction equilibrium of alkali metal picrate between dichloromethane and water was examined and the results have been shown in Table 2. In determining the extraction efficiency, it was assumed that the picrate did not form a complex in the water phase and that the picrate was present only in the complexed form in the dichloromethane phase.[21] As shown in Table 2, percent picrate extracted in dichloromethane phase decreased in the order of crown ether, cyclic formal, and glyme. This was the same order as in the case of the activating of Reaction 1.

The efficiency of complexing agents in extracting

[Picric acid] $= 8 \times 10^{-5}$ M, [complexing agent] $= 35 \times 10^{-5}$ M, [metal hydroxide] $= 0.01$ M.

alkali metal cations would be controlled by ① the number of oxygen atoms in the complexing agent, ② the nature of the cation and anion of the salt, and ③ the structure of the complexing agent: cyclic or open chain and size of ring.

Let us consider a little more about these factors. Complexes are formed by the coordination of lone pair electrons of oxygen atoms to metal cations. The more oxygen atoms were contained in a complexing agent, the easier complex formation would be. When a salt is forming a complex, the easier the dissociation of the salt, the easier the complex formation. In Table 2, except 11-CF-4 and 12-CR-4, potassium picrate was extracted the most by all of the complexing agents, indicating that the ease of dissociation of the salt was the primary factor for complex formation.

The big advantage for symmetrical cyclic complexing agents in coordination is that all the oxygen atoms can participate equally. A crown ether is a cyclic oligomer of ethylene oxide and has a highly symmetrical structure. All the oxygen atoms in the ring are equivalent and the lone pair electrons can be equally directed towards the cation in complex formation. In open chain complexing agents, a pseudocyclic structure must be taken to make all oxygen atoms participate equally in coordination. This is a great disadvantage against open chain complexing agents in terms of entropy. Moreover, when it is difficult to take a pseudocyclic structure, only few oxygen atoms can participate in coordination leading to weak complex formation. In cyclic formal rings, the two acetal oxygens are not equivalent with other ether oxygens and the lone pair electrons on the acetal oxygens can only with difficulty coordinate to the metal cation. This means the effective oxygens for coordination are less than actual oxygens in the molecule.

It is also well recognized that the size of the ring is an important factor in order to form a strong complex. The ring sizes of 17-CF-6 and 14-CF-5 would be smaller than those of 18-CR-6 and 15-CR-5, respectively and the most suitable cyclic formals for potassium and sodium cations would be 20-CF-7 and 17-CF-6, respectively. This situation is well shown in Table 2. The percentages of potassium picrate extracted into the dichloromethane phase were 14.2 and 3.1, for 20-CF-7 and 17-CF-6, respectively. Moreover, the percentages of sodium picrate extracted were 1.4, 2.1, and 0.1 for 20-CF-7, 17-CF-6, and 14-CF-5, respectively. When the efficiency of cyclic formals was compared with that of the crown ethers, the low efficiency of the cyclic formals was apparent. This might indicate the importance of the exact agreement of the ring size with cation size and symmetry of the ring.

Table 3. Effects of complex concentration on initial rate, V_0/C (s^{-1})

Complexing agent	K^+	Na^+	Li^+
None	0.0	0.0	0.0

12-GL-4	2.5	0.0	0.0

Assuming that the precentage of picrate extracted into the dichloromethane phase is proportional to the concentration of the complexed species in the reaction system, V_0/C (V_0: initial rate in Table 1, C: concentration of picrate extracted in Table 2) was taken as the relative standard of the reactivity of the complex, the values of which have been shown in Table 3. The values are in the order of 10^1 for the most effectively activated potassium-18-CR-6 or 15-CR-5 systems and in the order of 10^0 for the moderately activated potassium-20-CF-7 or 17-CF-6 and sodium-18-CR-6 or 15-CR-5 systems. The value was less than 1 for the other slow reaction systems. This might indicate that in the effectively activated systems, not only the concentration of the complex but also the reactivity of the complex was high. It would be reasonable to consider that the easier the dissociation of the salt was and the stronger the complexing agent coordinated to the cation, the higher the concentration of the complex was and the looser complexed ion pair became. The looser ion pair would have a higher degree of nucleophilicity and effectively activate the substitution reaction.

The effectiveness of the macrocyclic formals as complexing agents was not sufficiently high compared with the crown ethers in the nucleophilic substitution reactions. However, they were much more efficient complexing agents than the open chain polyethers.

This research was partially supported by a Grant-in-Aid from the Ministry of Education (No. 285199).

$TiN_{0.07}O_{1.93}$ Semiconductor Electrodes for Photoassisted Oxidation of Water†

Taketsugu HIRAI,* Isao TARI, and Junichi YAMAURA

Department of Synthetic Chemistry, Faculty of Engineering, Okayama University, Tsushima, Okayama 700

(Received February 3, 1978)

Synopsis. As a new anode for the photoassisted oxidation of water, the $TiN_{0.07}O_{1.93}$ semiconductor electrode is proposed. Its photoanodic behavior in 0.1 M Na_3PO_4 was similar to those of n-type TiO_2 electrodes, but the photocurrent response was a little extended toward the long wavelength region. The electrode stability under the irradiation with ultraviolet light was good.

Much recent attention has been paid to the application of semiconductor electrodes to the photolysis of water and the direct conversion of solar to electrical energy. The n-type TiO_2 has been intensively studied as one of the most promising anode materials for such systems.[1-23] However, the n-type TiO_2 has a relatively wide band gap of *ca.* 3 eV[1,2,6] and thus makes inefficient use of solar energy. In addition, a certain deterioration of the photoanode characteristics of n-type TiO_2 under the irradiation from an artificial light source has been reported recently,[16,17] in opposition to the notion that the n-type TiO_2 electrode is chemically stable. Titanium nitride oxide $TiN_{0.07}O_{1.93}$, proposed here, is a novel photoanode material with the n-type semiconductivity. As shown by the formula of $TiN_{0.07}O_{1.93}$, this non-stoichiometric compound is one of the modified forms of TiO_2; it is easily prepared by the thermal treatment of metallic titanium substrate in a N_2–O_2 atmosphere. The idea of doping nitrogen together wtih oxygen into a titanium substrate is based on the fact that the titanium nitride TiN_x shows both good electronic conductivity and chemical stability, and on the possibility that the interstitial permeation of nitrogen atoms into the TiO_2 structure might produce some oxygen vacancies.

Experimental

Electrode Preparation. Commercial titanium plate (20 mm × 15 mm, 0.5 mm in thickness) with a short sleeve for the electrical connection to a leading wire was heated in a nitrogen gas atmosphere containing 0.5 vol % oxygen gas at 1100 °C for 3 h. Most electrodes thus obtained had a grayish appearance with a metallic luster. Prior to the measurement of the current-potential characteristics, the surface of the electrode was investigated by means of X-ray diffraction and ESCA (DuPont Model 650B) techniques. A copper lead wire was tied tightly around the sleeve of the electrode after the sleeve was scratched by a fine emery paper to expose the titanium substrate. The apparent working area for the photoanode was 1 × 1 cm^2 and the remaining portion was coated with solid paraffin.

Measurements of Current-potential Characteristics. The apparatus, comprising a light source, photoelectrochemical cell, and recording equipment, is shown in Fig. 1. A monochromatic light source was prepared by attaching an interference filter (Koshin Optics Ltd.) to a xenon lamp. The accelerated life testing for inspecting the stability of the electrode was performed under the ultraviolet irradiation from a 440 W high pressure mercury lamp.

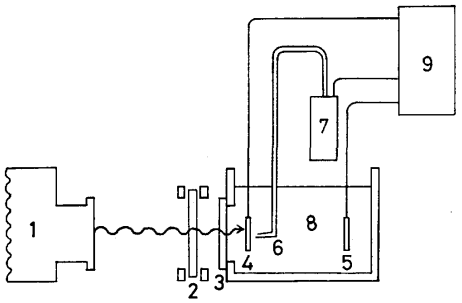

Fig. 1. Schematic representation of the experimental arrangement.
1: 450 W xenon lamp, 2: interference filter, 3: quartz window (3 mm thick), 4: working electrode, 5: Pt counter electrode, 6: Luggin capillary, 7: SCE reference electrode, 8: 0.1 M Na_3PO_4 (pH=6), 9: potentiostat and recorder.

Results

The X-ray diffraction analysis of the electrode surface gave mixed diffraction profiles of rutile, anatase, and titanium substrate. The ESCA spectra showed the presence of N, O, and Ti atoms in the thin surface layer of the electrode. The emission peaks of N 1s, O 1s, Ti 2p3/2, and Ti 2p1/2 electrons were observed at binding energies of 395.5 and 399.3, 529.1 and 531.3, 457.7, and 463.7 eV, respectively. From the summation of the corresponding peak areas on the ESCA spectra and the atomic sensitivity corrections for the photoelectron emission, the chemical composition of the outer surface layer of the electrode was estimated to be $TiN_{0.07}O_{1.93}$. Among a number of TiN_xO_y electrodes prepared under various atmospheric and thermal conditions, an electrode having a surface composition near $TiN_{0.07}O_{1.93}$ was found by a preliminary test to perform best as a photoanode.

The current-potential characteristics of the electrode in 0.1 M Na_3PO_4 (adjusted to pH 6 by addition of a small quantity of concd H_3PO_4) are shown in Fig. 2. From the comparison of curves A and B in Fig. 2, it is obvious that the electrode behaves as a photoanode. In addition, gas evolution at the electrode surface was

† A preliminary report of this work was presented at the 18th Battery Conference, Osaka, November 1977.

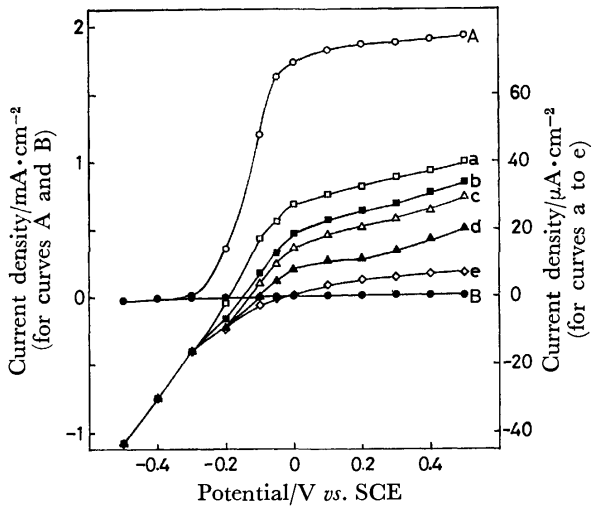

Fig. 2. Current-potential characteristics of $TiN_{0.07}O_{1.93}$ electrode in 0.1 M Na_3PO_4 (pH=6).
A: Under irradiation without interference filter, B: dark, a: under irradiation through a 400 nm interference filter, b: 440 nm, c: 420 nm, d: 450 nm, e: $\geqslant$460 nm.

observed in response to the passage of photocurrent. As shown by the curves a to e in Fig. 2, the electrode responded to the monochromatic light at wavelengths shorter than 460 nm, which corresponds to a band gap of *ca.* 2.7 eV. A small maximum of photocurrent at around 440 nm was a new feature of the electrode.

The accelerated stability test of the electrode was conducted in the following manner. Strong ultraviolet irradiation was directed, by use of a high pressure mercury lamp, onto the photoanode. This was short-circuited with the counter platinum cathode for 12 h and then operated with a constant anodic current density of 3.5 mA/cm² for 14 h. No significant change in the photocurrent-potential relation or in the electrode appearance was detected. These results demonstrate the stability of $TiN_{0.07}O_{1.93}$ electrode under ultraviolet irradiation.

Finally, the selection of Na_3PO_4 solution as electrolyte was due to its high pH-buffer action and its ability to detach the evolved bubbles from the electrode surface and move them into the bulk. In fact, the use of 0.1 M Na_2SO_4 as electrolyte caused a rapid decrease of the photocurrent with time.

We would like to thank Prof. Nobuatsu Watanabe and Dr. Tsuyoshi Nakajima of Kyoto University for their kind efforts in obtaining the ESCA spectra and for their helpful discussions.

Charge-transfer Model in Considering the Reactivity of Heteroaromatic Nitriles with the Enolate Anion

Masumi YAMAKAWA, Tanekazu KUBOTA,* Yoshihiro TERUI, Tsunetoshi HONMA, and Yukio TADA

Shionogi Research Laboratory, Shionogi and Co., Ltd., Fukushima-ku, Osaka 553

(Received January 25, 1978)

Synopsis. The reactivity of heteroaromatic nitriles with the enolate anion to give the enamino ketones was discussed on the basis of a reaction index calculated by the charge-transfer model and also using the total electron densities. The results were reasonable in interpreting the reaction mechanism.

Recently Honma and Tada[1] have reported the very useful reaction of heteroaromatic nitriles with the enolate anion to prepare enamino ketones. The reaction is shown in Scheme 1. The reactivity will be considered using the molecular orbital (MO) description of the charge-transfer (CT) theory.[2,3] Supposing that the MO energies of the nitriles and enolate anion are related as Fig 1 shows, and that the CT occurs

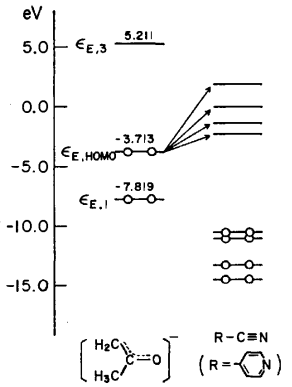

Fig. 1. Calculated MO energie of enolate anion and nitriles. The MO energies o heteroaromatic nitriles are more or less similar to th se given in this figure.

predominantly as shown by the arrows in Fig. 1, the stabilization energies due to CT can be written approximately by; $\Delta E_{rs}=2\sum_{k}^{VAC}[(C^{r}_{E.HO}\cdot C^{s}_{N.k})^2(H_{rs})^2/(\varepsilon_{E.HO}-\varepsilon_{N.k}+V^{E.HO}_{N.k})]$. $C^{r}_{E.HO}$ and $\varepsilon_{E.HO}$ are the πMO coefficients at the r-th atom in the highest occupied MO (HOMO) and the HOMO energy of the enolate anion respectively. Alternatively, $C^{s}_{N.k}$ and $\varepsilon_{N.k}$ stand for the πMO coefficient at the s-th atom in the k-th vacant πMO and the k-th πMO energy of nitriles respectively. H_{rs} is the resonance energy between the two πAO's. The intermolecular resonance interaction of the nitrile and the enolate anion was assumed to occur only through the two AO's. The electrostatic interaction energy between the MO's $\psi_{E.HO}$ and $\psi_{N.k}$ is expressed by $V^{E.HO}_{N.k}=\langle\psi^{*}_{E.HO}\cdot\psi^{*}_{N.k}|e^2/r|\psi_{E.HO}\cdot\psi_{N.k}\rangle$. For evaluating the $V^{E.HO}_{N.k}$ term, the geometrical configuration between each atom in nitriles and the enolate anion should be determined. Since this is quite difficult, we have disregarded the $V^{E.HO}_{N.k}$ term in the present calculation.[4] The reagent, the enolate anion, was always the same throughout the present experiments. Also assuming H_{rs} to be constant, we can now evaluate the value of $(CTA)_s=\sum_{k}^{VAC}[(C^{S}_{N.k})^2/(\varepsilon_{E.HO}-\varepsilon_{N.k})]$. The $\varepsilon_{E.HO}$ may be put as a constant in all the calculations.[4] Thus, the CTA value (charge-transfer ability) can be used as a measure of the selectivity of the reaction position, to which the first bond is formed to bring about the nucleophilic reaction of the enolate anion with nitriles. Note that the CTA value has a physical meaning very similar to the nucleophilic superdelocalizability.[5] The calculation was done using the PPP SCFMO method of π electron approximation. The parameters pertinent to each atom and each bond were determined by referring to many previous studies.[6] The π-electron energy for the enolate anion was obtained using the molecular model in Fig. 1; we know that the $\varepsilon_{E.HO}$ is shallow in energy,[7] so the CT to $\varepsilon_{N.k}$ from $\varepsilon_{E.HO}$ is the most important one, and, also, the CH_2-group carbon atom in the enolate anion may be the most likely to attack nitriles, because the MO corresponding to $\varepsilon_{E.HO}$ is mainly localized on the CH_2 group πAO.

The calculation results of the CTA values at each atom of various kinds of nitriles are given in Table 1. The nitrile, which has a CTA value at the nitrile carbon atom larger than $|\approx 0.195|$ throughout all the nitriles examined, and which is also larger than those of any other atoms in the nitrile in question, was quite reactive with the enolate anion in producing the final enamino ketone, according to the reasonable reaction shown in Scheme 1. However, in a case such as 3-cyanopyridine, the CTA values at the 2, 4, and 6 carbons were quite large compared with those of the other atoms in the molecule. Thus, there are three cases for the reaction of this kind of molecule with the enolate anion; the first two are the formation of byproducts caused by a reaction at the suitable ring atoms and a decrease in the yield of enamino ketones, while there is no reaction in the third case. In view of the above findings, the CTA values obtained here seem

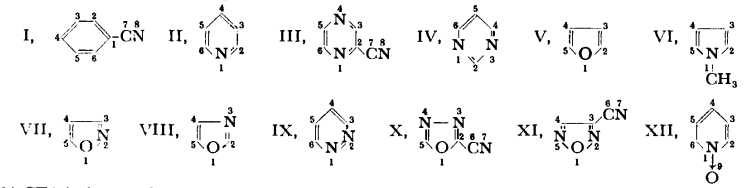
a) The formula and numbering for each substance are as follows:



b) CTA is the negative value. The absolute values are given in this Table. c) CNDO/2 total electron density at the C* atom bound to the CN group. d) The sum of the CNDO/2 total electron density on each atom in the $\overset{*}{\rangle C}-C\equiv N$ group. e) See Reference 1 in text. f) Side reactions occurred. g) The starting nitrile was recovered. h) Ring cleavage occurred. i) These mean the methyl substituted compounds which were used as starting materials to prevent the ring cleavage in the reaction process. j) Unpublished data.[1]

to give a reasonable reaction index for interpreting the experimental results (Table 1) except for the cases of a few molecules. With 2- and 4-cyanopyrimidines, the largest CTA value is at the carbon (C*) to which the CN group is bound, in spite of the considerable yield of the enamino ketone. One reason for this may be the several approximations employed in deriving the CTA values, especially the hypothesis of a constant H_{rs}, since the geometrical configuration of the reaction intermediate would not be the same for all nitriles.[8] Another possibility is that the electron density, the CTA value, *etc.*, at the C* atom may also contribute more or less to the reaction process (*vide infra*). Alternatively, the CTA value (0.190) at the nitrile carbon atom of 3-cyanoisoxazole is less than 0.195 (*vide supra*), but the largest among those for the other atoms in the molecule. Since this molecule gives the enamino ketone, the reason may be that the total electron densities in the $\rangle C-C\equiv N$ group are quite small, as the calculations employing the CNDO/2 method *etc.* have shown (Table 1), so that the reaction centers of the enolate anion and the $C-C\equiv N$ group easily become close enough to initiate the reaction by the charge transfer-process.

Kinetic Evidence for the Participation of a Diatomic Oxygen Species in Vapor-Phase Oxidation of Butadiene over Silver Catalyst

Masamichi AKIMOTO* and Etsuro ECHIGOYA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 15, 1978)

Synopsis. The participation of an adsorbed diatomic oxygen species in the oxidation of butadiene with O_2 or N_2O to maleic anhydride over silver catalyst was confirmed by the following finding: reaction order with respect to O_2 or N_2O is 0.83 or 1.95, respectively, whereas that to butadiene is negative.

Formation of O_2^- over reduced silver metal has been confirmed by means of ESR.[1-4] There are some observations showing that the diatomic oxygen species is active for epoxide formation.[4-7] However, no concrete evidence has been reported for the formation of the electronegative oxygen species during the course of oxidation of hydrocarbons over reduced silver metal. Our studies on the oxidation of furan over promoted anatase-titania catalyst revealed incorporation of oxygen atoms into maleic anhydride *via* the formation of O_2^-.[8] In this work, the formation of maleic anhydride in vapor-phase oxidation of butadiene with oxygen or nitrous oxide N_2O over silver catalyst has been kinetically investigated in order to confirm the formation of O_2^- during the oxidation.

Experimental

Vapor-phase catalytic oxidation of butadiene was carried out at 560—680 K using a conventional flow type fixed-bed reactor under atmospheric pressure. The shape of reactor and method of reaction were the same as those reported, and H_2O and CO_2 contained in air were removed in the same way as described.[8] Research grade butadiene (purity >99.9%) was used. Nitrogen, H_2, He and N_2O were supplied from commercial cylinders. Gas chromatographic analysis indicated a trace ($\approx$0.4 vol%) of O_2 in the N_2O. The silver catalyst was prepared by reacting $AgNO_3$ with NaOH in an aqueous medium followed by the reduction of the silver oxide formed with 36% formalin at pH=11$\pm$0.5.[9] The surface area was $<1.0\ m^2\ g^{-1}$. The catalyst was reduced with H_2 (100 NTPml min^{-1}) at 583 K for 1.0 h prior to the experiment. The gaseous effluent from the reactor was analyzed by gas chromatography.[8] Since maleic anhydride was confirmed to be the only acid formed, the anhydride was absorbed in water, followed by boiling of the solution in order to remove dissolved CO_2 and by titration with an aqueous solution of NaOH. Carbon monoxide was not analyzed. X-Ray diffraction study was carried out using nickel-filtered Cu $K\alpha$ radiation (30 kV, 20 mA).

Results

Table 1 shows the effect of reaction temperature on the oxidation of butadiene over silver catalyst. The reaction initiated at $\approx$560 K. However, butadiene was preferentially converted into CO_2 with low yields of 2,5-dihydrofuran (2,5-DHF), furan (F) and maleic anhydride (MA). The selectivity to 2,5-dihydrofuran was negligible above 602 K but that to furan decreased gradually in contrast to that to maleic anhydride.

Table 1. Effect of the reaction temperature on the oxidation of butadiene over silver catalyst[a]

Reaction temp (K)	Conversion of C_4'' (%)	Yield of CO_2 (%)	Selectivity (%)		
			2,5-DHF	F	MA
561	1.4	0.2	8.3	8.3	5.1
578	5.4	2.2	15.2	4.0	5.3
591	21.0	17.1	1.0	1.2	6.6
602	34.2	31.1	0.0	0.9	6.7
612	39.0	34.0	0.0	1.0	7.8
630	40.7	35.5	0.0	0.7	7.6

a) Feed concentration: C_4'' 3.82 vol %, O_2 10.0 vol%, Contact time W/F: 0.202 g-cat·h g-mol^{-1}.

The steady state of silver catalyst during the course of oxidation at 583 K, W/F=0.249 g-cat·h g-mol^{-1} and the feed concentration of butadiene 3.85 vol % and O_2 10.0 vol % was quenched by introduction of helium (200 NTPml min^{-1}) for 5 min to eliminate the reactant gas followed by rapid decrease in temperature. X-Ray diffraction revealed that the catalyst consists of silver metal (2θ=38.15, 44.34, and 64.45°) and a small amount of Ag_2O (2θ=26.71°) and Ag_2O_2 (2θ=34.20 and 37.26°). This structure was kept even when the feed concentration of O_2 was increased to 14.0 vol % and the temperature to 635 K. Oxidation of butadiene with Ag_2O at 551 K by means of pulse technique gave only CO_2 and a small amount of acrylaldehyde.

The rate of maleic anhydride formation was kinetically studied using a differential reactor:

$$r(\mathrm{MA}) = k_1[C_4'']^{-0.21}[O_2]^{0.83} \quad \text{at 573 K} \qquad \text{(A)}$$

overall activation energy=32.3 kcal g-mol^{-1}
C_4'': 3.3—7.8 vol %, O_2: 7.0—14.6 vol %

where

Table 2. Oxidation of butadiene with N_2O over silver catalyst[a]

Reaction temp (K)	Conversion of C_4'' (%)	Selectivity (%)		
		2,5-DHF	F	MA
606	7.9	0.8	0.0	2.0
633	13.4	1.2	0.0	4.1
637	17.7	1.3	0.0	4.6
660	49.1	1.1	0.0	4.9
679	45.6	0.8	0.0	4.1

a) Feed concentration: C_4'' 3.94 vol%, N_2O 20.0 vol%. Contact time W/F: 0.200 g-cat·h g-mol^{-1}. Yield of CO_2 was not determined because the retention times of CO_2 and N_2O were the same.

r(MA): initial rate of maleic anhydride formation,
k_1: overall reaction rate constant,
[ ]: concentration of butadiene or O_2 in the feed.

Formation of 2,5-dihydrofuran and maleic anhydride was also observed in the oxidation with N_2O (Table 2). Conversion of butadiene reached 49.1% at 660 K, but the selectivity to these oxidation products was low. The rate of maleic anhydride formation:

$$r(\mathrm{MA}) = k_2[\mathrm{C_4''}]^{-0.20}[\mathrm{N_2O}]^{1.95} \quad \text{at 613 K} \qquad (\mathrm{B})$$

overall activation energy = 28.5 kcal g-mol^{-1}
C_4'': 3.9—8.6 vol %, N_2O: 20.0—30.0 vol %

Discussion

The maximum conversion of butadiene (Tables 1 and 2) was attributed to the almost total consumption of O_2 or N_2O in the feed. 2,5-Dihydrofuran was postulated to be the first intermediate for maleic anhydride formation from butadiene: anhydride is formed from 2,5-dihydrofuran through two reaction paths, one *via* furan and the other *via* a direct path from 2,5-dihydrofuran.[10] Furan and maleic anhydride formation is in line with the above reaction mechanism. On the other hand, a negligible change was observed in the structure of silver catalyst with rise in oxygen concentration in the feed and with rise in temperature. No selective oxidation products in the reduction of Ag_2O with butadiene at 551 K suggests an important role of adsorbed oxygen species formed on metallic silver in the formation of 2,5-dihydrofuran, furan and maleic anhydride. Our previous studies on the formation of maleic anhydride from butadiene show that the activation energy for 2,5-dihydrofuran formation is the highest, the step thus being rate-determining.[10] Hence, the negative reaction order with respect to butadiene (A) indicates a competitive adsorption of butadiene with gaseous oxygen on the surface. The reaction of adsorbed species resulted in maleic anhydride formation. Accordingly, the reaction order with respect to gaseous oxygen, 0.83, is a strong indication of the reaction between an adsorbed diatomic oxygen species and adsorbed butadiene. Similarly, the negative reaction order with respect to butadiene (B) shows that the anhydride is formed through the Langmuir-Hinshelwood mechanism in the oxidation with N_2O as in the case with gaseous oxygen. Furthermore, as judged from the formation of O_2[11] and O_2^- [2] in the catalytic decomposition of N_2O over reduced silver metal, the reaction order of N_2O, 1.95 (B), is an evidence for the participation of an adsorbed diatomic oxygen species in the anhydride formation.

Olefinic hydrocarbons adsorbed on metal oxide generally have positive charge.[12] Since the surface of silver catalyst during the oxidation of butadiene is partially oxidized as shown elsewhere in this paper, the adsorbed butadiene species seems to be positively charged. It has not been clarified what kind of charge the adsorbed diatomic oxygen species has. However, judging from the ESR observation of O_2^- [1-4] and the addition of O_2^- to positively charged adsorbed furan species over promoted anatase-titania catalysts through a nucleophilic mechanism,[8] the diatomic oxygen species seems to be O_2^-. The reaction of adsorbed neutral oxygen molecule ($^3\Sigma_g^-$) with adsorbed butadiene seems to be less probable, since the former is electrophilic and less nucleophilic as judged from the electron affinity of 0.15 eV,[13] but it can not be denied either. The present work indicates the presence of an adsorbed diatomic oxygen species and its participation in the selective oxidation of butadiene over reduced silver catalyst. Oxygen atoms are possibly incorporated into maleic anhydride *via* the formation of this oxygen species. The oxygen species which promotes the complete oxidation of butadiene and serves to abstract hydrogen in maleic anhydride formation has not been clarified.

The Raman Spectra of Diazines Adsorbed on Silicas

Yoichiro YAMAMOTO and Haruka YAMADA*

Department of Chemistry, Kwansei Gakuin University, Nishinomiya 662

(Received March 14, 1978)

Synopsis. The Raman spectra of three diazines adsorbed on silicas have been measured. Spectra changes upon adsorption are interpreted as the result of hydrogen-bond formation between the surface OH group and the N atom of diazine. The order of the shifts of the Raman bands between three diazines is: 1,3-diazine>1,4-diazine>1,2-diazine.

Raman spectroscopy has recently been applied to the study of adsorbed species on solids, and the spectra of adsorbed pyridine have been measured considerably.[1-4] For the elucidation of the adsorption sites and the interactions between adsorbents and adsorbates, it is desirable to study the Raman spectra of several types of basic molecules in comparison with those of adsorbed pyridine. The present work will report on the Raman spectra of three diazines, 1,2-diazine (pyridazine), 1,3-diazine (pyrimidine), and 1,4-diazine (pyrazine), adsorbed on silicas.

Guaranteed reagents of 1,2-diazine and 1,3-diazine were obtained from the Tokyo Kasei Co. and a guaranteed reagent of 1,4-diazine, from the Nakarai Chem. Co.

Silica gel (*ca.* 20 mesh) was obtained from the Wako Chem. Co., and porous Vycor glass plate (Corning Glass No. 7930; 1 mm thick), from the Corning Glass Works. They were used after degassing, heating, and oxygen treatment, as has been described previously.[4,5] The surface area after the pretreatment was 620 m^2/g for the silica gel and 170 m^2/g for the porous Vycor glass. Gaseous diazine was adsorbed on the pretreated silica, and then the sample was evacuated for 0.5—30 min.

The Raman spectra were measured with a Jasco R-300 spectrophotometer equipped with an argon ion laser JEOL-04. The 488.0 nm excitation line and the 90° sample illumination were employed.[4]

The observed Raman spectra are shown in Fig. 1. The peak frequencies, with the relative intensities, are listed in Table 1, together with those of the liquids and CCl_4 solution (this work). The Raman spectrum of

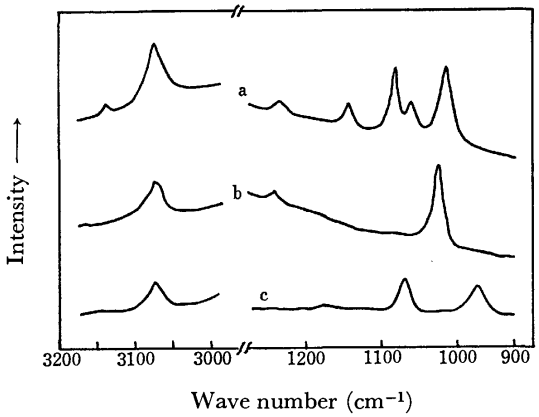

Fig. 1. Raman spectra of diazines adsorbed on silica gel; (a) 1,3-diazine, (b) 1,4-diazine, and (c) 1,2-diazine.

1,3-diazine adsorbed on the silica gel is quite similar to that of pyridine adsorbed on the silica gel. The ring-stretching band at 993 cm^{-1} shifts by 17 cm^{-1} to a higher frequency side from that of the liquid 1,3-diazine, while the CH stretching band at 3060 cm^{-1} shifts by 15 cm^{-1}. These shifts are a little larger than those observed for the pyridine adsorbed on the silica gel, 16 and 9 cm^{-1} respectively, and are interpreted as representing the hydrogen-bond formation between the surface OH group and the N atom of 1,3-diazine.

The shifts observed for 1,4-diazine and 1,2-diazine are smaller than those for 1,3-diazine. The spectra observed on the porous Vycor glass are almost the same as those observed on the silica gel. The Raman shifts observed, upon adsorption, on the silica gel are in the order of:

1,3-diazine > pyridine > 1,4-diazine > 1,2-diazine,

in agreement with the order of adsorption strength based on the upper limit temperatures of adsorption reported by Pichat:[6] 1,3-diazine 1,4-diazine 1,2-diazine. This

also corresponds to the order of the π-electron density of the N atom for the basic molecules,[7] but differs from the order of the first ionization potentials or the pK_a:[8]

pyridine $>$ 1,2-diazine $>$ 1,3-diazine $>$ 1,4-diazine.

Consequently, 1,3-diazine may be used, instead of pyridine, as a basic molecule for the study of adsorption on solid surfaces.

Dipole Moments of Molecules Containing Single Chlorine Atoms

Masaaki SUGIE,* Harutoshi TAKEO, and Chi MATSUMURA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received April 4, 1978)

Synopsis. The dipole moments of CD_2ClF, CHDClF, CH_3CHClF, $CH_3CCl{=}CH_2$, and DCOCl have been determined from the $J=1\leftarrow0$ transitions of their microwave spectra. For the analyses of the Stark effects, the method of the intermediate field case proposed by Mizushima has been used.

In our laboratory the structures of halogeno-substituted hydrocarbons have been systematically investigated. These studies have clarified that the C–C, C–Cl, and C–F bond lengths are shortened regularly with further substitution of the chlorine or fluorine atoms for the hydrogen atoms,[1,2] and that the nuclear quadrupole coupling constants of Cl are mutually related to the bond lengths of C–Cl to a certain degree. It would be interesting to examine how the dipole moment of a molecule is influenced by the structure, whereas the informations on dipole moments are not enough for this purpose because of lack of the precise data for molecules containing atoms with nuclear quadrupoles. In the present work the dipole moments of some molecules containing single chlorine atoms are determined.

The Stark shift of the transition frequency was measured by using a d.c. voltage with a superimposed small a.c. voltage on the electrode plate inserted in the waveguide. Fluke 415B was used for the supply of a d.c. voltage, and the peak to peak height of an a.c. voltage was measured with Takeda TR-6334 digital voltmeter. The center frequency of a shifted spectral line was obtained as the zero-crossing point of the output of the phase-sensitive detector. The electrode spacing was calibrated by the Stark shift of the $J=2\leftarrow1$ transition of OCS[3] and determined to be 0.486 ± 0.002 cm.

From the viewpoint of analysis it is desirable to determine the dipole moment from the Stark shift of the $J=1\leftarrow0$ transition in the case of a molecule which has a rotational spectrum with hyperfine structure. Since the $J=1\leftarrow0$ transitions of CD_2ClF, CHDClF, CH_3CHClF, and $CH_3CCl{=}CH_2$ fall into a suitable frequency region, their dipole moments were determined in the present study. The dipole moment of DCOCl,[2] which had been determined with the weak field approximation, was re-determined in order to refine the value.

Generally speaking, the Stark components of asymmetric-top molecules shift proportionally to the square of the electric field strength. For a molecule with nuclear quadrupole coupling, the proportionality breaks down when the applied electric field is so strong that the Stark shift is comparable to or slightly larger than the splitting due to quadrupole coupling interaction.

The Stark effect of a molecule containing a single chlorine atom can be estimated by the method proposed by Mizushima, *i.e.*, the method of the intermediate field case.[4] The energy levels are characterized by the set of good quantum numbers J, I, M_J, M_I, and the pseudoquantum number τ. The shifts of an energy level due to the Stark effect are given as solutions of the following secular equation

$$|(J, \tau, I, M_J, M_I|H_Q|J, \tau, I, M_J', M_I') + (E_{J,\tau,I=0,M}-E)\delta_{M_J,M_J'}\delta_{M_I,M_I'}| = 0.$$

In the above equation, the first and the second terms represent the splitting due to nuclear quadrupole coupling and the Stark shift in case the nuclear quadrupole is absent, respectively. Kellogg *et al.* gave the matrix elements in the first term, which do not vanish only if $M_J+M_I=M_{J'}+M_{I'}$.[5] The secular equation is factorized into blocks for each value of $M(=M_J+M_I)$, which can be easily solved.

The dipole moment of DCOCl was determined from the measurements of the shifts for five Stark components of the $1_{11}\leftarrow0_{00}$ by a least squares fit. The result is given in Table 1, which shows a marked improvement of the accuracy compared to the values of $\mu_a=0.3(2)$ and $\mu_b=1.6(2)$ previously determined by using the weak field approximation.

The dipole moments of CD_2ClF, CHDClF, and CH_3CHClF were determined by observing $1_{11}\leftarrow0_{00}$ transitions with an electric field of 200—800 V/cm, and that of $CH_3CCl{=}CH_2$ was determined from the $1_{01}\leftarrow0_{00}$

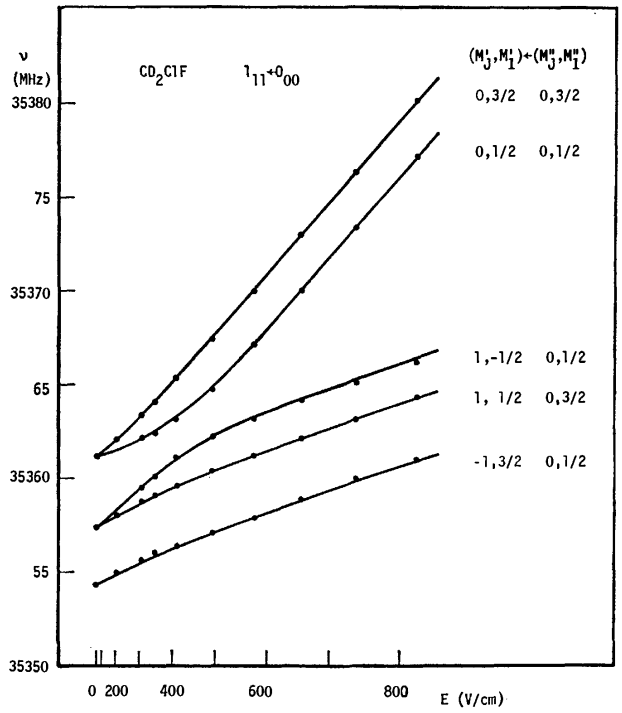

Fig. 1. The Stark shifts of CD_2ClF. The circles denote the measured displacements and the solid lines are theoretical ones.

Table 1. Dipole moments and their components (Debye)

Molecule	μ_a	μ_b	μ_c	μ_{total}
DCOCl	0.322(3)	1.780(15)	—	1.809(15)
CD_2ClF	0.302(3)	1.810(10)	—	1.834(10)
CHDClF	0.279(2)	1.787(10)	0.198(13)	1.819(10)
CH_3CHClF	0.953(8)	1.836(15)	0.013(24)	2.068(14)
$CH_3CCl{=}CH_2$	1.633(10)	0.211(14)	—	1.647(10)

transition with an applied field of 200—1000 V/cm. The Stark shifts of the $1_{11}\leftarrow 0_{00}$ transition for CD_2ClF are shown in Fig. 1 as a typical example. The dipole moments and their components determined by least squares fitting are given in Table 1. The limits of error were estimated by adding the errors due to the uncertainty of the applied electric fields to three times the standard deviations in the analysis.

The molecule which contains an atom with a nuclear quadrupole has the advantage that all the components of the dipole moment can be determined from the $J=1\leftarrow 0$ transition alone.[6] In addition, the analysis with the intermediate field approximation has been proved to give a sufficiently accurate dipole moment. In fact, the μ_c component of CHDClF could be determined, as shown in Table 1, although it has a rather large relative error because the energy levels which interact with the 0_{00} or 1_{11} level through the μ_c component are separated considerably. The dipole components of CHDClF obtained are consistent with the values calculated from those of CD_2ClF by rotation of the principal axes.

Solubility and Diffusion Coefficient of Sulfur in Silver

Kazuo FUEKI, Kenichiro OTA,* and Kohji KISHIO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received April 10, 1978)

Synopsis. The solubility N_s and the diffusion coefficient D of sulfur in silver were determined at 604—752 °C by means of a previously proposed method.[1] The results can be represented by the following equations:

$$\log N_s(\text{atom fraction}) = -0.818 - \frac{2.28\times10^3}{T},$$

$$D = 2.34 \times 10^{-3} \exp\left(-\frac{26300}{RT}\right) \text{ cm}^2\text{ s}^{-1}.$$

In the high temperature oxidation of alloys, the rate is significantly affected by the formation of an internal oxidation layer. Since this internal oxidation is caused by the diffusion of oxygen atoms into the alloy from the metal-oxide interface and the formation of dispersed particles of the less noble constituent, the knowledge of the solubility and the diffusion coefficient of oxygen in the alloy are necessary in order to analyze the oxidation rate of alloys.

Similarly, the solubility and the diffusion coefficient of sulfur in metals must be known to study the sulfidation of alloys. The solubility of sulfur can be determined by the combustion method and the vacuum fusion method. The solubility and diffusion coefficient can be measured by means of the tracer method, X-ray diffraction method, and the electrochemical method using solid electrolytes. However, these methods are rather complicated.

Fueki and Ouchi have studied the solubility and the diffusion coefficient of sulfur in copper by a new method wherein a thin cuprous sulfide film was formed on copper specimens and the decrement of the film after diffusion annealing was determined by the coulometric method.[1] In the present study the solubility and the diffusion coefficient of sulfur in silver were determined by the method proposed by Fueki and Ouchi and compared with data obtained by other methods.

Experimental

The experimental method employed was similar to that of the study on the solubility and diffusion of sulfur in copper.[1] Rectangular silver specimens, 15 mm×6 mm in area and 0.015—0.02 mm in thickness, were used. The result of the chemical analysis of silver is given in Table 1. The specimens were polished with alumina polishing powder, rinsed in alcohol, and dried in a desiccator. The surface of the specimen was anodized in a 2 g/l-Na_2S solution at a current density of 10^{-1} mA/cm² to form a thin sulfide film. The surface film thickness was determined by means of the coulometric method.

Table 1. Results of chemical analysis

Impurity	Content (wt %)
Cu	0.060
Si	0.0039
Fe	0.00062

The silver specimen covered with silver sulfide was placed in a Vycor tube, which was then evacuated to 10^{-4} Torr and sealed. The sealed tube was placed in an electric furnace kept at the desired annealing temperature (within±2 °C). After a length of time the tube was taken out from the furnace and the thickness of the remaining sulfide film was determined coulometrically. The specimen was immersed in a 0.1M-KCl solution and the surface sulfide was reduced cathodically at a constant current density of 10^{-1} mA/cm². From the reflection point of the potential-time curve, the electric charge necessary for the reduction of sulfide was calculated.

During annealing, the silver sulfide on the surface decomposes into sulfur and silver and the sulfur diffuses into silver; thus

$$Ag_2S(\text{film}) = 2Ag + S(\text{in Ag}). \quad (1)$$

The amount of sulfur $\bar{N}_t$ (atom fraction) in silver after annealing was calculated from the difference between the initial and final amounts of sulfide film. The solubility of sulfur N_s was obtained from the saturation value of the $\bar{N}_t$-t plot.

When a silver specimen is covered with a thin sulfide film and sulfur is allowed to diffuse from both surfaces of the specimen, the diffusion is expressed by the following equation:[1]

$$\log\frac{N_s-\bar{N}_t}{N_s} = \log\left(\frac{8}{\pi^2}\right) - \frac{\pi^2 D}{2.303}\left(\frac{t}{l^2}\right), \quad (2)$$

where l is the thickness of the specimen and D is the diffusion coefficient of sulfur in silver. Therefore, the diffusion coefficient can be determined from the slope of the plot of log $\{(N_s-\bar{N}_t)/N_s\}$ against t/l^2.

Results and Discussion

Figure 1 shows the amount of sulfur in silver $\bar{N}_t$ plotted against t/l^2 and Fig. 2 gives the Arrhenius plots for N_s. The data obtained by the previous investigators are also plotted in the same figure. Barbouth *et al.* used the radio isotope ^{35}S to measure the solubility.[2] Raub

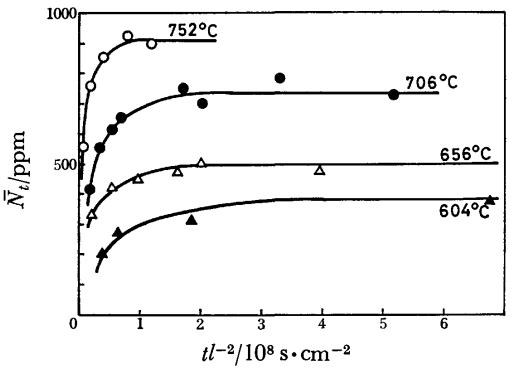

Fig. 1. Solubility of sulfur in silver.

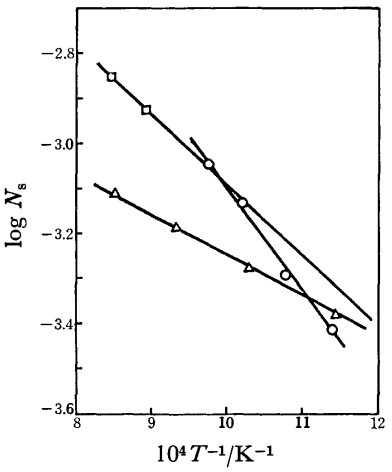

Fig. 2. Arrhenius plot of solubility of sulfur in silver.
○ This work, △ Barbouth,[2] □ Raub.[3]

measured the sulfide formation temperature during the cooling of a silver–sulfur solution and determined the solubility.[3] The data of the present work agree well with the other two. The solubility of the present work is represented by the following equation:

$$\log N_s = -0.818 - 2.28 \times 10^3 \left(\frac{1}{T}\right). \quad (3)$$

From Eq. 3 the enthalpy and entropy change for the dissolution of sulfur in silver were calculated. They are as follows:

$$\Delta H^\circ = 10.4 \text{ kcal/mol}$$

$$\Delta S^\circ = -3.74 \text{ cal/mol·deg.}$$

Figure 3 shows the relation between $\log\{(N_s - N_t)/N\}$ and t/l^2. The diffusion coefficient D of sulfur was determined from the slope of the plot. Figure 4 shows the Arrhenius plot of D. For comparison, Barbouth's results obtained by the tracer method[4] and Wang's results obtained by means of the relaxation method[5] are shown in the same figure. These results agree with each other. The Arrhenius equation for the present work is

$$D = 2.34 \times 10^{-3} \exp\left(-\frac{26300}{RT}\right) \text{ cm}^2 \text{ s}^{-1}, \quad (4)$$

where R is the gas constant (cal/mol·deg).

Homoconjugation in Bicyclo[3.2.1]octa-3,6-dien-2-yl and 6,9-Dihydro-5,9-methano-5*H*-benzocycloheptene-6-yl Radicals as Studied by Electron Spin Resonance[1)]

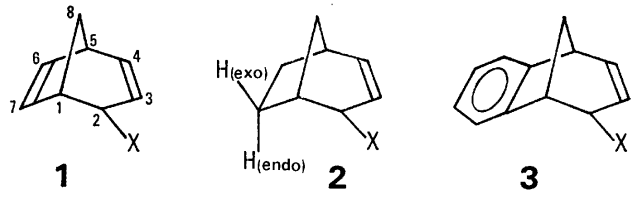
Takashi KAWAMURA,* Yoh'ichiro TAKEICHI, Shigeru HAYASHIDA, Masaaki SAKAMOTO, and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received April 12, 1978)

Synopsis. The radicals in the title and the bicyclo[3.2.1]oct-3-en-2-yl radical are examined with ESR. The extent of the odd electron delocalization due to π-π homoconjugation in the bicyclo[3.2.1]octa-3,6-dien-2-yl radical is estimated to be in the order of a few per cent.

Brown and Occolowitz[2)] found an enhanced reactivity of bicyclo[3.2.1]octa-2,6-diene (**1h**) in a base-catalyzed allylic-proton exchange in comparison with that of bicyclo[3.2.1]oct-2-ene (**2h**). This was attributed to a strong π-π homoconjugation in the intermediate anion, **1a**. A similar but somewhat damped homodelocalization was reported for **3a** by Rosenthal and Winstein.[3)]



h: X = H, a: X = ⊖, r: X = •

Scheme 1.

Experimental evidence for the homodelocalization in **1a** was given by its ^{1}H NMR spectrum.[4)] However, Trimitsis and Tuncay[5)] reported that long-range π interactions can not be safely concluded by examining only the ^{1}H NMR of the anions.

We have now examined the homoconjugation involved in **1r** and **3r** by comparing their ESR spectra with that of **2r**. Toward the end of our study, a paper by Sustmann and Gellert[6)] appeared reporting a study similar to ours. Our analysis of the spectrum of **2r** is, however, somewhat different from that of Sustmann and Gellert, although the difference is not very important for the analysis of the homoconjugation.

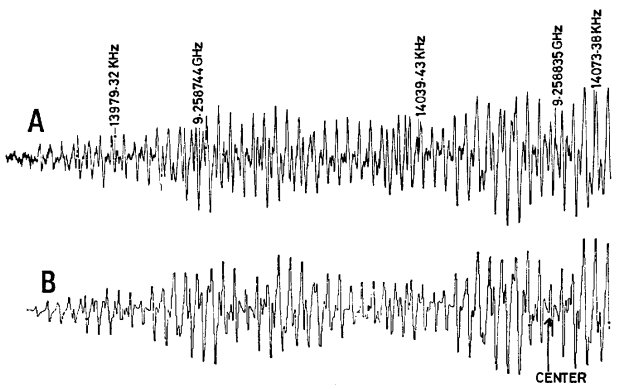


Fig. 1. Low-field half of observed (A) and simulated (B) spectra of **2r**. The numbers at markers in kHz and GHz units are ^{1}H NMR radio and ESR microwave frequencies, respectively.

An ESR spectrum of **2r** (Fig. 1) was observed during the photolysis of a cyclopropane solution of a mixture of **2h** and di-*t*-butyl peroxide at −120 °C. The spectrum was analyzed as 14.32 (2H), 4.93 (2H), 3.19 (1H), 1.80 (2H), 1.11 (1H), 1.02 (1H), and 0.54 G (2H). The *g* factor was 2.00256. A comparison of these hyperfine splitting constants (hfsc) with those of allylic cycloalkenyl radicals[7)] leads to the assignments of $a(H_2)=14.32$ and $a(H_3)=3.19$ G. The remaining two sets of doublets (1.11 and 1.02 G) are due to two protons on C_8. The hfsc of the triplet of 4.93 G is about a half of that of the exo-6 proton of the 2-norbornyl radical,[8)] suggesting an assignment to H_{6exo}. The triplet of 1.80 G is attributed to the bridgehead protons because triplet splittings of *ca.* 1.8 G were observed in the spectra of **1r**—**3r** (*vide infra*). The remaining triplet of 0.54 G is due to endo-6 and -7 protons. The **1r** and **3r** radicals were generated by the removal of a hydrogen atom by the *t*-butoxy radical from **1h** and **3h** respectively. The resolved hfsc's of **1r** and **3r** and their assignments are listed in Table 1, together with those of **2r**.

TABLE 1. OBSERVED hfsc's OF **1r**, **2r**, AND **3r**

Radical	*g*	a(H)[a)]				
		H_2	H_3	H_1	H_6	H_8
2r	2.00256	14.32	3.19	1.80	4.93[b)]	1.11
					0.54[c)]	1.02
3r	2.00272	14.23	3.19	1.78		1.21[d)]
1r	2.00276	14.07	3.25	1.87	1.35	1.35[d)]

a) In G units. b) *exo* protons. c) *endo* protons. d) Two nonequivalent protons have, accidentally, the same hfsc.

The hfsc of H_6 of **1r** has a magnitude between those of H_{6endo} and H_{6exo} of **2r**, in which the π-π homoconjugation is not involved. Thus, the extent of the homoconjugation can not be deduced directly from the hfsc of H_6 of **1r**. These is a shift in $a(H_2)$ in the order of **2r**>**3r**>**1r**. There exists a possibility that this is due to strain exerted on the allylic moiety, because this is the decreasing order of the bond length between C_6 and C_7. The hfsc's of the protons on the terminal carbon atoms of allylic moieties in the cyclohexenyl and in the more strained cyclopentenyl radicals are quite similar (14.35 and 14.30 G respectively),[7)] implying that the observed shift of $a(H_2)$ of **1r**—**3r** is not likely to originate

from the change in the geometry of the allylic moiety in these radicals.

Another possible origin of the shift of $a(H_2)$ is the delocalization of the odd electron from the allylic π system onto the etheno or benzo bridge. To examine this possibility, logarithms of the relative reactivities of **1h**—**3h** in the base-catalyzed allylic-proton exchange[2,3] were plotted against the values of the $a(H_2)$ of the corresponding radicals in Fig. 2. The fair correlation in Fig. 2 impies that the π-π homoconjugation in **1r** and **3r** is dominant, but not strong enough to exceed sufficiently other factors in shifting $a(H_2)$ and/or that the homoconjugation in anions is not linearly related to that in radicals.

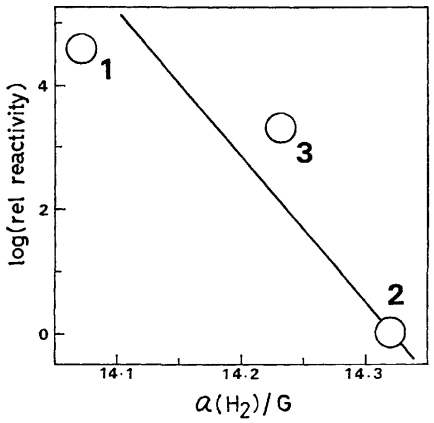

Fig. 2. Relation between kinetic acidity of olefin and hfsc of H_2 of the corresponding radical.

The odd electron density in the allylic π system can reasonably be expected to be proportional to $a(H_2)$; the odd electron density in the allylic π system of **1r** is estimated to be around 2% less than that of **3r**. This 2% decrease would more or less reflect the extent of the π-π homoconjugation in **1r**, as is suggested by the fair correlation between $a(H_2)$ and the kinetic acidity. Thus, we conclude that the extent of the odd electron delocalization from the allylic π system to the π system of the etheno bridge in **1r** is of the order of a few per cent, corresponding to the resonance integral (in Hückel approximation) between π atomic orbitals (AO) on C_2 and C_7 (β_{27}) of a magnitude of 5—20% of the integral between π AO's involved in a carbon-carbon double bond (β).

Experimental

Three hydrocarbons, **1h**,[9] **2h**,[9] and **3h**,[10] were prepared according to known procedures. The equipment and procedures for the photolysis-ESR experiments have been described earlier.[11]

Complex Isomerism in 7-Methylbenzo[*a*]phenazinium Tetracyano-*p*-quinodimethanide

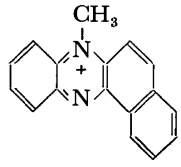
Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 1, 1978)

Synopsis. 7-Methylbenzo[*a*]phenazinium tetracyano-*p*-quinodimethanide is dark green when it is prepared in boiling ethanol and violet when it is prepared in acetonitrile. Examination of the electronic, vibrational, and ESR spectra revealed that the former form is essentially non-ionic, and the latter, ionic.

N-Methylphenazinium tetracyano-*p*-quinodimethanide, (NMP-TCNQ) is among the highest conducting TCNQ anion radical salts.[1] On the basis of the strong similarity of the electronic spectra of a wide variety of conducting TCNQ salts to each other and to $Cs_2(TCNQ)_3$ Torrance, Scott and Kaufman have suggested that NMP-TCNQ is not fully ionic.[2] The degree of ionicity has been estimated to be 0.94 by an NMR study and about 0.9 by measurements of the Seebeck coefficient.[3,4] These values are definitely larger than those reported for the well-known organic metal, TTF-TCNQ, 0.48—0.67.[5,6] Earlier, the present author demonstrated that the crystal charge-transfer complexes can be rather clearly classified into two groups, namely, non-ionic and ionic complexes.[7] NMP-TCNQ and TTF-TCNQ may be supposed to be in the region of non-ionic-to-ionic transitions of crystal charge-transfer complexes. Furthermore, it was shown that the probability of finding non-ionic complexes can be increased by choosing component molecules with larger differences in size and shape. Consequently, if the 7-methylbenzo[*a*]-phenazinium ion ($NMBP^+$) is employed in place of the



NMP^+ ion, a smaller degree of ionicity in the resulting complex may be foreseen. The recent work by Soos *et al.* indicating that phenazine–TCNQ systems are close to the non-ionic-to-ionic separation[8] prompted the present author to study the above-mentioned combination.

Benzo[*a*]phenazine was prepared by means of a condensation reaction between 1,2-naphthoquinone and *o*-phenylenediamine dissolved in 50% acetic acid at 0 °C,[9] and was purified by sublimation in a vacuum. NMBP methyl sulfate was obtained by boiling a benzene solution of the base and excess dimethyl sulfate for several hours. By the treatment of the methyl sulfate in hot absolute alcohol with a boiling ethanolic solution of one equivalent of LiTCNQ, dark green NMBP-TCNQ crystals were precipitated. Found: C, 77.14; H, 3.71; N, 18.52%. Calcd for $C_{17}H_{13}N_2$–$C_{12}H_4N_4$: C, 77.49; H, 3.81; N, 18.70%. Metathesis in aceto-nitrile instead of ethanol gave dark violet crystals. Found: C, 77.44; H, 3.64; N, 18.69%. The former form could be transformed into the latter by recrystallization from acetonitrile.

The electronic spectra recorded as Nujol mineral oil mulls are shown in Fig. 1. The sharp peaks located at 10.6 and $12.2\times10^3\ cm^{-1}$ in the spectrum of the

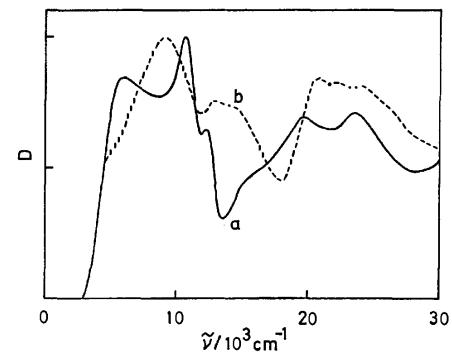


Fig. 1. Electronic spectra of 7-methylbenzo[*a*]phenazinium tetracyano-*p*-quinodimethanide, (a) the green form and (b) the violet form.

green form (Curve a) may be assigned to the monomeric $TCNQ^-$ anion radicals trapped in the crystals. Such peaks are not observed in the spectrum of the violet form. The shoulder appearing near $5\times10^3\ cm^{-1}$ suggests that the sample is contaminated with the green form. If this shoulder is ignored, the rest of the spectrum is that of a typical simple TCNQ salt, *e.g.*, pyridinium-TCNQ. Because of the close resemblance between this spectrum and that of the dimeric ion $(TCNQ)_2^{2-}$ in an aqueous solution,[10] the anion radicals in the violet form appear to be in predominantly pair-by-pair interaction. The two forms of NMBP-TCNQ exhibit spectra considerably different from each other. The lowest-energy absorption shown by the green form is at $6.0\times10^3\ cm^{-1}$. Assuming that this absorption arises from the charge transfer from 7-methylbenzo[*a*]phenazin-7-yl radical to TCNQ molecule, the ionization potential of the former species may be estimated to be about 6.6 eV. This value is so low that the combination can form an ionic complex provided the molecules are closely packed in the crystal.

The vibrational spectra of the green and violet forms examined as Nujol mulls are compared in Fig. 2. No band assignable to an N–H stretching vibration could be detected in the region from 3000 to $3500\ cm^{-1}$. Therefore, the reduction of the diamagnetic $NMBP^+$ ion to the $HNMBP^+$ cation radical during the course of preparation may be excluded from possible causes of the dimorphism. Although the relative intensities of

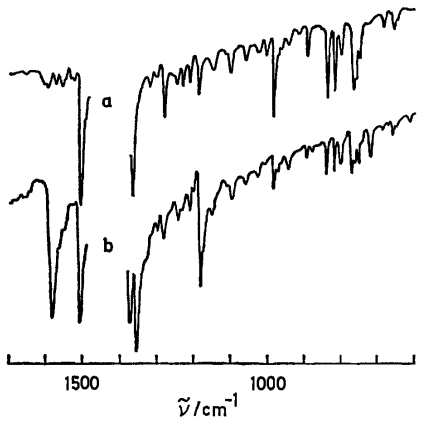

Fig. 2. Vibrational spectra of 7-methylbenzo[*a*]phenazinium tetracyano-*p*-quinodimethanide, (a) the green form and (b) the violet form.

bands are different, the locations in the region below 1300 cm^{-1} are rather similar to each other. In the spectrum of the violet form, strong bands appearing at about 1580, 1360, and 1180 cm^{-1} approximately constitute the pattern of the $TCNQ^-$ anion observed with the solid lithium salt. They are absent in the spectrum of the other form. However, no strong band is found in the latter spectrum near 1550 cm^{-1}, where solid TCNQ is known to give a relatively strong band.

The ESR spectra of the two forms were examined at the X-band. The green form gives a single resonance. The distance between the points of maximum slope is about 1.0 G. In addition to a strong narrow center line, three pairs of resonance lines characteristic of triplet-spin excitons were observed with the violet polycrystals. As the temperature is increased, the resonance lines broaden and the zero-field splitting parameters, $|D/g\beta|$ and $|E/g\beta|$, become smaller. The values obtained on the assumption that the isotropic g value is equal to the free electron value are 147 and 24 G at −30 °C and 140 and 20 G at 90 °C respectively. They are comparable to those reported for a number of the simple TCNQ salts, namely, 143—165 G for $|D/g\beta|$ and 17—25 G for $|E/g\beta|$.[11] The collapse of the three pairs into a single broad line was noted around 140 °C. The singlet-triplet separation was estimated to be 0.16 eV by relative-intensity measurements in the range from −30 to +10 °C.

The electrical resistivities measured with polycrystalline compactions were in the order of 10^5 ohm cm at room temperature for both the forms. The plots of the logarithm of the resistivity recorded between −125 and 110 °C against $1/T$ are not straight, indicating that the extrinsic conduction is dominant below room temperature. The activation energies for semiconduction were estimated to be about 0.3 eV for the high-temperature region. Thus, all the results presented above lead to the conclusion that the violet form of NMBP-TCNQ is essentially ionic, while the green form is not. The two forms may be called complex isomers, and this phenomenon, complex isomerism.

The author wishes to express his thanks to Mr. Nobuhiko Miyajima for the preparation of benzophenazine and to Mr. Shigeo Ikeura for the electrical resistivity measurements. The work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 234028).

Magnetic Susceptibility of the So-Called Zero-Valent Aluminium Complex of 2,2′-Bipyridine, $[Al(bpy)_3]^0 \cdot 1/2THF$

Motomichi INOUE,* Tatsuo HORIBA,† and Ken-ichi HARA††
Department of Chemistry, Nagoya University, Chikusa, Nagoya 464

(Received May 15, 1978)

Synopsis. The magnetic susceptibility of tris(2,2′-bipyridine)aluminium(0) was determined between 4.2 and 300 K. It can be explained by a radical ion model in which three 2,2′-bipyridine radical ions are coordinated to an aluminium-(III) ion. Antiferromagnetic interaction operates between the radical ions with the exchange integral $J/k=-110$—115 K.

Tris(2,2′-bipyridine) complexes in apparently unusual valency states of metals have been prepared and characterized.[1] An electronic-spectrum study of the so-called zero-valent aluminium complex $[Al(bpy)_3]^0$ showed that bpy^- ions are involved in the complex molecules.[2] The magnetic susceptibility was found to obey the Curie-Weiss law between 80 and 300 K.[3] The magnetic moment $\mu=3.38$ B.M. evaluated from the Curie constant is inconsistent with the formula $[Al^0(bpy^0)_3]$, in which an unpaired electron exists in a molecule. From these, we can propose the formula $[Al^{3+}(bpy^-)_3]$ rather than $[Al^0(bpy^0)_3]$. If this is correct, magnetic interaction is presumed to operate between paramagnetic bpy^- ions within $[Al(bpy)_3]$. Thus, the proposed formula can be confirmed by getting information on the magnetic interaction. Therefore, we have determined the magnetic susceptibility down to 4.2 K, because the magnetic interaction may be effective at low temperatures.

Experimental

The material was prepared by the method reported by Herzog *et al.*[4] Recrystallization from THF yielded deep green crystals. On heating *in vacuo* at about 90 °C, the crystals librated THF gas. Weight loss amounted to 8.0%, indicating that the crystals were those of a THF adduct, $Al(bpy)_3 \cdot 1/2$ THF (Found: Al, 4.8; THF, 8.0%. Calcd: Al, 5.1; THF, 6.8%). The effective magnetic moment 2.38 B. M. at 290 K agreed with 2.32—2.44 B. M. reported for $Al(bpy)_3$.[3,4]

The magnetic susceptibility was determined by the Gouy method in the temperature range 80—300 K and by the Faraday method below 80 K. The molar magnetic susceptibility[5] was corrected for diamagnetic contributions (10^{-6} emu mol^{-1}) from 2,2′-bipyridine (−93) and THF (−55).[6]

Results and Discussion

The reciprocal molar susceptibility is plotted against temperature in Fig. 1. It obeys the Curie-Weiss law in the two temperature ranges, $T \gtrsim 180$ K and $T \lesssim 40$ K (broken lines in Fig. 1): the Curie and Weiss constants are determined as $C_h=1.31$ emu K mol^{-1} and $\theta_h=-244$ K for the high temperature range, and $C_l=0.37$ emu K mol^{-1} and $\theta_l=-9.7$ K for the low temperature range. Between 40 and 180 K, the magnetic susceptibility deviates from the Curie-Weiss law. This is confirmed by the temperature dependence of the signal intensity in the ESR powder spectrum (Fig. 1), which has an isotropic g factor equal to 2.003 and a peak-to-peak width equal to 1.5 mT.

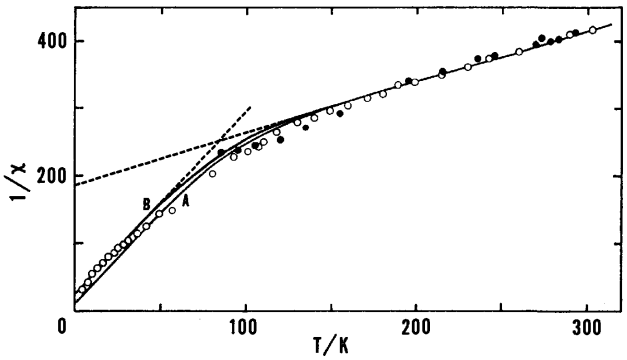

Fig. 1. Reciprocal magnetic susceptibility, $1/\chi$ in emu, (○) and relative ESR-signal intensity (●) of $[Al(bpy)_3]$ The curves A and B show theoretical susceptibilities calculated with the exchange integrals $J/k=-115$ K and -110 K, respectively, on the assumption of the formula $[Al^{3+}(bpy^-)_3]$.

The magnetic moment $\mu_h=3.24$ B.M. evaluated from C_h is nearly equal to $(3\times3)^{1/2}$ B.M. of a molecule having three independent unpaired electrons. The moment $\mu_l=1.72$ B.M. evaluated from C_l indicates that the ground state is doublet ($\mu_{s=1/2}=1.73$ B.M). This shows that the magnetic unit of the complex consists of three spins interacting antiferromagnetically with each other, supporting the proposed formula $[Al^{3+}(bpy^-)_3]$, in which each bpy^- ion carries an unpaired electron and aluminium is diamagnetic. For the spin system, eight spin functions are derived. Four of them correspond to $S=3/2(m_s=\pm3/2, \pm1/2)$ and the remaining four functions can be divided into two sets each corresponding to $S=1/2$ ($m_s=\pm1/2$). Because three bpy^- ions can be presumed to be equivalent with each other in a complex molecule, the magnetic susceptibility is given by[7]

$$\chi = \frac{Ng^2\mu_B^2}{4kT}\left[\frac{1+5\exp(3J/kT)}{1+\exp(3J/kT)}\right], \quad (1)$$

where J is the exchange integral, the absolute value of which is equal to one third of the energy separation between the doublet and quartet states. When magnetic interaction operates between complex ions, Eq. 1 can be rewritten as[8]

$$\chi = \frac{Ng^2\mu_B^2}{4k(T-\Delta)}\left[\frac{1+5\exp(3J/kT)}{1+\exp(3J/kT)}\right], \quad (2)$$

† Present address: Hitachi Research Laboratory, Hitachi Ltd., Hitachi 319-12.

†† Present address: Central Research Laboratory, Fuji Electric Co., Ltd., Yokosuka 240-01.

where Δ denotes the Weiss constant that takes into account the interaction. The solid curve A in Fig. 1 shows the magnetic susceptibility calculated from Eq. 2 with $J/k=-115$ K, $\Delta=-5$ K, and $g=2.00$, yielding the best fit to the observed data. When the Weiss constant Δ is assumed to be equal to θ_1, the curve B calculated with $J/k=-110$ K agrees well with the observed χ-T curve (Fig. 1).

The antiferromagnetic interaction between bpy^- ions takes place probably through aluminium atoms. Kobayashi *et al.*[9] propose a mechanism in which a charge transfer between bpy^- ions yields the antiferromagnetic interaction: the unpaired electron of a bpy^- ion can migrate to other bpy^- ions within an $[Al(bpy)_3]$ molecule through the vacant 3d orbitals of aluminium, and the resulting charge-transfer state stabilizes the doublet state rather than the quartet state. In this mechanism, aluminium 3d orbitals play an important part. Wulf and Herzog[3] determined the magnetic susceptibility of $[Sc(bpy)_3]^0$ between 80 and 350 K. It obeys the Curie-Weiss law in two temperature ranges: $\mu_h=3.67$ B.M. and $\theta_h=-667$ K for $T\gtrsim220$ K, and $\mu_l=1.76$ B.M. and $\theta_l=-20$ K for $T\lesssim134$ K. This magnetic behavior can be explained well with Eq. 2, the parameters being determined as $J/k=-200$ K, $\Delta=-20$ K, and $g=2.00$. Thus, three paramagnetic bpy^- ions are coordinated to a diamagnetic scandium(III) ion also in $[Sc(bpy)_3]^0$. The absolute J value of the scandium complex is larger than that of the aluminium complex. This arises from difference in the nature of central-metal d orbitals, because 3d orbitals contribute to metal-nitrogen bonding to a greater extent in the scandium complex. This provides evidence for the important role of the d orbitals in the magnetic interaction.

In our previous papers,[8,10,11] we reported that the magnetic susceptibilities of the $[M(bpy)_n]^0$ type complexes of manganese, beryllium, and magnesium can be explained by radical ion models in which bpy^- ions are coordinated to central-metal ions having normal oxidation states in the complexes. The present investigation along with the previous reports[8,10,11] has provided a convincing example in support of a conclusion that the "excess electrons" are localized mostly on the ligand molecules in the so-called zero-valent complexes of 2,2′-bipyridine.

Gas-chromatographic Measurements of Nitrous Oxide(N_2O) in Air Using a Molecular Sieve Trap

Michio HIROTA

Meteorological Research Institute, Koenji-kita, Suginami-ku, Tokyo 166

(Received February 8, 1978)

Synopsis. The atmospheric mixing ratio of N_2O was measured at the MRI, Koenji (Tokyo), between May and September, 1977, by a gas-chromatographic method. The mean value was 0.32_7 ppm. Judging from the measurements over the last 10 years, the atmospheric N_2O seems to have increased about 20%.

The stratospheric ozone is produced by the photochemical reaction and destroyed by reactions with such tracer components as O, NO, NO_2, HO, HO_2, and halogen atoms. If such species are released in large quantities by man's activity (SST flights or the use of aerosol sprays and nitrogen fertilizer, for instance), the natural balance of the ozone will be damaged. The depletion of the stratospheric ozone will increase the biologically harmful UV radiation on the earth's surface, and will probably lead to the climatic change.[1,2]

The N_2O which is produced by micro-biological activity in soils and waters is the major source of the stratospheric NO. The N_2O released into the atmosphere is considered stable in the troposphere, at least stable under solar UV radiation,[3] and is transferred to NO mainly by Reaction 1 in the lower stratosphere.[4] In order to assess the influence of nitrogen fertilizer on the natural ozone balance, the atmospheric concentration and distribution of N_2O must also be examined.

$$N_2O + O(^1D) \longrightarrow 2NO \qquad (1)$$

The atmospheric N_2O is mainly measured by two methods, *i.e.*, the infrared spectroscopic and gas-chromatographic (GC) methods. In the latter case, N_2O is preconcentrated on a silica-gel trap[5] or, in many cases, on a molecular sieve trap.

The method of collecting N_2O on the molecular sieve trap was first adopted by Bock and Schütz,[6] and some improvements have since been made by Schütz *et al.*,[7] LaHue *et al.*,[8] and Hahn.[9,10] In the present paper, the results of some measurements at the MRI, Koenji (Tokyo), will be reported and compared with those of recent studies.

Experimental

Sampling of N_2O. Thirty litre of air was drawn through a series of three U-shaped adsorption tubes (i.d. 8 mm) at a flow rate of 30 l/h. The first tube was filled with drierite to remove the water vapor, the second with sodium asbestos to remove the CO_2, and the third with molecular sieve 5A(1/16 in. pellets, 10 g) to adsorb the N_2O. The third tube was submerged in a Dry Ice–ethanol bath (−72 °C). Impurities were excluded from the molecular sieve by heating the tube to 350 °C and by then passing He gas (99.99%) for 1 or 2 h.

Gas-chromatographic Analysis. GC measurements were performed using a Shimadzu Gas Chromatograph GC-6AM equipped with a thermald conductivity detector (90 °C). He gas was used as the carrier gas at a flow rate of 50 ml/min.

After the sampling, the molecular sieve tube was placed in a gas sampler (Shimadzu, MGS-4). The adsorbed N_2O was transferred from the tube to the GC column by heating the tube to 350 °C. Carrier gas was passed through for 7 min and then for 10 additional min after 8 min's interruption. The N_2O was again adsorbed at 65 °C on the glass column filled with 30/60 mesh molecular sieve 5A (3 mm i.d. × 1.5 m). The GC analysis was started by raising the column temperature to 245 °C at a rate of 15 °C/min. The peak of N_2O appeared 9 min after, and that of CO_2 appeared 1 min after that of N_2O.

The detector response was linear in the range from 3.9 to 30 μl of N_2O.* For the reference measurements, N_2O was injected directly into the column from the gas syringe (Terumo, GAN- 0.25).

Results and Discussion

In 10 reference measurements of 15 μl N_2O over three days, the standard deviation (SD) was 2.4%, while it was 3% in 15 measurements over three months. The error of the calibration curve in the range from 3.9 to 30 μl N_2O was ±4%.

The amount of molecular sieve in the tube was the same as that used by LaHue *et al.*[8] As the sampling time, however, was doubled, the tube was cooled (—72 °C) to ensure the quantitative collection of N_2O. The quantitative collection of N_2O was confirmed by the measurements of 20 μl N_2O which had been diluted with N_2** in a 30 l *aflon* bag and then trapped on the molecular sieve tube. Three measurements showed the value of 19.2±0.4 μl compared with the reference measurements of 20 μl N_2O. The total accuracy of the method was estimated as about ±7% because of 3% error of the flow meter.

Field measurements were performed 14 times between May and September, 1977, at the Meteorological Research Institute (Tokyo). The air was sampled at 1 m above a ground surface covered with weeds through a vinyl tube leading to the inside of the building.

The results were scattered widely between 0.24_8 and 0.45_4 ppm, and the mean was 0.32_7 ppm. The mean values of previous and the present studies are shown in Fig. 1. A wide distribution of the values have also been observed at Mainz, Schauinsland,[7] and Yokohama.[11] The values of 0.45_4 and 0.41_5 ppm were unusually high. Such high values have also been observed elsewhere.[11,12] The values observed over the sea and in the United

* Assuming the N_2O mixing ratio of 3×10^{-7}, 30 l of the sampled air contains 9 μl N_2O.

** The N_2 used was 99.9995%, and a molecular sieve tube (−72 °C) was placed before the bag.

Date (1977)	Sampling start	Mixing ratio (ppm)	Date (1977)	Sampling start	Mixing ratio (ppm)
23, May	10:40	0.30_9	30, Aug.	13:50	0.30_0
24, May	16:15	0.34_3	31, Aug.	13:40	0.29_4
25, May	14:10	0.45_4	31, Aug.	16:30	0.27_0
26, May	10:00	0.30_5	1, Sep.	9:10	0.25_8
4, July	14:55	0.38_9	1, Sep.	10:10	0.30_4
5, July	11:30	0.32_7	1, Sep.	13:45	0.24_8
6, July	15:05	0.35_9	1, Sep.	17:00	0.41_5

States, on the other hand, have shown a rather small distribution.[13] The distribution must be strongly dependent on the meteorological condition of the observatory and on the sampling platform (ground station, balloon, aircraft, *etc.*). According to Ehhalt *et al.*,[12] a surface station like that of Schütz *et al.* observes both surface air with a high value and free tropospheric air; therefore, the values would be scattered widely.

The values of 4 measurements on September 1 were scattered. A similar feature was also observed by Katou *et al.*[11] Brice *et al.* reported a regular diurnal variation of N_2O on the basis of measurements over 10 days.[14]

In comparison with the mean values, especially in Refs. 7, 19, and 20, it is evident that the atmospheric N_2O has increased over the last 10 years (about 20%), at least as shown by the GC data. The value was, however, exceptionally low in Ref. 11. This variation was considered significant because the SD was 10% in the measurements of Schütz *et al.*,[7] while those of the others were all less than 3.1%, though they were not shown in Ref. 10 and 15, and the values of Katou *et al.* and the present study were very scattered.

In the calculation of the mean, unusually high values which, according to Ehhalt *et al.*,[12] did not represent the tropospheric value were also used. This is because the ground surface is considered not only as the source of N_2O but also as its sink;[14] therefore, the lower value does not neccessarily represent the tropospheric value.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (10), 3077—3078 (1978)

Flux Growth of Double Oxides of Niobium and Rare-earth Elements (Ln_3NbO_7)

Yuichi YAMASAKI and Yoshinori SUGITANI*

Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 300-31

(Received April 24, 1978)

Synopsis. Crystals of double oxides of rare-earth and niobium Ln_3NbO_7, where Ln=Ho, Y, Er, Dy, and La, and those of rare-earth and tantalum Ln_3TaO_7, where Ln=Y, Er, and Gd, were grown by Bi_2O_3–B_2O_3 and PbF_2–PbO fluxes for the Ln_3NbO_7, and by PbF_2–PbO flux for the Ln_3TaO_7. The composition of Ln_3NbO_7 or Ln_3TaO_7 is not yet known in natural minerals.

Double oxides of niobium (or tantalum) and a rare-earth element occur in nature as fergusonite $Y(Nb,Ta)O_4$ and samarskite $Y_4[(Nb,Ta)_2O_7]_3$ *etc.*[1] These compounds have high melting points of over 2000 °C, which depend mainly upon the component ratios between Nb and Ta in the solid solution. We reported that a series of compounds $LnNbO_4$[2,3] and $LnTaO_4$ were able to be grown by the flux method at lower temperatures than 1300 °C. These oxide compounds are attractive materials due to their electro-optical and/or ferroelastic characters,[4] in addition to the possibility of being a new laser matrix. We are now attempting the flux growth of compounds which have a different atomic ratio between the rare-earth element and niobium (or tantalum) than the naturally known minerals. This report describes the syntheses of Ln_3NbO_7 and Ln_3TaO_7 type compounds.

Mixtures of Ln_2O_3 (purity 4N) and Nb_2O_5 (purity 4N) with the molar ratio of 3: 1 were used as starting materials. Fluxes were added to the starting materials in the molar ratio of several to tens of times. The flux systems where we tried to grow Ln_3NbO_7 and Ln_3TaO_7 type crystals were PbF_2–PbO, Bi_2O_3–B_2O_3, B_2O_3–$Na_2B_4O_7$, Bi_2O_3–V_2O_5, and Li_2O–MoO_3. The purity of PbF_2 and PbO was 99.9%, and the others were all of the analytical reagent grade.

The starting material was put in a platinum crucible together with one of the flux materials, and was covered tightly by a platinum lid. This was placed in an electric muffle furnace at 1300 °C and was kept for 2 to 5 h at the same temperature. After that it was cooled slowly down to 900 °C in the rate of 1 to 5 °C/h by a programmed controller. At the final temperature it was taken out of the furnace and was air quenched to room temperature. Products in the crucible were washed with hot diluted HNO_3 for several hours. Crystals thus obtained were identified with the desired materials by X-ray powder diffraction.

The crystals of Y_3NbO_7 are shown as an example in Fig. 1. They are mostly octahedrons in shape and come to about 2 mm in the largest distance. Products obtained by the use of different fluxes are listed in Table 1. Crystals having Ln_3NbO_7 composition were obtained both from the flux systems of Bi_2O_3–B_2O_3 (the flux ratio ranges from 10: 0 to 8: 2) and from PbF_2–PbO (9: 1 to 7: 3). A list of Ln_3NbO_7 and Ln_3TaO_7 type compounds obtained in this work is given in Table 2. Compounds Ln_3TaO_7 were grown using the PbF_2–PbO flux system (from 9: 1 to 7: 3). The growth of crystals containing other rare-earth elements than those listed in Table 2 has not yet been successful. In the course of the runs, $Pb_2Nb_2O_7$ (pyrochlore type structure), $Pb_3Nb_2O_8$, and $LnNbO_4$ type crystals were obtained as by-products.

Precession and Weissenberg photographs show that the crystals given in Table 2, except for La_3NbO_7,

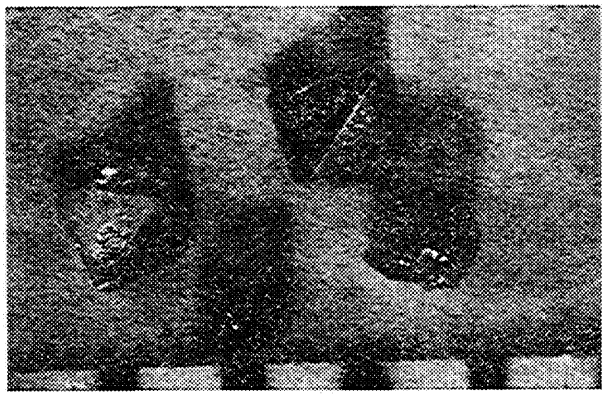

Fig. 1. Crystals of Y_3NbO_7.
(1 division=1 mm.)

Table 1. Flux systems used and their products (starting materials are Y_2O_3 and Nb_2O_5 in 3: 1 molar ratio)

Flux	Products
PbF_2–PbO	Y_3NbO_7, $YNbO_4$
Bi_2O_3–B_2O_3	Y_3NbO_7
B_2O_3–$Na_2B_4O_7$	$NaNbO_3$
Bi_2O_3–V_2O_5	$V_3Nb_{17}O_{50}$
Li_2O–MoO_3	$LiNbO_3$

Table 2. List of products having Ln_3NbO_7 and Ln_3TaO_7 composition

Compound	Color	Crystal system	Lattice parameter		
			a (Å)	*b* (Å)	*c* (Å)

Pyrolytic Sulfurization Gas Chromatography. IV. Removal of Trace Amounts of Organic Compounds in Sulfur by Refluxing with Oxides

Tadashi HARA,* Kaoru FUJINAGA, Katsuya TSUJI, and Fujio OKUI

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received May 12, 1978)

Synopsis. Oxides of aluminium, silicon, and titanium, instead of the magnesium oxide used in the Bacon-Fanelli method, were found to be effective for the elimination of trace amounts of organic compounds in sulfur. Prolonged refluxing in an inert gas atmosphere were especially favorable for the removal of organic compounds

The atomic ratio between C, H, O, and N in a sample can be simultaneously determined by pyrolytic sulfurization gas chromatography.[1] Since the high purity of sulfur was indispensable for the analysis, various purification methods such as distillation,[2] recrystallization, refluxing, decomposition of sodium thiosulfate, vacuum sublimation were investigated. The Bacon-Fanelli method[3] was found to be most promising for the present purpose. Sulfur was refluxed with several kinds of oxides including the magnesium oxide (MgO) in the Bacon-Fanelli method, its purity being examined gas chromatographically. Aluminium oxide(Al_2O_3), silicon oxide(SiO_2), and titanium oxide(TiO_2), which do not react with sulfur under the reaction conditions in a sealed quartz tube, were found to be effective for the elimination of carbonaceous impurities similarly to MgO. However, calcium oxide(CaO) and zinc oxide (ZnO), which react with sulfur to evolve sulfur dioxide (SO_2) under the same conditions as above, were unfavorable. Since the amounts of H, O, and N in the sulfur obtained by the present method, in which sulfur is refluxed with one of Al_2O_3, SiO_2, and TiO_2, were almost definite and small in comparison with those of carbonaceous impurities, the removal of carbonaceous impurities was exclusively investigated for the purification of sulfur.

Experimental

Reagents. Of the oxides, Al_2O_3 and SiO_2 were of GC-grade and MgO, TiO_2, ZnO, and CaO were of guaranteed grade. They were ignited at 950 °C for 1 h in the air before use. By this treatment, magnesium and calcium carbonates were expected to decompose with evolution of carbon dioxide (CO_2). Practically no CO_2 was detected in the gas chromatogram for the analysis of MgO. Sulfur as a starting material was of chemical grade.

Standard Procedure. About 100 g of sulfur was placed in a 300 ml four-hole flask with a reflux condenser and fused with an electric furnace, followed by addition of 1% (wt) MgO to sulfur. The contents were refluxed for about 24 h, and then the melts were filtered through the cylindrical glass filter held at 125 °C with a ribbon-heater. To the filtrate was added about 1% (wt) MgO and the same operation as above was repeated. About 75 g of sulfur was recovered after filtration. The oxides such as Al_2O_3, SiO_2, TiO_2, ZnO, and CaO were also used instead of MgO.

Analysis. The sulfur obtained in each purification step was analyzed by the same procedure as that given in the previous paper.[1] Twenty milligrams of sulfur was used for analysis. Carbonaceous impurities were determined as follows: A definite volume of a dilute glycine solution was taken in a reaction tube (a transparent quartz tube with one end closed) and evaporated to dryness in an oven at 65 °C, followed by addition of 20 mg of purified sulfur. The reaction tube was closed at the other end and the contents were analyzed. A calibration curve obtained on the basis of chromatograms was used for the determination of carbonaceous impurities.

Results and Discussion

Choice of Oxides. Since MgO did not react with sulfur, no SO_2 was evolved from MgO used in the Bacon-Fanelli method. The reaction between sulfur and oxides other than MgO was examined. Al_2O_3, SiO_2, and TiO_2 were found to be non-reactive with sulfur. Sulfur was purified by use of these oxides and the sulfur obtained was analyzed. The peaks of CO_2, carbonyl sulfide (COS), and carbon disulfide (CS_2) coming from carbon in the sample are shown in the gas chromatogram. The carbon content in the sulfur sample obtained in each purification step was determined by multiplying the correction factors[4] of CO_2, COS, and CS_2 by their peak areas and summing up the products. As seen from the relationship between the number of filtration and the content of carbonaceous impurities (Fig. 1), Al_2O_3, SiO_2, and TiO_2 are effective for the purification of sulfur similarly to the case of MgO, but not ZnO and CaO. Since the reaction

$$2AgNO_3 + 2S_2 \longrightarrow Ag_2S + 3SO_2 + N_2 \qquad (1)$$

reached completion, the relative conversion of the reaction between an oxide and sulfur was calculated from the amount of SO_2, based on the conversion of 1=1.0. There is a good correlation between the efficiency of the oxides (Fig. 1) and the relative conversion (Table 1). According to Bacon and Fanelli the effectiveness of MgO for the purification of sulfur is attributed to the basicity of MgO which shows an affinity to organic and inorganic acids in sulfur.[3] However, the reactivity of oxides to sulfur was concluded, on the basis of experimental results, to be more predominant than the basicity of the oxides.

Determination. The content of carbonaceous impurities in several sulfur samples was determined by means of the curve: 30—50 ppm in chemical grade sulfur, 3—6 ppm in sulfur purified with Al_2O_3, SiO_2, TiO_2, and MgO, and >100 ppm in commercial high purity sulfur (purity 99.9999%).

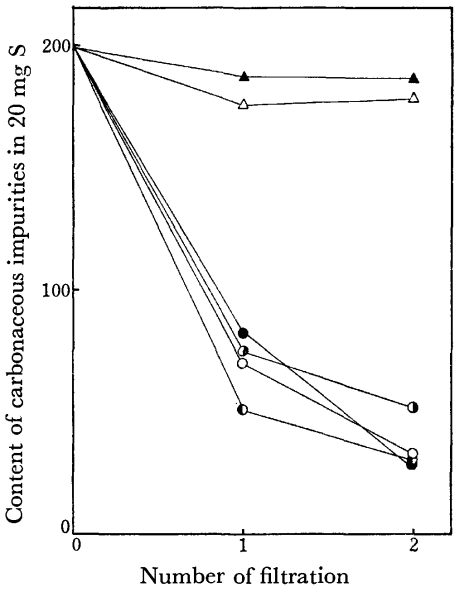

Fig. 1. The relationship between the number of filtration and the content of carbonaceous impurities.
○: MgO, ●: Al_2O_3, ◑: SiO_2, ◐: TiO_2, ▲: ZnO, △: CaO.

Table 1. Relative conversion in the reaction between an oxide and sulfur

Metal oxide	Relative conversion
MgO	0
Al_2O_3	0
SiO_2	0
TiO_2	0
CaO	0.67
ZnO	1.1

Organic Test. The spot test[3] to detect an organic substance in sulfur was applied to the sulfur obtained by refluxing with MgO, Al_2O_3, SiO_2, and TiO_2, but no black spot was hardly ever confirmed. However, a black spot appeared distinctly in the sulfur obtained by treatment with ZnO and CaO. This is in line with the results shown in Fig. 1. A fraction of the black spot was isolated and analyzed. Since the presence of carbonaceous impurities was confirmed gas chromatographically, the appearance of black color being attributed to the presence of an organic substance.

Reaction Time. Bacon and Fanelli pointed out that the organic substance in sulfur is isolated as a black cake during the course of refluxing and removed by filtration, a similar phenomenon to that above being also observed.[3] That is, sulfur was purified by refluxing for some time and by filtering a sludge in the absence of oxides. The effect of refluxing times 6 and 24 h on the removal of carbonaceous impurities was investigated by use of Al_2O_3 and the content of carbonaceous impurities was found to decrease with increase in refluxing time.

Effect of Oxygen. It was also found by use of Al_2O_3 that carbonaceous impurities are removed more effectively in nitrogen atmosphere than in the air. The result is contrary to what we expected. The reason remains unknown. A dark gray sludge sample obtained by refluxing sulfur with MgO in the air and by filtering the melts was analyzed and the peak area of CO_2 was found to be abnormally large.

From the results, it can be concluded that the purification of sulfur is mainly achieved by the adsorption of organic substances on the oxide, but not by the atmospheric oxidation of organic substances.

The authors wish to express their thanks to Mr. Hiroshi Suzuki, Dr. Masanori Nakae, and Dr. Yoshizo Miyake, Government Industrial Research Institute, Osaka, for the supply of purified sulfur sample.

Reaction of α-Keto Sulfoxides with Hydrogen Chloride and Trichloroacetic Acid

Toshimitsu WAKUI, Yoshio NAKAMURA, and Shinichi MOTOKI*

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received December 22, 1977)

Synopsis. α-Keto sulfoxides (**1**) reacted with hydrogen chloride to afford chloroformates, disulfides, and thiosulfonates. **1** also reacted with trichloroacetic acid to give methyl trichloroacetate, disulfide and thiosulfonate.

α-Keto sulfoxides have been postulated as unstable intermediates in the thiocarboxylic *S*-acid oxidation with NBS, iodosobenzene,[1] and *m*-chloroperbenzoic acid[2] and isolated as stable compounds by oxidizing thiocarbonate *O,S*-diesters and related substances with *m*-chloroperbenzoic acid.[3] This new class of organic compounds are interesting and have attracted the attention of organic chemists to their chemical behavior.

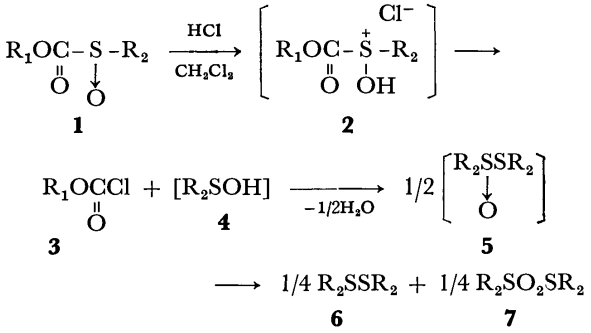
Recent studies by Chaves das Neves and Machete have shown that ethoxycarbonyl benzyl sulfoxide reacts with thionyl chloride and *S*-benzyl *O*-ethyl thiocarbonate.[4] Furukawa and his co-workers also reported that benzyloxycarbonyl benzyl sulfoxide reacts with acetic anhydride to give 1-(acetylthio)benzyl sulfoxide together with other products.[5] In this note, the reactions of α-keto sulfoxides with hydrogen chloride and trichloroacetic acid will be reported.

Dry hydrogen chloride was bubbled at room temperature for 2 h into a solution of phenoxycarbonyl ethyl sulfoxide (**1a**) in dichloromethane. After the solution was stirred for an additional 20 h, it was shown by TLC that **1a** was consumed, and from the reaction mixture, phenyl chloroformate (**3a**), diethyl disulfide (**6a**) and *S*-ethyl ethanethiosulfonate (**7a**) were isolated in fairly good yields. The structures of the products were determined from their spectroscopic data.

In the reactions of methoxycarbonyl benzyl sulfoxide (**1b**), methoxycarbonyl phenyl sulfoxide (**1c**) and ethoxycarbonyl benzyl sulfoxide (**1d**) with hydrogen chloride, the yields of alkyl chloroformates (**3**) were determined by conversion into the alkyl phenyl carbonate derivatives. The disulfides (**6**) and the thiosulfonates (**7**) were separated by column chromatography using benzene–petroleum ether (1 : 1) as the eluent. The reaction of benzyloxycarbonyl benzyl sulfoxide (**1e**) with hydrogen chloride similarly gave benzyl chloroformate (**3e**), dibenzyl disulfide (**6e**) and *S*-benzyl toluene-α-thiosulfonate (**7e**). The yields of **3e** and **6e** were calculated by the integrated ratio of the PMR spectrum of the mixture since they could not be separated by ordinary column chromatography. The results are shown in Table 1.

Table 1. Reaction of α-keto sulfoxides **1** with hydrogen chloride

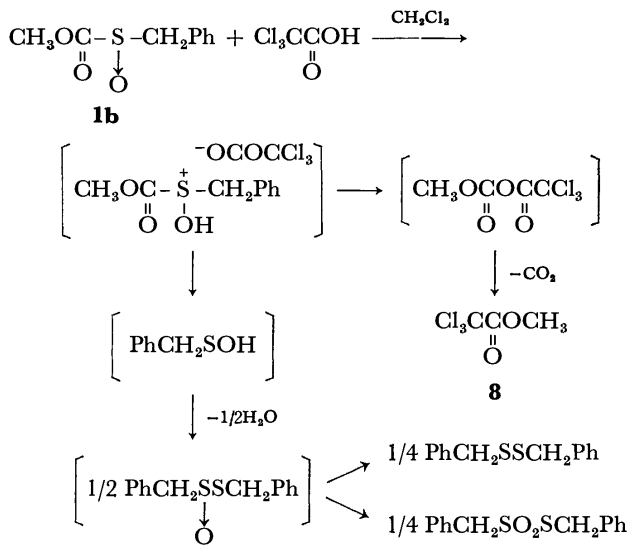
α-Keto sulfoxide	R_1	R_2	Yield (%)		
			3	**6**	**7**
1a	Ph	Et	74	63	76
1b	Me	$PhCH_2$	69	90	91
1c	Me	Ph	59	99	84
1d	Et	$PhCH_2$	57	92	93
1e	$PhCH_2$	$PhCH_2$	65	86	93



Scheme 1.

The reaction probably proceeds *via* an initial protonation of the sulfoxide **1** affording an unstable sulfonium ion such as **2** which is further converted to the alkyl (or aryl) chloroformate **3** and the sulfenic acid **4**. Then **4** may give the thiosulfinate **5** which disproportionates further to give the final products, the disulfide **6** and the thiosulfonate **7**. This scheme is based on the observation that the sulfenic acids afford water and the thiosulfinates through dimerization[6] while the thiosulfinates smoothly disproportionate in acidic conditions to the disulfides and the thiosulfonates.[7]

Both the reaction of **1d** with hydrogen chloride and with thionyl chloride gave closely similar products such



Scheme 2.

as ethyl chloroformate, dibenzyl disulfide, and *S*-benzyl toluene-α-thiosulfonate, but the yields of the products are better in the former case.

When a solution of **1b** and trichloroacetic acid in dichloromethane was refluxed for 15 h, methyl trichloroacetate (**8**, 42%), dibenzoyl disulfide (40%) and *S*-benzyl toluene-α-thiosulfonate (46%) were the products. These results may be rationalized according to Scheme 2.

Experimental

All the melting and boiling points are uncorrected. The IR spectra were obtained on a 260-10 Hitachi Model infrared spectrophotometer. PMR spectra were recorded with a JEOL JNM-PMX 60 spectrometer, in $CDCl_3$ solution with TMS as an internal standard.

Materials. α-Keto sulfoxides **1d** and **1e** were obtained by the methods described in the literature.[3] Other α-keto sulfoxides **1a**—**c** were prepared in a similar manner and their physical properties are as follows: **1a**: mp 67—69 °C; IR (Nujol): 1760 cm^{-1} (C=O); PMR (δ): 1.27 (t, 3H), 2.85 (q, 2H), 7.17 (s, 5H). **1b**: mp 81 °C; IR (Nujol): 1765 cm^{-1} (C=O); PMR (δ): 3.92 (s, 3H), 4.23 (s, 2H), 7.33 (s, 5H). **1c**: mp 77—78 °C; IR (Nujol): 1760 cm^{-1} (C=O); PMR (δ): 3.93 (s, 3H), 7.70 (m, 5H).

General Procedure for Reactions of α-Keto Sulfoxides (1) with Hydrogen Chloride. Dry hydrogen chloride was bubbled at room temperature for 2 h with stirring into a solution of **1** (3–23 mmol) in dichloromethane. The reaction mixture was stirred at the same temperature for 20 h and each product was separated as follows.

1a: After the solvent had been removed under reduced pressure, distillation of the residue gave 0.44 g (63%) of diethyl disulfide (**6a**), bp 50—60 °C/31 Torr, 2.68 g (74%) of phenyl chloroformate (**3a**), bp 60—62 °C/8 Torr, and 0.68 g (76%) of *S*-ethyl ethanethiosulfonate (**7a**), bp 90—100 °C/5 Torr.

1b: The solvent and methyl chloroformate (**3b**) were distilled under reduced pressure. The distillate was then added to a solution of phenol (0.94 g, 10 mmol) and triethylamine (5 g, excess) in ether (50 ml) and the mixture stirred for 5 h. Water (100 ml) was added to the mixture and the organic layer that separated, was successively washed with dilute sodium hydroxide solution, dilute hydrochloric acid, and water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to afford 0.95 g (69%) of methyl phenyl carbonate.

The residue obtained after the solvent and **3b** had been removed, was column chromatographed on silica gel C-200. Elution with benzene–petroleum ether (1 : 1) gave 0.50 g (90 %) of dibenzyl disulfide (**6b**), mp 68.5—69 °C, and 0.57 g (91 %) of *S*-benzyl toluene-α-thiosulfonate (**7b**), mp 108—109 °C.

1c, *1d*: The products obtained by the reactions of **1c** and **1d** with hydrogen chloride were isolated in a similar manner as above.

1e: After the solvent had been removed under reduced pressure, the residue was subjected to column chromatography on silica gel to afford the mixture of benzyl chloroformate (**3e**) and dibenzyl disulfide (**6e**), and 0.20 g (96%) of *S*-benzyl toluene-α-thiosulfonate (**7e**) by elution with benzene–petroleum ether (1 : 1). The yields of **3e** and **6e** (as determined by PMR) were 65 and 86%, respectively.

Reaction of 1b with Trichloacetic Acid. A mixture of **1b** (1.78 g, 9 mmol) and trichloroacetic acid (1.47 g, 9 mmol) in dichloromethane (30 ml) was refluxed for 15 h and the solvent removed under reduced pressure. The residue was distilled to give 0.63 g (42%) of methyl trichloroacetate (**8**), bp 50—56 °C/19 Torr. The residue obtained after distillation was dissolved in ether (100 ml) and the solution succesively washed with water, dilute sodium hydroxide solution, and water. After being dried over anhydrous sodium sulfate, the solvent was removed. The residue was column chromatographed on silica gel to afford 0.22 g (40%) of dibenzyl disulfide and 0.29 g (46%) of *S*-benzyl toluene-α-thiosulfonate, by elution with benzene–petroleum ether (1 : 1).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (10), 3083—3084 (1978)

The Preparation of 6-Nitro-3-acetamidotoluene

Aoi ONO

Chemical Laboratory, Takada Branch, Faculty of Education, Niigata University, Nishishiro-cho, Joetsu 943

(Received February 3, 1978)

Synopsis. *m*-Acetamidotoluene was nitrated with fuming nitric acid in acetic acid or in a mixture of acetic and sulfuric acids at 20 °C, affording 6-nitro-3-acetamidotoluene in 38.6 and 53.7% yields respectively. The melting point of the product was found to be different from that reported in the literature.

In order to analyze mononitro acetamidotoluenes and toluidines by GLC, an authentic, pure sample of 6-nitro-3-acetamidotoluene was prepared by the simplest way. Noelting[1] reported that 6-nitro-3-aminotoluene could be obtained by the nitration of *m*-toluidine in a mixture of nitric and sulfuric acids. Coffey[2] nitrated *m*-acetamidotoluene with copper(II) nitrate. Cohen *et al.*[3] and Cook *et al.*,[4] nitrated *m*-acetamidotoluene with fuming nitric acid in acetic acid. Cohen *et al.*[5] and Morgan *et al.*[6] nitrated *m*-acetamidotoluene with a mixture of nitric and sulfuric acids. Morgan *et al.*,[7] Wibant,[8] and Cook *et al.*[4] compared the yields and ratios of 6- and 4-nitro-3-acetamidotoluenes formed under various conditions. However, the ratio of products (6- and 4-nitro-3-acetamidotoluenes) still remains ambiguous and the reported purification procedure seems unsatisfactory. The present author has, therefore, reinvestigated the procedure and found that an erroneous melting point of 6-nitro-3-acetamidotoluene was reported.

Experimental

The GLC analyses were performed on a 100 cm column (i.d. 3.0 mm) packed with C_{22} 60—80 mesh coated with 3% Silicone OV-17 or 20% Silicone KF-54 at 220 °C, using a Shimadzu GC-5A GC apparatus with FID. The IR and NMR spectra were recorded on a Hitachi EPI-S2 IR spectrophotometer and a Varian T-60 NMR spectrometer respectively. The measurement of the mp (corrected) and DTA were performed with a Yanagimoto Micro-Melting-Point Apparatus and a Rigaku Thermal TG-DTA M8075 respectively.

Reagent. The *m*-acetamidotoluene was prepared by refluxing a mixture of 70 g of *m*-toluidine (guaranteed grade, from the Nakarai Chemical Co.) and 300 ml of acetic acid (extra pure reagent, also from the Nakarai Chemical Co.) for 8 h. Fuming nitric acid (*d*, 1.50) and sulfuric acid (95%) of an extra pure reagent grade were purchased from the Nakarai Chemical Co.

Preparation. Part 1. Twenty grams of *m*-acetamidotoluene, suspended in 50 ml of acetic acid, were nitrated by adding 40 ml of fuming nitric acid (*d*, 1.50) over a period of 10 min with effective stirring below 20 °C. After the reaction, the contents were poured into 1 litre of ice water, and then the solid was filtered and dried. Pure 6-nitro-3-acetamidotoluene was obtained in a 38.6% yield after twice recrystallizations from 30% aqueous ethanol. Part 2. Twenty grams of *m*-acetamidotoluene were nitrated in a mixture of 30 ml of acetic and 30 ml of sulfuric acids with fuming nitric acid by the procedure described in Part 1. The yield was 53.7%. The melting point of the compound recrystallized from 30% aqueous ethanol or benzene was 117 °C, in contrast to the reported values of 101—102[9] and 103—104 °C.[3] Found: C, 50.98; H, 5.72; N, 13.49%. Calcd for $C_9H_{12}N_2O_4$: C, 50.94; H, 5.60; N, 13.20%. GLC retention time: 16.00 min on Silicone KF-54; 4.00 min on Silicone OV-17. TLC R_f; 0.50 on a silica gel plate; 0.80 on an alumina plate (solvent; carbon tetrachloride: ethyl acetate, 9: 1, v/v) at room temperature. IR; 3600—3200 (νNH_2), 1680 (νCO), 870 (δNO_2), and 750 cm^{-1} (δNH_2) NMR; δ (TMS, CD_3OD), 2.13 (s, 3H), 2.38 (s, 3H), 7.53—7.75 (m, 2H) and 7.90—8.11 (m, 1H).

6-Nitro-3-aminotoluene was obtained by the hydrolysis of 6-nitro-3-acetamidotoluene. Mp 136—138 °C (lit, 136—138,[5] 138—140 °C[7]); Found: C, 55.30; H, 5.29; N, 18.74%. Calcd for $C_7H_8N_2O_2$: C, 55.25; H, 5.30; N, 18.41%. GLC retention time; 6.00 min on Silicone KF-54; 1.00 min on Silicone OV-17. TLC R_f; 1.70 on a silica gel plate; 2.00 on an alumina plate (solvent: carbon tetrachloride: ethyl acetate, 9:1, v/v) at room temperature. IR; 3550, 3400 (νNH_2), 1620 ($\nu C{=}C$), 1300, 1250 (νNO_2), 850 (δNO_2), and 815 cm^{-1} (δNH_2). NMR; δ (TMS, CD_3OD), 2.61 (s, 3H), 6.56 (m, 2H), and 7.93—8.10 (m, 1H).

Results and Discussion

As has been mentioned in the Experimental section, when *m*-acetamidotoluene was nitrated in acetic acid or in a mixture of acetic and sulfuric acids (1: 1, v/v), 6-nitro-3-acetamidotoluene was obtained in a 38.6 or 53.7% yield respectively, after twice recrystallizations from 30% aqueous ethanol. The purity of the product was confirmed by GLC, TLC, IR, and NMR.

However, the melting point of the product was 117 °C, which is apparently different from that reported in the literature (lit, 101—102,[9] 103—104 °C[3]). Then DTA and elemental analyses were undertaken. The results of elemental analyses were reported in the Experimental section, the diagram of DTA had two peaks, at 117 and 102 °C, and the weight loss on DTA at 102 °C corresponded to the weight of one molecule of water. From these data, the prepared product was identified as 6-nitro-3-acetamidotoluene monohydrate. Details concerning the molecular structure of this prepared product will be reported elsewhere in the near future.

(Hydroxyalkyl)pyridines as Bifunctional Catalysts. Dehydrobromination of 7-Bromocholesterol

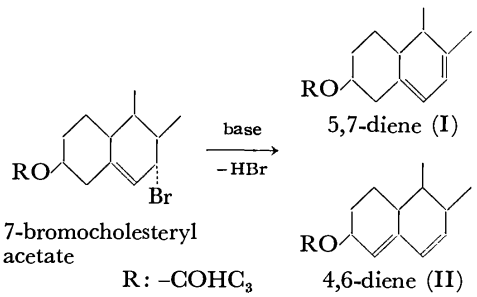
Yoji TACHIBANA

Ueda Factory, Nisshin Chemical Co., Ltd., Kamishiodiri, Ueda-shi, Nagano 386

(Received March 8, 1978)

Synopsis. In the dehydrobromination of 7-bromocholesterol, the reactions catalyzed by 2- and 3-(hydroxyalkyl)-pyridines afforded 5,7-diene and 4,6-diene as the main product, respectively. The relative isomer ratio has been related to the position of the hydroxyalkyl group of the (hydroxyalkyl)pyridines. The results have been interpreted in terms of a concerted mechanism through a cyclic intermediate.

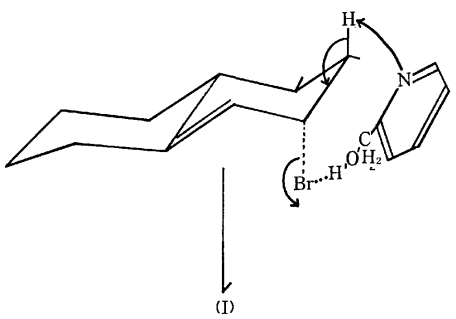
Increased attention has been paid to bifunctional catalysts in connection with biochemical reactions.[1-6] A selective rearrangement of penicillin *S*-oxide to isothiazolone using (hydroxyalkyl)pyridines as catalysts has been reported and the mechanism interpreted as a concerned reaction through a cyclic intermediate.[7] In the course of studies on the catalytic activities of (hydroxyalkyl)pyridines, it has been found that 2- and 3-(hydroxyalkyl)pyridines act as bifunctional catalysts in the dehydrobromination of 7-bromocholesterol.



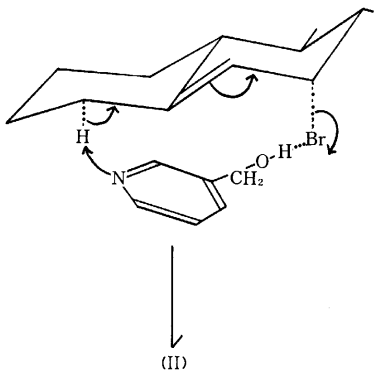
7-bromocholesteryl acetate

R: $-COHC_3$

It is known that the dehydrobromination of esters of 3-β-hydroxy-7-bromo-Δ^5-steroids gives a mixture of products, in which either a 5,7-diene or a 4,6-diene predominates, depending on the nature of the dehydrobrominating agent. Organic and inorganic bases do not act selectively and give mixtures of isomers.[8-10] When the dehydrobromination was carried out in the presence of 2-(hydroxyalkyl)pyridines, the 5,7-diene (I) was obtained as the main product. The reaction catalyzed by 3-(hydroxyalkyl)pyridines, on the other hand, afforded the 4,6-diene (II) selectively. The employment of 4-(hydroxyalkyl)pyridines showed no selectivity in the formation of (I) or (II) compared with the 2- and 3-(hydroxyalkyl)pyridines. The results are summarized in Table 1.



(I)



(II)

Table 1. Yield and relative ratio (I/II)

Base	Yield(%)[a] (I)	Yield(%)[a] (II)	Relative ratio[b] (I/II)
2-(Hydroxymethyl)pyridine	43.9	31.1	1.41
2,6-(Dihydroxymethyl)pyridine	44.1	30.8	1.43
2-(2-Hydroxyethyl)pyridine	46.1	29.0	1.59
2-(3-Hydroxypropyl)pyridine	41.9	31.2	1.34
Pyridine	23.4	35.4	0.66
2-Ethylpyridine	26.5	31.2	0.84
2-Propylpyridine	26.8	27.8	0.96
3-(Hydroxymethyl)pyridine	19.7	56.3	0.35
3-(3-Hydroxypropyl)pyridine	20.5	54.0	0.38
3-Ethylpyridine	22.6	35.9	0.63
4-(Hydroxymethyl)pyridine	24.6	49.3	0.50
4-(3-Hydroxypropyl)pyridine	25.8	49.7	0.53
4-Ethylpyridine	23.7	42.1	0.56
4-Propylpyridine	22.8	42.1	0.54

a), b) Yield and relative ratio were determined by GLC.

The interpretation is that a 5,7-diene (I) would be formed when the bromine atom on the carbon atom in position 7 is α, since hydrogen linked with the carbon atom in position 8 is always β. 7-Bromocholesteryl acetate employed in the reaction is considered to consist primarily of 7-α-bromocholesteryl acetate as suggested by Bernstein.[9] However, Jaworeska observed no relation between the configuration of the bromine atom in position 8 and the yield of 5,7-diene(I), and suggested the possibility of a rapid epimerization of the bromine atom.[11]

As can be seen in Table 1, 2- and 3-(hydroxyalkyl)-pyridines showed selectivity in the formation of (I) and (II) compared to the corresponding alkylpyridines. This

suggests that the steric and inductive effects are excluded and the hydroxyl group plays an important role in the selective formation of (I) and (II). The reported results above are most readily rationalized by a concerted mechanism involving a cyclic intermediate. The reaction may be initiated by the abstraction of a proton in position 8 or 4. The abstraction of the proton in position 8 competes with that in position 4, giving rise to the 5,7-diene (I) and the 4,6-diene (II), respectively. In the case of 2-(hydroxyalkyl)pyridines, the base abstracts the proton in position 8 and the reaction is considered to proceed through the cyclic intermediate by the interaction of the hydroxyl group with the bromine atom to give (I) as the main product.

When 3-(hydroxyalkyl)pyridines are employed, the preferential formation of (II) can be interpreted by assuming the selective abstraction of the proton in position 4 followed by the formation of a cyclic intermediate as depicted in the figure. It is highly probable that 4-(hydroxyalkyl)pyridines can not form cyclic intermediates since the interaction of the hydroxyl group with the bromine atom is considered to be difficult. This explains the absence of selectivity observed in the reaction catalyzed by 4-(hydroxyalkyl)pyridines compared with 2- and 3-(hydroxyalkyl)pyridines. The most plausible mechanism explaining the catalytic activities of 2- and 3-(hydroxyalkyl)pyridines is shown below.

Further work including a extension of the reaction and a mechanistic study of the reaction is now in progress.

Experimental

GLC was recorded on a Hitachi 023 gas chromatograph equipped with a flame ionizer detector.

A typical procedure is described for the reaction of cholesteryl acetate with 2-(hydroxymethyl)pyridine; A hexane solution (100 ml) of cholesteryl acetate (4.3 g, 10 mmol), *N*-bromosuccinimide (2.1 g, 12 mmol) and a catalytic amount of benzoyl peroxide was allowed to reflux for 1 h. After the reaction, the hexane solution was filtered to remove succinimide and the filtrate evaporated to dryness under reduced pressure. The residue was dissolved in butyl acetate (50 ml) and 2-(hydroxymethyl)pyridine (1.3 g, 12 mmol) was added. The mixture was heated under reflux for 1 h. The solution was washed with dilute hydrochloric acid and water, dried over anhydrous Na_2SO_4 and the extract condensed under reduced pressure. The residue was analyzed by GLC.

The author wishes to thank the Nisshin Chemical Co., Ltd., for permission to publish this report. The author is also grateful to Drs. K. Nakagawa and H. Fukawa of the Central Research Laboratory, Nisshin Flour Milling Co., Ltd., for their interest throughout this work.

The Oxidative Amination of Diethyl 2-Hydroxyazulene-1,3-dicarboxylate and Cycloheptimidazol-2(1*H*)-one

Katsuo KIKUCHI,* Yuji MAKI, and Noriyuki SAITO

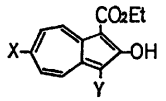
Department of Chemistry, Faculty of Science, Yamagata University, Koshirakawa-cho, Yamagata 990

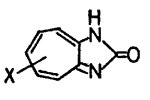
(Received March 22, 1978)

Synopsis. The reaction of diethyl 2-hydroxyazulene-1,3-dicarboxylate with morpholine, pyrrolidine, piperidine, and dimethylamine in the presence of copper(II) acetate gave the respective 6-aminoazulene derivatives. Similarly, the reaction of cycloheptimidazol-2(1*H*)-one with morpholine gave the 6-aminocycloheptimidazole derivative, while the reaction with pyrrolidine gave the 4-(or 5-)aminocycloheptimidazole derivative.

Azulene derivatives carrying amino groups on a seven-membered ring have usually been obtained by the nucleophilic substitution reaction,[1-3] by the Schmidt reaction on acetylazulene derivatives,[4] or by the reaction of acetamidotropolone with ethyl cyanoacetate.[5] Similarly, 4-, 5-, and 6-aminocycloheptimidazole derivatives have also been obtained by the nucleophilic substitution reaction,[6,7] Schmidt reaction,[8] or reduction of nitro group.[6] In the preceding paper,[9] we have reported that the reaction of tropone and tropolone with several kinds of amines in the presence of copper(II) salt afforded 2-aminotropones and 3- and 5-aminotropolones. In the course of the investigation of the oxidative amination of seven-membered aromatics, it was found that the title compounds were also aminated on treatment with amines, and these results will be reported in this paper.

When diethyl 2-hydroxyazulene-1,3-dicarboxylate (**1**) was heated with a solution of copper(II) acetate and morpholine in ethanol, a yellow crystalline product (**2a**), $C_{20}H_{23}O_6N$, was obtained in about 20% yield. The UV spectrum exhibited maxima at 234, 265, 348, 405, and 430 nm (sh), suggesting that **2a** is an azulenic compound. The NMR spectrum exhibited signals at 7.14 (C_5– and C_7–H, d, J=12 Hz) and 9.10 ppm (C_4– and C_8–H, d, J=12 Hz) besides the signals due to the hydroxyl, morpholino methylene, and ester ethyl groups. The elemental analysis and these spectral data indicate that **2a** is diethyl 2-hydroxy-6-morpholinoazulene-1,3-dicarboxylate. The treatment of **1** with pyrrolidine, piperidine, and dimethylamine under similar conditions gave 6-(1-pyrrolidinyl) (**2b**), 6-piperidino (**2c**), and 6-dimethylamino (**2d**) derivatives, respectively. The alkaline hydrolysis and decarboxylation of **2a** to obtain 2-hydroxy-6-morpholinoazulene failed, and the product obtained was ethyl 2-hydroxy-6-morpholinoazulene-1-carboxylate (**3a**). Similarly, monomethyl esters (**3b** and **3c**) were also obtained from **2b** and **2c**.





2a: X=morpholino Y=CO_2Et
2b: X=1-pyrrolidinyl Y=CO_2Et
2c: X=piperidino Y=CO_2Et
2d: X=dimethylamino Y=CO_2Et
3a: X=morpholino Y=H
3b: X=1-pyrrolidinyl Y=H
3c: X=piperidino Y=H

4: X=H
5a: X=6-morpholino
5b: X=4-(or 5-)-(1-pyrrolidinyl)

When cycloheptimidazol-2(1*H*)-one (**4**) was heated with a solution of copper(II) acetate and morpholine in methanol, a yellowish-orange crystalline product (**5a**), $C_{12}H_{13}O_2N_3$, mp 310 °C (dec) was obtained in about 15% yield. The UV spectrum of **5a** showed maxima at 255, 292, and 420 nm. The NMR spectrum (in trifluoroacetic acid) exhibited signals at 7.76 (C_5– and C_7–H, d, J=13.2 Hz) and 8.23 ppm (C_4– and C_8–H, d, J=13.2 Hz), indicating that **5a** is 6-morpholinocycloheptimidazol-2(1*H*)-one. On the other hand, when **4** was treated with pyrrolidine under similar conditions, yellow crystals (**5b**) $C_{12}H_{13}ON_3$, mp 297 °C (dec) were obtained. The NMR spectrum (in trifluoroacetic acid) exhibited signals due to aromatic protons at 7.3—8.1 ppm (4H) as a complex multiplet; the splitting pattern is quite different from that of **5a**. The UV spectrum, which shows maxima at 245, 279, 367, and 457 nm is also quite different from that of **5a**. Therefore, **5b** must be 4-(or 5-)(1-pyrrolidinyl)cycloheptimidazol-2(1*H*)-one.

Experimental

All the melting points were uncorrected. The NMR spectra were determined on a Hitachi H-60 instrument (Me_4Si), the UV spectra were recorded on a Hitachi EPS-3T spectrometer, and the IR spectra were taken on a Hitachi EPI-S spectrometer.

The Reaction of Diethyl 2-Hydroxyazulene-1,3-dicarboxylate (1) with Morpholine, Pyrrolidine, Piperidine, and Dimethylamine. To a solution obtained by dissolving copper(II) acetate (1.00 g) in ethanol (3 ml) and morpholine (3 ml), **1** (0.72 g) was added, and the mixture was heated at 70—75 °C for 48 h. The reaction mixture was diluted with water. The precipitate was collected, washed with water, and dried. Then it was dissolved in chloroform, hydrogen sulfide was passed through, and copper(II) sulfide was removed. After the solvent was evaporated, the residue was dissolved in benzene and passed through a silica gel column. The fraction eluted with benzene gave 380 mg of starting material, and the fraction eluted with a mixture of chloroform and ethanol (99: 1) gave 185 mg (20%) of diethyl 2-hydroxy-6-morpholinoazulene-1,3-dicarboxylate (**2a**) as yellow needles (from ethanol), mp 169.5—170.5 °C. UV (methanol) max: 234 (log ε 4.35), 265 (4.43), 348 (4.74), 405 (4.23), and 430 nm (sh, 4.10). Found: C, 64.07; H, 6.08; N, 3.71%. Calcd for $C_{20}H_{23}NO_6$: C, 64.33; H, 6.21; N, 3.75%.

The reaction of **1** with pyrrolidine, piperidine, and dimethylamine was carried out similarly.

Diethyl 2-hydroxy-6-(1-pyrrolidinyl)azulene-1,3-dicarboxy-

late (**2b**). Orange yellow prisms (from dioxane), mp 205—208 °C (dec). Yield, 23%. UV (methanol) max: 266 (log ε 4.44), 348 (4.77), 402 (4.25), and 431 nm (4.22). NMR ($CDCl_3$): δ, 6.60 (C_5- and C_7-H, d, J=12 Hz), and 8.90 (C_4- and C_8-H, d, J=12 Hz). Found: C, 67.51; H, 6.55; N, 3.56%. Calcd for $C_{20}H_{23}NO_5$: C, 67.21; H, 6.49; N, 3.92%.

Diethyl 2-hydroxy-6-piperidinoazulene-1,3-dicarboxylate (**2c**). Orange yellow prisms (from ethanol), mp 128—129 °C. Yield, 26%. UV (methanol) max: 232 (log ε 4.35), 266 (4.48), 351 (4.77), 402 (4.32), and 431 nm (4.25). NMR ($CDCl_3$): δ, 7.13 (C_5- and C_7-H, d, J=12 Hz), and 9.09 (C_4- and C_8-H, d, J=12 Hz). Found: C, 67.74; H, 6.68; N, 3.62%. Calcd for $C_{21}H_{25}NO_5$: C, 67.90; H, 6.78; N, 3.77%.

Diethyl 2-hydroxy-6-dimethylaminoazulene-1,3-dicarboxylate (**2d**). Orange prisms (from dioxane), mp 187—188 °C. UV (methanol) max: 230 (log ε 4.31), 265 (4.48), 347 (4.79), 402 (4.23), and 430 nm (4.17). NMR ($CDCl_3$): δ, 6.72 (C_5- and C_7-H, d, J=13 Hz), and 8.95 (C_4- and C_8-H, d, J=13 Hz). Found: C, 65.60; H, 6.50; N, 4.14%. Calcd for $C_{18}H_{21}NO_5$: C, 65.24; H, 6.39; N, 4.23%.

*The Alkaline Hydrolysis and Decarboxylation of **2a**, **2b**, and **2c**.* A solution of sodium hydroxide (150 mg) in water (1.5 ml) and ethanol (3 ml) was refluxed with **2a** (280 mg) for 5 h on a water bath. The mixture was diluted with water and acidified. The crystalline precipitate was washed with water and dried. The chromatographic separation on preparative TLC using Merck Silica Gel PF_{254} gave 80 mg of **2a** and 95 mg of ethyl 2-hydroxy-6-morpholinoazulene-1-carboxylate (**3a**), orange prisms (from dioxane), mp 166—168 °C. UV (methanol) max: 221 (log ε 4.45), 338 (4.76), and 400 nm (4.08). NMR ($CDCl_3$): δ, 6.57 (C_3-H, s), 7.0 (C_5- and C_7-H, m), 7.91 (C_4-H, d, J=12 Hz), and 8.77 (C_8-H, d, J=11 Hz). Found: C, 67.88; H, 6.50%. Calcd for $C_{17}H_{19}NO_4$: C, 67.76; H, 6.36%.

Ethyl 2-hydroxy-6-(1-pyrrolidinyl) azulene-1-carboxylate (**3b**). Orange yellow scales (from dioxane), mp 185—186 °C. UV (methanol) max: 219 (log ε 4.39), 241 (4.03), 345 (4.83), 406 (4.12), and 438 (3.98). NMR ($CDCl_3$): δ, 6.5 (C_3-, C_5-, and C_7-H, m), 7.77 (C_4-H, d, J=12 Hz), and 8.61 (C_8-H, d, J=12 Hz). Found: C, 71.79; H, 6.93%. Calcd for $C_{17}H_{19}NO_3$: C, 71.56; H, 6.71%.

Ethyl 2-hydroxy-6-piperidinoazulene-1-carboxylate (**3c**). Orange crystals (from ethanol), mp 114—115 °C. UV (methanol) max: 221 (log ε 4.41), 345 (4.73), and 409 nm (4.14). NMR ($CDCl_3$): δ, 6.45 (C_3-H, s), 6.9 (C_5- and C_7-H, m), 7.82 (C_4-H, d, J=12 Hz), 8.67 (C_8-H, d, J=11 Hz). Found: C, 72.57; H, 7.26%. Calcd for $C_{18}H_{21}NO_3$: C, 72.21; H, 7.07%.

*The Reaction of Cycloheptimidazol-2(1H)-one (**4**) with Morpholine and Pyrrolidine.* To a solution obtained by dissolving copper(II) acetate (2.00 g) in methanol (4 ml) and morpholine (4 ml), **4** (0.73 g) was added under stirring, and the mixture was heated at 70—75 °C for 48 h. Water was added to the reaction mixture and the precipitate was collected by filtration. The precipitate was dissolved in dilute hydrochloric acid, hydrogen sulfide was passed through the solution, and copper(II) sulfide was filtered off. The filtrate was neutralized with sodium hydrogencarbonate and the resulting crystalline precipitate was collected. Recrystallization from water gave 6-morpholinocycloheptimidazol-2(1*H*)-one (**5a**) as yellow needles, mp 310 °C (dec). Yield, 150 mg (15%). UV (methanol) max: 255 (log ε 4.37), 292 (sh, 3.78), and 420 nm (4.42). IR (KBr): 3300 and 1630 cm^{-1}. NMR (CF_3CO_2H): δ, 4.15 (morpholine CH_2, s, 8H), 7.76 (C_5- and C_7-H, d, J=13.2 Hz), and 8.23 (C_4- and C_8-H, d, J=13.2 Hz). Found: C, 62.33; H, 5.65; N, 18.07%. Calcd for $C_{12}H_{13}N_3O_2$: C, 62.32; H, 5.67; N, 18.07%.

A similar treatment of **4** with pyrrolidine (neutralization of the filtrate with sodium hydrogencarbonate, however, did not afford any precipitate and repeated extraction with chloroform was necessary) gave 4-(or 5-)(1-pyrrolidinyl)cycloheptimidazol-2(1*H*)-one (**5b**) as orange crystals, mp 297 °C (dec). Yield, 14%. UV (methanol) max: 245 (log ε 4.24), 279 (4.38), 367 (4.15), and 457 nm (4.09). IR (KBr): 3450 and 1625 cm^{-1}. NMR (CF_3CO_2H): δ, 2.1—2.6 (pyrrolidine CH_2, m, 4H), 3.9—4.4 (pyrrolidine CH_2, m, 4H), and 7.3—8.1 (aromatic H, m, 4H). Found: C, 67.09; H, 5.92; N, 19.04%. Calcd for $C_{12}H_{13}N_3O$: C, 66.95; H, 6.09; N, 19.52%.

Reversible Oxygen Transfer Reactions between Sulfoxides and Sulfides. Relative Stabilities of Acyloxysulfonium Ions

Rikuhei TANIKAGA,* Koji NAKAYAMA, Kazuhiko TANAKA, and Aritsune KAJI

Department of Chemistry, Faculty of Science, Kyoto University Kitashirakawa, Sakyo-ku, Kyoto 606

(Received April 14, 1978)

Synopsis. Sulfides and acyloxysulfonium ions generated from sulfoxides and trifluoroacetic anhydride undergo a reversible reaction at −80 °C. The acyloxysulfonium ions with electron-donating groups or less bulky groups were found to be more stable than those having electronwithdrawing or bulky substituents.

Intermolecular oxygen transfer reactions are known to occur between sulfoxides and sulfides. For example, the reaction between thiolane 1-oxide and dibenzyl sulfide in refluxing acetic acid gives dibenzyl sulfoxide,[1] and the refluxing of diaryl sulfides in dimethyl sulfoxide affords the corresponding sulfoxides in good yields.[2] Oae investigated an intramolecular oxygen migration reaction of *o*-(alkylthio)phenyl aryl sulfoxides in sulfuric acid, and proposed a mechanism involving the nucleophilic attack of the sulfide sulfur atom on the acyloxysulfonium sulfur atom.[3] Recently, we found a rapid reaction between sulfoxides and dimethyl sulfide in trifluoroacetic anhydride (TFAA), which can be applied for the convenient reduction of sulfoxides to the corresponding sulfides.[4] Interestingly, dimethyl sulfoxide is an oxidizing agent in one case, while dimethyl sulfide is a reducing agent in the other case. However, no reversible oxygen transfer reaction between sulfoxides and sulfides has yet been studied.

In extending our observation, we have studied the reversible oxygen transfer reactions between various sulfoxides and sulfides using TFAA, and determined the relative stabilities of acyloxysulfonium ions which had not been estimated.

Experimental

The NMR spectra were recorded on a JEOL PS-100 spectrometer. GLPC determination was performed on a Varian 920 apparatus, using 1.2 m × 6 mm column packed with 20% Silicone DC-550 on 40—60 mesh Celite support. Sulfoxides and sulfides employed were prepared by the known methods. Dichloromethane and acetonitrile were distilled over CaH_2 and P_2O_5, respectively. Commercially available TFAA was used without further purification.

Typical Procedure. A solution of TFAA (12 mmol) in dichloromethane (5 ml) and acetonitrile (5 ml) was added dropwise to a solution of methyl phenyl sulfoxide (**1f**, R=CH_3, R′=C_6H_5)(1.40 g, 10 mmol) and ethyl phenyl sulfide (**4**)(1.38 g, 10 mmol) in dichloromethane (10 ml) and acetonitrile (10 ml) during 5 min at −80 °C, and the mixture was stirred for 90 min. After addition of a small amount of aq NaOH, the mixture was stirred for 5 min at −80 °C and allowed to warm to room temperature. A saturated NaCl solution (50 ml) was added, the layers were separated, and the aq phase was washed with two 30 ml portions of dichloromethane. The combined organic phase was washed with aq $NaHCO_3$ and water, and dried over $MgSO_4$. Evaporation of the solvent gave a liquid (2.7 g). TLC GLPC revealed that the liquid contained four compounds: that is, **1f**, methyl phenyl sulfide (**2f**), ethyl phenyl sulfoxide (**3**), and **4**. No other compound was detected in the NMR spectrum of the liquid. The relative yield of each compound was determined by GLPC and NMR using the authentic samples: **2f/4**=53/47, and **3/1f**=53/47.

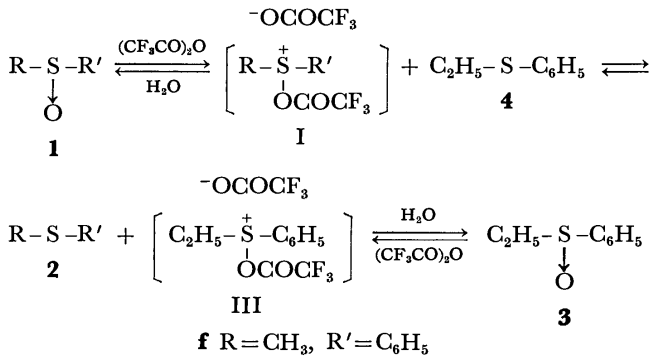
In order to determine whether quenching with aq NaOH was complete in 5 min at −80 °C, dimethyl sulfide (1.24 g, 20 mmol) was added to the mixture at −80 °C after stirring with aq NaOH for 5 min, but **1f**, **2f**, **3**, and **4** were obtained in the same yields as above.

Following a similar procedure, **2f/4**=51/49 was obtained from **2f** and **3**.

Results and Discussion

Since sulfoxides (**1**) were instantaneously reduced to sulfides (**2**) with TFAA and dimethyl sulfide at −80 °C,[4] the formation of acyloxysulfonium ions (I) from **1** is assumed to be very rapid and quantitative. When TFAA was added to a solution of **1f** in dichloromethane and acetonitrile at −80 °C, and after 90 min the reaction mixture was quenched with aqueous NaOH, **1f** was recovered quantitatively. This finding means that **1** never underwent the Pummerer rearrangement at −80 °C.

When TFAA was added to a solution of **1f** and **4** at −80 °C, and after 90 min the mixture was quenched with aqueous NaOH at −80 °C, **1f**, **2f**, **3**, and **4** were obtained, but no other product was detected. Upon similar treatments, **1f**, **2f**, **3**, and **4** were also obtained from **2f** and **3** in nearly the same yields. The relative yields of **2f/4** were found to be nearly equal to those of **3/1f**, suggesting that the following equilibrium exists:



If **1f** and III were not quenched within a few minutes at −80 °C, dimethyl sulfide would rapidly react with **1f** and III to give **2f** and **4**, but not to give **1f** and **3**.[4] The addition of dimethyl sulfide during quenching, however, did not affect the yields of the products.

A NMR spectrum of **1f**, **4**, and TFAA (mol ratio: 1.0: 1.0: 1.2) in CH_2Cl_2–CD_3CN (v/v=1/1) at −80 °C

showed peaks at 2.7, 2.4, 1.2, 1.1 ppm corresponding to the methyl groups of **1f**, **2f**, III, and **4**, respectively. Although the relative yields of **2f**/**4** could not be determined because of overlapping of two methyl signals of III and **4**, those of **2f**/**1f** were found about 50/50.

The above findings mean that the III/**1f** ratio would be essentially the same as the **3**/**1f** (or **2f**/**4**) ratio.

The conceivable pathway from I and **4** to **2** and III (and *vice versa*) may involve the nucleophilc attack of the sulfide sulfur atom on the sulfonium sulfur atom.[3-5]

The results obtained with other sulfoxides, and **4**, are shown in Table 1.

Table 1. Relative yields of **2**/**4** from **1** and **4** (or **2** and **3**)

	R	R′	Yield ratio (**2**/**4**)
a	CH_3	CH_3	0/100
b	CH_3	n-C_6H_{13}	2/98
c	CH_3	p-CH_3O-C_6H_4	36/64
d	CH_3	p-CH_3-C_6H_4	47/53
e	CH_3	o-CH_3-C_6H_4	66/34
f	CH_3	C_6H_5	53/47
g	CH_3	p-Cl-C_6H_4	76/24
h	CH_3	o-Cl-C_6H_4	94/6
i	CH_3	p-NO_2-C_6H_4	100/0
j	i-C_3H_7	C_6H_5	54/46
k	CH_2Cl	C_6H_5	100/0
l	C_6H_5	C_6H_5	99/1

Since the above equilibrium is considered to depend on the relative stabilities of the acyloxysulfonium ions I and III, the smaller **2**/**4** ratio means that I is more stable. On this basis, the relative thermodynamic stabilities of I can readily be determined. Thus, we may reasonably conclude that an electron-donating group can make I more stable, and the steric bulkiness, for example, of an o-substituent makes I slightly unstable. The former conclusion also suggests that I obtained from basic **1** must be stable. In fact, the stabilities of I were found qualitatively to parallel the pK_a values of **1**,[6] though attempts to find out the exact relationships between them were unsuccessful.

The position of the equilibrium was little affected by the presence of 2,6-lutidine. The time necessary to attain the equilibrium varied from a few seconds (*i.e.*, from **2a** and **3**) to a few hours (*i.e.*, **1i** and **4**).

Since dimethyl sulfoxide forms the most stable acyloxysulfonium ion, other sulfoxides can be reduced with dimethyl sulfide in TFAA.[4] The intramolecular oxygen migration of o-alkylthiophenyl aryl sulfoxides also showed that alkyl(aryl)(oxy)sulfonium ions are more stable than diaryl(oxy)sulfonium ions.[3] When one component is removed in the equilibrium, the equilibrium can be displaced to the unfavorable direction. This is the case of the oxidation of sulfides with dimethyl sulfoxides.[2]

When trichloroacetic anhydride, trichloroacetyl chloride, and thionyl chloride were used in the place of TFAA, the **3**/**1** yield ratios were found to be 56/44, 55/45, and 55/45, respectively, and the order of the relative stabilities of the oxysulfonium ions was identical to that obtained with TFAA. When dichloroacetic anhydride was used, it took a much longer time to reach the equilibrium. No intermolecular oxygen exchange reaction of a sulfoxide and a sulfide took place in sulfuric acid at room temperature, or in acetic anhydride at 100 °C, unlike the intramolecular reaction.[3] Evidently such a decrease in reactivities corresponds to a decrease in the leaving group tendency; for example, $CF_3COO^- > CCl_3COO^- > CHCl_2COO^- > CH_3COO^-$.

The present work was partially supported by a Grant-in-Aid from the Ministry of Education (No. 254156).

Preparation of Fluorinated Imidazole Derivatives Using Hexafluoro-1,2-epoxypropane

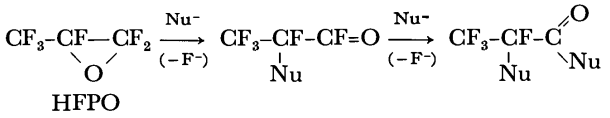
Hamdy A. HAMMOUDA† and Nobuo ISHIKAWA*

Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 28, 1978)

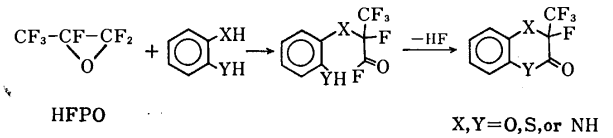
Synopsis. Utilizing the reactivity of hexafluoro-1,2-epoxypropane, several new fluorine-containing imidazole derivatives were prepared. The reactions involve 2-mercaptobenzimidazole, 2-mercapto-4,5-diphenylimidazole, 2-imidazolidinethione, and 2-aminobenzamide.

It is well known that nucleophiles readily attack the central carbon atom of hexafluoro-1,2-epoxypropane (HFPO, hexafluoropropylene oxide), resulting in the formation of α-substituted tetrafluoropropionyl fluorides, which further react with an additional molecule of the nucleophiles to form esters and amides:[1-3]



HFPO

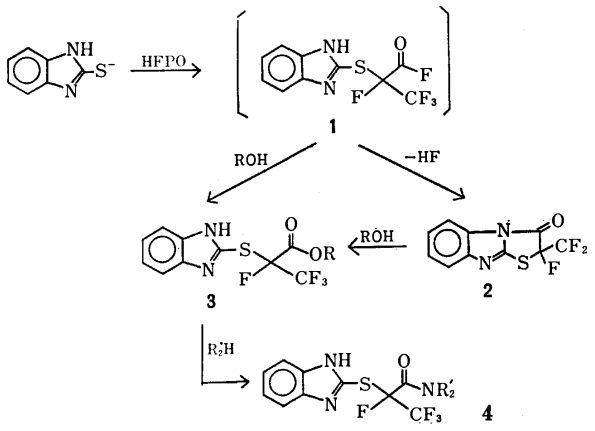
Utilizing this reactivity of HFPO, we have previously reported on the preparation of several new benzo heterocyclic compounds containing CF_3 or C_2F_5 groups by allowing it react with ortho bifunctional benzenes:[4]



HFPO X,Y=O,S,or NH

This work has now been extended in order to search for more biologically active compounds; we wish here to report on the preparation of several new benzimidazole derivatives carrying a fluoroalkyl group.

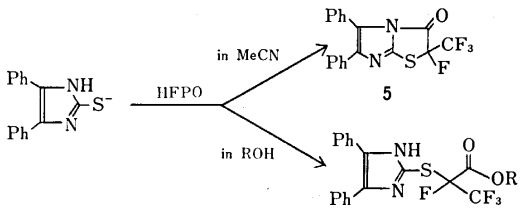
As benzimidazole derivatives with a fused thiazole ring are known to be highly interesting from the physiological point of view, we first examined the preparation of fluorine-containing compounds of this type. 2-Mercaptobenzimidazole (or, better, its sodium salt) reacted with HFPO to give the acyl fluoride, **1**, which cyclized intramolecularly in aprotic solvents, such as dioxane or acetonitrile, to afford 2,3-dihydrothiazolo-[3,2-*a*]benzimidazol-3-one (**2**):



On the other hand, when the reaction was carried out in alcohols, the acid fluoride, **1**, acylated one molecule of the solvent immediately to give the esters, **3**, in good yields. These esters were also prepared from the cyclic compound, **2**, by heating it with alcohol for a short period.

As amides are generally more hydrophilic than esters, and are biologically more useful, we prepared various amides, **4**, by the aminolysis of the esters, **3**. For example, by heating the ethyl ester **3** (R=Et) with an excess of an aqueous ammonia, the amide **4** (R=H) was precipitated. The *N*-alkylated amides were obtained from the ethyl ester by allowing it to react with an excess of the alkylamine at room temperature.

Another group of similar compounds, **5** and **6**, was obtained by the reaction of HFPO with 2-mercapto-4,5-diphenylimidazole, as is shown below:



The all of the above compounds showed two characteristic signals, a doublet and a quartet at a 3:1 ratio of intensities, in their ^{19}F NMR spectra, thus supporting the presence of $\overset{CF_3}{\underset{F}{\diagdown C \diagup}}$ group. The ^1H NMR spectra data are also in agreement with the assigned structures (Table 1).

HFPO is known to isomerize to pentafluoropropionyl fluoride under the influence of a base such as triethylamine.[5] We have previously reported[6] a convenient method for the pentafluoropropionylation of amines, alcohols and thiols, which consists in allowing the nucleophile, triethylamine, and HFPO to react altogether in acetonitrile. By applying this procedure, 2-imidazolidinethione and 2-aminobenzamide were acylated to give the thioesters, **7**, and the amide, **8**,

respectively. The latter compound, **8**, could be cyclized to the benzimidazole compound, 2-(pentafluoroethyl)-3,4-dihydroquinazolin-4-one (**9**), by heating it in *N,N*-dimethylformamide.

Experimental

2-Fluoro-2-(trifluoromethyl)-2,3-dihydrothiazolo[3,2-a]benzimidazol-3-one (2). HFPO (1.7 g, 0.01 mol) was bubbled into a stirred suspension of sodium 2-benzimidazolethiolate (1.7 g, 0.01 mol) in acetonitrile (20 ml) at −78 °C. The cooling bath was then removed, and stirring was continued for 4 h at room temperature using a Dry Ice condenser. The reaction mixture was filtered from a slight turbidity, and the filtrate was evaporated to dryness under a vacuum. The solid residue was dissolved in benzene and filtered from a trace of an insoluble material. The benzene was again removed, and the product was crystallized from hexane.

2-(2-Benzimidazolylthio)-2,3,3,3-tetrafluoropropionic Acid Esters (3): General Procedure. Sodium 2-mercaptobenzimidazolethiolate (0.01 mol) was stirred in the appropriate hydroxy compound. HFPO (0.01 mol) was then bubbled into the resulting, almost clear solution which was kept at −78 °C. The stirring was continued for 4 h at room temperature using a Dry Ice condenser. The reaction mixture was filtered, and the filtrate was poured into ice-cooled water. The crystalline material was collected, washed with water, and recrystallized from the proper solvent.

MS (*m/e*) for **3** (R=Et), 322 (M^+), 277 (M^+−OEt), 276 (M^+−EtOH), 229 (M^+−EtOH−CO−F), and 149 ($C_6H_4CHN_2S^+$).

2-(2-Benzimidazolylthio)-2,3,3,3-tetrafluoropropionamide (4, R'=H). The ethyl ester **3** (1 g) was stirred with a 25% aqueous ammonia (50 ml) for 2 h at room temperature. The reaction mixture was then boiled for a further 15 min and cooled in ice, and the separated crystals were collected and recrystallized from water.

The N-Alkyl Derivatives (4, R'=H, alkyl), The ethyl ester **3** (1 g) was stirred with an alkylamine solution (5 ml) (40% methylamine and 70% ethylamine solutions were used) for 5 h at room temperature. The clear solution was poured onto crushed ice and slightly acidified by adding a few drops of hydrochloric acid. The crystals that separated were collected, washed with water, dried well, and recrystallized.

The N,N-Dialkyl Derivatives (4, R'=alkyl). The ethyl ester **3** was stirred at room temperature with dimethylamine or diethylamine (3 ml). Exothermic dissolution first took place, followed by the precipitation of a white solid. After stirring for 5 h, the reaction mixture was poured on ice-cooled water, slightly acidified by adding a few drops of hydrochloric acid. The crystals that separated were filtered off, washed with water, dried well, and recrystallized.

2-Fluoro-2-(trifluoromethyl)-5,6-diphenyl-2,3-dihydroimidazolo-[2,1-b]thiazol-3-one (5). Sodium 4,5-diphenyl-2-imidazolethiolate (0.01 mol) was stirred with acetonitrile (20 ml) in a pressure tube. The mixture was then cooled to −78 °C, and liquefied HFPO (0.01 mol) was introduced. Stirring was continued for 4 h. The solvent was then evaporated under a vacuum, and the solid product was crystallized from hexane.

2-(4,5-Diphenyl-2-imidazolylthio)-2,3,3,3-tetrafluoropropionic Acid Esters (6): General Procedure. Liquefied HFPO (0.01 mol) was introduced into a solution of sodium 4,5-diphenyl-2-imidazolethiolate in the appropriate hydroxy compound (20 ml) at −78 °C. Stirring at room temperature was continued for 4 h. The reaction mixture was then filtered, and the filtrate was diluted with water. The precipitated crystals were filtered off, washed with water, dried, and recrystallized.

S-(2-Imidazolin-2-yl) Pentafluoropropanethioate (7). A mixture of 2-imidazolidinethione (1.02 g, 0.01 mol) and triethylamine (1.01 g, 0.01 mol) was stirred in acetonitrile (10 ml) at −78 °C. Liquefied HFPO (0.01 mol) was then introduced, and the stirring was continued for 30 min at room temperature. The reaction mixture was poured into ice-cooled water, and the crystals that separated were collected and recrystallized from hexane.

2'-Carbamoylpentafluoropropionanilide (8). 2-Aminobenzamide and HFPO were reacted in acetonitrile in the presence of triethylamine according to the procedure described above for the preparation of **7**. The product was recrystallized from aqueous methanol.

3,4-Dihydro-2-(pentafluoroethyl)quinazolin-4-one (9). The amide **8** (1 g) was refluxed in *N,N*-dimethylformamide (30 ml) for 3 h, cooled, and poured into cold water. The crystals that separated were filtered off, washed with water, dried, and recrystallized from aqueous methanol.

The Nucleophilic Substitution Reaction of 1-Halogeno-2-methylsulfonylphenazine 5-Oxides

Masao TADA

The Research Institute for Tuberculosis and Cancer, Tohoku University, Seiryomachi, Sendai 980

(Received April 28, 1978)

Synopsis. The halogen atom in 1-halogeno-2-methylsulfonylphenazine 5-oxide is reactive toward the anionoid reagents through the activating effects of both the sulfone group and the *N*-oxide group. By the nucleophilic substitutions, some 1-substituted 2-methylsulfonylphenazine derivatives have been prepared in high yields.

In a previous paper,[1] it has been shown that direct comparison of the reactivities of the halogen atoms in 1- and 2-halogenophenazines and their *N*-oxides has confirmed the activating effect of the *N*-oxide group. The halogen-activating effects from the presence of oxide groups have been shown in other compounds.[2] Heppolette *et al.*[3] reported that the halogen displacement in 2-halogenonitrobenzene could be strongly promoted by the introduction of a sulfone group in the 4-position. The author's interest in the activating effects of both a sulfone group and a *N*-oxide group has led to the suggestion that a halogen atom of 1-halogeno-2-methylsulfonylphenazine 5-oxide will be reactive toward anionoid reagents. As part of the synthetic study of phenazines with potential biological activities, this note will describe the preparation and the reaction of 1-halogeno-2-methylsulfonylphenazine 5-oxides.

The reaction of 1,2-dichlorophenazine (**1**)[4] and its 5-oxide (**2**)[4] with an equimolecular quantity of sodium methanethiolate gave the corresponding methylthiophenazines, **3** and **4**. Compound **4** was deoxygenated by the treatment with zinc dust in acetic acid to give **3**, from which sulfone (**5**) was then prepared by the oxidation with a limited amount of hydrogen peroxide in acetic acid. The further oxidation of **5** with an excess of hydrogen peroxide afforded 1-chloro-2-methylsulfonylphenazine 5-oxide (**6**), which was also derived from **4** by the oxidation. The position of the chlorine atom in **6** was confirmed by the following piperidination. The refluxing of **6** with piperidine in ethanol for 2 h afforded 2-methylsulfonyl-1-piperidinophenazine 5-oxide (**7**), which was also derived from 1-bromo-2-methylsulfonylphenazine 5-oxide (**8**).[5]

The heating of **6** or **8** with morpholine in ethanol for 2 h gave 2-methylsulfonyl-1-morpholinophenazine 5-oxide (**9**), whereas **5** was unreactive toward morpholine under similar conditions. The reactivity to the amine of either **6** or **8** is in contrast with that of 1-chlorophenazine 5-oxide (**10**).[6] The treatment of **8** with aqueous ethanolic alkali for 1.5 h afforded both 1-ethoxy- (**11**) and 1-hydroxy-2-methylsulfonylphenazine 5-oxides (**12**). The former was also obtained by the reaction of **6** or **8** with sodium ethoxide in ethanol, and the latter was also derived from **6** or **8** by the treatment with aqueous alkali. The reaction of **8** with active methylene compounds, such as diethyl malonate and ethyl cyanoacetate, gave the corresponding products, **13** and **14**.

The results of these substitutions of 1-halogeno-2-methylsulfonylphenazine 5-oxide show that the displacement of a halogen group in Position 1 can be strongly promoted by the presence of a methylsulfonyl group in Position 2.

Experimental

The melting points, the appearances, the solvents of recrystallization, and the results of elemental analyses are all listed in Table 1. The infrared spectra were taken with a Hitachi Model EPI-S_2 spectrophotometer.

1-Chloro-2-methylthiophenazine (3). *From 1*: To a hot solution of **1** (2.5 g) in ethanol (0.5 l), a 20% aqueous solution of sodium methanethiolate (3 ml) was added. The mixture was refluxed for 10 h and diluted with water. The crystals thereby separated were chromatographed over alumina, using chloroform as the solvent, to give **3** (960 mg, 37%).

From 4: To a solution of **4** (150 mg) in acetic acid (30 ml), zinc dust (0.5 g) was added in small portions. The mixture was then warmed on a water bath for 5 min and filtered while hot. The filtrate was diluted with water to afford **3** (135 mg, 92%).

1-Chloro-2-methylthiophenazine 5-Oxide (4). To a hot solution of **2** (5.3 g) in ethanol (0.8 l), a 20% aqueous solution of sodium methanethiolate (6 ml) was added. The solution was refluxed for 5 h and diluted with water. The crystals which separated were chromatographed over alumina using chloroform as the solvent. From the effluent, **4** (3.54 g, 64%), **3** (550 mg, 11%), and 1,2-bis(methylthio)phenazine 5-oxide[7] (120 mg, 2%) were obtained.

1-Chloro-2-methylsulfonylphenazine (5). A solution of **3** (260 mg) in acetic acid (10 ml) and a 30% aqueous solution of hydrogen peroxide (2 ml) was warmed at 55 °C for 3 h to give **5** (270 mg, 93%).

1-Chloro-2-methylsulfonylphenazine 5-Oxide (6). *From 3*: To a solution of **3** (520 mg) in acetic acid (20 ml) and

a) All the melting points are uncorrected. b) Needles and leaflets are abbreviated as n and l, respectively.

acetic anhydride (1 ml), a 30% aqueous solution of hydrogen peroxide (3 ml) was added. The mixture was warmed at 55 °C for 15 h to give **6** (600 mg, 97%).

From 4: **4** (550 mg) and a 30% aqueous solution of hydrogen peroxide (3 ml) were treated, following the procedure used in the preparation of **5**, to afford **6** (600 mg, 97%).

From 5: **5** (580 mg) was treated as in the case of the "From **3**" above to give **6** (590 mg, 95%).

2-Methylsulfonyl-1-piperidinophenazine 5-Oxide (7). From 6: A mixture of **6** (310 mg) and piperidine (0.5 ml) in ethanol (50 ml) was refluxed for 2 h and then diluted with water to give **7** (320 mg, 90%).

From 8: **8** (350 mg) was treated as in the case described above to give **7** (330 mg, 92%).

2-Methylsulfonyl-1-morpholinophenazine 5-Oxide (9). A mixture of **6** (310 mg) and morpholine (0.5 ml) in ethanol (50 ml) was refluxed for 2 h to afford **9** (300 mg, 84%). **8** (350 mg) was treated in a similar way to give **9** (310 mg, 86%).

1-Hydroxy-2-methylsulfonylphenazine 5-Oxide (11). A suspension of **8** (350 mg) in a 5% aqueous solution of potassium hydroxide (20 ml) was refluxed for 2 h, filtered, and acidified with diluted acetic acid to give **11** (250 mg, 86%). **6** (310 mg) was treated in a similar way to give **11** (240 mg, 83%). IR (KBr): 3120 cm^{-1}.

1-Ethoxy-2-methylsulfonylphenazine 5-Oxide (12). To a solution of **8** (350 mg) in absolute ethanol (50 ml), sodium (100 mg) was added. The resulting mixture was refluxed for 2 h to give **12** (285 mg, 90%). **6** was treated in a similar way to give **11** (85%).

To a suspension of **8** (530 mg) in ethanol (30 ml), a 10% aqueous solution of potassium hydroxide (10 ml) was added. The mixture was refluxed for 1.5 h and diluted with water. The resulting crystals gave **12** (250 mg, 52%); from the filtrate, **11** (180 mg, 41%) was obtained.

1-[Bis(ethoxycarbonyl)methyl]-2-methylsulfonylphenazine 5-Oxide (13). To a sodium ethoxide solution prepared from sodium (92 mg) and absolute ethanol (40 ml), diethyl malonate (640 mg) was added. **8** (706 mg) was then added to the mixture and the resulting mixture was refluxed for 1 h to give **13** (660 mg, 76%). IR (KBr): 1762 and 1724 cm^{-1}.

1-(1-Cyano-1-ethoxycarbonylmethyl)-2-methylsulfonylphenazine 5-Oxide (14). A mixture of **8** (706 mg) and ethyl cyanoacetate (432 mg) was treated, following procedure used in the preparation of **13**, to afford **14** (690 mg, 90%). IR (KBr): 2250 and 1751 cm^{-1}.

The author is grateful to Professor Atsushi Oikawa of Tohoku University for his encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (10), 3095—3096 (1978)

A Convenient Synthesis of 2-Substituted 3-Nitro-2*H*-chromene Derivatives[1)]

(Received May 2, 1978)

Synopsis. On reaction with salicylaldehyde, ω-nitrostyrene and 4,6-dimethoxy-5-(2-nitrovinyl)pyrimidine gave a mixture of 3-nitro-4-hydroxyflavan and 3-nitro-2-phenyl-2*H*-chromene or 2-(4,6-dimethoxy-5-pyrimidinyl)-3-nitro-2*H*-chromene, respectively, whereas 4,6-dichloro-5-(2-nitrovinyl)-pyrimidine afforded substitution products: 4-chloro-6-(2-formylphenoxy)-5-(2-nitrovinyl)pyrimidine and 4,6-bis(2-formylphenoxy)-5-(2-nitrovinyl)pyrimidine.

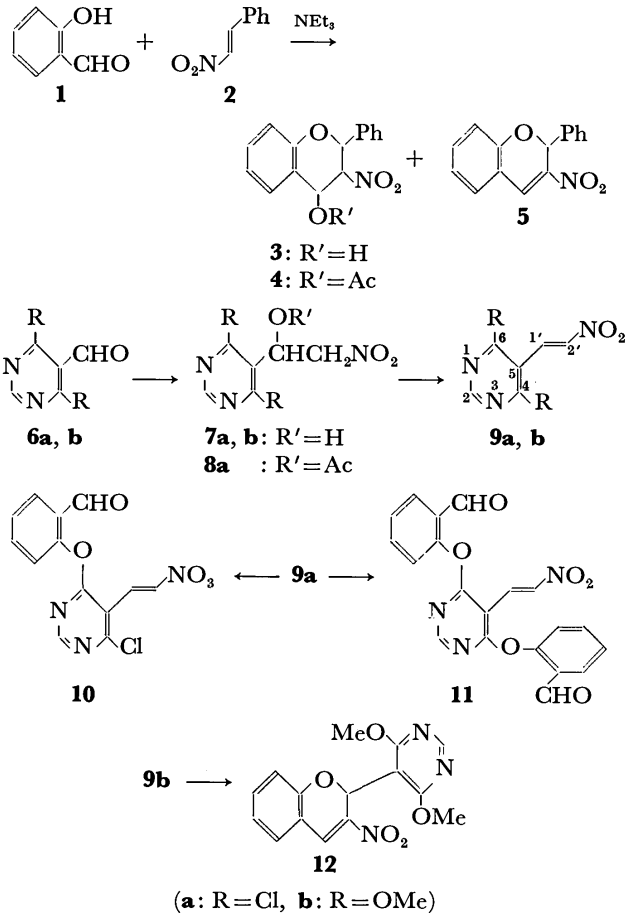
C-Nucleosides frequently have interesting biological activities, and several synthetic studies on these compounds have been reported.[2)] In a series of studies on nucleophilic addition reactions to nitro olefin derivatives, we designed the synthesis of C-nucleosides from β-hydroxy aldehyde and nitro olefins. As a preliminary examination we have carried out the reaction of (2-nitrovinyl)pyrimidine derivatives with salicylaldehyde.

Treatment of salicylaldehyde (**1**) with ω-nitrostyrene (**2**) in the presence of triethylamine afforded a mixture of two cyclic compounds, 3-nitro-4-hydroxyflavan (**3**) and 3-nitro-2-phenyl-2*H*-chromene (**5**), in a *ca.* 1:1 ratio in 69% yield. The *trans-trans* structure of the nitro alcohol **3** was determined by the NMR spectrum of its nitro acetate **4**; $J_{2,3}=10$, $J_{3,4}=8.3$ Hz. The structure of 3-nitro-2-phenyl-2*H*-chromene (**5**) was deduced from analytical, IR, and NMR data.[3)]

To extend this ring formation, (2-nitrovinyl)-pyrimidine derivatives **9a** and **9b** were prepared from the corresponding 5-formylpyrimidine **6a** and **6b**, respectively. Nitromethane condensation of 4,6-dichloro-5-formylpyrimidine **6a**[4)] in the presence of sodium or potassium hydroxide, sodium methoxide, or triethylamine as a basic catalyst failed. However, in the presence of barium hydroxide the intended nitro alcohol **7a** was isolated in 62% yield. On the other hand, 4,6-dimethoxy-5-formylpyrimidine **6b**[5)] smoothly reacted with nitromethane in the presence of triethylamine, giving the nitro alcohol **7b**. Acetylation of the nitro alcohol **7a** and **7b** with acetic anhydride-boron trifluoride etherate and subsequent elimination of acetic acid with sodium hydrogencarbonate afforded the nitro olefins **9a** and **9b**, respectively.

Treatment of the nitro olefin **9a** with equimolar salicylaldehyde under various conditions (solvents, reaction temperature, and amounts of triethylamine) resulted in a colored solution, from which no desired product was isolated. When **9a** was treated with salicylaldehyde in the presence of *ca.* 1.4 equivalents of sodium 2-formylphenoxide in DMSO, 4-chloro-6-(2-formylphenoxy)-5-(2-nitrovinyl)pyrimidine (**10**) was isolated in 65% yield. A similar treatment of **9a** with 2.1 equivalents of sodium 2-formylphenoxide yielded 4,6-bis(2-formylphenoxy)-5-(2-nitrovinyl)pyrimid ine. These results showed that the chlorine atoms were more reactive to 2-formylphenoxide than the nitro olefin moiety under the conditions employed.

Under the conditions used for preparation of the flavan **3** and chromene **5**, the reaction of **9b** with salicylaldehyde did not occur, because **9b** was immediately precipitated when triethylamine was added. But treatment of **9b** with two equivalents of salicylaldehyde in the presence of 0.1 equivalent of sodium 2-formylphenoxide in DMSO at room temperature for 24 h gave the 2*H*-chromene derivative **12** as yellow crystals in 46% yield. Its IR spectrum showed the presence of a conjugated nitro group and characteristic absorption bands due to pyrimidine and benzene ring. The NMR spectrum supports the structure of **12.**



Experimental

Melting points were taken in capillaries and are uncorrected. NMR spectra were recorded at 60 MHz on a Varian T-60 spectrometer (except compound **4**, which was analyzed at 100 MHz on a JNM-4H-100 (JEOL) spectrometer), in chloroform-*d* using tetramethylsilane as internal standard.

t-*3-Nitro*-c-*2-phenyl*-r-*1-chromanol (3).* To a solution of **2** (3.0 g, 20 mmol) in **1** (7.5 g, 61.5 mmol) was added 0.2 g

(2 mmol) of triethylamine. The mixture, which gradually solidified, was allowed to stand for 16 h at room temperature. The resulting crystalline solid was broken up and dissolved in hot ethanol. The solution was filtered to remove insoluble material. After evaporation of the filtrate, the residue was washed several times with carbon tetrachloride and recrystallized from ethanol to give 1.68 g (31%) of **3** as colorless crystals: mp 138.5—139.5 °C; IR 3290 (OH), 1552, and 1376 cm^{-1} (NO_2). Found: C, 66.50; H, 4.79; N, 5.27%. Calcd for $C_{15}H_{13}NO_4$: C, 66.41; H, 4.83; N, 5.16%.

t-3-Nitro-c-2-phenyl-r-1-chromanyl Acetate (4). A solution of **3** (300 mg, 1.1 mmol) in 3 ml of acetic anhydride was left at room temperature for 6 h in the presence of catalytic amounts of boron trifluoride etherate. Addition of 20 ml of water to the reaction mixture gave a precipitate (312 mg, 90.5%), which was recrystallized from ethanol to give colorless needles of **4** (87%): mp 183—184 °C; IR 1738 (C=O), 1550 and 1368 cm^{-1} (NO_2); NMR δ 2.13 (Ac), 5.39 (1H, d, $J_{2,3}$= 10 Hz, H-2), 5.15 (1H, d, $J_{3,4}$=8.3 Hz, H-3), and 6.98 (1H, d, H-4). Found: C, 65.15; H, 4.79; N, 4.50%. Calcd for $C_{17}H_{15}NO_5$: C, 65.17; H, 4.82; N, 4.47%.

3-Nitro-2-phenyl-2H-chromene (5). The carbon tetrachloride solution obtained in the preparation of **3** was evaporated to give a yellow residue, which was recrystallized from ethanol to afford yellow crystals (1.9 g, 38%) of **5**: mp 92.5—93.5 °C (lit,[3] 87 °C); IR 1640 (C=C), 1502 and 1320 cm^{-1} (NO_2); NMR δ 6.59 (1H, s, H-2) and 8.09 (1H, s, H-4). Found: C, 70.86; H, 4.37; N, 5.73%. Calcd for $C_{15}H_{11}NO_3$: C, 71.14; H, 4.37; N, 5.53%.

4,6-Dichloro-5-(1-hydroxy-2-nitroethyl)pyrimidine (7a). To a mixture of **6a**[4] (500 mg, 2.8 mmol) and nitromethane (3.44 g, 56 mmol) in methanol (20 ml) at room temperature was added barium hydroxide octahydrate (221 mg, 0.7 mmol). The mixture was stirred for 3 h at 5 °C and then neutralized with cation-exchange resin (Mitsubishi Diaion SK 1). Evaporation of the solvent gave a solid residue, which was recrystallized from ethanol to yield colorless crystals of **7a** (419 mg, 62.4%): mp 102.5—103.5 °C; IR 3250 (OH), 1548 and 1377 cm^{-1} (NO_2). Found: C, 30.51; H, 2.09; N, 18.02%. Calcd for $C_6H_5Cl_2N_3$: C, 30.25; H, 2.10; N, 17.65%.

5-(1-Acetoxy-2-nitroethyl)-4,6-dichloropyrimidine (8a). A solution of **7a** (500 mg, 2.1 mmol) in 5 ml of acetic anhydride was allowed to stand for 6 h at room temperature in the presence of a catalytic amount of boron trifluoride etherate, and then poured into water (20 ml). The crystalline precipitate was collected and washed well with water. Recrystallization from ethanol gave colorless crystals of **8a** (511.6 mg, 87%): mp 87.5—88.5 °C; IR 1758 (C=O), 1548 and 1378 cm^{-1} (NO_2). Found: C, 34.29; H, 2.49; N, 15.24%. Calcd for $C_8H_7Cl_2N_3O_4$: C, 34.29; H, 2.50; N, 15.00%.

4,6-Dichloro-5-(2-nitrovinyl)pyrimidine (9a). To a solution of **8a** (500 mg, 1.79 mmol) in 30 ml of methanol was added solid sodium hydrogencarbonate (150 mg, 1.78 mmol). The mixture was stirred for 1 h at room temperature and then poured into 100 ml of water. The precipitate was collected and recrystallized from ethanol to give yellow crystals of **9a** (303 mg, 77%): mp 90.5—91.5 °C; IR 1642 (C=C), 1504, and 1340 cm^{-1} (NO_2); NMR δ 7.85 (1H, d, $J_{1',2'}$=14 Hz, H-2'), 8.22 (1H, d, H-1'), and 8.83 (1H, s, pyrimidine ring proton). Found: C, 33.00; H, 1.38; N, 19.31%. Calcd for $C_6H_3Cl_2N_3O_2$: C, 32.73; H, 1.36; N, 19.09%.

5-(1-Hydroxy-2-nitroethyl)-4,6-dimethoxypyrimidine (7b). To a mixture of **6b**[5] (500 mg, 2.97 mmol) and nitromethane (3.63 g, 59.5 mmol) in 50 ml of ethanol was added triethylamine (29 mg, 0.3 mmol). The mixture was allowed to stand for 4 h at room temperature and then evaporated to afford a solid residue, which was recrystallized from ethanol to give colorless crystals of **7b** (518 mg, 76%): mp 121—122 °C; IR 3200 (OH), 1550 and 1375 cm^{-1} (NO_2); NMR δ 4.45 (1H, q, J_{gem}=12.5, $J_{1a',2'}$=4 Hz, H-1a'), 4.92 (1H, q, $J_{1b',2'}$=9 Hz, H-1b'), 5.75 (1H, q, H-2'), and 8.45 (1H, s, pyrimidine ring proton). Found: C, 41.83; H, 4.95; N, 18.48%. Calcd for $C_8H_{11}N_3O_5$: C, 41.92; H, 4.84; N, 18.34%.

4,6-Dimethoxy-5-(2-nitrovinyl)pyrimidine (9b). Crude acetate obtained from **7b** (1.30 g, 5.67 mmol) under the same conditions as described above was directly treated with sodium hydrogencarbonate (510 mg, 6 mmol) in methanol at room temperature for 1 h. The mixture was evaporated to give a solid residue, which was washed completely with water and then recrystallized from ethanol to afford 791 mg (66%) of **9b** as light yellow crystals: mp 131—132 °C; IR 1620 (C=C) and 1500 cm^{-1} (NO_2); NMR δ 7.95 (1H, d, $J_{1',2'}$=14 Hz, H-2'), 8.32 (1H, d, H-1'), and 8.51 (1H, s, pyrimidine ring proton). Found: C, 45.38; H, 4.28; N, 20.04%. Calcd for $C_8H_9N_3O_4$: C, 45.50; H, 4.30; N, 19.90%.

4-Chloro-6-(2-formylphenoxy)-5-(2-nitrovinyl)pyrimidine (10). A solution of **9a** (220 mg, 1 mmol), sodium 2-formylphenoxide (196 mg, 1.36 mmol) and salicylaldehyde (1 ml) in DMSO (20 ml) was allowed to stand at room temperature for 20 h. The mixture was poured into water (50 ml) and the precipitate was collected and recrystallized from ethanol to give yellow crystals of **10** (65%): mp 126 °C; IR 1700 (C=O), 1633 (C=C), 1522 and 1340 cm^{-1} (NO_2). Found: C, 50.76; H, 2.81; N, 13.40%. Calcd for $C_{13}H_8ClN_3O_4$: C, 51.06; H, 2.62; N, 13.75%.

4,6-Bis(2-formylphenoxy)-5-(2-nitrovinyl)pyrimidine (11). A treatment of **9a** (220 mg) with sodium 2-formylphenoxide (300 mg, 2.1 mmol) similar to that described above gave yellow crystals of **11** (46%): mp 229—230 °C; IR 1692 (C=O), 1629 (C=C), and 1512 cm^{-1} (NO_2). Found: C, 60.93; H, 3.36; N, 10.64%. Calcd for $C_{20}H_{13}N_3O_6$: C, 61.38; H, 3.35; N, 10.74%.

2-(4,6-Dimethoxy-5-pyrimidinyl)-3-nitro-2H-chromene (12). To a solution of sodium 2-formylphenoxide (14.1 mg, 0.1 mmol) in DMSO (20 ml) were added **9b** (211 mg, 1 mmol) and **1** (183 mg, 1.5 mmol). The mixture was allowed to stand for 24 h at room temperature and then poured into ice-water. The precipitate was collected and recrystallized from ethanol to give 145 mg (46%) of **12** as yellow crystals: mp 143.5—144.5 °C; IR 1652 (C=C), 1502 and 1328 cm^{-1} (NO_2); NMR δ 3.82 (6H, s, 2×OMe), 7.27 (1H, s, H-2), 7.99 (1H, s, H-4), and 8.43 (1H, s, pyrimidine ring proton). Found: C, 56.97; H, 4.15; N, 13.39%. Calcd for $C_{15}H_{13}N_3O_5$: C, 57.14; H, 4.16; N, 13.33%.

The Bimolecular Reduction of Acridine and 9-Substituted Acridines by Sodium 1-Benzyl-1,4-dihydronicotinamide-4-sulfinate

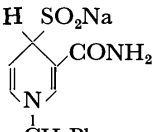
Hiroo INOUE,* Ichiro SONODA, Nobuaki INOGUCHI, and Eiji IMOTO**

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

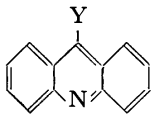
(Received May 11, 1978)

Synopsis. Sodium 1-benzyl-1,4-dihydronicotinamide-4-sulfinate is found to undergo the bimolecular reduction of acridine or 9-substituted acridines to the corresponding 9,9′-biacridans.

The reducing behavior of sodium 1-benzyl-1,4-dihydronicotinamide-4-sulfinate (BNA-SO_2Na)[1] has received little attention. Recently we have found that BNA-SO_2Na reacts with various halogen compounds through the cleavage of its carbon-sulfur bond to give sulfones, olefins, and reduction products.[2] In order to explore further the chemical reactivity of BNA-SO_2Na, the reactions of BNA-SO_2Na were carried out with acridine (**1**) and its derivatives (**2**—**4**), with a methoxy, chloro, or cyano group at the 9-position. Herein, we wish to report our findings on these reactions.

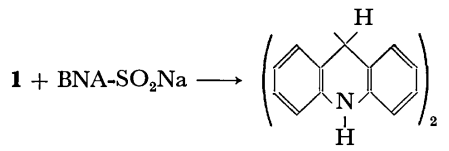


BNA-SO_2Na

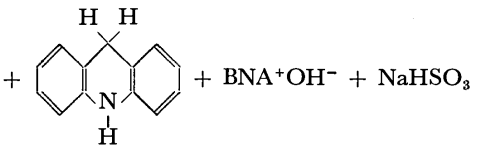


Y=H (**1**), CH_3O (**2**), Cl (**3**) and CN (**4**)

As Table 1 shows, the reaction of **1** with BNA-SO_2Na in 80 vol % aqueous methanol at 25 °C afforded 9,9′-biacridan (**5**), together with a small amount of acridan (**6**). In this reaction, BNA-SO_2Na was converted to 1-benzylnicotinamide hydroxide (BNA$^+$OH$^-$) and a sulfite ion. The formation of **5** along with an equivalent amount of BNA$^+$OH$^-$ constitutes the bimolecular reduction of **1** by BNA-SO_2Na. On the other hand,

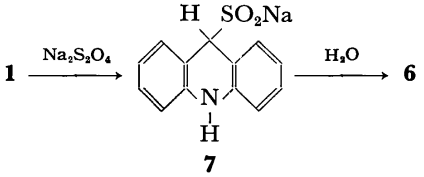


5 (major)



6 (minor)

the reaction of **1** with 1-benzyl-1,4-dihydronicotinamide (BNAH) or sodium dithionite afforded only **6**, without the formation of any **5**. Sodium dithionite would undergo the reduction of **1**, probably *via* the intermediary formation of an adduct (**7**), followed by the decomposition of **7** by water to give **6**.[3] Similar phenomena were also found in the reaction of 10-methylacridium chloride (**8**) with BNA-SO_2Na (Table 1). Thus, it is concluded that BNA-SO_2Na shows a reducing behavior different from that of BNAH and sodium dithionite.



7

Table 1. The reductions of **1** and **8** with BNA-SO_2Na or $Na_2S_2O_4$[a]

Substrate	Reducing agent	Time h	Product, %[b] Biacridans	Acridans	BNA$^+$OH$^-$	SO_3^{2-}
1	BNA-SO_2Na	12	76	7	36	32
1	$Na_2S_2O_4$	2	0	75	—	—
8	BNA-SO_2Na	12	69	13	35	35
8	$Na_2S_2O_4$	2	12	41	—	—

a) Concentration of **1** and **8**: 6×10^{-2} mol/l. Solvent: 80 and 50 vol % MeOH–H_2O for BNA-SO_2Na and $Na_2S_2O_4$ respectively. Reducing agent/substrate molar ratio: 1. b) Biacridans% = {2 × biacridans (mol)/substrate (mol)} × 100. Acridans, BNA$^+$OH$^-$ and SO_3^{2-}% = {products (mol)/substrate (mol)} × 100.

Table 2. The reductions of **2**, **3**, and **4** with BNA-SO_2Na[a]

Substrate	Solvent	Time, h	Product (%)[b]
2	80% MeOH–H_2O	20	**9** (41), Acridone(6), BNA$^+$OH$^-$(43)[c]
3	EtOH	6	**10** (58), Acridone(37), BNA$^+$Cl$^-$(59)
4	DMF	3	**11** (91), BNA$^+$OH$^-$(100)

a) Concentration of **2**, **3**, and **4**: 6×10^{-2} mol/l. Reducing agent/substrate molar ratio = 1 (for **2** and **3**) and 2 (for **4**). b) **9** and **10**% = {2 × **9** and **10** (mol)/substrate (mol)} × 100. **11**, acridone, and BNA$^+$OH$^-$ (Cl$^-$) % = {products (mol)/substrate (mol)} × 100. c) Recovery% of **2**: 45%.

The reactions of 9-substituted acridines with BNA-SO_2Na were affected by the nature of the substituents. The reaction of **2** or **3** with BNA-SO_2Na afforded 9,9′-dimethoxy-9,9′-biacridan (**9**) or 9,9′-biacridine (**10**) respectively as the reduction product, as Table 2 shows. In both reactions, however, acridone was obtained as another product. In addition, in the case of **2**, the **2** was recovered in considerable amounts. On the other hand, BNA-SO_2Na was converted to BNA$^+$OH$^-$ (Cl$^-$) in larger amounts than those of **9** and **10**. Furthermore,

** Present address: Department of Industrial Chemistry, College of Engineering, Kyushu Sangyo University, Shokadai, Higashi-ku, Fukuoka 813.

the reduction of **2** with KBH_4 in 80 vol % aqueous methanol was found to afford acridone in a 40% yield, with a 45% recovery of **2**. These facts suggest that the 9,10-dihydro-compounds of **2** and **3**, which may be easily oxidized with air to acridone and the starting material, are produced in addition to **9** and **10**. In the reaction of **4** with BNA-SO_2Na, 9-cyanoacridan (**11**) was produced in a high yield, without the formation of any 9,9'-dicyano-9,9'-biacridan. Thus, the existence of an electron-withdrawing group, such as the cyano group, at the 9-position of the acridine ring favored the formation of a dihydro-compound by two-electron reduction.[4]

Experimental

Material. The BNA-SO_2Na was prepared according to the procedures described in our proceding paper.[2]

Reduction by BNA-SO_2Na. Acridine (1): A solution of a mixture of 3.06 mmol of **1** and 3.05 mmol of BNA-SO_2Na in 50 cm^3 of 80 vol% aqueous methanol was stirred under nitrogen at 25 °C for 12 h. A white precipitate (0.42 g, 76%) of **5** was formed and recrystallized from DMSO under nitrogen: mp 260—262 °C (lit,[5] 260—261 °C). (Found: C, 86.72; H, 5.26; N, 7.73%. Calcd for $C_{26}H_{20}N_2$: C, 86.63; H, 5.59; N, 7.77%). Its IR spectrum was identical with that of the authentic specimen. After the precipitate had been removed by filtration, 50 cm^3 of water was added to the filtrate to give 0.038 g (7%) of a white precipitate of **6** (mp 168—169 °C (lit,[5] 170 °C)). After the removal of **6** by filtration, the filtrate was acidified by concentrated hydrochloric acid to bring about the evolution of sulfur dioxide. The amount of sulfur dioxide evolved (32% was determined by the method described previously.[2] The solution thus acidified was evaporated *in vacuo*, and the residue was treated by the procedures described previously to yield 0.28 g (36%) of BNA$^+$Cl$^-$ (mp 230—233 °C (lit,[2] 236 °C)). Similar procedures were used for the reactions of **1** or **8** with BNAH, sodium dithionite, or BNA-SO_2Na. 10,10'-Dimethyl-9,9'-biacridan (mp 271—273 °C (lit,[5] 272—274 °C)) was obtained in a 69% yield. (Found: C, 86.65; H, 6.15; N, 6.96%. Calcd for $C_{28}H_{24}N_2$: C, 86.56; H, 6.23; N, 7.21%).

9-Methoxyacridine (2): To a solution of 1.49 mmol of **2** in 25 cm^3 of 80 vol% aqueous methanol, we added 1.5 mmol of BNA-SO_2Na. The solution was stirred under nitrogen at 25 °C for 20 h. A pale yellow precipitate which was thus deposited (0.13 g) was removed by filtration, washed under nitrogen with 80 vol% aqueous methanol, and dried *in vacuo*: mp>260 °C (The color turned to brown at 172 °C). The elementary analysis of the precipitate was carried out without purification, since it was oxidized easily with air in an organic solvent.

Found: C, 79.67; H, 5.60; N, 6.78%. Calcd for $C_{28}H_{24}N_2O_2$: C, 79.97; H, 5.75; N, 6.66%.

The pattern of its IR spectrum was similar to that of **5**. Its UV spectrum ($CHCl_3$) showed a peak at 280 nm, thus being similar to that of **5**. In contact with air, however, the UV spectrum changed completely to that of **2**, which had two peaks at 256 and 354 nm (ε: 1.4×10^5 and 8.3×10^3). Based on these facts, it was identified as **9**. Yield: 41%. On the other hand, the filtrate was concentrated to one-fifth of its original volume, and the orange precipitate thus deposited (0.31 g) was removed by filtration, washed with water, and dried *in vacuo*. The precipitate was chromatographed on silica gel. Elution with chloroform gave 0.14 g (45%) of **2** and 0.016 g (6%) of acridone. The combined filtrate was developed on an anion-exchange resin (Amberlite IRA-400) to yield 0.16 g (43%) of BNA$^+$Cl$^-$.

9-Chloroacridine (3): To a solution of 2.89 mmol of **3** in 50 cm^3 of ethanol, we added 3.11 mmol of BNA-SO_2Na. The mixture was stirred under nitrogen at 25 °C for 6 h. A pale yellow precipitate (**10**) thus deposited was removed by filtration, washed successively with ethanol and water, dried *in vacuo*, and recrystallized from toluene; mp>360 °C. Yield: 58%. Its IR spectrum was similar to that of **1**. (Found: C, 87.77; H, 4.83; H, 8.03%. Calcd for $C_{26}H_{16}N_2$: C, 87.61; H, 4.53; N, 7.86%). The filtrate was concentrated to one-fifth of its original volume, and 50 cm^3 of water was added. Extraction with dichloromethane gave 0.21 g (37%) of acridone. The aqueous layer was treated by a method similar to that used in the case of **1** to yield 0.42 g (59%) of BNA$^+$Cl$^-$.

9-Cyanoacridine (4): A solution of a mixture of 2.94 mmol of **4** and 6.01 mmol of BNA-SO_4Na in 50 cm^3 of DMF was stirred under nitrogen at 25 °C for 3 h. The solution immediately showed a red color, and then it turned orange. The reaction mixture was added to 200 cm^3 of water to give 0.55 g (91%) of a white precipitate of **11** (mp 146—147 °C (lit,[5] 146 °C)). Its IR spectrum was identical with that of the authentic specimen. After the removal of **11** by filtration, the filtrate was treated by a method similar to that used in the case of **1** to yield 0.73 g (100%) of BNA$^+$Cl$^-$.

Unusual Reductive Deamination of 2,6-Dibromo-3,4,5-trimethylaniline by Alkyl Nitrites in *N,N*-Dimethylformamide. Simultaneous Side-chain Nitration[1]

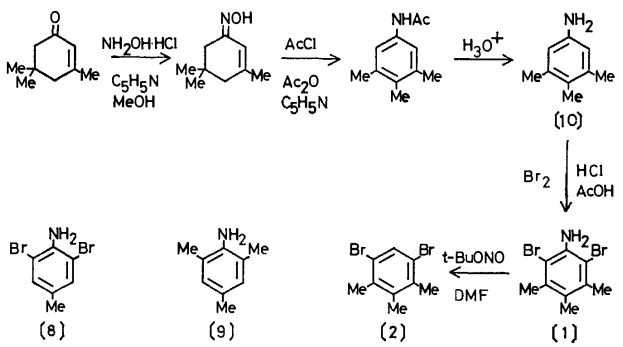
Hitomi SUZUKI,* Tadashi MISHINA, and Terukiyo HANAFUSA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received May 22, 1978)

Synopsis. Treatment of 2,6-dibromo-3,4,5-trimethylaniline with *t*-butyl nitrite in *N,N*-dimethylformamide at 60—65 °C was found to give a significant amount of a side-chain nitration product, 3,5-dibromo-2,6-dimethylphenylnitromethane, in addition to the expected 4,6-dibromo-1,2,3-trimethylbenzene.

In the course of our studies of the reactions of polyalkyl aromatics, it became necessary to prepare 4,6-dibromo-1,2,3-trimethylbenzene (**2**). The synthesis of this compound was performed along the five-step sequence shown in Scheme 1. The outcome in the last step was unexpected, however. The solid material obtained from the reaction of 2,6-dibromo-3,4,5-trimethylaniline (**1**) with *t*-butyl nitrite in *N,N*-dimethylformamide (DMF) according to the procedure of Doyle[2] was found to be a two-component mixture of an approximately 1 : 1 composition. Chromatography of this mixture over silica gel using hexane as eluant gave the expected **2** as early eluate, mp 143—144 °C, and a pale yellow solid as late eluate, mp 134—136 °C. The elemental analysis and molecular weight of the latter compound were consistent with the formula $C_9H_9NO_2Br_2$. Its IR spectrum showed strong bands at 1550 and 880 cm^{-1}, indicating the presence of an aliphatic nitro group. Its PMR spectrum contained peaks at δ 2.48, 5.66, and 7.89 ppm, with a relative intensity ratio of 6 : 2 : 1, indicating the presence of two methyl groups, one methylene group, and one aromatic proton. These analytical and spectral data agree with the structure of 3,5-dibromo-2,6-dimethylphenylnitromethane (**3**). Its mass spectrum showed all the features expected for the assigned structure: characteristic triplet peaks centered at *m/e* 323 (M^+) and 277 (M^+—NO_2; base peak), and fragment peaks of these at *m/e* 242 and 244 (M^+—Br), 196 and 198 (M^+—NO_2—Br), and 117 (M^+—NO_2—2Br). The phenylnitromethane obtained was not contaminated with the isomeric 2,3-dimethyl-4,6-dibromophenylnitromethane (**7**) in any detectable amount.

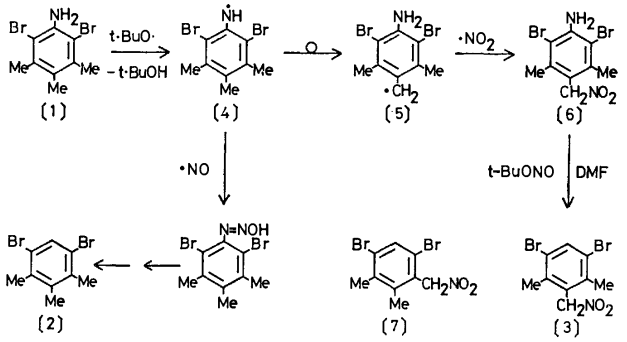


Scheme 1.

We tried to preclude this undesired side product by carrying out deamination in boiling tetrahydrofuran as a hydrogen donor.[3] The product obtained was nearly identical with those derived from the corresponding reaction in DMF. The replacement of *t*-butyl nitrite by butyl nitrite did not have much influence on the product composition. Since the compound **2** was inert to the reagent under the reaction conditions employed, the unusual product **3** should have been formed from **1** through a pathway competing with the normal deamination.

Alkyl nitrites have been successfully used in the aprotic diazotization of various arylamines.[4] To the best of our knowledge, however, no report seems to have appeared on the simultaneous deamination and side-chain nitration during the reaction of alkylanilines with alkyl nitrites. In order to ascertain the scope of this anomaly, several other methylanilines were treated in a similar manner. 2,6-Dibromo-4-methylaniline (**8**) gave 3,5-dibromotoluene in a 50% isolated yield. Spectral inspection of the crude product mixture indicated the presence of a side-chain nitration product which, however, could not be isolated due to its small quantity. Both 2,4,6- and 3,4,5-trimethylanilines (**9** and **10**) yielded the expected hydrocarbons together with considerable amounts of polymeric substances, proving the Doyle's method to be synthetically less useful for the deamination of these reactive amines. The PMR spectrum of the crude product from **9** contained a minor peak (δ 5.21 ppm) in the region where phenylnitromethanes usually absorb.[5] In contrast, no side-chain substitution product could be detected in the deamination product from **10**. The unusual course of deamination, therefore, seems to be important only for a narrow range of alkylanilines.

We have not made a mechanistic study of this unusual reaction, but a possible mechanism for the regiospecific side-chain nitration may be depicted by assuming the rearrangement of the hindered anilino radical (**4**) into the benzyl radical (**5**) (Scheme 2). Thus, alkyl nitrite decomposes homolytically to give alkoxyl radical and nitrogen oxide. The former abstracts a hydrogen atom from the amino group of arylamine, giving the assumed anilino radical intermediate **4**, while the latter is oxidized to nitrogen dioxide, as is evidenced by the liberation of brown fumes. In analogy to the conversion of hindered phenoxyl radicals to benzyl radicals,[6] **4** would isomerize to 4-aminobenzyl radical **5** which combines with nitrogen dioxide to form the amine **6**; this will undergo further reductive deamination,



Scheme 2.

giving the arylnitromethane **3** as the final product. Although **6** could not be isolated as such, its intermediacy is highly probable.

Experimental

Melting points were determined on a hot stage apparatus and are uncorrected. IR spectra were obtained in Nujol mulls with a Hitachi 215 spectrophotometer. PMR spectra were run in deuteriochloroform on a Varian T-60 spectrometer using TMS as internal standard. Mass (MS) spectra were recorded on a Hitachi RMS-4 mass spectrometer with 70 eV ionizing current.

Butyl nitrites were prepared in the usual manner.[7] 2,4,6-Trimethylaniline (**9**; bp 145 °C/57 mmHg; lit,[8] bp 225—226 °C), 3,4,5-trimethylaniline (**10**; mp 77—78 °C; lit,[9] mp 78.5—79 °C), 2,6-dibromo-4-methylaniline (**8**; mp 74—75 °C; lit,[10] mp 79 °C), and 2,6-dibromo-3,4,5-trimethylaniline (**1**; mp 163—165 °C; lit,[9] mp 162.5—163.5 °C) were prepared as reported. *N,N*-Dimethylformamide was distilled from calcium hydride prior to its use.

Reaction of 2,6-Dibromo-3,4,5-trimethylaniline with t-Butyl Nitrite in DMF. To a stirred solution of *t*-butyl nitrite (0.74 g; 7.2 mmol) in dry DMF (10 ml) maintained at 60—65 °C, amine **1** (0.7 g; 2.4 mmol) in the same solvent (5 ml) was added dropwise over a 5 min period and the solution was stirred at this temperature for a further 20 min. After cooling, the mixture was diluted with ether (50 ml), washed successively with dilute hydrochloric acid, aqueous sodium hydrogencarbonate, and water, dried over sodium sulfate, and evaporated to leave a yellow residue (0.78 g), which was dried and chromatographed on silica gel. Elution with hexane gave **2** as early eluate; white needles, mp 143—144 °C. Yield, 0.28 g (42%). PMR: δ 2.31 (3H, s), 2.35 (6H, s), and 7.60 ppm (1H, aromatic H); IR: ν_{max} 1560, 1000, 900, and 850 cm^{-1}. Found: C, 38.72; H, 3.60%. Calcd for $C_9H_{10}Br_2$: C, 38.88; H, 3.63%.

Further elution with the same solvent gave **3** as straw-colored needles, mp 134—136 °C. Yield, 0.25 g (32%). The ratio **2** to **3** in the crude product mixture as determined by PMR analysis was approximately 10 to 11. Found: C, 33.65; H, 2.84; N, 4.27%. Calcd for $C_9H_9NO_2Br_2$: C, 33.47; H, 2.81; N, 4.34%.

In the corresponding reaction of 2,6-dibromo-4-methylaniline **8** with *t*-butyl nitrite, the reddish brown oil obtained on removal of the solvent was shown by PMR (singlet peak at δ 5.31 ppm) and IR spectra (strong band at 1560 cm^{-1}) to contain a nitromethyl compound which, however, could not be isolated due to its small quantity. After passage in a pentane solution through an alumina column, 3,5-dibromotoluene was obtained as colorless plates, mp 36—37 °C (lit,[11] mp 36.8—37 °C). Yield, 50%.

Structures of Copper(II) Complexes Which Deposit Copper in Chemical Copper-plating Bath

Seigo OHNO

Electron Device Laboratory, Oki Electric Industry Co., Ltd., 4-10-12 Shibaura, Minato-ku, Tokyo 108

(Received September 21, 1977)

Synopsis. The deposition of copper from alkaline solutions containing various copper(II) complexes and formaldehyde was studied. It was found that one-to-one copper(II) complexes of hepta-, hexa-, and quadridentate ligands deposit copper on reduced platinum by means of autocatalytic reduction, and that, under particular conditions, copper(I) oxide is deposited on oxidized platinum from the solutions containing quadridentate ligands.

It is well known that copper metal is catalytically deposited on the surfaces of noble metals from solutions which contain some kinds of copper(II) complexes and reducing agents. As the deposited copper also has a good catalytic activity, the reduction proceeds autocatalytically. This reduction method has been widely utilized as "chemical copper plating" in industry, especially in the manufacture of printed circuit boards.

For this reduction, several reaction mechanisms have been proposed. Saubestre[1] reported the following half-reactions for reductions in alkaline solutions containing the tartrate ion as the complexing agent and formaldehyde as the reducing agent:

$$HCHO + 3OH^- \longrightarrow HCOO^- + 2H_2O + 2e^- \quad (1\text{-a})$$

$$Cu^{2+} + 2e^- \longrightarrow Cu \quad (1\text{-b})$$

Although hydrogen gas is evidently generated on the plating surface, he discussed no details of the evolution of hydrogen. Tilley[2] and Lukes[3] proposed the following half-reactions:

$$2HCHO + 4OH^- \longrightarrow 2HCOO^- + H_2 + 2H_2O + 2e^- \quad (2\text{-a})$$

$$Cu^{2+} + 2e^- \longrightarrow Cu \quad (1\text{-b})$$

Konishi[4] and Saito[5] reported that not the hydrated copper(II) ion, but the copper(II) complex, participates in this reduction. It seems, however, that there is no direct evidence for what kind of copper(II) species deposits copper. A study has, therefore, been made to deepen our understanding of this reduction.

Experimental

Preparation of Plating Solutions. The following reagents were used as the complexing agents for the copper(II) ion: D-mannitol, D-sorbitol, dulcitol, ethylenediaminetetraacetic acid (H_4edta), 1,2-cyclohexanediaminetetraacetic acid (H_4-cdta), *N*-(2-hydroxyethyl)ethylenediaminetriacetic acid (H_3-hedta), diethylenetriaminepentaacetic acid (H_5dtpa), L-, D-, and *meso*-tartaric acids, *meso*-erythritol, ethylenediamine (en), diethylenetriamine (dien), and triethylenetetramine (trien). Known amounts of copper(II) sulfate, one of the above complexing agents, and sodium hydroxide were dissolved in deionized water in the above order. These mixtures were then kept at 29 °C for 24 h. Known amounts of a formaldehyde solution kept at 29 °C were added to the above mixtures before use. All the reagents used were of an A. R. grade.

Apparatus and Procedure. A cleaned platinum substrate (0.2 mm × 14 mm × 20 mm) was oxidized electrolytically in nitric acid (1 : 1) (oxidized substrate). In some runs, the substrate was reduced by immersing it in a 0.2 mol/dm^3 formaldehyde and 0.4 mol/dm^3 sodium hydroxide solution (reduced substrate) in order to differentiate the reactivities of the copper(II) complexes studied. Copper or copper(I) oxide was deposited on the substrates by immersing them in the plating solutions (250 cm^3) at 29 °C for 60 min. The amounts of deposits were determined by chelatometric titration. The amounts of hydrogen evolved during the deposition were measured by the use of the apparatus shown in Fig. 1 in the following manner. The apparatus, filled with a plating solution, was kept at 29.0 °C, and then the air in the apparatus and dissolved in the plating solution was replaced with hydrogen by bubbling. The substrate, S, was placed over the plating solution by means of a hanger, H, and a magnet, M, and then the plug, P, and the stopcoek, S, were closed. The substrate was immersed in the plating solution by moving the magnet. After an appropriate time, the substrate was raised and the pressure increase was measured by means of a water manometer, WM.

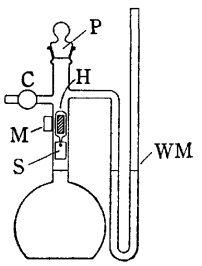

Fig. 1. Apparatus for measuring hydrogen evolution.

Results and Discussion

The deposition rate of copper on the oxidized substrate is shown in Fig. 2, with H_4edta used as the complexing agent. The rate was virtually independent of the concentration of H_4edta added. The rate on the reduced substrate was the same as that on the oxidized substrate within the limits of experimental errors.

It is well known that H_4edta forms a stable one-to-one complex with the copper(II) ion.[6] Therefore, the concentration of this complex must be almost constant under the present conditions, whereas the concentration of the hydrated copper(II) ion decreases steeply with an increase in the concentration of H_4edta as follows:

$$[Cu^{2+}] \approx c_c/K(c_l - c_c), \quad (3)$$

where K is the stability constant of the complex and where c_c and c_l represent the concentrations of copper(II) sulfate and the complexing agent respectively.

The above findings, therefore, suggest that not the hydrated copper(II) ion, but the copper(II) complex deposits copper. The slight decrease in the rate shown

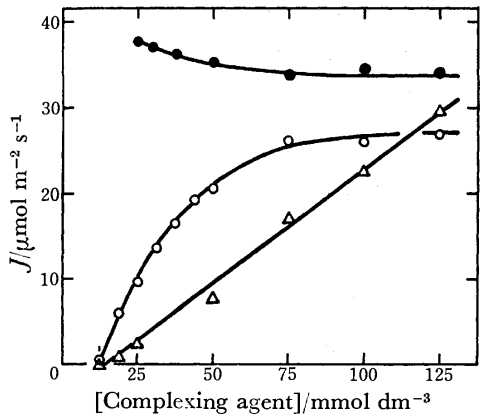

Fig. 2. Relations between the deposition rate of copper and the concentration of the compexing agent in Cu(II)–H_4edta (●), Cu(II)–D-mannitol (○), and Cu(II)–D-sorbitol (△) plating solutions. $CuSO_4$: 25, HCHO: 100 mmol/dm^3, pH: 12.8, Temp: 29 °C.

in Fig. 2 may be explained in terms of retardation due to the adsorption of edta^{4-}, Hedta^{3-}, *etc.*

Hexitols such as D-mannitol and D-sorbitol have six OH groups. These reagents may be expected to form two-to-one and/or one-to-one complexes with the copper(II) ion. Hence, the reactivity of their complexes was studied. As is shown in Fig. 2, the deposition of copper began just at $c_l/c_c=0.50$ in both plating solutions, and the rate increased with the increase in the c_l. In the range of $2c_l<c_c$, copper(II) hydroxide was precipitated. These findings indicate that D-mannitol and D-sorbitol react with the copper(II) ion as follows:

$$2Cu^{2+} + H_nL + 4OH^- \rightleftarrows [Cu_2H_{(n-4)}L] + 4H_2O, \quad (4)$$

$$Cu^{2+} + H_nL + 2OH^- \rightleftarrows [CuH_{(n-2)}L] + 2H_2O, \quad (5)$$

where H_nL represents a ligand, and that the one-to-one complex ($[CuH_{(n-2)}L]$) deposits copper.

In order to obtain further proof, the reactivities of various copper(II) complexes were studied. These complexes can be classified into three categories. The first-group complexes consist of the copper(II) ions and either hepta- or hexadentate ligands such as H_4edta, H_4cdta, H_3hedta, H_5dtpa, D-mannitol, D-sorbitol, and dulcitol and deposit copper by forming hydrogen, regardless of the surface state of the substrate. The second-group complexes are composed of the copper(II) ions and quadridentate ligands such as L-, D- and *meso*-tartaric acids, and *meso*-erythritol and deposit copper accompanied by the formation of hydrogen on the reduced substrate and copper(I) oxide, but not accompanied by the formation of hydrogen on the oxidized substrate under particular conditions ($c_l/c_c\approx2$). In this group, the species which give copper are probably one-to-one complexes, in view of the findings described in the preceding paragraphs. The formation of a one-to-one copper(II)–tartrate complex was previously verified by EPR under conditions similar to the present case.[7] The third-group complexes are those with the copper(II) ions surrounded by nitrogen atoms only (en, dien, and trien); they are completely inactive.

In all the cases of copper deposition, each plating solution gave almost the same rates for both oxidized and reduced substrates under the same conditions. It can, therefore, be suggested that the platinum oxide (PtO_x) formed on the oxidized substrate is quickly reduced when it is immersed in the plating solutions and that the reduced platinum catalyzes the deposition of copper.

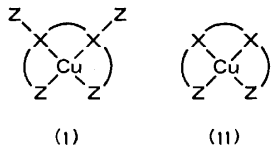
The amounts of hydrogen formed during the deposition were measured in the plating solutions containing H_4edta. The H_2/Cu ratios ranged from 0.94 (pH=11.3) to 0.96 (pH=12.8), in agreement with Lukes' results.[3] It is well known that the formate ion, a product of Reaction 1-a or 2-a, is also a reducing agent. However, no deposits were obtained from the present solutions when sodium formate was used as the reducing agent. Accordingly, Reaction 2-a must be operative, at least in more than 94% of the total deposits.

From these results, it may be concluded that the one-to-one copper(II) complexes, whose general structures are shown in Fig. 3, are autocatalytically reduced by formaldehyde in an alkaline solution as follows:

$$PtO_x \xrightarrow{HCHO,\ OH^-} Pt \quad (6)$$

$$[CuH_{(n-2)}L] + 2HCHO + 4OH^- \xrightarrow{Pt,\ Cu} Cu + 2HCOO^- + H_2 + 2H_2O + H_{(n-2)}L^{2-}. \quad (7)$$

As has been described above, the second-group



(I) (II)

Fig. 3. General structures of copper(II) complexes which deposit copper.
X's are N or O atoms. Z's are polar groups such as $-COO^-$, $-CH_2COO^-$, $-CH_2OH$ or $-CH(OH)CH_2OH$.

complexes gave copper(I) oxide on the oxidized substrate at $c_l/c_c\approx2$. This finding suggests that, under these conditions, PtO_x is not reduced, but catalyzes the partial reduction of some copper(II) species to deposit Cu_2O as:

$$\text{Cu(II)-species} \xrightarrow{HCHO,\ OH^-/PtO_x} Cu_2O. \quad (8)$$

A study of this deposition is now in progress.

Correlation of Solvation Free Energy of Electron with Empirical Parameters of Solvents. A Criterion for Electrophilic Effects of Solvents

Hideo IMAI* and Kazuo YAMASHITA

Faculty of Integrated Arts and Sciences, Hiroshima University, Hiroshima 730

(Received January 5, 1978)

The solvation free energy of electrons in *N,N*-dimethylformamide, methanol, and water was estimated by means of electron photoemission into solution, and the data were compared with empirical parameters such as thermodynamic quantities, structural and kinetic parameters of solvents. It was confirmed that the interaction of an electron with solvent molecules is purely electrostatic and that the solvation free energy can be used as a tentative criterion of electrophilic properties of solvents.

The empirical parameters of solvents have been proposed as a measure of polarity or nucleophilic and electrophilic properties of solvents. These parameters were deduced from the solvent effects on the band shift of optical absorption spectra of particular solutes, NMR solvent shift, thermodynamic quantities of solvation, or kinetic parameters of solvent dependent processes.

The interaction of a solute with solvent molecules has been conceptualized from various points of view. Stengle *et al.*[1] proposed a three-region model: (1) the region of ordering effect of a solute on its immediate neighborhood, (2) the region of disordering of solvent structure, and (3) the bulk region where solvent structure is unperturbed. Cox *et al.*[2] classified the interaction into five types: (1) electrostatic interactions (either Born type or its modifications), (2) different hydrogen-bonding donor or acceptor properties of ions and solvents, (3) different types and extent of solvent structure, (4) dispersion force interactions, and (5) different Lewis acidity and basicity of ions and solvents. Some of these interactions are interrelated, *e.g.*, influence of hydrogen-bonding properties of solvents on their structure. The solvation effect would be more involved in kinetic processes where the structure of the activated complex plays an important role.

A solvent molecule and the usual solute are, in general, of dipolar character, so that the nucleophilic interaction occurs simultaneously with electrophilic interaction at different sites of a molecule depending the structural characteristics of the solute and solvent. However, a solvated electron is known to be the simplest entity with a unit negative charge held in a cavity created by dilated solvent molecules, so that the interaction of an electron with solvent molecules gives information on the simple electrostatic interaction.

The solvation free energy of an electron in polar solvents has been estimated by means of electron photoemission (EPE) into solution.[3] In this paper a discussion is given on how the solvation free energies of electrons in various polar solvents correlate with the empirical parameters of solvents and how these values can be used as a tentative criterion of electrophilic solvent effects.

Results and Discussion

Solvation Free Energy of Electron. The solvation free energy of a photoemitted electron was estimated by the EPE method. The photoemission current was measured in a cell equipped with a three-electrode system where the working electrode (mercury pool electrode) was illuminated by ultraviolet light (365 nm wavelength) under a controlled potential. The cell contained a highly concentrated supporting electrolyte solution saturated with dinitrogen oxide as an electron scavenger. The photoemission current, I_p, is expressed by the law of five-halves[4]

$$I_p = A(h\nu - h\nu_0 - e\phi)^{5/2}, \quad (1)$$

where A is a constant, $h\nu$ the energy of incident light, ν_0 the threshold frequency, and ϕ the electrode potential. The plot of $I_p^{0.4}$ *versus* ϕ gives a straight line, and extrapolation of the plot to $I_p=0$ gives the threshold potential, ϕ_0. Thus, we have $h\nu_0 = h\nu - e\phi_0$. The difference in energies required for the photoemission from mercury into vacuum and from mercury into solution gives the solvation free energy of the eletron ($\Delta G_s(e^-)$):

$$\begin{aligned} -\Delta G_s(e^-) &= W_{m-v} - h\nu_0 + e\Phi \\ &= W_{m-v} - h\nu + e(\phi_0 + \Phi), \end{aligned} \quad (2)$$

where W_{m-v} is the work function of electron photoemission from mercury into vacuum, Φ the Volta potential difference between mercury and solution.

The values of $\Delta G_s(e^-)$ thus obtained are the energy difference between electrons *in vacuo* and in solution, corresponding to those of the solvation free energy of ions estimated by Born-Haber cycle. It is noteworthy that the hydration energy of the fully hydrated electron was estimated to be 161[5] or 165[6] kJ mol^{-1} by radiation chemical studies, while our result is 108 kJ mol^{-1}. Our value presumably corresponds to the so-called damp or unlocalized electron, which is assumed to exist in solution only for a few tens picoseconds[7] before being fully solvated.

We had difficulty in estimating the values of $\Delta G_s(e^-)$ in various solutions due to the absence of information on the values of Volta potential difference for non-aqueous solutions. Only three data on *N,N*-

Table 1. Values of solvation free energy of electron, $\Delta G_s(e^-)$, and donor number (*DN*)

Solvent	DMF	MeOH	H_2O
$-\Delta G_s(e^-)$/kJ mol^{-1}	62	98	108
DN[a]	26.6	19.0	18.0

a) The values of *DN* are given in kcal mol^{-1} (1 cal = 4.184 J.

dimethylformamide (DMF), methanol (MeOH), and water (H_2O) are available (Table 1), which do not seem sufficient for a discussion of the general features of solvent effects. However, they are in line with the values estimated by a modified Born equation for fully solvated electrons in polar solvents.[8]

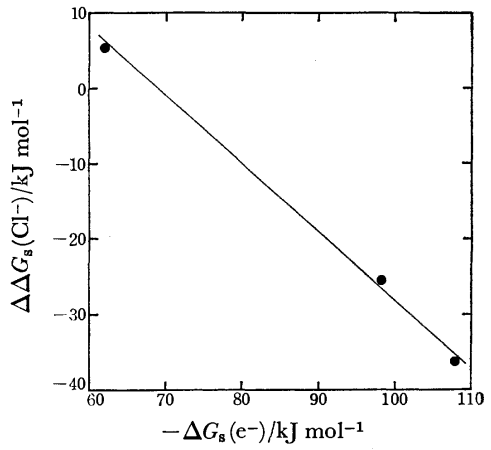

Fig. 1. Relationship between solvation free energy of electron, $\Delta G_s(e^-)$, and solvation free energy of chloride ion, $\Delta\Delta G_s(Cl^-)$ (reference solvent: acetonitrile).

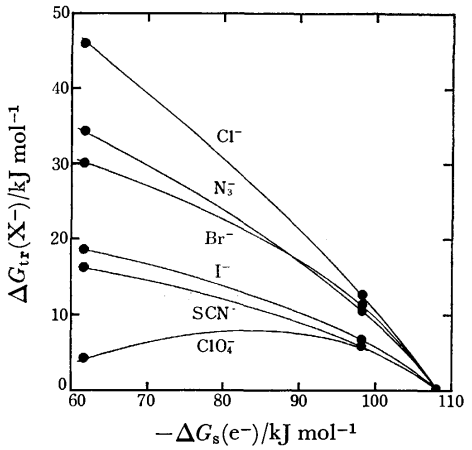

Fig. 2. Relationship between solvation free energy of electron, $\Delta G_s(e^-)$, and free energy of transfer of anions, $\Delta G_{tr}(X^-)$ (reference solvent: water).

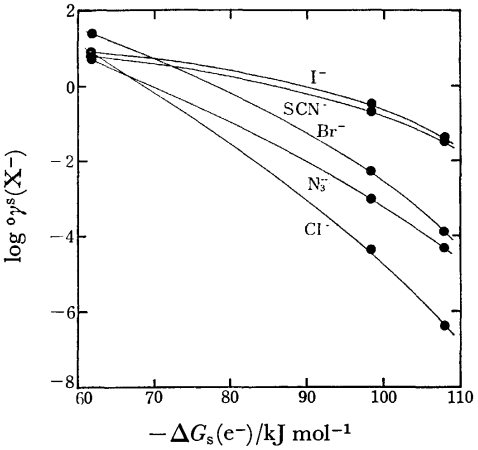

Fig. 3. Relationship between solvation free energy of electron, $\Delta G_s(e^-)$, and logarithm of solvent activity coefficient of anions, log $^{\circ}\gamma^s(X^-)$ (reference solvent; acetonitrile).

Correlation of $\Delta G_s(e^-)$ with Solvation Free Energy of Halide Ions. The values of $-\Delta G_s(e^-)$ are plotted against the solvation free energies of chloride ion in DMF, MeOH, and H_2O in Fig. 1, where $\Delta\Delta G_s(Cl^-)$ denotes the difference between the solvation free energy of Cl^- in a given solvent and that in acetonitrile.[9] The plot gives a straight line. When we plot the values of $-\Delta G_s(e^-)$ against the free energy of transfer, $\Delta G_{tr}(X^-)$, for several anions,[2] the plot of Cl^- is closest to a straight line, the deviation from linearity being pronounced in the order $Cl^- < N_3^- < Br^- < I^- < SCN^- < ClO_4^-$ (Fig. 2). The logarithm of the solvent activity coefficient, log $^{\circ}\gamma^s$, shows a similar trend (Fig. 3), where $^{\circ}\gamma^s$ is given in molar scale at 25 °C with acetonitrile as a reference solvent.[10] The order of deviation from linearity among the anions is the same as in the case of the free energy of transfer of anions, as can be predicted from the relation, $\Delta G_{tr} = -RT \ln {}^{\circ}\gamma^s$ and also from the valence-bond description. If we assume that chloride ion is the least polarizable anion among the anions considered and that the solvated electron is a simple entity with a unit negative charge in solution, the close correlation between the solvation free energy of chloride ion and that of electron is understandable.

The solvent shift of a halogen nucleus such as ^{35}Cl, ^{79}Br, or ^{127}I in respective halide ion[1] and also of ^{19}F in hexafluorophosphate ion, PF_6^-,[11] shows no trend of correlation with $\Delta G_s(e^-)$. Hall[12] suggested the origin of the NMR solvent shift as follows: (1) molecular volume and packing geometry, (2) hydrogen-bonding interactions, (3) charge transfer to solvent interactions, (4) orbital overlap with large atoms in solvent, and (5) charge distributions in solvent molecule. Stengle *et al.*[1] emphasized the prevailing effect of charge transfer interactions. It seems that the solvent shift depends primarily on short-range interactions, the solvent shift thus showing a considerable discrepancy from the trend of $\Delta G_s(e^-)$.

Correlation of $\Delta G_s(e^-)$ with AN-, E_T-, and Z-Values. The value of $\Delta G_s(e^-)$ will be discussed as a criterion of electrophilic properties of solvents in relation to several empirical parameters of solvents.

The acceptor number (*AN*) was proposed by Mayer *et al.*[13] as a measure of electrophilic property of solvents. The value is based on the measurement of NMR solvent shift of ^{31}P nucleus in triethylphosphine oxide, $(C_2H_5)_3PO$. The oxygen atom in $(C_2H_5)_3PO$ is attacked by solvent molecules, and the π-bonding character of the P–O bond is reduced. The effect, coupled with possible polarization of σ-bonding of the P–O bond, results in the decrease of the electron density of ^{31}P nucleus, causing NMR chemical shift. In order to standardize the *AN*-values, the chemical shift was extrapolated to null concentration of the substrate, the value of 1:1 adduct of $(C_2H_5)_3PO$ and $SbCl_5$ in 1,2-dichloroethane being taken as 100. The values of $-\Delta G_s(e^-)$ are plotted against *AN*-values (Fig. 4), the plot showing a straight line with only a slight deviation. The deviation can be attributed

either to the hydrogen-bonding of hydroxyl solvent or to the change in solvent structure caused by the nucleophilic substrate. It seems that the remaining coordination sites of phosphorus atom in $(C_2H_5)_3PO$ is almost completely blocked from the solvent attack. This effect is quite different from the case of carbonyl compounds. When we plot the values of $-\Delta G_s(e^-)$ against the chemical shift of ^{13}C or ^{17}O nucleus in acetone,[14-16] linearity is no longer observed (Fig. 5). Maciel and Ruben[14] attributed the predominant effect of hydroxyl solvents to the dipolar or Lewis base interaction coupled with intermolecular hydrogen-bonding. However, it is more likely that the coordination sites of the carbon atom in the carbonyl group are poorly shielded toward the nucleophilic attack of solvent molecules.

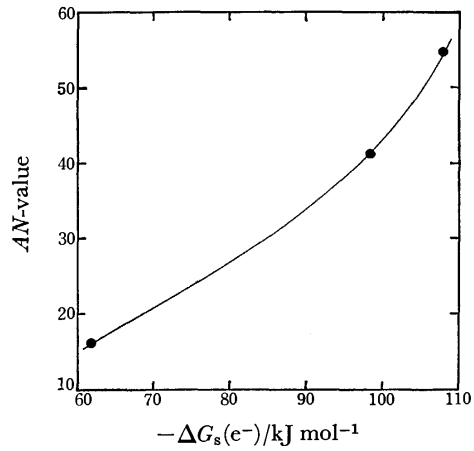

Fig. 4. Relationship between solvation free energy of electron, $\Delta G_s(e^-)$, and Mayer-Gutmann-Gerger's acceptor number (*AN*).

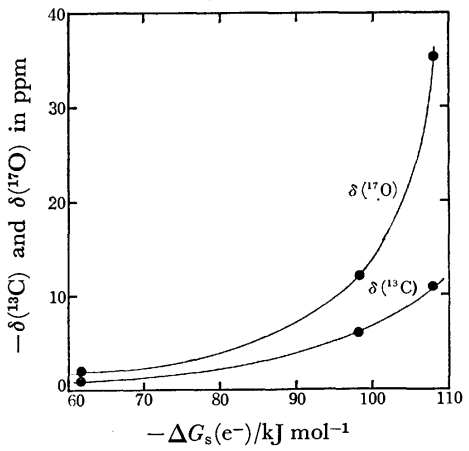

Fig. 5. Relationship between solvation free energy of electron, $\Delta G_s(e^-)$, and NMR solvent shift of ^{13}C and ^{17}O nuclei in acetone, $\delta(^{13}C)$ and $\delta(^{17}O)$.

A similar correlation to the case of *AN*-value can be seen in the plot of $-\Delta G_s(e^-)$ *versus* E_T- or *Z*-value (Fig. 6). The E_T-value was proposed by Dimroth *et al.*,[17] the value representing the energy of the lowest electronic transition of *p*-(1-pyridinio)-phenolate in various solvents. The oxygen atom of the solute is highly basic and sterically accessible for solvent molecules. The *Z*-value, proposed by Kosower[18] as a measure of solvent polarity, is the energy of charge transfer band of 1-ethyl-4-(methoxycarbonyl) piridinium iodide, the iodide ion of which is attacked by solvent molecules. Both E_T- and *Z*-values primarily represent the electrophilic properties of solvents, but from the curvilinear plots in Fig. 6 the effect of donicity or hydrogen-bonding of solvents seems to exist.

Correlation of $\Delta G_s(e^-)$ *with Kinetic Parameters of Solvent Dependent Processes.* A typical solvent parameter for a kinetic process is the *Y*-value proposed by Grunwald and Winstein[19] as a series of the ionizing power of solvents. This is defined as $Y=\log(k/k_0)$, where k and k_0 represent the first order solvolysis rate constant of *t*-butyl chloride at 25 °C in a given solvent and in a reference solvent (80% ethanol and 20% water), respectively. The plot of $-\Delta G_s(e^-)$ *versus Y* is shown in Fig. 7, where the datum of DMF is taken from the work of Mayer *et al.*[13] A set of data on the ionization rate constant, k_1, of 2-methyl-2-(*p*-methoxyphenyl)propyl *p*-toluenesulfonate is given by Smith *et al.*[20] The plot of $-\Delta G_s(e^-)$ *versus* $\log k_1$ is also shown in Fig. 7. Both plots show a remarkably

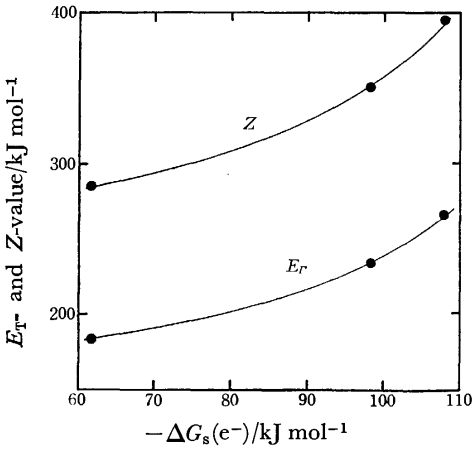

Fig. 6. Relationship between solvation free energy of electron, $\Delta G_s(e^-)$, and Dimroth-Reichardt-Siepmann-Bohlmann's E_T-value or Kosower's *Z*-value.

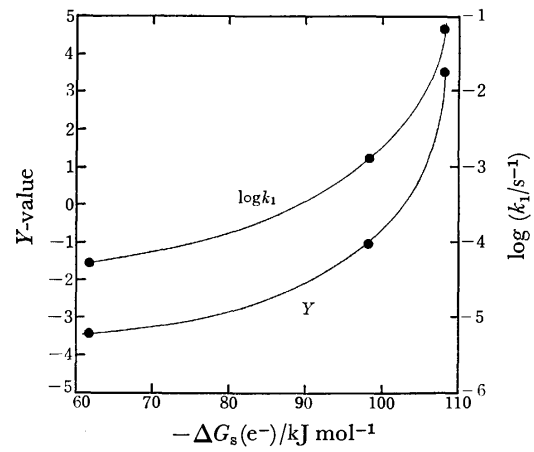

Fig. 7. Relationship between solvation free energy of electron, $\Delta G_s(e^-)$, and Grunwald-Winstein's *Y*-value or Smith-Fainberg-Winstein's log k_1-value.

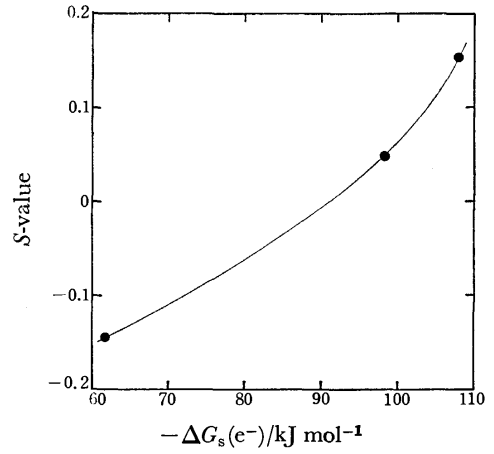

Fig. 8. Relationship between solvation free energy of electron, $\Delta G_s(e^-)$, and Brownstein's S-value.

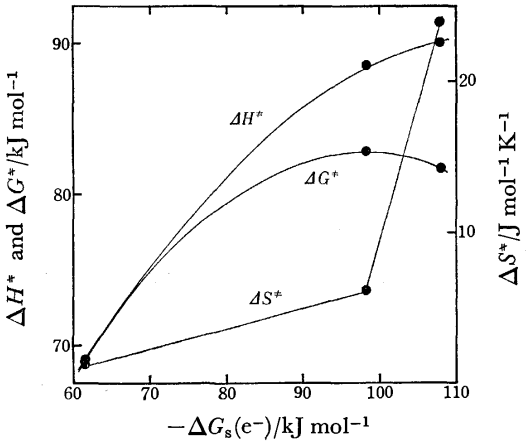

Fig. 9. Relationship between solvation free energy of electron, $\Delta G_s(e^-)$, and Arrhenius energy, ΔH^*, free energy of activation, ΔG^*, and entropy of activation, ΔS^*, for reaction, n-$C_4H_9Br+N_3^-=n$-$C_4H_9N_3+Br^-$.

curvilinear correlation, the effect of hydroxyl solvents being enhanced.

The S-value proposed by Brownstein[21] as a solvent dependent parameter was defined by the relation, $\log(k_{solvent}/k_{EtOH})=SR$, where k is a reaction rate constant, equilibrium constant or a function of spectral shift, and R a constant characteristic of the sensitivity of a given reaction. The plot of $-\Delta G_s(e^-)$ *versus* S-values also show a similar curvilinear trend to that of Y-values and log k_1-values (Fig. 8). The curvilinear correlation can be interpreted by taking the concerted effect of nucleophilic and electrophilic interactions into consideration. The nucleophilic attack of solvent is more pronounced in DMF (DN=26.6) than in MeOH or H_2O, while the electrophilic interaction is more enhanced in H_2O than DMF, MeOH being the intermediate (Table 1).

Delpuech[22] reported the Arrhenius energy for a substitution reaction, n-$C_4H_9Br+N_3^-=n$-$C_4H_9N_3+Br^-$, in various solvents. The plot of $-\Delta G_s(e^-)$ *versus* ΔH^*, ΔG^*, and ΔS^* is shown in Fig. 9. In this reaction the solvent attack on the anion seems to play a predominant role, stronger solvation requiring higher Arrhenius energy. It is noteworthy that the entropy of activation is fairly negative in the case of water. Thus, the free energy of activation is smaller in the case of water than in that of methanol. A possible hydrogen bonding of water molecule may increase the orderliness of the activated complex.

In view of the results obtained the solvent parameter can be expressed in terms of three effects: (1) nucleophilic effect represented by the donor number (2) electrophilic effect represented by the solvation free energy of electron, and (3) hydrogen-bonding energy. The three terms have the same dimension and can be expressed in the same unit, *e.g.* J mol^{-1}. Thus, we can estimate the overall solvent effect by the linear combination of the three terms provided the appropriate coefficients for each term are determined experimentally.

Refractive Indices and Polarizabilities of Several Molten Rare Earth Chlorides

Junichi MOCHINAGA,* Kazuo IGARASHI, Toshio AOKI, and Yasuhiko IWADATE

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

(Received January 11, 1978)

Refractive indices of molten $LaCl_3$, $PrCl_3$, $NdCl_3$, $DyCl_3$, and YCl_3 were measured by the cylindrical lens method. The measurements were carried out with the lights of four wavelengths, and the refractive indices so obtained were represented by empirical equations as linear functions of temperature. From the data molar refractivities were calculated. The refractive indices at infinite wavelength were calculated by use of Cauchy's relation for dispersion, and electronic polarizabilities were obtained for the salt molecules in molten state, and also the electronic polarizabilities of La^{3+}, Pr^{3+}, Dy^{3+}, and Y^{3+} ions in the melts were obtained.

The refractive indices of molten salts are related to the polarizabilities, and especially the values extrapolated to infinite wavelength are directly related to the electronic polarizabilities of molecules or ions in the melts. But there are only a few available data of refractive indices for molten salts, because the experimental difficulties exist in such measurements. Zarzycki and Naudin[1] have reported the refractive indices of some alkali halides and alkali nitrates in molten states for the light of 546.1 nm, and Bloom *et al.* have reported the refractive indices[2] and other experimental data[3] of some nitrites, nitrates, chlorides, and binary chloride systems in molten states for the light of 589.3 nm, using the bent stick method. Marcoux[4,5] has measured the refractive indices of some gases in liquid and solid states and some molten ionic salts by the cylindrical lens method. Nakamura and Tanemoto[6] have also reported the refractive index of molten KCl measured by a He-Ne laser (632.8 nm).

In the present experiment, the refractive indices of molten $LaCl_3$, $PrCl_3$, $NdCl_3$, $DyCl_3$, and YCl_3 were measured by the cylindrical lens method with the lights of wavelengths, 656.3, 589.3, 486.2, and 434.1 nm.

Experimental

Preparations of $LaCl_3$, $PrCl_3$, $NdCl_3$, $DyCl_3$, and YCl_3. These rare earth chlorides were prepared by heating the mixtures of respective rare earth oxide and NH_4Cl according to the similar procedure in the previous paper.[7] Then, the crude chlorides were purified by sublimation, and their purities are shown in Table 1. The YCl_3 crystal had the similar purity as in the previous paper.[7]

Measurements of Refractive Indices. The apparatus used is based on that reported by Marcoux,[5] which measures the position of a focal point with a cylindrical lens. The schematic diagram of the apparatus is shown in Fig. 1, in which D is a transparent quartz cylinder tube of about 7 mm diameter. The distance between the center of the quartz tube and the position of the focal point depends on the refractive index of a liquid in the quartz tube. The distances were measured with a microscope by the precision of 1/100 mm for the several reference liquid materials of known refractive indices. The refractive index of a molten salt, therefore, can be obtained from the calibration curves in which the refractive indices of the reference materials were plotted against the measured distances. The calibration curves were drawn from the observed values at room temperature for CH_2I_2, $C_{10}H_7Br$, and CS_2 as the reference liquid materials, because the coefficient of expansion of quartz is very small (5.5×10^{-7}/deg). As the light source, a monochromator of UV-VIS spectrophotometer(HITACHI 139) was used, and the wavelengths

of lights used in this measurements were C(656.3 nm), D (589.3 nm), F(486.2 nm), and G(434.1 nm) lines. The refractive indices of the molten KCl observed in this apparatus were in fair agreement with the values in literature[2] as shown in Fig. 2.

Results and Discussion

As $PrCl_3$ and $NdCl_3$ melts have the absorption bands in the measured wavelengths, the refractive indices of $PrCl_3$ melt were measured at 656.3, 589.3, and 434.1 nm, and those of $NdCl_3$ melt at 486.2 nm only. The temperature dependence of refractive indices for these molten rare earth chlorides were linear at respective wavelength in the measured range of temperature. The results obtained at 486.2 nm are shown in Fig. 3. From the measured data, the refractive indices were represented by use of the method of least-squares as functions of temperature. The results are given in Table 2. In Table 2, σ is the standard error of estimate in refractive index equation. The relations of the refractive indices of $LaCl_3$, $PrCl_3$, $DyCl_3$, and YCl_3 melts *vs.* wavelength are shown in Fig. 4, in which the refractive indices slightly decrease in longer wavelength region, whereas in shorter wavelength region the dispersions of the refractive indices for $LaCl_3$, $PrCl_3$, and YCl_3 melts are observed.

Molar refractivity is one of the characteristic properties and is given by the following equation,

$$R_\lambda = \{(n_\lambda^2-1)/(n_\lambda^2+2)\}\times V_m,$$

where R_λ is the molar refractivity of the molten salt in cm^3, n_λ the refractive index of the molten salt for the light of wavelength λ, V_m the molar volume of the molten salt at the measured temperature, and λ represents C, D, F, or G line. The molar refractivities calculated are shown in Table 3. The molar refractivities are almost independent of temperature, and therefore the results in Table 3 are the averaged values over the measured temperature range.

The refractive indices at infinite wavelength can be calculated by Cauchy's approximate relation,

$$n_\lambda = A + B/\lambda^2,$$

where n_λ is the refractive index, A and B the constants for respective melt, and λ the wavelength. The electronic polarizabilities of molecules in a melt are given by the following equation,

$$\alpha_\infty^m = \{3/(4\pi N)\}\{(n_\infty^2-1)/(n_\infty^2+2)\}V_m,$$

where α_∞^m is the electronic polarizability of molecule in the melt, N Avogadro number, V_m the molar volume of the melt, and n_∞ the value of n_λ at $\lambda=\infty$. The obtained values of n_∞ and α_∞^m are shown in Table 4, in which n_∞ were calculated by the method of least-squares. As shown in Table 4, the order of magnitude in the electronic polarizabilities for the molten rare earth chlorides is in agreement with the order of the radii of cations contained in the molecules, and this fact satisfies the result of lanthanide contraction. The

differences in electronic polarizabilities of molecules, therefore, are equal to those of cations, because the rare earth chloride molecules have chloride ion as a common anion. The values of polarizabilities for chloride ion in crystal at λ=589.3 nm(D-line) were reported by Tessman *et al.*[8] and by Kordes[9] to be 2.96 and 2.72 ($\times 10^{-24}$ cm^3), respectively, while that reported by Böttcher[10] for the same ion and wavelength in aqueous solution was 3.00×10^{-24} cm^3. The polarizabilities (α_D) of the rare earth cations in molten state calculated approximately using the above polarizabilities of chloride ion are shown in Table 5. Tessman *et al.*[8] have reported that the electronic polarizability was 2.97 ($\times 10^{-24}$ cm^3) for chloride ion in crystal, and Böttcher[11] reported the value 2.60 ($\times$ 10^{-24} cm^3) for chloride ion in aqueous solution. The electronic polarizabilities (α_∞) of the rare earth cations in molten state approximately calculated using these values are shown in Table 6. The values in Tables 5 and 6 were calculated by the following equation,

$$(n_\lambda^2-1)/(n_\lambda^2+2) = (4\pi/3)\sum N_i\alpha_{\lambda,i},$$

where N_i is the number of i-th ion per unit volume, and $\alpha_{\lambda,i}$ the polarizability of i-th ion at wavelength λ. According to Cauchy's relation, the longer the wavelength of light used in measurement is, the less polarizability of ion is obtained. The values of chloride ion in aqueous solution reported by Böttcher[10,11] are not appropriate for the estimation in molten state.

Table 4. n_∞ and α_∞^m of the rare earth chlorides in molten state

	Temp (°C)	Refractive index at $\lambda=\infty$ n_∞	Electronic polarizability of molecule α_∞^m ($\times 10^{-24}$ cm^3)
$LaCl_3$	920	1.696	11.91
	980	1.695	12.05
$PrCl_3$	820	1.702	11.52
	920	1.672	11.51
$DyCl_3$	720	1.663	10.92
	880	1.628	10.85
YCl_3	800	1.617	10.59
	920	1.594	10.50

Table 5. Polarizabilities of rare earth cations in molten state (α_D) calculated from data of chloride ion in literatures ($\times 10^{-24}$ cm^3)

Rare earth cation	Polarizability (α_D)[a)] calculated from		
	Tessman's value	Kordes' value	Böttcher's value
La^{3+}	3.38	4.10	3.26
Pr^{3+}	3.10	3.82	2.98
Dy^{3+}	2.31	3.03	2.19
Y^{3+}	1.95	2.67	1.83

a) The temperature ranges are the same as those in Table 3.

Table 6. Electronic polarizabilities of rare earth cations in molten state (α_∞) calculated from data of chloride ion in literatures ($\times 10^{-24}$ cm^3)

Rare earth cation	Electronic polarizability (α_∞) calculated from		Temp (°C)
	Tessman's value	Böttcher's value	
La^{3+}	3.00	4.11	920
Pr^{3+}	2.60	3.71	920
Dy^{3+}	1.94	3.05	880
Y^{3+}	1.59	2.70	920

The electronic polarizabilities of rare earth ions in molten state seem to be close to the values estimated from the chloride ion polarizability by Tessman *et al.*[8] *viz.* 2.97×10^{-24} cm^3. The estimations seem to yield good approximate polarizabilities of rare earth cations in molten state, though the chloride ion polarizabilities in different conditions were used.

Since the cylindrical lens method tends to give an error in the measurement of the focal distance for a substance with a large refractive index, it is desirable that the goniometry method reported by Nakamura and Tanemoto[6] is used.

Calculations were carried out with the computers in the University of Tokyo and Chiba University.

Metal-ion Complexation of Noncyclic Poly(oxyethylene) Derivatives. III.[1] Complexation in Aprotic Solvent and Isolation of Their Solid Complexes†

Shozo YANAGIDA,* Kazutomo TAKAHASHI, and Mitsuo OKAHARA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received January 18, 1978)

The interaction of homogeneous polyethylene glycol(PEG)(EO*n*, *n*=1—8) with the alkali and magnesium metal cations and the ammonium cation was investigated on the basis of ^{1}H NMR(PMR) downfield shifts in acetone-d_6 or in acetonitrile-d_3. The specific complexations of EO4 with Mg^{2+}, EO6 with Na^+ and Ca^{2+}, and EO7 with K^+ were demonstrated by PMR studies, and their solid complexes were isolated. No specific interaction was detected for Rb^+ and Cs^+ in PMR studies. The magnesium ion interacts strongly with 15-crown-5, 18-crown-6, and PEG in acetone, and the $Mg(SCN)_2$-EO4 and the $Mg(SCN)_2$-above crown ether complexes were isolated. The terminal hydroxyl groups of PEG play an important role in the complexation with Li^+ and Mg^{2+} in acetone. The formation of the 1:1 complex with $Ca(SCN)_2$ was observed both for EO6 and for EO7. Strontium and barium thiocyanates formed solid complexes with PEG(EO*n*, *n*=2—8) and with glymes(tri- to octaglyme). Some novel complexes of 12-crown-4 and 15-crown-5 with NaSCN and $Ca(SCN)_2$ were also isolated. The mechanism of metal-ion complexation of poly(oxyethylene) derivatives is discussed in terms of the coordination geometry.

PMR spectroscopy has often been used to detect ligand-metal cation interactions[1-7] The changes in the PMR spectra induced by the typical metal cations are intrinsically complex phenomena. The use of the coordinating species as the solvent tends to mask the shifts, probably due to the competitive complexation. When aromatic anion salts such as tetraphenylborate[2] or fluorenyl salts[4] are used, the close proximity of the aromatic ring of the anion above the participating proton nuclei induces the upfield shifts, in spite of the complexation with the counter metal cation, which by itself would cause a downfield shift of the proton signals due to the increased electronegativity of the coordinating donor atom. Our previous study[1] revealed that the downfield shifts of PEG protons caused by the interaction with alkaline earth metal thiocyanates in methanol can be a qualitative measure of the extent of their complexation. On the basis of PMR downfield shifts, it was demonstrated that homogeneous PEG's with at least more than five oxyethylene units have strong complexing powers toward Ca^{2+}, Sr^{2+}, and Ba^{2+} in methanol; these are quite comparable with those of crown ethers, cyclic poly(oxyethylene). However, the downfield shifts induced by the alkali or magnesium metal cations or the ammonium ion were too small for either PEG or crown ethers to predict a complexing tendency. This phenomenon can be attributed to the competitive complexation of the methanol solvent. When a less polar nonaqueous solvent, *e.g.*, acetone or acetonitrile, is used, the downfield shifts are found to be large enough to evaluate the intrinsic complexing tendency.

On the basis of the previous and present PMR analyses, we have isolated solid complexes of PEG with alkali and alkaline earth metal salts. Further, we have attempted to point out some inconsistency in the ion-radius cavity concept regarding the metal complexation of the crown ethers.

† This work was presented at the 26th IUPAC Congress, Tokyo, September 1977.

Experimental

Materials. The following chemicals were obtained in the best available purity from the sources indicated; acetone-d_6 and acetonitrile-d_3 (CEA products through Nakarai Chemicals Ltd.), sodium tetraphenyl borate (Specially prepared reagent) (Nakarai Chemicals Ltd.), triethylene glycol monomethyl ether (Tokyo Kasei Kogyo Co., Ltd.).

Hexaethylene glycol monomethyl ether(MeEO6)(167—171 °C/0.15 mmHg) and octaethylene glycol monomethyl ether(MeEO8)(215 °C/0.16 mmHg) were prepared by the reaction of diethylene glycol 2-chloroethyl methyl ether with tetraethylene glycol and with pentaethylene glycol, respectively.

Other salts and poly(oxyethylene) derivatives were the same as in the previous paper.[1]

Measurement of Spectra. The PMR spectra were obtained using a JEOL LMN-PS-100 spectrometer(100 MHz) on an expanded scale (sweep width, 270 Hz), with 8% dioxane in benzene as the external reference, as previously described, except for weighing the thiocyanates:[1] thiocyanate concentration, 0.05 mol/kg; POE derivatives concentration, 1 wt %. Weighing the salts was done as follows: the acetone or methanol solution was injected in NMR tubes using a microsyringe and the NMR tubes were placed in a vacuum to evaporate the solvent. The chemical shifts for the split signals of EO7 and EO8 in acetonitrile-d_3 were averaged for the calculation of the downfield shifts.

The ^{13}C NMR spectra were obtained using a JEOL JNM-FX-60 spectrometer.

The IR spectra were recorded with a Japan Electroscopic IR-E spectrophotometer.

Isolation of Solid Complexes. Solid complexes of cyclic and noncyclic poly(oxyethylene) derivatives (POE) were isolated by the following methods. An anhydrous metal salt was powdered in a mortar and was heated with a slightly more than equimolecular quantity of POE without solvent until the pasty mixture became an entirely homogeneous solution. Generally, the complexes solidified on cooling. The resulting complexes were purified by recrystallization (Method 1), or were brodken up to pieces, washed throughly to remove excess POE or the salt, filtered, and dried under reduced pressure(Method 2).

It was found that some complexes could also be easily isolated from solution. Acetone or methanol was saturated with a salt and the stoichiometric quantity of POE was added to the above solution. The precipitation of the complexes was immediate(Method 3). The complexes were worked up as in Method 1 or in Method 2. The results are summarized in Tables 1, 2, and 4. The melting points were determined on a Büchi SMP-20 apparatus.

Typical examples are as follows.

Preparation of Crystalline KSCN Complex of Heptaethylene Glycol(EO7). Method 1. A mixture of 1.00 g(3.0 mmol) of EO 7 and 0.238 g(2.5 mmol) of powdered KSCN was melted in a test tube. The mixture solidified on cooling. The complex was broken up to pieces, washed with a small quantity of acetone, dried, and recrystallized twice from acetone. A crystalline 1 : 1 complex was obtained (0.47 g, 45% yield).

Preparation of $Ba(SCN)_2$ Complex of Tetraglyme(MeEO-4Me). Method 2. A mixture of 0.232 g (0.9 mmol) of powdered $Ba(SCN)_2$ and 0.210 g (0.95 mmol) of MeEO4Me was heated up in a test tube until the mixture become entirely homogeneous. After cooling, a mixture of benzene and acetone (9 : 1) was added to the mixture, giving the complex(0.12 g). When benzene was added to the filtrate, additional complex(0.13 g) was precipitated(total yield 58%).

Preparation of $Mg(SCN)_2$ Complex of Tetraethylene Glycol-(EO4). Method 2. A mixture of 0.228 g(1.0 mmol) of $Mg(SCN)_2 \cdot 4H_2O$ and 0.203 g (1.0 mmol) of EO4 was heated up in a test tube until the mixture became a clear solution. During the workup, the evolution of water and the complex formation were observed. The resulting complex was washed with acetone and dried in a vacuum. The complex(0.117 g) was obtained. Additional complex (0.076 g) was recovered from the filtrate(total yield 58%).

Preparation of $Mg(SCN)_2$ Complex of 15-Crown-5. Method 3. In acetone (1 g), 0.216 g (1.0 mmol) of $Mg(SCN)_2 \cdot 4H_2O$ was dissolved, and the solution was filtered. To the filtrate, 0.223 g(1.0 mmol) of 15-crown-5 was added. White crystals were immediately formed. After a while, some additional 15-crown-5(0.235 g, 1.1 mmol) was added, but no further precipitation was observed. The crystals were filtered, washed with acetone, and dried. The complex(0.231 g) was obtained(53% yield). The filtrate was concentrated in a rotary evaporator, yielding some additional complex (Table 4).

Preparation of $Ca(SCN)_2$ Complex of 12-Crown-4. Method 3. 12-Crown-4(0.128 g, 0.73 mmol) was dissolved in 0.364 g of methanol. The methanol solution of $Ca(SCN)_2$ prepared from 0.109 g of anhydrous $Ca(SCN)_2$ and 0.6 ml of methanol was added to the above solution. After a while, white crystals precipitated. After the workup, 0.155 g of the complex with water of crystallization were obtained (60% yield) (Table 4).

Results and Discussion

Complexation with Alkali Metal and Ammonium Cations in Aprotic Solvent. Recent studies on the structure of crown ether complexes have revealed their induced fit for metal cations, *i.e.*, their oxyethylene (EO) chains are flexible enough to coordinate to various metal cations in spite of their ring structure.[8-10] Thus, it seems appropriate to make use of the downfield shift for crown ethers as a probe to evaluate the complexation of acyclic POE derivatives.

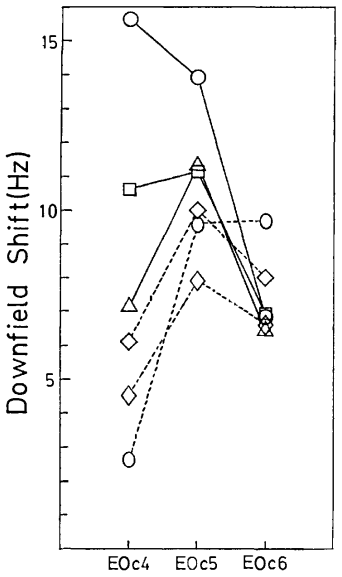

Fig. 1. Downfield shifts for crown ethers induced by alkali metal and ammonium cations in acetone-d_6. Thiocyanate concentration, 0.05 mol/kg; crown ether concentration, 1 wt %. △: Li^+, ○: Na^+, □: K^+, ◇: Rb^+, ◇: Cs^+, ○: NH_4^+.

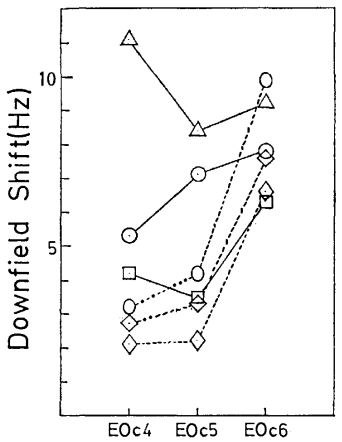

Fig. 2. Downfield shifts for crown ethers induced by alkali metal and ammonium cations in acetonitrile-d_3. The conditions and symbols used are identical with those in Fig. 1 and all of the following figures.

The downfield shifts of the crown ethers' protons by the complexation of the alkali metal and ammonium cations were measured both in acetone-d_6 and in acetonitrile-d_3. The results are shown in Figs. 1 and 2 as a function of the number of EO units. It is seen that the downfield shifts are generally larger in acetone-d_6 than in acetonitrile-d_3. And it is also seen that in acetonitrile the signals of 18-crown-6-(EOc6) show the largest shifts for most of the cations, while in acetone the largest shifts are observed mostly for 15-crown-5(EOc5). On careful examination, the chemical shift of 18-crown-6 in acetonitrile-d_3 was found to be *ca.* 5—7 Hz upfield, compared with those of the other crown ethers and PEG. The unusual upfield shift for 18-crown-6 is attributable to the magnetic anisotropy due to its specific interaction with the cyano group of acetonitrile.[11,12] Thus, the observed largest

downfield shifts for 18-crown-6 in the presence of cations do not necessarily imply the strongest complexing power. It may be inferred that the specific interaction of 18-crown-6 with acetonitrile would easily disappear in the presence of cations.

On the basis of these large downfield shifts for the crown ethers in the presence of the cations, the corresponding shifts for a series of homogeneous PEG's were determined in acetone-d_6 and partly in acetonitrile-d_3; the results are plotted against the number of EO units in Figs. 3—4 and 7—10. The shifts for the crown ethers were also plotted in the respective figures for comparison. In general, the presence of the cations made the signals of ethylene glycol(EOl) broaden and also those of the diethylene glycol(EO2) complex, but with small downfield shifts.

In the interaction of EO*n* with Li^+ in acetone-d_6 (Fig. 3), the specific complexation of hexaethyle glycol (EO6) is to be noted. The shift for EO6 is far less than those of 12-crown-4 and 15-crown-5, but is quite comparable with that of 18-crown-6. Rather weak complexation of 12-crown-4 with Li^+ in acetone, implied by the small shift, can not be explained. In acetonitrile (Fig. 3), the larger shifts were observed for PEG with more than five EO units, but no specific complexation was observed. It should be noted

that the signals of heptaethylene glycol(EO7) and octaethylene glycol(EO8) were split into two peaks when measured in the absence of cations by an expanded scale (Fig. 6), and that the addition of LiSCN caused the coalescence of the signals with appreciable downfield shifts.

With regard to Na^+ in acetone-d_6(Fig. 4), the large shifts were observed for EO*n* with more than four EO units and the signal of EO6 was clearly split into two peaks with a larger downfield shift than that of 18-crown-6(Fig. 5). The shifts in acetonitrile-d_3 (Fig. 4) were not so large as those in acetone-d_6, but the clear splittings of the signals were observed not only for EO6 but also for EO7(Fig. 6). These splittings are in agreement with those observed in methanol-d_4,[1] but the splittings accompanying the downfield shifts suggest that EO6 and EO7 should take more rigid conformation on complexation with Na^+ in the aprotic solvent.

The study of K^+ in acetone-d_6(Fig. 7) found appreciable downfield shifts for EO*n* with more than four EO units. Pentaethylene glycol(EO5), EO7, and EO8 accompanied the splitting of the signals. EO7 gave the characterictic splitting which was observed in methanol-d_4.[1] The complexing power of EO*n* with more than four EO units, inferred from the large shifts, is far less than those of 12-crown-4 and 15-crown-5, but is quite comparable with that of 18-crown-6. This fact is quite consistent with the solid-liquid phase transfer catalysis of glymes with more than four EO units.[13] The shifts in acetonitrile-d_3(Fig. 7) make the specific complexation of EO7 with K^+ more apparent.

For Rb^+ and Cs^+ in acetone-d_6(Fig. 8), the large shifts comparable with those of the crown ethers were observed; splitting occurerd for EO*n* with more than four EO units. These are almost proportional to the number of EO units, suggesting their rather non-specific interactions.

For the ammonium ion in acetone-d_6(Fig. 9), no remarkable complexation comparable with those of 15-crown-5 and 18-crown-6 was observed among the PEG investigated. However, increasing the number of EO units seems to increase the tendency of complexation.

Complexation with Magnesium Cation in Acetone. The magnesium cation had been considered not to interact with any crown ethers, since the magnesium ion radii is apparently too small to fit the cavity of crown ethers larger than 12-crown-4. It has now been found that in acetone-d_6, the proton signal of 15-crown-5 shifts *ca.* 31 Hz downfield by the presence of $Mg(SCN)_2$ and the complex with the 1:1 composition precipitates under the conditions of the downfield shift measurment. Similarly, 18-crown-6 yielded the complex with the composition of 18-crown-6·$Mg(SCN)_2 \cdot 4H_2O$(see Table 4). It is surprising to note, however, that 12-crown-4 neither formed any solid complex nor showed any appreciable shift in the presence of Mg^{2+}. In the light of the ion-radius cavity concept, 12-crown-4 should have shown the

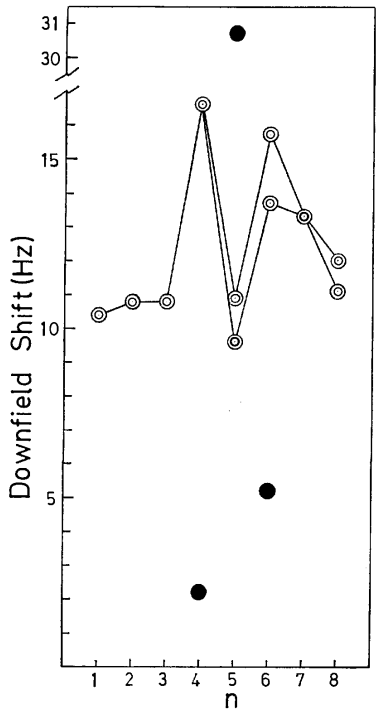

Fig. 10. Magnesium-ion induced downfield shifts for the homogeneous PEG and crown ethers in acetone-d_6.
●: The shifts for the crown ethers.

maximum interaction with Mg^{2+}. The fact is quite contradictory to the concept.

As is shown in Fig. 10, large downfield shifts were confirmed for a series of PEG's ranging from EO1 to EO8. Significant splitting or broadening of the signals were observed for PEG's with a longer chain than EO5. To our surprise, the 1:1 complex of EO4 with $Mg(SCN)_2$ was precipitated in acetone-d_6 just as those of 15-crown-5 and 18-crown-6. However, we could not succeed in isolating any other complexes of PEG. These facts indicate that Mg^{2+} interacts specifically with EO4.

The Role of Terminal Hydroxyl Groups in Complexation of PEG in Aprotic Solvents. Recently, a variety of noncyclic POE derivatives with chelating groups on the terminals have been reported to show remarkable complexing properties with metal cations.[14-16] The significance of these findings is that they demonstrate the importance of the terminal groups which stabilize the metal-ion complexation. In preceding papers,[1,17] however, we demonstrated that the TGT conformation of EO groups and the resulting helical conformation of the repeating EO units are the driving forces of the metal-ion complexation of noncyclic POE derivatives, and that the role of the terminal hydroxyl groups in the complexation of PEG varies with the properties of the metal cations and with the polarity of the solvent.

In this study, the effect of the terminal hydroxyl groups on complexation with Li^+, Na^+, K^+, and Mg^{2+} in aprotic solvent was also examined by comparing the downfield shifts of PEG with those of the methylated PEG. As is shown in Fig. 11, the hydroxyl groups of PEG play an important role in the effective complexation with Li^+ and Mg^{2+} in acetone. With regard to Na^+ in acetone(Fig. 12), the same is true for the tri-(oxyethylene) derivatives. In case of the hexa-(oxyethylene) derivatives, no drastic decrease in the shifts by methylation were observed, indiacting that the terminal hydroxyl groups are not necessarily so important for complexation with Na^+ in acetone. This also holds true for potassium ion complexation of the octa(oxyethylene) derivatives in acetonitrile(Fig. 12).

Isolation of Solid Complexes. Some polar compounds have recently been found to form solid complexes with metal salts under appropriate conditions.[18-20] Our previous and present studies of PMR indicated that some homogeneous PEG should react

with alkali and alkaline earth metal thiocyanates to give stable solid complexes. However, our preliminary attempts of isolation using methanol as a solvent were unsuccessful. When a roughly 1 : 1 mixture of PEG and metal thiocyanates, which showed appreciable PMR downfield shifts, was heated up without solvent, some solid complexes were formed almost quantitatively, with a few exceptions(Table 1).

Among alkali metal thiocyanates, NaSCN gave a solid complex with EO6, while KSCN and RbSCN formed solid complexes with EO7. The complex with NaSCN was not isolated because of the difficulty in purification. The complex with $NaBPh_4$ was isolated and analyzed instead. Their compositions were all 1 : 1. Hexaethylene glycol(EO7) also produced a solid 1 : 1 complex with KI. Our attempts to isolate complexes with LiSCN and CsSCN, however, were all unsuccessful.

Ammonium thiocyanate gave a 1 : 1 complex with EO7, although two examples of the ammonium complexes with the diphenoxylated EO4 and EO6 have recently been reported.[19]

The magnesium complex with EO4 was confirmed to form on heating without solvent even when the thiocyanate has water of crystallization, and evolution of its water was observed during the complexation. Surprisingly, the resulting complex is no longer hygroscopic.

Calcium thiocyanate yielded the 1 : 1 complexes not only with EO6 but also with EO7. The solid complex

with EO8 was also isolated and its elemental analysis agreed with the 3:2 composition.

With $Sr(SCN)_2$ and $Ba(SCN)_2$, not only PEG with more than two EO units, but also glymes with more than two or three EO units gave the solid complexes with various compositions(Tables 1 and 2). As expected, the complex of EO7 with BaI_2 was also isolated.

Some of the above complexes could be recrystallized from aprotic solvent, suggesting that they are stable even in solution. This fact is also supported by ^{13}C NMR and PMR spectra of the complexes, in which, compared with the spectra of PEG, the splitting of signals or the shifts were observed especially in the PMR spectra(Table 3).

Remarkable differences between the IR spectra of PEG or glymes and those of their complexes may be noticed. The greatest changes are observed in the region 1000—1200 cm^{-1} which is assigned to the CH_2 rocking band and the C–C and C–O stretching bands.[21] It was reported[21] that the crystalline PEG's($n \geqq 3$) exhibit strong bands at about 1150, 1100—1115, and 1060—1065 cm^{-1}. Upon complexation, the bands are shifted to lower energy, giving one strong band which has a few shoulder peaks ranging from 1020—1080 cm^{-1}. The shifts are very similar to those of the crown ether complexes (see Table 4).[22] From these observations, it may be inferred that the structures of the complexes with PEG would be very similar to those of the crown ethers.[23]

Mechanism of Metal-ion Complexation of Poly(oxyethylene) Derivatives. From the ion-radius concept, it is widely recognized that the selective and strong metal-ion complexation of crown ethers is related to the relative sizes of the metal cations and the hole sizes of the crown ethers.[24–27] As is shown in Table 4, we have also succeeded in isolating some novel complexes of the crown ethers with thiocyanates of comparatively small ion-radius alkali and alkaline earth metals. The significance of these findings is that 12-crown-4, of which the cavity diameter is less than 1.2 Å, coordinate to both Li^+ (ion diameter 0.78 Å) and Ca^{2+}-(1.06 Å) with the 1 : 1 stoichiometry, but never to Mg^{2+} (0.78 Å). Further the 2 : 1 complex of 12-crown-4 with NaSCN including water of crystallization was found to form only in the presence of water, and could be recrystallized in acetone. The latter fact, implies along with the largest downfield shift on its complexation with Na^+ in acetone, that the complex is stable even in acetone. As was noted, $Mg(SCN)_2$ very easily gave the stable complexes with 15-crown-5 and 18-crown-6. Recently some magnesium complexes with benzo-15-crown-5 were reported.[28] From these various observations, it may be concluded that the cavity size of crown ethers is not the substantial factor governing their strong complexing properties. The poor complexing abilities of some rigid cyclic polyethers also support this conclusion.[29–32]

On the other hand, studies of the coordination geometry of the alkali metal cations based on PMR or metal element magnetic resonance experiments have attracted special interest recently. For the sodium ion, the existence of the four coordinated species were confirmed in THF,[3,33] DMSO,[34,35] or 1-methyl-2-pyrrolidone[35] by the PMR studies. Detellier and Laszlo[36] reported on the basis of the ^{23}Na NMR study that the tetracoordination and tetrahedral configuration of the sodium cation is of lowest energy. On the basis of the largest PMR downfield shifts, we have observed the strongest complexing ability of 15-crown-5 with the alkali and alkaline earth metal cations in acetone or methanol, with a few exceptions. Furthermore, it has been confirmed that there exists the specific interaction of PEG with the smaller metal cations, that is, Mg^{2+} with EO4, Na^+ and Ca^{2+} with EO6, and K^+ with EO7. These facts suggest that the fulfilment of the energetically favorable coordination geometry of the alkali and alkaline earth metal cations and the compatibility of the POE ligands should be the important factors governing the specific or the selective complexation. This mechanistic concept well explains an inclination of the induced fit of the crown ethers in complexation.[7,8]

The authors wish to express their thanks to Mrs. Y. Miyaji for her kind performance of the elaborate PMR measurements. They also wish to thank Miss J. Maenaka, Mr. and Mrs. Muneishi, and Miss Y. Sako for elemental analyses.

Microwave Spectrum, Structure, and Quadrupole Coupling Constant of *s-cis* *o*-Chlorophenol-*d*

Masao ONDA* and Ichiro YAMAGUCHI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Tokyo 102

(Received February 8, 1978)

The microwave spectrum of *o*-chlorophenol-*d* has been observed in the frequency range 17—34 GHz. The rotational and centrifugal distortion constants have been obtained. The analysis of the hyperfine structure has given the following nuclear quadrupole coupling constants for the ^{35}Cl species: $\chi_{aa}=-67.1$, $\chi_{bb}=33.1$, and $\chi_{cc}=34.0$ (MHz). The spectrum assigned has been attributed to the *s-cis*-form (the hydroxyl hydrogen pointed toward the chlorine) from the consideration of the r_s-coordinates of hydrogen and chlorine atoms. The non-bonded Cl···H distance is 2.373±0.001 Å.

In the previous paper,[1] we suggested that the intense lines observed in the microwave spectrum of *o*-chlorophenol should be attributed to the *s-cis* form. In this paper, we report the spectrum of *o*-chlorophenol-*d*. Using the r_s-coordinates of the hydrogen and chlorine atoms, we have confirmed the *s-cis*-structure of the molecule, and determined the structural parameters which reproduce the observed rotational constants and the H···Cl non-bonded distance. We have also obtained the Cl quadrupole coupling constants.

Experimental

o-Chlorophenol-*d* was produced by mixing the normal species with D_2O. The obtained sample was dried over anhydrous calcium chloride, followed by trap-to-trap distillation *in vacuo*. The content of the *d*-species in the sample was estimated to be about 50% from the intensity ratio of the same rotational transition of the deuterated and normal species. The microwave spectrum was measured with a conventional spectrometer with 100 kHz square-wave Stark modulation. The D_2O vapor was introduced into the waveguide and pumped out for several hours, and then the sample was introduced. Measurements were made at *ca.* −20 °C with a sample pressure of 0.6—7 Pa.

Results and Discussion

Analysis of the Spectrum. The frequencies of the spectral lines were predicted from the structural models for both the regular and the distorted hexagonal skeleton structure of *s-cis* *o*-chlorophenol.[1] The initial step of the assignment was made for b-type Q-branch transitions with high-J values. The lines of several Q-branch series are the most intense in our observed frequency region. Their hyperfine structure is a clean doublet in which the separation of lines is a few MHz. The separation varies smoothly according as the J-value changes. The center of the doublet was taken as the unperturbed frequency, since only the first order perturbation was taken into account in the analysis of the hyperfine structure. To confirm the assignment of the Q-branch lines, the splitting widths observed were compared with the ones calculated from the χ-values obtained for *o*-$^{35}ClC_6H_4OH$[1] and the model structure.

The frequencies of the R-branch transitions were predicted from the values of κ and $(A-C)/2$ obtained from the analysis of the Q-branch transitions, together with an assumption of the molecular planarity. The hyperfine structure for the R-branch transitions, however, was not expected to be observed, because the magnitude of the hyperfine splitting was predicted to be smaller than the resolution of the spectrometer. A group of the a- and b-type transitions $J_{0,1}\leftarrow J-1_{1,J-1}$, $J_{1,J}\leftarrow J-1_{1,J-1}$, $J_{0,J}\leftarrow J-1_{0,J-1}$, and $J_{1,J}\leftarrow J-1_{0,J-1}$ was observed as a quartet for $J=9$ and 10. In the quartet, the intensities of a- and b-type transitions are comparable to each other. This indicates that the components of the dipole moment, μ_a and μ_b, of this molecule are comparable in magnitude, as observed for the normal species. The assigned transitions are given in Table 1. The rotational constants, and the centrifugal distortion constants constrained by the planarity conditions among $\tau_{aa\beta\beta}$'s, were obtained by the least-squares fitting and are given in Table 2. The values of the distortion constants obtained are fairly close to those for the normal species, but are smaller than those for most of the aromatic molecules studied.

Molecular Structure. The inertia defect for the isotopic species, *o*-$^{35}ClC_6H_4OD$, was almost the same as that for the normal species, *o*-$^{35}ClC_6H_4OH$,[1] and was found to be of very small positive value compared with those of other planar aromatic molecules. This fact is a strong indication of the planar configuration of this molecule. The isotopic substitution at the hydroxyl group, from H to D, reduces further the magnitude of the inertia defect. Therefore, a negative contribution to the inertia defect can be interpreted as coming from the OH torsion. The Kraitchman's equation was used to calculate the coordinates of the hydrogen atom. The values obtained are given in Table 3, where the errors come from those in the moments of inertia. A very small value of the c-coordinate has been obtained with a large error and it seems rather reasonable to consider that the hydrogen atom practically lies in the A-B plane. On the other hand, a very small imaginary value of the c-coordinate for the chlorine atom was obtained by applying the Kraitchman's equation for the two species, *o*-$^{35}ClC_6H_4OH$ and *o*-$^{37}ClC_6H_4OH$.[1] Therefore, the chlorine atom also lies effectively in the A-B plane. The planar structure of this molecule is plausible. No ambiguity in the sign of r_s-coordinates arises in this case, since the other choice of the sign of the H-coordinates leads to an impossible configuration, with too small a distance between the H atom and C–C bond of the

benzene ring. The non-bonded H···Cl distance was obtained from the r_s-coordinates of Cl[1] and H, as shown in Table 3. The obtained H···Cl distance, 2.373 Å, implies that the assigned spectrum is of the *s-cis*-form of this molecule. As discussed in the previous paper,[1] the a- and b-components of the dipole moment for the *s-cis*-form are comparable in magnitude to each other. Therefore, the comparable intensities of the observed a- and b-type transitions also support the *s-cis*-form of the molecule studied here.

Assuming the rigid planar structure of this molecule, five structural parameters have been obtained from the three isotopic species, $^{35}ClC_6H_4OH$, $^{37}ClC_6H_4OH$, and $^{35}ClC_6H_4OD$. Here, the benzene ring was assumed to be of the same distorted skeleton as obtained for chlorobenzene from its complete r_s-coordinates analysis.[2] The parameters obtained are given in Table 4. These parameters reproduce the observed nine moments of inertia within 0.1 amu Å^2 and the r_s-non-bonded distance (Cl···H) within 0.01 Å. The structural parameters around the OH group are similar to those of phenol. The small differences in r_{OH}, $\angle C_1C_2O$, and $\angle C_2OH$, *i.e.*, the slightly longer bond length r_{OH} and the slightly narrower angles of the $\angle C_1C_2O$ and $\angle C_2OH$, where C_1 is bonded to Cl and C_2 to O, compared with those of phenol, suggest the existence of an intra-molecular hydrogen bonding.

Quadrupole Coupling Constants. The apparent splitting of the doublet was measured for each of the high-J b-type Q-branch transitions listed in Table 1. The hyperfine structures due to ^{35}Cl were analyzed, based on the first-order quadrupole correction computation using the rotational constants in Table 2. The quadrupole coupling constants in the principal inertia axis system, χ_{aa}, χ_{bb}, and χ_{cc}, were obtained using the least-squares method, as shown in Table 5. In this procedure, a quantity, the inverse of the squared standard deviation (in the measurements) for the splitting divided by the splitting width, was taken as the weight for each line. The uncertainties of the values in Table 5 were estimated from the error in the frequency measurements of the unresolved F components. Assuming that the principal z-axis of the χ-tensor lies along the C–Cl bond, the values of χ_{zz} and χ_{yy} are calculated as given in Table 5. The χ_{xx}, the component perpendicular to the molecular plane, is the same as χ_{cc}. The χ_{gg}-values (g=x,y, and z) of $^{35}ClC_6H_4OH$ was recalculated for the molecular structure obtained in this work. The ambiguity of the angle of θ_{za} was within ±0.1° when estimated from the structure in Table 4. The χ-values calculated for the normal and deuterated species coincide within the error limits. The value of χ_{zz}(−68.7 MHz) in this molecule is larger than that in chlorobenzene[3] (χ_{zz}=−71.10±0.50 MHz) by 2.4 MHz. This difference suggests an increase of ionicity of the Cl atom compared with that

in chlorobenzene. The double bond character of the C–Cl bond should be negligible because the η-value is vanishingly small. This situation appears also in other chlorobenzene derivatives.[5]

Judging from the quadrupole coupling constant alone, the interaction between chlorine and hydrogen atoms is rather weak. The small difference in the χ_{zz} between *o*-chlorophenol and monochlorobenzene reveals no clear effect of hydrogen bonding on the nuclear quadrupole coupling constant of chlorine. The same conclusion had been obtained for 2-chloroethanol.[6]

Chemisorption of Sulfur on Thermally Decomposed Copper and Iron Sulfides

Nakamichi YAMASAKI

Research Laboratory of Hydrothermal Chemistry, Faculty of Science, Kochi University, Asakura, Kochi 780

(Received February 10, 1978)

The chemisorption of sulfur on thermally decomposed copper and iron sulfides was studied and its application to the desulfurization process of heavy oil was attemped. Thermal decomposition of sulfides was carried out by calcining CuS and FeS_2 at 200—800 °C under 10^{-3} mmHg and with 5 °C/min. Sulfur was adsorbed on the calcined sulfides in toluene. Thermally decomposed copper sulfide (Cu/S: 1—2) easily chemisorbs free sulfur in toluene below 100 °C, but not iron sulfide (Fe/S: 1—0.5). The relationship between sulfur affinity and the structure of partially decomposed sulfide was discussed in terms of the kinetics of initial chemisorption of sulfur and the sulfur adsorption coefficient calculated from the ratio of the adsorbed sulfur to the sulfur required to reform starting CuS and FeS_2. The partially decomposed copper sulfide ($Cu_{1-2}S$) easily chemisorbs free sulfur in heavy oil. Chemisorption might be applied to the desulfurization of heavy oil.

The colloidal or dissolved sulfur in solvent is gradually oxidized by air, forming sulfur oxides. In industry, the sulfur oxides not only cause the corrosion of steel container or pipe line, but also produce substances harmful to human life. Active carbon or zeolite is used as an adsorbent of sulfur. The adsorption mechanisms of sulfur on active carbon and zeolite are explained by the physical trapping or van der Waals bonding. It is supposed that the thermally decomposed sulfides which partially release sulfur in a vacuum have the defect of sulfur atoms in crystal lattice. Such sulfides are expected to be strong adsorbents of sulfur reforming the chemical bonding of sulfur in defective positions of the crystal.

The partially decomposed sulfide in a vacuum generally has a skelton structure and is active to the reverse reaction, that is, adsorption. The thermal decomposition processes and phase diagrams of CuS and FeS_2 were discussed by Samsonov and Drozdova,[1] and the formation energies of CuS and FeS_2 were reported by Richardson and Jeffes.[2] However, no report seems to have appeared on the thermal decomposition of these sulfides in a vacuum and the chemisorption of sulfur. The relation between the sulfur release from starting sulfide and the chemisorption of sulfur is of interest as regards the development of new sulfur adsorbent.

The major sulfur compounds contained in heavy oil are mercaptan, disulfide and aromatic sulfide as thiophen. These sulfur compounds have analogy to H_2S in the redox-reaction. H_2S is easily oxidized by SO_2 even at room temperature, forming free sulfur. Sulfur compounds in heavy oil are also oxidized by SO_2 gas to sulfur at relatively high temperature or high pressure. Such free sulfur can be easily removed by adsorption on metal sulfide decomposed thermally in a vacuum.

In order to obtain a strong sulfur adsorbent, it is necessary to study the relationship between the various degree of decomposition of sulfide in a vacuum and the rate of chemisorption of sulfur.

Experimental

Preparations of Samples. The mode of the thermal decomposition of CuS and FeS_2 in a vacuum largely depends on the conditions of the preparation of starting materials. A distinct difference was observed between two kinds of CuS precipitated in alkaline and acidic solutions respectively, as regards the decomposition temperature in a vacuum. However, the two kinds of CuS have the same crystal structure.

Precipitation of starting materials was carried out as follows. FeS_2 was prepared by the dry method of Titarenko.[3] CuS was prepared by a wet method. An aqueous solution of Na_2S was added slowly to 10% aq solution of $Cu(NO_3)_2$ with stirring at 25 °C. The resulting precipitate (CuS) was aged on a hot plate for two hours with bubbling of nitrogen gas, filtered, and washed with ethanol, carbon disulfide, and then acetone. The product was kept to dry in a vacuum dessicator.

Thermal Decomposition. Proper calcination temperatures were selected from the results of TG-DTA. The starting FeS_2 or CuS was set in a quartz container in furmace, degassed slowly, and heated at a heating rate of 5 °C/min, under 10^{-3} mmHg, as in the case of TG-DTA. After the desired temperature of the container had been reached, the furnace was removed immediately and the container was cooled from outside with a fan. The samples calcined at various temperatures were subjected to elemental analysis, X-ray powder diffraction, and determination of specific surface area. The data of TG-DTA and specific surface area are shown in Figs. 1 and 2, and the X-ray powder patterns at various temperatures in Figs. 3 and 4. The preferable sulfur adsorbents selected according to the data of sulfur release and crystal structures are given in Table 1.

Elemental Analysis (Determination of Metal/S). In the Lunge method, the sample is dissolved in aqua regia on a steam bath. In order to suppress the formation of insoluble free sulfur, $KClO_3$ or Br_2 is added to the solution as an exhaustive oxidizing agent. In the present experiment, however, the sample was dissolved in nitric acid instead of aqua regia. After the evolution of H_2 gas had ceased, the solution was subjected to centrifugation and the insoluble residue separated was put into a glass tube, the liquid phase being kept for the subsequent procedure. A small amount of nitric acid centrifuged was added to the glass tube and sealed. The sealed tube was set in a micro-autoclave of inner volume of 25 ml. The outside of the tube was filled with water to prevent the breakdown of the glass tube. The autoclave was heated at 250 °C for a few minutes and cooled quickly. After the glass tube had been opened, the contents were added to the solution which had been centrifuged. The combined solution was treated according to a process similar to the Lunge method. Fe^{3+} was determined by colorimetry.[4]

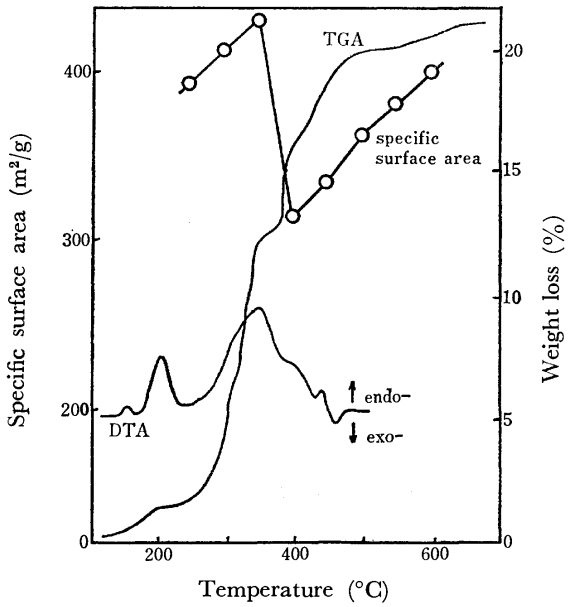

Fig. 1. Thermal decomposition pattern of CuS.

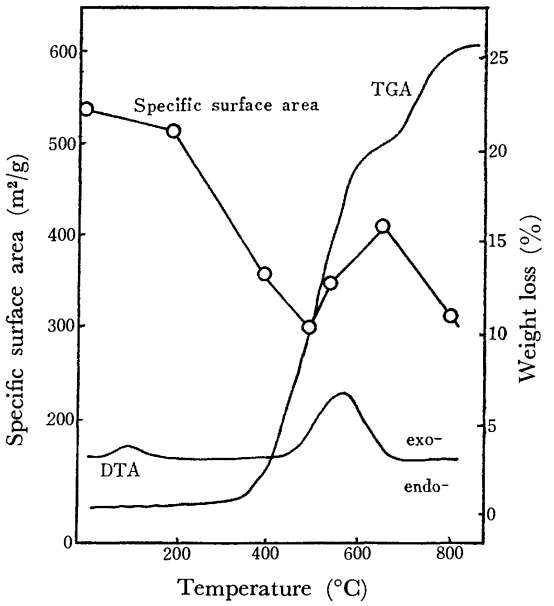

Fig. 2. Thermal decomposition pattern of FeS_2.

Sulfur Adsorption Procedure. The kinetics and quantities of sulfur adsorption were measured as follows.

The thermally decomposed iron sulfide adsorbed no sulfur in toluene under 100 °C. However, it reacted with sulfur vapor in a sealed glass tube at 200—260 °C.

A half gram of the decomposed iron sulfide was put into a glass tube with 0.5 g of sulfur (in excess), the tube then being sealed in a vacuum. This was heated in an electric furnace. After cooling, iron sulfide was washed with ethanol, acetone, and then CS_2, and dried in a vacuum oven. The quantity of the adsorbed sulfur was determined from the weight change and elemental analysis. The crystal structure was identified by means of X-ray diffraction.

The sulfur adsorption on active carbon was carried out as follows. Active carbon (animal charcoal) washed with 20% H_2SO_4 and 5 M NaOH solution was dried, and 1.000 g of the dried active carbon was added to 10 ml of toluene saturated with sulfur. Adsorption was carried out as in the case of copper sulfide.

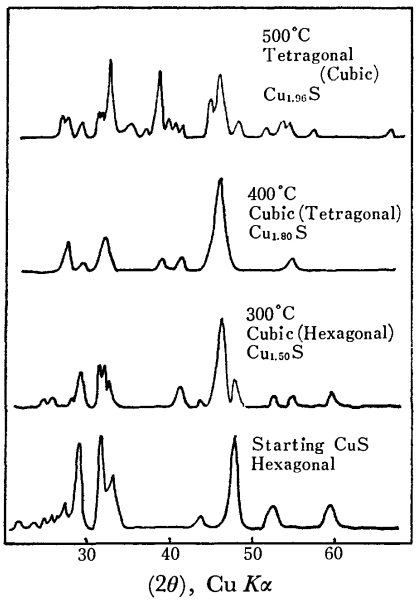

Fig. 3. X-Ray profiles of $Cu_{1-2}S$ at various calcined temperatures.

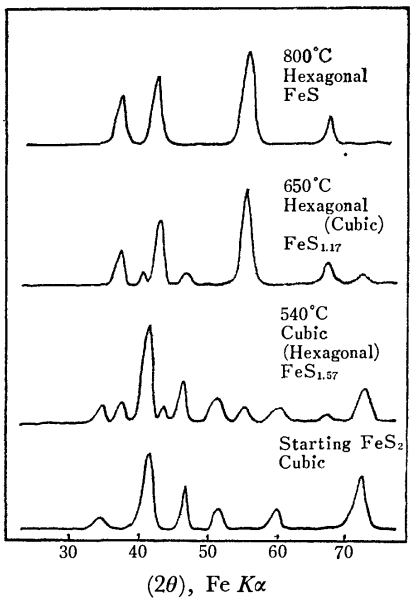

Fig. 4. X-Ray profiles of FeS_{1-2} at various calcined temperatures.

Application Procedure to Desulfurization Process of Heavy Oil. A B-class heavy oil (sulfur content 1.42%) was used as a starting material. The SO_2 gas of 2 kg/cm² and B-class heavy oil of 3 ml were introduced in a micro-autoclave shown in Fig. 5, and heated with stirring in a revolving furnace (Fig. 6) at 300 °C for 15 min. A half gram of thermally decomposed copper sulfide obtained by calcination of CuS in a vacuum at 500 °C for 90 min was added to the resulting heavy oil of 1.5 ml. The mixture was warmed on a water bath at 80 °C with stirring for 60 min. Heavy oil was separated from copper sulfide by filtration. The sulfur content of the heavy oil was determined by JIS K-2541, the desulfurization ratio being calculated. In order to confirm the chemisorption of sulfur, *viz.*, the formation of CuS ($Cu_2S+S=2CuS$), the crystal structure of the resulting copper sulfide was examined by means of X-ray diffraction.

Table 1. Ratios of metal/sulfur and structure at various calcined temperatures for sulfur adsorption

Calcined temp (°C)	Cu/S	Structure
100	1.00	hexagonal
250	1.20	hexagonal, (cubic)[a]

Results and Discussion

The decomposition of CuS at 200—500 °C in a vacuum (Fig. 1) does not proceed linearly with the rise in temperature because of the existence of metastable state in the temperature range 380—400 °C. The crystal structure in the temperature range is cubic $Cu_{1.80}S$ (Fig. 3). On the other hand, the decomposition of FeS_2 is the constant release of sulfur in vacuum calcination (Figs. 2 and 4).

The ratios of metal/sulfur and the structures of decomposed sulfides at various temperatures are given in Table 1.

Transformation of Structure with Sulfur Chemisorption. The crystal structures of partially decomposed sulfides vary with sulfur adsorption (Figs. 7 and 8). The figures show that the process of sulfur chemisorption is opposite that of thermal decomposition in a vacuum. The tetragonal $Cu_{1.96}S$ calcined at 500 °C adsorbs sulfur 100 °C, forming hexagonal CuS through cubic $Cu_{1.80}S$. The X-ray profiles of Figs. 7 and 8 for the final product adsorbed sulfur show that the half value width of the X-ray peaks is about twice that of the starting CuS before thermal decomposition, and the crystalline size of the final product of copper sulfide is smaller than that of the starting materials. The results suggest that the starting CuS particles break in a vacuum at high temperature, new CuS particles being formed.

In the case of iron sulfide the chemisorption of sulfur occurs at high temperature above 200 °C, proceeding continuously.

Sulfur Adsorption Coefficient. The sulfur adsorption coefficient was calculated by means of the equation

$$K = (S_2/S_1) \times 100,$$

where K is adsorption coefficient, S_1 the amount of sulfur required to form starting sulfides CuS and FeS_2, and S_2 the amount of the adsorbed sulfur estimated from weight change and mole ratio of sulfur/metal by chemical analysis.

These coefficients increase with rise in adsorption temperature (Figs. 9 and 10). These data and results of X-ray anlysis (Figs. 7 and 8) show that the sulfur adsorption cause $Cu_{1.80}S$ or CuS. The adsorption is the reverse of the thermal decomposition of sulfide in a vacuum. Sulfur release is very small in copper sulfide calcined at 200 °C, and the sulfur adsorption coefficient (approximately 90% even at room temperature) is large as shown in Fig. 9. This suggests that the number of the empty site which can adsorb sulfur is small. However, the sample has a strong affinity to sulfur.

All the curves of adsorption coefficient for the samples calcined at above 300 °C are of similar form. This suggests that the mechanisms of sulfur adsorption at 400 and 500 °C are similar.

The adsorption temperatures of thermally decomposed copper sulfides are relatively lower than those of iron sulfides (Figs. 9 and 10). These results agree with those in which the formation energies for CuS and FeS_2 are −66.5 and +32 kcal/mol, respectively. The formation energy of CuS is endothermic, but that of FeS_2 is exothermic. The formation of CuS from $Cu_{1-2}S$ (released sulfur partially) occurs at relatively low temperature.

Activation Energies on Sulfur Adsorption. In general, the specific surface area is estimated by means of powder activity. In this experiment the copper

sulfide sample calcined at 400 °C gave the same adsorption coefficient as the one at 500 °C, but their crystal structures differ. Activation energies for

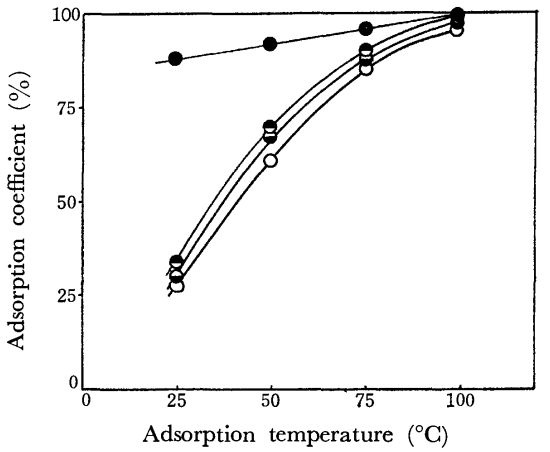

Fig. 9. Adsorption coefficient at various adsorption temperature (Comparison between different calcination temperature about $Cu_{1-2}S$).
Calcination temperature, ●: 250 °C, ◓: 300 °C, ◒: 400 °C, ○: 500 °C.

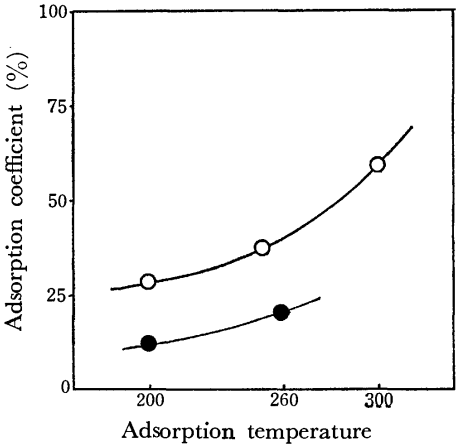

Fig. 10. Comparison of sulfur adsorption coefficient of FeS_{1-2} between different calcination temperature of 540 (○) and 800 °C (●).

sulfur adsorption were calculated from the adsorption kinetics of copper sulfides calcined at 400 and 500 °C and of iron sulfides calcined at 540 and 800 °C. The Arrhenius plots of sulfur adsorption on copper and iron sulfides are shown in Figs. 11 and 12, respectively. The activation energies of copper sulfides are 12.7 and 9.7 kcal/mol for the two calcination temperatures. The results show that the sample calcined at 400 °C is more stable than the one calcined at 500 °C. This suggests that the thermally decomposed sample which is more stable on thermal decomposition is less active for the reverse reaction, that is, sulfur adsorption. The specific surface area is an important factor for the facility of sulfur adsorption. The crystal strain or distortion seems to influence the sulfur adsorption. In order to estimate the effect of the surface area on reactivity, the activity of partially decomposed sulfide was defined as the product of unit formula weight per specific surface area and reciprocal of activation energy. The values estimated for copper sulfides calcined at 400 and 500 °C are 1.73×10^{-6} and 1.83×10^{-6} mol²/kcal·m², respectively. This suggests

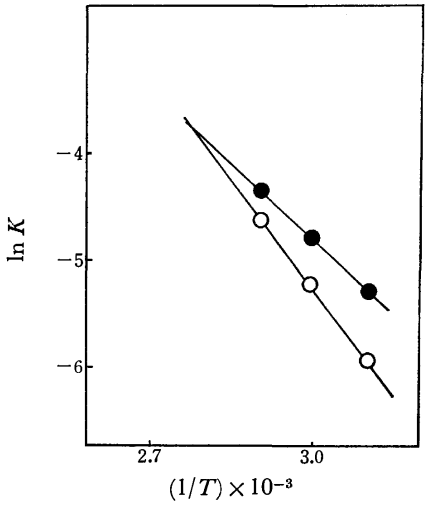

Fig. 11. Arrhenius plots of sulfur adsorption rates of $Cu_{1.80}S$, (○, calcined at 400 °C) and $Cu_{1.96}S$, (●, calcined at 500 °C).

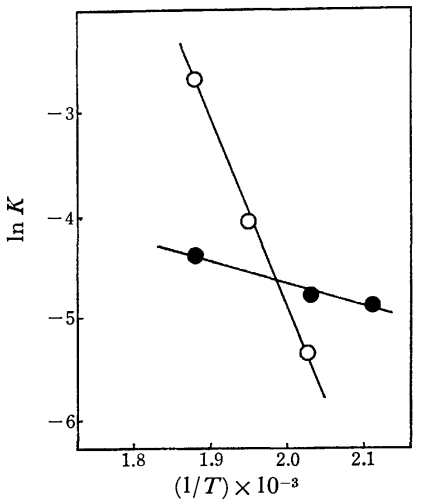

Fig. 12. Arrhenius plots of sulfur adsorption rates of $Fe_{0.64}S$ (○, calcined at 540 °C) and $Fe_{1.02}S$ (●, calcined at 800 °C).

that the sample calcined at 400 °C (cubic $Cu_{1.80}S$) is more stable than that calcined at 500 °C (mixed structure of cubic and tetragonal). Arrhenius plots of sulfur adsorption on iron sulfides calcined at 540 and 800 °C are shown in Fig. 12. The activation energies are 36.9 and 4.3 kcal/mol, respectively. This suggests that different adsorption mechanisms exits for the two species of iron sulfides. The sample calcined at 800 °C, in which the number of empty sites for bonding sulfur is large, has a low activation energy for the sulfur adsorption. This suggests that the diffusion of sulfur vapor is the rate-determing step in the adsorption kinetics.

Comparison with Active Carbon Used. The sulfur adsorbed on active carbon was washed out completely with CS_2. The amount of adsorbed sulfur was negligible. In the case of thermally decomposed copper sulfides the bond between sulfur and copper is chemical, but not that between sulfur and carbon.

Sulfur Adsorption in Heavy Oil on Thermally Decomposed Sulfide. A comparison of the sulfur contents and the desulfurization percentage of heavy oil by different treatment is given in Table 2. The heavy oil oxidized only with SO_2 has a higher sulfur content 1.61%, its desulfurization percentage being negative (−13.4%). The heavy oil washed with 5% H_2O_2 shows a 1.25% sulfur content decrease, the desulfurization percentage increasing by 12%. Asdorption on thermally decomposed copper sulfide ($Cu_{1.96}S$) gave the lowest sulfur content (1.13%) and the highest desulfurization percentage (20.4%). Results of a blank test without SO_2 gas treatment are given in Table 3. Adsorption by $Cu_{1.96}S$ as an adsorbent indicates 1.43% sulfur, almost the same value as in the case of no treatment. A comparison of the data given in Tables 2 and 3 shows the obvious effect of SO_2 on desulfurization. However, at 300 °C in an autoclave the sulfur content shows a slight decrease (Table 3). In copper sulfide after adsorption treatment partial existence of Cu(II)S was observed by means of X-ray diffraction (Table 2). It seems that the thermally decomposed copper sulfide does not react with sulfur compounds in heavy oil, but reacts with the free sulfur formed by SO_2 oxidation in heavy oil. The desulfurization percentage 20% is low for practical use. However, a higher percentage is expected by selection of temperature, pressure, mixing mole ratio, and by repetition of SO_2 oxidation and adsorption.

Table 2. Comparison of desulfurization percentage between two different treatments of B-class heavy oil being oxidized with SO_2 gas in autoclave

Treatment	Sulfur content (%)	Desulfurization percentage
No treatment	1.61	−13.4
Washing out with 5% H_2O_2	1.25	+12.0
Adsorption by $Cu_{1.96}S$	1.13	+20.4

Table 3. Blank test without SO_2 gas treatment

Treatment	Sulfur content (%)
No treatment (starting B-class heavy oil)	1.42
Washing out with 5% H_2O_2	1.24
Adsorption by $Cu_{1.96}S$ at atmospheric pressure	1.43
Adsorption by $Cu_{1.96}S$ with heating in micro-autoclave	1.37

The author wishes to express his thanks to Profs. K. Matsuoka and J. Yamasaki for valuable suggestions and to Messrs. S. Kanahara, M. Okazaki, M. Horibe, T. Kuroki, and A. Ishihara for their assistance.

Solvochromism and Thermochromism of Cobalt(II) Complexes Solubilized in Reversed Micelles

Junzo SUNAMOTO* and Tomiko HAMADA

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received March 2, 1978)

Configurational change takes place between tetrahedral and octahedral species, when cobalt(II) complexes are cosolubilized in reversed micelles formed by the cationic or ampholytic detergents in chloroform. This is accompanied by the elimination-addition reaction of ligand water from and to the metal ion in the reversed micellar core. The phenomenon is interpreted in terms of solvochromism and thermochromism. The nature and state of "*naked*" metal ion and "*free*" water molecule afforded in a highly restricted field of reversed micelles have been discussed on the basis of equilibrium constants and thermodynamic parameters for the configurational change, particular attention being given to the structure of micelles. Their resemblance to the active site of metalloenzymes is also discussed.

The resemblance of reversed micelles to hydrophobic pockets of enzymes or biomembranes has attracted much attention.[1] One of specific features of the reversed micelles is that some reversed micelles can solubilize a considerably large amount of water in their interior cores. Earlier works on fluorescent properties,[2] relaxation mechanisms in NMR,[3] electronic spectra,[4] and kinetics of reactions occurring in the micellar core[5] have demonstrated that the nature of water solubilized in reversed micelles differs a great deal from that of ordinary bulk water. Careful survey of these studies aroused our interest to investigate the properties of water in various reversed micelles paying particular attention to the coordination chemistry and metal ion catalysis. Elimination and addition of water molecules from and to the metal ion cosolubilized in the reversed micelles should be closely related to the nature of water present in a highly restricted field.

Cobalt(II) ion is only one of d^7 transition metal ions which show relatively easy octahedral-tetrahedral configuration change accompanied by the addition-elimination of ligands.[6] An octahedrally coordinated cobalt(II) ion should have three spin allowed d-d transitions, which are from the ground state, $^4T_1(F)$, to the states $^4T_2(\nu_1)$, $^4A_2(\nu_2)$, and $^4T_1(P)(\nu_3)$. The visible absorption of hexaaquacobalt(II) ion, $[Co(H_2O)_6]^{2+}$, is weak and the aqueous solution shows pale pink color. On the other hand, the visible absorption band of tetrahedrally coordinated cobalt(II) ion lies in the red part of the spectrum, giving intense blue color. This absorption band stems from the d-d transition from the $^4A_2$ ground state to the $^4T_1(P)$ state, and its fine structure results from spin-orbit coupling.[7] The octahedral-tetrahedral configuration change takes place in two ways. When cobalt(II) chloride is dissolved in water, octahedrally coordinated ion is formed. In alcohols or acetone, a blue color due to the tetrahedral species, $CoCl_2L_2$, is observed.[8,10c] This is interpreted in terms of the solvochromic effect. On the other hand, Swift and Connick found evidence of a tetrahedral species, $[Co(H_2O)_4]^{2+}$, near 100 °C by NMR relaxation studies.[9] Aqueous solutions of cobalt(II) chloride and bromide show a reversible color change from pink to violet in the temperature range 100—200 °C.[10] This was discussed in terms of the thermochromic effect.

Wells obtained an interesting result on the interior water pool of phosphatidylcholine micelles in ether by use of cobalt(II) chloride, attention being given to the correlation between the nature of bound water and the activity of phospholipase A_2 on the membrane surfaces.[11] In this work, we have studied the solvochromic and thermochromic behavior of the cobalt(II) complexes and the properties of bound and free water in the restricted field formed by various reversed micelles.

Experimental

Materials. Analytical grade samples of cobalt(II) chloride $CoCl_2 \cdot 6H_2O$, (Wako Pure Chemical Ind. Ltd.) and nitrate, $Co(NO_3)_2 \cdot 6H_2O$, (Nakarai Chemicals Ltd.) were used without further purification. The concentrations of their aqueous solutions were determined by the usual procedures with EDTA.

Commercial hexadecyltrimethylammonium bromide (CTAB)[12] and sodium 1,2-bis(2-ethylhexyloxycarbonyl)-1-ethanesulfonate (AOT)[13] were purified by recrystallization. Dodecylammonium propionate (DAP) was prepared and purified.[14] *N,N*-Dimethyl-*N,N*-dioctadecylammonium chloride (QD) was supplied by the Tokyo Institute of Kao Soap Co., Ltd. Egg lecithin was extracted from egg yolk and purified.[15]

Reagent grade chloroform was distilled and stored over a Linde type 4A molecular sieve, the water content of which being less than 4 ppm. Chloroform was chosen as the solvent since it is the only solvent which affords the completely homogeneous systems of reversed micelles cosolubilizing water and cobalt(II) complexes.

Spectrophotometric Measurements. All the visible and near infrared spectra were measured on a Hitachi 323 or Hitachi 124 recording spectrophotometer equipped with a thermoregulated cell compartment. Three milliliters of the detergent solution (about 0.20 M, M = mol dm^{-3}) in chloroform was placed in a cuvette. After the injection of 3.0 μl of aqueous cobalt(II) solution (about 3.0 M) into the cell, it was shaken on a Vortex mixer and kept in the thermostatted cell compartment for 20 min to attain equilibrium.

Results and Discussion

Solvochromic Effect. In aqueous solution the cobalt(II) ion is octahedrally complexed with water to afford $[Co(H_2O)_6]^{2+}$, giving pink coloration to the

solution. When the concentrated aqueous solution of $CoCl_2$ or $Co(NO_3)_2$ is injected into the solutions of certain detergents in chloroform, it is readily dissolved, giving intense blue or violet solutions. Their visible spectra differ with detergent. When the cobalt(II) ion is cosolubilized in the DAP reversed micelles, the coloration is violet, while in the CTAB or QD micelles it is intensely blue. However, in AOT micelles, no color change from pink to blue is observed due to the cosolubilization of the cobalt(II) ion. In the anionic reversed micelles such as AOT, it is possible that the detergent molecules themselves coordinate to the metal ion forming stable octahedral complexes. The spectra in different reversed micelles are shown in Figs. 1 and 2. Spectral data are summarized in Table 1 for cobalt(II) chloride and nitrate.

The visible spectra of the cobalt(II) complexes in the CTAB or QD reversed micelles closely resemble those for the tetrahedral complex, $[CoX_4]^{2-}$, as reported by Cotton and his co-workers.[7] These cationic detergents carry halogen as counter anions. Thus the species formed in the micellar core may be $[CoBr_4]^{2-}$

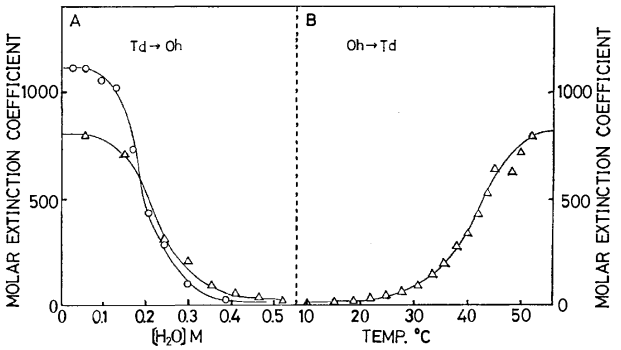

Fig. 3. The solvochromic effect with water (A) and thermochromic effect (B) for the configurational change of cobalt(II) complexes in the CTAB reversed micelles. —○—; $Co(NO_3)_2$, —△—; $CoCl_2$.

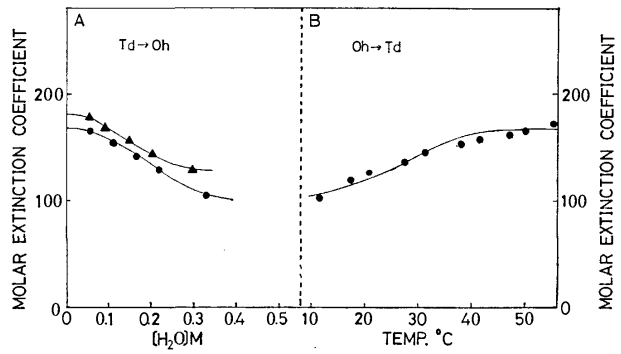

Fig. 4. The solvochromic effect with water (A) and thermochromic effect (B) for the configurational change of cobalt(II) complexes in the DAP reversed micelles. —▲—; $CoCl_2$, —●—; $Co(NO_3)_2$.

in the CTAB micelles and $[CoCl_4]^{2-}$ in the QD micelles. However, in view of the slight difference between the visible spectra of cobalt(II) chloride and nitrate in the CTAB micelles, we can not disregard the possibility of the coexistence of other mixed complexes[10c] such as $[Co(NO_3)_2Cl_2]^{2-}$, $[Co(NO_3)_2Br_2]^{2-}$, or $[CoCl_2Br_2]^{2-}$. The structures of complexes formed in each case can not be clarified at present. Contrary to what would be expected from the cloud expanding effect of ligands, halide ions are more strongly coordinating to the metal ion pushing away water molecules in the reversed micellar core.[16] This would be responsible for the effect of the very restricted field of the reversed micelles. Antipora-Karataeva and Vainshtein observed a similar phenomenon in different solvents such as methanol, ethanol, acetone, and ethyl methyl ketone, and pointed out the importance of chloride ion since solutions of $Co(NO_3)_2$ never become blue.[17] We found that even nitrate shows exactly the same phenomenon as that observed with chloride (Figs. 1 and 2).

When water is added to the reversed micelles cosolubilizing metal ions, the blue or violet color fades as reflected by the decrease in the molar absorbancy of the tetrahedral complex. Finally the solution becomes pale pink again, indicating the reproduction of an octahedral species. This configurational change from the tetrahedral complex to the octahedral one causes the spectral change with isosbestic points. As seen in Figs. 3-A and 4-A, configurational changes occur sigmoidally with water concentration. With both DAP and CTAB micelles, inflection points were observed around the point where the molar ratio of water to the detergent molecule is about unity. Inflection was more enhanced in the cationic CTAB reversed micelles than in the DAP micelles. The most plausible mechanism for the phenomena can be interpreted by the "two step hydration mechanism."[3,11] When water is first introduced into the reversed micelles, water tends to interact more strongly with the polar head group of the detergent rather than with the metal ion. Upon completion of the first hydration in the micellar core, water molecules start to coordinate to the metal ion, affording a octahedral complex with a concomitant decrease in intensity in red region of visible spectra. The strength of interaction of water in the first hydration stage with detergents should be affected by the kind of detergent molecule. Water molecules in the second hydration stage would behave differently from those of the first, *i.e.*, those tightly bound to detergents. The hydrolysis of norleucine *p*-nitrophenyl ester was significantly promoted by the copper(II) ion in the AOT reversed micelles.[18] The catalytic effect becomes maximum at the point where the water content is almost equivalent to the detergent concentration. When water concentration is less than that at the maximum, the formation constants of the complex between the copper(II) ion and substrate are surprisingly large ($\log K_f$=8—9 at 25 °C). At the maximum of catalytic effect in the reversed micelles, nucleophilic rate constants with water k_{H_2O} increase by about 10^3-fold as compared with those in bulk water.[18] This is closely related to the configurational change of metal complex in the reversed micelles. During the course of first hydration stage, the metal ion can easily form a complex with the substrate ester using vacant coordination sites of the metal ion. In the second hydration stage, water molecules start to coordinate to the metal ions or attack the substrate activated on complex formation with the metal ion. The "free" water molecules should be very reactive. The water further added in the second hydration stage finally tends to resemble pure bulk water.[3,11] A similar conclusion regarding the state of water in the AOT reversed micelles has recently been attained by Wong and his co-workers in NMR relaxion studies of water.[3]

Thermochromic Effect. When the pink solution was warmed after the completion of second hydration in the reversed micellar sphere, the intensely blue color appeared again. The thermochromism looks like a mirror image of the solvochromism shown in Fig. 3. The configurational change between the tetrahedral and octahedral complexes with temperatures was certainly reversible; upon cooling the solution, the original pink color appeared again. It is noteworthy that in the reversed micellar systems the reversible change of configuration occurs even at 10—60 °C, while much higher temperatures are necessary in aqueous solutions.[9,10]

Evaluation of Equilibrium Constant. The configu-

TABLE 2. EQUILIBRIUM CONSTANTS AND THERMODYNAMIC PARAMETERS FOR THE CONFIGURATIONAL CHANGE OF THE COBALT(II) COMPLEXES IN REVERSED MICELLES

In DAP reversed micelles;

$$\underset{T_d}{CoL_2X_2} + 2L \overset{K_1}{\rightleftharpoons} \underset{O_h}{CoL_4X_2}$$

$\ln K_1 = 1.17 \pm 0.18$ (25 °C) for chloride
$\ln K_1 = 1.10 \pm 0.06$ (25 °C) for nitrate
$\Delta G^0 = -0.69 \pm 0.11$ kcal mol^{-1}
$\Delta H^0 = -10.8 \pm 0.3$ kcal mol^{-1}
$\Delta S^0 = -33.6 \pm 1.0$ e.u.

In CTAB reversed micelles;

$$\underset{T_d}{[CoX_4]^{2-}} + 2L \overset{K_2}{\rightleftharpoons} \underset{O_h}{[CoX_4L_2]^{2-}}$$

$\ln K_2 = 6.64 \pm 0.50$ (25 °C) for nitrate
$\ln K_2 = 6.23 \pm 0.22$ (25 °C) for chloride
$\Delta G^0 = -3.69 \pm 0.13$ kcal mol^{-1}
$\Delta H^0 = -27.2 \pm 0.7$ kcal mol^{-1}
$\Delta S^0 = -72.2 \pm 2.2$ e.u.

rational change of the cobalt(II) complexes in the reversed micelles can be classified as follows.

(I) In the DAP micelles:

$$\underset{T_d}{CoL_2X_2} + 2L \overset{K_1}{\rightleftharpoons} \underset{O_h}{CoL_4X_2}, \quad (1)$$

where L is water and X is the halide ions or NO_3^-.

(II) In the CTAB micelles:

$$\underset{T_d}{[CoX_4]^{2-}} + 2L \overset{K_2}{\rightleftharpoons} \underset{O_h}{[CoX_4L_2]^{2-}}. \quad (2)$$

In the CTAB or QD micelles, other mixed complexes such as $[CoX_2Y_2]^{2-}$ or $[CoX_2Y_2L_2]^{2-}$ may be formed. Even if this is the case, the equilibrium of addition-elimination of water will be essentially similar to Eq. 2. Equilibrium constants K_1 and K_2 for the addition reactions (Eqs. 1 and 2) could be calculated by the procedure of Sacconi *et al.*[19]

$$K_1 = \frac{[CoL_4X_2]}{[CoL_2X_2][L]^2} \quad (3)$$

$$K_2 = \frac{[CoX_4L_2{}^{2-}]}{[CoX_4{}^{2-}][L]^2} \quad (4)$$

Modifying these we get the following equation which will be valid for different water concentrations:

$$\ln \frac{1-\alpha}{\alpha} = \ln K - 2 \ln [L]_f, \quad (5)$$

where α is the fraction of the tetrahedral complex of the total concentration of cobalt(II) ion adopted and $[L]_f$ is the concentration of the "free" ligand, the difference between the concentration of water initially added and twice the concentration of the adduct, the octahedral species. Figure 5 shows the reliability of equilibria 1 and 2. The maximum of the $\approx$17200 cm^{-1} band of the tetrahedral complexes was used for the concentration measurement. Corrections for the overlap by the absorption of the octahedral complexes are negligible because of the very much smaller molar extinction coefficients of the octahedral complexes (Table 1). From a comparison of the respective equilibrium constants for the two different types of micellar systems (Table 2), it seems that the second hydration occurs more easily in the CTAB reversed micelles than in the DAP micelles.

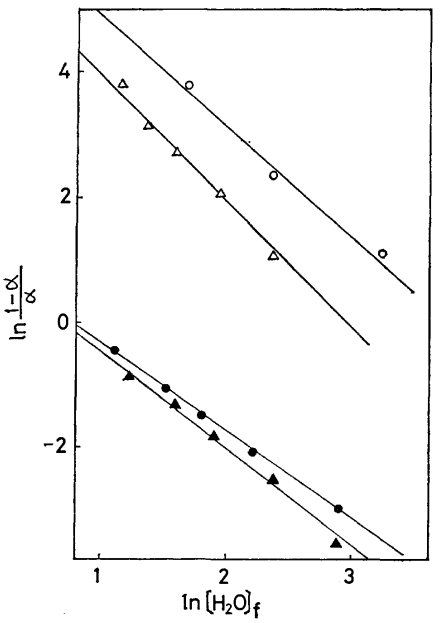

Fig. 5. Plots of $\ln (1-\alpha)/\alpha$ against $\ln [H_2O]_f$ related with the Eq. 5 in the text; $Co(NO_3)_2$(○) and $CoCl_2$(△) in the CTAB reversed micelles; $Co(NO_3)_2$(▲) and $CoCl_2$(●) in the DAP reversed micelles.

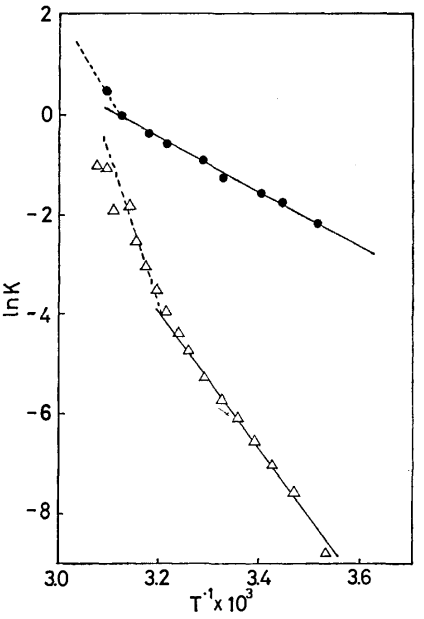

Fig. 6. Plots of $\ln K$ against $1/T$ for the thermochromism in the DAP reversed micelles cosolubilizing $Co(NO_3)_2$(●) and in the CTAB reversed micelles cosolubilizing $CoCl_2$(△).

The standard molar thermodynamic parameters are evaluated by means of the usual relationships $\Delta G^0 = -RT \ln K = \Delta H^0 - T \cdot \Delta S^0$ using the data of thermo-

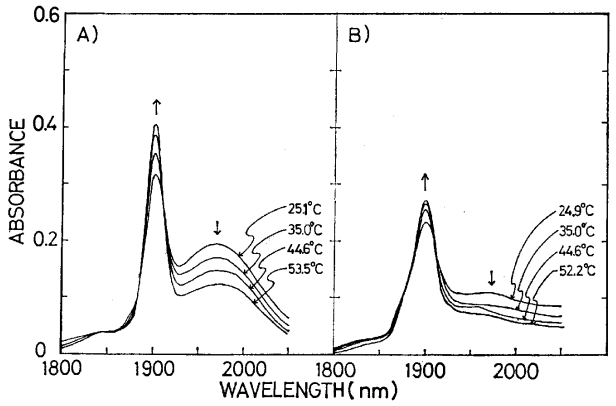

Fig. 7. The temperature effect on the near infrared spectra of water (0.203 M) solubilized in the 0.20 M CTAB (A) and in the 0.20 M DAP (B) reversed micelles formed in chloroform at different temperatures.

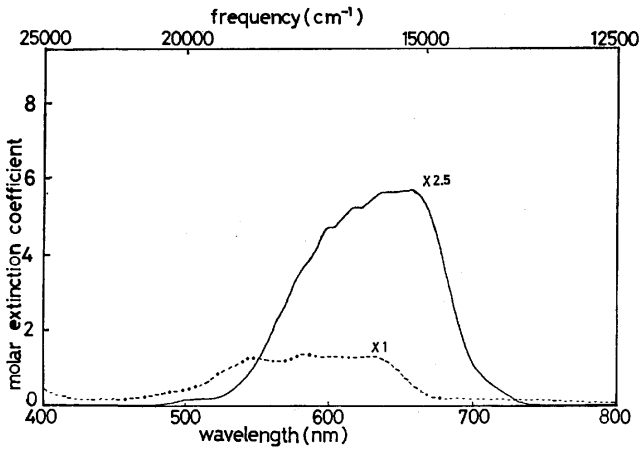

Fig. 8. Visible spectra of $CoCl_2$(——) and $Co(NO_3)_2$ (----) cosolubilized in the egg lecithin reversed micelles at 25 °C.

chromism for the configurational change. The results are given in Fig. 6 and parameters evaluated in Table 2. The data indicate that the addition reaction of water on the tetrahedral complex to afford the octahedral one is energetically more favorable in the CTAB micelles than that in the DAP micelles ($\Delta\Delta H^0 \fallingdotseq 16$ kcal mol^{-1}). On the basis of unfavorable entropy, on the other hand, we can imagine that the CTAB micelles may provide the more rigid hydration shell than the DAP micelles ($\Delta\Delta S^0 \fallingdotseq 38$ e.u.). Negative values of ΔG^0 are essential to form the more stable octahedral complexes. The values of parameters strongly resemble those obtained for the configurational equilibrium[10c] between Co(isoquinoline)$_2$Cl$_2$ and Co(isoquinoline)$_4$Cl$_2$,[20] Co(py)$_2$X$_2$ and Co(py)$_4$X$_2$[21,22] in chloroform, or $[Co(H_2O)_4]^{2+}$ and $[Co(H_2O)_6]^{2+}$ in aqueous solution.[23] Plots of $1/T$ against $\ln K$ indicate the presence of two energetically distinct equilibria. It was more obvious in the CTAB reversed micellar systems. The equilibrium in the partition of water molecules between the micellar core and bulk phase may play a role.

The near infrared spectra of water in the CTAB and DAP reversed micelles were determined over the range 1800—2000 nm. The water solubilized in the reversed micelles shows a relatively sharp band at 1902 nm and a broad band around 1970—1980 nm. The former band is ascribed to the free water dispersed in the bulk phase, and the latter to the water strongly bound to detergent molecules.[24] With temperature rise from 25 to 55 °C, the intensity of the band of free water increases, while that of the bound water decreases (Fig. 7). Rise in temperature causes the increase in the mobility of the water molecule encapsulated in the micellar core, resulting in easier dispersion into the bulk phase of organic solvent. The temperature effect on the equilibrium depends on the kind of micelle. It is more drastic in the CTAB micelles than in the DAP micelles. The results are in line with those observed in the thermochromism of the cobalt(II) complexes. The infrared spectra of the CTAB micellar system are sharper, relative amounts of bound water in the micellar core to those of free water in bulk appearing to be larger in the CTAB micelles than in the DAP ones.

The IR data might reflect the fact that in the micellar sphere the water interacts more strongly with CTAB than with DAP. The behavior of water molecules in the micelles closely correlates with the thermochromism and solvochromism of the cobalt(II) complexes.

Egg Lecithin Reversed Micelles. In all the reversed micelles except for egg lecithin micelles, no specific difference was observed in visible spectra between the chloride and nitrate. In the egg lecithin reversed micelles, however, there is much difference, especially in absorption maximum, as shown in Fig. 8. When cobalt(II) chloride was cosolubilized in the egg lecithin micelles, it gave a blue solution with a broad absorption at 620—670 nm, which was identical with the result in the phosphatidylcholine micelles obtained by Wells.[11] When nitrate was introduced into the same micelles, on the other hand, the broad absorption was observed at 540—640 nm range, its molar absorptivity being relatively small. In both cases, however, solvochromism and thermochromism were observed, though not distinctly.

We might conclude that in a very restricted field formed by reversed micelles, specifically reactive water molecule and "*naked*" metal ion can be afforded, where the situation resembles the hydrophobic pocket of metalloenzymes.

Monolayer Properties of Mixtures of Poly(octadecyl methacrylate) and Poly(butyl methacrylate) and Their Corresponding Copolymers†

Satoshi Yoshikawa,* Minoru Ueno, and Kenjiro Meguro
Department of Chemistry, Faculty of Science, Science University of Tokyo, 1-3 Kagurazaka, Shinjuku-ku, Tokyo 162
(Received March 10, 1978)

The monolayer properties of mixtures of poly(octadecyl methacrylate) and poly(butyl methacrylate) have been compared with those of their corresponding copolymers of octadecyl methacrylate and butyl methacrylate, using the measurements of their surface pressure-area isotherms at the air/water interface at 20 °C. The results showed that the isotherms of the mixed monolayers had three break points, and the surface pressures of the lower two break points agreed with those of poly(butyl methacrylate). This suggests that at lower surface pressures, the mixtures of the two homopolymers are compatible in a bidimensional state when each phase contains a small amount of the other homopolymer, and otherwise these are incompatible, while at higher surface pressures, up to 70 segment mol% of poly(octadecyl methacrylate) they are incompatible and above 80%, they are compatible. The copolymers showed characteristic isotherms different from those of the mixtures. The properties of the copolymers in the bidimensional state are affected by variations in the vitrified, liquid, or crystalline states with an increase in the mean lengths of the side chains in the three-dimensional state.

Monolayer studies of polymer mixtures or of copolymers of two kinds of monomers have been reported by many authors.[1–10] Kargin *et al.*[1] investigated the monolayer properties of the copolymers of methyl acrylate and hexadecyl acrylate in order to study the influence of the side chain at the air/water interface. Isemura *et al.*[2] showed that surface pressure-area isotherms of the copolymer monolayers of vinyl acetate and vinyl stearate above 50% of vinyl stearate content were almost consistent with the isotherm of poly(vinyl stearate), due to the strong cohesive interaction of octadecyl groups.

However, there have been few studies[3] about the difference of monolayer properties between copolymerized substances from two kinds of monomers, one of which has very long side chains and the other short ones, and mixtures of the corresponding two pure homopolymers.

In this paper, we have studied the monolayer properties of the mixtures of poly(octadecyl methacrylate) and poly(butyl methacrylate) (abbreviated as POMA and PBMA, respectively) and those of the copolymers of octadecyl methacrylate and butyl methacrylate (abbreviated as OMA and BMA, respectively) by surface pressure measurements. Further, the compatibility of the mixtures and the transition of the copolymers at a bidimensional state will also be discussed.

Experimental

Materials. OMA and BMA were supplied by Kyoei Oil Chemical Co., Ltd. These monomers were purified by reduced pressure distillation (nitrogen atmosphere). POMA, PBMA, and the various corresponding copolymers (abbreviated as COP OB-*n* for copolymer; *n*=segment mol % of OMA) were prepared by radical polymerization at 60 °C under a nitrogen gas flow. α,α′-Azobisisobutyronitrile was used as the initiator and benzene as the solvent. The products were purified by repeated precipitation from their benzene solutions into a large excess of methanol. The purified polymers were dried by the refrigeration method, and then the trace solvent was removed *in vacuo* at room temperature. The average molecular weights of these polymers were determined by viscosity measurements. Their average molecular weights were about 3.85 and 1.22×10^5 (g/mol) for POMA and PBMA, respectively. The composition ratios of the copolymers calculated from the results of the elemental analyses are listed in Table 1 with those of the mixtures (abbreviated as MIX OB-*m* for mixture; *m*=segment mol % of OMA).

Measurements. A modified Wilhelmy-type film balance was used to measure the surface pressure. The apparatus was enclosed in a chamber to allow thermostatic control at 20.0±0.5 °C. The water in the though was kept at 20.0±0.5 °C by circulating the water from the thermostat bath. The trough and the glass barriers were carefully coated with parafin wax. The distilled water used as the substrate had a pH of 5.0—6.0 at 20 °C. The monolayers of two homopolymers and corresponding copolymers were spread on the distilled water from their benzene solutions

Table 1. The composition ratios of copolymers and mixtures

Copolymer	Composition ratio/(segment mol %)	
	OMA	BMA
PBMA	—	100.0
COP OB-20	20.3	79.7
COP OB-45	45.3	54.7
COP OB-63	63.2	36.8
COP OB-82	82.0	18.0
POMA	100.0	—
Mixture	**POMA**	**PBMA**
MIX OB-10	10.0	90.0
MIX OB-20	20.0	80.0
MIX OB-30	30.0	70.0
MIX OB-40	40.0	60.0
MIX OB-50	50.0	50.0
MIX OB-60	60.0	40.0
MIX OB-70	70.0	30.0
MIX OB-80	80.0	20.0
MIX OB-90	90.0	10.0

† A preliminary report of this work was presented at the 34th National Meeting of the Chemical Society of Japan, Hiratsuka, April 1976.

(0.07 g polymer/100 ml) with an Alfa micro syringe. Thirty minutes were allowed for the solvent to evaporate before the start of film compression. The initial spreading area was 1100 (cm^2)/0.035 (mg). The rate of compression was 20.0 (cm^2/min). The measurement of the surface pressure was done at more than 5 min after the stop of every short compression so that the equilibrium was attained. The results were reproducible within the range of experimental errors.

Results and Discussion

1. Surface Pressure-area Isotherms of Pure and Mixed Polymer Monolayers. The surface pressure-area isotherms obtained for the monolayers of POMA, PBMA, and nine pairs of their mixtures with various ratios from 10 to 90 segment mol % of OMA on the water at 20 °C are shown in Fig. 1. The isotherm for POMA exhibited a collapse at high surface pressure of 52.6 (dyn/cm). On the other hand, the isotherm for PBMA exhibited two break points, corresponding to a transition and a complete collapse, at 14.3 and 16.7 (dyn/cm), respectively. POMA and PBMA monolayers gave the limiting areas of 24.8 and 32.8 (Å^2/residue), respectively, and formed a solid-condensed film and a liquid-condensed one, respectively. The monolayer properties characteristic of pure POMA and PBMA obtained here were in rather fair agreement with those obtained by Nakahara *et al.*[11,12] and Wu and Huntsberger,[4] respectively. The isotherms for the mixtures of two homopolymers, shown in Fig. 1, showed shapes similar to those of both POMA and PBMA, and exhibited three break points corresponding to transition or collapse at pressures of about 14, 17, and 44—52 (dyn/cm). For convenience, the three break points are denoted here as (A), (B), and (C) in the order of increasing pressures. Break points (A) and (B) were almost consistent with those for PBMA corresponding to the transition and the collapse at 14.3 and 16.7 (dyn/cm), respectively. On the other hand, break point (C) was located between the collapse pressures of the POMA and the PBMA isotherms. Three break points (A), (B), and (C) of the isotherms for the mixtures can be found clearly at each constant surface pressure up to 70 segment mol % of OMA, as shown in Fig. 2.

On the other hand, the isotherms for the MIX OB-80 and -90 did not show break points (A) and (B) but exhibited only one break point (C) corresponding to the collapse at higher surface pressures, as shown in Fig. 2; the values for their break point (C) increased along the ideal dotted line with an increase in the composition ratios of OMA. Crisp[5] has reported as a bidimensional phase rule that if two components are compatible in the monolayer, the surface pressure of the break point is dependent on the composition, and otherwise it is independent of the composition. It may be supported by this rule that, at higher surface pressures, the mixtures of POMA and PBMA are nearly incompatible up to 70 segment mol % of OMA, while they are compatible above 80% in the bidimensional state, as shown in Fig. 2. Such a phenomenon for the incompatible mixtures has also been reported by Gabrielli[6] and Wu and Huntsberger.[4]

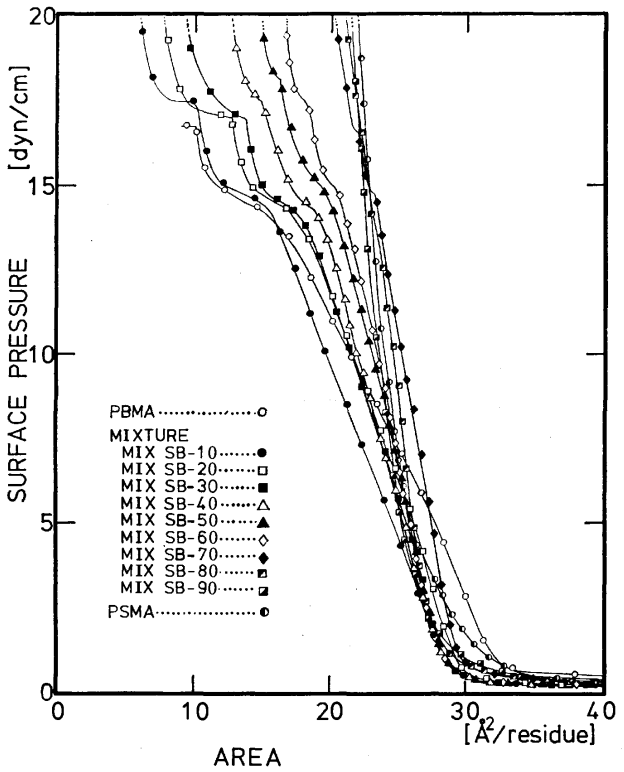

Fig. 1. Surface pressure-area isotherms of PSMA, PBMA, and their mixtures on distilled water at 20 °C.

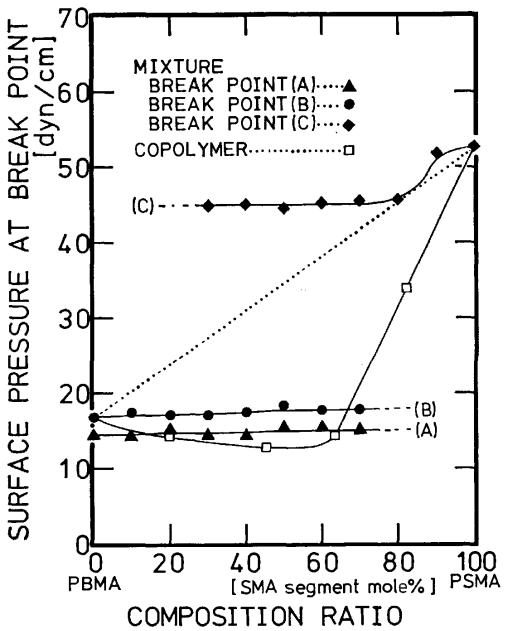

Fig. 2. Surface pressures at break points of copolymers (□) and mixtures (▲, ●, ◆) as a function of composition ratio.

In order to find the precise properties of the mixed monolayers in lower surface pressures, their limiting areas are plotted against the segment molar ratios of POMA in Fig. 3. The limiting areas for the mixtures containing a very small amount of POMA in PBMA exhibited intermediate values between those of POMA and PBMA, and then decreased

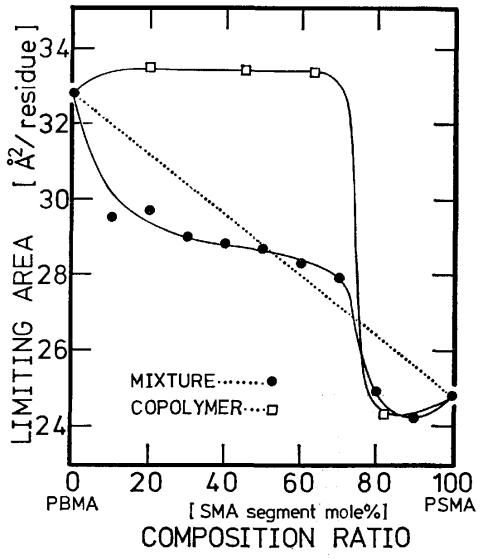

Fig. 3. Limiting areas of copolymers (□) and mixtures (●) as a function of composition ratio.

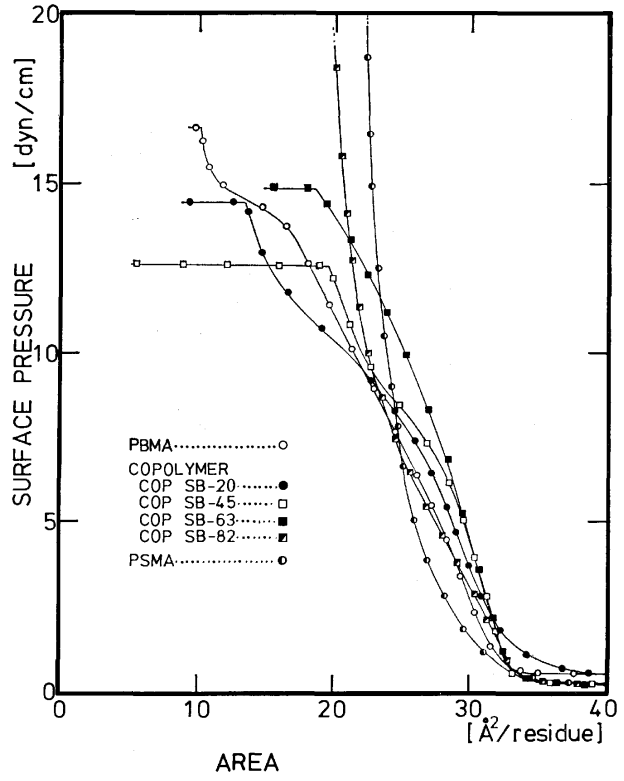

Fig. 4. Surface pressure-area isotherms of PSMA, PBMA, and copolymers of SMA and BMA on distilled water at 20 °C.

slightly with an increase in composition ratios of POMA up to 70 segment mol %. On the other hand, above 80%, their values were almost the same as that of POMA. These results imply that the mixtures containing small amounts of POMA are compatible in a bidimensional state at lower surface pressures, and become gradually incompatible with an increase in composition ratios of POMA up to 70 segment mol %, even at lower surface pressures, as shown in Fig. 3. These findings suggest that the mixed monolayers are gradually separated into one POMA rich film and another PBMA rich one with an increase in surface pressure, and near the collapse pressure of PBMA (break point (B)) the PBMA rich films are squeezed out from the incompatible monolayers, and then the other POMA rich films collapse completely at break point (C).

On the other hand, above 80%, the mixtures are considered to form more stable and compatible films due to the intermolecular cohesive forces of the large amount of octadecyl groups in POMA, at both lower and higher surface pressures, as shown in Figs. 2 and 3.

2. Surface Pressure-area Isotherms of Copolymer Monolayers. The surface pressure-area isotherms for four copolymers with various composition ratios of OMA and BMA on the water at 20 °C are shown in Fig. 4, together with those of POMA and PBMA for comparison. Their isotherms of the copolymers had only one break point, corresponding to the break point (B) or (C) for the mixtures, as shown in Fig. 2, and showed very different shapes from those of binary mixtures of homopolymers. With increasing OMA content of the copolymers the surface pressures corresponding to the break point decreased and then the long plateaus appeared at the break point. Subsequently, above 50 segment mol % of OMA the surface pressures corresponding to the break point increased again rapidly and the plateau disappeared gradually.

Each isotherm of COP OB-20, -45, and -63 formed liquid condensed films, while that of COP OB-82 formed a solid one similar to that of POMA. On the other hand, at the three-dimensional state, PBMA exhibited a vitrified state, and COP OB-20, -45, and -63 exhibited liquid states, while COP OB-82 and POMA exhibited solid cristalline ones at 20 °C. These results suggest that the properties in the bidimensional state are affected by those in the three-dimensional state.

The changes of the monolayer properties of copolymers from liquid condensed to solid states can be seen clearly from the curve in Fig. 2. These results imply that the transition from liquid condensed films to solid ones occurs at about 70 segment mol % of OMA. This transition is also recognized in Fig. 3. Up to 70% of OMA, their limiting areas gave approximately the same values as that of PBMA (32.8 Å²/residue), but above 80% of OMA, COP OB-82 gave the same limiting area as that of POMA (24.8 Å²/residue). From these results, the monolayer of COP OB-82 is considered to form a strongly condensed film, due to the intermolecular and intramolecular cohesive forces among a number of octadecyl groups in the same molecules, and also to have properties similar to the mixture monolayer having the same composition ratio.

Nakahara *et al.*[12] have reported that the poly(*n*-alkyl methacrylate) series form many kinds of films at 20 °C, depending on their side chain lengths, such as liquid ones for poly(nonyl, dodecyl, and tetradecyl

methacrylate), a solid one for POMA, and an intermediate one between liquid and solid state for poly(hexadecyl methacrylate). As COP OB-20, -45, -63, and -82 have the mean lengths of the side chains corresponding to 6.8, 10.3, 12.8, and 15.5 carbon numbers, respectively, their isotherms suggest the changes of the monolayer properties from liquid condensed to solid state due to the difference of the mean lengths of their side chains.

The Study of Solutions of Alkali Halides in Acetone by Means of Vapor-pressure Osmometry and Conductometry

Ha Chung LEE and Yutaka MIYAHARA*
Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received March 13, 1978)

Vapor-pressure depressions and electric conductivities at 40.3 °C have been measured for LiCl, LiBr, NaI, KI, and RbI in acetone. The greatest care has been taken to minimize the contact of salts and their solutions with air. In order to account for the data of vapor-pressure osmometry (VPO) for lithium salts in acetone, the dissociation-association equilibria of the salts, MX, expressed as

$$M^+ + X^- \rightleftharpoons MX \rightleftharpoons 1/2(MX)_2$$

are proposed. The analysis of the conductance data of LiCl and LiBr, without considering the dimerization of the salts, leads to irrationally large values of the ionic association constants. For LiCl, NaI, and KI, VPO and conductometry give similar values of the dissociation constants, while for LiBr and RbI the agreement is not so satisfactory, though still within a factor of ten.

In a series of papers,[1-4] the vapor-pressure depression of various electrolytes in non-aqueous solutions has been measured by means of a vapor-pressure osmometer (VPO), and the concentration dependence of the activities of the salts has been analyzed, assuming the existence of a dissociation equilibrium.

In the first paper[1] (I) of this series, however, it has been reported that some lithium salts show an anomalous behavior in their acetone solutions. In order to account for it, it was assumed that an association equilibrium is present between the neutral salt molecules and their dimers.

In the present paper, the vapor-pressure depression of LiCl and LiBr in acetone is measured. Great care is taken to prevent moisture from coming in contact with the samples and their solutions, and measurements of the electric conductivity are also carried out in order to examine the existence of the dissociated ions. In order to account for the present data of VPO for lithium salts in acetone, an assumption of the existence of dissociation-association equilibria is proposed. Measurements of the VPO and conductometry for such salts as NaI, KI, and RbI are also made for the sake of reference.

Theoretical

When a salts, MX, dissolved in a non-aqueous solvent exhibits two-step equilibrium of dissociation and association as

$$M^+ + X^- \overset{K_d}{\rightleftharpoons} MX \overset{K_a}{\rightleftharpoons} 1/2(MX)_2 \qquad (1)$$

the Gibbs-Duhem equation becomes

$$\ln a_1 = -(1/N_1)(m_2+2m_4+m_d+2\int_0^{m_4} m_4 \, d\ln\gamma_4), \qquad (2)$$

$$\begin{aligned} m_3 &= m_4 = m\alpha, \\ m_2 &= m(1-\alpha-2\beta), \\ m_d &= m\beta, \end{aligned} \qquad (3)$$

where

a_1: the activity of the solvent,
N_1: the mole number of 1 kg of the solvent,
m: the molality of the salt as-a-whole,
m_2: the molality of undissociated or unassociated salt, MX,
m_3, m_4: the molalities of the M^+ and X^- ions, respectively,
m_d: the molality of the dimer, $(MX)_2$,
α, β: the degrees of dissociation and association respectively,
γ_4: the mean activity coefficient of the ions,
K_d: the equilibrium constant of dissociation,
K_a: the equilibrium constant of association.

In Eq. 2, the activity coefficients of MX and $(MX)_2$ are assumed to be unity. If we assume that the activity coefficients of the ions are represented by the Debye-Hückel limiting law, we obtain

$$2\int_0^{m_4} m_4 \, d\ln\gamma_4 = -\frac{4.604A}{3d_0}(\sqrt{m_4 d_0})\sigma(x), \qquad (4)$$

$$x = Ba_0\sqrt{m_4 d_0}, \qquad (5)$$

$$\sigma(x) = \frac{3}{x^3}\left\{(x+1) - \frac{1}{x+1} - 2\ln(x+1)\right\}. \qquad (6)$$

The notations in these equations are shown in the preceding paper[4] in detail. As in the previous papers, a function, h, defined as

$$h = \frac{N_1 \ln a_1}{m} + 1, \qquad (7)$$

was used for the analysis of the experimental results.

Experimental

Materials. LiCl, LiBr, KI, and RbI used were guaranteed pure-grade reagents supplied by the Merck Co., Ltd. (Germany). Before use, the salts were dried over a period of five days in a vacuum oven at 50 °C with molecular sieves 3 A (1/8 in. pellects). The molecular sieves were renewed each day. The dryness reached by this method was much the same as that obtained by heating in an oven at temperatures as high as 400 °C. The method used in preparing acetone, KCl, and conductivity water was the same as reported in the preceding paper.[4] To avoid the contact of salts and their solutions with moisture in the air, a dry box filled with nitrogen gas was used, as before.

Conductometry and Vapor-pressure Osmometry. The experimental methods were reported in the preceding paper[4] in detail. The measurements were made at 40.3 °C for

both methods.

Results and Discussion

The numerical values of h obtained by the VPO at 40.3 °C for the salts, NaI, KI, RbI, LiCl, and LiBr, are listed in Table 1, while the plots of h *vs.* the molality, m, are shown in Figs. 1 and 2. The profiles of the plots are similar to those reported in the preceding paper.[4] It should be noted, however, that the values of h for LiCl are positive at the concentrations higher than 3×10^{-3} mol kg^{-1}.

In the earlier paper (I), the values of h/m (not h) were plotted against m, and the curves obtained for LiCl and LiBr showed a tendency for h/m to increase with decrease in m at low concentrations. To account for this result, we assumed that an equilibrium

$$2MX \rightleftharpoons (MX)_2$$

prevails at these concentrations. According to this assumption,

$$\lim_{m\to0}\frac{h}{m} = K_a.^{8)}$$

In this paper, on the contrary, h tends to $-\infty$ at $m\to0$. This discrepancy is probably due to the in-

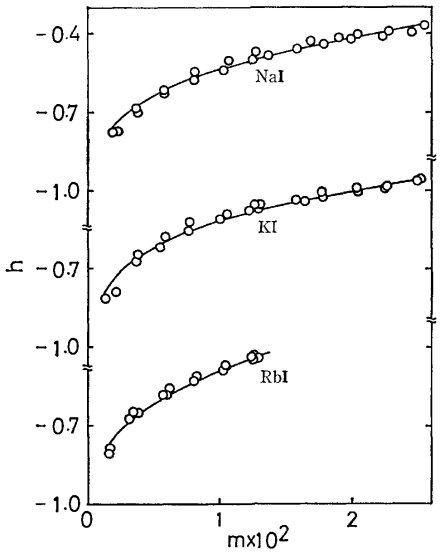

Fig. 1. Relationships between h and concentration for NaI, KI, and RbI at 40.3 °C.

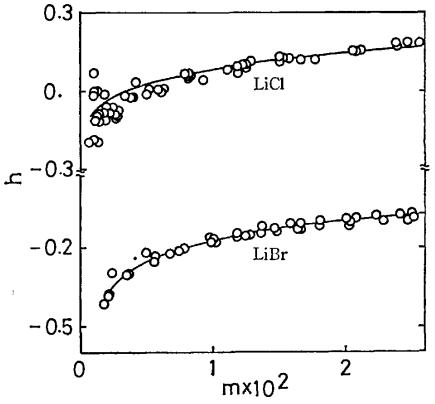

Fig. 2. Relationships between h and concentration for LiCl and LiBr at 40.3 °C.

complete drying of the lithium salts in the previous experiments.

In order to represent the experimental curves for LiCl and LiBr, we assume the two-step equilibria of Eq. 1. The dissociation equilibrium of the left-hand side is necessary in order to represent the shapes of curves at low concentrations, and the association equilibrium is inevitable to account for the fact that h is positive at moderate concentrations.

We have tried to estimate the most probable values of K_a and K_d by means of curve-fitting Eqs. 2, 3···, and 7. The curve-fitting was made by the method of non-linear least-squares. The results are shown in Table 2.

The measurements for NaI, KI, and RbI were also made for comparison. In the preceding paper,[4] the data were analyzed on the basis of the assumption that only the dissociation equilibrium exists, and the deviation from the ideality of undissociated molecules was taken in account. Similar analyses were carried out in the present investigation; the results are shown in Table 3, where β_2 is a parameter, given in the preceding paper, for compensating for the non-ideal behavior of the MX species in solution (not β in Eq. 3). The curves in Figs. 1 and 2 are theoretical ones calculated by the use of the parameters shown in the tables. The agreements with the experimental values are satisfactory.

Table 2. K_a and K_d for LiCl and LiBr (40.3 °C in molality scale)

	$K_d \times 10^3$	$K_a \times 10^3$	Standard deviation for the h function

			179.5	197.5 (6)
RbI	254.8	224.3		

Table 5. Comparison of dissociation constants by VPO and conductometry at 40.3 °C (in terms of molality)

	VPO	Conductometry
LiCl	0.00952×10^{-3}	0.00617×10^{-3}
LiBr	0.432×10^{-3}	0.253×10^{-3}
NaI	10.99×10^{-3}	8.31×10^{-3}
KI	8.64×10^{-3}	8.49×10^{-3}
RbI	10.00×10^{-3}	5.11×10^{-3}

The electric conductances of the acetone solutions of LiCl, LiBr, NaI, KI, and RbI were measured at 40.3 °C. The results were analyzed by the use of Shedlovsky's equation.[5] The parameters, K_A and Λ_0, in Shedlovsky's equation, as obtained from our experimental results, are shown in Table 4, where those at 25 °C found in the literature[6] are also given for comparison. Shedlovsky's equation is

$$\frac{1}{\Lambda S(z)} = \frac{1}{\Lambda_0} + \frac{C\Lambda f_\pm^2 S(z) K_A}{\Lambda_0^2}, \tag{8}$$

$$S(z) = \left\{\frac{S\sqrt{C\Lambda}}{2\Lambda_0^{3/2}} + \left[1 + \left(\frac{S\sqrt{C\Lambda}}{2\Lambda_0^{3/2}}\right)^2\right]\right\}^2, \tag{9}$$

$$\ln f_\pm = -\frac{4.606 A\sqrt{C\alpha}}{1 + Ba_0\sqrt{C\alpha}}, \tag{10}$$

where Λ_0 is the equivalent conductance at an infinite dilution, K_A; the association constant ($=1/d_0K_d$, d_0 being the density of the solvent) has its usual meaning, and α is the degree of dissociation.

The values of K_A thus obtained are converted to K_d and are shown in Table 5, together with the values from VPO. In the table, the agreement between the values from VPO and conductometry is really satisfactory for LiCl, NaI, and KI. For LiBr and RbI, the agreement is not satisfactory, but it is still within a factor of ten.

In order to account for the profiles of the *h-m* plots for LiCl and LiBr, it is assumed that an equilibrium of the monomer-dimer exists at the higher concentration. The conductometry data can tell nothing about the presence of the dimer because of its electrically neutral nature. It should be emphasized here that the study with VPO is essentailly necessary for the study of the solution properties of non-aqueous solutions.

(Received March 20, 1978)

The adsorbed state of water on TiO_2 was studied by temperature programmed desorption (TPD) in the range 0—1000 °C. Pure anatase and rutile samples, the TPD spectra of water from which were not affected by any contaminant, could be obtained by the hydrolysis of titanium oxalate and tetrachloride solutions, respectively. Two desorption peaks were observed for anatase with the peak maxima at 69—127 (I) and 191—256 °C (II), and three for rutile at 32—90 (I), 188—265 (II), and 310—356 °C (III). The sum of adsorbed amounts for peaks II, and III are within a monolayer coverage, that of peak I exceeding it. The enthalpies of adsorption were evaluated to be 36 and 55—69 $kJ \cdot mol^{-1}$ for peaks I and II of anatase, and 36, 64, and 104 $kJ \cdot mol^{-1}$ for peaks I, II, and III of rutile, respectively. From these results, the corresponding adsorbed species of peak I was tentatively assigned to physical adsorption, that of peak II to chemisorption on surface oxygen ion by hydrogen bond, and that of peak III to chemisortpion on Ti^{4+} by the coordination of oxygen atom of water molecule. The last species may be dissociated into surface OH groups.

Most metal oxides are covered with hydroxyl groups under normal conditions.[1] Since surface hydroxyl groups seem to have a great influence on the physical and chemical properties of metal oxide surface, it is important to have information on the adsorbed state of water on the surface.

The adsorbed state of water on titanium dioxide has been investigated by many authors by various methods: specific chemical reactions,[1] adsorption measurement,[2] infrared spectroscopy,[3] and temperature programmed desorption spectroscopy.[4-6] However, many problems remain unsolved: (1) whether surface hydroxyl groups are isolated freely or associated with each other through hydrogen bond, (2) whether there exists molecular species adsorbed by chemical or physical cohesion bond besides surface hydroxyl groups, (3) the amount and the adsorption bond strength of each adsorbed species, and (4) the difference between anatase and rutile. In the present work, these subjects were studied in detail by the temperature programmed desorption (TPD) technique.

Experimental

Materials. The crystal form of titanium dioxide prepared by the hydrolysis of titanium salts depends on the sort of electrolyte in the solution and on the calcination temperature.[7-9] Rutile is usually obtained by calcination above 900 °C. The rutile sample thus obtained, however, is not adequate for studying the surface phenomena because of its small surface area. In the present work, three kinds of anatase (A-1—3) and two kinds of rutile (R-1,2) samples were used (Table 1). Sample A-1 is of extra pure grade (Wako Pure Chemical Industries, Ltd.). Sample A-2 was prepared from titanium sulfate obtained by the reaction of titanium dioxide with concd H_2SO_4. The titanium sulfate solution was hydrolyzed with ammonia. The precipitate was washed with distilled water to remove sulfate ions thoroughly, and dissolved in an aqueous solution of oxalic acid. The hydrolysis of the titanium oxalate solution was then repeated twice with ammonia. Finally the washed precipitate was dried at 120 °C, and calcined at 600 °C in the air for 5 h. Sample A-3 was obtained by the hydrolysis of a titanium tetrachloride solution with ammonia in the presence of ammonium sulfate, followed by thorough washing, drying at 120 °C, and then calcination at 730 °C in the air for 3 h.

The hydrolysis of a titanium tetrachloride solution in the absence of ammonium sulfate gave rise to the formation of rutile crystals by calcination at 600 °C (the sample is denoted by R-1). Sample R-2 was also obtained by the hydrolysis of titanium tetrachloride, followed by washing with ammonium nitrate solution to improve the filtration yield.

The samples were confirmed by X-ray diffraction analysis to be pure anatase or rutile except sample R-2, which contains a small amount of anatase crystals. The surface areas of the samples were measured by the BET method with nitrogen as an adsorbate. Granules of 20—80 mesh were used for TPD experiments.

Apparatus. The apparatus used for the TPD experiments is essentially the same as that described previously.[10] Equipments added were a path of oxygen for pretreatment under oxygen atmosphere, and a water vapor supplier consisting of a saturated solution of sodium chloride held at 0 or 20 °C. Water vapor was supplied to the sample by passing a carrier gas through the supplier for a certain period. Helium was used as a carrier gas. Commercial helium and oxygen were dried with a phosphorus pentoxide column.

Procedure. A fixed amount of TiO_2 (0.25, 0.5, or 1.0 g) was loaded into the reactor. The sample was heated at 600 °C for 1 h under a stream of mixed gas of oxygen 10% and helium 90% (50 $cm^3 \cdot min^{-1}$) and then under a stream of helium for 1 h. After the sample had been cooled to 0 or 20 °C, the water vapor was supplied and adsorbed from the supplier for a certain period with a helium carrier (50 $cm^3 \cdot min^{-1}$). The partial pressure of water vapor was 0.61 or 2.34 kPa. The water vapor in gas phase was then purged by the helium carrier, programmed heating being started from 0 or 20 to 1000 °C at a constant rate of $b = 3.5$—25 $K \cdot min^{-1}$. Gas desorption during the course of heating was recorded as a TPD chromatogram with a conventional thermal conductivity detector. The desorbed species was identified by gas chromatography. The amount of desorbed species was calculated from the peak area of the TPD chromatogram.

Results and Discussion

Desorption Chromatogram. Figure 1 shows the TPD chromatograms from three kinds of anatase sam-

Table 1. TiO_2 Samples used

Sample	Preparation method	Calcination	Surface area/$m^2 \cdot g^{-1}$	X-Ray diffraction
A-1	Commercial TiO_2	600 °C-5 h	6.4	Anatase
A-2	Hydrolysis of $Ti(SO_4)_2$ → dissolve in $(COOH)_2$ → hydrolysis → washed by distd H_2O	600 °C-5 h	34.2	Anatase
A-3	Hydrolysis of $TiCl_4$ in the presence of $(NH_4)_2SO_4$ → washed by distd H_2O	730 °C-3 h	11.2	Anatase
R-1	Hydrolysis of $TiCl_4$ → washed by distd H_2O	600 °C-5 h	14.5	Rutile
R-2	Hydrolysis of $TiCl_4$ → washed by NH_4NO_3 soln	600 °C-5 h	15.4	Rutile (+Anatase)

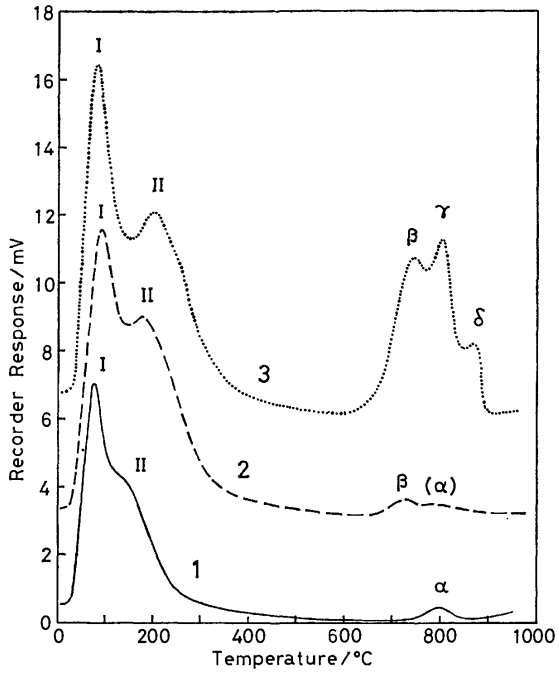

Fig. 1. TPD chromatograms from three anatase samples. Water vapor was fully preadsorbed at 0 °C after pretreated at 600 °C. Heating rate $b=15\ K \cdot min^{-1}$. 1: Sample A-1 1.0 g, 2: sample A-2 0.25 g, 3: sample A-3 0.5 g. For clarity, chromatograms 2 and 3 have been translated by 3 and 6 units along the ordinate, respectively.

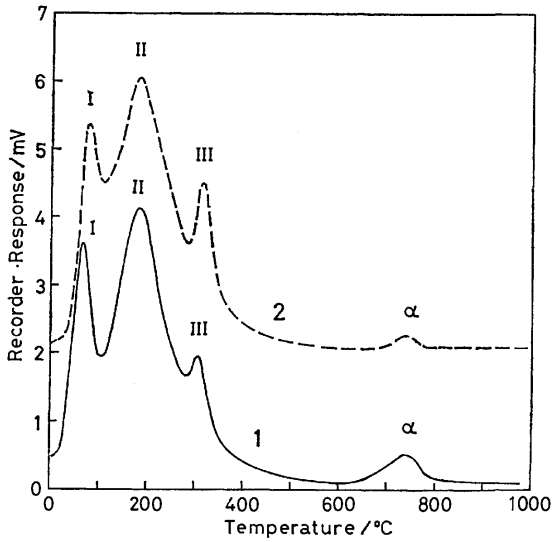

Fig. 2. TPD chromatograms from two rutile samples. Water vapor was fully preadsorbed at 0 °C after pretreated at 600 °C. $b=15\ K \cdot min^{-1}$. 1: Sample R-1 0.5 g, 2: sample R-2 0.5 g. For clarity, the chromatogram 2 has been translated by 2 units along the ordinate.

ples, which were pretreated at 600 °C and then allowed to adsorb water vapor at 0 °C, in the range 0—1000 °C. Similar results obtained from two kinds of rutile samples are shown in Fig. 2. The crystal structure of samples did not change with pretreatment. All samples pretreated showed no desorption peak up to 600 °C unless water was preadsorbed, but above 600 °C the same chromatograms were also observed without the preadsorption of water.

The chromatograms (Figs. 1 and 2) can be divided broadly into two groups; one with desorption peaks below and the other above 600 °C. The desorbed gases at lower temperatures were identified to be water alone by gas chromatography. Two desorption peaks I and II from sample A-2 well correspond to those from sample A-3. In the case of sample A-1, peak II was faintly observed as a shoulder of peak I. Munuera *et al.*[4] also reported two desorption peaks with the peak maxima at 175 and 215 °C. The rutile samples, on the other hand, gave three desorption peaks of water. Lower temperature peaks I and II correspond to those from anatase, no peak III being observed in the latter. The desorption peaks at 250 and 370 °C reported by Munuera and Stone[5,6] seem to be equivalent to peaks II and III (Fig. 2), though the peak temperatures are higher than the present results. Munuera[5] also reported another peak near 500 °C in the first TPD experiment using a fresh rutile sample evacuated at 400 °C, and attributed the peak to free OH groups from the original hydroxide. However, no such peak has been observed in the present work even though the sample was pretreated at 400 °C.

On the other hand, for the desorption peaks above 600 °C the desorbed gases were not water. Gas chromatographic analysis showed that peak α of sample

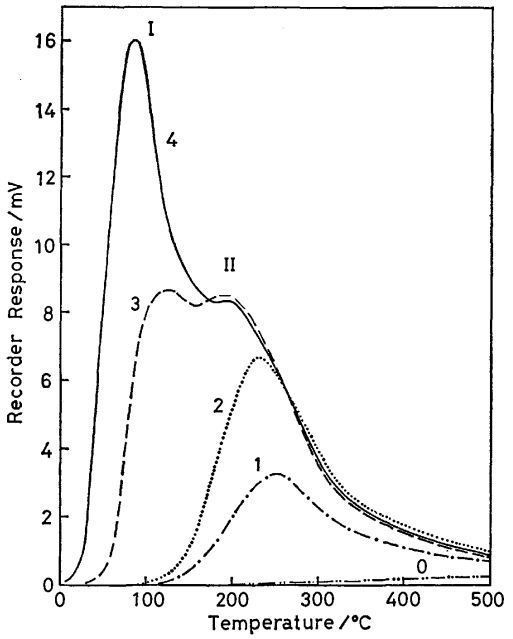

Fig. 3. The change of TPD chromatogram of water from sample A-2 (1.0 g) by the preadsorbed amount V_a of water. V_a value in each run is given in Table 2. $b=15$ K·min^{-1}. Run 0: no adsorption, 1: adsorption for 10 min, 2: 20 min, 3: 40 min, 4: 60 min.

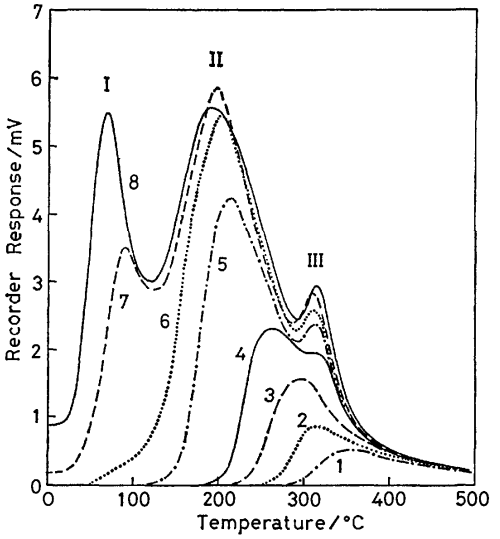

Fig. 4. The change of TPD chromatogram of water from sample R-1 (1.0 g) by the preadsorbed amount V_a of water. V_a value in each run is given in Table 3. $b=10$ K·min^{-1}. Run 1: adsorption for 1 min, 2: 1.5 min, 3: 2.5 min, 4: 4 min, 5: 9 min, 6: 12 min, 7: 15 min, 8: 21 min.

R-1 or R-2 at about 740 °C and peak α of sample A-1 at 800 °C arises from the desorption of surface oxygen. Several types of adsorbed oxygen species have been proposed over various metal oxides such as O_2^-, O^-, and O^{2-}. Peak α could be assigned to O^{2-} species since the former two species should be desorbed up to 600 °C.[10,11] The amount of α oxygen obtained from peak area of sample R-1 was evaluated to be 8.6×10^{-8} mol·m^{-2} of TiO_2 surface, corresponding to the surface coverage of *ca.* 1% with respect to surface titanium atoms. In the case of sample A-2, nitrogen was also detected in addition to oxygen as a desorbed gas. In particular most of peak β was due to the desorption of nitrogen. For large peaks β, γ, and δ from sample A-3 the desorbed gases were not oxygen, but nitrogen and unknown species. Lower calcination temperature caused the enlargement of these peaks as compared with peak II. From the results, it is concluded that the abnormally large, higher temperature peaks should correspond to the desorption with decomposition of ammonium sulfate residue used for preparation. Thus the preparation method of sample A-3 is not appropriate for pure anatase.

In the case of sample A-2, the coverage of impurity can be estimated to be only a few percent since the area of peak β is much smaller than that of peak II which corresponds to the adsorption amount within a monolayer coverage. When sample A-2 was pretreated at 850 °C to remove the impurity the feature of the desorption chromatogram of water was the same as the result in Fig. 1, though the recorder response was very low because of the decreased surface area. Thus, the influence of impurity for sample A-2 is negligible and the spectrum up to 600 °C (Fig. 1) can be taken to represent the desorption chromatogram of water from pure anatase surface.

Peak II of commercial sample A-1 represents a smaller peak area and a lower peak temperature than that of sample A-2. This may be caused by some impurities. Commercial sample is likely to contain some iron compounds or some phosphates.[12] Munuera *et al.*[4] reported that the addition of phosphate ions to anatase results in the disappearance of peak II.

Changes of Desorption Chromatograms by Adsorbed Amounts. Anatase and rutile show different TPD chromatograms; the former has two desorption peaks, the latter three. These peaks should reflect the different types of adsorbed states of water on the different surface sites. In order to obtain further information on the corresponding adsorbed states of these peaks, TPD chromatograms were measured at various amounts of water preadsorbed.

Figure 3 shows the TPD chromatograms from sample A-2 of anatase form after water vapor had been preadsorbed in various amounts at 0 °C. The amount of water preadsorbed was varied by passing helium carrier gas over the saturated solution of sodium chloride held at 0 °C for the periods 0—65 min. When the preadsorbed amount V_a was small, only one peak (II) appeared. With increasing V_a, peak II was enhanced, the peak temperature being lowered. However, the increase of peak II was saturated to a certain limit and another peak I appeared in the lower temperature region at $V_a=11.63$ μmol·m^{-2}. Similar results were also obtained in the case of sample A-1.

Figure 4 shows the results from sample R-1 of rutile form. Only one peak was observed for runs 1, 2, and 3, where the preadsorbed amount was less than 2.43 μmol·m^{-2}. The chromatogram started to separate into two peaks (II and III) at $V_a=3.53$ μmol·m^{-2} (run 4), the peak separation becoming clear by the further adsorption of water. At $V_a=9.08$ μmol·m^{-2}

a) Preadsorbed amount, the sum of V_d for peaks I, II, and III. b) At $b=10$ K·min^{-1}.

(run 6), both these peaks almost attained their saturated heights. Peak I appeared at a preadsorbed amount greater than $V_a=12.6$ μmol·m^{-2}. A comparison of peak temperatures suggests that peaks I and II of rutile correspond to two peaks of anatase; peak III is characteristic of rutile form.

Taking into account the long tailing of peak II from anatase, however, it is reasonable to consider that the adsorbed species corresponding to peak III from rutile should exist on the anatase surface. Smaller amount or lower desorption temperature than that of rutile may interfere with the appearance of a discrete peak.

Peak II of anatase and peaks II and III of rutile have attained the saturated adsorption. This indicates that the peaks should arise from the desorption of some species chemisorbed within a surface monolayer. For the sake of confirmation, the amounts of desorbed gas were determined from the peak areas of TPD chromatograms (Figs. 3 and 4). The results are given in Tables 2 and 3, respectively. The temperature at the minimum of chromatogram was taken as the boundary between two peaks. Assuming that every surface oxygen ion with the coordination number less than three is hydroxylated, the maximum amounts of desorbed water from the (100), (001), and (110) planes of anatase are calculated to be 9.28, 11.7, and 13.1 μmol·m^{-2}, respectively. For the (110), (101), and (001) planes of rutile, they amount to 8.64, 9.93, and 15.7 μmol·m^{-2}, respectively.

The maximum values observed for peak II of anatase and for peak II+III of rutile are in good agreement with the calculated values for low index planes. It is concluded that either peak II or III corresponds to chemisorbed species on the surface. On the other hand, the desorbed amount of peak I did not attain a saturated value, but increased over a monolayer coverage (Tables 2 and 3). It might be concluded that peak I corresponds to the physical adsorption species.

The Enthalpy of Adsorption. In order to estimate the adsorption strength of each species, the enthalpy of adsorption ΔH was measured for two peaks of sample A-2 and for three peaks of sample R-1. ΔH was determined according to the method of Konvalinka *et al.*[13] who extended the theory of Cvetanovic and Amenomiya.[14]

For the first order desorption from a homogeneous surface with freely occurring readsorption, peak temperature T_M of a desorption peak is correlated with ΔH and heating rate b by

$$2\log T_M - \log b = \frac{\Delta H}{2.303RT_M} + \log\frac{(1-\theta_M)^2 V_s \Delta H}{FAR}. \quad (1)$$

For second order desorption with freely occurring readsorption, Eq. 1 may be written as

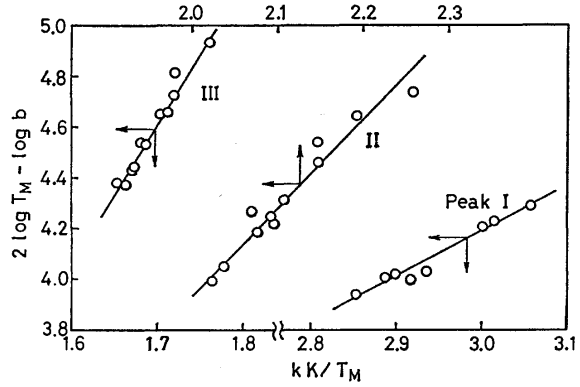

Fig. 5. Plots of (2 log $T_M - \log b$) *vs.* $1/T_M$ for three TPD peaks from sample R-1.

$$2\log T_M - \log b = \frac{\Delta H}{2.303RT_M} + \log\frac{(1-\theta_M)^2 V_s v_m \Delta H}{2\theta_M FAR}, \quad (2)$$

where R is the gas constant, V_s the volume of the solid phase, v_m the amount of gas adsorbed at full coverage per unit volume of the solid in a certain adsorbed state, F the flow rate of carrier gas, θ_M the coverage at $T = T_M$, and A is equal to $\exp(\Delta S/R)$, where ΔS is the entropy of adsorption. The flow rate of carrier gas 50 $cm^3 \cdot min^{-1}$ fulfills the condition with freely occurring readsorption, because desorption without readsorption cannot be realized unless the flow rate is set at 10^7 $cm^3 \cdot h^{-1}$ per gram of solid.[13] Since θ_M varies very slightly with heating rate, the slope of the plot of (2 log T_M $-\log b$) *vs.* $1/T_M$ should provide the enthalpy of adsorption at constant F and at constant initial surface coverage both for the first and second order desorption. Figure 5 shows the plots of (2 log T_M $-\log b$) *vs.* $1/T_M$ for three peaks of sample R-1. In all cases, a linear relation holds. ΔH's calculated from the slopes are also given in Tables 2 and 3.

Day *et al.*[15] reported the values 45—52 $kJ \cdot mol^{-1}$ for the heat of adsorption of water on rutile at 25 °C in the region of monolayer coverage. Morimoto *et al.*[16] obtained the values 79.5 and 105.4 $kJ \cdot mol^{-1}$ for the heats of hydration of rutile and anatase, respectively, from the measurement of heat of immersion in water. The values of Day *et al.* are intermediate between the ΔH values for peaks I and II. The values of Morimoto *et al.* are close to the present result for peak III of rutile, which is in good agreement with the result of Munuera and Stone.[6] However, Day *et al.* and Morimoto *et al.* paid no attention to the difference of adsorbed species. The different species should exhibit a different heat of adsorption or immersion.

Adsorbed State of Water. The ΔH value 36 $kJ \cdot mol^{-1}$ for peak I agrees with the heat of vaporization of water at 100 °C, 41 $kJ \cdot mol^{-1}$. The ΔH values for peak II are in the range 55—69 $kJ \cdot mol^{-1}$, greater than the heat of vaporization. Hydrogen bonds would participate in the adsorption of peak II species. From the fact that peak I arises after peak II has attained saturation, peak II can be assigned to the chemisorbed species held on the surface oxygen

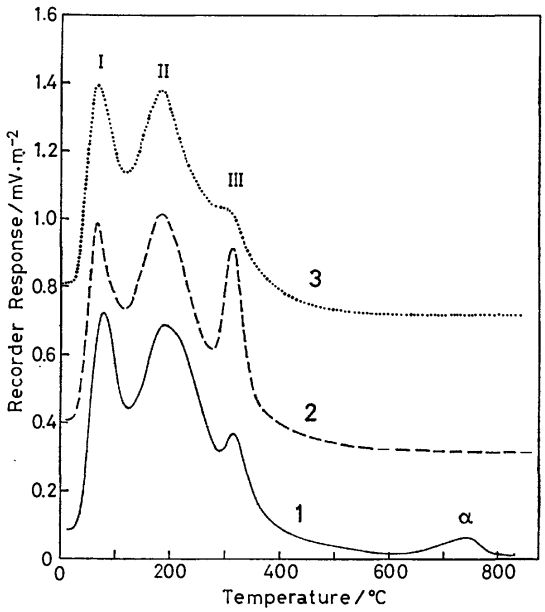

Fig. 6. The influence of pretreatment on the adsorption sites of sample R-1. 1: First run after pretreated at 600 °C, 2: second run after first TPD up to 830 °C, 3: third run after pretreated at 1000 °C for 30 min. Water was fully preadsorbed at 20 °C. $b = 10$ K·min^{-1}. For clarity, the chromatograms 2 and 3 have been translated by 0.3 and 0.7 units along the ordinate.

ions by hydrogen bond within a monolayer, and peak I to the multilayer physical adsorption on the chemisorbed water molecules. The hydrogen bond of water molecule with surface oxygen ion O^{2-} is considered to be stronger than that between water molecule since O^{2-} ion has a higher proton affinity than the oxygen atom of water molecule.

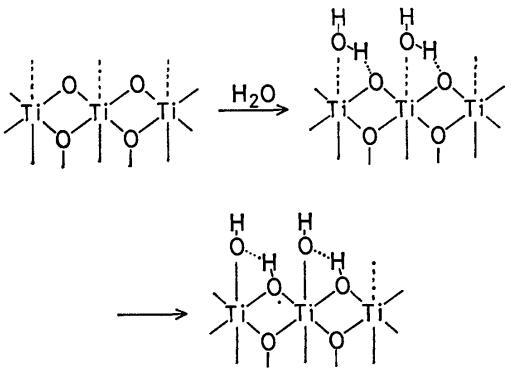
The ΔH value 104 $kJ \cdot mol^{-1}$ for peak III of rutile is considerably greater than that expected for the adsorption through hydrogen bond. On the other hand, it is indicated by infrared study[17] that free OH groups remain on the surface of silica gel or alumina even after evacuation at 650—950 °C. Thus free OH groups are likely to be able to desorb only at very high temperatures. Peak III can be tentatively assigned to the adsorbed species through the coordination of oxygen atom of water to the surface titanium ion.

In order to confirm the participation of Ti^{4+} ions in the peak III adsorption, the following experiments were carried out. After the surface oxygen (peak α) had been desorbed from sample R-1 by the first TPD procedure up to 830 °C (curve 1, Fig. 6), the sample was quenched to 20 °C in a stream of helium. Water was then readsorbed and the TPD chromatogram was recorded again. The result is shown in curve 2, where recorder response was plotted per unit area since the surface area decreased from 14.5 to 5.3 $m^2 \cdot g^{-1}$ by the first TPD run up to 830 °C. The magnitude of peak III markedly increased in the second run, that of peak II remaining almost unchanged. The increase of peak III is probably due to the increase of the number of Ti^{4+} sites by the desorption of surface oxygen ions. Elongated heat treatment above 800 °C caused a gradual decrease in surface area. The sintering

process would bring about the change of surface structure, in particular the decrease of the active Ti^{4+} sites, which results in the reduction of peak III. The result on sample R-1 pretreated at 1000 °C for 30 min, the surface area of which decreased to 1.65 $m^2 \cdot g^{-1}$, is given by curve 3. The reduction of peak III is considerable, but the magnitude of peak II per unit area remains unchanged. The results suggest the participation of Ti^{4+} sites in the adsorption of peak III species; the peak II species seem to be independent of Ti^{4+} sites. The possibility that reduced Ti^{3+} ions might be the peak III adsorption sites can be eliminated since in such a case curve 3, representing the run after pretreatment at the highest temperature in the inert gas, should exhibit the largest peak III.

Similar experiments were carried out on anatase sample A-2, but no clear peak III could be observed by any pretreatment. Thus the sites of Ti^{4+} on anatase are much fewer or weaker than those on rutile. This can be explained as follows. Since the cleavage of anatase crystal along (100), (001), and (110) planes produces 5-coordinate surface Ti^{4+} ions in each case, the oxygen atom of water molecule could be coordinated to only one Ti^{4+} ion at its vacant ligand position. In the case of rutile, a water molecule can be doubly coordinated to two adjacent 4-coordinate Ti^{4+} ions on the (100) and (110) planes. Such adsorption modes may be reflected in the difference of the desorption spectrum of peak III.

Primet *et al.*[3] suggested from infrared spectroscopic study that the surface of anatase and rutile evacuated at 200 or 300 °C for 20 h contains hydroxyl groups, and that OH groups bonded with each other by hydrogen bridges should be removed by evacuation at 350 °C and isolated OH groups at 400 °C. The former OH groups seem to be equivalent to peak III in the present work from the coincidence of desorption temperature. It is likely that a water molecule coordinated to Ti^{4+} ion would form the hydrogen bond with an adjacent surface O^{2-} ion, and dissociate into two OH groups by proton shift through hydrogen bond as follows:



(3)

On the other hand, no desorption of free OH groups was observed as a peak in TPD chromatogram. However, it should be related to the long tailing part of chromatogram which starts at about 350 °C and continues above 600 °C, since the desorbed gas from a long tail was also found to be water. Thus the present results suggest the existence of some free OH groups still above 400 °C, contrary to the suggestion of Primet *et al.*[3]

Conclusion

The TPD chromatogram of water from anatase surface consists of two peaks, (I) T_M=69—127 °C, ΔH=36 kJ·mol^{-1} and (II) T_M=191—250 °C, ΔH=55—69 kJ·mol^{-1}, while that from rutile consists of three peaks, (I) T_M=32—90 °C, ΔH=36 kJ·mol^{-1}, (II) T_M=188—265 °C, ΔH=64 kJ·mol^{-1}, and (III) T_M=310—356 °C, ΔH=104 kJ·mol^{-1}. Peaks I and II from both samples well correspond to each other. Peak II of anatase and peaks II and III of rutile attain saturated adsorption within a surface monolayer coverage. On the other hand, the adsorption of peak I on both samples was not saturated but increased over a monolayer coverage. Three desorption peaks are concluded to correspond to the following adsorbed states.

peak I: Physically adsorbed species on surface hydroxyl groups or chemisorbed water molecules.

peak II: Chemisorbed species on surface oxygen ions through hydrogen bonds.

peak III: Chemisorbed species on Ti^{4+} ions through coordination bond. The species can be transformed into two OH groups by proton transfer to an adjacent surface oxygen ion.

Catalytic Activities of La_2O_3, Y_2O_3, and CeO_2 for Decomposition of 4-Hydroxy-4-methyl-2-pentanone and Isomerization of Butenes

Yasuo FUKUDA, Hideshi HATTORI, and Kozo TANABE*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 31, 1978)

The decomposition of 4-hydroxy-4-methyl-2-pentanone and the isomerization of 1-butene were carried out over La_2O_3, Y_2O_3, and CeO_2. The activities for both types of reactions were in the following order; $La_2O_3 > Y_2O_3 > CeO_2$. With La_2O_3, the change in the activity for the decomposition with the pretreatment temperature of the catalyst correlated well with the change in basicity, the activity and basicity maxima being observed when the catalyst was pretreated at 500 °C. Yttrium sesquioxide showed a maximum activity for the decomposition when pretreated at 700 °C. For the isomerizations of 1-butene and *cis*-2-butene, La_2O_3 exhibited activity maxima when pretreated at 700 °C. The *cis*/*trans* selectivities from 1-butene were considerably greater than unity, and the *trans*/1 selectivities from 2-butene were less than unity. The coisomerization of *cis*-2-butene-d_0/d_8 revealed that the reaction involved an intramolecular H(or D) transfer. The isotope effects for the formation of 1-butene from *cis*-2-butene were 4—10, while those for the formation of *trans*-2-butene were about 1.

Rare earth oxides have recently been recognized as solid base catalysts. Rosynek *et al.* studied the surface properties and catalytic behavior of La_2O_3 and reported that basic sites on La_2O_3 were essential for the isomerization of butenes.[1-3] Minachev *et al.* investigated the catalytic action of rare earth oxides for the hydrogenation of ethylene and concluded that the basicity of the oxides correlated with the activity.[4] Although the basic property was thus regarded as an important property in catalytic actions, the number of basic sites has not yet been measured.

In this study, the number of basic sites of La_2O_3 was measured and correlated with the catalytic activities for the decomposition of 4-hydroxy-4-methyl-2-pentanone and the isomerization of butenes. In the isomerization of butenes, a mechanistic study was done by the coisomerization method.[5] For a comparison with La_2O_3, oxides of elements of the same IIIa group, Y_2O_3 and CeO_2, were also studied.

Experimental

The lanthanum sesquioxide (La_2O_3), Y_2O_3, and CeO_2 were obtained by the evacuation of each hydroxide at temperatures between 400 and 800 °C for 3 h. The final pressure was in the range of 10^{-2} Pa. The hydroxides were prepared by precipitation from nitrate solutions with aqueous ammonia.

The number of basic sites (basicity) on La_2O_3 were measured by titrating the sample suspended in dry benzene with a benzene solution of 0.1 mol/dm^3 benzoic acid, 2,4,6-trinitroaniline ($pK_{BH}=12.2$) being used as an indicator.[6] The suspension of the sample in dry benzene was performed under flowing dry nitrogen to prevent poisoning by air.

For the measurements of the IR spectra, $La(OH)_3$ was pressed into a disk and outgassed at various temperatures for 3 h *in situ*.

The decomposition of 4-hydroxy-4-methyl-2-pentanone was carried out at 30 °C in a liquid phase while magnetically stirring the reactant (10 ml) and the powdered catalyst. The reaction mixture (catalyst, reactant, and product; 1-ml portions) was periodically transferred into another vessel for the centrifugal separation of the catalyst from a solution. The solution was then analyzed by means of a gas chromatograph with a 1-m column containing polyethylene glycohol on Celite.

The isomerization of butenes was carried out in a closed circulation system (*ca.* 1370 ml) on *ca.* 0.1-g catalysts at temperatures between 0 and 200 °C and at an initial pressure of 46.6 kPa. For the coisomerization of *cis*-2-butene-d_0/d_8, a microcatalytic pulse reactor was employed and a mixture containing equal amounts of *cis*-2-butene-d_0 and *cis*-2-butene-d_8 was reacted at 0 °C. The products were gas-chromatographically separated and subjected to mass-spectrographic analysis.

Results

Basicity and IR Spectra of La_2O_3. The variations in the basicity as a function of the pretreatment temperature are shown in Fig. 1. The basicity of lanthanum sesquioxide increased on pretreatment above 400 °C, attained a maximum value when pretreated at 500 °C, and then gradually decreased as the pretreatment temperature was raised above 500 °C.

The IR spectra of La_2O_3 exhibited strong peaks around 1500—1300 cm^{-1}, which could be assigned to carbonate groups. A large number of carbonate

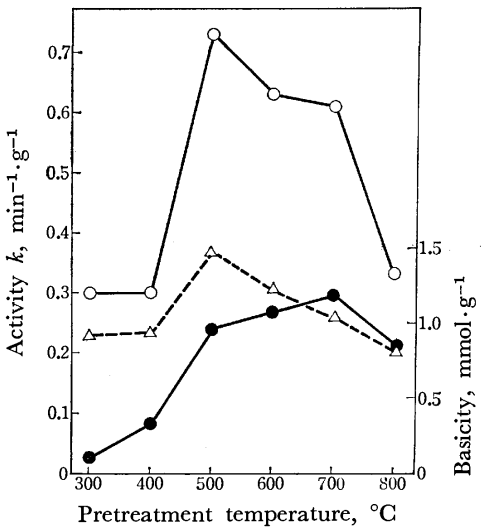

Fig. 1. Variations of basicity (—△—) of La_2O_3 as a function of pretreatment temperature and variations of activities of La_2O_3 (—○—) and Y_2O_3 (—●—) for decomposition of 4-hydroxy-4-methyl-2-pentanone at 30 °C.

Table 1. Catalytic activities and selectivities for the isomerization of 1-butene

Catalyst	Reaction temp °C	*cis*-2-Butene (%/m²·min)	*trans*-2-Butene (%/m²·min)	Selectivity
La_2O_3	0	8.6	3.3	2.8
Y_2O_3	0	2.2×10^{-2}	0.56×10^{-2}	3.9
CeO_2	0	0	0	—
CeO_2	200	3.1×10^{-2}	1.4×10^{-2}	2.2

groups still remained on the sample even when it was outgassed at 500 °C, and most of the carbonate groups was desorbed as CO_2 by raising the outgassing temperature from 500 to 600 °C.

Decomposition of 4-Hydroxy-4-methyl-2-pentanone. Only acetone was produced by the decomposition of 4-hydroxy-4-methyl-2-pentanone over La_2O_3, Y_2O_3, and CeO_2 at 30 °C. The decomposition followed the first-order rate equation with respect to the concentration of the reactant. The activity was represented by the first-order rate constant, k. Variations in the activities of La_2O_3 and Y_2O_3 on a unit of weight are also plotted as a function of the pretreatment temperature in Fig. 1. A maximum activity was obtained by pretreatment at 500 °C for La_2O_3 and at 700 °C for Y_2O_3. In the case of La_2O_3, the variation in the activity with the pretreatment temperature was similar to that of the basicity. The rate constants of CeO_2 pretreated at 700 and 800 °C were 1.02×10^{-2} and 1.17×10^{-2} $min^{-1}\cdot g^{-1}$ respectively. On comparing the maximum activities of La_2O_3 and Y_2O_3 to 1.17×10^{-2} $min^{-1}\cdot g^{-1}$ for CeO_2, the activities for the decomposition reaction are in the following order, $La_2O_3 > Y_2O_3 > CeO_2$.

Isomerization of Butenes. The activity was represented by a % conversion per min per unit weight or surface area of the catalyst in the initial stage of the reaction. The activities of La_2O_3, Y_2O_3, and CeO_2 pretreated at 700° for the isomerization of 1-butene are compared in Table 1 on the basis of a unit surface area, where the *cis*/*trans* selectivities in the initial stage of the reaction are also given. Cerium dioxide did not show any activity at 0 °C. The activity and the selectivity in the reaction at 200 °C are also given for the sake of comparison. The order of the activities is; $La_2O_3 > Y_2O_3 > CeO_2$. The *cis*/*trans* selectivities were greater than 2 for all catalysts.

The activity and *cis*/*trans* and *trans*/1 selectivities in the isomerizations of 1-butene and *cis*-2-butene are plotted against the pretreatment temperature in Figs. 2 and 3. The activities for both reactions appeared on pretreatment above 400 °C. The maximum activities were observed when La_2O_3 was pretreated at 700 °C for both reactions. The *cis*/*trans* and *trans*/1 selectivities were markedly changed by raising pretreatment temperature from 600 to 700 °C. In all cases, the *cis*/*trans* selectivities were greater than 2 and the *trans*/1 selectivities were less than 1.

The results of the coisomerization of *cis*-2-butene-d_0/d_8 over La_2O_3 pretreated at 600 and 700 °C are summarized in Table 2. Non-exchanged products were predominant. This indicates that the reaction

involves an intramolecular H(or D) transfer. The ratio of "light molecules (d_0—d_2)" to "heavy molecules (d_6—d_8)" is plotted against the conversion in Fig. 4. The zero conversion intercept gives an isotope effect. The isotope effects for the formation of 1-butene were about 10 and 4 for La_2O_3 pretreated at 600 °C and 700 °C respectively. On the contrary, the isotope effects for the formation of *trans*-2-butene were small (≈ 1) for both catalysts. The ratio for 1-butene decreased with an increase in the conversion, while the ratio for *trans*-2-butene increased. This is attributable to a large isotope effect for the conversion of 1-butene to *trans*-2-butene.

Discussion

The catalytic actions of La_2O_3, Y_2O_3, and CeO_2 in the decomposition of 4-hydroxy-4-methyl-2-pentanone and the isomerization of butenes could be attributed to their basic property as a decisive property. The good correlation of the basicity with the activity for the decomposition of 4-hydroxy-4-methyl-2-pentanone found on La_2O_3 is similar to that found on alkaline earth oxides.[7] The order of the activities of alkaline earth oxides on a unit surface area basis followed the order of strength of the basic sites, that is, BaO>SrO>CaO>MgO. Although the basic properties of Y_2O_3 and CeO_2 were not measured, the order of the activities on a unit surface area basis, $La_2O_3>Y_2O_3>CeO_2$, suggests that the basic strength of the active sites is also $La_2O_3>Y_2O_3>CeO_2$. The activity of La_2O_3 was one order of magnitude greater than that of MgO (1.4×10^{-3} min$^{-1}\cdot$m^{-2}).[7]

For the isomerization of 1-butene over La_2O_3, our results on the activity and selectivity are similar to those reported by Rosynek and Fox.[3] In their study, a maximum activity was obtained when the substance was pretreated at 650 °C, while it was obtained at 700 °C in our study. The *cis*/*trans* ratios were considerably higher than unity in both studies.

One of the criteria for the base-catalyzed isomerization of 1-butene is a high *cis*/*trans* selectivity.[8-11] The high selectivity observed for La_2O_3, combined with the existence of basic sites, seems to indicate that the isomerization is a base-catalyzed reaction, in which the initial step is an abstraction of an allylic H in the form of H^+ by a basic site to form an allyl carbanion. The *cis* form is much more stable than the *trans* form in the π-allyl carbanion. The H^+ thus abstracted transfers to the 1 carbon atom to form mainly *cis*-2-butene. In this case, an intramolecular H transfer can be observed provided that there are no H^+ around the carbanion other than the abstracted one. The observed result of an intramolecular H transfer also supports the idea that the isomerization is a base-catalyzed reaction.

There are two forms in the π-allyl carbanion, *syn* and *anti* π-allyls. Interconversion between the two allyls probably proceed by means of a σ-allyl. If the interconversion between two π-allyls is a slow step, the

conversion of *cis*-2-butene to *trans*-2-butene will be slow and the isotope effect for the formation of the *trans*-2-butene will be small. These were the observed sequences. Therefore, the slow step for the direct conversion of *cis*-2-butene to *trans*-2-butene is the conversion of *anti* π-allyl to *syn* π-allyl. The increase in the ratio of "light molecules" to "heavy molecules" for *trans*-2-butene as the reaction proceeded indicates that a large part of the *trans*-2-butene was produced *via* 1-butene in the intermediate stage of the reaction. The large isotope effect for the formation of 1-butene from *cis*-2-butene suggests that an H transfer is involved in the slow step. Provided that the initiation step is common for the formations of *trans*-2-butene and 1-butene from *cis*-2-butene, a small isotope effect for the formation of *trans*-2-butene shows that the abstraction of H^+ is not a slow step. Therefore, it may be considered that the migration of the H^+ to the 3 carbon atom is the slow step for the formation of 1-butene from *cis*-2-butene.

Rosynek and Fox[3] suggested, on the basis of the different activation energies for the formations of *cis*-2-butene and *trans*-2-butene, that the formations of two 2-butene isomers from the 1-butene reactant may occur on dissimilar sites. However, it does not seem necessary to postulate dissimilar sites, it is sufficient to assume different slow steps for the formations of the two 2-butene isomers.

A marked increase in the activity for the isomerizations of butenes by raising the outgassing temperature from 500 to 600 °C corresponded to an increase in the desorbed amount of carbonate groups. Therefore, it may be considered that the active sites for isomerization are generated by the removal of surface carbonate groups.

The active sites for the isomerization of butenes and for the decomposition of 4-hydroxy-4-methyl-2-pentanone may be dissimilar, because the pretreatment temperatures at which maximum activities were exhibited different for the two reactions and because basic sites generated by pretreatment at 400 °C catalyzed the decomposition, while they did not catalyze the isomerization. Perhaps, the isomerization needs stronger basic sites than the decomposition does.

The Photoreduction of the Silver Ion in a Zinc Oxide Suspension

Hiroshi HADA,* Hatsumi TANEMURA, and Yoshiro YONEZAWA

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received April 1, 1978)

Quantum yields of from 0.235 to 0.385 have been determined for the reduction of Ag^+ by the irradiation of 365 nm light on a ZnO surface in aqueous solutions containing 5×10^{-5} to 1×10^{-3} M $AgClO_4$. It is proposed that these results can be interpreted by a reaction scheme based on the assumption that some conduction-band electron produced in the ZnO by the irradiation transfers to the Ag^+ adsorbed on the ZnO surface. The surface-energy barrier under the present experimental conditions was discussed with the aid of the electrochemical measurement of the ZnO sinter. The photoreduction of Ag^+ is optically sensitized by the addition of xanthene dyes, such as Uranine and Rhodamine B. In this case, it is observed that the photoreduction of Ag^+ is accompanied by the photolysis of dye molecules. The apparent quantum yields (the number of reacted molecules/the number of photons absorbed in the suspension) of the dye-sensitized photoreduction of Ag^+ and the photolysis of dye molecules are 0.015 and 0.007 for Uranine, and 0.003 and 0.0003 for Rhodamine B, respectively.

The electronic energy transfer in the semiconductor-aqueous solution interface is a fundamental process for semiconductor photochemistry and electrochemistry, and the detailed analysis of this process is closely related to the elucidation of related topics in photobiology, photographic science, and catalysis science, as well as the utilization of solar energy. Many reports[1–6] in which ZnO is used as a working electrode have been published in the fields of semiconductor electrochemistry. They cover the investigations of dye-sensitized photocurrents and the redox reactions as well as the construction of solar cells. In the photochemistry of ZnO powder, Cunningham *et al.*[7–13] have investigated the photoreduction of several molecules and ions on the ZnO–gas and ZnO–solution interfaces, and Dixon *et al.*[14] have reported on the photocatalytic reaction of H_2O on the ZnO–solution interface.

As to the photoreduction of metal ions, Tammann[15] has reported the darkening of an emulsion containing ZnO and Ag^+ under UV-irradiation. Recently, Fleischauer *et al.*[16,17] have investigated the photoreduction of $AgNO_3$ on the surface of ZnO and TiO_2 (rutile) single crystals by means of 365 nm light and obtained quantum yields of from 0.08 to 0.4 for the $AgNO_3$ concentrations of from 0.1 to 1.0 M respectively on the ZnO and also obtained quantum yields of from 0.016 to 0.03 for the $AgNO_3$ concentrations of from 0.001 to 0.01 M respectively on the TiO_2.

We have observed that the irradiation of an aqueous suspension of ZnO containing $AgClO_4$ by means of 365 nm light, which belongs to the fundamental absorption band of ZnO, produces colloidal silver adsorbed on the ZnO surface, and that this reaction can be optically sensitized by the addition of xanthene dyes. This reaction seems to be suitable for the study of the electron-transfer process in the interface because of its rather simple reaction. We have thus investigated the photoreduction of $AgClO_4$ in a ZnO aqueous suspension by means of 365 nm light and the optical sensitization of this reaction by two xanthene dyes, Uranine and Rhodamine B. It has been found that these dye molecules are decomposed in the course of the photoreduction of Ag^+. We also carried out preliminary measurements of the electrochemical properties of the ZnO–aqueous solution interface. Hence, we have obtained several significant conclusions regarding the reaction mechanism of the photoreduction of Ag^+ on the ZnO–aqueous solution interface.

Experimental

The ZnO used in the present study was a highly purified powder sample, labeled SAZEX-4000, which had been obtained by courtesy of the Sakai Kagaku Co., Ltd., Osaka. This material has a surface area of 4.6 m^2/g-ZnO, an average particle size of 0.5 μm, and very low impurities of Pb (0.002%) and Cd (0.0002%). $AgClO_4$, $AgNO_3$, and Uranine are of special grade, purchased from the Nakarai Chemicals Co., Ltd. The perchlorate salt of Rhodamine B was provided by the Nippon Kanko Shikiso Co., Ltd., Okayama. Distilled water was used for the preparation of all the aqueous suspensions of ZnO powder and of all the aqueous solutions employed in the study.

The reaction cell was a cylindrical quartz vessel of 4 cm in diameter and 20 cm in height. It was equipped with a flat window of 1.6 cm in diameter at the bottom for the irradiation of light and with a glass cap with a glass cock to introduce N_2 gas at the top. N_2 replacement was not carried out except when measuring the amount of dissolved oxygen in the suspension. All the parts of the reaction cell except for the flat window were covered with black cloth to avoid the entrance of any stray light. The aqueous suspensions were prepared in the dark. For the study of the dye-sensitized reduction, 0.5 g-ZnO powder was suspended in an 50 ml aqueous solution composed of $AgClO_4$ and xanthene dye. The buffer solution was not added in either case, because this might cause some undesirable reactions. The reaction mixture was rigorously mixed by a magnetic stirrer under a constant velocity throughout the reaction.

A 500 W xenon lamp, Type UXL-500D, with a Type DSB-500SS, power supply (Ushio Denki Co., Ltd.), was used as the light source. The monochromatic light for irradiation was selected by the combination of a monochromator (Shimadzu Seisakusho Co., Ltd.) and an appropriate glass filter (Toshiba Co., Ltd.). For the study of the unsensitized reduction, 365 nm light was used. For the study of the dye-sensitized reductions, 490 nm light was used for Uranine and 560 nm light for Rhodamine B (designated as dye-light). The irradiation was commenced after the adsorption equilibrium had been established. It takes about 30 min for the unsensitized system, and about 180 min for the dye-sensitized system, to attain the adsorption equilibrium. After the irradiation, the reaction mixture in the solid state was collected through a sintered glass filter, washed completely with a large excess of distilled water, dissolved by

HNO_3, and then submitted to the quantitative analysis of the Ag^+. The details of the silver analysis by means of the differential potentiometric titration method were presented in our previous paper.[18] The decomposition products of ZnO and dyes by HNO_3 did not hinder the analysis of the reduced silver.

The incident intensities of 365 nm light on the reaction vessel were measured by the use of the ferrioxalate actinometer, using the quantum yields determined by Parker.[19] Those of dye-light were determined with the aid of a photometer, Type IL-600 (International Light Co., Ltd.). In this work, the numbers of incident photons were 9.10×10^{14} photon/cm^2 s at 365 nm, 2.78×10^{15} photon/cm^2 s at 490 nm, and 1.89×10^{15} photon/cm^2 s at 560 nm. To calculate the number of photons absorbed by suspensions, the transmittance and the reflectance of suspensions were measured by the use of the spectrophotometers, MPS-5000 and QV-50 equipped with an integrating sphere (Shimadzu Seisakusho Co., Ltd.). The quantum yields of the photoreduction of Ag^+ for the unsensitized systems and the apparent quantum yield (the number of reacted molecules/the number of photons absorbed by suspension) for the dye-sensitized system were determined as follows:

$$\Phi = \frac{1}{Q}\cdot\frac{d[Ag]}{dt}, \quad (1)$$

where Φ is the quantum yield for the unsensitized system or the apparent quantum yield for the dye-sensitized system, $d[Ag]/dt$ the initial rate of the formation of the reduced silver (atom/s), and Q the number of photons absorbed by the suspension (photon/s). It is easy to determine the quantum yield for the unsensitized system by means of Eq. 1, because all the photons absorbed by the suspension at 365 nm are absorbed by ZnO itself. On the contrary, it is difficult to determine the quantum yield for the dye-sensitized system because some of the incident photons absorbed by free dye molecules in the solution, not by the dye adsorbed on ZnO, do not contribute to the photoreduction. Therefore, for the dye-sensitized system we have determined only the apparent quantum yield by means of Eq. 1.

The photobleach reactions of Uranine and Rhodamine B were studied in the suspensions described above. After the irradiation by dye-light, the suspension was filtered out and the optical density of the filtrate at this wavelength was measured. From this, the amount of dyes photobleached during the sensitized photoreduction was determined. The adsorption isotherm of Ag^+ adsorbed in equilibrium was determined after the ZnO powders had been immersed in 5×10^{-5} to 1×10^{-3} M solutions of $AgClO_4$ for 3 h under a constant stirring.

The electrochemical measurements of the ZnO sinter electrode were carried out in a conventional manner.[6,20] ZnO powder SAZEX-4000 was placed, in pellets, on a disk of 10 mm in diameter and 0.5 mm thick, and then sintered at 1000 °C for 2 h in air. After cooling to room temperature, it was activated at 550 °C under 1×10^{-4} mmHg for 3 h. The surface of ZnO electrode was etched by 85% H_3PO_4 and washed with distilled water before use. A platinum plate was used as the counter electrode, and a saturated KCl-Ag/AgCl electrode of the double-junction type was used as the reference electrode. The electrochemical measurements of the cell thus constructed were carried out by means of a potentiostat equipped with an electrometer, Type HA-104 (Hokuto Denko Co., Ltd.). The electrolyte solutions were composed of 0.5 M KNO_3 or of a mixed solution of 0.5 M KNO_3 and 1.0×10^{-4} M $AgClO_4$. Before the measurements, dissolved O_2 was purged by the introduction of high-purity N_2 gas.

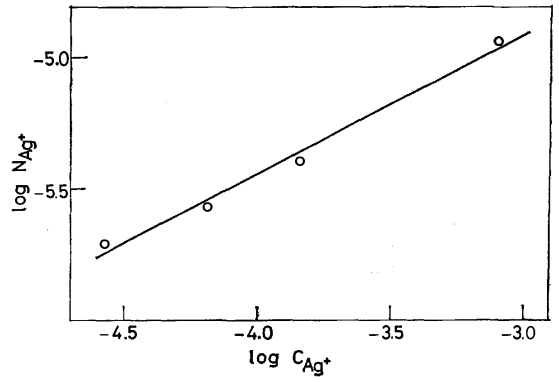

Fig. 2. Plots showing the Freundlich type adsorption for Ag^+ on ZnO surface. Index of adsorption is 0.53. N_{Ag^+}, and C_{Ag^+} denote the amount of adsorbed Ag^+ (mol/g-ZnO) and the concentration of Ag^+ in aqueous phase (mol/l).

Results

Photoreaction in the Unsensitized System. The dependence of the amount of reduced silver on the irradiation time of 365 nm light for the ZnO–$AgClO_4$ aqueous suspension is given in Fig. 1. The thermal reduction in the dark is negligible as compared with the photoreduction. From the rate of Ag^+ reduction obtained by means of the method of least squares in Fig. 1, and the number of photons absorbed at 365 nm in the suspensions, the quantum yield of the photoreduction of Ag^+ was calculated. The values are 0.385±0.016, 0.303±0.021, and 0.235±0.004 for $AgClO_4$ concentrations of 1.0×10^{-3}, 1.0×10^{-4}, and 5.0×10^{-5} M respectively. The pH values of the suspensions are 6.8, 6.6, and 6.5 for $AgClO_4$ concentrations of 1.0×10^{-3}, 1.0×10^{-4}, and 5.0×10^{-5} M respectively. The pH change during the irradiation was not remarkable after 30 min irradiation. The quantum yields obtained here are much larger than

those predicted by the extrapolation of the results of Fleischauer *et al.*[16] on the photoreduction of $AgNO_3$ on the ZnO single crystal. Cunningham *et al.*[10] reported that $NaNO_3$ is reduced to $NaNO_2$ by UV-light in the ZnO–aqueous suspension. Therefore, we have carried out the photoreduction of $AgNO_3$ by the same reaction system as $AgClO_4$. The quantum yields for $AgNO_3$ are nearly equal to that for $AgClO_4$. Therefore, these results seem to suggest the differences in the physicochemical properties of the ZnO employed by different investigators.

The adsorption isotherm of Ag^+ on the ZnO surface was measured at 20 °C. It is given in Fig. 2. In the equilibrium state, the concentration of Ag^+ in the aqueous phase, C_{Ag^+}, and the amount of adsorbed Ag^+ on the surface of 1.0 g-ZnO, N_{Ag^+}, satisfy Freundlich's adsorption formula:

$$N_{Ag^+} = \alpha(C_{Ag^+})^{1/n}, \tag{2a}$$

$$\log N_{Ag^+} = \log \alpha + \frac{1}{n} \log C_{Ag^+}. \tag{2b}$$

(α, n: constant)

The adsorption index, $1/n=0.53$, is a rather reasonable value.

We tried to clarify the behavior of the positive hole by the detection of the increases in the dissolved O_2 and Zn^{2+} in the aqueous phase during the photoreaction. A 50 ml aqueous suspension of 0.5 g of the ZnO and 1.0×10^{-3} M $AgClO_4$ was prepared. The dissolved O_2 was measured by the use of an oxygen meter, Model DO-2A (Toa Denpa Co., Ltd.). The amount of O_2 dissolved in the suspension is decreased by the introduction of N_2 gas in the dark under constant stirring. Then, the suspension was irradiated with 365 nm light for 40 min, and the increase of the dissolved O_2 was recorded. The observed value of 2.6×10^{-6} mol is nearly equal to the amount of photoreduced silver of 3.9×10^{-6} mol under the same reaction conditions. The increase in Zn^{2+} was examined by colorimetric analysis using Xylenol Orange as an indicator.[21-23] The same suspension described above was also irradiated by 365 nm light for 40 min and then filtered. 0.1% Xylenol Orange and a buffer solution (pH=5.6) were added to the filtrate, and the absorption spectra were recorded. A characteristic peak was observed at 571 nm which was not distinct in the unirradiated case. This surely implies that Zn^{2+} increases after the irradiation. From these results, the positive hole produced by 365 nm light can be thought to react with the chemisorbed oxygen ion or water molecule on the ZnO surface, as well as with the oxygen ion in the ZnO lattice.[14,24,25]

The current-voltage characteristics of the ZnO sinter electrode were also studied. The electrolyte solution was composed of either 0.5 M KNO_3 or a mixture of 0.5 M KNO_3 and 1.0×10^{-4} M $AgClO_4$. The polarization curves obtained are given in Figs. 3 and 4. The solid line and the dashed line indicate the currents measured under the irradiation and in the dark respectively. The dotted line indicates the partial anodic photocurrents.[26-28] This is obtained by the subtraction of the current in the dark from

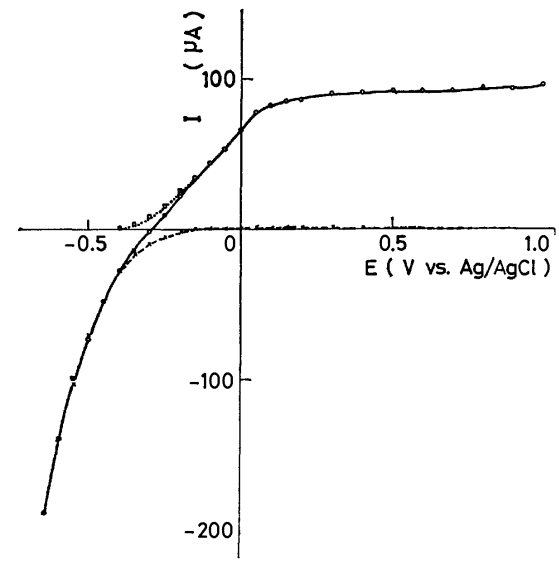

Fig. 3. Polarization curves of ZnO electrode in 0.5 M KNO_3 solution. ○——○: Measured currents under irradiation, ×----×: measured currents in the dark, □·····□: the partial anodic photocurrents defined in the text.

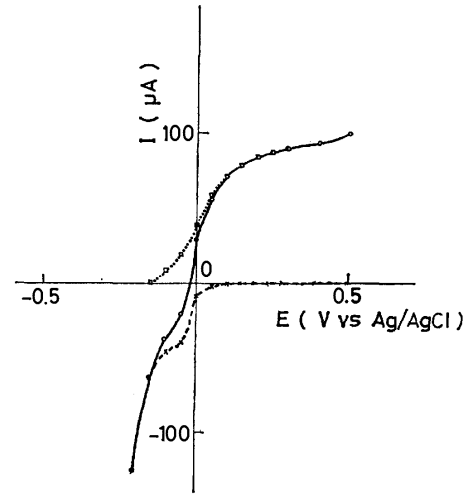

Fig. 4. Polarization curves of ZnO electrode in 0.5 M KNO_3 solution containing 1×10^{-4} M $AgClO_4$. ○——○: Measured currents under irradiation, ×----×: measured currents in the dark, □·····□: the partial anodic photocurrents defined in the text.

the current measured under the irradiation. Because the irradiation should not affect the cathodic current, the cathodic current measured in the dark is equal to that under the irradiation. Therefore, the partial anodic photocurrent indicates the real anodic element of the current under the irradiation.

Under the irradiation at the electrode potential of —0.030 V *vs.* Ag/AgCl in Fig. 4, the cathodic current cancels the anodic current on the ZnO sinter electrode, so the total current is zero (Zero-current-potential). The cathodic current at this potential is 24 μA in Fig. 4, but it is almost zero at this potential in Fig. 3. If all the cathodic current contributes to the reduction

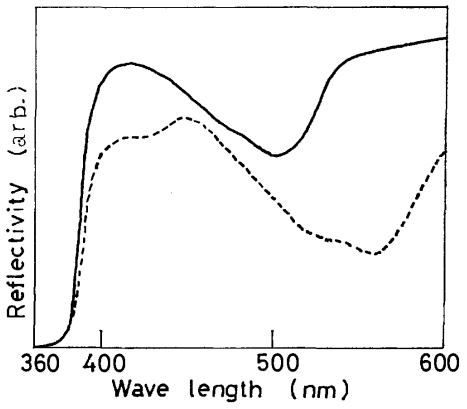

Fig. 5. Reflection spectra of ZnO-$AgClO_4$-Uranine (——) and ZnO-$AgClO_4$-Rhodamine B (----) aqueous suspensions.

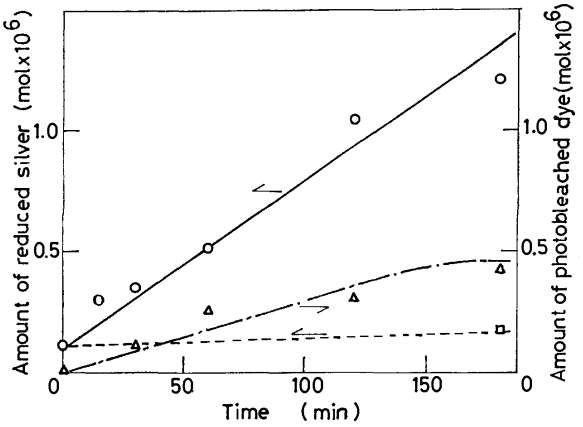

Fig. 6. Growth of the amount of reduced silver in ZnO suspension containing $AgClO_4$ and Uranine with irradiation of 490 nm light (O——O) and in the dark (□----□). Growth of the amount of photobleached dye is also given (△———△).

of Ag^+, we can determine the rate of photoreduction of Ag^+ on this electrode from this value. Indeed, the rate evaluated in this manner is in accord with the value obtained by the chemical-analysis method in the same electrode reaction system, within the limits of experimental error. Therefore, almost all the cathodic current at the zero-current-potential can be said to contribute to the photoreduction of Ag^+.

The onset point of the partial anodic photocurrents corresponds to the flat-band potential. We can see that this potential (—0.40 V *vs.* Ag/AgCl in Fig. 3) is shifted to a more positive value (—0.15 V *vs.* Ag/AgCl in Fig. 4) when $AgClO_4$ is added to the electrolyte solution.

Photoreaction in the Dye-Sensitized Systems. The diffuse reflection spectra of ZnO–$AgClO_4$ aqueous suspensions containing dye were recorded on a MPS-5000 spectrophotometer. The results are given in Fig. 5. The absorption band shorter than 385 nm corresponds to the fundamental absorption of ZnO. The monomer absorption maxima of dyes exist at 490 nm for Uranine and 560 nm for Rhodamine B. No peaks due to the dye aggregation were found.

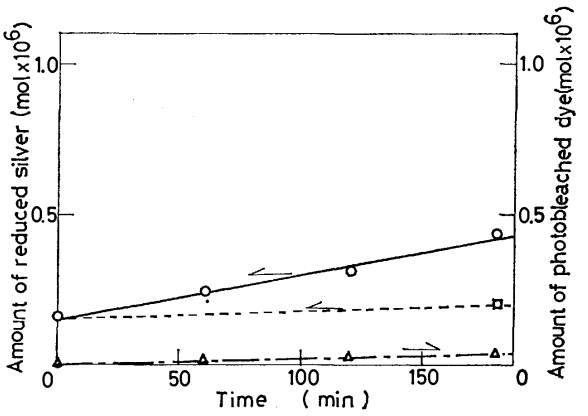

Fig. 7. Growth of the amount of reduced silver in ZnO suspension containing $AgClO_4$ and Rhodamine B with irradiation 560 nm light (O——O) and in the dark (□----□). Growth of the amount of photobleached dye is also given (△———△).

In the case of the Uranine system, the dependence of the amounts of photoreduced silver on the irradiation time is given in Fig. 6. The concentrations of $AgClO_4$ and dye are 1.0×10^{-4} and 1.0×10^{-5} M respectively. From the initial slope of the photoreduction curve and the number of absorbed photons, the apparent quantum yield of the photoreduction of Ag^+ is found to be 0.015. It is observed that a photobleach of the dye proceeds simultaneously with the Ag^+ reduction. The dependence of the amount of photobleached dye on the irradiation time is also shown in Fig. 6. The apparent quantum yield of this reaction is 0.007. We have found that the photoreduction of Ag^+ and the photobleach of the dye cannot occur in the absence of ZnO. Therefore, it is impossible that Ag^+ is directly reduced by the dye molecules without the participation of ZnO. The amount of reduced silver is about twice as large as the amount of Uranine which exists in the suspension at the beginning. This means that at least two Ag^+s are reduced by one Uranine molecule.

As to the Rhodamine B system, the amounts of reduced silver and photobleached dye are given in Fig. 7. The concentrations of $AgClO_4$ and dye are the same as in the Uranine system. The apparent quantum yields of 0.003 and 0.0003 were obtained for the photoreduction of Ag^+ and the photobleach of Rhodamine B respectively. These values are smaller than those in the Uranine system.

Discussion

Reaction Scheme. The amount of adsorbed Ag^+ plays a significant role in the photoreduction. We tried to interpret the dependence of the quantum yields on the $AgClO_4$ concentrations with the help of the simple reaction scheme of Fleischauer *et al*:[16]

$$ZnO + h\nu \xrightarrow{\theta} e(s) + p, \quad (3a)$$

$$e(s) + Ag^+(s) \xrightarrow{k_1} Ag(s), \quad (3b)$$

$$e(s) \xrightarrow{k_2} \text{non-reactive state}, \quad (3c)$$

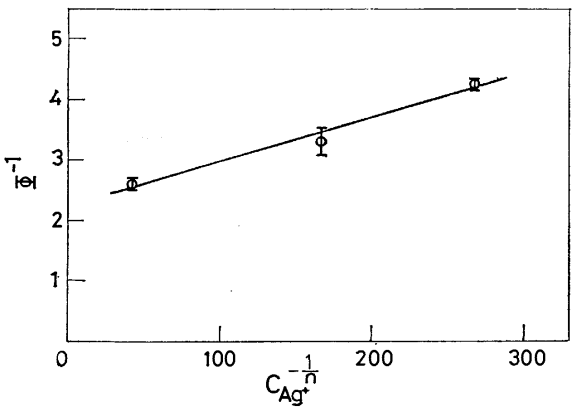

Fig. 8. Reciprocal plots between the quantum yield Φ and $(C_{Ag^+})^{1/n}$.

where e(s) and p denote the surface electron and the free hole produced by the light, and where $Ag^+(s)$ and Ag(s) denote the silver ion and the atom adsorbed on ZnO surface, respectively. In this scheme, the excitation of ZnO produces a surface electron with an efficiency of θ. This electron reacts with the adsorbed silver ion at the solid-liquid interface with the rate constant of k_1. Some part of this electron will be converted to the non-reactive state, with the average rate constant of k_2, by trapping, recombination, or reaction with some impurites on ZnO. Assuming the stationary concentration of e(s), the quantum yield of the Ag formation is expressed as

$$\Phi = \frac{\theta k_1 N_{Ag^+}}{k_2 + k_1 N_{Ag^+}}. \quad (4)$$

From Eqs. 2a and 4, we can obtain

$$\Phi^{-1} = \frac{k_2}{\alpha k_1 \theta}(C_{Ag^+})^{-1/n} + \frac{1}{\theta}. \quad (5)$$

The experimental relation between Φ^{-1} and $(C_{Ag^+})^{-1/n}$ given in Fig. 8. confirms our assumption that the adsorption equilibrium of Ag^+ on the ZnO surface is not perturbed very much in the earlier stage of the photoreaction and that the dependence of the quantum yield on the Ag^+ concentration can be interpreted by means of this scheme.

ZnO–Aqueous Solution Interface. It is well known[12,25,29] that there exists a surface-energy barrier for electrons in the space-charge layer of ZnO left in air due to electron localization on the surface-energy levels of the chemisorbed oxygen. When ZnO is in contact with an aqueous solution, the surface barrier will change with the pH or some other properties of the solution. In the aqueous suspension of ZnO studied here, both Ag^+ and ClO_4^-, as well as H^+, OH^-, and H_2O exist in the solution. Therefore, the surface barrier would be considerably changed from that in air.

Now, let us assume that the results of the ZnO suspension can be analyzed by an electrochemical study of the ZnO sinter. This is supported by the fact that the quantum yield of the photoreduction of Ag^+ on the ZnO sinter is almost the same as that in the ZnO suspension. First, let us consider the surface-energy barrier of the ZnO sinter in view of the results of the electrochemical measurements. In the "local cell model" of the photoreaction on the ZnO sinter, the electrode potential of the ZnO sinter immersed in the solution under the irradiation is equal to the zero-current-potential, noted before. We also found from the photopotential measurement of the ZnO electrode, that the electrode potential is indeed −0.030 V *vs.* Ag/AgCl under the irradiation and that it shifts to a more positive value (0.315 V *vs.* Ag/AgCl was measured), when the 365 nm light is cut off. According to the results of the photocurrent and the photopotential measurements cited above, it may be concluded that the upward band bending still exists in the space-charge layer of ZnO, because the flat-band potential of the ZnO electrode in the presence of Ag^+ is more negative than the electrode potential either in the dark or under the irradiation. It is evident that the bottom of the conduction band at the surface does not change so much as the electrode potential on the irradiation. From these facts, the surface barrier of the ZnO sinter in the $AgClO_4$ solution can surely be said to be much smaller under the irradiation of 365 nm light. This effect may be due to the rapid consumption of the positive hole, and the resultant accumulation of photoelectrons in the conduction band under the influence of the electric field of the space-charge layer. The photoelectrons in the conduction band can react with $Ag^+(s)$ over the surface barrier, which is considerably smaller than that in the dark. The rate of the photoreduction of Ag^+ is equal to the rate of hole consumption in the photostationary state. This corresponds to a "local cell model."[26–28]

In Figs. 3 and 4 the shift of the flat-band potential is observed upon the addition of $AgClO_4$. Lohmann[4] has demonstrated that the flat-band potential of a ZnO electrode is shifted as the pH of the solution is changed. The pH value of the solution containing 0.5 M KNO_3 is 5.1, and that of the solution containing 0.5 M KNO_3 and 1×10^{-4} M $AgClO_4$ is 5.2, so the shift of the flat-band potential observed in our case is much larger than that to be expected from the pH change by the addition of $AgClO_4$. Therefore, we can assume that when $AgClO_4$ is added, the pH change and also the specific adsorption of Ag^+ on the ZnO surface contribute to the shift of the flat-band potential. Ag^+ is specially adsorbed in the Helmholtz layer on the surface of ZnO and causes the changes in the physicochemical properties of the surface. This is not inconsistent with Freundlich's adsorption isotherm of Ag^+ on the surface of ZnO, which can be interpreted in terms of the assumption that the adsorbate can occupy various surface points whose adsorption energies are distributed exponentially. Morrison[3] reported that the flat-band potential of a ZnO electrode does not change when several other metal ions are added to the electrolyte solution. However, we think that Ag^+ may play a specific role, in contrast to the ions reported by him. The exact determination of the flat-band potential of the ZnO electrode by the impedance measurement when Ag^+ is added to the electrolyte solution is in progress. Our results will be published in forthcoming paper.

In the reaction scheme discussed in the previous section, it was assumed that the surface barrier under the irradiation does not change even if the concentrations of Ag^+ in the solution are varied. In fact, the differences between the flat-band potential and the electrode potential under the irradiation in Figs. 3 and 4 are almost the same. This means that, although the flat-band potential of the electrode is changed by the addition of $AgClO_4$, the surface barrier under the irradiation does not change very much by the addition of $AgClO_4$.

Cunningham *et al.*[7,10] have obtained that quantum yields of about 10^{-5} for the photoreduction of N_2O on the surface of ZnO powder and of 10^{-1} to 10^{-3} for the photoreduction of various molecules and ions in a ZnO aqueous suspension. They interpreted the greatly enhanced quantum efficientcies of the photoreaction at ZnO–water interface relative to the ZnO–gas interface, at least in part, by the assumption that there exists a rather downward band bending due to the predominance of H^+ over OH^- on the surface of ZnO at a neutral pH, but such bending would not be reasonable in our case. The much larger quantum yields and the relatively small dark reaction rates obtained by us must be mainly the result of the decrease in the surface barrier for the conduction-band electron, as has been described above.

The Mechanism of Dye Sensitization. There have been many studies of the dye sensitization of ZnO in terms of both photoelectric and electrochemical properties. In these studies, the external electric field was applied to the ZnO material, and the photocurrent caused by the energy transfer or the charge transfer from the dye in contact with them was measured. In our study, the photoelectron is moved by the electric field of the space-charge layer originally present in the ZnO–aqueous solution interface.

Because ZnO plays a decisive role in the dye-sensitized photoreduction of Ag^+, the following reaction mechanism seems probable. In the first step, the energy transfer or the charge transfer from the dye molecules adsorbed to ZnO occurs, and the concentration of the conduction-band electron increases, then the conduction-band electron in ZnO transfers to the Ag^+ adsorbed on the surface through the interface in the same manner as the unsensitized reduction of Ag^+. If we assume that the surface barrier of ZnO in the presence of $AgClO_4$ can hardly be affected by the addition of dyes, the quantum yield of the dye-sensitized photoreduction of Ag^+ would be of the same magnitude as the product of the quantum yields of the photocurrent generation and the unsensitized photoreduction of Ag^+. According to Tsubomura *et al.*,[20] the quantum yield of the photocurrent of a ZnO electrode by Rose Bengal, one of the xanthene dyes, is 0.22. In our study, the quantum yields of 0.23 to 0.50 have been determined for the reduction of Ag^+ by 365 nm light on the ZnO surface. Therefore, the apparent quantum yields of 0.015 and 0.003 obtained by us for the dye-sensitized photoreduction of Ag^+, which correspond to the minimum of the real quantum yields, are rather reasonable.

A large difference was found in quantum yields of the photobleach between the two dyes. The ratios of the apparent quantum yields of the photoreduction of Ag^+ by dyes to those of the photobleach of dyes are 2.2 for Uranine and 10 for Rhodamine B. It seems that these numbers show how many times one dye molecule contributes to the photoreduction of Ag^+. We think that the photobleach and the reproduction of dyes are related to the sensitization mechanism of a semiconductor.

The authors wish to thank the Nippon Kanko Shikiso Co., Ltd., Okayama, for kind providing the dyes, and the Sakai Kagaku Co., Ltd., Osaka, for the ZnO. This work was carried out with financial support from the Ministry of Education of Japan (Grant-in-Aid No. 147073).

Crystal Structures of Dichlorobis(azocyclohexane)palladium(II) and Dichlorobis(azoisopropane)palladium(II)

Takashi YAMANE,* Tamaichi ASHIDA, Hiroharu SUZUKI,†
Kenji ITOH,†† and Yoshio ISHII†††

Department of Applied Chemistry and Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa, Nagoya 464

(Received April 26, 1978)

The structures of dichlorobis(azocyclohexane)Pd(II) and dichlorobis(azoisopropane)Pd(II) have been determined. The crystallographic data are: dichlorobis(azocyclohexane)Pd(II), Im3, $a=16.538(2)$Å, $Z=6$, $R=8.9\%$ for 667 reflections; dichlorobis(azoisopropane)Pd(II), Pbca, $a=7.461(1)$, $b=17.096(1)$, $c=14.784(1)$Å, $Z=4$, $R=6.8\%$ for 1451 reflections. In dichlorobis(azocyclohexane)Pd(II), a disorder occurs at the azo group, and the coordination mode of the ligand is not clear. The structure of dichlorobis(azoisopropane)Pd(II) agrees with that of dichlorobis(azobenzene)Pd(II).

The transition-metal which generates a nitrene R–N has attracted much attention from both organic and inorganic chemists in the last decade. A possible precursor is *N,N*-dichloroamine, which may generate nitrenes or nitrenoids by a reductive elimination of two chlorine atoms with some low-valent transition-metal complexes. Little is known about this process. Previously, some of the present authors reported that *N,N*-dichloroamine or -amide generated nitrenoids by a reaction with $Fe_2(CO)_9$,[1] and that tetrakis(methoxycarbonyl)palladiacyclopentadiene, $[PdC_4(COOCH_3)_4]_n$,[2,3] induced a ring-opening of the palladole skeleton with *N,N*-dichloroacylamides.[4]

This paper will describe some X-ray structure analyses of dichlorobis(azocyclohexane)palladium(II), $PdCl_2(c\text{-}C_6H_{11}\text{–}N{=}N\text{–}C_6H_{11}\text{-}c)_2$ I, which was obtained by the reaction of $[PdC_4(COOCH_3)_4]_n$ and $c\text{-}C_6H_{11}\text{–}NCl_2$, and of the related dichlorobis(azoisopropane)-palladium(II), $PdCl_2(i\text{-}C_3H_7\text{–}N{=}N\text{–}C_3H_7\text{-}i)_2$ II, which was prepared by a ligand-exchange reaction between an excess of azoisopropane and dichlorobis(benzonitrile)palladium(II). The X-ray structure indicated unequivocally that the cyclohexylnitrene generated by the palladium complex was dimerized to azocyclohexane, which was then coordinated to the palladium(II). The azocyclohexane complex, I, exhibits a substantial disorder around the azo nitrogen atoms. However, the structure of the azoisopropane complex, II, has the lone-pair coordination of the azo group, in a fashion similar to the dichlorobis(azobenzene)-palladium(II).[5]

Experimental

Preparation of Dichlorobis(azocyclohexane)palladium(II) I. A benzene (2 ml) solution of *N,N*-dichlorocyclohexylamine (0.678 g, 4.04 mmol) was stirred into a benzene (10 ml) suspension of $[PdC_4(COOCH_3)_4]_n$ (0.359 g, 0.921 mmol) under an argon atmosphere at room temperature. The mixture turned to an orange solution, which was then stirred overnight. Ethyl ether (5 ml) was added to the mixture, resulting in the formation of a reddish brown solid of $c\text{-}C_6H_{11}NH_2\cdot HCl$, which was then filtered off. The brown filtrate was concentrated to *ca.* 2 ml under reduced pressure. A mixed solvent composed of ethyl ether and methanol (1:1 vol ratio) was added to the oily residue, and the mixture was kept in a refrigerator for a few days to give $PdCl_2(c\text{-}C_6H_{11}\text{–}N{=}N\text{–}C_6H_{11}\text{-}c)_2$ as yellow prisms in a 16.7% yield. Mp 159.5—160.0 °C. IR(KBr); 2930, 2850(C-H), 1596, 1433, and 338(Pd-Cl)cm^{-1}. NMR($CDCl_3$); δ 5.45(br, 2H, CH-N), 5.35(br, 2H, CH-N), 0.79—2.55(m, 40H, other cyclohexyl protons). CMR($CDCl_3$); δ 32.59(C(1)), 29.40, 29.29(C(2)), 25.41, 25.12, 24.03, and 23.84(C(3), C(4)).

Found: C, 51.05; H, 7.89; N, 9.74%. Calcd for $C_{24}H_{44}N_4Cl_2Pd$: C, 50.94; H, 7.84; N, 9.90%.

The same complex was prepared in a 55.2% yield by the reaction of dichlorobis(benzonitrile)palladium(II) (209.8 mg) with an excess of azocyclohexane (0.6 ml) in benzene (10 ml). The X-ray analysis indicated that this is the same as the above complex. Found: C, 50.96; H, 8.07; N, 9.72%.

Preparation of Dichlorobis(azoisopropane)palladium(II) II. An excess of azoisopropane (0.5 ml) was stirred, drop by drop, into a benzene (10 ml) solution of dichlorobis(benzonitrile)palladium(II) (198 mg, 0.517 mmol) at room temperature. The reaction took place instantaneously to give a pale yellow solution. The benzene and the excess azoisopropane were removed under reduced pressure after 1 h. The crude II was obtained quantitatively and was recrystallized from 8 ml of dry methanol to yield yellow prisms. Mp 136—137 °C. IR(KBr); 2960, 2920 (C–H), 1594, and 335(Pd–Cl)cm^{-1}. NMR($CDCl_3$); δ 5.60(brm, 2H, CH-N), 4.87(m, 2H, $J=7$ Hz, CH-N), and 1.51(d, 24H, $J=7$ Hz, CH_3).

Found: C, 35.49; H, 7.29; N, 13.92%. Calcd for $C_{12}H_{28}N_4Cl_2Pd$: C, 35.53; H, 6.96; N, 13.81%.

Crystallographic Procedure. The crystal data are as follows. Complex I; *F.W.*=566.0, Im3, $a=16.538(2)$Å, $Z=6$, $D_m=1.27$, $D_x=1.247$ g cm^{-3}, and μ(Mo $K\alpha$)=8.17 cm^{-1}. Complex II; *F.W.*=405.7, Pbca, $a=7.461(1)$, $b=17.096(1)$, $c=14.784(1)$Å, $Z=4$, $D_m=1.38$, $D_x=1.434$ g cm^{-3}, and μ(Mo $K\alpha$)=12.1 cm^{-1}.

For I, the intensity data were collected on a Hilger & Watts automatic diffractometer (at the Faculty of Science, Nagoya University) using Zr-filtered Mo $K\alpha$ radiation. 741 reflections with $2\theta\leq50°$ were measured by the θ-2θ step-scan technique. For II, 2148 reflections with $2\theta\leq55°$ were obtained by the use of a Rigaku automatic diffractometer (at the Institute for Protein Research, Osaka University), using Mo $K\alpha$ radiation and a Graphite-crystal monochro-

mator (monochromator $2\theta=12.16°$). The θ-2θ scan was adopted . The crystals used for the data collection had the dimensions of $0.20\times0.25\times0.16$ mm for I and of $0.33\times0.30\times0.14$ mm for II. The intensity data were corrected for Lorentz and polarization effects, but no absorption correction was made.

Structure Determination

The structures were solved by the heavy-atom method. The refinement was carried out by the full-matrix least-squares method for I and by the block-diagonal least-squares method for II.[6] In the refinement, non-zero reflections were included and the weight $w=1/(\sigma^2(F)+a|F_o|+b|F_o|^2)$ was assigned, where $\sigma(F)$ is the standard deviation based on the counting statistics. The isotropic temperature factors for the H atoms were kept constant at 5.0 Å^2.

The space group of I is either Im3, I23, or $I2_13$, judging from the systematic absences of the reflections. However, $I2_13$ is excluded because the space group can not contain 6 molecules in a unit cell. If the space group is Im3, there exists an mmm symmetry in the complex, while in I23 a complex has a 222 symmetry. The refinement was carried out independently with Im3 and I23. The final R's for 667 reflections were: 8.9%(a=0.1181 and b=0.0062) for Im3 and 8.3% for I23. The R value with Im3 is inferior to that with I23. However, the structure of the cyclohexane group in I23 is greatly distorted from normal, while the structure in Im3 is reasonable. Thus the space group Im3 seems the more plausible. There is a disorder associated with the azo group. The correlation matrix, λ, shows that the correlation between the x parameters of N(1) and N(2) is significant ($\lambda_{jj'}=0.32$). The other correlations are insignificantly small.

The final R of II is 6.8% (a=0.0221 and b=0.0011) for 1451 reflections.

The atomic scattering factors were taken from "International Tables for X-Ray Crystallography," Vol. IV.[7] The calculations were carried out on the FACOM 230-60/75 computers at Nagoya University. The final atomic parameters are listed in Tables 1, 2, 3, and 4.[8]

Description of Structures

Complex I. A disorder is observed at the azo group. A quarter part of the composite Fourier map is drawn in Fig. 1, where Cl is not drawn, since the Cl atom is in front of Pd. The two N atoms of the azo group are equivalent, and should be located at the d position of the space group Im3.[9] However, the Fourier and D-Fourier maps prepared with and without N(1) and N(2) made clear that the azo nitrogen atoms do not satisfy this situation. Therefore N(1) and N(2), with occupancies of 0.5 each, were located at the other special positions, g. This disordered model satisfies the symmetry, though no reasonable skeleton with proper covalent bonds can be proposed for this

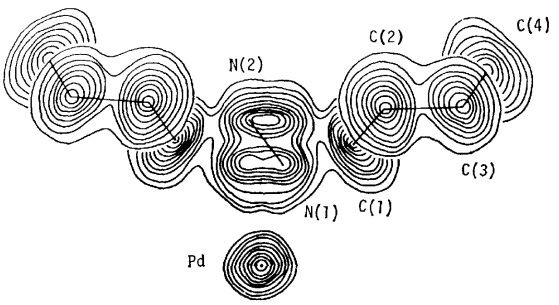

Fig. 1. Dichlorobis(azocyclohexane)Pd(II): The composite Fourier map. Cl is in front of Pd, and is not shown. For Pd, first contour 5 eÅ^{-3}, interval 10 eÅ^{-3}. For N and C, first contour 0.5 eÅ^{-3}, interval 0.5 eÅ^{-3}.

complex. The refinement of the model structures gave the proper temperature factors for both N(1) and N(2), as compared with those of the other atoms. All the H atoms were found in the D-Fourier map. The H(1) peak is most prominent, with a height of 0.62 eÅ^{-3}. The other peaks ranged from 0.30 to 0.54 eÅ^{-3}. The stereoscopic view of one of the model structures drawn by ORTEP II[10] is shown in Fig. 2. The dimensions are given in Fig. 3. The e.s.d.'s are: 0.02—0.04 Å for bond lengths except for Pd–Cl (0.006 Å) and 1.7—2.2° for bond angles. The model shown in Figs. 2 and 3 is just a tentative one. Therefore, low-temperature work is desirable for this complex.

Complex II. The bond lengths and angles are given in Fig. 4. The e.s.d.'s are 0.007—0.014 Å for all the bond lengths except for Pd–Cl (0.002 Å), and 0.2—0.9° for the angles. The best planes and the related data are given in Table 5.

In II, there is no disorder, and a proper coordination mode is found which is similar to those of the other azo complexes. The symmetry of II is only a center of inversion. The two isopropyl groups are not equivalent to each other. The bond lengths and angles of the azo group of II are compared with those of dichlorobis(azobenzene)Pd(II), AZB,[5] in Table 6. The structures of the azo groups in both complexes are very similar to each other, though AZB has no symmetry in the molecule. The N(1)–C(1) length is larger than N(2)–C(4). The N–C bond lengths in AZB are much shorter than those in II. The bond angles concerning N(1), which coordinates to Pd, are in good agreement between II and AZB. However, the N(1)–N(2)–C(4) angles are significantly different in these complexes. The corresponding angle in II is smaller than that in AZB.

Short contacts involving the H atoms are found in these complexes. The H···Pd contacts are 2.56 Å in II, and 2.60 and 2.61 Å in AZB. Fairly short H···Cl contacts are observed: 2.78 Å in II, and 2.59 Å in AZB.

Discussion

When $[PdC_4(COOCH_3)_4]_n$[2,3] reacted with *N,N*-dichlorocyclohexylamine at room temperature, yellow-orange crystals with the composition of $PdCl_2(c\text{-}C_6H_{11}N)_4$, I, were obtained in a 16.7% yield. A complete elimination of the diene unit, $C_4(COOCH_3)_4$, from the palladiacyclopentadiene skeleton indicates the formation of a highly reactive Pd(0) state which abstracts two Cl atoms from *N,N*-dichlorocyclohexylamine to generate cyclohexylnitrene. The X-ray analysis of I made it clear that cyclohexylnitrene was dimerized to azocyclohexane, followed by the coordination of the dichloropalladium(II) moiety. The latter process was confirmed by the independent preparation of I from dichlorobis(benzonitrile)palladium(II) and azocyclohexane. This behavior is different from similar reactions between $[PdC_4(COOCH_3)_4]_n$ and several *N,N*-dichloroacyl amides,[4] which gave σ-4-chloro-1,2,3,4-tetrakis(methoxycarbonyl)buta-1,3-dienylpalladium complexes by the ring-opening of only one Pd–C bond of the palladiacyclopentadiene skeleton.

The NMR spectrum of I indicates two broad signals due to H(1) at δ 5.45 and 5.35; these signals show substantial low-field shifts from free azocyclohexane (δ 3.26) on coordination. The separation and intensive broadening of the two signals indicate that the two H(1)'s are not equivalent to each other in solution. The difference between the two cyclohexyl rings in solution is also consistent with the CMR spectrum of I, in which three signals corresponding to the C(2), C(3), and C(4) atoms are observed.

On the contrary, the NMR spectrum of II shows a well-separated multiplet(J=7 Hz) at δ 4.87, indicative of H(4), as well as a broad multiplet at δ 5.60, which is ascribed to H(1). This fact clearly suggests that the coordination mode of II in solution is consistently identical with that in the solid state.

The authors wish to express their thanks to Professor Masao Kakudo of Osaka University and Professor Jiro Tanaka of Nagoya University, who kindly allowed them to use the diffractometers in their laboratories. The authors are also grateful to Dr. Noritake Yasuoka of Osaka University for his helpful discussion.

Carrier Effect of Reversed Micelle on Imidazole Catalyst

Kijiro KON-NO, Ayao KITAHARA,* and Masami FUJIWARA
Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received May 10, 1978)

The reversed micelles of neither didodecyldimethyl ammonium bromide(DDAB) nor sodium 1,4-bis(2-ethylhexyl) 2-sulfonatosuccinate(AOT) catalyse the decomposition of *p*-nitrophenyl acetate(PNPA) by themselves. However, these reversed micelles increase the action of imidazole in the decomposition of PNPA by solubilizing it. This interesting carrier effect of the reversed micelle on imidazole was investigated in both anhydrous and hydrous systems. The carrier effect of DDAB was greater than that of AOT. This difference was related to the different interaction between imidazole and each of the surfactants. The existence of the different interaction was made clear from the investigation on the change of chemical shift of the H(1) proton of imidazole upon solubilization by the reversed micelle. The mechanism of the decomposition of PNPA was partially explained from NMR measurements. Aminolysis occurred in anhydrous systems and hydrolysis in hydrous systems. Water pooled in the reversed micelle was more effective than bulk water in enhancing the catalytic effect of imidazole.

It has been recently reported that oil-soluble surfactants such as alkylammonium carboxylate catalyse a variety of reactions in nonaqueous media.[1-4] It is thought that the reversed micelles formed by these oil-soluble surfactants play an important role in the catalysis. The reversed micelles can solubilize some oil-insoluble or oil-soluble ploar substances. Solubilized substances may affect the catalytic activity through their interaction with the surfactants. The effect of solubilized water on the catalytic activity of alkylammonium carboxylate has been previously published.[3-6] Also, the effect of methanol, propylamine or acetic acid solubilized by dodecylammonium propionate on the decomposition of PNPA has been reported by these authors.[7] Similarly, non-catalysing reversed micelles may change the catalytic properties of a solubilized catalyst through an interaction between the catalyst and micelle.

In this paper, the effects of the non-catalysing reversed micelle of cationic and anionic surfactants on the catalytic activity of imidazole for the decomposition of PNPA is studied in anhydrous and hydrous systems and these effects related to the interaction between the reversed micelle and imidazole. Because nonionic surfactants showed behavior differing from that of the ionic surfactants used here, studies on nonionic surfactants will be reported separately.

Experimental

Materials. Didodecyldimethyl ammonium bromide (DDAB) and sodium 1,4-bis(2-ethylhexyl) 2-sulfonatosuccinate(AOT) were used as typical oil-soluble cationic and anionic surfactants. Preparation and purification of the surfactants are described elsewhere.[8] The guranteed reagent grades of imidazole and *p*-nitrophenyl acetate(PNPA), the catalyst and the substrate, respectively, were utilized. Carbon tetrachloride (CCl_4) was used as the solvent for both UV and NMR measurements. The solvent was purified as usual and carefully dried with Molecular Sieve 4A. However, a small quantity of water in the reaction systems was inevitable because of the hydroscopicity of the surfactants. Water content measured with the Karl-Fischer method was approximately 2 mmol kg^{-1} for the DDAB system and 7 mmol kg^{-1} for the AOT system for the anhydrous systems.

Methods. The decomposition of PNPA was followed by measurement of the changes in UV absorption at 318 nm, the wavelength of maximum absorption for the *p*-nitrophenol produced by the reaction. The UV spectrometer was a Shimadzu Double Beam Spectrophotometer UV-200. The initial concentration of PNPA was always 6.45×10^{-4} mol kg^{-1}. The decomposition of PNPA was always observed to be a pseudo-first order for PNPA.

NMR spectra were taken with a Hitachi NMR Spectrometer R-21(60 MHz). Chemical shifts were obtained relatively to an external TMS standard.

UV and NMR spectra were taken at 30 and 35 °C, respectively. All of the concentrations were expressed in molality(m, mol kg^{-1}) except those in Fig. 1.

Results and Discussion

Anhydrous Systems. Changes in the observed rate constants (k_{obsd}) varying the concentration of imidazole and holding the surfactant concentration constant(0.1 m) were depicted in Fig. 1. Changes in the imidazole–dodecylammonium propionate(DAP) system were shown for comparison in the figure. Because the solubility of imidazole in CCl_4 is only 5 mmol kg,$^{-1}$ the increase of k_{obsd} with increased concentration of imidazole, as seen in Fig. 1, is due to solubilized imidazole. It is seen from Fig. 1 that

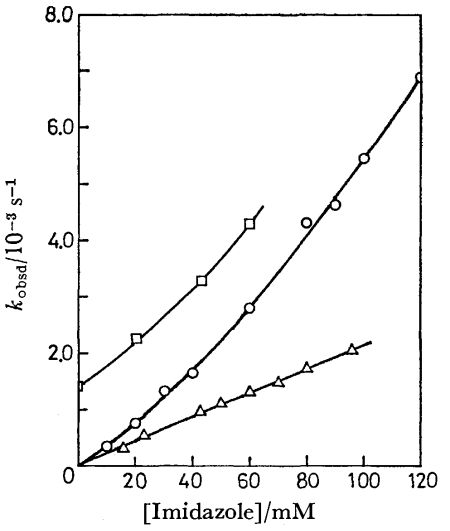

Fig. 1. Plots of k_{obsd} *versus* concentration of imidazole (mmol l^{-1}) at a fixed concentration of surfactants (0.1 m). —○—: DDAB, —△—: AOT, —□—: DAP.

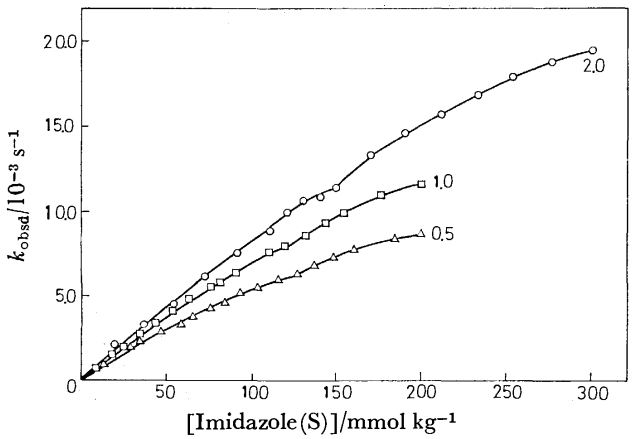

Fig. 2. Plots of k_{obsd} *versus* concentration of Imidazole-(S) in DDAB solutions. Figures show molar ratio of imidazole to DDAB.

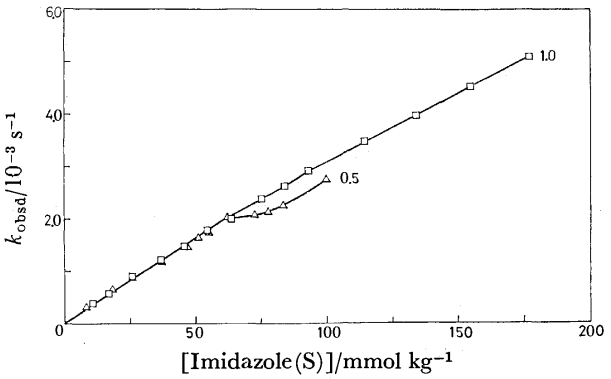

Fig. 3. Plots of k_{obsd} *versus* concentration of Imidazole-(S) in AOT solutions. Figures show molar ratio of imidazole to AOT.

DAP catalyzes the reaction in the absence of imidazole; however, neither DDAB nor AOT do so.

In order to investigate the effect of solubilization by non-catalsing micelle on the catalytic activity of imidazole, the systems solubilizing imidazole at a fixed ratio to a surfactnat were used and the change of reaction constant(k_{obsd}) with the concentration of solubilized imidazole was measured. The molar ratios of imidazole to the surfactant used were 0.5, 1.0, and 2.0. Imidazole solubilized at a fixed ratio is designated as "Imidazole(S)" or "Im(S)".

The relationship between k_{obsd} and the concentration of Im(S) for DDAB and AOT solutions is shown in Figs. 2 and 3. A linear relation can be seen at low concentration for both surfactant systems. The relation shows a curved line at higher concentration, some inflection appearing on the way. These changes may be due to changes in the size or shape of reversed micelles in this range. However, the present discussion forcuses on the lower concentration range.

The slope of the linear part gives the first order rate constant for Im(S), which was listed as k_1 in Table 1. To obtain the rate constant for imidazole dissolved in pure CCl_4, the rate constant for a small quantity of imidazole in the absence of any surfactant was measured. The rate constant obtained was designated as k_1°. The ratio, k_1/k_1° listed in Table 1 is a measure

Table 1. Rate constants for imidazole solubilized in anhydrous media

Surfactant	Molar ratio	k_1 (kg mol^{-1} s^{-1})	k_1/k_1° [a]
DDAB	0.5	0.067	5.4
	1.0	0.077	6.2
	2.0	0.080	6.4
AOT	0.5	0.033	2.6
	1.0	0.033	2.6

a) k_1°: the first order rate constant for imidazole in pure CCl_4: the value is 0.0124 kg mol^{-1} s^{-1}.

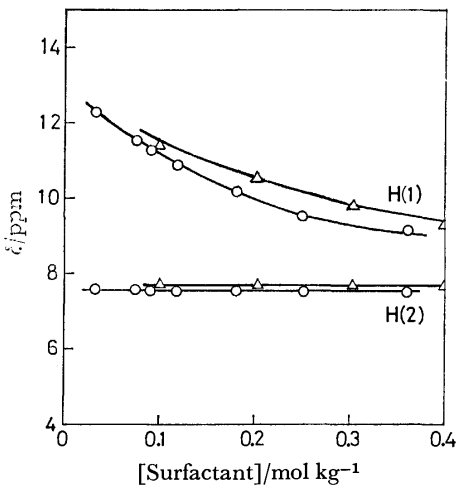

Fig. 4. Change of chemical shift of H(1) and H(2) protons of imidazole with concentration of surfactants. —○—: In DDAB solutions, —△—: in AOT solutions.

of the carrier effect of the surfactants. It is apparent that both surfactants show carrier effect for imidazole. DDAB shows a greater effect than AOT as seen in Table 1. Increase of the values of k_1/k_1° with increase of the molar ratios for DDAB as seen in Table 1 seems to show a concentrating effect of imidazole in the reversed micelle. It is considered that the difference in the observed rate constants of two surfactants is due to different interaction with imidazole.

The chemical shifts of the H(1) and H(2) protons of imidazole were measured in order to examine the interactions mentioned above. The result was shown in Fig. 4. It was observed that the chemical shift of the H(1) proton in both DDAB and AOT solutions shifts to higher field with increase of surfactant concentrations, though that of the H(2) proton does to minor extent. The high field shift shows the existence of the interaction of the H(1) proton with the polar part of the surfactant molecule in the reversed micelle. It is considered that the high field shift resulting from the interaction is due to electron-donation from bromide ion or sulfonate ion of each surfactant to the proton. Here bromide is more electron-donative(basic) than sulfonate, because the latter is partially hindered by neighboring sodium ion.

The interaction has been also discussed by NMR method on the solubilization of methanol and acetic acid by DDAB and other surfactants.[9] Higher field

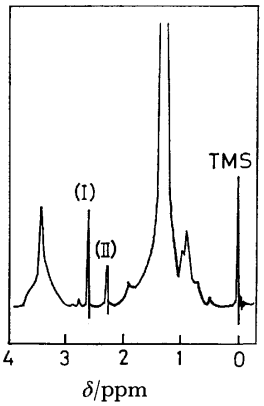

Fig. 5. NMR spectrum of DDAB–imidazole–PNPA solution in anhydrous CCl_4. Peak (I): $C\underline{H}_3CO$- of acetylimidazole, peak (II): $C\underline{H}_3CO$- of PNPA.

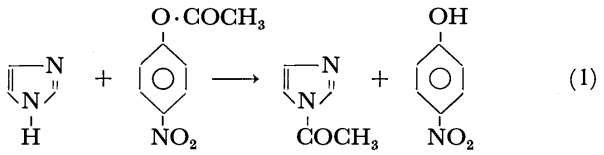
shifts correspond to higher interaction constants.[9] Therefore, the higher field shift of the H(1) proton in DDAB solution than that in AOT solution seen in Fig. 4 shows that the interaction of the H(1) proton with the reversed micelle is more intensive in the DDAB solution. This correlates with the higher values of $k_1/k_2^?$ for DDAB than AOT in Table 1. Minor change of the H(2) proton shows that the proton interacts with the surfactant in the micelle to minor extent.

NMR was further used to obtain some information on the reaction mechanism involved. Here, a higher concentration of PNPA was used in order to obtain a significant peak in the spectrum. A mixture of DDAB, imidazole and PNPA in CCl_4 (each component 0.1 m) was prepared and allowed to stand overnight. The NMR spectra of the mixture was shown in Fig. 5. The appearance of a peak corresponding to $C\underline{H}_3CO$– of 1-acetylimidazole(I) but none corresponding to acetic acid, shows that the reaction is a kind of aminolysis as shown in Eq. 1 and does not proceed to hydrolysis which may be expected from minor inevitable content of water.



(1)

The NMR spectra of the AOT–imidazole–PNPA solution in CCl_4 were similar to those of DDAB solution. Similar aminolysis of the ester by benzamidine and piperidine has also been observed.[10,11] The proposed mechanism was further supported by the UV spectra of the mixture of AOT(0.1 m), imidazole(0.1 m), and PNPA(6.4×10^{-4}m) in hexane, which showed a gradual decrease of the peak corresponding to PNPA (263 nm) and the simultaneous increase of the peaks corresponding to *p*-nitrophenol(313 nm), and 1-acetylimidazole(220 nm) during the successive mixing for 4 h.

Acceleration of Reaction 1 by the reversed micelle may be due to combined catalytic action by imidazole and the basic part of the micelle(Br^- in DDAB or SO_3^- in AOT). This action is well known in aqueous solutions, as in the action of imidazole and hydroxide

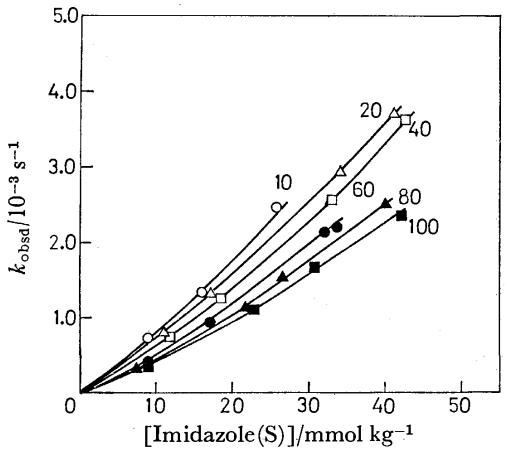


Fig. 6. Plots of k_{obsd} *versus* concentration of imidazole at a fixed concentration of water (0.020 m). Figures show concentration of DDAB (mmol kg^{-1}).

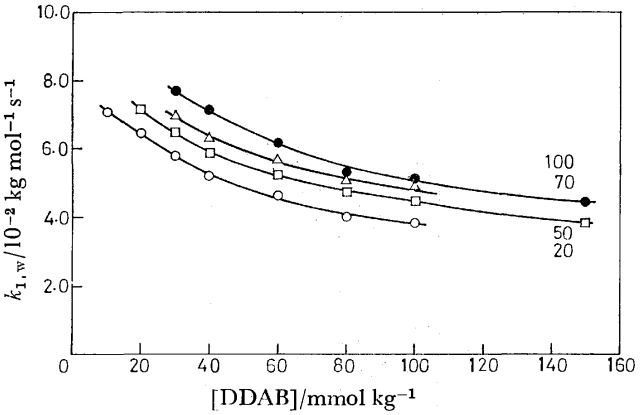

Fig. 7. Plots of $k_{1,w}$ *versus* concentration of DDAB. Figures show concentration of water(mmol kg^{-1}).

anion.[12] The existence of such an interaction between imidazole and the basic part of a reversed micelle can be seen from the remarkable shift of the H(1) proton in Fig. 4. Differences between DDAB and AOT with regards to interaction and acceleration of reaction may result from a difference in the structure of their reversed micelles. In the DDAB systems, the anion is exposed to the interior of the micelle, while in the AOT system, the anion is partially covered by Na^+. The effect of didodecyldimethyl ammonium chloride (DDAC) and iodide(DDAI) was compared with that of DDAB to check the basic activity. The order of the effects on both the rate and the chemical shift was DDAC>DDAB>DDAI. The order corresponds to that of the basicity of halogen ions.

Hydrous Systems. The quantity of water added to the reaction systems of imidazole–PNPA–surfactant in CCl_4 was of the same order as the surfactant. Because partition of water between the micelle and the solvent is of great advantage to the micelle, though the solubility of water in the solvent is 0.045 m at 30 °C, it was reasonably assumed that all of water added is solubilized in the reversed micelle and that water affects the imidazole catalyst under the state trapped in the interior of the micelle.

The change of k_{obsd} with concentration of imidazole

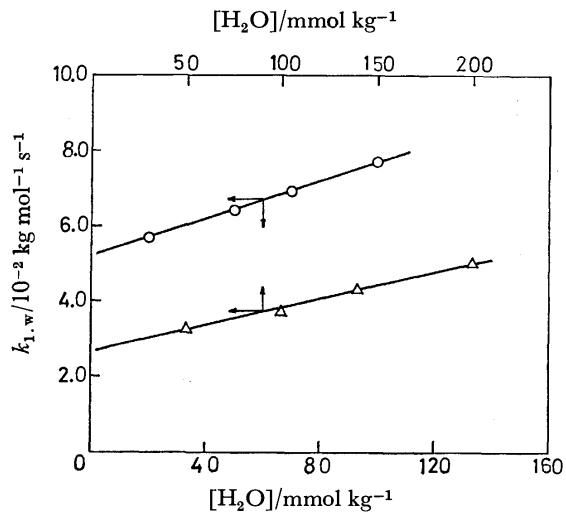

Fig. 8. Plots of $k_{1,w}$ *versus* concentration of water. —○—: solution of 30 mmol kg^{-1} of DDAB, —△—: solution of 20 mmol kg^{-1} of AOT.

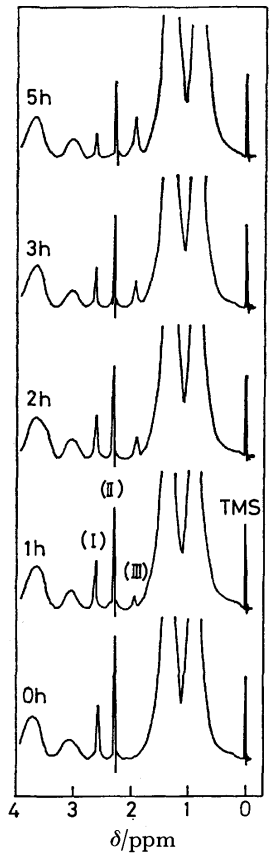

Fig. 9. NMR spectra of solution of DDAB-imidazole-PNPA-H_2O in CCl_4. Peak (I): $C\underline{H}_3CO$- of acetylimidazole, peak (II): $C\underline{H}_3CO$- of PNPA, peak (III): $C\underline{H}_3CO$- of acetic acid.

was measured by selecting the concentration of surfactant or water as a parameter. An example using the DDAB system(the concentration of water: 0.020 m) is given in Fig. 6. Similar plots were also obtained for 0.050, 0.070, and 0.100 m of H_2O. The initial slope of these plots is considered to be the first order rate constant for imidazole($k_{1,w}$), though the linearity is not complete. The values of $k_{1,w}$ were plotted against the concentration of DDAB,[DDAB], for various choices of the concentration of water, [H_2O], in Fig. 7. Relations quite similar to those shown in Figs. 6 and 7 were obtained for AOT system. The decrease of $k_{1,w}$ with increasing [DDAB] apparent in Fig. 7 shows the effect of dilution of the imidazole by the surfactant.

TABLE 2. RATE CONSTANT PARAMETERS FOR IMIDAZOLE IN HYDROUS MEDIA

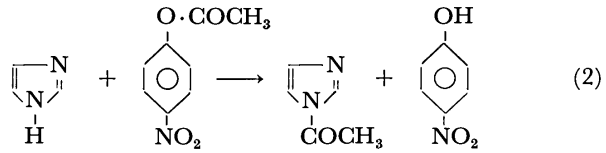
Surfactant	Concentration of surfactant (mmol kg^{-1})	$k^{r}_{1,w}$ [a] (kg mol^{-1} s^{-1})	$k^{r}_{1,w}/k^{\circ}_{1,w}$ [b]
DDAB	30	13.9	21.5
	40	13.9	21.5
	60	10.9	16.9
	80	8.6	13.3
	100	8.4	13.0
AOT	20	4.1	6.3
	40	3.1	4.9
	60	1.9	2.9
	100	0.7	1.1

a) $k^{r}_{1,w}$: rate constant calculated for 1 kg of water solubilized. b) $k^{\circ}_{1,w}$: rate constant for imidazole in pure water (the value is 0.645 kg mol^{-1} s^{-1}).

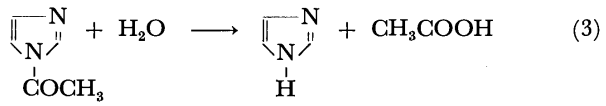
In Fig. 8 were rearranged the relation of Fig. 7 as plots between $k_{1,w}$ and [H_2O]. The slope of the resulting lines in Fig. 8 shows the increment of $k_{1,w}$ relative to [H_2O] of 1 mmol kg^{-1} in the reversed micelles. Therefore, the reduced rate constant, $k^{r}_{1,w}$, could be calculated by multiplying the slope by the molar concentration of pure water, 55.5 mol kg.$^{-1}$ The values obtained are listed in Table 2.

The effect of water pooled in the reversed micelle on the catalytic activity of imidazole was estimated by comparing these reduced rate constants($k^{r}_{1,w}$) with the first order rate constants of the catalytic reaction of imidazole in pure water ($k^{\circ}_{1,w}$) which was measured separately. The values of the ratio, $k^{r}_{1,w}/k^{\circ}_{1,w}$ in Table 2 show that water pooled in the reversed micelle accelerates the catalytic effect of imidazole more markedly than free water. It is also seen in Table 2 that DDAB has a greater acceleration effect than AOT and that $k^{r}_{1,w}$ and $k^{r}_{1,w}/k^{\circ}_{1,w}$ decrease with increasing concentration of surfactants, showing the effects of the dilution of imidazole by the surfactants.

Again, to obtain some information on the reaction mechanism in hydrous systems, changes in the NMR spectra with time for the mixture of DDAB, imidazole, PNPA, and water in CCl_4, each component being 0.1 m, were measured. The result was shown in Fig. 9. Immediately after mixing, a peak corresponding to $C\underline{H}_3CO$- of 1-acetylimidazole appeared. As time elapsed, this peak(I) decreased and a peak corresponding to $C\underline{H}_3CO$- of acetic acid(III) appeared and gradually increased. Hence we can safely assign the following well known hydrolysis mechanism(Eqs. 2 and 3) to the systems solubilizing imidazole and considerable amount of water.



(2)



(3)

The rate of Eq. 2 was very fast due to the large quantity of PNPA used(0.1 m). Similar time dependence was observed in the NMR spectra of the AOT–imidazole–PNPA–H_2O system in CCl_4. However, it has not yet been determined how much water is necessary for Reaction 3 to proceed.

The Crystal and Molecular Structure of Daphnetin 8-β-D-Glucopyranoside Dihydrate Isolated from *Daphne odora*

Katsuhiko UENO,* Norio SAITO,** and Mitsuhiko SATO***

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221

*** Chemical Laboratory, Meiji-gakuin University, Minato-ku, Tokyo 108*

**** Department of Biology, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 154*

(Received May 13, 1978)

The crystal structure of daphnetin 8-β-D-glucopyranoside dihydrate has been determined by the X-ray method. The crystal is monoclinic, space group $P2_1$, with the lattice parameters $a=7.773(1)$, $b=22.478(5)$, $c=4.715(1)$ Å, $\beta=99.77(2)°$, and $Z=2$. The structure was determined by the direct method and refined by least-squares to a final R of 0.041 for 2690 observed reflexions. The daphnetin moiety is approximately planar, and little effect from glucosylation is observed in the bond lengths and angles, compared with daphnetin itself. The glucopyranoside is in C_1 chair conformation, with the ring torsion angles ranging from 48 to 66°. The anomeric C–O bond is twisted by 78.2° against the coumarin plane, which is the largest value in aromatic glycopyranosides so far reported and which is concomitant with a small valence angle, 114.4°, at the oxygen atom linking the coumarin and the glucose group.

During the course of studies on the biosyntheses of naturally occuring dihydroxycoumarins, Sato and Hasegawa found new enzymes from *Daphne odora* and *Cichorium intybus*. These enzymes show high substrate specificities for the hydrolysis and transglucosylation of dihydroxycoumarins and their glucosides.[1-4] As a part of investigations on the reaction mechanism of these enzymes, the structures of daphnetin (or 7,8-dihydroxycoumarin)[5] and esculetin(or 6,7-dihydroxycoumarin) have already been reported and some effects of the tautomerism were suggested in the molecular structures of 7-hydroxylated coumarins.[6] The present paper deals with the conformation of glucosylated coumarin and the effects of the glucosylation on the structure of the coumarin molecule.

Experimental

The crystals were obtained as transparent prisms by slow evaporation from an aqueous ethanol solution. The lattice constants and intensity data were obtained on a Rigaku four-circle diffractometer with graphite monochromated Mo $K\alpha$ radiation. A crystal $0.3\times0.2\times0.3$ mm in size was used. The scan mode of $2\theta/\omega$ was applied, with the scanning rate and range in ω of 2° min^{-1} and $(1.0+0.5\tan\theta)°$, respectively. Stationary background counts were made for 10 s before and after each scan. Of 3017 independent reflexions measured within $2\theta\leq65°$, 2690 had intensities greater than $3\sigma(|F_o|)$ and were used for the structure determination. No correction was made for absorption. The crystallographic data of daphnetin 8-β-D-glucopyranoside $2H_2O$ are: $C_{15}H_{16}O_9\cdot2H_2O$, $F.W.=376.3$. Monoclinic, $P2_1$, $a=7.773(1)$, $b=22.478(5)$, $c=4.715(1)$ Å, $\beta=99.77(2)°$. $Z=2$, $D_x=1.53$, $D_m=1.54$ g cm^{-3} (by flotation in a mixture of hexane and carbon tetrachloride). μ(Mo $K\alpha$) = 1.60 cm^{-1}. Systematic absence, $0k0$ with k odd.

Structure Determination

The structure was solved by the multi-solution method using 237 reflexions with $|E|\geq1.50$.[7,8] A phase set with the lowest R-value[9] gave an E-map which revealed the coumarin moiety. All the other non-hydrogen atoms emerged in successive Fourier maps. The structural parameters were refined by the block-diagonal least-squares method. The hydrogen atoms were located on a D-map at the stage of $R=0.09$ and their positional and isotropic thermal parameters were included in the refinement. The weighting scheme of $w=(20.0/|F_o|)$ if $|F_o|\geq20.0$, $w=1.0$ if $20.0>|F_o|\geq10.0$, and $w=(|F_o|/10.0)$ if $|F_o|<10.0$ was applied. The final R was 0.041 for 2690 observed reflexions. The atomic scattering factors were taken from International Tables for X-Ray Crystallography.[10] A list of observed and calculated structure factors is given in Table 1.[11] The final atomic parameters are shown in Table 2.

Results and Discussion

Molecular Geometry. The perspective drawing of the molecule with the numbering system is shown in Fig. 1. The bond lengths and angles are given in Fig. 2. The molecule is bent down at the glucosidic oxygen with a dihedral angle between the coumarin plane and the mean plane of the glucose ring of 116°. The daphnetin moiety is nearly planar. The equation of the best plane for the daphnetin moiety is given by

$$-0.3451X-0.5255Y-0.7777Z+8.3748=0.0,$$

where X, Y, Z refer to the crystallographic axes a, b, c* in Å units. The C(3), O(2), and O(1′) atoms show somewhat large deviations from this plane (−0.046, 0.045, and −0.038 Å, respectively). Compared with daphnetin,[5] the corresponding endocyclic bond lengths and angles deviate by no more than 0.01 Å and 0.7°, respectively, except for the angles around C(7) and, C(8); the C(6)–C(7)–C(8) angle is smaller by 2.0° the C(7)–C(8)–C(9) is larger by 1.5°, and the C(7)–C(8)–O(1′) is markedly larger by 3.4° than in daphnetin. The C(7)–O(7) bond is significantly shorter than those in other 7-hydroxylated coumarins, such as daphnetin, esculetin,[6] and 4-methylumbelliferone[12] (1.366, 1.358, and 1.393 Å, respectively). The C(8)–O(1′) bond is close to the bond length of the 8-methoxy group in xanthotoxin(1.375 Å).[13]

The glucopyranose moiety is in C_1 chair conformation and C–C bond lengths have similar values to those in other pyranoses observed in the X-ray studies.[14] Some relevant torsion angles are listed in

Table 3. The endocyclic torsion angles vary from 48 to 66°. The pyranose ring has an approximate mirror symmetry normal to the mean plane of the ring and passing through the ring O and C(3′) atoms.[15] The maximum deviation from this pseudo mirror palne in torsion angle is 3.7°(between C(1′)–C(2′) and C(4′)–C(5′).) The conformation of the primary alcohol group is in a gauche-gauche orientation. although slightly distorted from the ideal 60° staggered form.

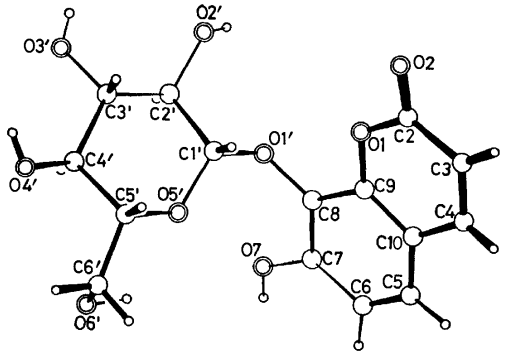

Fig. 1. Perspective drawing of the molecule with numbering system used.

Conformation of Glucosidic Bond. The bond lengths and angles in the sequence C(5′)–O(5′)–C(1′)–O(1′)–R have been discussed as an anomeric effect; it is expected that in the β-pyranose C(5′)–O(5′)≃O(5′)–C(1′)>C(1′)–O(1′), while in the α-anomer C(5′)–O(5′)>O(5′)–C(1′)≃C(1′)–O(1′).[14,16,17] In this crystal, however, C(5′)–O(5′) is significantly longer than O(5′)–C(1′) and C(1′)–O(1′). A similar geometry has been observed in some other aromatic β-pyranosides, such as *p*-nitrophenyl β-D-*N*-acetylglucosaminide[18] and 6-bromo-2-naphtyl β-D-glucopyranoside.[19] The relevant

valence angles are consistent with those in the β-anomer. Table 4 shows the geometry of the glycosidic bond lengths and angles in some pyranosides.

The valence angle of the oxygen atom linking the coumarin and glucose group is markedly smaller than those in the other aromatic glycopyranosides and is rather close to those in the methyl glucosides(Table 4).

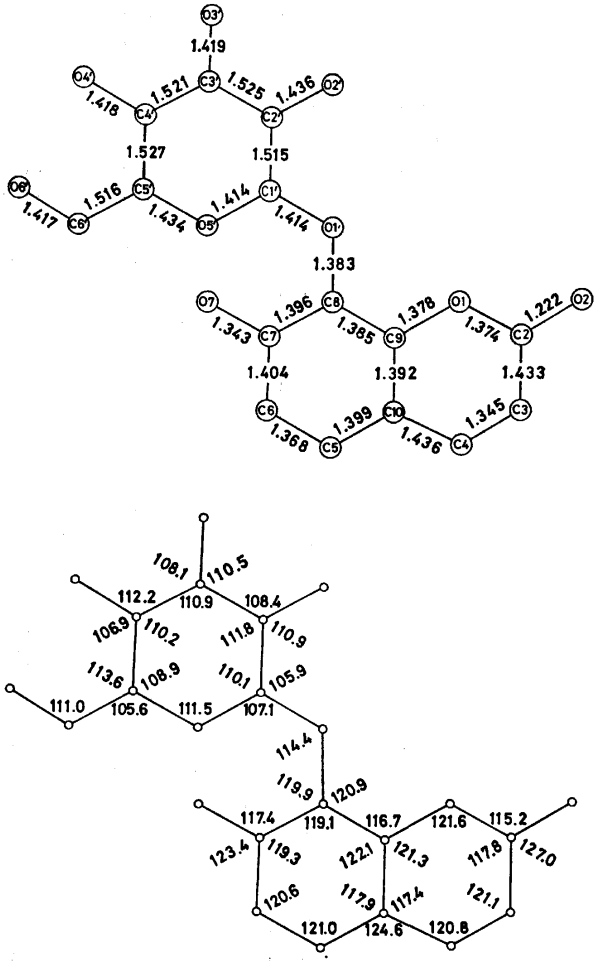

Fig. 2. Bond lengths (Å) and angles (°). The estimated standard deviations are 0.003—0.004 (Å) for lengths and 0.2—0.3 (°) for angles.

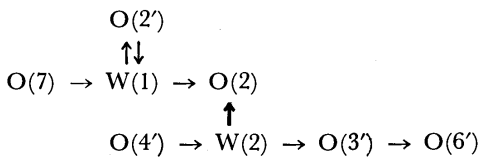
The O(1′)–C(1′) bond is twisted by 78.2° against the coumarin plane, which is the largest value in aromatic glycosides (φ in Table 4), probably owing to the repulsion between the O(7) and O(5′) atoms. The orientation of the O(1′)–C(8) bond is gauche and trans to the C(1′)–O(5′) and C(1′)–C(2′) bonds (−66.6 and 174.0°, respectively).

Crystal Structure. The crystal structure viewed down the c axis is shown in Fig. 3. The hydrogen bond lengths and angles are listed in Table 5. The O···O distances range from 2.716 to 2.918 Å. When a water molecule acts as a donor the lengths tends to be slightly larger than in other cases. This tendency is generally observed in the hydrogen bonds of amino acids and sugars.[24] The scheme of the three-dimensional hydrogen bond network is shown below:



where → indicates the donor direction. The water molecule W(1) is concerned with four hydrogen bonds in a tetrahedral arrangement, whereas W(2) is concerned with three hydrogen bonds in a pyramid. The difference in the hydrogen bond modes may reflect the discrepancy between the thermal parameters of these water molecules. The hydroxyl group O(6′)H does not act as a hydrogen bond donor, although some weak interaction to intramolecular O(5′)

Table 3. Endo- and exocyclic torsion angles
Only for exocyclic angles is the whole sequence of atoms given.

Endocyclic		Exocyclic	
C(1′)C(2′)	54.3°	O(8)C(1′)C(2′)O(2′)	−69.3°

Absolute Configurations of Asperlin, a Metabolite of *Aspergillus nidulans*, and Its Related Compounds

Keiichi FUKUYAMA,* Yukiteru KATSUBE, Akihiro NODA,**
Takashi HAMASAKI,** and Yuichi HATSUDA**
Faculty of Engineering, Tottori University, Koyama, Tottori 680

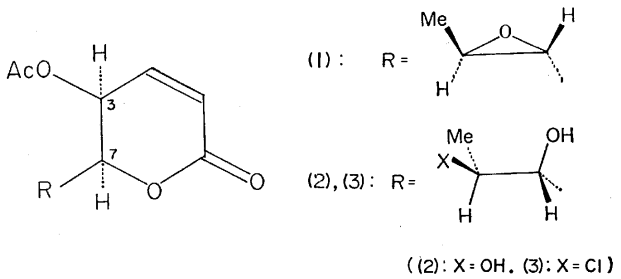
(Received May 26, 1978)

The structures of asperlin (**1**) $C_{10}H_{12}O_5$ and asperlinol (**2**) $C_{10}H_{14}O_6$, isolated from *Aspergillus nidulans*, and a chloro derivative of asperlin (**3**) $C_{10}H_{13}O_5Cl$ have been studied by the X-ray diffraction method. The absolute configuration of **3** has been determined by the Bijvoet method by utilizing the anomalous scattering of chlorine atom for Cu $K\alpha$ radiation. The present analysis has verified the configurations of the atoms in an $\alpha\beta$-unsaturated δ-lactone ring as suggested by spectroscopy. In each compound, the acetoxyl group occupies a quasi-axial and the three-carbon side chain a quasi-equatorial position on the lactone ring. All the crystals are orthorhombic, space group $P2_12_12_1$ with $Z=4$. The cell dimensions are $a=26.536$, $b=5.955$, $c=6.973$ Å for **1**, $a=25.496$, $b=7.097$, $c=6.329$ Å for **2**, and $a=26.050$, $b=5.899$, $c=7.548$ Å for **3**. The structures of **1**, **2**, and **3** were refined by the block-diagonal least-squares method to $R=0.068$ for 1084 reflections, $R=0.056$ for 1127 reflections, and $R=0.051$ for 831 reflections, respectively.

Extensive investigations have been made on the structures[1-4] and biosynthesis[5,6] of various kinds of lactone derivatives isolated from the genus *Aspergillus*. Although the configurations at the C(3) and C(7) atoms in asperlin (**1**), a metabolite isolated from *Aspergillus nidulans*, have been suggested by spectroscopy,[1,3] the whole stereochemistry has not yet been established. Recently we have isolated a new compound $C_{10}H_{14}O_6$ (**2**), named asperlinol, from *Aspergillus nidulans* together with asperlin. Asperlinol (**2**) was suggested to be one of the hydrated compounds of asperlin on the basis of spectroscopic evidence, but a definitive structure remained to be determined because of its instability in solution. For the establishment of the absolute configurations of these compounds, the chloro derivative (**3**) was prepared from asperlin to utilize the anomalous scattering of the chlorine atom for X-radiation. In this paper we report the results of the X-ray analyses of **1**—**3**.



Experimental

Isolation of Asperlin (1) and Asperlinol (2). *Aspergillus nidulans* Wint. IFO 6390 was grown on malt extract medium in stationary culture at 24 °C for three weeks. The culture filtrate was adsorbed on activated carbon at pH 2—3 adjusted by hydrochloric acid. The carbon was extracted with acetone. Chloroform-soluble fraction of the acetone extract was concentrated, and chromatographed on a column of silicic acid. **1** was eluted with benzene, and **2** subsequently with benzene–acetone (9:1 v/v). **1** was recrystallized with ether to give colorless plates, which had physical constants identical with those for asperlin. **2** was further subjected to silicic acid column chromatography. The fraction eluted with benzene-acetone (4:1 v/v) yielded a colorless solid, which was recrystallized from an acetone–hexane solution to give colorless prisms (49 mg), mp 117—118 °C. Found: C, 52.38; H, 6.14%. Calcd for $C_{10}H_{14}O_6$: C, 52.18; H, 6.13%. $[\alpha]_D^{18}=220°$ ($c=0.9$, EtOH), λ_{max} (EtOH) 205(9200), ν_{max} (KBr) 3500, 3000, 2950, 1750, 1720, and 1640 cm^{-1}, δ(DMSO-d_6, 60 MHz) 7.07 (1H, dd, $J=6$ and 10 Hz), 6.12 (1H, d, $J=10$ Hz), 5.25 (1H, dd, $J=2.5$ and 6 Hz), 5.03 (1H, d, $J=5$ Hz), 4.48 (1H, d, $J=5$ Hz), 4.36 (1H, dd, $J=2.5$ and 9 Hz), 3.5—4.0 (2H, m), 2.01 (3H, s), and 1.03 (3H, d, $J=6$ Hz).

Preparation of Chloro Derivative (3). Asperlin (950 mg) was treated with hydrochloric acid (6 M, 10 ml) in diethyl ether (12 ml) at room temperature. Slow evaporation of ether gave colorless crystals from the aqueous solution, which were filtered and washed with water. Recrystallization with methanol gave chloro derivative (**3**) as colorless needles (440 mg), mp 187—189 °C. Found: C, 48.37; H, 5.46; Cl, 14.00%. Calcd for $C_{10}H_{13}O_5Cl$: C, 48.30; H, 5.27; Cl, 14.26%. $[\alpha]_D^{16}=280°$ ($c=0.9$, EtOH), λ_{max} (EtOH) 205 (10300), ν_{max} (KBr), 3450, 2980, 2925, 1750, 1720, and 1640 cm^{-1}, δ(DMSO-d_6, 60 MHz), 1.43 (3H, d, $J=6.5$ Hz), 2.02 (3H, s), 3.97 (1H, m, $J=2$, 6, and 10 Hz), 4.25 (1H, dq, $J=2$ and 6.5 Hz), 4.50 (1H, dd, $J=2.5$ and 10 Hz), 5.26 (1H, dd, $J=2.5$ and 6 Hz), 5.85 (1H, d, $J=6$ Hz), 6.15 (1H, d, $J=10$ Hz), and 7.08 (1H, dd, $J=6$ and 10 Hz).

Crystal Data. (a) Asperlin (**1**), $C_{10}H_{12}O_5$, $M=212.2$, orthorhombic, $P2_12_12_1$, $a=26.536(6)$, $b=5.955(4)$, $c=6.973(4)$ Å, $V=1101.9$ Å^3, $Z=4$, $D_x=1.279$ g cm^{-3}, $\mu=8.9$ cm^{-1} (for Cu $K\alpha$). (b) Asperlinol (**2**), $C_{10}H_{14}O_6$, $M=230.2$, orthorhombic, $P2_12_12_1$, $a=25.496(6)$, $b=7.097(4)$, $c=6.329(4)$ Å, $V=1145.2$ Å^3, $Z=4$, $D_x=1.335$ g cm^{-3}, $\mu=9.6$ cm^{-1} (for Cu $K\alpha$). (c) Chloro derivative of asperlin (**3**), $C_{10}H_{13}O_5Cl$, $M=248.7$, $a=26.050(7)$, $b=5.899(5)$, $c=7.548(5)$ Å, $V=1159.9$ Å^3, $Z=4$, $D_x=1.424$ g cm^{-3}, $\mu=29.9$ cm^{-1} (for Cu $K\alpha$).

Crystallographic Measurements. Preliminary photographic investigation showed all these crystals to be orthorhombic with the systematic absences uniquely characterizing $P2_12_12_1$. The approximate crystal size used for intensity measurement was $0.2\times0.4\times0.1$ mm^3 for **1**, $0.2\times0.3\times0.1$ mm^3 for **2**, and $0.2\times0.5\times0.2$ mm^3 for **3**. Each crystal was mounted with the b axis parallel to the ϕ axis of the diffractometer.

All the crystallographic measurements for **1** and **2** were

made under the same experimental conditions. The cell constants were determined by least-squares treatement of the angular settings of 13 reflections measured on a Rigaku computer-controlled four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation. The intensities were measured by the θ-2θ scan technique with a scan speed of 2° min^{-1} in θ. The scan width for each reflection was calculated with the formula; $\Delta(\theta)=1.0°+0.15°\tan\theta$. The background counts were taken for 8 s at each end of the scan range. Attenuators were inserted automatically to keep the counting rate below 10^4 cps. The intensities of 1085 and 1127 independent reflections were collected for **1** and **2** respectively in the range $0<\sin\theta/\lambda<0.58$.

The cell constants of **3** were determined from Bragg angles of the reflections of (h00), (0k0), and (00l). The intensities were measured in the left-handed coordinate system on a Rigaku tape-controlled four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation. The θ-2θ scan technique was used with the scan speed of 2° min^{-1} in θ. The scan width was 1.2° in θ for all reflections and the backgrounds were counted for 5 s at both sides of the scan. The intensities of 831 independent reflections were measured in the range 0<

$DEL=B_{ex}/B_{th}$, $B=2.0(Q-1)/(Q+1)$, $Q=F(hkl)/F(\bar{h}\bar{k}\bar{l})$. B_{ex} is the mean value of two B's observed individually. B_{th} has been calculated from the parameters at the final stage of the refinement including anomalous dispersion terms of chlorine atom; $\Delta f'_{Cl}=0.348$ and $\Delta f''_{Cl}=0.702$.

$\sin\theta/\lambda<0.53$.

The intensities were corrected for the Lorentz and polarization factors, but were not corrected for absorption.

Structure Determination and Refinement. *a)*: The structure of asperlin (**1**) was elucidated by MULTAN.[7] The 250 reflections with $|E|$ values greater than 1.2 were used for phase determination, and a set of phases of the highest figure of merit was chosen for the calculation of an E map. The map revealed the positions of all non-hydrogen atoms except the terminal methyl carbon atom; the atom was easily located by Fourier synthesis. The structure was refined by the block-diagonal least-squares method.[8] The atomic species and types of bonds were determined on the basis of temperature factors, and interatomic distances and angles as well as chemical information. The difference Fourier synthesis computed after the anisotropic refinement of the non-hydrogen atoms revealed the positions of hydrogen atoms. However, several minor residual peaks were found around the methyl gourp in the synthesis. The final refinement, including the contribution of these hydrogen atoms with isotropic temperature factors, reduced R to 0.068 for 1084 independent reflections ($R=0.052$ for non-zero reflections). The weighting scheme used in the final refinement was: $w=0.5$ for $F_o=0$ and $w=[\sigma^2(F_o)+0.004F_o^2]^{-1}$ for $F_o>0$, where the values of $\sigma(F_o)$ were calculated from counting statistics. However, zero weight was given for the strongest reflection, 601. The final atomic coordinates are given in Table 1(a).

b): The determination and the refinement of the structure of asperlinol (**2**) were made with the same way as that of asperlin. The final refinement, including the hydrogen atoms located in the difference Fourier synthesis with isotropic temperature factors, reduced R to 0.056 for 1127 independent reflections ($R=0.043$ for non-zero reflections). The weighting scheme used in the final refinement was $w=0.4$ for $F_o=0$ and $w=[\sigma^2(F_o)+0.03F_o]^{-1}$ for $F_o>0$.

The final atomic coordinates are given in Table 1(b).

c): The structure of chloro derivative (**3**) was solved by the heavy-atom method, and refined by the block-diagonal least-squares method in the same way as described above. After the absolute configuration of this molecule was determined (see below), the anomalous scattering factor of chlorine atom was included in the refinement. The positions of all hydrogen atoms were assigned from the difference Fourier synthesis. The final refinement, including the contribution of the hydrogen atoms with isotropic temperature factors, reduced R to 0.051 for 831 independent reflections, where the following weighting scheme was used; $w=0.5$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq 15$, and $w=[1.0+0.4(F_o-15)]^{-1}$ for

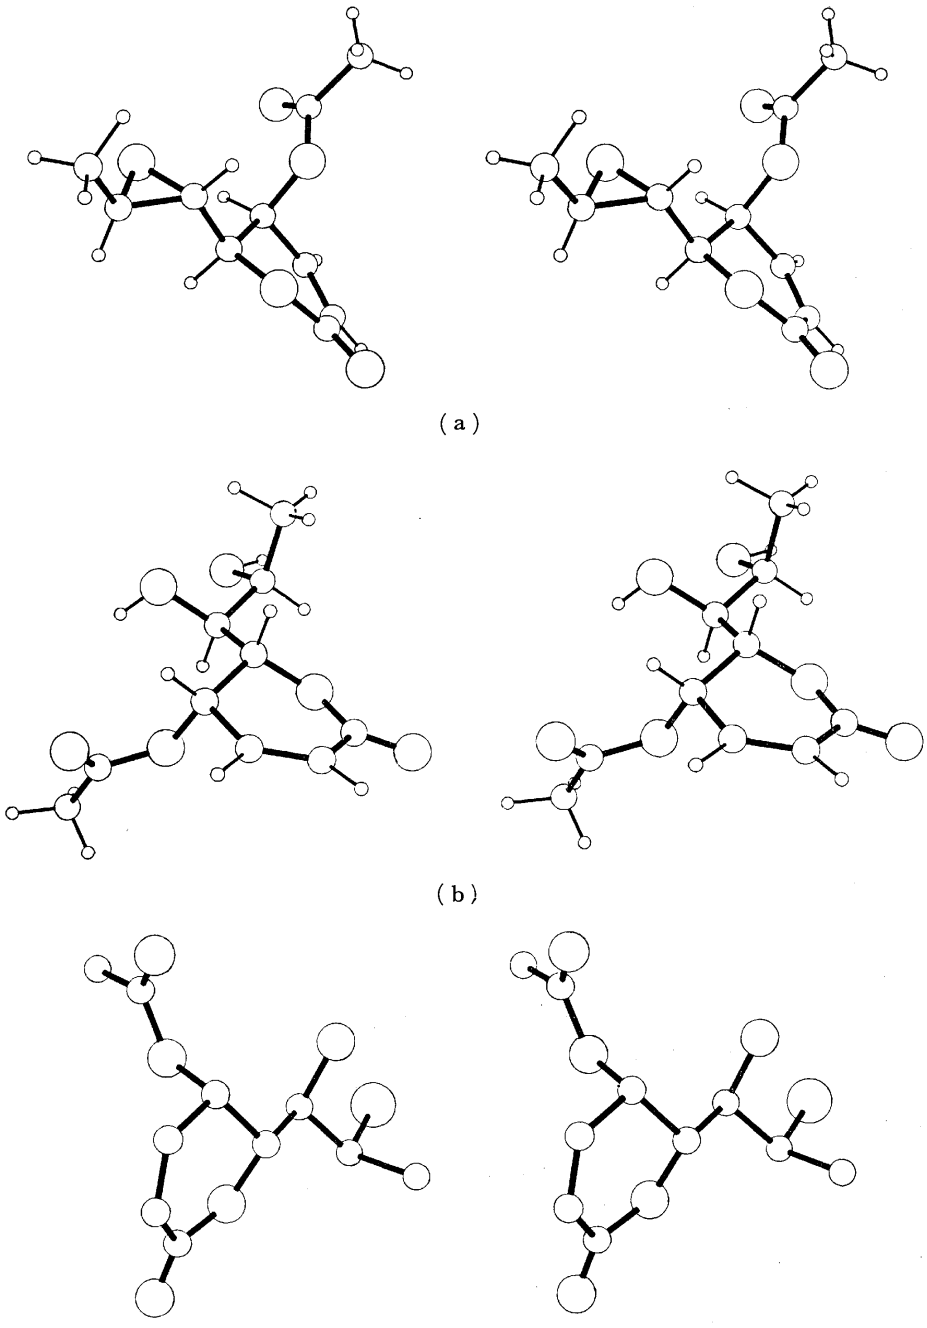

Fig. 2. (a) Stereoscopic view of asperlin (**1**). (b) Stereoscopic view of asperlinol (**2**). (c) Stereoscopic view of chloro derivative of asperlin (**3**). Each figure is drawn with the correct absolute configuration.

$15<F_o$. The final atomic coordinates are given in Table 1(c).

The temperature factors and the list of observed and calculated structure factors for each compound are kept as Document No. 7839 at the Chemical Society of Japan.

Absolute Configuration. The absolute configuration of **3** has been determined by the Bijvoet method.[9] The structure factors were calculated including anomalous scattering of chlorine atom for Cu $K\alpha$ radiation, and eighteen reflections sensitive to the choice of enantiomer were selected manually. The intensities of each pair of reflections, hkl and $h\bar{k}l$, were measured alternately twice. The experimental conditions for the Bijvoet measurement were the same as those for F_o-data collection previously described except the scan speed (1°/min in θ) and background counting time (10 s). The result of the Bijvoet measurement is given in Table 2. Since the measurement was made in a left-handed coordinate system, the absolute configuration of **3** is correctly represented by the atomic coordinates given in Table 1(c) referred to a right-handed coordinate system. Accordingly the absolute configurations of **1** and **2** have been established; the atomic coordinates in Table 1 in a right-handed coordinate system give the correct absolute configurations for **1** and **2**. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[10]

(III) $x, 1+y, 1+z$ (IV) $x, 1+y, -1+z$
(V) $1/2-x, -y, 1/2+z$
(VI) $1/2-x, 1-y, -1/2+z$
(VII) $1-x, 1/2+y, 1/2-z$
(VIII) $1-x, 1/2+y, -1/2-z$
(IX) $1-x, 1/2+y, 3/2-z$

Results and Discussion

The crystal structures and the numbering scheme of atoms used in this paper are shown in Fig. 1, and a stereoscopic view of each molecule plotted by a local version of PLUTO[11] in Fig. 2. The bond lengths and angles for non-hydrogen atoms are listed in Table 3, the selected torsion angles in Table 4, the equations of the least-squares planes and deviations of atoms from each plane in Table 5, and intermolecular distances less than 3.8 Å in Table 6.

The present X-ray crystallographic analysis has verified the configurations at the C(3) and C(7) atoms suggested by spectroscopy.[3] The hydrogen atoms in the epoxide ring of **1** are *trans*, the configurations at the C(8) and C(9) atoms being *S* and *R*, respectively. The configuration of the C(9) atom in **1** is opposite to that in **2** and **3**. This fact is consistent with the known mechanism that Walden inversion occurs at the atom to which nucleophile attack to open the epoxide ring.[12] The conformations found in the $\alpha\beta$-unsaturated δ-lactone rings are similar to each other. The planes of the lactone ring and olefinic double bond are not coplanar; the dihedral angles for **1**, **2**, and **3** are 12.4, 6.9, and 11.8°, respectively. The C(7) and O(4) atoms deviate to the same side of the plane of the olefinic double bond by different amounts. Such features are also found in related compounds.[13,14] As suggested by spectroscopy,[1,3,4] the hydrogen atoms at C(3) and C(7) are quasi-equatorial and quasi-axial, respectively. Since the NMR spectrum is reasonably explained by the results from the present crystallographic analysis, it is almost certain that the conformation of the lactone ring in solution is the same as that in the crystalline state. Beecham discussed the relationship between the chirality in the system C=C-C=O in an $\alpha\beta$-unsaturated lactone and the sign of the Cotton effect in the CD spectrum; he suggested that right or left-handed chirality causes a negative or positive Cotton effect in the $n\rightarrow\pi^*$ transi-

tion respectively.[13] In asperlin (**1**), the chirality in the system C=C-C=O in the crystalline state is left handed with the torsion angle being —163.6°. This fact is, according to Beecham's idea, consistent with the positive Cotton effect of **1**.[13]

In the crystals of **2** and **3**, an intermolecular hydrogen bond between one of the hydroxyl group(s) and the acetyl group, O(5)–H(O5)···O(1), connects molecules related by a screw axis. The distance of H(O5)··· O(1) is 1.81 Å for **2** and 1.87 Å for **3**, and the angle of O(5)–H(05)···O(1) is 163° for **2** and 166° for **3**, and that of H(O5)···O(1)–C(2) is 131° for **2** and 127° for **3**. The crystal structures of **2** and **3** are isotypic to each other (the b and c axes of **3** correspond to c and —b axes of **2** respectively), although **2** has an additional intermolecular hydrogen bond between the other hydroxyl group and the carbonyl oxygen atom of the lactone group, O(6)–H(O6)···O(3); the distance of H(O6)···O(3) is 2.08 Å, and the angles of O(6)–H(O6)···O(3) and H(O6)···O(3)–C(6) are 155° and 148° respectrively. There is no intramolecular hydrogen bond in the present three compounds. No abnormality in bond lengths and angles or in intermolecular distances is found in the crystals of **1**—**3**.

We wish to thank the staff of the Institute for Protein Research of Osaka University for the use of the Rigaku computer-controlled four-circle diffractometer. We are also indebted to Mr. Toshiaki Ogawa and Mr. Katsushi Tanikawa for valuable assistance in X-ray work.

Metachromasy. IV. The Simultaneous Determination of the Bound Dye Spectra and the Equilibrium Constants between Metachromatic Dyes and Various Polyelectrolytes by the Extended Principal Component Analysis Method

Kiwamu YAMAOKA* and Mineo TAKATSUKI

Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received June 3, 1978)

Fourteen sets of visible absorption spectra of two metachromatic dyes, Crystal Violet (CV) and Trypaflavine (TF), were measured in the presence of seven widely different polyelectrolytes—sodium polyphosphate, polyacrylate, and poly(ethylenesulfonate), sodium and potassium poly(*p*-styrenesulfonate)s, and native and denatured calf thymus DNA—in polymer residue-to-dye ratios between 0 : 1 and about 1 : 1. The optical titration curves of these dye-polyanion systems showed either of two changes, sigmoidal or monotonous. The method of principal component analysis was applied to the observed spectra of each dye–polyanion system in order to determine both the equilibrium constant of the binding reaction and the pure spectrum of the bound dye. An empirical parameter α was introduced into the expression for the equilibrium constant in such a way that $K=[\text{complex}]/[\text{free dye}][\text{unoccupied binding site}]^{\alpha}$, by which the sigmoidal titration curves could be reproduced only with $\alpha>1$ and the monotonous ones, with $\alpha\leqq 1$. The spectra of bound CV and TF showed metachromasy bands, which depend on the functional group and the conformation of the polyanions, in wavelength regions both shorter and longer than the peak wavelength of the free dyes.

Metachromasy is the well known phenomenon of the spectral change in staining dyes in the presence of polyelectrolyte in aqueous solution. A new absorption band often appears in the wavelength region shorter than the peak wavelength of free dye; it is called the *metachromasy* band (hereafter denoted as the Meta band). Various types of metachromasy, however, have been observed for different combinations of dyes and polyelectrolytes.[1-30] For example, metachromatic changes in Crystal Violet (CV, a triphenylmethane dye)[2] and Trypaflavine (TF, an acridine dye)[3] have been shown to depend on the degree of polymerization of sodium polyphosphate (NaPP) in solution. A remarkable Meta band appears in the CV–NaPP system, whereas no such band is apparent in the TF–NaPP system. Shirai *et al.*[29,30] recently reported that the peak position of the Meta band of Methylene Blue depends on the functional group of polyanions. Since metachromasy is a complicated phenomenon involving a multiple binding between dye and polyanion, it is necessary to know the pure absorption spectrum of the bound dye and the equilibrium scheme between the reaction components for quantitative and systematic studies. Nevertheless, surprisingly few spectra of bound dyes have been unraveled so far,[16,22,31] although the spectra of dimeric dyes have been determined in the absence of polymers.[32-36]

The method of principal component analysis (the PCA method)[37-39] was previously extended and successfully applied to the absorption spectra of various dyes for the simultaneous determinations of not only the number of absorbing components involved in equilibrium mixtures, but also their molar absorption coefficients, and of the equilibrium constant for the acid-base or dimerization reaction.[32] In the PCA method, only the initial concentrations of components and a set of observed absorption spectra are needed as experimental data. It is not necessary to measure the equilibrium concentrations of the various components by experiments such as equilibrium dialysis,[12,16,31] the use of which is limited by the size of permeable molecules of a relatively low molecular weight, the ionic strength of solution, and the dyes extremely adsorbable to the dialysis membrane. The PCA method circumvents these difficulties and should be suited for the determination of an equilibrium scheme for the binding of dye to polyelectrolyte.

In this investigation, the PCA method was applied to fourteen dye–polyelectrolyte combinations in order to obtain information necessary for the quantitative study of metachromasy. As sample dyes, cationic CV and TF were chosen because of their different metachromatic behavior,[1-3] while anionic polyelectrolytes were selected from the point of view of their backbone structure, functional group, and counter-ion. The pure spectrum of the bound dye and the equilibrium constant for the binding reaction were estimated for each dye–polyanion complex system. The results revealed that, in each case, the spectrum of the bound dye has the Meta bands in the wavelength regions shorter and longer than the pronounced peak of the free dye. The peak positions of these bands were found to depend on the functional group and conformation of the polyanions. These are important findings for investigating metachromasy quantitatively in terms of the electronic states of bound dye.[9,40] The optical titration data showed two types of titration curves, sigmoidal and monotonous, depending on the particular combinations of CV or TF with polyanions. An empirical parameter α was introduced into the equilibrium expression for the binding reaction between a dye and a polyanion. By using the parameter α, which may characterize the binding process, the sigmoidal and monotonous optical titration curves could be reproduced successfully.

Experimental

Materials. The dyes, CV and TF, are the same samples as were reported previously.[2,32] The number-average degree of polymerization ($\bar{n}$) of sodium polyphos-

phate (NaPP) is 154, the highest refractionated sample in the previous study.[2] Purified sodium polyacrylate (NaPA, mol wt 7.24×10^5) was described elsewhere.[41] The sodium poly(ethylenesulfonate) (NaPES, $\bar{n}=65$) was a gift of Dr. Masamitsu Shirai of the University of Osaka Prefecture. The potassium poly(*p*-styrenesulfonate) (KPSS, mol wt *ca.* 7.5×10^5) was given by Dr. Koshiro Yoshioka of the University of Tokyo. Both samples were used without further purification. Native calf thymus DNA (nDNA) was purchased from Worthington Biochemical Corp. and was heat-denatured to prepare the denatured sample (dDNA).[31] Sodium poly(*p*-styrenesulfonate) (NaPSS) was prepared by dialyzing the KPSS, which had been dissolved in 3 M aqueous NaCl, against a 1 M NaCl aqueous solution for two days and then against distilled water for four days. All the polyanion samples except DNA were dried *in vacuo* at 56 °C for 6 h and used to prepare the stock solutions (*ca.* 10^{-2} M). Just prior to the absorption measurements, the stock solutions were diluted with distilled water to the desired concentrations.

Procedures. Two matched pairs of 1.0 and 2.0 cm quartz cells were used for CV and TF respectively. The inner wall of the sample cell was pre-equilibrated with a concentrated dye solution to avoid errors due to the adsorption of the dye. The dye adsorbed on the wall was calibrated against distilled water in a clean reference cell. The sample cell was dried and then filled with a fixed volume (3.5 and 7 ml for 1.0 and 2.0 cm cells respectively) of a dye solution. The concentration of the dye solution was optically determined from the molar absorption coefficient ε (9.20×10^4 at 592 nm for CV, 4.67×10^4 at 452 nm for TF) immediately before the addition of a polyanion solution, since the adsorption of dye to galssware is unavoidable and since the actual concentration of the stock dye solution was inevitably reduced in storage.

The series of the absorption spectra of a dye solution were measured by titrating it with a polyanion solution delivered through a microburet. The volume change of the titrate was made as small as possible so as not to shift the binding equilibrium. The volume correction was made for the observed absrobance A_{obsd} which was read out to the maximum of four digits:

$$A = A_{\mathrm{obsd}}\frac{v_{\mathrm{I}}+v_{\mathrm{add}}}{v_{\mathrm{I}}},$$

where v_{I} and v_{add} are the initial volume of the dye solution, and the volume of the polyanion solution added to it, respectively.

Measurements. A Hitachi Model EPS-3T recording spectrophotometer was used. The temperature of the cell holder was kept at 25 °C by circulating water through it. The solutions in the cells were always equilibrated for 5—10 min before measurements.

The Concept of the Extended Principal Component Analysis Method

A detailed description of the PCA method and of its application to the equilibrium systems of dye molecules was given in a previous paper;[32] therefore, the concept of the extended PCA method is described here only briefly. In an equilibrium system which contains p absorbing components out of a total of q components, m different absorption spectra can be measured by varying the compositions between these components. This suggests that some correlation must exist between the m absorption spectra because of the contribution from the p absorbing components. These m absorption spectra can be expressed by a data matrix **D** whose element, $D_{ij}(i=1,\ m \text{ and } j=1,\ n)$, denotes the absorption coefficient of the ith spectrum at the jth selected wavelength. According to Beer's law, the **D** matrix must be represented by the product of a concentration matrix **C** and an absorption coefficient matrix $\boldsymbol{\varepsilon}$:

$$\mathbf{D} = \mathbf{C}\boldsymbol{\varepsilon} = \begin{pmatrix} C_{11} \cdots C_{1j} \cdots C_{1p} \\ \cdots\cdots\cdots\cdots \\ C_{i1} \cdots C_{ij} \cdots C_{ip} \\ \cdots\cdots\cdots\cdots \\ C_{m1} \cdots C_{mj} \cdots C_{mp} \end{pmatrix} \begin{pmatrix} \varepsilon_{11} \cdots \varepsilon_{1j} \cdots \varepsilon_{1n} \\ \cdots\cdots\cdots\cdots \\ \varepsilon_{i1} \cdots \varepsilon_{ij} \cdots \varepsilon_{in} \\ \cdots\cdots\cdots\cdots \\ \varepsilon_{p1} \cdots \varepsilon_{pj} \cdots \varepsilon_{pn} \end{pmatrix} \tag{1}$$

where C_{ij} is the equilibrium concentration of the jth component in the ith solution, and ε_{ij} is the molar absorption coefficient of the ith component at the jth selected wavelength. The matrices, **C** and $\boldsymbol{\varepsilon}$, however, are not known *a priori* in most cases. Hence, the purpose of the application of the PCA method to chemical equilibria is to determine those unknown quantities simultaneously.

In the PCA method, the second moment matrix **A** is first constructed by the product of the **D** matrix and its transposed matrix. The eigenvectors $\boldsymbol{e}_i(i=1,\ n)$ and the eigenvalues $\Lambda_i(i=1,\ n)$ of the **A** matrix can then be calculated by diagonalization. The eigenvectors are the fundamental components which are common to the m absorption spectra, while the eigenvalues represent the contribution of the corresponding eigenvectors to the m spectra.[32] The relation between A_{jk}, Λ_i, and e_{ik} is given as

$$\sum_{j=1}^{n} A_{jk}e_{ij} = \Lambda_i e_{ik}. \tag{2}$$

The eigenvectors giving rise to extremely large eigenvalues are considered to be the principal components. When the eigenvalues are arranged in the order of magnitude, the following relation must hold for the data matrix **D** composed of p absorbing components:

$$\Lambda_1 \geqq \Lambda_2 \geqq \cdots \geqq \Lambda_p \gg \Lambda_{p+1} \geqq \cdots \geqq \Lambda_n > 0. \tag{3}$$

The **D** matrix can, then, be represented by a linear combination of p eigenvectors:

$$\mathbf{D} = \mathbf{f}\boldsymbol{e}, \tag{4}$$

where the **f** matrix of the (m,p) type is a linear combination coefficient matrix and can be calculated by the least-squares method. The $\boldsymbol{\varepsilon}$ matrix can also be related to the p eigenvectors by means of a transformation matrix **t** of the (p,p) type as follows:[32]

$$\boldsymbol{\varepsilon} = \mathbf{t}\boldsymbol{e}. \tag{5}$$

Therefore, the concentration matrix **C** can be computed as follows:

$$\mathbf{C} = \mathbf{f}\mathbf{t}^{-1}. \tag{6}$$

In order to determine the values of the elements of the **t** matrix, an appropriate equilibrium expression must be assumed for the system containing q components in which the absorbing components are p ($p \leqq q$). In the present work, the following general expression was assumed to describe the binding reaction between a dye and a polyanion:

$$K = \prod_{i=1}^{q} [\mathrm{X}_i]^{\nu_i}, \tag{7}$$

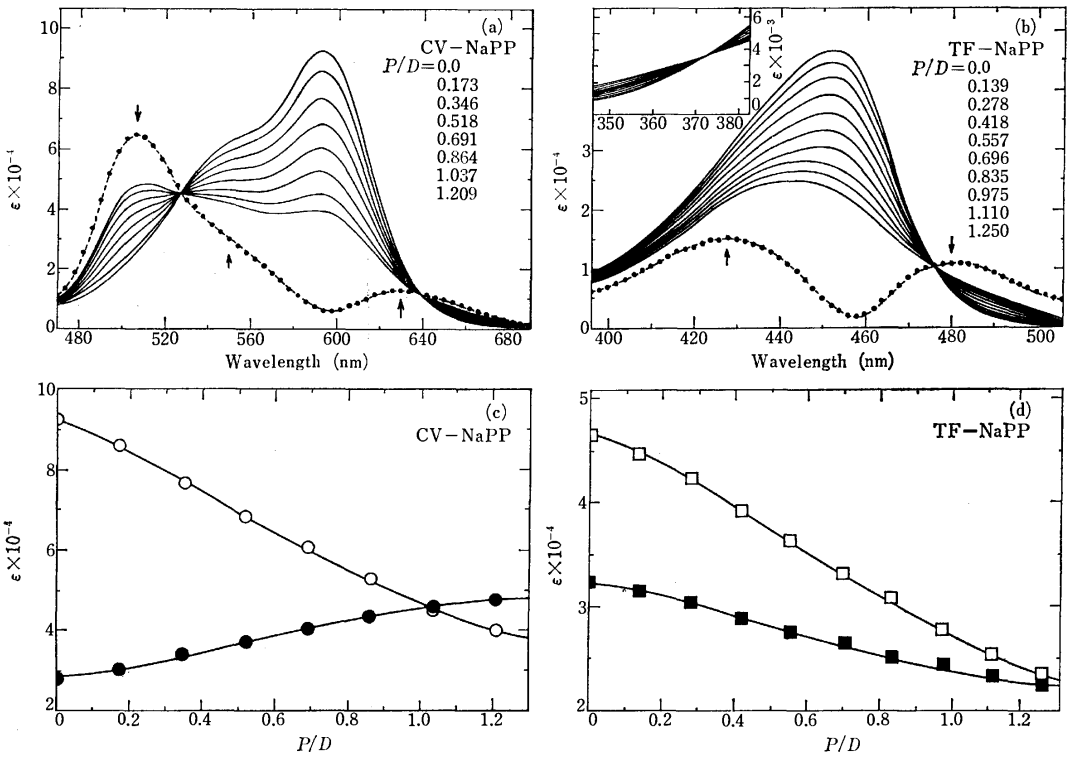

Fig. 1. Absorption spectra of CV and TF (solid curves) in the presence and absence of NaPP, the pure absorption spectra of bound dyes (closed circles) and optical titration curves.
The initial concentrations of CV and TF are 8.76 and 11.0 μM ((a) and (b)), respectively. The concentrations of NaPP are given in the respective figures in terms of *P/D*, the order of which corresponds to the order of the decrease in the maximum absorbances. The apparent molar absorption coefficients ε at 510 nm (●) and 592 nm (○) for CV and at 430 nm (■) and 450 nm (□) for TF are plotted against *P/D* in (c) and (d), respectively.

where K is the equilibrium constant, X_i is the ith absorbing or nonabsorbing component, and ν_i is the stoichiometric coefficient of X_i, whose equilibrium concentration is denoted by the brackets. The presence of nonabsorbing components in a given dye–polyanion system is subject to the equation of mass balance. Their equilibrium concentrations, therefore, can be calculated from their analytical concentrations and the **C** matrix if a set of the initial values for the elements of the **t** matrix is available. The substitution of m sets of the equilibrium concentrations in the right-hand side of Eq. 7 yields m different values for K, unless both the elements of the **t** matrix and the assumed equilibrium expression for the dye–polyanion system are correct. In order to discriminate the most probable **t** matrix and the equilibrium expression from the remainder, the coefficient of variation, S, is defined by Eq. 8 and used as a criterion:

$$S = \left(\frac{1}{m}\sum_{j=1}^{m}(K_j-\bar{K})^2\right)^{1/2}\Big/\bar{K}, \qquad (8)$$

where $\bar{K}$ denotes the mean value of K_j. The elements of the **t** matrix, and the equilibrium expression which yield the minimum S value can be determined by iterative calculations. The value of $\bar{K}$ corresponding to the minimized S value is considered as the most probable equilibrium constant. In this work, an acceptable upper limit of 0.15 was set for the minimized value of S in view of the experimental errors.[32]

Results

Application of the PCA Method to CV- and TF–NaPP Systems. The visible absorption spectra of CV and TF in the presence of NaPP are shown in Figs. 1(a) and (b) respectively. The spectra were measured at different stages of titration with the titrant NaPP solution up to the molar ratios of polymer residue-to-dye (*P/D*) of 1.21 and 1.25 for CV and TF respectively. The apparent molar absorption coefficients (ε) were calculated using the analytical concentrations of the dye in the solution. The spectra of CV–NaPP reveal a remarkable Meta band near 510 nm and three isosbestic points at 460, 529, and 639 nm (Fig. 1(a)), whereas TF–NaPP shows no such Meta band, but does show two isosbestic points at 371 and 476 nm (Fig. 1(b)). The apparent maximum absorption bands remain for CV, but are shifted gradually toward the shorter wavelengths for TF with an increase in the *P/D*.

The optical titration curves are plotted against *P/D* in terms of ε for CV and TF in Figs. 1(c) and (d) respectively. The titration curves were drawn at 510 and 592 nm for CV and at 430 and 450 nm for TF. It is clear from Figs. 1(c) and (d) that all these titration curves change with *P/D* sigmoidally but not monotonously. However, it can be expected from the existence of isosbestic points in the spectra of either

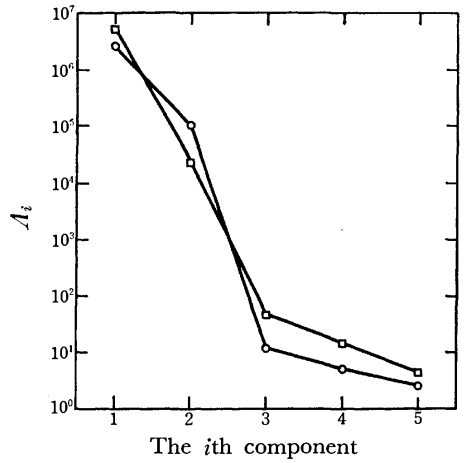

Fig. 2. Variation in eigenvalue Λ_i (i=1, 5) with the ith absorbing component. ○: CV–NaPP, □: TF–NaPP.

the CV– or TF–NaPP solution that there are two different absorbing components in the system. Such sigmoidal titration behavior was noted in the Acridine Orange–poly(α-L-glutamic acid) (PGA) system in the P/D range of 0—1 by Myhr and Foss.[15] They simply attributed the sigmoidal change to the equilibrium between three different absorbing components, *i.e.*, the free monomeric and dimeric dyes and the PGA-bound dye.

Since the advantage of the PCA method is that the likely number of the absorbing components involved in an equilibrium state can be determined by itself, it was applied to the sets of the observed spectra of dye-polyanion solutions over the entire P/D range shown in Figs. 1(a) and (b). The data matrix for CV–NaPP was composed of a set of absorbances at 56 selected wavelengths from 470 to 690 nm, at intervals of 4 nm, and a set of eight solutions differing in P/D, while the matrix for TF–NaPP was composed of a set of absorbances at 56 selected wavelengths from 396 to 512 nm, at intervals of 2 nm, and a set of ten solutions. The variations in eigenvalue Λ_i(i=1, 5) with the ith component are shown for both CV– and TF–NaPP systems in Fig. 2. It is clear that a large gap in eigenvalues exists between the second and third components for each system. This result confirms that the families of spectra in both Figs. 1(a) and (b) are composed of two, but not three, absorbing components, probably free and bound dyes. Schwarz[18] proposed a graphical method to analyze the absorption spectra of dye–polyion systems. The method, however, cannot be applied to sigmoidally changing titration curves like those of the CV– and TF–NaPP systems.

The extended PCA method is effective in analyzing the data of an unknown equilibrium system, since it assumes, successively, possible equilibrium schemes for a dye–polyanion system as *modus operandi*. Some specific equilibrium formulas based on Eq. 7 must first be considered for the equilibrium system. Three binding reactions frequently postulated for the system containing two absorbing components in the low P/D range are

$$D + P \rightleftharpoons DP, \quad K = \frac{[DP]}{[D][P]}, \tag{9}$$

$$2D + PP \rightleftharpoons DPDP, \quad K = \frac{[DPDP]}{[D]^2[PP]}, \tag{10}$$

and

$$D + 2P \rightleftharpoons PDP, \quad K = \frac{[PDP]}{[D][P]^2}, \tag{11}$$

where D is the free, unbound dye; P is the unoccupied binding site of polyanion; DP is the complex, *i.e.*, the bound dye; PP denotes two nearest-neighboring unoccupied sites; DPDP is the dimeric unit of bound dyes, and PDP is the complex in which a dye is bound to two nonneighboring polymer sites. The unknown absorbing components are DP, DPDP, and PDP, while the nonabsorbing components are P and PP. Unless otherwise stated, the computations were carried out under the assumption that the absorption spectrum of the free dye D is known. Equations 9 and 10 showed only monotonous titration curves, whereas Eq. 11 produced sigmoidal ones. In each of these three cases, the value of S in Eq. 8 could be minimized by varying the elements of the **t** matrix iteratively. However, the **t** matrix at this minimum S yielded some negative values for the molar absorption coefficient or the equilibrium concentration of the unknown absorbing component. Hence, the three schemes (9)—(11) should be concluded to be physically unsuitable for the experimental data.

Into the above three expressions, only the binding site P was taken as a nonabsorbing component which can not be directly detected as the eigenvector by the PCA method. In addition, solvent water and the counter-ions of the dye and NaPP, *i.e.*, Cl^- and Na^+, are all present in the solution as nonabsorbing components. Water is the solvent, so its concentration should be constant in equilibrium systems.[42] Consequently, the counter-ion Cl^- was taken into the fourth equilibrium scheme for the formation of a dye-polymer complex as follows:

$$D + Cl^- + P \rightleftharpoons DClP^-,$$

$$K = \frac{[DClP^-]}{[D][Cl^-][P]} = \frac{[DClP^-]}{[D]^2[P]}, \tag{12}$$

where $DClP^-$ is the complex and where $[D]=[Cl^-]$. No sigmoidal titration curve could be simulated with Eq. 12. Some K values calculated from the **t** matrix, which minimized S, deviated greatly from the mean value $\bar{K}$; moreover, some of them became negative. Thus, the equilibrium scheme (12) is also unsuitable for the CV– and TF–NaPP systems.

As the fifth equilibrium scheme, the participation of the counter-ion Na^+ was assumed:

$$D + Na^+ + P \rightleftharpoons DNaP^+, \quad K = \frac{[DNaP^+]}{[D][Na^+][P]}, \tag{13}$$

where $DNaP^+$ is the complex and an absorbing component with an absorption spectrum different from that of free dye. Since the initial concentration of Na^+ is equal to that of the binding site of NaPP, Eq. 13 is reduced to

$$K = \frac{[DNaP^+]}{[D][P]^2}, \tag{14}$$

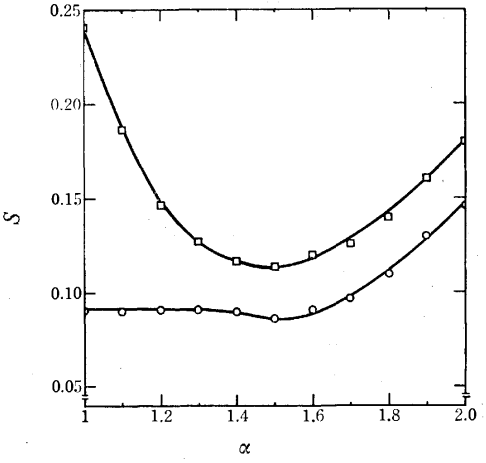

Fig. 3. Variation in the minimized S values with the empirical parameter α for the equilibrium formula (15) (see text). ○: CV–NaPP, □: TF–NaPP.

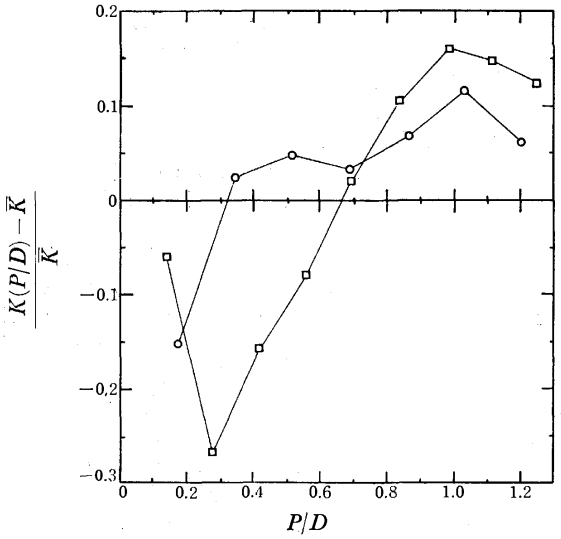

Fig. 4. Deviation of the equilibrium constant K from the mean value $\bar{K}$ at various P/D. The K values are computed with the optimum value of α in Eq. 15. ○: CV–NaPP, □: TF–NaPP.

A considerable sigmoidal change was manifested in the titration curve which was simulated with Eq. 14. Although the ε^b's of the bound dye and the values of K were always positive, the value of S was converged no less than 0.2, which exceeds the preset upper limit of 0.15.

The results of the above five equilibrium schemes led to the following conclusions. If the exponent of [D] is equal to, or larger than, that of [P], the optical titration data give rise to a monotonous curve. On the other hand, if the exponent of [P] is larger than that of [D], a sigmoidal titration curve results. Therefore, Eq. 14 is generalized by introducing an empirical parameter α into the equilibrium expression as

$$K = \frac{[DP^*]}{[D][P]^\alpha}, \qquad (15)$$

where DP* is the bound dye which differs from the free dye as regards the absorption spectrum. Both

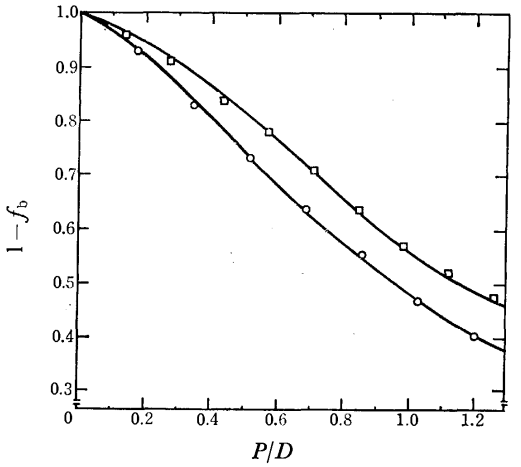

Fig. 5. Variation in the fraction of free dye $(1-f_b)$ with P/D for CV– and TF–NaPP. The fractions calculated at each P/D from Eq. 6 are represented by (—○—) and (—□—) for CV and TF, respectively. The fractions calculated from Eq. 15 with the values of α and the corresponding K given in Table 3 are drawn with solid curves.

monotonous and sigmoidal titration curves of various types can be produced from Eq. 15 by varying the parameter α.

Figure 3 shows the variations in the S values minimized by the **t** matrix with the empirical parameter α in Eq. 15 for both CV– and TF–NaPP systems. With an α value of 1.5, the values of S for the CV– and TF–NaPP systems reach the minimum points of 0.08 and 0.113 respectively. Both points are below the limit of 0.15. The variations in K with P/D at these points of S are shown in Fig. 4 for CV– and TF–NaPP. The scattering of each K from the mean value is only moderate, showing no systematic trend. These results suggest that equilibrium scheme (15) is acceptable for the binding reaction between NaPP and CV or TF if α is taken as 1.5.

The **t** matrix elements which minimized the S value are used for the calculation of the pure spectrum of the bound dye in terms of the molar absorption coefficient at the wavelength λ, ε^b_λ, determined in accordance with Eq. 5. The pure spectra of bound CV and TF are shown by closed circles in Figs. 1(a) and (b) respectively. The pure spectrum of bound CV reveals two peaks and a shoulder, while that of bound TF reveals two peaks (indicated by arrows). Although the Meta band of TF is not discernible at all in the observed spectra, the pure spectrum of bound TF demonstrates that a band does exist in the wavelength region shorter than the dominant peak of free TF. The characteristics of these spectra of bound dyes will be discussed later. Lastly, it should be noted that similar calculations were carried out with an assumption that the spectrum of the free dye D is unknown. The simulated spectrum of the free dye under this condition became identical to the observed one with $\alpha=1.5$ in Eq. 15.

The fraction of the bound dye, f_b, defined as C_b/C, could also be calculated at each P/D from the same

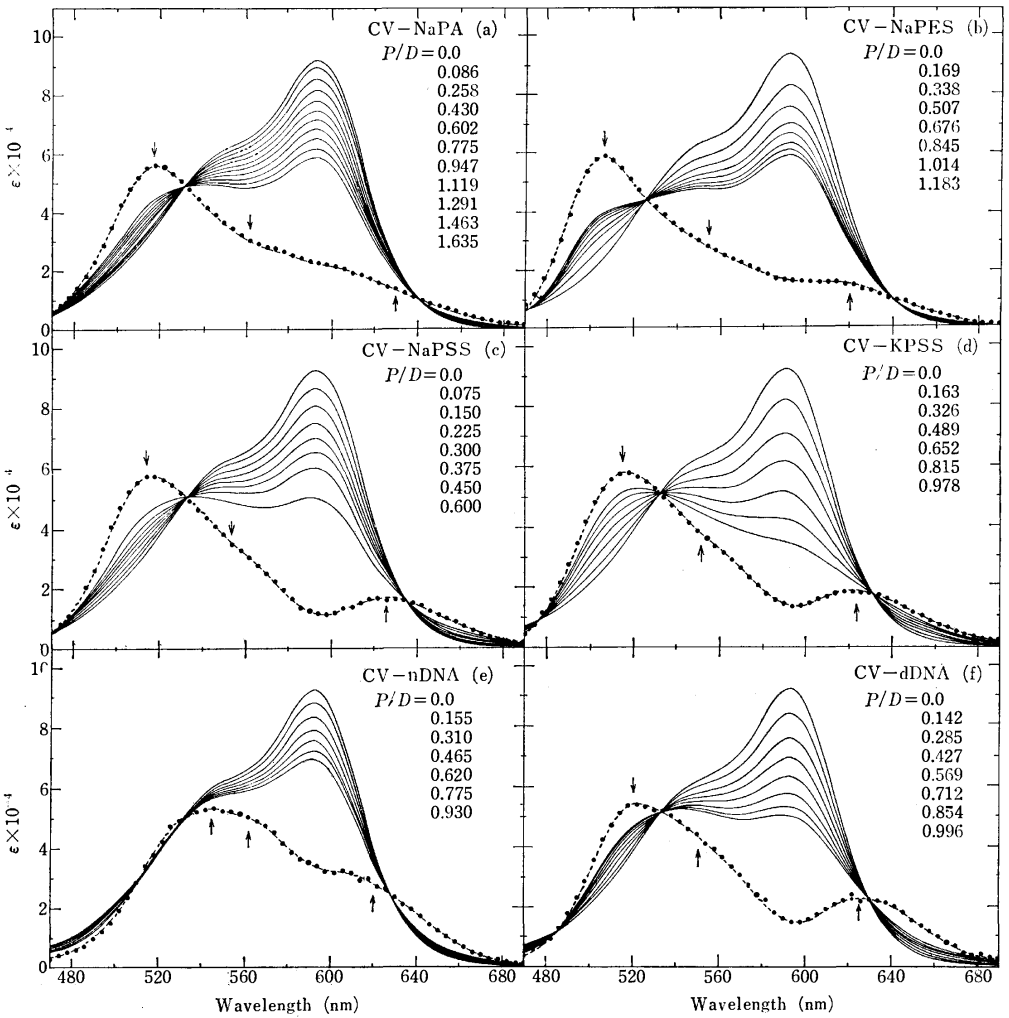

Fig. 6. Absorption spectra of CV in the presence and absence of polyanions (solid curves) and the pure absorption spectra of bound CV (closed circles).
Polyanions are; (a) NaPA, (b) NaPES, (c) NaPSS, (d) KPSS, (e) nDNA, and (f) dDNA. Neither polyanion nor dye solution contains neutral or buffer salts except for the DNA-dye solutions in which 1 mM NaCl is always present. The concentrations of CV are: (a) 8.33 μM, (b) 8.51 μM, (c) 8.67 μM, (d) 9.08 μM, (e) 9.05 μM, and (f) 11.9 μM. The concentrations of polyanions are listed in each figure in terms of P/D, the order of which corresponds to the order of the decrease in maximum absorbances. The isosbestic points are at (a) 476, 533, and 642 nm, (b) 460, 526, and 641 nm, (c) 473, 532, and 631 nm, (d) 473, 532, and 631 nm, (e) 628 nm, and (f) 486, 533, and 631 nm.

elements of the **t** matrix in accordance with Eq. 6, where C_b and C are the concentrations of the bound dye and the sum of the bound and free dyes respectively. The C_b at a given P/D is the mean of the C_b^λ values calculated from the observed spectrum at selected wavelengths, where C_b^λ is equal to $C(\varepsilon_\lambda - \varepsilon_\lambda^f)/(\varepsilon_\lambda^b - \varepsilon_\lambda^f)$. Therefore, the points in Fig. 5 represent the mean values of the normalized observed optical titration curves at selected wavelengths for CV- and TF-NaPP (circles and squares). These results are compared with the fractions of bound dye which were calculated from Eq. 15 with the values of α (=1.5) and K in Table 3; they are plotted with solid lines in Fig. 5. The agreement between them is excellent for both CV- and TF-NaPP. It should be noted that the sigmoidal decrease in the fraction of the unbound dye $(1-f_b)$ is quite clear.

Application of the PCA Method to Some CV–Polyelectrolyte Systems. Six polyelectrolytes, NaPA, NaPES, NaPSS, KPSS, nDNA, and dDNA, are chosen. The backbone structure of NaPA, NaPES, and NaPSS is identical, but their functional groups differ from one another. The difference between NaPSS and KPSS is only for the counter-ion, while nDNA and dDNA as biopolymers are different only in conformation. The absorption spectra of CV titrated with each polyanion are shown in Figs. 6(a)—(f). In all cases, the apparent ε at 592 nm decreases with the increase in P/D. The appearance of the Meta band in the observed spectra depends on the kind of polyanion; that is, a typical Meta band of CV appears near 510 nm in the presence of KPSS, whereas the Meta band appears only as a shoulder in the presence of NaPA, NaPES, and NaPSS. The presence of the Meta band is not manifested in the nDNA and dDNA. Two isosbestic points are clearly observed for each of the systems, suggesting

that two or more absorbing components are present. The eigenvalues of the second moment matrix were calculated from each set of spectra in Figs. 6(a)—(f). The ratios of the eigenvalues of the second, third, and fourth components to the eigenvalue of the first component are listed in Table 1. The ratios (expressed in terms of the logarithm) clearly indicate that a large gap exists between the second and third eigenvalues in each system, while the difference between the third and fourth eigenvalues is very small. These data verify that, in each CV–polyanion system, two absorbing components are involved in the binding reaction.

The pure spectra of bound CV are shown by closed circles in Figs. 6(a)—(f). For all the CV–polyanion systems, they exhibit two bands: a peak and a shoulder in the shorter-wavelength region and a band in the wavelength region longer than the peak position of free CV. These absorption bands will hereafter be abbreviated as follows: the Meta S_1 and Meta S_2 bands for the shorter-wavelength ones and the Meta L band for the longer-wavelength one (the numbering is from the one closest to the peak position of the free dye). The locations and ε^b's of the three Meta bands all depend on the polyanions, as is shown in Fig. 6 and Table 2. Especially, the Meta S_1 and S_2 bands of nDNA and dDNA seem to reflect their different conformations (the double helix *vs.* single-stranded coil).

TABLE 1. THE SECOND, THIRD, AND FOURTH EIGENVALUES NORMALIZED TO THE FIRST EIGENVALUE FOR CV- AND TF-POLYANION SYSTEMS

Dye	Polyanion	$\log(\Lambda_2/\Lambda_1)$	$\log(\Lambda_3/\Lambda_1)$	$\log(\Lambda_4/\Lambda_1)$
CV	NaPP	−1.39	−5.36	−5.72
	NaPA	−2.29	−5.46	−5.71
	NaPES	−2.14	−5.00	−5.60
	NaPSS	−2.09	−5.72	−5.91
	KPSS	−1.61	−4.90	−5.79
	nDNA	−2.90	−5.16	−5.68
	dDNA	−2.60	−4.97	−5.21
TF	NaPP	−2.34	−5.02	−5.55
	NaPA	−3.25	−5.80	−6.16
	NaPES	−2.68	−5.08	−5.74
	NaPSS	−2.17	−5.37	−5.69
	KPSS	−2.26	−5.59	−5.70
	nDNA	−2.89	−5.08	−6.02
	dDNA	−2.47	−4.63	−5.03

The optical titration curves of CV at 592 and 510 nm with six polyanions were found to be divided into two classes. Sigmoidal titration curves were observed for NaPA and KPSS just for NaPP (Fig. 5) and monotonous curves for NaPSS, NaPES, nDNA, and dDNA. The fractions of the bound dye, f_b, were calculated from Eq. 6; they are shown in Figs. 7(a)—(f). With the values of α and K which gave rise to the smallest S (the values are listed in Table 3 for each system), the observed titration curve can be reproduced quite excellently, as is indicated by the solid lines. It should be noted that the sigmoidal titration curve was observed whenever the value of α is greater than one, while a monotonous titration curve resulted when the value of α is equal to, or less than, one.

Application of the PCA Method to Some TF–Polyelectrolyte Systems. The same six polyanions are also

	dDNA	1.0	$(1.30\pm0.05)\times10^{5}$	1.3×10^{5}	1.0	$(1.8\pm0.3)\times10^{5}$	1.8×10^{5}

a) The dimension is given by $[\mathrm{l/mol}]^{\alpha}$. b) $K'=K\cdot[\mathrm{P}]^{\alpha-1}$ at $P/D=1$.

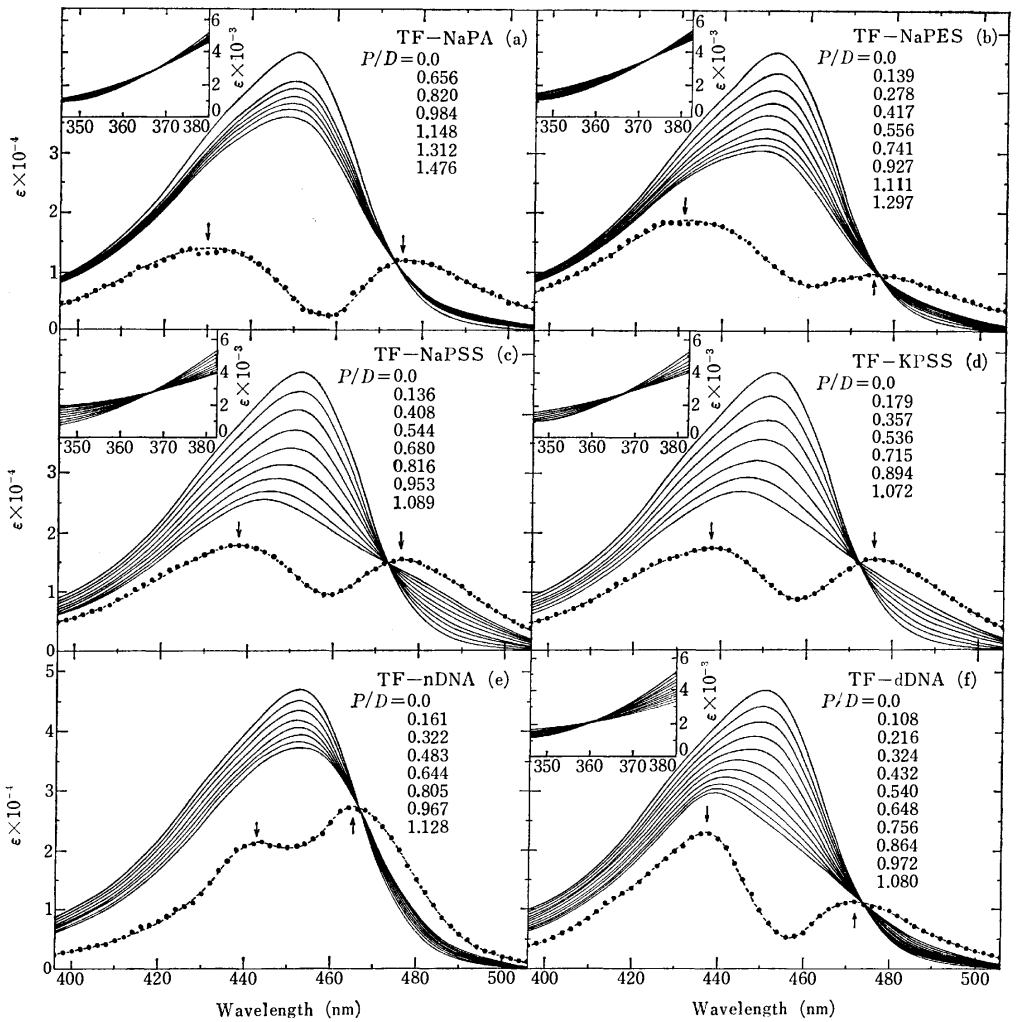

Fig. 8. Absorption spectra of TF in the presence and absence of polyanions (solid curves) and pure absorption spectra of bound TF (closed circles).
Polyanions are; (a) NaPA, (b) NaPES, (c) NaPSS, (d) KPSS, (e) nDNA, and (f) dDNA. Neither polyanion nor dye solution contains neutral or buffer salts except for the DNA–dye solutions in which 1 mM NaCl is always present. The concentrations of TF are: (a) 11.0 μM, (b) 7.77 μM, (c) 9.56 μM, (d) 8.28 μM, (e) 8.69 μM, and (f) 11.0 μM. The concentrations of polyanions are listed in each figure in terms of P/D, the order of which corresponds to the order of the decrease in maximum absorbances. The isosbestic points are at (a) 369 and 473.5 nm, (b) 372 and 476 nm, (c) 368 and 472 nm, (d) 368 and 472 nm, (e) 466 nm, and (f) 359 and 474.5 nm.

used for the titration of TF; the results are shown in Figs. 8(a)—(f). The spectra of all the TF–polyanion systems differ from those of the corresponding CV–polyanion systems in showing hypo- and hypsochromic effects without any Meta bands in the P/D range examined. The spectra of TF in the presence of polyanions show, without exception, an isosbestic point in the wavelength region longer than the peak position of the free TF. Another isosbestic point is also noted in the shorter-wavelength region (*cf.* the insert in each figure) except for the case of nDNA. Judged from the eigenvalues listed in Table 1, only two absorbing components are again sufficient to describe the spectral behavior in each TF–polyanion system. The pure spectra of bound TF are shown by closed circles in Figs. 8(a)—(f). Although none of the observed spectra manifests the presence of the Meta band, the bound spectra clearly show two such bands—the Meta S and Meta L bands — in all cases. The spectral profiles of the bound TF differ from those of the bound CV as regards the number of bands. The locations and ε^b's of those two Meta bands depend on the kinds of polyanions. They are listed in Table 2.

The empirical parameter α and the equilibrium constant K in Eq. 15 at the minimized S, which result from the application of the PCA method to the TF–polyanion spectra, are listed in Table 3 for all the systems. The values of α are, again, greater than one for those systems which yield the sigmoidal titration curves, whereas the values of α are equal to, or less than, one for those systems which produce the monotonous curves. As is shown in Figs. 7(a)—(f), the optical titration curves are sigmoidal for NaPA, NaPSS, and KPSS just for NaPP (*cf.* Fig. 5), while they are monotonous for NaPES, nDNA, and dDNA. The value of α obtained for the TF–polyanion system, however, is not necessarily identical with the value of α for the corresponding CV–polyanion system. This suggests that the value of α reflects the complexity and diversity of the binding reaction between a dye and a polyanion, the importance of the combination thereof, and the specificity of the chemical structure of the dye. It should also be noted in Fig. 7 that the fraction of the free, unbound dye decreases with the increase in the value of P/D, while no simple relation exists between TF and CV as regards their binding ability toward polyanions.

Discussion

The Method of Extended Principal Component Analysis. As has been described in a previous paper,[32] the PCA method has been proven to be exceedingly useful for an equilibrium system like dilute dye solutions composed of two or three absorbing components. In the equilibrium system of small molecules, the equilibrium schemes are relatively simple and the neglect of such a thermodynamic variable as activity coefficient may not affect the result too seriously. On the other hand, the binding of a dye to the polymer site is probably influenced by a large number of complicated factors in dye–polymer systems. In order to estimate the equilibrium scheme and the binding constant for these systems, and in order to evaluate the bound-dye spectrum, the equilibrium concentrations of the colored components have usually been determined by means of the absorption spectra and equilibrium dialysis combined.[12,16,20,27,31] Such a combined method, however, is difficult to apply to systems in which either a relatively small polymer cannot be retained by a semipermeable membrane, a dye is easily adsorbed on it, or the ionic strength imposes severe limitations as a result of the Donnan effect.

On the other hand, only the initial concentrations of the chemical species participating in a binding reaction and a set of the absorption spectra of solutions are needed in the PCA method; therefore, using it, a number of plausible equilibrium schemes can be tested successively. In order to determine the most probable absorption spectra of colored components and the equilibrium constant for the binding reaction, the only requirements are that the coefficient of variation S should reach a preset minimum value and that none of the spectra and equilibrium concentrations of the components should have a negative value. The latter condition is imposed by the physical restrictions and is quite useful for selecting appropriate parameters.[32] Thus, the only problem is concerned with the availability of adequate equilibrium expressions which describe the complicated binding processes between the dye and the polymer. In this work, an empirical parameter α was introduced into a relatively simple expression (Eq. 15) to circumvent the complexity. Since the PCA method could be applied to multicomponent dye systems,[32] its use may also be extended in the future to the dye–polyelectrolyte systems over the whole P/D range where more than two absorbing components coexist.

Absorption Spectra of Bound CV and TF. The term "metachromasy" has been used for the phenomenon of the hypo- and hypsochromic changes of the spectrum of a dye, often with a new band on the short-wavelength side which has been called the "metachromasy band." However, this concept of metachromasy is an oversimplification, as has been pointed out by a number of reports which more or less emphasize the simultaneous bathochromic effect of various polyelectrolytes on the spectrum of the dye.[1–3,43–45] The present work has proven that both bound CV and TF exhibit absorption spectra in which the new bands are clearly unraveled on the short- and long-wavelength sides of the peak of the corresponding free dyes (Figs. 1, 6, and 8). Fredericq and Houssier[16] have observed a similar result in the Acridine Orange–DNA system. The term "metachromasy band" may now be enlarged to include the long- and short-wavelength bands of a bound dye, both of which are abbreviated as "Meta bands."

The Meta S band for TF and the Meta L band for CV and TF are close to the peak of the free dyes and are simply hidden in the observed spectra, although their presence has been predicted from linear and circular dichroic studies.[44–47] The locations and ε^b's of the Meta bands for a given dye depend on the poly-

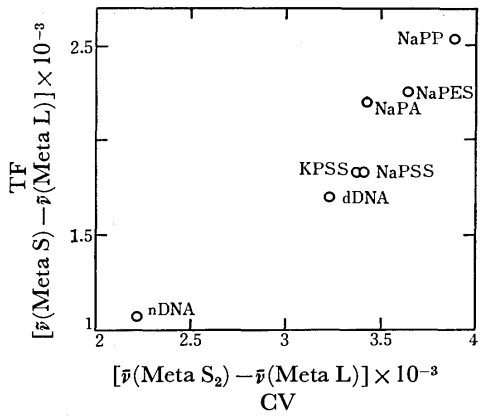

Fig. 9. Correlation between the energy separation between the Meta S_2 and L bands of CV and the separation between the Meta S and L bands of TF bound to seven polyanions. Scales are expressed in terms of wavenumbers $\bar{\nu}$.

anions (Table 2). The Meta bands of CV and TF bound to NaPA, NaPES, and NaPSS differ from one another depending on their functional groups, in spite of the fact that their backbone structure is identical. On the other hand, the Meta bands of nDNA and dDNA differ considerably in shape and position, although their backbone and functional groups are also identical. The Meta bands of either TF or CV are almost identical for NaPSS and KPSS. These results lead to the conclusion that the Meta bands sharply reflect the conformation of dye–polyanion complexes besides the functional group of the polyanions and that the kind of counter-ion scarcely affects the location and ε^b of the Meta bands.

A considerable positive correlation exists between the energy separation between the Meta S_2 and L bands of CV and the separation between the Meta S and L bands of TF, as is shown in Fig. 9; this indicates that the peak position of Meta bands depend mainly on the overall nature of the polyanions. The energy separation between the Meta S and L bands for a given dye may result from the different mean distance between the binding sites of a polyanion. The mean distance may, in turn, depend on the flexibility of the backbone in addition to the structure of the sidechain of the polyanion. The spectral aspects of the Meta band of bound dyes have now been clarified in sufficient detail. For a quantitative discussion of metachromasy, however, information is necessary on the electronic states and transition moments of dyes in the absence and presence of polyanions. The LCAO calculations may provide such information.

Empirical Parameter α and Equilibrium Constant. The absorption spectra of solutions containing both a dye and a polyanion vary in a complicated manner when a wide range of P/D is covered.[1-3] For example, the isosbestic points appear at different wavelengths depending on the P/D range, as has already been noted for CV– and TF–NaPP systems.[2,3] This strongly suggests that two or more of the absorbing components, *i.e.*, the bound dye species exclusive of the free dye, are present over the whole P/D range. In this work, the spectral changes in each dye–polyanion system are limited only in the low P/D range of 0—1, where a single set of isosbestic points is observed. In this P/D range, only a free dye and one kind of bound dye are present, as is confirmed by the eigenvalues of the second moment matrix (*cf.* Table 1). The empirical parameter α is indeed useful in simulating the optical titration curves and in classifying the dye–polyanion systems (Figs. 1 and 7). However, the values of the equilibrium constant K as such cannot be compared in order to characterize the different dye–polyanion systems, because the dimension of K $(=[\text{l/mol}]^{\alpha})$ now depends on α and is not identical in all the systems. The constant K defined in Eq. 15 may be related to the frequently granted equilibrium constant K' for the binding scheme (9) in such a way that $K'=[\text{DP}]/[\text{D}]\cdot[\text{P}]=K\cdot[\text{P}]^{\alpha-1}$. The values of K' calculated at $P/D=1$ using the K values listed in Table 3 are also given in the same table. Interestingly, these K' values compare favorably with the binding constants previously reported for various dye–polymer systems.[8,12,16,18,31]

The values of α for NaPA, NaPES, NaPSS, and KPSS differ from one another in ways reflecting the difference in the functional group or counter-ion of the polyanions (Table 3). Moreover, the α values also depend on the kind of dye to some extent. The difference in α-value between NaPSS and KPSS in the presence of either CV or TF suggests that the counter-ion plays some important role in the binding process of the dye to the polyanion, but does not affect the bound spectra. On the other hand, the values of α are unity for the dye–DNA systems and independent of the kinds of dyes and conformations of DNA, for which the distance between the charged sites of DNA appears to be responsible. Hence, the parameter α may be an indicator which reflects the local situation of the binding site of the polyanion, including the conformation, functional group, the counter-ion, and the structure and binding mode of the dye. Although the value of α is at present regarded as a constant in a low P/D range, it may be a function of P/D and could also represent the dependence of the activity coefficient of the polyelectrolyte on the residue concentration. Once the physical significance of the parameter α is clarified, it should be of great help for the better understanding of the metachromatic behavior of dye–polyelectrolytes. However, the parameter seems to contain many factors, such as temperature, counter-ion, and added salts. Thus, the clarification of the nature of α still awaits further quantitative studies.

Conclusions

The extended PCA method has now been demonstrated to be applicable to relatively complicated equilibrium systems between dyes and polyanions. By the use of this method, the quantitative studies of metachromasy are greatly facilitated as regards the number of dye species involved in dye–polyanion systems in equilibrium, the equilibrium constants, and the pure absorption spectra of the bound dye species. For each dye–polyanion system presently studied in

the low P/D range between zero and near one, only a single bound dye species is present besides a free, unbound dye. The pure spectra of bound CV and TF both show two remarkable metachromasy bands on the short- and long-wavelength sides of the absorption peak of free, unbound dyes. The spectral features of these bands are related to the functional group and the conformation of the polyanions. The equilibrium scheme between the bound and unbound absorbing components is not so simple as is often assumed, but requires an empirical parameter α to reproduce satisfactorily both the sigmoidal and monotonous optical titration curves of CV and TF. This parameter is probably an indicator of the local situation of the dye-bound polymer sites.

Resonance Raman Spectra of *p*-Benzosemiquinone Anion Dimer

Satoshi YAMAGUCHI,* Kenji YOKOYAMA, and Shiro MAEDA
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Midori-ku, Yokohama 227

(Received June 21, 1978)

Resonance Raman specta have been observed for the dimer of *p*-benzosemiquinone anion. When the exciting-light frequency was exactly resonant with the absorption band characteristic of this dimer, a new polarized Raman line appeared at 177 cm^{-1} with a striking resonance enhancement. The resonant behavior and the frequency value both indicate that it can reasonably be assigned to the interradical stretching vibration of the parallel D_{2h} dimer molecule, much as in the case of the previous Würster's cation dimers.

The oxidation-reduction process between quinone and the corresponding hydroxy compound is known to proceed *via* an intermediate radical anion.[1] *p*-Benzosemiquinone anion (SQ^-) can be obtained by oxidizing hydroquinone dissolved in alkaline ethanol with air.[2] The solution is yellow at room temperature due to the absorption bands of SQ^- about 400 nm,[1-5] but it turns blue under −100 °C. The color change is due to the appearance of a new absorption band at 585 nm, as is shown in Fig. 1, which is associated with the formation of an ion dimer $(SQ^-)_2$.[2] The radical anion is also produced by irradiating UV light on a glassy ethanol matrix of hydroquinone at the temperature of liquid N_2.[2,4] The yellow glass thus obtained turns blue when it becomes fluid upon being warmed up to about −130 °C, but the blue color remaining unchanged after it cools down again, indicating the validity of presuming dimer formation.

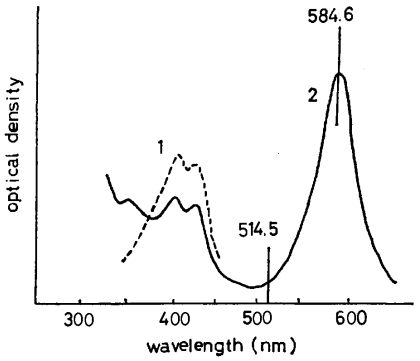

Fig. 1. Electronic absorption spectra of a SQ^- solution at room temperature (Curve 1) and at −196 °C (Curve 2). (from Ref. 2.)

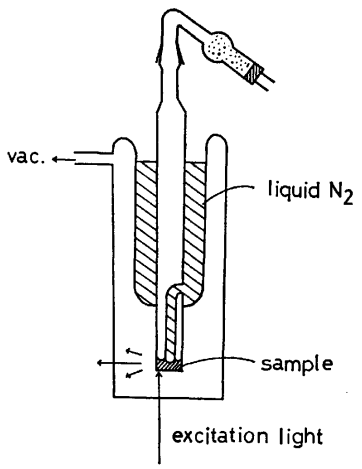

Fig. 2. Raman cell.

The long-wavelength absorption band has assigned to a dimer's transition characterized by interradical charge-transfer, which may affect the interradical binding considerably.[2] Accordingly, there is a good possibility of observing the interradical vibration of $(SQ^-)_2$ in the resonance Raman spectrum associated with the above absorption band, in much the same way as was previously reported for Würster's cation dimers.[6]

Experimental

SQ^- was prepared by oxidizing a 2 mM hydroquinone solution in alkaline ethanol (15 mM KOH) with ambient air. Before the further oxidation to quinone took place, the yellow solution was cooled with liquid N_2 in a proper rate to form a blue glassy matrix in a Raman cell, as is shown in Fig. 2. The Raman spectra were recorded on a JEOL JRS 400D spectrometer, with a CR 52G Ar^+ laser and a CR 590 dye laser (Rhodamine 6G). The dye laser is tuned by bireflingent filters and often brings weak satellite radiations, resulting in spurious lines in the spectra. Therefore, the exciting laser light was passed through a simple dispersing system to eliminate those satellite frequencies.

Results and Discussion

Figure 3 shows the Raman spectra of the blue glassy matrix obtained above by off-resonant 514.5 nm and exactly resonant 584.6 nm exciting radiations. Three Raman lines, at 177, 359, and 545 cm^{-1}, are polarized and are obviously enhanced by the resonance with the 585-nm absorption band. The most strikingly resonant line at 177 cm^{-1} is rather like, in all respects, the interradical vibration of *p*-phenylenediamine cation dimer reported previously,[6] and can probably be assigned to the SQ^--SQ^- stretching mode. We could not obtain a distinct spectrum of the monomer, probably because the resonance enhancement was insufficient to show up the Raman lines in the present dilute solution, but the resonance features of the Raman lines observed above seem to admit no other interpretation than dimer vibrations. The weakly resonant and relatively sharp 359 cm^{-1} and 545 cm^{-1} lines are probably due to such out-of-plane modes of SQ^- moieties that can couple with the interradical stretching, borrowing the intensity from the last mode.

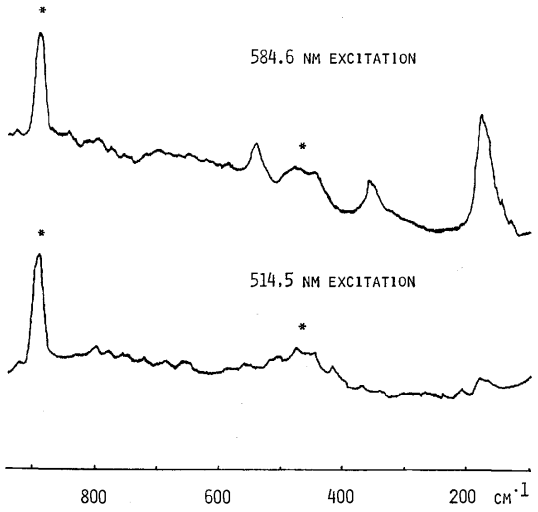

Fig. 3. Raman spectra of $(SQ^-)_2$ in ethanol matrix at −196 °C. * Ethanol lines.

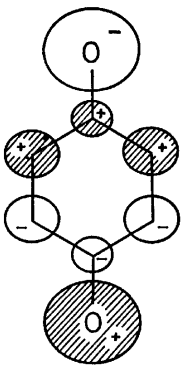

Fig. 4. Illustrated distribution of the b_{3g} molecular orbital of SQ^-.

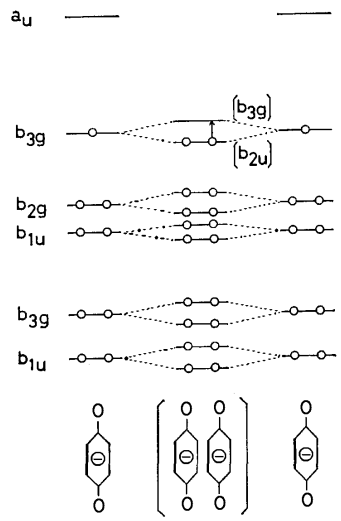

Fig. 5. MO energy scheme for SQ^- and $(SQ^-)_2$.

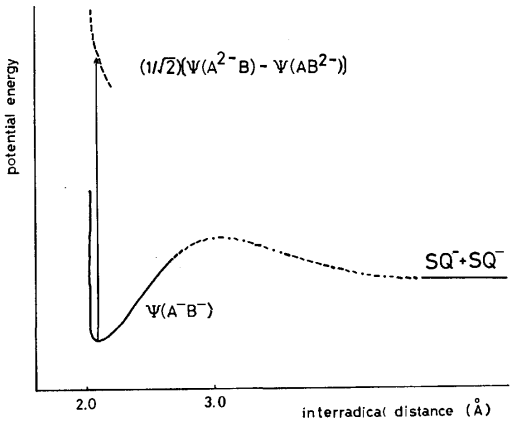

Fig. 6. The potential curve of $(SQ^-)_2$ for changing interradical distance.

The ground state of SQ^- has been shown[7] to be $^2B_{3g}$, principally represented by the π MO configuration:

$$(b_{1u})^2(b_{3g})^2(b_{1u})^2(b_{2g})^2(b_{3g}),$$

where the singly occupied b_{3g} MO has the form illustrated in Fig. 4. Therefore, the formation of the dimer may most reasonably be understood by considering the covalent interaction between the outer b_{3g} MO's for the parallel D_{2h} configuration, as is schematically shown in Fig. 5. The 585 nm absorption is thus assignable to the electron transition $[b_{2u}]\rightarrow[b_{3g}]$, which is characterized by a charge transfer between anion radicals:

$$\Psi(A^-\cdot B^-) \rightarrow (1/\sqrt{2})[\Psi(A^2\text{-}B) - \Psi(AB^{2-})],$$

where A and B represent each SQ monomer. The situation is quite like that of the previous *p*-phenylenediamine cation dimer.[5]

If the 177 cm^{-1} vibration is assumed to be entirely of an interradical stretching mode, the force constant can be calculated to be 1.09 md/Å, very close to the corresponding value of $(PPD^+)_2$.[6] Figure 6 gives the potential curve of $(SQ^-)_2$ for changing the interradical distance, where the part of trapping potential has been calculated by a CNDO approximation† and has been appropriately connected with the level of non-interacting monomer anions calculated on the CNDO basis. The dam in the transitional region is formed by the balance between the long-range electrostatic repulsion and the short-range binding interaction mentioned above. Although the present observed result is inevitably involved in the complex interaction with counter ions and solvent molecules, the binding aspect given above seems essentially applicable.

In conclusion, experimental evidence from vibrational spectroscopy has been given for the dimer formation of *p*-benzosemiquinone anion, indicating a close correspondence to *p*-phenylenediamine cation dimer, in accordance with the theoretical expectation.

Structural Study of Optical Resolution. VI. The Crystal Structure of $(+)_{589}$-*cis*-Chloroamminebis(ethylenediamine)cobalt(III) *d*-3-Bromocamphor-9-sulfonate Monohydrate

Masahiro KURAMOTO, Yoshihiko KUSHI, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Hiroshima 730

(Received January 23, 1978)

The crystal structure of *cis*-chloroamminebis(ethylenediamine)cobalt(III) *d*-3-bromocamphor-9-sulfonate monohydrate, $(+)_{589}$-$[CoClNH_3(en)_2](d\text{-}BCS)_2\cdot H_2O$, has been determined by three-dimensional X-ray analysis. The deep red crystals are orthorhombic, space group $P2_12_12_1$, with four formula units in the unit cell of dimensions $a=34.97(2)$, $b=14.25(1)$, and $c=7.08(1)$ Å. The calculated density of 1.64 g·cm^{-3} compares well with the observed density 1.65 g·cm^{-3}. The structure has been refined by the block -diagonal least-squares method to an *R*-factor of 0.096 for 2662 reflection data points. In the complex cation, one of the two ethylenediamine chelate rings has a "50% *ob*, 50% *lel*" type disordered character in its conformation and the other ring is in a "*lel*" type. The absolute configuration of the complex cation is denoted as $\Lambda[(50\%\lambda, 50\%\delta)\delta]$, which was determined by comparison with that of the *d*-BCS anion. There are notable differences between the two crystallographically independent *d*-BCS anions with respect to their local packing modes.

Historically, *cis*-chloro- and -bromo-amminebis(ethylenediamine)cobalt(III) cations, *cis*-$[CoXNH_3(en)_2]^{2+}$ ($X=Cl^-$ and Br^-), were first resolved by Werner and King;[1] their hypothesis of octahedral coordination was thereby confirmed.[1,2] In their study of optical resolution, silver *d*-3-bromocamphor-9-sulfonate, *d*-BCS·Ag, was employed as a resolving agent. Since then, optical resolutions of many metal complexes were performed using this agent.[3]

Recently, we reported the crystal structure of *cis*-dichlorobis(ethylenediamine)cobalt(III) *d*-3-bromocamphor-9-sulfonate, $(+)_{589}$-$[CoCl_2(en)_2]d$-BCS, as a part of our structural studies of optical resolution,[4-8] and found an interesting "face-to-face type" close contact of the complex cation with the bromocamphor part of the *d*-BCS anion.

It is of interest to compare the structural features of the diastereoisomer, $(+)_{589}$-$[CoClNH_3(en)_2]$ $(d\text{-}BCS)_2\cdot H_2O$, with that of the previously determined $(+)_{589}$-$[CoCl_2(en)_2]d$-BCS. Moreover, the absolute configuration of *cis*-$[CoClNH_3(en)_2]^{2+}$ cation has not been determined by the X-ray method.[9] Therefore, the X-ray crystal structure analysis of the title compound was undertaken.

Experimental

The racemic *cis*-$[CoClNH_3(en)_2]Cl$ was prepared by the published method.[10] The racemic complex was resolved by the method of Garbett and Gillard, using *d*-BCS·NH_4 as a resolving agent.[9] The deep red crystals thus obtained were recrystallized from hot aqueous solution. Well formed crystals were separated out. Found: C, 33.01; H, 5.68; N, 7.98%. Calcd for $C_{24}H_{49}O_9N_5S_2ClBr_2Co$: C, 33.13; H, 5.68; N, 8.05%.

The unit cell dimensions were determined by the least-squares refinement of the *hk*0, *h*0*l*, 0*kl*, reflection data recorded on Weissenberg photographs. The sodium chloride diffraction lines were superimposed on the films for calibration. The crystal data are as follows: orthorhombic, $a=34.97(2)$, $b=14.25(1)$. $c=7.08(1)$ Å; $D_c=1.65$ g·cm^{-3} (by flotation in chloroform-bromoform mixture); $Z=4$; and $D_c=1.64$ g·cm^{-3}. From the systematic absence for *h*00 ($h=2n+1$), 0*k*0 ($k=2n+1$), and 00*l*($l=2n+1$), the space group is $P2_12_12_1$.

A crystal 0.65 mm long with a cross-sectional area of (0.20×0.23) mm^2 was adopted for recording the *hk*0—*hk*4 intensity data with Ni $K\alpha$ radiation, using the multiple-film equi-inclination Weissenberg technique. Another crystal, 0.42 mm long with (0.27×0.31) mm^2 cross-sectional area, was used to record the intensity data of *h*0*l*. The intensities were estimated visually with a calibrated intensity scale. The range of relative intensities was 1—3322. A total of 2662 independent reflections were used for the structure determination. Lorentz, polarization, and spot-shape corrections were applied in the usual manner; corrections for absorption were not made since the linear absorption coefficient, μ(Ni $K\alpha$), was 72.6 cm^{-1} ($\mu r=0.78$ for the former crystal).

Determination and Refinement of Crystal Structure

The structure was solved by the heavy-atom method. The positions of the two bromine atoms were easily found from the three-dimensional Patterson map. The subsequent Fourier synthesis revealed the positions of all the non-hydrogen atoms, excluding one water molecule. The position of the water molecule was found in the difference map which was synthesized at the stage of $R=0.16$ after the block-diagonal least-squares refinement of the other atoms for the 2662 observed reflections, where the *R*-value is $\Sigma||F_o|-|F_c||/\Sigma|F_o|$. The difference map showed a peak with the height of 4.0 e/Å^3 at the position $x=0.223$, $y=0.954$, and $z=0.275$. The presence of one water molecule was suggested by the elemental analysis for this compound. Thus, the peak was interpreted as due to a water molecule of crystallization.

Four cycles of further refinement with isotropic temperature factors for all the non-hydrogen atoms reduced the *R*-value to 0.14. The refinement(excluding the hydrogen atoms) was continued by applying anisotropic temperature factors for Br, Co, Cl, and S atoms and isotropic ones for O, N, and C atoms. After three cycles an *R*-value of 0.105 was obtained.

However, the value of the isotropic temperature factor of C(E2) was rather high($B=9.1$ Å^2) and the

resulting C(E1)–C(E2) distance, 1.32 Å, was fairly short. These results were observed also in several ethylenediamine metal complexes.[11]

Recently, Brouty *et al.* reported the crystal structure of the racemic tris(ethylenediamine)chromium(III) thiocyanate. They found the same character in its ethylenediamine ring, and tried to explain this anomaly more precisely.[12]

According to their approach, the difference map was recalculated after excluding the C(E1) and C(E2) atoms. Three peaks appeared in the map: two spherical peaks([peak I] 2.0 e/Å^3, x=0.202, y=0.770, z=0.935; [peak II] 2.2 e/Å^3, x=0.216, y=0.736, z=0.900) and one elongated peak([peak III] 3.2 e/Å^3, x=0.223, y=0.826, z=0.840). The occurrence of the "*ob-lel*" type disorder in the N(1)–C(E1)–C(E2)–N(2) ethylenediamine chelate ring[13] was thus suggested. The normal "*ob*" and "*lel*" models of the ethylenediamine ring were set up.[14] We tried to fit these models to the corresponding peaks in the difference map. The resulting positions of the four carbon atoms, C(E1A)–C(E2A) (*ob*) and C(E1B)–C(E2B) (*lel*), were included in the calculations for further refinement.

Five models with different ratios of the population of the C(E1A) and C(E2A) atoms to that of C(E1B) and C(E2B), (20% *ob*, 80% *lel*), (40, 60), (50, 50), (60, 40), and (80, 20), were refined. The starting values of the isotropic temperature factors of these four carbon atoms were set at 3.5 Å^2 (the average value of the other carbon atoms in this crystal at the stage of R=0.105). Hydrogen atom coordinates(excluded the water molecule and the methyl- and ammine- groups) were calculated(C–H 1.05, N–H 1.00 Å) assuming tetrahedral angles at carbon and nitrogen. Contributions from these forty hydrogen atoms with fixed positions and an isotropic temperature factor of B=3.5 Å^2 were also included in further least-squares iterations.

After three cycles of refinement based on the respective models, the best conventional *R*-value 0.096 was attained for the 50%-*ob*/50%-*lel* model. In the region of the corresponding four carbon atoms, a final difference map of this model showed no peak higher than 0.5 e/Å^3.

The final values of *R*-factors, isotropic temperature factors, and selected bond lengths and bond angles in the above five models are summarized in Table 1. These results suggest that the most probable ratio of conformational distribution of this ethylenediamine ring is 50%-*ob* and 50%-*lel*.

The quantity minimized was $w(|F_o|-k|F_c|)^2$ and the weighting scheme employed was w=1.0 for $F_o \geq 6.3(2.5\times F_{min})$ and w=0.5 for $F_o<6.3$. The atomic scattering factors for the Br^-, Co^{3+}, and Cl^- ions and for the neutral S, O, N, C, and H atoms were taken from Ref. 15. The dispersion effects were neglected.

All the computations were carried out by a HITAC-8700 computer at the Hiroshima University Computer Center. The computer programs used were FOUR-

MMM(Fourier synthesis)[16] and HBLS-IV (Least-squares calculation) with slight modification.[17]

The final atomic parameters, temperature factors (with their estimated standard deviations) and populations(m) are listed in Tables 2 and 3. Complete lists of the $5F_o$ and $5F_c$ values and the final atomic parameters of the hydrogen atoms have been preserved by the Chemical Society of Japan(Document No. 7835).

Results and Discussion

Cation and Anion Geometries. Figure 1 shows the crystal structure viewed along the c-axis. The crystal is built up of discrete $(+)_{589}$-*cis*-$[CoClNH_3(en)_2]^{2+}$ cations, two kinds of *d*-BCS anions(denoted as *d*-BCS(A) and *d*-BCS(B)), and water molecules. The bond distances and bond angles are listed in Table 4.

In the complex cation, the bond distances and bond angles around the cobalt atom are in good agreement with those found in the previous studies.[4,18] There are two ethylenediamine rings in the complex cation. The conformation of one ethylenediamine ring(N(1)–C(E1)–C(E2)–N(2)) is in "50% *ob*(N(1)–C(E1A)–

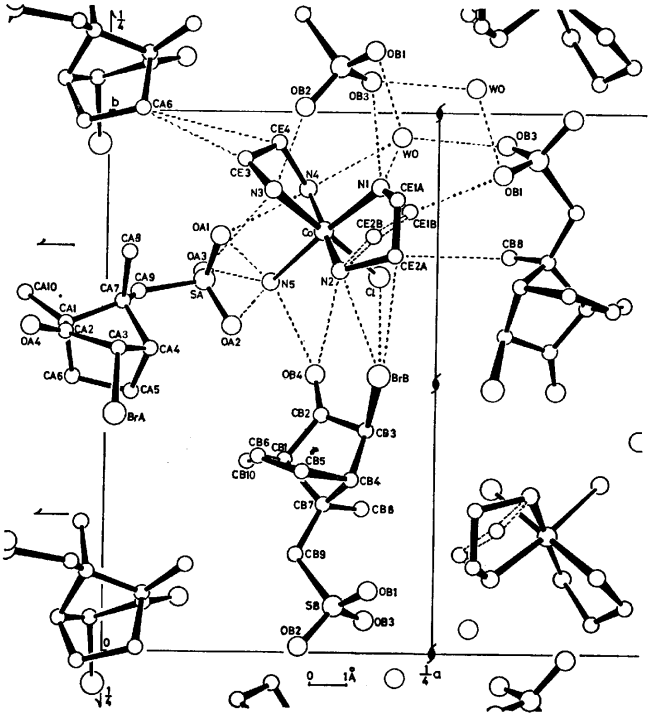

Fig. 1. A perspective drawing of the contents of the unit cell along the c-axis. Possible hydrogen bonds and short contacts are indicated by broken lines. The round brackets in the numbering scheme of the atoms are omitted.

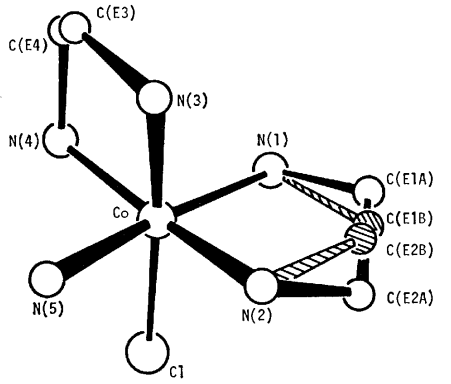

Fig. 2. The absolute configuration of the complex cation.

C(E2A)–N(2)), 50% *lel*(N(1)–C(E1B)–C(E2B)–N(2)),” as described in the refinement part. The other ethylenediamine ring(N(3)–C(E3)–C(E4)–N(4)) is in the *lel* conformation. Thus the conformation of the two ethylenediamine rings is designated as a “(50% *ob*, 50% *lel*), *lel*” type.

The absolute configuration of the complex cation was assigned as *Λ* for the $(+)_{589}$-isomer, based on the *d*-BCS anion as an internal reference.[19] This configuration is in accordance with the result previously reported on the basis of spectral evidence.[9] Thus, the absolute configuration of the complex cation is denoted as *Λ*[(50% *λ*, 50% *δ*)*δ*],[13] as illustrated in Fig. 2.

Roman numerals as superscripts refer to the following equivalent positions relative to the reference molecule at *x*, *y*, *z*:
I (*x*, 1+*y*, *z*), II (*x*, *y*, 1+*z*)
III (*x*, 1+*y*, −1+*z*), IV (1/2−*x*, 1−*y*, −1/2+*z*)
V (−*x*, −1/2+*y*, 3/2−*z*)

a) Possible hydrogen bonds. b) H1, H2, H3, H13, and H14 belong to the *ob* conformation and H9, H10, H11, H17, and H18 to the *lel*.

The bond distances and bond angles in both *d*-BCS anions are summarized in Table 4. The structures of both *d*-BCS anions are in accordance with each other and also with the results reported in the previous studies.[4,19] The bromine atoms are in the *endo* position on C(A3) and C(B3). The sulfonate groups are attached to C(A9) and C(B9), that is in *trans-π* position to the keto group. Selected intermolecular bond distances are summarized in Table 5.

The Local Packing Modes of the d*-BCS Anions.* There are notable differences between the two crystallographically independent *d*-BCS anions with respect to their local packing modes in this crystal.

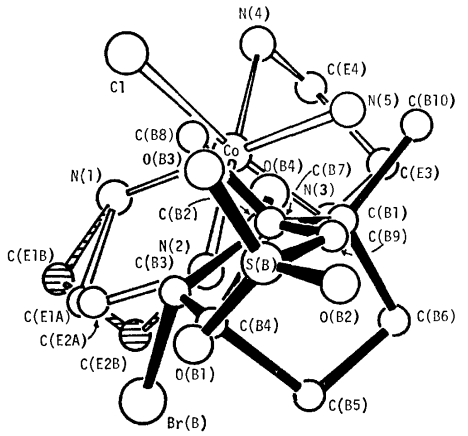

Fig. 3. A projected sketch displaying the spacial arrangement of the *d*-BCS anion and the complex cation.

In the *d*-BCS(A) anion, only the sulfonate group has short contacts with the complex cation. The distances are O(A1)···N(4) 3.05, O(A1)···N(5) 3.21, O(A2)···N(5) 3.32, O(A3)(x, y, $1+z$)···N(3) 3.05 and O(A3)(x, y, $1+z$)···N(5) 2.94 Å, suggesting the existence of the hydrogen bonds shown in Fig. 1. The bromocamphor part of the *d*-BCS(A) anion has no short contacts with the complex cation, though a few van der Waals contacts are present. These distances are C(A6)($-x$, $1/2+y$, $1/2-z$)···C(E3) 3.86 and C(A6)($-x$, $1/2+y$, $1/2-z$)···C(E4) 3.99 Å.

On the other hand, the packing mode around the *d*-BCS(B) anion bears a resemblance to that of the *d*-BCS anion in $(+)_{589}$-$[CoCl_2(en)_2]$*d*-BCS.[4] Namely, the sulfonate group tightly links the adjacent complex cations through the O···H–N hydrogen bonds and the bromocamphor part has short contacts with the complex cation. Figure 3 shows the sketch of the "$[CoClNH_3(en)_2]$*d*-BCS (B)" group projected on the "N(2), N(5), Cl" plane of the complex cation. The distances of the bromocamphor part(*d*-BCS(B)) to the complex cation are O(B4)···N(2) 2.92, O(B4)···N(5) 3.01, Br(B)···N(2) 3.59, Br(B)···C(E2A) 3.59, and Br(B)···Cl(x, y, $1+z$) 3.43 Å.

Though the bromocamphor part(*d*-BCS(B)) comes near to the "N(2), N(5), Cl" triangular facet of the octahedral complex cation, the distinct "three-to-four type" close contact found in our previous structural studies of $(+)_{589}$-$[CoCl_2(en)_2]$*d*-BCS[4] and tris(ethylenediamine)metal(III) *d*-tartrate systems[5,6,8] is not formed between the $[CoClNH_3(en)_2]^{2+}$ cation and the *d*-BCS(B) anion.

Including the "N(1), N(3), N(4)" plane of the complex cation, a hydrogen bond network is built up among the sulfonate groups of the *d*-BCS(B) anions and water molecules, as shown in Fig. 1. The hydrogen bond distances are O(B2)(x, $1+y$, z)···N(3) 2.95, O(B3)(x, $1+y$, z)···N(1) 2.87, O(B1)(x, $1+y$, $-1+z$)···WO 2.83, WO···N(1) 3.06, and WO···N(4) 2.90 Å.

Several van der Waals contacts also exist between the complex cations and the bromocamphor part of the *d*-BCS(B) anions along the b-axis, as shown in Fig. 1; C(E1B)···O(B1)($1/2-x$, $1-y$, $-1/2+z$) 3.18 and C(E2A)···C(B8)($1/2-x$, $1-y$, $1/2+z$) 3.54 Å.

The Packing of the Water of Crystallization. Hydrogen bonds in a right-handed spiral chain are formed between the sulfonate groups of the *d*-BCS(B) anions and the waters of crystallization along the twofold screw axis parallel to c($x=1/4$, $y=1$). The sequence of the chain is as follows; WO···O(B3)–S(B)–O(B1)($1/2-x$, $1-y$, $-1/2+z$)···WO($1/2-x$, $2-y$, $1/2+z$)···O(B3)–S(B)–O(B1)(x, $1+y$, z)···WO(x, y, $1+z$). The bond distances of hydrogen bonds are WO···O(B1)(x, $1+y$, $-1+z$) 2.83 and WO···O(B3) ($1/2-x$, $1-y$, $-1/2+z$) 2.76 Å.

Analogy between d-*BCS Systems and* d-*Tartrate Systems.* The ratios of the complex cation to the resolving agent-(*d*-BCS) in the crystals of $(+)_{589}$-$[CoCl_2(en)_2]$*d*-BCS and $(+)_{589}$-$[CoClNH_3(en)_2]$ $(d\text{-BCS})_2\cdot H_2O$ are 1 : 1 and 1 : 2 respectively.

It is found that the bromocamphor part of the *d*-BCS anion has a close contact with one triangular facet of the octahedral complex cation in both crystal structures. Another crystallographically independent *d*-BCS anion is present in the $(+)_{589}$-$[CoClNH_3(en)_2]$ $(d\text{-BCS})_2\cdot H_2O$, but the bromocamphor part of this anion(*d*-BCS(A)) is apart from any triangular facet of the complex cation. For a diastereomeric discrimination, the key-and-lock type association model was proposed by Fischer,[20] in which two chiral species make a compact fit. If this model is valid, the above results suggest that, though there are two *d*-BCS anions in the $(+)_{589}$-$[CoClNH_3(en)_2]$ $(d\text{-BCS})_2\cdot H_2O$, one of the *d*-BCS anions, *d*-BCS(B), plays a more important role in the diastereomeric discrimination.

Recently, three crystal structures of tris(ethylenediamine)metal(III) *d*-tartrate complexes, $(+)_{589}$-$[Co(en)_3]Br\cdot d\text{-tart}\cdot 5H_2O$, $Li\{(+)_{589}\text{-}[Cr(en)_3]\}(d\text{-tart})_2\cdot 3H_2O$, and $H\{(+)_{589}\text{-}[Co(en)_3]\}(d\text{-tart})_2\cdot 3H_2O$, have also been determined as a part of our structural studies of optical resolution.[5,6,8] The ratios of the complex cation to the resolving agent are 1 : 1, 1 : 2, and 1 : 2, respectively. Comparing the crystal structure of the 1 : 1 compound with that of the 1 : 2, we found as a common characteristic a "face-to-face type" close contact between the triangular facet of the complex cation and one *d*-tartrate anion. Moreover, though another crystallographically independent *d*-tartrate anion is present in $Li\{(+)_{589}\text{-}[Cr(en)_3]\}(d\text{-tart})_2\cdot 3H_2O$ and $H\{(+)_{589}\text{-}[Co(en)_3]\}(d\text{-tart})_2\cdot 3H_2O$ crystals, one of the two –COO groups of this *d*-tartrate anion takes the place of the bromine atom in $(+)_{589}$-$[Co(en)_3]Br\cdot d\text{-tart}\cdot 5H_2O$.[5,6,8] These results again imply that one of the *d*-tartrate anions probably plays a more important role in the diastereomeric discrimination in the above 1 : 2 type salts.

It is worthy of note that only one resolving agent probably plays a more dominant role in the diastereomeric discrimination in both *d*-tartrate and *d*-BCS systems in which two crystallographically independent resolving agents are contained.

We thank the Hiroshima University Computer Center for a generous allocation of computer time and acknowledge a Grant-in-Aid for Scientific Research from the Ministry of Education.

Solution Equilibria of Ternary α-Amino Acid–Copper(II) Complexes with Electrostatic Ligand-Ligand Interactions

Takeshi SAKURAI, Osamu YAMAUCHI, and Akitsugu NAKAHARA*

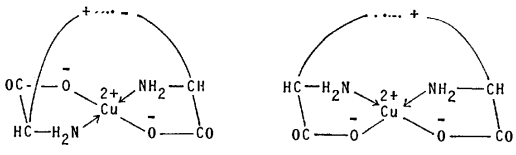
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received February 16, 1978)

The stability constants for the parent and mixed copper(II) complexes involving an acidic α-amino acid (aspartic acid or glutamic acid, abbreviated as A) and/or a basic α-amino acid (arginine, lysine, or ornithine, abbreviated as B) have been determined by potentiometric titration at 25 °C in 0.1 and 0.03 M KNO_3 (M=mol dm^{-3}). The protonated ternary species Cu(L-A)(L-B)(H) and Cu(D-A)(L-B)(H) (species 1111) have essentially the same stability constants, the log β_{1111} values being in the range 25.0—27.5. The species distribution curves for the systems Cu(II)–L- or D-glutamic acid–L-lysine at the ionic strength I=0.1 and 0.03 reveal that species 1111 is more predominant at I=0.03 than at I=0.1, suggesting that electrostatic ligand-ligand interactions between the carboxylate group in the side chain of A and the ammonium or the guanidinium group in the side chain of B are reinforced in solution at lower ionic strength to favor the ternary complex formation. The constants for deprotonation from species 1111 to form 1110, *e.g.* Cu(L-A)(L-B), are given by the difference log β_{1111} − log β_{1110}, which is higher for the Cu(II)–A–B systems than for the systems containing alanine in place of A. The results indicate that intramolecular electrostatic interactions are present in the ternary species 1111, stabilizing them under favorable conditions.

Ternary metal complexes have been extensively studied because of their possible significance as models for biological processes assisted by metal ions. Since non-covalent interactions are supposed to be an important source of specificity or selectivity in biological reactions,[1] mixed ligand copper(II) complexes involving aromatic ring stacking[2] and electrostatic ligand-ligand interactions[3] have attracted considerable attention.

On the basis of the electrostatic enzyme-substrate interactions found in the carboxypeptidase A–glycyl-L-tyrosinate complex, we designed mixed amino acid–copper(II) complex systems capable of forming intramolecular electrostatic bonds between the two amino acids, and inferred from synthetic and spectroscopic studies that such ligand-ligand interactions exist in the systems containing an acidic and a basic amino acid.[3] The IR spectra of the isolated complexes[3b] and successful optical resolution of acidic and basic amino acids *via* complex formation[5] indicate that the diastereomers Cu(L-A)(L-B)(H) and Cu(D-A)(L-B)(H), where A refers to aspartate (asp) or glutamate (glu), B to argininate (arg), lysinate (lys), or ornithinate (orn), and H to proton, are probably *cis-trans* isomers arising from the steric requirements for the ligand-ligand interactions (Scheme 1).



Cu(L-A)(L-B)(H) Cu(D-A)(L-B)(H)

Scheme 1.

Brookes and Pettit[6] determined the stability constants for the ternary systems containing copper(II), L- or D-histidine (L- or D-his), and a basic amino acid (L-B), and found the stability differences between the complexes Cu(L-his)(L-B)(H) and Cu(D-his)(L-B)(H), which they ascribed to the intramolecular electrostatic bonding. Steric hindrance has been reported to give rise to stereoselectivity in the ternary copper(II) complexes of *N*-substituted α-amino acids with α-amino acids.[7] Although many other mixed amino acid–copper(II) systems have been studied potentiometrically,[8] no systematic investigations of the ternary systems, copper(II)–L-A–L-B, seem to have been reported. In order to clarify the effects of electrostatic ligand-ligand interactions on the stability of the metal complexes in solution and the factors affecting the optical resolution of DL-A and DL-B, we have carried out a potentiometric study of the ternary amino acid–copper(II) complexes containing A and B.

Experimental

Materials. L-Arginine hydrochloride, L-lysine hydrochloride, L-ornithine hydrochloride, L- and D-aspartic acid, and L- and D-glutamic acid of grade A from Nakarai Chemicals, Ltd. were dried *in vacuo* over P_4O_{10} before use. All other chemicals used were of highest grade available. Water was distilled and deionized.

pH *Titrations.* *Reagents*: Carbonate-free potassium hydroxide (0.1 M, M=mol dm^{-3}) was prepared by the method of Armstrong,[9] standardized against potassium hydrogen phthalate, and stored under a nitrogen atmosphere. Copper(II) nitrate (0.01 M) was prepared by dissolving copper(II) nitrate trihydrate in water and standardized against standard zinc by chelatometric titration.

Apparatus: An Orion Research 801A digital pH meter equipped with a 90-01-00 glass electrode and a 91-02-00 double junction reference electrode was used for measuring the pH values after standardization with Horiba standard buffer solutions (pH 4.01, 6.86, and 9.18).

Procedure: For determination of the acid dissociation constants of the ligands, an aqueous solution (4×10^{-3} M) of protonated A or B was titrated with 0.1 M KOH at 25± 0.05 °C under a nitrogen atmosphere. For determination of the stability constants of the binary and the ternary systems, 1:2 copper(II)–A or B and 1:1:1 copper(II)–A–B solutions, respectively, were titrated with 0.1 M KOH at a constant copper(II) concentration of 2×10^{-3}M under the same conditions. Titration was carried out in the presence of 0.1 or 0.03 M KNO_3. Aliquots of A and B to be titrated were taken from stock solutions freshly prepared before use. The

pH value was measured for each addition of a small amount of 0.1 M KOH. The apparent ion products of water, pK_w', at the ionic strength $I=0.1$ and 0.03 were determined to be 13.90 and 14.02, respectively, by titration of 0.01 M HNO_3 with 0.1 M KOH, which also gave the hydrogen ion concentrations, $[H^+]$, as $10^{-pH}/0.865$ at $I=0.1$ and $10^{-pH}/0.902$ at $I=0.03$.

Results and Discussion

Calculations. The equilibria of binary and ternary systems and the stability constants β_{pqrs} are expressed by

$$pCu + qA + rB + sH \overset{\beta_{pqrs}}{\rightleftharpoons} Cu_pA_qB_rH_s, \quad (1)$$

$$\beta_{pqrs} = \frac{[Cu_pA_qB_rH_s]}{[Cu]^p[A]^q[B]^r[H]^s},$$

where p, q, r, and s denote the numbers of copper(II), A, B, and H, respectively, contained in the complex (charges are omitted). Each species will be represented as *pqrs* hereinafter.

Curves 1—4 correspond to the following systems: 1, L-asp; 2, Cu(II)-L-asp; 3, L-lys; 4, Cu(II)-L-lys.
a: Moles of alkali added per mole of ligand.

The stability constants were calculated from the pH titration data by non-linear least-squares refinement with the use of the computer program SCOGS.[10] The initial estimates for the refinements were taken from the literature[11] or guessed from the values for analogous systems. At the final stage of refinement the difference between experimental and calculated titers were well within 0.02 ml in the pH ranges considered. The acid dissociation constants (pK_a) of the ligands were calculated separately with the aid of a computer.

Stability Constants of Binary Copper(II) Complexes. Typical titration curves for the systems with a ligand alone and with copper(II) and a ligand are shown in Fig. 1. Table 1 summarizes the pK_a values of the amino acids, most of which are in good agreement with the reported values.[6b,11] To avoid erroneous results suspected at low concentrations of solutions,[9] we did not determine the constants for the α-carboxyl groups of all the amino acids whose acid dissociation occurs at around pH 2. For calculations of the stability constants, such pK_a values were taken from the litera-

Table 1. Acid dissociation constants of ligands (25 °C; $I=0.1$(KNO_3))[a]

Ligand	pK_{a_1}	pK_{a_2}
L-asp	9.75	3.79

ture[11] when necessary. However, they did not affect the present calculations seriously.

The stability constants for the binary complexes are shown in Tables 2 and 3. The titration curves for the binary copper(II)–A systems were satisfactorily reproduced by considering species 1101, 1100, and 1200 excluding the protonated bis-complexes 1202 and 1201. Although Clarke and Martell[12] detected species 1021 in the Cu(II)–arg system at pH ≈11, the present results are explained by the protonated species 1011 and 1022, deprotonation from which was not observed because of precipitation around this pH. On the other hand, the deprotonated species were found to be formed appreciably in the systems Cu(II)–orn and Cu(II)–lys at pH>8, which is illustrated in the species distribution for the 1 : 2 Cu(II)–L-orn system plotted against pH (Fig. 2). The standard deviations expressed in titer were usually larger for the systems with arg than for the systems with the other ligands probably owing to the errors in the pH measurement in a strongly alkaline solution.

Deprotonations from species 1022, where the proton is bound to the ω-amino group, to give 1021 and 1020 are represented by

$$Cu(L\text{-}B)_2(H)_2 \overset{K_{c1}}{\rightleftharpoons} Cu(L\text{-}B)_2(H) + H, \quad (2)$$

$$Cu(L\text{-}B)_2(H) \overset{K_{c2}}{\rightleftharpoons} Cu(L\text{-}B)_2 + H. \quad (3)$$

The dissociation constants pK_{c_1} (=$-\log K_{c_1}$) and pK_{c_2} are given by the differences $\log\beta_{1022}-\log\beta_{1021}$ and $\log\beta_{1021}-\log\beta_{1020}$, respectively. The pK_{c_1} values are lower than the pK_{a_1} values of orn and lys (Tables 1 and 3), and the Cu(II)–orn system has a smaller pK_{c_1} value than that of the Cu(II)–lys system, indicating that orn coordinates to copper(II) at the apical position through its δ-amino group, whereas lys does not coordinate in the same way. This is in line with the ORD[13] and CD[3a,14] spectral behaviors of these systems. Because the pK_{c_2} values for both systems do not differ very much from the respective pK_{a_1} values, they suggest that the δ-amino group of the second orn is not effectively involved in the apical coordination.

Stability Constants of Ternary Copper(II) Complexes. The stability constants for the systems were obtained from the titration curves such as those shown in Fig. 3 by the least-squares refinement starting from known

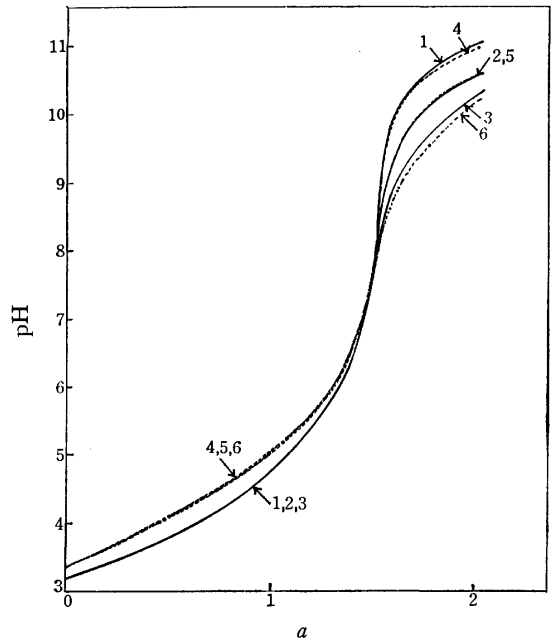

Fig. 3. Titration curves for the 1 : 1 : 1 ternary systems, Cu(II)-L-A-L-B(25 °C; I=0.1(KNO_3)).

(a): Cu(II)–L-asp–L-arg, (b): Cu(II)–L-asp–L-lys, (c): Cu(II)–L-asp–L-orn.

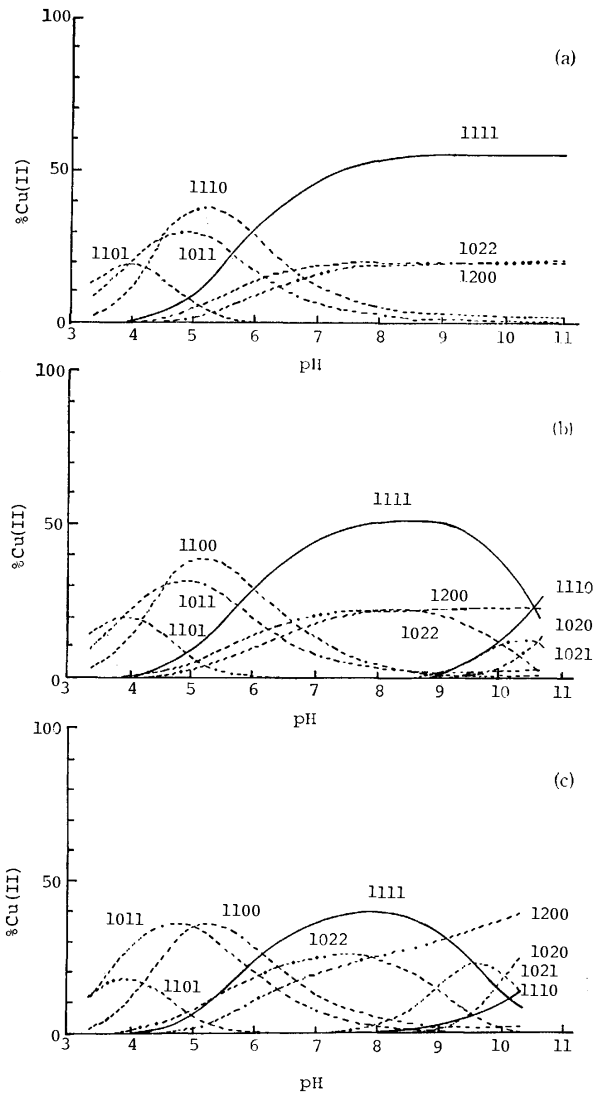

Fig. 5. Species distribution curves for the 1:1:1 Cu(II)–L-glu–L-B systems (25 °C; I=0.1 (KNO_3)).
Total concentrations: each ligand=0.002000 M; Cu(II)=0.002016 M.
(a): Cu(II)–L-glu–L-arg, (b): Cu(II)–L-glu–L-lys, (c): Cu(II)–L-glu–L-orn.

The only ternary species detected in the Cu(II)–L-A–L-arg systems is 1111 because of the tight association of the proton in the guanidinium group, whereas for the other systems both protonated (1111) and deprotonated (1110) species were found to be formed at neutral—alkaline pH. Figures 4 and 5 show the species distribution curves for the Cu(II)–L-asp–L-B and Cu(II)–L-glu–L-B systems, respectively. Although considerable amounts of the binary species are present in the latter systems as compared with the former, the ternary species 1111 are predominant at neutral pH in all the systems. We may take this as evidence supporting the previous assumption that the CD magnitude enhancements are ascribable to the ternary complexes (1111) with increased rigidity resulting from ligand-ligand interactions.[3]

A comparison of the stability constants with the statistically estimated values may offer another measure of preferential formation of the ternary species. The statistical values for species 1111 and 1110 are given by[16]

$$\log \beta_{1111(\mathrm{calcd})} = \frac{1}{2}(\log \beta_{1200} + \log \beta_{1022}) + \log 2, \quad (4)$$

$$\log \beta_{1110(\mathrm{calcd})} = \frac{1}{2}(\log \beta_{1200} + \log \beta_{1020}) + \log 2. \quad (5)$$

For most systems the experimental $\log \beta_{1111}$ values are greater than the calculated ones, substantiating the stabilization of species 1111, whereas the deprotonated species 1110 are usually less stable than expected from Eq. 5 (Table 5). The differences, $\log \beta_{1111} - \log \beta_{1110}$, are greater for Cu(L-A)(L-lys) and Cu(L-A)(L-orn) than for Cu(L-ala)(L-lys) and Cu(L-ala)(L-orn), probably reflecting the intramolecular electrostatic bonding.

Stereoselectivity in Solution. Optical resolution of

a) Calculated according to Eq. 4. b) Calculated according to Eq. 5.

racemic A and B has established that the systems Cu(II)–DL-A–L-B and Cu(II)–L-A–DL-B preferentially give the *meso* complexes as crystals incorporating the D-enantiomers of A and B with various optical purities, respectively.[5] We see from Table 4 that the diastercomers, which may exist as geometric isomers (Scheme 1), have virtually the same stability constants and that no stereoselectivity is detected at least in the solution with $I=0.1$. Therefore, the optical resolution may be primarily due to the solubility difference and not to the stability difference between the diastereomers in solution under the conditions used.[5]

Effects of Ionic Strength on Ternary Complex Formation. In the Cu(II)–L-glu–L-lys system the stability constants for the ternary species 1111 and 1110 at lower ionic strength (0.03) were found to be higher than those at $I=0.1$ (Table 4), the increments being 0.32 for 1111 and 0.77 for 1110. The diastereomeric system Cu(II)–D-glu–L-lys exhibited the same stability increase at $I=0.03$. A similar observation was made by Nagypál *et al.*,[17] who found that the stability difference between experimental and statistical values for the copper(II)–glycine–aspartic acid complex varies with the ionic strength because of the change in charge on complex formation. The distributions of the ternary species in the present system are more predominant at lower ionic strength regardless of the enantiomers of A and B used.[18] Since such a trend is also expected for the other ternary systems and the CD spectral magnitude decrease due to increased ionic strength[3a,3c] has confirmed its effect on the electrostatic ligand-ligand interactions, the above result indicates that the stabilities of the complexes in aqueous solution are enhanced as the ligand-ligand interactions are reinforced.

In a hydrophobic region, such as is found in biological systems, electrostatic interactions as well as hydrogen bonds are certainly of importance, and elucidation of the complex formation *in vivo* will require further information on such non-covalent interactions, which might be more effective in biofluids than in experimental aqueous media.

This work was supported in part by a grant from the Ministry of Education.

18) The distribution of 1111 species increased from 52% at $I=0.1$ to 60% at $I=0.03$. The pK_a values and the stability constants for the binary species at $I=0.03$ are as follows: L-Glu: $pK_{a_1}=9.67$ (0.001), $pK_{a_2}=4.20$ (0.001), $\log \beta_{1100}=8.48$ (0.005), $\log \beta_{1101}=12.64$ (0.006), and $\log \beta_{1200}=15.05$ (0.007); L-Lys: $pK_{a_1}=10.83$ (0.001), $pK_{a_2}=9.12$ (0.001), $\log \beta_{1022}=35.65$ (0.02), $\log \beta_{1021}=25.74$ (0.03), $\log \beta_{1020}=15.35$ (0.02), and $\log \beta_{1100}=18.41$ (0.02).

Fluxional Behavior of Palladium(II) and Platinum(II) Complexes Containing both a Metal–Aryl Bond and a Pyrazole-derived Ligand†

Masayoshi ONISHI,* Koji SUGIMURA, and Katsuma HIRAKI*

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received February 22, 1978)

New (acetophenone oximato, 2-*C,N*)- and (benzophenone oximato, 2-*C,N*)palladium(II) complexes containing poly(1-pyrazolyl)borato ligand (BPz_4 or $HBPz_3$, Pz=1-pyrazolyl) or poly(1-pyrazolyl)methane (CPz_4 or $HCPz_3$) were prepared and investigated by means of ^{1}H-NMR spectroscopy. For the BPz_4 complexes, the tumbling motion of the BPz_4 ligand averaged the environments of all four pyrazolyl groups to give spectroscopic equivalence above 65 °C, and was virtually frozen at *ca.* −9 °C. With regard to the $HBPz_3$, CPz_4, and $HCPz_3$ complexes, all pyrazolyl groups were equivalent at high temperature exhibiting stereochemical nonrigidity. The well-defined slow-exchange limiting spectra were not obtained at *ca.* −34 °C. In addition, new (acetophenone oximato, 2-*C,N*)platinum(II) complexes involving the BPz_4 or $HBPz_3$ ligand were prepared. The bidentate coordination of the BPz_4 ligand in the BPz_4 platinum(II) complex was stereochemically rigid in the range of 29 to 110 °C in DMSO-d_6. Three pyrazolyl groups in the $HBPz_3$ platinum(II) complex were equivalent at 85 °C in DMSO-d_6, while the fluxional motion was fairly restricted at room temperature.

Trofimenko[1,2] synthesized π-allylpalladium(II) complexes, $[Pd(\pi\text{-}C_3H_5)(PBz_4)]$ (Pz=1-pyrazolyl) and $[Pd(\pi\text{-}C_3H_5)(CPz_4)]PF_6$, reported that each of the 3-, 4-, and 5-H's of the four pyrazolyl groups in these complexes showed only one signal in the ^{1}H-NMR spectra at room temperature, and explained the fluxional behavior in terms of a "tumbling process."[1]

It is interesting to compare the fluxional behavior of the pyrazole-derived chelate ligands in the other square-planar complexes with those of the π-allylpalladium(II) complexes[1,2] and related platinum(II) complexes.[3] In a previous paper,[4] the fluxional behavior has been reported for several polypyrazolylborato palladium(II) complexes, which were prepared from dimeric cyclopalladated complexes derived from *N,N*-dimethylbenzylamine, azobenzene, 2-phenylpyridine, and benzo[*h*]quinoline.

This paper will deal with several new polypyrazolylborato (BPz_4 or $HBPz_3$) and polypyrazolylmethane (CPz_4 or $HCPz_3$) palladium(II) complexes, derived from cyclopalladated complexes, di-μ-chloro-bis(acetophenone oximato, 2-*C,N*)dipalladium(II)[5] $[\{PdCl(apo)\}_2]$ {apo=$-C_6H_4-C(=NOH)CH_3$,2-*C,N*} or di-μ-chloro-bis(benzophenone oximato, 2-*C,N*)dipalladium(II)[5] $[\{PdCl(bpo)\}_2]$ {bpo=$-C_6H_4-C(=NOH)C_6H_5$, 2-*C,N*}, and with the fluxional behavior of the pyrazole-derived ligands in these complexes by means of ^{1}H-NMR spectroscopy.

New platinum(II) complexes, $[Pt(apo)(BPz_4)]$ and $[Pt(apo)(HBPz_3)]$ were also obtained and compared with the corresponding polypyrazolylborato palladium(II) complexes.

Experimental

General Procedures. Melting points were determined on a Yanagimoto MP-S3 microstage apparatus and are uncorrected. IR spectra were recorded on a Hitachi model 285 spectrometer. ^{1}H-NMR spectra were run on a Japan Electron Optics Laboratory model JNM-MH-100 (100 MHz) spectrometer using tetramethylsilane as the internal standard. The temperatures of the NMR samples were determined with methanol or 1,3-propanediol.

$[\{PdCl(apo)\}_2]$,[5] $[\{PdCl(bpo)\}_2]$,[5] $[PtCl(apo)(Hapo)]$,[5] sodium tetrakis(1-pyrazolyl)borate {$Na(BPz_4)$},[6] sodium hydrotris(1-pyrazolyl)borate {$Na(HBPz_3)$},[6] CPz_4,[2] and $HCPz_3$[7] were prepared and purified according to the methods described in the literature.

Syntheses of the BPz_4 Palladium(II) Complexes. $[\{PdCl(bpo)\}_2]$ (1.6 g) and $Na(BPz_4)$ (1.5 g) were mixed in ethanol (80 ml) and the suspension stirred at room temperature for *ca.* 20 h. The precipitate was extracted with hot benzene, the solvent evaporated, and the residue recrystallized from ethanol to give yellow crystals of $[Pd(bpo)(BPz_4)]\cdot C_2H_5OH$, 0.9 g. This complex was converted into the non-solvated complex (**1**), by recrystallization from benzene.

The acetophenone oxime analogue, (**2**) and the ethanol monosolvate were obtained by a similar method.

Syntheses of the $HBPz_3$ Palladium(II) Complexes. A solution of $Na(HBPz_3)$ (0.9 g) in ethanol (20 ml) was added dropwise to a stirred suspension of $[\{PdCl(bpo)\}_2]$ (1.3 g)

10	50	Orange	218—220	37.70(37.65)	3.29(3.35)	18.17(18.08)

a) Based on the starting palladium(II) or platinum(II) complexes. b) All complexes decomposed without melting. c) Measured in dinitrogen atmosphere.

in ethanol (10 ml). After stirring for *ca.* 20 h, the suspension was filtered and the precipitate washed with dichloromethane and methanol to yield a pale yellow powder of [Pd(bpo)-($HBPz_3$)] (**3**), 1.1 g: IR (Nujol) 2410 and 2425 cm^{-1} (ν_{BH}).

The complex [Pd(apo)($HBPz_3$)] (**4**) was prepared similarly except the washing was conducted with dichloromethane: IR (Nujol) 2425 and 2440 cm^{-1} (ν_{BH}).

Syntheses of the CPz_4 Palladium(II) Perchlorate Complexes. A mixture of CPz_4 (0.1 g) and [{PdCl(bpo)}$_2$] (0.12 g) in methanol–water (35 ml) (1:3), was stirred for *ca.* 20 h at room temperature.

The mixture was filtered and a solution of sodium perchlorate in methanol–water added to the filtrate. The resulting precipitate was recrystallized from methanol to give a yellow solid of [Pd(bpo)(CPz_4)]ClO_4 (**5**), 0.09 g.

The complex [Pd(apo)(CPz_4)]ClO_4 (**6**) was prepared in a similar method as described for **5**, where the corresponding precipitate was washed with benzene, dichloromethane, and water in place of recrystallization.

Syntheses of the $HCPz_3$ Palladium(II) Perchlorate Complexes. A mixture of [{PdCl(bpo)}$_2$] (0.37 g) and $HCPz_3$ (0.24 g) in methanol–water (30 ml) (1:3) was stirred for 5 h at room temperature and the reaction mixture filtered. Sodium perchlorate was added to the filtrate, and the resulting precipitate was recrystallized from methanol to afford a yellow solid of [Pd(bpo)($HCPz_3$)]ClO_4 (**7**) 0.28 g: IR (KBr) 3000 cm^{-1} (ν_{CH} of $HCPz_3$).

The complex [Pd(apo)($HCPz_3$)]ClO_4 (**8**) was prepared similarly: IR (KBr) 2990 cm^{-1} (ν_{CH} of $HCPz_3$).

Syntheses of [Pt(apo)(BPz_4)] and [Pt(apo)($HBPz_3$)]. After a mixture of Na(BPz_4) (0.3 g) and [PtCl(apo)(Hapo)] (0.41 g) was stirred for *ca.* 20 h in benzene (20 ml), the solvent was removed. The residue was extracted with dichloromethane and the extract evaporated to dryness. The resulting solid was washed with diethyl ether and ethanol to yield an orange powder of [Pt(apo)(BPz_4)] (**9**), 0.2 g.

The complex [Pt(apo)($HBPz_3$)] (**10**) was obtained similarly, and recrystallized from methanol: IR(Nujol) 2430 and 2410 cm^{-1} (ν_{BH}).

Results and Discussion

Physical Properties. The analytical data and the physical properties of the new palladium(II) and platinum(II) complexes are summarized in Table 1. The BPz_4 palladium(II) complexes, **1** and **2** were soluble in chloroform and DMSO, and slightly soluble in ethanol and benzene. The $HBPz_3$ palladium(II) complexes, **3** and **4**, were less soluble than the corresponding BPz_4 complexes, **1** and **2**, respectively. The ^{1}H-NMR spectrum of **3** was not obtainable. The complexes were stable in the solid state. However, complex **4** decomposed slowly in dichloromethane to give metallic palladium. The cationic palladium(II) complexes, **5**, **6**, **7**, and **8** involving polypyrazolylmethane were insoluble in common organic solvents except for acetonitrile and methanol. The polypyrazolylmethane complexes were thermally more stable than the corresponding polypyrazolylborato ones in the solid

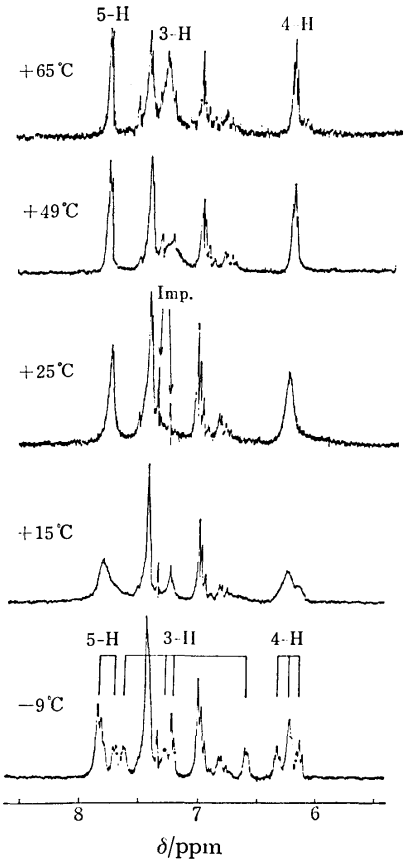

Fig. 1. ^{1}H-NMR spectra of **1** in $CDCl_3$. Two impurities are $CHCl_3$ and C_6H_6.

Table 2. Solvent effects on the chemical shifts of pyrazolyl protons[a)]

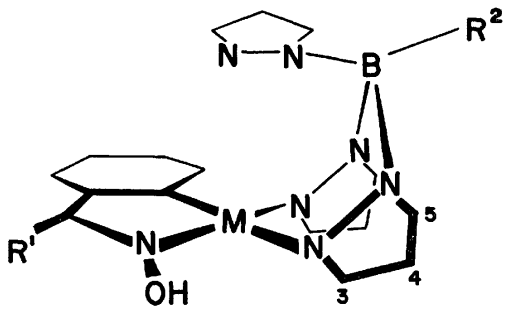

Fig. 2. The proposed geometrical arrangement.

state, complexes, **5** and **6** decomposing in acetonitrile at 80 °C.

The polypyrazolylborato platinum(II) complexes, **9** and **10** were stable in the solid state, slightly soluble in DMSO at room temperature, and insoluble in other common organic solvents.

Each of the ν(BH) bands in the $HBPz_3$ complexes consisted of two peaks, which were associated with $\nu(^{10}BH)$ and $\nu(^{11}BH)$ corresponding to the natural abundance of boron isotopes.

^{1}H-NMR Spectra of the BPz_4 Palladium(II) Complexes. Figure 1 shows the ^{1}H-NMR spectra of **1** in $CDCl_3$ at several temperatures between −9 and 65 °C. The line shapes of the three signals at δ 7.44 (5H), 7.01 (3H), and 6.80 (1H) were independent of temperature, and were unaffected by the exchange process. The first signal was assigned to the phenyl protons, and the remaining two to the metallated *o*-phenylene group. The protons of the four pyrazolyl groups showed signals which were remarkably temperature-dependent. At 65 °C, a signal at δ 6.22 (4H) exhibited a triplet and was ascribed to 4-H's. Signals at δ 7.28 (4H) and 7.76 (4H) were associated with 3-H's and 5-H's, respectively, on the basis of the temperature-dependency of each signal (*vide infra*). At this temperature, each of the three kinds of protons belonging to the four pyrazolyl groups exhibited spectroscopic identity, indicating a tumbling motion of the BPz_4 group as observed for [Pd(π-C_3H_5)(BPz_4)].[1)]

The signal for the 5-H's became gradually broader on cooling and separated into two signals at δ 7.79 (3H) and 7.66 (1H) at −9 °C. The signal for the 3-H's was apparently missing at 25 °C, and reappeared at δ 7.56, 7.26, 7.21, and 6.64 at −9 °C. These facts indicate that at this temperature the four pyrazolyl groups are spectroscopically unequal, and the BPz_4 ligand is coordinated to the central metal in a stereochemically rigid state. In this state, one can expect that the differences in environments and chemical shifts among the four 3-H's are larger than those among the 5-H's, respectively, by considering the proposed arrangement shown in Fig. 2. At 45 °C, a broad peak at δ 5.15 was observed in $CDCl_3$ and ascribed to an oxime proton, since it disappeared with the addition of D_2O.

Table 2 shows the NMR data of the pyrazolyl protons of **1** recorded at 76 °C in C_6D_6 and DMSO-d_6, and indicates an appreciable degree of solvent effect on the chemical shifts of the 3-H's, in contrast to that of the 5-H's. This confirms the above-mentioned assignment of the 3-H's.

At −16 °C, complex **2** exhibited a low-temperature limiting spectrum, in which a signal at δ 7.58 was attributed to two protons overlapping each other, assignable to one of the 3-H's and one of the 5-H's. The other signals of **2** exhibited very similar patterns to those of **1**.

In the BPz_4 complexes, the tumbling motion averages the environments of all four pyrazolyl groups to give spectroscopic equivalence at high temperature. The motion is thought to involve the coordination of one uncoordinated pyrazolyl group to the axial site of palladium accompanied instantaneously by the dissociation of one previously coordinated group and the inversion of the Pd–(N–N)$_2$–B boat-type six-menbered ring. In consideration of the proposed conformation shown in Fig. 2, it is reasonably expected that one uncoordinated pyrazolyl group easily approaches the axial site of the palladium atom. The tumbling motion is probably restricted to an appreciable degree in these aromatic oximato complexes, in which the *trans* positions of the BPz_4 ligand are coordinated with nitrogen donor and aryl group, in contrast to the π-allyl analogue. The comparatively weak *trans* influence of the nitrogen donor in the cyclometallated moiety of **1** and **2** possibly resulted in a moderately strong binding of Pd–Pz bond *trans* to the nitrogen donor and in an easy fixation of tumbling motion of the BPz_4 ligand.

^{1}H-NMR Spectra of the Other Palladium(II) Complexes. In the NMR spectra of [Pd(apo)($HBPz_3$)], the three pyrazolyl groups were spectroscopically equivalent at 36 °C, indicating the fluxional motion of the $HBPz_3$ ligand. The peaks for pyrazolyl groups began to broaden at −24 °C. At *ca.* −34 °C, a new peak appeared near δ 6.5, which was tentatively ascribed to one proton of 3-H's. However, a slow-exchange limiting spectrum was not obtained even at this temperature. The fluxional motion of the $HBPz_3$ complex was more hardly fixed than that of the corresponding BPz_4 complex.

Each signal for the 3-, 4-, and 5-H's of the CPz_4

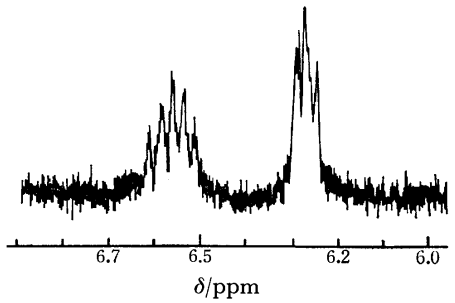

Fig. 3. 4-H's signals in ^{1}H-NMR spectrum of **9** in DMSO-d_6 at 30 °C.

complexes, **5** and **6**, showed only one signal at *ca.* 50 °C in CD_3CN, demonstrating the spectroscopic equivalence of all four pyrazolyl groups and the tumbling motion of the CPz_4 ligand. The signals for the 3- and 5-H's of the pyrazolyl groups became broad at temperatures below −10 °C, and began to separate at *ca.* −30 °C. In contrast to the polypyrazolylborate ligands, the fixation of the fluxional motion of the polypyrazolylmethane ligands was comparatively difficult.

The $HCPz_3$ complexes, **7** and **8**, at room temperature gave well-defined fast-exchange limiting spectra, showing spectroscopic equivalence of the three pyrazolyl groups and stereochemical nonrigidity.

^{1}H-NMR Spectra of Platinum(II) Complexes. Coordination of the BPz_4 ligand in the platinum(II) complex **9** was stereochemically rigid even at 110 °C on the basis of the ^{1}H-NMR spectra, and the compound decomposed at *ca.* 130 °C in DMSO-d_6. No fluxional behavior was observed. The 4-H's resonances showed a triplet at δ 6.28 and a multiplet at δ 6.55 in the ratio of 2:2, as shown in Fig. 3. The apparent multiplet was assigned to the 4-H protons with attendant ^{195}Pt satellites in two coordinated pyrazolyl groups, indicating that the BPz_4 ligand acted as a bidentate ligand and the complex was four-coordinated. For the ^{1}H-NMR spectra of methyl(polypyrazolylborato)platinum(II) complexes, similar ^{195}Pt satellites were observed for the 4-H protons of the pyrazolyl groups coordinated to platinum.[3]

In the $HBPz_3$ platinum(II) complex **10**, three signals, a slightly broad peak (3H) at δ 7.89, a doublet (3H) at δ 7.74, and a triplet (3H) at δ 6.37 were observed for the pyrazolyl protons at *ca.* 85 °C and the triplet was assigned to the 4-H's. Three pyrazolyl groups were spectroscopically equivalent at this temperature showing stereochemical nonrigidity of the $HBPz_3$ ligand. At room temperature, the 4-H's signal separated into two signals in a 2:1 intensity ratio and the coordination of the $HBPz_3$ ligand became comparatively rigid on the NMR time scale. The slow-exchange limiting spectrum was not obtained due to poor solubility of **10** below room temperature. The fluxional motion of the $HBPz_3$ platinum(II) complex was easily fixed in contrast to that of the corresponding palladium(II) complexes.

Table 3. Fast-exchange limiting ^{1}H-NMR spectra[a] of pyrazolyl groups in the $HBPz_3$, CPz_4, and $HCPz_3$ complexes

Complex	Temp (°C)	4-H	3-H or 5-H

(Received April 3, 1978)

The pyridine(py), 4-methylpyridine(4-Me-py) and 4-cyanopyridine(4-CN-py) adducts of bis(3-hydroxy-2-methyl-4-pyronato) complexes (ML_2) of cobalt(II), nickel(II), and zinc(II) have been synthesized: $CoL_2(py)_n$ (where $n=2$ or 3), $NiL_2(py)_3$, $ZnL_2(py)$, $ML_2(4\text{-Me-py})_2$ (where M=Co(II), Ni(II), and Zn(II)), $ML_2(4\text{-CN-py})$ (where M=Co(II) and Zn(II)), and $NiL_2(4\text{-CN-py})_2$. Based on the magnetic, spectral, and thermogravimetric data, three of these complexes, $ZnL_2(py)$ and $ML_2(4\text{-CN-py})$ (where M=Co(II) and Zn(II)), are presumed to have a five-coordinate structure, while the other complexes are presumed to be octahedral. In the case of the 4-cyanopyridine complexes, the infrared spectra show that the pyridine-ring nitrogen is linked to the metal ion and that the nitrogen atom of the nitrile group is not coordinated.

In previous papers it was reported that, when treated with 2,2′-bipyridine(bpy) or 1,10-phenanthroline (phen), the aqua ligands of the diaquabis(3-hydroxy-2-methyl-4-pyronato) complexes of Co(II), Ni(II), and Zn(II) were replaced by the base,[1] whereas bis(3-hydroxy-2-methyl-4-pyronato)palladium(II) gave mixed ligand complexes, $[PdL(bpy)]ClO_4$ and $[PdL(phen)]ClO_4$.[2] On the other hand, an aliphatic amine, such as ethylenediamine(en), propylamine(pa), and benzylamine(ba), replaced both of the ligands in $[PdL_2]$ to afford a complex containing 3-hydroxy-2-methyl-4-pyronate (Fig. 1) as counter ions, $[Pd(en)_2]L_2\cdot 2H_2O$,[2] $[Pd(pa)_4]L_2$, or $[Pd(ba)_4]L_2$.[3] In the course of our studies it was noticed that pyridine and 4-substituted pyridines react with diaquabis-(3-hydroxy-2-methyl-4-pyronato) complexes of Co(II), Ni(II), and Zn(II) to produce five- or six coordinate mixed-ligand complexes containing the pyronate anion and the base.

This paper will report on the syntheses and structural studies of the pyridine, 4-methylpyridine, and 4-cyanopyridine adducts of bis(3-hydroxy-2-methyl-4-pyronato) complexes of Co(II), Ni(II), and Zn(II).

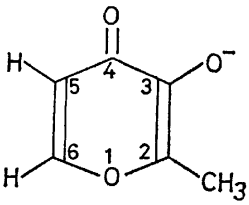

Fig. 1. 3-Hydroxy-2-methyl-4-pyronate anion.

Experimental

Materials. The preparation of three diaquabis(3-hydroxy-2-methyl-4-pyronato) complexes of Co(II), Ni(II), and Zn(II), $(CoL_2(OH_2)_2$, $NiL_2(OH_2)_2$, and $[ZnL_2(OH_2)_2]\cdot 1/2H_2O)$ has previously been reported.[1] Reagent-grade pyridine, 4-methylpyridine, and 4-cyanopyridine were used without further purification. The ethanol was purified by the fractional distillation of the ternary azeotrope, benzene–ethanol–water. The mercury(II) tetrakis(isothiocyanato)-cobalt(II) was prepared according to the literature[4] and was used as a referecne substance for the magnetic measurements.

*Preparation of Complexes. Bis(3-hydroxy-2-methyl-4-pyronato)bis(pyridine)cobalt(II) Pyridine, $[CoL_2(py)_2](py)$ (**1**):* In 10 ml of hot pyridine–ethanol (1 : 2 by volume) we dissolved 1.0 g of $CoL_2(OH_2)_2$, the solution was then heated on a hot-plate for 10 min with stirring and stored overnight in a refrigerator. The brown precipitate thus obtained was filtered and dried *in vacuo* at room temperature. The yield was 1.4 g (87%).

*Bis(3-hydroxy-2-methyl-4-pyronato)bis(pyridine)cobalt(II), $[CoL_2(py)_2]$ (**2**):* This compound was produced when Complex **1** was kept at *ca.* 95 °C for 2 h in an atmosphere of flowing nitrogen (50 ml/min).

The corresponding pyridine adducts of Ni(II) and Zn(II), $[NiL_2(py)_2](py)$ (**3**) and $[ZnL_2(py)]$ (**4**), were also prepared, by the method used for Complex **1** using $NiL_2(OH_2)$ and $[ZnL_2(OH_2)_2]\cdot 1/2H_2O$ instead of $CoL_2(OH_2)_2$, in 92 and 93% yields respectively.

*Bis(3-hydroxy-2-methyl-4-pyronato)bis(4-methylpyridine)cobalt-(II), $[CoL_2(4\text{-Me-py})_2]$ (**5**):* One gram of $CoL_2(OH_2)_2$ was added little by little to 5 ml of 4-methylpyridine with stirring. The mixture was heated on a hot-plate with stirring for 15 min, and then cooled to room temperature. The brown precipitate thus obtained was filtered, washed with ethanol and petroleum ether, and dried *in vacuo* at room temperature. The yield was 1.3 g (91%).

In a similar fashion, $[NiL_2(4\text{-Me-py})_2]$ (**6**) and $[ZnL_2(4\text{-Me-py})_2]$ (**7**) were obtained in 98 and 86% yields respectively.

*(4-Cyanopyridine)bis(3-hydroxy-2-methyl-4-pyroanato)cobalt(II), $[CoL_2(4\text{-CN-py})]$ (**8**):* To an ethanol solution (120 ml) of 4-cyanopyridine (0.52 g, 0.005 mol) we added 1.72 g (0.005 mol) of $CoL_2(OH_2)_2$. The mixture was heated on a hot-plate with stirring. The solution was concentrated to begin the formation of a precipitate, and was then left standing overnight in a refrigerator. The brown precipitate thus obtained was filtered, washed with ethanol, and dried *in vacuo* at room temperature. The yield was 1.4 g (67%).

The corresponding 4-cyanopyridine adducts of Ni(II) and Zn(II), $[NiL_2(4\text{-CN-py})_2]$ (**9**) and $[ZnL_2(4\text{-CN-py})]$ (**10**), were also prepared by the reaction of $NiL_2(OH_2)_2$ or $[ZnL_2(OH_2)_2]\cdot 1/2H_2O$ respectively with two or three times as many moles of 4-cyanopyridine in a manner similar to that used for Complex **8**. The yields were 81% and 80 respectively.

Analyses and Measurements. The metal contents in these complexes were determined by atomic absorption spectroscopy. The visible and ultraviolet reflection spectra were

obtained with a Shimadzu MPS-5000 recording sepctrophotometer. The infrared spectra (4000—200 cm^{-1}) were obtained with a Jasco DS-701G infrared spectrophotometer in Nujol mull between CsI plates. The magnetic susceptibility was determined at room temperature by the Faraday method with an automatically recording magnetic balance (Shimadzu Seisakusho Co., Ltd.). Mercury(II) tetakis(isothiocyanato)cobaltate(II) was used as a reference substance. The diamagnetic corrections were calculated from Pascal's constants. The thermogravimetric curves were obtained with a Shimadzu TGA-20B thermobalance at a heating rate of 5 °C/min in an atmosphere of nitrogen flowing at 50 ml/min. The PMR spectra were measured in $CDCl_3$ at 100 MHz with a JNM-PS-100 spectrometer (Japan Electron Optics Lab. Co., Ltd.) using tetramethylsilane as the internal reference. The molecular weight was determined in chloroform at 35 °C with a vapor-pressure osmometer of the Hitachi Perkin-Elmer 115 type, employing benzil as a reference substance.

Results and Discussion

Ten mixed-ligand complexes isolated are listed in Table 1, together with their colors and analytical and magnetic data. As may be seen in Table 2, the observed molecular weights of Complexes **5**—**10** are remarkably smaller than the calculated values, indicating that these complexes dissociate extensively in solution. Furthermore, the electronic spectra of the nickel(II) and cobalt(II) complexes in ethanol (**1**, **2**, **3**, **5**, and **6**) or chloroform (**8** and **9**) changed on the addition of the corresponding base to the solution, suggesting again the dissociation of these complexes in solution. Therefore, the structural study of the complexes was done mainly on the basis of thermogravimetic, IR, reflection-spectral, and magnetic data in the solid state.

Thermogravimetric Data. The thermogravimetric (TG) curves for the pyridine, 4-methylpyridine, and 4-cyanopyridine complexes are given in Figs. 2 and 3.

Complex **1** begins to liberate pyridine at around 30 °C and loses two molecules up to *ca.* 160 °C to give $CoL_2(py)$ (weight loss at 160 °C; found: 29.54%, calcd for 2 py: 28.95%.). The TG curve does not show distinctly whether or not the two pyridine molecules are liberated in two steps, but Complex **2** was

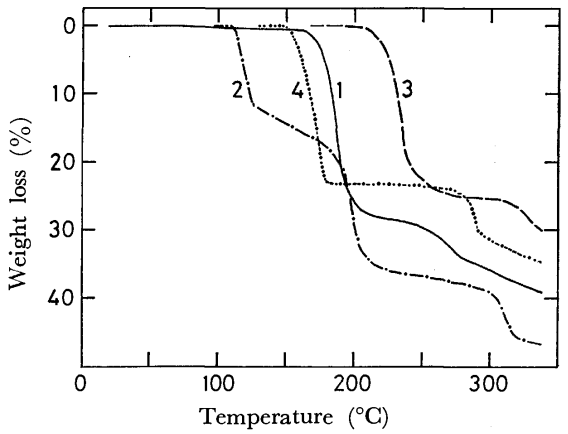

Fig. 3. The TG curves for complexes **5**(1), **7**(2), **8**(3), and **10**(4).

obtained by keeping Complex **1** at *ca.* 95 °C for 2 h in an atmosphere of flowing nitrogen. Complex **2** loses a further pyridine molecule in the same temperature range in which Complex **1** loses two pyridine molecules (weight loss at 160 °C; found: 17.14%, calcd for py: 16.93%.). Based on these results and on the IR spectral data, which indicate that an uncoordinated pyridine molecule is contained in Complex **1**, but not in Complex **2**, it may be concluded that the former complex loses an uncoordinated pyridine molecule most easily. The pyridine in the residual compound, $CoL_2(py)$, seems to be held much more tightly. Complex **3** begins to decompose at *ca.* 80 °C, and no stable intermediate is detected. Complex **4**, on the other hand, begins to liberate pyridine at 120 °C to give ZnL_2 in the temperature range of 160—250 °C to give ZnL_2 (weight loss at 200 °C; found: 20.31%, calcd for py: 20.04%.).

The TG curve for Complex **7** shows that the liberation of 4-methylpyridine takes place in three steps: *i.e.*, $ZnL_2 \cdot 2B \xrightarrow[110-125\,^\circ C]{-0.6B} ZnL_2 \cdot 1.4B \xrightarrow[125-190\,^\circ C]{-0.4B} ZnL_2 \cdot B \xrightarrow[190-250\,^\circ C]{-1B} ZnL_2$ (where B is 4-methylpyridine), although the metastable intermediate compounds have not been isolated. The TG curves for Complexes **8** and **10** indicate that these complexes lose 4-cyanopyridine in a single step (weight loss of **8** at 290 °C; found: 25.28%, calcd for 4-CN-py: 25.19%, and weight loss of **10** at 270 °C; found: 24.12%, calcd for 4-CN-py: 24.81%.).

For the five-coordinate complexes, a rough order of thermal stability, is estimated from the temperature at which the complexes begin to lose weight, is: $ZnL_2(py) \leq ZnL_2(4\text{-CN-py}) < CoL_2(4\text{-CN-py})$.

Infrared Spectral Data. The infrared spectral data for the isolated complexes are shown in Table 3. In all of these complexes, the 3-hydroxy-2-methyl-4-pyronate ligand is coordinated to the metal ion through the two oxygen atoms of the carbonyl and hydroxyl groups, since the frequencies of the C=O and C=C stretching vibrations are smaller by *ca.* 50 cm^{-1} than those in the free ligand.[1] The coordination of pyridine can be readily inferred from the shift of the 604 (an inplane ring deformation) and 405 cm^{-1} (an out-of-plane ring deformation) bands for uncoordinated pyridine to about 625 and 420 cm^{-1} respectively.[5-7] The magnitude of the frequency shift depends on the stereochemistry of the complex and on the radii of the metal ions.[6] For Complexes **1** and **3**, the bands due to both the coordinated and uncoordinated pyridines are observed. However, Complex **2** shows bands due to coordinated pyridine only. From these results, which are consistent with those of the thermogravimetric analysis, it may be concluded that two of the pyridine molecules in Complexes **1** and **3** are coordinated, while one is uncoordinated. Clark and Williams indicated that the 604 cm^{-1} band is more sensitive to the stereochemistry of the complex, but the frequencies of both the 604 and 405 cm^{-1} bands increase with a decrease in the ionic radius of the metal for the series of polymeric octahedral chloro compounds, $M(py)_2Cl_2$, where M=Mn(II), Fe(II), Co(II), Ni(II), and Cu(II).[7] Complex **4** shows absorption at 640 and 420 cm^{-1}; the position of the former band is apparently higher than those of the other pyridine complexes. This difference may stem from the difference in stereochemistry, since the zinc complex has a five-coordinate structure, while the others are octahedral.

For the 4-methylpyridine complexes of metal halides, Gill and Kingdon previously noted that the bands due to 4-methylpyridine move to higher frequencies except for the band at 728 cm^{-1}, which moves to

Table 4. PMR spectra of the zinc(II) complexes in chloroform solution (δ, ppm)

Compound	L⁻				py or 4-Me-py		
	CH_3	H^5	H^6	$J_{5,6}$	H^2, H^6	H^3, H^5	H^4 or CH_3
py					8.54	7.19	7.57
4	2.42	6.49	7.68	5.2 Hz	8.59	7.34	7.78
4-Me-py					8.41	7.06	2.31
7	2.47	6.53	7.69	5.2 Hz	8.42	7.12	2.34

a lower frequency.[8] They further pointed out that the magnitude of the shift of the bands in the monomeric octahedral complexes increases with the series from the manganese to the nickel complexes, particularly for the 996, 515, and 484 cm^{-1} bands of the free ligand. Table 3 shows that these tendencies are also observed in Complexes **5**, **6**, and **7** obtained in the present study, revealing that both of the 4-methylpyridine molecules are coordinated to the metal ion in these complexes.

With regard to the 4-cyanopyridine complexes, it is well known that, when the nitrile nitrogen is coordinated to a metal ion, the stretching frequency of the nitrile group moves to a higher value than that for the free ligand.[9-12] On the other hand, when the pyridine ring nitrogen is coordinated to the metal ion, the ν(CN) band at 2242 cm^{-1} suffers little influence, but the bands (1081, 1075sh, and 988 cm^{-1}) due to the ring-breathing mode suffer appreciable shifts.[9-12] In complexes **8**, **9**, and **10**, the nitrile stretching frequency is decreased a little and the ring-breathing frequencies are shifted (Table 3). These data suggest that 4-cyanopyridine in these complexes is coordinated to the metal ion *via* the ring nitrogen.

The metal-oxygen stretching bands are assigned tentatively by reference to the literature.[1,13]

PMR Spectra of Zn(II) Complexes. The PMR data for Complexes **4** and **7** in $CDCl_3$ solutions are shown in Table 4. The assignments are based on the relative peak areas and on a comparison with the spectra of $[ZnL_2(OH)_2]\cdot 1/2H_2O$,[1] pyridine, and 4-methylpyridine.[14] In the spectrum of Complex **4**, the resonance peaks due to pyridine are shifted downfield on ligation as compared to those of free pyridine. The shifts for the 2 and 6 protons are much smaller than those for the 3, 5, and 4 protons. The molecular weight of this complex was determined to be 400± 10 in chloroform, very close to the calculated value of 394.7, indicating that the compound is stable and retains the five-coordinate structure in chloroform. However, it is not certain whether the complex has a square pyramidal structure or a trigonal bipyramidal structure. In the case of Complex **7**, only one set of resonance peaks due to the pyrone and 4-methylpyridine was observed, although the data of the molecular weight of this complex indicated that the complex dissociates extensively in chloroform. This result suggests that the dissociation and addition reactions of 4-methylpyridine in **7** are so rapid as to average the magnetic environments. The magnitudes of the downfield shift of the 2 and 6 protons of pyridine and 4-methylpyridine are considerably small as compared with those of the 3 and 5 protons of the base. This might be attributable to the operation of the magnetic anisotropy effect of the carbonyl group of the pyronate ligand on the 2 and 6 protons. Unfortunately, Complex **10** is not soluble enough to give a PMR spectrum in nondonor common solvents.

The analogous pyridine or 4-methylpyridine adducts of bis(acetylacetonato)zinc(II) have been previously reported by Graddon and Weeden.[15] Their measurement of the molecular weight of the compounds showed that the mono-adducts, $[Zn(acac)_2(py)]$ and $[Zn(acac)_2(4\text{-Me-py})]$, are monomeric in benzene and triphenylmethane, whereas $[Zn(acac)_2(4\text{-Me-py})_2]$ dissociates in these solutions to form a five-coordinate mono-adduct, while $[Zn(acac)_2(py)_2]$ is extremely unstable, losing pyridine rapidly even in the solid state to give monopyridine compound. From these properties of the adducts and the absence of crystal-field stabilization in the octahedral zinc(II) complexes, they inferred that the five-coordinate adduct is more favorable for Zn(II) than the octahedral bis-adduct.[15] In the present pyridine, 4-methylpyridine, and 4-cyanopyridine adducts of bis(3-hydroxy-2-methyl-4-pyronato)zinc(II), the five-coordinate adducts seem also to be favorable, although we could not isolate $[ZnL_2(4\text{-Me-py})]$.

Electronic Spectra and Magnetic Data. The reflection spectra of the cobalt(II) and nickel(II) complexes are shown in Figs. 4 and 5 respectively, their magnetic moments being listed in Table 1. Complexes **2**, **5**, and **8** show bands at 7.4(sh), 8.7, 17.8, and *ca.* 23.0 kK; 9.3, 16.8(sh), 17.8, and 21.7 kK; and 8.0, *ca.* 17.5, *ca.* 20.0, and 22.2 kK, respectively. From the spectra and the observed magnetic moments of **2**(5.02 B.M.), **5**(4.87 B.M.), and **8**(4.66 B.M.), it may be inferred that Complexes **2** and **5** are octahedral and Complex **8** is octahedral or five-coordinated, since the magnetic moments previously reported for the high-spin octahedral and five-coordinate cobalt(II) complexes lie in the ranges of 4.7—5.2 and 4.3—5.5 B.M. respectively.[16] However, taking account of the IR data for Complex **8**, which show that 4-cyanopyridine is coordinated to the cobalt ion solely with the ring nitrogen, the possibility of an octahedral structure for Complex **8** seems to be excluded. Furthermore, it has been reported that, for high-spin metal complexes, the five-coordination is favored in the order of: Co(II), Cu(II), Zn(II)>Fe(II), Ni(II)>Mn(II).[17] In the present work, the 4-CN-py adduct of cobalt(II) and Zn(II) complexes have one 4-CN-py moleucle, while the corresponding nickel(II) adducts has two 4-CN-py molecules, in conformity with the above series,

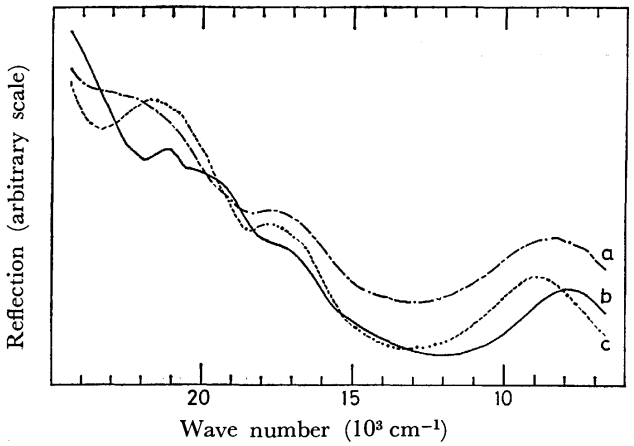

Fig. 4. The reflection spectra of complexes **2**(a), **8**(b), and **5**(c).

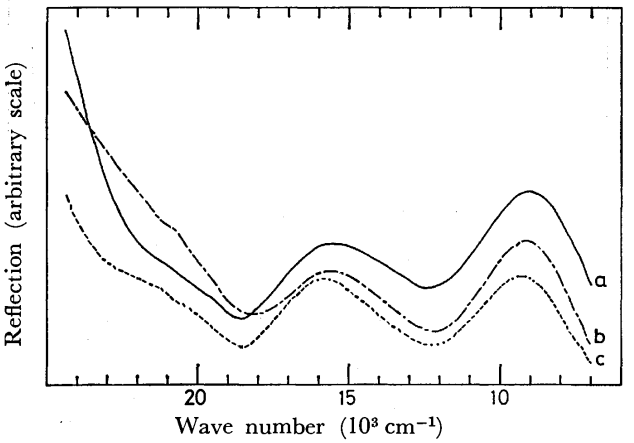

Fig. 5. The reflection spectra of complexes **9**(a), **3**(b), and **6**(c).

The reflection spectra of Complexes **9**, **3**, and **6** in the 20—7 kK region exhibit bands at 9.0 and 15.5 kK; 9.2 and 15.6 kK, and 9.3 and 15.8 kK respectively. The order of the increasing wave numbers of the bands is consistent with the order of the increasing ligand-field strength of the base, (4-CN-py<py<4-Me-py). The spectra and the observed magnetic moments of **3**(3.17 B.M.), **6**(3.23 B.M.), and **9**(3.16 B.M.) suggest that these complexes are octahedral.

The authors wish to express their thanks to Dr. Shunji Utsuno of Shizuoka University for lending the facilities for the measurement of the reflection spectra. We would also like to thank Miss Noriko Onishi and Miss Sachiko Takahara for their experimental assistance. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

The Computer-assisted Characterization of Terpenes and Related Compounds by the Use of Combined Spectrometric Data

Shin-ichi SASAKI,* Hidetsugu ABE,*** Keiji SAITO,** and Yoshiaki ISHIDA**
Miyagi University of Education, Aoba, Sendai 980
(Received April 10, 1978)

Basic research to prepare a combined retrieval system based on three different sets of spectrometric data, infrared, mass, and ^{1}H NMR, for terpenes and related compounds is described. The system may be used either for searching all three types of spectra, for two, or for one only. The results of 112 test searches are presented. The combined method is proved to be a good tool for the identification of such compounds, especially those in a structurally close relationship.

A number of search systems for the structure characterization of chemical compounds have been reported, but most of them are designed for a single type of spectra.[1-29] However, to improve the possibility of identification, several kinds of combined retrieval systems based on different spectrometric data have also been developed.[30-37] The present authors are doing basic research to make a new searching system combining three different sets of spectrometric data (NMR, IR, and MS) to characterize organic compounds as a link in the study of the CHEMICS system (a computer program system for the structural elucidation of organic compounds).[38] In this paper the identification of terpenes and the related compounds will be described. The spectrometric data of these compounds, which number over, 110, were taken from a spectral atlas;[39] all of the data were packed in a computer in the form of normalized data. The normalization of the spectrometric data was carried out in a manner to be described later. The sorting experiment was implemented by the successive comparison of one of the stored compounds with all of them. The results given by the combined comparison are shown to be completely reliable.

Data Base. Numerals, 1, 2, 3,···, and 112 were given for each terpene and related compound, as is shown in Table 1. Their NMR, IR, and mass spectra were normalized and recorded in a computer. The normalization of spectra was performed as follows: the NMR was converted into G and S values according to Eqs. 1 and 2, where G stands for the center of gravity of a whole spectrum, and S, the standard deviation of each signal to the center:[40]

$$G = \sum_{i=1}^{n} (W_i A_i) / \sum_{i=1}^{n} A_i, \quad (1)$$

$$S = \left(\sum_{i=1}^{n} (W_i - G)^2 A_i / \sum_{i=1}^{n} A_i \right)^{1/2}. \quad (2)$$

Here, A_i and W_i express the weight of the proton(s) and the position of the ith signal, respectively. For example, the NMR of β-selinene (101)(Fig. 1) is converted into $G(=1.778)$ and S $(=1.121)$.

The IR is normalized by expressing it with the positions and intensities of the absorption bands. The spectral region of 4000 to 650 cm^{-1} is divided into 18 main divisions, at 3200, 2800, 2300, 2000, 1900, 1800, 1700, 1600, 1500, 1400, 1300, 1200, 1100, 1000, 900, 800, and 700 cm^{-1}. Further, each division is divided into 10 equal parts to make subdivisions, 1—10. The position (P) of the strongest band in each division is expressed numerically with the number of the subdivision where the top of the band is located. To code the band intensity (I), the following equations (Eqs. 3 and 4) are necessary to convert the apparent transmittance (T) into A' *via* the pesudo absorbance (A):

$$A = -\log T \quad (3)$$

$$A' = A/A_{max} \times 100 \quad (4)$$

Here, T, A, and A_{max} stand for the apparent transmittance based on the base line of the spectral chart, the pseudo absorbance, and the intensity of the strongest band in the whole spectrum respectively. The numerals 1, 2, and 3 are given for the intensity (I) when $A' \leqq 30$, $30 < A' \leqq 70$, and $A' > 70$ respectively.

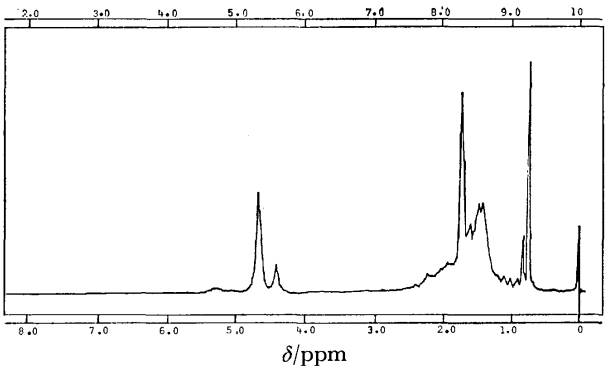

Fig. 1. NMR of β-selinene.

A line of numerals is given for the IR of β-selinene (101)(Fig. 2) as follows: 0 307 102 0 0 0 103 206 0 206 203 104 106 106 107 303 103 110. In numeral 307, the first figure 3 stands for the intensity and the last figure 7 the location of the strongest band in the division of 3200—2800. A band located just on the boundary is regarded as being in the higher division.

The mass spectrum was normalized by expressing it with the position and intensity of the two most intense peaks at 14 m.u. intervals, starting at m/e 40. To express the intensity, 1, 2, and 3 are given for the peak in accordance with its relative intensity, $\leqq 35\%$, $>35\%$ and $\leqq 75\%$, and $>75\%$, respectively. The mass spectrum of β-selinene (101)(Fig. 3) was converted into a numerically normalized state as follows: 413 131 532 552 672 691 793 813 912 933 1053 1073 1192 1212 1332 1351 1472 1491 1612 1751

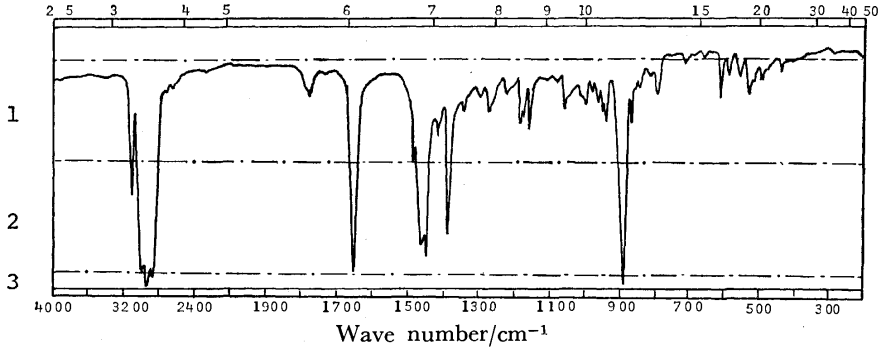

Fig. 2. IR of β-selinene.

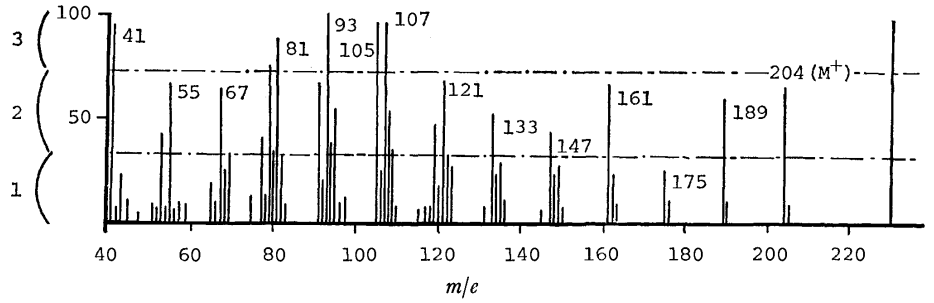

Fig. 3. MS of β-selinene.

1761 1892 1901 2042 2051. The last figure of each numeral indicates the intensity.

These normalized data of the NMR, IR, and MS of each compound are stored, with its code number (instead of compound name) in the computer.

Comparison of Spectra. On NMR comparison, when the conditions of $|G_y-G_x| \leqq 0.03$ and $|S_y-S_x| \leqq 0.04$ are satisfied, the x spectrum is judged to be equal to the y spectrum, where G_x and G_y mean the G values, and where S_x and S_y mean the S values, of the x and y spectra, respectively.

A parameter (E) defined by Eq. 5 is used for the IR comparison, where P_{xi} and P_{yi} mean the position of the strongest band in the ith main division of a

$$E = \sum_i |P_{xi}-P_{yi}| \quad (5)$$

spectrum registered in the file, and that of the spectrum to be compared, respectively. When two spectra were compared, another parameter (M) was also used; this parameter represents the sum of the main divisions which have similar P values but different I values. As the most appropriate value, 20 for E and 6 for M are chosen by trial and error.

Two kinds of parameters (D and Q) are used in the MS comparison. D is the number of peaks which have a similar mass but a different intensity in the comparison of an unknown with each of the stored compounds. Q is the number of peaks which are lacking in the spectrum of an unknown but which are present in that of to be compared. The spectra of 10 compounds collected arbitrarily were measured at several different conditions in order to decide the most appropriate threshold values of D and Q. As a result, it was observed that D is distributed within the range from 0 to 3, and Q, within that from 0 to 4. Thus, taking a sufficient allowance into account, 5 and 7 were selected as the threshold values of D and Q, respectively. When D and Q are observed to be below the thresholds in the sorting upon MS, the two spectra are regarded as identical.

Results

The data base consists of terpenes and related compounds. They are in a structurally close relationship with each other, and a similar type of pattern

is observed for their spectra in many cases. If sorting can discriminate one spectrum from all the other spectra in the system containing such kinds of compounds, the method may be considered to be a good tool for structure identification. Indeed, the sorting by the combined spectrometric data of NMR, IR, and MS gave excellent results.

Table 1 shows the sorting results afforded by the use of either all three types of spectra, of two, or of one only. As is shown in the table, one completely correct compound is retrieved by sorting either NMR, IR, or MS alone for almost one-third (2, 5, 6, 11, 25, 28, 31, 32, 40, 43, 44, 45, 47, 51, 59, 60, 61, 69, 70, 73, 78, 79, 81, 95, 100, 108, 110, and 111) of the registered compounds. The remaining two-thirds are contaminated with noise(s) when sorted with a single set of spectrometric data. However, the number of these compounds accompanied by contamination rapidly diminishes by sorting with either two or three types of spectra. For example, compound 101 is contaminated with one (145), nine (3, 15, 31, 33, 45, 67, 107, 173, and 183), and eight (9, 39, 45, 67, 117, 173, and 175) noises by sorting with only NMR, IR, or MS respectively. However, sorting with two types of spectra (NMR+IR, NMR+MS) gives no noise, though sorting with IR and MS gives three noises (45, 67, 173). Furthermore, as is shown in the most right column of Table 1, when three types of spectra are used, only one correct answer is always obtained for all compounds. The fact that nothing was retreived when three types of spectra of α-pseudowiddrene, which had not yet been registered in the data base, were compared with the store also proves the authors' method to be completely reliable.

Phase Equilibria in Europium(III) Oxide–Titanium(IV) Oxide System at Temperatures from 900 to 1400 °C

Bunji Iwasaki

Research Institute of Underground Resources, Mining College, Akita University, Tegata-Gakuen machi, Akita 010

(Received April 13, 1978)

The phase equilibria in the Eu_2O_3–TiO_2 system has been established at temperatures from 900 to 1400 °C in air using coprecipitated gels as starting materials. In this system, Eu_2O_3, TiO_2, Eu_2TiO_5, and $Eu_2Ti_2O_7$ are stable. The stoichiometric $Eu_2Ti_2O_7$ has a cubic pyrochlore type structure with $a=1.0210(3)$ nm, and forms a solid solution with TiO_2. The TiO_2 contents and the lattice constants of these solid solutions equilibrated with TiO_2 at different temperatures were [given as mol %, a/nm, θ/°C]: 70.4(5), 1.0187(1), 1409(9); 69.5(5), 1.0193(1), 1292(8); 68.9(5), 1.0197(1), 1191(9); 68.4(5), 1.0200(1), 1099(2); 68.1(5), 1.0202(1), 996(4); and 68.0(5), 1.0203(1), 898(3). Numbers in parentheses are errors in the last digits.

Europium(II) titanium(IV) trioxide (perovskite type), $EuTiO_3$, is an interesting compound in field of inorganic chemistry and geochemistry, because it forms an extensive solid solution with respect to oxygen.[1] It may be used as an oxygen barometer, according to the principle that it is formed from dieuropium(III) dititanium(IV) heptaoxide, $Eu_2Ti_2O_7$, at a given temperature and oxygen fugacity.[2] In order to furnish thermodynamic data on the $EuTiO_3$ solid solution at high temperatures, a phase diagram for the system europium(III) oxide[3]–titanium(IV) oxide[4] is required. This binary system has not been systematically studied, while the europium–titanium–oxygen system at 1400 °C including this binary system has been reported McCarthy *et al.*[1] On the other hand, dieuropium(III) titanium(IV) pentaoxide, Eu_2TiO_5,[5] and $Eu_2Ti_2O_7$[6] have been observed in this binary system.

The purposes of this study are to establish the phase relations in this binary system in the temperature range between 900 and 1400 °C in air, to determine the solubility of titanium(IV) oxide in $Eu_2Ti_2O_7$, and to obtain the phase diagram of this binary system.

Experimental

Materials. The samples prepared by the coprecipitation method were used as starting materials. Both the stock solutions of europium and titanium were prepared separately as follows: (i) the freshly ignited Eu_2O_3 having a purity of 99.9% was dissolved in conc. hydrochloric acid; (ii) Guaranteed reagent-grade $TiCl_4$ was dissolved in 3 mol/dm^3 hydrochloric acid solution at a temperature below 65 °C.[7] Both the metals in the 1 mol/dm^3 hydrochloric acid solution prepared by mixing the stock solutions in the desired ratios were coprecipitated with aqueous ammonia. After being washed thoroughly with water, these coprecipitates were dried at about 100 °C for 12 h, heated at about 400 °C for 12 h, and finely ground by an agate mortar.

Furnaces and Temperature Control. Vertical tube quench furnaces with a 60%Pt-40%Rh winding were used for the equilibration runs.

Furnace temperatures were kept constant within the temperature range given in Table 1 by means of an electric controller activated by a Pt-(87%Pt-13%Rh) thermocouple inserted close to the hot spot of the furnace. The actual temperatures within the furnace were measured with the other thermocouple which was calibrated within ±0.5 °C against the melting points of diopside, 1394 °C, and gold, 1064 °C.

General Procedure. About 0.1-g powdered starting material was placed in a 60%Pt-40%Rh foil envelope, about 0.05 mm in thickness and 10×10 mm in area, and heated in air at the temperatures listed in Table 1. After heated during the reaction time given in Table 1, the samples were quenched rapidly to the temperature of ice by burning away the thin Pt wire with an electric current. In a single run, 10 or 12 charges were heated together by suspending these envelopes over the hooks of a 60%Pt-40%Rh wire netting.

Identification of Phases and Determination of Lattice Constants. The phases present in the starting materials and the quenched samples were identified by X-ray powder diffraction method using a scintillation counter diffractometer with Ni-filtered Cu $K\alpha$ radiation.

Lattice constants were determined by the same method with a scanning rate of 1/4° or 1/8° per min and with an internal standard of high-purity silicon.

Chemical Analysis. The titanium content in the titanium stock solution was determined by precipitating as titanium(IV) oxide hydrate in the presence of acetic acid, and igniting the precipitates to titanium(IV) oxide.

After the freshly ignited starting materials and the quenched samples were fused with potassium disulfate, the cold melt obtained was dissolved in sulfuric acid solution. The europium content in the sulfuric acid solution was determined by precipitating as europium(III) oxalate and igniting the precipitates to europium(III) oxide, while the titanium content in the solution was determined photometrically by the hydrogen peroxide method.[8]

Table 1. Temperature and reaction time

A group[a]		B group	
θ/°C	t/d	θ/°C	t/d
901±1	32.8	898±3	29.9
998±2	30.8	996±4	26.8
1100±1	19.8	1099±2	23.8
1209±10	14.9	1191±9	14.9
1295±6	9.9	1292±8	9.8
1406±6	7.9	1409±9	6.9

a) The samples with different chemical compositions were divided into two groups, according to the period when the samples were prepared. One group is composed of 10 or 12 samples heated together at constant temperature.

Table 2. Results of equilibration runs in the temp range between 900 and 1400 °C

No.[a]	Materials		Phase[b]
	TiO_2(mol %)	Eu_2O_3(mol %)	
B-1[c]	15.4	84.6	E + Y
B-2	30.6	69.4	E + Y
A-1	35.9	64.1	E + Y
B-3	49.8	50.2	Y
A-2	55.8	44.2	Y + P
A-3	57.8	42.2	Y + P
A-4	62.6	37.4	Y + P
B-4	67.4	32.6	Ps
A-5	72.4	27.6	Ps + R
A-6	74.2	25.8	Ps + R
A-7	77.1	22.9	Ps + R
A-8	81.4	18.6	Ps + R

a) The samples labeled as A and B, respectively, belong to A group and B group in Table 1. For example, the sample of A-1 was heated at the temperatures and for the reaction times given as A group in Table 1. b) E=Eu_2O_3, Y=Eu_2TiO_5, P=$Eu_2Ti_2O_7$, Ps=$Eu_2Ti_2O_7$ solid solution, R=TiO_2. c) Only one of the most intense reflections of Eu_2TiO_5 in addition to reflections of Eu_2O_3 was detected in the sample heated at 898 °C.

Results and Discussion

Reaction Time for Equilibration. According to preliminary experiments, in which, Eu_2TiO_5, the poorest crystalline substance in this system, was synthesized from oxide mixtures, trace amounts of $Eu_2Ti_2O_7$ and europium(III) oxide in addition to Eu_2TiO_5 were detected in the sample heated at 1200 °C for 13.6 d, and further heat treatment was necessary to obtain Eu_2TiO_5 as a single phase. Therefore, the samples prepared by the coprecipitation method were selected as starting materials in order to shorten the time of equilibration.

More than both phases were not detected in all the quenched samples obtained in this study (Table 2). Furthermore, Eu_2TiO_5 was definitely identified in all the quenched samples expected to contain this phase, except in the sample B-1 heated at 900 °C. Each reaction time listed in Table 1 is thought to be sufficient as the reaction time needed for equilibrium.

Chemical Composition. The ratios of europium to titanium in the starting materials were in agreement with those in the quenched samples within the limit of analytical errors. The chemical compositions of the samples listed in Table 2 are based on chemical analyses.

Phases in Starting Materials. Most of the starting materials indicated an amorphous condition. Small amounts of europium(III) chloride oxide, EuClO,[9] were identified in a few of the starting materials, *e.g.* B-3. The occurrence of this compound may be attributed to the thermal decomposition of europium(III) chloride dihydroxide, $EuCl(OH)_2$, precipitated from the mixtures of both the stock solutions. Trace amounts of $Eu_2Ti_2O_7$ were detected in few of them, *e.g.* B-7.

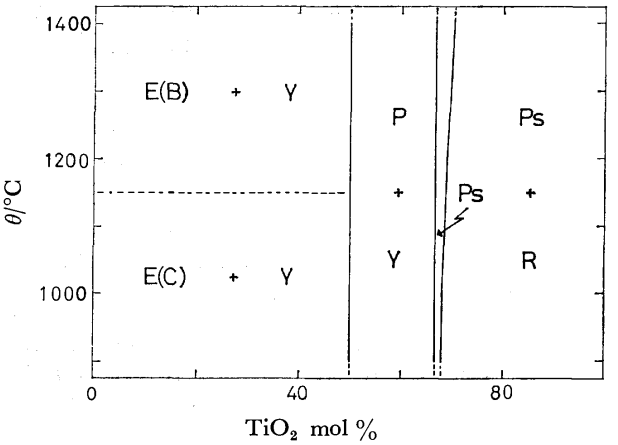

Fig. 1. Phase diagram for Eu_2O_3–TiO_2 system. Abbreviations are the same as those in Table 2 except for the followings: E(B)=Eu_2O_3(B-form), E(C)=Eu_2O_3 (C-form).

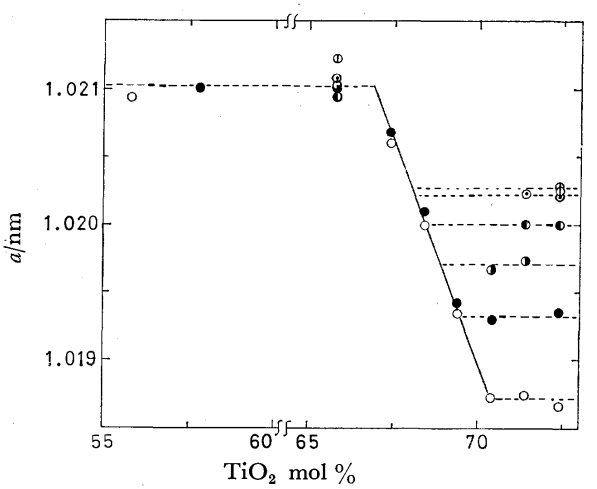

Fig. 2. Lattice constant, *a*, of $Eu_2Ti_2O_7$ solid solution *vs.* chemical composition.
○: 1409 °C, ●: 1292 °C, ◑: 1191 °C, ◐: 1099 °C, ⊙: 996 °C, ⓓ: 898 °C, ◔: 1409 and 1191 °C.

Phases and Phase Relations. The equilibrium data obtained at temperatures ranging from 900 to 1400 °C are summarized in Table 2, and illustrated graphically in Fig. 1 together with the addtiona data shown in Fig. 2.

In the present system, four compounds were stable: Eu_2O_3, TiO_2, Eu_2TiO_5, and $Eu_2Ti_2O_7$.

Europium(III) Oxide: This oxide[3] found in this study occurred in a cubic C-type form below 1100 °C, and crystallized in a monoclinic B-type structure above 1200 °C. Warshaw and Roy[10] have reported that trace amounts of the C-form were converted to the B-form after 30 h at 1105 °C. The present findings are compatible with their observations.

Titanium(IV) Oxide: The tetragonal rutile type structure of this oxide,[4] which is believed to be thermodynamically stable,[11] was observed under the present experimental conditions.

Dieuropium(III) Titanium(IV) Pentaoxide: This compound[5] found in this study had an orthorhombic

TiY_2O_5 type structure. The lattice constants were $a=1.054(1)$* nm, $b=1.133(1)$ nm, $c=0.376(1)$ nm, and $V=0.449$ nm^3, which is in good agreement with those reported by McCarthy *et al.*[5] ($a=1.054$ nm, $b=1.132$ nm, $c=0.378$ nm, and $V=0.451$ nm^3.)

The lattice constants of this compounds equilibrated with europium(III) oxide and with $Eu_2Ti_2O_7$ were identical with each other, irrespective of temperature. Therefore, there is the possibility that this compound is stoichiometric.

Dieuropium(III) Dititanium(IV) Heptaoxide: This compound[6] with a cubic pyrochlore type structure was stable in this study, and formed a solid solution with titanium(IV) oxide.

Figure 2 shows the relationship between the titanium(IV) oxide contents in the samples and the lattice constants of this solid solution. The lattice constants of this solid solution within the region for the coexistence of both $Eu_2Ti_2O_7$ and Eu_2TiO_5 phases were identical with each another within the limit of experimental errors, regardless of temperature. The datum was $a=1.0210(3)$ nm, while this compound has been reported to have a lattice constants of $a=1.0193$ nm.[6] The data within the $Eu_2Ti_2O_7$-stable region showed such a straight line as represented by the equation

$$a = 1.0648 - 0.0654X(TiO_2), \quad (1)$$

where a and $X(TiO_2)$, respectively, represent the lattice constant and the titanium(IV) oxide content given in mol% of $Eu_2Ti_2O_7$. The data on $Eu_2Ti_2O_7$ within the region for the coexistence of both $Eu_2Ti_2O_7$ and titanium(IV) oxide phases were identical with each other at constant temperature, and decreased with an increase in temperature.

The chemical composition of this solid solution equilibrated with Eu_2TiO_5 was calculated to be 66.9 mol%TiO_2, by substituting the a-value given above in Eq. 1, indicating good agreement with the stoichiometric value, 66.7 mol % TiO_2. The chemical compositions of these solid solutions equilibrated with titanium(IV) oxide at each temperature have been calculated according to the same treatment reported above, and illustrated in Fig. 1.

Solubility of Titanium(IV) Oxide in Dieuropium(III) Dititanium(IV) Heptaoxide. The equation for the solution of rutile in the pyrochlore phase may be written as

$$TiO_2(\text{rutile}) = TiO_2(\text{in pyrochlore}), \quad (2)$$

for which the equilibrium constant is

$$K = \frac{a(TiO_2)^p}{a(TiO_2)^r}, \quad (3)$$

where $a(TiO_2)^p$ and $a(TiO_2)^r$, respectively, indicates the activity of titanium(IV) oxide in the pyrochlore phase and in the rutile phase. As the rutile is considered to be pure, the activity of rutile may be taken as unity; also the solubility of rutile is low as given below, and the activity of titanium(IV) oxide in the pyrochlore phase may be assumbed to be proportional to the mole fraction, if Henry's law is applicable.

* Numbers in parentheses here and elsewhere are estimated experimental errors in limits of the last significant digit.

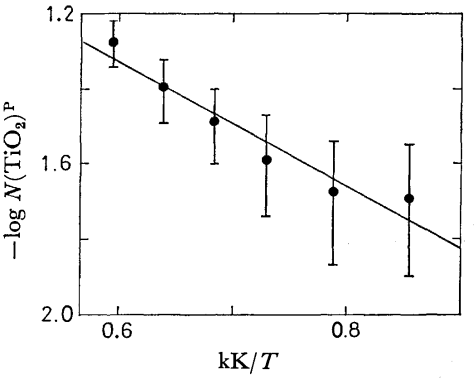

Fig. 3. Change of the solubility of TiO_2 in $Eu_2Ti_2O_7$ with temperature.

Hence,

$$K = kN(TiO_2)^p, \quad (4)$$

where k is the Henry's constant, and $N(TiO_2)^p$ denoted the mole fraction of titanium(IV) oxide in the pyrochlore phase.

The solubility of rutile in $Eu_2Ti_2O_7$, calculated from such chemical compositions of these solid solutions equilibrated with rutile as obtained above, are given as $N(TiO_2)^p$, θ/°C: 0.020(8), 898; 0.021(8), 996; 0.026(8), 1099; 0.033(8), 1191; 0.040(8), 1292; and 0.053(8), 1409. Figure 3 shows the relationship between temperature and the solubility of rutile in $Eu_2Ti_2O_7$. It may be seen from Fig. 3 that the amount of rutile increases with an increase in temperature, while a linear relationship exists between them, as predicted from the equation

$$\left[\frac{\partial \ln K}{\partial(1/T)}\right]_P = -\frac{\Delta H}{R}, \quad (5)$$

where T is the absolute temperature, P is the pressure, ΔH indicates the enthalpy change of Eq. 2, which corresponds to the relative partial enthalpy of solution,[12] and R is the gas constant. This line may be represented by the equation

$$\log N(TiO_2)^p = -\frac{1700}{T} - 0.33, \quad (6)$$

corresponding to $\Delta H=33(2)$ kJ.

The Phase Diagram. The present results obtained are shown as a phase diagram in Fig. 1. A comparison of this phase diagram with those of the systems M_2O_3–TiO_2 (M=La,[13] Gd,[13] Dy,[15] Yb[16]) shows that the present phase diagram is the most similar to that for the Gd_2O_3–TiO_2 system among them. The similarity in phase diagrams may be due to the similarity in ionic radii.

We wish to express our sincere thanks to Dr. Takashi Katsura, Professor of the Tokyo Institute of Technology for his encouragement throughout the present study.

X-Ray Diffraction Studies on the Structures of Tetraammine- and Triamminemonochlorozinc(II) Ions in Aqueous Solution

Toshio YAMAGUCHI and Hitoshi OHTAKI*

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received April 14, 1978)

X-Ray scattering measurements have been carried out on ammoniacal aqueous solutions of zinc(II) chloride at the NH_3/Zn mole ratios of 3.8, 5.0, and 6.6. The radial distribution curves show that the tetraamminezinc(II) complex is formed as the main species, the ammonia molecules within the complex being tetrahedrally coordinated to zinc(II) ion at a distance of (2.03±0.02) Å. Analysis of the radial distribution curve obtained for the solution at the NH_3/Zn ratio of 3.8 indicates formation of the mixed complex $ZnCl(NH_3)_3^+$, the Zn–NH_3 and Zn–Cl bond lengths being (2.00±0.03) and (2.30±0.03) Å, respectively.

According to the results of formation constants,[1] enthalpic and entropic measurements[1] and spectrophotometry,[2] a zinc(II) ion combines with four ammonia molecules at most, the structure of the tetraamminezinc(II) complex presumably being in a tetrahedral form. However, no X-ray crystallographic data are available because of the difficulty in the preparation of a stable single crystal.

In the present investigation we have attempted to determine the structure of the tetraamminezinc(II) complex as well as other zinc(II)–ammine complexes in ammoniacal aqueous solutions with various NH_3/Zn mole ratios (3.8, 5.0, and 6.6) by the X-ray diffraction method. Raman spectroscopic measurements were also carried out as a supplement to the structural determination of the main complex.

Experimental

Preparation and Analysis of Sample Solutions. The sample solutions were prepared by dissolving zinc(II) chloride (Wako Pure Chemicals, Co., reagent grade), which had been recrystallized twice from water, in a concentrated aqueous ammonia solution (Wako Pure Chemicals, Co., reagent grade, 28%). The concentration of ammonia was adjusted to the desired value by introducing gaseous ammonia (99.99%) into the sample solutions.

The concentration of zinc(II) ion was determined by EDTA titration and electrogravimetry. The results obtained by the two methods were found to agree with each other within 0.2%. Ammonia content in the sample solutions was determined by the Kjeldahl method. Concentration of the chloride ion was determined from the stoichiometry of the zinc(II) chloride.

The density of the solutions was determined pycnometrically.

The composition of the sample solutions is given in Table 1.

X-Ray Scattering Measurements. X-Ray scattering measurements were carried out by using a θ-θ JEOL diffractometer in a room thermostated at (25±1) °C. Mo $K\alpha$ Radiation (λ=0.7107 Å) was used. The diffracted beam was monochromatized with a Johansson-type LiF crystal and then a pulse height analyzer. The accessible range of scattering angle (2θ) was 2—140°, corresponding to the range 0.31 Å^{-1}<s<16.6 Å^{-1} ($s=4\pi\lambda^{-1}\sin\theta$). The time required for counting 40000 counts was recorded at each angle. The measurements over the whole angle range were carried out twice for each solution. The divergence of the measured intensities was within ±2%. The average intensities thus measured at each scattering point were used in the subsequent calculations. Details of the measurements are described in previous papers.[3,4]

Raman Spectroscopic Measurements. Raman spectra for the sample solutions were measured with a JEOL laser Raman spectrophotometer JRS-S1 with use of the 4880 Å excited line of Ar^+ laser.

Treatment of Intensity Data. The measured intensities $I(s)$ were corrected in the usual way for absorption and polarization of the X-ray beam.[3-5] The corrected intensities were normalized to electron units by the conventional methods,[6,7] from which the incoherent scatterings $\sum n_i\phi(s)I_i^{inco}(s)$ were subtracted (n_i=the number of atom i, $\phi(s)$=the fraction of the incoherent radiation reaching the counter). The Breit-Dirac effect was taken into account. Correction for double scattering[8] was made, which did not exceed 4% of scattered intensities of solutions investigated. The values of coherent, incoherent and anomalous scatterings of all atoms were the same as those used previously[9] except for N, the values of which were taken from the literature.[10] The coherent intensities $I^{coh}(s)$ thus obtained are shown in Fig. 1 for each sample solution.

The radial distribution function $D(r)$ was calculated by

$$D(r) = 4\pi r^2\rho_0 + \frac{2r}{\pi}\int_0^{s_{max}} si(s)M(s)\sin(rs)\mathrm{d}s, \qquad (1)$$

where ρ_0 is the average scattering density in the stoichiometric volume V containing one Zn atom, s_{max} the maximum s-value attained in the measurements (s_{max}=16.7 Å^{-1}). $M(s)$ represents the modification function

$$[\sum n_i\{(f_i(0)+\Delta f_i')^2+(\Delta f_i'')^2\}/\sum n_i\{(f_i(s)+\Delta f_i')^2 + (\Delta f_i'')^2\}]\exp(-0.01s^2), \qquad (2)$$

where $f_i(0)$ and $f_i(s)$ denote the scattering factors of atom i at angle 0 and s, respectively. $\Delta f_i'$ represents the real part of the anomalous dispersion, whereas $\Delta f_i''$ is the imaginary one. The reduced intensity $i(s)$ is given by

$$i(s) = I^{coh}(s) - \sum n_i\{(f_i(s)+\Delta f_i')^2+(\Delta f_i'')^2\}. \qquad (3)$$

Before the Fourier transform, the reduced intensities experimetally obtained were smoothed by use of spline function.[11] Spurious peaks appearing below 1 Å in the radial distribution curves were eliminated by the reported method.[9] Curve (a) in Fig. 2 represents the $(D(r)-4\pi r^2\rho_0)$ curve obtained by a Fourier transform of the reduced intensities of solution C after a correction for only spurious peaks within the hard-core radius (<1 Å). The curve still shows periodic ripples in the range of large r values. The ripples were eliminated when the intensity data were further corrected by the smoothing procedure (Fig. 2, curve (b)). Thus, the data-smoothing procedure in combination with a hard-core correction is needed to correct spurious peaks in $D(r)$

TABLE 1. THE COMPOSITION (g-atoms/dm³) AND STOICHIOMETRIC VOLUME V PER ZINC ATOM IN THE SOLUTIONS

Solution	Zn	Cl	N	O	H	$\frac{NH_3}{Zn}$	$\frac{V}{Å^3}$	Density / g cm^{-3}
A	2.679	5.359	10.09	37.99	106.3	3.8	619.7	1.217
B	2.364	4.727	11.79	32.30	99.96	5.0	702.4	1.170
C	2.217	4.434	14.66	32.61	109.2	6.6	749.0	1.139

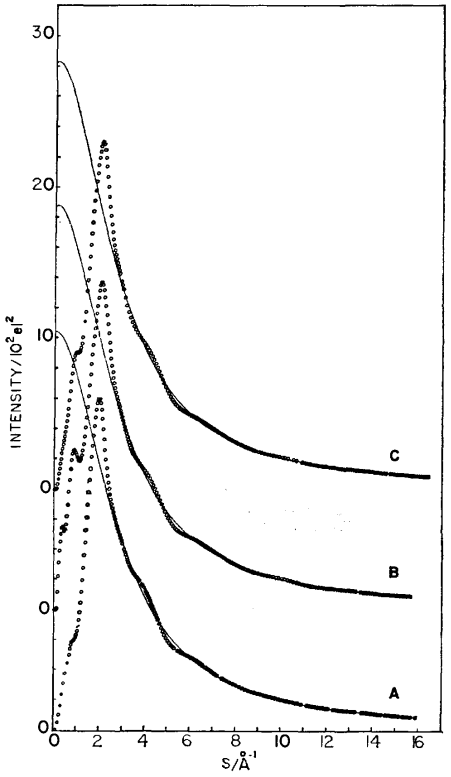

Fig. 1. X-Ray diffraction patterns for the sample solutions A, B, and C. Experimental coherent scattering intensities $I^{coh}(s)$ are shown by circles and calculated independent scattering intensities by solid lines.

curves over the whole angle range measured. It should be noted that the smoothing procedure leads sometimes to erroneous results when the intervals between data points are large. The separation between the points should be less than 0.3 Å^{-1} in s. For solutions containing heavy atoms the smoothing correction for the scattered intensities might be unnecessary.

The $s\cdot i(s)$, $D(r)$, and $(D(r)-4\pi r^2\rho_0)$ curves obtained after the smoothing correction are shown in Figs. 3, 4, and 5, respectively, for each solution.

The theoretical peak shape of an atom pair i-j was estimated from the calculated reduced intensity:

$$i_{calc}(s) = n_{ij}\{(f_i(s)+\Delta f_i')(f_j(s)+\Delta f_j')+(\Delta f_i'')(\Delta f_j'')\} \times \frac{\sin(r_{ij}s)}{(r_{ij}s)}\exp(-b_{ij}s^2), \quad (4)$$

where r_{ij}, b_{ij}, and n_{ij} denote the distance, the temperature factor and the frequency factor of the atom pair i-j, respectively.

All calculations were performed with the aid of electronic computers HITAC 8700 and M 180 by means of the KUR-VLR program.[12]

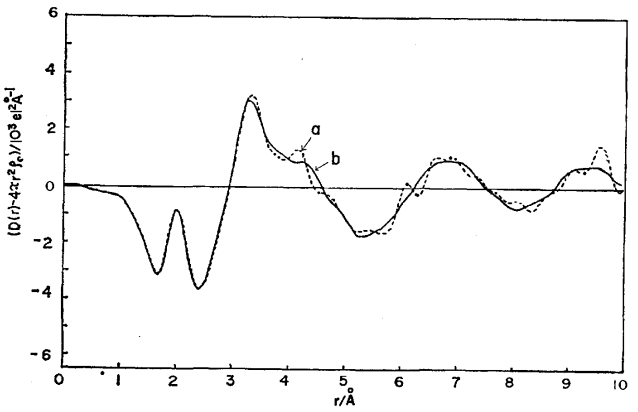

Fig. 2. The $(D(r)-4\pi r^2\rho_0)$ curves obtained after the hard-core correction alone (curve (a)) and further data-smoothing correction (curve (b)) for solution C.

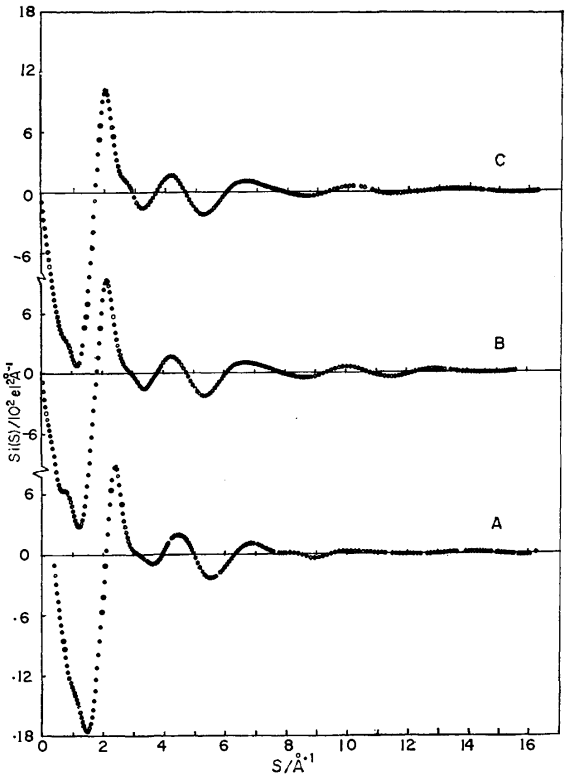

Fig. 3. The reduced intensities $i(s)$ multiplied by s for solutions A, B, and C.

Results and Discussion

Structure of Tetraamminezinc(II) Ion. Solutions B and C (Table 1) predominantly contain the tetraamminezinc(II) complex according to the formation con-

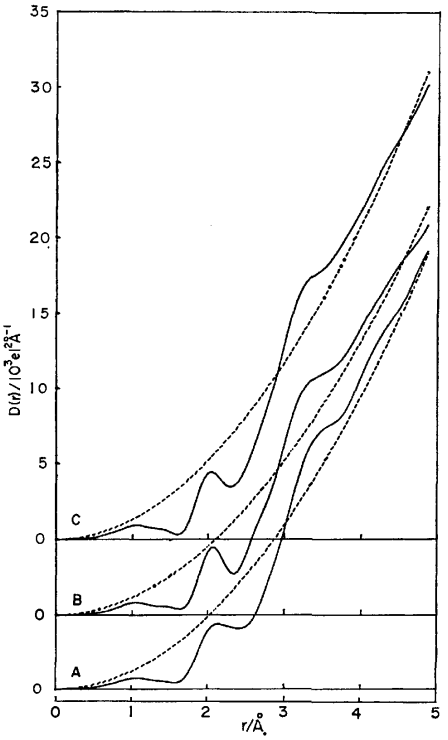

Fig. 4. The radial distribution curves, $D(r)$, for solutions A, B, and C. The curves of $4\pi r^2\rho_0$ are shown by dashed lines.

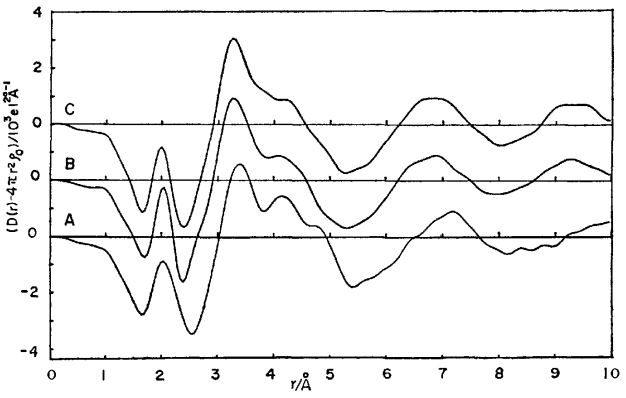

Fig. 5. The $(D(r)-4\pi r^2\rho_0)$ curves for solutions A, B, and C.

stants so far reported.[1] Therefore, the data obtained from these solutions are assessed to the tetraamminezinc(II) species rather than triammineaquazinc(II) and other amminezinc(II) complexes, although nitrogen and oxygen atoms coordinated to the metal ion are undistinguishable by the X-ray method. In each $D(r)$ curve four peaks appear around 1.0, 2.0, 3.3, and 4.2 Å (Fig. 4). The small and broad peak at about 1.0 Å is due to the O–H bonds in water. The N–H bonds in ammonia molecules may partly contribute to the peak. The second peak located at 2.0 Å can be ascribed to the interaction between the zinc(II) ion and the nearest ammonia molecules as is expected from the sum of the sizes of a Zn^{2+} ion and an ammonia molecule. The third peak at about 3.3 Å is mainly due to the Cl–O contacts.[13–16] The fourth peak found

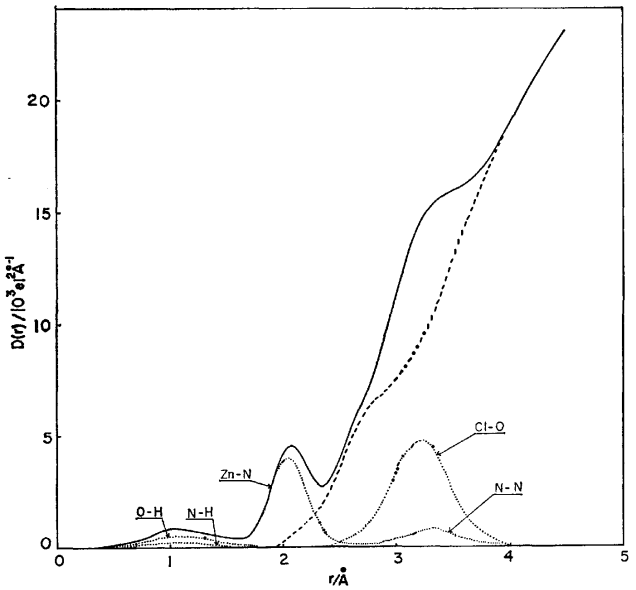

Fig. 6. The radial distribution curve for solution B. The dashed line shows the residual curve after subtraction of the theoretical peaks calculated for the O–H and N–H bonds within H_2O and NH_3, the Zn–N and N···N contacts within $Zn(NH_3)_4^{2+}$ and the Cl–O pair within $Cl(H_2O)_6^-$ from $D(r)$ curve.

around 4.2 Å may be due to the interactions between the zinc(II) ion and the molecules in the second coordination sphere.[17]

The $D(r)$ curve of solution B is essentially the same as that of solution C. The area under the peak at 2.0 Å gives about four ammonia molecules bonded to the zinc(II) ion. The area and the location of the peak rule out the existence of the $Zn(NH_3)_4(OH_2)_2^{2+}$ species of the octahedral form and the formation of the contact ion pair between zinc(II) and chloride ions, the peak maximum due to the Zn–Cl atom pair being expected to appear at about 2.3 Å.[16] The position and the area of the peak are not affected by increase in the NH_3/Zn ratio. The Zn–N bond length within the tetraamminezinc(II) ion was determined by the trial-and-error method so as to obtain a smooth background curve with no indication of any other intramolecular interactions within the first coordination layer of the zinc(II) ion. The temperature factor calculated from the half-width of the peak at 2.0 Å in $D(r)$ was 0.002—0.003 Å^2, which is in good agreement with 0.0022 Å^2 obtained from spectroscopic data.[18] The length of the Zn–N bond was finally determined to be (2.03±0.02) Å. The results are shown in Fig. 6, together with the contribution from the hydrated chloride ion to the $D(r)$ curve calculated by using the distance and the temperature factor of the Cl–O bond within the $Cl(H_2O)_6^-$ ion reported by Narten *et al.*[13] There is no appreciable peak in the residual curve (Fig. 6, dashed line) in the range $r<4$ Å except for a broad peak around 2.8 Å which corresponds to the adjacent O–O bond of bulk water and N–O bond of dissolved ammonia.[19]

Structure of Triamminemonochlorozinc(II) Ion. Solution A might contain a small amount of triammine-

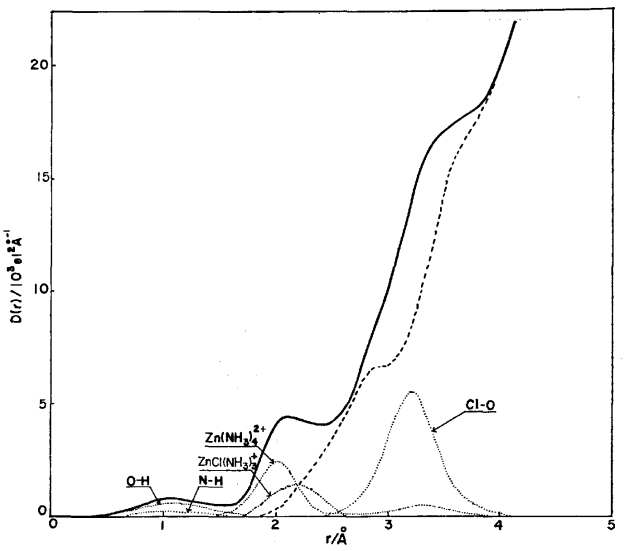

Fig. 7. The radial distribution curve for solution A. The dashed line shows the difference between the $D(r)$ curve and theoretical peak shapes calculated for the O–H and N–H bonds within H_2O and NH_3, the Zn–N and N···N contacts within $Zn(NH_3)_4^{2+}$, the Zn–N and Zn–Cl bonds within $ZnCl(NH_3)_3^+$ and Cl–O pair within $Cl(H_2O)_6^-$.

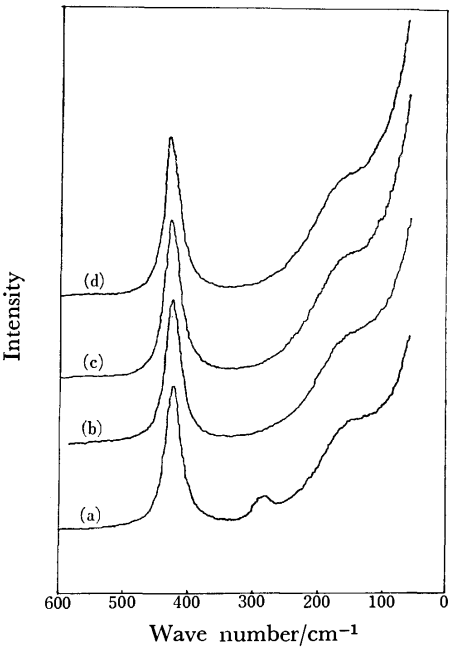

Fig. 8. Raman spectra of solutions. (a) Solution A; (b) solution B; (c) solution C; (d) solution at NH_3/Zn ratio=10.

zinc(II) complex besides the predominant tetraamminezinc(II) ion. Since the solution contains a large amount of chloride ions, mixed chloro-ammine complexes may be formed in the solution. Although no formation constants of the mixed chloro-ammine complexes of zinc(II) ion have been reported, the formation constants can be estimated by an appropriate equation for the formation equilibria of the mixed complexes. The equilibrium for the formation of a mixed complex $ZnCl_v(NH_3)_y^{(2-v)+}$ is written as follows:

$$Zn^{2+} + vCl^- + yNH_3 = ZnCl_v(NH_3)_y^{(2-v)+}. \quad (5)$$

If we use Dyrssen's equation[20] for the calculation of the equilibrium constant of the complex, we obtain β_{1vy} as follows:

$$\log \beta_{1vy} = \log \frac{(v+y)!}{v!y!} + \frac{v}{v+y} \log \beta_{1,v+y,0} + \frac{y}{v+y} \log \beta_{1,0,v+y}, \quad (6)$$

where the constant β_{1vy} is defined as $[ZnCl_v(NH_3)_y^{(2-v)+}]/[Zn^{2+}][Cl^-]^v[NH_3]^y$. Thus, the stepwise formation constant $K=[ZnCl(NH_3)_3^+]/[Zn(NH_3)_3^{2+}][Cl^-]$ is given by

$$Zn(NH_3)_3^{2+} + Cl^- = ZnCl(NH_3)_3^+,$$
$$K = \beta_{113}/\beta_{103}. \quad (7)$$

The value of β_{113} was estimated by insertion of the values of β_{104} and β_{140}[1] into Eq. 6 (β_{103} was also quoted from the same literature). The stepwise formation constant K thus evaluated was 1.2. The composition of solution A was estimated to be 60 mol % of $Zn(NH_3)_4^{2+}$, 34 mol % of $ZnCl(NH_3)_3^+$ and 6 mol % of $Zn(NH_3)_3(OH_2)^{2+}$.

The theoretical peaks of the radial distribution curve of solution A were calculated on the basis of the composition of the complexes. The peak shapes for each atom pair are shown in Fig. 7. The parameter values of the $Zn(NH_3)_4^{2+}$ ion used were those obtained in the previous section. The parameter values of the structure of the $ZnCl(NH_3)_3^+$ complex were obtained by the trial-and-error method. The formation of the $Zn(NH_3)_3(OH_2)^{2+}$ ion was neglected, because of its small amount and the structure practically undistinguishable from $Zn(NH_3)_4^{2+}$ by means of X-ray. The distances of the Zn–NH_3 and Zn–Cl bonds within the $ZnCl(NH_3)_3^+$ complex thus determined were (2.00±0.03) and (2.30±0.03) Å, respectively. The smooth background curve, except for a broad peak around 2.8 Å due to the structure of bulk water, indicates no significant intramolecular interaction being left within the first coordination shell of the zinc(II) ion.

Raman spectra have been observed in a solution containing the tetraamminezinc(II) ion[21] and in the solid $[Zn(NH_3)_4]I_2$ compound having the tetrahedral $Zn(NH_3)_4^{2+}$ moiety.[2] In aqueous solution the only totally symmetric Zn–NH_3 frequency was found at 428 cm^{-1}, the band being almost identical to the 431.2 cm^{-1} band of the solid state. In the spectra of all the solutions A, B, and C, a totally symmetric Zn–NH_3 stretching vibration appeared at (429±1) cm^{-1} (Fig. 8). No change in the Raman spectrum was observed even in a solution of $NH_3/Zn=10$ prepared by introduction of gaseous ammonia into solution C. The results suggest that the tetraamminezinc(II) ion is the main species in solutions of an NH_3/Zn ratio larger than 3.8 and that no higher-ammine–zinc(II) complexes can be formed even in solutions of high ammonia content. In solution A, a small polarized band was observed at *ca.* 285 cm^{-1} (Fig. 8). In Raman spectroscopic studies of zinc(II) chloride solution in the presence of ammonium chloride at various pH

values, Beer *et al.* assigned the band at 284 cm^{-1} observed for the solutions at high pH values to the Zn–Cl stretching frequency of the chloro-ammine complexes.[22] Perchard and Novak[23] reported on the Raman spectra of the $ZnCl_2(NH_3)_2$ crystal and assigned the bands at 420 and 283 cm^{-1} to the Zn–NH_3 and Zn–Cl stretching frequencies, respectively. The band around 285 cm^{-1} might be due to the symmetric Zn–Cl stretching vibration of the triamminemonochlorozinc(II) ion present in the solution, the Zn–N stretching frequency overlapping the 429 cm^{-1} band of the predominant tetraamminezinc(II) ion.

As is seen in Fig. 1, a small peak appears at about 0.8 $Å^{-1}$ in s in all the X-ray diffraction patterns. According to Dorosh and Skryshevskii[24] and Marques and Marques,[25] the peak is due to the "superarrangement" of cations in the solution. The distance between the cations, R_c, is calculated by

$$R_c = 7.73/s_m, \quad (8)$$

where s_m denotes the s-value of the peak maximum. The distance R_c thus calculated is about 9Å, in good agreement with the calculated zinc(II)–zinc(II) distance from the stoichiometric volume given in Table 1. The distances are 8.5, 8.9, and 9.1 Å for the solutions A, B, and C, respectively.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

The Partition Mechanism of Thenoylacetone and Thenoyltrifluoroacetone in Water/Alcohol Systems

Nobuo SUZUKI,* Hidenori SHIBUYA, and Hitoshi WATARAI
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received April 17, 1978)

The apparent partition coefficients of thenoylacetone (TA) in ten alcohol/water systems and the enol fractions of TA in both phases were determined. Comparing the results with those of thenoyltrifluoroacetone (TTA), the substituent effect of methyl and trifluoromethyl groups on the partition behavior of the β-diketones in the alcoholic partition systems was examined. The experimental results showed that the apparent partition coefficient of TA is larger than that of TTA, while the partition coefficient of the enol form of TA is smaller than that of TTA. This was related to the differences in the partitioning species of TA and TTA; that is, TA is in keto and enol forms, while TTA is in enol, hydrate, and hemiacetal forms. The partition coefficient of each species was discussed in terms of the solubility parameter of alcohol.

The two-phase system composed of alcohol and water is known to be effective for the extraction of a neutral metal complex which is co-ordinatively unsaturated. For example, the Co(II)–TTA complex can be extracted more effectively by butanol than by benzene.[1] In such extraction studies, TTA has frequently been used as an extractant. However, our information about the partition behavior of TTA in alcohol/water systems is limited. The purpose of our present study is to elucidate the partition mechanism of TTA. In a previous study,[2] the chemical species of TTA in wet higher alcohols are identified as of the enol, hydrate, and hemiacetal forms, and the high reactivity of TTA with hydroxylic solvents was interpreted in terms of the electron-withdrawing effect of the trifluoromethyl group. Such a characteristic property of TTA is expected to affect its partition behavior. In this study, we obtain the partition equilibrium data for TA in alcohol/water systems and examine the substituent effect of the trifluoromethyl group by comparing the partition data of TA with those of TTA.[3]

Experimental

Materials. The TA was synthesized by the Claisen acylation of acetylthiophene.[4] The crude product was purified by the copper salt method[5] and by subsequent vacuum sublimation. The elemental analysis of the purified reagent showed: C: 57.24% and H: 4.79% (calcd for C: 57.11%, H: 4.80%), while the mp is 33.7—34.5 °C. The alcohols were purified by the method described previously.[2] The β-naphthol was purified by recrystalization from ethanol and by vacuum sublimation. The other reagents were used as purchased in the reagent-grade.

Partition Experiment. Five ml of a water-saturated alcohol solution of TA (0.002 M) and an equal volume of the alcohol-saturated aqueous phase (I=0.1 by $NaClO_4$, pH=3.5) were agitated for over 3 h at 25±0.5 °C. After centrifugation, an aliquot of the aqueous phase was pipetted out into a quartz cell and the concentration of TA was determined photometrically (295 nm, $\varepsilon=7.94\times10^3$). The concentration in the aqueous phase and the initial concentration allowed the calculation of the apparent partition coefficient of TA. The experiment was repeated six times for each partition system. On the other hand, the apparent partition coefficients of TTA were reported previously by one of the authors for most alcohols except for heptanol,[3] for which we determined the partition coefficient by a procedure similar to that described above.

Bromination. The enol fractions and the enolization rate constants of TA in several water-saturated alcohols were determined by Meyer's bromination method.[6] The procedure was as follows. A 0.01 M solution of TA in water (I=0.1, pH=3)-saturated alcohol was prepared. After the solution has stood for over 6 h, 5 ml of the solution was mixed with an equal volume of a 0.1 M alcoholic solution of bromine. After a certain interval, the bromination reaction was stopped by adding a 0.05 M ethanol solution of β-naphthol. Subsequently, after 50 ml of ethanol and 10 ml of the aqueous solution of potassium iodide has been added, and after the mixture had stood for 30 min, the iodine was titrated with a sodium thiosulfate solution. The end point was determined from the vanishing of the color of iodine. The sodium thiosulfate solution used in the titration was standardized by potassium iodate. By this procedure, the enol concentration at a certain time after the initiation of bromination was determined. Hence, the enol fraction at equilibrium was obtained from the enol concentration at reaction time zero, and the enolization rate constant from the slope of the plot of the logarithmic enol concentration against the time.

UV Absorption Measurement. The UV spectra of alcoholic solutions of TA show two absorption maxima, at 264 and 320 nm. The maximum at the longer wavelength is thought to be due to the enol form.[7] The absorption coefficient at the wavelength was determined for each water-saturated alcohol and for each alcohol-saturated aqueous solution. In order to estimate the enol fraction of TA in an aqueous solution, the following measurements were carried out. An alkaline (pH=11.6) solution of TA(2×10^{-5} M) in which TA (pK_a=8.1) dissociates entirely and diluted perchloric acid were rapidly mixed by means of a sample-mixing device (Union Co. Type MX-7), and the subsequent increase in the transmittance at 340 nm was recorded on a Hitachi 356 spectrophotometer. At the time of mixing, TA is thought to be in the enol form completely.[8,9] Hence, the ratio of the absorbances at time zero and at equilibrium refers to the enol fraction. Furthermore, from the absorption change, the tautomerization rate constant of TA in an aqueous solution was obtained.

Results

Apparent Partition Coefficients. The observed partition coefficients of TA are shown in Table 1, together with those of TTA. The value for TA is larger than that for TTA in every alcohol–water pair.

Enol Fractions and Tautomerization Rate Constants. The enol fractions and the enolization rate constants of TA, which were determined by bromination tech-

nique, are listed in Table 2 for four alcohols. In the other alcohols, reproducible results were not obtained; therefore, the following convenient method was adopted. A simple correlation between the enol fraction of TA in the four alcohols and the absorption coefficients at the absorption maximum, ε_{max}, was obtained:

$$\text{Enol fraction} = 0.566\varepsilon_{max}. \quad (1)$$

The enol fractions for the other alcohols were calculated from Eq. 1; they are listed in Table 2. The enol fraction in an aqueous solution was obtained as 0.13_4 from the kinetic experiment. From the experiment, the enolization rate constant, 1.62×10^{-2} s^{-1}; the ketonization rate constant, 1.19×10^{-1} s^{-1}, and the absorption coefficient of the enol form at 340 nm, $\varepsilon_e=1.78\times10^4$, were also obtained. The enol fractions of TA in alcohol-saturated water were estimated by the ratio of the apparent absorption coefficient to ε_e, they are shown in Table 2.

Discussion

The Tautomerization of TA in Aqueous and Alcoholic Phases. As is shown in Table 2, the enol fractions

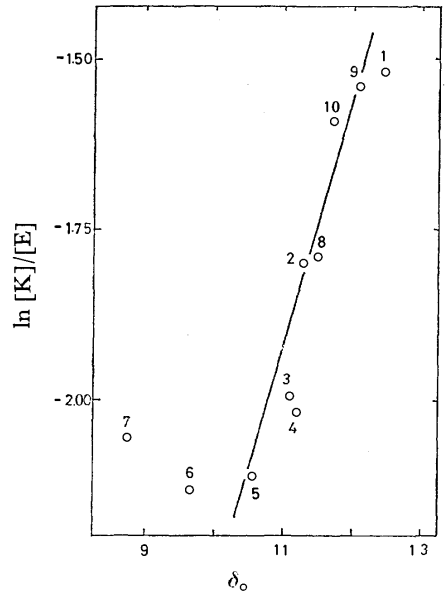

Fig. 2. Correlation between the keto-enol equilibrium constant and the solubility parameter of alcohol. The numbers correspond to those in Table 2.

of TA in water-saturated alcohols seem to increase with a decrease in the solvent polarity. This tendency was also noted in the case of TTA, as was reported in a previous paper,[2] in which the solvent effect was discussed in terms of electrostatic theory and the regular solution theory. The electrostatic theory proposes that an equilibrium constant depends on the dielectric constant, ε, of the solvent through the terms of $(\varepsilon-1)/V_o(2\varepsilon+1)$, in which V_o is the molar volume of the solvent.[10] On the other hand, the regular solution theory relates an equilibrium constant to the solubility parameter of the solvent.[11] The dependencies of the keto-enol equilibrium constant on the dielectric factor

Table 3. The partition coefficients of the enol (P_E) and the keto (P_K) forms of TA and those of the enol (P_E) and the hydrate (P_H) forms of TTA at 25 °C

No.	Solvent	TA		TTA

5	1-Octanol	325	6.19	1640	11.7
6	2-Ethyl-1-hexanol	293	5.49	1420	8.5
7	2-Octanol	333	6.74	1780	13.6
8	3-Methyl-1-butanol	246	7.50	1480	19.7
9	Cyclohexanol	256	10.11	1160	27.4
10	2-Methyl-1-propanol	128	5.88	812	16.3
11	Benzyl alcohol	—	—	1950	36.3

$(\varepsilon-1)/V_o(2\varepsilon+1)$ and on the solubility parameter of alcoholic phase are shown in Figs. 1 and 2 respectively. In both figures, satisfactory relationships are obtained. The positive sign of the slopes of the figures seems to be related to the more dipolar character of the keto form than the enol form. The enolization rate constant of TA is about 2.5×10^{-2} s^{-1} for most alcohols, and no significant solvent dependency is observed, different from the enolization rate of the hemiacetal form of TTA.[2]

The Partition Coefficient of Each Species of TA and TTA. The TTA in the alcohol phase is in the enol, the hydrate and the hemiacetal forms, while in the aqueous phase, it is in the enol and hydrate forms. On the other hand, TA is thought to be in the enol and the keto forms in both phases. Consequently, the partition schemes of the two diketones are considerably different and can be drawn as follows:

$$\begin{array}{lcl} \text{TA;} & \text{K}\rightleftharpoons\text{E} & \text{org.} \\ & \Updownarrow\ \Updownarrow & \\ & \text{K}\rightleftharpoons\text{E} & \text{aq} \end{array} \qquad \begin{array}{lcl} \text{TTA;} & \text{H}\rightleftharpoons\text{E}\rightleftharpoons\text{A} & \text{org.} \\ & \Updownarrow\ \Updownarrow & \\ & \text{H}\rightleftharpoons\text{E} & \text{aq} \end{array} \qquad (2)$$

Here E, K, H, and A refer to the enol, keto, hydrate, and hemiacetal forms respectively. On the basis of the above schemes, the partition coefficients of the enol (P_E), keto (P_K), and hydrate (P_H) forms can be represented by

$$P_E=\frac{f_o}{f}P,\quad P_K=\frac{1-f_o}{1-f}P,\quad P_H=\frac{g_o}{1-f}P, \qquad (3)$$

where f, f_o, and g_o refer to the enol fraction in the aqueous phase, the enol fraction in the organic phase, and the hydrate fraction in the organic phase respectively, and where P refers to the apparent partition coefficient. The values of P_E and P_K for TA and those of P_E and P_H for TTA are shown in Table 3. The order of the magnitude of the partition coefficient is: $P_E(\text{TTA})>P_E(\text{TA})>P_H(\text{TTA})>P_K(\text{TA})$.

For the solvent effect of alcohol on the partition coefficients, it is difficult to draw out any regularity instantaneously. In an earlier work, one of the present authors demonstrated the utility of the regular solution theory for an interpretation of the solvent effect in

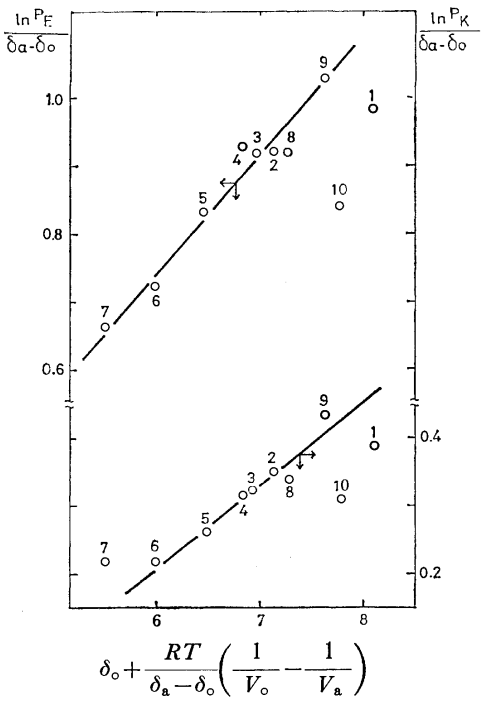

Fig. 3. Correlation between the partition coefficients of the keto (P_K) and the enol (P_E) forms of TA and the solubility parameter of alcoholic phase. The numbers correspond to those in Table 3.

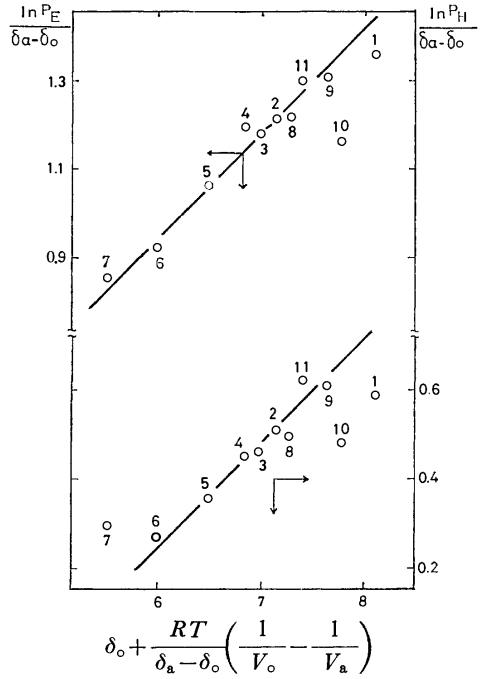

Fig. 4. Correlations between the partition coefficients of the enol (P_E) and the hydrate (P_H) forms of TTA and the solubility parameter of alcoholic phase. The numbers correspond to those in Table 3.

alcohol/water systems.[3] Hence, we employed this treatment for the partition coefficient of each species of TA and TTA. On a certain species, i, the following equation is derived from the regular solution approximation for the present partition system:[3]

$$\frac{\ln P_i}{\delta_a-\delta_o}=\frac{V_i}{RT}\left\{\delta_o+\delta_a-2\delta_I+\frac{RT}{\delta_a-\delta_o}\left(\frac{1}{V_o}-\frac{1}{V_a}\right)\right\}, \qquad (4)$$

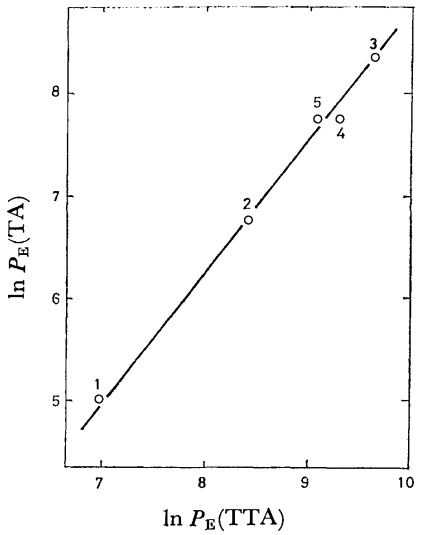

Fig. 5. Correlation between ln P_E(TA) and ln P_E-(TTA). The numbers correspond to those in Table 3.

where P is the partition coefficient; V, the molar volume and δ, solubility parameter, and where the subscripts i, and o refer to the solute i, the aqueous phase, and the organic phase respectively. Figures 3 and 4 show the plots based on the above relation. A satisfactory correlation is obtained in each case.

Comparison of the Partition Coefficients of TA with Those of TTA. As is shown in Table 3, P_E(TTA) is larger than P_E(TA). In addition, a linear correlation appears between ln P_E(TTA) and ln P_E(TA), as is shown in Fig. 5. This relationship may be understood from the point of view of the linear free-energy relationship. The partition coefficient is related to a transfer free energy, ΔG, from the aqueous phase to the organic phase by the following equation:

$$-RT \ln P = \Delta G. \tag{5}$$

Assuming an additivity of group-transfer free energy,[12] the ΔG of the enol forms of TA and TTA can be represented as

$$\begin{aligned} \Delta G(\mathrm{TA}) &= \Delta G(\mathrm{CH_3}) + \Delta G(\mathrm{R}), \\ \Delta G(\mathrm{TTA}) &= \Delta G(\mathrm{CF_3}) + \Delta G(\mathrm{R}), \end{aligned} \tag{6}$$

where R refers to the group of $-\mathrm{COCHCOC_4H_3S}$. Hence, the partition coefficients are

$$\begin{aligned} \ln P(\mathrm{TA}) &= \ln P(\mathrm{CH_3}) + \ln P(\mathrm{R}), \\ \ln P(\mathrm{TTA}) &= \ln P(\mathrm{CF_3}) + \ln P(\mathrm{R}). \end{aligned} \tag{7}$$

Equation 7 provides

$$\ln P(\mathrm{TA}) - \ln P(\mathrm{TTA}) = \ln P(\mathrm{CH_3}) - \ln P(\mathrm{CF_3}). \tag{8}$$

Equation 8 and the intercept in Fig. 5 allow the estimation of $\Delta G(\mathrm{CH_3}) - \Delta G(\mathrm{CF_3})$ as 1.4 kcal/mol. Similar analysis has been performed for the previous results in apolar solvent/water systems;[13] the free energy difference was estimated as 2.1 kcal/mol. The larger value for the apolar system corresponds to a general tendency for a fluorocompound to show a high solubility in an apolar solvent.

Finally, let us discuss the effect of the solution species on the apparent partition coefficient. On the basis of the scheme of Eq. 2, the apparent partition coefficient of TA can be represented by

$$P(\mathrm{TA}) = \frac{[\mathrm{E}]_o + [\mathrm{K}]_o}{[\mathrm{E}] + [\mathrm{K}]} = \frac{[\mathrm{E}]_o}{[\mathrm{E}] + [\mathrm{K}]} + \frac{[\mathrm{K}]_o}{[\mathrm{E}] + [\mathrm{K}]} = P'(\mathrm{E}) + P'(\mathrm{K}). \tag{9}$$

Since the ratio of $P'(\mathrm{K})/P'(\mathrm{E})$, which is identical with the keto-enol equilibrium constant in the alcoholic phase, is much smaller than unity, it may be concluded that the magnitude of P_E(TA) is primarily governed by that of P'(E). On the other hand, the apparent partition coefficient of TTA can be separated into the following terms:

$$P(\mathrm{TTA}) = \frac{[\mathrm{E}]_o}{[\mathrm{E}] + [\mathrm{H}]} + \frac{[\mathrm{H}]_o}{[\mathrm{E}] + [\mathrm{H}]} + \frac{[\mathrm{A}]_o}{[\mathrm{E}] + [\mathrm{H}]} = P'(\mathrm{E}) + P'(\mathrm{H}) + P'(\mathrm{A}). \tag{10}$$

The relative magnitude among P'(E), P'(H), and P'(A) is equal to that among $[\mathrm{E}]_o$, $[\mathrm{H}]_o$, and $[\mathrm{A}]_o$ (*cf.* Table 1 in the preceding paper).[2] Hence, we found that the contribution of P'(H), or approximately $P_H = [\mathrm{H}]_o/[\mathrm{H}]$, to P(TTA) is the most important because the major species of TTA in the alcohol phase is the hydrate form in most cases. However, in 2-ethyl-1-hexanol P'(A) plays the most important role because of the high fraction (50%) of the hemiacetal form in the solvent. In conclusion, we can state that P(TA) is governed by P'(E), and P(TTA) by P_H and P'(A). Although P_E(TTA) is larger than P_E(TA), because of the small contribution of P_E(TTA) P(TA) is larger than P(TTA).

Binuclear Metal Complexes. XXIV.[1] Synthesis and Magnetism of Binuclear Cobalt(II) Complexes in Mixed-spin State[2]

Naoyuki TORIHARA, Hisashi OKAWA,* and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received May 1, 1978)

Binuclear cobalt(II) complexes, $Co_2(fsaR)(py)_3$ and $Co_2(fsaR)MeOH\cdot 1/2H_2O$ with 3-formylsalicylic acid-diamine Schiff bases, H_4fsaR (R=en, pn, bn, ch, and ph), were prepared and characterized. Mixed-spin states of these complexes were demonstrated by the cryomagnetic measurements and no spin-exchange interaction was observed between high-spin and low-spin cobalt(II) ions. The absence of spin-exchange interaction in these complexes was discussed on the basis of the electronic configuration of the low-spin cobalt(II) ion and in comparison with the antiferromagnetic Cu(II)–Co(II) ($s=3/2$) complexes with the same ligands.

Binuclear metal complexes are classified into four types: homo-metal binuclear complexes (*e.g.*, Cu(II)–Cu(II)), mixed-spin binuclear complexes (*e.g.*, Ni(II)-($s=0$)–Ni(II)($s=1$)), mixed-valence binuclear complexes (*e.g.*, Cu(I)–Cu(II)), and hetero-metal binuclear complexes (*e.g.*, Cu(II)–Ni(II)). Among these complexes homo-metal binuclear complexes have been most extensively studied because of the ease of preparation. Recently much attention has been denoted to the mixed-valence and the hetero-metal binuclear complexes in connection with metalloenzymes and homogeneous catalysis. On the other hand, there are very few characterized binuclear complexes in mixed-spin state.

Although there have been obtained some binuclear complexes with high-spin cobalt(II) ion,[3–8] no mixed-spin binuclear cobalt(II) complexes have yet been obtained. In the previous papers of this series,[9–13] the mixed-spin binuclear nickel(II) complexes[9] and the hetero-metal binuclear complexes[10–13] were obtained by use of 3-formylsalicylic acid-diamine Schiff bases (H_4fsaR). In $CuCo(fsaR)(H_2O)_{2-3}$ complexes with these ligands,[11,12,14] the high-spin cobalt(II) ion is bonded to the "outside" coordination site with two water molecules at the apical positions. On the other hand, the "inside" coordination site of these ligands quite resembles the coordination site of *N,N'*-disalicylideneethylenediamine and its homologues capable of forming low-spin cobalt(II) complexes. Thus, we aimed in this study to prepare mixed-spin binuclear cobalt(II) complexes with 3-formylsalicyclic acid-diamine Schiff bases and to investigate the spin-exchange interaction between high-spin and low-spin cobalt(II) ions.

The 2:1 condensation product of 3-formylsalicyclic acid with ethylenediamine, propylenediamine, 2,3-butanediamine, 1,2-cyclohexanediamine and *o*-phenylenediamine are abbreviated as H_4fsaen, H_4fsapn, H_4fsabn, H_4fsach, and H_4fsaph, respectively.

Experimental

Synthesis. 3-Formylsalicylic acid-diamine Schiff bases, H_4fsaR (R=en, pn, bn, ch, and ph), were obtained as yellow prisms by the reaction of 3-formylsalicylic acid and a diamine in ethanol in the 2:1 mole ratio. Syntheses of complexes were carried out in an atmosphere of nitrogen by means of a VAC Inert Atmosphere & Vacuum Deposition Equipment Model HE-43-2.

$Co_2(fsaen)(py)_3$. Cobalt(II) acetate tetrahydrate (500 mg) and H_4fsaen (350 mg) were dissolved in pyridine (20 ml) to form a deep red solution. When the solution was stirred at 60 °C for 30 min red prisms separated. Stirring was continued for additional two hours at 100 °C and the reaction mixture was allowed to stand overnight to give red-purple prisms. They were collected and dried at ordinary pressure.

In the same way as the above $Co_2(fsapn)(py)_3$, $Co_2(fsabn)(py)_3$, $Co_2(fsach)(py)_3$, and $Co_2(fsaph)(py)_3$ were obtained.

$Co_2(fsaen)MeOH\cdot 1/2H_2O$. To a solution of H_4fsaen (700 mg) in methanol (50 ml) was added cobalt(II) acetate tetrahydrate (1.0 g) and the mixture was stirred under reflux for 24 h. After the reaction mixture was left standing overnight, red fine-crystals which separated were collected and dried.

$Co_2(fsach)MeOH\cdot 1/2H_2O$ and $Co_2(fsaph)MeOH\cdot 1/2H_2O$ were obtained by the procedures similar to that for $Co_2(fsaen)MeOH\cdot 1/2H_2O$. Syntheses of metal complexes with H_4fsach and H_4fsabn were also carried out. Red prisms obtained became black on exposure to air. Composition of black product was assumed to be $Co_2(fsaR)(MeOH)_2\cdot O_2\cdot 1/2H_2O$ (R=pn, bn).

Elemental analyses of the complexes are tabulated in Table 1.

Measurements. Infrared spectra of the complexes were measured with a Hitachi Infrared Spectrophotometer Model 215 on a KBr disk. Electronic spectra were measured with a Shimadzu Multipurpose Spectrophotometer Model MSP-5000 by the reflection on a powder sample. ESR spectra were measured with a JES-ME-3 Spectrometer by the X-band. Magnetic susceptibility was measured by the Faraday method in the temperature range from liquid nitrogen temperature to room temperature. The apparatus was calibrated by use of $HgCo(NCS)_4$. Magnetic moments were calculated by the expression, $\mu_{eff}=2.828(\chi_M\times T)^{1/2}$, where χ_M is the magnetic susceptibility per molecule corrected for diamagnetism by use of Pascal's constants.

Results and Discussion

Reaction of H_4fsaR with cobalt(II) acetate in pyridine always resulted in the formation of $Co_2(fsaR)(py)_3$. Since in $CuCo(fsaR)(H_2O)_{2-3}$ the cobalt(II) ion is in the "outside" coordination site and has a pseudo-octahedral configuration with water molecules at the apical positions[14], it is likely that the "outside" cobalt(II) in $Co_2(fsaR)(py)_3$ also has a pseudo-octahedral structure coordinated by pyridine at the apical positions. It is known[15] that *N,N'*-disalicylidene-ethylenediaminatocobalt(II) (Co(salen)) reacts with pyridine

Table 1. Elemental analyses of complexes

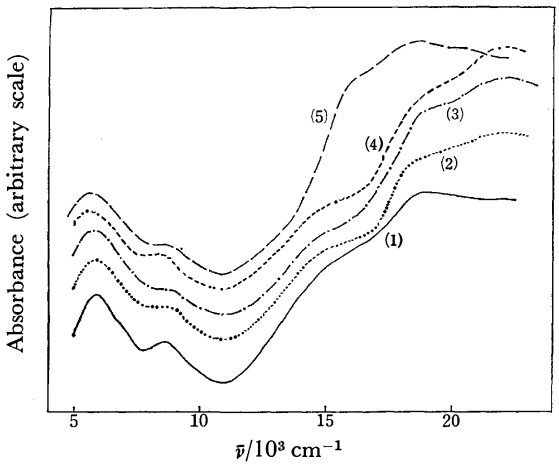

Fig. 2. Reflectance spectra of (1) $Co_2(fasen)(py)_3$, (2) $Co_2(fsapn)(py)_3$. (3) $Co_2(fsabn)(py)_3$, (4) $Co_2(fsach)(py)_3$, and (5) $Co_2(fsaph)(py)_3$.

to form Co(salen)py, where the cobalt(II) is in the low-spin state and has a tetragonal-pyramidal geometry with pyridine at the apex. Therefore, it is likely that $Co_2(fsaR)(py)_3$ has a binuclear structure composed of a low-spin tetragonal-pyramidal and a spin-free pseudo-octahedral cobalt(II) ions (Fig. 1). Coordination of pyridine was demostrated by the infrared absorption band around 700 cm^{-1}.

Reflectance spectra of $Co(fsaR)(py)_3$ are shown in Fig. 2. Each spectrum possesses several absorption bands in the region 5000—25000 cm^{-1}. The spectrum must be the superposition of the spectra of the "inside" and the "outside" cobalt(II) chromophores. Despite the difference in the apical ligands, the "outside" cobalt(II) in $Co_2(fsaR)(py)_3$ should display a spectrum similar to that of the "outside" cobalt(II) in $CuCo(fsaR)(H_2O)_{2-3}$, because pyridine does not differ much from water in the ligand field strength. In $CuCo(fsaR)(H_2O)_{2-3}$ d-d bands due to the "outside" cobalt(II) were found at 8300, 11000, and 19200 cm^{-1}.[12] On the other hand, the spectrum of the "inside" cobalt(II) in $Co_2(fsaR)(py)_3$ should be similar to that of Co(salen)py, which has d-d bands at 6000, 9000, 13500, and 16000 cm^{-1}.[16,17] Accordingly the spectra shown in Fig. 2 can be interpreted in terms of the superposition of the spectra of the five-coordinate "inside" cobalt(II) and the six-coordinate "outside" cobalt(II) ions.

Two types of complexes, $Co_2(fsaR)MeOH\cdot 1/2H_2O$ (R=en, ch, ph) and $Co_2(fsaR)(MeOH)_2\cdot O_2\cdot 1/2H_2O$ (R=pn, bn), were obtained by the reaction in methanol. The latter is tentatively assumed to be an oxygen-carrying complex, since its color turned black from red when exposed to air and its elemental analysis quite agrees with the formula shown above. It is to be noted that the oxygen-carrying complexes contain two molecules of methanol, while the complexes lacking oxygen-carrying ability contain one molecule of methanol. Since low-spin cobalt(II) complexes with the quadridentate Schiff bases usually exhibit the oxygen-carrying ability when coordinated by a base at the fifth position,[18] it is supposed that one of the methanol molecules in $Co_2(fsaR)(MeOH)_2\cdot O_2\cdot 1/2H_2O$ coordinates to the "inside" cobalt(II) ion.

Reflectance spectra of $Co_2(fsaR)MeOH\cdot 1/2H_2O$ are not well resolved and exhibit broad bands around 6000, 12000—14000, and 18000 cm^{-1}. Because of the complexity in the composition and in the visible spectra, we could not deduce a difinite structure to $Co_2(fsaR)MeOH\cdot 1/2H_2O$.

Magnetic moments of $Co_2(fsaR)(py)_3$ and $Co_2(fsaR)MeOH\cdot 1/2H_2O$ at room temperature are in the range 4.9—5.6 B.M. Since low-spin cobalt(II) and high-spin cobalt(II) (octahedral) have magnetic moments of 1.9—2.8 and 4.3—5.2 B.M.,[19] respectively, the magnetic moments expected for high-spin binuclear cobalt(II), mixed-spin binuclear cobalt(II) and low-spin binuclear cobalt(II) complexes are 6.1—7.4, 4.7—5.9, and 2.7—4.0 B.M. respectively, provided that no

TABLE 2. EFFECTIVE MAGNETIC MOMENTS NEAR LIQUID NITROGEN TEMPERATURE AND AT ROOM TEMPERATURE, AND WEISS CONSTANT OF COMPLEXES

	μ_{eff}(T) (BM)		θ (K)
Co_2(fsaen)$(py)_3$	4.91(82.9)	4.92(297.4)	≈0
Co_2(fsapn)$(py)_3$	5.32(81.2)	5.34(297.4)	≈0
Co(fsabn)$(py)_3$	5.31(90.3)	5.29(296.8)	≈0
Co_2(fsach)$(py)_3$	5.44(82.8)	5.58(298.3)	−8
Co_2(fsaph)$(py)_3$	5.24(81.7)	5.31(296.8)	−4
Co_2(fsaen)MeOH·1/2H_2O	5.18(87.4)	5.34(297.8)	−10
Co_2(fsach)MeOH·1/2H_2O	5.09(81.7)	5.15(289.3)	−3
Co_2(fsaph)MeOH·1/2H_2O	5.23(84.6)	5.34(296.6)	−4

spin-exchange interaction is operating between the cobalt(II) ions. Thus, the present complexes may be mixed-spin binuclear complexes or magnetically coupled high-spin binuclear complexes. As already mentioned above electronic spectra of Co_2(fsaR)$(py)_3$ are in favor of a mixed-spin binuclear structure. Mixed-spin state for Co_2(fsaR)$(py)_3$ as well as Co_2(fsaR)-MeOH·1/2H_2O was further demonstrated by the magnetic susceptibility measurements down to liquid nitrogen temperature. Plots of inverse magnetic susceptibility *versus* temperature obey the Curie law or the Curie-Weiss law with a very small negative Weiss constant; some representatives of the $1/\chi_M$ *vs.* T plot being shown in Fig. 3. In Table 2 the magnetic moments at room temperature and near liquid nitrogen temperature and the Weiss constants determined by the Curie-Weiss plot are given. It is evident that the magnetic moments of the present complexes are almost independent on the temperature. Thus, it is concluded that Co_2(fsaR)$(py)_3$ and Co_2(fsaR)MeOH·1/2H_2O are mixed-spin binuclear complexes and no spin-exchange interaction is operating between the low-spin and the high-spin cobalt(II) ions.

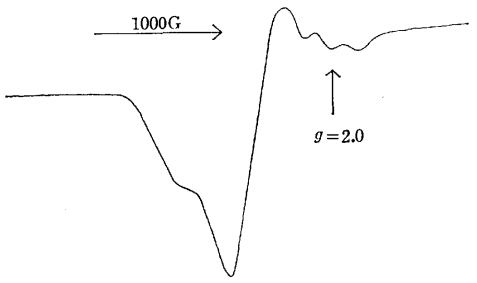

Fig. 4. ESR spectrum of CoMg(fsaen)$(py)_3$ (in DMF at liq. nitrogen temperature).

Since a considerably strong antiferromagnetic spin-exchange interaction was observed for CuCo(fsaR)-$(H_2O)_{2-3}$,[11,12] the difference in magnetic exchange interaction between the Cu(II) (s=1/2)–Co(II) (s=3/2) and the Co(II) (s=1/2)–Co(II) (s=3/2) systems may be attributed to the difference in the ground-state electronic configuration between copper(II) and low-spin cobalt(II) ions. In general copper(II) has an unpaired electron on $d_{x^2-y^2}$ orbital (x and y axes are taken on the donating atoms in the tetragonal plane). On the other hand, in low-spin cobalt(II) complexes an unpaired electron is in either a d_{yz} or d_{z^2} orbital. It is known that in Co(salen) an unpaired electron occupies d_{yz} orbital, while Co(salen)py has the ground-state electron configuration in which an unpaired electron occupies d_{z^2} orbital.[17,20-22] The main difference between the "inside" cobalt(II) of Co_2(fsaR)$(py)_3$ and Co(salen)py is in the donating phenolic oxygen; a bridging oxygen in the former while a simply donating oxygen in the latter. It is unlikely that a considerable change in the electronic configuration is brought about when the phenolic oxygen acts as a bridge.

In order to determine precisely the electronic configuration of the "inside" cobalt(II) ion, we measured ESR spectra of Co_2(fsaR)$(py)_3$ and their related complex, CoMg(fsaen)$(py)_3$. Although no ESR signal was detected for Co_2(fsaR)$(py)_3$ owing to the "outside" high-spin cobalt(II) ion, an *N*,*N*-dimethylformamide solution of CoMg(fsaen)$(py)_3$ displayed a well defined ESR spectrum, in which g_x, g_y, and g_z are found to be *ca.* 2.40, 2.25, and 2.00, respectively (Fig. 4). Three-lined hyperfine structure with hyperfine splitting constant of *ca.* 90 G around g=2.00 clearly indicates that pyridine is coordinated to the "inside" cobalt(II) ion. This ESR spectrum is quite similar to the spectrum of Co(salen)py[17] and can be interpreted in terms of a d_{z^2} ground-state electronic configuration. Based on these facts we may conclude that the "inside" cobalt(II) ion in Co_2(fsaR)$(py)_3$ has an unpaired electron in d_{z^2} orbital. Thus, it is presumed that no spin-exchange interaction in Co_2(fsaR)$(py)_3$ and Co_2(fsaR)MeOH·1/2H_2O is attributed to a negligibly small overlapping between the metal d_{z^2} orbital and the bridging oxygen orbital.[23]

The authors are grateful to the Ministry of Education for a Scientific Research Grant-in-Aid. We also thank to Mr. Y. Nonaka for the measurement of ESR spectra.

Chemical Vapor Deposition of Titanium Disulfide

Seiji MOTOJIMA,* Kazuaki ITOH, Yasutaka TAKAHASHI, and Kohzo SUGIYAMA

Department of Synthetic Chemistry, Faculty of Engineering, Gifu University, Kakamigahara, Gifu 504

(Received May 15, 1978)

Chemical vapor deposition of TiS_2 was examined. TiS_2 was deposited on a quartz substrate above 300 °C from a gas mixture of $TiCl_4$, H_2S, and Ar. Maximum deposition rate was attained at 700—800 °C for a 0.7 gas flow ratio $H_2S/(TiCl_4+H_2S)$ irrespective of temperature. Crystal morphology and composition were strongly affected by temperature and gas compositions. Well-formed TiS_2 crystals were grown either at 600 °C or from a gas mixture of low flow ratio 0.2 of $H_2S/(TiCl_4+H_2S)$. Single phase of TiS_2 was deposited in the temperature range 400—850 °C.

There are several non-stoichiometric compounds in the system Ti–S. Of these, titanium disulfide has a CdI_2-type structure and is of interest as a dry-lubricant,[1] catalyst,[2] electrical contact operating under friction,[3] reversible electrode,[4] and cathode material for electric vehicle propulsion.[5,6]

Titanium disulfide has been prepared by the reaction between the elements,[7–10] reaction of titanium with hydrogen sulfide,[9,11] titanium dioxide with hydrogen sulfide and carbon,[12] and by chemical transport technique in closed ampoules,[13–18] and in open flow system.[19] Single crystals of titanium disulfide have so far been prepared only by chemical transport in a closed system.

The aim of the present study is to examine the growth conditions of titanium disulfide crystals by the chemical vapor deposition in an open flow system. Over-all reaction used is as follows, unless otherwise stated.

$$TiCl_4 + 2H_2S = TiS_2 + 4HCl. \quad (1)$$

Experimental

Materials. Commercial GR grade titanium and chlorine were used without further purification. Hydrogen was dehydrated by passing over calcium chloride and phosphorus pentaoxide, successively. Argon and hydrogen were also dehydrated by passing through concentrated sulfuric acid. Titanium tetrachloride was prepared *in situ (vide infra)*.

Growth Apparatus and Procedure. The apparatus is shown in Fig. 1. A quartz tube, outer dia. 7 mm, length 70 mm, was used as a substrate, into which a silicon carbide heater was inserted. The substrate was held in a vertical quartz tube, inner diam. 19 mm, heated with a nichrome heater from the outside. Titanium tetrachloride was prepared by chlorination of titanium sponge at 350—400 °C and carried by argon into the upper inlet of the reaction tube. Hydrogen sulfide was introduced through an uppermost inlet and allowed to mix with the stream of titanium tetrachloride just above the substrate. The surface temperature of the substrate was measured with an infrared thermometer (Japan Sensor Co., Model TSS-2P) through an observation window. The temperature had been calibrated with a chromel-alumel thermocouple. The flow rate of titanium tetrachloride was calculated from that of the chlorine stream to a bed of titanium sponge assuming full conversion.

Analysis of Crystals. Titanium content in the crystals was determined by the gravimetric method. A collection of crystallites was pulverized, weighed, and oxidized to titanium dioxide in an air flow at 1000 °C for an hour. Non-stoichiometry number x of TiS_x was calculated by the following equation:

$$x = \frac{W_{TiS_x} - W_{TiO_2}\dfrac{A.W.\,(Ti)}{M.W.\,(TiO_2)}}{A.W.\,(S)} \Bigg/ \frac{W_{TiO_2}\dfrac{A.W.\,(Ti)}{M.W.\,(TiO_2)}}{A.W.\,(Ti)} = \frac{1}{32.06}\left(79.90\frac{W_{TiS_x}}{W_{TiO_2}} - 47.90\right),$$

where W_{TiS_x} and W_{TiO_2} are weights of titanium disulfide sample and its oxidized product, respectively, and $A.W.$(i) and $M.W.$(j) are the atomic weight of element i and the molecular weight of compound j, respectively.

Thermoelectric Power. With use of silver conducting paint, a plate-like crystal of titanium disulfide was contacted to two copper plates (3×5 mm) separated 1 mm from each other, one of which was heated by a nichrome heater. The temperature difference of two sides of the crystal was measured with a 100 μm dia. chromel-alumel thermocouple. Thermoelectric power was measured in an argon atmosphere.

Results and Discussion

Effects of Substrate Temperature. Deposition rates of titanium disulfide crystals plotted against the temperature of substrate are shown in Fig. 2. The sum of the flow rates of titanium tetrachloride and hydrogen sulfide, and total gas flow rate were kept at 0.4 and

Fig. 1. Apparatus. 6.0 cm³/s, respectively (linear velocity at room temperature, 2.4 cm/s). The deposition rate reached a maximum at 700—800 °C. The temperature range 700—800 °C corresponding to that of maximum growth rate has been used in chemical vapor transport.[17] Saeki,[18] Biltz *et al.*,[19] and Winn and Steele[20] reported on the equilibrium partial pressure of diatomic sulfur over the non-stoichiometric titanium disulfide. The pressure[20] is shown in Fig. 3, together with that of diatomic sulfur formed in dissociation of hydrogen sulfide in the case of inlet partial pressure of hydrogen sulfide of 40 Torr. Although the pressure of titanium disulfide is very low[21] in comparison with the disulfur pressure in the temperature range of the present work, the equilibrium sulfur pressure increases steeply with

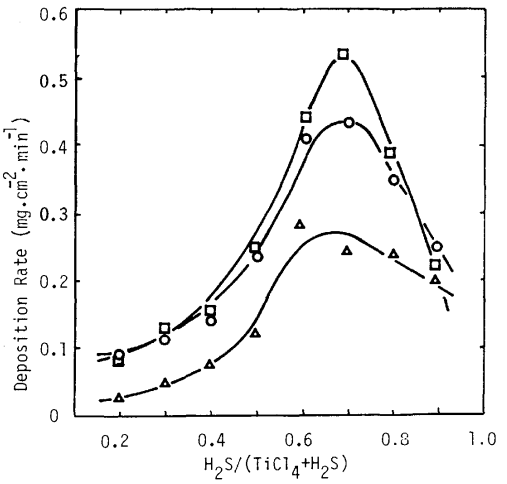

Fig. 4. Effect of gas flow ratio of $H_2S/(TiCl_4+H_2S)$ on the deposition rate. Reaction time: 15 min, $TiCl_4+H_2S$: 0.4 cm³/s, Ar: 5.6 cm³/s, substarte temperature: (△) 600 °C, (○) 700 °C, (□) 800 °C.

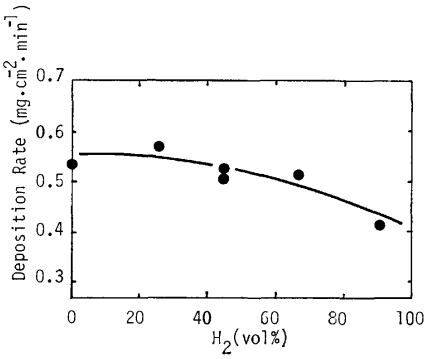

Fig. 5. Effect of hydrogen flow rate on the deposition rate. Reaction time: 15 min, H_2S: 0.1 cm³/s, $TiCl_4$: 0.1 cm³/s, H_2+Ar: 2.2 cm³/s, substrate temperature: 800 °C.

the increase of the sulfur content in titanium disulfide and with the increase of temperature especially above 800 °C. Thus, the decrease of the deposition rate above 800 °C can be attributed to the degradation of titanium disulfide to a lower sulfide phase and disulfur. The maximum deposition efficiency of titanium disulfide with respect to the feed of titanium tetrachloride was estimated to be about 20 per cent.

Effects of Gas Composition and Flow Rate. The effects of gas flow ratio $H_2S/(TiCl_4+H_2S)$ ("H_2S" ratio hereafter) on the deposition rate of titanium disulfide, with substrate temperature used as parameter, are shown in Fig. 4. The deposition rate increases with increase in the H_2S ratio, reaching a maximum at the ratio of *ca.* 0.7, which is roughly in agreement with the stoichiometrical ratio (0.67) of Reaction 1. The optimum H_2S ratio shifts to the lower value when hydrogen is introduced in the input gas. For example, H_2S ratio corresponding to the maximum deposition rate varies to 0.5 when hydrogen is introduced up to 80 per cent. The deposition rates of titanium disulfide increase with increase in the sum of the flow rates of titanium tetrachloride and hydrogen sulfide, attaining

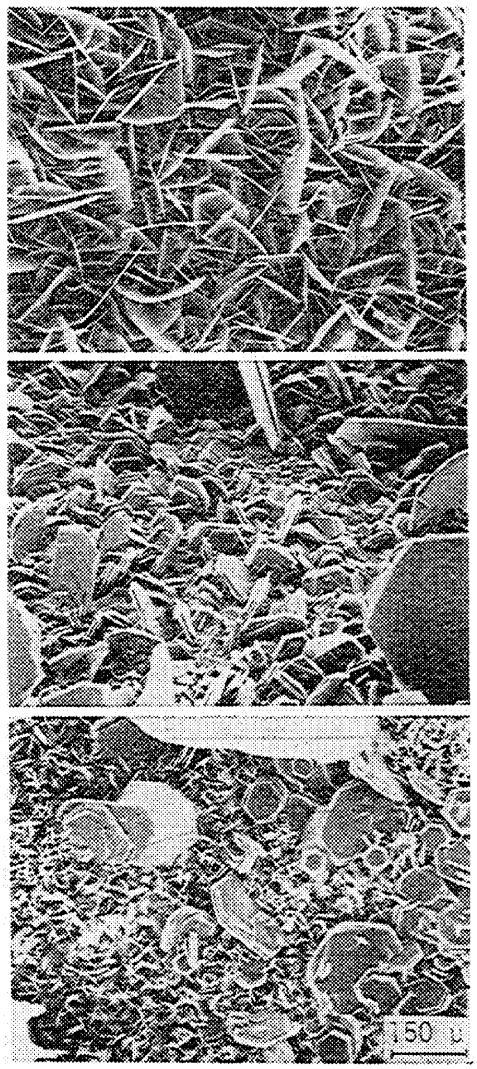

Fig. 6. Morphologies of TiS_2 crystals (1). $H_2S/(TiCl_4+H_2S)$: 0.2, substrate temperature: (A) 600 °C, (B) 800 °C, (C) 1000 °C.

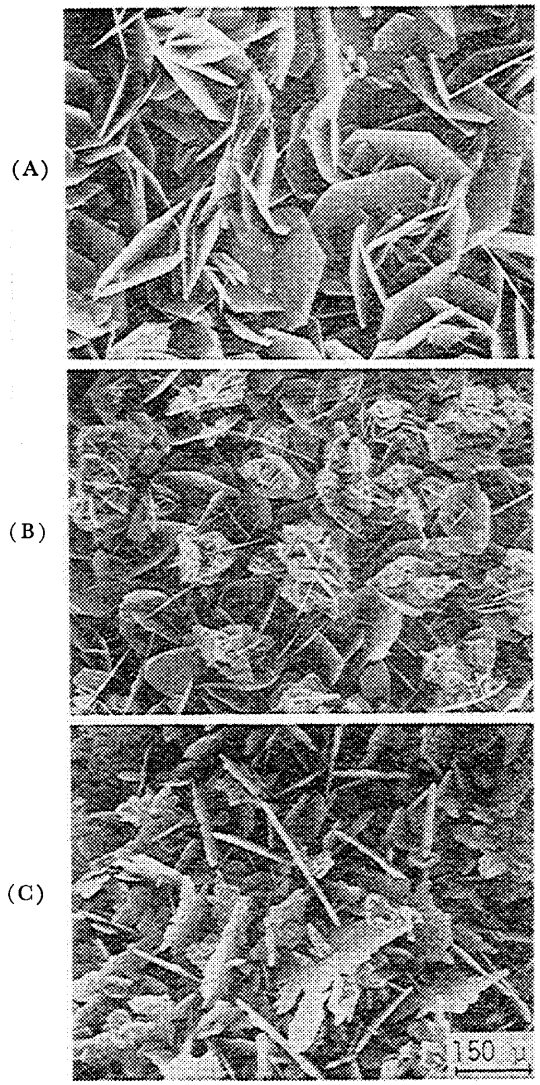

Fig. 7. Morphologies of TiS_2 crystals (2). $H_2S/(TiCl_4)$: 0.5, substrate temperature: (A) 600 °C, (B) 800 °C, (C) 1000 °C.

a constant value for the flow rate above 0.2 cm^3/s, irrespective of substrate temperature. Introduction of hydrogen resulted in negative effect on the deposition rate of titanium disulfide as shown in Fig. 5, probably due to the depression of the dissociation of hydrogen sulfide. The dissociation degree of hydrogen sulfide is estimated to be 7.4 per cent at 800 °C.[22]

Effect of Growth Time. The deposition rate of titanium disulfide became roughly constant after an induction period of 3—5 min. Hexagonal plate-like crystals of average diagonal of 2 mm having mirror faces were formed after an hour growth.

Effects of Temperature and Gas Composition on Crystal Morphology. The morphology of titanium disulfide is affected by substrate temperature and H_2S ratio as shown in Figs. 6, 7, and 8. Thin plate-like crystals up to 1 μm thick grew vertically to the surface of the substrate at 600 °C. The growth rate in direction *c* is very low as compared with that in direction *a*. However, at a low H_2S ratio such as 0.2, crystals grew appreciably in direction *c*, hexagonal crystals of 20 μm thick being obtained (Figs. 6B and 6C). Under a high H_2S ratio (Figs. 7B and 7C) or high substrate temperature (Figs. 8B and 8C) secondary deposition is apt to take place. Strotzer *et al.*[23] reported on the color-change of the Ti–S system compounds in connection with the sulfur content. The crystals grown in the present study were golden-yellow independent of the substrate temperature and gas compositions.

Effects of Temperature and Gas Composition on Crystal Compositions. X-Ray diffraction profiles of titanium sulfides grown at various temperature with the H_2S ratio kept at 0.7 are shown in Fig. 9. Peaks of titanium trisulfides (TiS_3) and sesquisulfide (Ti_3S_4) are found only on the profiles of the crystals grown below 350 °C and at 1000 °C, respectively (Figs. 9C and 9D). On the profiles of crystals grown at 400—850 °C, only the peaks of titanium disulfide are seen irrespective of the H_2S ratio (Fig. 9B).

Titanium disulfide is a well-known non-stoichiometric compound. From the results of gravimetric analysis of titanium in relation with growth temperature and H_2S ratio, the atomic ratio of sulfur to titanium (S/Ti) in crystals was determined as shown in Fig. 10. The

atomic ratio of S/Ti decreases with increase in temperature, attaining a maximum of 1.83—1.90 at *ca.* 800 °C and increasing above 800 °C, except for that of crystals grown from a gas mixture of the H_2S ratio 0.6. Crystals having a high atomic ratio of 2.07—2.09 were grown at 600 °C with H_2S ratio of 0.4—0.7. Rimmington and Balchin,[17] Jeannin,[24] and Bartran[25] reported the limit of atomic ratio of S/Ti for titanium disulfide phase as 1.96—1.89, 1.98—1.81, and 2.00—1.50, respectively. Deposition limits of the single phase of titanium disulfide are shown in relation with growth temperature and gas flow ratio in Fig. 11, in which compositions of crystals are divided into three regions according to the phase limits.[24]

The lattice parameters of titanium disulfide crystals of S/Ti of 1.98 were determined to be 3.407 Å for *a* and 5.712 Å for *c*. The former agrees with those of $TiS_{1.96\pm0.03}$.[17] However, the latter is higher than those reported by Rimmington and Balchin[17] and lower than that reported by Norrby and Franzen.[28]

Etching Patterns. A titanium disulfide crystal grown at 850 °C from a gas mixture of H_2S ratio 0.5 was etched by 3 mol/dm³ nitric acid for 5 min at room temperature. The etching pattern on a (001) face is shown in Fig. 12A. Loop or open etch-pit arrays are observed with the order of density 10^2—10^3/cm². Cross section of a plate-like crystal was polished with abrasive paper and chromium trioxide powder, and etched (Fig. 12B). As expected, a plane vertical to the *c*-plane is weak against etching, cleavages of 0.5—2 μm thick being observed.

Thermoelectric Power. The thermoelectric power of titanium disulfide crystal is shown in Fig. 13 together with that reported on the titanium sulfides. Thermoelectric power of the crystals of S/Ti ratio 2.00 and 1.89 are 35 and 28 μV/°C at 20 °C, respectively, increasing linearly with increasing temperature. The thermoelectric power of the titanium sulfides was reported by Dubrovskaya and Oranesyan[26] to be 3.4 μV/°C (TiS) and 10 μV/°C (Ti_2S_3) and McTaggart[27] to be 200 μV/°C ($TiS_{1.95}$) and 600 μV/°C (TiS_3) on the pressed samples of fine powder. Thermoelectric power of the titanium sulfides increases with increase in sulfur content irrespective of the crystallographic nature, as in the Zr–S system.[27]

Conclusion

Crystals of titanium disulfide were grown by chemical vapor deposition in an open flow system.

1) Deposition rate reached a maximum at 700—800 °C. The flow ratio $H_2S/(TiCl_4+H_2S)$ near that of reaction stoichiometry, 0.67, resulted in the maximum rate irrespective of temperature.

2) Titanium trisulfide and sesquisulfide were found among the disulfide deposits below 350 °C and at 1000 °C, respectively.

3) It was found that well-formed hexagonal crystals grow either at low temperature such as 600 °C or from a gas mixture of a 0.2 flow ratio of $H_2S/(TiCl_4+H_2S)$.

4) Atomic ratio of S/Ti in grown crystals decreased to 1.83—1.90 with increase of temperature up to 800 °C.

5) Thermoelectric power of the crystals with the S/Ti ratios 2.00 and 1.89 was determined to be 35 and 28 μV/°C at 20 °C, respectively.

Asymmetric Induction on the Reaction of Prochiral Olefins with Chloro-L-aminocarboxylato-η^2-ethyleneplatinum(II)

Yoshiro TERAI,** Hiroaki KIDO, Kazuo KASHIWABARA,*** and Kazuo SAITO*

Chemistry Department, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980

(Received May 17, 1978)

Addition of a large excess of *trans*-2-butene (tbn) or 2-methyl-2-butene (mbn) to an acetone solution of *cis*- or *trans*(*N*, ethylene)[PtCl(L-am)(C_2H_4)] (L-am, 9 kinds of L-aminocarboxylate) gave first increase and then gradual decrease in CD strength in the region $\simeq$26500 cm^{-1}. The kinetic optical yield amounted to 53% whereas that at the equilibrated state was much less (up to 27% for *cis*(*N*, olefin) complexes and 6 to 12% for trans complexes). *trans*-2-Butene gives larger yields than mbn. Kinetic analysis of the growth and decay curve of the CD strength disclosed that the first fast increase in CD reflects the greater rate of substitution of the prochiral olefins for ethylene in *S*-configuration than that in *R*-configuration. The second step seems to involve the exchange of coordinated tbn or mbn catalyzed by ethylene which was made free in the first step. The mechanism of asymmetric induction has been discussed from both steric and electronic viewpoints. Asymmetry of the coordinated nitrogen seems to give a dominating effect.

Corradini, Paiaro, and Pununzi observed asymmertic coordination of *trans*-2-butene (tbn) on the reaction between *cis*[$PtCl_2$((*S*)- or (*R*)-α-methylbenzylamine)(tbn)] and free tbn, and claimed that the selectivity is thermodynamically controlled.[1] We found that the replacement of coordinated *S,S*- or *R,R*-tbn in *trans*(*N*, olefin) [PtCl(L-pro)(*S,S*- or *R,R*-tbn[^3H])] (L-pro, L-prolinate) by free tbn in acetone takes place more easily with retention than with inversion of configuration. The stereoselectivity is considered to be caused by the steric interaction between the incoming tbn and the coordinated tbn and/or L-prolinate.[2] In order to clarify the source of such a stereoselective olefin exchange, we investigated the exchange of tbn between [$PtCl_3$(*S,S*-tbn[^3H])]$^-$ and free tbn, and found that the main source of asymmetric induction is in the interaction between the coordinated and the free tbn in the square pyramidal transition state.[3] However, this complex anion gives smaller ratio of rates of olefin exchange with retention and with inversion of the configuration than *trans*(*N*, olefin) [PtCl(L-am)(*S,S*-tbn)]. This suggests the significant role of L-aminocarboxylate ligand in the stereoselective substitution. This paper deals with the kinetics of substitution reaction of tbn and 2-methyl-2-butene(mbn) for the ethylene in *trans*- and *cis*(*N*, olefin) [PtCl(L-am)(C_2H_4)] and the accompanying thermodynamic and kinetic stereoselectivity, which is dependent on the geometrical isomerism of the complex and the variety of L-aminocarboxylates.

Experimental

Materials. All the complexes [PtCl(L-am)(ethylene)] were prepared according to previously reported methods.[4,5] The following ligands were employed; *trans*(*N*, olefin) complexes: L-am's are L-prolinate (L-pro), 4-hydroxy-L-prolinate (L-hyp), allo-4-hydroxy-L-prolinate (L-ahyp), *N*-methyl-L-prolinate (*N*-me-L-pro), *N*-methyl-4-hydroxy-L-prolinate (*N*-me-L-hyp), *N*-ethyl-L-prolinate (*N*-et-L-pro), *N*-benzyl-L-prolinate (*N*-bz-L-pro), *N*-benzyl-L-valinate (*N*-bz-L-val), L-valinate (L-val) and L-alaninate (L-ala); *cis*(*N*, olefin) complex; L-am is L-pro.

allo-4-Hydroxy-L-proline was prepared from 4-hydroxy-L-proline.[6,7] The *N*-substituted L-aminocarboxylic acids, *N*-me-L-proH, *N*-me-L-hypH, *N*-et-L-proH, *N*-bz-L-proH and *N*-bz-L-valH were synthesized by the reported methods.[8,9] The new *trans*(*N*, ethylene) complexes and their tbn and mbn derivatives containing L-ahyp, *N*-me-L-hyp, *N*-et-L-pro, *N*-bz-L-val were identified by elemental analysis of C, H, and N, and ultraviolet (UV) absorption spectra in acetonitrile (AN).

Results and Kinetic Analysis

Overall Progress of the Substitution Reaction between the Ethylene Complex and tbn. The change in CD pattern of *trans*(*N*, olefin) [PtCl(*N*-me-L-pro)(C_2H_4)] in the presence of a large excess of tbn is shown in Fig. 1. The change in CD strength at 26300 cm^{-1} is plotted against time in Fig. 2. The CD strength increases at the initial stage of the reaction to reach a maximum ($\Delta\varepsilon_{max}$) (first step). The UV absorption spectrum

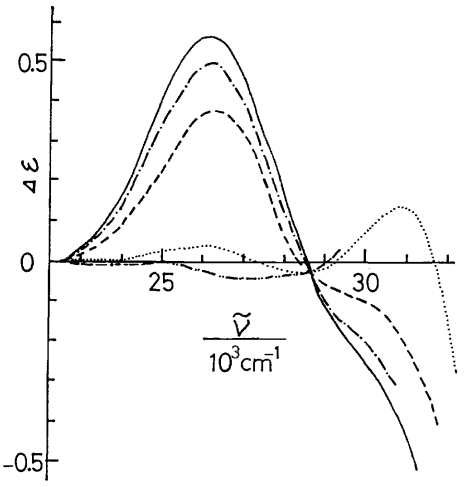

Fig. 1. Change of the CD spectrum with time on the reaction of *trans*(*N*,ethylene)[PtCl(*N*-me-L-pro)(C_2H_4)] (0.00154 mol dm^{-3}) with *trans*-2-butene (0.279 mol dm^{-3}) in acetone at −28.0 °C; dotted line: the original ethylene complex, broken line: 1 min, broken line with a dot: 2 min, solid line: 4 min, broken line with double dotts: infinite time.

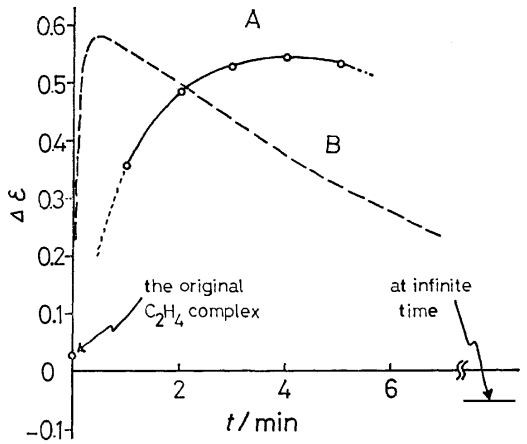

Fig. 2. Change in the CD strength with time on the reaction of *trans*(*N*,ethylene)[PtCl(*N*-me-L-pro)(C_2H_4)] with *trans*-2-butene in acetone.
A: Open circles correspond to the CD strength at the peak (26300 cm^{-1}) of the curves in Fig. 1.
B: The broken line represents the CD strength at 26300 cm^{-1} recorded continuously by the method reported in Ref. 4. ([complex]=0.00164 mol dm^{-3}, [*trans*-2-butene]=0.268 mol dm^{-3}, at 8.0 °C).

in the 32000—45000 cm^{-1} region of the original ethylene complex slightly changes simultaneously and approaches that of the tbn complex. This step should involve a stereoselective formation of the *S,S*-tbn complex by the substitution of tbn for the coordinated ethylene shown by

$$[PtCl(L\text{-am})(C_2H_4)] + tbn \rightarrow [PtCl(L\text{-am})(tbn)] + C_2H_4. \quad (1)$$

By the end of the first step, almost all the ethylene should have been replaced by tbn (*vide infra*). In the second step, the CD strength at 26300 cm^{-1} gradually decreases, while the UV absorption spectrum remains unchanged. The first step proceeds faster than the second step, and their kinetics can be studied separately. All the other ethylene complexes gave similar changes in CD and UV spectra except that for L-ala and L-val complexes, which gave change in the UV pattern but not in CD strength.

The apparent optical yields in the first step (p_{max}) were calculated by[10]

$$p_{max} = (\Delta\varepsilon_{max}-\Delta\varepsilon_{vic})/(\Delta\varepsilon_{resolv}-\Delta\varepsilon_{vic}), \quad (2)$$

where $\Delta\varepsilon_{resolv}$ is the CD peak strength in the region 26000—27000 cm^{-1} of the resolved tbn complex, and $\Delta\varepsilon_{vic}$ the CD strength due to the vicinal effect of L-aminocarboxylate (L-am), which is represented by the CD strength of the ethylene complex at the same wave number. The p_{max} values for a variety of L-aminocarboxylate complexes are shown in Table 1.

The second step gives no change in UV absorption spectrum, and hence is considered to be the replacement of asymmetrically coordinated tbn by free tbn toward a thermodynamically equilibrated state:

$$[PtCl(L\text{-am})(S,S\text{-tbn})] + tbn \rightarrow [PtCl(L\text{-am})(R,R\text{-tbn})] + tbn. \quad (3)$$

The optical yields at the equilibrium were calculated by

$$p_{eq} = (\Delta\varepsilon_{eq}-\Delta\varepsilon_{vic})/(\Delta\varepsilon_{resolv}-\Delta\varepsilon_{vic}), \quad (4)$$

where $\Delta\varepsilon_{eq}$ is the CD strength in the equilibrated state. The p_{eq} values are given in Table 1.

When mbn was used in place of tbn, similar changes in UV and CD spectra were observed. Equations 2[9] and 4 are applicable to the mbn complexes, the optical yields being given in Table 1.

Kinetic Analysis of the First Step. The increase in the CD strength ($\Delta\varepsilon_t$) at $\bar{\nu}_{max}$ (Table 1) in the first step obeyed the following first order kinetic formula 5 for all the complexes,

$$k_{obsd,i} = -\ln[(\Delta\varepsilon_t-\Delta\varepsilon_{max})/(\Delta\varepsilon_1-\Delta\varepsilon_{max})]/t, \quad (5)$$

where $\Delta\varepsilon_1$ is the initial CD strength in this step. $k_{obsd,i}$ increases linearly with increase in free tbn concentration to give

$$Rate_i = k_{obsd,i}[complex] = k_{2,i}[tbn][complex]. \quad (6)$$

The $k_{2,i}$ values are given in Table 2. The Reaction (1) should consist of two reactions,

$$[PtCl(L\text{-am})(C_2H_4)] + tbn \xrightarrow[k_{2[ES]}]{} [PtCl(L\text{-am})(S,S\text{-tbn})] + C_2H_4$$
$$\xrightarrow[k_{2[ER]}]{} [PtCl(L\text{-am})(R,R\text{-tbn})] + C_2H_4. \quad (7)$$

The relation between $k_{2[ES]}$, $k_{2[ER]}$, the optical yield p_{max} and $k_{2,i}$ is given by

$$(1+p_{max})/(1-p_{max}) = k_{2[ES]}/k_{2[ES]}, \quad (8)$$

$$k_{2,i} = k_{2[ES]} - k_{[ER]}. \quad (9)$$

The formation rate constants of the *S,S*- and *R,R*-tbn complexes from the ethylene complex, $k_{2[ER]}$ and $k_{2[ER]}$, can be calculated by Eqs. 8 and 9. (Table 2).

Kinetic Analysis of the Second Step. The rate of decrease in the CD strength ($\Delta\varepsilon_t$) at time t is expressed by the first order kinetic formula

$$k_{obsd,d} = -\ln[(\Delta\varepsilon_t-\Delta\varepsilon_{eq})/(\Delta\varepsilon_2-\Delta\varepsilon_{eq})]/t, \quad (10)$$

where $\Delta\varepsilon_2$ denotes the initial CD strength in this step. The $k_{obsd,d}$ is independent of the concentration of free tbn, but dependent on that of the complex:

$$k_{obsd,d} = k_{2,d}[complex]. \quad (11)$$

Since $k_{obsd,d}$ was obtained by the first order kinetic treatment with respect to the complex concentration, the rate of decrease in the CD strength is apparently proportional to the square of platinum(II) complex concentration:

$$Rate_d = k_{2,d}[complex]^2. \quad (12)$$

Such a kinetic formula is unusual for the substitution of a square planar complex, but can be accounted for by considering the catalytic action of ethylene liberated by Eq. 1 (*vide infra*). The concentration of free ethylene in the presence of a large excess of tbn should be equal to that of the initial complex, so that Eq. 12 can be rewritten as

$$Rate_d = k_{2,d}[complex][C_2H_4]. \quad (13)$$

In order to verify this, addition of a known amount of ethylene is desirable, but not practicable. Alternatively various amounts of *trans*(*N*, olefin) [PtCl(L-ala)-

TABLE 1. KINETIC AND THERMODYNANIC OPTICAL YIELDS OF *trans*(*N*, olefin)[PtCl(L-am)(olefin)] ON THE REACTION OF THE CORRESPONDING ETHYLENE COMPLEX WITH OLEFINS, ALONG WITH CIRCULAR DICHROISM DATA FOR THE COMPLEXES

a) $\Delta\varepsilon$ values for the resolved olefin complexes at $\bar{\nu}_{max}$ in acetone. b) $\Delta\varepsilon$ values for the ethylene complexes at $\bar{\nu}_{max}$ in acetone. c) In acetone at 8.0 °C unless otherwise stated; DCM: in dichloromethane, AN: in acetonitrile, MA: in L-menthylacetate; figures denote temperature in °C. d) From Eq. 2, always formation of (*S*,*S*)-*trans*-2-butene and (*S*)-2-methyl-2-butene complexes is preferred. e) From Eq. 4, *S* and *R* in parentheses indicate the configuration of olefin in the preferred diastereomer at the equilibrium. f) *cis*(*N*, olefin) isomers. g) Ref. 4. h) For the *R*,*R*-isomers; the other for the (*S*,*S*)-*trans*-2-butene or (*S*)-2-methyl-2-butene isomers. i) In the presence of *trans*-(*N*, ethylene) [PtCl(L-ala)(C_2H_4)] (see the text). j) Very sparingly soluble in acetone, and only an appoximate value is given. k) Not observed.

(C_2H_4)] were added to mixtures of *trans*(*N*, olefin)-[PtCl(*N*-bz-L-val)(C_2H_4)] and tbn in acetone at 8.0 °C, and the changes in the CD strength at 26300 cm^{-1} with time were measured. The rate of decrease in the CD strength in the second step is represented by

$$Rate_d = k_{2,d}[N\text{-bz-L-val complex}]([N\text{-bz-L-val complex}] + [\text{L-ala complex}]). \quad (14)$$

The L-ala complex undergoes rapid replacement of ethylene by free tbn without stereoselectivity (*cf.* Table 2). Thus the substrate complex for giving the CD change should be the *N*-bz-L-val complex alone. Under the given experimental conditions, practically all the ethylene should have been liberated from both the complexes during the first step of the reaction, and should be present as free ethylene in the reaction mixture. Thus, the term in parentheses in Eq. 14 is represented by the ethylene concentration [C_2H_4], so that Eq. 13 holds for this system. The $k_{2,d}$ values obtained from Eqs. 12 and 14 are 1.09 and 1.15 s^{-1}-mol^{-1} dm^3, respectively, for the *N*-bz-L-val complex at 8 °C, indicating the legitimacy of such a kinetic treatment.

The $k_{2,d}$ values can be compared to the k_2 values for the pure epimerization of *trans*(*N*, olefin) [PtCl-(L-am) (*S*,*S*-tbn)] in the presence of tbn under similar conditions.[4] The larger values for $k_{2,d}$ than for k_2 may be interpreted by considering the catalytic action of ethylene as in the following.

Catalytic Action of Ethylene in the Second Step. Less bulky olefins give larger values of k_2 on the substitution for tbn in *trans*(*N*, olefin) [PtCl(L-pro)(tbn)].[2] Hence, ethylene should be a more effective nucleophile than tbn towards [PtCl(L-am)(*S*,*S*- or *R*,*R*-tbn)], and the contribution of direct substitution of tbn can be ignored. Individual second order rate constants for the ethylene-

catalyzed epimerization

$$\begin{array}{l}[PtCl(L\text{-am})(S,S\text{-tbn})] + C_2H_4 \\ \qquad\qquad \nwarrow\!\searrow\ k_{2[SE]} \\ \qquad k_{2[ES]}\ \searrow\!\nwarrow \qquad [PtCl[(L\text{-am})(C_2H_4)] \\ \qquad k_{2[RE]}\ \nearrow\!\swarrow\ k_{2[ER]} \qquad\qquad + \text{tbn}, \quad (15) \\ [PtCl(L\text{-am})(R,R\text{-tbn})] + C_2H_4\end{array}$$

are written as follows:

$$d[S]/dt = k_{2[ES]}[E][\text{tbn}] - k_{2[SE]}[S][C_2H_4], \quad (16)$$

$$d[E]/dt = k_{2[SE]}[S][C_2H_4] - (k_{2[ES]}+k_{2[ER]})[E][\text{tbn}] + k_{2[RE]}[R][C_2H_4], \quad (17)$$

$$d[R]/dt = k_{2[ER]}[E][\text{tbn}] - k_{2[RE]}[R][C_2H_4], \quad (18)$$

$$[C] = [S] + [E] + [R], \quad (19)$$

where [E], [S], and [R] represent the concentrations of the ethylene, *S,S*-tbn and *R,R*-tbn complexes containing a given L-am, respectively; [C] is their total. Under the present experimental conditions where the free tbn overwhelms the initial ethylene complex and the first step has reached completion, the ethylene complex should be present only as an intermediate in Eq. 15, and a steady state treatment can be applied to Eq. 17, *i.e.* $d[E]/dt=0$. Hence the rate of decrease of [S] can be written by

$$-d[S]/dt = (k_{2[SE]}k_{2[ER]}[S] - k_{2[RE]}k_{2[ES]}[R]) \times [C_2H_4]/(k_{2[ES]}+k_{2[ER]}). \quad (20)$$

Integrating, we get

$$-\ln\left\{\frac{[S]-(k_{2[RE]}k_{2[ES]}[R]/k_{2[SE]}k_{2[ER]})}{[S]+[R]}\right\}\Big/t = (k_{2[SE]}k_{2[ER]} + k_{2[RE]}k_{2[ES]})[C_2H_4]/(k_{2[ES]}+k_{2[ER]}) \quad (21)$$

In the equilibrated state, the left side of Eq. 20 should be zero, and we obtain

$$K_{RS} = [S]_\infty/[R]_\infty = k_{2[RE]}k_{2[ES]}/k_{2[SE]}k_{2[ER]}. \quad (22)$$

Expressing [S], [R], $[S]_\infty$, and $[R]_\infty$ in Eqs. 21 and 22 in terms of $\Delta\varepsilon_t$, $\Delta\varepsilon_2$, and $\Delta\varepsilon_\infty$, we have

$$-\ln\{(\Delta\varepsilon_t-\Delta\varepsilon_\infty)/(\Delta\varepsilon_2-\Delta\varepsilon_\infty)\}/t = (k_{2[SE]}k_{2[ER]}+k_{2[RE]}k_{2[ES]})[C_2H_4]/(k_{2[ES]}k_{2[ER]}). \quad (23)$$

This corresponds to the experimental kinetic formula Eq. 13, $k_{2,d}$ being written as

$$k_{2,d} = (k_{2[SE]}k_{2[ER]}+k_{2[RE]}k_{2[ES]})/(k_{2[ES]}/k_{2[ER]}). \quad (24)$$

From Eqs. 8, 16, 22, and 24, individual rate constants were calculated by use of the following equations:

$$k_{2[SE]} = (1-p_{eq})k_{2,d}/(1-p_{max}), \quad (25)$$

$$k_{2[RE]} = (1+p_{eq})k_{2,d}/(1+p_{max}). \quad (26)$$

The data for tbn and mbn complexes are given in Table 2.

Discussion

Stereoselectivity in the Equilibrium State. The p_{eq} value for the tbn complexes in the equilibrium state (end point of the second step) can be reckoned as to

reflect the difference of stability between the *S,S*- and the *R,R*-tbn complexes. The stability should be directly related to the structure of both isomers. Table 1 indicates that the *cis*(*N*, olefin) complex gives a rather large negative p_{eq}. Molecular models of the two optical isomers of *cis*(*N*, olefin) [PtCl(L-pro)(tbn)] suggest that the coordinated *S,S*-tbn is subject to a larger steric hindrance than *R,R*-tbn is, giving a large negative p_{eq} value (favorable for *R,R*-configuration).

trans(*N*, tbn)-Complexes with various L-aminocarboxylates containing asymmetric nitrogens give larger $|p_{eq}|$ values than those without asymmetric nitrogens. Molecular model studies cannot account for such a selectivity. An indirect influence coming from solvent molecules does not seem significant, since similar optical yields were observed for the *N*-bz-L-pro and *N*-bz-L-val complex in different solvents (Table 1). There can be an electronic effect from the asymmetric nitrogen to the coordinated tbn through platinum(II) d-orbitals. We studied the CD spectra of *trans*(*N*, olefin)[PtCl(L-am)(*S,S*-tbn)], and suggested an electronic perturbation from asymmetric nitrogen upon coordinated tbn.[11] However, the L-pro, L-hyp, and L-ahyp complexes give positive, and the *N*-me-L-pro, *N*-me-L-hyp and *N*-bz-L-val complexes negative signs. The reason for such a difference cannot be understood at the present stage.

A similar trend in p_{eq} values is observed for the mbn complexes, the signs being the same as those for the tbn complexes. However, the figures for the mbn complexes are smaller than those for the tbn complexes with given L-aminocarboxylates.

Asymmetric Induction on the Substitution of tbn. The *S,S*-tbn complexes are formed from the corresponding ethylene complexes more readily than the *R,R*-tbn complexes. The extent can be represented by the p_{max} values. The complexes containing asymmetric nitrogens give p_{max} values from 20 to 55%, while the L-ala and L-val complexes without asymmetric nitrogens fail to give appreciable optical yields. Thus the asymmetric induction should be governed by the symmetry of the coordinated amino nitrogen. The energy diagram for the forward process of Eq. 7 can be written as shown in Fig. 3. The $\delta\Delta G^*$ is expressed by

$$-\delta\Delta G^* = RT\ln[(1+p_{max})/(1-p_{max})] = RT\ln(k_{2[ES]}/k_{2[ER]}). \quad (29)$$

The sign of p_{max} is not always equal to that of p_{eq} for a given complex. The sequence of magnitude of p_{max}'s of the complexes containing various aminocarboxylates is neither parallel to that of p_{eq}'s. The difference between $k_{2[ES]}$ and $k_{2[ER]}$ for a given complex cannot be interpreted by the difference in stability between the *S,S*- and *R,R*-tbn complexes. The transition state on the substitution reaction should be considered.

Substitution reactions of square-planar complexes are understood to proceed *via* five coordinated transition states. The kinetic ease of formation of the *S,S*- and *R,R*-tbn complexes should reflect the stability of the transition state. Two possible structures are considered for the five coordinated transition state.[12] Whenever a trigonal bipyramidal structure is formed as intermediate or transition state, the ligand to be replaced is reckoned to be located at the basal position. In the present complex either amino nitrogen or carboxyl oxygen occupies the basal position depending on the trans or cis isomerism of the original complex, respectively. The mutual location between the incoming tbn, which always occupies one of the basal positions, and the asymmetric nitrogen, which should play the most important role in determining the selectivity, should differ depending on the geometrical isomerism. In the square pyramidal structure, on the other hand, the mutual locations between nucleophilic tbn and asymmetric nitrogen do not differ much for both geometrical isomers. From our experimental results, however, the p_{max} values are almost equal for the formation of *trans* and *cis*(*N*, olefin) [PtCl(L-pro)(*S,S*-tbn)], indicating that the transition state would be more appropriately apporoximated by the square pyramidal structure. This interpretation is in line with the suggestion made for the isotopic exchange between [$PtCl_3$(tbn[^3H])] and tbn.[3]

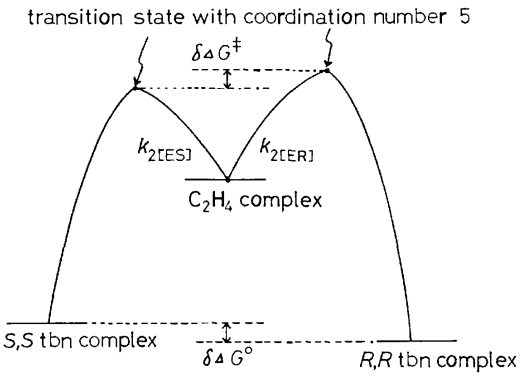

Fig. 3. Schematic diagram of the change in Gibbs free energy on the reaction of *trans*(*N*,ethylene)[PtCl(L-am)(C_2H_4)] with prochiral olefins.

Detailed structure of the transition state cannot be discussed at the present stage, but the side from which the incoming olefin approaches platinum(II) plane might be as follows. The substituent on the amino nitrogen in the complex extends to the opposite side of the square plane to that where the pyrrolidine ring of L-prolinate does. The p_{max} values depend on the variety of the *N*-substituent, but the location of hydroxyl group on the 4-position of the pyrrolidine ring (L-hyp and L-ahyp) affects neither the p_{max} nor the rate constant. Thus the incoming tbn will approach platinum(II) from the opposite side to that occupied by the pyrrolidine. The bulkiness of the substituent on amino nitrogen of the aminocarboxylate affects the p_{max} in different ways depending on the kind of aminocarboxylate; *e.g.* introduction of benzyl group on L-valinate increases whereas that on L-prolinate decreases the p_{max}. Studies with molecular models suggest that the approach of tbn to the platinum(II) bound to *N*-substituted aminocarboxylate would be easier in *S,S*-configuration than in *R,R*-configuration. More than one factor should affect the p_{max} and $k_{2,d}$ values.

Asymmetric Induction on the Reaction with mbn. The p_{max} values for the formation of *S*-mbn complexes are

smaller than those of tbn complexes (Table 1). The transition state for the reactions with mbn should be similar to those with tbn. Free mbn has two methyl groups on one side of C=C double bond axis, and one methyl group and methine hydrogen on the other side. When the former side is directed to the coordinated L-amino nitrogen in the transition state, no difference is expected in the steric interactions, regardless of the orientation of the methine hydrogen. Such an attack does not result in a stereoselective substitution. When the other side faces the asymmetric nitrogen, a stereoselective formation can be expected to give p_{max} values similar to those on the attack of tbn. Participation of these two different transition states should be responsible for the smaller values of p_{max} on the substitution of mbn than those on reaction with tbn.

Comparison of Overall Rate Constants and the Contribution by the Substituents of the Coordinated L-Aminocarboxylates. Table 2 indicates that the individual rate constants, $k_{2[ES]}$, $k_{2[ER]}$, $k_{2[SE]}$, and $k_{2[RE]}$ are largely dependent on the variety of L-aminocarboxylate. However, an overall trend is obvious; *i.e.* the second order rate constants decrease in the following sequence, which is equal to that for the exchange of tbn in *trans*(*N*, olefin) [PtCl(L-am)(*S*,*S*-tbn)].[4]

L-hyp > L-pro > L-ahyp > *N*-me-L-hyp > *N*-bz-L-val >

N-me-L-pro > *cis*(*N*, olefin) L-pro > *N*-bz-L-pro

Introduction of trans OH (L-hyp) on 4-position of pyrrolidine ring increases whereas that of cis OH(L-ahyp) decreases the k_2 values both for L-pro and *N*-me-L-pro complexes. However, this effect is smaller than that of the introduction of *N*-substituents on the L-aminocarboxylates. Thus, the reaction rates of individual courses of olefin exchange is largely controlled by the moiety around amino nitrogen, and to a less extent by the substituents on the 4-position of the pyrrolidine ring. Such a trend seems to be interpreted by the stereochemistry of the transition state mentioned above.

Structural Study of Optical Resolution. IV-b.** The Crystal Structure of $(+)_{589}$-Oxalatobis(ethylenediamine)cobalt(III) Hydrogen-*d*-tartrate Monohydrate and Its Thermal Behavior

Masahiro KURAMOTO, Yoshihiko KUSHI, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Hiroshima 730

(Received May 24, 1978)

The crystal structure of $(+)_{589}$-oxalatobis(ethylenediamine)cobalt(III) hydrogen-*d*-tartrate monohydrate, $(+)_{589}$-[Co(ox)en_2]H-*d*-tart·H_2O, has been determined by three-dimensional X-ray analysis. The red crystals are monoclinic, space group $P2_1$, with two molecules in a unit cell of dimensions $a=8.27(1)$, $b=14.60(1)$, $c=7.02(1)$ Å, and $\beta=104.8(2)°$. The structure was solved by Patterson and Fourier methods, and refined by anisotropic block-diagonal least-squares to a conventional R-value of 0.100 for the 1265 independent reflections observed. In the diastereoisomer, the optically active complex cation is locked by the $\{H\text{-}d\text{-tart}\}_\infty$ units of the right-handed spiral chains formed along the b-axis. The TG and DSC measurements have been carried out on both less- and more-soluble diastereoisomers of oxalatobis(ethylenediamine)cobalt(III) hydrogen-*d*-tartrate; the difference of their thermal behavior is discussed.

As parts of our structural studies of optical resolution,[1-6] we reported the structures of several diastereoisomers in crystals containing *d*-tartrate anion (*d*-tart^{2-}; *d*-$C_4H_4O_6^{2-}$)[2-4] as the resolving agent. In these compounds, "face-to-face" close contacts between a triangular face of the octahedral complex cation and the *d*-tart^{2-} anion were found.[2-4] The results seem to support the famous "key and lock" hypothesis of Fischer for the diastereomeric discrimination.[7]

Recently, optical resolutions of several complex cations were effected by using hydrogen-*d*-tartrate (H-*d*-tart$^-$; *d*-$C_4H_5O_6^-$) anion as a resolving agent.[8-12] Among them, a simple one-step resolution which provides both optical isomers of oxalatobis(ethylenediamine)cobalt(III) cation, $[Co(ox)en_2]^+$, in high yield was established.[10]

We thought it would be worthwhile to compare the packing manner of the H-*d*-tart$^-$ anion in the above-mentioned diastereoisomers with those of the *d*-tart^{2-} anion in the previous studies. Thus, three-dimensional X-ray analysis of the less-soluble $(+)_{589}$-[Co(ox)en_2]H-*d*-tart·H_2O has been undertaken.

Besides the single crystals of the less-soluble diastereoisomer, the single crystals of the more-soluble isomer, $(-)_{589}$-[Co(ox)en_2]H-*d*-tart·$2H_2O$, could also be obtained, and the thermal behavior of these two diastereoisomers has been examined.

A preliminary communication of this study has already been published.[1]

Experimental

Preparation of Compound. *(a) $(+)_{589}$-[Co(ox)en_2] H-d-tart·H_2O*: The less-soluble diastereoisomer was prepared by the method of Jordan *et al.*[10] Recrystallization from hot aqueous solution of the diastereoisomer gave red crystals. The crystals have a trapezoidal rod shape. Found: C, 27.40; H, 5.32; N, 12.58%. Calcd for $(+)_{589}$-[Co(ox)en_2]H-*d*-tart·H_2O: C, 27.56; H, 5.30; N, 12.90%. The optical purity of these crystals was also checked by the CD-measurement(a JASCO Model J-40CS spectrophotometer with 1 cm cell. ($\Delta\varepsilon_{520}=+2.70$).

(b) $(-)_{589}$-[Co(ox)en_2]H-d-tart·$2H_2O$: After removal of the precipitated crystals of the $(+)_{589}$-diastereoisomer,[10] the filtrate solution was evaporated for 2—3 days at room temperature. The filtration of the $(+)_{589}$-diastereoisomer was continued. This step was repeated three times. As a result, the red crystals of more-soluble $(-)_{589}$-diastereoisomeric salt dihydrate were separated out. The crystals have an octagonal rod shape. Found: C, 26.65; H, 5.64; N, 12.59%. Calcd for $(-)_{589}$-[Co(ox)en_2]H-*d*-tart·$2H_2O$: C, 26.55; H, 5.57; N, 12.39%. The optical purity of these crystals was also checked by the CD-measurement ($\Delta\varepsilon_{523}=-2.18$).

X-Ray Data Measurement. *(a) The Less-soluble Diastereoisomer*: Weissenberg photographs indicated a monoclinic unit cell with systematic extinctions for $0k0$, $k=2n+1$. Of the two possible space groups, $P2_1$ and $P2_1/m$, the latter was eliminated because of the optical activity of the compound. The unit cell dimensions were determined by the least-squares refinement of the $hk0$, $h0l$, and $0kl$ reflection data recorded on Weissenberg photographs. The sodium chloride diffraction lines were superimposed on the films for calibration. The crystal data are as follows: monoclinic, space group $P2_1$, $a=8.27(1)$, $b=14.60(1)$, $c=7.02(1)$ Å, $\beta=104.8(2)°$, $D_m=1.74$ g/cm^3 (by flotation in chloroform-bromoform mixture), $Z=2$, and $D_c=1.76$ g/cm^3.

A crystal 0.80 mm long with a cross-sectional area of (0.40×0.35) mm^2 was selected for obtaining the $hk0$—$hk5$ intensity data with Ni $K\alpha$ radiation, using the multiple-film equi-inclination Weissenberg technique. Another crystal, 0.25 mm long with (0.25×0.38) mm^2 cross-sectional area, was used to obtain the intensity data $0kl$—$2kl$. The intensities were estimated visually with a calibrated intensity scale. A total of 1318 independent reflections were collected. Among them 1265 reflections were observed ($|F_o|>0$) and used for the structure determination. Lorentz, polarization, and spot-shape corrections were applied in the usual manner; corrections for absorption were not made since the value of linear absorption coefficient, μ(Ni $K\alpha$), was 26.7 cm^{-1}.

(b) The More-soluble Diastereoisomer: The crystal data of the more-soluble diastereoisomer were determined similarly. They are as follows: orthorhombic, space group $P2_12_12$, $a=16.56(1)$, $b=14.14(1)$, $c=7.39(1)$ Å, $D_m=1.72$ g/cm^3, $Z=4$, and $D_c=1.74$ g/cm^3.

Thermogravimetric Analysis(TG). TG data were obtained by using a Rigaku Thermal Analyzer Model 8005. A heating rate of 3 °C/min and a static air atmosphere were employed and 9.36—9.71 mg samples were used in each run.

Differential Scanning Calorimetry(DSC). A Rigaku Differential Scanning Calorimeter(Model-8055Cl) was used to

measure the DSC curves. In order to determine the ΔH values of dissociation of the water of crystallization for both diastereoisomers, the instrument was calibrated using the ΔH values of fusion of pure indium, tin, and lead metals as standards. Weights of samples were 8.03 to 13.1 mg. A heating rate of 10 °C/min was used in each run. The dry nitrogen gas(25 ml/min) was used as a furnace atmosphere.

Determination and Refinement of Crystal Structure

The structure was solved by the heavy-atom method. The position of the cobalt atom was determined from the three-dimensional Patterson map. The subsequent Fourier synthesis revealed the positions of all the non-hydrogen atoms. Refinement employing these atomic positions with isotropic thermal parameters converged to a conventional R factor of 0.132 for the 1265 observed reflections, where the R value is $\Sigma||F_o|-|F_c||/\Sigma|F_o|$.

Hydrogen atom co-ordinates, excluding the water molecule and the glycolic hydroxyl and carboxyl groups of H-*d*-tart anion, were calculated (C–H 1.08, N–H 1.00 Å) assuming tetrahedral angles at carbon and nitrogen atoms. Refinement with anisotropic temperature factors for all the non-hydrogen atoms and with fixed hydrogen atom contributions(the isotropic temperature factor $B=3.0$ Å^2 was used) was continued. After four cycles an R value of 0.100 was obtained and the refinement was terminated. The quantity minimized was $w(|F_o|-k|F_c|)^2$ and Cruickshank's weighting scheme[13] was used, where $w=1/(a+|F_o|+b|F_o|^2)$ with $a=5.80$ and $b=0.037$. The atomic scattering factors from the International Tables[14] were used. The dispersion effects were neglected.

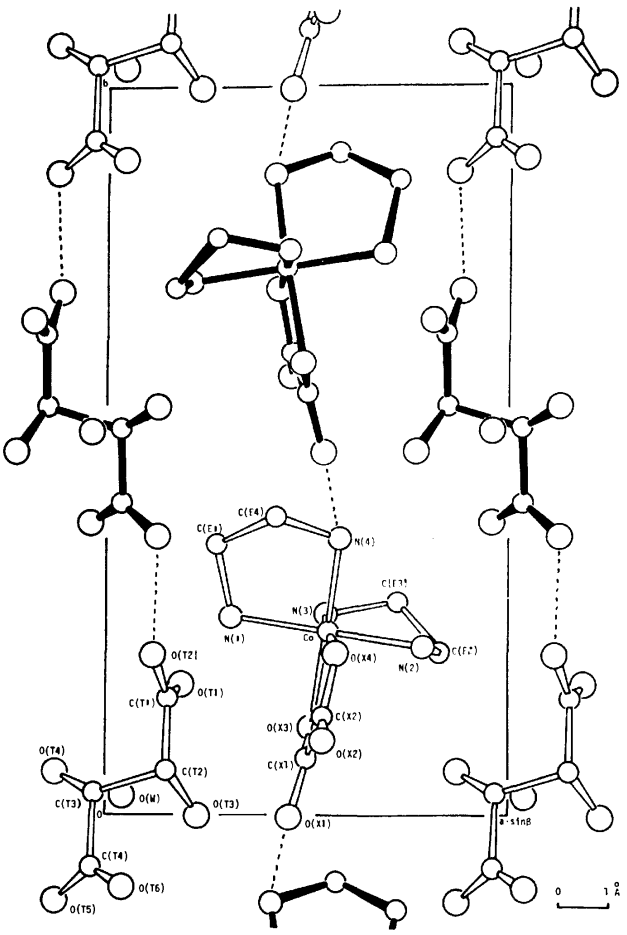

Fig. 1. A perspective drawing of the contents of the unit cell viewed along the c-axis.

All the computations were carried out by a HITAC-8700 computer at the Hiroshima University Computer Center. The computer programs used were FOUR-2/M(Fourier synthesis)[15] and HBLS-IV(Least-squares calculation) with a slight modification.[16]

The final atomic parameters and temperature factors(with their estimated standard deviations) are listed in Tables 1 and 2. Complete lists of the $10F_o$ and $10F_c$ values and the final atomic parameters of the hydrogen atoms have been preserved by the Chemical Society of Japan (Document No. 7838).

Results and Discussion

The crytsal structure consists of discrete $(+)_{589}$-$[Co(ox)en_2]^+$ cations, H-*d*-tart anions, and water molecules. Figures 1 and 2 show the projections of the crystal structure along the c- and b-axis, respectively. Bond distances and angles within the complex cation and the H-*d*-tart anion are listed in Table 3. The water molecules exist around the twofold screw axis at (0, y, 1/2). Each complex cation is surrounded by eight H-*d*-tart anions in a deformed cubic environment.

within the complex cation are in good agreement with those in the previous studies.[17,18] The absolute configuration of the complex cation was assigned as *Λ*-*δλ* for the $(+)_{589}$-$[Co(ox)en_2]^+$ cation, based on the H-$(+)_{589}$-tartrate anion as an internal reference.[19] Therefore, the geometry of the complex cation is the mirror image of those reported by Aoki *et al.*[17] and Toriumi *et al.*[18]

Recently, it has been reported that, in the $[M(en)_3]^{3+}$ complex cations, the *lel-lel-ob* conformation of three ethylenediamine molecules is the most stable form.[20] Three independent crystal structure analyses are available at present for the $[Co(ox)en_2]^+$ cation, including the present result.[17,18] If these structures were projected down the quasi-threefold axis of the complex cation, a *lel-ob* conformation of the two ethylenediamine molecules was found in every case, though the sizes of the counter anions(Br^-,[17] $(+)_{589}$-$[Co(CN)_2(mal)(NH_3)_2]^-$,[18] and H-*d*-tart$^-$) vary considerably. These results suggest that, in the $[Co(ox)en_2]^+$ cation, the *lel-ob* conformation is the most stable form.

Anion Geometry. The projected sketch of the H-*d*-tart anion is illustrated in Figs. 1 and 2. The O(T1)C(T1)O(T2) group with bond distances C(T1)–O(T1)(1.21 Å) and C(T1)–O(T2)(1.29 Å) and with bond angles O(T1)–C(T1)–C(T2)(122°) and O(T2)–C(T1)–C(T2)(112°) is asymmetric with regard to the C(T1)–C(T2) axis, and obviously this group is considered to be the non-ionized side of the H-*d*-tart anion. In contrast, another O(T5)C(T4)O(T6) group with distances 1.25 and 1.24 Å and with angles 115 and 118° is considered to be the ionized side. These bond distances and angles are in accordance with the previously reported values in H-*d*-tart anions.[19,21–23] Additionally, a short intermolecular distance, O(T2)···O(T5)′ 2.44 Å, was observed. Therefore, the hydrogen atom on the non-symmetrical carboxyl group is possibly bound to O(T2).

The planes including tht five non-hydrogen atoms of each α-hydroxycarboxylate moiety are approximately coplanar. The equations of the least-squares planes are expressed by $-0.840x-0.153y-0.520z+3.464=0$ for the [C(T1), C(T2), O(T1), O(T2), O(T3)] plane and by $0.920x-0.150y-0.361z+4.498=0$ for the [C(T3), C(T4), O(T4), O(T5), O(T6)] plane respectively. The angle between the two planes is slightly less than the corresponding angles of H-*d*-tart anions in other crystals (55.8 *vs.* 62.0,[19] 58.9,[21] 68.7,[22] and 72,1°[23]).

Crystal Packing. In the crystal, H-*d*-tart anions are arranged to make a specific chain structure along the b-axis; they are linked to each other through the hydrogen bonding as shown in Fig. 1. The hydrogen bond distance O(T2)···O(T5) ($-x$, $1/2+y$, $2-z$) is 2.44 Å. This hydrogen bond distance is slightly shorter than those of (−)-adrenaline hydrogen-*d*-tartrate,[21] (+)-[(−)-1-methyl-3-benzoylpiperidinium hydrogen-*d*-tartrate]H_2O,[22] and (−)-[(−)-1-methyl-3-ethyl-3-benzoylpiperidinium hydrogen-*d*-tartrate][23] (2.49, 2.63, and 2.49 Å respectively).

Along the b-axis, there is another chain of complex

cations, which are also joined by the hydrogen bond; N(4)···O(X1)($1-x$, $1/2+y$, $1-z$) 2.92 Å. Both chains have the right-handed twofold screw symmetry along the b-axis, as is shown in Fig. 2. Besides, these screw chains are mutually in contact with the following short distances: O(T1)···N(1) 2.91, O(T1)···C(X2) 2.94, O(T1)···O(X2) 3.10, O(T3)···O(X1) 3.01, O(T3)···O(X2) 2.90, O(T4)($1+x$, y, z)···N(2) 2.97, O(T4)($1+x$, y, z)···C(X2) 3.06, O(T4)($1+x$, y, z)···C(X1) 3.02, O(T6)($1-x$, $1/2+y$, $2-z$)···N(2) 2.89, and O(T6)($1-x$, $1/2+y$, $2-z$)···N(4) 3.00 Å.

Table 4. Intermolecular distances($\leq$3.25 Å)

C(X2)···O(T4)^{II}	3.06	—	—
O(T2)···O(T5)^{VI}	2.44[a]	—	—
O(W)···O(T1)	3.10	—	—
O(W)···O(T3)	3.03[a]	—	—
O(W)···O(T4)	2.84[a]	—	—
O(W)···O(T6)^{I}	2.81[a]	—	—

Roman numerals as superscripts refer to the following equivalent positions relative to the reference molecule at x, y, z:

I(x, y, $-1+z$), II($1+x$, y, z)
III($1-x$, $1/2+y$, $2-z$), IV($1-x$, $1/2+y$, $1-z$)
V(x, y, $1+z$), VI($-x$, $1/2+y$, $2-z$)

a) Possible hydrogen bonds.

Moreover, along the c-axis, adjacent H-*d*-tart chains are linked by the water molecules with the hydrogen bond distances; O(W)···O(T1) 3.10, O(W)···O(T3) 3.03, O(W)···O(T4) 2.84, and O(W)···O(T6)(x, y, $-1+z$) 2.81 Å. Thus around the water molecule a distorted tetrahedral environment is formed by these four oxygen atoms, and this water molecule has no short contact with the complex cation. Selected intermolecular bond distances and angles are summarized in Table 4.

Difference between d-*Tart*$^{2-}$ *and H-*d*-tart*$^{-}$ *Systems.* Figure 3 shows the arrangement of the $(+)_{589}$-[Co(ox)en_2]$^{+}$ cation and the H-*d*-tart anions projected down the quasi-threefold axis of the complex cation. The adjacent distances between the complex cation and H-*d*-tart anion are: N(1)···O(T2)(x, y, $-1+z$) 3.12, N(2)···O(T6)′($1-x$, $1/2+y$, $2-z$) 2.89, N(4)···O(T6)′($1-x$, $1/2+y$, $2-z$) 3.00, and N(4)···O(T3)′($1-x$, $1/2+y$, $2-z$) 3.24 Å. In this case, there-

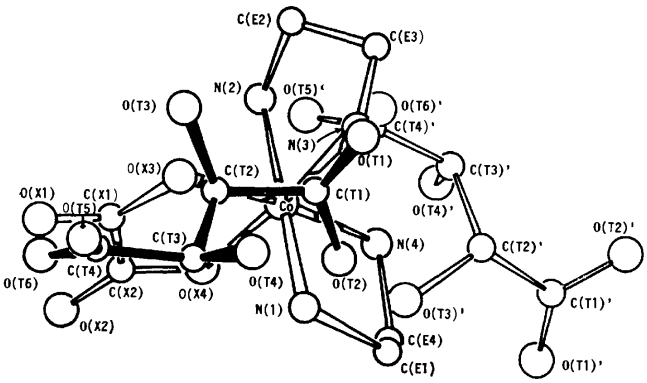

Fig. 3. The arrangement of the complex cation and H-*d*-tart anions projected down the quasi-threefold axis of the complex cation.

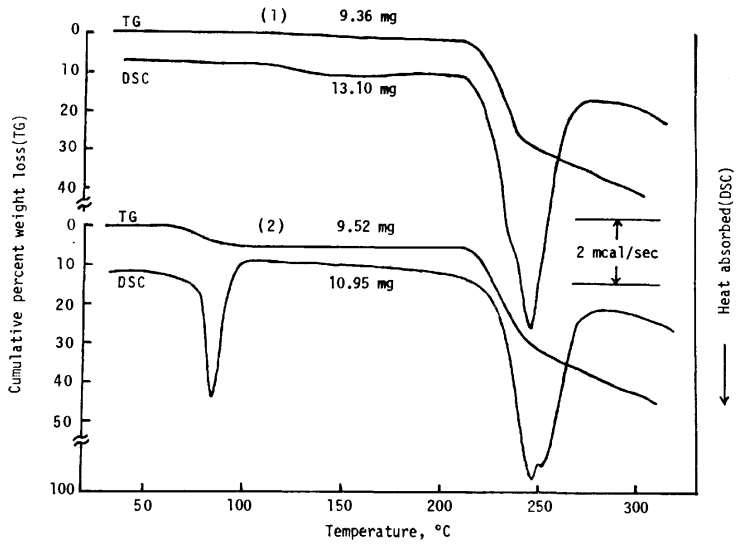

Fig. 4. TG and DSC curves of both diastereoisomers:
(1) $(+)_{589}$-[Co(ox)en_2]H-*d*-tart·H_2O; (2) $(-)_{589}$-[Co(ox)en_2]H-*d*-tart·$2H_2O$.

fore, the characteristic "face-to-face" close contact does not exist between the triangular facet of the octahedral complex cation and the H-*d*-tart anion. Thus, it is suggested that, in the optical resolution process, the discriminative role of the H-*d*-tart anion to the complex cation is quite different from that of the *d*-tartrate anion in the $[M(en)_3]^{3+}\cdots d\text{-tart}^{2-}$ system.[2-4] In other words, in the case of the H-*d*-tart anion, the diastereomeric discrimination is effected even without the "face-to-face" compact fit proposed by Fischer.[7] In the present diastereoisomer the optical-active complex cation, $\Lambda\text{-}\delta\lambda\text{-}(+)_{589}\text{-}[Co(ox)en_2]^+$, is locked by the right-handed spiral chain of $\{\text{H-}d\text{-tart}\}_\infty$ units formed along the b-axis. Then, it seems that the discrimination of optical isomers in this crystal originates in the formation of such a "lock-in-column" mode bonding through the strong hydrogen-bond network.

Thermal Behavior. It is supposed that the thermal behavior of the water of crystallization in both diastereoisomers reflects the difference of the crystal packing modes in these compounds. Therefore, the TG and DSC measurements of both diastereoisomers have been performed. These results are shown in Fig. 4.

The results clearly show that the crystals of the less-soluble diastereoisomer are thermally more stable than those of the more-soluble diastereoisomer. In fact, the water of crystallization is stable up to about 115 °C in the less-soluble salt, the release of the water molecule proceeds very slowly, and no DSC peak is observed. On the other hand, the crystals of the more-soluble salt begin to release the water of crystallization at about 78 °C and the process ceases at 90 °C. The weight loss accompanying this thermal transition is found to be 5.8%. This value is very close to the expected value of the dehydration of $1.5H_2O$(6.0%). A distinct endothermic DSC peak is also observed, as shown in Fig. 4. The ΔH value for the dehydration step is found to be 12.8 kcal/mol(53.6 kJ/mol), which is quite silmilar to those of $(\pm)\text{-}[Co(en)_3]Cl_3\cdot nH_2O$[24] and $(\pm)\text{-}[Cr(en)_3](NCS)_3\cdot H_2O$.[25] Both diastereoisomers are decomposed at about the same temperature(228 °C). Consequently, it is thought that the water of crystallization in the more-soluble salt is more loosely packed crystallographically than that of the less-soluble salt.

Recently, the solubilities of both salts were studied by Shimura and Tsutsui.[26] They mentioned that the solubility of the more-soluble salt, $(-)_{589}\text{-}[Co(ox)en_2]\text{H-}d\text{-tart}\cdot 2.5H_2O$, is three times larger than that of the less-soluble salt, $(+)_{589}\text{-}[Co(ox)en_2]\text{H-}d\text{-tart}\cdot H_2O$, at 25 °C. Moreover, the result of the three-dimensional crystal structure analysis of the more-soluble salt[27] also revealed that the waters of crystallization in this crystal were packed more loosely than those of the less-soluble salt.

We thank the Hiroshima University Computer Center for a generous allocation of computer time and acknowledge a Grant-in-Aid for Scientific Research from the Ministry of Education. We are also grateful to Dr. Kozo Akabori, Hiroshima University, for TG and DSC measurements and for his valuable suggestions.

An X-Ray Photoelectron Spectroscopic Study of Dioxime Metal Complexes

Tooru YOSHIDA

Osaka Prefectural Industrial Research Institute, Enokojima, Nishi-ku, Osaka 550

(Received June 13, 1978)

The O(1s) and N(1s) electron-binding energies were measured for the dioxime complexes of several transition metals by means of the X-ray photoelectron spectroscopic method. On the basis of their chemical shifts, the strength of the intramolecular hydrogen bonds and the charge distribution around the nitrogen atoms in the complexes are discussed. Two kinds of oxygen atoms were observed for all the complexes, and their binding energy differences were in the range of 1.3—1.9 eV. This difference was found to decrease with the increase in the strength of the hydrogen bonds. However, only one kind of nitrogen atom was observed for all the compounds except one. The N(1s) chemical shifts were in the range of 0.2—0.8 eV, and were found to increase slightly in the order of Cu^{II}< Ni^{II}<Pd^{II}<Pt^{II}.

It is well known that dimethylglyoxime is the first selective organic reagent[1] applied in the analyses of metals. In order to establish the structure of dimethylglyoxime complexes of transition metals, several complexes have been investigated by X-ray diffraction,[2-7] infra-red spectrophotometry,[8-14] magnetic[15-17] and stability[18,19] measurements. These investigations confirmed the square planar structure of the dimethylglyoxime complexes with a metal-ligand ratio of 1:2 of nickel, palladium, platinum, and copper. Furthermore, these investigations proved more important factors stabilizing the dioxime complexes to be the intramolecular hydrogen bonds in the planar configuration and the metal→ligand donor-acceptor π bonds in the chelate rings.

There have been two different opinions regarding the intramolecular hydrogen bonds in the Ni complex of dimethylglyoxime; one is that they are symmetric,[2,8,14,20] and the other that they are unsymmetric.[11] These conflicting results are due to the complexity of assigning the band of a hydroxyl group in IR. The former opinion is based only on the apparent centrosymmetric structure of the complex, the short O–O distance, and the low OH stretching frequency. No direct location of the protons has been carried out.

It has been known that X-ray photoelectron spectroscopy (XPS) is suitable for the detection of a protonated atom.[21] The purpose of the present study is to examine the hydrogen bonds and the π bonds in several dioxime complexes of transition metals by means of XPS.

Experimental

The X-ray photoelectron spectra were measured on an AEI ES200 spectrometer. Al $K\alpha$ (1486.6 eV) X-ray radiation was used as the excitation source. Samples were ground to a powder and then dusted onto a double-backed adhesive tape. The measurements were run at room temperature under a vacuum of about 10^{-7} Torr. Dimethylglyoxime, benzil dioxime, 1,2-cyclohexanedione dioxime (abbreviated as LH, L'H, and L''H) were used as ligands, and nickel(II), palladium(II), platinum(II), copper(II), and cobalt(III), as metal ions. All the free ligands were commercially available and of an analytical grade, and were used without further purification. All the complexes were prepared by the literature methods, and were checked by elemental analysis.

All the C(1s) electron spectra showed nearly symmetrical single peaks with the full-width at a half-maximum height (FWHM) of 1.8—2.0 eV for benzil dioxime and 1,2-cyclohexanedione dioxime and their metal complexes, and of 2.0—2.2 eV for dimethylglyoxime and its metal complexes. It is reasonable to assume that the C(1s) binding energy is nearly constant within the complexes with the same ligand. Furthermore, as only the relative binding energies were considered in the present study, the binding energy of the C(1s) peak was used as the energy standard throughout the experiments; it was taken to be 285.0 eV. The reproducibilities of the values thus obtained were within ±0.1 eV.

Results

The O(1s) and N(1s) electron-binding energies measured are given in Table 1.

The O(1s) Spectra. The O(1s) electron spectra of the dimethylglyoxime complexes are shown in Figs.

TABLE 1. MEASURED BINDING ENERGIES

Compound[a]	Binding energy (eV)			N(1s) chemical shift (eV)[c]
	N(1s)	O(1s)	ΔE[b]	
PtL_2	400.8	532.8; 531.0	1.8	0.8
PdL_2	400.7	532.8; 531.0	1.8	0.7
NiL_2	400.5	532.5; 531.2	1.3	0·5
CuL_2	400.3	532.8; 531.1	1.7	0.3
$Co^{III}L_3$	400.3	532.9; 531.0	1.9	0.3
$[Co^{III}(NH_3)_2L_2]Cl$	400.7; 399.4	532.6; 531.2	1.4	0.7
$HCo^{III}L_2Cl_2$	400.7	532.8; 531.2	1.6	0.7
PtL_2'	401.4	533.4; 531.7	1.7	0.6
PdL_2'	401.2	533.4; 531.7	1.7	0.4
NiL_2'	401.1	533.0; 531.7	1.3	0.3
CuL_2'	401.0	533.4; 531.7	1.7	0.2
PtL_2''	400.9	533.1; 531.2	1.9	0.7
PdL_2''	400.8	533.1; 531.2	1.9	0.6
NiL_2''	400.6	532.6; 531.2	1.4	0.4
CuL_2''	400.4	533.0; 531.1	1.9	0.2
LH	400.0	532.8		
L'H	400.8	533.5		
L''H	400.2	533.0		

a) LH, L'H, and L''H indicate dimethylglyoxime, benzil dioxime, and 1,2-cyclohexanedione dioxime respectively. b) The binding-energy difference of the two O(1s) peaks. c) The N(1s) binding-energy difference of a complex and a free ligand.

a: PtL_2, b: PdL_2.

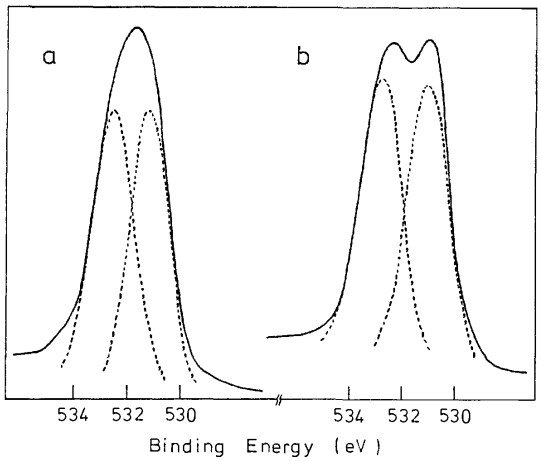

Fig. 2. O(1s) electron spectra.
a: NiL_2, b: CuL_2.

1—3. All the spectra showed multiple peaks, or one broad peak with the FWHM of 2.7—2.9 eV. The peaks with the FWHM of about 1.8 eV, indicated by the broken lines in the figures, were obtained by a graphical resolution. The peak with the highest binding energy of the three peaks in Fig. 1b can be assigned to the $Pd(3p_{3/2})$ electron. As is seen in Figs. 1—3, at least two kinds of oxygen atoms were observed for all the complexes. The intensity ratio of the two kinds of oxygens was nearly 1:1 for all the complexes except for $HCoL_2Cl_2$, for which the ratio was about 3:1.

The O(1s) spectra of the benzyl dioxime and 1,2-cyclohexane-dione dioxime complexes of each metal ion were very similar in appearance to that of the corresponding dimethylglyoxime complex. The O(1s) spectra of all the free ligands showed nearly symmetrical single peaks with an FWHM of 2.0—2.1 eV.

The N(1s) Spectra. Figure 4 shows the N(1s) spectra of NiL_2 and $[Co(NH_3)_2L_2]Cl$. The peaks indicated by the broken lines were obtained as in the case of the O(1s) spectra.

The N(1s) spectrum of NiL_2 showed a single main peak with an FWHM of 1.6 eV and a broad satellite with a low intensity in the region of higher energies

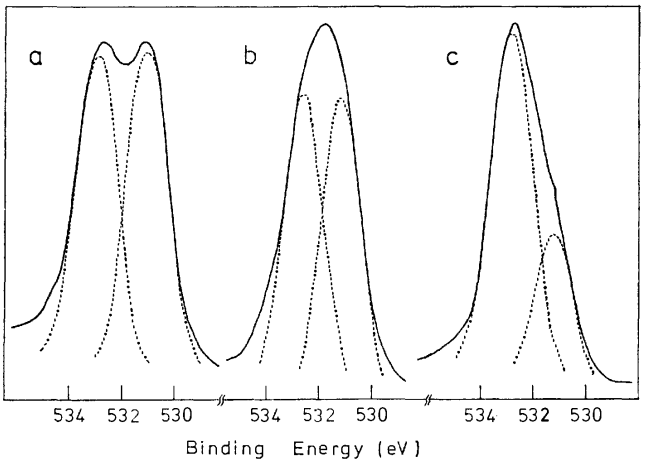

Fig. 3. O(1s) electron spectra.
a: CoL_3, b: $[Co(NH_3)_2L_2]Cl$, c: $HCoL_2Cl_2$.

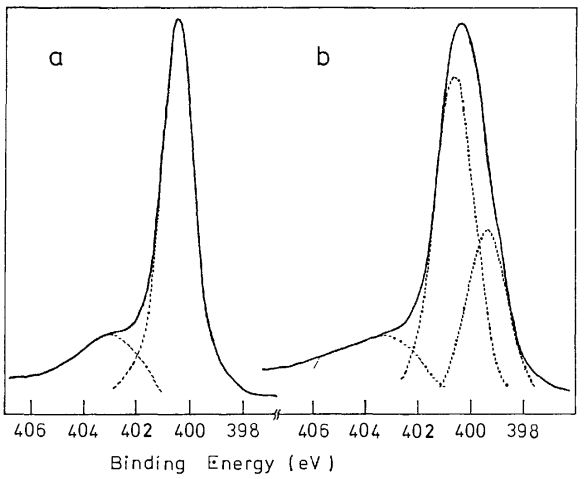

Fig. 4. N(1s) electron spectra.
a: NiL_2, b: $[Co(NH_3)_2L_2]Cl$.

than the main peak. The N(1s) spectra of all the other compounds were similar in appearance to that of NiL_2 except for the $[Co(NH_3)_2L_2]Cl$ shown in Fig. 4b. This indicates the presence of only one kind of nitrogen atom in all the compounds studied here except for $[Co(NH_3)_2L_2]Cl$.

The N(1s) spectrum of $[Co(NH_3)_2L_2]Cl$ showed an unsymmetrical broad peak with an FWHM of 2.3 eV (Fig. 4b). This suggests the presence of two kinds of nitrogen atoms. The intensity ratio of about 2:1 of the two peaks clearly indicates that the peak with the higher binding energy is due to the nitrogen atom of dimethylglyoxime, and the other, to the nitrogen of ammonia.

Discussion

The O(1s) Spectra. For all the metal complexes of the three ligands, the peaks with high and low binding energies may be assigned to the protonated and deprotonated oxygen atoms, –OH and $–O^-$ respectively, because the binding energy of the former was close to that of the free ligand.

The magnitude of the O(1s) binding-energy differ-

ences between the above two peaks may be correlated with the difference in the electronic charge between the two oxygen atoms. That is, the binding energy difference becomes large as the charge difference becomes large.

An increase in the strength of an OH···O hydrogen bond results in decreases in the O–O distance and the charge difference between the two oxygen atoms, giving rise to a small binding-energy difference between the two O(1s) peaks. Therefore, it may be considered that the hydrogen bond in the Ni complex, which has the smallest binding-energy difference, is stronger than those of the Pt and Pd complexes. This coincides with the results previously obtained by X-ray analysis[2–4] and IR studies.[8,20]

The O–O distances of the Pt, Pd, and Ni complexes of dimethylglyoxime, as determined by the X-ray analyses, were 3.03, 2.59, and 2.44 Å respectively.[2–4]

It is striking that the binding-energy differences of the two peaks for both the Pt and Pd complexes of dimethylglyoxime are the same, while there is an appreciable difference in the O–O distance between the two complexes.

The binding-energy difference between the two peaks for $[Co(NH_3)_2L_2]^+$, in which the O–O distance is 2.65 Å,[6] is 1.4 eV. The binding-energy differences between the two peaks in the O(1s) spectra for *o*- and *p*-aminobenzoic acids,[22] in which the O–O distances of the intermolecular hydrogen bonds are 2.54[23] and 2.61—2.64 Å,[24] were 1.4 and 1.5 eV respectively. Therefore, it seems that the binding-energy difference for PdL_2 was fairly large compared with those for the compounds stated above with O–O distances similar to that of PdL_2. Though the reason for this cannot be explained clearly as yet, it is possibly due to the difference in the bonding type of the hydrogen bond, such as a bent or straight hydrogen bond. That is, the former type may be supposed for the Pd complexes, and the latter type, for the complexes quoted above as comparison and the Pt complexes.

It seems reasonable that the binding-energy differences observed in the complexes in Table 1 which have the intramolecular hydrogen bonds are equal to or smaller than that for CoL_3, in which the presence of a hydrogen bond analogous to those in the above complexes cannot be expected.[10a,10c]

It is very interesting that the present experiment for the three Ni complexes showed the presence of two kinds of oxygen atoms. In a symmetrical O···H··· O hydrogen bond, the equivalence of the two oxygen atoms may be expected, because the proton occupies a central position between the two oxygen atoms. Therefore, it seems that the hydrogen bonds in the three Ni complexes are unsymmetrical.

The crystal-structure analysis[5] of CuL_2 showed that this complex exists as a dimer bridged by two oxygen atoms, and that it involves two kinds of intramolecular hydrogen bonds: weak and strong ones. Therefore, four kinds of oxygen atoms should be present in the complex. However, the O(1s) spectrum for CuL_2 could roughly be divided into only two peaks, like the other two Cu complexes.

It is clear from the dominant presence of the protonated oxygen atom over the deprotonated one, as may be seen in Fig. 3c, that, in the $HCoL_2Cl_2$ complex, an additional proton exists near an oxygen atom. This agrees with the results obtained by IR studies[10c,12] of the complex.

In the intramolecular hydrogen bonds studied here, the protons may be considered to be rapidly changing in their position from near one oxygen atom to near the other. In general, the lifetime of proton tautomers is much longer than the time (10^{-16}—10^{-18} s) needed in an ionization process in XPS.[25] Therefore, it was considered that the two kinds of oxygen atoms, the individual tautomers could easily be detected in this experiment.

The N(1s) Spectra. The N(1s) spectra of all the complexes were expected to show two well-resolved peaks or a single broad peak, because the complexes contain two kinds of nitrogen atoms bonded with different groups, –OH and $-O^-$. However, only a single peak with almost the same FWHM as the free ligand was observed in the N(1s) spectrum for all the complexes. This is probably due to the cyclic delocalization[13,18,19,26] based upon the metal→ligand donor-acceptor π bond in the five-membered rings. Such delocalization is considered to equalize the charges on the four nitrogen atoms.

The positive N(1s) chemical shift, which is the difference between the N(1s) binding energies of the complex and the free ligand, is, in all the complexes, considered to be due to the change in the electron density on the nitrogen atom caused by the coordination of lone-pair electrons of the nitrogen atom to the metal and the above-stated cyclic delocalization of electrons.

The magnitudes of the N(1s) chemical shifts were found to increase gradually in the order of Cu<Ni< Pd<Pt complexes. This indicates that, of the four complexes, the electron density around the nitrogen atom is the smallest in the Pt complex and the largest in the Cu complex. This order corresponds well to the decreasing order of the C=N frequencies of these complexes, where fewer frequencies indicate more conjugation in a chelate ring.[13]

The weak peak observed about 2.5 eV on the higher-energy side of the main peak, as is seen in Fig. 4, may be partly assigned to the shake-up satellite peak, which is mainly due to the co-excitations of valence electrons (L-L transition) on the ejection of the innner electrons, on the basis of the following facts. Such a weak peak was also observed in the N(1s) spectrum of each free ligand in the present study. In our laboratory, such peaks have previously been observed in the N(1s) spectra only of compounds containing unsaturated nitrogen groups in addition to the compounds listed in Table 1.[27] Furthermore, the electron spectra of the compounds containing the unsaturated bonds with a hetero-atom in the molecule generally show the absorption bands due to n-π^*, π-π^* transitions in a region of about $(10—50)\times10^3$ cm^{-1}.[28] In the case of NiL_2, such bands are observed in the vicinity of 20×10^3 and 40×10^3 cm^{-1},[29,30] which approximately correspond to 2.5 and 5.0 eV respectively.

The Estimation of the Charge Difference. In the point charge model,[31] a core-binding energy can be expressed by

$$Eb = kq_i + V_i + l + E_r, \quad (1)$$

where Eb is the binding energy for a particular core level in a given atom (the "ionized" atom), q_i is the charge of the ionized atom, $V_i(=\sum_{i\neq j} q_j/R_{ij})$ is the Coulomb potential energy at the site of the ionized atom due to the other charged atoms of the molecule, k and l are empirical constants for the studied atom, and E_r is the relaxation energy associated with the shift of electrons toward the core hole.

The O(1s) binding energies of two oxygen atoms in the nickel dimethylglyoxime complex can be given by

$$\text{B. E.}(O_1) = k_O q_{O_1} + V_{O_1} + l_O + E_r, \quad (2)$$

$$\text{B. E.}(O_2) = k_O q_{O_2} + V_{O_2} + l_O + E_r. \quad (3)$$

The following equation can be obtained by using the interatomic distances previously reported[2] and by considering the D_{2h} symmetry of the complex:

$$\Delta q = \frac{1}{k_O - 0.42}\{\Delta E - q_H(1/R_{O_1H} - 1/R_{O_2H})\}, \quad (4)$$

where $\Delta q = q_{O_1} - q_{O_2}$ and where $\Delta E = \text{B.E.}(O_1) - \text{B.E.}(O_2) = 1.3$ eV. By substituting $R_{O_1H} = 1.15$Å and $R_{O_2H} = 1.29$ Å, obtained by the application of Lippincott's model equation,[32] and $k_O = 25.8$ eV/(unit charge), determined empirically by Siegbahn *et al.*,[33] into Eq. 4, Δq was estimated as follows:

$$\Delta q = \frac{1}{25.4}(1.3 - 0.003q_H) \approx \frac{1}{25.4} \times 1.3 \fallingdotseq 0.051.$$

Therefore, it seemed that the intramolecular hydrogen bond of the nickel dimethylglyoxime complex was slightly unsymmetrical, with a charge difference of about 0.05 unit charge.

The author wishes to thank Drs. Kiyoshi Yamasaki and Shigemasa Sawada for their many helpful discussions and suggestions during this work, and Mr. Taichiro Hirohara for the elemental analysis of all the samples.

(Received January 14, 1978)

3,6-Diazido-3,6-dideoxy-1,2-*O*-isopropylidene-α-D-glucofuranose was converted into the corresponding derivative of α-D-glucopyranose, which was transformed into 3,4,6-triazido-3,4,6-trideoxy-1,2-*O*-isopropylidene-α-D-glucopyranose (**7**) through the sequence of reactions involving displacement of sulfonate ester function with benzoate, followed by debenzoylation, sulfonylation, and nucleophilic substitution. Hydrogenolysis of **7** afforded the corresponding triamino derivative **8**. The tri-*N*-benzyloxycarbonyl derivative of **8** was *O*-deisopropylidenated and oxidized with periodate to afford the piperidinose derivative **11**, deformylation of which yielded 2,3,5-tris(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabinopyranose (**13**). "Pfitzner-Moffatt" oxidation of **11** failed to give the corresponding lactam **15**. Condensation of the 6-*N*-benzyloxycarbonyl derivative of **8** (**18**) with cyanogen bromide afforded the cyclic guanidine derivative (**20**) hydrobromide. The triazido derivative **7** was converted into 3,4,6-tris(benzyloxycarbonylamino)-3,4,6-trideoxy-D-glucitol (**23**), which was then oxidized successively with periodate and chromium trioxide–acetic acid–pyridine to give 2,3,5-tris(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabono-1,4-lactone (**25**); this was further transformed into 2,3,5-trianimo-2,3,5-trideoxy-D-arabono-1,5-lactam (**16**).

2,3,5-Triamino-2,3,5-trideoxy-D-arabono-1,5-lactam (**16**) has proved to be a useful intermediate for the synthesis of 2,3,5-triamino-2,3,5-trideoxy-D-arabonic acid derivatives, such as streptolidine[1,2] (**21**) and streptolidine lactam[3] (**27**). Synthesis of the lactam **16** was first accomplished from D-ribose through 2,3,5-triacylamino-2,3,5-trideoxy-D-arabinofuranose.[1,2] Recently **16** has been prepared through a new stereospecific route from 3,4-anhydro-D-iditol derivative.[3]

In view of the preparation of lactam **16**, we were interested in some synthetic approaches to the triamino-D-arabonic acid derivatives from 3,4,6-triazido-3,4,6-trideoxy-1,2-*O*-isopropylidene-α-D-glucopyranose (**7**) which was synthesized from 3,6-diazido-3,6-dideoxy-1,2-*O*-isopropylidene-α-D-glucofuranose[4] (**1**). The following approaches were attempted: (i) transformation of 3,4,6-tris(benzyloxycarbonylamino)-3,4,6-trideoxy-D-glucopyranose derived from **7** to **16** *via* 2,3,5-tris(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabinopyranose derivative (**11**) (Chart 2), (ii) conversion of triamino glucopyranose derivative **8** into streptolidine **21** (Chart 3), and (iii) transformation of **7** into 2,3,5-tris(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabono-1,4-lactone (**25**) which can be converted into **16** (Chart 4).

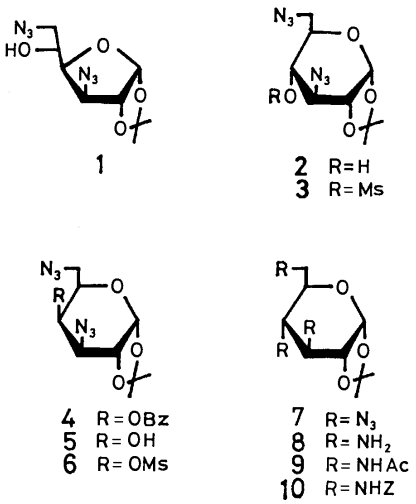

Chart 1.

3,4,6-Triazido-3,4,6-trideoxy-1,2-O-isopropylidene-α-D-glucopyranose (7). 3,6-Diazido-3,6-dideoxy-1,2-*O*-isopropylidene-α-D-glucofuranose[4] (**1**) was converted into 3,6-diazido-3,6-dideoxy-1,2-*O*-isopropylidene-α-D-glucopyranose (**2**) in 55% overall yield by *O*-deisopropylidenation of **1** with warm aqueous acetic acid and the subsequent 1,2-*O*-isopropylidenation with 2,2-dimethoxypropane in hot DMF in the presence of *p*-toluenesulfonic acid.

Kiso and Hasegawa[5a] reported that isopropylidenation of D-glucose with 2,2-dimethoxypropane–DMF–*p*-toleuensulfonic acid gives no 1,2-*O*-isopropylidene-α-D-glucopyranose. The result is not in line with ours. They also reported[5b] that isopropylidenation of D-xylose with the same reagent gives 1,2-*O*-isopropylidene-α-D-xylopyranose as a minor product in 16% yield. Meyer zu Reckendorf and Bischef[6] reported that treatment of 3-(*N*-methylbenzamido)-3-deoxy-D-xylose with the same reagent affords the corresponding 1,2-*O*-isopropylidene-D-xylopyranose derivative in 40% yield. The difference between isopropylidenation of D-glucose and of 3,6-diazido-3,6-dideoxy-D-glucose, in which the hydroxyl groups at C-3 and C-6 position of D-glucose are absent, may thus be explained.

O-Mesylation of **2** afforded the corresponding 4-*O*-mesylate **3** (90% yield), which was allowed to react with sodium benzoate in boiling DMF to give 3,6-diazido-4-*O*-benzoyl-3,6-dideoxy-1,2-*O*-isopropylidene-α-D-galactopyranose (**4**) in 84% yield. Debenzoylation of **4** with sodium methoxide in methanol afforded **5**, the 4-epimer of **2**, in 93% yield. The 4-*O*-mesylate **6** prepared from **5** in 89% yield, was heated with sodium azide in DMSO to give 3,4,6-triazido-3,4,6-trideoxy-1,2-*O*-isopropylidene-α-D-glucopyranose

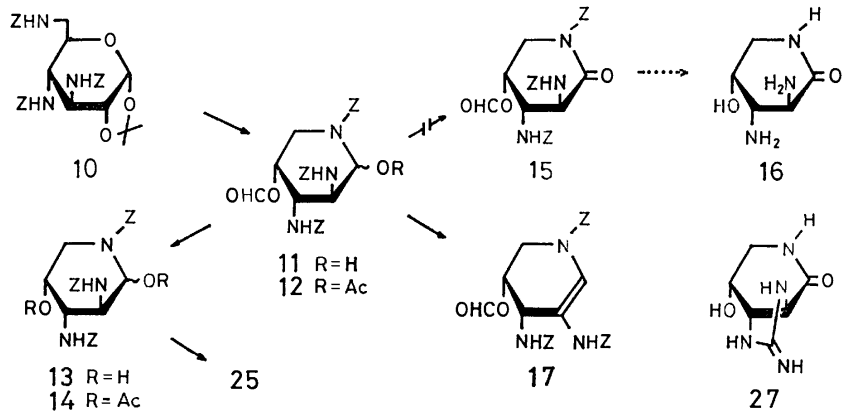

Chart 2.

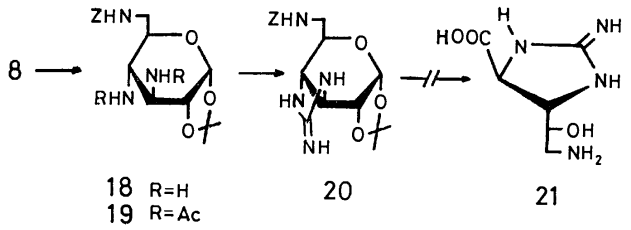

Chart 3.

(**7**) as a syrup in 69% yield after being subjected to chromatography.

Synthetic Approach to Triamino Arabono-1,4-lactam ***16*** *from Triazido Glucose Derivative* ***7***. Hydrogenolysis of **7** over palladium black afforded 3,4,6-triamino-3,4,6-trideoxy-1,2-*O*-isopropylidene-α-D-glucopyranose (**8**) as a colorless syrup, which led to the crystalline tri-*N*-acetyl derivative **9** on treatment with acetic anhydride in methanol. The crystalline tri-*N*-benzyloxycarbonyl derivative **10** was also obtained by the reaction of **8** with benzyl chloroformate in pyridine in 70% yield after being subjected to chromatography. Compounds **8**, **9**, and **10** are the derivatives of the new triamino glucose.

The 1,2-*O*-isopropylidene group of **10** was removed with warm aqueous acetic acid and the resulting free sugar was subjected to periodate oxidation in aqueous acetone to afford a crystalline piperidinose derivative, 4-*O*-formyl-2,3,5-tris(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabinopyranose (**11**) in 71.5% yield. Compound **11** was converted into the 1-*O*-acetate **12** in good yield. Deformylation of **11** with ammonia in aqueous dioxane gave **13** as crystals (93% yield), which could be converted into the 1,4-di-*O*-acetate **14**.[2b] The PMR spectra of **11**, **12**, **13**, and **14** showed signals in line with piperidinose structure.[7]

Transformation of **11** into **16** was attempted. However, no desired lactam **15** was obtained on treatment with DMSO–DCCI–pyridine–trifluoroacetic acid.[8] Instead, only 2,3,5-tris(benzyloxycarbonylamino)-1,2,3,5-tetradeoxy-4-*O*-formyl-D-*erythro*-pent-1-enopyranose (**17**), the dehydration product, was obtained in 82% yield. The structure of **17** was confirmed by PMR spectroscopy (singlet at δ 7.48 due to the H-1 olefinic proton) and by elemental analysis. When **11** was treated with DMSO–trifluoroacetic anhydride in dichloromethane at —70 °C according to the method of Huang *et al.*[9] no reaction product was detected in TLC, but when the mixture was warmed up to room temperature, the formation of **17** was observed. Oxidation of **11** with chromium trioxide–acetic acid–pyridine,[10] with bromine–water, or with *N*-bromosuccinimide in dioxane afforded only the unchanged material.

*Attempt to Synthesize Streptolidine (****21****) from Triamino Glucose Derivative* ***8***. Selective *N*-benzyloxycarbonylation of **8** with *N*-(benzyloxycarbonyloxy)-succinimide[11] in aqueous DMF yielded the 6-*N*-benzyloxy-carbonylated product **18** as a major product in 46% yield after being subjected to chromatography. Acetylation of **18** afforded the di-*N*-acetyl derivative **19**, whose PMR spectrum showed signals at δ 3.03 (H-3) and 2.53(H-4); those of **18** being shifted to downfield by acetylation.

Treatment of **18** with one equivalent of cyanogen bromide in water gave the cyclic guanidine derivative **20** as crystalline hydrobromide in 93% yield after being subjected to chromatography. *O*-Deisopropylidenation of **20** followed by successive oxidation with periodate and with bromide–water afforded no expected product from which streptolidine (**21**) could be derived. Periodate oxidation of the *O*-deisopropylidenation product might have yielded a piperidinose derivative as an intermediary product which resists oxidation with bromine–water as in the case of **11**.

Transformation of Triazido Glucose Derivative ***7*** *into Triamino Sugar Lactam* ***16***. A synthetic approach to triamino sugar lactam **16** involving the conversion of the triazido D-glucose derivative **7** into the glucitol derivative **23** was performed. *O*-Deisopropylidenation of **7** with 20% aqueous acetic acid, followed by sodium borohydride-reduction in aqueous ethanol, afforded 3,4,6-triazido-3,4,6-trideoxy-D-glucitol (**22**) in 60% yield. Hydrogenolysis of **22** over palladium black and subsequent *N*-benzyloxycarbonylation with *N*-(benzyloxycarbonyloxy)succinimide gave the crystalline 3,4,6-tris(benzyloxycarbonylamino)-3,4,6-trideoxy-D-glucitol (**23**) in 98% yield. Periodate-oxidation of **23** afforded the furanose derivative **24**[2b] whose TLC showed a single spot having R_f-value differing from that of piperidinose derivative **13**. With-

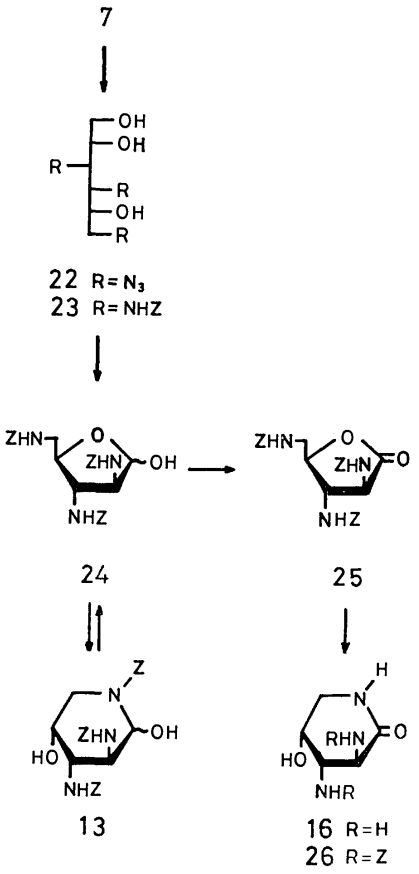

Chart 4.

out purification, **24**, was oxidized with chromium trioxide–acetic acid–pyridine to give the corresponding crystalline 1,4-lactone **25**[2b] as the sole product in 66% yield from **23** after being subjected to chromatography. When the oxidation of **24** was carried out with bromine–water[3] instead of the chromium trioxide reagent, a considerable amount of **13** was isolated together with **25** on column chromatography of the reaction product. During the slow oxidation reaction with bromine–water, **24** might have partially been converted into **13** which resisted bromine-oxidation.

Lactone **25** was also obtained in 42% yield by oxidation of **13** with chromium trioxide reagent. Hydrogenolysis of **25** over palladium black gave **16**, whose structure was confirmed by conversion into 2,3-di-*N*-benzyloxycarbonylated triamino sugar lactam **26**.[3]

Experimental

Melting points were determined on a micro hot-stage and are uncorrected. IR spectra were taken on a Hitachi 225 spectrophotometer, PMR spectra on a Varian A-60D spectrometer using TMS as an internal standard. Specific rotations were determined with a Zeiss Photoelectric polarimeter. TLC was performed on Wakogel B-5 and column chromatography on Wakogel C-200. Hydrogenolysis was conducted under bubbling with hydrogen at room temperature. Concentration was carried out below 40 °C under reduced pressure.

3,6-Diazido-3,6-dideoxy-1,2-O-isopropylidene-α-D-glucopyranose (2). A mixture of 3,6-diazido-3,6-dideoxy-1,2-*O*-isopropylidene-α-D-glucofuranose (**1**)[4] (31.5 g) and 50% aqueous acetic acid (320 ml) was heated at 90—100 °C for 6.5 h, the resulting solution being evaporated to give free sugar as pale yellow crystals (24.6 g, 92%). A mixture of the product (24.6 g), dry DMF (246 ml), 2,2-dimethoxypropane (64 ml), and *p*-toluenesulfonic acid (3.53 g) was kept at 60 °C for 2.5 h, the reaction mixture being poured into cold water (250 ml) and extracted with chloroform (250 ml × 3). The combined extracts were washed with saturated NaCl solution, dried, and evaporated. The residual syrup (31.6 g) was chromatographed on silica gel (1.3 kg) with benzene–ethyl acetate (15:1) to afford a homogeneous sample of **2** (17.2 g, 60%) as a colorless syrup. Chromatography also gave **1** (0.19 g, 0.7%) and a mixture of **1** and **2** (2.0 g, 7%). **2**: $[\alpha]_D^{14}$ +95° (*c* 1.4, $CHCl_3$); $\delta(CDCl_3)$ 1.41 and 1.62 [each s, 6H, $C(CH_3)_2$], 3.6—3.9(m, 5H, H-3,4,5,6,6′), 4.18(dd, H-2 $J_{1,2}$=4.8, $J_{2,3}$=5.9 Hz), and 5.63 (d, H-1).

Found: C, 40.15; H, 5.09; N, 30.77%. Calcd for $C_9H_{14}N_6O_4$: C, 40.00; H, 5.22; N, 31.10%.

3,6-Diazido-3,6-dideoxy-1,2-O-isopropylidene-4-O-mesyl-α-D-glucopyranose (3). A sample of **2** (17.1 g) was mesylated with mesyl chloride (5.36 ml) in pyridine (86 ml) at room temperature for 5 h. Work-up of the reaction mixture in the usual way afforded a practically pure syrup of the 4-*O*-mesylate (**3**) in quantitative yield (22.0 g). Analytical sample of **3** was obtained in 90% yield after being subjected to chromatography on silica gel with benzene–ethyl acetate (12:1); $[\alpha]_D^{17}$ +80° (*c* 1.9, $CHCl_3$); $\nu_{max}^{CCl_4}$ (0.1 M) 2100 (N_3), 1380 and 1185 cm^{-1} (SO_3); $\delta(CDCl_3)$ 1.39 and 1.60 [each s, 6H, $C(CH_3)_2$], 3.12(s, 3H, OMs), *ca.* 3.6(m, 2H, H-6,6′), *ca.* 4.1(m, 1H, H-5), 4.12(dd, 1H, H-3, $J_{2,3}$=4.2, $J_{3,4}$=8.8 Hz), 4.29(dd, 1H, H-2, $J_{1,2}$=4.6 Hz), 4.68(dd, 1H, H-4, $J_{4,5}$=4.3 Hz), and 5.63(d, 1H, H-1).

Found: C, 34.76; H, 4.47; N, 23.83; S, 9.42%. Calcd for $C_{10}H_{16}N_6O_6S$: C, 34.47; H, 4.62; N, 24.12; S, 9.20%.

3,6-Diazido-4-O-benzoyl-3,6-dideoxy-1,2-O-isopropylidene-α-D-galactopyranose (4). A mixture of **3** (669 mg), sodium benzoate (1.39 g), and dry DMF (62 ml) was refluxed for 4 h. The cooled reaction mixture was filtered, and the insoluble matter was washed with ethyl acetate (65 ml). The combined filtrate and washings were evaporated to a syrup, which was dissolved in chloroform, washed with water and saturated NaCl solution, dried and evaporated. The residual yellow syrup was chromatographed on silica gel with benzene–ethyl acetate (12:1) to afford colorless syrup of **4** (604 mg, 84%): $[\alpha]_D^{20}$ +156° (*c* 1.6, $CHCl_3$); ν_{max}^{liq} 2100 (N_3), 1730 cm^{-1} (ester); $\delta(CDCl_3)$, 1.46 and 1.61[each s, 6H, $C(CH_3)_2$], *ca.* 3.5(m, 2H, H-6,6′), 4.01(dd, 1H, H-3, $J_{2,3}$=6.2, $J_{3,4}$=4.0 Hz), *ca.* 4.3(m, 1H, H-5), 4.32(dd, 1H, H-2, $J_{1,2}$=4.6 Hz), 5.58(dd, 1H, H-4, $J_{4,5}$=3.2 Hz), and 5.74(d, 1H, H-1).

Found: C, 51.12; H, 4.56; N, 22.25%. Calcd for $C_{16}H_{18}N_6O_5$: C, 51.33; H, 4.85; N, 22.45%.

3,6-Diazido-3,6-dideoxy-1,2-O-isopropylidene-α-D-galactopyranose (5). A 0.82 M methanolic sodium methoxide solution (2.95 ml) was added to a solution of **4** (604 mg) in methanol (12 ml) and the mixture was kept at room temperature for 3 h. The solution was neutralized with 20% acetic acid and evaporated. The residue was dissolved in ethyl acetate, washed with water and saturated NaCl solution, dried, and evaporated. The residual yellow syrup was chromatographed on silica gel with benzene–ethyl acetate (12:1) to afford **5** as a syrup (406 mg, 93%): $[\alpha]_D^{18}$ +91° (*c* 1.4, $CHCl_3$); $\delta(CDCl_3)$ 1.43 and 1.57[each s, 6H, $C(CH_3)_2$], 2.45(1H, OH), 3.4—4.1(m, 5H, H-3,4,5,6,6′), 4.32(dd, 1H, H-2, $J_{1,2}$=4.6, $J_{2,3}$=7.0 Hz), and 5.71(d, 1H, H-1).

Found: C, 40.22; H, 5.26; N, 31.25%. Calcd for $C_9H_{14}N_6O_4$: C, 40.00; H, 5.22; N, 31.10%.

*3,6-Diazido-3,6-dideoxy-1,2-O-isopropylidene-4-O-mesyl-α-D-galactopyranose (**6**).* A sample of **5** (382 mg) was mesylated in the usual way to afford **6** (493 mg) in quantitative yield. Analytical sample was obtained by silica gel column chromatography with benzene-ethyl acetate (12:1) in 89% yield as a pale yellow syrup: $[\alpha]_D^{20}$ +74° (*c* 2.0, $CHCl_3$); $\nu_{max}^{CHCl_3}$ (0.1 M) 2100(N_3), 1360 and 1175 cm^{-1} (SO_3); δ($CDCl_3$) 1.42 and 1.57[each s, 6H, $C(CH_3)_2$], 3.18(s, 3H, OMs), 3.53(m, 2H, H-6,6'), 3.88(dd, 1H, H-3, $J_{2,3}$=6.5, $J_{3,4}$= 2.8 Hz), *ca.* 4.2(m, 1H, H-5), 4.21(dd, 1H, H-2, $J_{1,2}$=4.2 Hz), 4.94(dd, 1H, H-4, $J_{4,5}$=3.8 Hz), and 5.61(d, 1H, H-1).

Found: C, 34.73; H, 4.65; N, 24.10; S, 9.03%. Calcd for $C_{10}H_{16}N_6O_6S$: C, 34.47; H, 4.62; N, 24.12; S, 9.20%.

*3,4,6-Triazido-3,4,6-trideoxy-1,2-O-isopropylidene-α-D-glucopyranose (**7**).* A mixture of **6** (375 mg), sodium azide (211 mg) and dry DMSO (7.6 ml) was heated under stirring at 95—100 °C for 1.5 h and then poured into cold water (7.7 ml). The mixture was extracted with chloroform and the combined extracts were washed with saturated NaCl solution, dried, and evaporated. The residual brown syrup was chromatographed on silica gel with benzene-ethyl acetate (30:1) to afford a pale yellow syrup of **7** (218 mg, 69%). A part of this sample was again chromatographed on silica gel with hexane-ethyl acetate (20:1) to give an analytical sample: $[\alpha]_D^{20}$ +239° (*c* 1.47, $CHCl_3$); $\nu_{max}^{CHCl_3}$ 2110 cm^{-1} (N_3); δ($CDCl_3$) 1.42 and 1.59[each s, 6H, $C(CH_3)_2$], 3.5—3.9(m, 5H, H-3, 4,5,6,6'), 4.19(dd, 1H, H-2, $J_{1,2}$=4.8, $J_{2,3}$=5.0 Hz), 5.67(d, 1H, H-1).

Found: C, 36.84; H, 4.49; N, 42.48%. Calcd for $C_9H_{13}N_9O_3$: C, 36.61; H, 4.44; N, 42.70%.

*3,4,6-Triamino-3,4,6-trideoxy-1,2-O-isopropylidene-α-D-glucopyranose (**8**).* The triazido compound **7** (114 mg) was hydrogenolized over palladium black in methanol to afford the triamino derivative **8** (77.3 mg, 92%), which was used for the subsequent reaction without purification.

*Tri-N-acetyl Derivative (**9**):* Acetylation of **8** (69.1 mg) with acetic anhydride (0.09 ml) in methanol at room temperature for 1 h gave **9** (91.3 mg, 84%) as needles after silica gel chromatography (5:1, chloroform-methanol): mp 253 °C (dec); $[\alpha]_D^{22}$ +59°(*c* 0.59, MeOH); ν_{max}^{KBr} 1645 and 1533 cm^{-1} (amide).

Found: C, 52.24; H, 7.25; N, 12.04%. Calcd for $C_{15}H_{25}N_3O_6$: C, 52.47; H, 7.34; N, 12.24%.

*Tri-N-benzyloxycarbonyl Derivative (**10**):* A sample of **8** (244 mg) was *N*-benzyloxycarbonylated with benzyl chloroformate (0.64 ml) in dry pyridine (4 ml) at −40——35 °C for 3 h. The reaction mixture was diluted with water and extracted with chloroform. The extracts were washed with saturated NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel with benzene-acetone (10:1) to afford **10** (490 mg, 71%) as crystals. Recrystallization from ethyl acetate-petroleum ether gave a pure sample: mp 124—125 °C; $[\alpha]_D^{18}$ −28°(*c* 1.21, $CHCl_3$); ν_{max}^{KBr} 3320 (NH), 1690 and 1530 cm^{-1} (amide); δ($CDCl_3$) 1.32 and 1.55[each s, 6H, $C(CH_3)_2$], 3.7—4.3(m, 6H, H-2,3, 4,5,6,6'), 5.20(s, 6H, CH_2Ph), *ca.* 5.5(3H, NH), 5.63(d, 1H, H-1, $J_{1,2}$=4.8 Hz), and 7.48(s, 15H, Ph).

Found: C, 63.83; H, 6.11; N, 6.63%. Calcd for $C_{33}H_{37}N_3O_9$: C, 63.96; H, 6.02; N, 6.78%.

*2,3,5-Tris(benzyloxycarbonylamino)-2,3,5-trideoxy-O-formyl-D-arabinopyranose (**11**).* Treatment of **10** (1.78 g) with 67% aqueous acetic acid (26.7 ml) at 55—60 °C for 4.5 h afforded a crystalline free sugar (1.60 g, 96%), which was suspended in acetone (48 ml) to which added a solution of sodium metaperiodate (1.77 g) in water (18 ml). The mixture was stirred at 33°C for 40 h, and the resulting precipitates were collected by filtration and washed with acetone and water to give **11** as a colorless powder (1.14 g, 72%). A part of this product was chromatographed on silica gel with chloroform-ethyl acetate (10:1) to afford an analytical sample: mp 198—199 °C(dec); $[\alpha]_D^{17}$ −20°(constant for 48 h, *c* 0.75, dioxane); ν_{max}^{KBr} 3430 (OH), 3300 (NH), 1718 (OCHO), 1680 and 1540 cm^{-1} (urethane); δ(DMSO-d_6) *ca.* 3.2—4.1(m, 4H, H-2,3,5,5'), 5.10 and 5.18(each s, 6H, OCH_2Ph), *ca.* 5.2(m, 1H, H-4), *ca.* 5.8(m, 1H, H-1), *ca.* 6.5, 7.2, and 7.5(m, 3H, NH and OH), 7.45(s, 15H, Ph), and 8.27(s, OCHO); δ(pyridine-d_5) 3.82(m, 1H, H-5, $J_{5,5}$ = 14.2 Hz), *ca.* 4.4—5.3(m, 5H, H-1,2,3,5', and OH), 5.18(s, 6H, OCH_2Ph), 5.75(m, 1H, H-4), *ca.* 6.7 and 7.4(m, 2H, NH), and 8.10(s, 1H, OCHO).

Found: C, 62.48; H, 5.52; N, 7.09%. Calcd for $C_{30}H_{31}N_3O_9$: C, 62.38; H, 5.41; N, 7.28%.

*1-O-Acetyl Derivative (**12**).* A sample of **11** (35.6 mg) was acetylated with acetic anhydride (0.02 ml) in pyridine (0.36 ml) to afford colorless powder of **12** (32.9 mg, 86%): mp 194—198 °C (MeOH); $[\alpha]_D^{19}$ −43° (*c* 1.8, $CHCl_3$); δ($CDCl_3$) 2.10(s, 3H, OAc), *ca.* 3.3 and 4.2—4.5(m, 4H, H-2,3,5,5'), 5.08(s, 4H, OCH_2Ph at 2- and 3-N), 5.21(ABq, OCH_2Ph at 5-N), 5.0—5.4(br, 3H, two NH, H-4), 7.05(m, H-1), 7.37(s, 15H, Ph), and 7.98(s, 1H, OCHO).

Found: C, 62.24; H, 5.51; N, 6.70%. Calcd for $C_{32}H_{33}N_3O_{10}$: C, 62.03; H, 5.37; N, 6.78%.

*2,3,5-Tris(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabinopyranose (**13**).* A mixture of **11** (47.4 mg), dioxane (0.5 ml), and 10% aqueous ammonia (0.1 ml) was kept at room temperature for 2 h. The reaction mixture was evaporated to dryness and the residue was washed with ethanol to afford **13** as a powder (41.9 mg, 93%): R_f 0.64(silica gel, 3:1 benzene-acetone); mp 204—206 °C; δ(DMSO-d_6) *ca.* 3.2(m, 1H, H-5), 3.8—4.0(m, 4H, H-2,3,4,5'), 5.12 and 5.19(each s, 6H, OCH_2Ph), 5.75(m, 1H, H-1), *ca.* 6.6(m, 2H, NH), *ca.* 7.4(m, 1H, NH), and 7.41(s, 15H, Ph); δ(pyridine-d_5) 3.79(m, 1H, H-5, $J_{5,5}$=13.2 Hz), 4.4—5.3(m, 7H, H-1, 2,3,4,5', OH) 5.18 and 5.21(each s, OCH_2Ph), *ca.* 6.6 and 7.8(2H, NH), and 7.26(s, 15H, CH_2Ph).

Found: C, 63.22; H, 5.85; N, 7.47%. Calcd for $C_{29}H_{31}N_3O_8$: C, 63.38; H, 5.69; N, 7.65%.

*1,4-Di-O-Acetyl Derivative (**14**).* A sample of **13** (15 mg) was acetylated with acetic anhydride (0.025 ml) in pyridine (0.15 ml) for 48 h. The crystalline product was recrystallized from chloroform-hexane to afford the pure sample of **14** (12.1 mg, 70%): mp 192.5—194.5 °C (lit,[2b] 186—186.5 °C); $[\alpha]_D^{19}$ −41°(*c* 2.05, $CHCl_3$); δ(DMSO-d_6) 1.92 and 2.11(each s, 6H, CH_3CO), 3.19(dd, 1H, H-5, $J_{5,5'}$= 15 Hz), 4.2—4.4(m, 3H, H-2,3,5'), 5.0—5.2(m, 9H, CH_2Ph, H-4, NH), 6.99(m, 1H, H-1), 7.35—7.40(each s, Ph).

Found: C, 62.52; H, 5.62; N, 6.46%. Calcd for $C_{33}H_{35}O_{10}N_3$: C, 62.55; H, 5.57; N, 6.63%.

*2,3,5-Tris(benzyloxycarbonylamino)-1,2,3,5-tetradeoxy-4-O-formyl-D-erythro-pent-1-enopyranose (**17**).* A mixture of dry DMSO, dry pyridine, and trifluoroacetic acid (10:1:0.473 by volume) (3.12 ml) was added to a solution of **11** (1.00 g) in dry DMSO (10 ml). DCCI (1.07 g) was then added to the mixture, and stirred at room temperature for 1 day. The reaction mixture was poured into ice-water (15 ml). The pale yellow precipitates formed were collected by filtration and washed with water. The dried solid was dissolved in dioxane, the insoluble matter was filtered off, and the filtrate was evaporated to afford a colorless solid of **17** (793 mg, 82%). The analytical sample was obtained by silica gel chromatography with benzene-ethyl acetate (6:1): mp 174—177 °C (dec); $[\alpha]_D^{18}$ +90°(*c* 0.5, dioxane); ν_{max}^{KBr} 3320 (NH), 1730(ester), 1695 and 1525 cm^{-1}(amide); δ(DMSO-d_6) 3.4—3.9(m, 3H, H-3,5,5'), *ca.* 4.9(m, 1H, H-4), 5.22 and 5.37(each

s, 6H, CH_2Ph), 7.3—7.8(m, 2H, NH), 7.48(s, 1H, H-1), 7.60(s, 15H, Ph), and 8.42(s, CHO).

Found: C, 64.14; H, 5.30; N, 7.23%. Calcd for $C_{30}H_{29}N_3O_8$: C, 64.39; H, 5.08; N, 7.23%.

*3,4-Diamino-6-(benzyloxycarbonylamino)-3,4,6-trideoxy-1,2-O-isopropylidene-α-D-glucopyranose (**18**).* A solution of *N*-(benzyloxycarbonyloxy)succinimide (810 mg) in DMF (7.1 ml) was added dropwise to a solution of **8** (706 mg) in 75% DMF-water (14.1 ml) at −30——20 °C under stirring over a period of 30 min. After being kept at room temperature for 1 h, the reaction mixture was evaporated, the resulting syrup was dissolved in chloroform (20 ml), washed with saturated $NaHCO_3$ and saturated NaCl solution successively, dried, and evaporated. The syrupy residue (1.4 g) was chromatographed on silica gel (140 g) with chloroform-methanol (5:1) to afford a homogeneous sample of the 6-*N*-benzyloxycarbonylated product **18** (527 mg, 40%) as a colorless syrup, which was used for subsequent synthesis without further purification: $\nu_{max}^{CHCl_3}$ (0.1 M) 3400 (NH), 1710 and 1510 cm^{-1}(amide); δ ($CDCl_3$) 1.37 and 1.56 [each s, 6H, $C(CH_3)_2$], 1.66(s, 4H, NH) 2.53(dd, 1H, H-4, $J_{3,4}$=6.0, $J_{4,5}$=8.3 Hz), 3.03(dd, 1H, H-3, $J_{2,3}$=5.0 Hz), 3.6—3.8(m, 3H, H-5,6,6'), 4.07(dd, 1H, H-2, $J_{1,2}$=5.0 Hz), 5.21(s, 2H, CH_2Ph), *ca.* 5.4(m, 1H, NH), 5.63(d, 1H, H-1), and 7.48(s, 5H, Ph).

*3,4-Di-*N*-acetyl Derivative (**19**).* A sample of **18** (33.6 mg) was acetylated with acetic anhydride (0.02 ml) in methanol (0.67 ml) at room temperature for 20 min. Evaporation of the reaction mixture followed by chromatography on silica gel (4 g) with chloroform-methanol (20:1) afforded the pure sample of **19** as a glassy solid (38.5 mg, 93%): $[\alpha]_D^{25}$ +38°(*c* 0.66, $CHCl_3$); ν_{max}^{KBr} 3300 (NH), 1700, 1650 and 1530 cm^{-1}(amide); δ($CDCl_3$) 1.37 and 1.59[each s, 6H, $C(CH_3)_2$], 1.96 and 1.99(each s, 6H, NAc), 3.4—4.5(m, 6H, H-2,3,4,5,6,6'), 5.21(s, 2H, CH_2Ph), 5.65(d, 1H, H-1, $J_{1,2}$=4.8 Hz), *ca.* 5.7 and 6.3(3H, NH), and 7.47(s, 5H, Ph).

Found: C, 57.63; H, 6.58; N, 9.42%. Calcd for $C_{21}H_{29}N_3O_7$: C, 57.92; H, 6.71; N, 9.65%.

*3,4-(1,3-Guanidinediyl)-6-benzyloxycarbonylamino-3,4,6-trideoxy-1,2-O-isopropylidene-α-D-glucopyranose (**20**) Hydrobromide.* Cyanogen bromide (138 mg) was added to a solution of **18** (458 mg) in water (4.6 ml) under stirring. After being left to stand at room temperature for 1 h, the reaction mixture was evaporated and the residue was chromatographed on silica gel (60 g) with chloroform-ethanol (5:1) to afford the crystalline hydrobromide of **20** (555 mg, 93%): mp 122—125 °C (dec); ν_{max}^{KBr} 3400—3000 (NH^+), 1700 and 1530(amide), 1675 cm^{-1} (guanidium I); $[\alpha]_D^{20}$ +59°(*c* 0.55, MeOH); δ($CDCl_3$) 1.36 and 1.52[each s, 6H, $C(CH_3)_2$], 3.7—4.4(m, 6H, H-2,3,4,5,6,6'), 5.23(s, 2H, CH_2Ph), *ca.* 5.7(1H, H-1), *ca.* 6.2(br, 1H, NH), 7.2—7.7(br, 4H, guanidinium), and 7.46(s, 5H, Ph).

Found: C, 47.39; H, 5.72; N, 12.41; Br, 17.14%. Calcd for $C_{18}H_{25}N_4O_5Br$: C, 47.27; H, 5.51; N, 12.25; Br, 17.47%.

*3,4,6-Tris(benzyloxycarbonylamino)-3,4,6-trideoxy-D-glucitol (**23**).* A mixture of **7** (916 mg) and 20% acetic acid (27.5 ml) was heated at 100—110 °C for 1.5 h and then evaporated. The residual brown syrup was chromatographed on silica gel (43 g) with benzene–ethyl acetate(2:1) to afford 3,4,6-triazido-3,4,6-trideoxy-D-glucose (682 mg, 86.2%) A solution of sodium borohydride (57 mg) in 80% ethanol (1.0 ml) was added to a solution of free sugar (682 mg) in ethanol (5.1 ml) under ice-cooling. The mixture was stirred at the same temperature for 0.5 h, and then warmed up to room temperature, stirring being continued for 3 h, and neutralized with Amberlite IR-120(1.5 ml). The resulting solution was evaporated and the residue was chromatographed on silica gel (65 g) with benzene-ethyl acetate (1:1) to give a colorless syrup of **22** (415 mg, 60%). Triazido compound **22** (632 mg) was hydrogenolized over palladium black in methanol (12 ml) for 4 h to afford the triamino compound as a pale yellow syrup. A solution of *N*-(benzyloxycarbonyloxy)succinimide (2.0 g) in DMF (4 ml) was added to a solution of the triamino compound (450 mg) in DMF (4 ml) and water (0.2 ml). After being kept at room temperature, the reaction mixture was poured into ice-water (150 ml). The precipitates formed were collected by filtration, washed with water, and dried to yield a colorless crystalline solid of **23** (1.43 g, 98% from **22**). Recrystallization from methanol afforded an analytical sample: mp 148.5—149.5 °C; $[\alpha]_D^{20}$ +53°(*c* 0.94, DMF).

Found: C, 62.11; H, 6.04; N, 7.20%. Calcd for $C_{30}H_{35}N_3O_9$: C, 61.95; H, 6.07; N, 7.23%.

*2,3,5-Tris(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabono-1,4-lactone (**25**).* (a) A solution of sodium metaperiodate (273 mg) in water (2 ml) was added to a solution of **23** (430 mg) in acetone (9 ml), and the mixture was stirred at room temperature for 1 h. The mixture was diluted with acetone (9 ml). The precipitates were filtered off, and the filtrate was evaporated to afford 2,3,5-tris(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabinofuranose (**24**) (404 mg) as a colorless solid: R_f 0.56(silica gel, 3:1 benzene-acetone). Furanose **24** (404 mg) was oxidized with the chromium trioxide-acetic acid-pyridine reagent** (9.2 ml) at room temperature for 1.5 h. The reaction mixture was diluted with water (20 ml), extracted with chloroform, the extracts being washed with saturated NaCl solution, dried, and evaporated. The syrupy residue (300 mg) was chromatographed on silica gel (30 g) with benzene-acetone (6:1) to give **25** (265 mg, 66%) as a colorless solid: mp 89—91 °C (benzene); $[\alpha]_D^{18}$ −26° (*c* 0.97, $CHCl_3$); ν_{max}^{KBr} 3320 (NH), 1785 (1,4-lactone), 1680 and 1510 cm^{-1}(amide); δ($CDCl_3$) *ca.* 3.6, 4.3, and 4.7(m, 5H, H-2,3,-4,5,5'), 5.10(s, 6H, CH_2Ph), *ca.* 5.8(br, 3H, NH), and 7.32(s, 15H, Ph).

Found: C, 63.70; H, 5.47; N, 7.49%. Calcd for $C_{29}H_{29}N_3O_8$: C, 63.61; H, 5.34; N, 7.68%.

(b) A sample of **13** (10.8 mg) was treated with the chromium trioxide-acetic acid-pyridine reagent (0.25 ml) at room temperature for 3 h. The reagent (0.25 ml) was added to the mixture. After being stirred for 30 min, the reaction mixture was worked up as described in (a) to afford a sample of **25** (4.1 mg, 42%) as a semicrystalline solid, whose IR spectrum was identical with that of the sample of **25** prepared from **24**.

*5-Amino-2,3-bis(benzyloxycarbonylamino)-2,3,5-trideoxy-D-arabono-1,5-lactam (**26**).* A sample of **25** (209 mg) was hydrogenolized in methanol (6 ml) over palladium black for 5 h. During the course of reaction a fresh catalyst was added every hour. The crude triamino sugar lactam **16** was purified by silica gel chromatography with chloroform-methanol-17% aqueous ammonia (6:6:1) to afford a practically pure sample of **16** (39.7 mg, 72%). Treatment of the sample of triamino sugar lactam **16** with 3 equivalent of *N*-(benzyloxycarbonyloxy)succinimide in aqueous DMF gave a crystalline sample of **26** in 85% yield after being subjected to chromatography with chloroform-methanol (10:1). The sample was identical with the authentic sample[3] of **26**.

The authors wish to thank Mr. Saburo Nakata for carring out the microanalyses.

**The reagent[10] is composed of chromium trioxide (1 g), acetic acid (30 ml) and pyridine (1 ml).

Aromatic Solvent-induced Shifts (ASIS). II. Interpretation of Benzene and Hexafluorobenzene Induced Shifts by Means of the Electrostatic Interaction Model

Kunio NIKKI* and Naoya NAKAGAWA

The University of Electro-Communications, Chofu, Tokyo 182

(Received January 31, 1978)

The relationships between the ASIS in proton magnetic resonance and charge distribution in the solute and solvent molecules were studied. The results obtained are as follows. Protons lying in the positive charge-region of the solute dipole showed an up-field shift in C_6H_6 and a down-field shift in C_6F_6, while protons lying in the negative charge-region showed a down-field shift in C_6H_6 and an up-field shift in C_6F_6. There exists a linear relationship between the ASIS and the solute dipole moments of monosubstituted methanes, *t*-butyl derivatives, and para substituted toluenes. Shifts of para substituted toluenes and 4-methyl-4′-nitrobiphenyl are in good agreement with those expected from the electrostatic interaction model.

Aromatic solvent-induced shifts (ASIS) in ^1H NMR spectroscopy have been well investigated.[1,2] The benzene-induced shifts observed for carbonyl compounds are conveniently explained by an empirical rule, the so-called "Carbonyl plane rule."[3]

In the earlier models of ASIS, *i.e.*, the dipole-induced dipole interaction model, the quadrupole-induced quadrupole interaction model,[4] and in the H-bond interaction model,[5] the nature of intermolecular interactions was discussed without much success.

Since then, two models have been proposed to explain ASIS. One is the solute–solvent specific 1:1 complex model and the other is the time-averaged cluster model. In the former model Williams *et al.* assumed the existence of solvent molecules with favorable distances and orientations to the solute molecules; these would show the feature of ASIS.[1] Laszlo *et al.* pointed out in the latter model that the solute dipole should be the cause of clustering.[2] They did not discuss, however, the nature of the solute-solvent interaction.

In our previous paper,[6] benzene-induced shifts of methyl protons on *d*-camphor were discussed in terms of the electrostatic dipole(*d*-camphor)-quadrupole-(benzene) interaction. The results were in good agreement with the experimental ASIS values. If the main interaction between solute molecule and solvent mole cules is assumed as the electrostatic interaction, the flat surface of benzene molecules near the positive charge end of the dipole are likely to face to the positive end. Thus, benzene molecules induce up-field shifts due to their magnetic anisotropy for the protron near the positive end. On the other hand, the periphery part of benzene molecules near the negative charge end of the dipole are likely to face to the negative end. Thus, they induce down-field shifts for the proton near the negative end. These favorable orientations are similar to those proposed by Williams[1] and Ledaal.[7]

Recently, it was shown that a different solvent effect was induced by hexafluorobenzene, which generally shows shifts opposite to those induced by benzene.[8-17] The carbonyl plane rule for that solvent was also proposed,[16] but the nature of the intermolecular interaction was not discussed.

The main purpose in this paper is to clarify the mechanism of ASIS: these shifts are caused by the orientation of solvent molecules around the dipole due to intermolecular electrostatic interactions. Furthermore, it will be shown that the hexafluorobenzene(which has a different charge distribution than benzene)-induced shifts were also caused mainly by the electrostatic interaction, as in the case of benzene-induced shifts.

Thus the aromatic solvent-induced shifts (ASIS) in benzene and hexafluorobenzene of monosubstituted methanes, *t*-butyl derivatives, para substituted toluenes, and 4-methyl-4′-nitrobiphenyl were determined. Besides these determinations, the observed ASIS values of para substituted toluenes and 4-methyl-4′-nitrobiphenyl were calculated on the basis of the electrostatic interaction between solute and solvent molecules.

Experimental

ASIS(C_6H_6) and ASIS(C_6F_6) of the compounds given in Table 1 were measured with a Hitachi R-20B spectometer operating at 60 MHz as 1 mol % solutions, with cyclohexane as the internal reference. Carbon tetrachloride was assumed to be inert. The ASISs were defined by

$$\mathrm{ASIS}(C_6H_6) = \delta_{C_6D_6} - \delta_{CCl_4},$$

$$\mathrm{ASIS}(C_6F_6) = \delta_{C_6F_6} - \delta_{CCl_4},$$

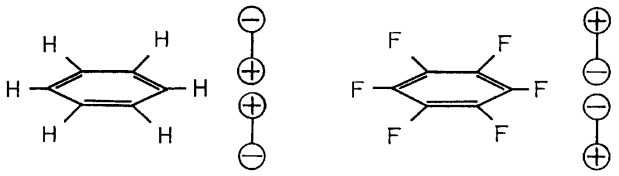
where $\delta_{C_6D_6}$, δ_{CCl_4}, and $\delta_{C_6F_6}$ are the chemical shifts in benzene-d_6, carbon tetrachloride, and hexafluorobenzene from the internal reference of cyclohexane, respectively. The chemical shifts were determined by the sideband method with the aid of a frequency counter. The standard deviation in all cases was less than ± 0.01 ppm.

Calculation

The electric charge distributions in benzene and hexafluorobenzene molecules were approximately

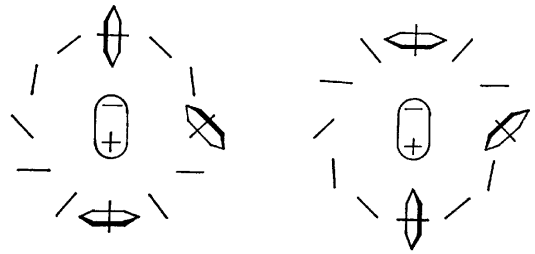
TABLE 1. SOLUTE MOLECULES

	Compound	Substituent
(I)	CH_3-X	X=NO_2, CN, CCl, I, SCN
(II)	$(CH_3)_3C$-X	X=CN, Cl, Br, NH_2, OCH_3, OH
(III)	*para*-$CH_3C_6H_4$-X	X=$\begin{cases}NO_2, CN, CHO, Br, Cl, I\\ OCH_3\ NH_2, N(CH_3)_2\end{cases}$
(III′)	$CH_3C_5H_4N$(4-methyl pyridine)	
(IV)	$CH_3C_6H_4C_6H_4NO_2$(4-methyl-4′-nitrobiphenyl)	



a) C_6H_6 b) C_6F_6

Fig. 1. Benzene molecule(a) and hexafluorobenzene molecule(b) are approximately expressed by electric bar-quadrupoles.



C_6H_6 C_6F_6

Fig. 2. The most stabel orientation of solvent molecules around a solute molecules due to the dipole (solute)-quadrupole(solvent) interaction ($U \propto \mu Q/r^4$).

represented by electric bar-quadrupoles (see Fig. 1). The principal values of the quadrupole moment tensor, with the Z-principal axis along with the six-fold molecular axis, and the anisotropy of the magnetic susceptibility ($\Delta\chi = \chi_{\parallel} - \chi_{\perp}$; the subscripts $\parallel$ and $\perp$ here mean parallel and perpendicular to the highest axis of symmetry of the molecule) are given in Table 2. Then the ASIS value of a polar solute molecule induced by these solvents can be calculated if the orientation of these quadrupoles (solvent) around the solute dipole is assumed.

The most stable orientation of benzene molecules and hexafluorobenzene molecules around a dipole is shown in Fig. 2. The calculation of ASIS based on the electrostatic dipole(solute)-quadrupole(solvent) interaction was reported in detail in the previous paper of this series.†,[6]

The calculations were performed by computer with the HITAC 8300 at the University of Tokyo.

† We found some errors in Figs. 2 and 4 in the previous paper.[6]

The expressions of the dihedral angle (ϕ) between the plane containing $\vec{\mu}$ and $\vec{r}$ and that containing $\vec{r}$ and $\vec{B}$ in Figs. 2 and 4 should be corrected as follows:

	Q_{ZZ} ——	+17.2	

Results and Discussion

The ASIS of methyl protons *versus* dipole moments of monosubstituted methanes(I) and *t*-butyl derivatives(II) are plotted in Fig. 4. The ASIS values *versus* their dipole moments for methyl-protons and *ortho*-protons of para substituted toluenes(III) are plotted in Fig. 5. The experimental values and the calculated ones of these ASIS are summarized, together with those of the dipole moments, in Tables 3(a)—(b).

There exists a linear relationship between the ASIS and the solute dipole moments in benzene solutions. Of the protons in question, those on solute molecules lying in the positive-charge region of the solute dipole exhibit up-field shifts, while the protons lying in the negative-region exhibit down-field shifts or only minor up-field shifts.

For the convenience of further discussion, the substituted molecules can be classified into two groups according to the directions of their dipole moments. (see Table 4.) In the proposed classification, group (A) consists of protons of the methyl group and those on the aromatic ring of p-$CH_3C_6H_4X_A$ which are lying in the positive-region of the solute dipole and show up-field shifts, while group (B) consists of those which show down-field shifts or only slight up-field shifts.

ASIS(C_6H_6) values of molecules of (III), (III'), and (IV) expressed as a function of the distance between the proton in question and the carbon on the base of the substituent are plotted in Fig. 6. The "sense" of the shifts is quite different for group (A) and group (B) molecules. In order to express this difference, the "Carbonyl plane rule" is conveniently extended to other polar substituents, and renamed as the "Dipole plane rule." A dipole plane can be assumed on the polar substituents, as illustrated in Fig. 7(a). Protons lying in the positive region of the dipole are assumed to show up-field shifts. However, the dipole planes of 4-methylpyridine (III') and 4-methyl-4'-nitrobiphenyl(IV) are located near the center of these molecules.

Conversely, in hexafluorobenzene solutions, sensor protons lying in the positive-region of the solute dipole showed down-field shifts while the protons in the negative-region showed up-field shifts. Therefore, a dipole plane can be illustrated as in Fig. 7(b). Here the protons lying in the positive-region of the dipole are assumed to show down-field shifts.

The experimental "Dipole plane rule" can, though

a) μ represents a dipole moment.

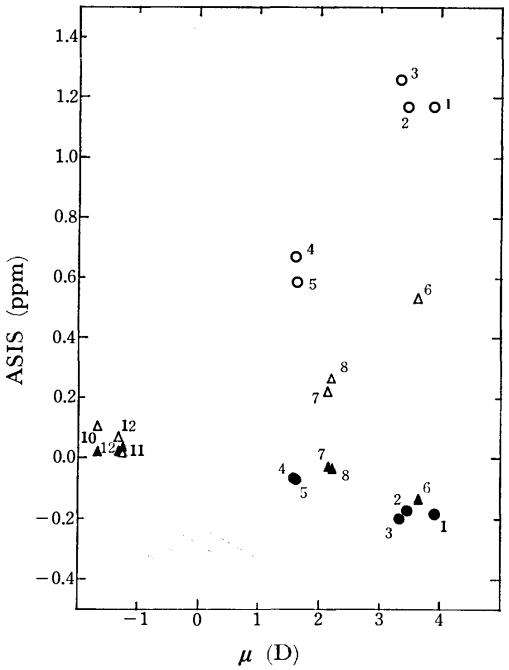

Fig. 4. ASIS values of methyl-protons *vs.* dipole moments(μ) of monosubstituted methanes (○: in C_6H_6, ●: in C_6F_6, and substituent; 1: CN, 2: NO_2, 3: SCN, 4: I, 5: CCl_3) and *t*-butyl derivatives (△: in C_6H_6, ▲: in C_6F_6, and substituent; 6: CN, 7: Cl, 8: Br, 9:SH, 10: OH, 11: OCH_3, 12: NH_2).

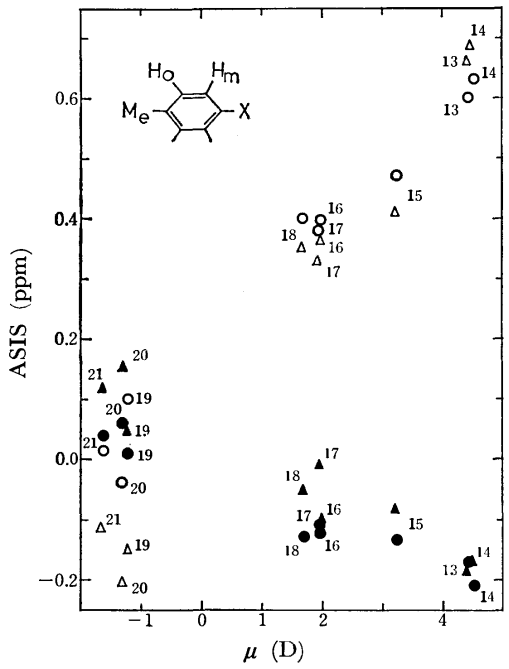

Fig. 5. ASIS values of methyl-protons (○: in C_6H_6 and ●: in C_6F_6) and *ortho*-protons (△: in C_6H_6 and ▲: in C_6F_6) *vs.* dipole moments (μ) for para substituted toluenes)(substituent; 13: CN, 14: NO_2, 15: CHO, 16: Br, 17: Cl, 18: I, 19: OCH_3, 20: $N(CH_3)_2$, 21: NH_2).

only in a qualitative manner, express ASIS values except for the proton near the dipole plane.

Figure 6 indicates that significiant differences between ASIS (C_6H_6) and ASIS(C_6F_6) are in the "sense" of the shifts and the position of the dipole planes. In hexafluorobenzene, the plane should be placed between the substituent and the center of the molecules.

As a general feature of the shifts, the magnitude of up-field shifts is larger than those of down-field shifts in benzene, while the magnitude of up-field shifts is comparable with down-field shifts in hexafluorobenzene, and the magnitude of ASIS(C_6H_6) is larger than those of ASIS(C_6F_6) for the same solute molecules. Those features of the ASIS are explainable in terms of the electrostatic interaction model. In a benzene solution, the more stable orientation of a solvent molecule around the solute dipole takes configuration (C) on the positive-charge region of the solute dipole while it takes configuration (D) on the negative-charge (see Figs. 2 and 8). As both benzene and hexafluorobenzene molecules have a flat, disk-like shape, the distance from the center of the solute dipole to the center of the solvent quadrupole is shorter in configuration (C) than in (D) ; furthermore the distance from the proton in question of the solute to the solvent molecules is also shorter in configuration (C) than in (D).

The stabilization energy of configuration (C) on the positive region is thus greater than that of (D) on the negative-region(see our previous paper[6]). In view of the known magnetic anisotropy of the benzene ring, configuration (C) should give an up-field shift,

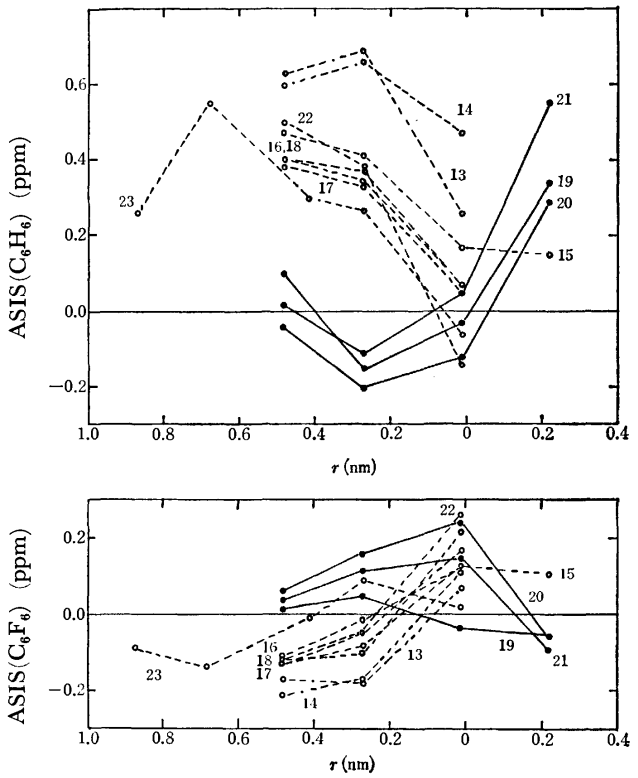

Fig. 6. The relations between ASIS values and the position of protons on para substituted toluenes and on 4-methyl-4′-nitrobiphenyl in C_6H_6 and in C_6F_6 (----: group (A) molecules and ——: group (B) molecules, substituent; 13: CN, 14: NO_2, 15: CHO, 16: Br, 17: Cl, 18: I, 19: OCH_3, 20: $N(CH_3)_2$, 21: NH_2, and molecules; 22: III′, 23: IV).

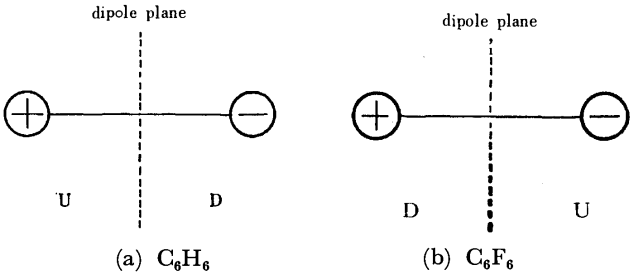

Fig. 7. A dipole plane rule in C_6H_6 (a) and in C_6F_6 (b). (U: up-field shift region and D: down-field shift region.)

while (D) should give a down-field shift for solute protons. Therefore the up-field shifts should show larger values than the down-field shifts.

In hexafluorobenzene solutions, however, the most stable orientation are configuration (D) on the positive-region of the solute dipole and configuration (C) on the negative-region. And the stabilized energy due to the dipole-quadrupole interaction on the positive-region is less than that on the negative-region; the effect of down-field shifts on the positive-region, is however, comparable with the up-field shifts on the negative-region, since the other attractive interaction between the local positive charge of the solute dipole and the localized dipole of C–F bond is not so small.

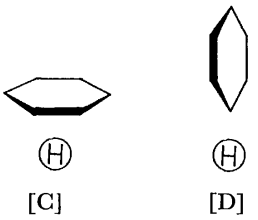

Fig. 8.

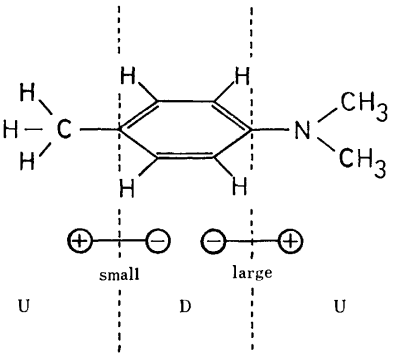

Fig. 9. Dipole plane rule on a *N*,*N*-dimethyl-*p*-toluidine. (U: up-field shift region and D: down-field shift region.)

Almost all the ASIS are interpreted by the orientation of the quadrupoles(solvent moleucles) around the solute dipole due to the electrostatic interaction, and are in good accord with the dipole plane rule. However, three exceptions were found.

One is the ASIS of methyl protons of the molecules in (III) when X=OCH_3, NH_2, or $N(CH_3)_2$. The ASIS values of these molecules showed a very slight up-field shift with hexafluorobenzene. These molecules are classified in group (B) and so the Hammett's σ_p values of the methyl group has the same sign as the Hammett's σ_p values of the OCH_3, NH_2, $N(CH_3)_2$ groups, but the direction of the bond dipole of the methyl group is opposite to that of the substituents in group (B). In this case, the effect of the bond dipole on the ASIS of the methyl group must be taken into consideration. This effect is especially great in the case of benzene solution, because benzene molecules around methyl protons are located in the positive-region of the methyl dipole, and so their more stable orientation gives large up-field shifts.(See Fig. 9.)

The second exception is a remarkable up-field shift found in the ASIS(C_6F_6) of *meta*-protons of the molecules in (III) in which X=$N(CH_3)_2$. As $N(CH_3)_2$ is a bulky substituent, no other solvent molecules are permitted to exist within it. As the exclusion space is located in the positive-region, the proton in question is not influenced by solvents that will cause down-field shifts. Herein the proton is considered to be influenced mainly by solvents in the negative-region and to show up-field shifts.

The third exception is that both solvents will induced a large up-field shift of protons on NH_2 on a group (III) molecule. It is presumed that the up-field shift is caused by the hydrogen bond-like interaction between the NH_2 group and π-electrons of the

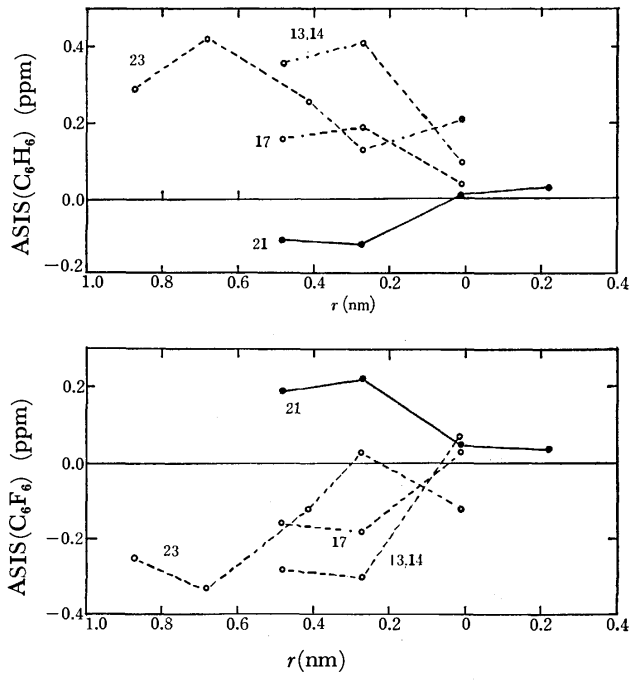

Fig. 10. The relations between calculated ASIS values and the position of protons on para substituted toluenes and on 4-methyl-4′-nitrobiphenyl in C_6H_6 and in C_6F_6 (substituent; 13: CN, 14: NO_2, 17: Cl, 21: NH_2, and molecule; 23: IV).

aromatic ring.

The calculated ASIS values of protons on para-substituted toluenes and 4-methyl-4′-nitrobiphenyl with benzene and hexafluorobenzene are illustrated in Fig. 10.

These exceptions are mostly due to the point-dipole and point-quadrupole approximations. Our model is, however, much more quantitative than the arbitrary models of Williams,[1] Ledaal,[7] and Verkade *et al.*[8-17] There is no need to say that a 1:1 complex is highly unlikely.

Our calculation is performed based on real physical numerical quantities without using the arbitary parameters such as in Laszlo *et al.*[2] The calculated values are in a good agreement with the observed values in the "sense" and in the order of magnitude. And the magnitude of shifts on the same molecule or on the molecules with a similar shape can be compared.

Thus, the ASIS of various solute molecules in ^1H NMR caused by benzene and hexafluorobenzene can be explained by the orientation of solvent molecules around a polar solute molecule(see Fig. 2) due to electrostatic interaction.

The authors wish to express their thanks to Dr. Yosito Takeuchi of the University of Tokyo for his helpful advice.

The Formation of Ethers from Unsaturated Aliphatic Alcohols in the Presence of Boron Trifluoride Etherate

Kimiko NAGAI,* Mitsuru NAKAYAMA,** and Shûichi HAYASHI**

Yasuda Women's University, Kamiyasu, Yasufuruichi-cho, Hiroshima 731-01

** *Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730*

(Received February 3, 1978)

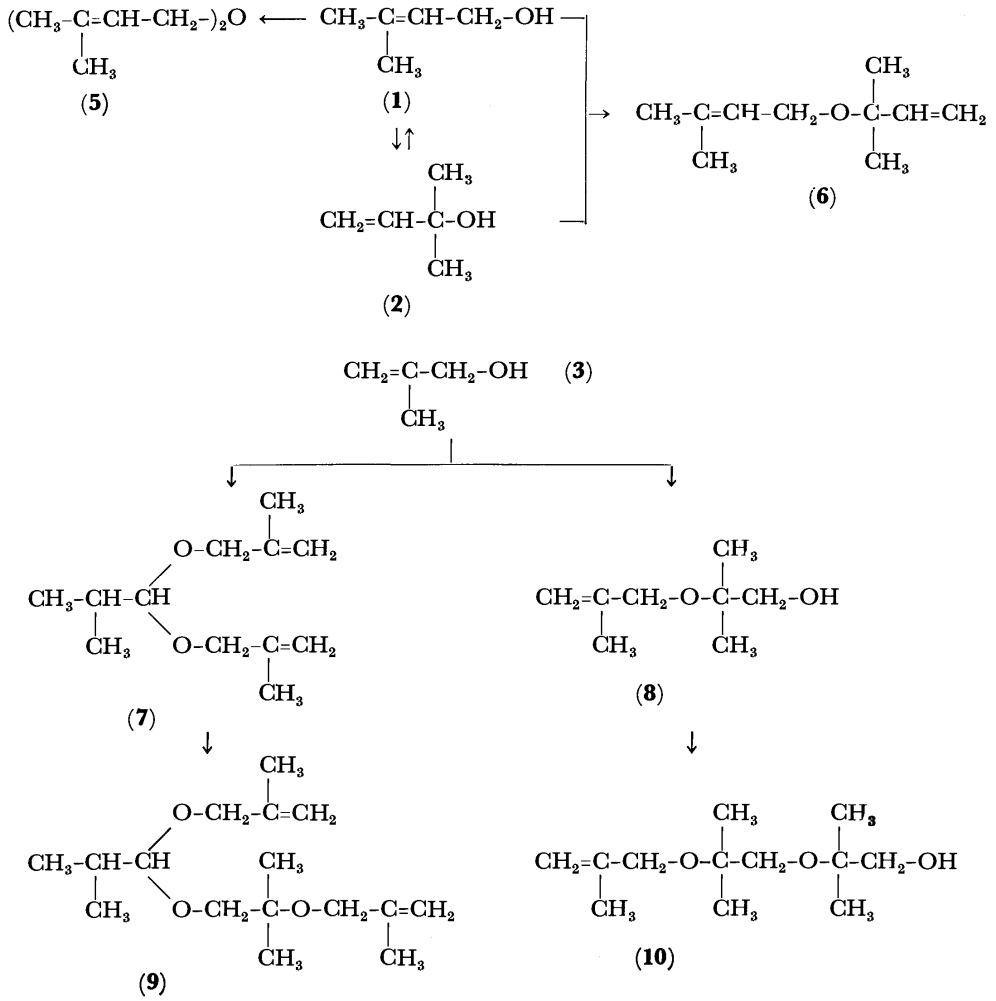
Unsaturated acyclic alcohols of carbon numbers four and five reacted with boron trifluoride etherate to give eight ethers. Of these ethers, novel acyclic di- and tri-ethers were found in the reaction products of 2-methyl-2-propen-1-ol. Boron trifluoride etherate catalyzes double-bond migration, allylic rearrangement, intermolecular dehydration, and Markownikov addition reactions in unsaturated aliphatic alcohols.

In previous papers it has been reported that ethers of several types were obtained by reactions of monoterpene alcohols, of allylic geraniol,[1] nerol,[2] homoallylic *l*-isopulegol,[3] saturated bicyclic *d*-borneol,[4] and *dl*-isoborneol[4] with boron trifluoride etherate in the acid-catalyzed intermolecular dehydration of these alcohols and/or their isomers. Citronellol, in which one double bond is at the ζ-position for the hydroxyl group, gave cyclic and acyclic ethers upon intermolecular addition.[5]

In the present work, studies of analogous acid-catalyzed reactions of four unsaturated acyclic alcohols, allylic 3-methyl-2-buten-1-ol (**1**), 2-methyl-3-buten-2-ol (**2**), 2-methyl-2-propen-1-ol (**3**), and homoallylic 3-methyl-3-buten-1-ol (**4**), will be reported.

Results and Discussion

Upon treatment with boron trifluoride etherate at room temperature, **1** of a primary alcohol was dimerized to give two ethers, one symmetrical and one unsymmetrical, in yields of 4 and 32% respectively, by means of the intermolecular dehydration of the starting material and/or its isomer. On the other hand, **2** of a tertiary alcohol gave only a unsymmetrical ether in a 40% yield. The structures of these ethers were determined to be bis(3-methyl-2-butenyl) ether (**5**) for the symmetrical ether and 3-methyl-2-butenyl 1,1-dimethyl-2-propenyl ether (**6**) for the other one on the basis of their spectral data and chemical behavior.



In these reactions, on double-bond migration occurs, the allylic rearrangement of the hydroxyl group takes place at a high rate, and the equilibrium is probably shifted from **1** to **2**.

2-Methyl-2-propen-1-ol (**3**), which contains a isopropenyl group, gave two kinds of polyethers (**7** and **9**) and two kinds of hydroxyl ethers (**8** and **10**). The novel ethers (**7** and **9**) are thought to be produced by the method of double-bond migration, followed by the dehydration condensation with **3** *via* the aldehyde form. On the other hand, the hydroxyl ethers appear to be formed by the Markownikov addition of the hydroxyl group to the double bond.

On the other hand, 3-methyl-3-buten-1-ol (**4**), which has two methylene groups between the double bond and the hydroxyl group, gave two hydroxyl ethers (**11** and **12**) according to the Markownikov rule and no di- or tri-ether (**7** or **9**), as has been mentioned in the case of the **3** alcohol.

Experimental

Apparatus. The GLC analyses were carried out using a Hitachi-063 apparatus, equipped with an FID detector, a stainless-steel separating column (3 mm×3 m) packed with Carbowax 6000 (10%) on Diasolid L (60—80 mesh) and Carbowax 20 M (10%) on Diasolid L (60—80 mesh); the flow rate of the nitrogen carrier gas was 20 ml/min. The mass spectra were recorded on a Hitachi RMS-4 spectrometer at an ionization voltage of 80 eV, an ion-accelerating voltage of 1800 eV, and an ionization chamber temperature of 100 °C. The PMR spectra were measured in CCl_4 solutions using a 60 MHz spectrometer, Hitachi R-20, with TMS as the internal reference. The CMR spectrum was obtained in a $CDCl_3$ solution on a JEOL FX-60 spectrometer under those conditions: pulse repetition, 3 s; accumulation, 1200 times, and frequency range, 4 kHz. The preparative-GLC separations were carried out by means of a Yanagimoto G-80 apparatus, with Carbowax 20 M (10%) on Diasolid L (6 mm×2 m); temperature program: 5 °C/min, from 150 °C to 200 °C.

Materials. Commercial **2**, **3**, and **4** were used without purification. These alcohols exhibited single peaks in GLC with DEGS and Carbowax 6000.

$BF_3 \cdot Et_2O$ of a chemical grade (BF_3 47%) was used without any purification.

*1) Reaction of **1** with $BF_3 \cdot Et_2O$.* Ten grams of **1**[6] were submitted to a reaction with $BF_3 \cdot Et_2O$ (0.6 ml) at room temperature (*ca.* 20 °C) for 24 h, and then extracted with ether after being diluted with water (50 ml). The extract was washed with a 10% aqueous solution of sodium carbonate and then with water, and dried over anhydrous sodium sulfate. The reaction mixture showed the presence of two compounds upon GLC and TLC, these compounds (**5** and **6**) were separated by means of a silica-gel column using a mixed solvent of hexane containing 5% ethyl acetate.

*Bis(3-methyl-2-butenyl) Ether (**5**):* One of the above-mentioned compounds was isolated as a colorless oil: Rast's molecular weight, 158 (Calcd, 154); IR (liq.) 1070 (C–O–C), 1675, 830 cm^{-1} (–CH=$\overset{|}{C}$–); PMR (CCl_4) δ 1.61, 1.70 (each 6H, br s, CH_3–$\overset{|}{C}$=$\overset{|}{C}$–×4), 3.79 (4H, d, J=7 Hz, –$\overset{|}{C}$=CH–CH_2–O–×2), 5.24 ppm (2H, m, –CH=$\overset{|}{C}$–×2).

*Catalytic Hydrogenation of **5**:* Compound **5** (250 mg) was hydrogenated over PtO_2 (25 mg) in acetic acid (5 ml) to take up two equivalent moles of hydrogen. The spectral data of tetrahydro-**5** were superimposable on those of the diisopentyl ether synthesized from 3-methyl-1-butanol (1.0 g)

and diisopentyl bromide (0.5 g). Colorless oil; bp 171—172 °C, d_4^{20} 0.776. IR (liq.) 1385, 1371 (CH_3–CH–CH_3), 1130, 1111 cm^{-1} (C–O–C); PMR (CCl_4) δ 0.89 (12H, d, J= 6 Hz, CH_3–CH–CH_3 ×2), 1.49 (4H, t, J=7 Hz, –CH–CH_2 –CH_2– ×2), 1.30—1.78 (2H, m, CH_3–CH–CH_3 ×2), 3.40 ppm (4H, t, J=7 Hz, –CH_2–CH_2–O– ×2).

*3-Methyl-2-butenyl 1,1-Dimethyl-2-propenyl Ether (**6**)*: The second compound was obtained as a colorless oil. Rast's molecular weight (155) and the molecular ion (M^+ 154) in the mass spectrum corresponded to a molecular formula of $C_{10}H_{18}O$. Mass *m/e* 41 (75%), 55 (20), 57 (25), 69 (base), 85 (33), 110 (15), 124 (24), 137 (7, M^+-CH_3), 154 (5, M^+, $C_{10}H_{18}O$); IR (liq.) 1145, 1060 (C–O–C), 1680, 830 (–CH=C–), 3080, 1645, 1001, 920 cm^{-1} (CH_2=CH–); PMR (CCl_4) δ 1.20 (6H, s, –O–C(CH_3)$_2$–C=C–), 1.62, 1.71 (6H, br s, CH_3–C=C– ×2), 3.82 (2H, d, J=7 Hz, =CH–CH_2–O–), 4.91—5.80 ppm (4H, q and m, CH_2=CH– and –CH=C–).

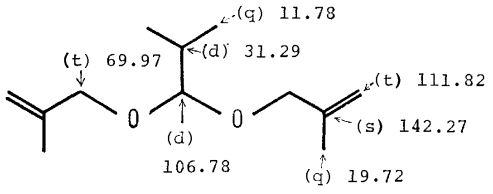
*Tetrahydro Derivative of **6***: Colorless oil. IR (liq.) 1390, 1371, 1368 (CH_3–CH–CH_3), 1088 cm^{-1} (C–O–C); PMR (CCl_4) δ 0.82 (3H, t, J=6 Hz, CH_3–CH_2–C–), 0.88 (6H, d, J=6 Hz, CH_3–CH–CH_3), 1.10 (6H, s, $(CH_3)_2$–C–O–), 1.43 (2H, t, J=6 Hz, $(CH_3)_2$–CH–CH_2–CH_2–), 3.31 ppm (2H, t, J=6 Hz, –O–CH_2–CH_2–).

*2) Reaction of **2** with $BF_3 \cdot Et_2O$.* The **2** alcohol (10 g) was allowed to react with $BF_3 \cdot Et_2O$ (0.6 ml) according to the procedure previously described. A colorless oil was thus obtained; Rast's molecular weight, 156 (Calcd, 154). The spectral data of the compound and its tetrahydro derivative were identical with those of Compound **6** and its tetrahydro-**6** respectively.

*3) Reaction of **3** with $BF_3 \cdot Et_2O$.* The **3** alcohol (10 g) was submitted to a reaction with $BF_3 \cdot Et_2O$ (0.5 ml) at room temperature (*ca.* 20 °C) for 72 h. The reaction mixture showed the presence of four compounds (**7**, **8**, **9**, and **10**) by GLC with Carbowax 20 M; these compounds were separated into individual compounds by means of preparative-GLC.

*2,8-Dimethyl-5-isopropyl-4,6-dioxa-1,8-nonadiene (**7**)*: The first compound was isolated from the reaction mixture as a colorless oil. The molecular formula corresponded to $C_{12}H_{22}O_2$, judging from the molecular weight (Rast's 200; Calcd, 198). Mass *m/e* 55 (base), 71 (31%, C_4H_7O), 127 (9, M^+-CH_2=C(CH_3)–CH_2–O–), 155 (12H, $M^+-C_3H_7$), 198 (trace, $C_{12}H_{22}O_2$); IR (CCl_4), 3081, 1665, 905 (CH_2=C(CH_3)–), 1397, 1380 (CH_3–CH–CH_3), 1311, 1111, 1071, 1041 cm^{-1} (C–O–C); PMR (CCl_4) δ 0.91 (6H, d, J=7 Hz, CH_3–CH–CH_3), 1.75 (6H, br s, CH_3–C=C– ×2), 1.70—2.10 (1H, m, $(CH_3)_2$–CH–CH–), 3.84 (4H, br s, –O–CH_2–C=C– ×2), 4.09 (1H, d, J=7 Hz, –O–CH(O–)–CH–), 4.81, 4.91 ppm (each 2H, br s, CH_2=C– ×2). The CMR spectrum of the compound was reasonably explained by the following assignments.

*Tetrahydro Derivative of **7***: Colorless oil. Mass *m/e* 57 (base), 73 (28%, C_4H_9O), 125 (10, $M^+-(CH_3)_2$–CH–CH_2–O–); IR (CCl_4) 1384, 1370 (CH_3–CH–CH_3), 1080, 1050 cm^{-1} (C–O–C); PMR (CCl_4) δ 0.89, 0.92 (12H and 6H, each d, J=6 Hz, CH_3–CH–CH_3 ×3), 1.51—2.05 (3H, m, $(CH_3)_2$–CH–CH_2 ×2 and $(CH_3)_2$–CH–CH–), 3.10 (4H, d, J=6 Hz, –CH–CH_2–O– ×2), 4.09 ppm (1H, d, J=7 Hz, –O–CH(O–)–CH–).



*2,2,5-Trimethyl-3-oxa-5-hexen-1-ol (**8**)*: The second compound was isolated as a colorless oil. The Rast's molecular weight, 145 (Calcd, 144), corresponded to the molecular formula of $C_8H_{16}O_2$. Mass *m/e* 55 (base), 113 (32%, M^+-CH_2OH), 126 (3, M^+-H_2O), 144 (trace, M^+, $C_8H_{16}O_2$); IR (liq.) 3480, 1155 (–OH), 1103, 1060 (C–O–C), 3080, 1664, 905 (CH_2=C–), 1380, 1370 cm^{-1} (CH_3–CH–CH_3); PMR (CCl_4) δ 1.15 (6H, s, CH_3–C–CH_3), 1.72 (3H, br s, CH_3–C=C–), 1.91 (1H, br s, –OH), 3.30 (2H, s, –C–CH_2–OH), 3.47 (2H, br s, =C–CH_2–O–), 4.78, 4.90 ppm (each 1H, br s, CH_2=C–).

*Acetyl Derivative of **8***: The acetylation of Compound **8** (300 mg) was carried out with acetic anhydride (1 ml) in dry pyridine (3 ml) at room temperature for 72 h. Colorless oil. IR (CCl_4) 1746, 1236 (CH_3COO–), 3080, 1660, 901 (CH_2=C–), 1100, 1050 cm^{-1} (C–O–C); PMR (CCl_4) δ 1.10 (6H, s, –O–C(CH_3)$_2$–), 1.72 (3H, br s, CH_3–C=C–), 2.00 (3H, s, CH_3COO–), 3.75 (2H, br s, –C=C–CH_2–O–), 3.92 (2H, s, CH_3COO–CH_2–C–), 4.73, 4.92 ppm (each 1H, br s, CH_2=C–).

*Dihydro Derivative of **8***: Colorless oil. IR (CCl_4) 3580, 3420, 1152 (–OH), 1080, 1057 (C–O–C), 1383, 1371 cm^{-1} (CH_3–CH–CH_3); PMR (CCl_4) δ 0.90 (6H, d, J=6 Hz, CH_3–CH–CH_3), 1.17 (6H, s, CH_3–C(O–)–CH_3), 1.60—2.01 (1H, m, $(CH_3)_2$–CH–CH_2–), 2.20 (1H, br s, –OH), 3.10 (2H, d, J=6 Hz, –CH–CH_2–O–), 3.40 ppm (2H, m, –C–CH_2–OH.)

*2,5,5,11-Tetramethyl-8-isopropyl-4,7,9-trioxa-1,11-dodecadiene (**9**)*: The third compound was also obtained as a colorless oil. The molecular formula had $C_{16}H_{30}O_3$ from Rast's molecular weight, 274 (Calcd, 270). Mass *m/e* 55 (base), 71 (15%), 81 (7), 101 (12), 115 (27), 155 (31), 227 (2, $M^+-C_3H_7$), 270 (trace, M^+, $C_{16}H_{30}O_3$); IR (CCl_4) 1110, 1060 (C–O–C), 3080, 1165, 903 (CH_2=C–), 1391, 1380, 1370 cm^{-1} (CH_3–CH–CH_3); PMR (CCl_4) δ 0.92 (6H, d, J=7 Hz, CH_3–CH–CH_3), 1.20 (6H, s, –CH–C–O–), 1.65 (6H, br s, –C(CH_3)$_2$=C– ×2), 1.76—2.10 (1H, m, $(CH_3)_2$–CH–CH–), 3.22, 3.40 (each 1H, d, J_{AB}=12 Hz, –O–CH_2–C(CH_3)–O–), 3.69, 3.89 (each 2H, s, =C–CH_2–O– ×2), 4.09 (1H, d, J=7 Hz, –O–CH–CH–), 4.80, 4.90 ppm (each 2H, br s, CH_2=C(O–)– ×2).

*Tetrahydro Derivative of **9***: Colorless oil. IR (CCl_4) 1390, 1384, 1370 (CH_3–CH–CH_3 and CH_3–C–CH_3), 1111, 1058 cm^{-1} (C–O–C); PMR (CCl_4) δ 0.89, 0.91 (18H, each d, J=6 Hz, CH_3–CH–CH_3 ×3), 1.19 (6H, s, CH_3–C–CH_3), 1.70—2.05 (3H, m, $(CH_3)_2$–CH–CH– ×3), 3.15 (4H, d, J=

6 Hz, -O-C**H**$_2$-CH-×2), 3.20, 3.39 (each 1H, d, J_{AB}= 12 Hz, -O-C**H**$_2$-C-O-), 4.09 ppm (1H, d, J=7 Hz, -O-CH-C**H**-).

*2,2,5,5,8-Pentamethyl-3,6-dioxa-8-nonen-1-ol (**10**)*: The last compound was isolated as a colorless oil; Rast's mol wt, 220 (Calcd, 216, $C_{12}H_{24}O_3$). Mass *m/e* 55 (base), 73 (22%), 101 (9), 113 (28), 127 (7), 143 (4), 185 (4, M^+-CH_2OH), 216 (trace, M^+, $C_{12}H_{24}O_3$); IR (liq.) 3480, 1071 (-OH), 1170, 1095, 1068 (C-O-C), 3080, 1662, 903 (CH$_2$=C-), 1397, 1370 cm^{-1} (CH$_3$-C-CH$_3$); PMR (CCl_4) δ 1.10, 1.16 (each 6H, s, C**H**$_3$-C-C**H**$_3$×2), 1.73 (3H, br s, C**H**$_3$-C=C-), 2.33 (1H, br s, -O**H**), 3.18 (2H, s, -C-C**H**$_2$-O-), 3.28 (2H, s, -C-C**H**$_2$-OH), 3.78 (2H, br s, -C=C-C**H**$_2$-O-), 4.76, 4.90 ppm (each 1H, br s, C**H**$_2$=C-).

*Acetyl Derivative of **10***: Colorless oil. IR (CCl_4) 1746, 1235 (CH$_3$COO-), 1170, 1095, 1045 (C-O-C), 3080, 1660, 900 cm^{-1} (CH$_2$=C-); PMR (CCl_4) δ 1.10, 1.18 (each 6H, s, -O-C-(C**H**$_3$)$_2$×2), 1.73 (3H, br s, C**H**$_3$-C=C-), 2.01 (3H, s, C**H**$_3$COO-), 3.15 (2H, s, -C-C**H**$_2$-O-), 3.78 (2H, br s, =C-C**H**$_2$-O-), 3.96 (2H, s, CH$_3$COO-C**H**$_2$-C-), 4.78, 4.93 ppm (each 1H, br s, C**H**$_2$=C-).

*Dihydro Derivative of **10***: Colorless oil. IR (CCl_4) 3470, 1070 (-OH), 1088, 1060 (C-O-C), 1389, 1375 cm^{-1} (CH$_3$-C-CH$_3$ and CH$_3$-CH-CH$_3$); PMR (CCl_4) δ 0.90 (6H, d, J=6 Hz, C**H**$_3$-CH-C**H**$_3$), 1.13, 1.18 (each 6H, s, C**H**$_3$-C-C**H**$_3$×2), 1.65—1.98 (1H, m, (CH$_3$)$_2$-C**H**-CH$_2$-), 2.24 (1H, br s, -O**H**), 3.10 (2H, d, J=7 Hz, -CH-C**H**$_2$-O-), 3.17 (2H, br s, -C-C**H**$_2$-O-C-), 3.40 ppm (2H, m, -C-C**H**$_2$-OH).

*4) Reaction of **4** with $BF_3 \cdot Et_2O$.* The reaction of **4** (10 g) was carried out with $BF_3 \cdot Et_2O$ (0.5 ml) according to the procedure described above.

*3,3,7-Trimethyl-4-oxa-7-octen-1-ol (**11**)*: The compound from the first eluate was obtained as a colorless oil. The molecular formula was $C_{10}H_{20}O_2$ (M^+ 172, Rast's mol wt, 176). Mass *m/e* 31 (41%), 41 (30), 59 (6), 69 (base), 87 (22), 99 (16), 117 (5), 127 (5), 155 (3), 172 (2, M^+, $C_{10}H_{20}O_2$); IR (CCl_4) 3510, 1145 (-OH), 1170, 1075, 1035 (C-O-C), 1652, 899 (CH$_2$=C-), 1380, 1369 cm^{-1} (CH$_3$-C-CH$_3$); PMR (CCl_4) δ 1.27 (6H, s, (C**H**$_3$)$_2$-C-O-), 1.65 (2H, t, J=6 Hz, -C-C**H**$_2$-CH$_2$-OH), 1.72 (3H, br s, C**H**$_3$-C=C-), 2.20 (2H, t, J=6 Hz, -CH$_2$-C**H**$_2$-C=C-), 2.67 (1H, br s, -O**H**), 3.47 (2H, t, J=6 Hz, -CH$_2$-C**H**$_2$-O-), 3.62 (2H, t, J=6 Hz, -CH$_2$-C**H**$_2$-OH), 4.80 ppm (2H, br s, C**H**$_2$=C-).

*Acetyl Derivative of **11***: Colorless oil. IR (CCl_4) 1745, 1245, 1239 (CH$_3$COO-), 1387, 1378 (CH$_3$-C-CH$_3$), 3081, 1653, 893 (CH$_2$=C-), 1171, 1035 cm^{-1} (C-O-C); PMR (CCl_4) δ 1.26 (6H, s, (C**H**$_3$)$_2$-C-O-), 1.65 (2H, t, J=6 Hz, -C-C**H**$_2$-CH$_2$-), 1.70 (3H, br s, -C=C-), 2.00 (3H, s, C**H**$_3$COO-), CH$_3$

2.20 (2H, t, J=6 Hz, =C-C**H**$_2$-CH$_2$-), 3.40 (2H, t, J= 6 Hz, -CH$_2$-C**H**$_2$-O-), 4.10 (2H, t, J=6 Hz, -CH$_2$-C**H**$_2$-COOCH$_3$), 4.68 ppm (2H, br s, C**H**$_2$=C-).

*Dihydro Derivative of **11***: Colorless oil. Mass *m/e* 41 (32%), 43 (85), 59 (55), 69 (43), 70 (11), 71 (base), 89 (18), 129 (59, $M^+-(CH_2-CH_2-OH)$), 159 (7, M^+-CH_3), 174 (trace, M^+, $C_{10}H_{22}O_2$); IR (CCl_4) 3490, 1148 (-OH), 1079 (C-O-C), 1391, 1371 cm^{-1} ((CH$_3$)$_2$-CH-, CH$_3$-C-CH$_3$); PMR (CCl_4) δ 0.90 (6H, d, J=6 Hz, (C**H**$_3$)$_2$-CH-), 1.23 (6H, s, (C**H**$_3$)$_2$-C-O-), 1.50 (2H, t, J=6 Hz, -CH-C**H**$_2$-CH$_2$-O-), 1.66 (2H, t, J=6 Hz, -O-C-C**H**$_2$-CH$_2$-OH), 2.16 (1H, br s, -O**H**), 3.40 (2H, t, J=6 Hz, -CH$_2$-C**H**$_2$-O-), 3.78 ppm (2H, t, J=6 Hz, -CH$_2$-C**H**$_2$-OH).

*3,3,7,7,11-Pentamethyl-4,8-dioxa-11-dodecen-1-ol (**12**)*: As the second compound, a colorless oil was isolated. The molecular formula was determined to be $C_{15}H_{30}O_3$ (M^+ 258, Rast's 263). Mass *m/e* 31 (6%), 41 (32), 43 (13), 59 (6), 69 (base), 99 (20), 105 (12), 115 (7), 127 (5), 139 (6), 173 (5), 258 (1, M^+, $C_{15}H_{30}O_3$); IR (CCl_4) 3400, 1143 (-OH), 1075, 1025 (C-O-C), 3075, 1655, 900 (CH$_2$=C-), 1380, 1369 cm^{-1} (CH$_3$-CH-CH$_3$ and CH$_3$-C-CH$_3$); PMR (CCl_4) δ 1.13, 1.20 (each 6H, s, CH$_3$-C-CH$_3$×2), 1.65 (4H, t, J=6 Hz, -O-C-C**H**$_2$-CH$_2$-O- and -O-C-C**H**$_2$-CH$_2$-OH), 1.73 (3H, br s, C**H**$_3$-C=C-), 2.18 (2H, t, J=6 Hz, =C-C**H**$_2$-CH$_2$-), 2.50 (1H, br s, -OH), 3.38 (4H, t, J=6 Hz, -CH$_2$-C**H**$_2$-O-×2), 3.52 (2H, t, J=6 Hz, -CH$_2$-C**H**$_2$-OH), 4.70 ppm (2H, br s, C**H**$_2$=C-).

*Acetyl Derivative of **12***: Colorless oil. IR (CCl_4) 1740, 1240, 1225 (CH$_3$COO-), 1075, 1030 (C-O-C), 3078, 1650, 889 cm^{-1} (CH$_2$=C-); PMR (CCl_4) δ 1.17, 1.21 (each 6H, s, (C**H**$_3$)$_2$-C-O-×2), 1.65 (4H, t, J=6 Hz, -O-C-C**H**$_2$-CH$_2$-O- and -O-C-C**H**$_2$-CH$_2$-OH), 1.75 (3H, br s, C**H**$_3$-C=C-), 2.00 (3H, s, C**H**$_3$COO-), 2.20 (2H, t, J=6 Hz, =C-C**H**$_2$-CH$_2$-), 3.40 (4H, t, J=6 Hz, -CH$_2$-C**H**$_2$-O-×2), 4.10 (2H, t, J=6 Hz, -CH$_2$-C**H**$_2$-COOCH$_3$), 4.70 ppm (2H, br s, C**H**$_2$=C-).

*Dihydro Derivative of **12***: Colorless oil. IR (CCl_4) 3500, 1145 (-OH), 1078 (C-O-C), 1386, 1370 cm^{-1} (CH$_3$-CH-CH$_3$ and CH$_3$-C-CH$_3$); PMR (CCl_4) δ 0.90 (6H, d, J= 6 Hz, CH$_3$-CH-C**H**$_3$), 1.22 (12H, s, (C**H**$_3$)$_2$-C-O-×2), 1.50 (2H, t, J=6 H, (CH$_3$)$_2$-CH-C**H**$_2$-CH$_2$-O-), 1.65 (4H, t, J=6 Hz, -O-C-C**H**$_2$-CH$_2$-O- and -O-C-C**H**$_2$-CH$_2$-OH), 2.30 (1H, br s, -O**H**), 3.41 (4H, t, J=6 Hz, -CH$_2$-C**H**$_2$-O-×2), 3.77 ppm (2H, t, J=6 Hz, -CH$_2$-C**H**$_2$-OH).

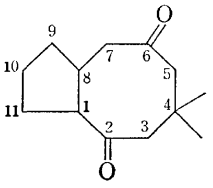
(Received February 16, 1978)

The crystal structure of 7-bromo-4,4-dimethylbicyclo[6.3.0]undecane-2,6-dione has been determined in order to elucidate the configuration and the conformation of 4,4-dimethylbicyclo[6.3.0]undecane-2,6-dione. The crystals of this compound are triclinic with space group $P\bar{1}$ and the unit cell dimensions are, $a=7.178$, $b=16.934$, $c=6.091$ Å, $\alpha=96.22$, $\beta=100.91$, $\gamma=115.39°$, and $Z=2$. The crystal structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method. The final R value for 1473 non-zero reflexions was 0.067. The ring fusion of this compound is *trans* and the 8-membered ring has a boat-chair conformation.

In a previous paper,[1] it was reported that 4,4-dimethylbicyclo[6.3.0]undecane-2,6-dione (I) is given by the retro-aldol cleavage of 2-acetoxy-4,4-dimethyltricyclo[6.3.0.$0^{2,7}$]undecane-6-one which is the photoadduct of cyclopentene with the enol acetate of dimedone. This compound (I) has a fused ring system consisting of a five-membered ring and an eight-membered ring. No study concerning the conformations on such 5—8 fused ring compounds has been reported. Furthermore, no report concerning the relative stabilities of the *cis* and *trans* isomers of the 5—8 fused ring systems has appeared. Consequently the configuration of I at the ring juncture has not been assigned. In this work ^{1}H-NMR spectroscopy is not available for stereochemical study, because the ^{1}H-NMR spectra of I does not exhibit much difference in chemical shift and the definite assignment of each proton is not possible. In order to elucidate the conformation of I and to know whether the ring fusion is *cis* or *trans*, X-ray analysis of the monobromo derivative of I, 7-bromo-4,4-dimethylbicyclo[6.3.0]undecane-2,6-dione (II)†,[2] has been conducted, because II forms more suitable crystals for X-ray analysis than I. Since II is easily debrominated[3] by zinc dust in acetic acid at room temperature giving rise to the original dione (I), the ring fusion of I is probably the same as that of II.



(I)

Experimental

7-Bromo-4,4-dimethylbicyclo[6.3.0]undecane-2,6-dione (II) was synthesized by the bromination of I with pyridinium bromide perbromide in ethanol.[2] Crystals of suitable quality for X-ray analysis were obtained from hexane in the form of colourless plates elongated along the b axis. The three-dimensional intensity data were collected on a Rigaku automatic four-circle diffractometer with graphite-monochromatized Cu $K\alpha$ radiation. The density was measured by the flotation method in a mixture of carbon tetrachloride and petroleum ether. The cell dimensions were determined by the least-squares method using the 2θ values of 20 strong reflexions in the range $36°\leqq 2\theta \leqq 50°$.

Crystal Data. 7-Bromo-4,4-dimethylbicyclo[6.3.0]-undecane-2,6-dione, $C_{13}H_{19}O_2Br$, *F.W.* 287.2, mp 111—113 °C, triclinic, $a=7.178$ (3), $b=16.934$ (8), $c=6.091$ (3) Å, $\alpha=96.22$ (4), $\beta=100.91$ (3), $\gamma=115.39$ (4)°, $V=642$ Å^3, $D_m=1.49$ g/cm^3, $D_c=1.486$ g/cm^3, $Z=2$, space group $P\bar{1}$.

The three dimensional intensity data were collected with a $\omega/2\theta$ scan technique at a constant scanning rate of 2 deg/min. Reflexions having an intensity exceeding the corresponding standard deviations by three times were treated as observed. 1473 reflexions with $2\theta \leqq 140°$ were retained and corrected for Lorentz and polarization factors but not for absorption and extinction factors.

Determination of the Structure

From the three dimensional Patterson map, the position of the bromine atom could easily be deduced. On the basis of the coordinates of the bromine atom, and from the Fourier synthesis all the 15 non-hydrogen light atoms in the asymmetric unit were deduced. The R-value was 0.52 at this stage. Refinement was conducted by the block-diagonal least-squares method. After several cycles of the refinement, the R-value was reduced to 0.295. Three cycles of calculations assuming the anisotropic thermal vibration for all the atoms gave an R-value of 0.098. From a second Fourier map, all hydrogen atoms except the five hydrogen atoms (H(5), H(8), H(11), H(13), and H(17)), were deduced. Three more cycles of refinement were performed using anisotropic temperature factors for the bromine, oxygen and carbon atoms and isotropic temperature factors for the hydrogen atoms. The final R-value for 1473 non-zero reflexions was 0.067. The scattering factors for bromine were taken from the International Tables for X-Ray Crystallography.[4] For these calculations, computer programs made by Stewart *et al.*[5] were used. The complete F_o-F_c tables are kept by the office of the Chemical Society of Japan (Document No. 7833).

The final values of the positional and thermal parameters are given in Tables 1 and 2. The molecular structure and the numbering of 7-bromo-4,4-dimethylbicyclo[6.3.0]undecane-2,6-dione (II) determined by the present analysis is shown in Fig. 1. Figure 2 shows

† II was assumed to be the 5-bromo derivative in a previous paper,[2] but this analysis showed it to be the 7-bromo derivative.

TABLE 1. FRACTIONAL ATOMIC COORDINATES ($\times 10^4$) AND ANISOTROPIC THERMAL PARAMETERS ($\times 10^4$) OF THE NON-HYDROGEN ATOMS

The estimated standard deviations are given in parentheses. The anisotropic temperature factors are of the form: $\exp[-2\pi^2(a^{*2}h^2U_{11}+b^{*2}k^2U_{22}+c^{*2}l^2U_{33}+2a^*b^*hkU_{12}+2a^*c^*hlU_{13}+2b^*c^*klU_{23})]$.

the conformation and thermal vibration of the molecule drawn by the ORTEP.[6] The bond lengths and angles of the molecule, calculated from the coordinates given in Table 1, are shown in Table 3. Important torsion angles are shown in Table 4. The projection of the crystal structure along the c axis is shown in Fig. 3.

Discussion

For the conformation of 8-membered rings, a boat-chair (BC) form was shown by the calculation of strain

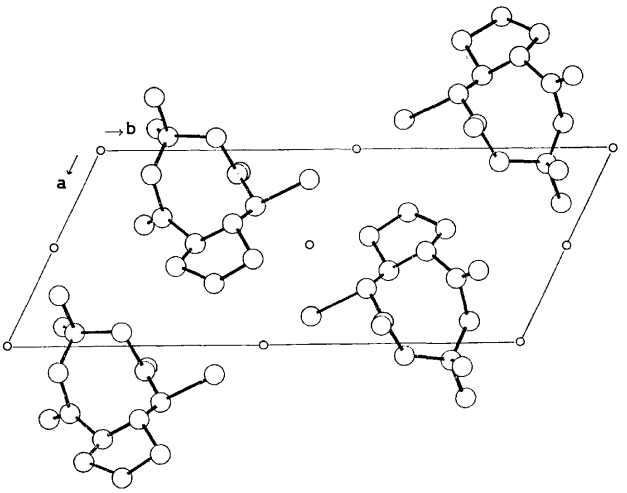

Fig. 3. Crystal structure projected along the c axis.

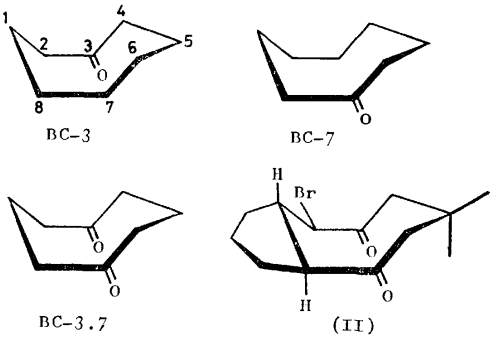
energies to be the most stable.[7] Cyclooctane and its simple derivatives have been found to be exist predominantly in the BC form,[8–10] however, since the energy differences from other conformations are small, the cases with crown family conformations (crown, chair-chair, and twist-chair-chair) are also reported.[10,11] For 8-membered ring ketones, Anet *et al.*[12] showed by NMR studies at low temperature that cyclooctanone and 1,5-cyclooctanedione exist in BC-3 (or BC-7) and BC-3,7 forms, respectively.



According to the results of this study, it has been shown that the 8-membered ring of II has a BC-3,7 conformation. In Table 5, the conformation of the 8-membered ring in II is shown in terms of torsion angles.[13] In these values, the torsion angles around the ring juncture and C(4) bearing two methyl groups, that is, C(8)–C(1), C(3)–C(4), and C(4)–C(5) deviated from the values of *cis*- and *trans*-1,2-cyclooctanedicarboxylic acids[8] and the calculated values for cyclooctane,[7] while the others are similar. When the 8-membered ring of II has a BC form, it is expected that the transannular repulsions occur between the three hydrogen atoms H(2), H(5), and H(7) which are directed towards the inside of the 8-membered ring. Although H(5) was not located the H(2)···H(7) interatomic distance was determined to be 2.4 Å. Since the interatomic distance is not small, these transannular interactions perhaps are weak, if any, in the crystalline

	−65.0	−44.7	102.2	−65.0

state.

The C–C–C bond angles in the 8-membered ring at C(1), C(3), C(5), and C(7) which are at α-positions of the carbonyl groups are 115—117 °C. Although these values are larger than the normal values of 109.5°, they are similar to the values observed in the 8-membered ring of 1,2-cyclooctanedicarboxylic acid.[8] As shown in Table 3, the four C–C bond lengths containing carbonyl carbon atoms (C(2) and C(6)) are C(1)–C(2)=1.442 Å, C(2)–C(3)=1.500 Å, C(5)–C(6)=1.498 Å, and C(6)–C(7)=1.461 Å, respectively. In these values, the C(1)–C(2) bond length is significantly shorter than that for the usual C_{sp^2}–C_{sp^3} single bond (1.501 Å).[14] The value of the C(2)–O(1) bond length s 1.257 Å which is longer than the characteristic value for the C=O double bond length. In the 8-membered ring, the distance between the two carbonyl carbon atoms, C(2)···C(6) is 2.951 Å and this is considerably shorter than the other distances between two carbon atoms in the 1,5 positions: C(1)···C(5)=3.598 Å, C(3)···C(7)=3.673 Å, C(4)···C(8)=3.693 Å.

The ring fusion of the 5-membered ring and the 8-membered ring in II is *trans* because the torsion angle H(1)–C(1)–C(8)–H(7) is 177.2° as shown in Table 5. Therefore the ring fusion of I may be assumed to be *trans*.

As shown in Figs. 1 and 2, the bromine atom in II was found to be bonded to C(7) in disagreement with what was assumed in a previous paper,[2] *i.e.* bromine substitution at C(5). Also in a previous paper[2] it was reported that the C=O at position 6 and C–Br in II greatly deviated from co-planarity on the basis of IR and UV data. This is consistent with the result of this study because the torsion angle O(2)–C(6)–C(7)–Br is 110.8°, whereas the torsion angle O(2)–C(6)–C(7)–H(6) is 0.0°.

Thus the 8-membered ring of II has a BC-3,7 conformation which appears to be the most stable. Consequently it may be assumed that I has a similar conformation.

The authors are grateful to Professor Yoichi Iitaka, University of Tokyo, for his valuable discussion.

Structural Studies on Anthglutin, an Inhibitor of γ-Glutamyl Transpeptidase, from *Penicillium Oxalicum*

Takeshi KINOSHITA* and Sadamasa MINATO†

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140

† *Fermentation Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140*

(Received February 23, 1978)

Anthglutin, a new γ-glutamylphenylhydrazine and an inhibitor of γ-glutamyl transpeptidase, has been isolated from the cultured medium of *Penicillium oxalicum*. Spectral studies indicate that it has the structure of 1-γ-L-glutamyl-2-(2-carboxyphenyl)hydrazine.

γ-Glutamyl transpeptidase [EC 2.3.2.2] is an enzyme widely distributed in the tissues and body fluids of animals,[1] microorganisms,[2] plants,[3] and coelenterates.[4] Serum γ-glutamyl transpeptidase activity is assayed in clinical diagnosis.[5] A strong inhibitor of γ-glutamyl transpeptidase has been isolated from the cultured medium of *Penicillium oxalicum* SANK 10477 and named anthglutin.[6] The new compound anthglutin is a competitive and specific inhibitor for γ-glutamyl transpeptidase. This paper deals with the structure determination of anthglutin.

Experimental

Spectra. IR spectra were obtained with a JASCO IRA-2 spectrometer, and NMR spectra with a Varian A-60D spectrometer using tetramethylsilane as an internal standard. GLC analyses were carried out on a JEOL JGC-20KFP gas chromatograph and GC-MS analyses on a JEOL JMS D-100 gas chromatograph mass spectrometer. Field desorption mass spectra (FD-MS) were obtained with a double focusing JEOL JMS-OlSG instrument equipped with a combined f.d.f.i.e.i. ion source. Conventional low and high resolution mass spectra were taken on a JEOL JMS-OlSG spectrometer, using a direct insertion probe and an ionization energy of 75 eV.

Material. Anthglutin was obtained by the method described in a previous paper.[6] The result of elemental analysis agreed with the formula $C_{12}H_{15}N_3O_5$.

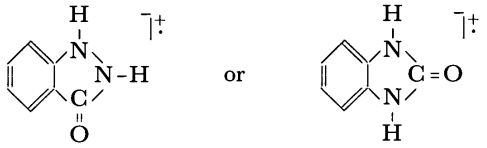
Found: C, 51.07; H, 5.51; N, 14.65; O, 28.87%. Calcd for: C, 51.24; H, 5.38; N, 14.94; O, 28.44%.

Preparation of Derivatives. Trimethylsilyl (TMS), perdeuteriotrimethylsilyl (TMS-d_9), and trifluoroacetyl (TFA) derivatives of anthglutin (I) were prepared according to methods in literature.[7-10] *N*-[(Dimethylamino)methylene] methyl ester derivatives of amino acids were also prepared according to the reported method.[11]

Results and Discussion

The formula $C_{12}H_{15}N_3O_5$ of anthglutin (I) was substantiated by high resolution mass measurement on the quasi-molecular ion $(M+H)^+$ at *m/e* 282 in the field desorption mass spectrum (Fig. 1). The NMR spectrum of I in D_2O at basic pD is shown in Fig. 2. The signals at δ 6.8—8.2 correspond to four aromatic hydrogens, indicating the presence of an *ortho*-disubstituted benzene. The remaining signals consist of a triplet at δ 3.90 (1H, J=6 Hz) and a complex pattern centered at δ 2.5 (4H), corresponding to those of L-glutamic acid whose occurence in I was expected by bioassay and amino acid analysis.[6] The IR spectrum (Nujol) of I exhibits absorption bands which can be attributed to >N-H (3290 cm^{-1}), >C=O (1675, 1655 cm^{-1}), and *ortho*-disubstituted benzene (760 cm^{-1}).

Major structure analysis was carried out by means of fragmentation analysis of the mass spectra. A strong peak is seen at *m/e* 134 ($C_7H_6N_2O$, *M.W.* obsd=134.0475, *M.W.* calcd=134.0480) corresponding to $[M-C_5H_9NO_4]^+$ ion (Fig. 3). Since the atomic composition of $C_5H_9NO_4$ is identical to that of glutamic acid and the NMR spectrum of I suggests the presence of an *ortho*-disubstituted benzene ring, the structure of this fragment ion at *m/e* 134 should be one of the following:



II or III

As shown in Fig. 2, the signals in the down-field of the NMR spectrum of I resemble those of *o*-aminobenzoic acid very closely in chemical shifts and spectral

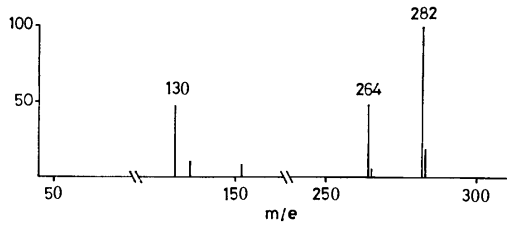


Fig. 1. The field desorption mass spectrum of **I**: heating current 17 mA, *m/e* 282=$C_{12}H_{16}N_3O_5$ (*M.W.* calcd=282.1088, *M.W.* obsd=282.1079).

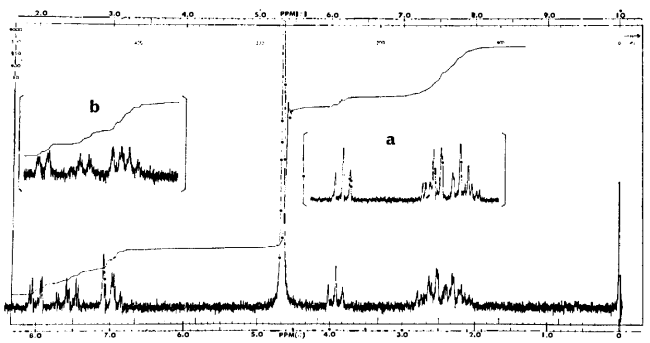

Fig. 2. The NMR spectrum of **I** in D_2O containing a small amount of NaOH; the spectra in brackets: (a) L-glutamic acid in D_2O and (b) *o*-aminobenzoic acid in $(CD_3)_2CO$: D_2O (3:1).

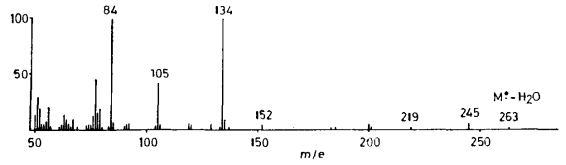

Fig. 3. Mass spectrum of **I**.

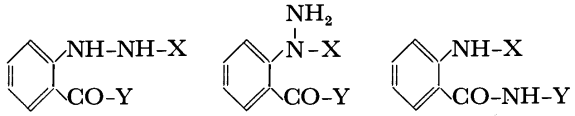
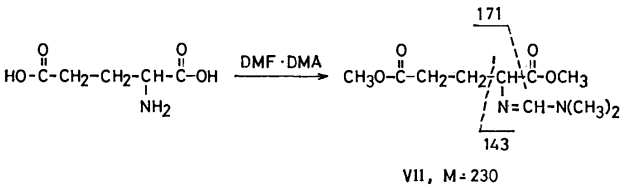
patterns. Thus, structure II seems more likely. The fragment ion at *m/e* 134 can be derived from one of the structural units of the following types in which X plus Y should be $C_5H_9NO_4$.



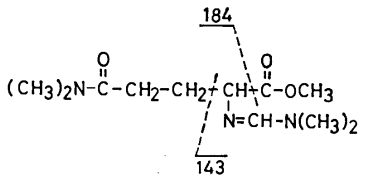
In order to determine the whole structure, the reactions of I with some reagents were carried out. The product derived from the reaction of I with *N,N*-dimethylformamide dimethyl acetal (DMF–DMA)[11] is labile even at 230 °C (Fig. 4). Gas chromatography mass spectrometry (GC-MS) was applied for further analysis to the products derived from the partial pyrolysis at the injection port of a gas chromatograph.

The mass spectrum of GLC peak A in Fig. 4 is identical to that of the product (VII) from the reaction of L-glutamic acid with DMF–DMA (Fig. 5-(a)).



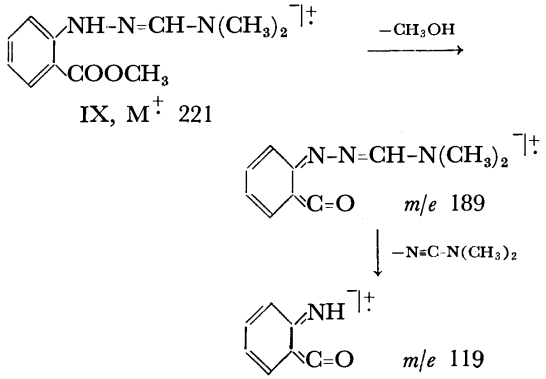
VII, M=230

The structural assignment for peak B is based on its mass spectrum which is analogous in fragmentation patterns to that of VII as shown below.



VIII, M=243

Peak C seems to be derived from compound IX as indicated by its mass spectrum (Fig. 5-(b)).



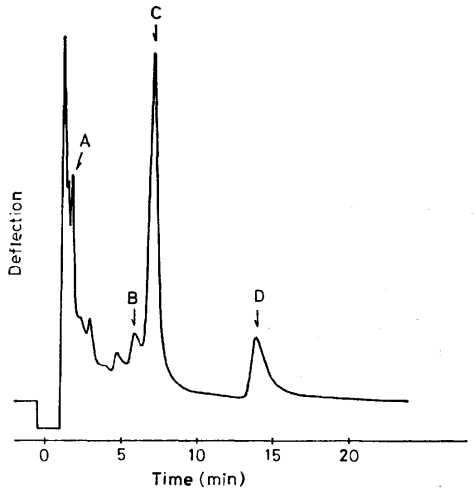


Fig. 4. Gas chromatogram of the reaction products of **I** with DMF-DMA taken by total ion current of GC-MS. Column of 2% Silicone OV-1 on Chromosorb G, 1 m×2 mm i.d. glass column, col. temp: 145 °C, inj. temp: 230 °C, flow rate: 23 ml/min He.

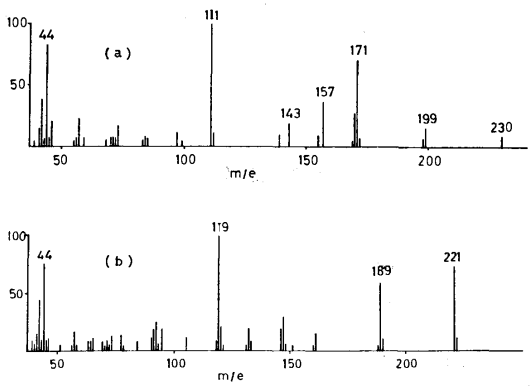

Fig. 5. Mass spectra of peak A (a) and peak C (b).

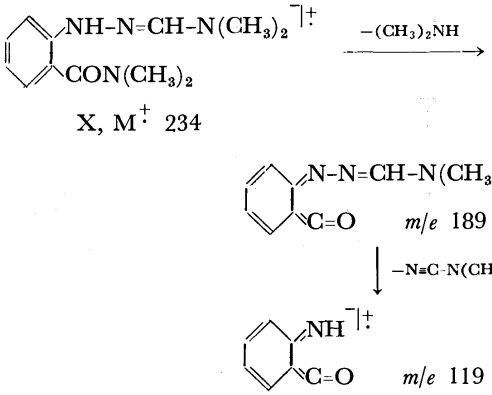
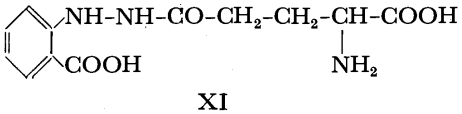
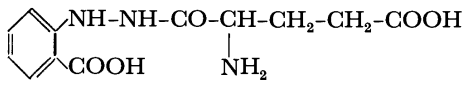
For peak D, the assignment was done by the analysis of the corresponding GC-MS spectrum which is analogous in fragmentation modes to that of IX.



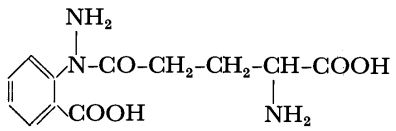
The above data suggest that the structure of I should be one of the following five structures XI—XV.



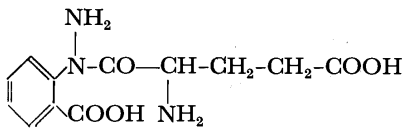
XI



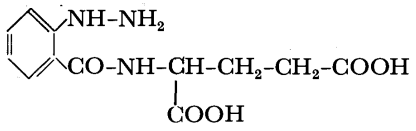
XII



XIII

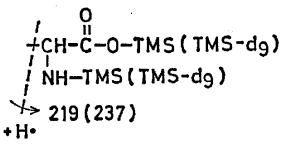


XIV



XV

Further information was obtained by a study of the mass spectra of the trimethylsilyl (TMS) and the perdeuteriotrimethylsilyl (TMS-d_9) derivatives of I (Figs. 6 and 7). The occurrence of the fragment ions at *m/e* 219 and 237 (Figs. 6 and 7) suggests that I has an α-amino acid moiety as part of its structure.



The result of the color reaction of I with ninhydrin, a strong purple color being obtained at elevated temperature, also suggests that a free α-amino acid moiety might occur in I. Thus, of the five possible structures, only structures XI and XIII seem likely. The information for differentiating XI and XIII was obtained from the mass spectrum of the *N*-trifluoroacetyl-*O*-trimethylsilyl (*N*-TFA-*O*-TMS) derivative of I. *N*-TFA-*O*-TMS derivatives are easily prepared by trimethylsilylation with *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) followed by selective *N*-acylation with *N*-methylperfluorodiacetamide (MPFDA).[9]

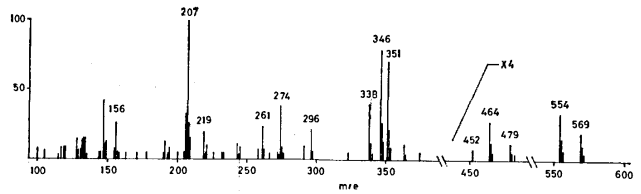


Fig. 6. Mass spectrum of the TMS derivative of **I**.

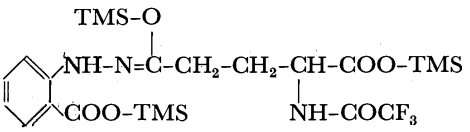
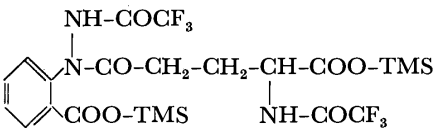
TABLE 1. HIGH RESOLUTION MASS MEASUREMENTS OF PRINCIPAL IONS IN MASS SPECTRUM OF TMS DERIVATIVE OF I

Observed	Calculated	Formulae
569.2619	569.2591	$C_{24}H_{47}N_3O_5Si_4$
554.2370	554.2356	$C_{23}H_{44}N_3O_5Si_4$
479.2067	479.2090	$C_{21}H_{37}N_3O_4Si_3$
464.1832	464.1855	$C_{20}H_{34}N_3O_4Si_3$
452.2201	452.2219	$C_{20}H_{38}N_3O_3Si_3$
351.1573	351.1559	$C_{16}H_{27}N_2O_3Si_2$
346.1709	346.1729	$C_{14}H_{32}NO_3Si_3$
338.1574	338.1587	$C_{15}H_{26}N_2O_3Si_2$
296.1394	296.1375	$C_{13}H_{24}N_2O_2Si_2$
274.1315	274.1294	$C_{11}H_{24}NO_3Si_2$
261.1066	261.1059	$C_{13}H_{17}N_2O_2Si$
219.1093	219.1109	$C_8H_{21}NO_2Si_2$
207.0962	207.0954	$C_{10}H_{15}N_2OSi$
206.0885	206.0876	$C_{10}H_{14}N_2OSi$
156.0832	156.0844	$C_7H_{14}NOSi$

Subsequent acylation of the TMS derivative of I with MPFDA gave a mass shift of the molecular ion of 24 mass units as compared with the original derivative (Fig. 8). This indicates that the TMS derivative of I has only one *N*-trimethylsilyl group. It can be concluded that the *N*-TFA-*O*-TMS derivative of I is XVI and not XVII.



XVI, M=593



XVII, M=617

Consequently, the proposed structure of anthglutin (I) is 1-γ-L-glutamyl-2-(2-carboxyphenyl)hydrazine (XI). The structural assignments of fragment ions of the TMS derivative of I (Fig. 6) were confirmed by high resolution mass measurements (Table 1) and by comparison with the mass spectrum of the TMS-d_9 derivative of I. The peaks at *m/e* 569, 452, 351, 346, 338, and 219 in the mass spectrum of the TMS derivative shifted to *m/e* 605, 479, 369, 373, 356, and 237, respectively, in that of the TMS-d_9 derivative (Fig. 7). These peaks decide the selection of structure XI as the most likely structure for I. The formation of these ions can be illustrated as shown in Fig. 9.††

The major fragmentation routes of I in its mass spectrum (Fig. 3) are shown in Scheme 1. High resolution measurements of these fragment ions have been carried out (Table 2). A similar strong ion

†† Substituting a TMS group for the hydrogen atom of –NH–N=C< in the TMS derivative of I seems to be difficult because of the steric hindrance of the bulky group, –CO–O–TMS, at the *ortho* position in the phenyl group.

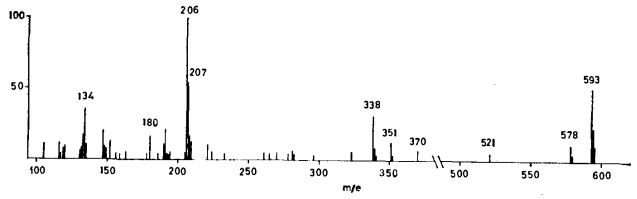


Fig. 8. Mass spectrum of the TMS derivative of **I** followed by *N*-acylation with MPFDA.

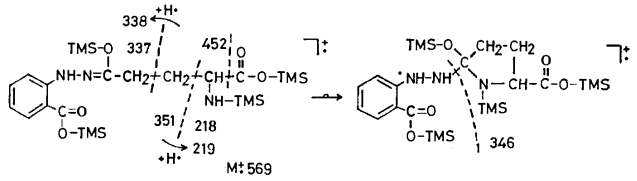

Fig. 9. Mass spectral fragmentation modes of the TMS derivative of **I**.

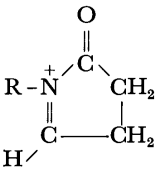
peak at *m/e* 84 (C_4H_6NO) was also observed in the mass spectra of glutamic acid and its derivatives such as glutamine, 4-(γ-L-glutaminyl)phenol,[12] and glutamic acid diethyl ester.[13]

The proposed structure of the fragment ion at *m/e* 84 is in line with the results showing that in the case of the TMS and the TMS-d_9 derivatives of I, the corresponding ions appear at *m/e* 156 and 165, respectively.



R=TMS, *m/e* 156
R=TMS-d_9, *m/e* 165

It can be said that the structural assignment for the strongest fragment ion of *m/e* 134 derived from the ion of *m/e* 152 as shown in Scheme 1 is supported by the fact that *o*-hydrazinobenzoic acid is easily converted into indazolone.[14]

A synthetic investigation of 1-γ-L-glutamyl-2-(2-carboxyphenyl)hydrazine (XI) is in progress.

We are grateful to Dr. Chihiro Tamura for his valuable discussions. Thanks are also due to Mr. Hidemi Nagaki for his assistance in obtaining field desorption spectra.

Solvent Effects on Intramolecular Photocycloaddition of Poly(1-vinylnaphthalene)

Takao KAMIJO, Masahiro IRIE,* and Koichiro HAYASHI
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565
(Received February 24, 1978)

Photocycloaddition reaction of naphthalene side groups in poly(1-vinylnaphthalene) was studied in cyclohexane, benzene, and dichloromethane. In cyclohexane the reaction proceeds following the first order kinetics to a high conversion of 70%, while in dichloromethane the reaction levels off at a very low conversion of 20%. The reaction behavior in benzene is intermediate between cyclohexane and dichloromethane. Quenching and sensitizing experiments proved that a triplet mechanism is predominant in cyclohexane, while in dichloromethane a singlet mechanism, presumably excimer mechanism, takes place. The solvent effect was interpreted by the formation of ground state dimer due to the conformational change of the polymer chain in poor solvents.

Photocycloaddition of aromatic compounds, in particular anthracene and acenaphthylene, is of interest from photochemical and photophysical points of view.[1] It has been assumed that the excimer state is the intermediate state in the formation of cyclodimers of anthracene derivatives.[2] Recently, experimental evidence of the mechanism has accumulated by use of a single crystal of the anthracene dimer[3] or the bichromophoric systems.[4]

In the case of photocycloaddition of acenaphthylene, however, other schemes have been proposed in addition to the singlet excimer mechanism[1f] *e.g.* bimolecular reaction between triplet state and ground state molecules, and pseudounimolecular photo-reaction of a ground state associated dimer. Although the latter unimolecular mechanism has attracted little attention[1e] because of the absence of the spectroscopic evidence of the postulated ground state dimer, it is worthwhile to reconsider this mechanism since several non-conjugated bichromophoric systems have recently been reported to undergo intramolecular cycloaddition *via* excitation of ground state complexes.[4,5]

In a previous paper[6] a report was given on spectroscopic evidence for the formation of a ground state dimer in poly(1-vinylnaphthalene) and 1,3-di-1-naphthylpropane in fluid and solid cyclohexane, respectively. This paper deals with the cycloaddition mechanism of naphthalene side groups in poly(1-vinylnaphthalene), especially the effect of solvent on the reaction, and a consideration on the role of the ground state dimer in the cycloaddition reaction. The intramolecular cyclodimerization of 1,3-di-1-naphthylpropane was also carried out as a model system of the polymer. These studies are expected to give valuable information on the precursors of the cycloaddition process of naphthalene and its homologes.[7]

Experimental

Preparation and purification methods of poly(1-vinylnaphthalene) have been described.[6] Cyclohexane and dichloromethane were of spectrograde. All samples were degassed by the freeze-pump-thaw-cycles under a reduced pressure less than 10^{-5} mmHg in the dark.

A super high pressure mercury lamp (1 kW) was used as a radiation source. Wavelengths longer than 280 nm were selected with a Toshiba UV-29 filter. Absorption and emission spectra were measured with a Shimadzu UV-200 spectrophotometer and a Hitachi MPF-2A spectrofluorometer, respectively.

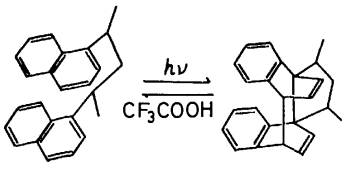
Quantum yields of the cycloaddition reaction were determined with a chemical actinometer of potassium ferioxalate system. The mercury line of 297 nm was isolated with a grating monochrometer (Ritsu MC-20), the initial concentration being so controlled as to make the absorbance at 297 nm less than 0.1.

Results and Discussion

Photocycloaddition in Solutions. Poly(1-vinylnaphthalene) exhibits monomer, dimer, and excimer emissions in dichloromethane, while in cyclohexane a dimer emission becomes predominant, the excimer emission not being discerned.[6,8] This indicates that the dimer conformation is stable even in the excited state in cyclohexane, though the excimer conformation is favorable in dichloromethane. The absorption spectrum in cyclohexane also notably differs from the spectrum in dichloromethane, indicating the formation of the ground state dimer in a cyclohexane solution.[6] The conformation of the polymer in poor solvents is conceived to be more rigid as compared to conformation in good solvents, the conformational change in the excited state being restricted. On the other hand, higher mobility of the chain in good solvents makes it possible to attain the most stable conformation, an excimer conformation, in the excited state.

Photoillumination of poly(1-vinylnaphthalene) in the two solvents, cyclohexane and dichloromethane, results in a photochemical reaction of the naphthalene side groups. The photochemical reaction was followed by measurements of the absorption spectra of the naphthalene side groups in the 250—350 nm region (Figs. 1 and 2). In both cases the intensity of the absorption decreases with photoillumination.

Addition of a trace amount of trifluoroacetic acid to the illuminated sample restores the initial absorbance.[7a] The recovery indicates that the decrease in absorbance induced by photoillumination is due to the photocycloaddition of the naphthalene side groups as shown in the following:



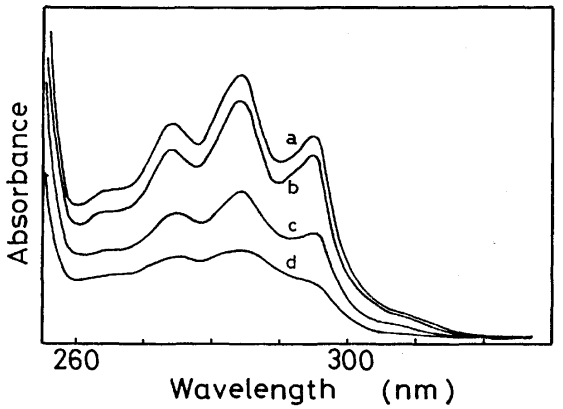


Fig. 1. Absorption spectra of poly(1-vinylnaphthalene) in cyclohexane before and after photoillumination by the light passed through Toshiba UV-29 filter ($\lambda >$ 280 nm) at 20 °C. Illumination times are (a) 0, (b) 0.2, (c) 11 and (d) 36 min. Initial concentration of poly(1-vinylnaphthalne) is 5×10^{-5} M.

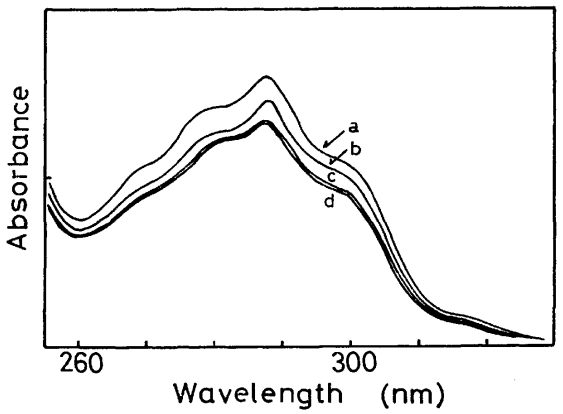

Fig. 2. Absorption spectra of poly(1-vinylnaphthalene) in dichloromethane before and after photoillumination at 20 °C. Illumination times are (a) 0, (b) 0.5, (c) 4 and (d) 20 min. Initial concentration of poly(1-vinylnaphthalene) is 5×10^{-5} M.

In order to confirm the cycloaddition reaction, NMR spectra of the sample were measured before and after photoillumination (Fig. 3). The intensity ratio of aromatic and vinyl protons to the alkyl proton is 2.23 before photoillumination, while it decreases to 1.64 after illumination for 3 h. The corresponding theoretical values before and after the cycloaddition should be 2.33 and 1.50, respectively. Although the values include some errors even before photoillumination probably due to chain end groups, the value after illumination is located between the initial and theoretical values. In addition to the above ratio the NMR spectrum after illumination shows a new peak at 6.1 τ attributable to methine proton.[7c] These results indicate that the photochemical reaction of poly(1-vinylnaphthalene) corresponds to the cycloaddition.

Figure 4 shows the relative changes in absorbance of naphthalene side groups in cyclohexane, dichloromethane and benzene during the course of photolysis. The photocycloaddition of 1,3-di-1-naphthylpropane in cyclohexane is also shown for the sake of comparison

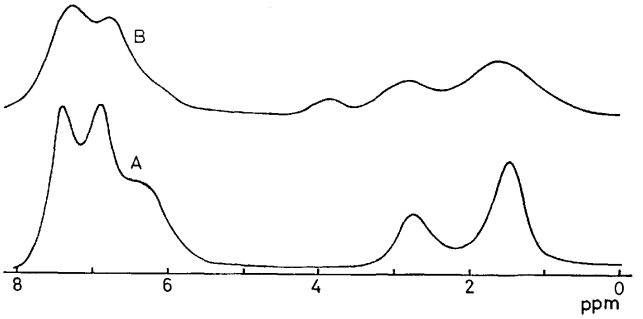

Fig. 3. NMR spectra of poly(1-vinylnaphthalene) (A) before and (B) after photoillumination for 3 h in benzene at 20 °C. $CDCl_3$ was used as a solvent.

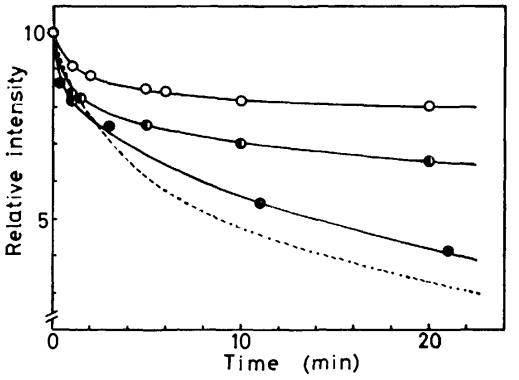

Fig. 4. Photocycloaddition of poly(1-vinylnaphthalene) in (○) dichloromethane, (◐) benzene and (●) cyclohexane and of 1,3-di-1-naphthylpropane (---) in cyclohexane at 20 °C. The reaction was followed by measurements of absorbance at 295 nm.

with the corresponding polymer system. In this experiment the concentrations of the polymer and 1,3-di-1-naphthylpropane were so controlled as to have the same absorbance at 297 nm. In cyclohexane the reaction proceeds following the first order kinetics except in the very early stage. The behavior is similar to the reaction of 1,3-di-1-naphthylpropane.[7c] This suggests that the cycloaddition of naphthalene side groups in cyclohexane occurs between the isolated dimer pairs, which are formed stably in the ground state. A statistical calculation predicts the degree of pairing of the side groups to be 84.46% when the side groups make a pair randomly.[9] In a real polymer system, however, the degree of pairing is naturally less than the theoretical prediction due to the conformational restriction. Thus, the conversion of 70% is explained by the dimerization of the naphthalene pairs formed in the ground state independent of each other.

On the other hand, in dichloromethane the reaction levels off at a very low conversion of *ca.* 20%. The flexibility of the polymer chain in dichloromethane makes the reaction possible between nonadjacent naphthalenes.[5] The reaction between the nonadjacent molecules presumably produces the macro-ring to make the polymer chain rigid. The regidity thus formed is considered to prevent the reaction between the residual side groups, giving rise to the low conversion.

The reaction behavior in benzene is intermediate between cyclohexane and dichloromethane. The

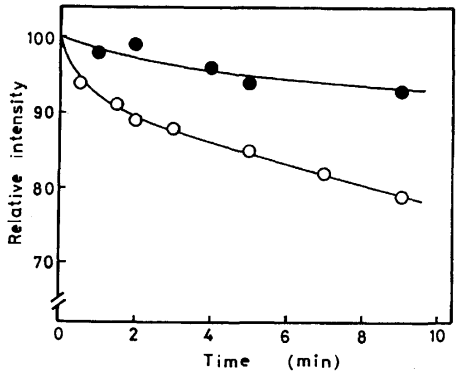

Fig. 5. Photocycloaddition reaction of poly(1-vinylnaphthalene) in cyclohexane in the absence (○) and in the presence (●) of 5×10^{-4} M of 1,3-pentadiene at 20 °C.

cycloaddition reaction proceeds up to 40% conversion but after that it levels off. The intensity of the dimer absorption in benzene is weaker than that in cyclohexane, though it is much higher than in dichloromethane. The higher conversion in benzene is attributable to the photo-reaction of the ground state dimers.

The quantum yields of cycloaddition by the mercury line of 297 nm were measured to be 0.04 and 0.02 in cyclohexane and dichloromethane, respectively, at 20 °C. The yield in dichloromethane is the value in the initial stage at 2×10^{-5} M, since it decreases with time and finally becomes very small after prolonged illumination. The higher value in cyclohexane indicates that the rigid dimer conformation is favorable to the cycloaddition reaction in comparison with the mobile conformation in dichloromethane.

Reaction Mechanism. The difference in the reaction behavior in cyclohexane and dichloromethane was further confirmed by quenching and sensitizing experiments. Figure 5 shows the effect of the addition of 1,3-pentadiene upon the cycloaddition reaction in cyclohexane. The reaction is suppressed by 1,3-pentadiene in cyclohexane. In this experiment very low concentration of 1,3-pentadiene (5×10^{-4} M) was adopted in order to avoid the addition reaction between the naphthalene side groups in the excited singlet state and 1,3-pentadiene.[10] In dichloromethane, however, no noticeable difference was observed in the reaction even in the presence of the same concentration of 1,3-pentadiene.[11] The quenching experiment confirmed that the solvent alters the reaction mechanism. In cyclohexane a triplet excited state is mainly responsible for the reaction. The reaction was suppressed not only by 1,3-pentadiene but also by oxygen which is a typical triplet quencher. Ineffectiveness of 1,3-pentadiene in dichloromethane suggests a singlet mechanism, since the triplet state of naphthalene is known to be effectively quenched by 1,3-pentadiene.

In order to substantiate the triplet mechanism in cyclohexane, the triplet sensitization by benzophenone was carried out as shown in Fig. 6. The reaction was followed by the fluorescence intensity of the naphthalene moiety. Decrease in intensity was observed even when the excitation wavelength was restricted to the

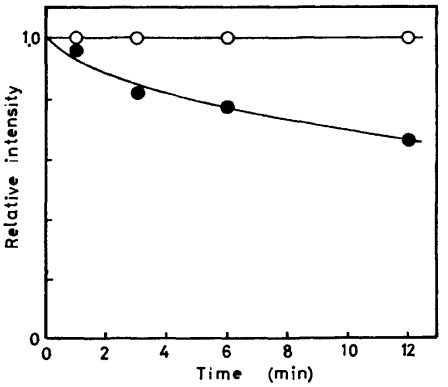

Fig. 6. Photosensitized cycloaddition of poly(1-vinylnaphthalene) in (●) cyclohexane and (○) dichloromethane in the presence of benzophenone by excitation wavelengths longer than 340 nm at 20 °C. The reaction was followed by measurements of the fluorescence intensity of the naphthalene moiety. The areas of the whole spectra plotted against wave number scale were compared.

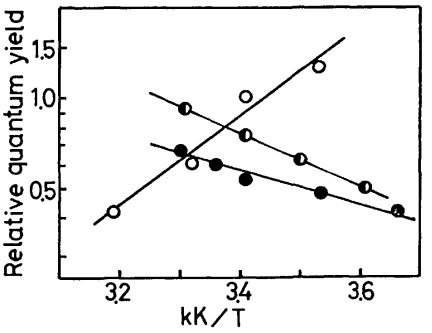

Fig. 7. Temperature dependence of relative quantum yields of photocycloaddition of poly(1-vinylnaphthalene) in (○) cyclohexane and (●) dichloromethane and of 1,3-di-1-naphthylpropane in cyclohexane(◐).

absorption of benzophenone ($\lambda>390$ nm). The decrease is not due to the reaction between a naphthyl side group and benzophenone, since the fluorescence of 1-methylnaphthalene retains the same intensity even after prolonged photoillumination in the presence of benzophenone. The result provides unambiguous evidence that the cycloaddition reaction in cyclohexane occurs in the triplet excited state.

On the other hand, the fluorescence intensity shows no decrease in a dichloromethane solution by photosensitization with benzophenone under identical conditions. The result confirms the singlet mechanism, presumably excimer mechanism, of the cycloaddition reaction in dichloromethane.

The temperature dependence of the quantum yield of cycloaddition is shown in Fig. 7. The slope in dichloromethane gave an activation energy of 2.0 kcal/mol, which is smaller than the value 4.3 kcal/mol for 1,3-di-1-naphthylpropane. The difference suggests that in this temperature range polymer chains assist the cycloaddition reaction. The enthalpy change associated with the excimer formation is conceived to be similar both in the polymer and 1,3-di-1-naphthylpropane, while the activation energy necessary to attain

the excimer conformation or dimer conformation is considered to depend on the chain length. The low activation energy in the polymer system indicates that the naphthyl side groups, which are in a favorable conformation to make the cyclodimer, react in the initial stage of the reaction in dichloromethane.

The temperature dependence in cyclohexane, on the other hand, gave a negative value of −5.7 kcal/mol. The reaction scheme in cyclohexane can be expressed as follows:

$$\mathrm{N} + \mathrm{N} \underset{k_m,}{\overset{k_d}{\rightleftharpoons}} (\mathrm{N{\cdot}N}) \quad (1)$$

$$(\mathrm{N{\cdot}N}) \xrightarrow{h\nu} {}^1(\mathrm{N{\cdot}N})^* \qquad I_0, \quad (2)$$

$${}^1(\mathrm{N{\cdot}N})^* \longrightarrow {}^3(\mathrm{N{\cdot}N})^* \qquad k_{ISC}, \quad (3)$$

$${}^1(\mathrm{N{\cdot}N})^* \longrightarrow \mathrm{N} + \mathrm{N} \qquad k_f + k_n, \quad (4)$$

$${}^3(\mathrm{N{\cdot}N})^* \longrightarrow \mathrm{N{-}N} \qquad k_D, \quad (5)$$

$${}^3(\mathrm{N{\cdot}N})^* \longrightarrow \mathrm{N} + \mathrm{N} \qquad k_p + k_n'. \quad (6)$$

Here, N, (N·N) and N–N are a naphthalene side group, an associated dimer and a photodimer, respectively. Equations 4 and 6 involve all deactivation processes in the excited singlet and triplet states, respectively. Using the steady-state approximation, the quantum yield of the cycloaddition reaction, Φ_D, is given by

$$\Phi_D = k_{ISC} \cdot k_D \cdot \tau_1 \cdot \tau_3 \cdot \frac{k_d \bar{\varepsilon}_d}{k_d \bar{\varepsilon}_d + k_m \bar{\varepsilon}_m},$$

where τ_1 and τ_3 are lifetimes of singlet and triplet excited states, respectively, $\bar{\varepsilon}_d$ and $\bar{\varepsilon}_m$ average extinction coefficients of dimer and monomer, respectively, at the excitation wavelength. The negative activation energy is attributable to τ_3 and $k_d\bar{\varepsilon}_d/(k_d\bar{\varepsilon}_d + k_d\bar{\varepsilon}_m)$, since other terms are insensitive or have positive temperature coefficient. The increase in the mobility of polymer chain at higher temperatures is considered to cause the decrease of the triplet state lifetime due to the increase in the rates of non-radiative deactivation processes and prevent the formation of cyclodimer, giving a low quantum yield.

8) Monomer emission signifies the fluorescence from isolated naphthalene side groups excited to its first excited singlet state. Dimer emission is the fluorescence emitted from an excited dimer produced by excitation of the associated dimer of the side groups with its conformation in the ground state essentially unchanged. Excimer signifies a kind of excited dimer the conformation of which is suitable for strong interaction in the excited state between the side groups but repulsive in the ground state. This conformation clearly differs from that of the associated dimer formed in the ground state.

11) External heavy atom effect of the solvent is negligible. Dichloromethane scarcely alters the triplet lifetime of the polymer. Conversely, low viscosity of dichloromethane increases the collision frequency between the polymer and the quencher.

Oxidative Degradation of Polymers. VI. Photooxidation of Polystyrene Powder and Some Model Compounds

Takeo SHIONO,* Etsuo NIKI, and Yoshio KAMIYA
Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113

(Received March 1, 1978)

The rates and products of photooxidation of polystyrene powder were studied at 70 °C under irradiation of a 30W low pressure mercury lamp. It was found that the rate of oxidation is remarkably high but the amount of oxygen incorporated into the polystyrene chain is very small. About a half of the absorbed oxygen appeared as carbon dioxide, independent of the conversion, irradiation time, oxygen pressure, and molecular weight. A trace amount of phenol was detected by GLC. The isotachophoretic analysis showed the formation of formic acid, oxalic acid, and glyoxylic acid. It was found that the mechanism of photooxidation is dependent on the state of the substrate, *i.e.*, crystalline solid, melt(viscous liquid) or solution. It is concluded that the polystyrene powder is photooxidized from its surface and aromatic ring of polystyrene is cleaved to give carboxylic acids. It was suggested that ozone played an important role in the photooxidation of polystyrene. The conclusions are supported by the results obtained in the photooxidation of some model compouds such as 1,2-diphenylethane, hexamethylbenzene, azobenzene, and phenylazotriphenylmethane.

Although it is accepted that the oxidation of polymers proceeds by a similar mechanism to that in the oxidation of simple hydrocarbons, the modes of polymer oxidation are complicated and need to be clarified.[1] Photochemical oxidation of polymers has been studied by numerous investigators mostly on films.[2,3] Formation of hydrogen molecule was observed when polystyrene films were irradiated with 253.7 nm light *in vacuo*.[4,5] On the other hand, water and carbon dioxide were found as the only volatile products in the photooxidation of polystyrene films at 28 °C with 253.7 nm light.[6] Rabek and Rånby[7] proposed a new mechanism in the photooxidation of polystyrene as film or in benzene, where the cleavage of benzene ring plays an important role in the reaction pathway. They suggested the contribution of singlet oxygen molecule as a reactive species.

We have found that isotactic polypropylene powder is oxidized quite rapidly by irradiation with a 30 W low pressure mercury lamp, approximately half of the oxygen absorbed appearing as carbon dioxide independent of the extent of oxidation.[8] As an extension we have studied the photooxidation of polystyrene powder using a low pressure mercury lamp as a light source. The principal object is to measure rates and products of oxidation with particular attention on the absorbed oxygen balance. Polystyrene powder has an advantage over polypropylene powder in that it is soluble in organic solvents, making analyses of the oxidized polystyrene easier than for polypropylene. The data on the quantitative product analyses are lacking, but they are apparently most needed for the understanding of the nature of the reaction. Photooxidation of several relevant model compounds has also been carried out in order to elucidate the mechanism of the photooxidation of polystyrene.

Experimental

Materials. Polystyrene powders obtained from Pressure Chemical Co. were used, the molecular weight being 4000, 9000, and 20400. 1,2-Diphenylehtane (mp 52.5 °C) and azobenzene (mp 58 °C) were recrystallized twice from ethanol and benzene, respectively. Reagent grade hexamethylbenzene powder was used. The electronic spectrum of azobenzene in benzene solution shows two distinct maximum transition regions at 318 and 435 nm in the π-π^* and n-π^*, respectively. Thus the azobenzene is trans.[9] Phenylazotriphenylmethane was used without futher purification. Commercial azobisisobutyronitrile(AIBN) and azobiscyclohexanecarbonitrile (ACN) were recrystallized from methanol and used as a radical initiator. Water was purified by passing through an ion-exchange resin.

A 30W low pressure mercury lamp was used as an ultraviolet light source, the main emission being the resonance lines of 184.9 and 253.7 nm.

Procedure. Fifty or one hundred mg polystyrene powder was weighed into a 50 ml quartz vessel. 10 ml of water was then introduced. The vessel was connected to a vacuum line and degassed by freeze and thaw cycles. Oxygen was then introduced. Amounts of initial and final gases were determined with use of a Toepler pump and by subsequent gas analysis by means of gas chromatography.[8]

After the oxidation and analysis of the final gases noncondensable at −80 °C had been carried out, the vessel was opened and the reaction mixture was filtered with a glass filter 1G-4. The polystyrene powder recovered was washed several times with water, dried in a vacuum at 70 °C, weighed, and then analyzed by IR, NMR,[10] gel permeation chromatography[11] and elemental analysis. The filtrate was analyzed by iodometric and neutralization titration. Low-boiling products were determined by gas liquid chromatography (GLC, Porapak-Q, 2 m, 50/80 mesh; PEG 20 M, 20 wt %, 7 m, 80/100 mesh). Low molecular weight acids were determined by isotachophoretic analysis with a Shimadzu Isotachophoretic analyzer IP-1B. Aqueous solution of 0.01 M gultamic acid was used as a terminal solution and aqueous solution containing 0.01 M L-histidine and 0.01 M L-histidine hydrochloride as a leading solution.

Results and Discussion

Photooxidation of Polystyrene Powder. The results of photooxidation of polystyrene powder of different molecular weight at different irradiation time are summarized in Table 1. Photooxidation was carried out under atmospheric pressure of oxygen. The rate of oxidation is remarkably great, the average rate of oxygen absorption being *ca.* 0.2 mol O_2/mol PS/h. The amount of oxygen absorbed per monomer unit of poly-

styrene is as high as 0.80 mol/mol in 3 h and 1.50 mol/mol in 6 h (Runs 3 and 4). Nevertheless, approximately 90% of polystyrene powder could be recovered after photooxidation. This significance will be discussed later. About half of the absorbed oxygen was found as carbon dioxide. This is true even at 3.7% conversion, independent of irradiation time or the extent of oxidation. The effect of molecular weight of polystyrene is small both on rate and products of oxidation(Table 1).

It was found by isotachophoretic analyses that carboxylic acids such as formic, glyoxylic and oxalic acids

are formed and their amounts increase with increasing irradiation time (Fig. 1). Hydroperoxide and hydrogen peroxide were also detected by iodometric titration in the presence and absence of catalase: for example, 6.8 μmol(2.1% based on absorbed oxygen) and 30.5 μmol(9.5%), respectively in Run 4. A trace amount of phenol was also found by GLC analysis.

The rate of oxidation increases with increasing oxygen pressure up to 400 Torr, further increase in oxygen pressure showing little effect(Fig. 2). Even at low oxygen pressures, carbon dioxide is the only gaseous product, about a half of the oxygen absorbed appearing as carbon dioxide.

Figure 3 shows the relation between conversion and the ratio of carbon dioxide formed to the oxygen absorbed. Although there is some scatter of data, the yield of carbon dioxide is approximately 50% of

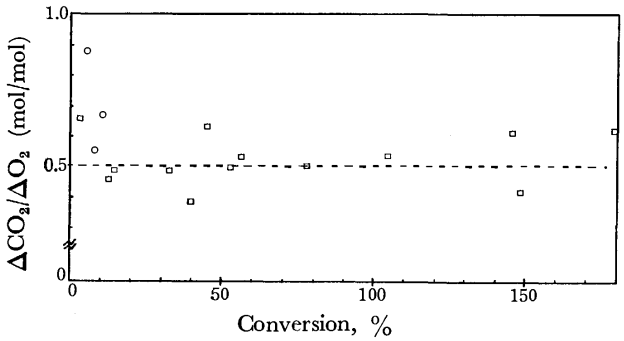

Fig. 3. Relation between $\Delta CO_2/\Delta O_2$ and conversion in the photooxidation of polystyrene powder. □: Po_2=1 atm, ○: Po_2=reduced pressure.

the absorbed oxygen independent of conversion.

The results of elemental analyses of the initial and photooxidized polystyrene powders are summarized in Table 2. Although the amount of oxygen absorbed per monomer unit is quite high, the amount of oxygen incorporated into the polymer chain is exceedingly small, the ratio of carbon to hydrogen remaining constant. For example, 0.4 mol oxygen is absorbed per monomer unit, but little oxygen remained in the polystyrene(Run 2).

The ratio of aromatic to aliphatic proton for the initial and photooxidized polystyrenes obtained by integration of proton NMR spectra is given in Table 3. About 100 mg of polystyrene powder with molecular weight 4000 was used for analysis. The conversion based on monomer unit was 33 and 106% for 1.5 and 4.5 h irradiation, respectively. The ratio of aromatic to aliphatic proton remains constant.

Figure 4 shows the gel permeation chromatograms of initial and photooxidized polystyrene with molecular weight of 4000. Molecular weight distribution was shifted by oxidation to higher fractions rather than to

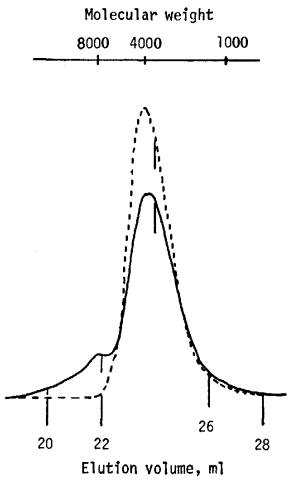

Fig. 4. Gel permeation chromatograms of photooxidized polystyrene powder. Molecular weight: 4000. ----: Initial polystyrene, ——: photooxidized polystyrene.

lower fractions. Similar results were obtained for polystyrene with molecular weight of 9000 and 20400. The results indicate that crosslinking prevails over chain scission.

The results of photooxidation of polystyrene powder observed differ remarkably from those of thermal[12,13] or even γ-ray[14] oxidation of polystyrene at moderate temperature, where the major products are hydroperoxide, benzaldehyde and acetophenone with little carbon dioxide or carbon monoxide.

Oxidation of Model Compounds. In order to clarify the nature of the photooxidation of polystyrene powders, the photooxidation of several relevant model compounds was performed under similar conditions. 1,2-Diphenylethane and hexamethylbenzene were used as model compounds for aromatic hydrocarbons containing benzylic hydrogen(Table 4) while azobenzene

and phenylazotriphenylmethane were used as model compounds that give phenyl radical(Table 5).

1,2-Diphenylethane is a crystal at 30 °C, its photooxidation proceeding rapidly, and absorbs approximately equimolar oxygen in 2 h(Table 4, Run 11). The most striking result is that carbon dioxide is formed as a major product, its yield being as high as 40% of oxygen absored in spite of low reaction temperature and low conversion(Run 10). Essentially the same results were obtained at higher conversion (Run 11). After the photooxidation of 1,2-diphenylethane crystal, the reaction mixture was filtered and the recovered 1,2-diphenylethane washed and dried in a vacuum. The recovered diphenylethane was found to be identical with the initial, unoxidized 1,2-diphenylethane by GLC, NMR, IR, and elemental analyses. However, the formation of carbon dioxide decrease as 1,2-diphenylethane changes from crystal to melt and to solution, whereas the formation of carbon monoxide increase. The thermal oxidation initiated by AIBN or ACN gave neither carbon dioxide nor carbon monoxide and the major product was peroxide, the reaction being typical autoxidation. From the results of photooxidation of hexamethylbenzene powder (Table 4), oxidation is seen to be similar to that of polystyrene and 1,2-diphenylethane crystal. The rate is high, about half of the oxygen absorbed appearing as carbon dioxide. Carboxylic acids were another major product (33% based on oxygen uptake). Formation of acetic and formic acids suggests the cleavage of aromatic ring.

Azobenzene powder(515 μmol) was floated on the water surface and irradiated with a low pressure mercury lamp at 30 °C under atmospheric pressure of oxygen (Run 18). After 2 h, 178 μmol oxygen was absorbed and 30 μmol nitrogen and 96 μmol carbon dioxide evolved. The isotachophoretic analysis of the aqueous phase showed the presence of 14 μmol formic acid, 3 μmol glyoxylic acid, and 4 μmol oxalic acid. These acids account for three quarters of the total acid observed by titration. After the oxidation was over, the powder floating on the water surface was collected, washed, and dried at room temperature in a vacuum. 483 μmol Azobenzene was recovered, 99.6% of nitrogen being accounted for. The NMR, UV, IR, and elemental analyses for the recovered azobenzene gave identical results with those of the initial azobenzene. Thus, azobenzene should cleave photolytically to give nitrogen and phenyl radicals, which cleave to give eventually acids, carbon dioxide and other products.

The photooxidation of azobenzene was also carried out at 70 °C(Run 19). Azobenzene becomes a viscous liquid when warmed to 70 °C, forming a thin layer on the water surface. The nitrogen evolution did not increase appreciably with rise in temperature from 30 to 70 °C. However, the amount of oxygen absorption at 70 °C was about three times as much as that at 30 °C. This can be ascribed partly to the phase change but mostly to the temperature difference. The temperature did not affect the product distribution, 46% of absorbed oxygen being found as carbon dioxide.

Phenylazotriphenylmethane(PAT) was oxidized either photochemically or thermally. Photooxidation was carried out with solid PAT, and thermal oxidation in benzene solution. The results show that considerable carbon dioxide was formed by photochemical oxidation, while in contrast, none was observed by thermal oxidation even at higher conversion(Table 5).

Mechanism and Active Species in the Photooxidation of Polystyrene Powder. Polystyrene powder is oxidized remarkably fast by irradiation with a 30 W low pressure mercury lamp. Approximately half of the oxygen absorbed gives carbon dioxide even at low temperature and low conversion. The yield for carbon dioxide remains constant independent of the extent of oxidation.

a) 2.3 cm H_2O filter was placed between light source and quartz cell(3 cm). b) By monomer unit, molecular weight=4000. c) By titration.

That the photooxidation of polystyrene powder takes place exclusively on its surface is supported by the following results: (1) the oxygen incorporated into polymer chain is quite small in spite of high oxygen uptake(Table 2), and (2) much of the powders of polystyrene, azobenzene, PAT and 1,2-diphenylethane is recovered after photooxidation.

If we assume that one styrene monomer unit yields eight molecules of carbon dioxide and four molecules of water, then the remaining polystyrene is estimated by

$$\text{Calculated recovery } (\%) = 100 \times \frac{[PS]_0 - \Delta CO_2/8}{[PS]_0},$$

where $[PS]_0$ is the initial amount of polystyrene and ΔCO_2 is carbon dioxide formed. As shown in Table 1, the calculated recovery agrees well with the observed recovery. On the other hand, if we assume that aromatic carbons are not oxidized to carbon dioxide and only two molecules of carbon dioxide are formed from one monomer unit, the agreement between calculated and observed recoveries is poor.

Formation of low molecular weight carboxylic acids and the importance of crosslinking observed in this study indicate the contribution of ozone, since they resemble the ozonation of polystyrene[10] and aromatic compounds.[15] 184.9 nm light converts oxygen molecule into ozone,[16] which is decomposed to $O(^1D)$ and singlet oxygen molecule by 253.7 nm light.[17] Since 184.9 nm light is absorbed by air, it was first assumed that only monochromatic 253.7 nm light would be introduced into the vessel.

In order to study the effect of wavelength of the incident light and contribution of ozone, photooxidation

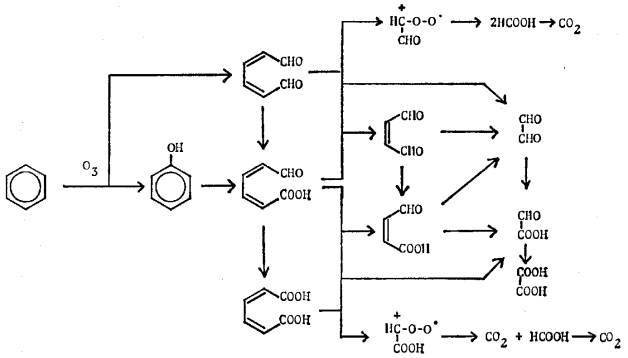

Fig. 5. Ozonation of aromatic ring. Substituents are neglected.

was carried out in the presence and absence of a water filter placed between light source and quartz vessel. The main emission of the light source is the resonance lines of 184.9 and 253.7 nm. The former should be absorbed by water. The results of photooxidation of polystyrene powder with and without a water filter are given in Table 6. We see that the water filter decreases both rate of oxidation and formation of carbon dioxide.

It should be noted that photooxidation of polystyrene gives formic acid, glyoxylic acid, oxalic acid, malealdehyde, and maleic acid and/or 2,4-hexadienedioic acid. The products are similar to the ozonation products from aromatic compounds,[10,15] strongly indicating the contribution of ozone in the cleavage of aromatic ring.[18] These products should be formed according to the scheme shown in Fig. 5. The formation of ozone in the reaction vessel was confirmed by passing the gas through an aqueous solution of potassium iodide.

However, it is not clear how carbon dioxide is formed in as high as 50% yield and why the yield decreases when the state of substrate changes from solid to melt and to solution.

Conclusion

Polystyrene powder was found to be oxidized rapidly when irradiated with a low pressure mercury lamp. The major product was carbon dioxide with approximately 50% yield based on oxygen absorbed. The yield is independent of irradiation time, oxygen pressure and molecular weight. The molecular weight did not decrease appreciably by oxidation, crosslinking being observed instead. Formic acid and other low molecular weight carboxylic acids were also observed. It was suggested that ozone plays an important role as an active species, especially in the cleavage of aromatic ring.

The authors are grateful to the Shimadzu Seisakusho for permission to use their isotachophoretic analyzer.

A New Synthesis of L-4-Amino-2-hydroxybutyric Acid. Carboxyl-Assisted Nitrile Synthesis from Primary Amides

Toshio YONETA,* Seiji SHIBAHARA, Shunzo FUKATSU, and Shigeo SEKI

Central Research Laboratories, Meiji Seika Kaisha, Ltd., Morooka-cho, Kohoku-ku, Yokohama 222

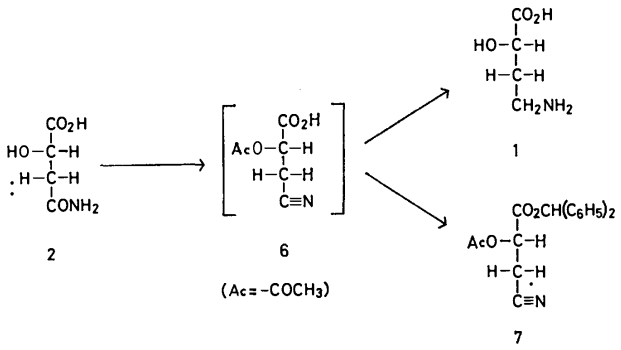
(Received March 11, 1978)

L-2-Hydroxysuccinamic acid prepared from L-asparagine was dehydrated with acetic anhydride in pyridine, affording the respective ω-cyano acid, which, on catalytic hydrogenation, gave the title compound. Similarly, the amide groups of some other β- and γ-amic acids were dehydrated to give the respective cyano acids in good yields.

Butirosin B,[1,2] an antibiotic produced by *Bacillus circulans*, is a derivative of ribostamycin acylated with the title acid (**1**) at the C-1 amino group of the 2-deoxystreptamine moiety, and it is active against ribostamycin- and kanamycin-resistant organisms, including *Pseudomonas* strains. Kawaguchi *et al.*[3] synthesized amikacin (BB-K8) by the condensation of kanamycin A with **1** at the C-1 amino group of the deoxystreptamine moiety. Amikacin is also active against kanamycin-resistant organisms. On the basis of these facts, **1** is presumed to be a valuable amino acid in chemical-modification studies of amino-sugar antibiotics.

Although **1** had previously been synthesized by the partial deamination of L-2,4-diaminobutyric acid[2,4] or by the Hofmann degradation of L-2-hydroxyglutaramic acid[5] prepared from L-glutamine, we have searched for other potential methods which might be more convenient and adequate for large-scale perparation. We wish now to describe a three-step synthesis of **1** using L-asparagine as the starting material.

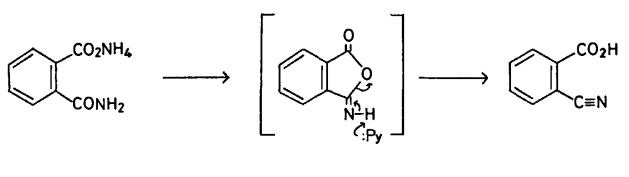
L-Asparagine was first converted to L-2-hydroxysuccinamic acid (**2**) by treatment with sodium nitrite.[6] Then we attempted to transform the amide group of **2** into the nitrile group without the protection of the other functional groups. Among several known dehydration methods of primary amides into nitriles, *p*-toluenesulfonyl chloride–pyridine[7] or trifluoroacetic abhydride–pyridine[8] methods were assumed to be adequate. However, the treatment of **2** with these reagents according to the described procedures afforded no cyano derivatives, but only a tarry product. Pyriadi *et al.*[9] reported that *N*-alkylmaleamic acids were easily converted to 4-(alkylimino)-2-butenolides with an acetic anhydride–triethylamine or acetyl chloride–triethylamine mixture. This fact prompted us to consider that the 3-iminophthalide produced from primary amide and carboxylate by the above methods might be convertible to nitrile and carboxyl groups as is shown in Scheme 1. As expected, the treatment of ammonium phthalamate (**3**) with two equivalents of acetic anhydride in pyridine afforded the *o*-cyanobenzoic acid (**5**) as a single product. Under similar conditions, benzamide was not converted to benzonitrile, but was recovered unchanged. Judging from these experimental results, the reaction is likely to proceed through the intermediary 3-iminophthalide (**4**), as is shown in Scheme 1. Indeed, the treatment of **2** with acetic anhydride in pyridine at room temperature afforded L-2-acetoxy-3-cyanopropionic acid (**6**). The hydrogenation of **6** with platinum oxide in aqueous ethanol under acidic conditions afforded **1** in a 30% yield form L-asparagine. As **6** was unstable,[10,11] the structure was confirmed as that of the corresponding benzhydryl ester (**7**).



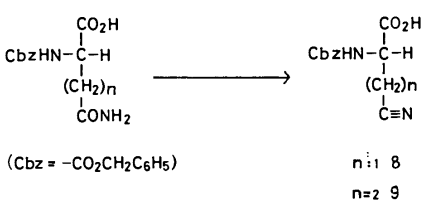
Scheme 2.

In order to extend this dehydration reaction further, we treated N^2-benzyloxycarbonyl-L-asparagine with acetic anhydride in pyridine. The product isolated in an 83% yield was identical with authentic *N*-benzyloxycarbonyl-3-cyano-L-alanine (**8**).[13] Similary, N^2-benzyloxycarbonyl-L-glutamine gave L-2-(benzyloxycarbonylamino)-4-cyanobutyric acid (**9**) in a good yield as a thick syrup. The hydrogenation of **9** gave ornithine and a trace amount of proline, both of which were identified by paper chromatography.[13]

The mild conditions, easy dehydration, and reasonable yields of **5**, **6**, **8**, and **9** indicate that this dehydration method would be useful for the synthesis of various β- and γ-cyano carboxylic acids.



Scheme 1.



Scheme 3.

Experimental

The melting points are uncorrected. The optical rotation were measured with a Perkin-Elmer Model 241 polarimeter. The NMR spectra were recorded at 60 MHz with a Varian S-60T spectrometer.

o-Cyanobenzoic Acid (5). A solution of ammonium phthalamate (**3**) (165 mg) and acetic anhydride (0.2 ml) in pyridine (4 ml) was kept at room temperature for 1 h. Almost all of the solvent was then removed by evaporation under reduced pressure, and the residue was diluted with ethyl acetate (15 ml). The resulting solution was washed with 1M-hydrochloric acid and a saturated aqueous sodium chloride solution, and dried over sodium sulfate. The solution was subsequently concentrated to give a white powder (105 mg). Recrystallization from ethyl acetate afforded a white granule of **5** (72 mg); mp 227—228 °C (lit,[10] mp 226—230 °C); IR (KBr): 1690 (COOH) and 2240 cm^{-1} (CN).

Found: C, 65.19; H, 3.50; N, 9.78%. Calcd for $C_8H_5NO_2$: C, 65.30; H, 3.43; N, 9.52%.

L-4-Amino-2-hydroxybutyric Acid (1). A solution of L-2-hydroxysuccinamic acid (**2**)[6] (532 mg) and acetic anhydride (1.5 ml) in pyridine (15 ml) was kept at room temperature for 1 h. The solution was then concentrated to thick syrup under reduced pressure. The resulting crude L-2-acetoxy-3-cyanopropionic acid (**6**) was dissolved in a mixture of ethanol (20 ml), water (5 ml), and concd hydrochloric acid (1 ml), and hydrgenated with platinum oxide (50 mg) for 6 h under a pressure of 3 atm. After the removal of the catalyst, the filtrate was concentrated to a thick syrup, which was dissolved in water (10 ml) and chromatographed on Dowex 50W-X4 resine (H^+ form). After being washed with water, the column was developed with 0.5M-ammonium hydroxide. The eluted fraction was concentrated to give a crude compound, **1** (291 mg). This was dissolved in a mixture of methanol (9.6 ml) and water (2.3 ml) and then stored at 5 °C overnight. The crystals thus precipitated were collected and dried. 177 mg (37.2%); mp 197—198.5 °C, $[\alpha]_D^{25}$ −28.2° (*c* 1.2, water) (lit, mp 203—206 °C,[2] 200—200.5 °C,[4] $[\alpha]_D^{25}$ −28.2° (*c* 1.22, water),[2] −29.1° (*c* 1.0, water)[4]); NMR (D_2O): δ 1.97 (2H, m, CH_2), 3.16 (2H, t, N-CH_2), 4.16 (1H, q, C<u>H</u>(OH)COOH).

Found: C, 40.27; H, 7.65; N, 12.01%. Calcd for $C_4H_9NO_3$: C, 40.33; H, 7.62; N, 11.76%.

Benzhydryl L-2-Acetoxy-3-cyanopropionate (7). To a solution of crude **6**, obtained from **2**, (775 mg) as described for **1**, in acetone (16 ml), we added diazodiphenylmethane[12] (2 g) in acetone (6 ml). The solution was then allowed to stand at room temperature for 2 h. After working up with acetic acid, almost all of the solvent was removed under reduced pressure, and the residue was diluted with benzene (50 ml). The resulting solution was washed with water and dried over sodium sulfate. The solution was concentrated to *ca.* one-fifth in volume, and this residue was chromatographed on silica gel. Subsequent elution with benzene–ethyl acetate (50:1) afforded a thick syrup of **7** (1.5 g, 84%) on evaporation, $[\alpha]_D^{25}$ −36.3° (*c* 1.2, methanol); NMR ($CDCl_3$) : δ 2.13 (3H, s, $COCH_3$), 2.85 (2H, d, CH_2CN), 5.37 (1H, t, C<u>H</u>($OCOCH_3$)), 6.87 (1H, s, $CH(C_6H_5)_2$), 7.30 (10H, s, C_6H_5). IR (KBr): 2260 cm^{-1} (CN). Found: *m/e* 323.1163. Calcd for $C_{19}H_{17}NO_4$: M, 323.1157.

N-Benzyloxycarbonyl-3-cyano-L-alanine (8). A solution of N^2-benzyloxycarbonyl-L-asparagine (2.66 g). in acetic anhydride (1.2 ml) and pyridine (30 ml) was kept at room temperature for 1 h. The solution was then concentrated to a thick syrup under reduced pressure, and the residue was diluted with 1M-hydrochloric acid to give colorless needles of **8** (2.05 g, 83%). Recrystallization from 1,2-dichloroethane afforded pure **8**; mp 129—131.5 °C, $[\alpha]_D^{25}$ −18.7° (*c* 1.27, methanol) (lit,[13] mp 131—134 °C, $[\alpha]_D^{25}$ −19.0° (*c* 1.25, methanol)); IR (KBr): 1745 (COOH) and 2280 cm^{-1} (CN); NMR (C_5D_5N–D_2O): δ 3.43 (2H, d, CH_2CN), 5.11 (1H, t, C<u>H</u>(COOH)).

Found: C, 58.33; H, 4.91; N, 11.23%. Calcd for $C_{12}H_{12}N_2O_4$: C, 58.05; H, 4.88; N, 11.29%.

L-2-(Benzyloxycarbonylamino)-4-cyanobutyric Acid (9). A solution of N^2-benzyloxycarbonyl-L-glutamine (1 g) in acetic anhydride (0.44 ml) and pyridine (15 ml) was kept at room temperature overnight. Most of the solvent was then removed under reduced pressure, and the residue was diluted with elthyl acetate (50 ml). The solution was washed with 1M-hydrochloric acid and a saturated aqueous sodium chloride solution, and then dried over sodium sulfate. The solution was concentrated to *ca.* 5 ml, which quantity was chromatographed over silica gel. Elution with chloroform–methanol (5 : 1) afforded a thick syrup of **9** (855 mg, 91%) on evaporation, $[\alpha]_D^{25}$ −12.5° (*c* 1.18, methanol); IR (film): 2245 cm^{-1} (CN). Found: *m/e* 262.0931. Calcd for $C_{13}H_{14}N_2O_4$: M, 262.0953.

The hydrogenation of this compound with palladium on charcoal in the presence of hydrochloric acid led to ornithine and proline, the structure of which were confirmed by paper chromatography.

(Received March 16, 1978)

The crystal and molecular structures of dichlorobis(2-pyridinethiolato)tin(IV) have been determined by X-ray analysis. The crystal belongs to the triclinic system: $a=8.340(8)$, $b=12.456(7)$, $c=7.178(3)$ Å, $\alpha=86.46(4)$, $\beta=111.06(5)$, $\gamma=99.18(6)°$, space group $P\bar{1}$ with $Z=2$. The structure was determined by the heavy atom method and refined by the block-diagonal least-squares method ($R=0.058$). The complex is a distorted octahedral complex in which 2-pyridinethiolato ligands act as bidentate ligands, two four-membered (Sn, S, C, and N) chelate rings being present. Two Sn–Cl bonds are *cis*, two Sn–N bonds are *cis*, and two Sn–S bonds are *trans* configuration.

The synthesis of dichlorobis(2-pyridinethiolato)-tin(IV) (**1**) and its possible structures were described in a previous report.[1] Complex (**1**) is very stable. However, bis(benzenethiolato)dichlorotin(IV)[1] or dichlorobis(4-pyridinethiolato)tin(IV)[2] could not be isolated probably because of its instability. On the basis of IR spectral observation[1] the stability of complex (**1**) is ascribed to the intramolecular four-membered chelate ring formation for the six-coordination of the tin atom.

2-Pyridinethiolato ligand acts as a uni- or bi-dentate or a bridging ligand in rhodium,[3] iridium,[4] and ruthenium(II)[5,6] complexes.

This paper describes the crystal and moleuclar structures of **1** obtained by X-ray analysis: octahedral structure with four-membered chelate ring condensed with pyridine ring.

Experimental

Dichlorobis(2-pyridinethiolato)tin(IV) (**1**) was prepared by the reaction of di-2-pyridyl disulfide and tin(II) chloride in benzene in the presence of perhydroazepin-2-one.[1] The crystal for the X-ray analysis was obtained by recrystallization from acetonitrile solution.

The crystal system was determined as triclinic from the oscillation and Weissenberg photographs. The density was measured by the flotation method in an aqueous solution of ZnI_2. The unit-cell parameters were determined by the least-squares method, using 20 reflections carefully measured on a Syntex model $P2_1$ four-circle diffractometer with graphite-monochromatized Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). The intensity data were collected on a diffractometer with the 2θ-ω scanning mode ($2\theta\leqq50°$). The variable-scan method was used, the minimum and maximum scan rates being 1° and 24° min^{-1}, respectively. Background was counted for half the scan time on each side of a reflection. The size of the crystal was $0.2\times0.1\times0.4$ mm. In order to confirm the stability of the crystal and the counting system, the intensities of three standard reflections were measured every 99 reflections. The standard reflections were stable to 1.0% from their mean values. Neither absorption nor extinction correction was made. This might reduce the accuracy of the structure obtained.

$D_m=1.992$, $D_c=2.000$ g·cm^{-3}

Determination and Refinement of the Structure

The structure was determined by the heavy atom method. The coordinates of the tin atom were obtained from the Patterson map. Other atoms were found by successive Fourier synthesis. Refinement of the structure was performed by the block-diagonal least-squares method with 2209 independent reflections of $|F_o|\geqq3\sigma$. The final refinement was carried out with anisotropic thermal parameters for all the atoms. The strongest reflections at low scattering angles were omitted from the refinement in order to exclude extinction effects. The R-index converged to 0.058 with an equal weight for each reflection. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[7] The program ORTEP coded by Johnson[8] was used for drawing Figs. 1 and 2. The observed and calculated structure factors are given in Table 2.[9]

Results and Discussion

The positional and thermal parameters with their standard deviations are given in Tables 3 and 4, respectively. The molecular structure for **1** and the numbering scheme of atoms are shown in Fig. 1. Bond lengths and bond angles with their standard deviations are given in Tables 5 and 6, respectively. The tin atom is six-coordinated and two 2-pyridinethiolato ligands act as bidentate ligands, forming two four-membered (Sn, S, C, and N) chelate rings. Two Sn–Cl bonds are of *cis* configuration as suggested by IR spectral data.[1] Two Sn–N bonds are of *cis* and two Sn–S bonds are of *trans* configurations.

Deviations of ligand atoms from several least-squares planes are given in Table 7. Considerable deviations are observed from the mean plane (A) of five atoms (Sn, two Cl, and two N atoms), mean plane (B) of five atoms [Sn, Cl(1), N(1), and two S atoms], and mean plane (C) of five atoms [Sn, Cl(2), N(2), and two S atoms]. The angles of three pairs of *trans* bondings, Cl(1)–Sn–N(1), Cl(2)–Sn–N(2), and S(1)–Sn–S(2) are 161.1, 162.9, and 154.2°, respectively. The data show a distorted octahedral structure of **1**.

The lengths of C–S bonds of two 2-pyridinethiolato ligands in **1** are greater than the C–S bond of 2(1*H*)-pyridinethione (1.68 Å),[10] while the lengths of C–N bonds in the ligands are samller than the C–N bond length in 2(1*H*)-pyridinethione (1.39 Å).[10] This suggests that the ligands act as bidentate ligands forming four-membered chelate rings. The same phenomena have been observed for the corresponding ruthenium complex.[5a]

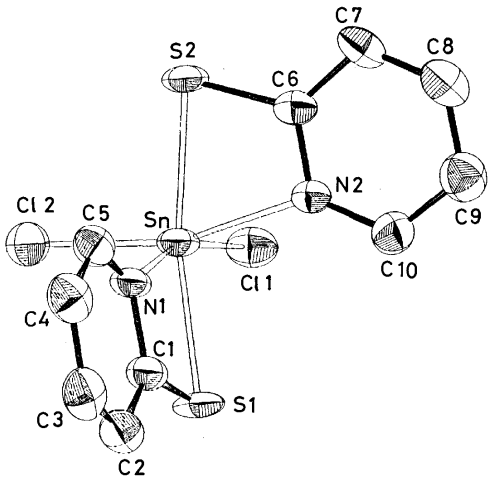

Fig. 1. The molecular structure for **1** and the numbering scheme of atoms. The ellipsoid encloses the region in which the center of the atom is found with probability 50%.

The bond lengths of two Sn–S bonds and two Sn–N bonds in **1** are nearly equal to the lengths of Sn–S bond [2.496(1) Å] and Sn–N bond [2.217(3) Å], respectively, in [2-[[(2-mercaptophenyl)imino]methyl]-phenolato]diphenyltin(IV), in which sulfur and nitrogen atoms are bonded to the tin atom forming five-membered chelate ring.[11] On the other hand, the lengths of two Sn–S bonds and two Sn–N bonds in **1** are smaller than those of the Sn–S bond [2.576(7) Å] and the Sn–N bond [2.62(2) Å], respectively, in triphenyl(4-pyridinethiolato)tin(IV), which has a polymeric structure formed by the intermolecular bridging through the nitrogen atom of the pyridine ring.[12] This suggests that two 2-pyridinethiolato ligands are bonded to the central tin atom through both nitrogen and sulfur atoms.

The deviation of S(1) atom from plane (D) of the pyridine ring [C(1—5) and N(1)] is 0.07 Å and that of S(2) from plane (E) of the pyridine ring [C(6—10) and N(2)] is 0.03 Å (Table 7). The sulfur atom lies practically on the same plane as the pyridine ring plane to which the atom is bonded. The deviations

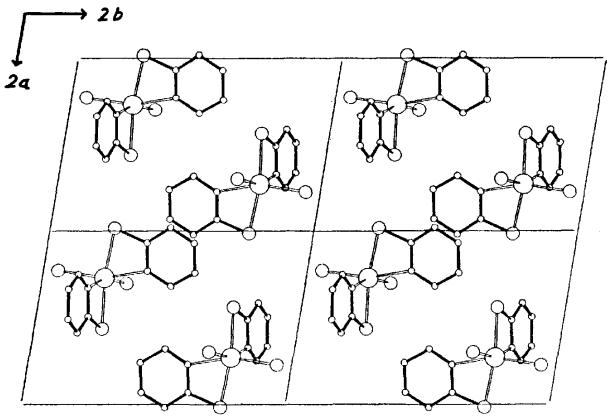

Fig. 2. The crystal structure of **1**.

of tin atom from planes (D) and (E) are 0.12 and 0.16 Å, respectively. The values of deviation seem to be comparatively small. This is supported by the fact that eight atoms [C(1—5), N(1), S(1), and Sn] are nearly on plane (F) within a deviation of 0.07 Å. The deviations of eight atoms [C(6—10), N(2), S(2), and Sn] from the mean plane (G) are also small (Table 7). This is in line with the IR spectral observation that the absorption bands due to pyridine ring vibrations and C–H out of plane bending vibrations in **1** appear in

a higher spectral region than those in di-2-pyridyl disulfide, suggesting the depletion of π-electron density of the pyridine ring.[1] The four-membered chelate ring condensed with the pyridine ring seems to be stabilized by mesomeric effect. The results support the assumption that the stability of **1** is based on the intramolecular chelation for six-coordination of the tin atom.[1]

The crystal structure is shown in Fig. 2. Intermolecular contacts are normal.

The Effect of Surfactants and β-Cyclodextrin on the Photooxidation of Stable Carbanions

Kazutoshi YAMADA,* Kiyoshi SHIGEHIRO, Tetsuo TOMIZAWA, and Hirotada IIDA

Department of Industrial Chemistry and Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

(Received March 27, 1978)

The micellar effect on the photochemistry of α-(4-hydroxyimino-2,5-cyclohexa-dienylidene)-α-phenylacetonitrile and its derivatives has been studied. 4-Nitrobenzophenone derivatives were obtained by the irradiation of ethanolic alkaline aqueous solutions of the oximes. 4-Nitrosobenzophenone derivatives formed as an intermediate were thermally oxidized to give the corresponding nitro compounds. The reaction was found to be the photochemical oxidation by singlet oxygen. The addition of an anionic surfactant (sodium dodecyl sulfate) and a nonionic surfactant (Tween #80) to the reaction solution scarcely changed the pK_a values of oximes, whereas the addition of a cationic surfactant such as hexadodecyltrimethylammonium bromide (HTAB) caused a considerable decrease. This indicates that HTAB promotes the formation of a stable carbanion. The presence of HTAB enhanced the rate of photooxidation by a factor of 10^2. The catalytic effect becomes maximum at the pH value of the reaction solution near the pK_a measured in the presence of HTAB or β-CDX.

Various chemical reactions modeled to the specific enzymatic interactions have been carried out in recent years. The reactions in certain aqueous micellar systems and the kinetics of organic reactions have been dealt with as a model for the enzymatic interaction. In the photooxidation of chlorophyll-a the addition of a nonionic sufactant to the reaction solution increased the rate of photooxidation ($k_{obsd}/k_0=21$).[1] Luciferin has been found to be chemiluminescent in the presence of a micellar cationic surfactant, but not in an anionic ones.[2] Cationic surfactants enhance the stability of anions, and anionic ones stabilize cations by forming micelles with them.

Minch *et al.*[3] reported that (4-nitrophenyl)phenyl acetonitrile is converted into the stable carbanion form in an aqueous alkaline solution, the addition of HTAB to this solution greatly enhancing the formation of its carbanion. In order to study the micellar effects on the photochemical reactions of the ionic species, carbanions, we used the derivatives of α-(4-hydroxyimino-2,5-cyclohexadienylidene)-α-phenylacetonitrile (**1**) which dissociate to form stable carbanion in alkaline solution. The synthetic method of these oximes was reported by Davis and his co-workers.[4] They also reported that the hydrogen peroxide oxidation of these oximes in methanolic alkaline solution gives 4-nitrobenzophenones. This paper provides

detailed information on the photooxidation of stable carbanions formed by the ionization of the oxime compounds, and the catalytic effects of various surfactants (hexadecyltrimethylammonium bromide (HTAB), sodium dodecyl sulfate (SDS), Tween #80, and β-cyclodextrin (β-CDX)). The kinetic has also been studied.

Results and Discussion

Photoreaction of Oxime Derivatives. 4-Nitrobenzophenone derivatives and its dimers (4,4'-diaroylazoxybenzenes) were obtained as photoreaction products by irradiation of an ethanolic alkaline aqueous solution of oximes **1** and **2**. The structures of products were determined by comparison of mp, NMR and mass spectra with those of authentic samples. The photooxidation was carried out by irradiating an ethanolic alkaline aqueous solution of the oxime with a high pressure mercury lamp under aerobic conditions. The photooxidation was followed by means of UV spectroscopy (Fig. 1). The maximum absorbance of the oxime **1** at 405 nm decreased during the course of irradiation, a new maximum having an isosbestic point at 334 nm appearing at 288 nm. The maximum at 288 nm shifted to 264 nm which corresponds to that of 4-nitrobenzophenone. A new small absorbance corresponding to that of the dimer of oxime appeared at 345 nm together with one at 264 nm. The shift of

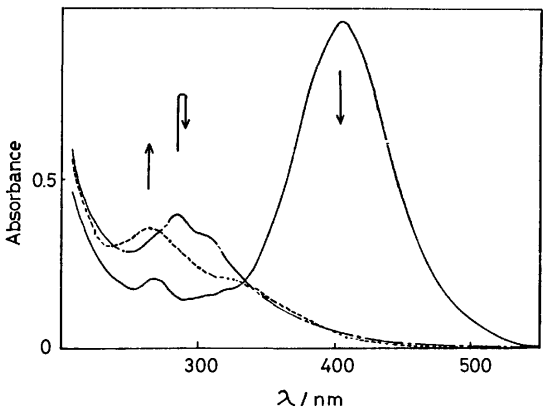

Fig. 1. Spectra of a 10% ethanolic aqueous buffer solution (pH 9.20) of oxime **1**. ——: Before irardiation, ———: after 80 min of irradiation, ---: after 240 min of irradiation.

the maximum at 288 nm to 264 was observed both under irradiation and in the dark. The first band appearing at 288 nm agrees very closely with the characteristic absorbance (λ_{max} 283 nm) of nitrosobenzene. 4-Nitrosobenzophenone seems to be formed as an intermediate.

Source of the Oxidizing Agent. Photochemical oxidation with oxygen is known in bioorganic chemistry. Chlorophyll-a was photooxidized by a molecular oxygen.[1] The photooxidation of bilirubin proceeds with singlet oxygen, bilirubin acting as a sensitizer to form singlet oxygen. As a source of energy to form the highly reactive species, singlet oxygen, the triplet dye was recognized in many oxygenation reactions.[6] The mechanism of the present photooxidation is considered as that of the photooxidation of bilirubin.

The photooxidation proceeds extremely slowly in the absence of oxygen. In the presence of β-carotene (1.27×10^{-5} M), which is a singlet oxygen quencher,[7] the quantum yield of the reaction decreases by a factor of 5. However, it increases considerably in the presence of Rose Bengal (7.70×10^{-6} M), a photosensitizer to form singlet oxygen,[6a] by a factor of 12. In the presence of a free radical inhibitor such as 2,6-di-*t*-butylphenol (up to 1×10^{-2} M),[6a,8] the reaction is not suppressed. It is obvious that the reaction is photochemical oxidation by singlet oxygen.

The Effect of Surfactant on Visible Spectra. Remarkable micellar effects of HTAB are observed in the visible spectra of the oxime. The addition of HTAB to the neutral and alkaline solution containing the oxime causes a red shift of the λ_{max} values for the neutral and anion form of the oxime. A similar effect was also observed on addition of β-CDX. The λ_{max} values for the neutral and anion forms of the oxime in 25—10% ethanolic water, aqueous HTAB, and β-CDX are given in Table 1.

The Effects of Surfactants on the pK_a Value. The pK_a values determined in 25—10% ethanolic aqueous solution with and without surfactants are given in Tables 2 and 3. The pK_a values of all oximes decrease when the micellar concentration of HTAB is used. This is also the case for β-CDX. On the other hand, the pK_a values of the oximes are random in the case of SDS and Tween #80. The decrease in the pK_a values results from the stabilization of the anion form of the substrates, arising from (a) an electrostatic interaction with cationic head groups of HTAB and the anion form, and (b) an electron delocalization by the hydrogen bond between an adjacent hydroxyl group of β-CDX and an oxygen atom of 4-nitroso group of the substrate which forms 1:1 inclusion complex with β-CDX.

Effects of Surfactants on Quantum Yields. The quantum yields of the catalytic action of the HTAB (Φ_2) in the photooxidation of oximes were analyzed by means of a modified form of Lineweaver-Burk equation.[14] Φ_0 and Φ_{obsd} are the quantum yields for the formation of oxidized products in the absence and presence of the HTAB. The quantum yield (Φ_2) increased by a factor of 370 in the presence of

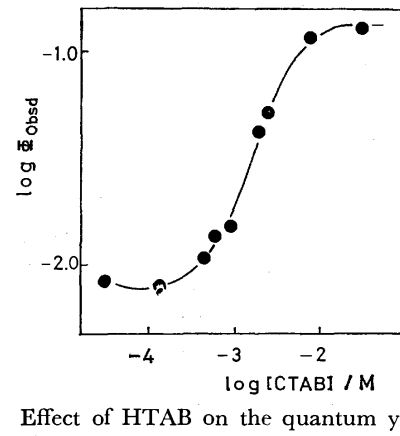

Fig. 2. Effect of HTAB on the quantum yield for the photooxidation of 5.18×10^{-5} M of oxime **1** in 10% ethanolic aqueous buffer (pH 7.31).

HTAB (1×10^{-2} M). The critical micellar concentration (CMC) of HTAB in the photooxidation of **1** is estimated to be 6×10^{-4} M from the plot of $\log \Phi_{obsd}$ *vs.* $\log C_D$(surfactant concentration) as shown in Fig. 2. The quantum yield of this photooxidation becomes maximum at the surfactant concentration of 10^{-2} M. The value of Φ_{obsd} varies with the concentration of β-CDX, reaching maximum at a certain concentration. Such a phenomenon is characterized in the enzyme reaction which follows Michaelis-Menten kinetics. A general mechanism involving the micell-substrate complex similar to that used for an enzymatic catalysis[9] was applied. The effect of HTAB and β-CDX at a particular pH value was examined according to the Scheme (Experimental), using a technique worked out by Colter *et al.*[10] The results are given in Table 4. The quantum yield for the photooxidation of **1** in the micellar phase is large by a factor of 220 as compared with that in aqueous phase.

pH-Dependence. Stabilization of carbanion was examined in the photooxidation of oxime **1**, and was confirmed by measuring the quantum yields Φ_0 and Φ_{obsd} in the pH 3 to 12 region in the presence of HTAB, β-CDX, SDS, and Tween #80, respectively. As shown in Fig. 3, the presence of HTAB increases the quantum yield over the whole pH region. In the pH region above the pK_a value of oxime, the quantum yield increases irrespective of the presence or absence of the surfactant (Fig. 3). This indicates that the formation of the carbanion agrees with the increase in quantum yield. In the case of β-CDX, a similar phenomenon was observed. The extent of the catalytic effect of HTAB and β-CDX depends on the pH values of the reaction solution (Fig. 4). The catalytic effect

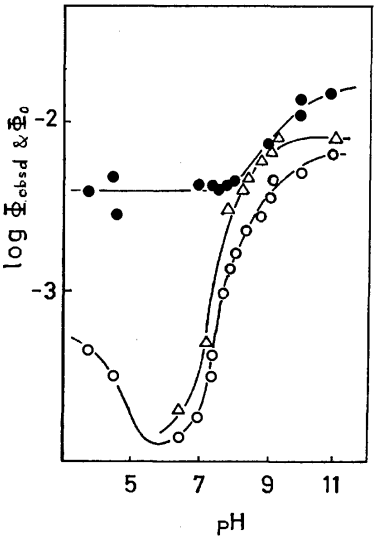

Fig. 3. pH-Dependence on the photooxidation of oxime **1** in a 10% ethanolic aqueous buffer (○), in the presence of 7.10×10^{-4} M HTAB (●), and 4.85×10^{-3} M β-CDX (△).

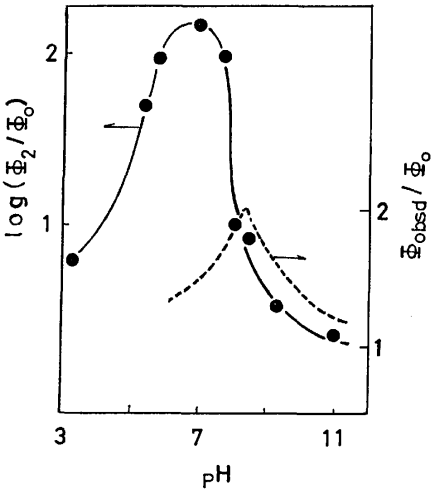

Fig. 4. pH-Dependence on the photooxidation of oxime **1** in the presence of HTAB (-●-) and β-CDX (——).

become maximum in the pH value around the pK_a's of the oxime determined in the presence of surfactant. On the other hand, the relation of the pH value and the quantum yield is not clear when SDS and Tween #80 were used. From the results, the mechanism is considered as follows. The stabilization of the carbanion in the hydrophobic cavity of β-CDX does not increase the quantum yield as in HTAB. This is because the steric hindrance of β-CDX inhibits the attack of singlet oxygen on the carbanion. HTAB does not inhibit the approach of singlet oxygen for the loosely bound carbanion. Consequently the stabilization of the carbanion in the presence of HTAB is reflected on the increase in the quantum yield.

Effect of Chloro-Substituent on the Rate Constant and the Association Constant. There is some difference in the reactivity of three oximes having a chloro-substituent. The rate constants of the photooxidation of the oxime

were determined in the presence or absence of HTAB. The rate constant k_2 for the formation of the product in the micellar phase and the association constants were calculated by means of Eq. 2. The relative values against those of **1** are given in Table 5. The steric hindrance is responsible for the least reactivity of the 2-chloro-substituted oxime. The catalytic effect of a cationic surfactant is recognized to be nearly equal to that observed for all the oximes, independent of the position of the chloro-substituent.

Experimental

All melting points were measured with a Yanagimoto micro melting point apparatus and are uncorrected. The ultraviolet spectra were taken on Hitachi EPS-3T and Shimadzu UV-200 spectrometers, mass spectra on a Hitachi RMU-6E mass spectrometer. The pH was measured with a TOA Electronics, Ltd., model HM-5A pH meter. Buffer solutions were chosen[11] according to the required pH region. CH_3-COOH (pH 3), M/15 KH_2PO_4-Na_2HPO_4 (pH 4—6), M/20 H_3BO_3-$Na_2B_4O_7$ (pH 6—8), M/20 H_3BO_3-KCl-NaOH (pH 8—10), and M/20 Na_2HPO_4-NaOH (pH 10—12). Column chromatography separation was carried out with Merck silica gel Art. 7734.

Materials. Commercial HTAB and SDS were recrystallized twice from methanol-ether and ethanol, respectively.[12,13] Other materials were used without further purification. All the compounds of oximes **1**—**10** were prepared from substituted nitrobenzene and substituted phenylacetonitriles by the procedure of Davis *et al.*[4a,b] The products were recrystallized twice from benzene.

*Irradiation of **1** and **2**.* A solution of 1 g of **1** in 2 liter of ethanol–aqueous alkaline (NaOH) solution was irradiated with an Ushio UM-452 450W high pressure mercury lamp for 10 h. After irradiation, the solvent was removed with rotary evaporators, the oily residue being chromatographed on silica gel to give two products. These were identified as nitrobenzophenone, mp 126 °C (lit,[4] 120 °C) and MS, *m/e* 227 (M^+); and 4,4′-dibenzoylazoxybenzene, mp 198—199 °C (lit,[4] 202—203 °C) and MS, *m/e* 406 (M^+). Irradiation of **2** in a similar manner gave 4-chloro-4′-nitrobenzophenone, mp 99 °C (lit,[4] 100—101 °C) and MS, *m/e* 261 (M^+), and 263 ($M^+ +2$); and 4,4′-bis(*p*-chlorobenzoyl) azoxybenzene, mp 292—296 °C (lit, [4] 291—293 °C) and MS, *m/e* 475 (M^+) and 477 ($M^+ +2$).

pK_a *Values.* The pK_a values of all the compounds were calculated by means of the equation,[3]

$$pK_a = pH_{obsd} + \log \frac{A_{max} - A_{obsd}}{A_{obsd}}. \quad (1)$$

The pH_{obsd} is the pH value at the inflection point estimated from the plot of absorbance *vs.* pH value of the solution. A_{max} and A_{obsd} are the absorption values for fully dissociated and partially dissociated (at pH_{obsd}) solutions of the oximes. The pK_a values of oximes in 5×10^{-3} M *β*-CDX, in 10^{-2}M HTAB, in 10^{-2} M SDS and in 6.6×10^{-2} g/dl Tween ♯80 were determined in a similar manner. All the compounds were dissolved in a small amount of ethanol before dilution with water, the final solution containing 25—10% ethanol.

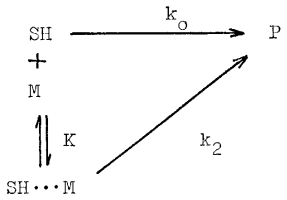
Kinetic Method. In numerous kinetic runs, the sample kept in the dark showed no measurable change in absorption at λ_{max} of carbanion during the course of run ($\leq$5 h). A solution of 2.51×10^{-5} M of **1** in 10% ethanolic aqueous buffer reached equilibrium within for a few minutes. The solution kept for 2 days in the air still retained 97% of its absorbance at λ_{max} of carbanion, showing no change in th mode of absorption.

All the photoreactions were followed under pseudo-first-order kinetics conditions by monitoring the consumption of reactant at the λ_{max} of the carbanion.

After argon gas had been bubbled in the reactant solution for 1 h to remove dissolved oxygen, it was irradiated and the rate was measured. The k_{obsd} obtained was less than in the presence of dissolved oxygen by a factor of 50. The result indicates that dissolved oxygen participates in the photooxidation.

Various concentrations of *β*-carotene, Rose Bengal, and 2,6-di-*t*-butylphenol were dissolved in the reactant solutions. The rate of the photooxidation of these solutions was compared with that of the original solution.

The effect of HTAB at a particular pH region was examined according to the Scheme. SH, unionized and ionized, is



Scheme.

the total substrate present. Variation of surfactant concentration gave the rate constants for the product formation in the micellar phase, k_2, and the association constants for the substrate-micelle complex, K, by calculation by means of Eq. 2. The value of CMC obtained previously and the aggregation number (N 61 at HTAB) were used:

$$\frac{1}{k_{obsd}-k_0} = \frac{1}{k_2-k_0} + \frac{1}{k_2-k_0}\cdot\frac{N}{K(C_D-CMC)}. \quad (2)$$

C_D is the total concentration of the surfactant, k_0 the rate constant in the bulk solvent, and k_{obsd} the observed rate constant in the presence of HTAB. The estimated rate constant values were converted into the quantum yield.[14]

The effect of *β*-CDX was also examined according to the Scheme. The value of K, association constant of *β*-CDX-substrate complex, and k_2, the rate constant for the product formation in the bound species, were obtained by

$$\frac{1}{k_{obsd}-k_0} = \frac{1}{k_2-k_0} + \frac{1}{k(k_2-k_0)[CDX]}. \quad (3)$$

Synthesis of 6-*O*-Mycoloyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine with Antitumor Activity[1)]

Tetsuo SHIBA,* Satoshi OKADA, Shoichi KUSUMOTO,
Ichiro AZUMA,† and Yuichi YAMAMURA†
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
†*The Third Department of Internal Medicine, Medical School, Osaka University, Fukushima-ku, Osaka 553*
(Received March 27, 1978)

N-Acetylmuramyl-L-alanyl-D-isoglutamine corresponding to the minimum structure responsible for the immunoadjuvant activity of bacterial cell walls was acylated at the 6-hydroxyl group with various mycolic acids of long carbon chains in order to test their possible antitumor effects. Mycolic acids used were extracted from cell walls of *Mycobacterium*, *Nocardia*, and *Corynebacterium*. All the mycoloyl derivatives synthesized show antitumor activity based on a principle of immunotherapy.

In the course of synthetic studies on immunoadjuvant active *N*-acetylmuramyl-L-alanyl-D-isoglutamine (**1**), we attempted to synthesize a novel compound which would exhibit antitumor activity based on the principle of immunotherapy of cancer. Since *Mycobacterium bovis* Bacille de Calmette-Guérin (BCG) cell wall is highly effective in tumor immunotherapy, it was expected that a modification of the structure of **1**, the key substance in immuno reactions, might turn out to be desirable substance by simulation of the structure of the cell wall. An outer layer of the BCG cell wall consists of mycoloyl arabinogalactan which is linked with the peptidoglycan.[2)] The antitumor effect of the cell wall might be attributed to the lipophilic character of mycolic acid moiety connected with the adjuvant activity of muramyl peptide moiety.

We have prepared several lipophilic derivatives of **1** by acylation of the 6-hydroxyl group of the muramic acid residue.[3)] However, no antitumor effect was observed even in 6-*O*-stearoyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine,[4)] which possesses the maximum adjuvant activity among 6-*O*-acyl derivatives prepared so far.[5)] We have thus extended our synthetic program to preparation of more lipophilic derivative coupled with the natural mycolic acid isolated from *Mycobacterium*. 6-*O*-Mycoloyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine (**2a**) thus obtained[1)] showed distinct activity in a suppression test of hepatoma in mice.[6)] In the present paper, we report the details of the synthesis of the mycoloyl derivative (**2a**) as well as two other 6-*O*-acyl derivatives of **1** prepared by using mycolic acid analogs originated from cells of *Nocardia* and *Corynebacterium*.

The general name "mycolic acid" represents α-branched β-hydroxylated fatty acids of high molecular weight (Fig. 1). They are involved in mycobacterial cell walls as typical constituents, being always present as a homologous mixture of some subgroups.[7)] The mycolic acid from *Mycobacterium tuberculosis* strain Aoyama B[8)] was found to have an average molecular formula $C_{80}H_{158}O_{3.5}$ on the basis of acid titration and elemental analysis.

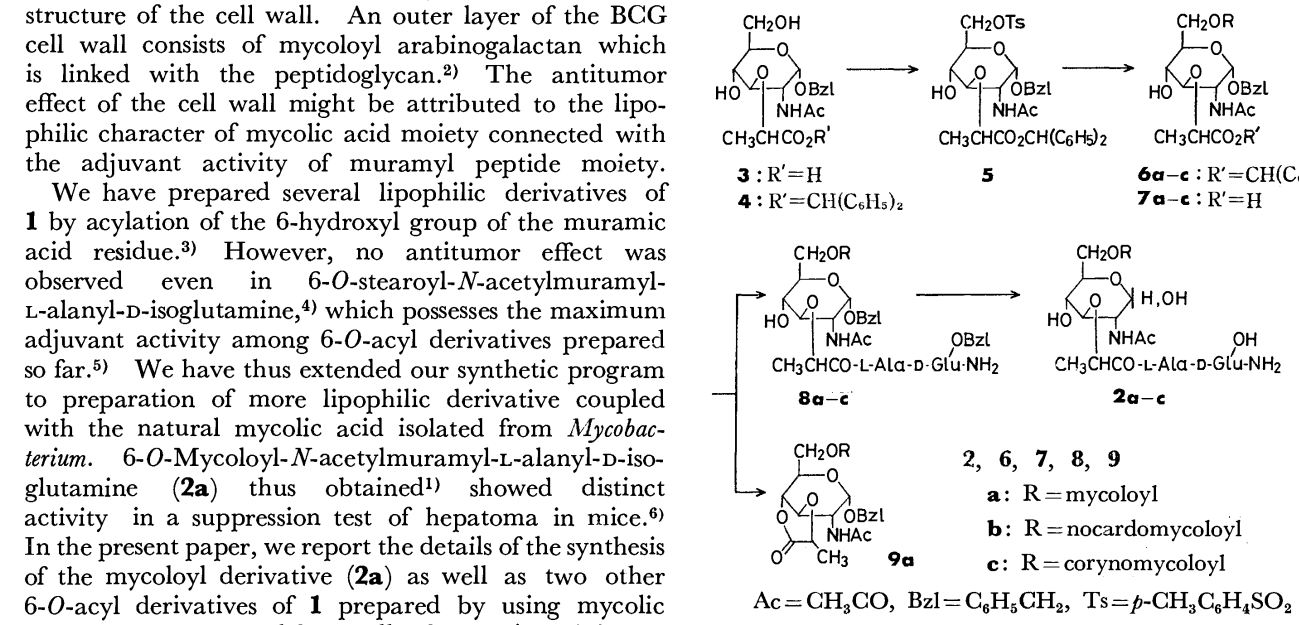

Fig. 1. The basic structure of mycolic acid analogs.

The synthetic route for 6-*O*-mycoloyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine (**2a**) is depicted in the scheme. It differs from the previous method for

the 6-*O*-stearoyl derivative in the following points. For introduction of the mycoloyl group into the muramic acid moiety, the acid chloride method, which was successfully used for the stearoyl derivative, should be avoided because of the presence of β-hydroxyl function in mycolic acid. An exchange reaction of 6-*O*-tosylate of a muramic acid derivative with potassium mycolate was employed for this purpose. Since the reaction conditions in this step are drastic, using a strongly basic reagent at high temperature, the peptide moiety had to be coupled after the reaction.

Benzyl *N*-acetyl-α-muramide (**3**)[3)] was converted with diphenyldiazomethane into the diphenylmethyl ester (**4**), which was then treated with excess tosyl chloride (11 mol equivalent) in pyridine under ice-cooling. Tosylation occurred almost exclusively at

TABLE 1. AVERAGE MOLECULAR WEIGHTS AND MOLECULAR FORMULAE OF MYCOLIC ACID ANALOGS USED IN THIS STUDY

	Average molecular weight[a]	Elemental analysis[b]		Average molecular formula calculated			
		C%	H%		C%	H%	mol wt
Mycolic acid	1180	81.45	13.55	$C_{80}H_{158}O_{3.5}$	81.70	13.54	1176
Nocardomycolic acid	766	79.84	12.76	$C_{51}H_{97}O_{3.6}$	79.77	12.73	768
Corynomycolic acid	483	76.97	12.38	$C_{31}H_{59}O_{3.3}$	76.83	12.27	485

a) Determined by acid titration, see Experimental. b) Mean values of two individual analyses.

the primary hydroxyl group, so that 6-*O*-monotosylate (**5**) was isolated in 89% yield after chromatographic purification. The exchange reaction of the tosylate with potassium mycolate proceeded smoothly in boiling benzene in the presence of 18-crown-6 to afford 1-α-*O*-benzyl-6-*O*-mycoloyl-*N*-acetylmuramic acid diphenylmethyl ester (**6a**). Although this reaction can also be performed without the crown ether in *N*,*N*-dimethylformamide (DMF) at higher temperature,[9] the yield became appreciably low. The diphenylmethyl group in the ester **6a** was then selectively removed with trifluoroacetic acid to give 1-α-*O*-benzyl-6-*O*-mycoloyl-*N*-acetylmuramic acid (**7a**), which was then subjected to the successive coupling reaction with the dipeptide moiety.

When the mycoloyl muramic acid (**7a**) was coupled with L-alanyl-D-isoglutamine benzyl ester[10] by means of the dicyclohexylcarbodiimide (DCC)–*N*-hydroxysuccinimide (HONSu) method, the desired product, 1-α-*O*-benzyl-6-*O*-mycoloyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine benzyl ester (**8a**), was obtained. However, the yield was rather low (38%) because of a competitive formation of an intramolecular ester (**9a**) (26%). The situation was somewhat improved by employing the following alternative procedure, in which an active ester of **7a** was prepared by ester-exchange reaction without use of dehydrating agent.[11] Thus, when **7a** was converted with pentachlorophenyl trichloroacetate into the pentachlorophenyl ester and then treated with the dipeptide benzyl ester under ice-cooling, formation of the internal ester (**9a**) was suppressed (17%) and the desired product (**8a**) was obtained in 47% yield. The final hydrogenolytic deprotection of **8a** was carried out in tetrahydrofuran (THF) in the presence of palladium black catalyst to afford 6-*O*-mycoloyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine (**2a**) in a good yield.

The mycoloyl-*N*-acetylmuramyl dipeptide (**2a**) thus obtained gave a positive antitumor effect.[6] When a suspension of **2a** in phosphate-buffered saline was administered intradermally with MH134 hepatoma cells to syngeneic mice, a distinct suppression of the tumor growth was observed. Accordingly, we synthesized two more analogs of **2a** with use of nocardomycolic acid and corynomycolic acid with different ranges of carbon numbers in order to estimate the influence of chain length in fatty acids on the antitumor activity.

Cells of *Nocardia* and *Corynebacterium*, closely related to *Mycobacterium* taxonomically, contain nocardomycolic (or nocardic) and corynomycolic acid, respectively, which have similar α-branched β-hydroxylated structures but with smaller carbon numbers than in the mycolic acid from *Mycobacterium*. Extraction of cells of *Nocardia asteroides* 131 and *Corynebacterium diphtheriae* PW8 afforded the corresponding nocardomycolic and corynomycolic acid, whose average molecular formulae were deduced to be $C_{51}H_{97}O_{3.6}$ and $C_{31}H_{59}O_{3.3}$, respectively, on the basis of elemental analyses and acid titrations. Average molecular weights and molecular formulae of the mycolic acid analogs are given in Table 1.

TABLE 2. SUPPRESSION OF MH-134 HEPATOMA WITH 6-*O*-MYCOLOYL-*N*-ACETYLMURAMYL DIPEPTIDES (**2a**—**c**)[6]

Compound	Dose (μg)	No. of mice tested	Tumor-free mice /mice survived[a]
2a	20	10	3/8
2b	20	10	5/9
2c	20	10	6/7
Control[b]	—	10	0/1

a) At 49 days. b) Only tumor cells were inoculated.

The syntheses of nocardomycoloyl- and corynomycoloyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine (**2b** and **c**) were performed in a similar way to that for **2a**. In the coupling reaction of nocardomycoloyl- and corynomycoloyl-*N*-acetylmuramic acid (**7b** and **c**) with the dipeptide moiety, 1-α-*O*-benzyl-6-*O*-nocardomycoloyl- and corynomycoloyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine benzyl ester (**8b** and **c**) could be obtained in better yields as compared to that for mycoloyl derivative (**8a**). In these cases, the intramolecular esters of type **9** were not formed from **7b** and **c**, although the DCC–HONSu method was employed under similar conditions to those for the coupling of mycoloyl derivative (**7a**).[12] Hydrogenolysis of **8b** and **c** afforded the final products, 6-*O*-nocardomycoloyl and corynomycoloyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine (**2b** and **c**). However, one of the two benzyl groups in **8b** and **c** resisted the cleavage at room temperature below 20 °C in this reaction. Thus, hydrogenolysis was carried out at 28—30 °C for 3 or more days to complete deprotection.[13,14]

The results of an antitumor test of the compounds synthesized in this study are summarized in Table 2.[6] Nocardomycoloyl and corynomycoloyl muramyl dipeptides (**2b** and **c**) also showed similar or even stronger activity to mycoloyl derivative (**2a**). Although the activity seemed to be less significant than natural BCG cell wall and not sufficient for practical use, this is the first case in which synthetic substances suppressed growth of a tumor on the basis of their im-

munoadjuvant activities. In order to clarify the role of the unique structure of mycolic acid, we are now preparing other acyl derivatives of *N*-acetylmuramyl dipeptide (**1**) using various kinds of synthetic fatty acids of high molecular weights.

Experimental

All melting points are uncorrected. Silica gel 60 (0.063-0.2 mm) and silica gel G, Merck, were used for column chromatography and TLC, respectively.

Preparation of Mycolic Acid, Nocardomycolic Acid, and Corynomycolic Acid from the Cells of Mycobacterium tuberculosis *Aoyama B*, Nocardia asteroides *131, and* Corynebacterium diphtheriae *PW8*. The cells[15] were defatted by repeated extraction with ether–ethanol (1:1) and $CHCl_3$–methanol (2:1), and then hydrolyzed by heating with 2.5% KOH in benzene–methanol (1:1) under reflux for 23 h. After the reaction mixture had been filtered, the filtrate was concentrated to dryness *in vacuo*, acidified with HCl and extracted with hexane. The solvent was removed from the extract by evaporation and the residue was heated in 2.5% HCl–methanol for 5 h. The products were subjected to column chromatography on silica gel and eluted with hexane–ether to afford methyl mycolates (1.7—2.2% from defatted cells). The free acids could be regenerated by hydrolysis of the corresponding methyl esters with 3 M KOH in methanol–benzene under reflux for 3 h.

Determination of the Average Molecular Formulae of Mycolic Acids and Preparation of Their Potassium Salts. i) Mycolic Acid: Mycolic acid (0.500 g) from *Mycobacterium* was dissolved in $CHCl_3$ (5 ml) and titrated with 0.176M KOH in methanol against phenolphthalein. After the solvent had been evaporated *in vacuo*, the residual potassium mycolate was washed with methanol and filtered; yield, 0.51 g (99%).

From the amount of alkali consumed (2.41 ml), the average molecular weight was deduced to be 1180. The average molecular formula $C_{80}H_{158}O_{3.5}$ was obtained from this molecular weight and the results of elemental analyses (Table 1).

ii) Nocardomycolic Acid: Nocardomycolic acid (0.870 g) in $CHCl_3$ (10ml) was titrated with 0.46 M KOH in methanol. The consumed volume of the solution to neutrality was 2.47 ml. After evaporation of the solvent *in vacuo*, the residue was treated with ether and insoluble material was filtered off. Evaporation of the solvent afforded the potassium salt as waxy residue; yield, 0.88 g (96%) (Table 1).

iii) Corynomycolic Acid: Corynomycolic acid (0.420 g) in $CHCl_3$ (10 ml) was titrated with 3.41 ml of 0.255M KOH in methanol and the resulting potassium salt was isolated as described in (ii); yield, 0.44 g (97%) (Table 1).

1-α-O-Benzyl-N-acetylmuramic Acid Diphenylmethyl Ester (4). Diphenyldiazomethane (0.80 g, 4.1 mmol) in THF (5 ml) was added to a stirred solution of benzyl *N*-acetyl-α-muramide (**3**) (1.00 g, 2.6 mmol) in THF (10 ml). After being left to stand at room temperature overnight, the solvent was evaporated *in vacuo*. The residue crystallized on trituration with hexane. The crystals were washed with hexane to remove excess diphenyldiazomethane and then recrystallized from ethyl acetate–hexane: yield, 1.30 g (91%); mp 151—153 °C. An analytical sample was again recrystallized from the same solvent system; mp 155—156°C; $[\alpha]_D^{22}$ +122° (*c* 1, $CHCl_3$).

Found: C, 67.62; H, 6.50; N, 2.52%. Calcd for $C_{31}H_{35}O_8N$: C, 67.74; H, 6.42; N, 2.55%.

1-α-O-Benzyl-6-O-tosyl-N-acetylmuramic Acid Diphenylmethyl Ester (5). Tosyl chloride (1.20 g, 6.3 mmol) was added to an ice-cooled solution of **4** (0.30 g, 0.55 mmol) in pyridine (3 ml) with stirring. After 1 h, excess reagent was decomposed with ice-water and the mixture was extracted with ethyl acetate. The organic layer was washed successively with 0.3 M NaOH, H_2O, 1 M HCl, and H_2O, dried ($MgSO_4$) and evaporated *in vacuo*. The residue was purified with silica gel column chromatography (benzene–ethyl acetate, 5:1). Fractions containing only the main product (monitored with TLC) were collected and evaporated *in vacuo* to afford colorless powder; yield, 0.34 g, (89%); mp 68—73 °C; $[\alpha]_D^{22}$ +84.4° (*c* 0.5, $CHCl_3$).

Found: C, 64.68; H, 5.92; N, 1.93; S, 4.31%. Calcd for $C_{38}H_{41}O_{10}NS$: C, 64.85; H, 5.87; N, 1.99; S, 4.56%.

1-α-O-Benzyl-6-O-mycoloyl-N-acetylmuramic Acid Diphenylmethyl Ester (6a). i) In Benzene and in the Presence of 18-Crown-6: A mixture of **5** (325 mg, 0.46 mmol), potassium mycolate (375 mg, 0.31 mmol) and 18-crown-6 (18 mg, 0.07 mmol) in anhydrous benzene (15 ml) was heated under reflux for 3 h. After evaporation of the solvent *in vacuo*, acetone-soluble material in the residue was subjected to silica gel column chromatography. Elution with hexane–ethyl acetate (5:1) gave a mixture of the product (**6a**) and a small amount of recovered mycolic acid. The mixture was treated with diazomethane and again chromatographed on silica gel. Elution with benzene–ethyl acetate (10:1) afforded pure **6a**; yield, 0.32 g (60%); mp 55—56 °C; $[\alpha]_D^{22}$ +32.6° (*c* 0.5, $CHCl_3$).

Found: C, 78.34; H, 11.48; N, 0.85%. Calcd for $C_{111}H_{191}O_{10.5}N$: C, 78.07; H, 11.27; N, 0.82%.

ii) In DMF: A mixture of potassium mycolate (49 mg, 0.040 mmol) and **5** (39 mg, 0.055 mmol) in DMF (1 ml) was heated at 125 °C for 19 h. The mixture was acidified with 0.5M H_2SO_4 under ice-coling and then neutralized with aqueous $NaHCO_3$. After evaporation of the solvent *in vacuo*, the product was isolated by means of preparative TLC on silica gel(benzene-ethyl acetate, 2 : 1), the main band of R_f 0.6—0.8 was extracted with ethyl acetate. The residue obtained by evaporation of the solvent was triturated with methanol and filtered; yield, 28 mg (41%); mp 50—56 °C. This product was identified with **6a** obtained in (i) on TLC.

1-α-O-Benzyl-6-O-mycoloyl-N-acetylmuramyl-L-alanyl-D-isoglutamine Benzyl Ester (8a). i) The DCC–HONSu Method: Trifluoroacetic acid (3 ml) was added to an ice-cooled solution of **6a** (0.30 g, 0.18 mmol) and anisole (1 ml) in $CHCl_3$ (20 ml) with stirring . After being stirred in an ice bath for 1 h, the mixture was diluted with acetone (100 ml) and the solvent was removed *in vacuo*. Trituration of the resulting syrup with ethanol gave **7a** as white powder, which was collected by filtration. To a solution of **7a** thus obtained in THF (10 ml) were added L-alanyl-D-isoglutamine benzyl ester hydrochloride (65 mg, 0.19 mmol), triethylamine (0.024 ml, 0.18 ml) and HONSu (75 mg, 0.65 mmol). To the mixture cooled in an ice bath was added DCC (37 mg, 0.18 mmol). After being stirred overnight, *N,N'*-dicyclohexylurea and triethylamine hydrochloride were filtered off; the filtrate was evaporated *in vacuo*, and the residue was triturated with methanol. The insoluble materials were subjected to silica gel column chromatography. A mixture of benzene–acetone (1:1) eluted the intramolecular ester (**9a**) in an early fraction; yield, 0.07 g (26%); mp 46—51 °C (Found: N, 0.86%. Calcd for $C_{98}H_{179}O_{9.5}N$: N, 0.92%). Further elution with the same solvent and recrystallization from benzene–methanol afforded **8a**; yield, 0.12 g (36%); mp 171—172 °C; $[\alpha]_D^{22}$ +30.2° (*c* 0.5, $CHCl_3$).

Found: C, 73.63; H, 11.05; N, 3.18%. Calcd for $C_{113}H_{200}O_{13.5}N_4$: C, 74.13; H, 11.01; N, 3.06%.

ii) The Pentachlorophenyl Ester Method: A solution of **6a**

(0.33 g, 0.19 mmol) and anisole (1 ml) in $CHCl_3$ (20 ml) was treated with trifluoroacetic acid (3 ml) and worked up as in (i). Resulting **7a** and pentachlorophenyl trichloroacetate[11] (0.20 g, 0.49 mmol) were dissolved in a mixture of DMF and THF (1:1, 15 ml), triethylamine (0.038 ml, 0.27 mmol) being added under ice-cooling. After being stirred at this temperature for 2.5 h, benzene was added and the mixture was washed with water, dried ($MgSO_4$) and evaporated *in vacuo*. Trituration of the residue with acetone gave the pentachlorophenyl ester of **7a** as powder. This was dissolved in THF (10 ml) and added to a mixture of L-alanyl-D-isoglutamine benzyl ester hydrochloride (76 mg, 0.22 mmol) and triethylamine (0.031 ml, 0.22 mmol) in THF (3 ml). After being stirred at room temperature for 3 h, triethylamine hydrochloride was filtered off, the filtrate was concentrated *in vacuo*, and the residue was chromatographed on silica gel as in (i). After **9a** (yield, 0.05 g (17%); mp 45—50 °C), **8a** was eluted. This was recrystallized from ether–methanol; yield, 0.17 g (47%); mp 171—172 °C.

6-O-Mycoloyl-N-acetylmuramyl-L-alanyl-D-isoglutamine (2a). Compound **8a** (76 mg, 0.04 mmol) in THF (20 ml) was hydrogenolyzed in the presence of palladium black catalyst. After removal of the catalyst and evaporation of the solvent *in vacuo*, the residue was recrystallized from ether–ethanol; yield, 64 mg (93%); mp 137—160 °C (dec); $[\alpha]_D^{22}$ +25.8° (*c* 0.4, THF–H_2O, 50: 1, after 20 h).

Found: C, 71.08; H, 11.40; N, 3.26%. Calcd for $C_{99}H_{188}O_{13.5}N_4 \cdot H_2O$: C, 71.26; H, 11.48; N, 3.36%.

1-α-O-Benzyl-6-O-nocardomycoloyl-N-acetylmuramic Acid Diphenylmethyl Ester (6b). A mixture of **5** (0.35 g, 0.50 mmol), potassium nocardomycolate (0.30 g, 0.37 mmol) and 18-crown-6 (19 mg, 0.07 mmol) in anhydrous benzene (15 ml) was heated under reflux for 3 h. After addition of benzene (15 ml), the resulting solution was washed with 0.1 M HCl and water, dried (Na_2SO_4) and then concentrated *in vacuo*. The residue was chromatographed on silica gel. Elution with benzene–ethyl acetate (5:1) and complete evaporation of the solvent afforded **6b** as waxy residue; yield, 0.34 g (70%); $[\alpha]_D^{27}$ +46.7° (*c* 1, $CHCl_3$).

Found: C, 75.38; H, 10.15; N, 1.03%. Calcd for $C_{82}H_{130}O_{10.6}N$: C, 75.79; H, 10.08; N, 1.08%.

1-α-O-Benzyl-6-O-nocardomycoloyl-N-acetylmuramyl-L-alanyl-D-isoglutamine Benzyl Ester (8b). To an ice-cooled solution of **6b** (0.24 g, 0.18 mmol) and anisole (0.1 ml) in CH_2Cl_2 (10 ml) was added trifluoroacetic acid (1.5 ml) with stirring. After 30 min, the solvent was removed *in vacuo* and the residue was chromatographed on a silica gel column ($CHCl_3$–methanol, 5:1) to afford **7b**. This was added to a suspension of L-alanyl-D-isoglutamine benzyl ester hydrochloride (75 mg, 0.22 mmol) and triethylamine (0.030 ml, 0.22 mmol) in THF (5 ml). To the mixture cooled in an ice-salt bath (−13 °C) were added HONSu (36 mg, 0.31 mmol) and DCC (39 mg, 0.19 mmol) with stirring. After 1 h, the cold bath was removed and the mixture was stirred at room temperature overnight. The insoluble materials were filtered off, the filtrate was evaporated *in vacuo* and the residue was chromatographed on silica gel. Elution with $CHCl_3$–methanol (30:1) and recrystallization from methanol–water gave **8b**; yield, 0.14 g (53%); mp 164—167 °C; $[\alpha]_D^{17}$ +44.7 ° (*c* 1, $CHCl_3$).

Found: C, 71.05; H, 9.87; N, 3.65%. Calcd for $C_{84}H_{139}O_{13.6}N_4$: C, 70.91; H, 9.85; N, 3.94%.

6-O-Nocardomycoloyl-N-acetylmuramyl-L-alanyl-D-isoglutamine (2b). Compound **8b** (84 mg, 0.06 mmol) in THF (5 ml) was hydrogenolyzed in the presence of palladium black at 28 °C for 3 days. After the usual work-up, the product was recrystallized from $CHCl_3$–acetone; yield, 51 mg (68%); mp 154—157 °C (dec); $[\alpha]_D^{20}$ +30.0° (*c* 1, THF–H_2O, 50: 1, after 24 h).

Found: C, 66.07; H, 10.58; N, 4.26%. Calcd for $C_{70}H_{127} \cdot O_{13.6}N_4 \cdot 1.5H_2O$: C, 66.23; H, 10.32; N, 4.41%.

1-α-O-Benzyl-6-O-corynomycoloyl-N-acetylmuramic Acid Diphenylmethyl Ester (6c). A solution of **5** (0.48 g, 0.68 mmol), potassium corynomycolate (0.31 g, 0.59 mmol), and 18-crown-6 (30 mg, 0.11 mmol) in anhydrous benzene (15 ml) was heated under reflux for 3 h. The mixture was then treated as for **6b** and subjected to column chromatography on silica gel. Elution with benzene–ethyl acetate (5 : 1) yielded **6c** as waxy solid; yield, 0.30 g (50%); $[\alpha]_D^{25}$ +58.4° (*c* 1, $CHCl_3$).

Found: C, 72.85; H, 9.27; N, 1.40%. Calcd for $C_{62}H_{92}O_{10.3}N$: C, 73.28; H, 9.13; N, 1.38%.

1-α-O-Benzyl-6-O-corynomycoloyl-N-acetylmuramyl-L-alanyl-D-isoglutamine Benzyl Ester (8c). This compound was prepared in a similar way to that for nocardomycoloyl derivative (**8b**). After the diphenylmethyl group of **6c** (0.52 g, 0.51 mmol) had been removed with trifluoroacetic acid, the resulting **7c** was mixed with L-alanyl-D-isoglutamine benzyl ester hydrochloride (0.21 g, 0.61 mmol) and triethylamine (0.087 ml, 0.62 mmol) in THF (10 ml). HONSu (101 mg, 0.88 mmol) and DCC (100 mg, 0.49 mmol) were added to the mixture under cooling and worked up as above. The product (**8c**) was isolated and purified by silica gel column chromatography followed by recrystallization from methanol–water; yield, 0.28 g (48%); mp 172—175 °C; $[\alpha]_D^{14}$ +53.7° (*c* 1, $CHCl_3$).

Found: C, 67.16; H, 9.08; N, 4.99%. Calcd for $C_{64}H_{101}O_{13.3}N_4$: C, 67.47; H, 8.94; N, 4.92%.

6-O-Corynomycoloyl-N-acetylmuramyl-L-alanyl-D-isoglutamine (2c). Compound **8c** (127 mg, 0.11 mmol) in THF (10 ml) was subjected to hydrogenolysis in the presence of palladium black at 28 °C for 3 days. After evaporation of the solvent, the residue was dissolved in a mixture of ether–methanol (1:1). On addition of acetone, white powder precipitated; yield, 77 mg (71%); mp 156—159 °C (dec); $[\alpha]_D^{18}$ +33.0° (*c* 1, THF–H_2O, 50:1, after 24 h).

Found: C, 61.64; H, 9.48; N, 5.59%. Calcd for $C_{50}H_{89}O_{13.3}N_4 \cdot H_2O$: C, 61.46; H, 9.39; N, 5.73%.

Determination of Antitumor Activity.[6] A mixture of tumor cells of MH 134 hepatoma (1×10^5) and **2a**, **b**, or **c** (20 μg) suspended in phosphate-buffered saline was inoculated intradermally into C3H mice and tumor growth was observed in inoculated sites.

The work was carried out with a Grant-in-Aid for Scientific Research from the Ministry of Education.

7) Mycolic acids can be classified according to the type of modification in the α-branched β-hydroxylated structure. Thus, typical subgroups contain double bonds, cyclopropane rings, or methoxy substituents in the main chains. Each subgroup exists again as a mixture of homologs with various chain lengths. J. Asselineau, "The Bacterial Lipids," Herman, Paris (1966).

8) The natural mycolic acid was used without separation into subgroups.[7]

9) These reaction conditions were described by G. Brochere-Ferreol and J. Polonsky in the synthesis of trehalose 6,6′-di-*O*-mycolate (the so-called cord factor) *via* the same type of substitution. *Bull. Soc. Chim. Fr.*, **1958**, 714.

10) S. Kusumoto, Y. Tarumi, K. Ikenaka, and T. Shiba, *Bull. Chem. Soc. Jpn.*, **49**, 533 (1976).

11) M. Fujino and C. Hatanaka, *Chem. Pharm. Bull.*, **16**, 929 (1968).

12) Internal ester formation was observed in the preparation of neither 6-*O*-stearoyl-,[3] nocardomycoloyl- nor corynomycoloyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine derivatives. It seems that the ease of ester (**9a**) formation from **7a** can be attributed to the length of mycolic acid, which keeps the molecule in a certain conformation in the solution to make contact between the active ester and the dipeptide difficult.

13) The trouble was not encountered in the case of preparation of **2a**, when the ambient temperature was over 25 °C.

14) When the reaction was interrupted before completion, the product had to be purified by means of column chromatography first on silica gel ($CHCl_3$–methanol–acetic acid, 5:1:0.01) then on Sephadex LH20 (THF). The latter column was necessary to remove the trace of inorganic materials eluted from silica gel.

15) Cells of *M. tuberculosis* and *N. asteroides* were cultured in Sauton's synthetic medium, while those of *C. diphtheriae* were in the medium of Mueller and Miller. For details, see: I. Azuma, F. Kanetsuna, T. Taniyama, Y. Yamamura, H. Hori, and Y. Tanaka, *Biken J.*, **18**, 1 (1975).

Reactions of Azomethine Derivatives. IV.[1] The Synthesis of 2,3,5-Trisubstituted 2-Pyrrolin-4-ones and Their Oxidation to 2,4,5-Trisubstituted 1,3-Oxazin-6-ones

Masahiko TAKAHASHI,* Nobuyuki INABA, Hiroji KIRIHARA, and Shin-ichi WATANABE

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Hitachi, Ibaraki 316

(Received March 28, 1978)

The reaction of aromatic azines with diphenylcyclopropenone in refluxing toluene gave 5-aryl-2,3-diphenyl-2-pyrrolin-4-ones (**4**) in moderate yields *via* initial [2+3] 1:1 cycloaddition and subsequent elimination of an aromatic nitrile from the adducts. Treatment with phosphorus pentasulfide deoxygenated the compounds **4** to 5-aryl-2,3-diphenyl-pyrroles. The same compounds **4** were oxidized to 2-aryl-4,5-diphenyl-1,3-oxazin-6-ones (**11**) by refluxing the pyridine solution in a stream of oxygen, by treatment with hydrogen peroxide, or by irradiation of the chloroform solution in a stream of oxygen. Treatment with alkali in aqueous pyridine converted **4** into 3-aroylamino-2,3-diphenylacrylic acids. These were also obtained from the hydrolysis of **11**. When *p*-dimethylaminobenzaldehyde azine reacted with diethyl azodicarboxylate in refluxing toluene, a 1:2 conjugated adduct, 3,6-bis(*p*-dimethylaminophenyl)-1,2,7,8-tetrakis(ethoxycarbonyl)-1,2,4,5,7,8-hexaaza-3,5-octadiene, and a 1:1 conjugate adduct, 3,6-bis(*p*-dimethylaminophenyl)-1,2-bis(ethoxycarbonyl)-1,2,4,5-tetraaza-3,5-hexadiene, were obtained.

The cycloaddition reactions of azines with various dipolarophiles generally give criss-cross 1:2 adducts.[2] Eicher *et al.* have reported [2+3] cycloaddition reactions of aldimines,[3] ketimines,[4] guanidines,[5] and benzamidines[5] with diphenylcyclopropenone to give 2,3-diphenyl-2-pyrrolin-4-ones as reaction intermediates or products. When appropriately substituted amidines and guanidines were used for the reaction, 5,6-dihydropyrimidin-4-ones were produced.[6]

In the course of our study of cycloaddition reactions of heterodienes containing azomethine groups,[1] these publications prompted us to investigate the reaction of azines **1** with diphenylcyclopropenone (**2**); we obtained 5-aryl-2,3-diphenyl-2-pyrrolin-4-ones (**4**).[7] These pyrrolinones **4** were found to be oxidized by oxygen, by hydrogen peroxide, or by irradiation in a stream of oxygen to 2-aryl-4,5-diphenyl-1,3-oxazin-6-ones (**11**). Although many oxidation reactions of pyrroles have been reported,[8] little is known concerning the oxidation reactions of 2-pyrrolin-4-ones: 2,5-dimethyl-1-phenyl-2-pyrrolin-4-one was reported to be oxidized to 5-hydroxy derivative,[9] and 2,3-dimethyl-2-pyrrolin-4-one was found to be oxidized to tetramethylpyrrole indigo[10] or 3-pyrrolin-5-one derivative.[11] To the best of our knowledge the oxidative ring-enlargement of 2-pyrrolin-4-ones has not been reported. Moreover, the resulting oxadinones **11** belong to relatively rare derivatives of 1,3-oxazines.[12]

When azines **1** reacted with diethyl azodicarboxylate, similar cycloaddition reactions were not observed; the 1:2 and 1:1 conjugate addition products (**13** and **14**, respectively) were obtained in the case of **1e**.

Results and Discussion

When a mixture of *p*-methoxybenzaldehyde azine (**1a**) and diphenylcyclopropenone (**2**) in toluene was refluxed, a yellow crystalline product was obtained in 55% yield. The molecular formula $C_{23}H_{19}O_2N$ was confirmed on the basis of the elemental analysis and the mass spectrum (M^+, 341). The IR spectrum showed NH and CO absorptions at 3200 and 1640 cm^{-1}, respectively. These data suggest that the product is not an expected product such as a criss-cross 1:2 adduct **5a** or a [2+3] 1:1 adduct **3a**, but an addition-elimination product **4a** or **6a** (Scheme 1).

c: R=*p*-$Me_2CHC_6H_4$ **d**: R=C_6H_5
e: R=*p*-$Me_2NC_6H_4$

Scheme 1.

In order to distinguish between two regioisomers, **4a** and **6a**, conversion of the product into the known pyrrole derivative was attempted. Thus, treatment of the product with phosphorus pentasulfide in refluxing benzene gave a deoxygenated product, which seemed to be (*p*-methoxyphenyl)diphenylpyrrole (**7a**) or (**8a**). An authentic specimen **7a**[13] prepared from **9a** was identical with the deoxygenated product; this proved that the addition-elimination product was not **6a** but 5-(*p*-methoxyphenyl)-2,3-diphenyl-2-pyrrolin-4-one (**4a**).

Other 2-pyrrolin-4-ones (**4b**—**e**) were also obtained in a similar manner from **1b**—**e** in moderate yields (35—87%). The compounds **4b** and **4d** were converted

into the corresponding pyrroles **7b** and **7d**, whose structures were identified by comparison with the authentic samples prepared from **9b** and **9d**, respectively.

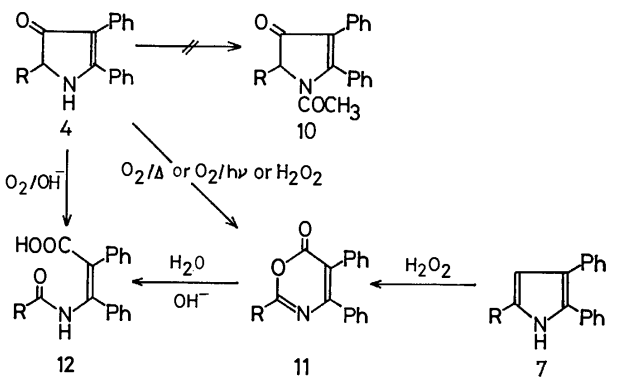
As shown in Scheme 1, the reaction is considered to proceed *via* the formation of a [2+3] cycloadduct **3**, followed by elimination of RCN. A similar process involving the initial cycloaddition to azomethine group of azine followed by elimination of RCN has been reported in the case of the reaction of azines with diphenylketene.[14]

In the course of the structure elucidation of **4a**, a mixture of **4a** in acetic acid and acetic anhydride was heated for acetylation. A product was separated in 23% yield by column chromatography. This compound showed no NH absorption and a new carbonyl absorption at 1738 cm^{-1} in the IR spectrum, but the absorption at 1640 cm^{-1} present in **4a** disappeared. These data imply that the product is not the desired acetate **10** but an auto-oxidation product, 2-(*p*-methoxyphenyl)-4,5-diphenyl-1,3-oxazin-6-one (**11a**) (Scheme 2). The compound **11a** was identical with the authentic sample prepared from **7a** by oxidation with hydrogen peroxide, according to the literature method.[15] These results suggest the possibility that **4** are generally oxidized by oxygen to 1,3-oxazin-6-ones (**11**). In fact, when the solutions of **4a—d** in pyridine were refluxed in a stream of oxygen, **11a—d** were obtained in 38—50% yields. The structures of **11b—d** were established by spectral data or by comparison with the samples derived from **7**.

Oxidations of **4** to **11** in different manners were further examined. When the solutions of **4** in chloroform were irradiated by a mercury lamp in a stream of oxygen, photooxidation products **11a** (21%), **11b** (14%), and **11c** (16%) could be isolated by column chromatography, but pure products were not obtained from **4d** and **4e**. Oxidation of **4** by hydrogen peroxide in acetic acid proceeded smoothly only in the cases of **4a** and **4c** to yield **11a** (85%) and **11c** (32%), respectively.

When a solution of **4a** in aqueous pyridine containing potassium hydroxide was stirred at room temperature, an acidic product (36%) was produced, accompanied by a mixture of neutral products, whose structures could not be determined because of low yields and difficulties in purification. The IR spectrum of the acidic product showed carboxyl absorptions at 3020 and 1688 cm^{-1} and an amide absorption at 1640 cm^{-1}. Consideration of the mass and the NMR spectra suggested that the acidic products was 3-(*p*-methoxybenzamido)-2,3-diphenylacrylic acid (**12a**). The structure of **12a** was further confirmed by comparing the samples obtained by the alkaline hydrolysis of **11a** under the same conditions. The compounds **12b** (25%), **12c** (26%), and **12d** (41%) were similarly obtained, and their structures were assigned by the spectral data or by comparison with the samples derived from **11**.

To explain the formation of 3-aroylamino-2,3-diphenylacrylic acids and indenone derivatives from aldimines and diphenylcyclopropenone, Eicher *et al.*[3] proposed a mechanism where the initially formed

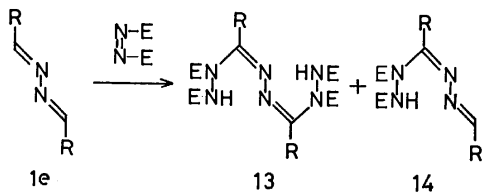


a: R=*p*-$MeOC_6H_4$ **b**: R=*p*-MeC_6H_4
c: R=*p*-$Me_2CHC_6H_4$ **d**: R=C_6H_5

Scheme 2.

2-pyrrolin-4-ones were oxidized by air to 1,3-oxazin-6-ones, which subsequently underwent hydrolysis to acrylic acids or ring-opening, followed by cyclization to indenones. Taking into account this explanation and our experiments on the hydrolysis of **11** to **12**, the oxidative cleavage of **4** to **12** appears to proceed *via* **11**. On the other hand, for the formation of **11**, the following pathway seems plausible: 2-pyrrolin-4-ones (**4**) are first cleaved to acrylic acids **12**, which are subsequently dehydrated to **11**. This pathway, however, may not be possible, since treatment of **12d** under the same conditions as the oxidation of **4** to **11**, that is, heating of **12d** in pyridine in a stream of oxygen, yielded **11d**, but the corresponding **11a—c** were not formed in the cases of **12a—c**, which gave unidentified products. To clarify the oxidation mechanism more detailed experiments will be needed.

During further studies of the reaction of azines, diethyl azodicarboxylate was found to add to *p*-dimethylaminobenzaldehyde azine (**1e**) in refluxing toluene, although no reaction occurred in the cases of **1b—d** and purification of the products from **1a** was difficult. Chromatographic separation of the reaction mixture from **1e** afforded two products. The first and the second eluated products proved to be a 1:2 adduct and a 1:1 adduct, respectively, on the basis of the elemental analyses and the mass spectra. The NMR spectrum of the 1:2 adduct **13** showed a singlet peak at δ 3.08 ppm due to two equivalent dimethylamino groups, suggesting a symmetrical structure. On the other hand, the NMR spectrum of the 1:1 adduct **14** showed two singlet peaks at δ 3.00 and 3.07 ppm due to two non-equivalent dimethylamino groups, suggesting an unsymmetrical structure. Moreover, the UV spectra of both **13** and **14** were very similar



R=*p*-$Me_2NC_6H_4$ E=$CO_2C_2H_5$

Scheme 3.

to those of the starting azine **1e**. From the above observations it was concluded that both **13** and **14** were not the anticipated cycloadducts, but 1,4-conjugate adducts. Although Marchetti *et al.*[16] reported the reactions of ketazines with diethyl azodicarboxylate, that is, the formation of 2-[*N*,*N'*-bis(ethoxycarbonyl)-hydrazino]cyclohexanone azines from cyclohexanone azines by conjugate addition, no reactions of aldazines have appeared in the literature.[2]

Experimental

The measurements of IR, UV, and NMR spectra and the elemental analyses were performed with the same instruments as previously described.[1b]

Preparation of 5-Aryl-2,3-diphenyl-2-pyrrolin-4-ones (4). General Procedure: A mixture of **1** (1.0 mmol) and **2** (1.2 mmol) in toluene (10 ml) was refluxed for 18—48 h. After cooling the precipitates were collected by filtration and recrystallized to give yellow needles **4**.

*Compound **4a***: Reaction time 18 h. Yield 55%. Mp 282—285 °C (C_6H_6). IR (KBr): 3200, 1640, 1600, 1580, 1540, 1507 cm^{-1}. UV (MeOH) nm (log ε): 243 (4.35), 383 (3.88), 250 sh (4.34). MS *m/e* (%): 341 (M^+, 42), 339 (M^+-H_2, 28), 326 (M^+ —NH, 28), 298 (326—CO, 5.1), 178 (PhC≡CPh, 100). Found: C, 81.30; H, 5.23%. Calcd for $C_{23}H_{19}O_2N$: C, 80.91; H, 5.61%.

*Compound **4b***: Reaction time 48 h. Yield 49%. Mp 269—271 °C (C_6H_6). IR (KBr): 3230, 1640, 1605, 1582, 1540, 1508 cm^{-1}. UV (MeOH) nm (log ε): 254 (4.33), 383 (3.84). Found: C, 85.01; H, 5.64%. Calcd for $C_{23}H_{19}ON$: C, 84.89; H, 5.89%.

*Compound **4c***: Reaction time 48 h. Yield 42%. Mp 274—275 °C (THF–MeOH). IR (KBr): 3240, 2960, 1640, 1605, 1582, 1542, 1510 cm^{-1}. UV (MeOH) nm (log ε): 255 (4.32), 378 (3.81). Found: C, 85.00; H, 6.23%. Calcd for $C_{25}H_{23}ON$: C, 84.95; H, 6.56%.

*Compound **4d***: Reaction time 24 h. Yield 35%. Mp 279—284 °C (sublimation) (DMF). IR (KBr): 3230, 1640, 1605, 1580, 1540, 1512 cm^{-1}. UV (MeOH) nm (log ε): 254 (4.31), 385 (3.84). Found: C, 84.81; H, 5.26%. Calcd for $C_{22}H_{17}ON$: C, 84.86; H, 5.50%.

*Compound **4e***: Reaction time 18 h. Yield 87%. Mp 244—247 °C (C_6H_6). IR (KBr): 3200, 3040, 2880, 2800, 1633, 1600, 1580, 1540, 1510 cm^{-1}. UV (MeOH) nm (log ε): 261 (4.35), 400 (4.09). Found: C, 81.47; H, 5.84%. Calcd for $C_{24}H_{22}ON_2$: C, 81.32; H, 6.26%.

Preparation of 5-Aryl-2,3-diphenylpyrroles (7). General Procedure: A mixture of **4** (0.50 mmol) and powdered phosphorus pentasulfide (1.0 mmol) in C_6H_6 (10 ml) was refluxed for 3 h. After cooling the undissolved materials were removed from the mixture by decantation, and the solvent was removed under reduced pressure. The resulting residue was washed with a small amount of MeOH and recrystallized once to give **7**. In the case of **7d** the residue was purified by column chromatography on silica gel with $CHCl_3$.

*Compound **7a***: Yield 70%. White prisms; mp 180—182 °C (MeOH) (lit,[13] 180 °C). IR (KBr): 3370, 3050, 1605, 1530 cm^{-1}. MS *m/e* (%): 325 (M^+, 100). NMR ($CDCl_3$): δ 3.80 (s, 3H, OMe), 6.5—7.6 (m, 15H, ArH), 8.32 (braod s, 1H, NH).

*Compound **7b***: Yield 26%. White needles; mp 116—118 °C (MeOH). IR (KBr): 3460, 3020, 2920, 1603, 1493 cm^{-1}. NMR ($CDCl_3$): δ 2.35 (s, 3H, Me), 6.6—7.5 (m, 15H, ArH), 8.35 (broad s, 1H, NH). Found: C, 89.14; H. 6.11%. Calcd for $C_{23}H_{19}N$: C, 89.28; H, 6.19%.

*Compound **7d***: Yield 31%. Pale yellow plates; mp 137—138 °C (C_6H_6-petroleum ether) (lit,[17] 140 °C).

*Preparation of **7** from **9***. Compounds **7a** (73%), **7b** (26%), and **7d** (24%) were prepared from the corresponding **9a**, **9b**, and **9d**, respectively, according to the literature method,[13] and showed the same mps and IR spectra as those of **7** prepared from **4**.

*Treatment of **4a** with a Mixture of AcOH and Ac_2O.* A solution of **4a** (300 mg) in a mixture of AcOH (30 ml) and Ac_2O (0.3 ml) was refluxed for 10 h. The solvent was removed under reduced pressure and the resulting residue was purified by column chromatography on silica gel with $CHCl_3$ to give 2-(*p*-methoxyphenyl)-4,5-diphenyl-1,3-oxazin-6-one (**11a**) (93 mg, 23%). Recrystallization from MeOH–THF afforded yellow needles; mp 204—205 °C. IR (KBr): 1738, 1598, 1570, 1535, 1510 cm^{-1}. NMR (CF_3COOH): δ 4.03 (s, 3H, OMe), 7.1—8.5 (m, 14H, ArH). MS *m/e* (%): 355 (M^+, 53), 327 (M^+ —CO, 53), 135 (100). Found: C, 77.88; H, 4.88%. Calcd for $C_{23}H_{17}O_3N$: C, 77.73; H, 4.82%.

*Oxidation of **4** by Oxygen. General Procedure*: A solution of **4** (1.0 mmol) in pyridine (10 ml) was refluxed for 6—11 h in a stream of oxygen. After removal of the solvent under reduced pressure, the resulting residue was washed with a small amount of MeOH and recrystallized to give 2-aryl-4,5-diphenyl-1,3-oxazin-6-ones (**11**).

*Compound **11a***: Reaction time 6 h. Yield 46%. The mp and the IR spectrum were identical with those described above.

*Compound **11b***: Reaction time 9 h. Yield 38%. Yellow needles; mp 203—204 °C (MeOH). IR (KBr): 1730, 1610, 1600, 1570, 1545, 1505 cm^{-1}. NMR ($CDCl_3$): δ 2.45 (s, 3H, Me), 7.3—8.4 (m, 14H, ArH). Found: C, 81.17; H, 5.01%. Calcd for $C_{23}H_{17}O_2N$: C, 81.39; H, 5.05%.

*Compound **11c***: Reaction time 11 h. Compound **11c** was separated from the residue by column chromatography on silica gel with $CHCl_3$. Yield 50%. White needles; mp 131—134 °C (MeOH–THF). IR (KBr): 2960, 1732, 1610, 1600, 1565, 1548 cm^{-1}. NMR ($CDCl_3$): δ 1.28 (d, J=6.8 Hz, 6H, 2Me), 2.99 (m, 1H, CH), 7.2—8.3 (m, 14H, ArH). Found: C, 81.75; H, 5.77%. Calcd for $C_{25}H_{21}O_2N$: C, 81.72; H, 5.76%.

*Compound **11d***: Reaction time 9 h. Yield 45%. Yellow needles; mp 206—207 °C (MeOH–THF). The mp and the IR spectrum were identical with those of an authentic specimen prepared according to the literature.[15]

*Preparation of **11** from **7***. Compounds **11a** (36%), **11b** (30%), and **11d**(14%) were prepared from the correponding **7a**, **7b**, and **7d**, respectively, according to the literature method.[15] The mps and the IR spectra were identical with those described above.

*Photooxidation of **4**. General Procedure*: A solution of **4** (0.50 mmol) in $CHCl_3$ (200 ml) was irradiated by means of a 100W high-pressure mercury arc lamp with stirring in a stream of oxygen for 4 h. Removal of the solvent followed by column chromatography on silica gel with $CHCl_3$ gave the products **11**. Compounds **11a** (21%), **11b** (14%), and **11c** (16%) were obtained. The mps and the IR spectra were identical with those described above.

*Oxidation of **4** by Hydrogen Peroxide.* To a suspension of **4a** (340 mg, 1.0 mmol) in AcOH (10 ml) was added 30% H_2O_2 (0.45 g, 4.0 mmol) and the mixture was stirred at room temperature. After one day another equal amount of 30% H_2O_2 (0.45 g) was added and the reaction mixture was stirred for an additional day. The precipitates were

collected by filtration, washed with a small amount of MeOH, and recrystallized to give **11a** (290 mg, 85%). In the case of **4c** the reaction mixture was evaporated to dryness and the residue was chromatographed on silica gel with $CHCl_3$ to give **11c** (32%). The mps and the IR spectra were identical to those described above.

*Alkali Treatment of **4**.* General procedure: A solution of **4** (1.0 mmol) in a mixture of 1.0 M KOH (4.0 ml) and pyridine (16 ml) was stirred at room temperature for 2—3 h. The reaction mixture was poured into water (200 ml) and the precipitates were filtered off. The filtrate was acidified with dil HCl and allowed to stand. The separated precipitates were collected by filtration and once recrystallized to give 3-aroylamino-2,3-diphenylacrylic acids (**12**).

*Compound **12a***: Reaction time 2 h. Yield 36%. White prisms; mp 189—192 °C (MeOH). IR (KBr): 3020 (broad), 1688, 1640, 1600, 1584, 1560 cm^{-1}. NMR (DMSO-d_6) : δ 3.86 (s, 3H, OMe), 7.0—8.1 (m, 14H, ArH). MS *m/e* (%): 373 (M^+, 8.1), 355 ($M^+ - H_2O$, 4.2), 329 ($M^+ - CO_2$, 41), 222 (7.8), 135 (100). Found: C, 73.68; H, 5.25%. Calcd for $C_{23}H_{19}O_4N$: C, 73.98; H, 5.13%.

*Compound **12b***: Reaction time 2 h. Yield 25%. White needles; mp 190—191 °C (MeOH). IR (KBr): 3180, 1655, 1610, 1595, 1575 cm^{-1}. NMR (DMSO-d_6): δ 2.38 (s, 3H, Me), 7.1—9.1 (m, 14H, ArH). Found: C, 77.49: H, 5.67%. Calcd for $C_{23}H_{19}O_3N$: C, 77.29; H, 5.36%.

*Compound **12c***: Reaction time 3 h. Yield 26%. White needles; mp 197—198 °C (MeOH). IR (KBr): 3160, 2960, 1670, 1605, 1595, 1575 cm^{-1}. NMR (DMSO-d_6): δ 1.23 (d, J=6.8 Hz, 6H, 2Me), 2.95 (m, 1H, CH), 7.8—8.0 (m, 14H, ArH). Found: C, 77.79; H, 6.22%. Calcd for $C_{25}H_{23}O_3N$: C, 77.90; H, 6.01%.

*Compound **12d***: Reaction time 2 h. Yield 41%. White needles; mp 151—152 °C (EtOH). IR (KBr): 3060, 2860, 1690, 1650, 1615, 1593 cm^{-1}. Found: C, 73.01; H, 5.19%. Calcd for $C_{22}H_{17}O_3N \cdot H_2O$: C, 73.11; H, 5.30%.

*Alkali Treatment of **11***. Compounds **11** were treated with alkali in the same manner as described in the case of **4**. Compounds **12a** (65%), **12b** (63%), and **12d** (20%) were obtained and their mps and IR spectra were identical to those described above.

*Reaction of **1e** with Diethyl Azodicarboxylate.* A mixture of **1e** (1.30 g, 4.5 mmol) and diethyl azodicarboxylate (1.58 g, 9.1 mmol) in toluene (30 ml) was refluxed for 5 h. After removal of the solvent the resulting residue was subjected to column chromatography on silica gel with $CHCl_3$–AcOEt (1:1). Both the first and the second eluated fractions gave oils **13** (1.1 g, 77%) and **14** (430 mg, 42%), respectively, which crystallized upon adding a small amount of MeOH.

*3,6-Bis(p-dimethylaminophenyl)-1,2,7,8-tetrakis(ethoxycarbonyl)-1,2,4,5,7,8-hexaaza-3,5-octadiene (**13**).* Yellow powders; mp 188—189 °C (MeOH–H_2O). IR (KBr) : 3180, 2960, 1735, 1705, 1585, 1518 cm^{-1}. NMR (DMSO-d_6) : δ 0.92—1.35 (m, 12H, 4Me), 3.08 (s, 12H, $2NMe_2$), 3.83—4.15 (m, 8H, $4CH_2$), 8.58 (s, 2H, 2NH), 6.95 (d, J=9.0 Hz, 4H, 4*m*-H of ArH), 7.72 (d, J=9.0 Hz, 4H, 4*o*-H of ArH). UV (MeOH) nm (log ε): 241 (4.22), 320 sh (4.25), 382 (4.65).[18] MS *m/e* (%): 642 (M^+, 9.4), 467 (42), 454 (23), 351 (13), 294 (22), 280 (100), 266 (21), 175 (42). Found: C, 56.07; H, 6.54%. Calcd for $C_{30}H_{42}O_8N_8$: C, 56.06; H, 6.59%.

*3,6-Bis(p-dimethylaminophenyl)-1,2-bis(ethoxycarbonyl)-1,2,4,5-tetraaza,-3,5-hexadiene (**14**).* Yellow powders; mp 120—122 °C (MeOH–H_2O). IR (KBr): 3280, 2980, 2920, 1735, 1710, 1680, 1600, 1557, 1520 cm^{-1}. NMR ($CDCl_3$): δ 1.20 (t, J=7.5 Hz, 3H, Me), 1.27 (t, J=7.5 Hz, 3H, Me), 3.00 (s, 6H, NMe_2), 3.07 (s, 6H, NMe_2), 4.14 (q, J=7.5 Hz, 2H, CH_2), 4.22 (q, J=7.5 Hz, 2H, CH_2), 5.17 (s, 1H, CH), 6.70 (d, J=9.0 Hz, 2H, 2*m*-H of ArH), 6.85 (d, J=9.0 Hz, 2H, 2*o*-H of ArH), 7.70 (d, J=9.0 Hz, 4H, 2*o*- and 2*m*-H of ArH), 8.56 (s, 1H, NH). UV (MeOH) nm (log ε): 243 (4.26), 325 sh (4.28), 388 (4.61). Found: C, 61.31; H, 6.94%. Calcd for $C_{24}H_{32}O_4N_6$: C, 61.52; H, 6.88%.

The authors wish to express their thanks to Dr. Masatoshi Hirayama and Mr. Mamoru Sekine for the NMR measurements, and to Sankyo Co., Ltd., for the mass measurements.

Reactive Troponoids and *o*-Aminophenol. II. The Formation of Cyclohepta[*b*][1,4]benzoxazine and 11*H*-Cyclohepta[*b*][1,4]benzoxazin-10-one Derivatives from Isomeric Isopropyl-2-chlorotropones

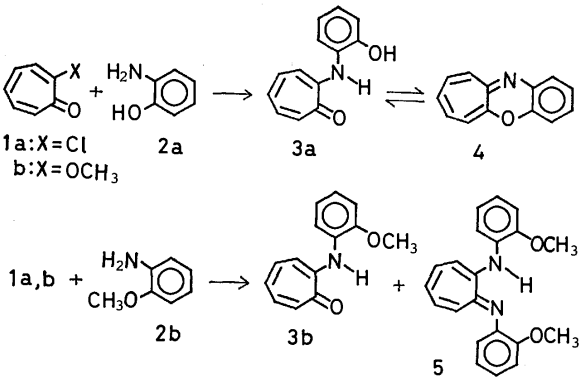
Tetsuo Nozoe and Taichi Someya*

Central Research Laboratory of Takasago Perfumery Co., Ltd., Kamata, Ohta-ku, Tokyo 144

(Received March 30, 1978)

The reactions of three isomeric isopropyl-2-chlorotropones with *o*-aminophenol were investigated. 8-Isopropylcyclohepta[*b*][1,4]benzoxazine was obtained from 5-isopropyl-2-chlorotropone, while 4- and 6-isopropyl-derivatives gave the same mixture of 7- and 9-isopropylcyclohepta[*b*][1,4]benzoxazine. These facts showed that the amino group of *o*-aminophenol attacked both the C-1 and C-2 positions of 2-chlorotropones. Also 6-, 7-, and 8-isopropyl-11*H*-cyclohepta[*b*][1,4]benzoxazin-10-ones were obtained as the minor products of these reactions.

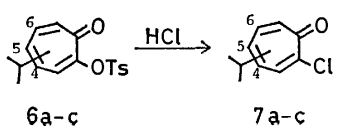
In the preceding paper,[1] we reported the formation of 2-(*o*-hydroxyanilino)tropone (**3a**) and cyclohepta[*b*]-[1,4]benzoxazine (**4**) by the reaction of 2-chloro- (**1a**) or 2-methoxytropone (**1b**) with *o*-aminophenol (**2a**). Since the reaction of **1a, b** with *o*-methoxyaniline (**2b**) resulted in the formation of a small amount of 1-(*o*-methoxyanilino)-7-(*o*-methoxyphenylimino)-1,3,5-cycloheptatriene (**5**), besides the corresponding aminotropone (**3b**), it has been shown that the amino group of *o*-aminophenol reacted not only with C-2 (or C-7), but also with the carbonyl group (C-1).[2]



In order to confirm the position attacked by the amino group of the reagent on the seven-membered ring, we investigated the reactions of three isomeric isopropyl-2-chlorotropones (**7a—c**) with *o*-aminophenol. From the kinds of products obtained and their ratio, the amino group of the reagent was found to attack both the C-1 and C-2 positions of 2-chlorotropones approximately equally.

Results and Discussion

The most popular method of the synthesis of 2-chlorotropone is to treat tropolone with thionyl chloride,[3] but this method is not convenient when using alkyltropolones. We found the reaction of 2-tosyloxytropone with dry hydrogen chloride in dioxane[4] is most advantageous in such a case. By the use of this method,



three isomeric isopropyl-2-chlorotropones (**7a—c**) were obtained in about a 90% yield from the corresponding tosylates (**6a—c**),[5] which indicated that normal replacement has taken place in these reactions.

The reaction of 2-chloro-5-isopropyltropone (**7b**) with *o*-aminophenol in acetic acid afforded **8b** (78%) and **9b** (0.5%). The heating of **8b** with 2 eq. of ethanolic alkali resulted in the quantitative formation of **10b**, along with a minute amount of **9b**, and **10b** reverted to **8b** quantitatively when heated in acetic

acid in the presence of concd sulfuric acid. From these results, and from their elemental analytical and spectral data, **8b** was determined to be 8-isopropylcyclohepta[*b*][1,4]benzoxazine and **10b** as 5-isopropyl-2-(*o*-hydroxyanilino)tropone.

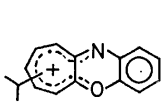
The reaction of 2-chloro-4-isopropyltropone (**7a**) with *o*-aminophenol afforded **8a** (40%) and **8c** (38%), besides **9a** (0.5%). In the same reaction, 2-chloro-6-isopropyltropone (**7c**) also gave **8a** (36%) and **8c** (42%), besides **9c** (0.5%). The structures of **8a** and **8c** were determined to be 9-isopropyl- (**8a**) and 7-isopropylcyclohepta[*b*][1,4]benzoxazine (**8c**) from their NMR spectra, shown in Table 1.

When **8a** was heated with 2 eq. of ethanolic alkali, **10a** was obtained quantitatively, along with traces of **9a**. In the same manner, **10c** and traces of **9c** were obtained from **8c**. **10a** and **10c** were reverted to **8a** and **8c** respectively by heating in acetic acid in the presence of concd sulfuric acid. From these results, **10a** and **10c** were determined to be 4-isopropyl- and 6-isopropyl-2-(*o*-hydroxyanilino)tropone, respectively (Scheme 2).

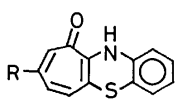
The NMR spectral measurement of **8b** in trifluoroacetic acid, which exists as a cation, **11**, shows, as in the case of the parent **4**,[1] shifts of the seven-membered ring protons by 1.22—1.37 ppm and those of the benzene-ring protons by 0.11—0.20 ppm to a lower magnetic field (Table 1).

It should be noted in these reactions that the same mixture of **8a** and **8c** was obtained from both **7a** and **7c**, indicating that the amino group of *o*-aminophenol attacked both C-2 and C-1 positions to the same extent. It is clear from the formation of these products that the so-called cine-reaction[6] (abnormal substitution at C-7 instead of C-2) has not taken place. Tropones act as tropylium ions in an acidic medium, so C-1 positions also seem liable to be attacked by nucleophiles.

The three products (**9a**—**c**) obtained in small amounts were found to be isomers with the same formula of $C_{16}H_{15}NO_2$, and their IR absorptions at 3200—3250 cm^{-1} (NH) and 1607—1610 cm^{-1} (C=O) agree with those at 3218 cm^{-1} (NH) and at 1607 cm^{-1} (C=O) in the 11*H*-cyclohepta[*b*][1,4]benzothiazin-10-one (**12a**) obtained earlier.[7]

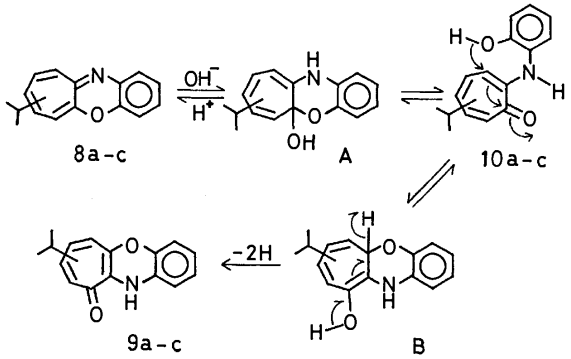


11



12 a: R = H
b: R = iPr

In the NMR spectrum of **9c**, the broad singlet at δ 6.98 ppm was considered to be the proton on C-9, next to the carbonyl group in the seven-membered ring; this agrees well with the absorption at δ 7.05 ppm (br s, C_9–H) in the NMR spectrum of 11*H*-8-isopropylcyclohepta[*b*][1,4]benzothiazin-10-one (**12b**).[8] From this evidence, **9c** was determined to be 11*H*-8-isopropylcyclohepta[*b*][1,4]benzoxazin-10-one. It was considered that **9c** was formed by the dehydrogenation of the intermediate B, derived from the cyclization of **10c** at the C-3 position. A similar explanation can be put forward for the formation of 11*H*-6-isopropyl- (**9a**) and 11*H*-7-isopropylcyclohepta[*b*][1,4]benzoxazin-10-one (**9b**) from **10a** and **10b** respectively. Interconversion between **8** and **10** obviously proceeds *via* the hydrated intermediate, A (Scheme 2).



Scheme 2.

Experimental

All the melting points are uncorrected. TLC and preparative TLC were carried out on Kiesel gel 60 F_{254} (Merck) and Wakogel BF-5 (Wako) respectively, developed with benzene, and spots were detected with an UV lamp. The IR and UV spectra were taken on a Hitachi EPI-G2 and a Hitachi 124 spectrophotometer respectively. The UV spectra in an acidic or basic medium were measured by adding three drops of 1 M HCl or 1 M NaOH to the sample solution. The NMR spectra were recorded on a 60 MHz Hitachi-R-24A and a 100 MHz Varian HA-100 spectrometer, with TMS as the internal standard. The mass spectra were recorded on a Hitachi RMU-6M mass spectrometer operating at 75 eV.

2-Chloro-5-isopropyltropone (7b). A solution of 5-isopropyl-2-tosyloxytropone (**6b**)[5] (1.6 g, 5.0 mmol) in dry dioxane (30 ml) was refluxed by passing dry hydrogen chloride through for 20 min. After the dioxane has been removed under reduced pressure, the residue was dissolved in ether. The ether solution was passed through an alumina column to give 0.9 g (97%) of **7b** as a pale yellow oil.

By the same procedure, 2-chlorotropone was obtained from 2-tosyloxytropone in a 96% yield.

2-Chloro-4-isopropyltropone (7a) and 2-Chloro-6-isopropyltropone (7c). 4-Isopropyl- (**6a**) and 6-isopropyl-2-tosyloxytropone (**6c**) were prepared from β-thujaplicin by the reported method.[5] By the method described above, from **6a** (2.1 g, 6.6 mmol) 1.1 g (90%) of **7a** were obtained as a pale yellow oil. Similarly, 3.3 g (94%) of **7c** were obtained from **6c** (6.2 g, 19.5 mmol); subsequent recrystallization from hexane afforded pale yellow needles; mp 48 °C. (Lit,[5] 46.5—48.5 °C)

8-Isopropylcyclohepta[b][*1,4*]*benzoxazine (8b).* A mixture of **7b** (0.8 g, 4.4 mmol), **2a** (0.8 g, 7.3 mmol), and acetic acid (4 ml) was refluxed for 2 h. After the removal of the acetic acid under reduced pressure, 30 ml of water was added to the residue, and it was extracted with $CHCl_3$. The extract was evaporated, the residue of dark brown oil was dissolved in EtOH, and an EtOH solution of picric acid was added. When the resulting picrate was filtered and washed with ether, 1.46 g were obtained; mp 193—196 °C. The picrate was stirred with EtOH (5 ml) and 1M NaOH (25 ml) for 20 min at room temp. The mixture was then extracted with benzene. The extract was washed with water, dried over Na_2SO_4, and evaporated. The recrystallization of the residue from hexane gave 0.76 g (78%) of **8b** as dark

brown plates; mp 105 °C; λ_{max}^{MeOH} nm (log ε): 214 (4.24), 263 (4.31), 270 (4.27), and 418 (3.99); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 221 (4.27), 265 (4.32), 273 (4.46), 320 (3.80), and 436 (3.82); NMR (see Table 1). Found: C, 81.00; H, 6.41; N, 6.07%; M^+, 237. Calcd for $C_{16}H_{15}NO$: C, 80.98; H, 6.37; N, 5.90%; M, 237. Picrate: brown needles (from EtOH); mp 198 °C (dec).

11H-7-Isopropylcyclohepta[b][*1,4*]*benzoxazin-10-one* (**9b**). From the filtrate of the preparation of the picrate, 50 mg of **7b** and 6 mg (0.5%) of **9b** were obtained by preparative TLC. Recrystallization from ethyl acetate gave red needles; mp 114 °C; λ_{max}^{MeOH} nm (log ε): 208 (4.39), 228 (4.45), 257 (4.35), 268 (4.34), 285 (4.25), 420 (3.79)^{sh}, and 480 (3.97); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 208 (4.37), 228 (4.48), 260 (4.28), 270 (4.29), 286 (4.36), 325 (3.85), and 470—490 (3.93); IR (KBr): 3240 (NH) and 1610 cm^{-1} (C=O). Found: C, 75.65; H, 6.01; N, 5.58%; M^+, 253. Calcd for $C_{16}H_{15}NO_2$: C, 75.87; H, 5.97; N, 5.53%; M, 253.

Reaction of **7a** *with* **2a**. A mixture of **7a** (1.0 g, 5.5 mmol), **2a** (1.0 g, 9.2 mmol), and acetic acid (4 ml) was refluxed for 2 h. By a method similar to the reaction of **7b** with **2a**, 3g of dark brown crystals were obtained. These crystals were shown by TLC to be a mixture of two components. Then **8a** (0.52 g, 40%) and **8c** (0.49 g, 38%) were obtained by preparative TLC. From the filtrate which the picrate was separated, 7 mg (0.5%) of **9a** were obtained by preparative TLC.

9-Isopropylcyclohepta[b][*1,4*]*benzoxazine* (**8a**): Dark brown needles (from hexane); mp 63 °C; λ_{max}^{MeOH} nm (log ε): 207 (4.17), 215 (4.17), 263 (4.31), 270 (4.29), and 414 (3.95); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 205 (4.13), 227 (4.20), 265 (4.24)^{sh}, 275 (4.28), 316 (3.83), and 435—450 (3.82); NMR (see Table 1). Found: C, 80.77; H, 6.27; N, 6.13%; M^+, 237. Picrate: brown needles (from EtOH); mp 221—222 °C (dec).

7-Isopropylcyclohepta[b][*1,4*]*benzoxazine* (**8c**): Dark brown needles (from hexane); mp 109 °C; λ_{max}^{MeOH} nm (log ε): 207 (4.23), 215 (4.24), 263 (4.31), 270 (4.29), and 415 (3.96); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 206 (4.22), 226 (4.33), 265 (4.25)^{sh}, 275 (4,28), 317 (3.84), and 435—450 (3.84); NMR (see Table 1). Found: C, 80.73; H, 6.23; N, 5.90%; M^+, 237. Picrate: brown needles (from EtOH), mp 201—202 °C (dec).

11H-6-Isopropylcyclohepta[b][*1,4*]*benzoxazin-10-one* (**9a**): Orange red needles (from EtOAc); mp 141 °C; λ_{max}^{MeOH} nm (log ε): 207 (4.36), 230 (4.45), 257 (4.34), 269 (4.33), 286 (4.28), 410 (3.76)^{sh}, and 470 (3.98); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 207 (4.34), 228 (4.49), 260 (4.28), 270 (4.31), 288 (4.37), 325 (3.82)^{sh}, and 450—470 (3.93); IR (KBr): 3200 (NH) and 1610 cm^{-1} (C=O); NMR (100 MHz in $CDCl_3$): δ 6.90 (m, 1H, C_9-H), 6.38—6.78 (m, 6H), 3.24 (m, 1H, CH), and 1.19 ppm (d, 6H, J=7.0 Hz, CH_3). Found: C, 75.75; H, 6.03; N, 5.57%; M^+, 253.

Reaction of **7c** *with* **2a**. A mixture of **7c** (3.0 g, 16.4 mmol), **2a** (3.0 g, 27.5 mmol), and acetic acid (20 ml) was refluxed for 2 h. After the treatment described above, **8a** (1.3 g, 36%), **8c** (1.5 g, 42%), **9c** (19 mg, 0.5%), and **7c** (0.25 g) were obtained.

11H-8-Isopropylcyclohepta[b][*1,4*]*benzoxazin-10-one* (**9c**): Red needles (from EtOAc); mp 172 °C; λ_{max}^{MeOH} nm (log ε): 205 (4.34), 233 (4.45), 258 (4.35), 270 (4.35), 283 (4.22) 415 (3.76)^{sh}, and 480 (3.97); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 205 (4.34), 230 (4.46), 260 (4.32)^{sh}, 270 (4.35), 285 (4.36), 322 (3.80)^{sh}, and 450—485 (3.94); IR (KBr): 3250 (NH), and 1607 cm^{-1} (C=O); NMR (100 MHz in $CDCl_3$): δ 6.98 (br s, 1H, C_9-H), 6.28—6.68 (m, 6H), 2.60 (m, 1H, CH), and 1.13 ppm (d, 6H, J=7.0 Hz, CH_3). Found: C, 75,73; H, 5.92; N, 5.54%; M^+, 253.

4-Isopropyl-2-(o-hydroxyanilino)tropone (**10a**). A solution of **8a** (0.5 g, 2.1 mmol) in ethanol (10 ml) and 1M NaOH (5 ml) was refluxed for 1 h. After the subsequent removal of the ethanol, the residue was dissolved in water (5 ml) and adjusted to make it slightly acidic with 1M HCl. The resulting precipitate was filtered and dried in a desiccator. Recrystallization from hexane afforded 0.47 g (88%) of **10a** as yellow needles; mp 170 °C. From the mother liquor, 2 mg of **9a** was obtained by preparative TLC. **10a**: λ_{max}^{MeOH} nm (log ε): 208 (4.45), 235(4.28), 255 (4.18), 343 (3.88), and 400 (4.07); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 208 (4.25), 245 (4.32), 257 (4.30), and 378 (3.92); $\lambda_{max}^{MeOH+NaOH}$ nm (log ε): 235 (4.85), 340 (3.62)^{sh}, and 410 (4.00); IR (KBr): 3300 (NH), 3050 (OH), and 1590 cm^{-1} (C=O); NMR (60 MHz in $CDCl_3$): δ 9.70 (br s, 1H, OH), 8.75 (br s, 1H, NH), 6.50—7.30 (m, 8H), 2.72 (m, 1H, CH), and 1.15 ppm (d, 6H, J=7.0 Hz, CH_3). Found: C, 75.23; H, 6.73; N, 5.55%; M^+, 255. Calcd for $C_{16}H_{17}NO_2$: C, 75.27; H, 6.71; N, 5.49%; M, 255.

5-Isopropyl-2-(o-hydroxyanilino)tropone (**10b**). By the method described above, 0.48 g (89%) of **10b** and 2 mg of **9b** were obtained from 0.5 g of **8b**. **10b**: Orange yellow needles (from hexane); mp 181 °C; λ_{max}^{MeOH} nm (log ε): 208 (4.38), 236 (4.42), 346 (3.96), and 409 (4.07); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 241 (4.41) and 382 (3.96); $\lambda_{max}^{MeOH+NaOH}$ nm (log ε): 236 (4.64), 346 (3.65), and 418 (4.00); IR (KBr): 3250 (NH), 3050 (OH), and 1600 cm^{-1} (C=O); NMR (60 MHz in $CDCl_3$): δ 9.60 (br s, 1H, OH), 8.60 (br s, 1H, NH), 6.70—7.25 (m, 8H), 2.75 (m, 1H, CH), and 1.16 ppm (d, 6H, J=8.0 Hz, CH_3). Found: C, 75.05; H, 6.74; N, 5.41%; M^+, 255.

6-Isopropyl-2-(o-hydroxyanilino)tropone (**10c**). By the method described above, 0.48 g (89%) of **10c** and 2 mg of **9c** were obtained from 0.5 g of **8c**. **10c**: Orange yellow needles (from hexane); mp 181 °C; λ_{max}^{MeOH} nm (log ε): 236 (4.28), 250 (4.28), 345 (3.87), and 400 (4.08); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 245 (4.20), 255 (4.19), and 383 (3.88); $\lambda_{max}^{MeOH+NaOH}$ nm (log ε): 235 (4.27) and 410 (3.88); IR (KBr): 3300 (NH), 3000 (OH), and 1590 cm^{-1} (C=O); NMR (60 MHz in $CDCl_3$): δ 9.30 (br s, 1H, OH), 8.50 (br s, 1H, NH), 6.45—7.20 (m, 8H), 2.70 (m, 1H, CH), and 1.10 ppm (d, 6H, J=7.0 Hz, CH_3). Found: C, 75.16; H, 6.58; N, 5.53%; M^+, 255.

Conversion of **10a—c** *into* **8a—c**. A solution of **10** (0.2 g) in acetic acid (2 ml) and one drop of concd H_2SO_4 was refluxed for 15 min. The solution turned dark brown. After the removal of the acetic acid, the residue was extracted with benzene. The extract was washed with aq $NaHCO_3$ and water, dried over Na_2SO_4, and evaporated. The recrystallization of the residue from hexane gave **8**. The yields were **8a** (90%), **8b** (89%), and **8c** (90%) respectively.

The authors wish to express their thanks to Professor Shô Itô and Dr. Yoshimasa Fukazawa (Tohoku University) for the assignment of the NMR spectra, and also to Dr. Masao Sugimura and the Sankyo Co., Ltd., for measuring some of the mass spectra and 100 MHz NMR spectra and for their elemental analyses.

Peptides. VII. Some Sulfonates of Strongly Acidic *N*-Hydroxy Compounds as Novel Coupling Reagents[1)]

Masumi ITOH,* Hiroshi NOJIMA, Jiyoji NOTANI, Daijiro HAGIWARA, and Kuniaki TAKAI

Research Laboratories, Fujisawa Pharmaceutical Co., Ltd., Kashima-cho, Yodogawa-ku, Osaka 532

(Received April 1, 1978)

Sulfonates of strongly acidic *N*-hydroxy compounds such as 6-chloro-1-(*p*-chlorophenylsulfonyloxy)benzotriazole have been found to be excellent coupling reagents for amide bond formation. Amides can be prepared through either an active ester or a mixed anhydride according to the chosen procedure. Several active esters and protected di- and tripeptides prepared are listed in the Tables. Racemization, possible side reactions, and reaction pathways of the amide bond formation have also been discussed.

Many reports on coupling methods and reagents for peptide synthesis have been published. Many of these reagents can be added directly to a mixture of a carboxyl and an amino components to simplify the technique. Of these, dicyclohexylcarbodiimide (DCC) is the most versatile and widely utilized one, although it has the following disadvantages:[2)] 1) the rearrangement of the active intermediate, *O*-acyl-*N*,*N*'-dicyclohexylisourea, to the inactive *N*-acyl-*N*,*N*'-dicyclohexylurea, 2) the contamination of products by *N*,*N*'-dicyclohexylurea which is to a certain extent soluble in many organic solvents, 3) the dehydration from the side chain amide group of *N*-protected asparagine or glutamine to the corresponding cyano group, 4) the racemization *via* oxazolone formation, and 5) the allergic property to humans. A recent investigation revealed that DCC might lead histidine-containing peptides to their N^{im}-(*N*,*N*'-dicyclohexylamidino) derivatives.[3)] The present authors wish to report some new sulfonate-type coupling reagents which promise the simple operation, high purity and high yield of products, and seem to be superior to DCC at the points mentioned above.

It has been reported that some carbonates of strongly acidic *N*-hydroxy compounds activated carboxylic acids by the formation of mixed anhydride-type intermediates which were subsequently transformed to esters in good yield by eliminating carbon dioxide. One of these carbonates, ethyl 2-(isobutoxycarbonyloxyimino)-2-cyanoacetate, may be employed as a coupling reagent in the mixed anhydride method.[4)] These results prompted the preparation of ethyl 2-(methylsulfonyloxyimino)-2-cyanoacetate (**3a**)[5)] and its potency as a coupling reagent was examined. Preliminary experiments showed that the coupling of a carboxylic acid with an amine proceeded smoothly by the use of **3a** and triethylamine at room temperature affording an amide in excellent yield. To demonstrate the superiority of **3a** to methanesulfonyl chloride (**1a**) itself or a combination of **1a**/ethyl 2-hydroxyimino-2-cyanoacetate (**2a**), ethyl *N*-benzyloxycarbonyl-L-prolyl-L-leucinate (**5**) was prepared using the above mentioned reagents. *N*-Benzyloxycarbonyl-L-proline (**6**) was allowed to react with the reagents in the presence of triethylamine in chloroform for 15 min at 0 °C, then a solution of ethyl L-leucinate (**7**) in chloroform was added to the resulting mixture. After stirring for 18 h at room temperature, **5** was obtained in 61.5, 76.9, and 80.2% yield by the use of **1a**, the combination of **1a**/**2a**, and **3a**, respectively. These results indicated the value of preparing other sulfonates of *N*-hydroxy compounds. The sulfonates were prepared by the reaction of alkane- or arenesulfonyl chlorides (**1**) with *N*-hydroxy compounds (**2**) under the conditions of the Schotten-Baumann reaction, and were stable, easy to prepare, and highly reactive crystalline materials. Some sulfonates were difficult to isolate such as 1-(trichloromethylsulfonyloxy)-benzotriazole. The sulfonates of *N*-hydroxy compounds prepared are listed in Tables 1 and 2. Most of the sulfonates are stable crystalline materials unless

exposed to atmospheric moisture for a long period, and are storable in a closed brown bottle without decomposition for three years. Some representative sulfonates were subjected to a rough comparison of their reactivity in the coupling of **6** or *N*-benzyloxycarbonyl-L-phenylalanine (**8**) with **7** at room temperature (Table 3). It is apparent from the table that the reactivity of each sulfonate is largely dependent on the acidity of both the parent *N*-hydroxy compound and the sulfonic acid. Electron-withdrawing substituents on the nuclei of both benzotriazole and benzenesulfonic acid increased the reactivity of the corresponding sulfonate. In contrast with the reactive sulfonates, the sulfonates of phenols such as the methanesulfonate[6] of 2,4-dinitrophenol (pK_a 4.11) showed far less reactivity.

Table 3. An approximate comparison of the reactivity of representative sulfonates

In another series of preliminary experiments, it was observed that **3a**, 3-(methylsulfonyloxy)- and 3-(phenylsulfonyloxy)-1,2,3-benzotriazine-4-ones (**3e** and **3f**) induced colored impurities into the products, whereas the sulfonates of the benzotriazole series gave satisfactory results. Consequently, the reagents of the benzotriazole series were subsequently studied. To select the most prominent one from the sulfonates, the reactivity in the coupling of **6** (5 mmol) and **7** hydrochloride (2.5 mmol) by the use of triethylamine (7.5 mmol) and the sulfonates (5 mmol) were compared by recording the time required for the disappearance of free **7** in the reaction mixture. At the same time, the stability to atmospheric moisture was examined by infrared and thin layer chromatography. Most of the sulfonates adsorbed atmospheric moisture gradually during exposure and showed partial decomposition to some extent. Table 4 summarizes the results, and it is clearly shown that the stability of the reagents has no relation to their reactivity, but with their hygroscopic characters. In consideration of the reactivity, stability and accessibility, 6-chloro-1-(*p*-chlorophenylsulfonyloxy)benzotriazole (**4v**) was finally chosen as the prominent member of the series.

Using the sulfonates of acidic *N*-hydroxy compounds, amides can be prepared by the following two procedures: (A) activation of a carboxyl component with a reagent prior to the addition of an amine component, and (B) the direct addition of the reagent into a mixture of the carboxyl and the amine components. The use of an equimolar amount of tertiary amine is essential in both procedures.

Procedure A:

$$R^1\text{-}SO_2\text{-}ON\begin{matrix}R^2\\R^3\end{matrix} + R^4\text{-}COOH \xrightarrow{\text{Base}}$$

$$R^4\text{-}COON\begin{matrix}R^2\\R^3\end{matrix} + R^1\text{-}SO_3H\cdot\text{Base}$$

$$\downarrow H_2N\text{-}R^5$$

$$R^4\text{-}CONH\text{-}R^5 + HON\begin{matrix}R^2\\R^3\end{matrix}$$

Procedure B:

$$R^1\text{-}SO_2\text{-}ON\begin{matrix}R^2\\R^3\end{matrix} + R^4\text{-}COOH + H_2N\text{-}R^5 \xrightarrow{\text{Base}}$$

$$R^4\text{-}CONH\text{-}R^5 + R^1\text{-}SO_3H\cdot\text{Base} + HON\begin{matrix}R^2\\R^3\end{matrix}$$

Scheme 1.

In procedure A, the active ester formation is rapid and is usually completed within one hour using triethylamine in chloroform or ethyl acetate at room temperature. When pyridine is employed as a base, a polar solvent such as acetonitrile is necessary to produce a smooth reaction. The active ester formed in this stage can be isolated in good yield, some examples of which are listed in Table 5. Aminolysis of the active esters is also completed within a few hours at room temperature.

In procedure B, the reaction mixture tends to be

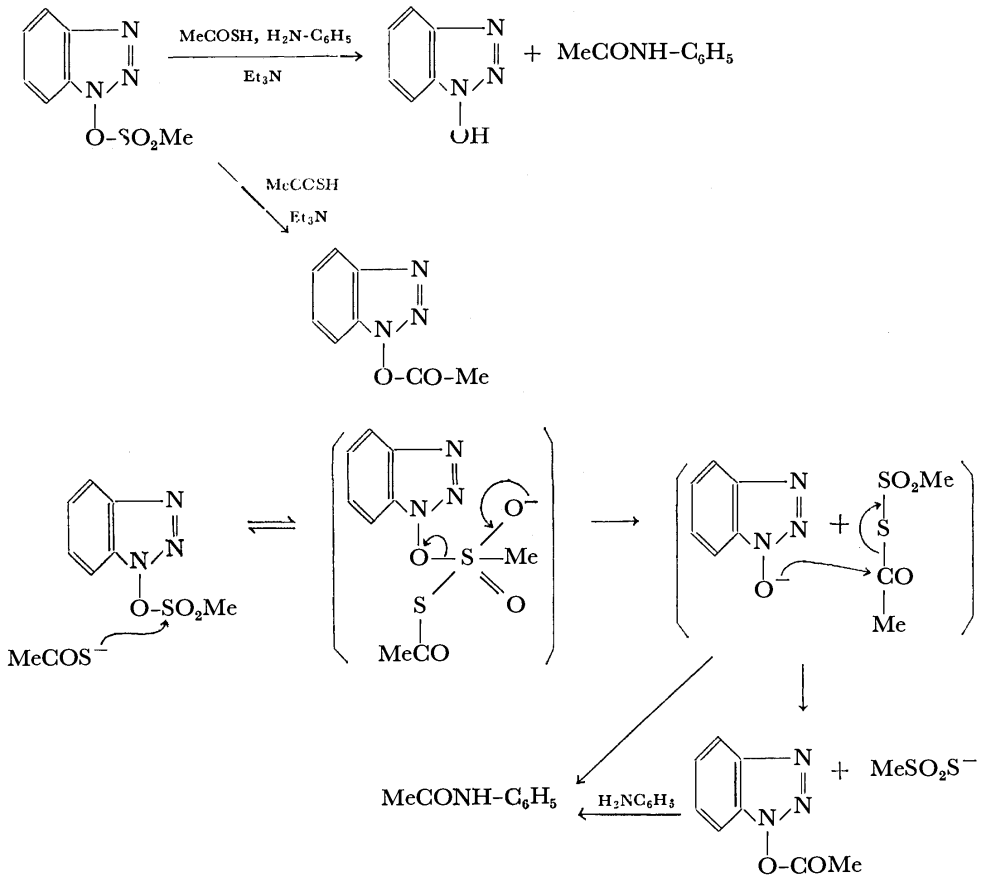
acidic by the formation of the *N*-hydroxy compound resulting in a retardation of the aminolysis of active intermediates, and 6 to 8 h is required for completion of the reaction by the use of triethylamine or *N*-methylmorpholine in chloroform or ethyl acetate, and 2 to 3 h in acetonitrile. When pyridine is employed as the tertiary base, the reaction may require nearly 2 days or more for completion even in acetonitrile. In general, neutralization of the acidic reaction mixture with extra an amount of tertiary base promoted the reaction. For example, the conventional coupling of **6** and **7** by the use of 1-(methylsulfonyloxy)benzotri-



Scheme 2.

azole (**4a**) required 8 h, while the same reaction was completed within 2 h by the periodic addition of an extra amount of triethylamine.

Reaction conditions employed and yields of model peptides are summarized in Tables 6 and 7. In the coupling of *N*-protected L-asparagine and L-glutamine with amine components, no dehydration from the ω-amide to the cyano group was detected in the infrared spectra of the crude products. Free hydroxy or imino groups did not cause any difficulty in the preparation of serine-, tyrosine- or histidine-containing peptides, and no racemate was detected in the preparation of ethyl *N*-benzyloxycarbonylglycyl-L-phenylalanylglycinate by fractional crystallization.

The use of **4v** appeared to be advantageous with oily products or products less soluble in organic solvents. Methyl *N*-benzyloxycarbonyl-L-glutaminyl-L-histidinate prepared by the DCC method was separated from *N,N'*-dicyclohexylurea by extraction with 2 M hydrochloric acid, whereas **4v** gave the product in excellent yield by a simple operation. The coupling of *N*-*t*-butoxycarbonyl-L-proline with benzyl *O*-benzyl-L-serylglycinate is another example to demonstrate the superiority of **4v** over DCC. In the DCC method the product can be isolated only with the help of counter current distribution to eliminate *N,N'*-dicyclohexylurea,[20] whereas the use of **4v** gave the pure product by the following conventional procedure.

A combination of **4v** with a macropolous cation exchange resin was examined in order to test a new technique for peptide synthesis in the liquid-solid phase method. Unlike common solid phase methods, this is designed to leave only the neutral product in the liquid phase after completion of the reaction, while the acidic by-products and unreacted carboxyl components are adsorbed on the resin. That is, a carboxylate anion on the resin is allowed to react with **4v** and forms an active intermediate first, which subsequently reacts with the free amine liberated from an amine hydrochloride on the resin affording an amide in the liquid phase. All the acidic by-products, hydrochloric acid, *p*-chlorobenzenesulfonic acid, 6-chloro-1-hydroxybenzotriazole, and unreacted carboxyl components will be retained on the resin enabling separation of the products. A mixture of an equimolar amount of **6**, the hydrochloride of **7**, **4v**, and 3 equivalents of the resin (Dowex MWA-1) in dichloromethane or chloroform was allowed to stand for 72 h with occasional stirring. The thin layer chromatogram of the liquid phase showed the presence of a large amount of **5** and trace amounts of impurities. Pure **5** was easily obtained by evaporation of the solvent and the recrystallization of the crude product. The results obtained are summarized at the bottom of Table 7.

A possible side reaction, which may occur due to the use of the sulfonates only in procedure B but not in procedure A, is sulfonamide formation from the sulfonates and the amine components. In practice the sulfonamide formation is so slow that it is not detectable in most cases. For instance, a mixture of equimolar amounts of **7** and **4a** in chloroform showed no sulfonamide formation at room temperature unless

a) The mixture was allowed to react for 24 h. b) Ethyl 2-(hydroxyimino)-2-cyanoacetate (1.2 equivalent). c) 6-Chloro-1-hydroxybenzotriazole (1.2 equivalent). d) Z-Phe-Ile-OH, **4v**, and *N*-methylmorpholine in DMF were allowed to react for 15 min before the addition of a solution of benzyl L-prolinate hydrochloride and *N*-methylmorpholine in DMF. e) Z-Phe-Ile-OH was allowed to react with **4v** for 1.5 h before the addition of benzyl L-prolinate solution.

triethylamine was added. The only exception was when 2-[3,5-bis(benzyloxy)phenyl]ethylamine (**9**) was acylated with **8** by the use of the arenesulfonates of 1-hydroxybenzotriazoles and triethylamine in dichloromethane. For example, the 41% yield of *N*-(*p*-chlorophenylsulfonyl)-2-[3,5-bis(benzyloxy)phenyl]ethylamine (**10**), accompanied by the 33% yield of *N*-(*N*-benzyloxycarbonyl-L-phenylalanyl)-2-[3,5-bis(benzyloxy)phenyl]ethylamine (**11**) was obtained in the acylation of **9** with **8** using **4v**. On the other hand, the alkanesulfonates of 1-hydroxybenzotriazole such as **4a** or 6-chloro-1-(methylsulfonyloxy)benzotriazole (**4p**) produced far less sulfonamide (**10**) than **4v** did. The use of *N*-methylmorpholine or pyridine in the place of triethylamine greatly assisted the suppression of sulfonamide formation even when **4v** was used. The isolation of pure **11** in high yield posed no practical problems. The effect of weaker bases may be due to the selective activation of the carboxyl group of **8** prior to the gradual liberation of free **9** from the hydrochloride.

To elucidate the reaction path of amide formation, **4a** was treated with a mixture of either thioacetic *S*-acid and triethylamine, or thioacetic *S*-acid, aniline and triethylamine. In the former case 1-acetoxybenzotriazole[21] (**13**) was obtained in 85% yield, and in the latter, acetanilide and 1-hydroxybenzotriazole (**2b**) were obtained in 89 and 88.7% yields, respectively. These results suggest that the thioacetate anion, carboxylate anion alike, attacks the sulfur atom of the sulfonate first, forming thioacetic methanesulfonic anhydride. The mixed anhydride may directly be aminolyzed with aniline affording acetanilide and **2b**, or be converted to **13**, which is subsequently aminolyzed to acetanilide or isolated in the absence of aniline.

The active intermediate in procedure A is doubtlessly 1-acyloxybenzotriazole, but specification of the intermediate in procedure B remains difficult. As described before the active ester formation is completed within 1 h, whereas the coupling reaction in procedure B requires 6 to 8 h under the same conditions unless the mixture is neutralized periodically. This suggests that a substantial portion of amides can be produced through 1-acyloxybenzotriazole, which is also a possible active intermediate of recently reported reagents, tris(dimethylamino)(1-benzotriazolyloxy)phosphonium hexafluorophosphonate[22] and tris(dimethylamino)(1-benzotriazolyloxy)phosphonium tetrafluoroborate.[23] The reaction mechanism of **4v** and related compounds in coupling reaction has been discussed in detail by Horiki and Murakami.[24]

The tendency toward racemization of **4v** was compared with those of DCC, 1-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) and diphenoxyphosphinyl azide (DPPA).[26] The racemization test was conducted using a modification of Bodanszky's method reported

by Fujino *et al.*[27] Coupling of *N*-benzyloxycarbonyl-L-phenylalanyl-L-isoleucine (**14**) with benzyl L-prolinate (**15**) or **7** was carried out mainly in *N,N*-dimethylformamide, in which significant racemization occurs. The contents of D-alloisoleucine (**16**) in the protected tripeptide preparations were determined by subjecting the hydrolyzates to amino acid analysis. The results obtained are summarized in Table 8. As Fujino *et al.*[27] have reported, severe racemization in the coupling of **14** with **15** in DCC method, **15** caused markedly more racemization than the other amino acid esters did. DCC produced 43.3% of **16**, which was suppressed to 17.7% by the addition of **2a**. **4v** and EEDQ showed the same extent of racemization, giving 23.9 and 24.0% of **16**, respectively. The use of **2a** with **4v** lowered the formation of **16** to 11.3%, but the use of 6-chloro-1-hydroxybenzotriazole, which was an effective additive in DCC method and a component of **4v**, was not so effective. DPPA which is said to proceed the coupling reaction through carboxylic azide formation gave 16.3% of **16**. The use of pyridine in place of *N*-methylmorpholine gave more satisfactory results in racemization suppression, although it usually required a longer reaction time. An unexpected result was that severe racemization comparable to DCC method was observed in procedure A, but was again suppressed with **2a** to 14.4%.

The conditions employed are suitable only for the detection of racemization, but not for practical coupling. Reactions need to be carried out using weak bases and amine components whose *N*-terminal amino acid residue is other than proline at low temperature. These results suggest that **4v** is a much superior reagent than DCC in racemization, especially when it is used with **2a**.

Experimental

Melting points were measured on a Hoover "Uni-Melt" apparatus and are uncorrected. The optical rotations were determined with a JEOLCO Model DIP-4.

Materials. Commercially available methane-, 1-butane-, benzene-, *p*-toluene-, *p*-chlorobenzene-, *p*-nitrobenzene- and 2,4,6-trimethylbenzenesulfonyl chlorides, *N*-hydroxysuccinimide, and 3-hydroxy-1,2,3-benzotriazin-4-one were used for the preparation of the sulfonates of *N*-hydroxy compounds. Phenylmethane-,[28] *dl*-10-camphor-,[29] β-styrene-,[30] and 3-pyridinesulfonyl chloride,[31] ethyl 2-hydroxyimino-2-cyanoacetate,[32] 2-hydroxyimino-2-cyanoacetamide,[32] 1-hydroxybenzotriazole,[33] 6-chloro-1-hydroxybenzotriazole,[34] and 6-nitro-1-hydroxybenzotriazole[35] were prepared according to the literature.

4-Chloro-1-hydroxybenzotriazole. A mixture of 2,3-dichloronitrobenzene (25 g, 0.13 mol) and hydrazine hydrate (19.5 g, 0.39 mol) in 99% ethanol (40 ml) was refluxed for 24 h. After removal of the solvent *in vacuo*, the residue was dissolved in 10% sodium carbonate solution. The solution was washed with ether and acidified with concentrated hydrochloric acid to precipitate the product, which was washed with water on a filter and dried; 20.6 g (93.4%); mp 160—166 °C. A part of the product was recrystallized from methanol (MeOH); mp 170—172 °C.

Found: C, 42.74; H, 2.27; N, 24.89%. Calcd for $C_6H_4ON_3Cl$: C, 42.50; H, 2.38; N, 24.80%.

*1-(Phenylsulfonyloxy)benzotriazole (**4e**). General Procedure for the Preparation of the Sulfonates of* N*-Hydroxy Compounds*: To a solution of 1-hydroxybenzotriazole (6.6 g, 0.049 mol) in 1 M-sodium hydroxyide solution (49 ml) was added dropwise benzenesulfonyl chloride (8.8 g, 0.05 mol) with stirring under ice-cooling. After stirring for 1 h, the product was extracted with ethyl acetate (EtOAc), and the extract was washed with water and dried over magnesium sulfate. Evaporation of the solvent *in vacuo* gave a residue, which was triturated in hexane and filtered to give 11.5 g (85.2%) of **4e**; mp 83—84 °C.

Found: C, 52.30; H, 3.09; N, 15.13%. Calcd for $C_{12}H_9O_3N_3S$: C, 52.35; H, 3.30; N, 15.27%.

Other sulfonates were prepared by similar procedures under conditions cited in Tables 1 and 2. Triethylamine (TEA) was used in place of sodium hydroxide when organic solvents were employed.

*1-(*N*-Benzyloxycarbonyl-*L*-phenylalanyloxy)benzotriazole. General Procedure for the Preparation of the Active Esters*: To an ice-cooled solution of *N*-benzyloxycarbonyl-L-phenylalanine (1.50 g, 5 mmol) and TEA (0.70 ml, 5 mmol) in EtOAc (15 ml) was added 1-(methylsulfonyloxy)benzotriazole (1.1 g, 5 mmol). The mixture was stirred for 1 h and allowed to stand overnight. After the addition of EtOAc and water, the organic layer was washed with water and dried over magnesium sulfate. Evaporation of the solvent and subsequent trituration of the residue with ether gave the product; mp 120—125 °C; 1.3 g (62%). IR (Nujol, cm^{-1}) 3330, 1735, 1690.

General Procedures for the Coupling of Amino and Carboxyl Components. Procedure A: To a solution of *N*-benzyloxycarbonyl-L-glutamine (1.40 g, 5 mmol) and TEA (0.70 ml, 5 mmol) in dry acetonitrile (MeCN)(10 ml) was added 1-(butylsulfonyloxy)-6-chlorobenzotriazole (1.47 g, 5 mmol) at room temperature. The mixture solidified immediately. On standing for 30 min, a solution of benzyl L-tyrosinate *p*-toluenesulfonate (2.20 g, 5 mmol) and TEA (0.70 ml, 5 mmol) in dry MeCN(20 ml) was added to the mixture with stirring. The reaction mixture was allowed to react for a total of 18 h, and clarified by the addition of water. After evaporation of MeCN *in vacuo* the residue was extracted with EtOAc. The extract was washed with water, 1 M hydrochloric acid, water, 5% sodium hydrogencarbonate solution, and water, dried over magnesium sulfate, and concentarted to dryness *in vacuo*. Recrystallization of the residue from MeOH gave 1.92 g (71.8%) of benzyl *N*-benzyloxycarbonyl-L-glutaminyl-L-tyrosinate; mp 173—174 °C (lit,[11] mp 174—175 °C).

Procedure B: To an ice-cooled solution of *N*-benzyloxycarbonyl-L-proline (1.25 g, 5 mmol), methyl L-serinate hydrochloride (0.78 g, 5 mmol) and TEA (1.40 ml, 10 mmol) in dry chloroform ($CHCl_3$)(20 ml) was added 1-(phenylsulfonyloxy)-6-chlorobenzotriazole (**4t**) (1.50 g, 5 mmol). The mixture was stirred for 1 h at room temperature and allowed to stand for a further 17 h. After the addition of EtOAc and water the organic layer was worked-up in the usual manner and concentrated to dryness *in vacuo*. The residue was triturated with a mixture of ether and petroleum ether, filtered, and recrystallized from EtOAc/petroleum ether to give 1.5 g (85.7%) of methyl *N*-benzyloxycarbonyl-L-prolyl-L-serinate; mp 97—100 °C (lit,[15] mp 103—104 °C).

Other protected peptides prepared by the procedures A and B are listed in Tables 6 and 7.

N-t-*Butoxycarbonyl-*L*-prolylglycine.* A solution of *N*-*t*-butoxycarbonyl-L-proline (1.08 g, 5 mmol), glycine (0.375 g, 5 mmol) and *N*-methylmorpholine (NMM)(0.60 ml) in water (7.5 ml) was adjusted to pH 7.0 by the addition of a

small amount of 1-hydroxybenzotriazole. A solution of 6-chloro-1-(*p*-chlorophenylsulfonyloxy)benzotriazole (**4v**) (1.72 g, 5 mmol) in dioxane (14 ml) was added to the solution described above under ice-cooling and the whole mixture stirred for 2.5 h at room temperature. After evaporation of dioxane *in vacuo*, the residue was dissolved in water, washed with EtOAc, acidified to pH 2 and extracted with EtOAc. The extract was washed with water, dried over magnesium sulfate and concentrated to dryness. The residue was dissolved in $CHCl_3$ and adsorbed on a silica gel column (Merck Kieselgel 60, 40 g). The column was eluted with 5% MeOH-containing $CHCl_3$ (150 ml) and then with 10% MeOH-containing $CHCl_3$ (200 ml). Evaporation of the second eluate gave the product (302 mg), which was recrystallized from $CHCl_3$ and petroleunm ether,; 225 mg (16.5%); 165—167 °C (dec).

Found: C, 52.88; H, 7.42; N, 10.33%. Calcd for $C_{12}H_{20}O_5N_2$: C, 52.93; H, 7.40; N, 10.29%.

The Coupling Reaction of N-*Benzyloxycarbonyl-*L-*proline with Ethyl* L-*Leucinate Using* **4v** *and the Macropolous Ion Exchanger.* To an ice-cooled mixture of *N*-benzyloxycarbonyl-L-proline (1.25 g, 5 mmol), ethyl L-leucinate hydrochloride (1.00 g, 5 mmol) and Dowex MWA-1 ion exchange resin (3.8 g, ≈15 mmol, dried over phosphorus pentoxide in a vacuum desiccator for 24 h) in dichloromethane (CH_2Cl_2) (20 ml) was added **4v** (1.72 g, 5 mmol) with occasional stirring. The mixture was allowed to react for 72 h with occasional stirring, and was then filtered. The resin was extracted five times with a small amount of CH_2Cl_2. The filtrate and the extracts were combined and evaporated to dryness, and the residue triturated with a small amount of hexane and filtrered; 1.676 g (85.8%); mp 65—67 °C.

N-(N-*Benzyloxycarbonyl-*L-*phenylalanyl)-2-[3,5-bis(benzyloxy)-phenyl]ethylamine (**11**) and* N-(p-*chlorophenylsulfonyl)-2-[3,5-bis(benzyloxy)phenyl]ethylamine (**10**).* To a mixture of *N*-benzyloxycarbonyl-L-phenylalanine (2. 99 g, 10 mmol), 2-[3,5-bis(benzyloxy)phenyl]ethylamine hydrochloride (3.69 g, 10 mmol) and TEA (2.80 ml, 20 mmol) in CH_2Cl_2 (25 ml) was added a solution of **4v** (3.44 g, 10 mmol) in CH_2Cl_2 (15 ml) under ice-cooling. After stirring at room temperature for 5.5 h, water and EtOAc were added to the reaction mixture which was subsequently filtered to remove insoluble material; mp 144—152 °C; 2.1 g. Recrystallization from MeOH gave pure **11**; mp 153—154.5 °C; 2.0 g (32. 6%).

Found: C, 75.88; H, 6.15; N, 4.56%. Calcd for $C_{39}H_{38}O_5N_2$: C, 76.20; H, 6.23: N, 4.56%.

The filtrate was concentrated to dryness and the residue (3.0 g) was recrystallized from MeOH to give **10**; mp 102—103.5 °C; 2.1 g (41.3%).

Found: C, 65.96; H, 5.05; N, 2.80; S, 6.58; Cl, 6.96%. Calcd for $C_{28}H_{26}NO_4SCl$: C, 66.19; H, 5.16; N, 2.76; S, 6.31; Cl, 6.98%.

11 was prepared in 73.0% yield by following procedure A in MeCN.

*The Reaction of 1-(Methylsulfonyloxy)benzotriazole (**4a**) with Thioacetic* S-*Acid.* To a mixture of thioacetic *S*-acid (0.36 ml) and TEA (0.70 ml) in CH_2Cl_2 (10 ml) was added **4a** (1.07 g) under ice-cooling. The mixture was stirred for 1 h and allowed to stand overnight. Water and EtOAc were added to the mixture and the organic layer separating out was washed with 1 M sodium hydrogencarbonate solution, water, 1 M hydrochloric acid and water, dried over magnesium sulfate and evaporated to dryness. The residue was triturated with an ether–petroleum ether mixture and recrystallized from the same solvents; mp 82—100 °C; 0.6 g. The product was identical with the one obtained from the reaction between acetyl chloride and 1-hydroxybenzotriazole or from **4a** and acetic acid.

*The Reaction of **4a** with Thioacetic* S-*Acid and Aniline.* The same reaction described above was carried out in the presence of an equimolar amount of aniline (0.5 g). After the addition of water and EtOAc, the organic layer was washed with 1 M sodium hydrogencarbonate, water, 1 M hydrochloric acid, and water, dried over magnesium sulfate and evaporated *in vacuo*. The residue was triturated with petroleum ether and filtered to give acetanilide; 0.60 g; mp 110—112 °C. The 1 M sodium hydrogencarbonate washing was acidified with hydrochloric acid, and extracted with 10% dioxane-containing EtOAc. The extract was washed with water, dried over magnesium sulfate and concentrated *in vacuo*. The residue was triturated with petroleum ether and filtered to give 1-hydroxybenzotriazole; 0.6 g (88.7%); mp 151—154.5 °C.

Modified Bodanszky's Test.[27] A typical example is as follows: To a solution of benzyl L-prolinate hydrochloride (241.7 mg, 1 mmol), *N*-benzyloxycarbonyl-L-phenylalanyl-L-isoleucinate (394.5 mg, 1 mmol), ethyl 2-hydroxyimino-2-cyanoacetate (170.5 mg, 1.2 mmol) and NMM (0.22 ml, 2 mmol) in dry *N,N*-dimethylformamide (5.0 ml) was added **4v** (344.2 mg, 1 mmol) under ice-cooling. The mixture was stirred for 3 h at 0—5 °C. After evaporation of the *N,N*-dimethylformamide under nitrogen, the residue was extracted with EtOAc. The extract was washed with water, 1 M sodium hydrogencarbonate (4 times), water, 1 M hydrochloric acid and water, dried over magnesium sulfate and concentrated to dryness. A part of the residue was hydrolyzed by 6 M hydrochloric acid at 105 °C in a sealed tube for 16 h. The hydrolyzate was subjected to amino acid analysis to determine the D-alloisoleucine content. Reaction conditions and the results are given in Table 8.

The authors wish to express their deep gratitude to Professor Nobuo Izumiya of Kyushu University and Dr. Shumpei Sakakibara, Director of the Peptide Institute, Protein Research Foundation, for their kind advice and encouragement.

Hydrogenation and Hydrogenolysis. XVI.[1] The Reactions of Two Isomeric Enol Ethers of 3-Methylcyclohexanone over Platinum Group Metals

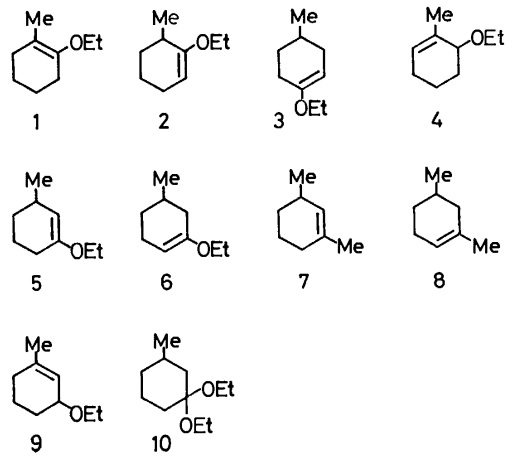
Shigeo NISHIMURA,* Kunihiro KAGAWA, and Nobuo SATO

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

(Received April 8, 1978)

The two isomeric enol ethers of 3-methylcyclohexanone, 1-ethoxy-3-methyl-, and 1-ethoxy-5-methylcyclohexenes (**5** and **6**), have been hydrogenated in ethanol with six platinum group metals as catalysts. Palladium, rhodium, and platinum efficiently catalyzed the addition of ethanol to the enol ethers to give the corresponding acetal, while iridium and ruthenium catalyzed it only slightly. Osmium was moderately active for the acetal formation. Extensive isomerization between **5** and **6** occurred over all catalysts. In addition, isomerization to an allyl ether, 3-ethoxy-1-methylcyclohexene (**9**), was observed with **5** over the metals other than palladium. Hydrogenation of **5** and **6** with palladium gave the *trans*-ether predominantly. With the other metals, the *cis*-ether was formed in large excess from **5** and the *trans*-ether in slight excess from **6** at the initial stage of hydrogenation. Hydrogenolysis of the ethoxyl group occurred extensively over platinum but only slightly with palladium and ruthenium. These results are compared with those obtained with the corresponding dimethylcyclohexenes and allyl ether **9**.

Previously we have studied the hydrogenation of the enol ethers of 2- and 4-methylcyclohexanone **1**, **2**, and **3** with platinum group metals as catalysts.[2,3] Hydrogenation of **3** in ethanol was accompanied by formation of the corresponding acetal which depended on the catalyst metal employed. Palladium, platinum, and rhodium catalyzed the acetal formation efficiently, while ruthenium, osmium, and iridium were only poor catalysts for this reaction. Hydrogenolysis of the ethoxyl group occurred extensively over platinum, while it was very slight with palladium and ruthenium. The order of activity of the platinum metals toward hydrogenolysis has been explained in terms of the activity of ionized adsorbed hydrogen on the catalyst surface which was estimated by the activity for the acetal formation and of the strength of olefin adsorption which was assumed to increase with decreasing activity for olefin isomerization. With palladium enol ethers **1**, **2**, and **3** all gave saturated *cis*-ethers with high stereoselectivity. This stereochemistry of hydrogenation has been explained on the basis of the selective formation of the half-hydrogenated states with the adsorption bond at the carbon bearing the ethoxyl group, together with the assumption that the product-controlling step is formation of the saturated ethers. Selective formation of such half-hydrogenated states has been supported by the fact that isomerization of enol ether **1** occurred extensively to the isomeric enol ether **2** but not to an isomeric allyl ether **4**.[3]



This paper reports the hydrogenation of the two isomeric enol ethers of 3-methylcyclohexanone, 1-ethoxy-3-methyl- and 1-ethoxy-5-methylcyclohexenes (**5** and **6**) that has been studied in ethanol with six platinum group metals as catalysts. Since the enol ethers were extensively isomerized to each other during hydrogenation, characteristic behaviors of **5** and **6** were observable only at the initial stage of hydrogenation. For this reason, the selectivities of platinum metals for acetal formation, isomerization, stereochemistry of hydrogenation and hydrogenolysis are discussed on the results at the initial stage of hydrogenation which were obtained by extrapolation. Further, the results have been compared with those obtained with the corresponding dimethylcyclohexenes **7** and **8** for isomerization and stereochemistry of hydrogenation and also with those on an isomeric allyl ether **9** with respect to hydrogenolysis.

Experimental

*1-Ethoxy-3-methyl- and 1-Ethoxy-5-methylcyclohexenes (**5** and **6**).* A mixture of **5** and **6** was prepared by heating 3-methylcyclohexanone diethyl acetal with a catalytic amount of ammonium dihydrogenphosphate.[4] Bp 171.5—172.5 °C. Pure **5** and **6** were obtained by purification on a preparative GLPC employing a column of PEG 20M. Enol ether **5**: n_D^{25} 1.4533; ^{1}H NMR (60 MHz, CCl_4), δ=0.93 (d, 3H, >CHC$\underline{H}_3$), 1.19 (t, 3H, OCH$_2$C$\underline{H}_3$), 1.33—2.33 (m, 7H, saturated ring protons), 3,52 (q, 2H, OC$\underline{H}_2$CH$_3$) and 4.27 ppm (d, 1H, olefinic proton). Enol ether **6**: n_D^{25} 1.4514; ^{1}H NMR (60 MHz, CCl_4), δ=0.93 (d, 3H, >CHC$\underline{H}_3$), 1.19 (t, 3H, OCH$_2$OC$\underline{H}_3$), 1.33—2.33 (m, 7H, saturated ring protons), 3.52 (q, 2H, OC$\underline{H}_2$CH$_3$) and 4.38 ppm (t, 1H, olefinic proton). The structures of **5** and **6** were determined from their NMR specta: the olefinic proton of **5** showed a doublet at a higher field (4.27 ppm) while that of **6** gave a triplet at a lower field (4.38 ppm). The structures thus assigned were supported by the occurrence of the isomerization of **5** to the allyl ether **9** and its absence with **6** during hydrogenation, and also by the similarities in stereochemistry of hydrogenation of **5** and **6** to the corresponding dimethylcyclohexenes **7** and **8**, respectively, as observed over the metals of low isomerization (Ru, Os,

Ir, Pt) (see Table 3).

1,3- and 1,5-Dimethylcyclohexenes (7 and 8). **8** was obtained by purification on a preparative GLPC of a mixture of **7** and **8** prepared by dehydrating 1,3-dimethylcyclohexanol with iodine.[5] **7** was prepared by pyrolysis of 2,6-dimethylcyclohexanol acetate at 400 °C[6] followed by purification on a preparative GLPC.

3-Ethoxy-1-methylcyclohexene (9). This is a known compound and was prepared by the method of Spangler and Hennis[7] followed by purification on a preparative GLPC.

All the compounds described above were obtained in greater than 99% purity by GLPC analysis.

Solvent. S. S. G. ethanol of Wako Pure Chemical Industries was dehydrated by refluxing with sodium metal and diethyl phthalate.[8]

Catalysts. All the catalysts used in this study were unsupported metals and prepared by reducing the corresponding metal hydroxides (Ru, Rh, Pd, Ir, Pt) or oxide (Os) with hydrogen in water at atmospheric or high pressure.[2,9] Great care was taken to remove traces of alkaline or acidic substances with repeated reductions and washings.[9]

Hydrogenations. All hydrogenations were carried out in a small glass bottle at 25 °C and atmospheric pressure. A high purity hydrogen gas (Nippon Sanso Co.) was used without further purification. The catalyst (1.5—4 mg) was shaken with hydrogen in ethanol (2 ml) for the time which differed with the catalyst metal used (15—20 min for Pd, Pt, and Rh; 1 h for Ir and Os; 2 h for Ru), and then the substance to be hydrogenated (0.04 ml) was added with a microsyringe through a silicone rubber stopper.

Product Analysis. The reaction mixture was taken into a microsyringe through the silicone rubber stopper during the course of hydrogenation and subjected to GLPC analysis (column: PEG 20 M, programmed at 2°C/min in the temperature range of 50 to 160 °C for the products from **5**, **6**, and **9**; TXP at 60 °C for the products from **7** and **8**). The peaks of *cis*- and *trans*-1-ethoxy-3-methylcyclohexanes were identified by comparison with those of a *cis*-rich sample of the ethers which was obtained by ethylating a *cis*-rich 3-methylcyclohexanol with sodium hydride and ethyl iodide in tetrahydrofuran.[10] The peak at a longer retention time was found to be that of the *cis* isomer. Other peaks were identified by comparison of their retention times with those of authentic samples.

Results and Discussion

In Figs. 1 and 2 are shown the changes in composition of reaction mixture during the course of hydrogenation of enol ethers **5** and **6** in ethanol. All hydrogenations were performed at 25 °C and atmospheric pressure with unsupported metals as catalysts. Although ethanol used as the solvent had been carefully dehydrated, some amounts of a hydrolysis product, 3-methylcyclohexanone, was formed together with the acetal **10** over rhodium and palladium and to a lesser extent over platinum. Since the hydrolysis is considered to be related to the acetal formation,[2,11] the ketone formed is included in the acetal in the figures. Usually hydrogenation of the acetal proceeded very slowly and did not go to completion.

Acetal Formation. As seen in Figs. 1 and 2, the extent of the acetal formation greatly depends on the catalyst metal used and to some extent on the enol ether hydrogenated as well. Table 1 summarizes the ratios of the acetal formed to the enol ether hydrogenated at initial stage of hydrogenation. The tendency of the platinum metals for the acetal formation is consistent in both the enol ethers. Thus palladium, rhodium and platinum are definitely more active for the acetal formation than the other platinum

metals. Iridium and ruthenium cause little or no acetal formation. Osmium is moderately active for this reaction and lies between the two extreme groups of the metals. The acetal formation is very sensitive to the preparations of catalyst metals, and therefore great care was taken to remove traces of alkaline or acidic substances according to the procedures described previously.[9)] The trend of the platinum metals shown in Table 1, however, is in good agreement with that reported previously with enol ether **3** except in a few cases. The acetal formation is an acid-catalyzed reaction and therefore it is considered that the high activity of palladium, rhodium, and platinum results from the presence of ionized hydrogen on the surfaces of these metals, as discussed previously.[2,11)]

Isomerization. As previously shown with enol ethers **1** and **2**, isomeric enol ethers are very liable to isomerization to each other.[3)] Enol ethers **5** and **6** also isomerized extensively to each other as seen in Figs. 1 and 2. In addition, with enol ether **5** the isomerization to an isomeric allyl ether **9** was observed over the metals other than palladium (see Fig. 3), although it was much less extensive than the isomerization to the isomeric enol ether. The isomerization of an enol ether to an allyl ether as observed here could not be detected previously in the hydrogenation of enol ether **1**.[3)] The initial ratios of isomerized product to enol ether hydrogenated are summarized in Table 2. The comparable data obtained with the corresponding cycloolefins **7** and **8** are also included in Table 2. Although the observed isomerization of enol ethers might be decreased by the acetal formation, it is seen that isomerization occurs much more extensively in the enol ethers than in the cycloolefins. With palladium, however, isomerization in the cycloolefins was as much or even more extensive. It is to be noted that isomerization occurs more easily from **5** to **6** than from **6** to **5**. Similar trend is also seen with cycloolefins **7** and **8**. It appears that more isomerization in **5** and **7** than in **6** and **8** may be related to the stereochemistry of hydrogenation of these compounds. As will be described later, with most catalysts both **5** and **7** give much greater amounts of *cis* isomers than **6** and **8**. If isomerization between **5** and **6** or **7** and **8** occurs *via* the

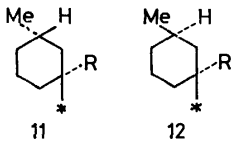
a) Hydrogenation including hydrogenolysis.

common half-hydrogenated states **11** and **12**, the one which will lead to the formation of *cis* isomers on further hydroegnation (**11**) is considered to be more unstable than that which will give rise to *trans* isomers (**12**), as presumed from the conformations shown in Fig. 4. Accordingly, the reversal of the half-hydrogenated states leading to isomerization may be expected to occur more easily in **11** than in **12**. More isomerization in **5** and **7** than in **6** and **8** may be accounted for by considering a more significant contribution of the half-hydrogenated state **11** in **5** and **7**.



R = OEt or Me

The ratio of the isomerizations **5** to **6** and **5** to **9** is informative on the nature of catalyst metals. It increases in the order: Os (3.1)<Ir (8.9)<Ru (12)≪ Rh (42)<Pt (76)<Pd (∞). It is pointed out that the metals which are active for acetal formation (Rh, Pt, Pd) isomerize **5** very selectively to the isomeric enol ether **6**. It is further noted that isomerization to **6** is three times more extensive than isomerization to **9** even over osmium which causes the latter isomerization more extensively than any other metals investigated. The selective isomerization of enol ethers is probably directed by the electron-releasing ethoxyl group which will force to form the half-hydrogenated state with an adsorption bond at the carbon bearing the ethoxyl group. The fact that the selectivity is especially high with platinum and palladium is consistent with the observation by Teratani and Takagi[12,13] that deuteration of 4-*t*-butyl-1-methoxycyclohexene gave the exchanged products with deuterium atoms at C_2 and C_6 but no deuterium at C_3 and C_5 in the cases of platinum and palladium.

Stereochemistry of Hydrogenation. Initial *cis*/*trans* isomer ratios of the saturated ether from hydrogenation of **5** and **6** are shown in Table 3, in comparison with those obtained with the cycloolefins **7** and **8**.

The results with palladium are characteristic in that both **5** and **6** give the *trans*-ether predominantly

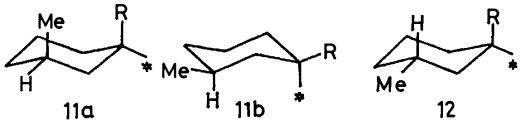

Fig. 4. Conformations of the half-hydrogenated states **11** and **12** (R=OEt or Me).

and, in contrast, the *cis* isomer is formed from both **7** and **8** with high selectivity. Previously it was shown that hydrogenation of the enol ethers **1**, **2**, and **3** with palladium give the *cis*-ethers with high stereoselectivity. The results have been explained on the basis of the preferential formation of the half-hydrogenated states with adsorption bonds at the carbons carrying the ethoxyl group, together with the assumption that the product-controlling step is formation of the saturated ethers. Application of the same explanation to the hydrogenation of enol ethers **5** and **6** expects a predominant formation of the *trans*-ether from both **5** and **6**, since the half-hydrogenated state leading to the *trans*-ether (**12**, R=OEt) will be more stable than that producing the *cis*-ether (**11**, R=OEt). The results shown in Table 3 are in accord with this expectation and may give further support for the explanation made previously for the stereochemistry of hydrogenation of enol ethers **1**, **2**, and **3**.

The predominant formation of the *cis* isomer in the cycloolefins **7** and **8** with palladium is consistent with the results by other investigators.[14] In these cases the stereochemistry of hydrogenation has been explained by assuming that the stability of the half-hydrogenated states decreases with increasing steric requirement at the adsorbed carbon.[14,15]

As in the case of palladium, the selective formation of the half-hydrogenated states **11** and **12** from **5** and **6** may also be considered over the other metals, as has been indicated by the extensive isomerization between **5** and **6**. However, in contrast to palladium, the stereochemistry of hydrogenation is not similar for **5** and **6**. In general the *cis*-ether is formed in large excess from **5** while the *trans*-ether is produced in slight excess from **6**. Further it should be noted that the stereochemistry is very similar for **5** and **7** and for **6** and **8**. These results suggest that the product-controlling step may be the same for the enol ethers and the cycloolefins, probably it being either adsorption of the substrates or formation of half-hydrogenated

a) Proportion of hydrogenolysis in mol % in hydrogenation and hydrogenolysis.

states.[16)] The stereoselective formation of *cis* isomers from **5** and **7** may be a result of a steric interaction between the methyl group at the allylic position and the catalyst surface, because the methyl group is considered to be in a quasi-axial conformation and may increase the addition of hydrogen from the opposite side to the methyl group.[17)] The *cis*/*trans* product ratios from **5** and **6** are rather small in the case of rhodium, although greater than with palladium. This is indicative that the rhodium catalyzed hydrogenation of enol ethers has some aspect similar to the hydrogenation with palladium.

Hydrogenolysis. The hydrogenation of enol ethers is accompanied by the hydrogenolysis of alkoxyl group which depends largely on the catalyst metal and solvent.[2)] The initial amounts of the hydrogenolysis products with **5** and **6** in ethanol are summarized in Table 4, together with the results obtained with an isomeric allyl ether **9** for comparison.

In agreement with the previous results on enol ether **3**,[2)] platinum is definitely more active for the hydrogenolysis than the other platinum metals. On the other hand, palladium and ruthenium show the least tendency toward the hydrogenolysis. Osmium, iridium and rhodium are intermediately active in this reaction. The order of the platinum metals in catalyzing the hydrogenolysis of an enol ether has previously been explained in terms of two factors: the activity of ionized adsorbed hydrogen and the strength of olefin adsorption. The former factor was estimated from the activity of catalyst metal for acetal formation in the presence of adsorbed hydrogen and for the latter it has been assumed that the strength of olefin adsorption increases with decreasing tendency of catalyst metal for olefin isomerization. On the basis of this explanation, the extremely high activity of platinum toward the hydrogenolysis can be accounted for by its high activity for acetal formation and its low activity for olefin isomerization. Only small amounts of hydrogenolysis with palladium is attributed to its extremely high acitivity for olefin isomerization which may surpass its high activity for acetal formation. Differences in the amounts of hydrogenolysis between osmium and iridium might result from their differences in acetal formation activity, rather than in olefin isomerization activity.

The factors that control the hydrogenolysis of an allyl ether appear not the same as in the hydrogenolysis of an enol ether. As seen in Table 4, the metals which are active for the hydrogenolysis of allyl ether **9** (platinum, palladium, and rhodium) are all those which are active for acetal formation (see Table 1). This result suggests that the action of ionized hydrogen may be the most important factor in the hydrogenolysis of an allyl ether. This consideration is also consistent with the fact that the hydrogenolysis of allyl and benzyl ethers is greatly promoted by the presence of acid.[18)]

The authors are grateful to Prof. Hiizu Iwamura of Institute for Molecular Sciences and Dr. Michiko Tsuchimoto of Tokyo University of Agriculture and Technology for the interpretation of the NMR spectra. The authors are also indebted to Mr. Noboru Naito, Mr. Fumitaka Imamura, and Mr. Koji Horii for the experiments with the dimethylcyclohexenes and allyl ether.

3β-Angeloyloxy-10β-hydroxy-9β-senecioyloxyfuranoeremophilane and 3β-Angeloyloxy-10β-hydroxyfuranoeremophilane. New Furanoeremophilane Derivatives from *Farfugium japonicum* Kitamura[1)]

Hajime NAGANO and Takeyoshi TAKAHASHI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received April 22, 1978)

Two new furanoeremophilane derivatives isolated from *Farfugium japonicum* Kitamura have been shown to be 3β-angeloyloxy-10β-hydroxy-9β-senecioyloxyfuranoeremophilane and 3β-angeloyloxy-10β-hydroxyfuranoeremophilane.

In the previous papers[2,3)] we have reported the isolation and structure determination of furanosesquiterpenes from *Farfugium japonicum* Kitamura (= *Ligularia tussilaginea* Makino). Two additional furanoeremophilane derivatives have now been isolated from the same plant. In this paper we wish to present evidence leading to 3β-angeloyloxy-10β-hydroxy-9β-senecioyloxyfuranoeremophilane (**1**) and 3β-angeloyloxy-10β-hydroxyfuranoeremophilane (**2**) for these new sesquiterpenes.

Compound **1**, a viscous oil, was positive to the Ehrlich test. The IR, UV, PMR, and mass spectra (*cf.* Experimental and Table 1) suggest the presence of a β-methyl-substituted furan ring with an α-proton, a tertiary hydroxyl, an angeloyloxyl, and a senecioyloxyl group.[3)] The PMR spectrum also shows the presence of a secondary and a tertiary methyl group. This sesquiterpene (**1**) was converted in five steps into the known acetoxy ketone (**3**) as follows.

Reduction of **1** with lithium aluminium hydride gave a triol (**4**), which was oxidized with active manganese dioxide[4)] in benzene to yield a dihydroxy ketone (**5**). Acetylation of **5** with acetic anhydride in pyridine at room temperature gave a monoacetate (**6**), whose IR spectrum still shows an absorption due to a tertiary hydroxyl group. The tertiary hydroxyl group of **6** was replaced by bromine atom using phosphorus tribromide in dichloromethane[5)] to give an α-bromo ketone (**7**). Debromination of **7** with active zinc dust in acetic acid[6)] afforded an acetoxy ketone (**3**), which was found to be identical (mp, mmp, $[\alpha]_D$, IR, PMR, and mass spectra) including absolute configuration with 3β-acetoxy-9-oxo-10α*H*-furanoeremophilane (**3**) prepared from epieuryopsonol[3,7)] (**8**; 3β-hydroxy-9-oxo-10α*H*-furanoeremophilane). Thus a 9-oxygenated furanoeremophilane skeleton with 3β-hydroxyl or 3β-acyloxyl group was shown for this series of compounds (**1**, **3**—**7**). The absolute configuration at C-3 was further confirmed as *S* by applying the Horeau's method[8)] to **5** (esterification 36%; optical yield (−) 62%).

The 9-oxo structure for both the dihydroxy ketone (**5**) and the monoacetate (**6**) received support from their UV spectra (λ_{max} 283—285 nm, ε 8800—9300).[3,9)] The tertiary hydroxyl group of **6** could only be placed on either C-10 or C-4. As the PMR spectrum of **6** shows the presence of a secondary methyl group (at C-4), this tertiary hydroxyl group must be located on C-10. Therefore, the triol (**4**) should be 3β, 6ξ, 10ξ-trihydroxyfuranoeremophilane. To confirm this result, the triol (**4**) was treated with chromium trioxide in pyridine to give 10ξ-hydroxy-3,9-dioxofuranoeremophilane (**9**); in the PMR spectrum of **9** a doublet due to a secondary methyl group (at C-4) was observed.

Treatment of **1** with ethanolic potassium hydroxide at room temperature gave a partially hydrolyzed compound (**10**). Spectral data of **10** show the presence of a secondary hydroxyl group and the absence of a senecioyloxyl group. Compound **10** is thus a decenecioyl derivative of **1**. In the PMR spectrum of **10** an allylic proton on hydroxyl-bearing carbon atom resonates at δ (C_6D_6) 4.31, while the corresponding allylic proton signal of **1** at δ (C_6D_6) 6.05. This observation shows that the hydroxyl group of **10** and the senecioyloxyl group of **1** are located on C-9. Therefore, **1** must be 3β-angeloyloxy-10ξ-hydroxy-9ξ-senecioyloxyfuranoeremophilane. The configurations at C-9 and at C-10 were determined as follows.

Acetylation of **4** with acetic anhydride in pyridine gave a diacetate (**11**). In the PMR sepctrum of **11** at 25 °C, two broad signals due to $C_{(9)}$–H and $C_{(12)}$–H appear at δ (CS_2) 5.48 and 6.97, respectively. At −40 °C these signals changed into a pair of signals at δ (CS_2) 5.26 (half-band width: $W_{1/2}$=3 Hz) and 6.02 ($W_{1/2}$=5 Hz) and δ (CS_2) 6.96 and 6.86 in a ratio of *ca.* 5:1, respectively; this indicates that **11** has

a) Coupling constants are expressed in Hz. s: singlet, d: doublet, q: quartet, m: multiplet.

a *cis*-AB-ring junction and exists in two interchangeable conformational isomers, so-called "steroid-like" (**11-A**) and "non-steroid-like" (**11-B**) chair-chair conformer.[10] A broad signal ($W_{1/2}$=*ca.* 22 Hz; axial proton) at δ (CS_2) 4.92 assigned to the 3α-proton in **11** suggests that **11** has predominantly the "non-steroid-like" conformation (**11-B**) at −40 °C.

Reduction of **5** with lithium aluminium hydride gave **4** and its C-9 epimer (**12**) in a ratio of 1:1. Acetylation of **12** with acetic anhydride in pyridine afforded a diacetate (**13**). In the PMR spectrum of **13** at 25 °C a broad signal of the C-12 proton was observed at δ (CS_2) 6.93. When the temperature was lowered to −40 °C this signal changed into a pair of signals at δ (CS_2) 6.89 and 6.97 in a ratio of 5:1. The broad signal ($W_{1/2}$=*ca.* 22 Hz) at δ (CS_2) 5.03 due to the C-3 proton indicates that the "non-steroid-like" conformer is the major one. The half-band width (5 Hz) observed for the PMR signal δ (CS_2) 5.52 of C-9 proton in **13** is larger than that (3 Hz) for the signal δ (CS_2) 5.26 of C-9 proton in **11**. This implies that the C-9 proton in **13** has a quasi-axial nature ("non-steroid-like" conformation) and that the C-9 proton in **11** has a quasi-equatorial nature ("non-steroid-like" conformation).[11] Therefore, the acetoxyl group at C-9 of **11** and **13** are in β- and α-configuration, respectively. The structure including absolute configuration of **1** is represented by 3β-angeloyloxy-10β-hydroxy-9β-senecioyloxyfuranoeremophilane.

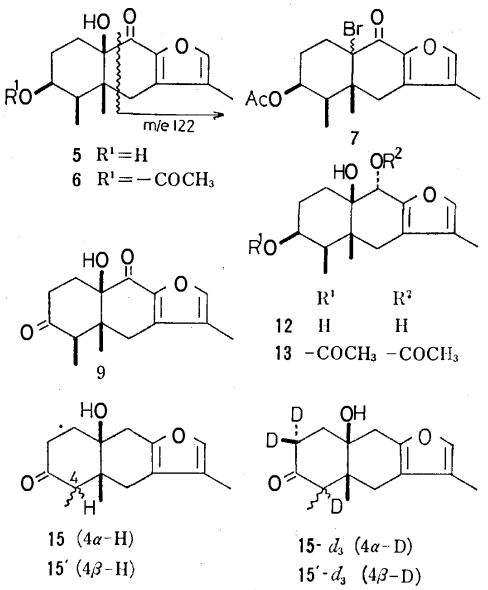
Compound **2** was also positive to the Ehrlich test. From the UV, IR, PMR, and mass spectra **2** is assumed to be the desenecioyloxyl derivative of **1** (*cf.* Experimental and Table 1).

Reduction of **2** with lithium aluminium hydride in ether gave a diol (**14**), which was also obtained by alkaline hydrolysis of **2**.

Oxidation of **14** with chromium trioxide in pyridine gave a hydroxy ketone (**15**). Deuterium-exchange reaction of **15** with CH_3OD in the presence of a trace of alkali afforded a mixture of deuterated products (**15**-d_3 and **15**'-d_3), whose mass spectrum shows an incorporation of three deuterium atoms. A doublet at δ 0.94 due to the secondary methyl in **15** changed into a pair of singlets at δ 0.94 (**15**-d_3) and δ 1.01 (**15**'-d_3). The carbonyl group of **15** and hence the secondary hydroxyl group of **14** could be placed on C-3, provided that these compounds have a furanoeremophilane skeleton.

Carbon skeleton including absolute configuration of the above compounds was determined on the basis of the following transformation. Reduction of **11** with lithium in ethylamine[12] yielded 3β,10β-dihydroxyfuranoeremophilane. Its spectroscopic data (IR, PMR, and mass spectra) are in complete accord with those of **14**. The absolute configuration (*S*) at C-3 in **14** was further confirmed by the Horeau's method[8] (esterification 100%; optical yield (−) 28%). Compounds **2**, **14**, and **15** were thus shown to be 3β-angeloyloxy-10β-hydroxyfuranoeremophilane, 3β,10β-dihydroxyfuranoeremophilane, and 10β-hydroxy-3-oxofuranoeremophilane, respectively.

In further support for the proposed structures, the intense peak at *m/e* 108 due to the *retro*-Diels-Alder fragmentation in ring B[13] was observed for the furanoeremophilane derivatives (**2**, **14**, and **16**), and the corresponding peaks at *m/e* 124, *m/e* 166, and *m/e* 122 for the compounds with 9-hydroxyl (**4** and **10**), 9-acetoxyl (**11** and **13**), and 9-oxo (**3**, **5**, **6**, and **9**) group, respectively.



In the PMR spectra (Table 2) of the hydroxy ketone (**15**), a remarkable pyridine-induced solvent shift[14] ($\delta^{CDCl_3}-\delta^{C_5H_5N}=-0.17$) of the tertiary methyl at C-5 arising from preferential association of pyridine with the hydroxyl group was observed. The carbonyl group at C-3 would cause[15] a small and positive solvent shift of the tertiary methyl signal for both structures

Table 2. Chemical shifts (δ values) and solvent shifts (Δ values) of methyl protons for compounds **15** and **15′-d_3**

Compound	Solvent	$C_{(4)}$-CH_3	$C_{(5)}$-CH_3	$C_{(11)}$-CH_3
15	CCl_4	0.94	0.92	1.87
	C_6H_6	0.94	0.76	1.73
	$\Delta^{CCl_4}_{C_6H_6}$	0.00	+0.16	+0.14
	$CDCl_3$	1.02	0.99	1.95
	C_5H_5N	1.10	1.16	1.92
	$\Delta^{CDCl_3}_{C_5H_5N}$	−0.08	−0.17	+0.03
15′-d_3	CCl_4	1.01	1.04	1.84
	C_6H_6	1.05	0.84	1.63
	$\Delta^{CCl_4}_{C_6H_6}$	−0.04	+0.21	+0.21

$\Delta^{CDCl_3}_{C_5H_5N}=\delta^{CDCl_3}-\delta^{C_5H_5N}$, $\Delta^{CCl_4}_{C_6H_6}=\delta^{CCl_4}-\delta^{C_6H_6}$.

with *cis*- and *trans*-AB-ring junction. The extent of the negative solvent shift value for the tertiary methyl suggests the structure with a *cis*-AB-ring junction for **15**, in which the dihedral angle between the hydroxyl group and the tertiary methyl would be approximately 60°, while a small solvent shift ($\delta^{CDCl_3}-\delta^{C_5H_5N}$ = *ca.* −0.04) is expected for the structure with a *trans*-AB-ring junction. This shows that the solvent shift is applicable for the structure determination of these compounds.

A small benzene-induced solvent shift[16] (Table 2) for the C-4 methyl signal adjacent to carbonyl group was observed in the PMR spectra of **15** and **15′-d_3**; this suggests equatorial nature for the secondary methyl. **15** and **15′-d_3** must exist preferably in a "steroid-like" (**15-A**) and in a "non-steroid-like" (**15′-d_3-B**) conformation, respectively.

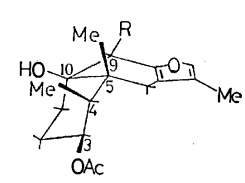
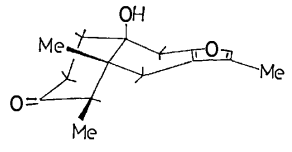
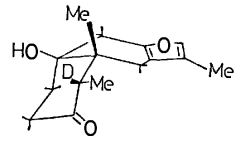
16-A (R=H)



11-B (R=OAc)
16-B (R=H)



15-A



15′-B

Acetylation of **14** with acetic anhydride in pyridine gave a monoacetate (**16**). The PMR spectrum in carbon disulfide at 30 °C showed a signal at δ 5.06 (quintet, J=*ca.* 4 Hz) due to the proton at C-3. As the temperature was lowered the signal broadened and at −46 °C the signal changed into a pair of signals at δ 4.78 (s, $W_{1/2}$ *ca.* 8 Hz) and δ 5.07 (quintet, J=*ca.* 5.5 Hz) in a ratio of 1:3, which are assigned to the C-3α proton (equatorial) in the "steroid-like" conformation (**16-A**) and the C-3α proton (axial) in the "non-steroid-like" conformation (**16-B**), respectively. An equilibrium between the "steroid-like" (**A**) and "non-steroid-like" (**B**) conformations on PMR time scale at room temperature was thus shown for **16**.

Experimental

IR, UV, and mass spectra were measured using a Hitachi EPI-G2, a Hitachi EPS-3, and a Hitachi RMU-6-Tokugata, spectrometers, respectively. Optical rotations, $[\alpha]_D$, were measured with a JASCO DIP-SL spectrometer. PMR spectra were taken on a JEOL PS-100 (100 MHz), a Hitachi R-20 (60 MHz), or a Hitachi R-24 (60 MHz) spectrometer. Chemical shifts are expressed in δ (TMS as an internal standard), and coupling constants in Hz. All melting points were determined on a hot block and reported uncorrected. Merck Kieselgel G and Kieselgel 60 PF_{254} were used for analytical and preparative TLC, respectively. For column chromatography, silica gel (Wakogel C-200) was used.

Isolation of 3β-Angeloyloxy-10β-hydroxy-9β-senecioyloxyfuranoeremophilane (1) and 3β-Angeloyloxy-10β-hydroxyfuranoeremophilane (2). The roots of *Farfugium japonicum* Kitamura (15 kg) were extracted with ether at room temperature for 3 days. The extract was then filtered, dried over anhydrous sodium sulfate, and the solvent was evaporated to give a viscous oil (80 g). The oil (36 g) was chromatographed on silica gel (500 g) using light petroleum–ether (10:1) as eluent. The eluted fractions (each 400 ml) were collected and examined by TLC. Fractions 10 and 11 gave a viscous oil (959 mg), containing **1**, which was purified by preparative TLC. Fractions 15—17 gave a viscous oil (1.06 g). The oil was purified by preparative TLC to afford **2**.

3β-Angeloyloxy-10β-hydroxy-9β-senecioyloxyfuranoeremophilane (1). Compound **1** (one spot on TLC), an oil, $[\alpha]_D^{16}$ +79° (*c* 1.05, EtOH), was positive to the Ehrlich test (pink in color). Characterization of **1** is as follows; UV (MeOH): λ_{max} 220 nm (ε 37000); IR(neat): 3500, 1710, and 1642 cm^{-1}; PMR (Table 1); MS: *m/e* 430 [1%, M^+ ($C_{25}H_{34}O_6$)], 412 (3%, $[M-H_2O]^+$), 83 (100%, $[CH_3CH=C(CH_3)CO]^+$ and $[(CH_3)_2C=CHCO]^+$) and 55 (42%, $[CH_3CH=CCH_3]^+$ and $[(CH_3)_2C=CH]^+$).

3β-Angeloyloxy-10β-hydroxyfuranoeremophilane (2). Compound **2** (one spot on TLC) was a viscous oil, $[\alpha]_D^{24}$ −13° (*c* 0.88, EtOH). Its spot on TLC plate showed purple color to the Ehrlich test. Spectral data of **2** are as follows; UV (MeOH): λ_{max} 218.5 nm (ε 19000); IR (CCl_4): 3500, 1710, 1645, and 1565 cm^{-1}; PMR (Table 1); MS: *m/e* 332 [6%, M^+ ($C_{20}H_{28}O_4$)], 124 (41%), 109 (100%), 108 (75%, *retro*-Diels-Alder fragment[13]), 83 (89%, $[CH_3CH=C(CH_3)CO]^+$), and 55 (64%, $[CH_3CH=CCH_3]^+$).

Reduction of 1 with Lithium Aluminium Hydride. To a suspension of lithium aluminium hydride (100 mg) in dry ether (6 ml) a solution of **1** (125 mg) in dry ether (6 ml) was added and the mixture was refluxed for 2.5 h under a nitrogen atmosphere. An excess of lithium aluminium hydride was decomposed with water and the product was extracted with ether. The usual treatment of the extract gave a crystalline product (86 mg), which was purified by preparative TLC (developed with ether) to afford 3β,9β,10β-trihydroxyfuranocremophilane (**4**: 34 mg), mp 158—159 °C (dec), $[\alpha]_D^{25}$ −5° (*c* 1.0, MeOH); UV (MeOH): λ_{max} 224 nm (ε 4200); IR (Nujol): 3250—3460 cm^{-1}; PMR ($CDCl_3$): δ 1.10 (d, J=6.5 Hz, $C_{(4)}$-CH_3), 1.21 (s, $C_{(5)}$-CH_3), 1.90 (d, J=1.2 Hz, $C_{(11)}$-CH_3), 2.15 (d, J=17 Hz, $C_{(6)}$-H),

2.53 (d, J=17 Hz, $C_{(6)}$-H), 4.02 (m, $C_{(3)}$-H), 4.47 (br s, $C_{(9)}$-H), and 7.12 (q, J=1.2 Hz, $C_{(12)}$-H); MS: *m/e* 124 (100%, *retro*-Diels-Alder fragment). A molecular ion peak at *m/e* 266 ($C_{15}H_{22}O_4$) was not observed. Found: C, 67.74; H, 8.17%. Calcd for $C_{15}H_{22}O_4$: C, 67.84; H, 8.33%.

Oxidation of ***4*** *with Active Manganese Dioxide.* To a solution of **4** (40 mg) in benzene (30 ml) was added active manganese dioxide (70 mg) and the mixture was stirred for 8 h under a nitrogen atmosphere. After filtration, the solvent was removed to give 3β,10β-dihydroxy-9-oxofuranoeremophilane (**5**; 26 mg); negative to the Ehrlich test; mp 138 °C (recrystallized from light petroleum–ether), $[\alpha]_D^{25}$ −18° (c 0.59, MeOH); UV (MeOH): λ_{max} 283 nm (ε 8800); IR (Nujol): 3450, 3340, 1670, 1605, and 1530 cm^{-1}; MS: *m/e* 264 [20%, M^+ ($C_{15}H_{20}O_4$)] and 122 (100%, *retro*-Diels-Alder fragment). Found: C, 68.43; H, 7.56%. Calcd for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63%.

Acetylation of ***5*** *with Acetic Anhydride in Pyridine.* Compound **5** (140 mg) was treated with acetic anhydride (1.5 ml) and pyridine (3 ml) overnight at room temperature. Methanol (2 ml) was added to decompose an excess of acetic anhydride. Evaporation of the solvent gave an oily residue which was chromatographed on silica gel (7 g) using hexane–ether (2:1; 75 ml) as eluent to yield the monoacetate, 3β-acetoxy-10β-hydroxy-9-oxofuranoeremophilane (**6**; 157 mg; one spot on TLC), an amorphous solid, IR (Nujol): 3450, 1735, and 1675 cm^{-1}; PMR (CCl_4): δ 0.98 (s, $C_{(5)}$-CH_3), 1.08 (d, J=*ca.* 7 Hz, $C_{(4)}$-CH_3), 2.00 (s, $C_{(11)}$-CH_3 and -OCOCH_3), 5.20 (m, $C_{(3)}$-H), and 7.37 (br s, $C_{(12)}$-H); MS: *m/e* 306 [6%, M^+ ($C_{17}H_{22}O_5$)], 263 (5%, [M−CH_3-CO]$^+$), 246 (11%, [M−CH_3COOH]$^+$), 124 (66%), 123 (63%), and 122 (100%, *retro*-Diels-Alder fragment).

Treatment of ***6*** *with Phosphorus Tribromide.* To a solution of **6** (73 mg) in dichloromethane (9 ml) was added a solution of phosphorus tribromide (0.1 ml) in dichloromethane (0.9 ml) and the reaction mixture was heated under reflux for 4 h under a nitrogen atmosphere. The reaction mixture was then cooled to 0 °C and a saturated aqueous solution of sodium hydrogencarbonate (5 ml) was added dropwise. The product was extracted three times with ether and a combined ethereal solution was washed with water and with saturated brine, and dried over anhydrous sodium sulfate. Evaporation of the solvent gave an oily product, 3β-acetoxy-10 ξ-bromo-9-oxofuranoeremophilane (**7**; 56 mg; one spot on TLC), IR (neat): 1730 and 1670 cm^{-1}; PMR (CCl_4): δ 1.00 (d, J=*ca.* 7 Hz, $C_{(4)}$-CH_3), 1.11 (s, $C_{(5)}$-CH_3), 1.99 (s, $C_{(11)}$-CH_3 and -OCOCH_3), 4.98 (m, $C_{(3)}$-H, $W_{1/2}$=*ca.* 12 Hz), and 7.34 (m, $C_{(12)}$-H); MS: *m/e* 370 [13%, M^+ ($C_{17}H_{21}O_4Br$)], 368 (13%, M^+), 289 (24%, [M−Br]$^+$), and 229 (100%, [M−Br−CH_3-COOH]$^+$).

Debromination of ***7*** *with Active Zinc Dust in Acetic Acid.* To a solution of **7** (56 mg) in acetic acid (3 ml) was added active zinc dust (107 mg) and the mixture was allowed to stir for 3.5 h at room temperature under a nitrogen atmosphere. Ether was then added. After filtration the solvent was evaporated under reduced pressure to give an oily residue, which was chromatographed on silica gel (7 g). Elution with hexane–ether (2:1, 100 ml) and hexane–ether (1:1, 80 ml) gave colorless crystals (30 mg). Recrystallization from hexane–ether afforded 3β-acetoxy-9-oxo-10α*H*-furanoeremophilane (**3**; 17 mg) as colorless needles, mp 172—174 °C, $[\alpha]_D^{28}$ +27° (c 0.55, MeOH), IR (Nujol): 1720 and 1655 cm^{-1}; PMR ($CDCl_3$): δ 0.98 (s, $C_{(5)}$-CH_3), 1.04 (d, J=*ca.* 7 Hz, $C_{(4)}$-CH_3), 2.00 (d, J=*ca.* 1 Hz, $C_{(11)}$-CH_3), 2.06 (s, -OCOCH_3), 5.01 (m, $C_{(3)}$-H), and 7.37 (m, $C_{(12)}$-H); *m/e* 290 [35%, M^+($C_{17}H_{22}O_4$)], 230 (58%, [M−CH_3COOH]$^+$), 215 (51%, [M−CH_3COOH−CH_3]$^+$), 162 (100%), and 122 (77%, *retro*-Diels-Alder fragment). This compound was found to be identical (mp, mixed mp, IR, PMR, and mass spectra) with **3** prepared from **8** (*vide infra*).

Acetylation of ***8*** *with Acetic Anhydride in Pyridine.* A solution of epieuryopsonol (**8**; 22 mg) in acetic anhydride (2 ml) and pyridine (3 ml) was allowed to stand overnight at room temperature to yield **3**, colorless needles (recrystallization from hexane–ether), mp 173—175 °C, $[\alpha]_D^{28}$ +28° (c 0.53, MeOH), IR (Nujol): 1720 and 1655 cm^{-1}; PMR ($CDCl_3$): δ 0.98 (s, $C_{(5)}$-CH_3), 1.04 (d, J=*ca.* 7 Hz, $C_{(4)}$-CH_3), 2.00 (d, J=*ca.* 1 Hz, $C_{(11)}$-CH_3), 2.06 (s, -OCOCH_3), 5.03 (m, $C_{(3)}$-H)1 and 7.36 (m, $C_{(12)}$-H); MS: *m/e* 290 [32%, M^+($C_{17}H_{22}O_4$)], 230 (54%, [M−CH_3COOH]$^+$), 215 (48%, [M−CH_3COOH−CH_3]$^+$), 162 (100%), and 122 (77%. *retro*-Diels-Alder fragment). Found: C, 70.33; H, 7.90%. Calcd for $C_{17}H_{22}O_4$: C, 70.34; H, 7.64%.

Application of the Horeau's Method to ***5****.* A solution of **5** (20.6 mg, 0.078 mmol) in pyridine (0.3 ml) was allowed to stand with α-phenylbutyric anhydride (85.0 mg, 0.259 mmol) overnight. The reaction mixture was then heated with one drop of water. After benzene was added, the mixture was titrated with 0.1 M potassium hydroxide solution in the presence of phenolphthalein. The aqueous layer was acidified with dilute sulfuric acid and then extracted with benzene. After usual treatment of the extract, the solvent was distilled off to give α-phenylbutyric acid. The optical rotation value (α_D −0.027°) was observed for benzene solution (1.5 ml) of the acid using a 0.1 dm cell. Esterification 36%; optical yield (−) 62%.

Oxidation of ***4*** *with Chromium Trioxide in Pyridine.* To a solution of chromium trioxide (419 mg) in pyridine (6 ml) was added a solution of **4** (193 mg) in pyridine (3 ml) with stirring at 0 °C. The mixture was allowed to stand for 24 h at room temperature under a nitrogen atmosphere, diluted with a mixture of ice and water, and extracted with ether. The extract was washed with water and dried over anhydrous sodium sulfate. The solvent was removed to give a residue (77 mg) which was chromatographed on silica gel (5 g; eluent: light petroleum–ether, 1:1) to give 10β-hydroxy-3,9-dioxofuranoeremophilane (**9**; 25 mg), mp 121—122 °C (recrystallization from light petroleum–ether); UV (EtOH): λ_{max} 285 nm (ε 9300); IR (Nujol): 3430, 1700, 1655, and 1530 cm^{-1}; PMR ($CDCl_3$): δ 1.05 (s, $C_{(5)}$-CH_3), 1.33 (d, J=7.5 Hz, $C_{(4)}$-CH_3), 1.97 (d, J=1 Hz, $C_{(11)}$-CH_3), 3.73 (s, OH; this signal disappeared on addition of D_2O), and 7.48 (q, J=1 Hz, $C_{(12)}$-H); MS: *m/e* 262 [34%, M^+($C_{15}H_{18}O_4$)], 178 (41%), and 122 (100%, *retro*-Diels-Alder fragment). Found: C, 68.57; H, 6.85%. Calcd for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92%.

Partial Hydrolysis of ***1*** *with Ethanolic Potassium Hydroxide.* A solution of potassium hydroxide (50 mg) in 95% ethanol (1 ml) was added to **1** (33 mg), and the solution was allowed to stand at room temperature for 3 h. To the reaction mixture was added water (10 ml), and the resulting aqueous solution was extracted with ether (each 30 ml) three times. A combined ethereal solution was washed with 10% hydrochloric acid (10 ml), saturated aqueous solution of sodium hydrogencarbonate (10 ml), and with water (20 ml), and finally dried over anhydrous sodium sulfate. Evaporation of the solvent gave a residue (23 mg), which was passed through a column of silica gel (200 mg) (eluent: light petroleum–ether, 2:1) to give partially hydrolyzed product (**10**; one spot on TLC), a viscous oil; IR (neat): 3450, 1710, 1640, and 1560 cm^{-1}; PMR (C_6D_6): δ 1.10 (m, $C_{(4)}$-CH_3), 1.17 (s, $C_{(5)}$-CH_3), 1.73 (d, J=*ca.* 1 Hz, $C_{(11)}$-CH_3), 1.95

(m, $-COC(CH_3)=CHCH_3$), 2.05 (d, $J=7$ Hz, $-COC(CH_3)=CHCH_3$), 4.31 (br s, $C_{(9)}$-H), 5.30 (m, $C_{(3)}$-H), 5.80 (q, $J=7$ Hz, $-CO(CH_3)C=CHCH_3$), and 7.05 (m, $C_{(12)}$-H); MS: *m/e* 348 [0.8%, M^+ ($C_{20}H_{28}O_5$)]. 330 (0.6%, [$M-H_2O$]$^+$), 124 (100%, *retro*-Diels-Alder fragment), 83 (20%, [$COC(CH_3)=CHCH_3$]$^+$), and 55 (21 %, [$C(CH_3)=CHCH_3$]$^+$).

Acetylation of ***4*** *with Acetic Anhydride in Pyridine.* A mixture of **4** (51 mg), acetic anhydride (0.2 ml), and pyridine (0.5 ml) was allowed to stand overnight at room temperature. After addition of methanol (1 ml), the solvent was removed under reduced pressure to give a residue. From the residue 3*β*, 9*β*-diacetoxy-10*β*-hydroxyfuranoeremophilane (**11**; one spot on TLC), an oil, was isolated by preparative TLC (developed with light petroleum–ether, 1:1). Spectral data of **11** are as follows ; IR (neat): 3480, 1735, and 1560 cm^{-1}; PMR (CCl_4): δ 1.05 (d, $J=7$ Hz, $C_{(4)}$-CH_3), 1.13 (s, $C_{(5)}$-CH_3), 1.92 (d, $J=ca.$ 1 Hz, $C_{(11)}$-CH_3), 2.00 (s, $-OCOCH_3$), 2.10 (s, $-OCOCH_3$), 5.10 (m, $C_{(3)}$-H), 5.65 (m, $C_{(9)}$-H), and 7.08 (q, $J=1$ Hz, $C_{(12)}$-H); PMR (CS_2): δ 0.99 (d, $J=7$ Hz, $C_{(4)}$-CH_3), 1.06 (s, $C_{(5)}$-CH_3), 1.88 (d, $J=ca.$ 1 Hz, $C_{(11)}$-CH_3), 1.91 (s, $-OCOCH_3$), 2.00 (s, $-OCOCH_3$), 4.94(m, $C_{(3)}$-H), 5.48 (m, $C_{(9)}$-H), and 6.97 (q, $J=ca.$ 1 Hz, $C_{(12)}$-H); MS: *m/e* 350 [1%, M^+ ($C_{19}H_{26}O_6$)], 332 (3%, [$M-H_2O$]$^+$), 290 (3%, [$M-CH_3COOH$]$^+$), 230 (4%, [$M-2CH_3COOH$]$^+$), 166 (37%, *retro*-Diels-Alder fragment), 124 (100%), and 43 (36%, [CH_3CO]$^+$).

Reduction of ***5*** *with Lithium Aluminium Hydride.* To a suspension of lithium aluminium hydride (97 mg) in dry ether (3 ml) was added a solution of **5** (52 mg) in dry ether (3 ml) and the mixture was stirred for 3.5 h at room temperature under a nitrogen atmosphere. An excess of lithium aluminium hydride was decomposed by addition of water and the product was extracted with ether. The usual treatment of the extract gave a residue, which was chromatographed on silica gel (300 mg) using ether as eluent to afford 3*β*,9*β*,10*β*-trihydroxyfuranoeremophilane (**4**; 21 mg) and 3*β*,9*α*,10*β*-trihydroxyfuranoeremophilane (**12**; 27 mg). The latter compound (**12**) showed a higher R_f value than that of **4** on TLC (silica gel) developed with ether. The separated compound (**12**) without further purification was used for acetylation.

Acetylation of ***12*** *with Acetic Anhydride in Pyridine.* A solution of **12** (27 mg), acetic anhydride (0.2 ml), and pyridine (0.5 ml) was allowed to stand overnight at room temperature. After addition of methanol (1 ml), the solvent was removed under reduced pressure. The residual oil was subjected to separation by preparative TLC (developed with light petroleum–ether, 3:5) to give 3*β*,9*α*-diacetoxy-10*β*-hydroxyfuranoeremophilane (**13**; 18 mg; one spot on TLC), an oil, IR (Nujol): 3460, 1730, and 1560 cm^{-1}; PMR (CCl_4): δ 1.11 (d, $J=7$ Hz, $C_{(4)}$-CH_3), 1.11 (s, $C_{(5)}$-CH_3), 1.92 (d, $J=ca.$ 1 Hz, $C_{(11)}$-CH_3), 2.00 (s, $-OCOCH_3$), 2.19 (s, $-OCOCH_3$), 5.25 (m, $C_{(3)}$-H), 5.70 (m, $C_{(9)}$-H), and 7.05 (q, $J=ca.$ 1 Hz, $C_{(12)}$-H); PMR (CS_2): δ 1.00 (s, $C_{(5)}$-CH_3), 1.04 (d, $J=7$ Hz, $C_{(4)}$-CH_3), 1.86 (d, $J=ca.$ 1 Hz, $C_{(11)}$-CH_3), 1.90 (s, $-OCOCH_3$), 2.07 (s, $-OCOCH_3$), 5.08 (dt, $J=11$ Hz and $J=5$ Hz, $C_{(3)}$-H), 5.54 (s, $C_{(9)}$-H), and 6.93 (q, $J=ca.$ 1 Hz, $C_{(12)}$-H); MS: *m/e* 350 [1%, M^+ ($C_{19}H_{26}O_6$)], 332 (7%, [$M-H_2O$]$^+$), 290 (4 %, [$M-CH_3COOH$]$^+$), 230 (6%, [$M-2CH_3COOH$]$^+$),), 215 (9%), [$M-2CH_3COOH-CH_3$]$^+$), 166 (31%, *retro*-Diels-Alder fragment), 124 (100%), and 43 (71%, [CH_3CO]$^+$).

Alkaline Hydrolysis of ***2****.* A solution of potassium hydroxide (250 mg) in ethanol (5 ml) was added to **2** (37 mg) and the mixture was refluxed for 1 h under a nitrogen atmosphere. After the solvent was distilled off, the residue was recrystallized from ether to give colorless crystals, **14**, mp 153—154 °C (dec). This compound was found to be identical (mp, IR, PMR, and mass spectra) with **14**, obtained from **2** by treatment with lithium aluminium hydride (*vide infra*).

Reduction of ***2*** *with Lithium Aluminium Hydride.* To a suspension of lithium aluminium hydride (210 mg) in dry ether (6 ml), an oil (893 mg) containing **2** as the major component was added and stirred for 4 h at room temperature under a nitrogen atmosphere. An excess of lithium aluminium hydride was decomposed by addition of water and the product was extracted with ether. The ethereal solution was dried over anhydrous sodium sulfate and the solvent was evaporated to give a residue(519 mg), which was chromatographed on silica gel (30 g). Fractions 8—10 eluted with light petroleum–ether (1:1) (each fraction 50 ml) gave a crystalline product (129 mg), which was recrystallized from acetone–diisopropyl ether to afford 3*β*,10*β*-dihydroxyfuranoeremophilane (**14**), mp 151—153 °C, $[\alpha]_D^{21}$ −11° (*c* 1.0, MeOH). Spectral data of **14** are as follows; UV (MeOH): λ_{max} 220 nm (ε 5800); IR (Nujol): 3425, 1655, and 1560 cm^{-1}; PMR ($CDCl_3$): δ 1.10 (d, $J=7$ Hz, $C_{(4)}$-CH_3), 1.14 (s, $C_{(5)}$-CH_3), 1.89 (d, $J=1.5$ Hz, $C_{(11)}$-CH_3), 4.02 (m, $C_{(3)}$-H), and 7.03 (m, $C_{(12)}$-H); MS: *m/e* 250 [14%, M^+ ($C_{15}H_{22}O_3$)], 109 (100%), and 108 (62%, *retro*-Diels-Alder fragment). Found: C, 72.16; H, 8.68%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.68%.

Oxidation of ***14*** *with Chromium Trioxide in Pyridine.* To a solution of chromium trioxide (102 mg) in pyridine (6 ml) was added a solution of **14** (95 mg) in pyridine (2 ml) with stirring at 0 °C. The mixture was allowed to stand at room temperature for 2.5 h under a nitrogen atmosphere, diluted with a mixture of crashed ice and water, and extracted with ether. The extract was washed with water and dried over anhydrous sodium sulfate. The solvent was removed to give a residue (77 mg). From the residue **14** (14 mg) and **15** (47 mg) were separated by preparative TLC (developed with light petroleum–ether, 1 : 4). 10*β*-Hydroxy-3-oxofuranoeremophilane (**15**; one spot on TLC); an oil, $[\alpha]_D^{24}$ +10° (*c* 1.07, MeOH); UV (EtOH): λ_{max}219 nm (ε 4500); IR (neat): 3450, 1700, 1645, and 1560 cm^{-1}; PMR (CCl_4): δ 0.92 (s, $C_{(5)}$-CH_3), 0.94 (d, $J=7$ Hz, $C_{(4)}$-CH_3), 1.87 (d, $J=1.5$ Hz, $C_{(11)}$-CH_3), and 6.96 (m, $C_{(12)}$-H); MS: *m/e* 248 [<5%, M^+ ($C_{15}H_{20}O_3$)] and 108 (100%, *retro*-Diels-Alder fragment).

Deuterium-exchange Reaction of ***15****.* A solution of **15** (25 mg) in CH_3OD (1 ml) was warmed at 70 °C in the presence of a trace of NaOD for 10 h in a sealed tube. The reaction mixture was diluted with water and the extracted with ether. The extract was washed with dilute hydrochloric acid, water, aqueous solution of sodium hydrogencarbonate, and then with water. The ethereal solution was dried over anhydrous sodium sulfate and the solvent was evaporated to give a residue. The residue was submitted once more to deuterium-exchange reaction in a similar manner. The resulting oil was purified by preparative TLC to afford a mixture of **15**-d_3 and **15′**-d_3(1 : 5). This mixture showed one spot on TLC developed with light petroleum–ether (1 : 1). Signals due to **15′**-d_3 in the PMR spectrum of the mixture are as follows; δ (CCl_4) 1.01 (s, $C_{(4)}$-CH_3), 1.04 (s, $C_{(5)}$-CH_3), 1.84 (d, $J=1.5$ Hz, $C_{(11)}$-CH_3), and 6.92 (m, $C_{(12)}$-H). Treatment of the mixture with sodium hydroxide in methanol gave a mixture of **15** and 10*β*-hydroxy-3-oxo-4*βH*-furanoeremophilane (**15′**), whose PMR spectra show a doublet due to the C-4 methyl in **15′** at δ (CCl_4) 1.00 (d, $J=7$ Hz) and δ (C_6H_6) 1.05 (d, $J=7$ Hz).

Reduction of ***11*** *with Lithium in Ethylamine.* To a solution of **11** (123 mg) in ethylamine (10 ml) cooled to −78 °C

was added lithium (80 mg) and the reaction mixture was stirred at this temperature. When the reaction mixture changed to blue in color saturated aqueous solution of ammonium chloride (10 ml) was added. The resulting solution was extracted with ether for three times and a combined ethereal solution was washed with dilute hydrochloric acid, water, and with saturated brine, and dried over anhydrous sodium sulfate. The crude product (65 mg) was chromatographed on silica gel (6 g). Elution with hexane–ether (1:1; 200 ml) yielded 3β,10β-dihydroxyfuranoeremophilane (**14**; 36 mg), mp 152—154 °C (recrystallization from acetone–diisopropyl ether), $[\alpha]_D^{28}$ −9° (*c* 1.3, MeOH), IR (Nujol): 3425 cm^{-1}; PMR ($CDCl_3$): δ 1.10 (d, J=7 Hz, $C_{(4)}$–CH_3), 1.15 (s, $C_{(5)}$–CH_3), 1.90 (d, J=*ca.* 1 Hz, $C_{(11)}$–CH_3), 4.02 (m, $C_{(3)}$–H), and 7.05 (m, $C_{(12)}$–H); MS: *m/e* 250 [10%, M^+ ($C_{15}H_{22}O_3$)], 109 (100%), and 108 (64%, *retro*-Diels-Alder fragment). This compound was found to be identical (mp, $[\alpha]_D$ IR, PMR, and mass spectra) with **14** prepared from **2**.

*Application of the Horeau's Method to **14**.* A solution of **14** (14 mg, 0.056 mmol) in pyridine (0.3 ml) was allowed to stand overnight with α-phenylbutyric anhydride (67.7 mg, 0.218 mmol) at room temperature. The reaction mixture was treated by a similar manner described above. Esterification 100%; optical yield (−) 28% (optical rotation α_D −0.027°, cell length 0.1 dm, benzene solution 1.5 ml).

*Acetylation of **14** with Acetic Anhydride in Pyridine.* A mixture of **14** (22 mg), acetic anhydride (0.5 ml), and pyridine (4 ml) was allowed to stand overnight at room temperature. After addition of methanol the solvent was evaporated under reduced pressure to afford a residue. The residue was passed through a silica gel column (2 g) (light petroleum–ether, 10:1) to give **16** (one spot on TLC), an oil, IR (neat): 3450 and 1735 cm^{-1}; PMR (CS_2 at 30 °C): δ 1.00 (d, J=8 Hz, $C_{(4)}$–CH_3), 1.04 (s, $C_{(5)}$–CH_3), 1.88 (d, J=*ca.* 1 Hz, $C_{(11)}$–CH_3), 1.97 (s, –$OCOCH_3$), 5.06 (quintet, J=4 Hz, $C_{(3)}$–H), and 6.94 (m, $C_{(12)}$–H); MS: *m/e* 292 [7%, M^+ ($C_{17}H_{24}O_4$)], 206 (76%), 109 (80%), 108 (51%, *retro*-Diels-Alder fragment), and 43 (100%, $[CH_3CO]^+$).

Preparation and Diels-Alder Reactions of 3-Substituted 3-Sulfolenes

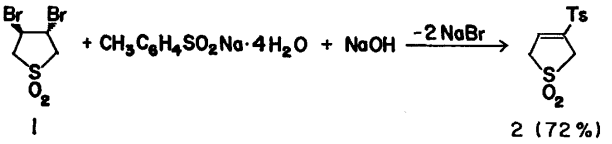
Katsuhiko INOMATA,* Hideki KINOSHITA, Hisayo TAKEMOTO,
Yasue MURATA, and Hiroshi KOTAKE
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received May 10, 1978)

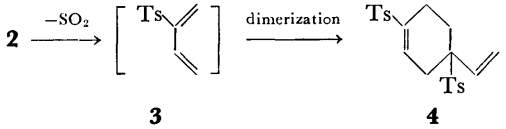
It was found that 3-(*p*-tolylsulfonyl)- and 3-(*p*-tolylsulfinyl)-3-sulfolenes prepared from 3-sulfolene react with various dienophiles to give the corresponding Diels-Alder cycloadducts in good yields, and that only the "para" substituted cycloadducts are obtained with monofunctionalized (CHO, $COCH_3$, CO_2CH_3, CN, and C_6H_5) ethylenes and methyl 2-methylpropenoate, respectively.

Readily available 3-sulfolene (2,5-dihydrothiophene 1,1-dioxide) loses SO_2, giving pure butadiene on heating at 110—130 °C.[1] However, only a few reports have been given on the preparation of substituted dienes starting from 3-sulfolene.[2] In this paper we wish to report on the preparation and the reactions of 3-(*p*-tolylsulfonyl)- and 3-(*p*-tolylsulfinyl)-3-sulfolenes (**2** and **9**) which produce the electron-deficient dienes, 2-(*p*-tolylsulfonyl)- and 2-(*p*-tolylsulfinyl)-1,3-butadienes, respectively.

*Preparation and Reaction of 3-(*p*-Tolylsulfonyl)-3-sulfolene.* 3-(*p*-Tolylsulfonyl)-3-sulfolene (**2**) was readily prepared by the reaction of *trans*-3,4-dibromosulfolane (**1**) obtained by the bromination of 3-sulfolene[3] with sodium *p*-toluenesulfinate tetrahydrate and sodium hydroxide in methanol, in a one-pot substitution-elimination reaction as shown in the following scheme.



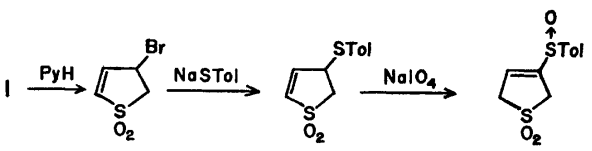
In order to confirm the reaction in which **2** thus obtained produces 2-(*p*-tolylsulfonyl)-1,3-butadiene (**3**) on heating, a solution of **2** in xylene was refluxed for 3 h. Evolution of SO_2 was confirmed by the color change in the universal indicator. However, the final product was not the expected **3** but its dimer **4** (97% yield). The structure of **4** was confirmed by elemental analysis and spectral data including ^{13}C-NMR spectrum of its reduction product. The fact that the dimer **4** was obtained in such an excellent yield indicates that the intermediate **3** is reactive to a dienophile. It was found that the reaction is accelerated by the addition of pyridine to capture SO_2.



Hence the Diels-Alder reaction of **2** with various dienophiles **5a**—**i** was attempted. Since the monofunctionalized ethylenes **5e**—**i** and methyl 2-methylpropenoate (**5d**) are liable to polymerize, the reactions were carried out in the presence of a catalytic amount of hydroquinone and pyridine (as a scavenger of SO_2, equimolar with **2**) in a sealed tube. It was found that the Diels-Alder reaction of **2** with dienophiles **5a**—**i** gives the corresponding cycloadducts **6a**—**i** in excellent yields in all cases except **5b,g** (Table 1).

All the products **6d**—**i** and dimer **4** are "para" substituted cycloadducts. Their structures were confirmed by elemental analyses and spectral data including ^{13}C-NMR spectra of their reduction products, which indicate four peaks assigned to the "para" substituted cyclohexanes. It is evident that the Diels-Alder reaction of **2** with the dienophiles **5d**—**i** proceeds regioselectively. The reaction of **2** with dienophiles **5a**—**c** is stereospecific.

*Preparation and Reaction of 3-(*p*-Tolylsulfinyl)-3-sulfolene.* 3-(*p*-Tolylsulfinyl)-3-sulfolene (**9**) was prepared in three steps from **1** as follows: 4-bromo-2-sulfolene (**7**), prepared from **1** by the procedure of Bailey and Cummins,[3] was reacted with sodium *p*-toluenethiolate to give 4-(*p*-tolylthio)-2-sulfolene (**8**). Oxidation of **8** by sodium periodate gave the desired **9** accompanied by the isomerization of the double bond.



The Diels-Alder reaction of **9** with various dienophiles **5b**—**g** was attempted in a similar manner. It was found that the reaction also proceeds regioselectively to give the corresponding "para" substituted cycloadducts **10d**—**g** (Table 2).

It is apparent that both the Diels-Alder reactions of 3-(*p*-tolylsulfonyl)- and 3-(*p*-tolylsulfinyl)-3-sulfolenes (**2** and **9**) give the corresponding "para" regioisomers in good yields *via* 2-substituted butadienes. These results are in line with those predicted by means of Houk's generalization.[4]

Experimental

All the melting points are uncorrected. The ^{1}H- and ^{13}C-NMR spectra were recorded on JEOL JNM/MH-60 and JEOL PFT/PS-100 NMR spectrometers, respectively. The chemical shifts are reported in the δ scale relative to TMS as an internal standard. The IR spectra were taken with JASCO IRA-1 diffraction grating infrared spectrometer.

Materials. All the solvents were distilled according to the usual methods and stored over a drying agent. Thin-layer chromatography (TLC) was performed on Merck's Kieselgel 60 PF_{254} (Art. 7749) using a mixture of benzene and ethyl acetate as an eluent, unless otherwise stated.

a) A: Refluxed in xylene for 3 h. B: Heated in a sealed tube at 140—150 °C in xylene for 2 h in the presence of catalytic amount of hydroquinone and pyridine (1 equiv). C: Toluene was used in the place of xylene in B at 110—120 °C. b) Based on **2**. c) Initial product subjected to hydrolysis followed by esterification with diazomethane in THF-ether. d) Dimer **4** isolated in 42% yield. e) Dimer **4** isolated in 11% yield. f) Dimer **4** isolated in 32% yield.

*3-(*p*-Tolylsulfonyl)-3-sulfolene (2).* To a methanol solution (300 ml) of sodium hydroxide (1.760 g, 44 mmol) were added sodium *p*-toluenesulfinate tetrahydrate (50 g, 200 mmol) and 3,4-dibromosulfolane (**1**, 11.118 g, 40 mmol).[3] After being refluxed for 5 h, the reaction mixture was poured over ice to give the crude **2** (8.596 g, mp 108—110 °C), which was recrystallized from ethanol (7.848 g, 72%): mp 125—126 °C; IR 1315, 1307, 1298, 1142, 1125 cm^{-1}; NMR ($CDCl_3$) δ 2.44 (s, 3H), 3.84 (m, 2H), 4.02 (m, 2H), 6.98 (m, 1H), 7.34 (d, 2H, J=9 Hz), 7.73 (d, 2H, J=9 Hz). Found: C, 48.63; H, 4.51; S, 23.24%. Calcd for $C_{11}H_{12}O_4S_2$: C, 48.53; H, 4.44; S, 23.51%.

*1,4-Bis(*p*-tolylsulfonyl)-4-vinylcyclohexene (4).* To a xylene solution (6 ml) of **2** (273 mg, 1 mmol) were added pyridine (79 mg, 1 mmol) and a catalytic amount of hydroquinone (*ca.* 5 mg). The mixed solution was heated at 140—150 °C in a sealed tube for 2 h. After addition of ethyl acetate and 1 M HCl, the organic layer was washed with a saturated solution of NaCl, dried over Na_2SO_4, filtered, and evaporated to dryness under reduced pressure. The crystalline residue was separated by preparative TLC to afford **4** (417 mg, mp 166—170 °C) in a nearly quantitative yield. Recrystallization from ethanol gave pure **4** (404 mg, 97%): mp 198—199 °C; IR 1280, 1145 cm^{-1}; NMR ($CDCl_3$) δ 1.7—3.0 (m, 6H), 2.40 (s, 6H), 4.87 (d, 1H, J=17 Hz), 5.23 (d, 1H, J=11 Hz), 5.63 (dd, 1H, J=11 and 17 Hz), 6.90 (m, 1H), 7.25 (m, 4H), 7.59 (d, 4H, J=8 Hz). Found: C, 63.52; H, 5.79; S, 15.35%. Calcd for $C_{22}H_{24}O_4S_2$: C, 63.45; H, 5.81; S, 15.37%.

Dimethyl cis*-4-(*p*-Tolylsulfonyl)-4-cyclohexene-1,2-dicarboxylate (6a).* A suspension of **2** (91 mg, 1/3 mmol) and maleic anhydride (**5a**, 10/3 mmol) in xylene (2 ml), which became a clear solution on heating, was refluxed for 3 h. After evaporation of the solvent, excess **5a** was removed by sublimation. The residue was treated with 6 M HCl and tetrahydrofuran (THF) to hydrolyze the product followed by concentration. The residue was redissolved in THF and dried over Na_2SO_4 followed by addition of an ethereal solution of diazomethane. After evaporation of the solvent, the residue was separated by preparative TLC to afford **6a** (116 mg) in a 99% yield. Recrystallization from ethanol gave pure **6a**: mp 144—146 °C; IR 1720, 1295, 1285, 1240, 1205, 1145 cm^{-1}; NMR ($CDCl_3$) δ 2.39 (s, 3H), 2.4—3.3 (m, 6H), 3.44 (s, 3H), 3.66 (s, 3H), 6.93 (m, 1H), 7.24 (d, 2H, J=9 Hz), 7.64 (d, 2H, J=9 Hz). Found: C, 57.86; H, 5.61; S, 9.24%. Calcd for $C_{17}H_{20}O_6S$: C, 57.95; H, 5.72; S, 9.08%.

In a similar manner except for esterification with diazomethane, other cycloadducts **6b** (=**6a**) and **6c** were obtained from **2** and the corresponding dienophiles **5b** and **5c**.

Table 2. Cycloadducts of 3-(*p*-tolylsulfinyl)-3-sulfolene (**9**) with various dienophiles

	Dienophile	Molar ratio **5**/**9**	Condition[a]	Isolated yield (%)[b] **10b—g**
5b		10	A	 66
5c		10	A	 89
5d		20	B	 74
5e		20	B	 97
5f		20	B	 63[c]
5g		10	C	 56

a) As in Table 1. b) Based on **9**. c) Consists of two diastereoisomers isolated in 29 and 34% yields, respectively.

6c: Mp 110—112 °C; IR 1720, 1300, 1200, 1140 cm^{-1}; NMR ($CDCl_3$) δ 1.6—3.2 (m, 6H), 2.43 (s, 3H), 3.61 (s, 3H), 3.66 (s, 3H), 6.97 (m, 1H), 7.30 (d, 2H, J=9 Hz), 7.69 (d, 2H, J=9 Hz). Found: C, 58.11; H, 5.62; S, 9.11%. Calcd for $C_{17}H_{20}O_6S$: C, 57.95; H, 5.72; S, 9.08%.

*Methyl 1-Methyl-4-(*p*-tolylsulfonyl)-3-cyclohexene-1-carboxylate (**6d**).* A mixture of **2** (273 mg, 1 mmol), methyl 2-methylpropenoate (**5d**, 2.002 g, 20 mmol), pyridine (79 mg, 1 mmol), and a catalytic amount of hydroquinone in xylene (5 ml) was heated at 140—150 °C in a sealed tube for 2 h. After addition of ethyl acetate, the solution was washed with water, dried over Na_2SO_4, and concentrated under reduced pressure. The residue was separated by preparative TLC to afford **6d** (287 mg) in 93% yield. Recrystallization from hexane gave pure **6d**: mp 72.5—73 °C; IR 1720, 1300, 1155, 1125 cm^{-1}; NMR ($CDCl_3$) δ 1.15 (s, 3H), 1.5—3.1 (m, 6H), 2.39 (s, 3H), 3.53 (s, 3H), 6.95 (m, 1H), 7.27 (d, 2H, J=9 Hz), 7.68 (d, 2H, J=9 Hz). Found: C, 62.38; H, 6.56%. Calcd for $C_{16}H_{20}O_4S$: C, 62.32; H, 6.54%.

In a similar manner, cycloadducts **6e—i** were obtained from **2** and the corresponding dienophiles **5e—i** in good yields (Table 1).

6e: Mp 58—60 °C; IR 1728, 1300, 1290, 1145 cm^{-1}; NMR ($CDCl_3$) δ 1.2—2.7 (m, 7H), 2.42 (s, 3H), 3.62 (s, 3H), 6.96 (m, 1H), 7.27 (d, 2H, J=9 Hz), 7.69 (d, 2H, J=9 Hz). Found: C, 61.14; H, 6.14%. Calcd for $C_{15}H_{18}O_4S$: C, 61.21; H, 6.17%.

6f: Mp 110—111 °C; IR 2230, 1285, 1140 cm^{-1}; NMR ($CDCl_3$) δ 1.6—3.2 (m, 7H), 2.39 (s, 3H), 6.90 (m, 1H), 7.30 (d, 2H, J=9 Hz), 7.69 (d, 2H, J=9 Hz). Found: C, 64.37; H, 5.70; N, 5.34%. Calcd for $C_{14}H_{15}NO_2S$: C, 64.36; H, 5.79; N, 5.36%.

6g: Mp 126—127 °C; IR 1295, 1280, 1145 cm^{-1}; NMR ($CDCl_3$) δ 1.5—3.2 (m, 7H), 2.45 (s, 3H), 7.16 (m, 1H), 7.32 (m, 5H), 7.43 (d, 2H, J=9 Hz), 7.91 (d, 2H, J=9 Hz). Found: C, 72.98; H, 6.47%. Calcd for $C_{19}H_{20}O_2S$: C, 73.06; H, 6.45%.

6h: Oil; IR 1725, 1290, 1150 cm^{-1}; NMR ($CDCl_3$) δ 1.5—2.7 (m, 7H), 2.38 (s, 3H), 6.95 (m, 1H), 7.24 (d, 2H, J=9 Hz), 7.64 (d, 2H, J=9 Hz), 9.55 (s, 1H). *Semicarbazone of **6h***: mp 217—218 °C (dec). Found: C, 55.95; H, 6.15; N, 13.03%. Calcd for $C_{15}H_{20}N_3O_3S$: C, 55.89; H, 6.25; N, 13.04%.

6i: Oil; IR 1700, 1310, 1295, 1280, 1140 cm^{-1}; NMR ($CDCl_3$) δ 1.2—2.7 (m, 7H), 2.12 (s, 3H), 2.38 (s, 3H), 6.94 (m, 1H), 7.23 (d, 2H, J=8 Hz), 7.63 (d, 2H, J=8 Hz). *Semicarbazone of **6i***: mp 218—219 °C. Found: C, 57.39; H, 6.35; N, 12.39%. Calcd for $C_{16}H_{21}N_3O_3S$: C, 57.30; H, 6.31; N, 12.53%.

*Reduction of **6d**.* A methanol solution of **6d** (155 mg, 0.5 mmol) and boron trifluoride etherate (142 mg, 1 mmol) was shaken vigorously under hydrogen atmosphere in the presence of Pd-C as a catalyst. After the usual treatment, the reduction product, methyl 1-methyl-4-(*p*-tolylsulfonyl)-1-cyclohexanecarboxylate, was separated by preparative TLC in a 71% (111 mg) yield. Recrystallization from hexane gave the pure compound: mp 122—123 °C; IR 1735, 1300, 1145 cm^{-1}; ^{13}C-NMR ($CDCl_3$) δ 21.6 (q, 1C), 23.1 (t, 2C), 27.7 (q, 1C), 34.3 (t, 2C), 42.8 (s, 1C), 51.9 (q, 1C), 62.7 (d, 1C), 128.9 (d, 2C), 129.6 (d, 2C), 134.2 (s, 1C), 144.5 (s, 1C), 176.3 (s, 1C). Found: C, 62.06; H, 7.04%. Calcd for $C_{16}H_{22}O_4S$: C, 61.92; H, 7.15%.

Similarly, the reduction product of **6e**, methyl 4-(*p*-tolyl-

sulfonyl)-1-cyclohexanecarboxylate, was obtained: mp 102—104 °C; IR 1728, 1285, 1150 cm^{-1}; ^{13}C-NMR ($CDCl_3$) δ 21.6 (q, 1C), 22.3 (t, 2C), 25.8 (t, 2C), 38.3 (d, 1C), 51.8 (q, 1C), 62.6 (d, 1C), 128.9 (d, 2C), 129.7 (d, 2C), 134.3 (s, 1C), 144.5 (s, 1C), 174.2 (s, 1C). Found: C, 61.04; H, 6.95%. Calcd for $C_{15}H_{20}O_4S$: C, 60.80; H, 6.80%.

The structures of **6f** and **6h** were confirmed by transformation into **6e**. They were hydrolyzed or oxidized to 4-(*p*-tolylsulfonyl)-3-cyclohexene-1-carboxylic acid giving **6e** by subsequent esterification with diazomethane. Their melting points and spectral data were identical with those of **6e**.

*Reduction of **6g**.* To a solution of **6g** (56 mg, 0.18 mmol) in THF-methanol (1:1) was added excess sodium borohydride at room temperature until **6g** disappeared on TLC. After the usual treatment, the reduction product, 1-phenyl-4-(*p*-tolylsulfonyl)cyclohexane, was separated by preparative TLC in a nearly quantitative yield (56 mg). Recrystallization from ethanol gave the pure compound: mp 153—154 °C; IR 1305, 1270, 1140 cm^{-1}; ^{13}C-NMR ($CDCl_3$) δ 21.6 (q, 1C), 25.9 (t, 2C), 32.6 (t, 2C), 43.1 (d, 1C), 63.0 (d, 1C), 126.3 (d, 1C), 126.5 (d, 2C), 128.4 (d, 2C), 129.0 (d, 2C), 129.7 (d, 2C), 134.3 (s, 1C), 144.5 (s, 1C), 145.7 (s, 1C). Found: C, 72.27; H, 7.02%. Calcd for $C_{19}H_{22}O_2S$: C, 72.59; H, 7.05%.

Similarly, the dimer **4** was reduced to 1,4-bis(*p*-tolylsulfonyl)-4-vinylcyclohexane: mp 226—228 °C; IR 1280, 1140 cm^{-1}; ^{13}C-NMR ($CDCl_3$) δ 20.9 (t, 2C), 21.6 (q, 2C), 27.2 (t, 2C), 62.0 (d, 1C), 67.0 (s, 1C), 123.8 (t, 1C), 128.8 (d, 2C), 129.1 (d, 2C), 129.8 (d, 2C), 130.9 (d, 2C), 131.5 (s, 1C), 132.6 (d, 1C), 134.1 (s, 1C), 144.8 (s, 1C). Found: C, 62.97; H, 6.02%. Calcd for $C_{22}H_{26}O_4S_2$: C, 63.15; H, 6.26%.

1-Acetyl-4-(p-tolylsulfonyl)cyclohexane. To a methanol solution of ***6i*** (278 mg, 1 mmol) was added excess sodium borohydride at room temperature. After evaporation, water and then ethyl acetate were added to the residue. The organic layer was separated, dried over Na_2SO_4, and concentrated to give crude 1-[4-(*p*-tolylsulfonyl)cyclohexyl]ethanol, which was further oxidized with Jones reagent. After the usual treatment, 1-acetyl-4-(*p*-tolylsulfonyl)cyclohexane was separated by preparative TLC in a 96% (268 mg) yield. Recrystallization from aqueous ethanol gave the pure compound: mp 110—112 °C; IR 1705, 1280, 1140 cm^{-1}; ^{13}C-NMR ($CDCl_3$) δ 21.6 (q, 1C), 24.8 (t, 2C), 26.9 (t, 2C), 28.2 (q, 1C), 49.7 (d, 1C), 62.5 (d, 1C), 128.9 (d, 2C), 129.7 (d, 2C), 134.0 (s, 1C), 144.7 (s, 1C), 210.2 (s, 1C). Found: C, 64.18; H, 7.26%. Calcd for $C_{15}H_{20}O_3S$: C, 64.27; H, 7.19%.

*4-(p-Tolylthio)-2-sulfolene (**8**).* To a methanol solution (4 ml) of **7** (394 mg, 2 mmol) prepared according to the procedure of Bailey and Cummins[3] was added dropwise a mixture of *p*-toluenethiol (248 mg, 2 mmol) and 1 M NaOH (2 ml, 2 mmol) with stirring at room temperature. After being stirred for 3 h, the reaction mixture was concentrated. Dichloromethane was added to the concentrate which was then washed with water, and dried over Na_2SO_4. The residue obtained by evaporation was separated by preparative TLC to afford **8** in a 69% (331 mg) yield: oil; IR 1305, 1145 cm^{-1}; NMR ($CDCl_3$) δ 2.31 (s, 3H), 3.09 (dd, 1H, J=5 and 14 Hz), 3.55 (dd, 1H, J=8 and 14 Hz), 4.30 (m, 1H), 6.55 (m, 2H), 7.05 (d, 2H, J=8 Hz), 7.27 (d, 2H, J=8 Hz).

*3-(p-Tolylsulfinyl)-3-sulfolene (**9**).* To a methanol solution (4 ml) of **8** (440 mg, 1.8 mmol) was added dropwise an aqueous solution (2 ml) of sodium periodate (385 mg, 1.8 mmol) with stirring at room temperature. After being stirred for 3 days, the resulting precipitate was removed by filtration, and the filtrate was evaporated under reduced pressure. The residue was redissolved in dichloromethane, and the solution was dried over Na_2SO_4. After concentration, the residue was separated by preparative TLC to afford **9** in a 75% (354 mg) yield. Recrystallization from ethanol gave the pure compound: mp 146—147 °C; IR 1300, 1130, 1050 cm^{-1}; NMR (DMSO-d_6) δ 2.36 (s, 3H), 3.63 (m, 2H), 4.08 (m, 2H), 6.81 (m, 1H), 7.31 (d, 2H, J=9 Hz), 7.50 (d, 2H, J=9 Hz). Found: C, 51.54; H, 4.43%. Calcd for $C_{11}H_{12}O_3S_2$: C, 51.56; H, 4.72%.

*Diels-Alder Reaction of **9**.* The Diels-Alder reaction of **9** with dienophiles **5b**—**g** was carried out in a similar manner to that for **2**. The structure of cycloadducts **10b**—**g**, all of which were oil, containing diastereoisomers based on the chiral center of sulfoxide group, were confirmed by transformation into the corresponding sulfones **6b**—**g** by oxidation with a mixture of acetic acid and hydrogen peroxide. The melting points and spectral data of the oxidation products were the same as those of the authentic **6b**—**g** prepared by Diels-Alder reaction of **2**.

Particularly in the case of 4-(*p*-tolylsulfinyl)-3-cyclohexene-1-carbonitrile (**10f**), two diastereoisomers were isolated by TLC in 29% and 34% yields, respectively. They were converted into 4-(*p*-tolylsulfonyl)-3-cyclohexene-1-carbonitrile (**6f**) by the oxidation in nearly 95% yields.

We wish to thank Dr. Y. Itatani for the determination of the ^{13}C-NMR spectra and for valuable discussions.

Dehydroannulenes. VIII. Synthesis of Position Isomers of Di-*t*-butyl-diphenyl-1,8-bisdehydro[14]annulene and Dimethoxy Derivative

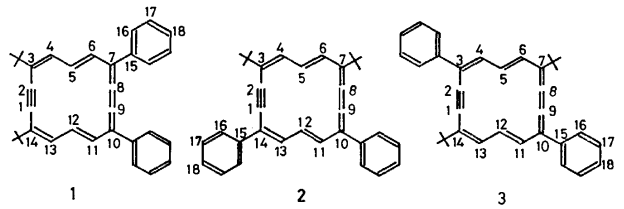
Tateo NOMOTO, Shin'ichi NAKATSUJI, and Masazumi NAKAGAWA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 15, 1978)

Two position isomers of di-*t*-butyl-diphenyl-1,8-bisdehydro[14]annulene corresponding to *o*- and *m*-isomers of terphenyl have been prepared by a stepwise reaction sequence, and their physical properties were compared with those of 3,10-di-*t*-butyl-7,14-diphenyl-1,8-bisdehydro[14]annulene which corresponds to the *p*-isomer of terphenyl. The marked difference in electronic spectra between *o*-, *m*-, and *p*-isomers of terphenyl could not be observed in the spectra of "*ortho*"-, "*meta*"-, and "*para*"-isomers of the [14]annulene. Dimethoxy derivative of the "*para*"-isomer, 3,10-di-*t*-butyl-6,13-dimethoxy-7,14-diphenyl-1,8-bisdehydro[14]annulene, has been synthesized.

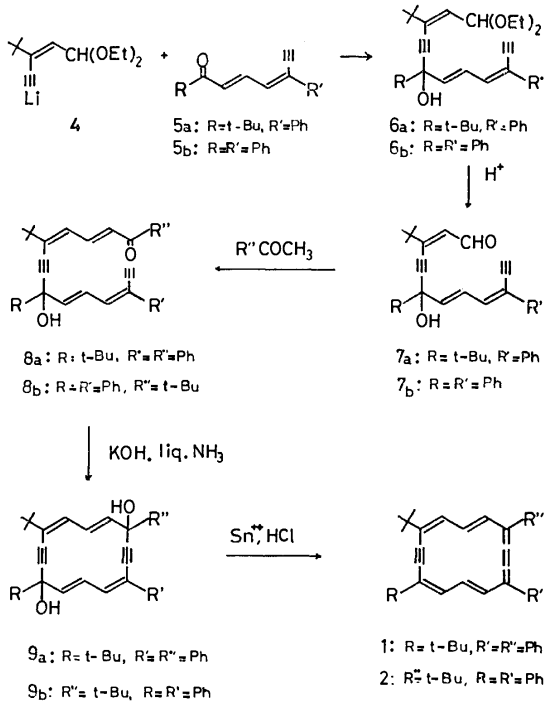
As reported in the previous papers, increase in the number of phenyl substituents on bisdehydro[14]-[1], tetrakisdehydro[18]-,[2] and tetrakisdehydro[22]annulene rings[3] caused appreciable bathochromic shifts of their electronic spectra indicating conjugative effect of π-electrons in the phenyl group on the annulene nucleus. Considering the remarkable difference in electronic spectral properties between position isomers of terphenyl,[4] we have carried out the synthesis of di-*t*-butyl-diphenyl-1,8-bisdehydro[14]annulenes (**1** and **2**) corresponding to *o*- and *m*-isomers of terphenyl.[5] The synthesis of 7,14-di-*t*-butyl-3,10-diphenyl-1,8-bisdehydro[14]annulene (**3**) which corresponds to *p*-terphenyl has been reported previously.[1]



1 2 3

Synthesis. As outlined in Scheme 1, 3-*t*-butyl-2-penten-4-ynal diethyl acetal[3b,c] was converted into lithio derivative (**4**) on treatment with phenyllithium. The reaction of the lithio derivative (**4**) with dienyne ketone (**5**) gave hydroxy acetal (**6**) in a high yield. Hydroxy aldehyde (**7**) was obtained on treatment of the acetal (**6**) in ethanol with an aqueous solution of tartaric acid. The aldol condensation of the hydroxy aldehyde (**7**) with methyl ketone yielded hydroxy ketone (**8**). A solution of the hydroxy ketone (**8**) in tetrahydrofuran was added to a suspension of finely powdered potassium hydroxide in liquid ammonia. The products were passed through a short column of alumina. Slightly crude cyclic glycol (**9**) thus obtained was subjected without further purification to the subsequent reaction. Treatment of the cyclic glycol (**9**) in ether with a solution of tin(II) chloride dihydrate in the same solvent saturated with hydrogen chloride at −15——17 °C afforded position isomers of di-*t*-butyldiphenyl-1,8-bisdehydro[14]annulene, (**1**) or (**2**).

In order to obtain further information on the effect of substituent on the electronic spectrum of 1,8-bisdehydro[14]annulene, dimethoxy derivative (**14**) of the isomer (**3**) has been prepared according to Scheme 2. The aldol condensation of 3-*t*-butyl-2-penten-4-ynal (**10**)[2b,6] with α-methoxyacetophenone (**11**)[7] gave



Scheme 1.

methoxydienyne ketone (**12**). Another geometrical isomer (**15**) can be considered for the methoxy ethynyl ketone. NMR spectroscopy of the ketone, *i.e.*, difference in chemical shift between carbon tetrachloride and deuteriobenzene solutions[8] and the NOE of H^3 or H^4 on irradiation of methyl protons in methoxyl groups, afforded no confirmative information on the discrimination between **12** and **15**. However, formation of the cyclic glycol (**13**) seemed to suggest the *trans* disposition of the methoxyl group with respect to H^3. Treatment of the methoxy ethynyl ketone (**12**) with a suspension of potassium hydroxide in liquid ammonia gave the cyclic glycol (**13**). Reductive dehydroxylation of the cyclic glycol (**13**) by tin(II) chloride dihydrate in ether saturated with hydrogen chloride yielded 3,10-di-*t*-butyl-7,14-diphenyl-6,13-dimethoxy-1,8-bisdehydro[14]annulene (**14**).

Properties. The color of crystals, melting points and ^1H NMR parameters of the position isomers of di-*t*-butyl-diphenyl-1,8-bisdehydro[14]annulene (**1** and **2**) and the dimethoxy derivative (**14**) are shown in Table 1 together with those of the other position isomer

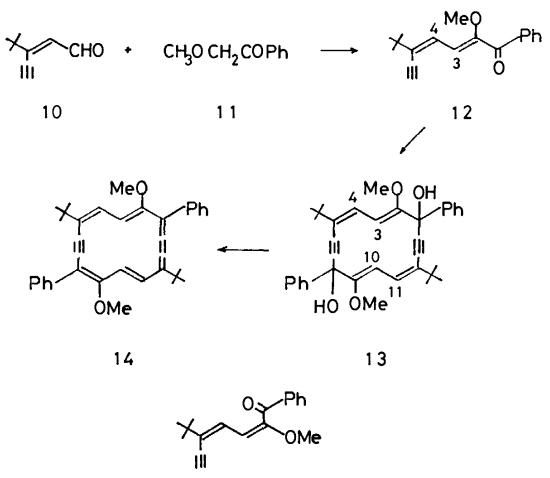
a) The spectra were obtained on a Varian XL-100 spectrometer operated at 25.2 MHz with deuteriochloroform internal lock using TMS as an internal standard.

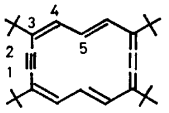


Scheme 2.

(**3**).[1]

The position isomers and the dimethoxy derivative (**1**, **2**, **3**, and **14**) were found to be strongly diatropic showing the signals of inner protons at high field and those of outer protons at low field. The close similarity of ^{1}H NMR behavior between the position isomers (**1**, **2**, and **3**) indicates that the difference of position of substituent group does not exert prominent effect on the π-electron system in the annulene nucleus at the ground state. Introduction of two methoxyl groups also exerts no essential change in NMR characteristics, although the group has both of electron attractive and donating property in the inductive and mesomeric modes. The low field shift of *ortho*-protons of phenyl groups as compared with that of *meta*- and *para*-protons can be reasonably attributed to the deshielding effect of diamagnetic ring current induced in the annulene ring. Inversely, the low field shift of outer protons of annulene ring adjacent to phenyl substituent indicates the ring current effect of benzene nucleus.

The ^{13}C NMR parameters are summarized in Table 2 together with those of tetra-*t*-butyl analogue (**16**). The assignment was made on the basis of chemical shifts, off resonance technique and the magnitude of NOE. The coupling constants are found to be J_{CH}=150—152 Hz, J_{CCH}=5 Hz and $J_{CCCH}\simeq$10 Hz. The fact that the sp-hybridized carbon atoms in the position isomers (**2** and **3**) exhibit two signals can be attributed to the difference of electron density between C^1 and C^2 which is caused by the difference of inductive effect between *t*-butyl and phenyl groups. However, it should be noted that the sp-hybridized carbon atoms in the isomer (**1**) showed only a signal in the corresponding



16

region. It is also to be noted that the sp-carbon exhibits siganl at an intermediate region of acetylene and cumulene reflecting the hybrid nature of the linkage incorporated in the aromatic system.

Remarkable difference in electronic spectra between the position isomers (**2** and **3**) was anticipated, because

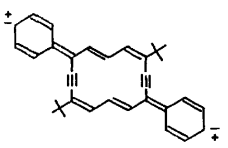
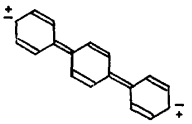
a) For absorption curves, see, Ref. 4. * Asterisk denotes shoulder.

the dipolar structure (**17**) may contribute in the excited state of (**3**) just as the case of *p*-terphenyl (**18**), and the contribution of such type of dipolar structure can be excluded in (**2**). However, in fact as shown in Table 3, the electronic spectra of the position isomers (**1**,**2** and **3**) and the dimethoxy derivative (**14**) showed close similarity except for the hyperchromism and bathochromic shift of the longest wavelength absorption band (I) of the dimethoxy derivative (**14**). The marked difference in electronic spectra between *p*- and *m*-terphenyls could not be observed in the spectra of the position isomers (**3** and **2**). This fact seems to be ascribable to the large difference in the stability of π-electron system between benzene nucleus and the 14-membered ring, and the general tendency that the electronic spectrum of a large conjugated system such as condensed benzenoid compound is less sensitive to the introduction of substituent group(s).



17



18

At first sight, the intensification of the longest wavelength band (I) in **14** seemed to suggest that the direction of polarization of the longest wavelength band (I) is perpendicular to the long axis of the bisdehydro[14]annulene nucleus.[5] However, the measurements of fluorescence excitation spectra of tetra-*t*-butyl-bisdehydro[14]annulene (**16**) and the position isomer (**3**), and the theoretical calculation by PPP and RPA methods performed by Tanaka *et al.* revealed the nature of electronic transitions and the direction of polarization.[9] Namely as shown in Fig., the longest wavelength band (I) is ^1L_b species and the direction of polarization is parallel to the long axis, the medium wavelength band (II) is ^1L_a species having perpendicular polarization and the short wavelength band (III) consists of parallel polarized ^1B_b species and perpendicular polarized ^1B_a species.

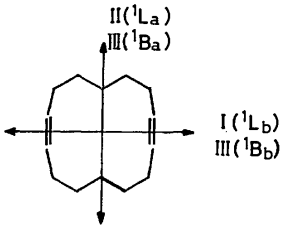


Fig. Direction of polarization of bisdehydro[14]-annulene.

Experimental

All the melting and boiling points are uncorrected. The melting points were measured an a Mettler FP-2 apparatus. The IR spectra were obtained on a Hitachi EPI-G3 or EPI-2 spectrophotometer by neat liquid film or KBr-disk method. Strong, medium, weak and broad bands were denoted by s, m, w and br, respectively. The electronic spectra were measured in THF using Hitachi EPS-3T spectrophotometer. The NMR spectra were obtained on one of the Varian spectrometerss of XL-100, A-60D, T-60 or a Hitachi R-24, and the parameters are given in τ-values with respect to TMS as an internal standard. The mass spectra were measured with a Hitachi RM-50 spectrometer (ionization potential 70 eV). The adsorbents used in the column chromatography are alumina (Merck, activity II-III or Woelm, activity I) and silica gel (Wako gel C-200). Evaporation of the solvent was performed under reduced pressure.

*3,6-Di-t-butyl-6-hydroxy-10-phenyl-2,7,9-dodecatriene-4,11-diynal Diethyl Acetal (**6a**).* 3-*t*-Butyl-2-penten-4-ynal diethyl acetal[3c] (0.9274 g, 0.00442 mol) in ether (80 ml) was mixed with 0.8 M of phenyllithium in ether (6.9 ml, 0.0055 mol) at −15——18 °C under nitrogen atmosphere to give the lithio derivative (**4**). After bing stirred for 10 min, a solution of the ketone (**5a**, 1.00 g, 0.0042 mol)[10] in ether (80 ml) was added dropwise over 1 h-period at the same temperature. After the mixture had been stirred for 1 h at 0 °C, stirring was continued overnight at room temperature. Cracked ice was added to the reaction mixture under external cooling. The organic layer was separated and the aqueous layer was extracted with ether. The combined ethereal solution was thoroughly washed with water and dried (K_2CO_3). Dark red liquid (2.1 g) obtained on evaporating the solvent was chromatographed on alumina (Merck,

100 g). The column was eluted with cyclohexane and benzene–cyclohexane (1:9) to remove a minor amount of starting material and by-product. Elution with benzene–cyclohexane (1:1) followed by benzene yielded **6a** as a pale yellow liquid, 1.21 g, 64%, IR(neat): 3425 (br, m, OH), 3300 (m, C≡CH), 1120, 1060, 960 (s, C–O–C) cm^{-1}. Further elution with ether–benzene (1:9) afforded **7** as a pale yellow viscous liquid (0.365 g, 23.2%).

*3,6-Di-t-butyl-6-hydroxy-10-phenyl-2,7,9-dodecatriene-4,11-diynal (**7a**).* A mixture of **6a** (2.9 g, 0.0065 mol), ethanol (290 ml), tartaric acid (1.5 g) and water (150 ml) was stirred for 3 h under ice-cooling and then for 2 h at 12 °C. The mixture was extracted with ether. The extract, after being washed with water and an aqueous solution of sodium hydrogencarbonate, was dried (K_2CO_3). A yellow viscous liquid (2.35 g) obtained on evaporating the solvent was dissolved in carbon tetrachloride and the solution was passed through a column of alumina (Merck, 95 g). Elution with benzene and ether–benzene (1:9) yielded a pale yellow viscous liquid (2.30 g, 95%) which was triturated with hexane to give **7a** as colorless crystals, mp 101.2—102.1 °C, 2.21 g, 91.3%, IR(KBr): 3450 (s, OH), 3280 (s, C≡CH), 1670 (s, C=O), 1580 (s, aromatic C=C) cm^{-1}, NMR(CCl_4): τ 8.90 (9H, d, *t*-Bu), 8.75 (9H, s, *t*-Bu adjacent to OH), 7.22 (1H, br s, C≡CH), 3.88 (1H, d, J=15 Hz, H^7), 8.83 (1H, d, J=8 Hz, H^2), 3.08 (1H, d, J=11 Hz, H^9), 2.75 (4H, m, *m,p*-H of Ph and H^8), 2.43 (2H, m, *o*-H of Ph), −0.16 (1H, d, J=8 Hz, CHO).

Found: C, 83.44; H, 8.10%. Calcd for $C_{26}H_{30}O_2$: C, 83.88; H, 8.07%.

*5,8-Di-t-butyl-1,12-diphenyl-8-hydroxy-2,4,9,11-tetradecatetraene-6,13-diyn-1-one (**8a**).* To a stirred solution of **7a** (1.24 g, 0.003 mol) and acetophenone (0.475 g, 0.004 mol) in ethanol (15 ml) was added at −5 °C a solution of sodium hydroxide (0.15 g, 0.38 mol) in water (1 ml) and ethanol (1 ml) under nitrogen atmosphere. After being stirred for 1 h at −5——10 °C, for 2 h at 2 °C and then for 1 h at 14 °C, the mixture was extracted with ether. A reddish liquid (1.7 g) obtained on evaporation of the ethereal extract, after being washed and dried (K_2CO_3), was dissolved in benzene–cyclohexane (1:9) and chromatographed on alumina (Merck, 70 g). Excess of acetophenone was removed on elution with benzene–cyclohexane (2:8—5:5). Further elution with benzene and ether–benzene (2:8) afforded a pale yellow viscous liquid (1.12 g, 71.2%) which crystallized on trituration with hexane to give **8a**, pale yellow needles, mp 88.5—89.5 °C, 1.09 g, 69.3%, IR(KBr): 3430 (m, OH), 3300 (m, C≡CH), 1655 (s, C=O), 1590 (s, aromatic C=C) cm^{-1}, NMR(CCl_4): 8.90 (9H, s, *t*-Bu), 8.77 (9H, s, *t*-Bu adjacent to OH), 7.15 (1H, s, disappeared on addition of D_2O), 6.67 (1H, s, C≡CH), 3.95—3.00 (6H, m, olefinic·H), 2.83—1.93 (10H, m, aromatic-H).

Found: C, 85.38; H, 7.56%. Calcd for $C_{34}H_{36}O_2$: C, 85.67; H, 7.61%.

*5,8-Di-t-butyl-1,12-diphenyl-2,4,9,11-cyclotetradecatetraene-6,13-diyn-1,8-diol (**9a**).* A solution of **8a** (0.45 g, 0.0009 mol) in THF (90 ml) was added over 8 h-period to a suspension of finely powdered potassium hydroxide (2.0 g) in liquid ammonia (280 ml) at −45——35 °C. After the mixture had been stirred for 12 h, powdered ammonium chloride (7.0 g) was added at −50——55 °C. After 15 min, the cooling bath was removed and the ammonia was allowed to evaporate. The residue was repeatedly extracted with ether. The extract was washed with saturated ammonium chloride solution and dried (K_2CO_3). The product obtained on evaporating the solvent was dissolved in ether–benzene (3:7) and passed through a column of alumina (Woelm, 10 g). Slightly crude **9a**, pale yellow fine crystals, 0.41 g, was used without further purification in the following reaction.

*3,14-Di-t-butyl-7,10-diphenyl-1,8-bisdehydro[14]annulene (**1**).* To a stirred solution of **9a** (410 mg) in ether (50 ml) was added at −12——15 °C a solution of tin(II) chloride dihydrate (500 mg) in the same solvent saturated with hydrogen chloride (10 ml). After being stirred for 3 min, cold water was added to the mixture. The organic layer was washed successively with water, aqueous sodium hydrogencarbonate solution and water, and dried (K_2CO_3). The crude product obtained on evaporating the solvent was chromatographed on alumina (Merck, 40 g) and eluted with ether–hexane (2:8). Rechromatography on alumina (Merck, 30 g) and elution with benzene afforded **1**, deep reddish violet crystals, 231 mg, 55.3% based on **8a**, which were recrystallized from ether–hexane (3:7) to give pure **1**, reddish violet plates with deep green metallic luster, mp 248.0—249.0 °C (dec).

Found: C, 92.12; H, 7.83%. Calcd for $C_{34}H_{34}$: C, 92.26; H, 7.74%.

*3-t-Butyl-6-hydroxy-6,10-diphenyl-2,7,9-dodecatriene-4,11-diynal Diethyl Acetal (**6b**).* To a stirred and cooled (ice–salt bath) solution of the lithio derivative (**4**), prepared from *t*-butyl-pentenynal diethyl acetal (2.10 g, 10 mmol) in ether (150 ml) on treatment with an ethereal phenyllithium solution (0.74 M, 18.5 ml, 13.7 mmol), was added under nitrogen atmosphere a solution of **5b** (3.00 g, 11.6 mmol)[2] in the same solvent (120 ml) over a period of 1.5 h. After being stirred for 15 min at 0 °C, and then for 14.5 h at a room temperature, the reaction mixture was poured onto ice-water. The organic layer was washed successively with cold water, cold brine and cold water, and dried (K_2CO_3). Reddish brown liquid (5.88 g) obtained on evaporation of the solvent was chromatographed on silica gel (160 g). 3-*t*-Butyl-pentenynal diethyl acetal was eluted with benzene–cyclohexane (1:1) and benzene. Further elution with ether–benzene(1:1) yielded **6b**, yellowish red powder, 4.05 g, 84.4%, IR(neat): 3380 (m, OH), 3303 (m, C≡CH), 2090 (w, C≡C), 1120, 1053, 972 (C–O–C) cm^{-1}, NMR($CDCl_3$): 2.31 (4H. m, *o*-H of Ph), 2.81 (7H, m, *m,p*-H of Ph and H^8), 4.17 (1H, d, J=7 Hz, H^2), 4.68 (1H, d, J=7 Hz, H^1), 6.32 (4H, m, CH_2), 6.47 (1H, s, C≡CH), 7.24 (1H, s, OH), 8.75 (9H, s, *t*-Bu), 8.78 (6H, t, J=7 Hz, CH_3).

The attempts to crystallize **6a** were unsuccessful.

*3-t-Butyl-6-hydroxy-6,10-diphenyl-2,7,9-dodecatriene-4,11-diynal (**7b**).* A solution of **6b** (3.03 g, 6.47 mmol) in ether (250 ml) and THF (10 ml) was added over 1 h-period to an ice-cooled aqueous solution of tartaric acid (1%, 150 ml). After being stirred for 2.5 h at 0—12 °C, the reaction mixture was poured onto ice-water and extracted with ether. The extract, after washing with brine and drying (K_2CO_3), was concentrated to give a reddish yellow solid (2.54 g), which was chromatographed on alumina and recrystallized from carbon tetrachloride and from cyclohexane to give pure **7b**, mp 84.3—85.7 °C, pale yellow plates, IR(KBr): 3325 (m, OH), 3290 (m, C≡CH), 1658 (s, C=O), 1580 (w, C=O) cm^{-1}, NMR($CDCl_3$): 8.74 (9H, s, *t*-Bu), 7.08 (1H, br, s, OH, disappeared on addition of D_2O), 6.38 (1H, s, C≡CH), 3.80 (1H, d, J=14 Hz, H^7), 3.70 (1H, d, J=8 Hz, H^2), 2.99 (1H, d, J=11 Hz, H^9), 2.61 (7H, m, *m,p*-H of Ph and H^8), 2.27 (4H, m, *o*-H of Ph), −0.16 (1H, d, J=8 Hz, H^1).

*7-t-Butyl-2,2-dimethyl-10,14-diphenyl-10-hydroxy-4,6,11,13-hexadecatetraene-8,15-diyn-3-one (**8b**).* A solution of sodium hydroxide (0.23 g, 5.75 mmol) in 50% aqueous ethanol (3.0 ml) was added under nitrogen atmosphere to an ice-cooled solution of **7b** (2.04 g, 5.18 mmol) and pinacolone (4.80 g, 47 mmol) in ethanol (25 ml). After being stirred for 2 h at 0 °C and for 24 h at a room temperature,

the reaction mixture was poured onto ice–water and extracted with ether. The extract was washed with water, brine and water, successively, and dried (K_2CO_3). A red liquid obtained on evaporation of the solvent was chromatographed on silica gel (Wako, 120 g) and eluted with cyclohexane–benzene–ether to give **8a**, a yellow solid, 1.97 g, IR(KBr): 3320 (m, OH), 3250 (m, C≡CH), 1675 (m, C=O), 1590 (s, C=C) cm^{-1}, NMR(CCl_4): 8.88 (9H, s, *t*-Bu), 8.76 (9H, s, *t*-Bu adjacent to C=O), 6.65 (1H, s, C≡CH), 3.83 (1H, d, J=16 Hz, H^{11}), 3.61 (1H, d, J=13 Hz, H^6), 3.45 (1H, d, J=15 Hz, H^4), 2.71 (8H, m, *m,p*-H of Ph and $H^{5,12}$), 2.40 (4H, m, *o*-H of Ph).

Crystallization of **8b** could not be achieved.

*1,5-Di-*t*-butyl-8,12-diphenyl-2,4,9,11-cyclotetradecatetraene-6,13-diyne-1,8-diol (**9b**).* A solution of **8b** (400 mg, 0.84 mmol) in THF (120 ml) was added to a stirred suspension of potassium hydroxide (3.0 g, 54 mmol) in liquid ammonia (700 ml) over a period of 22.5 h at −60——38 °C. After being stirred for further 3 h at −38——30 °C, powdered ammonium chloride was added to the reaction mixture and the ammonia was allowed to evaporate. The residue was mixed with water and extracted with ether. After being washed with a saturated solution of ammonium chloride, the extract was dried ($MgSO_4$). Removal of the solvent yielded a yellow solid, which gave IR and NMR spectra consistent with the 14-membered cyclic glycol (**9b**). The crude **9b** was used without further purification in the following reaction.

*3,7-Di-*t*-butyl-10,14-diphenyl-1,8-bisdehydro[14]annulene (**2**).* To a solution of crude **9b** in ether (40 ml) cooled in an ice–salt bath was added a solution of tin(II) chloride dihydrate (1.2 g) in the same solvent saturated with hydrogen chloride (15 ml). After being stirred for 15 min, ether was added to the reaction mixture, and the ethereal solution was washed successively with water and brine, and dried ($MgSO_4$). Deeply colored solid obtained on working up the extract was chromatographed on alumina (Merck, 30 g). Greenish violet crystals (8.2 mg, 20.5% based on **8b**) obtained on elution with hexane–ether were rechromatographed on alumina (Woelm) to give pure **2**, reddish green needles, mp 200.8—202.0 °C (dec).

Found: C, 92.17; H, 7.71%, mass (*m/e*): 442 (M^+). Calcd for $C_{34}H_{34}$: C, 92.26; H, 7.74%, mol wt: 442.612.

*5-*t*-Butyl-2-methoxy-1-phenyl-2,4-heptadien-6-yn-1-one (**12**).* To an ice-cooled solution of 3-*t*-butyl-2-penten-4-ynal (**10**, 6.7 g, 49 mmol)[2c,5] and ω-methoxyacetophenone (**11**, 7.6 g, 51 mmol)[6] in ethanol (250 ml) was added over 1 h-period a solution of sodium hydroxide (2.5 g, 83 mmol) in 50% aqueous ethanol (100 ml) under nitrogen atmosphere. After the resulting deep red solution had been stirred for 49 h at 12 °C, water was added to the mixture and extracted with ether. The extract was washed successively with water, brine and sodium hydrogencarbonate solution, and dried ($MgSO_4$). A yellow liquid obtained on evaporation of the solvent was chromatographed on alumina (Merck, 120 g). Elution with ether–hexane (1:9 to 2:8) gave **12**, a yellow liquid, 10.6 g, 80%, mass (*m/e*): 268 (M^+), Calcd for $C_{18}H_{21}O_2$: 268.348, IR(neat): 3290 (m, C≡CH), 2079 (w, C≡C), 1649 (s, C=O), 1598 (s, C=C), 1450 (s, O–CH_3), 1125 (s, C–O–C) cm^{-1}. The ^1H NMR parameters are given in Table 4. The ketone (**12**) was found to be rather unstable in neat, but can be kept for a month without appreciable decomposition in an ether solution under argon atmosphere at a room temperature. Distillation of **12** (bp 110—120 °C/ 7×10^{-5} Pa) accompanied with a remarkable decomposition.

*5,12-Di-*t*-butyl-1,8-diphenyl-2,9-dimethoxy-2,4,9,11-cyclotetradecatetraen-6,13-diyn-1,8-diol (**13**).* A solution of **12** (429 mg, 1.60 mmol) in THF (30 ml) was added to a suspension of potassium hydroxide (2.0 g, 56 mmol) in liquid ammonia (200 ml) over a period of 2.5 h at −64——63 °C. After stirring for 16 h at −64——30 °C, ammonium chloride was added to the reaction mixture at −60 °C, and the ammonia was allowed to evaporate. Water was added to the residue and the mixture was extracted with ether. The extract was worked up in the usual manner. Evaporation of the solvent afforded a brown liquid, which was chromatographed on alumina (Merck, 40 g). After being eluted thoroughly with cyclohexane–benzene (1:1) to remove the starting materials, the solvent was replaced by ether–benzene (1:9). Concentration of the eluate yielded a diastereomer of **13**, mp 247.9—249.1 °C (dec), colorless crystals, 68 mg, 17%. Elution with ether–benzene (1:1) gave another diastereomer of **13**, mp 265.2—266.1 °C (dec), colorless crystals, 128 mg, 30%, NMR($CDCl_3$): 8.83 (9H, s, *t*-Bu), 8.72 (1H, s, OH), 6.35 (3H, s, OCH_3), 3.46 (1H, d, J=11 Hz, H^3), 3.24 (1H, d, J=11 Hz, H^4), 2.77 (3H, m, *m,p*-H of Ph), 2.52 (2H, m, *o*-H of Ph).

Table 4. ^1H NMR parameters of **12**

	CCl_4	C_6D_6
o-H of Ph	2.20(2H, m)	2.21(2H, m)
m,p-H of Ph	2.57(3H, m)	2.87(3H, m)
H^4	3.10(1H, dd, J=0.6, 11)	2.86(1H, dd, J=0.6, 11)
H^3	3.39(1H, d, J=11)	3.06(1H, d, J=11)
OCH_3	6.28(3H, s)	6.46(3H, s)
C≡CH	6.70(1H, d, J=0.6)	7.04(1H, d, J=0.6)
t-Bu	8.80(9H, s)	8.87(9H, s)

Although the mass spectrum of the high melting isomer showed the presence of impurities, the material was subjected to the following conversion without further purification. Both of the diastereomers gave **14**.

*3,10-Di-*t*-butyl-6,13-dimethoxy-7,14-diphenyl-1,8-bisdehydro-[14]-annulene (**14**).* A diastereomeric mixture of crude **13** prepared from **12** (271 mg, 1.01 mmol) by the above-stated procedure was dissolved in ether (20 ml). A solution of tin(II) chloride dihydrate (1.4 g, 8.9 mmol) in ether saturated with hydrogen chloride (13 ml) was added to the stirred solution of **13** at −60 °C. After 2 min, the resulting deep reddish violet solution was poured onto ice–water, and extracted with ether. The extract, after being washed successively with water, brine, sodium hydrogencarbonate solution and water, and dried (K_2CO_3), was concentrated to give a black solid, which was chromatographed on alumina (Merck, 30 g). Elution with hexane and THF–hexane (0.5:9.5) gave **14**, green crystals, 84 mg, 33% based on **12**. Rechromatography on alumina (Woelm) followed by recrystallization from benzene–hexane (1:5) gave analytical specimen of **14**, deep green plates, mp 281.5—282.7 °C (dec).

Found: C, 85.97; H, 7.60%, mass (*m/e*): 502 (M^+). Calcd for $C_{36}H_{38}O_2$: C, 86.01; H, 7.62%, mol wt: 502.664.

Dehydroannulenes. IX. Effects of Substituents on the ^{1}H NMR Spectra of Tetrakisdehydro[18]- and Bisdehydro[14]annulenes

Shuzo AKIYAMA,† Masahiko IYODA, Kiyoshi YOSHITSUGU, Masatoshi FUKUOKA, and Masazumi NAKAGAWA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 15, 1978)

In order to obtain information on the cause of low field shift of ^{1}H NMR signals of 'acetylene-cumulene'-dehydroannulenes on introduction of substituents, the syntheses of 1,8-bisdehydro[14]- and 6,8,15,17-tetrakisdehydro[18]annulenes bearing *p*-substituted phenyl group(s) have been performed. The examination of their ^{1}H NMR spectra indicates that the low field shift of NMR signals can be regarded as a superposition of three effects, *i.e.*, 1) decrease of ring current in annulene nucleus by perturbation of substituent group(s), 2) Deshielding effect of ring current in aryl substituent(s) exerted on annulene protons, and 3) Electronic effect of *p*-substituent in phenyl group(s) transmitted to annulene ring.

Replacement of the methyl groups in 1,5,10,14-tetramethyl-6,8,15,17-tetrakisdehydro[18]annulene (**1a**)[1] by *t*-butyl groups to give tetra-*t*-butyl derivative (**1b**)[2] resulted in appreciable down field shifts of both of the outer and inner proton signals of the annulene ring. As pointed out in previous papers of this series,[3] further down field shifts of annulene protons were observed on successive replacement of the methyl groups in **1a** or *t*-butyl groups in **1b** by phenyl groups to give **1c**[3] or **1d**[4]. Furthermore, tetraphenyltetrakisdehydro[18]annulene (**1e**)[3] exhibits both of the inner and outer proton signals at even more low field than those of **1c** or **1d**.

Preparation of tetrasubstituted 1,8-bisdehydro[14]annulenes bearing various substituents has revealed the similar substituent effects on the chemical shifts of protons in 1,8-bisdehydro[14]annulene ring. Substitution of the hydrogens at 3,7,10 and 14-positions in the parent bisdehydro[14]annulene (**2a**)[5] by *t*-butyl groups (**2b**) resulted in an appreciable down field shifts of inner protons (H^5 and H^{12}) accompanying with slight high field shifts of the outer protons (H^4, H^6, H^{11}, and H^{13}). The H^1 NMR spectra of position isomers of di-*t*-butyl-diphenyl-1,8-bisdehydro[14]annulene, (**2c**),[6] (**2d**),[7] (**2e**),[7] and the tetraphenyl derivative (**2f**)[6] exhibit also low field shift of both of the inner and outer protons in the annulene ring as compared with those of **2b**.

In order to get further insight into the effect of substituents, we have carried out the syntheses of tetrasubstituted 'acetylene-cumulene'-dehydroannulenes bearing *p*-substituted phenyl group(s).

Syntheses. 3,7,10,14-Tetrasubstituted 1,8-bisdehydro[14]annulenes (**2g—m**) were obtained by a similar reaction sequence used in the preparation of other analogues (**2b, c**) outlined in Scheme 1.

Scheme 1.

The stepwise sequence of reactions employed for the preparation of "*ortho*"- (**2d**) and "*meta*"-isomers (**2e**)[7] was adopted to the synthesis of tri-*t*-butyl (*p*-methoxycarbonylphenyl)-1,8-bisdehydro[14]annulene (**2n**) (Scheme 2). Crude product of the aldol condenstation of the hydroxy aldehyde (**8**)[8] with *p*-acetyl-benzoic acid was converted into the methyl ester (**9**). The hydroxy ketone (**9**) was treated with potassium hydroxide in liquid ammonia and the product was methylated by diazomethane to give 14-membered cyclic glycol (**10**). Reductive dehydroxylation of **10** by means of tin(II) chloride dihydrate in ether saturated with hydrogen chloride yielded **2n**.

The tetrakis(*p*-methoxyphenyl)tetrakisdehydro[18]annulene (**1f**) was synthesized by the method used for the preparation of other analogous tetrakisdehydro[18]annulenes (**1a—e**).[1-4] The reaction sequence is outlined in Scheme 3. The diketone

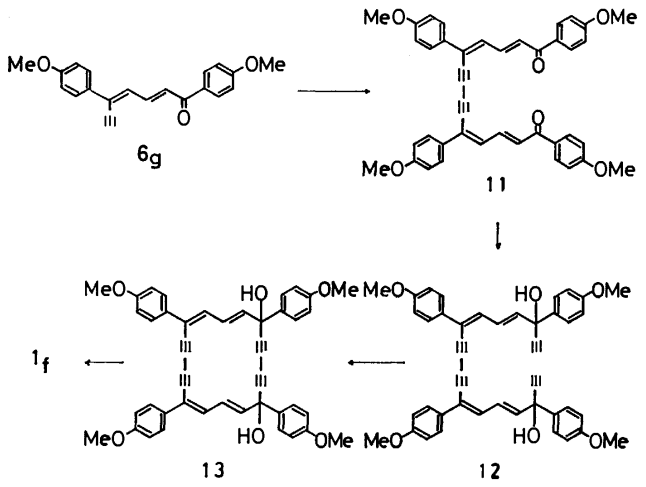

Scheme 3.

(**11**) obtained by the oxidative coupling of dienyne ketone (**6g**) by cupric acetate in pyridine was allowed to react with lithium acetylide-ethylenendiamine complex[9] in THF to give the acetylenic glycol (**12**). Oxidative coupling of **12** by cupric acetate in pyridine under high dilution conditions yielded the cyclic glycol (**13**), which could be converted into the tetrakis(*p*-methoxyphenyl)tetrakisdehydro[18]annulene (**1f**) on treatment with tin(II) chloride dihydrate in ether saturated with hydrogen chloride.

The color of crystals, melting points and the electronic spectral data of **2g**—**n** and **1f** are summarized in Table 1.

Discussion. The effect of alkyl groups on the chemical shifts of protons on 'acetylene-cumulene'-dehydroannulene rings is summarized in Table 2. The most remarkable change caused by the replacement of hydrogens by *t*-butyl groups (**2a**→**2b**) or methyl by *t*-butyl groups (**1a**→**1b**) is the appreciable low field shifts of inner protons signals. The essentially planar structures of tetra-*t*-butylbisdehydro[18]-[10] and [22]annulenes[11] have been proved by the X-ray structure analyses, and the almost temperature independent ^{1}H NMR spectra of this series of 'acetylene-cumulene'-dehydroannulenes indicate their high conformational stability.[1,3,14] Also the examination of molecular models of *t*-butylsubstituted derivatives reveals that they have no steric interference between the *t*-butyl group and the adjacent outer hydrogen atom. In view of the rather high diatropicity of **1** and **2**, it seemed to be reasonable to assume that the annulenes (**1** and **2**) hold essentially planar conformation in solution just as in crystalline state. Therefore, the marked low field shifts of inner protons seems to be difficult to ascribe solely to the deformation of annulene perimeter caused by introduction of substituent groups. Also the remarkable low field shifts can not be attributed to the change of electron density of the annulene ring induced by the introduction of substituent groups, becaues the ^{1}H NMR spectra of **14a**[12] and **14b**[12] bearing electron attractive acetyl

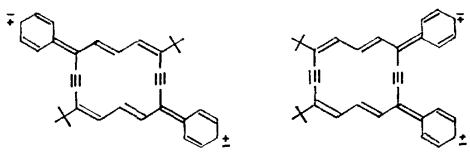
or carboxyl group exhibit essentially the same NMR trend as compared with **2a** and **2b** having hydrogen or electron donating alkyl groups.

The ^{1}H NMR parameters of aryl substituted tetrakisdehydro[18]annulene derivatives are recorded in Table 3 together with those of tetramethyl and tetra-*t*-butyl derivatives (**1a** and **1b**) as references. The ^{1}H NMR parameters of bisdehydro[14]annulenes bearing two aryl groups are summarized in Table 4 together with tetra-*t*-butyl derivative (**2b**) as a reference. It is to be noted that the position isomers of di-*t*-butyldiphenylbisdehydro[14]annulenes (**2c**, **2d**, and **2e**) show quite similar ^{1}H NMR spectra. This fact indicates that decrease of ring current by the contribution of dipolar structures such as **15a** or **15b** can be ignored in the ground state of 1,8-bisdehydro[14]-annulene system.[13]



15a 15b

As schematically illustrated in Fig., the magnitude of low field shifts of H^{15} and H^{16} in **2c**, **i**, **j**, **k**, **l**, and **2m** caused by the substituent group at the *p*-position of phenyl group is found to be in the same sequence with the corresponding positions ($H^{m'}$ and $H^{o'}$) in monosubstituted benzenes. This fact suggests that the perturbation of bisdehydro[14]annulene ring on benzene nucleus is not sufficiently large enough to alter the electronic state or electron density of the *p*-substituted phenyl group. Interestingly, as shown in Fig., low field shifts of outer protons of the annulene nuclei (H^4 and H^6), although in less extent being maximum values 0.19 and 0.23 ppm for H^4 and H^6, respectively, are found in the same sequence of H^{16} and $H^{o'}$. This fact indicates a transmission of the effects of *p*-substituent group to the annulene nuclei.

The ^{1}H NMR parameters of tetraaryl-1,8-bisdehydro[14]annulenes (**2f**, **g**, **h**) and tri-*t*-butyl(*p*-methoxycarbonylphenyl)-1,8-bisdehydro[14]annulene (**2n**) are recorded in Table 5. The tetraaryl derivatives (**2f**, **g**, **h**) showed inner proton signals at lower field

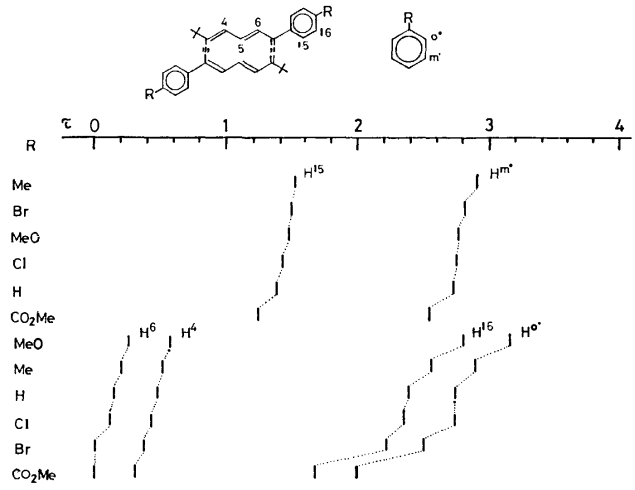


Fig. ^{1}H NMR chemical shifts of bis(*p*-substituted-phenyl)-di-*t*-butyl-1,8-bisdehydro[14]annulenes (**2c**, **i**—**m**) and corresponding monosubstuitedt benzenes.

than those for diaryl derivatives (Table 4). On the other hand, high field shifts of both of the inner and outer proton signals were observed in the monoaryl-derivative (**2n**) as compared with the diaryl derivatives (**2c**, **d**, **e**, **i**, **j**, **k**, **l**, **m**) shown in Table 4. This trend seems to indicate that the diamagnetic ring current induced in the aryl substituent(s) exerts deshielding effect on the outer and inner protons of the annulene nuclei.

The deshielding effect of phenyl group in di-*t*-butyl-diphenyl-1,8-bisdehydro[14]annulene (**2c**) on the annulene protons has been calculated assuming coplanar conformation of the phenyl groups with the annulene ring by the Johnson-Bovey's method. The low field shifts due to the diamagnetic ring current in phenyl groups were estimated to be as follows : H^6 -0.60—-0.50; $H^4 < -0.15$; H^5 -0.15——-0.20 ppm. In view of the observed much larger down field shifts, this results seem to indicate that some other effects cooperate with the deshielding effect of aryl substituents.

It is well recognized that the signals of inner protons show remarkable shifts on minor variation of diamagnetic ring current in contrast to rather insensitive outer proton signals.[14] Because as pointed out previ-

ously, steric effects of the substituent groups seem to be insufficient to explain the marked ^1H NMR change, a decrease of ring current as a result of perturbation of substituent(s) may be largely responsible for the marked low field shifts of the inner proton signals, although the nature of perturbation is not clear yet and the low field shift of outer protons in **1b** can not be explained in terms of decrease of ring current.[15] The diamagnetic ring current induced in aryl substituent exerts deshielding effect on both of inner and outer protons of annulene ring. Inversely, the deshielding effect of ring current induced in annulene ring is reflected in the low field shifts of *o*-protons of aryl substituent as compared with that of *m*-protons. Also the outer protons of annulene ring suffer a minor electronic effect of *p*-substituent in phenyl group as illustrated in Fig. The interesting ^1H NMR characteristics observed in substituted 'acetylene-cumulene'-dehydroannulenes should arise from the superposition of these various effects.

Experimental

The melting points were measured on a Mettler FP-2 apparatus and uncorrected. The IR spectra were obtained on a Hitachi EPI-G3 or a JASCO DS-402G spectrophotometer. The NMR spectra were measured on a Varian A-60D or XL-100 spectrometer, and the parameters were given in τ-values with respect to TMS used as an internal standard. The electronic spectra were obtained in THF on a Hitachi EPS-3T spectrophotometer. The adsorbents used in column chromatography are silica gel (Merck) and alumina (Merck, Act. II-III and Woelm Act. I). Evaporation of solvent was performed under reduced pressure.

2,2-Dichloroethyl p-*Methoxyphenyl Ketone.* To a stirred solution of *p*-methoxybenzoyl chloride (45.5 g, 0.266 mol) in 1,2-dichloroethane (500 ml) was added dropwise a solution of anhydrous aluminium chloride (41.0 g, 0.307 mol) in nitromethane (75 ml) under bubbling of vinyl chloride. After being stirred for 2 h, the reaction mixture was poured onto cracked ice. The organic layer was washed with sodium hydrogencarbonate solution. The crystals obtained on evaporation of the solvent were washed with ethanol to give fairly pure dichloroethyl ketone, pale yellow crystals, mp 58 °C (dec), 32.4 g, 52.2%, IR(KBr-disk): 1670 (C=O), 706 (C–Cl) cm^{-1}, NMR(CCl_4): 6.13 (3H, s, CH_3), 6.23 (2H, d, J=6 Hz, CH_2), 3.70 (1H, t, J=6 Hz, $CHCl_2$); 3.07 (2H, d, J=10 Hz, aromatic-H), 2.08 (2H, d, J=10 Hz, aromatic-H).

Found: C, 51.58; H, 4.29; Cl, 30.02%. Calcd for $C_{10}H_{10}Cl_2$: C, 51.53; H, 4.32; Cl, 30.42%.

2-Chlorovinyl p-*Methoxyphenyl Ketone (**3g**).* A solution of triethylamine (17.0 g, 0.086 mol) in ether (40 ml) was added at 5 °C to a solution of 2,2-dichloroethyl *p*-methoxyphenyl ketone (20.0 g, 0.086 mol) in the same solvent (260 ml). After being stirred for 3 h at the same temperature, the reaction mixture was kept in a refrigerator overnight. The amine hydrochloride deposited was removed by filtration. Crystalline solid obtained on concentrating the filtrate was extracted with petroleum ether (bp 35—60 °C). Evaporation of the solvent yielded pure **3g**, pale yellow crystals, mp 47 °C (dec), 17.0 g, quantitative, IR(KBr-disk): 1665 (C=O), 940 (CH=CH), 758 (C–Cl) cm^{-1}, NMR(CCl_4): 6.13 (3H, s, CH_3), 2.66 (1H, s, vinyl-H), 2.63 (1H, s, vinyl-H), 2.99 (2H, d, J=10 Hz, aromatic-H), 2.15 (2H, d, J=10 Hz, aromatic-H).

Found: C, 61.68; H, 4.75; Cl, 17.87%. Calcd for $C_{10}H_9O_2Cl$: C, 61.40; H, 4.64; Cl, 17.61%.

*1-Chloro-3-(*p-*methoxyphenyl)-1-penten-4-yn-3-ol (**4g**).* A solution of **3g** (16.9 g, 86.2 mmol) in THF (190 ml) was added to a stirred solution of lithium acetylide (prepared from lithium, 0.81 g, 0.12 g atm) in liquid ammonia (250 ml) over a period of 5 h at −60 °C. After the ammonia was allowed to evaporate, saturated ammonium chloride solution (100 ml) was added to the residue at −20 °C. The aqueous layer was extracted with ether and the extract was combined with the organic layer and dried (Na_2SO_4). Evaporation of the solvent yielded crude **4g**, reddish brown liquid, 19.0 g. Because attempted high vacuum distillation resulted in decomposition, the crude material was subjected to a chromatography on silica gel to give fairly pure **4g**, IR(neat): 3425 (O–H), 3300 (C≡CH), 2120 (C≡C), 1608 (CH=CH), 940 (CH=CH), 734 (C–Cl) cm^{-1}, NMR(CCl_4): 7.33 (1H, s, C≡CH), 6.30 (3H, s, CH_3), 6.63 (1H, s, OH), 4.00 (1H, d, J=13 Hz, vinyl-H), 3.51 (1H, d, J=13 Hz, vinyl-H), 3.26 (2H, d, J=9 Hz, aromatic-H), 2.59 (2H, d, J=9 Hz, aromatic-H).

*3-(*p-*Methoxyphenyl)-2-penten-4-ynal (**5g**).* A solution of **4g** (34.9 g, 0.12 mol) in THF (100 ml) was mixed with 1.5 M sulfuric acid (450 ml) and the mixture was stirred under nitrogen atmosphere for 3 days at 18 °C. The organic layer was separated and the aqueous layer, after neutralization with an aqueous sodium hydroxide solution, was extracted successively with ether and benzene. The combined organic solution was washed with brine and dried (Na_2SO_4). Crude brown crystals obtained on concentration of the solution were recrystallized from ethanol to give pure **5g**, yellow crystals, mp 120 °C (dec), 5.5 g, 26%, IR(KBr-disk): 3210 (C≡CH), 2080 (C≡C), 1670 (C=O) cm^{-1}, NMR($CDCl_3$): 6.23 (1H, s, C≡CH), 6.16 (3H, s, CH_3), 3.23 (1H, d, J= 8 Hz, vinyl-H), 3.06 (2H, d, J=10 Hz, aromatic-H), 2.26 (2H, d, J=10 Hz, aromatic-H), −0.24 (1H, d, J=8 Hz, CHO). **5g** was found to be rather unstable decomposing gradually in a dark at low temperature and gave less satisfactory elemental analysis.

Found: C, 77.05; H, 5.41%. Calcd for $C_{12}H_{10}O_2$: C, 77.40; H, 5.41%.

*1,5-Bis(*p-*methoxyphenyl)-2,4-heptadien-6-yn-1-one (**6g**).* A solution of sodium hydroxide (0.5 g, 12.5 mmol) in 50% aqueous ethanol (4 ml) was added at 5 °C to a stirred solution of *p*-methoxyacetophenone (1.53 g, 0.2 mmol) and **5g** (1.90 g, 10.2 mmol) in ethanol (70 ml). After being stirred overnight, deposited crystals were collected and washed successively with water and ethanol to give **6g**, yellow crystals, mp 111—112 °C, 1.95 g, 62%, IR(KBr-disk): 3230 (C≡CH), 2100 (C≡C), 1650 (C=O) cm^{-1}, NMR($CDCl_3$): 6.33 (1H, s, C≡CH), 6.18 (3H, s, CH_3), 6.13 (3H, s, CH_3), 3.10 (2H, d, J=9.0 Hz, aromatic-H), 3.05 (2H, d, J=9.0 Hz, aromatic-H), 2.31 (2H, d, J=9.0 Hz, aromatic-H), 2.05 (2H, d, J=9.0 Hz, aromatic-H), 2—3(3H, m, vinyl-H).

Found: C, 79.19; H, 5.70%. Calcd for $C_{21}H_{18}O_3$: C, 79.22; H, 5.69%.

*Preparation of 1,5-disubstituted 2,4-Heptadien-6-yn-1-one (**6h**—**m**).* Because the heptadienyne ketones (**6h**—**m**) were prepared by the aldol condensation of methyl ketones with 3-substituted-2-penten-4-ynals (**5**, R=Ph[3] and R=*t*-Bu[2]) under similar reaction conditions used in the synthesis of **6g**, the reaction conditions, physical properties, yields and elemental analyses are tabulated in Table 6. The IR and NMR spectra of **6h**—**m** were found to be consistent with the assigned structures.

*Preparation of 3,7,10,14-Tetrasubstituted 1,8-Bisdehydro[14]annulenes (**2g**—**m**).* The preparation of **2g**—**m** were per-

formed by the previously reported procedure.[7] Because the cyclic glycols (**7g**—**m**) were obtained as amorphous solids and found to be difficult to crystallize, the crude materials were subjected to the reductive dehydroxylation to give **2g**—**m**. The products were purified by chromatography on alumina (Merck or Woelm). The reaction conditions, melting points and analytical data are summarized in Table 7. The yields of **2g**—**m** were calculated on the basis of **6g**—**m**.

*1-(*p*-Methoxycarbonylphenyl)-5,8,12-tri-*t*-butyl-2,4,9,11-tetradecatetraene-6,13-diyn-1-one (**9**).* To a stirred solution of *p*-acetylbenzoic acid (0.5240 g, 3.19 mmol) in water (4 ml) containing sodium hydroxide (0.34 g, 8.5 mmol) was added under argon atmosphere at 15 °C a solution of hydroxy aldehyde[9] (**8**, 0.939 g, 2.65 mmol) in methanol (30 ml). After being stirred for 44.5 h, 1 M hydrochloric acid was added to the reaction mixture, and the resulting turbid yellow mixture was extracted with ether. Yellow solid obtained on working up the extract was treated with an ethereal solution of diazomethane. Chromatography of the product on alumina (Merck, 70 g) followed by elution with hexane–benzene (1:1) and ether afforded **9**, yellow solid, 523 mg, 38%, IR(KBr-disk): 3480 (O–H), 3300 (C≡CH), 2081 (C≡C), 1727 (C=O ester), 1655 (C=O), 1585 (CH=CH) cm^{-1}, NMR(CCl_4): 8.91 (9H, s, *t*-Bu), 8.83 (9H, s, *t*-Bu), 8.77 (9H, s, *t*-Bu), 7.00 (1H, s, OH), 6.80 (1H, s, C≡CH), 6.11 (3H, s, $COCH_3$), 4.13—1.89 (10H, m, olefinic and aromatic-H).

Attempts to crystallize **9** were unsuccessful.

*3,10,14-Tri-*t*-butyl-7-(*p*-methoxycarbonylphenyl)-1,8-bisdehydro[14]annulene (**2n**).* A solution of **9** (105.7 mg, 0.205 mmol) in THF (20 ml) was added over 6.5 h-period to a stirred suspension of powdered potassium hydroxide (4.0 g, 71.4 mmol) in liquid ammonia (300 ml) at −35—−40 °C. After the mixture had been stirred for further 15 h, ammonium chloride (4.0 g, 74.7 mmol) was added and the ammonia was allowed to evaporate. The residue was mixed with water and extracted with ether. The aqueous layer was acidified with 1 M hydrochloric acid and extracted with ether. The combined extract, after being washed successively with water and brine, and dried ($MgSO_4$), was concentrated in a small volume. An ethereal solution of diazomethane was added to the concentrate. As the purification of **10** was found to be difficult, the crude **10** in ether (10 ml) was treated with a solution of tin(II) chloride dihydrate (0.5 g) in the same solvent saturated with hydrogen chloride (10 ml) at −15 °C. After 5 min, the resulting deep reddish brown solution was poured on an aqueous solution of sodium hydrogencarbonate, and extracted with ether. The crude product obtained on working up the extract was chromatographed on alumina (Merck, 50 g). Elution with hexane–benzene (1:1) gave **2n**, reddish brown crystals, mp> 270 °C (dec), 93.2 mg, 32% based on **9**, IR (KBr-disk): 2075 (C–C≡C–C ↔ C=C=C=C=), 1714 (C=O), 1604 (CH=CH), 970 (*trans* CH–CH) cm^{-1}, mass (*m/e*): 480 (M^+), calcd for $C_{34}H_{40}O_2$: mol wt 480.66.

*1,5,10,14-Tetra-*p*-methoxyphenyl-2,4,10,12-tetradecatetraene-6,8-diyne-1,14-dione (**11**).* A solution of copper(II) acetate monohydrate (12.0 g) in pyridine–methanol (1:1, 200 ml) was added to a stirred solution of **6g** (5.4 g, 17 mmol) in the same solvent (200 ml) at 5 °C. The mixture was stirred overnight at a room temperature. Yellow crystals deposited were collected and washed successively with water and ethanol to give pure **11**, yellow crystals, mp 156.8 °C, 5.3 g, 98%, IR(KBr-disk): 2830 (C–H in O–CH_3), 1645 (C=O), 983 (CH=CH) cm^{-1}, NMR($CDCl_3$): 6.13 (12H, s, OCH_3), 3.10 (4H, d, J=9 Hz, aromatic-H), 2.86 (4H, d, J=9 Hz, aromatic-H), 2.33 (4H, d, J=9 Hz, aromatic-H), 2.03 (4H, J=9 Hz, aromatic-H), 1.9—2.3 (6H, m, olefinic-H).

Found: C, 79.44; H, 5.44%. Calcd for $C_{42}H_{34}O_6$: C, 79.48; H, 5.40%.

*3,7,12,16-Tetra-*p*-methoxyphenyl-4,6,12,13-octadecatetraene-1,8,10,17-tetrayne-3,6-diol (**12**).* A solution of **11** (2.050 g, 3.23 mmol) in THF (330 ml) was added over 2 h-period at 15—17 °C to a stirred suspension of lithium acetylide-ethylenediamine complex (4.2 g, 45.5 mmol) in the same solvent (50 ml) under bubbling of acetylene. After being stirred for further 4 h, saturated aqueous solution of ammonium chloride (50 ml) was added to the reaction mixture at −15 °C. The aqueous layer was extracted with benzene and combined with the organic layer, which was worked up to give a light brown solid. The material was chromatographed on alumina (Merck, 20 g) to give slightly crude **12**, 1.980 g, which was used without further purification in the subsequent reaction.

*1,5,10,14-Tetra-*p*-methoxyphenyl-6,8,15,17-tetrakisdehydro[18]annulene (**1f**).* To a vigorously stirred solution of copper(II) acetate monohydrate (3.7 g) in pyridine (60 ml), methanol (30 ml) and ether (180 ml) was added a solution of crude **12** (2.23 g) in pyridine (40 ml), methanol (20 ml) and ether (10 ml) over a period of 14 h at 40—45 °C. The residue obtained on evaporation of the solvent was digested with benzene. The benzene solution was washed successively with brine, sodium hydrogencarbonate solution and brine, and dried ($MgSO_4$). Evaporation of the solvent yielded brown crystalline solid, which was washed with benzene to give sufficiently pure **13**, pale yellow fine crystals, 0.514 g, 23.2% based on **11**.

A solution of tin(II) chloride dihydrate (1.0 g, 4.4 mmol) in ether saturated with hydrogen chloride (5 ml) was added at −78 °C to a stirred solution of **13** (100 mg, 0.15 mmol) in ether (20 ml) and THF (5 ml). After being stirred for 10 min at the same temperature, water (100 ml) was added to the reaction mixture. Crystals deposited were washed successively with ethanol and acetone to give fairly pure **1f**, deep green crystals, mp 169—171 °C (decomposed without fusion), 76 mg, 77%. A specimen obtained by passing repeatedly a solution of **1f** in THF through a column of alumina (Woelm) gave rather unsatisfactory elemental analysis.

Found: C, 84.38; H, 5.33%. Calcd for $C_{46}H_{34}O_4$: C, 84.90; H, 5.27%.

15) It was puzzling that *trans*-15,16-dihydropyrene showed smaller ring current than *trans*-15,16-dimethyldihydropyrene. The ESR studies on radical anion of *trans*-15,16-dihydropyrene provide a strong evidence for an exceptionally large hyperconjugative effect of inner hydrogen atoms (C. Elschenbroich, F. Gerson, and V. Boekelheide, *Helv. Chim. Acta*, **58**, 1245 (1975)), and the reduction of ring current of *trans*-15,16-dihydropyrene has been considered to be attributable to the hyperconjugative effect (T. Otsubo, R. Gray, and V. Boekelheide, *J. Am. Chem. Soc.*, **100**, 2449 (1978)). In the case of methyl or *t*-butyl substituted 'acetylene-cumulene'-dehydroannulenes, the possibility can not be excluded that the hyperconjugation of C–H bond in methyl or C–CH_3 bond in *t*-butyl group disposed in parallel direction with the *p*-orbital of adjacent sp^2-hybridized carbon atom of annulene ring is responsible for the ^1H NMR behavior of the 'acetylene-cumulene'-dehydroannulenes.

Dehydroannulenes. X. Synthesis and Properties of 3,9,12,18-Tetrasubstituted-1,10-bisdehydro[18]annulenes

Masahiko IYODA, Shuzo AKIYAMA,† and Masazumi NAKAGAWA*

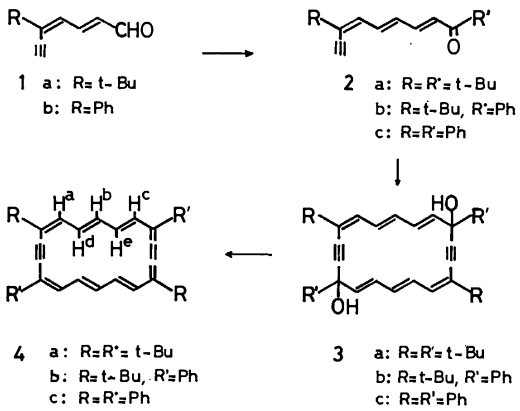
(Received May 15, 1978)

The cyclic dimerization of 1,7-disubstituted-1-oxo-2,4,6-nonatrien-8-ynes on treatment with a suspension of potassium hydroxide in liquid ammonia to give tetrasubstituted 18-membered cyclic glycols has been achieved. The cyclic glycols could be converted into 3,9,12,18-tetrasubstituted 1,10-bisdehydro[18]annulenes which were found to be conformationally stable and strongly diatropic.

As reported in previous papers,[1] 1,5-disubstituted 1-oxo-2,4-heptadien-6-ynes gave 14-membered cyclic glycols on treatment with a suspension of potassium hydroxide in liquid ammonia, and the cyclic glycols could be converted into 3,7,10,14-tetra-substituted 1,8-bisdehydro[14]annulenes by reductive dehydroxylation. The finding seemed to open a new route leading to higher members of bisdehydro[4n+2]annulenes provided that the cyclic dimerization can be realized for higher ethynylpolyene ketones.

In this paper we wish to report the cyclic dimerization of ethynyltriene ketones (**2**) to give 18-membered cyclic glycols (**3**) and their transformation into tetrasubstituted bisdehydro[18]-annulenes (**4**).[1]

Synthesis. The ethynyltriene ketones (**2a**[3,4] and **2c**[5]) were prepared by the reported methods. The trienyne ketone (**2b**) was obtained by the aldol condensation of acetophenone with 3-*t*-butyl-2,4-heptadien-6-ynal (**1a**).[3,4] A solution of ethynyltriene ketone (**2**) in tetrahydrofuran was added to a stirred suspension of finely powdered potassium hydroxide in liquid ammonia at *ca.* −35 °C. The cyclic glycol (**3a**) was obtained as a 1:1 mixture of diastereomers and could be separated into a high melting and a low melting isomers on chromatography on silica gel. Because the 18-membered cyclic glycols (**3b** and **3c**) were found to be difficult to purify, slightly crude materials were subjected to the following reductive dehydroxylation.



Scheme.

Finely powdered tin(II) chloride dihydrate was added to a stirred solution of **3a** in ether saturated with hydrogen chloride at −60 °C under nitrogen atmosphere. Resulting deeply colored solution was worked up and the product was chromatographed on alumina to give 3,9,12,18-tetra-*t*-butyl-1,10-bisdehydro[18]annulene (**4a**) as reddish violet crystals in 93% yield. Catalytic hydrogenation of **4a** over platinum catalyst yielded tetra-*t*-butyl-cyclooctadecane.

3,12-Di-*t*-butyl-9,18-diphenyl-1,10-bisdehydro[18]-annulene (**4b**) was obtained by a similar procedure as deep violet crystals.

Taking the poor solubility of **3c** and presumably of **4c** into account, a dilute solution of **3c** in dichloromethane was mixed with a solution of tin(II) chloride dihydrate in concentrated hydrochloric acid at −15 °C. 3,9,12,18-Tetraphenyl-1,10-bisdehydro[18]annulene (**4c**) was obtained as deep violet crystals in 59% yield. Full hydrogenation of **4c** over platinum catalyst yielded tetraphenylcyclooctadecane.

Properties. The bisdehydro[18]annulenes (**4a, b, c**) were found to be fairly stable being much stable than the corresponding tetrakisdehydro[18]annulenes.[6] 2,4,7-Trinitrofluorenone gave 1 : 1 CT complexes with **4a** and **4b**. However, CT complex with a definite composition could not be obtained with **4c**.

The electronic spectra of **4a, b, c** consist of three main absorption maxima characteristic of aromatic [4n+2]annulenes and showed close similarity to each other except for bathochromic shift along with the increase of phenyl substitution.[7] The numerical data of the electronic spectra are recorded in Table 1.

The ^{1}H NMR spectra of **4a, b, c** revealed that they sustain strong diamagnetic ring current exhibiting the inner proton signals at high field and those of outer protons at low field. The ^{1}H NMR parameters are summarized in Table 2. Replacement of *t*-butyl group by phenyl caused low field shift of inner and outer proton signals in **4b** and **4c**, which can be attributed, at least partly, to the deshielding effect of the diamagnetic ring current induced in phenyl groups. On the other hand, low field shift of *o*-proton signal of phenyl group as compared with that of *m,p*-protons indicate that the ring current in annulene ring exerts deshielding effect on the phenyl protons, and the *o*-protons suffer pronounced shift owing to their proximate position to the annulene nucleus. As recorded in Table 3, the ^{1}H NMR spectra of **4a** were found to be temperature independent being essentially unchanged up to 110 °C. This fact indicates the conformational stability of the tetrasubstituted 1,10-bisdehydro[18]annulene system. An attempted measurement of the NMR spectrum at 150 °C in deuteriobromo-

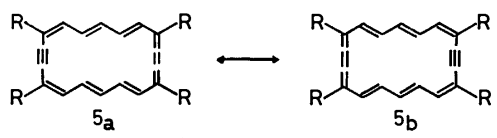
70	0.78, d J=13 Hz	0.30, t J=13 Hz	13.46, t J=13 Hz	8.10, s
110	0.81, d J=13 Hz	0.44, t J=13 Hz	13.28, t J=13 Hz	8.10, s

form resulted in a rapid decomposition of **4a**. Because the planar structure of **4a** has been revealed by the X-ray structure analysis,[8] the minor high field and low field shifts of outer and inner proton signals at higher temperature should be a reflection of increasing deviation of the annulene perimeter from the mean molecular plane owing to the increase of thermal vibration at higher temperature.

It has been generally recognized that dehydroannulenes have higher conformational stability than the corresponding annulenes. The conformational stability of dehydroannulene, which is rendered by the rigid and straight nature of acetylenic bond, is favorable for the study of aromaticity of annulene system. But, on the other hand, the diatropicity of dehydroannulene is suppressed by the perturbation of acetylenic linkage. On the contrary, dehydroannulenes containing an acetylenic and a cumulenic bonds ('acetylene-cumulene'-dehydroannulenes), such as 1,8-bisdehydro[14]annulene[9] and its tetrasubstituted derivatives[1] and **4a,b,c**, showed strong diatropicity and high conformational stability being the most adequate tool for the study of aromaticity of macrocyclic system. Because the acetylenic and cumulenic bonds in 1,8-bisdehydro[14]annulene[10] and in **4a**[8] have been proved to be identical by the X-ray structure analyses being a hybrid of acetylene and butatriene, the strong diatropicity in 'acetylene-cumulene'-dehydroannulene can be attributed to the presence of equivalent valence-bond structures such as **5a**↔**5b**.



Experimental

All melting points were measured on a Mettler FP-2 apparatus and uncorrected. The IR spectra were obtained on a Hitachi EPI-2 or EPI-G3 spectrophotometer and only the significant absorptions were recorded (s=strong, m=medium and w=weak). The NMR spectra obtained on a Varian A-60 or XL-100 spectrometer were recorded in τ-values with respect to TMS used as an internal standard. The mass spectra were obtained on a Hitachi RM-50 spectrometer (ionization potential=70 eV). TLC was performed on Kieselgel GF_{254}(Merck) plates. The adsorbents used in column chromatography were silica gel (Merck, Kieselgel 60) or alumina (Merck, act. II—III), unless stated otherwise. Evaporation of solvent was performed under reduced pressure.

1,4,10,13-Tetra-t-butyl-4,6,8,13,15,17-cyclooctadecahexaene-2,11-diyne-1,10-diol (3a). To a stirred suspension of finely powdered potassium hydroxide (900 mg, 1.60 mmol) in liquid ammonia (180 ml) was added at −34 °C a solution of **2a** (320 mg, 1.13 mmol) in THF (30 ml) over a period of 5 h. After being stirred for further 3 h at the same temperature, ammonium chloride (1.80 g, 33.6 mmol) was added and the ammonia was allowed to evaporate. Water and ether (20 ml) were added to the residue. The aqueous layer was washed successively with water and brine, and dried ($MgSO_4$). Evaporation of the solvent yielded pale yellow crystals, which were washed with hexane to give a mixture of diastereomers of **3a**, colorless crystals, 212 mg, 66.3%. The mixture was chromatographed on silica gel. Elution with benzene gave the high melting isomer of **3a**, colorless crystals, mp 230.5—231.5 °C; mass (*m/e*): 488 (M^+), 470 (M^+-18), 431 (M^+-57), 57 (*t*-Bu, base peak); IR(KBr-disk): 3560 m (OH), 2180 vw (−C≡C−), 1563 w (C=C), 985 vs (*trans* −CH=CH−) cm^{-1}; NMR($CDCl_3$): 2.75—4.20 (10H, m, olefinic), 8.2 (2H, br s, OH), 8.80 (18H, s, *t*-Bu), 8.92 (18H, s, *t*-Bu); UV: $\lambda_{max}^{99\%EtOH}$ (ε): 230 (21100), 280.5 (86900), 291 (113000), 327.5 (13800) nm.

Found: C, 83.53; H, 9.93%. Calcd for $C_{34}H_{48}O_2$: C, 83.55; H, 9.90%.

Elution with benzene–ether (19:1) gave the low melting isomer of **3a**, colorless crystals, mp 170.0—171.0 °C; mass (*m/e*): 488 (M^+), 470 (M^+-18), 431 (M^+-57), 57 (*t*-Bu, base peak); IR(KBr-disk): 3480 m, 3340 m (OH), 2180 vw (−C≡C−), 1563 w (C=C), 985 vs (*trans* −CH=CH−) cm^{-1}; NMR($CDCl_3$): 2.75—4.20 (10H, m, olefinic), 8.01 (2H, s, OH), 8.80 (18H, s, *t*-Bu), 8.92 (18H, s, *t*-Bu); UV: $\lambda_{max}^{99\%EtOH}$ (ε) 230 (18200), 280.5 (76300), 291 (98400), 327.5 (12300) nm.

Found: C, 83.72; H, 10.76%. Calcd for $C_{34}H_{48}O_2$: C, 83.55; H, 9.90%.

3,9,12,18-Tetra-t-butyl-1,10-bisdehydro[18]annulene (4a). To a solution of the diastereomeric mixture of **3a** (105 mg, 0.215 mmol) in ether saturated with hydrogen chloride (10 ml) was added at −60 °C under nitrogen atmosphere finely powdered tin(II) chloride dihydrate (400 mg, 1.77 mmol). The mixture was vigorously stirred at the same temperature for 10 min. The reaction mixture was poured onto ice-cooled sodium hydrogencarbonate solution. The mixture was extracted with ether and the ethereal solution was dried (K_2CO_3). Evaporation of the solution furnished dark red crystals, which were chromatographed on alumina (Woelm, act. I) and eluted with hexane–dichloromethane (19:1) to afford pure **4a**, dark reddish violet crystals, 91 mg, 93%. The crystals obtained on rechromatography on alumina were

washed successively with ether and hexane to give analytical specimen of **2a**, mp 260 °C (dec); mass (*m/e*): 454 (M^+), 397 (M^+-57), 57 (*t*-Bu, base peak); IR(KBr-disk): 3030 w, 2950 s, 2000 vw (−C≡C−↔−C=C=), 1041 m, 987 vs, 878 w cm^{-1}.

Found: C, 89.72; H, 10.18%. Calcd for $C_{34}H_{46}$: C, 89.80; H, 10.20%.

*CT Complex of **4a** with 2,4,7-Trinitrofluorenone.* A solution of **4a** (31.5 mg, 0.0694 mmol) in benzene–methanol (1:1, 40 ml) was mixed with a solution of the trinitrofluorenone (43.5 mg, 0.138 mmol) in benzene–methanol (2 : 1, 9 ml) at 40—50 °C. The solution was kept at 0 °C to deposite the CT complex, deep violet needles, mp *ca.* 260 °C, 41 mg, 77%.

Found: C, 73.37; H, 6.63; N, 5.43%. Calcd for $C_{34}H_{46}\cdot C_{13}H_5N_3O_7$: C, 73.32; H, 6.68; N, 5.46%.

The CT complex was found to be more stable and less soluble in organic solvents than **4a**. The electronic spectrum of the complex showed no CT band being a superposition of the spectra of components.

*Catalytic Hydrogenation of **4a**.* A solution of **4a** (42 mg, 0.0924 mmol) in ethyl acetate (25 ml) was added to platinum catalyst (from 150 mg of platinum(IV) oxide) in acetic acid (25 ml). The mixture was vigorously stirred at room temperature under hydrogen atmosphere for 2.5 h and the catalyst was removed by filtration and washed with ether (50 ml). The combined organic layer was washed successively with water, sodium hydrogencarbonate solution and brine, and dried ($MgSO_4$). Evaporation of the solvent gave a crystalline solid, which was chromatographed on alumina (Woelm, act. I) and eluted with hexane to yield 1,4,10,13-tetra-*t*-butyl-cyclooctadecane, 40 mg, 91%. An analytical specimen was prepared by recrystallization from ethyl acetate–methanol, colorless crystals, mp 151—154 °C; mass (*m/e*): 476 (M^+), 419 (M^+-57), 57 (*t*-Bu, base peak); IR(CCl_4): 2940 s, 2860 m, 1475 m, 1393 m, 1365 m cm^{-1}; NMR(CCl_4): 8.63 (32H, br s, $-CH_2-$, −CH=), 9.11 (36H, s, *t*-Bu).

Found: C, 85.62; H, 14.13%. Calcd for $C_{34}H_{68}$: C, 85.63; H, 14.37%.

*6-t-Butyl-1,3,5-octatrien-7-ynyl Phenyl Ketone (**2b**).* To a solution of sodium hydroxide (0.88 g, 0.022 mol) in aqueous ethanol (1:1, 6 ml) was added at 0 °C a solution of **1a** (3.56 g, 0.0219 mol) and acetophenone (2.64 g, 0.0220 mol) in ethanol (30 ml) under nitrogen atmosphere. The mixture was kept at the same temperature for 3 h and then acidified with 1 M sulfuric acid (20 ml). The mixture was extracted with ether (50 ml×3). The combined extract was washed successively with water, saturated sodium hydrogencarbonate solution and brine, and dried ($MgSO_4$). The residue obtained on evaporating the solvent was chromatographed on silica gel and eluted successively with hexane, benzene and ether–benzene to give **2b**, 4.41 g, 76%. Recrystallization of the material from petroleum ether (bp 40—60 °C) afforded an analytical specimen of **2b**, yellow crystals, mp 59.5—60.0 °C; mass (*m/e*): 264 (M^+); IR($CHCl_3$): 3320 m (C≡CH), 2060 vw (−C≡C−), 1658 s (C=O), 1590 s, 1550 s (C=C), 1016 s, 1002 s (*trans* −CH=CH−) cm^{-1}; NMR($CDCl_3$): 1.98—3.72 (10H, m, olefinic and aromatic), 6.50 (1H, s, C≡CH), 8.81 (9H, s, *t*-Bu); UV: $\lambda_{max}^{99\%EtOH}$ (ε) 225* (8710), 267.5 (10300), 359 (39100) nm.

Found: C, 86.27; H, 7.56%. Calcd for $C_{38}H_{38}$: C, 86.32; H, 7.63%.

*3,12-Di-t-butyl-9,18-diphenyl-1,10-bisdehydro[18]annulene (**4b**).* A solution of **2b** (350 mg, 1.32 mmol) in THF (50 ml) was added over 8 h-period to a stirred suspension of powdered potassium hydroxide (1.00 g, 17.8 mmol) in liquid ammonia (200 ml) at −34 °C. After being stirred for further 2 h at the same temperature, ammonium chloride (2.00 g, 37.4 mmol) was added and the ammonia was allowed to evaporate. The residue was mixed water and ether (20 ml). The aqueous layer was extracted with ether (15 ml×2). The combined organic layer was washed successively with water and brine, and dried ($MgSO_4$). Evaporation of the solvent yielded crude **3b**, light brown solid, *ca.* 350 mg. As the formation of **3b** was confirmed by spectroscopy and TLC analysis and the purification of **3b** was found to be difficult, the crude **3b** was used in the following reaction.

To a solution of the crude **3b** (*ca.* 350 mg) in ether (10 ml) was added at −60 °C ether saturated with hydrogen chloride (10 ml) and finely powdered tin(II) chloride dihydrate (1.00 g, 4.43 mmol). The mixture was vigorously stirred for 10 min at the same temperature and then poured onto an ice-cooled solution of sodium hydrogencarbonate. Ether was added to the mixture and the organic layer was separated, and dried (K_2CO_3). Evaporation of the solvent yielded violet crystals, which were chromatographed on alumina (Woelm, act. I) and eluted with hexane–benzene (4:1—1:1) to give pure **4b**, deep violet crystals, 108 mg, 33% based on **2b**. An analytical specimen was obtained on recrystallizing the crystals from benzene–methanol, mp 235 °C (dec); mass (*m/e*): 494 (M^+), 57 (*t*-Bu, base peak); IR(KBr-disk): 3025 w, 2950 m, 2010 vw (−C≡C−↔−C=C=), 1595 m (C=C), 983 s (*trans* −CH=CH−), 766 s (phenyl) cm^{-1}.

Found: C, 92.16; H, 7.67%. Calcd for $C_{38}H_{38}$: C, 92.26; H, 7.74%.

*CT Complex of **4b** with 2,4,7-Trinitrofluorenone.* A solution of **4b** (45.3 mg, 0.0916 mmol) in benzene–methanol (1:1, 40 ml) kept at 40 °C was mixed with a solution of the trinitro compound (57.7 mg, 0.183 mmol) in the same solvent (20 ml). The mixture was allowed to stand at 0 °C to deposite the CT complex, deep violet needles, mp *ca.* 250 °C (dec), 46.6 mg, 62.8%.

Found: C, 75.06; H, 5.23; N, 5.49%. Calcd for $C_{38}H_{38}\cdot C_{13}H_5N_3O_7$: C, 75.63; H, 5.35; N, 5.19%.

*3,9,12,18-Tetraphenyl-1,10-bisdehydro[18]annulene (**4c**).* A solution of **2c** (0.150 g, 0.77 mmol) in THF (40 ml) was added over 3 h-period at −34 °C to a stirred suspension of potassium hydroxide (3.00 g, 5.36 mmol) in liquid ammonia (200 ml). After the mixture had been stirred overnight at the same temperature, ammonium chloride (6.0 g, 0.113 mol)

was added. The residue obtained after being allowed the ammonia to evaporate was extracted with benzene (200 ml). The extract was washed with water, and dried ($MgSO_4$). Light solid (0.148 g) obtained on evaporating the solvent was dissolved in a small amount of benzene. Hexane was added to the benzene solution to precipitate **3c**, crystalline solid, 76 mg, 53%, which was found to be difficult to purify. A solution of tin(II) chloride dihydrate (0.30 g) in concentrated hydrochloric acid (5.0 ml) was added at −15 °C to a solution of the crude cyclic glycol (**3c**, 76 mg, 0.13 mmol) in dichloromethane (200 ml). After being stirred for 10 min at the same temperature, a solution of sodium carbonate was added to the mixture. The organic layer was washed with water, and dried ($MgSO_4$). The solution was passed through a short column of alumina (10 g). The residue obtained on concentrating the filtrate was triturated with benzene-hexane and the crystals deposited were washed with the same solvent to give **4c**, dark violet needles, mp 250 °C (dec), 41 mg, 59%. The tetraphenyl derivative (**4c**) was found to be sparingly soluble and stable compound. The crystals were recrystallized from THF and repeatedly chromatographed on alumina (Woelm, act. I) to give an analytical sample, mass (*m/e*): 534 (M^+); IR (KBr-disk): 2040 (−C≡C−↔−C=C=), 1595 (C=C), 980 (*trans* −CH=CH−), 761 (phenyl) cm^{-1}.

Found: C, 94.37; H, 5.61%. Calcd for $C_{42}H_{30}$: C, 94.34; H, 5.66%.

Catalytic Hydrogenation of ***4c***. Platinic oxide (100 mg) was added to a solution of **4c** (30 mg) in THF–ethyl acetate (1:1, 30 ml), and the mixture was vigorously stirred under hydrogen atmosphere for 3 h. The catalyst was removed by filtration and washed with benzene. The residue obtained on evaporation of the filtrate and washing was dissolved in hexane (5 ml) and passed through a thin layer of silica gel (0.2 g). Evaporation of the filtrate afforded colorless crystals, 27 mg, 90%, which were recrystallized twice from hexane–pentane to give 1,4,10,13-tetraphenylcyclooctadecane, mp 146—152 °C; mass (*m/e*): 556 (M^+); NMR(CD_2Cl_2): 2.83 (20H, s, aromatic), 7.35 (4H, m, −CH=), 8—9 (28H, m, $-CH_2-$).

Found: C, 90.80; H, 9.49%. Calcd for $C_{42}H_{52}$: C, 90.59; H, 9.41%.

Dehydroannulenes. XI. Synthesis and Properties of 3,11,14,22-Tetra-*t*-butyl-1,12-bisdehydro[22]annulene

Masahiko IYODA and Masazumi NAKAGAWA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

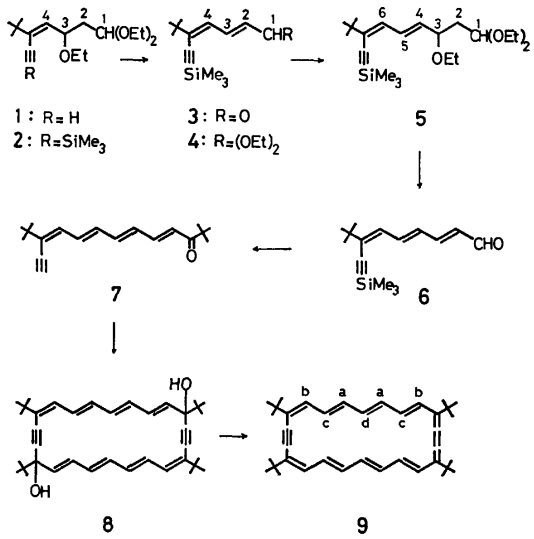
(Received May 15, 1978)

7-*t*-Butyl-9-trimethylsilyl-2,4,6-nonatrien-8-ynal prepared from 5-*t*-butyl-7-trimethylsilyl-2,4-heptadien-6-ynal diethyl acetal was converted into 8-*t*-butyl-1,3,5,7-decatetraen-7-ynyl *t*-butyl ketone. Treatment of the tetraenyne ketone with potassium hydroxide in liquid ammonia gave 22-membered cyclic glycol in a high yield. Reductive dehydroxylation of the cyclic glycol by tin(II) chloride and hydrogen chloride yielded tetra-*t*-butylbisdehydro[22]annulene in good yield. The [22]annulene was found to be strongly diatropic and conformationally stable.

The stable nature, strong diatropicity and high conformational stability observed in 3,9,12,18-tetrasubstituted 1,10-bisdehydro[18]annulenes[1] provide a stimulus to further efforts to synthesize higher analogues of this series of bisdehydro[4n+2]annulenes.

In this paper we wish to report the synthesis and properties of 3,11,14,22-tetra-*t*-butyl-1,12-bisdehydro-[22]annulene (**9**).

Synthesis. The synthesis of the bisdehydro[22]-annulene (**9**) has been achieved by the reaction sequence shown in Scheme. Because the diethyl acetal of 5-*t*-butyl-2,4-heptadien-6-ynal[2] was found to be rather unstable, 5-*t*-butyl-3-ethoxy-4-hepten-6-ynal diethyl acetal (**1**)[1] was converted into the trimethylsilyl derivative (**2**) in 92% yield on successive treatment with ethylmagnesium bromide and trimethylchlorosilane. Treatment of **2** with an aqueous acetic acid containing sodium acetate afforded trimethylsilyl derivative of 5-*t*-butyl-2,4-heptadien-6-ynal (**3**) in a yield of 89%, which was converted into the diethyl acetal (**4**) in the usual method. The reaction of ethyl vinyl ether with **4** in benzene in the presence of boron trifluoride etherate[2,3] gave ethoxy acetal (**5**) in 86% yield. Trimethylsilyltrienyne aldehyde (**6**) was obtained on treatment of **5** with an aqueous acetic acid containing sodium acetate. The trienyne aldehyde (**6**) was found to be fairly stable and could be isolated on rapid distillation *in vacuo* in a yield of 87%.



Scheme.

The aldol condensation of pinacolone with the trienyne aldehyde (**6**) under alkaline conditions resulted in tetraenyne ketone (**7**) in 60% yield accompanying the cleavage of trimethylsilyl group.

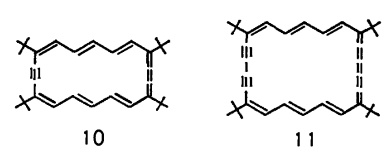
A diluted solution of the tetraenyne ketone (**7**) in tetrahydrofuran was added slowly to a stirred suspension of finely powdered potassium hydroxide in liquid ammonia. The 22-membered cyclic glycol (**8**) was obtained as a mixture of diastereomers which could be separated into the high melting isomer (**8a**, 31%) and the low melting isomer (**8b**, 58%) upon chromatography on alumina. The diastereomers (**8a**, and **8b**) gave identical electronic and NMR spectra, but slight difference was observed between their IR spectra measured by KBr-disk method.

Finely powdered tin(II) chloride dihydrate was added at −60 °C to a stirred suspension of the diastereomeric mixture of cyclic glycol (**8**) in ether containing hydrogen chloride under nitrogen atmosphere. The reaction mixture was worked up in the usual way and purified by chromatography on alumina to give 3,11,14,22-tetra-*t*-butyl-1,12-bisdehydro[22]annulene (**9**) in a yield of 94%.

Full hydrogenation of **9** in ethyl acetate and acetic acid over platinum catalyst at −15——20 °C afforded crystalline tetra-*t*-butylcyclodocosane as a mixture of stereoisomers. Recrystallization of the mixture resulted in a crude separation of stereoisomers. The bisdehydro[22]annulene (**9**) gave 1 : 1 CT complex with 2,4,7-trinitrofluorenone.

Properties. The tetra-*t*-butylbisdehydro[22]annulene (**9**) was found to be rather stable compound and could be kept without decomposition in a dark place at room temperature for a long period.

The electronic spectrum of **9** showed representative aromatic characteristic exhibiting three distinct main absorption bands. As illustrated in Fig. 1, the spectrum of **9** shows close similarity with those of 3,9,12,18-tetra-*t*-butyl-1,10-bisdehydro[18]annulene (**10**)[1] and 1,6,12,17-tetra-*t*-butyl-2,4,13,15-tetrakisdehydro[22]annulene (**11**).[2]



The ^{1}H NMR spectrum and the parameters are shown in Fig. 2 and Table, respectively. The minor

Table. ^{1}H NMR parameters of **9** in $CDCl_3$

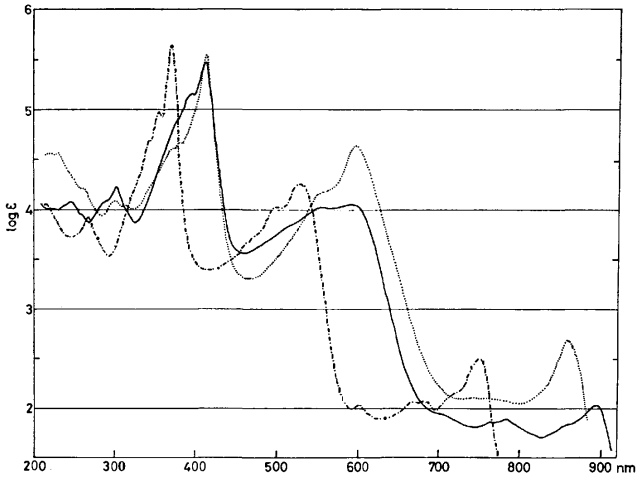

Fig. 1. Electronic spectra of **9** (——), **10** (—·—·) and **11** (·····) in THF.

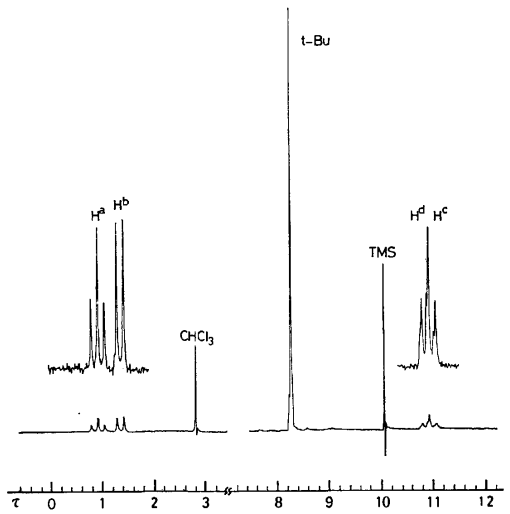

Fig. 2. 100 MHz ^{1}H NMR spectrum of **9** in $CDCl_3$ at 35 °C.

difference between the spectra measured at various temperatures indicates the conformational stability of **9**. An attempted measurement at 80 °C in deuteriobromoform resulted in a rapid decomposition of **9**. The ^{1}H NMR spectrum reveals that the bisdehydro[22]annulene (**9**) is strongly diatropic being stronger than that of monodehydro[22]annulene.[4] It has been reported that the parent [22]annulene[5] gave high-field multiplet at τ 10.4—11.2 (inner protons) and low-field multiplets at τ 0.35—0.7 and 0.9—1.5 (outer protons) at −90 °C being almost the same with the parameters of **9** obtained at 36 °C. However, obvious high-field and low-field shifts of outer and inner proton signals of **9** were observed as compared with those of the lower analogues, *i.e.*, 3,7,10,14-tetra-*t*-butyl-1,8-bisdehydro[14]annulene[6] and 3,9,12,18-tetra-*t*-butyl-1,10-bisdehydro[18]annulene (**10**).[1] The X-ray structure analysis of **9** revealed that the polyene parts in **9** have slight bond-alternation, and also one of the sp-sp linkages in **9** has more acetylenic and the other has more cumulenic character in contrast to the highly symmetrical structure of tetra-*t*-butylbisdehydro[18]annulene (**10**).[8] It has been predicted theoretically that the resonance energies per π-electron of [4n+2]annulenes should decrease and the bond-alternation should increase along with the increase of ring size.[9] Also the decrease of ring current in larger ring has been concluded theoretically.[9b,d,10] Consequently, the results obtained on bisdehydro[18]- and [22]annulenes (**10** and **9**) provide experimental supports to justify the theoretical prediction.

Experimental

All melting points were determined on a Mettler FP-2 apparatus and uncorrected. IR spectra were measured on a Hitachi EPI-2 or EPI-G3 spectrophotometer and only significant maxima are recorded. The intensities are denoted by the following abbreviation: strong=s, medium=m and weak=w. Electronic spectra were obtained on a Hitachi EPS-3T spectrophotometer and the shoulder was indicated by an asterisk. The NMR spectra were measured on a Varian A-60 or a XL-100 spectrometer using TMS as an internal standard and recorded in τ-unit. The mass spectra were obtained on a Hitachi RM-50 spectrometer operated at 70 eV of ionization potential. The TLC was performed on Kiesel Gel GF_{254} (Merck) plates. Silica gel (Merck, Kiesel Gel 60) or alumina (Merck, act. II-III) were used in the column chromatography, unless otherwise stated. Evaporation of the solvent was performed under reduced pressure.

5-t-Butyl-2,4-heptadien-6-ynal Diethyl Acetal. A solution of *p*-toluenesulfonic acid monohydrate (300 mg, 1.58 mmol) in ethanol (1 ml) was added to a solution of 5-*t*-butyl-2,4-heptadien-6-ynal[2] (2.88 g, 0.0178 mol) in triethyl ortho-

formate (7.70 g, 0.0520 mol). After being stirred overnight, the reaction mixture was worked up in the usual way. The residue obtained on evaporation of the solvent was distilled through a short column to furnish the diethyl acetal, a yellow liquid, bp 105 °C/267 Pa, 2.60 g, 62%; NMR(CCl_4): 3.27 (1H, dd, J=10.0, 15.5 Hz, H^{β}), 3.79 (1H, d, J=10 Hz, H^{γ}), 4.47 (1H, dd, J=5.0, 15.5 Hz, H^{α}), 5.09 (1H, d, J=5.0 Hz, acetal-H), 6.46 (4H, q, J=7.0 Hz, $-CH_2-$), 6.52 (6H, q, J=7.0 Hz, CH_3), 8.85 (9H, s, *t*-Bu).

*5-t-Butyl-3-ethoxy-7-trimethylsilyl-4-hepten-6-ynal Diethyl Acetal (**2**).* To a stirred solution of ethylmagnesium bromide (prepared from magnesium, 1.91 g, 0.0786 mol, ethyl bromide, 10.30 g, 0.0945 mol and THF, 30 ml) was added dropwise at 10—20 °C under nitrogen atmosphere a solution of the ethoxy acetal[2] (**1**, 14.80 g, 0.0524 mol) in the same solvent (30 ml) under ice-cooling. The mixture was stirred at 20 °C for further 30 min and then chilled on an ice-bath. Trimethylchlorosilane (10.26 g, 0.0945 mol) was added to the mixture at 0 °C. After being stirred for 1 h at the same temperature, ammonium chloride solution was added to the reaction mixture. The aqueous layer was extracted with ether (50 ml×3) and the extracts were combined with the organic layer. The combined organic layer was washed successively with water and brine, and dried ($MgSO_4$). The residue obtained on evaporation of the solvent was distilled *in vacuo* to give **2**, pale yellow liquid, bp 122—130 °C/333 Pa, 17.02 g, 91.6%; mass (*m/e*): 354 (M^+); IR(neat): 2125 m ($-C\equiv C-$), 1616 vw (C=C), 1250 s ($Si-CH_3$), 875 s, 842 vs, 758 m (Si–C) cm^{-1}; NMR(CCl_4): 4.45 (1H, d, J=8.5 Hz, H^4), 5.43 (1H, t, J=6.0 Hz, H^2), 5.67 (1H, m, H^3), 6.56 (6H, m, $O-CH_2-$), 8.32 (2H, t, J=6.0 Hz, H^2), 8.84 (9H, t, J=7.0 Hz, $-CH_3$), 8.88 (9H, s, *t*-Bu), 9.80 (9H, s, $-SiMe_3$).

Found: C, 67.48; H, 10.58%. Calcd for $C_{20}H_{38}O_3Si$: C, 67.75; H, 10.80%.

*5-t-Butyl-7-trimethylsilyl-2,4-heptadien-6-ynal (**3**).* A mixture of **2** (6.74 g, 0.0190 mol), sodium acetate (6.50 g, 0.0792 mol), acetic acid (56 ml) and water (4 ml) was stirred at 80 °C for 6 h under nitrogen atmosphere, and then allowed to stand overnight at room temperature. The reaction mixture was poured onto saturated sodium carbonate solution and extracted with ether (50 ml×2). The extracts were washed successively with saturated sodium carbonate and sodium chloride solutions, and dried ($MgSO_4$). The product obtained on evaporation of the solvent was distilled using a short-path appratus to give **3**, a yellow liquid, bp 105—108 °C/333 Pa, 3.98 g, 89.3%; mass (*m/e*): 234 (M^+); IR(neat): 2810 w (CHO), 2120 m, ($-C\equiv C-$), 1687 vs (CHO), 1613 vs (C=C), 1244 s, 1221 m ($Si-CH_3$), 878 vs, 843 vs, 759 s (Si–C) cm^{-1}; NMR(CCl_4): 0.42 (1H, d, J=8.0 Hz, H^1), 2.49 (1H, dd, J=11.5, 15.5 Hz, H^3), 3.50 (1H, d, J=11.5 Hz, H^4), 3.88 (1H, dd, J=8.0 Hz, 11.5 Hz, H^2), 8.78 (9H, s, *t*-Bu), 9.70 (9H, s, $Si-Me_3$).

The trimethylsilyl aldehyde (**3**) was more stable than 5-*t*-butyl-2,4-heptadien-6-ynal, but gradually decomposed on standing in air under diffused light at room temperature. Less satisfactory elemental analysis was obtained owing to the unstable nature.

*2,4-Dinitrophenylhydrazone of **3**.* A solution of 2,4-dinitrophenylhydrazine (95 mg, 0.48 mmol) in phosphoric acid (1 ml) and ethanol (1 ml) was added to a solution of **3** (56 mg, 0.24 mmol) in ethanol (15 ml). After the mixture had been allowed to stand at room temperature for 30 min, red precipitate deposited was collected by filtration and washed with ethanol to give the hydrazone, 62 mg, 63%, which was recrystallized from ethyl acetate to give red crystals, mp 201—202 °C (dec).

Found: C, 57.81; H, 6.39; N, 13.27%. Calcd for $C_{20}H_{26}N_2O_4Si$: C, 57.95; H, 6.32; N, 13.52%.

*5-t-Butyl-7-trimethylsilyl-2,4-heptadien-6-ynal Diethyl Acetal (**4**).* To a mixture of **3** (3.98 g, 0.017 mol) and triethyl orthoformate (30 ml) was added a solution of *p*-toluenesulfonic acid monohydrate (400 mg, 2.10 mmol) in ethanol (4 ml). After being stirred for 20 h at room temperature, the reaction mixture chilled in an ice-bath was poured onto an ice-cooled sodium carbonate solution, and extracted with ether (30 ml×3). The extracts were washed successively with saturated sodium carbonate and sodium chloride solutions, and dried (K_2CO_3). The residue obtained on evaporation of the solvent was distilled under reduced pressure to yield **4**, a pale yellow liquid, bp 118—120 °C/333 Pa, 4.92 g, 94%; mass (*m/e*): 308 (M^+), 263 (M^+-45); IR (neat): 2125 m ($-C\equiv C-$), 1644 vw (C=C), 1248 s, 1227 w ($Si-CH_3$), 881 vs, 842 vs, 760 m (Si–C) cm^{-1}; NMR(CCl_4): 3.20 (1H, dd, J=11.0, 15.5 Hz, H^3), 3.77 (1H, d, J=11.0 Hz, H^4), 4.37 (1H, dd, J=5.0, 15.5 Hz, H^2), 5.07 (1H, d, J=5.0 Hz, H^1), 6.49 (4H, m, $-CH_2-$), 8.83 (6H, t, J=7.0 Hz, $-CH_3$), 8.85 (9H, s, *t*-Bu), 9.76 (9H, s, $Si-Me_3$).

Found: C, 70.50; H, 10.30%. Calcd for $C_{18}H_{32}O_2Si$: C, 70.08; H, 10.46%.

*7-t-Butyl-3-ethoxy-9-trimethylsilyl-4,6-nonadien-8-ynal Diethyl Acetal (**5**).* A mixture of borontrifluoride etherate (20 mg) in benzene (1 ml) was added at 35 °C to a solution of **4** (4.92 g, 0.0159 mol) in the same solvent (20 ml), and a solution of ethyl vinyl ether (1.40 g, 0.0194 mol) in the same solvent (5 ml) was slowly added at the same temperature. After the mixture had been kept at the same temperature for 20 min, finely powdered potassium carbonate (1.0 g) was added. The inorganic material was removed by filtration and washed with ether. The residue obtained on evaporation of the filtrate and washings was distilled *in vacuo* to give **5**, a pale yellow liquid, bp 120—124 °C/1.2 Pa, 5.20 g, 86%; mass (*m/e*): 380 (M^+), 334 (M^+-46); IR(neat): 2120 m ($-C\equiv C-$), 1640 vw (C=C), 1248 s ($Si-CH_3$), 880 vs, 842 vs, 758 m (Si–C) cm^{-1}; NMR(CCl_4): 3.39 (1H, dd, J=10.5, 14.5 Hz, H^5), 3.81 (1H, d, J=10.5 Hz, H^6), 4.42 (1H, dd, J=7.0, 14.5 Hz, H^4), 5.44 (1H, t, J=5.5 Hz, H^1), 6.04—6.88 (7H, m, $O-CH_2-$, O–CH–), 8.29 (2H, m, H^2), 8.85 (18H, t, J=7.0 Hz, $-CH_3$), 8.86 (9H, s, *t*-Bu), 9.78 (9H, s, $Si-Me_3$).

Found: C, 69.14; H, 10.38%. Calcd for $C_{22}H_{40}O_3Si$: C, 69.42; H, 10.59%.

*7-t-Butyl-9-trimethylsilyl-2,4,6-nonatrien-8-ynal (**5**).* A mixture of **5** (2.00 g, 5.26 mmol), sodium acetate (2.00 g, 24.4 mmol), acetic acid (18 ml) and water (2 ml) was stirred for 6 h at 60 °C, and then allowed to cool to room temperature. The reaction mixture was poured onto saturated sodium carbonate solution and extracted with ether (20 ml×3). The extracts were washed successively with saturated sodium carbonate and sodium chloride solutions, and dried ($MgSO_4$). The residue obtained on concentration of the extracts was distilled *in vacuo* using a short-path apparatus to give **6**, a viscous yellow liquid, bp 111—114 °C/2.7 Pa, 1.19 g, 86.9%; mass (*m/e*): 260 (M^+); IR(neat): 2810 w, 2725 w (CHO), 2120 m ($-C\equiv C-$), 1683 vs (C=O), 1612 s, 1597 s (C=C), 1247 s ($Si-CH_3$), 1007 m, 987 m (*trans* –CH=CH–), 880 vs, 843 vs, 759 m (Si–C) cm^{-1}; NMR (CCl_4): 0.43 (1H, d, J=4.0 Hz, CHO), 2.56—4.13 (5H, m, olefinic), 8.81 (9H, s, *t*-Bu), 9.72 (9H, s, $Si-Me_3$).

*2,4-Dinitrophenylhydrazone of **6**.* To a solution of **6** (134 mg, 0.515 mmol) in ethanol (8 ml) was added a solution of 2,4-dinitrophenylhydrazine (119 mg, 0.601 mmol) in phosphoric acid (1 ml) and ethanol (1 ml). After the mixture was allowed to stand for 30 min at room temperature, reddish

brown precipitate formed was filtered and washed with ethanol to give the hydrazone, 164 mg, 72.3%, which was dissolved in benzene and passed through a short column of silica gel. The crystals obtained from the filtrate were recrystallized from hexane–benzene (1:1) to yield pure 2,4-dinitrophenylhydrazone of **6**, reddish brown crystals, mp 208—211 °C.

Found: C, 60.09; H, 6.38; N, 12.69%. Calcd for $C_{22}H_{28}N_4O_4Si$: C, 59.98; H, 6.41; N, 12.72%.

8-t-Butyl-1,3,5,7-decatetraen-9-ynyl t-Butyl Ketone (8). A solution of sodium hydroxide (209 mg, 5.22 mmol) in 50% aqueous ethanol (2 ml) was added to a solution of **6** (1.00 g, 3.84 mmol) and pinacolone (522 mg, 5.21 mmol) in ethanol (10 ml) at 0 °C under nitrogen atmosphere. After being kept at room temperature for 24 h, the mixture was acidified with 3 M hydrochloric acid (10 ml) and extracted with ether (20 ml×3). The extracts were washed successively with sodium hydrogencarbonate solution and brine, and dried ($MgSO_4$). The residue obtained on concentration of the extracts was chromatographed on alumina. Elution with hexane–benzene (9:1) afforded crystals, which were washed with methanol to give **7**, 618 mg, 59.5%. Recrystallization of the crystals from methanol gave analytical specimen of **7**, yellow crystals, mp 133.5—134.0 °C; mass (*m/e*): 270 (M^+); IR (CCl_4): 3325 m (–C≡CH), 2060 vw (–C≡C–), 1684 s (C=O), 1607 s (C=C), 1574 vs (C=C), 1070 vs, 1003 vs (*trans* –CH=CH–) cm^{-1}; NMR(CCl_4): 2.52—3.92 (7H, m, olefinic), 6.63 (1H, s, –C≡CH), 8.82 (9H, s, *t*-Bu), 8.86 (9H, s, *t*-Bu); UV: $\lambda_{max}^{99\%EtOH}$ (ε) 261 (5870), 359* (52000), 369 (53000) nm.

Found: C, 84.74; H, 9.75%. Calcd for $C_{19}H_{26}O$: C, 84.39; H, 9.69%.

1,4,12,15-Tetra-t-butyl-4,6,8,10,15,17,19,21-cyclodocosaoctaene-2,13-diyne-1,12-diol (8). A solution of the tetraenyne ketone (**7**, 160 mg, 0.592 mmol) in THF (60 ml) was added very slowly through a Hershberg dropping funnel over a period of 8 hr to a stirred suspension of finely powdered potassium hydroxide (2.00 g, 35.7 mmol) in liquid ammonia (150 ml) at −34 °C. After being stirred for further 6 h at the same temperature, ammonium chloride (4.00 g, 0.0748 mol) was added to the reaction mixture, and the ammonia was allowed to evaporate. The residue was treated with water and ether (20 ml). The aqueous layer was extracted with ether (15 ml×2). The combined organic layer was washed successively with water and brine, and dried ($MgSO_4$). The yellow crystals obtained on evaporation of the solvent were chromatographed on alumina (40 g). Elution with ether–benzene (1:49—1:19) afforded high melting isomer (**8a**), colorless crystals, 56 mg, 31%, which were washed thoroughly with ethyl acetate to give pure specimen, mp 252 °C (dec); mass (*m/e*): 540 (M^+), 483 (M^+-57), 57 (*t*-Bu^+, base peak); IR(KBr-disk): 3570 m (–OH), 2190 vw (–C≡C–), 1638 vw, 1607 w (C=C), 1001 vs, 977 vs, 960 s (*trans* –CH=CH–) cm^{-1}; NMR($CDCl_3$): 2.8—4.2 (14H, m, olefinic), 8.35 (2H, s, –OH, disappeared on addition of D_2O), 8.79 (18H, s, *t*-Bu), 8.90 (18H, s, *t*-Bu); UV: $\lambda_{max}^{99\%EtOH}$ (ε) 248.5 (22600), 292* (50600), 307 (120000), 320 (137000), 341* (34800), 359 (27800) nm.

Found: C, 84.15; H, 9.61%. Calcd for $C_{38}O_{52}O_2$: C, 84.39; H, 9.69%.

Further elution with ether–benzene (1:3) gave low melting isomer (**8b**), colorless crystals, 105 mg, 58%, which were washed with ethyl acetate to give pure material, mp 220—221 °C; mass (*m/e*): 540 (M^+), 483 (M^+-57, base peak), 57 (*t*-Bu^+); IR(KBr-disk): 3530 m, 3465 m (–OH), 2180 vw (–C≡C–), 1634 w, 1590 vw (C=O), 993 vs (*trans* –CH=CH–) cm^{-1}; NMR($CDCl_3$): 2.8—4.2 (14H, m, olefinic), 8.31 (2H, s, –OH, disappeared on addition of D_2O), 8.80 (18H, s, *t*-Bu), 8.90 (18H, s, *t*-Bu); UV: $\lambda_{max}^{99\%EtOH}$ (ε) 248.5 (22200), 292* (45400), 307 (109000), 320 (160000), 341* (34200), 359 (26100) nm.

Found: C, 84.56; H, 9.84%. Calcd for $C_{38}H_{52}O_2$: C, 84.39; H, 9.69%.

3,11,14,22-Tetra-t-butyl-1,12-bisdehydro[22]annulene (9). To a suspension of **8** (a mixture of diastereomers, 136 mg, 0.251 mmol) in ether (10 ml) was added ether saturated with hydrogen chloride (10 ml) at −60 °C under nitrogen atmosphere. Finely powdered tin(II) chloride dihydrate (600 mg, 2.66 mmol) was added to the mixture at the same temperature. After being stirred vigorously for 15 min at −60 °C, the reaction mixture was poured onto ice-cooled sodium carbonate solution, and extracted with dichloromethane. The extract, after being washed with brine, and dried (K_2CO_3), was chromatographed on alumina (Woelm, act. I). Elution with carbon tetrachloride–dichloromethane (19:1) afforded pure **9**, 120 mg, 94.2%. An analytical specimen was prepared on recrystallization from benzene–methanol, dark violet crystals, mp *ca.* 230 °C (dec); mass (*m/e*): 506 (M^+), 449 (M^+-57), 57 (*t*-Bu^+, base peak); IR(KBr-disk): 3020 w, 2950 s, 992 vs, 881 w; UV: λ_{max}^{THF} (ε) 221.5 (10400), 248 (11900), 261* (8810), 277* (9200), 290 (12100), 302.5 (17100), 316.5* (9610), 377* (7720), 395 (147000), 412.5 (300000), 512* (6640), 556 (10400), 591 (11300), 712* (83), 757* (72), 782 (77), 853* (66), 895 (106) nm.

Found: C, 90.38; H, 9.92%. Calcd for $C_{38}H_{50}$: C, 90.05; H, 9.95%.

CT Complex of 9 with 2,4,7-Trinitrofluorenone. To a solution of **9** (25 mg, 0.049 mmol) in benzene–methanol (1:1, 40 ml) was added a solution of 2,4,7-trinitrofluorenone (31 mg, 0.098 mmol) in the same solvent (10 ml). The mixture was allowed to stand at 18 °C to deposite the CT complex, black violet crystals, mp *ca.* 260 °C (dec), 32 mg, 79%.

Found: C, 74.39; H, 6.67; N, 5.14%. Calcd for $C_{38}H_{50}\cdot C_{13}H_5N_3O_7$: C, 74.52; H, 6.74; N, 5.11%.

Catalytic Hydrogenation of 9. A mixture of **9** (32 mg, 0.063 mmol) and platinum(IV) oxide (100 mg) in acetic acid–ethyl acetate (1:1, 40 ml) was vigorously stirred under hydrogen at −15—−20 °C overnight. The catalyst was removed by filtration and washed with ether (30 ml). The organic layer and washing were washed successively with water, saturated sodium carbonate and sodium chloride solutions, and dried ($MgSO_4$). Evaporation of the solvent gave a crystalline residue, which was chromatographed on alumina (Woelm, act. I) and eluted with hexane to give a mixture of stereoisomers of 1,4,12,15-tetra-*t*-butylcyclodocosane, 31 mg, 92%. Recrystallization of the crystals from ethyl acetate–methanol yielded colorless crystals, 15 mg, mp 104—112 °C; mass (*m/e*): 532 (M^+), 475 (M^+-57), 57 (*t*-Bu^+, base peak); IR(KBr-disk): 2930 vs, 2860 s, 1475 m, 1393 m, 1360 m cm^{-1}; NMR(CCl_4): 8.72 (40H, br s, $-CH_2-$, –CH–), 9.05 (36H, s, *t*-Bu).

Found: C, 85.35; H, 14.19%. Calcd for $C_{38}H_{76}$: C, 85.63; H, 14.37%.

The mother liquor of the recrystallization was concentrated, and the crystals deposited were recrystallized from ethyl acetate–methanol to give colorless crystals, 8 mg, mp 91—95 °C.

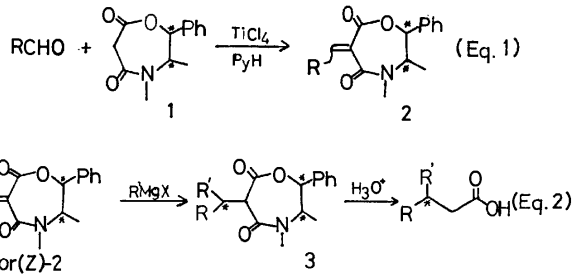
(Received May 30, 1978)

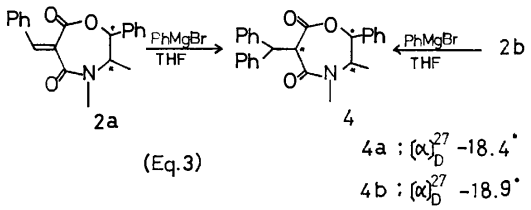
A general method was worked out for the preparation of highly optically pure β-substituted alkanoic acids from aldehydes with use of (2*R*,3*S*)-6-alkylidene-3,4-dimethyl-2-phenylperhydro-1,4-oxazepine-5,7-diones(**2**) as key intermediates. Oxazepines(**2**) were prepared in high yields by treating aldehydes with (2*R*,3*S*)-3,4-dimethyl-2-phenylperhydro-1,4-oxazepine-5,7-dione(**1**) in the presence of titanium tetrachloride. The conjugate addition of Grignard reagents to **2** in the presence of nickel chloride, followed by hydrolysis and decarboxylation afforded highly enantiomerically pure β-substituted alkanoic acids in good yields. The addition of lithium dialkylcuprate to **2** was examined. It was found that (*S*)-(+)-3-phenylheptanoic acid is obtained by the reaction of lithium dibutylcuprate with (*E*)- and (*Z*)-6-benzylidene derivatives of **1**, respectively.

Synthesis of optically active alkanoic acids is important in organic synthesis, and many works have appeared so far. Inouye and Walborsky[1] and Kawana and Emoto[2] reported that partial asymmetric induction is achieved by the addition of Grignard reagents to crotonic or cinnamic esters of (−)-menthol or some sugar derivatives, respectively. Tsuchihashi *et al.* reported that optically active 3-phenylbutanoic acid is obtained by the reaction of optically pure vinyl sulfoxide with diethyl malonate, followed by reduction, hydrolysis, and decarboxylation.[3] Recently, the syntheses of highly optically pure α-and β-substituted alkanoic acids were achieved with the use of optically active oxazoline derivatives.[4]

In a previous paper,[5] a report was given on the preparation of an almost optically pure 3-phenylheptanoic acid in high yield by the conjugate addition of butylmagnesium bromide to (*Z*)-(2*R*,3*S*)-6-benzylidene-3,4-dimethyl-2-phenylperhydro-1,4-oxazepine-5,7-dione (**2a**) in the presence of a catalytic amount of nickel chloride, followed by hydrolysis and decarboxylation of the adduct (**3**). It was thus shown that the 6-alkylidene derivatives of (2*R*,3*S*)-3,4-dimethyl-2-phenylperhydro-1,4-oxazepine-5,7-dione(**1**) are the key intermediates for the preparation of optically active β-substituted alkanoic acids. We have attempted to establish a general route for the synthesis of optically active alkanoic acids starting from aldehydes as in the following.



The first step consists of the condensation of aldehydes with the cyclic compound(**1**)[6] (Eq. 1). The reaction was carried out in the presence of titanium tetrachloride and pyridine using tetrahydrofuran(THF) as a solvent as in the method for the preparation of alkylidenemalonic esters reported by Lehnert.[7] The IR and NMR spectral data of the product(**2b**) obtained from benzaldehyde and **1** do not agree with those of (*Z*)-6-alkylidene derivative(**2a**).[5] In order to determine the configuration of **2b**, **2a** and **2b** were treated with phenylmagnesium bromide (Eq. 3). The NMR and IR spectra of the adducts (**4a** and **b**) were identical, the



value of the specific rotation of **4a** being the same as that of **4b**. Thus, the structure of **2b** was determined to be *E* isomer of **2a**. The configuration of the alkylidene group of **2c—f** was also determined by a comparison of its IR and NMR spectra with those of **2a** and **2b**. It was confirmed that a small amount of *Z*-isomer is produced in the preparation of **2c—f**, almost pure *E* isomer of **2c—f** being obtained by recrystallization of the product. The yields and properties of the products(**2**) are summarized in Table 1.

The conjugate addition of Grignard reagents to **2a** was carried out under various conditions at −78 °C for 3 h (Table 2). Alkanoic acids were obtained by hydrolysis and decarboxylation of the crude adducts(**3**) in 3 M sulfuric acid and acetic acid (Eq. 2). The result shows that the optical purity of the acids depends on the conditions of the addition reaction. The best result was obtained when the reaction was carried out in the presence of a catalytic amount of nickel chloride at low temperature. Though the role of the metal salt in the conjugate addition remains to be resolved,

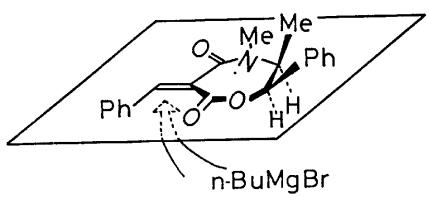


Fig. 1.

a) Benzene used as a solvent. b) $[\alpha]_{578}$. c) A mixture of THF (15 ml) and HMPT (4 ml) used as a solvent for 1.5 mmol of **2a**. d) Based on $[\alpha]_{578}$ −34.4° (*c* 8, benzene) for enantiomerically pure acid.[4c] e) The reported $[\alpha]_D^{28}$ max −60° (*c* 1.92, benzene) determined by resolution method.[2] f) Four mol % amounts of the salt used. g) Addition carried out at −100 °C.

the absolute configuration of (*R*)-(−)-3-phenylheptanoic acid indicates that the Grignard reagent attacks from the opposite side of the phenyl and methyl groups of the oxazepine ring as shown in Fig. 1.

In the same manner, various highly optically active β-substituted alkanoic acids were obtained in high yields utilizing **2a**—**f** (Table 3).

The relation between the absolute configuration of the alkanoic acid and the configuration of **2** is clearly shown in entries 2 and 5; (*R*)-(−)-3-phenylheptanoic acid was obtained by the reaction of the (*Z*)-6-benzylidene derivative of **1** with butylmagnesium bromide.

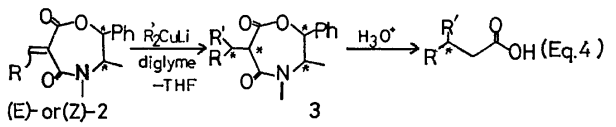
a) Benzene used as a solvent. b) $[\alpha]_{578}$.

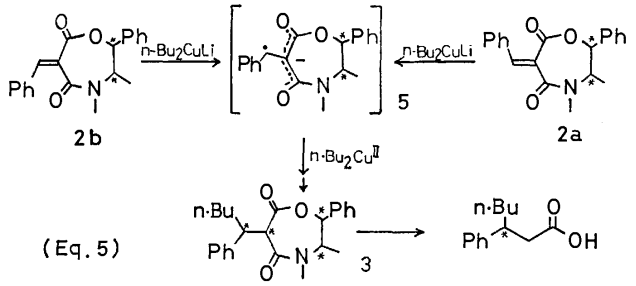
On the other hand, the (*S*)-(+) acid was obtained when the *E* isomer was employed.

It was found that the absolute configuration of the carboxylic acid obtained from **2** possessing the substituent R and Grignard reagent R′MgX differs from that of the carboxylic acid obtained from **2** having the substituent R′ and Grignard reagent RMgX(for example, entries 3 and 8). The results show that the Grignard reagent stereoselectively attacks **2** regardless of the configuration of the alkylidene group or the substituent R of **2**.

Asymmetric addition of lithium dialkylcuprate was also examined. A typical reaction is shown in the following: Lithium dialkylcuprate in diglyme was prepared according to the method for the preparation of the cuprate in ether reported by Whitesides *et al.*[14] The 6-alkylidene derivative of **1** in THF and diglyme was then added at −78 °C. The usual work-up gave the adduct (**3**). The corresponding optically active β-substituted alkanoic acid was obtained in good yield by hydrolysis and decarboxylation of the adduct (**3**) (Eq. 4). The results are summarized in Table 4.



Contrary to the results obtained in the reaction of Grignard reagents, alkanoic acids having the same absolute configuration were produced, regardless of the configuration of the starting 6-alkylidene-1,4-oxazepine(**2**), *viz.*, (*S*)-(+)-3-phenylheptanoic acid was obtained by the reaction of lithium dibutylcuprate with either (*E*)- or (*Z*)-6-benzylidene derivatives of **1**. This can be explained by assuming the existence of the radical anion intermediate(**5**) (Eq. 5).[15]



In conclusion, a general method for the preparation of highly optically pure β-substituted alkanoic acids from aldehydes was established by the use of (2*R*,3*S*)-3,4-dimethyl-2-phenylperhydro-1,4-oxazepine-5,7-dione-(**1**).

Experimental

*Reaction of Propionaldehyde with (2*R*,3*S*)-3,4-Dimethyl-2-phenylperhydro-1,4-oxazepine-5,7-dione(**1**).* Titanium tetrachloride (1.3 ml, 12 mmol) was added to a THF (53 ml) solution of **1**(2.33 g, 10 mmol), propionaldehyde (0.697 g, 12 mmol), and pyridine (2 ml) at −78 °C under an argon atmosphere with vigorous stirring. After being stirred at room temperature overnight, the reaction mixture was poured into a phosphate buffer solution (pH 7). The resulting white precipitate was filtered off through Celite and washed with dichloromethane. The aqueous mixture was extracted with dichloromethane. The combined dichloromethane solution was dried over anhydrous Na_2SO_4 and condensed under reduced pressure. The residue was chromatographed on silica gel (CH_2Cl_2–Et_2O) and (2*R*,3*S*)-3,4-dimethyl-2-phenyl-6-propylideneperhydro-1,4-oxazepine-5,7-dione(**2d**)(2.08 g, 76%) was obtained. Recrystallization (benzene–hexane) gave the pure *E* isomer: IR(KBr) 1725, 1640, 1600 cm^{-1}. NMR($CDCl_3$) δ 1.06 (t, *J*=8 Hz, 3 H), 1.18(d, *J*=7 Hz, 3 H), 2.0—2.7 (m, 2H), 3.05 (s, 3H), 3.67 (q, *J*=7 Hz, 1 H), 5.93 (s, 1 H), 7.28 (t, *J*=8 Hz, 1H), 7.42 (s, 5 H). The oxazepines (**2b—f**) were prepared from **1** and the corresponding aldehydes in a similar manner. The IR and NMR spectra of these compounds were in line with the assigned structures; **2b**;IR(KBr) 1750, 1640, 1600 cm^{-1}. NMR($CDCl_3$)δ 1.23 (d, *J*=7 Hz, 3H), 3.10 (s, 3H), 3.70 (q, *J*=7 Hz, 1 H), 6.20 (s, 1 H), 7.1—7.6(m, 10 H), 7.93 (s, 1 H). **2c**; IR(KBr) 1740, 1642, 1600 cm^{-1}. NMR($CDCl_3$)δ 1.17 (d, *J*=6 Hz, 3 H), 1.96 (d, *J*=7 Hz, 3 H), 3.02 (s, 3 H), 3.62 (q, *J*=6 Hz, 1 H), 5.85 (s, 1 H), 7.4—7.7 (m, 6 H). **2e**; IR(KBr) 1722, 1642, 1605 cm^{-1}. NMR($CDCl_3$)δ 0.6—1.8 (m, 10 H), 2.0—2.7 (m, 2H), 3.05 (s, 3 H), 3.3—3.8 (m, 1 H), 5.89 (s, 1H), 6.8—7.9 (m, 6H). **2f**; IR(KBr) 1725, 1640, 1605 cm^{-1}. NMR($CDCl_3$)δ 0.7—1.5 (m, 9 H), 2.4—2.8 (m, 1 H), 3.01 (s, 3H), 3.2—3.9 (m, 1 H), 5.80 (s, 1 H), 7.01 (d, *J*=10 Hz, 1H), 7.36 (s, 5H).

*Preparation of (S)-(−)-3-Methylheptanoic Acid by the Reaction of (E)-(2R,3S)-6-Ethylidene-3,4-dimethyl-2-phenylperhydro-1,4-oxazepine-5,7-dione(**2c**) with Butylmagnesium Bromide.* To a THF (14 ml) solution of **2c** (0.547 g, 2.0 mmol) and nickel chloride (0.013 g, 0.10 mmol) was added a THF solution (3.5 ml) of butylmagnesium bromide (2.45 mmol) at −78 °C under an argon atmosphere. After being stirred for 3 h, the reaction mixture was poured into a phosphate buffer solution (pH 7). The organic layer was extracted with dichloromethane and the extract was dried over anhydrous Na_2SO_4. Evaporation of the solvent gave the adduct, which was dissolved in acetic acid (20 ml) and 3M H_2SO_4 (40 ml). The reaction mixture was then refluxed for 6 h. The resulting oily substance was extracted with dichloromethane and the extract was dried over anhydrous Na_2SO_4. After the extract had been condensed under reduced pressure, the residue was distilled according to the Kugel-Rohr method (150—160 °C (bath temperature)/15 mmHg) to give (*S*)-(−)-3-methylheptanoic acid (0.236 g, 82%). The acids (Table 3) were obtained in a similar manner and the structures of the compounds identified by their IR and NMR spectra.

*Preparation of (S)-(+)-3-Phenylheptanoic Acid by the Reaction of (E)-(2R,3S)-6-Benzylidene-3,4-dimethyl-2-phenylperhydro-1,4-oxazepine-5,7-dione (**2b**) with Lithium Dibutylcuprate.* To a diglyme (10 ml) suspension of cuprous iodide (0.343 g, 1.8 mmol) was added a hexane solution (2.2 ml) of butyllithium (3.43 mmol) at −50 °C under an argon atmosphere. After 2 min, the reaction mixture was cooled to −78 °C. The oxazepine (**2b**) (0.482 g, 1.5 mmol) in THF (5 ml) and diglyme (5 ml) was added dropwise and the mixture was stirred for 2 h. It was then warmed to room temperature and poured into a phosphate buffer solution (pH 7). The resulting insoluble materials were filtered off through Celite and washed with dichloromethane. The aqueous mixture was extracted with dichloromethane. The combined dichloromethane solution was dried over anhydrous Na_2SO_4 and condensed under reduced pressure. The residue was chromatographed on silica gel (CH_2Cl_2–Et_2O) to give a mixture of diastereomers. The adducts were hydrolized and decarboxylated according to the above procedure to give the crude acid which was purified by silica gel chromatography (CH_2Cl_2–Et_2O) to yield 0.193 g (64%) of (*S*)-(+)-3-phenyheptanoic acid. It was then distilled for measurement of specific rotation by the Kugel-Rohr method (180—190 °C (bath temperature)/1.5 mmHg).

The acids (Table 4) were obtained in a similar manner and the structures of the compounds identified by their IR and NMR spectra.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Syntheses and Some Properties of 9,2′:7′,9″-, 9,2′:9′,9″-, and 9,4′:9′,9″-Terfluorene

Masahiro MINABE,* Masaaki YOSHIDA, and Kazuo SUZUKI

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321-31

(Received June 5, 1978)

Three kinds of terfluorene and 9,4′:9′,9″:4″,9‴-quaterfluorene were synthesized. The ^{1}H-NMR spectrum of 9′- and 9″-methine protons of 9,4′:9′,9″-terfluorene shows an AB spin pattern at room temperature, and that of 9,2′:9′,9″-terfluorene has an A_2 pattern. The π-π^* red shift of the UV spectra of some fulvalenes are in the order of 9,9′-bifluorenylidene, 4-(9-fluorenyl)-, and 4,4′-di(9-fluorenyl)-9,9′-bifluorenylidene. A homoconjugation effect was also observed in an alcohol series: 9-fluorenol, 4,9′-bifluoren-9-ol, and 9,4′:9′,9″-terfluoren-9′-ol.

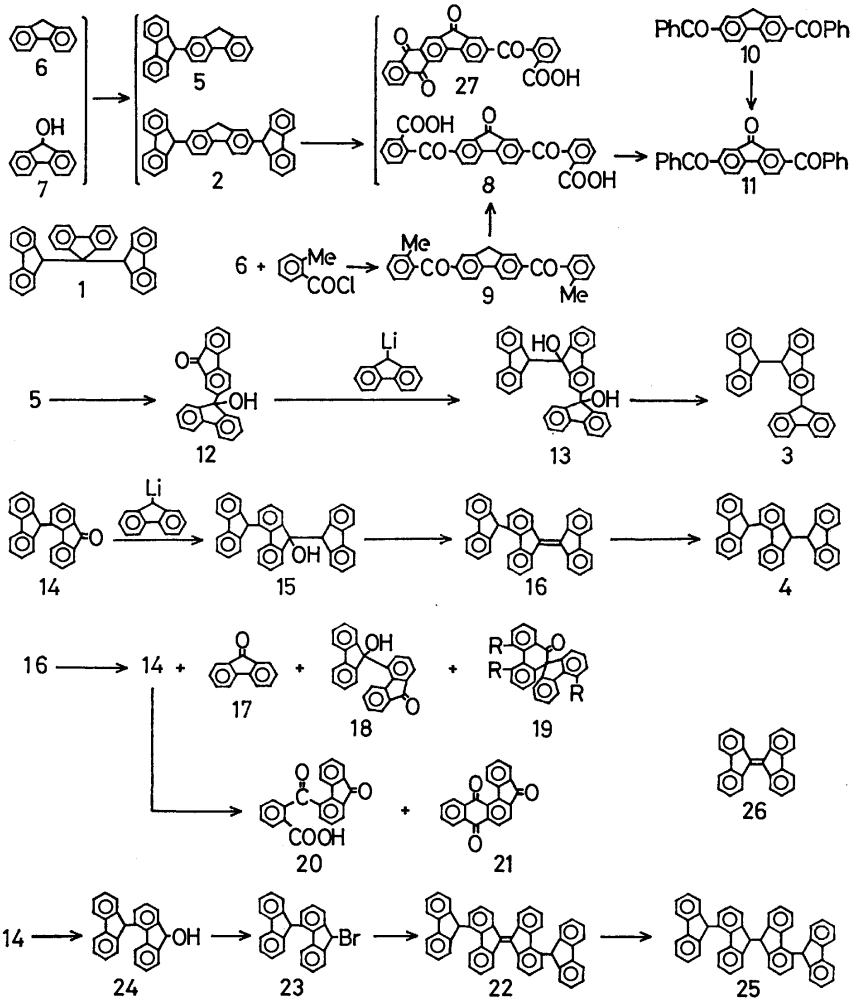
The synthesis and properties of the crowded molecule, 9,9′:9′,9″-terfluorene (**1**) have been reported in detail.[1] However, other types of terfluorenes have not been studied.

The present paper deals with the syntheses of 9,2′:7′,9″- (**2**), 9,2′:9′,9″- (**3**), and 9,4′:9′,9″-terfluorene (**4**) and also with the spectral properties of these terfluorenes in comparison with those of **1**.

Results and Discussion

Syntheses of Terfluorenes. A new terfluorene, **2** was obtained as one of by-products in the synthesis of 2,9′-bifluorene (**5**)[2] by condensation of fluorene (**6**) and 9-fluorenol (**7**). The oxidation of **2** with sodium dichromate afforded the corresponding dicarboxylic acid (**8**), which was identical with the compound obtained by oxidation of 2,7-di(*o*-toluoyl)fluorene (**9**). The oxidation of known 2,7-dibenzoylfluorene (**10**)[3] gave 2,7-dibenzoyl-9-fluorenone (**11**) derived from decarboxylation of the acid **8** (Scheme 1).

The reaction of 9-lithiofluorene with 9′-hydroxy-2,9′-bifluoren-9-one (**12**) yielded 9,2′:9′,9″-terfluorene-9,9′-diol (**13**), which was reduced to **3**. Also, the reaction of 9-lithiofluorene with 4,9′-bifluoren-9-one (**14**)[4] afforded 9,4′:9′,9″-terfluoren-9′-ol (**15**) and



Scheme 1. Compound **19**: One of R is 9-fluorenyl and the others are H.

2	4.94(2H, s)	3.16(2H, s)	6.95—7.80(22H, m)
3	4.46(2H, s) 4.74(1H, s)		6.41(1H, s) 6.62—7.75(22H, m)
4	4.69(2H, q) 6.10(1H, s)		6.60—8.09(23H, m)

4-(9-fluorenyl)-9,9′-bifluorenylidene (**16**), and the latter was reduced to **4**.

Oxidative cleavage at the central 9—9′ carbon-carbon double bond on **16** gave **14**, 9-fluorenone (**17**), and 9′-hydroxy-4,9′-bifluoren-9-one (**18**),[4] and a compound (**19**) having a melting point of 332—333 °C. The structure of **19** has not been determined, but **19** should be formed through the pinacol-pinacolone rearrangement of 4-(9-fluorenyl)-9,9′-bifluorene-9,9′-diol. Further oxidation of **14** yielded the corresponding carboxylic acid **20** and an anthraquinone derivative, **21**. This suggests that the ring closure of **20** occurs at the 3-position to form **21**, but not the 5-position.

One of the quaterfluorenes, 4,4′-di(9-fluorenyl)-9,9′-bifluorenylidene (**22**), was obtained by condensation of 9-bromo-4,9′-bifluorene (**23**), which was prepared from alcohol **24**. Hydrogenation of **22** afforded hydrocarbon **25**.

Spectral Observation of Terfluorenes and Their Derivatives. Table 1 shows the ^{1}H-NMR spectral data of **2**, **3**, and **4** in comparison with that of **1**.[1] Methine protons of 9′- and 9″-positions on **3** appears at 4.46 ppm as an A_2 spin pattern. This finding suggests that the 9′- and 9″-protons of **3** are magnetically equivalent to each other, as in the case of 9,9′-bifluorene (4.61 ppm).[1] On the contrary, those of **4** are shown at 4.69 ppm as an AB quartet (J=3.6 Hz, $\Delta\nu$=6.2 Hz) at room temperature. The splitting of the methine protons may be caused by the dihedral angle between H–$C_{9'}$–$C_{9'}$ and $C_{9'}$–$C_{9''}$–H. This quartet of **4** is changed with elevation of the temperature and the spectrum at 134.5 °C was observed as an A_2 singlet.

The methine proton on the 9-position of **4** appears at a lower field than that of the 9-position of **3** and than those of the 9- and 9″-positions of **2**. The rotation around the sp^3-sp^2 C–C single bond at 9—4′ positions of **4** may be hindered because of collisions between the adjacent hydrogen atoms on the 9- and 4′-fluorene planes. Therefore, the 9-methine proton of **4** could be situated on the deshielding zone of the 9′-fluorene plane, which shifts the signal to a lower field as in the case of the 4- or 5-proton of **6**[5] and also as in the cases of the 1,8,1′, and 8′-protons of **26**.[6] Actually, the 9′-methine proton of **14** has been observed at 5.89 ppm (CCl_4).[4]

Figure 1 shows the UV spectra of **1**,[7] **2**, **3**, **4**, and **25**. The spectra of **3** and **4** are very similar to that of **1**, but are somewhat different from that of **2**. Compound **2** has no 9—9′ C–C bond and the homoconjugation effect of **2** may be expected to be larger than

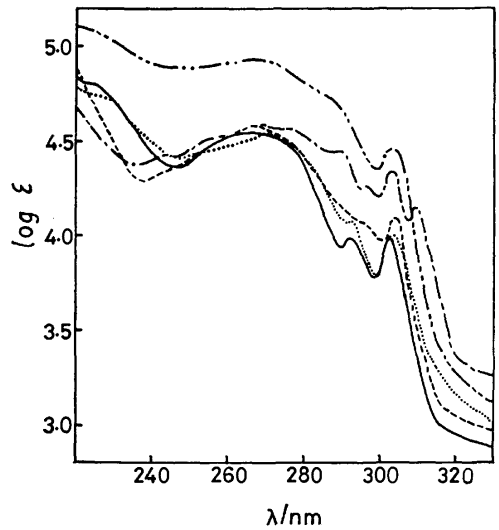

Fig. 1. UV spectra of **1** (——), **2** (— — —), **3** (----), **4** (·····), and **25** (— — —).

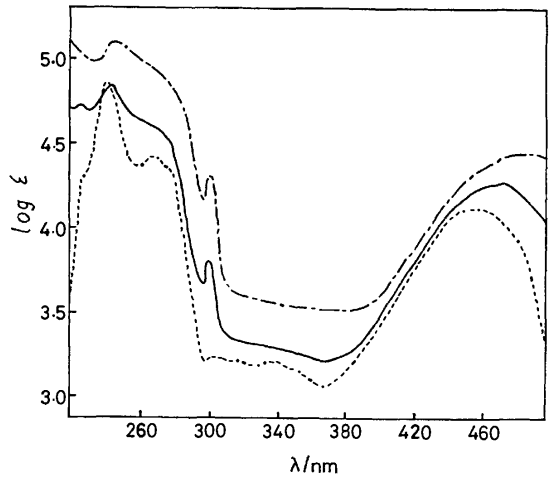

Fig. 2. UV and visible spectra of **16** (——), **22** (— — —), and **26** (----).

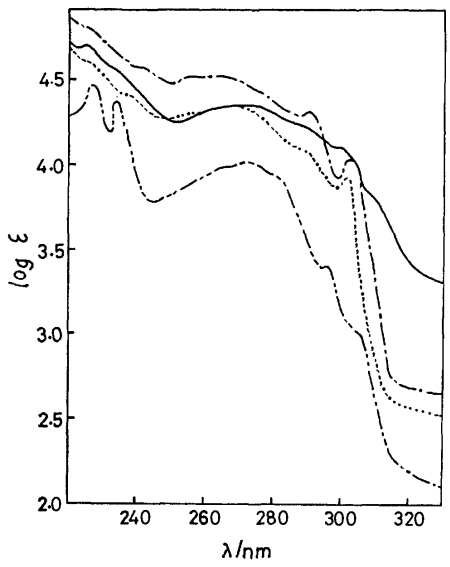

Fig. 3. UV spectra of **7** (— — —), **13** (——), **15** (— — —), and **24** (----).

that of the other terfluorenes. The spectrum of **25** suggests that the increase of absorbance is brought about by the substitution of the 9-fluorenyl group to the 4″-position of **4**, despite the fact that the coplanarity may be prevented at this position.

The UV and visible spectra of fulvalenes, **16**, **22**, and **26**[8-10] are given in Fig. 2. The π-π^* red shift and an increase of absorbance due to the central 9—9′ double bond are observed in the order of the increase of fluorene moiety: **26** (λ_{max} 455 nm, log ε 4.11); **16** (477 nm, 4.24); **22** (490 nm, 4.44). An additive property by the homoconjugation effect may also be postulated in an alcohol series, **7**, **13**, **15**, and **24**, as shown in Fig. 3.

Experimental

All the melting points are uncorrected. The UV, IR, ^{1}H-NMR, and MS spectra were obtained with a ORD/UV-5 apparatus (JASCO) in cyclohexane (scanning speed 0.76 s/nm), an IR-G spectrophotometer (JASCO) as KBr-pellets, a JNM-C60HL spectrometer (60 MHz) (JEOL), using TMS as an internal reference at 21 °C, and a RMU-6E apparatus (Hitachi) by means of a direct-inlet system, respectively.

*9,2′:7′,9″-Terfluorene (**2**).* A mixture of **6** (2.0 g) and **7** (4.0 g) in acetic acid (30 ml) was refluxed with concd sulfuric acid (0.15 ml) for 5 h. After being poured into cold water, the precipitate was collected and recrystallized from pyridine to give 0.10 g (2%) of **2**: mp 299—300 °C; NMR (C_5D_5N) δ=3.64 (2H, s), 5.27 (2H, s), and 7.15—8.10 (22H, m); MS, *m/e*, 494 (M^+), 329, and 165. Found: C, 94.54; H, 5.23%. Calcd for $C_{39}H_{26}$: C, 94.70; H, 5.30%.

The mother liquor was evaporated to dryness and the residue was recrystallized from benzene to afford 1.22 g (34%) of **5**: mp 225—226 °C (lit,[2] mp 225—226 °C).

*Structural Proof of **2**.* *a) Oxidation of **2***: An acetic acid (950 ml) solution of **2** (494 mg) was refluxed with sodium dichromate (19.0 g) for 3.5 h. Upon evaporation to dryness, the residue was extracted with aqueous alkaline and the extract was neutralized with dilute hydrochloric acid. The precipitate was collected and recrystallized from acetic acid to yield 73 mg (15%) of 2,7-bis(*o*-carboxybenzoyl)-9-fluorenone (**8**): mp 299—300 °C (dec); IR, 3420 (OH), 1715, and 1680 cm^{-1} (C=O); MS, *m/e*, 476 (M^+), 432, 388, 355, 311, and 283. Found: C, 73.23; H, 3.49%. Calcd for $C_{29}H_{16}O_7$: C, 73.11; H, 3.39%.

Additionally, 3 mg (1%) of *o*-[6,11,13-trioxo-13*H*-indeno-[1,2-*b*]anthracen-2-ylcarbonyl]benzoic acid (**27**) was isolated from the mother liquor: mp 340 °C (dec); IR, 3430 (OH), 1710, and 1670 cm^{-1} (C=O); MS, *m/e*, 458 (M^+), 414, 337, and 208. Found: C, 76.29: H, 2.70%. Calcd for $C_{29}H_{14}O_6$: C, 75.98; H, 3.08%.

*b) Synthesis and Oxidation of 2,7-Di(o-toluoyl)fluorene (**9**)*: The Friedel-Crafts reaction of **6** (1.66 g) and *o*-toluoyl chloride (3.90 g) was carried out at 120 °C in nitrobenzene (55 ml) during a period of 4 h in the presence of anhydrous aluminum chloride (3.33 g) to give 2.34 g (58%) of **9**: mp 175—176 °C (recrystallized from ethyl acetate); IR, 1650 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.36 (6H, s), 3.99 (2H, s), and 7.22—8.08 (14 H, m). Found: C, 86.65; H, 5.34%. Calcd for $C_{29}H_{22}O_2$: C, 86.54; H, 5.51%.

A solution of **9** (2.00 g) in pyridine (60 ml) was stirred with potassium permanganate (7.20 g) for 6.5 h at room temperature. The reaction mixture yielded 1.88 g (91%) of 2,7-di(*o*-toluoyl)-9-fluorenone: mp 197—199 °C; IR, 1718, 1663, and 1650 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.36 (6H, s) and 7.20—8.30 (14H, m); MS, *m/e*, 416 (M^+) and 401. Found: C, 83.44; H, 4.56%. Calcd for $C_{29}H_{20}O_3$: C, 83.63; H, 4.84%.

The foregoing fluorenone (827 mg) in benzene (80 ml) was refluxed with *N*-bromosuccinimide (2.12 g) for 1.5 h. Upon cooling, the reaction mixture was washed with water and evaporated to dryness. The residue was dissolved in acetic acid (40 ml) containing sodium dichromate (5.96 g) and refluxed for 3 h to yield 220 mg (25%) of **8**, which was identical in all respects with that obtained in a).

*c) 2,7-Dibenzoyl-9-fluorenone (**11**)*: A solution of **10** (480 mg) in pyridine (20 ml) was stirred with potassium permanganate (300 mg) at room temperature for 22 h giving 420 mg (84%) of **11**: mp 227—228 °C (recrystallized from ethyl acetate); IR, 1716 and 1648 cm^{-1} (C=O); MS, *m/e*, 388 (M^+) and 311. Found: C, 83.44; H, 4.54%. Calcd for $C_{27}H_{16}O_3$: C, 83.49; H, 4.15%.

*d) Decarboxylation of **8***: The foregoing dicarboxylic acid **8** (210 mg) was dissolved in quinoline (30 ml) and the solution was refluxed with copper bronze (200 mg) for 16 h. After cooling, the reaction mixture was filtered, then the filtrate was added to dilute hydrochloric acid and extracted with benzene. The extract was dried and chromatographed on an alumina column; 58 mg (34%) of **11** was obtained from the yellow band on the column. The compound was identical in all respects with that obtained in method c).

*Oxidation of 2,9′-Bifluorene (**5**).* Hydrocarbon **5** (3.00 g) in pyridine (150 ml) was stirred at 15—25 °C for 4 h in the presence of Triton B (40%, 0.5 ml) with gentle introduction of oxygen. The reaction mixture gave 2.83g (87%) of **12**: mp 184—185 °C; IR, 3550 (OH) and 1708 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.58 (1H, s) and 7.05—7.74 (15H, m); MS, *m/e*, 360 (M^+), 344, 315, and 180. Found: C, 86.67; H, 4.74%. Calcd for $C_{26}H_{16}O_2$: C, 86.65; H, 4.47%.

*9,2′:9′,9″-Terfluorene-9,9′-diol (**13**).* Alcohol **12** (720 mg) in xylene (60 ml) was allowed to react with 9-lithiofluorene (prepared from 1.32 g of **6**) under reflux for 1 h to afford 231 mg (22%) of **13**: mp 195—197 °C (dec) from benzene–cyclohexane (1:1); IR, 3580 and 3450 cm^{-1} (OH); NMR ($CDCl_3$) δ=2.34 (1H, s), 2.46 (1H, s), 4.70 (1H, s), and 6.85—7.67 (23H, m); MS, *m/e*, 526 (M^+), 509, 494, and 492. Found: C, 89.23; H, 4.72%. Calcd for $C_{39}H_{26}O_2$: C, 88.95; H, 4.98%.

*9,2′:9′,9″-Terfluorene (**3**).* Diol **13** (100 mg) was reduced with hydroiodic acid (57%, 3 ml) and red phosphorus (3 g) in acetic acid (50 ml) under reflux for 20 h, giving 65 mg (69%) of **3**: mp 214.5—216.5 °C (dec); NMR (C_5D_5N) δ=4.94 (2H, s), 5.01 (1H, s), 6.70 (1H, s), and 6.96—8.03 (22H, m); MS, *m/e*, 494 (M^+), 329, and 165. Found: C, 95.00; H, 5.12%. Calcd for $C_{39}H_{26}$: C, 94.70; H, 5.30%.

*9,4′:9′,9″-Terfluoren-9′-ol (**15**).* To a 9-lithiofluorene solution (prepared from 1.66 g of **6** in xylene), **14** (1.73 g) in xylene (100 ml) was added for 10 min at room temperature and then the reaction mixture was stirred at 70 °C for an additional 1 h to yield 1.82 g (72%) of **15**: mp 233—235 °C (dec); IR, 3550 cm^{-1} (OH); NMR ($CDCl_3$) δ=2.57 (1H, s), 4.81 (1H, s), 5.58 (1H, s), and 6.44—8.12 (23H, m); MS, *m/e*, 510 (M^+), 494, 492, 347, and 329. Found: C, 91.95; H, 5.19%. Calcd for $C_{39}H_{26}O$: C, 91.74; H, 5.13%.

Under different conditions, the reaction mixture was refluxed for 1 h; 0.23 g (9%) of **15** and 1.52 g (62%) of **16** were isolated: mp of **16**, 272—274 °C (dec) from ethyl acetate; NMR ($CDCl_3$) δ=6.14 (1H, s) and 6.33—8.61

(23H, m); MS, *m/e*, 492 (M^+) and 330. Found: C, 94.91; H, 5.22%. Calcd for $C_{39}H_{24}$: C, 95.09; H, 4.91%.

*9,4′:9′,9″-Terfluorene (**4**).* A solution of **16** (1.00 g) in benzene–ethanol (50 ml and 30 ml) was shaken with Raney nickel (W-7, 1.5 g) for 2 h at room temperature under an atmosphere of hydrogen. The reaction mixture was filtered, the filtrate was concentrated to a small volume, and 0.84 g (84%) of **4** crystallized out: mp 253—254 °C (dec); NMR (C_5D_5N) δ=5.06 (2H, q, J=3.6 Hz, $\Delta\nu$=5.3 Hz), 6.28 (1H, s), and 6.59—8.39 (23H, m); MS, *m/e*, 494 (M^+) and 329. Found: C, 94.98; H, 5.41%. Calcd for $C_{39}H_{26}$: C, 94.70; H, 5.30%.

*Oxidation of **16**.* A mixture of **16** (980 mg) and sodium dichromate (2.40 g) in acetic acid (150 ml) was refluxed for 1 h; **17** (170 mg, 47%, mp 82—84 °C), **14** (100 mg, 15%, mp 216—218 °C, lit,[4] mp 216.5—218.0 °C), and **18** (110 mg, 15%, mp 207.5—209.0 °C, lit,[4] mp 207.5—209.0 °C) were isolated by means of alumina-column chromatography.

In addition, 80 mg (8%) of **19** was obtained: mp 332—333 °C; IR, 1682 cm^{-1} (C=O); MS, *m/e*, 508 (M^+). Found: C, 92.28; H, 4.80%. Calcd for $C_{39}H_{24}O$: C, 92.10; H, 4.76%.

*Oxidation of 4,9′-Bifluoren-9-one (**14**).* A mixture of **14** (1.03 g) and sodium dichromate (19.6 g) in acetic acid (50 ml) was refluxed for 3.5 h to afford 530 mg (54%) of *o*-(9-oxofluoren-4-ylcarbonyl)benzoic acid (**20**): mp 210—212 °C; IR, 3070 (OH), 1722, and 1688 cm^{-1} (C=O); MS, *m/e*, 328 (M^+) and 207. Found: C, 76.83; H, 3.34%. Calcd for $C_{21}H_{12}O_4$: C, 76.82; H, 3.68%.

Additionally, 50 mg (5%) of 8*H*-indeno[1,2-*a*]anthracene-5,8,13-trione (**21**) was isolated: mp 321—323 °C (dec); IR, 1714 and 1687 cm^{-1} (C=O); MS, *m/e*, 310 (M^+), 282, and 254. Found: C, 80.98; H, 3.17%. Calcd for $C_{21}H_{10}O_3$: C, 81.28; H, 3.25%.

*9-Bromo-4,9′-bifluorene (**23**).* *a)*: A solution of **14** (500 mg) in benzene–ethanol (30 ml and 10 ml) was shaken at room temperature for 2.5 h in the presence of Raney nickel (W-7, 0.5 g) under an atmosphere of hydrogen to give 460 mg (92%) of 4,9′-bifluoren-9-ol (**24**): mp 195—196 °C; IR, 3385 cm^{-1} (OH); NMR (C_6D_6) δ=1.46 (1H, d, J=9.00 Hz), 5.40 (1H, d), 5.97 (1H, s), and 6.65—7.97 (15H, m); MS, *m/e*, 346 (M^+), 181, and 165. Found: C, 90.25; H, 5.37%. Calcd for $C_{26}H_{18}O$: C, 90.14; H, 5.24%.

The foregoing **24** (300 mg) was treated with hydrogen bromide in acetic acid to yield 310 mg (87%) of **23**: mp 192—193 °C (dec); NMR (C_6D_6) δ=5.70 (1H, s), 5.85 (1H, s), and 6.56—7.93 (15H, m); MS, *m/e*, 410, 408 (M^+), and 330. Found: C, 76.55; H, 3.98%. Calcd for $C_{26}H_{17}Br$: C, 76.29; H, 4.19%.

b): A mixture of 4,9′-bifluorene[7] (1.98 g) and *N*-bromosuccinimide (1.16 g) in benzene (75 ml) was refluxed for 6 h to give 1.75 g (72%) of **23**, which was identical in all respects with that obtained in a).

*Formation of 4,4′-Di(9-fluorenyl)-9,9′-bifluorenylidene (**22**).* A solution of **23** (1.10 g) in acetone (170 ml) was treated with potassium hydroxide (0.20 g) in methanol (10 ml) at −15 °C to afford 136 mg (15%) of **22**: mp 290—291 °C (dec); NMR (C_5D_5N) δ=6.28 (2H, s) and 6.53—8.63 (30H, m) (measured at 53 °C). Found: C, 94.91; H, 5.00%. Calcd for $C_{52}H_{32}$: C, 95.09; H, 4.91%.

*Reduction of **22**.* Olefin **22** (100 mg) in benzene (120 ml) was shaken for 3 h at room temperature with Raney nickel (W-4, 0.5 g) under an atmosphere of hydrogen, giving 71 mg (71%) of 9,4′:-9′,9″:4″,9‴-quaterfluorene (**25**): mp 292—293 °C (dec). Found: C, 94.52; H, 5.20%. Calcd for $C_{52}H_{34}$: C, 94.80; H, 5.20%.

The authors thank to Mr. Norio Eda and Miss Katsuko Nakada for their helpful assistance.

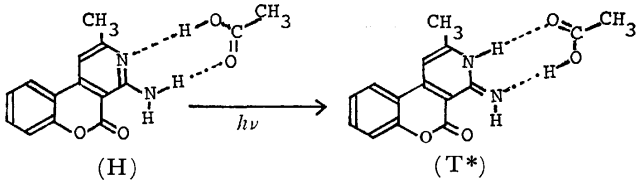
(Received January 23, 1978)

Synopsis. The nanosecond time-resolved spectra and apparent lifetime for the fluorescence of the proton transferred excited species (tautomer) between 4-amino-2-methyl-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one (BPP) and acetic acid have been measured in isooctane (2,2,4-trimethylpentane) at room temperature. It has been established that the rising time of the tautomer fluorescence was *ca.* 15 ns and the time required for the excited hydrogen-bonded species-tautomer equilibrium was *ca.* 40 ns. Solvent effects upon the fluorescence characteristics of the tautomer have also been investigated.

Recently, El-Bayoumi *et al.*[1] and Shizuka *et al.*[2] have measured the fluorescence with large Stokes shifts for 7-azaindole (7AI) and for 6-(2-hydroxy-5-methylphenyl)-*s*-triazines (TH), respectively. It has been suggested that the fluorescence of the former originates from a tautomer formed by a fast intermolecular double proton transfer reaction of the excited hydrogen-bonded dimer of 7AI.[1] In the latter case the fluorescence has been attributed to a tautomer (keto form) formed by a fast intramolecular proton transfer reaction of the excited hydrogen-bonded species (enol form) of TH.[2]

Previous studies have reported the fluorescence with a large Stokes shift, besides the fluorescence of hydrogen-bonded species for the BPP–acetic acid system in isooctane.[3] Accordingly, from the similarity of tautomer fluorescences for 7AI and TH, it is reasonable to assume that the fluorescence of the present system with a large Stokes shift corresponds to that from the tautomer (T*) formed *via* the intermolecular double proton transfer in the excited state of the doubly hydrogen-bonded species (H) as follows:



(H) (T*)

In addition, from the absorption spectra it has been shown that substantially all BPP molecules are present as H in isooctane when the concentration of BPP is 3.5×10^{-5} M and that of acetic acid 2.0×10^{-1} M.[3] In the present study, nanosecond time-resolved fluorescence spectral techniques were applied to the problem of the double proton transfer reaction between BPP in the lowest excited singlet state and acetic acid under the conditions as stated above.

Results and Discussion

The time-resolved fluorescence spectra of the BPP–acetic acid system in isooctane solution are given in Fig. 1. As shown in Fig. 1 two fluorescence bands with peaks at *ca.* 384 nm and 458 nm appear, which correspond to the emission bands of the hydrogen-bonded and proton transferred species[3] (tautomer) respectively. The fluorescence band maxima of these two species are scarcely shifted with a delay time (t). It seems that an equilibrium between H* and T* is established in the excited state as follows:

$$\text{H}^* \rightleftarrows \text{T}^*$$

where H* signifies the excited hydrogen-bonded species. The tautomer fluorescence at $t\approx15$ ns has the greatest intensity as seen in Fig. 1. The rising time of T* is *ca.* 15 ns. Figure 2 shows the plot of I_2/I_1 *vs.* t for the BPP–acetic acid system, where I_1 and

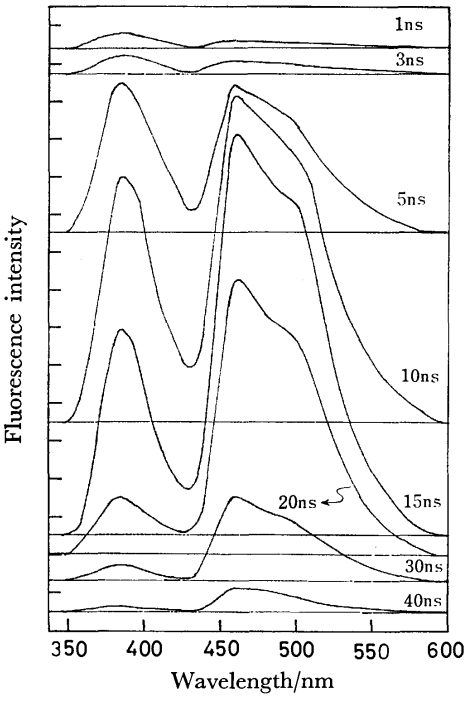


Fig. 1. Time-resolved fluorescence spectra of the BPP-acetic acid system in an isooctane solution at room temperature.

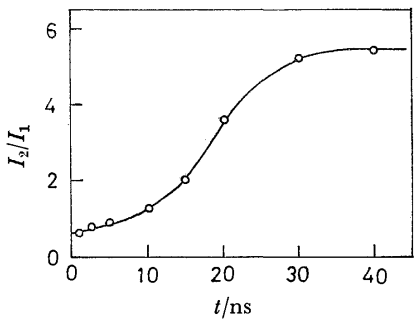

Fig. 2. The polt of I_2/I_1 *vs.* t.

I_2 represent the fluorescence intensities at 384 nm and 458 nm respectively. At first, I_2/I_1 increases with t and then is virtually invariant at $t \approx 40$ ns. Furthermore, the time-resolved fluorescence spectra at *ca.* 40 ns were the same as those in the stationary state of the BPP–acetic acid system. These results show that it takes about 40 ns to establish the H*–T* equilibrium. It should be noted that the rate of proton transfer in the excited state is generally fast,[1,2] while in the case of the system studied here that of proton transfer is relatively slow and the reaction takes time to reach the H*–T* equilibrium.

The fluorescence lifetime calculated from the integrated absorption intensity and the fluorescence quantum yield ($\Phi=0.14$[4]) of BPP in isooctane without acetic acid was estimated to be 1.0 ns. The lifetime of BPP in isooctane could not be obtained because it was shorter than the response time (few ns) of the apparatus. Nevertheless, the apparent fluorescence lifetimes (τ_T) of the tautomer T* in various solvents could be measured at room temperature. These was no wavelength effect upon the apparent lifetimes of T*. The values of τ_T at 470 nm in various solvents are listed in Table 1.

The other characteristics (the wave numbers of the band maxima and quantum yields) of the tautomer fluorescence measured in non-polar and slightly polar solvents are also given in Table 1 with dielectric constants. It is to be noted that with an incerase in the polarity of solvent the tautomer fluorescence band maximum shifted towards the red with a decrease in the fluorescence quantum yield, The apparent lifetime also decreases with an increase in the solvent polarity.

Experimental

The sample of BPP[6] was the same as reported previously.[3] The sample was recrystallized from pyridine and further purified by vacuum sublimation. Acetic acid and quinine bisulfate of extra pure grade were used without further purification. The solvent used here were commercially available and when purification was needed, they were further purified by distillation. The time-resolved fluorescence spectra and lifetimes were measured with a Hitachi MPF-4 spectrophotometer equipped with a time-resolved photometer at room temperature. An ultraviolet D_2 pulser was used for the excitation of the species. The pulse given by this lamp had a life-duration less than 5 ns. For the measurement of ordinary emission intensity, a Hitachi MPF-2A fluorescence spectrophotometer was used.

Table 1. Wave numbers (ν_T) of the band max., fluorescence quantum yields (Φ_T), and apparent fluorescence lifetimes (τ_T) of the tautomer T* in the BPP–acetic acid system measured in solvents having different polarity at room temp

Solvent	Dielectric const	ν_T $\times 10^3$ cm^{-1}	Φ_T[4]	τ_T ns
Hexane	1.88	21.8	0.088	8.1
Isooctane	1.95	21.8	0.081	8.0
Benzene	2.28	21.5	0.053	7.3
Chloroform	5.15	21.4	0.051	7.2
Chlorobenzene	5.53	21.4	0.050	7.1
Dichloromethane	8.90	21.3	0.036	6.7
Dichloroethane	10.37	21.3	0.035	6.4

The Carbon-13 NMR Spectra of Barbituric-acid Derivatives

Shozo ASADA and Jujiro NISHIJO*
Kobe Women's College of Pharmacy, Higashinada-ku, Kobe 658

(Received December 19, 1977)

Synopsis. The ^{13}C nuclear magnetic resonance spectra of thirty kinds of barbituric-acid derivatives were measured, and the chemical shifts of each carbon were assigned. The correlation between chemical shifts of the ring skeletal carbon and the pK_a values was examined.

There have been several reports concerning the ^{13}C nuclear magnetic resonance (NMR) spectra of barbituric-acid derivatives. Okada *et al.*[1] have measured the ^{13}C NMR spectra of some 5-monosubstituted barbituric-acids (I). They pointed out that (I) dissociated by releasing the hydrogen at the 5-position and that there was a good linear correlation between the ^{13}C chemical shifts of C-5 and the pK_a values. In 5,5-disubstituted and 1-methyl-5,5-disubstituted barbituric-acids (II) and (III), however, dissociation may be more complicated, as is shown in Chart 1. In order to gain a clew with regard to those dissociation schemes, we tried to assign the chemical shifts of each carbon for (II) and (III) and examined the correlation of the ^{13}C shifts of the ring skeletal carbons with the pK_a values of these compounds.

Experimental

Materials. The barbituric-acids used for the measurement of the ^{13}C NMR spectra are listed in Table 1. Compounds **2**, **3**, **7**, **9**, **10**, **11**, **13**, **14**, **28**, and **29** were synthesized by the methods described in the literature.[2,3] Compound **30** was synthesized by the methylation of **15** with CH_2N_2. The other compounds were those reported in the preceeding paper.[4]

Measurements of the Acid-dissociation Constants and the ^{13}C NMR Spectra of Barbituric-acid Derivatives. The apparent acid-dissociation constants, pK_a, were determined by means of a Hitachi model UV-200 spectrophotometer at 20 °C in an ionic strength of 0.75. The pK_a values of the new compounds were as follows : **2**=7.94, **3**=7.85, **7**=8.14, **9**=7.53, **10**=8.05, **11**=7.77, **13**=7.87, **14**=7.61, **28**=7.85, and **29**=7.90. The ^{13}C NMR spectra were measured at room temperature by means of a NEVA NV-21 (22.6 MHz) spectrometer. All the samples were dissolved in dimethyl-d_6 sulfoxide (1M). The chemical shifts were expressed in ppm downfield from tetramethylsilane (TMS).

Results and Discussion

Table 1 shows the ^{13}C chemical shifts of the ring skeletal carbons, assigned by using the off-resonance technique or by comparing them with the values in the literature.[1,5] The mean value of the chemical shifts of *N*-methyl carbon for (III) was given as 27.09±0.25 (n=15).

We attempted to correlate the ^{13}C shifts with the pK_a values as follows. The results of regression analyses concerning Eq. 1 are summarized in Table 2.

$$pK_a = a_0 + a_1\delta_c(\text{ring position}), \quad (1)$$

where δ_c indicates the ^{13}C shift of the ring skeletal

a) b) Symbol "×2" means twice the intensity. c) In Compounds **5**, **10**, and **11**, which have no *N*-methyl group, equivalent signals of carbons at the 4- and 6-positions split off in two. d) The δ_c 171.8 is the signal to C-4, and the δ_c 171.3 is that to C-6, which is situated nearer the *N*-methyl group. In **1**, δ_c 173.1×2 is assigned as the signals to C-4 and C-6. In **30**, these signals appear at a higher field, δ_c 171.4×2. e) The ^{13}C signal of the *N*-methyl group was shown as a quartet in the partial proton-decoupling state.

carbons for (II) and (III), and where a_0 and a_1 are constants. In a series of (II), it was found that the regression of pK_a with δ_c (4 and/or 6 position) was significant at the 5% level concerning the F-test for the variance ratio, as is shown in Eq. 3. On the other hand, the regression of pK_a with δ_c(2) or of pK_a with δ_c(5) was less significant, as is shown in Eq. 2 or Eq. 4. Thus, the ionization of (II) may produce (IIa) and/or (IIc). Further, in the (III) series, the regression of pK_a with δ_c(4) was highly significant,

a) pK_a=a_0+$a_1\delta_c$ (ring position). b) No. of samples: n=11 (No. 1—No. **14** except Nos. **5**, **10**, and **11**). Symbol ** indicates a substance to be significant at the 1% level, *, to be significant at the 5% level.

as had been expected (Eq. 6), while that of pK_a with δ_c(2) or of pK_a with δ_c(5) had little significance (Eq. 5 or Eq. 8). The regression of pK_a with δ_c(6) was also significant at the 1% level relative to the F-test (Eq. 7). It seems that this result is inconsistent with Chart 1. In this connection, Eriksson *et al.*[6] have reported that a tetrahedral substrate–hydroxide ion complex of 1-methylbarbituric-acid was formed in an alkaline solution. Accordingly, the ionization form (IIIc) shown in Chart 2 may be useful in predicting a good correlation of Eq. 7. A complete explanation must be left to further study because pK_a is related to the ^{13}C chemical shifts at the 4 and/or 6 position of 5,5-disubstituted barbituric-acid derivatives.

The authors wish to express their thanks to Miss Makiko Sugiura for the measurement of the ^{13}C NMR spectra.

Mass-transfer Experiment through the Water–Benzene Interface in a Capillary Tube

Teruya SHIMBASHI

Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received February 17, 1978)

Synopsis. In order to confirm a previous discussion of a mass-transfer experiment that indicated a high interfacial resistance, an experiment using a capillary tube was done for the transfer process of butylamine through the water–benzene interface at 50 °C. The results obtained agree with the preceding ones.

In a preceding paper,[1] it was described that the resistance ($\Delta F^*_{d2}=18$ kcal/mol, 50 °C) against which propylamine and butylamine molecules were transferred through the water–benzene interface agreed well with the results of another study[2] about the transfer rates of fatty acids through liquid-liquid interfaces. However, the experiment described in the preceding paper showed confused results that the diffusion coefficients measured with the same apparatus as in the transfer experiment were much larger than the values estimated from the literature, and that their concentration dependences could not be disregarded; the author ascribed this discrepancy to the large sectional-area of mass transfer and to the existence of a gas-liquid interface.

In the present paper, the results and its subsequent analysis of an experiment done in order to confirm the discussion in the preceding paper, are described for the transfer process of butylamine through the water–benzene interface at 50 °C, using a capillary tube so as to get diffusion coefficients nearly equal to the literature values.

Experimental and Results

The mass-transfer cell used is a U-shaped glass-tube on the whole, one arm of which has a 1.5 mm (ID) capillary with three Teflon cocks—at both ends and at the middle point; the part from the middle cock to the upper end is called the first capillary, which is to be filled with a benzene solution, while the lower half is called the second capillary, which is to be filled with water. The second capillary is equipped with an array of six pairs of platinum electrodes for determination of electric conductivity.

In order to obtain the temperature constancy and electric insulation of the leading wires, the cell is set in a cylindrical glass-container filled with chemically pure xylene, and then the whole is set in a thermostat.

Opening the middle cock of the cell causes the transfer of the solute (butylamine) from the first phase (benzene) to the second (water). The electrode circuits are automatically switched on and off in turn, and the conductivities are recorded.

In the case of the measurement of the diffusion coefficients in water, aqueous solutions were used instead of benzene solutions, but in the same manner. The electrode sensitivity (equivalent to the cell constant) for each pair of electrodes was referred to the conductivity for an 0.02 M aqueous solution of potassium chloride.

As a result of the transfer experiments, the time dependences of the conductivity of each pair of electrodes were obtained, and were then translated to the concentration changes. The concentration distributions in the second phase at various times were obtained by the interpolation of the concentration changes, and the fitting curves of the concentration distributions were obtained by means of the least squares; the amounts of transfer at the assigned times were obtained by the integration of the fitting curves.

In the measurement of the diffusion coefficients of butylamine in water at 30 and 50 °C, both values calculated from the time dependence of the concentration at the pair of electrodes nearest to the water–benzene interface and calculated from the change in the amount of transfer agreed well with that estimated by Wilke's method[3] from the literature; the diffusion coefficients in benzene were not measured because of the difficulty of determining them. In the calculation of the interfacial resistance, the diffusion coefficients estimated from the literature were used (D_1 (in benzene)$=3.21\times10^{-5}$, D_2 (in water)$=1.79\times10^{-5}$ cm^2/s).

Two points of special attention were found in this experiment. (1) When the initial concentration in the first phase was sufficiently high, the analysis became difficult, because the change in concentration tended to be complicated; this means that a turbulence, presumably caused by the Marangoni effect,[4] occurred and continued for a long time. Consequently, it was necessary to select an initial concentration low enough so as to get a normal pattern of the concentration change ($c_{10}<0.01$ M). (2) When the electrode sensitivities that had been determined in advance were used for obtaining the transfer amount after a long time (about 20 days), unreasonably large values[5] were obtained; this may signify that the electrode sensitivity gradually increased in this experiment. Nevertheless, a relative comparison of the transfer amounts after a long time is considered to be feasible,[6] because the variation in the electrode sensitivity may become negligible after a certain time.

The results of determination are indicated in Table 1. Here, suffixes a and b have the following meanings. When the transfer amount was computed by integration from the concentration-distribution observed, $c=a_1+a_2x+a_3x^2$ in (a) and $c=a_1+a_2x+a_3x^2+a_4x^3$ in (b) were used for the functional mode of concentration (c: concentration; x: distance from the interface; a_i:

parameters); l: depth of both phases; c_{10}: initial concentration of solute in the first phase; t_1, t_2, and t_3: contact times; q_1, q_2, and q_3: transfer amount of the solute at t_1, t_2, and t_3 respectively (mol/cm^2).

Estimation of the Interfacial Resistance

Assigning an arbitrary value to q_1 (or q_3) on the condition that q_1/q_3=const. determines a pair of values, q_1 and q_3, and enables one to compute the desorption rateconstant (k_{d2}) of the solute from the interface to the second phase and the average concentration (c'_{20}) in the second phase immediately after the cessation of an abnormally rapid process, if any, after the procedure described in the preceding paper. The computation was repeatedly made on varied values of q_1 so as to get Curve A on the k_{d2}-c'_{20} plane; Curve B was obtained in the same manner on the condition that q_2/q_3= constant.

As may be seen from drawing Curve A and Curve B from a theoretical change in the transfer amount on definite conditions, Curve A is a tangent which touches Curve B at a point representing the k_{d2} and c'_{20} given as the conditions. We take the k_{d2} sought to be at the minimum point of the difference, c'_{20}(B)-c'_{20}(A), where c'_{20}(A) and c'_{20}(B) are the values of c'_{20} on Curve A and Curve B respectively, corresponding to an assigned value of k_{d2}; the c'_{20} sought is also taken to be the average of c'_{20}(A) and c'_{20}(B) corresponding to the obtained k_{d2}.

The results of calculation are shown in Table 2.

Strictly speaking, the k_{d2} should be obtained by extrapolating the value to $c_{10}=0$,[1] but the values obtained above may be nearly equal to the extrapolated value, because the values of c_{10} are quite small in Table 1. We take the activation free energy of desorption from the interface to the second phase to be ΔF^{*}_{d2}=18.6 kcal/mol, converting the average value of k_{d2} in Table 2, 1.2×10^{-9} mol/cm^2 s;[7] this agrees with the result in the preceding paper.

The author is indebted to Professors Hikoji Inazumi and Tadao Shiba of this Institute for their helpful discussions concerning this subject.

Excitation Wavelength Dependence of Quinoline Phosphorescence Lifetime†

I-Fu HUNG,*,** Tadashi OKAMURA,*** Sam SUGAMORI, and R. W. YIP
Division of Chemistry, National Research Council of Canada, Ottawa, Canada
(Received April 19, 1978)

Synopsis. The quinoline phosphorescence lifetime in several rigid media at 77 K has been found to be dependent on excitation wavelength. The change of lifetime is especially remarkable in hydroxylic solvents. This observation has been attributed to the inhomogeneous broadening of spectral lines caused by the distribution of solvent environments around quinoline molecules.

The quinoline phosphorescence lifetime has been shown to be solvent dependent with the ones observed in hydrocarbons being shorter than in hydroxylic solvents.[1,2] These results were interpreted by Lim and Yu[1] as due to the solvent effect on the second order perturbation including spin-orbit coupling and vibronic interaction among the excited singlet and triplet states. This was supported from the polarization measurement where the phosphorescence is found to be more in-plane polarized in hydrocarbon than in hydroxylic solvents outside the 0,0 band. In order to examine such a solvent effect more in detail, the measurement of quinoline phosphorescence lifetime in several solvents has been conducted with the excitation wavelength varied across the first absorption band.

The results of lifetime measurements are listed in Table 1 and also shown in Fig. 1. It is clearly seen that the quinoline phosphorescence lifetime observed in hydroxylic solvents is markedly dependent upon the excitation wavelength whereas those measured in hydrocarbon solvents show only slight dependence. The lifetimes observed in hydroxylic and hydrocarbon solvents by excitation at the long wavelength edge (red edge) of the first absorption band are very similar except for the one in ethyl alcohol excited at 317.5 nm which is shorter than those for other solvents. Itoh and Azumi[3] observed a slight but significant spectral shift of quinoline phosphorescence in EPA by red edge excitation. In the present work as shown in Fig. 2, the phosphorescence spectra measured in ethyl alcohol show very little change in spectral profile and peak position with excitation outside the red edge region, except for a slight change in relative peak height which is barely observable under the experimental conditions (apparent 0,0 peak was observed at 314.5 nm in phosphorescence excitation spectrum). In consideration of these observations, it is not unlikely that the considerable change of phosphorescence lifetime observed by the red edge excitation is caused by the same sort of effect they observed, though the origin of such red edge effect has not been consistently interpreted for all molecules studied so far.[3,4]

Johnson and Levin[5] reported the excitation wavelength dependent phosphorescence lifetime of benzene and naphthalene in nonpolar rigid media and attributed such observations mainly to the change in the radiationless transition rate caused by the presence of a distribution of local environment for the solute molecules which shows up as an inhomogeneous line

broadening of the molecule. While the effect of solvent perturbation on the radiationless transition rate has been observed recently in anthracenes in the low temperature region,[6] it is not clear as to what extent this effect might have on both the radiative and the radiationless transition rate of the quinoline molecule. The greater change in lifetime observed in hydroxylic solvents appears to indicate the enhancement of inhomogeneous line broadening in hydroxylic solvents, though the effect of using a narrower bandwidth can not be entirely discounted. It is also worth noting that in a recent study of diphenylanthracence fluorescence in EtOH low temperature glass,[7] the fluorescence band shift with the excitation wavelength has been attributed to the effect caused by the inhomogeneous line broadening.

Thus, in view of these results, it is concluded that the excitation wavelength dependence of quinoline phosphorescence lifetime observed in this study is most likely due to the solvent induced inhomogeneous line broadening effect on both the radiative and the radiationless relaxation processes of the lowest triplet state.

Experimental

Quinoline used for the measurement of phosphorescence lifetime and spectrum was laboratory reagent (BDH Chemicals) and guaranteed reagent (Tokyo Kasei) respectively and these were further purified by successive vacuum distillation. Spectrograde ethyl alcohol was used as received for the measurement of phosphorescence spectrum and the other solvent used for the lifetime measurement were treated with activated charcoal to remove luminescent impurities. Quinoline solutions of 10^{-3} M concentration were all degassed and sealed in the supracil tubes. The phosphorescence lifetime was calculated from the oscilloscope trace obtained by using a xenon flash lamp excitation source of 5 microsecond duration which was coupled with a 1/4 meter B & L monochromator. Both the entrance and the exit slit widths were set at 1.0 mm (bandwidth of 7.4 nm) for measurement in EtOH and EPA solvents and 1.5 mm (bandwidth of 11.1 nm) for those measured in methylcyclohexane and 2-methyltetrahydrofuran. A Corning 3-73 filter was used in front of the photomultiplier to eliminate scattered light. Phosphorescence spectra were measured using a fluorescence spectrometer Hitachi MPF-2A with the spectral resolution set at 10 nm.

The authors are grateful to Professor T. Azumi for the reprints on subjects relevant to this study.

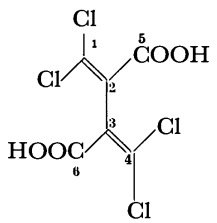
(Received April 28, 1978)

Synopsis. It was found that bis(dichloromethylne) succinic acid (BDCSA) has two crystal forms, the molecule having an *s-trans* conformation in each form. A frequency drop of about 1 MHz found for BDCSA might be explained in terms of a short intramolecular contact between the chlorine and oxygen atoms.

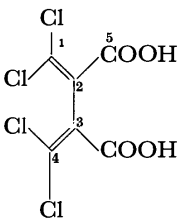
The ^{35}Cl NQR frequencies were measured for bis(dichloromethylene)succinic acid (BDCSA), its anhydride (BDCSAA), trichloroacrylic acid (TCAA), and methyl trichloroacrylate (MTCA) in order to investigate the structure of BDCSA. Details of NQR experiments and methods of preparation of the compound studied were reported.[1,2]

Crystals of BDCSA obtained by recrystallizations from ether gave NQR two lines (designated as α-spect rum), while a specimen crystallized from water afforded four lines (β-spectrum). It is evident that BDCSA has two crystal forms.[3] The resonance frequencies for these two spectra are given in Table 1, together with those for the related compounds. The spectra are also shown as stick diagrams in Fig. 1. Both α-and β-spectra exhibit considerably large frequency splittings of about 1 MHz. In the β-spectrum, the four lines seem to be devided into two frequency groups, a higher (38.430 MHz, average of ν_1 and ν_2) and a lower (37.535 MHz, average of ν_3 and ν_4).

As to the structure of BDCSA, there are two conformational possibilities, *i.e.*, *s-trans* (I) and *s-cis* (II)



(I)



(II)

forms.[4] If BDCSA has an *s-cis* form in both crystalline modifications, the NQR spectrum is expected to be similar to that for BDCSAA being forced to have an *s-cis* form. However, the lower frequency group of the former is situated far below the average (38.238 MHz) of ν_1 and ν_2 of the latter (Fig. 1). This suggests that BDCSA has an *s-trans* form.

From a comparison of the spectrum for TCAA with that of MTCA, their ν_2 and ν_3's can be assigned to geminal vinylic chlorine atoms. The NQR spectra of these two compounds and BDCSAA indicate that the geminal vinylic chlorine atoms in BDCSA would afford their NQR lines in a region, 38.2±0.3 MHz. The higher-frequency lines in BDCSA (ν_a in the α-, and ν_1 and ν_2 in the β-spectrum) appear in this anticipated region, but the lower-frequency lines lie in a frequency region significantly lower by about 1 MHz. Since both α- and β-spectra show a similar pattern, the large frequency drop might be attributed to an intramolecular phenomenon. The abnormal drop causes one to imagine an intramolecular hydrogen-bond formation between one of the chlorine atoms at C-1 position and the carboxyl group (at C-3 position) on the same side.[5] If this is correct, the magnitudes of the temperature coefficient of resonance frequencies for the lower-frequency lines should be smaller than those for the higher-frequency lines.[5] However, no such tendency was observed (Table 2).

Thus, the hydrogen-bond model does not seem to be applicable to the explanation of the large frequency drop. An alternative and most likely interpretation

TABLE 1. THE ^{35}Cl NQR FREQUENCIES (f) FOR BIS(DICHLOROMETHYLENE)SUCCINIC ACID AND RELATED COMPOUNDS AT 77 K

Compounds		No. of lines	f/MHz
BDCSA	α-spectrum	ν_a	38.489
		ν_b	37.478
	β-spectrum	ν_1	38.530

Surface Nonstoichiometry and Isoelectric Point of Manganese Oxide

Tetsuo MORIMOTO, Hidetoshi NAKAHATA, and Shigeharu KITTAKA*,†

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

† *Department of Chemistry, Faculty of Science, Okayama College of Science, 1-1 Ridaicho, Okayama 700*

(Received May 18, 1978)

The isoelectric point and the nonstoichiometric composition of the surface layer were measured for manganese oxide samples treated *in vacuo* or in air at elevated temperatures. It was found that the surface composition of most samples tested was oxygen-deficient with reference to the bulk composition, and that the IEP was determined by the bulk structure rather than the surface composition. This was ascribed to the fact that the surface is heterogeneous and the dissolution of the solid will take place preferentially at surfaces which involve defect structures or Mn(II) ions.

Transition metals form a variety of nonstoichiometric compounds not only in the interior but also on the surface of the solids. Accordingly, the oxygen content on the surface of such metal compounds as oxides is liable to be excessive or deficient with reference to the bulk composition, as revealed from ESR study[1,2] or the test of the oxidizing power of the solid surface.[3–5] This situation should affect significantly the physical and chemical properties of solid surfaces, but few quantitative relationships between the nonstoichiometry and the properties of solid surfaces have been disclosed. Several authors studied surface excess oxygen in NiO,[3,6] Cr_2O_3,[4,7,8] and MnO_2[5] in connection with their catalytic activity.

In the preceding paper[9] the isoelectric point (IEP) of manganese oxide was studied as a function of pretreatment temperature. The results showed that the IEP of manganese oxide had a value characteristic of the bulk composition of the solid, which changed in three stages with increasing temperature of treatment; the results obtained were interpreted in terms of the idea that the IEP is governed by the valency and the coordination number of surface manganese ions. The IEP of samples treated at temperatures lower than 300 °C had such small values that the existence of Mn(IV) ions with the coordination number 4 on the surface was suggested.

We can naturally expect a drastic change in surface composition when a sample is treated *in vacuo* at elevated temperatures. This paper is concerned with the effect of evacuation treatment on the IEP value of manganese oxide and on the surface composition.

Experimental

Materials. The original sample of manganese oxide used in this study was prepared by the pyrolysis of guaranteed grade $Mn(NO_3)_2 \cdot 6H_2O$ at 160 °C for 400 h in an electric oven.[9] Powdered oxide was washed sufficiently with distilled water and finally electrodialyzed until the electrical conductivity of the supernatant solution was approximately equal to the value of deionized water (1.43×10^{-6} $\mho cm^{-1}$). Then it was dried at 110 °C for 24 h in an electric oven, followed by the evacuation for 5 h at 300, 800, or 1000 °C in a vacuum of 1.33×10^{-3} Pa (M-300, M-800, and M-1000).

Another series of samples were also prepared by heating the samples M-300, M-800, and M-1000 for 5 h in air at 300, 800, and 1000 °C, respectively (M-300A, M-800A, and M-1000A).

Reaction of Surface Layer with KI. The reactivity of the solid surface with KI was examined in a vessel with the capacity of 300 cm^3, equipped with a breaking system of an ampoule containing the powdered sample. The sample was introduced into an ampoule by 2 m^2, evacuated at room temperature, and sealed. The ampoule was mounted on the ampoule holder and immersed in 100 cm^3 of a buffer solution containing 1.0 g KI. The space above the solution in the vessel was filled with N_2 to avoid the influence of air, and the vessel was thermostatted at 45 °C. After the equilibration of the system, the ampoule was broken and a vigorous shaking of the solution was started. For the preparation of buffer solutions the combination of $Na_2B_4O_7 \cdot 10H_2O$ and KH_2PO_4, which covers the wide range of pH values 5.4—9.0, was selected, because a preliminary test showed that a different combination of constituents of buffer solutions somewhat alters the reactivity of manganese oxide. After the attainment of reaction equilibrium, the amount of iodine was determined by titrating the solution with a standard $Na_2S_2O_3$ solution (1×10^{-3} mol/dm^3) by use of starch as an indicator. At the same time, the amount of Mn(II) ions dissolved was determined spectroscopically after treating the solution with 2% oxine.[10]

Measurement of IEP. The IEP value was measured by means of the streaming potential method, as described previously.[11]

Results and Discussion

Figures 1, 2, and 3 give the amounts of iodine and Mn(II) ions which were formed by the reaction of KI with manganese oxide surfaces, as a function of pH. The results obtained show that the amount of reaction products decreases exponentially with increasing pH and vanishes at pH 8. Under the present conditions, the dissolution of manganese oxide takes place according to the following reactions:

$$MnO + 2H^+ \longrightarrow Mn^{2+} + H_2O \quad (1)$$

$$MnO_2 + 4H^+ + 2I^- \longrightarrow Mn^{2+} + I_2 + 2H_2O \quad (2)$$

$$O(s) + 2H^+ + 2I^- \longrightarrow I_2 + H_2O \quad (3)$$

Reaction 1 implies the dissolution of Mn(II) oxide, which is an oxygen-deficient compound possibly formed on the surface of manganese oxide, and Reaction 3 the dissolution of excess oxygens on MnO_2 surfaces. If the surface composition of a sample is somewhat smaller in oxygen content than MnO_2, Reactions 1 and 2 will take place simultaneously, whereas if it is somewhat larger than MnO_2, Reactions 2 and 3 will occur simultaneously. The fact that the dissolved amounts of both iodine and Mn(II) ions

M-1000	0.536	Mn_3O_4		—	1.16	1.07	1.03	—	3.30
M-1000A	0.605	Mn_3O_4		1.15	—	1.12	1.11	—	3.22

a) Measured by N_2-adsorption, assuming the molecular area to be 0.162 nm^2.
b) Determined by X-ray analysis.

increase rapidly with decreasing pH is due to the increase in solubility and oxidation potential of manganese oxide with pH, as shown in Eqs. 1, 2, and 3.

The data in Figs. 1—3 permit the calculation of the composition of dissolved substances, as given in Table 1, where the x value in MnO_x is listed. In addition, the thickness of the dissolved layer can be estimated. It was found to be about 2.4 layers at maximum at pH 5.5 (Fig. 1) by assuming that the real surfaces are mainly composed of the (110) plane,[12] which has a Mn(IV) ion density of 5.55 nm^{-2}. Table 1 indicates that the surface composition of samples evacuated at elevated temperatures is deficient in oxygen with reference to the bulk composition, and that the succeeding treatment in air at the same temperature as before does not give such a large increment in surface oxygen. Thus the surface is still kept deficient in oxygen with respect to the bulk composition, except for the case of M-300A.

In Table 1, the *IEP* values of samples are also listed. Here, one can see that the sample treated *in vacuo* at 800 °C exhibits a small *IEP* value 4.54, but this increases to 8.17 when treated in air, and is accompanied by the conversion from Mn_3O_4 to α-Mn_2O_3 of the bulk composition. The present results, including this finding, have the same tendency as those obtained in the previous work:[9] manganese oxide gives *IEP* values characteristic of the bulk structure, which changes with heat treatment at different temperatures. Admittedly, no intimate correlation was found between surface composition and *IEP*. It seems at first sight strange that the *IEP* does not depend on the surface composition, but is determined by the bulk structure. This may be due to the fact that the solid surface is heterogeneous, and consequently the reaction with KI or the dissolution of the solid takes place preferentially at the surface, which involves defect structures or Mn(II) ions. On the same surface, a more stable structure which is dissolved only with difficulty should also be present: manganese ions on this part of the surface will determine the *IEP* of samples.

Finally, the extremely small *IEP* values of the 300-treated samples, *i.e.* less than 3, still have not been elucidated in this study; but there remains the possibility of the existence of Mn(IV) ions with the coordination number 4, which comes from the oxygen-deficient states of the surface.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (11), 3389—3390 (1978)

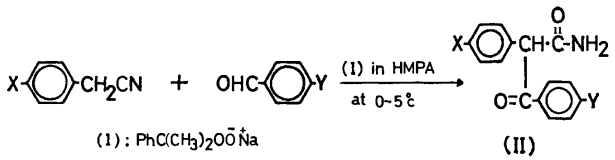
The Reaction of Phenylacetonitriles with Benzaldehydes in Hexamethylphosphoric Triamide Solution Containing the Sodium Salt of α,α-Dimethylbenzyl Hydroperoxide[1,2]

Kazumasa TAKAHASHI,* Kazutoshi YAMADA, and Hirotada IIDA
Department of Synthetic Chemistry, Chiba University, Yayoi-cho, Chiba 280

(Received December 5, 1977)

Synopsis. Treatment of phenylacetonitriles with *p*-substituted benzaldehydes in hexamethylphosphoric triamide solution containing the sodium salt of α,α-dimethylbenzyl hydroperoxide gave α-benzoyl-α-phenylacetamides as major products.

The reaction of phenylacetonitriles with *p*-substituted benzaldehydes was carried out in hexamethylphosphoric triamide (HMPA) solutions containing the sodium salt of α,α-dimethylbenzyl hydroperoxide (I). α-Benzoyl-α-phenylacetamide derivatives (II) were obtained as major products (Scheme 1 and Table 1). However, the treatment of diphenylacetonitrile and α-phenylpropionitrile having substituents in the α-position with *p*-anisaldehyde gave oxidation products of the starting materials, but not the corresponding benzoyl-acetamides. I has both strongly basic and oxidative properties. However, no report seems to have been made on the use of these properties of I in reactions. The properties were found to act effectively in an HMPA solution.



Scheme 1.

Results and Discussion

The reactions of phenylacetonitriles with *p*-substituted benzaldehydes were carried out in HMPA solutions in the presence of I, giving benzoyl-acetamides (II) in 40—55% yield (Table 1). The reaction of phenylacetonitrile with *p*-nitrobenzaldehyde, however, gave various products, but no product of type II. In all cases except the case of *p*-nitrobenzaldehyde, the color of the reaction solution was reddish orange. In the case of *p*-nitrobenzaldehyde, it was purple-blue, characteristic of nitrobenzene radical anions.[3]

The treatment of diphenylacetonitrile with *p*-anisaldehyde gave oxidation products, benzophenone and *p*-anisic acid. The yield of benzophenone was 78%. The expected benzoyl-acetamide was not obtained. Likewise, the treatment of α-phenylpropionitrile with *p*-anisaldehyde gave acetophenone and *p*-anisic acid, but not the corresponding benzoyl-acetamide either.

The mechanism for the formation of the benzoyl-acetamides (II) is assumed as follows. The acidic α-hydrogen of phenylacetonitrile is abstracted by I and the α-cyanophenylmethanide ion thus formed nucleophilically attacks the carbonyl group of benzaldehydes to give III (Eqs. 1 and 2, Scheme 2). Intermediate III is oxidized by the hydroperoxide shown in Eq. 1 or by I to give α-benzoyl-α-phenylacetamide II. The problem is how III is oxidized to give benzoyl-acetamide (II). The reaction of 2-cyano-1,2-diphenylethanol (III'), which is the protonated form of the hypothetical intermediate (III), was assumed to react with I. However, various attempts to synthesize III' were unsuccessful. It was presumed that the cyano group of α-cyanodeoxybenzoin (V) (Eq. 2) is oxidized by I. However, when α-cyanodeoxybenzoin (V) synthesized[4] was treated with I, no oxidation of the cyano group took place. When (*E*)-α-phenylcinnamonitrile (IV) obtained as a minor product in *ca.* 10% yield was treated with I, the corresponding benzoyl-acetamide (II) was obtained in 39% yield. The treatment of phenylacetonitrile and benzaldehyde using a base such as sodium hydroxide or sodium ethoxide has been reported to give IV in 87—97% yield.[10] The low yield of IV in the present work is due to the further conversion of IV into benzoyl-acetamide (II). The formation of the benzoyl-acetamide (II) is accounted for by both the nucleophilic reaction of I to the double bond, and the hydrolysis of the cyano group. The nucleophilic reaction is most likely caused by the complex of ROONa (I) with ROOH produced (Eq. 1), which is more reactive than ROONa itself.[11] The mechanism (Scheme 2) is further supported by the fact that the reaction with use of diphenylacetonitrile or α-phenylpropionitrile, which cannot form an intermediate such as IV, gave no products corresponding to the compound II.

The mechanism by which the reaction with use of diphenylacetonitrile or α-phenylpropionitrile gave the corresponding ketone is shown in Eqs. 3 and 4 (Scheme 2). The nucleophilic addition of a carbanion to a carbonyl group is thought to be a reversible process.[5] Since VI cannot undergo a process leading to the formation of α-phenylcinnamonitrile, the oxidation process to give benzophenone or acetophenone would proceed efficiently.

Experimental

All the melting points were uncorrected. The sodium salt of α,α-dimethylbenzyl hydroperoxide (I) was prepared from technical-grade α,α-dimethylbenzyl hydroperoxide according to the procedure of Belyaev and Nemtsov.[6] The peroxide content of I was estimated to be 65% by iodometric titration. *p*-Tolylacetonitrile and *p*-chlorophenylacetonitrile were synthesized by the reaction of *p*-methylbenzyl and *p*-chlorobenzyl chlorides with sodium cyanide.[7]

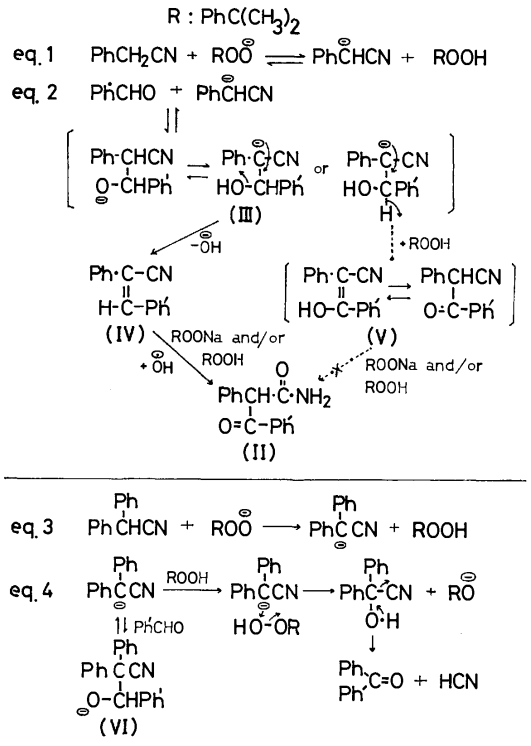
a) The product corresponding to IIe (X=H, Y=NO_2) was not obtained. b) The compound (IIc) is a known compound. However, all its physical data are given since the melting point differs from that (178 °C) reported.[9]



Scheme 2.

α-Cyanopropionitrile was prepared by the reaction of phenylacetonitrile with methyl bromide.[8]

Synthesis and Physical Properties of II. Into a 100-ml four-necked flask equipped with a thermometer and inlet and outlet tubes for nitrogen gas was placed 5.36 g(0.02 mol) of I dissolved in 25 ml of HMPA. To the solution maintained at 0—5 °C was added a mixture of 0.585 g(0.005 mol) of phenylacetonitrile and 0.682 g(5.5 mmol) of *p*-anisaldehyde in 5 ml of HMPA under nitrogen atmosphere. The mixture was stirred at 0—5 °C for 4 h and then poured into an aqueous solution of ammonium chloride . The aqueous layer was extracted several times with ether and then with benzene (*ca.* 200 ml each). The combined extracts were washed with water and dried over anhydrous sodium sulfate. After the solvents had been evaporated, compound IIa was separated as white crystals and recrystallized from benzene. Other acetamides (IIa—g) except IIe were prepared in a similar way. Their structures were confirmed by UV and IR spectra, MS and elementary analyses (Table 1).

α-Cyanodeoxybenzoin (V). The benzoin was synthesized by a modification of the procedure of Coan and Becker[4] and recrystallized from ethanol; mp 93—94.5 °C (lit,[9] 90 °C), MS: M^+ 221, IR(KBr): νC=O 1690 cm^{-1}, νCN 2250 cm^{-1}, UV: λ_{max}^{EtOH} 292 nm $\varepsilon=1.25\times10^4$. The benzoin (0.553 g, 2.5 mmol) was treated with (I) (2.68g, 2.5 mmol) dissolved in 15 ml of HMPA. However, no reaction took place, most of V being recovered.

(E)-*α-Phenylcinnamonitrile (IVc).* The physical properties of IVc (mp 83—84 °C), isolated together with the benzoyl-acetamide (IIc), agreed with those (mp 86 °C) of the known sample synthesized according to the procedure of Wawzonek and Smolin.[10] The cinnamonitrile (0.683 g, 3.3 mmol) was treated with I (3.57 g, 13 mmol) dissolved in 20 ml of HMPA at 0—5 °C for 4 h. The corresponding benzoyl-acetamide (IIc) was obtained in 39% yield.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (11), 3391—3392 (1978)

The Chemistry of Isocyanic Acid and Its Derivatives. Part V.[1] The Oxidative Coupling of Ethyl Carbamate and Urea with Cyclohexene, Tetrahydrofuran, and Cyclooctadiene Effected by Palladium(II) Chloride[2]

Shoichiro OZAKI* and Akihiro TAMAKI

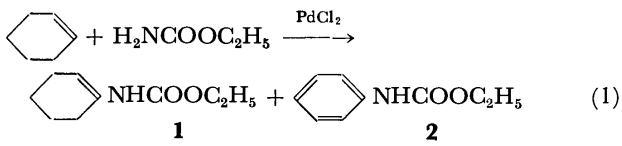
Research Center, Mitsui Toatsu Chemicals, Inc., Kasama-cho, Totsuka-ku, Yokohama 247

(Received December 16, 1977)

Synopsis. The reaction of ethyl carbamate with cyclohexene promoted by $PdCl_2$ gave ethyl 1-cyclohexenylcarbamate. The reaction of ethyl carbamate and tetrahydrofuran gave ethyl 2-tetrahydrofurylcarbamate. Ethyl carbamate and 1,5-cyclooctadiene–$PdCl_2$ complex (**4**) reacted to give ethyl 4-cyclooctenylcarbamate. The reaction of urea and **4** afforded cyclooctylurea and 4-cyclooctenylurea.

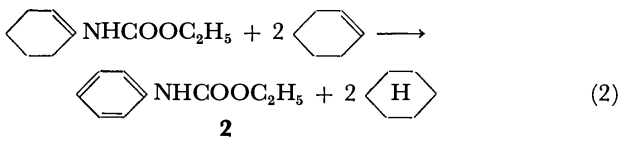
Although various compounds bearing active hydrogens are known to undergo oxidative coupling reactions by the aid of palladous chloride,[3] the reactions of carbamates and ureas have been little studied. The communications by Kasahara *et al.* on the *intra*molecular cyclization reactions of unsaturated amides[4] and ureas[5] prompted the present authors to publish the results of their studies[2] of the *inter*molecular oxidative coupling reactions of ethyl carbamate and urea with cyclic olefins.

Ethyl 1-cyclohexenylcarbamate (**1**) and ethyl phenylcarbamate (**2**) were obtained by heating a mixture of cyclohexene, ethyl carbamate, and palladium(II) chloride.[2a]



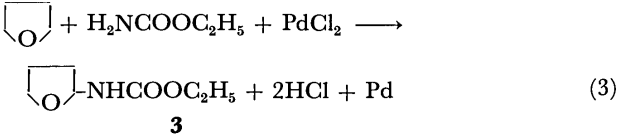
(1)

It is of interest that ethyl carbamate did not attack the allylic position of cyclohexene, while CN^- [6] and AcO^- [7] did. The hydrogen-transfer reaction, *e.g.*, Eq. 2, might be responsible for the formation of **2**:



(2)

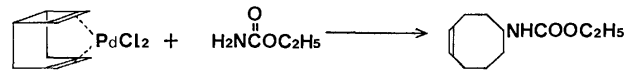
An attempted reaction of the same mixture in tetrahydrofuran did not give the expected products, but instead gave ethyl 2-tetrahydrofurylcarbamate (**3**) in a 30% yield.[2b]



(3)

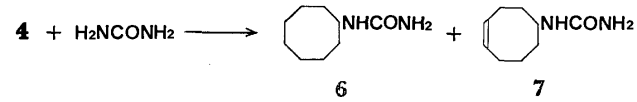
This reaction is a new type of oxidative coupling, in which tetrahydrofuran, instead of olefin, is activated by palladium(II) chloride. Attempted reactions in benzene, diethyl ether, anisole, ethanol, or *N,N*-dimethylformamide, did not give any oxidative coupling products.

Ethyl carbamate also reacted with the 1.5-cyclooctadiene palladous chloride complex (**4**) to afford ethyl 4-cyclooctenylcarbamate (**5**).[2c]



(4)

Urea did not give any coupling product with cyclohexene, in either the presence or absence of a solvent. Urea-olefin coupling products, cyclooctylurea (**6**) and 4-cyclooctenylurea (**7**), however, were obtained when **4** was made to react with urea in *N,N*-dimethylacetamide.



(5)

Experimental

Reaction of Cyclohexene with Ethyl Carbamate. Cyclohexene (15 g, 0.183 mol), ethyl carbamate (30 g, 0.337 mol), and palladium(II) chloride (1 g, 0.00562 mol) were mixed and stirred at 60 °C for 23 h. After agitation under an hydrogen atmosphere for 3 h, the reaction mixture was extracted with petroleum benzine, the solvent was removed by evaporation, and the residue was distilled under reduced pressure to give two fractions. The first fraction (0.39 g; 38.1%, based on palladium(II) chloride; bp 64 °C/0.18 mmHg) was found to be **1** by means of an NMR measurement [(neat) δ 1.22 (3H, triplet, CH_3), 1.17 (8H, multiplet, CH_2-ring) 4.02 (2H, quartet, OCH_2–C), 5.12 (1H, singlet, NH), 5.54 (1H, multiplet, –CH=)], and elemental analysis. Found: C, 64.13; H, 9.01; N, 7.97%. Calcd for $C_9H_{15}NO_2$: C, 63.88; H, 8.94; N, 8.28%. The second fraction (0.53 g; 53.0%; bp 78—82 °C/0.14 mmHg) was found to be **2** by means of an NMR measurement [(neat) δ 1.25 (3H, triplet, CH_3), 4.15 (2H, quartet, O–CH_2–C), 7.25 (5H, multiplet, C_6H_5+ NH)], and elemental analysis. Found: C, 65.22; H, 7.00; N, 8.19%. Calcd for $C_9H_{11}NO_2$: C, 65.44; H, 6.71; N, 8.48%.

*Ethyl 2-Tetrahydrofurylcarbamete (**3**).* A mixture of tetrahydrofuran (41 g, 0.5 mol), palladium(II) chloride (1.0 g, 0.0056 mol), ethyl carbamate (0.89 g, 0.01 mol), and disodium hydrogenphosphate (1.6 g, 0.0112 mol) was stirred for 1 h at room temperature, and then cyclohexene (5.0 ml, 0.049 mol) was added; there after the mixture was stirred for additional 17 h at room temperature and subsequently exposed to a hydrogen atmosphere for 4 h. The mixture was then filtered, and the filtrate was concentrated and, after the addition of a small amount of water, extracted with benzene and ether. The extract was dried with anhydrous sodium sulfate and distilled under reduced pressure. The

product (0.267 g, 30%) (bp 71—5 °C/0.08 mmHg), which slowly solidified at room temperature and which melted at 44—46 °C, was found to be **3** by means of an NMR measurement [(in $CDCl_3$) δ 1.24 (3H, triplet, CH_3), 1.92 (4H, multiplet, CH_2-ring), 3.87 (2H, quartet, OCH_2-ethyl), 4.14 (2H, triplet, OCH_2-ring) 5.53 (2H, multiplet, CH=NH)] and elemental analysis. Found: C, 53.01; H, 8.26; N, 8.68%. Calcd for $C_7H_{13}NO_3$: C, 52.81; H, 8.23; N, 8.80%.

Ethyl 4-Cyclooctenylcarbamate (5). A mixture of **4** (2.0 g, 7 mmol), ethyl carbamate (1.50 g, 16.9 mmol), sodium carbonate (0.787 g, 7.3 mmol), and *N,N*-dimethylacetamide (40 ml) was stirred for 5 h at room temperature. Calcium hydride (3 g) was then added, and the mixture was agitated for an additional 10 h. The precipitated palladium black was filtered off, and the filtrate was concentrated and distilled under reduced pressure. Ethyl 4-cyclooctenylcarbamate (**5**) (0.811 g, 58.7% based on **4**) was thus obtained as a viscous oil; bp 110 °C/0.2 mmHg; NMR ($CDCl_3$) δ 1.23 (3H, t, CH_3), 1.58 (6H, m, CH_2), 2.25 (4H, m, =CH-$\underline{CH_2}$), 3.75 (1H, m, CH), 4.02 (2H, m, O-CH_2), 5.68 (3H, m, CH=CH+NH); IR (KBr), 3360, 2925., 1964, 1528, 1468, 1245, 1100, 1050, 780 cm^{-1}. Found: C, 67.16; H, 10.07; N, 7.35%. Calcd for $C_{11}H_{19}NO_2$: C, 66.97; H, 9.71; N, 7.10%.

Reaction of **4** *with Urea.* Urea (7.5 g, 0.125 mol), **4** (15 g, 0.052 mol), and anhydrous sodium carbonate (5.6 g, 0.052 mol) were added to *N,N*-dimethylacetamide (150 ml), and the mixture was stirred for 6.5 h at room temperature; palladium black separated in the meantime. Agitation was continued for an additional 41 h while calcium hydride (18 g) was added in small portions. The mixture was then filtered, and the filtrate was concentrated and extracted with chloroform at 50 °C. The subsequent evaporation of the solvent left 5.48 g of a white, crystalline solid (mp 144—155 °C), which was a mixture of cyclooctylurea (**6**) and cyclooctenylurea (**7**); on hydrogenation over the Pd–C catalyst, it gave **6** (5.21 g, 58.3% based on **4**); mp 175.5—176 °C; NMR (DMSO-d_6) δ 1.51 (14H, multiplet, CH_2), 3.53 (1H, multiplet, CH), 5.20 (3H, multiplet, NH+NH_2); molecular weight by vapor-pressure osmometry, 171 (Calcd, 170.23). Found: C, 63.43; H, 10.85; N, 16.39%. Calcd for $C_9H_{18}N_2O$: C, 63.49; H, 10.66; N, 16.45%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (11), 3393—3394 (1978)

The Synthesis of Several Dipivaloylpolymethylbenzenes[1)]

Hitomi SUZUKI,* Yasuo AOMORI, Tadashi MISHINA, and Terukiyo HANAFUSA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received February 7, 1978)

Synopsis. 2,4-Dipivaloyl-1,3,5-trimethylbenzene, 4,6-dipivaloyl-1,2,3,5-tetramethylbenzene, and 3,6-dipivaloyl-1,2,4,5-tetramethylbenzene were prepared by the Friedel-Crafts dipropionylation of the corresponding polymethylbenzenes, followed by the exhaustive methylation of the resulting diketones with potassium *t*-butoxide and methyl iodide in boiling benzene–*t*-butyl alcohol. The PMR and IR spectra are reported for these new compounds.

In connection with our work on the non-conventional reactions of polysubstituted aromatics, we needed hindered ketones of the (**8**) type, bearing a methyl group at the position flanked both sides by the bulky electron-withdrawing groups. To our knowledge, there is no published preparation of ketones with this particular structure. The traditional method for the direct synthesis of pivalophenones (2,2-dimethyl-1-phenyl-1-propanones) involves the reaction of pivaloyl chloride with arylmagnesium halides[2)] or with arenes in the presence of the Friedel-Crafts catalyst,[3)] and the reaction of pivalonitrile] with the appropriate Grignard reagent.[4)] Our attempts to convert hindered polymethylpivalophenones to the title diketones by the Friedel-Crafts method led to extensive deacylation as well as the formation of a complicated mixture of hydrocarbons and polymeric substances. The reactions of pivaloyl chloride with the Grignard reagent[5)] derived from bromopolymethylpivalophenones resulted only in the recovery of the parent polymethylpivalophenones. Likewise, attempts to prepare the diketones by the reaction of polymethylbenzenedicarbonitriles with *t*-butylmagnesium chloride failed, since no reaction took place.

Next we planned to prepare the diketones starting from polymethylbenzene-1,3-dicarboxylic acids and following the reaction sequence: diacids — diacid dichlorides — dipivaloylbenzenes. In a search for a simple procedure for converting the hindered acid chloride groups into pivaloyl groups, we examined the reaction of several polymethylbenzoyl chlorides with *t*-butylmagnesium chloride with or without the use of transition metal catalysts.[6)] The results were unpromising, however. When polymethylbenzoyl chloride (**1b—c**) was treated with an excess of the Grignard reagent, the reductive 1,2-addition occurred sluggishly, giving an ester as the sole product.[7)] The analytical and spectral data of this compound were consistent with the highly crowded structure (**4b—c**) (Table 1). As expected, neither attempts to saponify this ester by heating it with ethanolic potassium hydroxide or concentrated hydrochloric acid, nor attempts to obtain an authentic specimen from the reaction of alcohol (**5**) and acid chloride (**1**), were successful. However, this ester underwent reductive cleavage with lithium aluminum hydride in boiling tetrahydrofuran, giving two benzylic alcohols (**5** and **6**) in accord with the assigned structure **4**. Two possible mechanisms for the formation of the ester are given in Scheme 1. In order to differentiate between these two pathways, the aldehyde (**2b**) and ketone (**3b**) were each treated with *t*-butylmagnesium chloride under the same conditions. The latter compound was recovered unchanged, while the former gave the expected alcohol **5b**, supporting the first mechanism, in which the reaction proceeds *via* the aldehyde as intermediate.

Finally, we have found that the compounds of the **8** and **10** types are accessible *via* an indirect route involving the Friedel-Crafts dipropionylation of polymethylbenzenes,[8)] followed by the treatment of the resulting diketones with potassium *t*-butoxide and methyl iodide in boiling benzene/*t*-butyl alcohol (Scheme 2).[9)] The exhaustive methylation of the ketones, **7** and **9**, proceeded with ease, and the concurrent formation of the enol ethers was not significant.

All the dipivaloylpolymethylbenzenes obtained are well-crystallized solids melting between 128 and 232 °C with partial sublimation. They are moderately soluble in benzene, chloroform, and ether, and slightly soluble in carbon tetrachloride, hexane, and methanol. The PMR signals for pivaloyl groups in **8a,b** and **10** showed a slight splitting ($\Delta\delta<0.02$ ppm), and those for ring methyl groups appeared as a somewhat broad singlet, suggesting the occurrence of stereoisomerism as a result of the restricted rotation about the sp^2-sp^2 carbon-carbon bond at room temperature. Ring methyl signals for each pair of diketones **7/8** or **9/10** appeared nearly at the same chemical shifts, indi-

a) Based on the isolated product. All new compounds gave satisfactory analyses. b) The PMR spectra were measured in deuteriochloroform.

cating that the preferred conformations of all the pairs of compounds are very similar.

On treatment with nitric acid in dichloromethane, **8b** underwent preferential attack upon the 2-methyl group at the most hindered position. This and other aspects of the reaction of this new compound will be reported in detail separately.

Experimental

The melting points were taken on a hot-stage apparatus and are uncorrected. The IR spectra were run as Nujol mulls on a Hitachi 215 spectrophotometer, and only prominent peaks were recorded. The PMR spectra were measured in carbon tetrachloride with a Varian T-60 spectrometer, using TMS as the internal standard, unless otherwise stated. The mass (MS) spectra were obtained on a Hitachi RMS-4 mass spectrometer with an ionizing potential of 70 eV.

The polymethylbenzoyl chlorides (**1a—c**) were prepared from the corresponding benzoic acids[10] by treatment with thionyl chloride. The dipropionylpolymethylbenzenes (**7a—b** and **9**) were prepared from the corresponding hydrocarbons according to the Perrier procedure of the Friedel-Crafts acylation.[8] The aldehyde (**2b**) and ketone (**3b**) were prepared as has previously been reported.[3,11] The physical properties and yields of dipropionyl- and dipivaloylpolymethylbenzenes (**7a—b** and **9**, and **8a—b** and **10**, respectively), and 1-(polymethylphenyl)-2,2-dimethylpropyl polymethylbenzoates (**4a—c**) obtained are summarized in Table 1. The general preparation of the hindered diketones and esters is illustrated below by the synthesis of **8b** and **4b**.

4,6-Dipivaloyl-1,2,3,5-tetramethylbenzene (8b). A mixture of the **7b** diketone (1.5 g; 0.006 mol), potassium *t*-butoxide (5.5 g; 0.050 mol), benzene (15 ml), and *t*-butyl alcohol (6 ml) was stirred, and then a solution of methyl iodide (15 g; 0.102 mol) in benzene (30 ml) was slowly added during the course of 30 min. Stirring was continued for 4 h under reflux, and then the reaction mixture was treated with water. The organic layer was separated and washed thoroughly with water, and the solvent was removed under reduced pressure. The residue was purified over a column of silica gel (hexane), giving **8b** as colorless plates (0.6 g; 33%); mp 166—168 °C. MS: *m/e* 302 (M^+), 287 (M^+-CH_3), and 245 (base peak; $M^+-C_4H_9$). Found: C, 79.67; H, 10.15%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%.

Compounds **8a** and **10** were obtained in a similar manner from 1,3,5-trimethylbenzene and 1,2,4,5-tetramethylbenzene respectively. **8a**: Found: C, 79.19; H, 9.74%. Calcd for $C_{19}H_{28}O_2$: C, 79.12; H, 9.78%. **10**: Found: C, 79.48; H, 10.13%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%.

1-(2,4,6-Trimethylphenyl)-2,2-dimethylpropyl 2,4,6-Trimethylbenzoate (4b). Into a solution of the Grignard reagent prepared from *t*-butyl chloride (5.0 g; 0.054 mol) and magnesium (1.3 g; 0.054 atom) in ether (30 ml), 2,4,6-trimethylbenzoyl chloride (5.9 g; 0.032 mol) in ether (20 ml) was stirred under ice-water cooling during the course of 0.5 h. After the acid chloride had then been added, the mixture was gently refluxed for 4 h and then treated with aqueous ammonium chloride. The organic layer was separated, and the aqueous layer was extracted with ether. The combined extracts were washed successively with aqueous sodium hydrogencarbonate and water, dried over magnesium sulfate, and evaporated. After standing overnight in a refrigerator, the oily residue gave an ester as a white solid which, on several recrystallizations from hexane, melted at 126—128 °C. Yield, 3.2 g (56%). MS: *m/e* 352 (M^+) and 295 (base peak; $M^+-C_4H_9$). Found: C, 82.05; H, 9.19%. Calcd for $C_{24}H_{32}O_2$: C, 81.77; H, 9.14%.

The Sesquiterpenes of *Dendropanax trifidus*

Kazuo YOSHIHARA* and Yoshio HIROSE

The Institute of Food Chemistry, Wakayamadai, Shimamoto-cho, Mishima-gun, Osaka 618

(Received March 16, 1978)

Synopsis. The volatile oils of the leaves, cortex and fruits of *Dendropanax trifidus* were investigated. Germacrene-D is enantiomeric, sesquiterpenes of other series, such as caryophyllene and selinenes, optically corresponding to those in higher plants.

Some volatile oils of *Aralia* species have simple compositions, consisting of germacrene-D, caryophyllene, humulene, *etc.*[1] We have studied the volatile oils of *Dendropanax trifidus*.

The volatile oils of the leaves, cortex and fruits were obtained by steam distillation, the components being isolated by silica gel column and gas chromatography. The isolated compounds and their $[\alpha]_D$ values are given in Table 1. Caryophyllene (**1**) was the major component in the leaf oil, the series, α- and β-neoclovenes(**2** and **3**) and β-panasinsene (**4**) being detected. The occurrence of **4** in nature is significant since it has been suggested to be a key intermediate in the caryophyllene-neoclovene conversion reaction.[2] Cadalene-type compounds (**6**—**9**) and selinenes (**10** and **11**) were also detected. In contrast to the leaf oil, only a trace of caryophyllene was found in the cortex oil, germacrene-D (**5**), a potential precursor of cadalene-type compounds, bourbonenes, *etc.*,[3] being the major component. These serial compounds were also detected. Selinenes were found in small amounts. In the fruit oil, almost all caryophyllene disappeared and no germacrene-D was present. However, various derivatives such as cadinenes (**6** and **7**) and muurolenes (**8** and **9**) were found together with neoclovenes and selinenes. A large amount of humulene was found in this oil. It is probable that caryophyllene and germacrene-D were further transformed into compounds, **2**, **3** and **6**—**9** for final storage in the fruits.

It is noteworthy that germacrene-D in the plant is dextrorotatory, containing an α-isopropyl group as shown in Fig. 1. The optical rotations show that the compounds of the germacrene-D series have also α-isopropyl groups, being enantiomers of those occurring in higher plants.[3] On the other hand, the selinenes have β-isopropyl groups. Thus, in this plant, germacrene-D series compounds and selinenes, which may be derived from a common germacrene-type precursor (**12**), have enantiomeric isopropyl configurations.

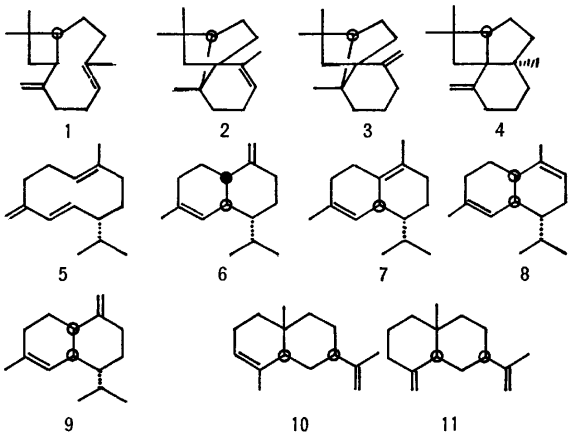

Fig. 1. Structures of selected compounds from Table 1.

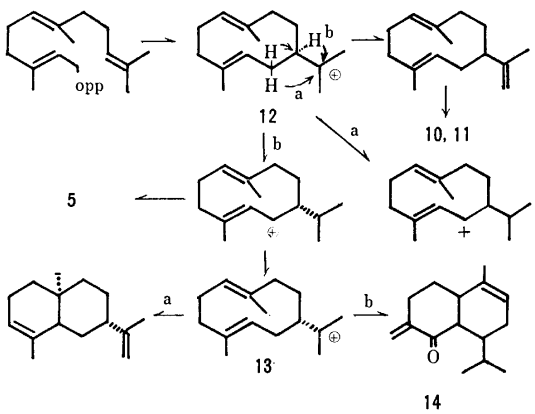

Fig. 2. Possible biosynthetic route involving enantiomeric germacrenoidal precursors (see the text).

Such coexistence of enantiomeric germacrene-D series and normal selinene-type compounds in a higher plant does not seem to have been found. A similar case was reported for a sort of liverwort, *Chiloscyphus polyanthus*, in which, in contrast to *D. trifidus*, α-selinene has an α-isopropyl group, and chiloscyphone (**14**), a cadalene-type ketone, has a β-isopropyl group.[4] Andersen *et al.* suggested that α-selinene and chiloscyphone in *C. polyanthus* are derived from enantiomeric germacrenoidal precursors (**12** and **13**, respectively). However, an alternative biogenetic route is also possible, *i.e.*, a single 1,3-hydride shift (path a) and two concerted 1,2-hydride shifts (path b) in the germacrenium-cation (**12**) can occur, resulting in an opposite orientation of the isopropyl group. If this is the case, the unusual coexistence of chiloscyphone with other enantiomeric compounds in *C. polyanthus* can be explained by the inversion of its isopropyl group through path b. Thus, *C. polyanthus* resembles other liverworts producing enantiomeric terpenes. The coexistence of enantiomeric germacrene-D series compounds in *D. trifidus* appears to support this view.

Experimental

Analytical Instrument. Analytical gas chromatography was carried out on a Hitachi-063-type apparatus fitted with a HB-2000 capillary column. Measurements of physical data were taken on a Hitachi EPI-G-2-type IR absorption spectrometer with NaCl cell, a JEOL-JNM-C-60-type NMR spectrometer and a Perkin-Elmer's 141-type polarimeter.

Isolation. The materials were collected in Osaka prefecture. 5.2 g of leaf oil (from 25 kg, 0.02%), 2.7 g of the cortical oil (from 12 kg, 0.02%), and 11.7 g of the fruit oil (from 8 kg, 0.146%) were obtained by steam distillation. Each oil was chromatographed on silica gel using hexane–ether as the carrier. Each eluted fraction was separated into pure compounds by means of a Varian MODEL-90-P-type gas chromatograph fitted with a Carbowax 20 M column.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (11), 3397—3398 (1978)

Transformation of *o*-Nitrobenzenes to Quinolines with Tetracarbonylhydridoferrate

Yoshihisa WATANABE,* Kunihiko TAKATSUKI, Sang Chul SHIM, Take-aki MITSUDO, and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received March 20, 1978)

Synopsis. Condensates of *o*-nitrobenzaldehyde with carbonyl compounds are reduced with tetracarbonylhydridoferrate under mild conditions to give quinolines in good yields.

Derivatives of tetracarbonylferrate such as hydrido-,[1] acyl-,[2] alkyl-,[3] and carbamoyl-[4] are powerful reducing reagents for the conversion of nitro compounds into the corresponding amines, amides and ureas. The present study deals with the applicability of tetracarbonylhydridoferrate to the synthesis of *N*-heterocycles from condensates of *o*-nitrobenzaldehyde and *o*-nitroaniline with carbonyl compounds and/or primary amines.

Experimental

Infrared spectra were measured with a 215 Hitachi Model spectrophotometer. Nuclear magnetic resonance spectra were measured with a JEOL-JNM-PM-60 NMR spectrometer in deuteriochloroform with Me_4Si as an internal standard. Melting points were uncorrected.

Materials. *o*-Nitrocinnamaldehyde, *o*-nitrobenzaldehyde, *o*-nitroaniline, 1-naphthylamine, acetophenone, iron pentacarbonyl and solvents were all commercial products and were used without further purification. *N*-(*o*-Nitrobenzylidene)-1-naphthylamine(**3a**), *N*-(*o*-nitrobenzylidene)-*p*-anisidine(**3b**) and *p*-chloro-*N*-(*o*-nitrobenzylidene)aniline (**3c**) were prepared from *o*-nitrobenzaldehyde and 1-naphthylamine, *p*-anisidine and *p*-chloroaniline, respectively. *o*-Nitro-*N*-benzylideneaniline(**6a**) and *o*-nitro-*N*-(*p*-chlorobenzylidene)aniline(**6b**) were prepared from *o*-nitroaniline and benzaldehyde and *p*-chlorobenzaldehyde, respectively. Potassium tetracarbonylhydridoferrate was prepared according to the method described in a previous paper.[5]

General Reaction Procedure. To the ferrate(11 mmol) in moist ethanol (50—100 ml), a nitro compound(11 mmol) was added and the mixture stirred under an argon atmosphere at room temperature for 1 h. Reaction products, quinoline, quinaldine and 2-phenylquinoline were analyzed by GLC using internal standards: a column(0.3 cm ϕ, 3 m) packed with 10% Versamid on Neopak 60—80 mesh. Other products were detected by chromatography on alumina, silica gel or florisil, IR and PMR spectroscopy and elemnetal analysis.

Condensates of *o*-nitrobenzaldehyde with acetaldehyde, acetone or acetophenone were prepared *in situ* and submitted for further reaction: a mixture of *o*-nitrobenzaldehyde(11 mmol) and a carbonyl compound(13 mmol) in ethanol (20 ml) was stirred in the presence of a certain amount of potassium hydroxide under an argon atmosphere at room temperature for 3—23 h and then to this mixture were added iron pentacarbonyl(11 mmol) and 1 M potassium hydroxide(30—33 mmol) solution in ethanol.

Reaction of o-*Nitro*-N-*benzylideneaniline(**6a**) with* $KHFe(CO)_4$. The brown reaction mixture obtained was filtered and evaporation of the filtrate gave a brown residue which was chromatographed on florisil (3 × 30 cm) using dichloromethane as an eluant. A yellow orange band fraction gave 2-phenylbenzimidazole(**7a**) as yellow crystals in 10% yield. The reaction of *o*-nitro-*N*-(*p*-chlorobenzylidene)aniline(**6b**) gave 2-(*p*-chlorophenyl)benzimidazole(**7b**) as yellow orange crystals in 16% yield.

Preparation of N-*(o-Nitrobenzylidene) Amines (**3**).* A mixture of *o*-nitrobenzaldehyde(20 mmol), a primary amine (20 mmol) and ethanol(15 ml) was stirred at room temperature for 5 h to give yellow or orange precipitates, which were separated by filtration and recrystallized from chloroform-ethanol. *N*-(*o*-Nitrobenzylidene)-1-naphthylamine(**3a**), yield 45%, yellow crystals. PMR($CDCl_3$): δ 9.0(s, 1, -C<u>H</u>=N-), 7—8.5(m, 11, Ar). IR(KBr): $\nu_{C=N}$ 1620 cm^{-1}. *N*-(*o*-Nitrobenzylidene)-*p*-anisidine(**3b**), 85%, orange crystals. PMR($CDCl_3$): δ 8.9(s, 1, -C<u>H</u>=N-), 6.8—8.4(m, 8, Ar), 3.8(s, 3, -OC<u>H</u>$_3$). IR(KBr): $\nu_{C=N}$ 1620 cm^{-1}. *p*-Chloro-*N*-(*o*-nitrobenzylidene)aniline(**3c**), 75%, yellow crystals. PMR($CDCl_3$): δ 8.9(s, 1, -C<u>H</u>=N-), 7—8.4(m, 8, Ar). IR(KBr): $\nu_{C=N}$ 1610 cm^{-1}.

Reaction of N-*(o-Nitrobenzylidene)amines (**3**) with* $KHFe(CO)_4$. A mixture of **3**, the ferrate and moist ethanol (100 ml) was stirred under argon at room temperature for 3 h. The reaction products, *N*-(*o*-aminobenzylidene) amines (**4**) were isolated by evaporating the filtered solution to dryness and purified by recrystallization from chloroform-ethanol.

N-(*o*-Aminobenzylidene)-1-naphthylamine(**4a**), yield 50%, yellow crystals mp 80.5—81.5 °C. PMR($CDCl_3$): δ 8.5 (s, 1, -C<u>H</u>=N-), 6.3—8.4(m, 13, Ar and -N<u>H</u>$_2$). IR (KBr): ν_{NH_2} 3370, $\nu_{C=N}$ 1620 cm^{-1}. Found: C, 83.04; H, 5.66; N, 11.08%. Calcd for $C_{17}H_{14}N_2$: C, 82.90; H, 5.73; N, 11.37%.

N-(*o*-Aminobenzylidene)-*p*-anisidine(**4b**), 8%, yellow crystals, mp 122.0—123.5 °C. PMR($CDCl_3$): δ 8.5 (s, 1, -C<u>H</u>=N-), 6.2—7.7(m, Ar and -N<u>H</u>$_2$), 3.8(s, 3, -OC<u>H</u>$_3$). IR(KBr): ν_{NH_2} 3470, $\nu_{C=N}$ 1620 cm^{-1}. Found: C, 73.96; H, 6.09; N, 12.30; O, 7.62%. Calcd for $C_{14}H_{14}N_2O$: C, 74.31; H, 6.24; N, 12.38; O, 7.07%.

p-Chloro-*N*-(*o*-aminobenzylidene)aniline(**4c**), 9%, white yellow crystals, mp 108.5—110.0 °C. PMR($CDCl_3$): δ 8.4(s, 1, -C<u>H</u>=H-), 6.1—7.9 (m, 10, Ar and -N<u>H</u>$_2$). IR (KBr): ν_{NH_2} 3460, $\nu_{C=N}$ 1620 cm^{-1}. Found: C, 67.99; H, 4.69; N, 12.13; Cl, 15.38%. Calcd for $C_{13}H_{11}N_2Cl$: C, 67.68; H, 4.81; N, 12.14; Cl, 15.37%.

Results and Discussion

Alcoholic tetracarbonylhydridoferrate has high reactivity for the conversion of condensates of *o*-nitrobenzaldehyde with carbonyl compounds into the corresponding 2-alkylquinolines under mild conditions. The results are summarized in Table 1.

o-Nitrocinnamaldehyde readily reacted with the ferrate to give quinoline quantitatively which appeared to be formed by an intramolecular cyclization of

Table 1. The reduction of *o*-nitrobenzenes to quinolines with $KHFe(CO)_4$[a]

Run	Nitro compound	Carbonyl compound	Condensation[b] KOH[c]	Condensation[b] Time (h)	Product	Yield %
1	*o*-Nitrocinnamaldehyde	—	—	—	Quinoline	100
2	*o*-Nitrobenzaldehyde	Acetaldehyde	0.49	10	Quinoline	33
3	*o*-Nitrobenzaldehyde	Acetone	0.06	3	Quinaldine	55
4	*o*-Nitrobenzaldehyde	Acetone	0.06	23	Quinaldine	45
5	*o*-Nitrobenzaldehyde	Acetophenone	0.06	23	2-Phenylquinoline	17

a) At room temperature under argon for 1—3 h. b) *o*-Nitrobenzaldehyde was treated with carbonyl compounds at room temperature and then the condensates obtained *in situ* were reduced. c) Molar ratio, potassium hydroxide/carbonyl compound.

o-aminocinnamaldehyde. *o*-Nitrocinnamaldehyde is a condensate of *o*-nitrobenzaldehyde with acetaldehyde. Two succesive treatments of *o*-nitrobenzaldehyde with such carbonyl compounds as acetaldehyde, acetone or acetophenone in the presence of potassium hydroxide and then with the ferrate gave quinoline(**2a**), quinaldine(**2b**) and 2-phenylquinoline(**2c**) in good yields, respectively. The potassium hydroxide used appears to play two roles, a catalyst for the aldol condensation of *o*-nitrobenzaldehyde with the carbonyl compounds and a reagent for the formation of the ferrate.

(**2**)

These results show that *o*-nitrobenzaldehyde combined with carbonyl compounds and with the ferrate as a reducing reagent can provide a simple route to a variety of 2-alkylquinolines.

N-(*o*-Nitrobenzylidene)amines(**3**), condensates of *o*-nitrobenzaldehyde with 1-naphthylamine, *p*-anisidine and *p*-chloroaniline, gave only the corresponding *N*-(*o*-aminobenzylidene)amines(**4**) in good to poor yields. The expected *N*-heterocycles, 2-alkylbenzopyrazoles(**5**), could not be detected.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (11), 3399—3400 (1978)

Synthesis of Chromenochlalcone Glucosides

Shigetoshi YAMADA,* Futara ONO, Takao KATAGIRI† and Juntaro TANAKA†

Department of Industrial Chemistry, Junior College of Technology, Shizuoka University, Hamamatsu 432

†*Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432*

(Received March 29, 1978)

Synopsis. Some chromenochalcone glucosides were synthesized in 24—62% yields from 6-acetyl-5,8-dihydroxy-2,2-dimethylchromene and various (β-glucosyloxy)-benzaldehydes.

Chalcones containing isoprene units which have biological activities[1,2] have been isolated from various plants[3-7] and synthesized.[8]

We reported the synthesis of Flemichapparin-A isolated from *Flemingia Chappar* ham (Legminosae),[9] and attempted to synthesize chromenochalcone glucosides.

As regards chalcone glucosides, many chalcones and flavonoids containing glucose moiety in ring A such as phloridzin[10-12] have been found in various species of plants. However, only a few chalcones and flavonoids containing glucose moiety in ring B such as Epimedoside-B have been found.[13,14] We wish to report on the synthesis of the latter compounds which are expected to have biological activities.

The Claisen-Schmidt condensation of 6-acetyl-5,8-dihydroxy-2,2-dimethylchromene (**1**) with helicin (**2**), 2-(β-glucosyloxy)-1-naphthaldehyde (**3**), isovanillinβ-D-glucoside (**4**), and *p*-(β-glucosyloxy)benzaldehyde (**5**) was carried out, chromenochalcone glucosides (**6**), (**7**), (**8**), and (**9**) being obtained in fair yields. Dihydrochalcone glucoside (**10**) which tastes sweet was obtained by the catalytic hydrogenation of (**6**) with palladium–carbon in 10% aq KOH.

Experimental

1 was prepared by the previous method.[9] **2** (mp 173.5—174 °C. 51% yield), **3** (mp 182.5—184.5 °C, 62% yield), **4** (mp 190.5—192 °C, 33% yield) and **5** (mp 162—163 °C, 57% yield) were prepared by Robertson's method.[15] The products were identified by means of mp and spectral data. The physical data of **2**, **4**, and **5** agreed with those found in literatures.[15-17]

3: mp 182—184.5 °C (brown amorphous). IR (cm^{-1}, KBr disk): 3300, 1650, 1240, 1050, 740, 710. Found: C, 61.47; H, 5.53%. Calcd for $C_{17}H_{18}O_7$: C, 61.07; H, 5.43%.

*Reaction of **1** with **2**.* On cooling, 50% alcoholic KOH (4 ml) was added to a stirred solution of **1** (300 mg) and **2** (284 mg) in ethanol (4 ml) under nitrogen and the mixture was stirred at room temperature for a week. The mixture was acidified with 0.5M HCl and extracted with ether. Chromatography of the ether extract on silica gel eluted by benzene-ethylacetate (22 : 3 v/v) afforded **6** in 56% yield.

*Reaction of **1** with **3**.* 60% Alcoholic KOH (4 ml) was added to a stirred solution of **1** (234 mg) and **3** (324 mg) in ethanol (4 ml) and the mixture was stirred at 60 °C for three days under nitrogen. By the same work-up as above, **7** was obtained in 33% yield.

*Reaction of **1** with **4**.* 40% Alcoholic KOH (4 ml) was added to a stirred solution of **1** (234 mg) and **4** (295 mg) in ethanol (4 ml) and the mixture was stirred at 60 °C for two days under nitrogen. By the same work-up as above, **8** was obtained in 24% yield.

*Reaction of **1** with **5**.* 60% Alcoholic KOH (4 ml) was added to a stirred solution of **1** (234 mg) and **5** (284 mg) in ethanol (4 ml) and the mixture was stirred at 60 °C for two days under nitrogen. By the same work-up as above, **9** was obtained in 62% yield.

The products were identified by means of their analytical and spectral data (Table 1).

*Hydrogenation of **6**.* **6** (200 mg) was dissolved in 10% aq KOH (2 ml) and the solution was cooled to 0 °C. To this solution was added 10% palladium–carbon catalyst

The Preparation of Isoxazole Derivatives from a Nitro Sugar with Dimethylsulfonium Phenacylide

Tohru SAKAKIBARA and Rokuro SUDOH

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 2, 1978)

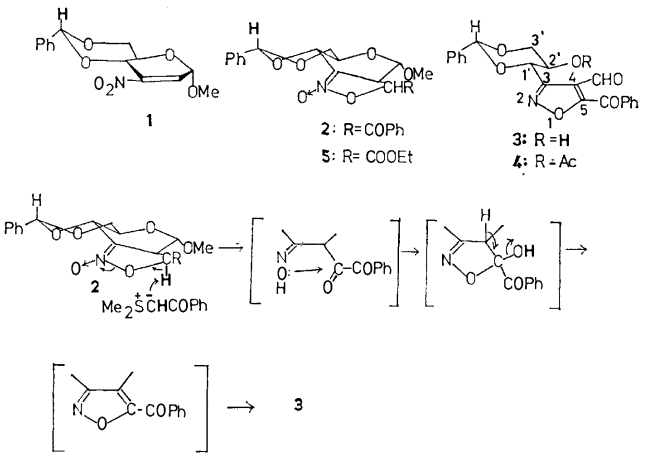
Synopsis. The reaction of methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-*erythro*-hex-2-enopyranoside or 5-benzoyl(methyl 4,6-*O*-benzylidene-2,3-dideoxy-α-D-*erythro*-hexopyranosido)[3,2-*c*]isoxazoline *N*-oxide with dimethylsulfonium phenacylide gave 5-benzoyl-3-(1,3-*O*-benzylidene-D-*erthro*-glyceryl)-4-isoxazolecarbaldehyde in a fairly good yield.

Recently we reported that the reaction of methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-*erythro*-hex-2-enopyranoside (**1**) (0.2 mmol) with dimethylsulfonium phenacyclide (0.25 mmol) afforded the isoxazoline *N*-oxide **2** in a good yield.[1] However, when this reaction was carried out on a larger scale, the isoxazole, **3**, was formed. The determination of the structure of **3** and the conversion of the isoxazoline *N*-oxide **2** into **3** is described herewith.

The treatment of **1** (293 mg, 1 mmol) with dimethylsulfonium phenacylide (1.5 mmol) in THF (10 ml) at room temperature for 3 h gave a NMR spectroscopically pure syrup, **3** (315 mg), with the odor of dimethyl sulfide. The IR spectrum showed the absorption bands for a hydroxyl (3400 cm^{-1} broad) and α,β-unsaturated carbonyl group (1670 cm^{-1}). The NMR spectrum revealed that **3** had lost the glycosidic methoxyl group, but retained the benzylidene group. The presence of 10-protons in the aromatic region suggested the presence of a benzoyl group. The two 1-proton signals at δ 9.15 and 3.00 (broad) were assigned to the formyl proton and the OH proton respectively. The H-1′ signal appeared as a doublet due to vicinal coupling with H-2′ ($J_{1',2'}$=9 Hz). The acetylation of **3** with acetic anhydride–sodium acetate gave the crystalline acetate, **4**, the NMR spectrum of which showed that the hydroxyl group attached originally at C-2′, since the signal of H-2′ had moved remarkably downfield as a result of the deshielding effect of the acetate group. The results of the elemental analysis of the acetate, **4**, agreed with the formula of $C_{23}H_{19}NO_7$, indicating that the products, **3** and **4**, have not a isoxazoline *N*-oxide ring, but a isoxazole.

The conversion of the isoxazoline *N*-oxide **2** into **3** was observed when **2** was treated with dimethylsulfonium phenacylide at 0 °C for 3 h, whereas the similar treatment of **2** with dimethyl sulfide resulted in the recovery of **2**. The reinvestigation[1] of the reaction between **1** and dimethylsulfonium ethoxycarbonylmethylide under similar conditions gave no evidence for the formation of an isoxazole corresponding to **3**. Furthermore, the treatment of the isoxazoline *N*-oxide, **5**, with dimethylsulfonium ethoxycarbonylmethylide or dimethyl sulfide afforded unchanged **5** in a quantitative yield.

On the basis of the mechanism proposed for the conversion of isoxazoline *N*-oxide into isoxazole[2] and the reports[3] in the literature that the hydrolysis of a pyranose derivative with unsaturated functional groups at the 2 position is facile and that the hydrolyzed product tends to exist in the open-chair aldehyde-form rather than with the pyranoside structure, the route shown in Scheme seems to be most plausible. In this reaction, the abstraction of the proton at C-5 (the isoxazoline ring proton) is probably the crucial step. Dimethylsulfonium phenacylide is basic enough for **2**, but dimethyl sulfide is not, and dimethylsulfonium ethoxycarbonylmethylide is not a sufficient base for **5** because the hydrogen atom (H-5) of **5** is less acidic than that of **2**.



Scheme.

Experimental

The melting point was determined in capillary and is uncorrected. The NMR spectra were determined for solutions in chloroform-*d* (with tetramethylsilane as the internal standard) with a JNM-4H-100 (JEOL) spectrometer.

*5-Benzoyl-3-(1,3-O-benzylidene-*D-erythro*-glyceryl)-4-isoxazolecarbaldehyde (3).* (a) To a solution of **1**[4] (293 mg, 1 mmol) in THF (10 ml), dimethylsulfonium phenacylide (270 mg, 1.5 mmol) was added at room temperature. The mixture was kept at the same temperature for 3 h and then evaporated under reduced pressure to give a dark orange syrup, which was subsequently extracted with benzene. The extract was washed with water, dried (Na_2SO_4), and evaporated to give an orange syrup (465 mg). Its MNR spectrum suggested that it was fairly pure; IR (NaCl) 3400 (broad, OH) and 1670 cm^{-1} (α,β-unsaturated CO); NMR δ=9.15 (s, 1, CHO), 5.60 (s, 1, PhCH), 5.20 (d, 1, H-1′), 4.45 (m, 1, H-2′),4.55 (q, 1, H-3e′), 3.76 (t, 1, H-3a′) and 3.00 (broad, s, 1, OH).

Without further purification the syrup was acetylated.

(b) To a solution of dimethylsulfonium phenacylide (13 mg, 0.07 mmol) in THF (0.22 ml) in either the presence

or absence of dimethyl sulfide (0.07 mmol), the isoxazoline *N*-oxide **2** (0.07 mmol) was added at 0 °C. The mixture was kept at 0 °C for 3 h and then evaporated at reduced pressure to give a syrup. Its NMR spectrum showed the complete conversion of **2** into **3**.

The treatment of **2** (0.07 mmol) with dimethyl sulfide in the absence of dimethylsulfonium phenacylide resulted in the recovery of **2**, as judged by NMR spectroscopy.

*3-(2-O-Acetyl-1,3-O-benzylidene-*D*-erythro-glyceryl)-5-benzoyl-4-isoxazolecarbaldehyde (**4**).* The crude isoxazole **3** (62 mg) was warmed in a water bath (90 °C) with sodium acetate (62 mg) in acetic anhydride (2 ml) for 1 h. The mixture was then poured into ice water, and the precipitate was collected and washed with water and chromatographed on silica gel (15×70 mm) with benzene. The eluate was evaporated to give a solid residue, which was subsequently recrystallized from ethanol to give 32 mg (46.4%) of colorless crystals of **4**; mp 123.5—124.5 °C; $[\alpha]_D^{20}$ −18.6° (*c* 1, $CHCl_3$); IR (KBr) 1740 (OAc) and 1670 cm^{-1} (α,β-unsaturated COPh and CHO); NMR δ=9.18 (s, 1, CHO), 5.70 (m, 1, H-2′, $J_{1',2'}$=10, $J_{2',3a'}$=10, $J_{2',3e'}$=5.0 Hz), 5.67 (s, 1, PhCH), 5.40 (d, 1, H-1′), 4.55 (q, 1, H-3e′, $J_{3a',3e'}$=10 Hz), 3.79 (t, 1, H-3a′), and 1.97 (s, 3, OAc).

Found: C, 65.60; H, 4.67; N, 3.06%. Calcd for $C_{23}H_{19}NO_7$: C, 65.55; H, 4.54; N, 3.32%.

The Photochemical SO Extrusion of 2,2,4,4-Tetraacylthietane 1-Oxides

Shoei Iro* and Jun-ichi Mori**

Department of Chemistry, Faculty of Science, Hirosaki University, Hirosaki 036

(Received May 10, 1978)

Synopsis. The irradiation of a benzene solution of 2,2,4,4-tetraacylthietane 1-oxides, which had been prepared from dimedone-aldehyde derivatives with SCl_2, followed by oxidation with peracid, was carried out to give the corresponding 1,1,2,2-tetraacylcylopropanes(**4**) or a mixture of **4** and the corresponding dihydrofuran derivative, depending on the C_3 substituent on the 1-oxides and wavelength.

Photochemical studies of various sulfoxides, one of them is the photoisomerization of 2-phenyl-2*H*-naphto-[1,8-*b*,*c*]thiophene 1-oxide to the corresponding sulfenate, have been undertaken.[1] However, few attempts seem to have been made for the photolysis of thietane 1-oxides.

An attempt to prepare an 3,3,5,5-tetraacyl-1,2-oxathiolane by the photoisomerization of the corresponding 2,2,4,4-tetraacylthietane 1-oxide was carried out. However, no 1,2-oxathiolane was obtained, although photodesulfurization occurred.

In this paper we wish to describe the photochemical reactions of 2,2,4,4-tetraacylthietane 1-oxide using 3,3,11,11-tetramethyl-7-thiadispiro[5.1.5.1]teradecane-1,5,9,13-tetrone 7-oxide(**3a**) and its 14-methyl(**3b**) and 14-isopropyl(**3c**) derivatives as model compounds.

The reaction of 2,2′-methylenebis[5,5-dimethyl-1,3-cyclohexanedione] (**1a**) and its derivatives(**1b**—**1d**) with an equimolar amount of sulfur dichloride in ethyl acetate or dichloromethane gave thietane derivatives (**2a**—**2d**) in good yields. The conversion of **2** into the dioxide was unsuccessful except for the case of **2d**, which also failed to be converted into the monoxide.

A water-cooling dilute solution of **3a** in benzene open to air was irradiated with a Toshiba 75 W high-pressure mercury lamp for 1 h through a Pyrex filter. The product was identified as 3,3,10,10-tetramethyldispiro[5.0.5.1]tridecane-1,5,8,12-tetrone(**4a**) by comparison with the reported spectral data[2] and the elemental analysis. The photolysis of **2a** was also carried out in oxygen-free benzene both in a sealed vessel and in an atmosphere of nitrogen in a manner similar to that describes above to afford **4a** quantitatively.

Therefore, the possibility of sulfur monoxide extrusion upon the irradiation open to air *via* the formation of sulfone by photooxidation, followed by sulfur dioxide extrusion, can be ruled out.

On the other hand, the exposure of a dilute benzene solution of **2a** to light through a quartz filter open to air for 1 h gave **3a**, together with 4,5,6,7-tetrahydro-4′,4′,6,6-tetramethylspiro[benzofuran-2(3*H*),1′-cyclohexane]-2′,4,6′-trione(**5a**), which was readily formed by the treatment of **1a** with bromine in acetic acid. These results are summarized in Table 1, together with the results for other 1-oxides(**3b** and **3c**). Unfortunately, a comparative study with the corresponding 1,1-dioxides(**6a**—**6c**) was not undertaken because of the failure to prepare the dioxides. Thietane **2a** gave only a resinous substance under similar reaction conditions.

Table 1. Photoreactions of **3**

No.	Products (%)		No.	Products (%)	
	4	**5**		**4**	**5**
3a(P)	100		**3b**(P)	50	15
3a(P)[a]	100		**3b**(Q)	50	20
3a(P)[b]	100		**3c**(P)	100	
3a(Q)	70	20	**3c**(Q)	50	20

P: Pyrex filter, Q: Quartz filter, a) In oxygen-free benzene (in a sealed vessel). b) Under nitrogen.

On the other hand, sulfone **6d** afforded neither the corresponding cyclopropane(**4d**) nor dihydrofuran(**5d**), but gave the octahydroxanthene derivative(**7d**) under similar reaction conditions.

No decomposition of **3a** occurred upon prolonged heating in boiling xylene, while the pyrolysis of **3a** in a sealed tube at the melting point resulted in the formation of only a resinous substance which could not be purified by column chromatography.

Chow *et al.* reported that the SO moiety of dibenzo-[*b*,*f*][1,4,6]thiadiazepin 1-oxide(**8**) was extruded in benzene or chloroform under reflux to give benzocinnoline, but no decomposition was observed when a benzene solution of **8** was irradiated in a Pyrex apparatus.[3] The difference in photolysis between **3** and **8** may be attributed to the low bond-dissociation energy of the carbon–sulfur bond of **3** caused by the four acyl groups. The photolysis of **3** presumably proceeds *via* a sulfenate-intermediate which, upon further photolysis, gives **4** and **5**, with SO extrusion by means of a concerted mechanism. Furthermore, the inability of compound **3** to form a thiiran 1-oxide may be responsible for the thermal stabitity of the compound.

a) Recrystallization solvent. b) Lit,[3] 147—148 °C. c) Lit,[3] 109—110 °C.

Experimental

General. All the melting points are uncorrected. The IR spectra were recorded with a JASCO-DS-601F spectrophotometer. The UV spectra were obtained on a Hitachi EPS-2 spectrophotometer. The NMR spectra were obtained on a JNM-C-60HL spectrometer, using TMS as the internal standard. The mass spectra were measured on a Hitachi RMU-6 spectrometer.

Materials. The *m*-chloroperbenzoic acid and sulfur dichloride were obtained commercially. The purity of *m*-chloroperbenzoic acid was determined by iodometry.

Irradiation. All the irradiations were carried out externally with a high-pressure mercury lamp (Toshiba SHL-100UV, 75 W) at the temperature of running water.

Preparation of ***2****.* *General Procedure*: To a stirred solution of the aldehyde-dimedone derivative (0.01 mol) in ethyl acetate (100 ml), cooled in an ice bath, a solution of sulfur dichloride (0.01 ml) in ethyl acetate (10 ml) was added, drop by drop, over a 20-min period. After additional stirring for 2 h at this temperature, the mixture was stirred at room temperature for 10 h. The evaporation of the solvent under reduced pressure afforded white crystals. Yields: **2a** (80%); **2b** (80%); **2c** (80%); **2d** (75%). The recrystallization solvents, mps, and elemental analyses are summarized in Table 2.

Oxidation of ***2*** *with* m-*Chloroperbenzoic Acid. General Procedure*: To a stirred solution of **2** (2 mmol) in benzene (100 ml), cooled in an ice bath, a solution of *m*-chloroperbenzoic acid (2 mmol) in benzene (50 ml) was added, drop by drop, over a 10-min period. After additional stirring for 1 h at this temperature, the mixture was stirred at room temperature for 19 h. The precipitate (*m*-chlorobenzoic acid) was then filtered off, and the filtrate was washed with a 5% cold $NaHCO_3$ solution and then with cold water. The evaporation of the solvent from the dried solution (Na_2SO_4) gave a solid substance which was fractionated by recrystallization. Yields: **3a** (63%); **3b** (30%); **3c** (45%); **6d** (20%). The recrystallization solvents, mps, and elemental analyses of the monoxides **3a**—**3c** and the dioxide **6d** are summarized in Table 2.

Preparation of ***5****.* Compounds **5a**—**5c** were prepared according to the previously reported method.[4] **5a**: Mp 210—212 °C (lit, 211—213 °C), **5b**: mp 197—198 °C (lit, 197—198 °C), **5c**: mp 186—187 °C, Found: C, 71.52; H, 9.06%. Calcd for $C_{20}H_{30}O_4$: C, 71.82; H, 9.04%.

*Irradiation of Thietane Monoxide(****3****) in Benzene. General Procedure*: A solution of **3** in benzene (0.006 M) was irradiated in a Pyrex vessel or a quartz vessel for 1 h. The subsequent evaporation of the solvent afforded a white solid, which was then recrystallized from an appropriate solvent. When a mixture was given, it was chromatographed on silica gel, using hexane, hexane–benzene, and then benzene. The results are summarized in Table 1.

Irradiation of ***3a*** *in Oxygen-free Benzene.* A benzene solution of **3a** was degassed at −70 °C under a high vacuum and then sealed. The irradiation of the solution was carried out in a manner similar to that described above.

Irradiation of ***3a*** *under Nitrogen.* Nitrogen gas was allowed to pass through a benzene solution of **3a** during the course of irradiation.

Irradiation of ***6d*** *in Benzene.* A solution of **6d** in benzene (0.006 M) was irradiated in a Pyrex vessel for 1 h. The subsequent evaporation of the solvent afforded a white solid, which was identified as the corresponding octahydroxanthene derivative (**7d**) by direct comparison with an authentic sample (yield, 95%).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (11), 3405—3406 (1978)

A Synthesis of (±)-epi-Seychellene

Kiyoyuki YAMADA,* Yoshinori KYOTANI, Shunichi MANABE, and Masaaki SUZUKI

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received May 15, 1978)

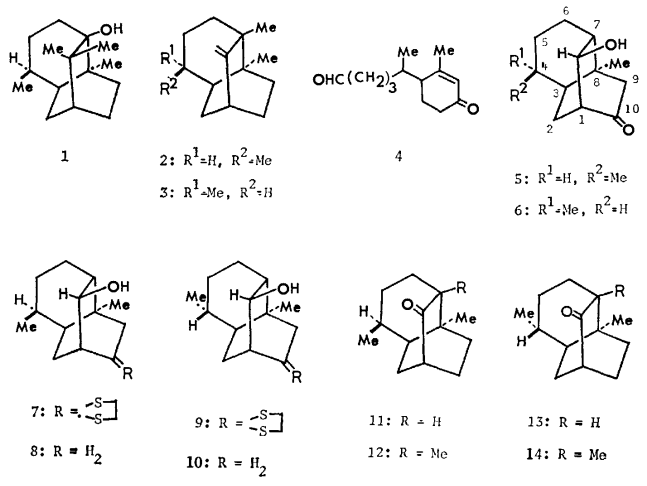
Synopsis. Starting from a mixture of two diastereomeric ketols, (±)-seychellene and (±)-epi-seychellene were synthesized in six steps.

Patchouli alcohol (**1**)[1] and seychellene (**2**),[2] constituents of patchouli oil, contain commonly the novel carbon framework, a tricyclo[5.3.1.$0^{3,8}$]undecane skeleton, and their synthetic studies have actively been carried out.[3]

In the previous investigation[4] we reported a method of constructing a tricyclo[5.3.1.$0^{3,8}$]undecane skeleton in one step by intramolecular cyclization of a conjugated cyclohexenone derivative. We have recently made a total synthesis of patchouli alcohol **1** and seychellene **2** in racemic form utilizing this method of cyclization:[5] a 1:1 mixture of the diastereomeric α,β-enones (**4**) was cyclized with potassium *t*-butoxide in *t*-butyl alcohol to afford two ketols, (**5**) (23%) and (**6**) (3%), only the former being obtained in pure form.[5] These ketols, **5** and **6**, were deduced to be diastereomers regarding C-4. Stereochemical assignments of **5** and **6** were made by consideration of the steric course of cyclization[5] and confirmed by the synthesis of the sesquiterpenes of defined structures, **1** and **2**, employing the major isomer **5**.[5]

In this note a synthesis of (±)-epi-seychellene (**3**) together with a synthesis of (±)-**2** is described, starting from a mixture of two diastereomers, **5** and **6**, and this result provides an additional evidence for the validity of the assigned stereochemistry of **5** and **6**. A synthesis of (±)-epi-seychellene was previously carried out by Fráter.[3d]

The mixture of the two ketols, **5** and **6**, was converted to a mixture of two thioacetals, (**7**) and (**9**), under the standard conditions, which was desulfurized with W-2 Raney nickel in ethanol under reflux,



affording a mixture of two diastereomeric alcohols, (**8**) and (**10**) in 99% overall yield. On oxidation with chromium trioxide in pyridine, a mixture of **8** and **10** gave a mixture of the corresponding ketones, (**11**) and (**13**) in 95% yield. Treatment of a mixture of the two ketones, **11** and **13** with lithium diisopropylamide (LDA) in tetrahydrofuran (THF) followed by reaction with methyl iodide at —50 °C afforded a mixture of two ketones, (**12**) and (**14**) in 93% yield. The mixture was separated by preparative gas chromatography (GC) to give (±)-norseychellanone **12** (liquid) identified by spectral (IR and NMR) data of the authentic specimen and the crystalline ketone **14**, mp 145—146 °C. Reaction of the mixture of **12** and **14** with methyllithium in ether and subsequent dehydration with thionyl chloride in pyridine–benzene produced a mixture of two olefins in 85% yield, which was purified by preparative GC to give (±)-seychellene **2** (liquid) and (±)-epi-seychellene **3**, mp 145—147 °C. The spectral (IR and NMR) data of the latter was in agreement with those[3d] of (±)-epi-seychellene reported.

Experimental

Melting points were uncorrected. IR spectra ($CHCl_3$) were recorded with JASCO Model IRS and JASCO DS-402G instruments. NMR spectra ($CDCl_3$) were obtained on a Varian HA-100D spectrometer using TMS as an internal standard. Low resolution and high resolution mass spectra were determined on Hitachi RMU-6C and JEOLCO GMS-01SG mass spectrometers, respectively. A Varian 1820-4 gas chromatograph was used for GC (5 ft. $\times$0.25 in. column packed with 5% SE-30 on Celite 545; helium as the carrier gas). For TLC silica gel 60 F_{254} and 60 PF_{254} (E. Merck, A. G., Germany) were used. Organic solutions were washed with saturated NaCl solution, dried over anhydrous Na_2SO_4, and evaporated by a vacuum rotary evaporator.

*Alcohols, **8** and **10**.* A solution of the 1 : 1 mixture of **5** and **6**[5] (200 mg) and $BF_3\cdot OEt_2$ (0.24 ml, distilled from CaH_2) in 1,2-ethanedithiol (10 ml) was stirred at room temperature for 20 min and diluted with a saturated $NaHCO_3$ solution. The mixture was extracted with $CHCl_3$ (4$\times$20 ml). The residue obtained on evaporation of the $CHCl_3$ extracts was dissolved in toluene and the solution was concentrated for complete removal of 1,2-ethanedithiol. Purification of the residue by preparative TLC ($CHCl_3$–EtOAc, 10:1) gave a mixture of thioacetals, **7** and **9** (273 mg) as a colorless liquid: IR 3520, 3360 cm^{-1}; NMR (δ) 0.77 and 1.10 (total 3H, d each, J=7.0 Hz), 0.88 and 0.96 (total 3H, s each), 2.9—3.6 (4H, complex m), 3.78 and 3.98 (total 1H, m each). To a solution of the mixture of **7** and **9** (273 mg) in EtOH (32 ml) was added W-2 Raney nickel (*ca.* 5.2 g). The suspension was refluxed for 30 min and filtered. The filtrate was evaporated, giving a mixture of alcohols, **9** and **10** (185 mg, 99% from the ketols, **5** and **6**) as a colorless liquid: IR 3550, 3400 cm^{-1}; NMR (δ) 0.76 and 1.10 (total 3H, d each, J=6.0 Hz), 0.86 and 0.95 (total 3H, s each), 3.65 and 3.73 (total 1H, dd each, J=2.0, 4.0 Hz); MS 194(M^+). Found: *m/e* 194.1666. Calcd for $C_{13}H_{22}O$:

194.1671.

*Ketones, **11** and **13**.* A suspension of CrO_3 (230 mg) in dry pyridine (5.6 ml, distilled from BaO) was added to a solution of the mixture of **8** and **10** (190 mg) in dry pyridine (2.5 ml). The mixture was stirred at room temperature for 6 h and diluted with ether (50 ml). The precipitates were filtered and washed with ether (40 ml). The combined filtrates were washed with 1M HCl (5×10 ml) and H_2O (3×10 ml), dried, and concentrated. The residue was purified by preparative TLC ($CHCl_3$), affording a mixture of **11** and **13** (181 mg, 95%) as a colorless liquid: IR 1715 cm^{-1}; NMR (δ) 0.80 and 1.17 (total 3H, d each, J=7.0 Hz), 1.10 and 1.11 (total 3H, s each); MS 192 (M^+). Found: *m/e* 192.1522. Calcd for $C_{13}H_{20}O$: 192.1514.

*(±)-Norseychellanone **12** and Ketone **14**.* To a stirred solution of *i*-Pr_2NH (0.66 ml, distilled from NaH) in dry THF (8.7 ml, distilled from potassium–benzophenone ketyl under nitrogen) at −78 °C was added under nitrogen a solution (2.6 ml) of 1.6M BuLi in hexane. A solution of the mixture of **11** and **13** (53 mg) in dry THF (2.6 ml) was added dropwise over a period of 20 min to the above LDA solution at −78 °C. The mixture was stirred at −50 °C for 20 min. Then MeI (0.87 ml, distilled from $CaCl_2$) was added at −50 °C. After 30 min NH_4Cl was added. The mixture was diluted with H_2O (1 ml). The cooling bath was removed. After 5 min the mixture was concentrated, diluted with H_2O (2 ml), and extracted with benzene (3×10 ml). The benzene extracts were dried and concentrated. The residue was purified by preparative TLC ($CHCl_3$–EtOAc, 200:1), giving a mixture of **12** and **14** (53 mg, 93%) as a colorless liquid. The mixture was separated by preparative GC (120 °C, 160 ml/min) to give (±)-**12** (retention time 14 min) and **14** (retention time 16 min). **14**: mp 145—146 °C (sealed tube); IR 1710 cm^{-1}; NMR (δ) 0.98 (3H, s), 1.04 (3H, s), 1.15 (3H, d, J=7.5 Hz), 2.31 (1H, m); MS 206 (M^+). Found: *m/e* 206.1690. Calcd for $C_{14}H_{22}O$: 206.1671.

*(±)-Seychellene **2** and (±)-epi-Seychellene **3**.* To a stirred solution of the mixture of **12** and **14** (10 mg) in dry ether (0.07 ml, distilled from Na) was added a solution (0.40 ml) of 1.15 M MeLi in ether under nitrogen. The mixture was stirred at room temperature for 4 h. Water (1 ml) was added and the mixture extracted with ether (4×10 ml). The ethereal extracts were dried and concentrated. The residue (10.8 mg) was dissolved in dry benzene (0.23 ml, distilled from Na)–dry pyridine (0.15 ml). To the cooled (0 °C) solution was added $SOCl_2$ (4.7 μl, freshly distilled) in dry benzene (0.14 ml). The mixture was stirred for 35 min at 0 °C, poured into ice–water (2 ml), and extracted with benzene (4×10 ml). The benzene extracts were dried and concentrated. The residue was purified by preparative TLC (pentane), affording a mixture of **2** and **3** as a colorless oil (8.5 mg, 85%). Separation of the mixture was made by preparative GC (110 °C, 150 ml/min) to give (±)-**2** (retention time 15 min) and (±)-**3** (retention time 17 min). (±)-**3**: mp 145—147 °C (sealed tube); IR (neat) 3060, 3000(sh), 2920, 2860, 1640, 1460, 1380, 1370, 1110, 1102, 1060, 1020, 980, 970 945, 888(strong) cm^{-1}; NMR (δ) 0.93 (3H, s), 0.96 (3H, s), 1.08 (3H, d, J=7.5 Hz), 4.61 (1H, d, J=1.5 Hz), 4.81 (1H, d, J=1.5 Hz); MS 204 (M^+). Found: *m/e* 204.1883. Calcd for $C_{15}H_{24}$: 204.1878.

The authors wish to thank Professor Y. Hirata for his encouragement and Professor A. Yoshikoshi, Tohoku University, for providing us with the spectral data of (±)-norseychellanone.

(Received May 22, 1978)

Synopsis. In the presence of sodium acetate, the reaction of 4-chromanone oxime with lithium tetrachloropalladate(II) affords an *ortho*-palladated binuclear complex. The reaction of the complex with carbon monoxide in methanol was also examined.

Following the first observation by Cope and Siekman[1] that azobenzene reacts with palladium(II) chloride to give an intramolecular *ortho*-palladation product with a carbon-to-metal σ-bond, considerable interest developed in this area.[2] Moreover, Onoue *et al.*[3] reported a reaction of aromatic ketoximes with palladium(II) chloride giving a dimeric σ-bonded complex. Herein, we wish to report on the *ortho*-metalation of 4-chromanone oxime (**1a**) with palladium(II) chloride and the reaction of the metalation product with carbon monoxide in methanol.

In the presence of sodium acetate, the reaction of **1a** with lithium tetrachloropalladate(II) in methanol gave a binuclear complex with palladium-carbon σ-bonding: di-μ-chloro-bis[4-chromanone oxime-5-*C*,*N*]dipalladium(II) (**2a**). Under the same conditions, flavanone oxime (**1b**) and 2-methyl-4*H*-1-benzothiopyran-4-one oxime (**1c**) also reacted with lithium tetrachloropalladate(II) to afford the *ortho*-palladated complexes, di-μ-chloro-bis[flavanone oxime-5-*C*,*N*]-dipalladium(II) (**2b**) and di-μ-chloro-bis[2-methyl-4*H*-1-benzothiopyran-4-one oxime-5-*C*,*N*]dipalladium-(II) (**2c**) respectively. On the basis of the microanalytical and spectroscopic data and the molecular weight, the **2a**—**c** complexes were shown to be intramolecularly *ortho*-palladated complexes. The molecular weights in chloroform are consistent with the values calculated for the binuclear complexes. The treatment of **2a**—**c** with triphenylphosphine gives results typical of a chlorine-bridged binuclear complex, affording the monomeric triphenylphosphine derivatives (**3a**—**c**). The IR spectra of **2a**—**c** showed the characteristic OH stretching frequency in the 3450—3350 cm^{-1} region and the characteristic deformation mode of 1,2,3-trisubstituted benzene at 790—785 cm^{-1} region, as shown in Table 1. Moreover, the C=N stretching frequency shifted to a slightly lower wave number (**2a**, 1635; **2b**, 1635; **2c**, 1620 cm^{-1}), characteristic of nitrogen lone-pair donation, as has been found for *ortho*-palladated aryloxime complexes.[3] In the far-infrared spectra of **2a**—**c** there are typicaly two bridged Pd–Cl stretching absorptions at 278—275 and 250—245 cm^{-1}. The NMR spectra of the **2a**—**c** complexes were in good agreement with the proposed structures. For example, the spectrum of **2a** has four bands: a triplet at 2.96 (J=6.0 Hz, 4H), a triplet at 4.24 (J=6.0 Hz, 4H), a multiplet at 6.60—7.40 (6H), and a broad singlet at 10.15 ppm (2H), the bands corresponding to $-CH_2-C=N$, $-O-CH_2-$, aromatic **H**, and **OH** respectively. These results and the IR spectral data show that one aromatic ring proton *ortho* to the C=N group was replaced by palladium(II). Similarly, the NMR spectra of **2b** and **2c** provide evidence for the occurrence of *ortho*-metalated aromatic rings (see Table 1).

The carbonylation of *ortho*-palladated products of azobenzene, Schiff bases, and tertiary benzylamines usually gives a variety of heterocyclic compounds.[4,5] In addition, it was found that benzophenone oxime gave 3-phenyl-1-isoindolinone by carbonylation in the presence of dicobalt octacarbonyl[6] or palladium(II) chloride in benzene.[3] We also studied the carbonylation of **2a**—**c** complexes. The attempted carbonylation of **2a**—**c** was unsuccessful, even at 100 °C; however, the triphenylphosphine derivatives, **3a**—**c**, in methanol were readily carbonylated at 100 °C to produce uncyclized and deoxymated esters (**4a**—**c**) in 28—45% yields. Maeda *et al.*[7] have recently shown that the C=N bond of ketoximes can be cleaved in the presence of the Pd(O) complex, with the subsequent formation of free ketone. The results of the carbonylation of **3a**—**c** complexes clearly suggest that a deoxymation of carbonylated intermediates with palladium species occurs.

Fig. 1.

Experimental

Materials and Measurement. All the melting points are uncorrected. The **1a**[8] and **1b**[9] compounds were prepared by the method prevously reported. The **1c** compound (mp 136—138 °C) was prepared by the usual oxymation of the corresponding carbonyl compound. The IR spectra were measured on KBr disks (4000—650 cm^{-1}) or in nujol mulls mounted on thin polythene windows (700—200 cm^{-1}). The NMR spectra were observed in $CDCl_3$ or in DMSO-d_6 at 90 MHz, using TMS as the internal standard. The molecular weight was determined in $CHCl_3$, using a Hitachi 115

Table 1. The *ortho*-palladation of oximes (**1a—c**)

Oxime	Product (mp (dec), yield)	Found (Calcd) % and mol wt	IR and NMR (in DMSO-d_6) spectra
1a	**2a** (215—218 °C, 90%)	C, 35.27 (35.53) H, 2.51 (2.63) N, 4.48 (4.60) Mol wt 591 (608)	IR: 3400 (OH), 1635 (C=N), 790 (1,2,3-trisubstituted aromatic ring), 275 and 250 cm^{-1} (bridged Pd-Cl). NMR: δ 2.96 (t, 4H, -C**H**$_2$-C=N), 4.24 (t, 4H, -O-C**H**$_2$-), 6.60—7.40 (m, 6H, aromatic **H**), and 10.15 ppm (br s, 2H, **OH**).
1b	**2b** (260—265 °C, 82%)	C, 47.25 (47.38) H, 2.93 (3.15) N, 3.29 (3.42) Mol wt 748 (760)	IR: 3450 (OH), 1635 (C=N), 790 (1,2,3-trisubstituted aromatic ring), 275 and 245 cm^{-1} (bridged Pd-Cl). NMR: δ 2.58—3.45 (m, 4H, -C**H**$_2$-C=N), 5.25 (d-d, 2H, -O-C**H**-), 6.60—7.81 (m, 16H, aromatic **H**), and 10.60 ppm (s, 2H, **OH**).
1c	**2c** (228—230 °C, 90%)	C, 35.78 (35.90) H, 2.83 (2.99) N, 4.06 (4.19) Mol wt 650 (668)	IR: 3350 (OH), 1620 (C=N), 785 (1,2,3-trisubstituted aromatic ring), 278 and 245 cm^{-1} (bridged Pd-Cl). NMR: δ 1.28 (d, 6H, -C**H**$_3$), 2.55—3.33 (m, 4H, -C**H**$_2$-C=N), 4.85 (m, 2H, S-C**H**-), 6.68—7.55 (m, 6H, aromatic **H**), and 10.45 ppm (br s, 2H, **OH**).

Table 2. The triphenylphosphine derivatives (**3a—c**)

Complex	Mp (dec) (yield)	Found (Calcd) % and mol wt	IR and NMR (in $CDCl_3$) spectra
3a	214—215 °C (70%)	C, 57.08 (57.25) H, 3.91 (4.06) N, 2.27 (2.47) Mol wt 548 (566)	IR: 3200 (OH), 1640 (C=N), 790 (1,2,3-trisubstituted aromatic ring), 305 cm^{-1} (terminal Pd-Cl). NMR: δ 3.05 (t, J=6.0 Hz, 2H, -C**H**$_2$-C=N), 4.25 (t, J=6.0 Hz, 2H, -O-C**H**$_2$-), 6.00—6.50 (m, 3H, aromatic **H**), 7.50)m, 15H, aromatic **H**), and 10.40 ppm (br s, 1H, **OH**).
3b	210—212 °C (75%)	C, 61.55 (61.69) H, 3.97 (4.20) N, 2.03 (2.18) Mol wt 625 (642)	IR: 3200 (OH), 1640 (C=N), 790, 740, 690 (aromatic ring), and 305 cm^{-1} (terminal Pd-Cl). NMR: δ 3.04 (d-d, J=17 and 12 Hz, 1H, -C**H**-C=N), 3.65 (d-d, J=17 and 3.5 Hz, 1H, -C**H**-C=N), 5.10 (d-d, J=12 and 3.5 Hz, 1H, O-C**H**-), 6.05 (m, 1H, aromatic **H**), 6.60 (m, 2H, aromatic **H**), 7.60 (m, 20H, aromatic **H**), and 10.50 ppm (br s, 1H, **OH**).
3c	208—210 °C (65%)	C, 56.16 (56.38) H, 4.05 (4.19) N, 2.27 (2.36) Mol wt 585 (596)	IR: 3200 (OH), 1640 (C=N), 785 (1,2,3-trisubstituted aromatic ring), and 310 cm^{-1} (terminal Pd-Cl). NMR: δ 1.25 (d, 3H, -C**H**$_3$), 2.97 (d-d, J=16 and 12 Hz, 1H, -C**H**-C=N), 3.55 (d-d, J=16 and 4 Hz, 1H, -C**H**-C=N), 4.68 (m, J=12 and 4 Hz, 1H, -C**H**-O), 6.11—6.58 (m, 3H, aromatic **H**), 7.50 (m, 15 H, aromatic **H**), and 10.40 ppm (br s, 1H, **OH**).

Table 3. The carbonylation products (**4a—c**)

Compound	Mp (yield)	Found (Calcd) % and mol wt	IR, NMR (in $CDCl_3$), and MS spectra
4a	38—40 °C (45%)	C, 63.38 (63.45) H, 5.88 (5.81) Mol wt (208)	IR: 1735 (ester), 1695 (C=O), 785 cm^{-1} (1,2,3-trisubstituted aromatic ring). NMR: δ 2.82 (t, 2H, -C**H**$_2$C=O), 3.94 (s, 3H, -COOC**H**$_3$), 4.56 (t, 2H, -C**H**$_2$-O), 7.05 (m, 2H, aromatic **H**), and 7.45 ppm (m, 1H, aromatic **H**). MS: *m/e* 208 (M^+).

vapor-pressure osmometer.

*General Procedure of the Preparation of Complexes **2a—c**.* A solution of 5 mmol of the **1a—c** oximes in methanol (50 ml) was added to a mixture of lithium tetrachloropalladate (II) (1.31 g, 5 mmol) and sodium acetate trihydrate (0.68 g, 5 mmol) in methanol (50 ml). The resulting mixture was stirred for 24 h at room temperature. The pale yellow precipitate thus formed was filtered off and purified by recrystallization from chloroform-hexane or by column chromatography (SiO_2–$CHCl_3$). The results are listed in Table 1.

*General Procedure for the Preparation of Triphenylphosphine Derivatives **3a—c**.* Triphenylphosphine (0.26 g, 1 mmol) and the **2a—c** complexes (0.5 mmol) were dissolved in benzene, and then the mixture was stirred for 6 h at room temperature. The solvent was removed under reduced pressure, and the products were obtained as pale yellow crystals from chloroform-hexane. The results are summarized in Table 2.

*The Carbonylation of The **3a—c** Complexes.* In 50 ml of methanol, the **3a—c** complexes were carbonylated at 100 °C under a carbon monoxide pressure of 60 atm for 20 h with shaking. The product was then isolated by filtering to remove a precipitated palladium and distilling under reduced pressure to remove the solvent. The residue was dissolved in hexane or benzene and chromatographed on silica gel to afford colorless crystals, which can be identified as 5-methoxycarbonyl derivatives (**4a—c**). The results are summarized in Table 3.

(Received May 25, 1978)

Synopsis. A convenient test for racemization using an amino acid analyzer was developed and applied to examine the effects of several *im*-protecting groups and synthesis of histidyl peptides.

Urethane protected L-amino acid moieties are recognized to be free from racemization under the usual conditions of peptide synthesis. Jorgensen *et al.*, however, observed appreciable racemization of *t*-butoxycarbonyl-N^{im}-benzyl-L-histidine during the course of synthesis of an analog of angiotensin.[1] They separated a diastereomeric mixture of DL-His(Bzl)-L-Glu[2] by an amino acid analyzer, and applied the procedure to determine the extent of racemization during the course of coupling of Boc-L-His(Bzl) and L-Glu(OBzl)-OBzl or L-Glu(OBzl)-resin.[3] After the examination of seven DL-histidyl-dipeptides (DL-His-L-A where A=Asp, Glu, Val, Leu, Ile, Ser, and Ala), we found that His-Ser and His-Ala are also suitable systems for the amino acid analyzer detection of as little as 0.1% racemization.[4] Using the His-Ser system, we have examined the relationships between the extent of racemization and various *im*-protecting groups, as well as various coupling conditions.

The results for the conventional peptide synthesis are given in Table 1. With use of the DCC method, *im*-Z, *im*-Ts, and *im*-Boc on urethane protected L-histidines gave little racemization in CH_2Cl_2 or DMF (entries 1—3). However, *im*-Bzl led to a slightly higher level (entry 4). Insufficient masking of the basicity of the imidazole function by Bzl group seemed to be the main reason for the higher degree of racemization. Low levels of racemization (0.2—0.3%; entries 5 and 7) were observed in the usual MA method. The activation of Z-L-His(Z) under the strict conditions introduced by Anderson *et al.*[5] suppressed the racemization to below 0.1% (entry 6). Windridge and Jorgensen reported 24% racemization by Woodward's reagent during the course of coupling of Boc-L-His(Bzl) and L-Glu(OBzl)-OBzl using DMF as a solvent.[3] The present study showed only 0.4% racemization by this method (entry 8) in the coupling of Z-L-His(Z) and L-Ser(Bzl)-OBzl in CH_3CN. The azide method is considered free from racemization; however, Z-L-His-N_3 causes a slight degree of racemization (entry 9), which might be due to the basicity of free imidazole moiety.

The results of racemization during the solid-phase method are also given in Table 1. More appreciable racemization takes place in synthesis carried out by the solid-phase method than that by the conventional method. The remarkably high racemization (37%; entry 13) of Z-L-His(Bzl) coincides with the result of Windridge and Jorgensen.[3] The use of Z-L-His also causes appreciable racemization (4.8%). Racemization was reduced to 0.9% with Z-L-His(Ts). Lin *et al.* observed almost no racemization of Boc-L-His(Ts) in the synthesis of [L-His(Ts)^{119}, Ile^{120}]-ribonuclease decapeptide in contrast to 2.3% racemization of His^{119} when Boc-L-His was used.[6] Addition of either HOSu or HOBt with DCC resulted in an extensive reduction of racemization to 0.2% (entry 11). Weygand *et al.* reported the occurrence of less than 1% racemization with DCC plus HOSu.[7] König and Geiger also reported suppressed racemization by the DCC method in the presence of HOBt.[8]

Experimental

Preparation of Diastereomers (DL-His-L-A). Amino Acid Derivatives: Z-DL-His(Z)·EtOH (**1**) was prepared in a similar way to that for the L-isomer;[9] yield, 54%; mp 92—94 °C. L-Ser(Bzl)-OBzl·TsOH (**2**) was prepared following the general procedure by Izumiya and Makisumi;[10] yield, 72%; mp 120—122 °C; $[\alpha]_D^{20}$ −19.0° (*c* 2, MeOH).

*Z-DL-His(Z)-L-Ser(Bzl)-OBzl (**3**)*: IBCF (1 mmol) was added to a chilled solution (−15 °C) of **1** (1 mmol) and TEA (1 mmol) in THF (4 ml). After 10 min, a mixture of **2** (1 mmol), TEA (1 mmol) and THF (4 ml) was added to the chilled solution. The reaction mixture was allowed to stand at 0 °C for 1 h and at 20 °C for 19 h, and evaporated. The residue was dissolved in EtOAc and the solution was washed with 2% HCl, 4% $NaHCO_3$, and dried (Na_2SO_4). Evaporation of the filtrate afforded an oil (**3**).

DL-His-L-Ser: A part (0.5 mmol) of the crude oil (**3**) dissolved in a mixture (6 ml) of AcOH-MeOH-H_2O (6:3:1, v/v) was treated with H_2 in the presence of Pd black. The filtrate from the catalyst was evaporated, and the residue (DL-His-L-Ser) was used in an experiment with the analyzer.

Other diastereomers (DL-His-L-A) were prepared in the same manner as described above.

Separation of DL-His-L-A by the Amino Acid Analyzer: A part (1 μmol) of the residue (DL-His-L-A) was dissolved in 0.2 M citrate buffer (pH 2.2) and analyzed on a Hitachi amino acid analyzer: column, 0.6×10 cm; solvent, standard 0.2 M citrate buffer (pH 4.25); flow rate, 60 ml/h; jacket temperature, 55 °C. Pure diastereomers of His-Ser were prepared for the identification of peaks, and for the determination of color yields by ninhydrin reaction.

Diastereomers of His-Ser. Z-L(or D)-His(Z)-L-Ser(Bzl)-OBzl (**4,5**): Z-D-His(Z)·EtOH was prepared as described for **1**; yield, 71%; mp 93—95 °C; $[\alpha]_D^{23}$ −30.4° (*c* 2, EtOAc). Compounds **4** and **5** were prepared from Z-L(or D)-His(Z)·EtOH and **2** as described for **3**. Crude products were recrystallized from EtOAc-petroleum ether.

*L(or D)-His-L-Ser (**6,7**)*: Compounds **4** and **5** were hy-

Table 1. Extent of recemization in conventional (entries 1—9) and solid-phase method (entries 10—14)

Entry	Coupling reagent	Acid component	Solvent	Reaction time (h)	Reaction temp (°C)	Extent of racemization (%)[a]
1	DCC	Z-L-His(Ts)	CH_2Cl_2	20	0, 20	0.3
2	DCC	Boc-L-His(Boc)	CH_2Cl_2	20	0, 20	0.4
3	DCC	Z-L-His(Z)	DMF	20	20	0.6
4	DCC	Z-L-His(Bzl)	DMF	20	20	1.8
5	IBCF	Z-L-His(Z)	THF	20	0, 20	0.2[b]
6	IBCF	Z-L-His(Z)	THF	20	0, 20	<0.1[c]
7	IBCF	Boc-L-His(Boc)	THF	20	0, 20	0.3[b]
8	Woodward's reagent	Z-L-His(Z)	CH_3CN	20	0, 20	0.4
9	Isopentyl nitrite	Z-L-His-$NHNH_2$	DMF	48	0	0.8
10	DCC	Boc-L-His(Boc)	CH_2Cl_2	4	20	1.5
11	DCC/HOSu or HOBt	Boc-L-His(Boc)	CH_2Cl_2	4	20	0.2
12	DCC	Z-L-His(Ts)	CH_2Cl_2	4	20	0.9
13	DCC	Z-L-His(Bzl)	DMF	4	20	37
14	DCC	Z-L-His	DMF	4	20	4.8

a) Defined as [100(D-L isomer)]/[(L-L isomer)+(D-L isomer)]. b) MA was prepared with TEA at −15 °C for 10 min and reacted at 0 °C for 1 h and at 20 °C for 19 h. c) MA was prepared with *N*-methylmorpholine at −15 °C for 1 min.

Table 2. Yields and physical constants of compounds **4**—**7**

Compounds[a]	Yield (%)	Mp (°C)	$[\alpha]_D^{20}$ (*c* 2)
Z-L-His(Z)-L-Ser(Bzl)-OBzl (**4**)	66	109—110	+23.5°[b]
Z-D-His(Z)-L-Ser(Bzl)-OBzl (**5**)	69	131—132	−32.7°[b]
L-His-L-Ser (**6**)[c]	69	192—193 (dec)	+4.1°[d]
D-His-L-Ser·H_2O (**7**)	67	197—198 (dec)	−6.0°[d]

a) Satisfactory elemental analyses were obtained for all compounds. b) Solvent, $CHCl_3$. c) G. Losse and G. Müller, *Chem. Ber.*, **94**, 2768 (1961), synthesized **6** from Trt-L-His(Trt)-L-Ser and afforded mp 138—141 °C. d) Solvent, 0.1 M NaOH.

drogenated as described for DL-His-L-Ser, and the crude products were recrystallized from water–EtOH. Melting points and other data of **4**—**7** are summarized in Table 2. Each dipeptide was subjected to analysis as described before; **6** was eluted at 85 ml of effluent volume, and **7** at 115 ml.

Detection of Racemization during the Conventional Method. Several acyl-L-histidines (1 mmol each) were coupled with **2** (1 mmol) by DCC,[11] IBCF,[5] Woodward's reagent,[12] and by the azide method.[13] The solvent of the reaction mixture was evaporated and the residue was worked up as described for **3**. The crude product was deblocked by a suitable method to afford His-Ser, a part (5 μmol) of which was subjected to analysis.

Detection of Racemization during the Solid-phase Method. Coupling was performed manually.[14] L-Ser(Bzl)-resin derived from Boc-L-Ser(Bzl)-resin (0.20 g, 0.06 mmol) was treated with four equivalents of DCC and a protected histidine (*e.g.*, Boc-L-His(Boc)). In some cases HOSu or HOBt (fourfold) was used together with DCC. The acyl-dipeptide-resin obtained was treated with HF (3 ml) at 0 °C for 1 h in the presence of anisole (0.3 ml). After removal of HF, the crude peptide was extracted with 1% AcOH, the extract being washed with ether and evaporated. The residue (His-Ser) was subjected to analysis.

Microwave Spectrum, Barrier to Internal Rotation, and Dipole Moment of Methyl Selenocyanate

Takeshi SAKAIZUMI,* Yoshio KOHRI, Osamu OHASHI, and Ichiro YAMAGUCHI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho, Chiyoda-ku, Tokyo 102

(Received January 17, 1978)

Microwave rotational spectra of five isotopic species of methyl selenocyanate (CH_3SeCN with ^{82}Se, ^{80}Se, ^{78}Se, ^{77}Se, and ^{76}Se) in the ground vibrational state, and two isotopic species of methyl selenocyanate-d_3 (CD_3SeCN with ^{80}Se and ^{78}Se) in the ground and first excited states of the methyl torsional mode have been assigned in the 8.0 to 35.5 GHz frequency range. For the most abundant species in the ground vibrational state, the rotational constants determined are $A_A=10147\pm2$, $B_A=3483.57\pm0.04$, and $C=2631.58\pm0.04$ MHz for $CH_3{}^{80}SeCN$ and $A=8322.57\pm0.81$, $B=3308.06\pm0.02$, and $C=2436.92\pm0.01$ MHz for $CD_3{}^{80}SeCN$. The A-E splittings due to the methyl internal rotation were observed for the rotational transitions in the ground vibrational state for the normal species and in the first excited state of the methyl torsional mode for the deuterated species. Analysis of the splittings gave a barrier height to the methyl internal rotation of 1241 ± 50 and 1228 ± 50 cal/mol for the CH_3 and CD_3 species, respectively. Stark measurements yielded the principal axis dipole moments of $\mu_a=4.35\pm0.04$, $\mu_b=0.76\pm0.10$, and the total dipole moment of $\mu=4.42\pm0.05$ D for $CH_3{}^{80}SeCN$, and $\mu_a=4.31\pm0.04$, $\mu_b=0.67\pm0.07$, and $\mu=4.36\pm0.04$ D for $CD_3{}^{80}SeCN$. The direction of the dipole moment in the molecule is discussed.

The microwave spectra of alkyl compounds having an isocyanato (–N=C=O) or an isothiocyanato (–N=C=S) group have been studied: ethyl isocyanate (CH_3CH_2NCO)[1] and ethyl isothiocyanate (CH_3CH_2NCS).[2] There have been several studies of the microwave spectra of molecules having a C–Se bond which is an axis of internal rotation, *e.g.*, CH_3SeH[3] and $(CH_3)_2Se$.[4]

Studies of the microwave spectra of a series of compounds, CH_3SeH,[3] CH_3SH,[5] and CH_3OH,[6] have been made. Among the series, methane selenol had the lowest potential barrier hindering the methyl internal rotation and the longest bond which is the internal rotation axis (see Table 13). The potential barrier of methanethiol is higher than that of methanol, while the C–S bond in methanethiol is longer than the C–O bond in methanol. There seems no simple parallelism between the height of the potential barrier and the bond length for this series, but for a series of dimethyl compounds, $(CH_3)_2Se$,[4] $(CH_3)_2S$,[7] and $(CH_3)_2O$,[8] it does exist as shown in Table 13.

Therefore, it is of interest to study the potential barrier of methyl selenocyanate and to compare it with those of the related compounds in relation to the bond length. In this paper, the spectrum of methyl selenocyanate will be reported, and the barrier height and dipole moment will be discussed.

Experimental

Methyl selenocyanate was prepared by mixing methyl iodide with a cold solution of potassium selenocyanate in ethanol.[9] An exothermic reaction occurred immediately after adding the iodide followed by the deposition of potassium halides. The mixture was mildly refluxed for 4 h after standing for 30 min at room temperature. The solvent was removed by distillation in a stream of nitrogen and the resultant slurry steam-distilled, giving crude yellow methyl selenocyanate (40 to 50% yield). Reduced pressure distillation with a nitrogen leak yielded a pale yellow product. Methyl selenocyanate-d_3 (CD_3SeCN) was prepared by reacting 99% enriched CD_3I (E. Merk Co., Ltd.) with KSeCN according to the method of normal species. The normal species was identified by the IR and proton NMR spectra, while the deuterated one only by the IR.

The rotational spectra were obtained in the frequency region from 8.0 to 35.5 GHz with a conventional 100-kHz squares-wave Stark modulation spectrometer. The waveguide was cooled with Dry Ice. Transition frequencies were measured with a Hewlett-Packard Model 5245L electronic counter with a 5257A transfer oscillator.

Results and Discussion

Assignment of Spectrum of CH_3SeCN. A model of the molecular structure was constructed based upon the following known molecular parameters: methyl group and C–N bond in CH_3SCN,[10] Se–CH_3 bond in CH_3SeH,[3] Se–CN bond in selenophene,[11] and angle C–Se–C in dimethyl selenide.[4] The assumed structural parameters are listed in Table 1. The assumed molecular structure and bond moment considerations indicated that the CH_3SeCN molecule should be an asymmetric prolate rotor ($\kappa=-0.77$) with a large component of the dipole moment lying along the a-principal axis. A search for the a-type R-branch transitions, $3_{13}\leftarrow2_{12}$, $3_{03}\leftarrow2_{02}$, and $3_{12}\leftarrow2_{11}$, in the predicted frequency range was fruitful. The transitions of the K-doublet ($K_{-1}=1$ and 2) on the higher frequency side with respect to the $K_{-1}=0$ line split into A and E components due to the hindered internal rotation of the methyl group. A characteristic A-E splitting of the $J=4\leftarrow3$ transition with $K_{-1}=3$ was observed for $CH_3{}^{80}SeCN$ as shown in Fig. 1. The assignments of the lines for the isotopic species (^{82}Se, ^{80}Se, ^{78}Se, ^{77}Se, and ^{76}Se) were made

Table 1. Assumed structural parameters

Length(Å)		Angle(°)

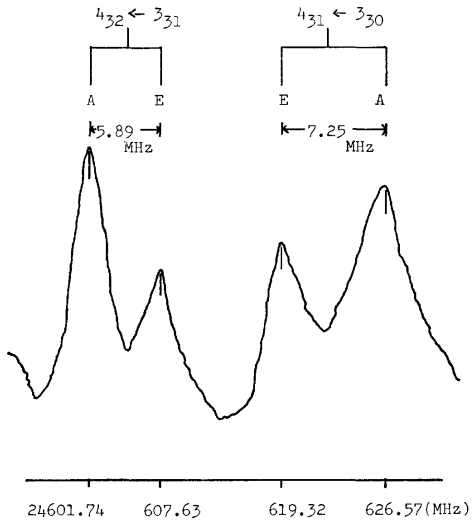

Fig. 1. Observed spectrum of $4_{32}\leftarrow3_{31}$ and $4_{31}\leftarrow3_{30}$ transitions in $CH_3{}^{80}SeCN$ showing their characteristic A-E splitting.

based on the Stark effects and the relative intensities corresponding to the natural abundances (9.1, 49.8, 23.5, 7.5, and 9.0%, respectively). The observed and calculated frequencies are in good agreement for transitions up to $J=5\leftarrow4$ of CH_3SeCN in the ground vibrational state as shown in Table 2. The rotational constants in the ground vibrational state of the A-species were obtained by the least-squares method and are listed in Table 3. Almost a constant value of $\Delta I(=I_c-I_b-I_a)$ was obtained for the ^{82}Se, ^{80}Se, ^{78}Se, ^{77}Se, and ^{76}Se isotopic species as shown in Table 3, indicating that the selenium atom is in the molecular symmetry plane as expected. The constant ΔI value also ensures the assignment of the transition lines.

The observed values of ΔI, -2.83 to -2.85 amu Å^2, are smaller than the values, -3.12 to -3.26 amu Å^2, usually obtained for molecules with a planar framework and a methyl group whose axis of symmetry lies in the plane.

Deuterated Species. The assignment of the spectrum for the ^{80}Se species was made by the same procedure as for the normal species. The absorption lines due to the excited state of the ^{80}Se species were found in the vicinity of the ground state as shown by the broken lines in Fig. 2. The assignment for the ^{78}Se species was made bearing in mind the Stark effects and the isotopic shifts

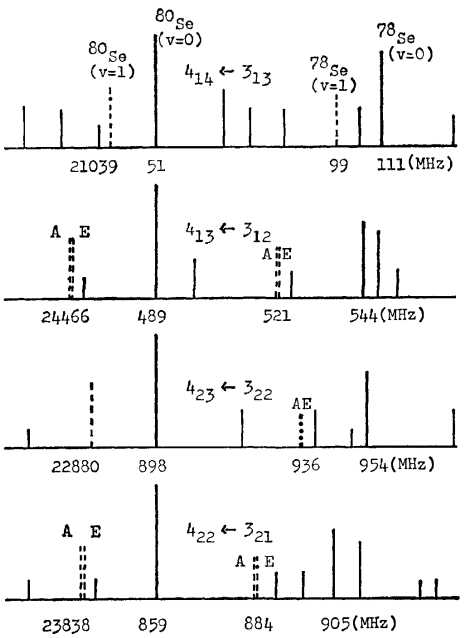

Fig. 2. Observed spectrum of $J=4\leftarrow3$ transitions in CD_3SeCN.

of the lines predicted from the model. In this spectrum the strong satellite lines due to the vibrationally excited state appeared in the vicinity of the ground state line. The observed lines for the excited state of the ^{78}Se species are also shown by the broken lines in Fig. 2. The broken lines were assigned to the first excited state of the methyl torsional mode because of the splitting of the A-E doublet. The observed and calculated frequencies for CD_3SeCN in the ground and first excited vibrational states of the A-species are in good agreement as given in Table 4. The rotational constants in the ground and excited states of the A-species are listed in Table 5.

$r_s(H\cdots H)$ Distance. The distance between the out-of-plane H atoms was determined from the moments of inertia for the normal and deuterated species. The distance between the H atoms is related to the effective moments of inertia as follows,

$$I_a^\circ + I_b^\circ - I_c^\circ = m_H r_e^2 - \Delta_c, \quad (1)$$

where r_e is the equilibrium distance between the two out-of-plane H atoms. The major contribution to Δ_c arises from the low-frequency in-plane motions of the heavy atom skeleton[12] and hence the effect of isotopic substitution of the out-of-plane hydrogen atoms on Δ_c should be small. The contribution of the in-plane vibration may be estimated by using the following approximate equation,[12]

$$\Delta_c = 4K/\omega, \quad (2)$$

where ω is the frequency of the lowest in-plane vibration in cm^{-1} and $K=h/8\pi^2=16.863$ amu Å^2 cm^{-1}. Equation 2 is given for planar molecules, but it is suitable for such cases as non-planar molecules (X_2YZ_2 and CH_3CXO) with a heavy planar skeleton.[12] Substitution of the infrared data for the C–Se–C bending mode ($\omega=166$ cm^{-1})[13] into Eq. 2 gives $\Delta_c=0.406$ amu Å^2. Using Eqs. 1 and 2 for ^{80}Se and ^{78}Se species the values of $r_e(H\cdots H)$ and $r_e(D\cdots D)$ obtained are listed in Table 6.

The change in the moments of inertia from the normal to the deuterated species gives the following relation,

a) This work. b) Ref. 14.

Table 7 shows a comparison of the H···H distance in some related molecules. The r_s in CH_3SeCN obtained in this work is larger than that in the other molecules.

The Bond Length $r_{Se-C(methyl)}$. The r_s-coordinate of the carbon atom in the methyl group could not be determined, because the spectrum of the $^{13}CH_3$ species was not observed. However the bond length r_{Se-C} may be obtained using the moments of inertia of the four isotopic species ($CH_3{}^{80}SeCN$, $CH_3{}^{78}SeCN$, $CD_3{}^{80}SeCN$, and $CD_3{}^{78}SeCN$). If the methyl group is assumed to have C_{3v} symmetry, r_{Se-C} is expressed by the relation (see Appendix),

$$r_{Se-C} = \sqrt{1/3}\, r_{C-H}\left[\sqrt{\cos\theta - 1 + (Z/r_{C-H}^2)} - \sqrt{2\cos\theta + 1}\right], \quad (4)$$

where θ and r_{C-H} are the angle H–C–H and the C–H bond length in the methyl group and Z is a quantity calculated from the observed moments of inertia (I_c) of the four isotopic species and their molecular weights. Assuming r_{C-H} to be 1.085 Å as in the case of the CH_3SeH molecule, the H–C–H angle θ may be obtained as 112° from the r_s(H···H) distance determined (Table 6). With these values, the bond distance, r_{Se-C}, may be estimated from Eq. 4 to be 1.950 Å. The error in r_{Se-C} depends on the estimation of r_{C-H} distance. If the estimation error of r_{C-H} is ±0.008 Å, the error of r_{Se-C} is ±0.025 Å.

The remaining parameters, $r_{C\equiv N}$, r_{Se-CN}, and the angle C–Se–C, have been fitted to all the observed moments of inertia (except for I_a in normal species). The obtained structural parameters are listed in Table 8 and the observed and calculated moments of inertia are shown in Table 9.

Barrier to Internal Rotation. The A-E splittings due to internal rotation of the methyl group were measured for each isotopic species and are shown in Tables 10 and 11. Analysis of the A-E splittings was achieved using the principal axis method (PAM) developed by Herschbach.[15] The Hamiltonians used in this analysis contained perturbation terms up to second order for A-species and up to third order for E-species. The values of the perturbation coefficients, $W_{v\sigma}^{(n)}$ ($v=0$ or 1 and $\sigma=$A or E) were taken from Hayashi and Pierce.[16] The assignment of the E-species transitions was made with the aid of the internal rotation calculation. The parameters required to compute the A-E splitting of the rotational transitions in the PAM formalism are A, B, C, I_α, λ_a, and s. The rotational constants A, B, and C were fixed to the effective values obtained from the least-squares fit of the A-species lines. Assuming r(C–H)=r(C–D), the value of the moment of intertia of the CH_3 group about its axis of symmetry, I_α, was determined using the following relation:

$$I_\alpha(CH_3) = [m_H/(m_D-m_H)][(I_a+I_b-I_c)_{CD_3} - (I_a+I_b-I_c)_{CH_3}]. \quad (5)$$

The values of $I_\alpha(CH_3)$ for the two pairs of isotopic species, $CH_3{}^{80}SeCN$-$CD_3{}^{80}SeCN$ and $CH_3{}^{78}SeCN$-$CD_3{}^{78}SeCN$ were determined, independently, using Eq. 5 and found to be in good agreement (within 0.017 amu Å^2). The average value of $I_\alpha(CH_3)=3.267$ amu Å^2 was used in the internal rotation analysis involving the methyl group. The moment of inertia of the deuterated methyl group, $I_\alpha(CD_3)$, was obtained from $I_\alpha(CH_3)$ using the relationship

$$I_\alpha(CD_3) = (m_D/m_H)I_\alpha(CH_3) \quad (6)$$

based on the assumption that CH_3 and CD_3 groups are identical except for the differing masses of the hydrogen and deuterium atoms. Substitution of the values of $I_\alpha(CH_3)=3.267$ amu Å^2 into Eq. 6 yields $I_\alpha(CD_3)=6.529$ amu Å^2, which was used in the internal rotation analysis of the methyl selenocyanate-d_3 species. The direction cosine, $\lambda_a(\lambda_a=\cos\varphi$, where φ is the angle between the axis of symmetry of the threefold symmetric top and the a-principal axis), may be obtained from the structural parameters listed in Table 8, assuming that the axis of symmetry of the CH_3 and CD_3 groups coincides with the C–Se bond. From the assigned transitions of the A- and E-species, an approximate value of s, a parameter of the Mathieu equation, could be evaluated. Using the approximate values of s and the internal rotation parameters, the transitions of the E-species were predicted. The E-species lines were observed in the vicinity of the predicted frequencies and consequently were assigned. The observed and calculated A-E splittings of CH_3SeCN and CD_3SeCN are in good agreement as shown in Tables 10 and 11. The s values for the various isotopic species were obtained by the least-squares fit to the observed A-E splittings. The results of the internal rotation analysis are listed in Table 12. The resulting barriers to the methyl internal rotation are 1241±50 and 1228±50 cal/mol for the CH_3 and CD_3 species, respectively.

Table 13 shows a comparison of the potential barrier in some related molecules. In the series of $(CH_3)_2Se$, $(CH_3)_2S$, and $(CH_3)_2O$, the potential barrier becomes higher as the C–M bond length (M=Se, S, and O) becomes shorter. The same trend holds for the series of CH_3SeCN and CH_3SCN. However, this trend does not hold for the series of CH_3SeH, CH_3SH, and CH_3OH.

Inspection of the data in Table 13 revealed a quantitative trend that the replacement of a hydrogen atom of the selenol group in CH_3SeH by a cyano group to make CH_3SeCN results in an increase of the barrier by about 240 cal/mol. This increment is consistent with the same replacement from CH_3SH to CH_3SCN.

a) $[MHz/(V/cm)^2]\times10^{-5}$.

Stark Effect and Dipole Moment. The dipole moments in the ground vibrational state were determined from the Stark coefficients of the $2_{02}\leftarrow1_{01}$, $2_{11}\leftarrow1_{10}$, $3_{03}\leftarrow2_{02}$, and $3_{12}\leftarrow2_{11}$ transitions for $CH_3{}^{80}SeCN$ and the $3_{03}\leftarrow2_{02}$ and $3_{12}\leftarrow2_{11}$ transitions for $CD_3{}^{80}SeCN$. The c-component of the dipole moment was assumed to be zero because of the plane of symmetry of the molecule as discussed above. The electric-field strength in the absorption cell was calibrated using the dipole moment of OCS, 0.71521 D[17] and the results are given in Table 14. The total dipole moment (4.42 D) is larger than the value of 3.91 D obtained from the dielectric measurement.[18] The same trend is noted for methyl thiocyanate, where the dipole moment obtained by the rotational spectrum is 4.03 D[10] while that obtained from the dielectric measurement is 3.59 D.[18] The replacement of the selenol hydrogen atom by a cyano group results in an increase of the dipole moment by about 3.1 D. This increment is consistent with that of 2.5 D found in changing from CH_3SH to CH_3SCN.

The direction of the dipole moment in the molecule was determined using the values of the dipole moment for both the normal and deuterated species. The observed value of γ ($\cos\gamma=\mu_a/\mu_{total}$), the angle between the direction of the dipole moment and the a-principal axis, is 10.2°±2° for the normal species. Therefore, two directions of the dipole moment are possible in the molecule as shown by two broken lines in Fig. 3. The angle between the a-principal axis for the normal species, CH_3SeCN, and for the deuterated species, CD_3SeCN, was calculated to be 3.8° from the structural parameters in Table 8. Two predicted directions, γ, in CD_3SeCN are 14.0 and 6.4°. The angle γ obtained from the observed data for CD_3SeCN is 8.6°. This is consistent with a predicted value 6.4±2° rather than the other one. Taking account of the electronegativities of the elements (or groups) in this molecule, the above discussion leads to the conclusion that the dipole moment of the molecule lies along the thick arrow shown in Fig. 3.

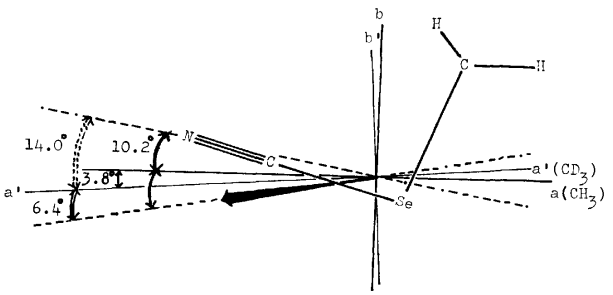

Fig. 3. The direction of dipole moment in methyl selenocyanate.

The authors wish to thank Dr. Teruhiko Ogata, Shizuoka University, for the use of a computer program for the PAM analysis.

Appendix

The molecules studied have a plane of symmetry. If the z axis is chosen as perpendicular to the plane of symmetry, the principal moment of inertia, I_z, is represented by the following equation,

$$I_z=\sum_i m_i r_i^2 - M(X^2+Y^2) \quad \text{(A1)}$$

the origin of the coordinate system being taken at an arbitrary point in the molecule, where m_i is the mass of the i-th atom in

the normal species and M is the total mass of the molecule. r_i represents the distance of the i-th atom from the origin. X and Y are the coordinates of the center of mass from the origin.

The z axis has been chosen as the principal axis c for the molecules studied in this work. If the selenium atom in the molecule is chosen as the origin of the coordinate system, the moment of inertia, I_c, are given by

$$I = \sum_i m_i r_i^2 - M(X^2+Y^2) \quad \text{(A2)}$$

for $CH_3{}^{80}SeCN$ and $CH_3{}^{78}SeCN$ molecules and

$$I = \sum_i m_i r_i^2 - M(X^2+Y^2) + \Delta m(r_4^2+2r_5^2) \quad \text{(A3)}$$

for $CD_3{}^{80}SeCN$ and $CD_3{}^{78}SeCN$ molecules, respectively, where the subscript c of I has been eliminated as unnessessary. In Eqs. A2 and A3, the summation is over all atoms in the molecules. r_i's can be identified in Fig. 4. Δm is the difference between the masses of deuterium and hydrogen atoms. The first terms in Eqs. A2 and A3 are identical for molecules with the same Se isotopic species. The coordinates of the center of mass, X and Y, are given by

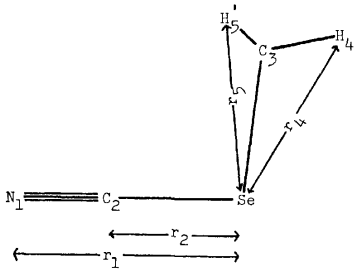

Fig. 4. Model for the calculation of the bond length of $r(Se–CH_3)$.

$$X = \sum_i m_i x_i / \sum_i m_i, \qquad Y = \sum_i m_i y_i / \sum_i m_i \quad \text{(A4)}$$

for $CH_3{}^{80}SeCN$ and $CH_3{}^{78}SeCN$, and

$$\left.\begin{aligned} X &= [\textstyle\sum_i m_i x_i + \Delta m(x_4+2x_5)]/(\sum_i m_i + 3\Delta m) \\ Y &= [\textstyle\sum_i m_i y_i + \Delta m(y_4+2y_5)]/(\sum_i m_i + 3\Delta m) \end{aligned}\right\} \quad \text{(A5)}$$

for $CD_3{}^{80}SeCN$ and $CD_3{}^{78}SeCN$. x_i and y_i are the coordinates of the i-th atom in the molecule and the summation in Eqs. A4 and A5 is over all the atoms in the molecules. The numerator in Eq. A4 and the first term of the numerator in Eq. A5 are equivalent for the molecules with the same Se isotopic species. From Eqs. A2, A3, A4, and A5, the following relation is obtained,

$$(r_4^2+2r_5^2) = [\mu\Delta I_A - \mu'\Delta I_B - (\mu/M_{A'} - \mu'/M_{B'}) \times (M\Delta I_{AB} + M'\Delta I_{A'B'})]/\Delta m(\mu-\mu'), \quad \text{(A6)}$$

where

$$1/\mu = 1/M_A + 1/M_{A'}, \qquad 1/\mu' = 1/M_B + 1/M_{B'},$$
$$1/M = 1/M_A - 1/M_B, \qquad 1/M' = 1/M_{A'} - 1/M_{B'},$$
$$\Delta I_A = I_{A'} - I_A, \qquad \Delta I_B = I_{B'} - I_B$$
$$\Delta I_{AB} = I_A - I_B, \qquad \Delta I_{A'B'} = I_{A'} - I_{B'}.$$

M_A, $M_{A'}$, M_B, and $M_{B'}$ are the total masses and I_A, $I_{A'}$, I_B, and $I_{B'}$ the principal moments of inertia, I_c, of $CH_3{}^{80}SeCN$, $CD_3{}^{80}SeCN$, $CH_3{}^{78}SeCN$, and $CD_3{}^{78}SeCN$, respectively.

Expressing the right side of Eq. A6 as Z, rewriting the left side in terms of $r_{Se-C(methyl)}$, r_{C-H}, and θ, and assuming that the methyl group has C_{3v} symmetry and the symmetry axis coincides with the Se–C(methyl) bond, then Eq. A6 leads to Eq. 4.

A Shock Tube Study on the Pyrolysis of Acetylene in the Presence of Nitrogen Oxide

Hiroo OGURA

Institute of Space and Aeronautical Science, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received Feburary 3, 1978)

The pyrolysis of acetylene in the presence of nitrogen oxide has been investigated by use of a single-pulse shock tube in the temperature range 1100—1650 K. The hydrocarbons produced in the presence of nitrogen oxide were quite the same as those obtained from the pyrolysis of acetylene by itself. The yield-temperature plots of 1-buten-3-yne showed that at temperatures below 1350 K the formation rate of 1-buten-3-yne is reduced by the addition of nitrogen oxide. The retarding effect of nitrogen oxide on the 1-buten-3-yne formation was interpreted in terms of the reactions of nitrogen oxide with 1-ethynylvinyl and 2-ethynylvinyl radicals to yield propynenitrile and hydrogen cyanide, respectively. An illustrative radical chain mechanism was presented for the pyrolysis of acetylene in line with the experimental results obtained from the pyrolysis inhibited by nitrogen oxide. The radical chain is initiated by the bimolecular reaction of acetylene, *viz.* $2C_2H_2 \rightarrow C_4H_3 + H$, ethynyl and 2-ethynylvinyl radicals being the chain carriers, where C_4H_3 is 1-ethynylvinyl radical.

Since the work by Staveley and Hinshelwood on the inhibiting effect of nitrogen oxide on the decomposition of hydrocarbons,[1] the technique of nitrogen oxide addition has been utilized to confirm the existence of chain processes in the systems of decomposing hydrocarbons.

Nitrogen oxide addition method was also applied to the pyrolysis of acetylene. Below 800 K the addition of nitrogen oxide to acetylene system inhibited the consumption of acetylene.[2,3] On the other hand, nitrogen oxide was found to have no effect on the pyrolysis of acetylene at *ca.* 2000 K.[4] It seems of interest to examine an inhibiting effect by nitrogen oxide on the pyrolysis of acetylene at intermediate temperatures.

Hardly any analysis of reaction products containing nitrogen and oxygen atoms has been made in pyrolysis experiments. Sherwood and Gunning investigated the mercuryphotosensitized decomposition of acetylene in the presence of nitrogen oxide by the analysis of the reaction products involving nitrogen and oxygen atoms. From their study on the substituted vinyl radical reactions with nitrogen oxide, they concluded that a radical mechanism is operative in the system.[5,6]

Analysis of the inhibiting effect of nitrogen oxide on the pyrolysis products together with that of the reaction products containing nitrogen and oxygen atoms will make it possible to identify the substituted vinyl radicals assumed in the radical chain mechanism.[7]

Experimental

Apparatus and Procedure. The apparatus and procedure were essentially the same as those described in previous papers.[7-9] A 4-cm single-pulse shock tube was used, the driven section being 277 cm and the driver section 128.5 cm in length. The ultimate vacuum was *ca.* 6.4×10^{-5} Torr, the leak plus outgassing rate being *ca.* 1.5×10^{-5} Torr/min. Prior to the introduction of gases under investigation into the driven section, the tube was flushed with argon several times. Helium was used as a driver gas. Shocks were fired within five minutes after the driven section had been filled with gases.

Materials. Seven mixtures were prepared in a glass vessel of 10-l volume with the ratios $C_2H_2/NO/Ar = 10/0.2/89.8$; 10/1/89; 10/2/88; 5/1/94; 5/2/93; 1/1/98; and $C_2H_2/Ar = 10/90$. The gases were stirred with a glass fan located in the glass flask for at least four hours before use.

Nitrogen oxide (Matheson Co.) was purified at first by bulb-to-bulb distillation, and then passed through a silica gel column cooled with a Dry Ice–acetone bath.

The standard gas mixtures for the calibration of gas chromatography were the same as those used in the pyrolysis experiments. Carbon monoxide (research grade, Matheson Co.) was used.

Hydrogen cyanide was generated in a vacuum by pouring concd sulfuric acid onto potassium cyanide powder.[10] The crude hydrogen cyanide was purified by bulb-to-bulb distillation at *ca.* −50 °C.

Propynenitrile (cyanoacetylene) was prepared by the method of Moureu and Bongrand:[11]

$$H\text{-}C{\equiv}C\text{-}COOCH_3 \xrightarrow[-10\,^\circ C]{NH_4OH} H\text{-}C{\equiv}C\text{-}CONH_2$$

$$\xrightarrow[\text{vac. } 120\,^\circ C]{P_2O_5,\ \text{sand}} H\text{-}C{\equiv}C\text{-}C{\equiv}N.$$

Propynal (propiolaldehyde) was prepared from propynol.[12] Cyanogen was generated by pouring an aqueous sodium cyanide solution onto copper(II) sulfate pentahydrate at 50 °C, and dried by passing through diphosphorus pentaoxide.[13] Formaldehyde was prepared by the distillation of paraformaldehyde at *ca.* 120 °C. All the gases synthesized were purified by trap-to-trap distillation at Dry Ice–acetone temperature. The purified gases were diluted with argon gas and used as reference gases for gas-chromatographic analysis.

Analytical. The reaction products were analyzed by gas chromatography.. The details of the hydrocarbon analysis were reported.[7] Propynenitrile, cyanogen, and propynal were analyzed in the same way as in the hydrocarbons. The order of elution was CH_4, C_2H_4, C_2H_2, allene, propyne, 1,3-butadiene, 1-buten-3-yne, 1,3-butadiyne, propynenitrile, cyanogen, and propynal at the temperature of 140 °C. The propynenitrile was identified by gas-chromatographic comparison with the synthesized gas. Cyanogen, however, has the same retention time as that of propynenitrile at 140 °C. Thus propynenitrile cannot be seperated from cyanogen on a Porapak N column at other temperatures.

Hydrogen cyanide and formaldehyde were analyzed at 60 °C on a 3 mm × 0.8 m column packed with Porapak Q using helium ionization detector. When water is contained in the test gas and shock heated sample gas, it interferes with the analysis of hydrogen cyanide and formaldehyde. However, neither sample gas nor the shock heated gas contained water

in detectable amounts. Carbon monoxide was analyzed at room temperature with a thermal conductivity cell, on a 1.2 m column packed with molecular sieve 13 X(80—100 mesh). Carbon monoxide appeared at the tail end of the nitrogen oxide peak, but no difficulty was encountered in the analysis, analytical error being larger at low concentration of carbon monoxide in the shock heated gas.

Results

The mixtures were subjected to shock heating in the temperature range 1100—1650 K. The total densities behind the reflected shock waves were *ca.* 2.67×10^{-5} mol/cm^3, the reaction times being *ca.* 900 μs. The shock heated samples were extracted into evacuated bulbs of 60 ml volume, and analyzed by gas chromatography.

Product analyses for the hydrocarbons produced in the presence and absence of nitrogen oxide showed that the hydrocarbons formed in the C_2H_2–NO system and in the C_2H_2–Ar system are quite the same; CH_4, C_2H_4, C_2H_6, allene, propyne, 1,3-butadiene, 1-buten-3-yne, 1,3-butadiyne, and benzene being generated. The major products were also 1-buten-3-yne, 1,3-butadiyne and hydrogen in the presence of nitrogen oxide, the shapes of their yield-temperature plots being similar to those in the absence of nitrogen oxide. The minor products were CH_4, C_2H_4, allene, propyne, and benzene, trace products being C_2H_6 and 1,3-butadiene as in the case of the pyrolysis of acetylene alone.

Besides the hydrocarbons, hydrogen cyanide and carbon monoxide were formed as the major products containing nitrogen and oxygen atoms in the temperature range studied. Propynenitrile was found in much smaller amounts. No other products containing nitrogen and/or oxygen atoms such as N_2, N_2O, CO_2, O_2, and H_2O were found in large amounts. Since the amount of carbon monoxide was approximately equal to that of hydrogen cyanide (Fig. 1), there would be no missing

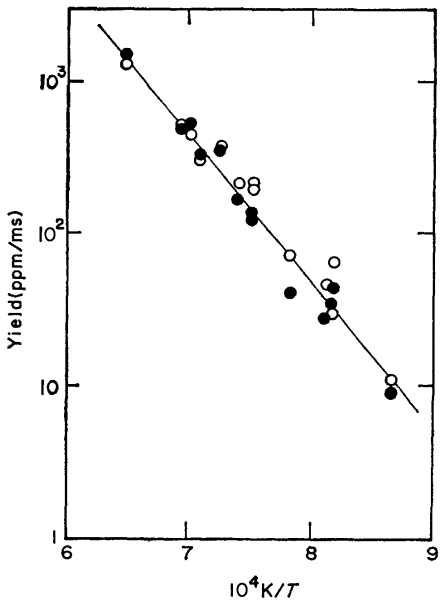

Fig. 1. Yields of carbon monoxide and hydrogen cyanide as a function of temperature (C_2H_2/NO/Ar=10/2/88). ●: Carbon monoxide, ○: hydrogen cyanide.

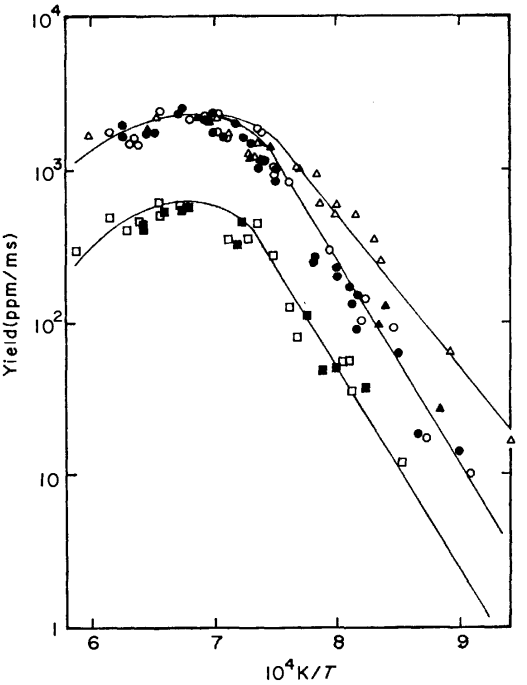

Fig. 2. Effect of nitrogen oxide on the rate of 1-buten-3-yne formation.
△: C_2H_2/Ar=10/90, ▲: C_2H_2/NO/Ar=10/0.2/89.8, ○: C_2H_2/NO/Ar=10/1/89, ●: C_2H_2/NO/Ar=10/2/88, □: C_2H_2/NO/Ar=5/1/94, ■: C_2H_2/NO/Ar=5/2/93.

products involving nitrogen and oxygen atoms. Thus the amount of nitrogen oxide consumed in the pyrolysis should be nearly equal to the yields of carbon monoxide and hydrogen cyanide.

Inhibited Rate of 1-Buten-3-yne Formation. The yields of 1-buten-3-yne for five mixtures with different composition of C_2H_2 and NO are plotted as a function of temperature in Fig. 2. The yield-temperature plots of 1-buten-3-yne show that at temperatures below 1350 K the yield decreases with the addition of nitrogen oxide, and that above 1350 K the yield is almost the same as that in the C_2H_2–Ar system. The rates of 1-buten-3-yne formation are also of second-order with respect to acetylene, and depend little on the amount of nitrogen oxide added at both lower and higher temperatures. The decrease in the yield of 1-buten-3-yne at lower temperatures can be attributed to the inhibition by nitrogen oxide added. An apparent second-order rate constant for the inhibited 1-buten-3-yne formation at temperatures below 1350 K was derived from 38 experiments by the least-squares method:

$$k_1(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = (4.5\pm2.4) \times 10^{15} \exp\{(-55700\pm2100)^*/RT\} \quad (1)$$

the errors denoting the standard deviation of the least-squares method. The Arrhenius plot of the second-order rate constants is shown in Fig. 3. The frequency factor in k_1 is considerably greater than that in the normal second-order rate constant.

* The activation energy is expressed in cal/mol (1 $\mathrm{cal_{th}}$ = 4.184 J).

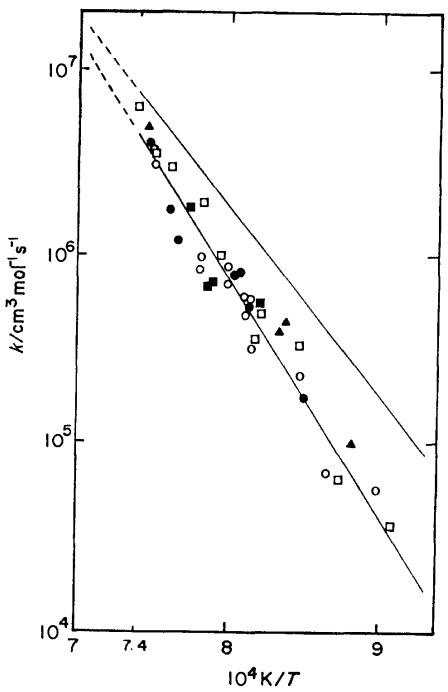

Fig. 3. Arrhenius plots of the second-order rate constants for 1-buten-3-yne formation inhibited by nitrogen oxide, the upper straight line showing the second-order rate constant obtained previously.[7]
▲: C_2H_2/NO/Ar=10/0.2/89.8, ○: C_2H_2/NO/Ar=10/1/89, ●: C_2H_2/NO/Ar=10/2/88, □: C_2H_2/NO/Ar=5/1/94, ■: C_2H_2/NO/Ar=5/2/93.

Rate of Hydrogen Cyanide Formation. Simultaneously with the reduction of 1-buten-3-yne yield, hydrogen cyanide and carbon monoxide were formed in approximately equal amounts. In order to determine the concentration dependence of hydrogen cyanide formation on acetylene and nitrogen oxide, the yields of

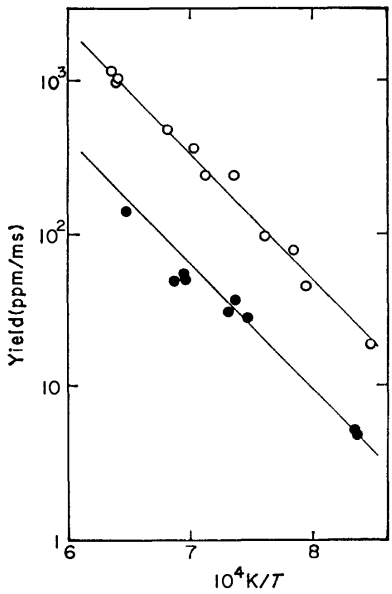

Fig. 4. Dependence of hydrogen cyanide formation rate on nitrogen oxide concentration.
○: C_2H_2/NO/Ar=10/1/89, ●: C_2H_2/NO/Ar=10/0.2/89.8.

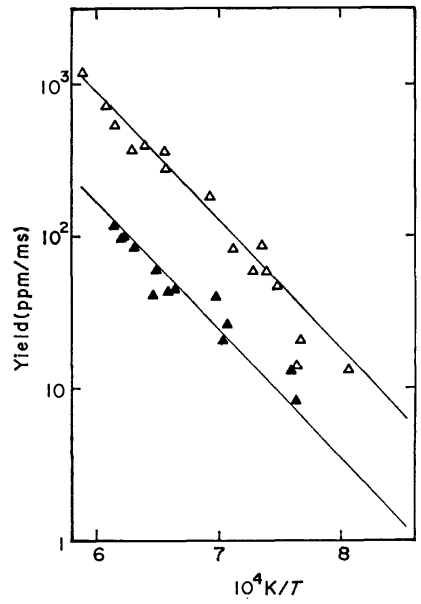

Fig. 5. Dependence of hydrogen cyanide formation rate on acetylene concentration.
△: C_2H_2/NO/Ar=5/1/94, ▲: C_2H_2/NO/Ar=1/1/98.

hydrogen cyanide for four mixtures, *viz.* C_2H_2/NO/Ar=10/0.2/89.9; 10/1/89; 5/1/94; and 1/1/98; are plotted against temperature in Figs. 4 and 5. We see that the rate of hydrogen cyanide formation is nearly of first-order in both acetylene and nitrogen oxide. An apparent second-order rate expression was fitted to the data (61 points obtained from the shock heated mixtures of C_2H_2/NO/Ar=10/0.2/89.8; 10/1/89; 10/2/88; 5/1/94; and 1/1/98) by the least-squares method:

$$k_2(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = (5.4\pm1.6) \times 10^{12} \exp\{(-37700\pm1300)/RT\}. \quad (2)$$

is shown in Fig. 6. Hydrogen cyanide and carbon monoxide continue to increase in the temperature range studied, whereas the yield of 1-buten-3-yne reaches its maximum at *ca.* 1500 K with a subsequent decrease.

Rate of Propynenitrile Formation. Propynenitrile was found at slightly higher temperatures and in smaller amounts than hydrogen cyanide. In determing the concentration dependence of acetylene and nitrogen oxide, the data obtained from the runs for the mixtures of C_2H_2/NO/Ar=10/1/89; 5/1/94; and 5/2/93 were adopted, since the yields of propynenitrile for the mixtures of C_2H_2/NO/Ar=10/0.2/89.8 and 1/1/98 were very small, involving large error. The rates of propynenitrile formation as a function of temperature are plotted in Fig. 7. The rate of propynenitrile generation is of the second-order with respect to acetylene. Although the data obtained from the runs for the mixture of C_2H_2/NO/Ar=5/2/93 scatter considerably, the rate of propynenitrile formation is expected to be also of the first-order with respect to nitrogen oxide by analogy with that of hydrogen cyanide production. An apparent second-order rate constant was derived by the least-squares method:

$$k_3(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = (9.9\pm2.3) \times 10^{13} \exp\{(-53300\pm2500)/RT\}. \quad (3)$$

For derivation, only the data in Fig. 7 (25 points) were adopted. The Arrhenius plot of the second-order rate constants is shown in Fig. 8.

Effects on the Other Products. The influence of added nitrogen oxide on the formation of hydrogen is illustrated in Fig. 9. The shape of yield-temperature plots for hydrogen is similar to that in the absence of nitrogen oxide. The yield of hydrogen increases considerably at higher temperatures, and appears to depend little on the concentration of nitrogen oxide added. The same is true for the yield-temperature plots of the other major and minor products.

Discussion

The same reaction product formation as in the absence of nitrogen oxide and similar shapes of the yield-temperature plots suggest that a similar mechanism is operative for the formation of the hydrocarbons in the C_2H_2–NO system. A mechanism for the pyrolysis of acetylene in the absence of nitrogen oxide was proposed from a thermochemical point of view:[7]

$$2C_2H_2 \longrightarrow C_4H_3 + H, \quad (4)$$
$$C_4H_3 + C_2H_2 \longrightarrow C_6H_5, \quad (5)$$
$$C_6H_5 + C_2H_2 \longrightarrow C_4H_4 + C_4H_3, \quad (6)$$
$$H + C_2H_2 \longrightarrow C_2H_3, \quad (7)$$
$$C_2H_3 + C_2H_2 \longrightarrow C_4H_4 + H, \quad (8)$$
$$2C_6H_5 \longrightarrow \text{termination}, \quad (9)$$
$$2C_2H_3 \longrightarrow \text{termination}, \quad (10)$$

where C_4H_3 radical is supposed to be 1-ethynylvinyl ($H_2C=\dot{C}-C_2H$) radical. Hereafter 1-ethynylvinyl and 2-ethynylvinyl($C_2H-CH=\dot{C}H$) radicals will be denoted by $C_4H_3(1)$ and $C_4H_3(2)$, respectively.

Initiation Step. Probable initiation steps for the radical chain mechanism of the pyrolysis of acetylene alone are as follows:

$$2C_2H_2 \longrightarrow C_4H_3(1) + H, \quad \Delta H^\circ = 46.2, \quad (4)$$
$$\longrightarrow C_4H_3(2) + H, \quad \Delta H^\circ = 67.1, \quad (11)$$
$$\longrightarrow C_2H_3 + C_2H, \quad \Delta H^\circ = 65.3. \quad (12)$$

In the presence of nitrogen oxide the abstraction reaction of H atom by nitrogen oxide could also be a probable initiation step:

$$C_2H_2 + NO \longrightarrow C_2H + HNO, \quad \Delta H^\circ = 62.0. \quad (13)$$

In the calculation of the heats of reaction, the heats of formation are based on the observed or estimated values.[14] At present stage, Reaction 4 is the most probable initiation step in view of the heat of reaction. Another probable initiation is the bimolecular reaction of nitrogen oxide when added in a large amount:

$$2NO \longrightarrow N_2O + O, \quad \Delta H^\circ = 36.0. \quad (14)$$

The rate constants of Reactions 4 and 14 are estimated to be[7,15]

$$k_4(\text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}) = 3.5\times10^{13}\exp(-47400/RT), \quad (15)$$
$$k_{14}(\text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}) = 1.3\times10^{12}\exp(-63800/RT). \quad (16)$$

The rate constant of Reaction 14 is much smaller than that of Reaction 4 in the temperature range studied. Thus Reaction 4 is the most predominant initiation step in the C_2H_2–NO system.

Mechanism of 1-Buten-3-yne Formation. The reduction of 1-buten-3-yne formation rate at temperatures below 1350 K is accompanied by the formation of hydrogen cyanide and carbon monoxide. No other products containing nitrogen and/or oxygen atoms are found except for the propynenitrile in much smaller amount. It seems likely that the hydrogen cyanide and carbon monoxide in nearly equal amounts are produced simultaneously or *via* the same intermediate. We have tried to interpret the inhibiting effect of nitrogen oxide on 1-buten-3-yne formation by the reactions of nitrogen oxide with the chain carrier radicals present in the above pyrolysis mechanism.

Examination of the Proposed Mechanism for the Pyrolysis: Sherwood and Gunning showed experimentally that C_2H_3 and $C_4H_3(2)$ radicals react with nitrogen oxide to generate formaldehyde, propynal, and hydrogen cyanide.[5] In general the reaction between the substituted vinyl radical and nitrogen oxide can be written as $XYC=\dot{C}Z + NO \longrightarrow XYC=O + ZCN$,

where X, Y, and Z are functional groups of hydrocarbons. Thus the radicals in the proposed mechanism are expected to react with nitrogen oxide as follows:

$$C_4H_3(1) + NO \longrightarrow H_2CO + C_2HCN, \quad \Delta H^\circ = -60.0, \quad (17)$$
$$C_6H_5 + NO \longrightarrow C_4H_3CHO + HCN, \quad (18)$$
$$H + NO \longrightarrow HNO, \quad \Delta H^\circ = -49.9, \quad (19)$$
$$C_2H_3 + NO \longrightarrow H_2CO + HCN, \quad \Delta H^\circ = -76.6, \quad (20)$$

where C_6H_5 is assumed to have the structure of $H_2C=C(C_2H)-CH=\dot{C}H$. In the present analysis, hydrogen cyanide and propynenitrile have been detected as compounds containing nitrogen atom. Accordingly, the substituted vinyl radicals scavenged by nitrogen oxide should be C_2H_3, $C_4H_3(1)$, and C_6H_5 radicals in the proposed scheme.

If the chain propagation of Reaction 7 and 8 were mainly responsible for the formation of 1-buten-3-yne, the same amount of H_2CO as that of HCN would be produced. Therefore, as in the absence of NO, nearly equal amounts of hydrogen and carbon monoxide would be produced by the reaction

$$H_2CO \longrightarrow H_2 + CO, \quad \Delta H^\circ = 1.3. \quad (21)$$

As shown in Figs. 1 and 9, the yield of hydrogen is smaller than that of carbon monoxide at lower temperatures. Tadasa *et al.* reported that in the pyrolysis of H_2CO with a large excess of NO at 773 K the amount of hydrogen is very small as compared with that of carbon monoxide; water and nitrogen are formed instead.[16] In the present experiments, however, no detectable amounts of water and nitrogen have been found in the shock heated samples. In any event the chain propagation step of Reactions 7 and 8 can be concluded to have minor importance in the formation of 1-buten-3-yne. The same result has been obtained from the analysis of the isotopic distributions of C_2H_2 and C_4H_4 in the mixtures of C_2H_2 and D_2.[8]

On the other hand, if the chain propagation process, $C_4H_3(1)$ and C_6H_5 radicals as the chain carriers, is predominant, propynenitrile along with hydrogen cyanide should be detected. This is the case in the present experiments. Applying the steady-state treatment to Reactions 4, 5, 6, and 9, the steady-state concentrations of $C_4H_3(1)$ and C_6H_5, $[C_4H_3(1)]_{ss}$ and $[C_6H_5]_{ss}$, are given approximately by

$$[C_4H_3(1)]_{ss}/[C_6H_5]_{ss} \cong k_6/k_5, \quad (22)$$
$$= 1.3\times10^2\exp(-16100/RT). \quad (22')$$

The rate constants adopted are as follows:[7,17]

$$k_5(\text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}) = 6.3\times10^{11}\exp(-6500/RT), \quad (23)$$
$$k_6(\text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}) = 7.9\times10^{13}\exp(-22600/RT). \quad (24)$$

Equation 22′ would hold approximately even in the presence of nitrogen oxide, assuming the rate constants k_{17} and k_{18} have the same order of magnitude because of the similarity of both reactions. Thus the rates of propynenitrile and hydrogen cyanide formation could be expressed by

$$R_{C_4HCN}/R_{HCN} \simeq (k_{17}[C_4H_3(1)]_{ss}[NO])/(k_{18}[C_6H_5]_{ss}[NO])$$
$$\simeq [C_4H_3(1)]_{ss}/[C_6H_5]_{ss}. \quad (25)$$

However, the above rate ratio obtained experimentally was

$$R_{C_2HCN}/R_{HCN} = 18 \exp(-15600/RT). \quad (26)$$

The observed rate for the formation of propynenitrile is much smaller than that predicted from the above mechanism. The chain propagation step of Reactions 5 and 6 is open to question; Reaction 6 particularly seems uncertain. The validity of the above discussion is based on the reliability of the rate constants used.

Alternative Mechanism for the Pyrolysis: An alternative chain propagation process is as follows:[17]

$$C_2H + C_2H_2 \longrightarrow C_4H_3(2), \quad \Delta H^\circ = -44.8, \quad (27)$$

$$C_4H_3(2) + C_2H_2 \longrightarrow C_4H_4 + C_2H, \quad \Delta H^\circ = 11.7. \quad (28)$$

The reaction of $C_4H_3(2)$ with NO produces HCN by

$$C_4H_3(2) + NO \longrightarrow C_2HCHO + HCN. \quad (29)$$

The C_2H radical is reported not to react with NO.[5] A fast conversion process of $C_4H_3(1)$ into $C_4H_3(2)$ or C_2H is essential for the above chain propagation step to be compatible with the most predominant initiation step, Reaction 4.

If the isomerization of $C_4H_3(1)$ to $C_4H_3(2)$ such as

$$C_4H_3(1) \longrightarrow C_4H_3(2), \quad \Delta H^\circ = 20.9 \quad (30)$$

were fast enough, the equilibrium would be established at an early stage of the reaction, since the reverse reaction would also be fast. The equilibrium concentrations are dominated by the heat of reaction because of the small entropy change of Reaction 30. At the present temperatures the equilibrium concentration of $C_4H_3(1)$ should be greater than that of $C_4H_3(2)$. This implies that the yield of propynenitrile should also be greater than that of hydrogen cyanide, which conflicts with the present observation. Thus the direct conversion of $C_4H_3(1)$ into $C_4H_3(2)$ will be too slow to be the initiation step.

Another process is the conversion of $C_4H_3(1)$ into C_2H radical. The H atom abstraction reaction of $C_4H_3(1)$ from C_2H_2 is an ineffective path to generate C_2H radical in view of the heat of reaction:

$$C_4H_3(1) + C_2H_2 \longrightarrow C_4H_4 + C_2H, \quad \Delta H^\circ = 32.6. \quad (31)$$

The following path seems most promissing. The addition of $C_4H_3(1)$ to C_2H_2 is much faster than Reaction 31 with the rate constant of k_5 (Eq. 23):

$$C_4H_3(1) + C_2H_2 \longrightarrow H_2C{=}C(C_2H){-}CH{=}\dot{C}H, \quad \Delta H^\circ = -20.5. \quad (5)$$

A successive H atom shift and the C–C bond rupture will occur:

$$H_2C{=}C(C_2H){-}CH{=}\dot{C}H \longrightarrow H\dot{C}{=}C(C_2H){-}CH{=}CH_2,$$

$$\longrightarrow HC{\equiv}C{-}CH{=}CH_2 + C_2H, \quad \Delta H^\circ = 53.1. \quad (32)$$

The radical chain mechanism of 1-buten-3-yne formation is completed by

$$2C_4H_3(2) \longrightarrow \text{termination}. \quad (33)$$

Application of steady-state approximation to $C_4H_3(1)$, $C_4H_3(2)$, C_6H_5, and C_2H radicals gives the following equations:

$$R_{C_4H_4} = k_{28}(k_4/2k_{33})^{1/2}[C_2H_2]^2, \quad (34)$$

$$[C_4H_3(1)]_{ss} = (k_4/k_5)[C_2H_2], \quad (35)$$

$$[C_4H_3(2)]_{ss} = (k_4/2k_{33})^{1/2}[C_2H_2]. \quad (36)$$

As in the mechanism previously proposed, the second-order rate of 1-buten-3-yne formation is also derived from the revised mechanism. The heat of reaction for Reaction 28 is smaller than the activation energy estimated for Reactions 6 and 8 (*ca.* 18—23 kcal/mol).[7] Consequently Reaction 28 is likely to occur as the alternative to Reaction 6 forming 1-buten-3-yne. Substituting the rate constants in the right-hand side of Eqs. 35 and 36 for estimated ones, the ratio of the two ethynylvinyl radicals is calculated. The rate constant k_{33} adopted is as follows:[7]

$$k_{33}(\text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}) = 2.0 \times 10^{12}. \quad (37)$$

The estimated values of $[C_4H_3(1)]_{ss}/[C_4H_3(2)]_{ss}$,

$$[C_4H_3(1)]_{ss}/[C_4H_3(2)]_{ss} = 19 \exp(-17200/RT), \quad (38)$$

agrees with the observed value of R_{C_2HCN}/R_{HCN}. This suggests that the revised mechanism is most probable one for the formation of 1-buten-3-yne in the presence and absence of nitrogen oxide.

Mechanism of Inhibited Pyrolysis. A radical chain mechanism for the inhibited formation of 1-buten-3-yne will be set up to be in line with that for the pyrolysis of acetylene by itself. Propynenitrile was not distinguished from cyanogen by the gas-chromatographic analysis. Shock tube experiments showed that the secondary reaction of hydrogen cyanide and that with acetylene and nitrogen oxide can be ignored in the temperature range studied.[18] Thus the propynenitrile originates from the reaction of nitrogen oxide with acetylene.

The characteristic features of inhibited 1-buten-3-yne formation by nitrogen oxide can be explained by the following radical chain mechanism:

$$2C_2H_2 \longrightarrow C_4H_3(1) + H, \quad (4)$$

$$C_4H_3(1) + C_2H_2 \longrightarrow C_6H_5, \quad (5)$$

$$C_4H_3(1) + NO \longrightarrow C_2HCN + H_2CO, \quad (17)$$

$$C_6H_5 \longrightarrow C_4H_4 + C_2H, \quad (32)$$

$$C_2H + C_2H_2 \longrightarrow C_4H_3(2), \quad (27)$$

$$C_4H_3(2) + C_2H_2 \longrightarrow C_4H_4 + C_2H, \quad (28)$$

$$C_4H_3(2) + NO \longrightarrow C_2HCHO + HCN, \quad (29)$$

$$C_2HCHO \longrightarrow C_2H + CHO, \quad (39)$$

$$CHO \longrightarrow CO + H \quad \Delta H^\circ = 28.6, \quad (40)$$

$$2C_4H_3(2) \longrightarrow \text{termination}. \quad (33)$$

Assuming the steady-state concentrations of the radicals in the above mechanism, we can derive

$$R_4 = 2R_{33} + (R_{29} - R_{39}). \quad (41)$$

Here the small effect of NO with $C_4H_3(1)$ radical on the reduction of 1-buten-3-yne formation rate is neglected. In the absence of nitrogen oxide Eq. 41 is reduced to

$$R_4 = 2R_{33}. \quad (41')$$

When the rate of Reaction 29 is greater than that of Reaction 39, the steady-state concentration of $C_4H_3(2)$ in the presence of nitrogen oxide ($[C_4H_3(2)]_{ss}^{NO}$) is lower than that in its absence ($[C_4H_3(2)]_{ss}$; the inhibition by nitrogen oxide occurs. The observed second-order rates with and without nitrogen oxide are directly

proportional to the steady-state concentrations of $C_4H_3(2)$ radical present in the systems:[7]

$$[C_4H_3(2)]^{NO}_{ss}/[C_4H_3(2)]_{ss} = R^{NO}_{C_4H_4}/R_{C_4H_4}, \quad (42)$$

$$= 18 \exp(-9300/RT). \quad (42')$$

It is observed that the inhibited rates of 1-buten-3-yne formation are hardly affected by the amounts of nitrogen oxide added (Fig. 2). The attainment of "limiting rate" can be easily accounted for by the above mechanism. When the amount of nitrogen oxide is increased to some extent, the rate of propynal generation is accelerated by Reaction 29 to the same extent, and in turn by Reaction 39 the same amount of the C_2H radical is regenerated as that of $C_4H_3(2)$ radical scavenged by Reaction 29 at a definite temperature. The C_2H radical is quickly converted into $C_4H_3(2)$ radical by Reaction 27. Thus the steady-state concentration of the $C_4H_3(2)$ radical is not affected by further addition of nitrogen oxide at a definite temperature. The present results are in agreement with those obtained at lower temperatures by Cullis *et al.*[3]

With increase in temperature the rate of Reaction 39 increases up to that of Reaction 29. In this case (Eq. 41') no inhibition occurs, the steady-state concentration of $C_4H_3(2)$ radical being the same as that in the absence of nitrogen oxide. Actually, however, the 1-buten-3-yne begins to decompose at around 1350 K. The yield-temperature plots of 1-buten-3-yne are almost the same as those in the C_2H_2–Ar system above 1350 K. This suggests that the radical concentrations relevant to its formation and decomposition remain unchanged in the presence of nitrogen oxide.

The rate of propynenitrile formation is given by

$$R_{C_4HCN} = k_{17}[C_4H_3(1)]_{ss}[NO]. \quad (43)$$

Since the yields of propynenitrile are very small as compared with those of hydrogen cyanide, the steady-state concentration of $C_4H_3(1)$ can be approximated by Eq. 35. Equation 43 is then expressed by

$$R_{C_4HCN} = (k_4k_{17}/k_5)[C_2H_2][NO]. \quad (43')$$

The rate expression of propynenitrile formation is the same in both inhibited and uninhibited regions. On the other hand, within the present errors the yield-temperature plots of hydrogen cyanide are fitted to a single straight line in the temperature range studied. For the sake of simplicity, the rate expression in the uninhibited region is extended to the inhibited region:

$$R_{HCN} = k_{29}[C_4H_3(2)]_{ss}[NO]$$

$$= k_{29}(k_4/2k_{33})^{1/2}[C_2H_2][NO]. \quad (44)$$

Since Reaction 17 and 29 are of the same type, k_{17} and k_{29} are expected to be nearly equal. As shown by Eqs. 43 and 44, the steady-state concentrations are related to the observed rates:

$$[C_4H_3(1)]_{ss}/[C_4H_3(2)]_{ss} = R_{C_4HCN}/R_{HCN}. \quad (45)$$

The validity of the discussion on the pyrolysis mechanism is verified under the above conditions. The agreement between the observed and calculated values (Eqs. 26 and 38) is excellent.

By a comparison with the observed rates for propynenitrile and hydrogen cyanide formation, k_{17} and k_{29} are estimated from Eqs. 43' and 44, respectively:

$$k_{17}(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = 1.8\times10^{12} \exp(-12400/RT), \quad (46)$$

$$k_{29}(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = 2.3\times10^{12} \exp(-14900/RT). \quad (47)$$

The small inhibiting effect of NO with $C_4H_3(1)$ radical being neglected, k_{17} is compared with k_{29} obtained in the inhibited region. The activation energy and frequency factor have approximately equal values in k_{17} and k_{29}. In the derivation of Eq. 45 (analogously Eq. 25), k_{17} was assumed to be equal to k_{29}, which is supported by Eqs. 46 and 47. It is noteworthy that the observed second-order rate constant for propynenitrile generation (k_3) has higher activation energy than that of hydrogen cyanide (k_2), whereas the activation energy of k_{17} is nearly the same as that of k_{29}. As can be seen from Eqs. 43 and 44, the difference between k_2 and k_3 results from the fact that in the present radical chain mechanism the steady-state concentration of $C_4H_3(1)$ is related to that of $C_4H_3(2)$ such as Eq. 38. Gay *et al.*[20] and Bopp and Kern[21] detected C_4H_3 radical in the pyrolysis of acetylene at temperatures above 1700 K by use of a time-of-flight mass spectrometer. The C_4H_3 radical as detected with mass spectrometer at $m/e=51$, however, cannot be distinguished among the C_4H_3 radical isomers. On the contrary, the addition of nitrogen oxide revealed that the C_4H_3 radicals are $C_4H_3(1)$ and $C_4H_3(2)$, both radicals being responsible for the formation of 1-buten-3-yne. Reaction 4 was predicted to be the most predominant initiation step on the basis of the heat of reaction. Detection of propynenitrile formation upon the addition of nitrogen oxide would provide experimental support for the occurrence of Reaction 4 as the initiation step.

Formation Mechanism for the Other Products. No significant change appears in the shape of yield-temperature plots of hydrogen (Fig. 9) and other major and minor products with appreciable increase in their yields at higher temperatures. The formation reactions will be unaltered, whereas the concentrations of the radicals relevant to their formation would increase considerably by the addition of nitrogen oxide.

As to the major products, the hydrogen will be generated by

$$H + C_2H_2 \longrightarrow H_2 + C_2H, \qquad \Delta H^\circ = 7.7, \quad (48)$$

and 1,3-butadiyne will be formed by

$$C_2H + C_2H_2 \longrightarrow C_4H_2 + H, \qquad \Delta H^\circ = -4.8. \quad (49)$$

H and C_2H are not scavenged by nitrogen oxide. Increase in H atom concentration will cause the increase of hydrogen and 1,3-butadiyne yields by Reactions 48 and 49, respectively. The H atom responsible for the increase in the yields of major and minor hydrocarbons will be generated by the decomposition of formyl radical:

$$CHO \longrightarrow H + CO. \quad (40)$$

Thus the concentration of H atom is increased by the presence of nitrogen oxide. H atom participated in all the secondary reactions to form ethylene, allene, propyne, and benzene such as[7]

$$H + C_2H_2 \longrightarrow C_2H_3 \xrightarrow{C_2H_2} C_2H_4,$$

$$C_2H_3 + C_2H_2 \longrightarrow C_4H_5 \xrightarrow{C_2H_2} C_6H_7,$$

$$C_6H_7 \longrightarrow C_3H_3 \xrightarrow{C_2H_2} C_3H_4,$$

$$\longrightarrow C_6H_6.$$

As can be seen from Fig. 9, the yields are hardly dependent on the amounts of nitrogen oxide added. At lower temperatures the yields of the above products are hardly increased by the addition of nitrogen oxide. The steady-state concentration of H atom in the absence of nitrogen oxide will be great enough relative to its increase by the addition of nitrogen oxide. With increase in temperature the H atom concentration increases gradually. The H atom, however, is converted into larger radicals by the subsequent reactions with acetylene. Thus the effect of the increase in the H atom concentration is averaged over the relevant radicals, the influence of the amounts of added nitrogen oxide being small.

The reactions mentioned above are too simple to give explicit formulas of major and minor hydrocarbons generation in the presence of nitrogen oxides. However, the main feature of the inhibited pyrolysis of acetylene can be interpreted by the present mechanism.

The author is grateful to Prof. Kenji Kuratani, Tokyo University, for his interest in this work and for his valuable discussions. Thanks are also due to Mr. Yoshinori Sano for the purification of nitrogen oxide and for the preparation of hydrogen cyanide.

The Reaction of Hydrogen Chloride with Nitrogen Oxide in Shock Waves

Tetsuo HIGASHIHARA, Ko SAITO,* and Ichiro MURAKAMI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730
(Received March 1, 1978)

The reaction of hydrogen chloride with nitrogen oxide in the temperature range 2670—3850 K and in the pressure range 2.5—3.5 atm has been studied behind reflected shock waves by monitoring the IR emission of HCl. When nitrogen oxide was added to the HCl–Ar system, the rate of HCl dissociation was found to be accelerated. For the early stage of reaction, the rate equation obtained was $-\mathrm{d[HCl]}/\mathrm{d}t = 10^{11.7} \exp(-33\ \mathrm{kcal}/RT)[\mathrm{HCl}]^{1.3}[\mathrm{NO}]^{0.5}$ mol cm^{-3} s^{-1}. As the initiation step, Reaction 1 was found to be more important than Reaction 2 under these experimental conditions:

$$\mathrm{HCl} + \mathrm{NO} \longrightarrow \mathrm{HNO} + \mathrm{Cl}, \quad (1)$$

$$\mathrm{HCl} + \mathrm{Ar} \longrightarrow \mathrm{H} + \mathrm{Cl} + \mathrm{Ar}. \quad (2)$$

The rate constant of Reaction 1 was determined to be $k_1 = 10^{13.2} \exp(-50.2\ \mathrm{kcal}/RT)$ cm^3 mol^{-1} s^{-1}.

The reactions of NO with H_2 or NH_3 have been studied by several investigators.[1-5] Asaba and coworkers[1,2] found the initiation step to be the abstraction of a hydrogen atom by nitrogen oxide, and determined its rate constant. This is the only datum available for the abstraction reaction by nitrogen oxide at high temperatures. In this paper, in order to clarify the role of nitrogen oxide in the decomposition of hydrogen containing compounds, we studied the reaction of hydrogen chloride with nitrogen oxide in shock waves by monitoring the IR emission of HCl.

Experimental

The shock tube was 5 cm in internal diameter, as described previously.[6] All experiments were performed behind reflected shock waves. The IR emission from the fundamental vibration-rotation bands of HCl at 3.45 μm was detected by an AuGe detector through a CaF_2 window which was placed at a position 2 cm upstream from the end plate. The appropriate wavelength was selected by a grating monochromator. The output signal was amplified and recorded on an oscilloscope. The mole fractions of the samples were as follows: 4% HCl–96% Ar, 8% HCl–92% Ar, 4% HCl–4% NO–92% Ar, 4% HCl–8% NO–88% Ar, 8% HCl–4% NO–88% Ar, and 8% HCl–8% NO–84% Ar. The post-shock pressure (P_5) and temperature (T_5) were in the ranges 2.5—3.5 atm and 2670—3850 K, respectively.

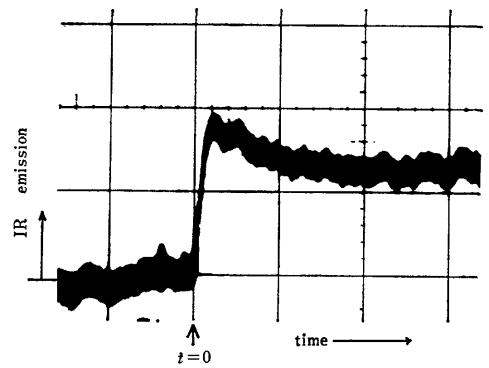

Fig. 1. A typical oscillogram of the IR emission at 3.45 μm. Run No. 231; conditions are summarized in Table 2. Sweep time=50 μs/division.

Results and Discussion

A typical oscillogram is shown in Fig. 1 (Run No. 231). This figure shows the IR emission at 3.45 μm, whose intensity corresponds to the concentration of HCl. The slow rise of the IR emission is due to the relatively long time constant (about 10 μs) of the AuGe detector. The rate of HCl dissociation ($-\mathrm{d[HCl]}/\mathrm{d}t$) was obtained from the initial gradient of the IR emission intensity. The Arrhenius plots of $-\mathrm{d[HCl]}/\mathrm{d}t$ obtained for four different mixtures are shown in Fig. 2. It is found that the rate of HCl dissociation was influenced by the initial concentrations of HCl and NO. The reaction orders with respect to the initial concentrations of HCl and NO were determined to be about 1.3 and 0.5, respectively. Thus,

$$-\mathrm{d[HCl]}/\mathrm{d}t = k_{\mathrm{overall}}[\mathrm{HCl}]^{1.3}[\mathrm{NO}]^{0.5}.$$

The Arrhenius plot of k_{overall} thus obtained is shown in Fig. 3. The best fit line gives the overall rate constant as

$$k_{\mathrm{overall}} = 10^{11.7} \exp(-33\ \mathrm{kcal}/RT)\ \mathrm{cm}^{2.4}\ \mathrm{mol}^{-0.8}\ \mathrm{s}^{-1}.$$

In order to check the experimental method used in this work, HCl–Ar mixtures were also shock-heated and the rates of HCl dissociation were measured similarly. In Fig. 4, the second order rate constants, k_{second}= (—d[HCl]/dt)/[HCl][Ar], are plotted in the Arrhenius form for mixtures with and without NO. In this figure, the data obtained by Jacobs *et al.*[7] are also shown by a broken line. In spite of different experimental conditions and methods of the data reduction in the two works, our rate data for the HCl dissociation without NO are in good agreement with those of Jacobs. It was also found, as seen in Fig. 4, that the rate of HCl dissociation was accelerated by the addition of NO, and this effect was more remarkable at lower temperatures.

To clarify the dissociation kinetics of hydrogen chloride in the system involving nitrogen oxide, 26 elementary reactions (Mechanism I) were selected and tabulated in Table 1. Values of the rate constants for Reactions 2—26 were cited from the references. The numerical integrations of simultaneous rate equations for 15 species listed in Table 1 were performed on an

a) Units: mol cm^{-3} for concentration, s for time.

electronic computer to obtain the time histories of the concentrations of the reactants and products. There are no data for the rate constant of Reaction 1. Thus in the calculations the value of k_1 was varied in the range 10^9—2×10^{10} cm^3 mol^{-1} s^{-1}, and the value of k_1 was determined as the value at which the calculated history of HCl agreed best with that obtained from experiment. The fit of the calculations to the experiment is shown

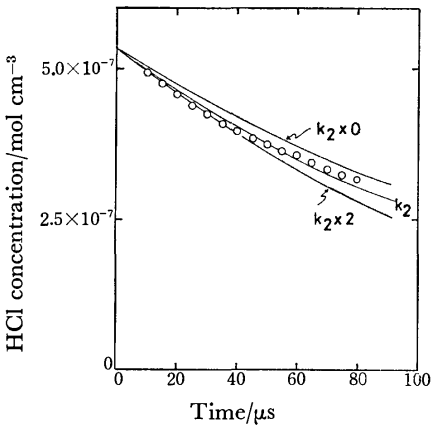

Fig. 6. Time histories of HCl calculated with various k_2 values for the conditions of Run No. 322. ○: Observed history, —: calculated histories for Mechanism I. The best fit value of k_2 is $k_2=10^{12.82}$ exp $(-70$ kcal/$RT)$[7] cm^3 mol^{-1} s^{-1} (middle curve). The value of k_2 is varied from 0 to 2 times the best-fit value.

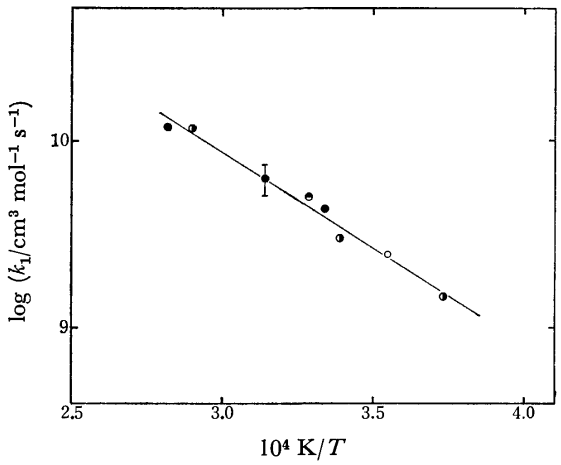

Fig. 7. Arrhenius plot of k_1. The error bar indicates the ±25% maximum uncertainty. Symbols are the same as in Fig. 2.

in Fig. 5 for Run No. 322 as an example. For checking the sensitivity, the value of k_1 was varied from 0 to 1.5 times the best value, and the histories of HCl were recalculated by using these values. The histories thus obtained are also shown in Fig. 5. From Fig. 5, it appears that the rate of HCl dissociation is strongly influenced by the value of k_1. The sensitivity of k_2 to the overall rate of HCl dissociation was also checked. The value of k_2 was varied from 0 to 2 times that listed in Table 1. Figure 6, which shows the results of the calculations for Run No. 322, reveals that the variation in k_2 has very little effect on the overall rate. Therefore, Reaction 1 is found to be predominant as the initiation step. The experimental conditions used for the estimation of k_1 and the values of k_1 determined at various temperatures are listed in Table 2. The Arrhenius plot of k_1 is shown in Fig. 7. The best fit line of the plot gives the rate expression as

$$k_1 = 10^{13.2} \exp(-50.2 \text{ kcal}/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

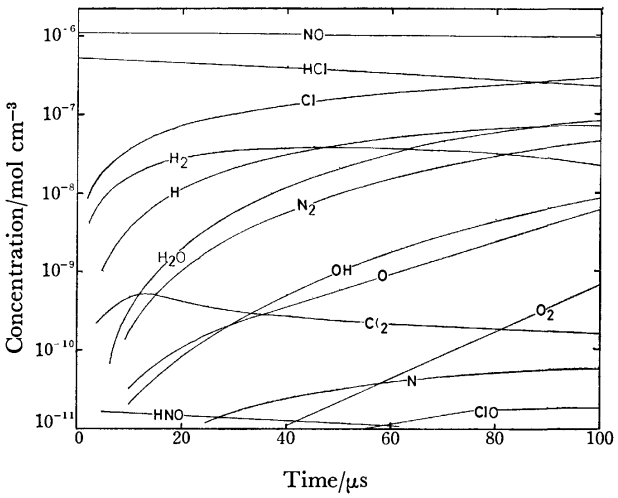

Fig. 8. Time dependent concentration changes of chemical species calculated with Mechanism I for the conditions of Run No. 322.

Figure 8 shows the time variation of the concentration of each chemical species for Run No. 322. The figure implies that Mechanism I can be reduced to only the first eight elementary reactions (1—8) (Mechanism II), since in the initial stage of reaction nitrogen oxide does not decrease largely and thus H_2O, OH, N_2, O, N, *etc.* are neglected. The calculated history of HCl for Mechanism II is shown by the broken line in Fig. 5.

Since the experimentally determined reaction orders were the average values in the initial stage (from 0 to about 30 μs), the reaction orders for HCl and NO, which were averaged between 0 and 30 μs, were calculated by using Mechanism I. The values calculated for HCl and NO were 1.06 and 0.62, respectively. Thus, the calculated reaction orders are comparable to the values determined experimentally. The rate of HCl

Table 2. Experimental conditions and determined rate constants

Run No.	Temp (K)	HCl (mol cm^{-3})	NO (mol cm^{-3})	Ar (mol cm^{-3})	$-$d[HCl]/dt (mol cm^{-3} s^{-1})	k_1 (cm^3 mol^{-1} s^{-1})
231	3185	9.295×10^{-7}	4.647×10^{-7}	1.023×10^{-5}	7.62×10^{-3}	6.23×10^{9}
232	2996	10.18	5.089	1.119	6.36	4.30
235	3544	8.062	4.031	0.887	8.02	11.6
261	3044	5.100	5.100	1.173	3.29	4.95
281	2819	11.94	11.94	1.253	10.6	2.46
321	2678	5.859	11.72	1.289	3.26	1.48
322	2949	5.345	10.69	1.176	3.75	3.00
331	3447	4.301	8.602	0.946	5.29	11.5

dissociation in Mechanism II is expressed as

$$-\mathrm{d[HCl]}/\mathrm{d}t = \underbrace{k_1[\mathrm{HCl}][\mathrm{NO}]}_{\text{term A}} + \underbrace{k_2[\mathrm{HCl}][\mathrm{Ar}]}_{\text{term B}} + \underbrace{(k_4[\mathrm{H}][\mathrm{HCl}] - k_5[\mathrm{H_2}][\mathrm{Cl}])}_{\text{term C}} + \underbrace{(k_6[\mathrm{Cl}][\mathrm{HCl}] - k_7[\mathrm{Cl_2}][\mathrm{H}])}_{\text{term D}}.$$

The contributions of terms A, B, C, and D to the rate of HCl dissociation are shown in Fig. 9 as a function of time for the conditions of Run No. 322. From this figure, it is found that terms A and C are important for the HCl consumption.

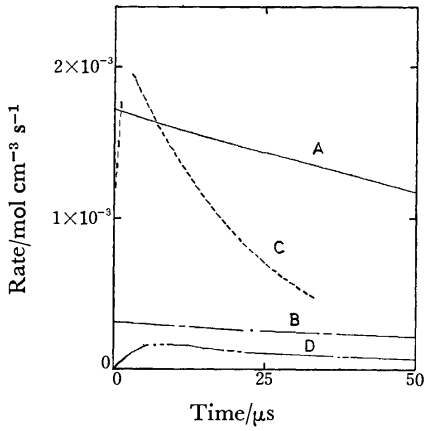

Fig. 9. Time variations of rate terms which contribute to the HCl dissociation. Symbols A, B, C, and D are explained in the text.

As the initiation step, the following three reactions are possible:

$$\mathrm{HCl} + \mathrm{NO} \longrightarrow \mathrm{HNO} + \mathrm{Cl}, \quad \Delta H^\circ_{298} = 53.2 \text{ kcal mol}^{-1}, \tag{1}$$

$$\mathrm{HCl} + \mathrm{NO} \longrightarrow \mathrm{H} + \mathrm{ClNO}, \quad \Delta H^\circ_{298} = 65.0 \text{ kcal mol}^{-1}, \tag{1'}$$

$$\mathrm{HCl} + \mathrm{Ar} \longrightarrow \mathrm{H} + \mathrm{Cl} + \mathrm{Ar}, \quad \Delta H^\circ_{298} = 103.1 \text{ kcal mol}^{-1}, \tag{2}$$

where the standard enthalpy changes (ΔH°_{298}) were calculated from JANAF Thermochemical Tables.[21] Reactions 1 and 1′ are not distinguishable because the decomposition rates of HNO and ClNO are very fast. However, because Reaction 1′ is more endothermic by 12 kcal mol^{-1} than Reaction 1, it seems to be reasonable to neglect Reaction 1′ as the initiation step. As shown in Fig. 6, even if Reaction 2 was ruled out, the rate of HCl dissociation did not change very much. Therefore, Reaction 1 was confirmed to be a more important initiation step than Reaction 2.

The activation energy of Reaction 1 was calculated by the bond-energy-bond-order (BEBO) method, which was developed by Johnston and Parr,[22,23] as 52.7 kcal mol^{-1}. The activation energy which was obtained in this work, 50.2 kcal mol^{-1}, is very close to this calculated value. It is interesting to compare the rate constant with that for a similar reaction

$$\mathrm{H_2} + \mathrm{NO} \longrightarrow \mathrm{HNO} + \mathrm{H}. \tag{27}$$

The rate constant of Reaction 27 was obtained as[2]

$$k_{27} = 10^{13.5} \exp(-55.2 \text{ kcal}/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

This activation energy is nearly equal to the standard enthalpy change (54.3 kcal mol^{-1}) of the reaction. The value of the A factor for k_{27} is larger than for k_1 by a factor of about 2. This difference is greater than the experimental error of ±25% maximum uncertainty in the determination of k_1. Since the ratio of the collision number for the H_2–NO system to that for the HCl–NO system was calculated as

$$Z_{\mathrm{H_2-NO}}/Z_{\mathrm{HCl-NO}} = 2.7,$$

the difference of the A factor may be due to the difference of collision numbers for Reactions 1 and 27.

The authors wish to thank Professor T. Asaba and Dr. N. Fujii of the University of Tokyo for providing us with the computer program.

The Reaction of Hydrogen Bromide with Nitrogen Oxide in Shock Waves

Tetsuo HIGASHIHARA, Ko SAITO,* and Ichiro MURAKAMI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received March 9, 1978)

The reaction of hydrogen bromide with nitrogen oxide in the temperature range 2000—3300 K and in the pressure range 0.7—3.8 atm has been studied behind reflected shock waves by monitoring the IR emission of HBr. For the early stage of the reaction, the rate equation obtained was $-d[HBr]/dt = k_{overall}[HBr]^{1\pm0.3}[NO]^{0.7\pm0.2}[Ar]^{0\pm0.1}$, where $k_{overall} = 10^{10.4\pm0.2} \exp\{-(23.2\pm3.0)\ \text{kcal}/RT\}\ \text{cm}^{2.1}\ \text{mol}^{-0.7}\ \text{s}^{-1}$. As the initiation step, Reaction 1 was found to be more important than Reaction 2:

$$HBr + NO \longrightarrow HNO + Br, \quad (1)$$

$$HBr + Ar \longrightarrow H + Br + Ar. \quad (2)$$

The rate constant of Reaction 1 was determined to be $k_1 = 10^{12.8} \exp(-30\ \text{kcal}/RT)\ \text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$.

There have been a few previous shock-tube investigations of the reactions of nitrogen oxide with other compounds. Asaba and coworkers[1,2] studied the reaction between H_2 and NO, and determined the initiation step and its rate constant to be

$$H_2 + NO \longrightarrow HNO + H, \quad (A)$$

$$k_A = 10^{13.5} \exp(-55.2\ \text{kcal}/RT)\ \text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}.$$

In the previous paper,[3] we studied the reaction of HCl with NO. In that work, we found that when nitrogen oxide was added to the HCl–Ar mixture the rate of HCl disappearance was significantly accelerated. On the basis of these experimental results, we discussed the role of NO in the HCl disappearance and determined the initiation step and its rate constant to be

$$HCl + NO \longrightarrow HNO + Cl, \quad (B)$$

$$k_B = 10^{13.2} \exp(-50.2\ \text{kcal}/RT)\ \text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}.$$

In order to make the role of NO in the disappearance rate of hydrogen halide more clear, we studied the reaction of hydrogen bromide with nitrogen oxide. Since the rate constant of Reaction 2 was determined in the HBr–Ar system by Giedt *et al.*[4] in the temperature range 2100—4200 K:

$$HBr + Ar \longrightarrow H + Br + Ar, \quad (2)$$

the influence of NO on the rate of HBr disappearance could be investigated by adding NO to the HBr–Ar system.

Experimental

The shock tube was 5 cm in internal diameter, and had a 3.8 cm long test section. The side of the tube was fitted with a CaF_2 window mounted flush with the interior surface at a position 2 cm upstream from the end plate. The shocks were generated by high pressure hydrogen in a 1.7 m long driver section. The system was pumped off by an oil-diffusion pump to less than 1×10^{-4} Torr before each run. All experiments were performed behind reflected shock waves.

The concentration change of hydrogen bromide was monitored by 3.93 μm emission, which was detected by an AuGe detector at 77 K. The detector was coupled to an amplifier, whose output was displayed directly on an oscilloscope.

Hydrogen bromide was produced by dropping bromine on tetrahydronaphthalene.[5] The gas thus obtained was solidified and degassed at the temperature of liquid N_2–ethanol slush and purified by trap to trap distillation at this temperature. Argon and nitrogen oxide from commercial cylinders were used without further purification.

The gas mixtures studied and the experimental conditions are listed in Table 1. Fig. 1 shows a typical oscillogram of

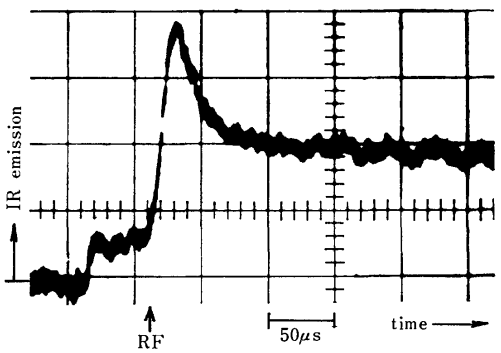

Fig. 1. Typical oscillogram of the experiments. Run No. 181; $T = 2977$ K, HBr $= 5.955 \times 10^{-7}$ mol/cm³, NO $= 2.975 \times 10^{-7}$ mol/cm³, Ar $= 7.400 \times 10^{-6}$ mol/cm³. The trace shows the IR emission at 3.93 ± 0.1 μm. RF indictes the time at which reflected shock front reached the window.

the experiments. The slow rise of IR emission is due to the relatively long time constant of the AuGe detector. From the signals of two piezo-gauges, the shock speed was calculated.

Results and Discussion

The rate of HBr disappearance ($-$d[HBr]/dt) was obtained from the gradient of the IR emission intensity in an early stage of reaction. Figures 2, 3, and 4 show the Arrhenius plots of $-$d[HBr]/dt for pairs of different samples. In Fig. 2, in each of these samples at about the same temperature the concentrations of NO and Ar are almost equal, but there are two- and four-fold differences in the concentration of HBr. In Fig. 3, there are differences in the concentration of NO, and in Fig. 4, the argon density is varied about two- and four-fold, holding the concentrations of the other reactants constant. The reaction orders with respect to the initial concentrations of HBr, NO, and Ar were obtained from these figures at 2500 K to be 1 ± 0.3, 0.7 ± 0.2, and 0 ± 0.1, respectively. The fact that the reaction order with respect to Ar is small, nearly zero, implies that Reaction 2 becomes unimportant with the addition of NO. Later, we will find that this value of

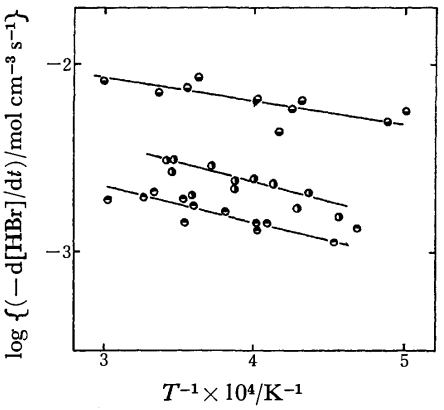

Fig. 2. Arrhenius plot of the rate of HBr disappearance for samples 2), 4), and 5). This figure shows that the reaction order for HBr is 1 ± 0.3 at 2500 K. Symbols are summarized in Table 1.

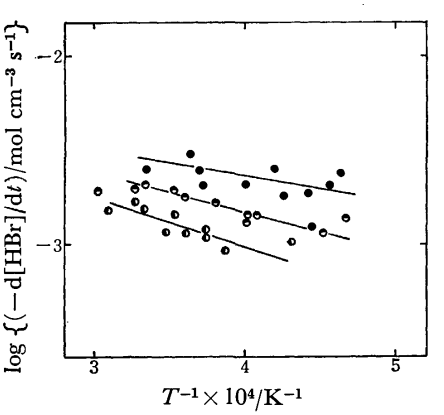

Fig. 3. Arrhenius plot of the rate of HBr disappearance for samples 3a), 4), and 6). This figure shows that the reaction order for NO is 0.7 ± 0.2 at 2500 K. Symbols are summarized in Table 1.

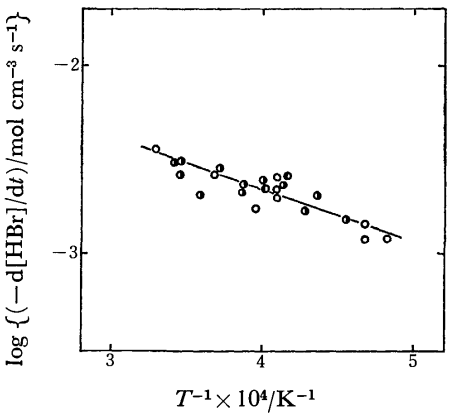

Fig. 4. Arrhenius plot of the rate of HBr disappearance for samples 1), 2), and 3b). This figure shows that the reaction order for Ar is 0 ± 0.1 at 2500 K. Symbols are summarized in Table 1.

the reaction order is in good agreement with the value (0—0.1) which was estimated from the calculations with an assumed reaction mechanism. From Fig. 3, the reaction order with respect to NO seems to decrease slightly with increasing temperature. This may be explained qualitatively by the fact that at higher temperatures Reaction 2 begins to contribute gradually to the rate of HBr disappearance (see Fig. 6). Thus, the overall rate equation can be expressed as

Table 2. Elementary reactions and kinetic parameters, $k=AT^B\exp(-E/RT)$

a) Units: mol cm^{-3} for concentration, s for time.

$$-d[HBr]/dt = k_{overall}[HBr]^{1\pm0.3}[NO]^{0.7\pm0.2}[Ar]^{0\pm0.1}.$$

It is to be noted that this equation can be applied in an early stage of reaction. Reaction orders change with time, because Reactions 4—7, which are shown in Table 2, become predominant with time. Calculations of the reaction orders with time are discussed later and shown in Fig. 11. Figure 5 shows the Arrhenius plot of $k_{orerall}$ for all data obtained under various experimental conditions. It is found that all data points fall around one straight line. The best fit line gives the rate expression as

$$k_{overall} = 10^{10.4\pm0.2} \exp\{-(23.2\pm3.0)\ \text{kcal}/RT\}\ \text{cm}^{2.1}\ \text{mol}^{-1}\ \text{s}^{-1}.$$

To ascertain the influence of NO on the rate of HBr disappearance, a 4% HBr–96% Ar mixture was also shock-heated, and the second order rate constants, $k_{second}=(-d[HBr]/dt)/[HBr][Ar]$, were compared between the mixtures with and without NO (Fig. 6). In this figure, the data obtained by Giedt *et al.*[4] for HBr–Ar mixture are also shown by a broken line. In spite of the different experimental conditions and methods of data reduction in the two works, our rate data for HBr disappearance without NO are in good agreement with those of Giedt *et al.* It is also found, in Fig. 6, that the rate of HBr disappearance is accelerated by the addition of NO; this effect is remarkable at lower temperatures. Similar facts for HCl–NO–Ar mixtures[3] were also found in previous work.

To clarify the kinetics of HBr disappearance for mixtures involving NO, 26 elementary reactions (Mechanism I) were selected and tabulated in Table 2. Using tabulated rate constants for Reactions 2—26, concentration changes of HBr were calculated and were compared with the histories of HBr (IR intensity) obtained experimentally, where the emission intensity at zero time was determined by extrapolating the emission trace to the reflected shock front. In the calculations, since there are no rate data for Reaction 1, the value of k_1 was varied and then determined so as to fit the experimental histories of HBr at various temperatures. The value of k_1 thus determined is expressed as

$$k_1 = 10^{12.8} \exp(-30\ \text{kcal}/RT)\ \text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}.$$

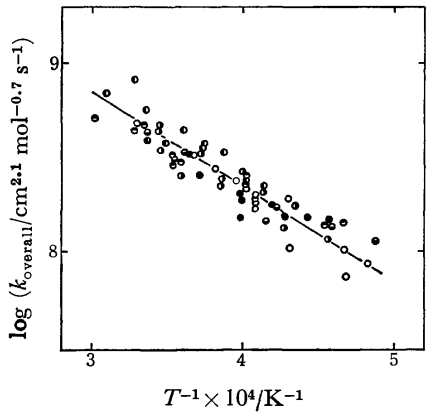

Fig. 5. Arrhenius plot of $k_{overall}$. Symbols are summarized in Table 1.

Examples of a fitting between the calculated and observed history are shown in Figs. 7a, b, c, and d for four cases under various experimental conditions. Figure 8 shows the time variations of the concentrations of HBr, NO, and the main products. As shown in this figure, NO does not decompose remarkably and the concentrations of N, O, OH, H_2O, and BrO are very low, at least in the early stages of reaction. Therefore, Mechanism I can be reduced to only the first eight elementary reactions (Mechanism II). The histories of HBr were also calculated by using Mechanism II and no discrepancy was found with those calculated with Mechanism I, implying that the rate of HBr disappearance was mainly governed by Reactions 1—8.

Sensitivity checks were performed on k_1 and k_2 for

(b) Run No. 204; T=2508 K, HBr=1.784×10^{-7} mol/cm^3, NO=6.337×10^{-7} mol/cm^3, Ar=8.925×10^{-6} mol/cm^3. (c) Run No. 110; T=2529 K, HBr=2.705×10^{-7} mol/cm^3, NO=2.075×10^{-7} mol/cm^3, Ar=3.381×10^{-6} mol/cm^3. (d) Run No. 181; conditions are the same as Fig. 1.

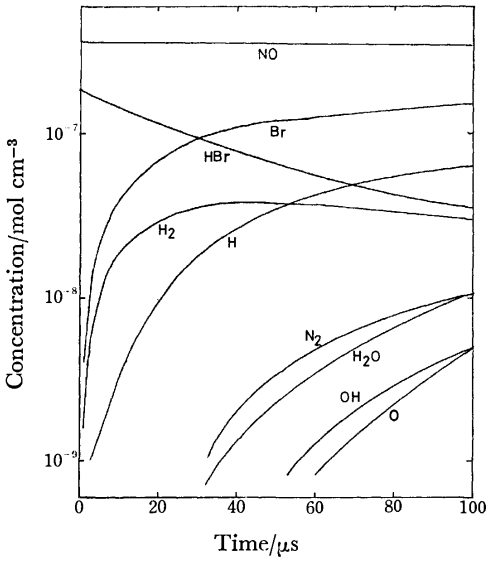

Fig. 8. Time dependent concentration changes of chemical species for Run No. 166. $T=2828$ K, HBr$=1.867\times10^{-7}$ mol/cm^3, NO$=3.735\times10^{-7}$ mol/cm^3, Ar$=9.337\times10^{-6}$ mol/cm^3.

the purpose of examining how the overall rate of HBr disappearance was influenced by k_1 and k_2. The values of k_1 and k_2 were varied in the ranges of 0 to 1.5 times and 0 to 2 times, respectively. The results of the calculations at temperatures 2179 and 2977 K are shown in Figs. 9 and 10, respectively. These figures show that the rate of HBr disappearance is remarkably influenced by the value of k_1. On the other hand, at 2179 K the influence of the variation of k_2 is very little, while at 2977 K it becomes slightly appreciable. These facts suggest that Reaction 1 is more important than Reaction 2 for the rate of HBr disappearance at least in the low temperature region, and that the importance of Reaction 2 increases with increasing temperature.

Figure 11 shows the time variations of reaction orders with respect to the concentrations of HBr, NO, and Ar; these were calculated by using Mechanism I for the conditions of Run No. 110. When the reaction order for HBr was calculated, for example, the initial concentration of HBr was changed by a factor of 2 and those of NO and Ar were not changed, then the rate of HBr disappearance was calculated and compared with that for the conditions of Run No. 110, where the rates were obtained as an average over every 2 μs intervals, *i.e.*, $-\mathrm{d[HBr]}/\mathrm{d}t=([\mathrm{HBr}]_t-[\mathrm{HBr}]_{t-2})/2$. From Fig. 11, in the initial stage, the reaction orders are 1, 0.5—0.9, and 0—0.1 with respect to HBr, NO, and Ar, respectively. These calculated reaction orders are in good agreement with those determined experimentally, as mentioned already. Several calculated results showed that the reaction orders with respect to NO and Ar were dependent on the value of k_1. That is, as the value of k_1 decreases, the reaction order for NO decreases and that for Ar increases. The agreement of the reaction orders between the calculation and the observation implies that the value of k_1 determined is reasonable.

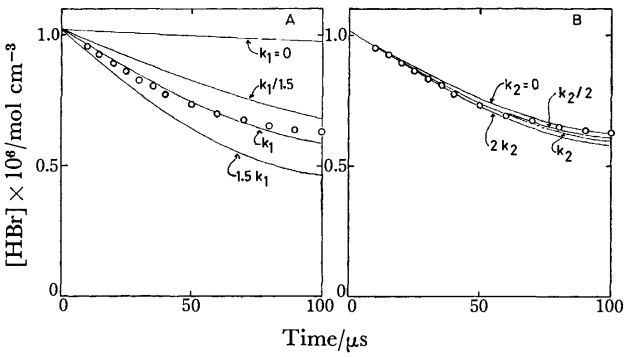

Fig. 9. Sensitivity of calculated HBr concentration to the value of k_1 (Fig. A) and k_2 (Fig. B) for Run No. 189. $T=2179$ K, HBr$=1.022\times10^{-6}$ mol/cm^3, NO$=5.112\times10^{-7}$ mol/cm^3, Ar$=1.278\times10^{-5}$ mol/cm^3. ○: Experimental history, —: histories calculated by using various values of k_1 and k_2.

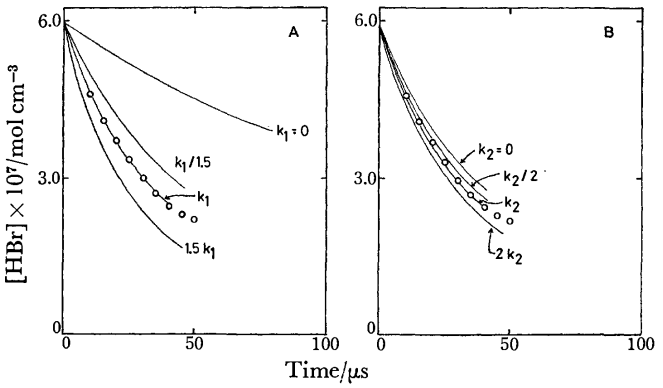

Fig. 10. Sensitivity of calculated HBr concentration to the values of k_1 (Fig. A) and k_2 (Fig. B) for Run No. 181. Conditions are the same as Fig. 1. ○: Experimental history, —: histories calculated by using various values of k_1 and k_2.

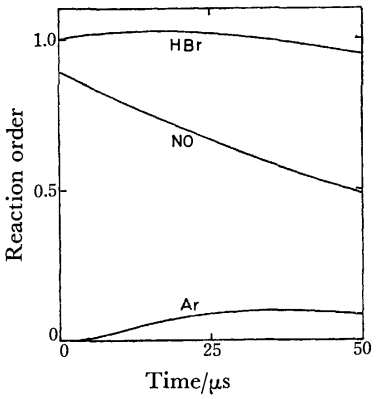

Fig. 11. Time variations of the reaction orders with respect to the initial concentrations of HBr, NO, and Ar for Run No. 110. Conditions are the same as Fig. 7 (c).

The rate of HBr disappearance in Mechanism II is expressed as

$$-\mathrm{d[HBr]}/\mathrm{d}t=\underbrace{k_1[\mathrm{HBr}][\mathrm{NO}]}_{\text{term A}}+\underbrace{k_2[\mathrm{HBr}][\mathrm{Ar}]}_{\text{term B}}+\underbrace{k_4[\mathrm{H}][\mathrm{HBr}]-k_5[\mathrm{H_2}][\mathrm{Br}]}_{\text{term C}}$$

$$+ \underbrace{k_6[HBr][Br] - k_7[Br_2][H]}_{\text{term D}}.$$

The contributions of terms A, B, C, and D to the rate of HBr disappearance are shown in Fig. 12 as a function of time for the conditions of Run No. 110. This figure shows that terms A and C are dominant in the rate of HBr disappearance, comfirming the importance of Reactions 1, 4, and 5.

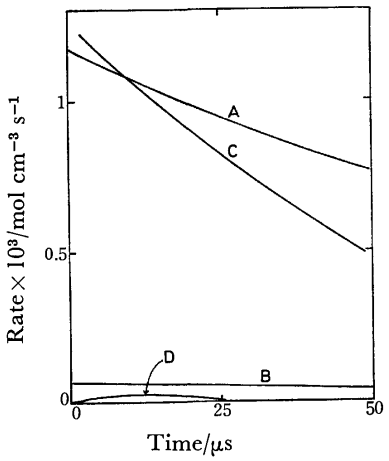

Fig. 12. Time variations of the rate terms which contribute to HBr disappearance for Run No. 110. Conditions are the same as Fig. 7(c). Terms A, B, C, and D are explained in the text.

Reaction B and Reaction 1 are expected to have similar activated complexes. According to the transition state theory, the ratio of k_B to k_1 is expressed as

$$k_B/k_1 = (F_{(HBr)}/F_{(HCl)}) \times (F^{\neq}_{(HCl-NO)}/F^{\neq}_{(HBr-NO)}) \times \exp\{-(E_{0(B)} - E_{0(1)})/RT\} \quad (I)$$

where $F_{(X)}$ is the partition function of species X, E_0 is the activation energy, and superscript $\neq$ denotes activated complex. Assuming that the electronical and vibrational partition functions are canceled out, Eq. I can be rewritten as

$$\begin{aligned} k_B/k_1 &= (f_{t(HBr)}/f_{t(HCl)}) \times (f_{r(HBr)}/f_{r(HCl)}) \\ &\quad \times (f^{\neq}_{t(HCl-NO)}/f^{\neq}_{t(HBr-NO)}) \times (f^{\neq}_{r(HCl-NO)}/f^{\neq}_{r(HBr-NO)}) \\ &\quad \times \exp\{-(E_{0(B)} - E_{0(1)})/RT\} \\ &= (M_{(HBr)}/M_{(HCl)})^{3/2} \times (I_{(HBr)}/I_{(HCl)}) \\ &\quad \times (M_{(HCl-NO)}/M_{(HBr-NO)})^{3/2} \\ &\quad \times (I_{A(HCl-NO)} I_{B(HCl-NO)} I_{C(HCl-NO)} / \\ &\quad I_{A(HBr-NO)} I_{B(HBr-NO)} I_{C(HBr-NO)})^{1/2} \\ &\quad \times \exp\{-(E_{0(B)} - E_{0(1)})/RT\}, \end{aligned} \quad (II)$$

where f_t and f_r are the translational and rotational partition functions, respectively, M is the mass of the molecule or activated complex, and I is the moment of inertia. Activation energies and bond lengths of activated complexes were calculated by the BEBO method. In the calculations, the bond angles of the complexes were assumed to be 108.6° for O–N–H and 180° for N–H–X. Thus, from Eq. II we obtain

$$\begin{aligned} (k_B/k_1)_{cal.} &= (81/36.5)^{3/2} \times (3.30/2.71) \times (66.5/111)^{3/2} \\ &\quad \times \{(1.72 \times 38.95 \times 40.67)/ \\ &\quad (1.82 \times 56.5 \times 58.36)\}^{1/2} \\ &\quad \times \exp\{-(52.7 - 36.7)\ \text{kcal}/RT\} \\ &= 1.26 \exp(-16.0\ \text{kcal}/RT). \end{aligned} \quad (III)$$

The ratio determined experimentally is

$$(k_B/k_1)_{exp.} = 2.51 \exp(-20.2\ \text{kcal}/RT). \quad (IV)$$

The agreement between the calculated and experimental ratios seems very good.

Oxidation of Propylene Adsorbed on Metal Oxides. Oxygen Species in Catalytic Oxidation

Yutaka KUBOKAWA* and Takehiko ONO

Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka 591

(Received March 18, 1978)

Adsorption of ethylene and propylene has been investigated volumetrically with various oxide catalysts. From the results together with those of oxidation of propylene adsorbed on oxides, it is concluded that the difference between the characteristics of oxidation of propylene adsorbed on the oxide catalysts for complete or selective oxidation is attributable to the difference in the oxygen species responsible for oxidation rather than that in the adsorbed state of propylene. A comparison of characteristics of the oxidation of adsorbed propylene in the presence of gaseous oxygen and in a vacuum suggests that on the catalysts for complete oxidation, adsorbed oxygen plays a significant role in the oxidation because of its higher activity as compared to that of lattice oxygen.

In order to obtain information on the mechanism of catalytic oxidation, investigation was carried out on the oxidation of olefins adsorbed on oxide catalysts by analysis of reaction products as well as by IR techniques.[1-3] In the case of ZnO, adsorbed propylene was converted into surface formate and acetate ions as well as OH groups with oxygen uptake, which were oxidized successively to CO_2 and H_2O. A marked difference in the oxidation of adsorbed propylene was observed with catalysts for selective oxidation such as V_2O_5[2] and Sn–Mo oxide.[4] For understanding the difference between the characteristics of oxidation of olefins adsorbed on oxides, it seems necessary to obtain information on how the oxygen species responsible for the oxidation as well as the nature of adsorbed state of olefins varies on going from one oxide to another. Work along this line has been undertaken in the present study.

As regards the adsorbed state of olefins, IR studies seem to be most promising. However, IR data are available only for a limited range of oxides such as ZnO,[5] Sn–Mo oxide,[4] and copper oxides[6] because of the inherent difficulties in the IR measurements of adsorbed species. Accordingly, volumetric adsorption measurements have been carried out for all the oxide catalysts for which the oxidation of adsorbed propylene was examined.[1,2]

Experimental

Details of apparatus, procedure and materials were reported.[1,2] The adsorption of ethylene and propylene as well as the oxidation or desorption was investigated with a closed circulation apparatus. In the case of the oxidation of adsorbed propylene, the temperature of the catalysts containing a known amount of adsorbed propylene was raised stepwise in the presence of oxygen. The amount of oxygen consumed and that of the reaction products were determined.

The surface area of the catalysts determined by the BET method using argon were as follows; Co_3O_4, 10.0; NiO, 3.3; CuO, 12.5; V_2O_5, 2.0; ZnO, 3.1; Fe_2O_3, 16.2; TiO_2, 2.0; MoO_3, 1.3 m^2/g.

Results and Discussion

Adsorption of Ethylene and Propylene on Oxides. The results of olefin adsorption experiments with various oxide catalysts are shown in Fig. 1. The amount of olefins adsorbed per unit area of the catalyst surface at 0 °C and 30 Torr as well as that of olefins remaining after evacuation at 0 °C are given. From these data we can obtain information on the activity of oxides toward the chemisorption of olefins. The strength of adsorption can be estimated from the remaining amount of adsorbed propylene after evacuation to the total amount adsorbed at 30 Torr. It is seen that both Co_3O_4 and ZnO exhibit the highest activity towards olefin chemisorption. The highest strength of adsorption of propylene is observed with Co_3O_4 and the lowest strength of adsorption with TiO_2 and MoO_3.

For the oxides such as ZnO, Fe_2O_3, and TiO_2 the amount of adsorbed propylene remaining after evacuation is larger than the corresponding amount of ethylene, while for the oxides such as Co_3O_4, NiO, CuO, and V_2O_5 the amounts of both olefins remaining are roughly the same. This suggests that the nature of the strong adsorption of olefins differs between both groups of oxide catalysts. Dent and Kokes[5] found that propylene undergoes adsorption to form π-allyl on ZnO while ethylene undergoes adsorption to form π-complex. They explained the difference between the remaining amounts of adsorbed propylene and ethylene.

On increasing the desorption temperature olefins adsorbed on ZnO desorbed as such without undergoing oxidation, while most olefins adsorbed on Co_3O_4 desorbed as CO_2 and H_2O. Thus, the difference between the nature of olefins adsorbed on both groups of oxides is confirmed.

Oxidation of Propylene Adsorbed on Oxides. The behavior of catalysts containing adsorbed propylene in the presence of oxygen, observed on raising the temperature, was described in previous papers.[1,2] In the case of ZnO one mole of the strongly adsorbed propylene took up two moles of oxygen to form surface formate and acetate ions,[1,3] which were oxidized successively to CO_2 and H_2O. A similar oxygen uptake was observed with other oxides such as Co_3O_4, NiO, Fe_2O_3, and CuO. On NiO, formation of carboxylate ions similar to that on ZnO was confirmed by IR techniques.[7] On the other hand, the interaction of oxygen with strongly adsorbed propylene on V_2O_5 led to little or no oxygen uptake, formation of water being observed at lower temperatures as compared to the cases of oxides such as Co_3O_4, ZnO, *etc.*[2] IR studies on Sn–Mo oxide[4] show that the interaction of oxygen with strongly adsorbed propylene causes formation of surface OH groups alone,

no surface carboxylate ions being observed. The results indicate that the behavior observed with the catalysts for complete oxidation, such as Co_3O_4 and ZnO, differs from that with the catalysts for selective oxidation, such as V_2O_5 and Sn–Mo oxide.

The results of oxidation of the propylene adsorbed are compared with those of the adsorption of olefins. Although there is a striking difference in the nature of propylene adsorbed on Co_3O_4 and ZnO, both exhibit a similar behavior in the oxidation of adsorbed propylene, *i.e.*, formation of carboxylate species with oxygen uptake occurs during the course of oxidation. Irrespective of a marked difference in the behavior of Co_3O_4 and V_2O_5 in the oxidation of adsorbed propylene, there seems little difference in the features of olefin adsorption, *e.g.*, for both oxides the amount of adsorbed ethylene remaining is roughly the same as the corresponding amount of propylene (Fig. 1).

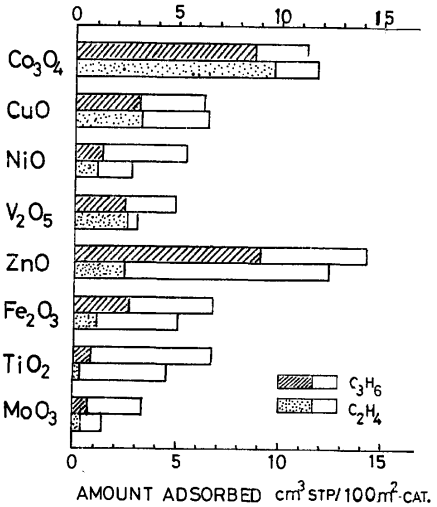

Fig. 1. Adsorption of propylene and ethylene on various oxides. Shaded parts show the fraction of the remaining amounts after evacuation. Temperature, 0 °C; Olefin pressure, 30 Torr (1 Torr=133.3 Pa); Adsorption time, 3 h.

Instead of propylene, acetone was adsorbed on NiO[8] and Sn–Mo oxide.[4] The oxidation of adsorbed acetone was carried out in a similar manner. Formation of surface carboxylate ions was observed for NiO, but not for Sn–Mo oxide. Essentially the same difference between the behavior of both oxides in the oxidation was observed as that with propylene adsorbed. It seems that the features of the oxidation of adsorbed propylene are not closely associated with its adsorbed state. Such a difference in the features of the oxidation could be attributed to the difference in the oxygen species responsible for oxidation.

Oxygen Species Responsible for Catalytic Oxidation.
A number of workers[9] have discussed the difference between the characteristics of the oxide catalysts for selective oxidation such as V_2O_5, MoO_3, and Bi–Mo oxide and for complete oxidation such as Co_3O_4, NiO, and Fe_2O_3 from the viewpoint of the type of metal–oxygen bonds.

The present paper is concerned with the relative roles of adsorbed and lattice oxygen in the oxidation on these oxide catalysts. The following experiments were carried out: The temperature of catalysts containing the strongly adsorbed propylene was raised stepwise in a vacuum, *i.e.*, desorption experiments were carried out. The amount of CO_2 formed during the course of temperature rise was compared with the corresponding amount in the presence of oxygen at 30 Torr. The results are shown by plots R *vs.* T, where R=(the amount of CO_2 formed during the temperature rise from 0 to T °C)/(the amount of propylene strongly adsorbed at 0 °C)$\times 3$.

In the case of Co_3O_4 the plots R *vs.* T in the presence of oxygen shift to a lower temperature by about 150 °C as compared with that in a vacuum, suggesting participation of adsorbed oxygen in the oxidation (Fig. 2). A similar behavior is observed with Fe_2O_3 (Fig. 3). On ZnO, most part of adsorbed propylene was removed in a vacuum without undergoing oxidation, in contrast

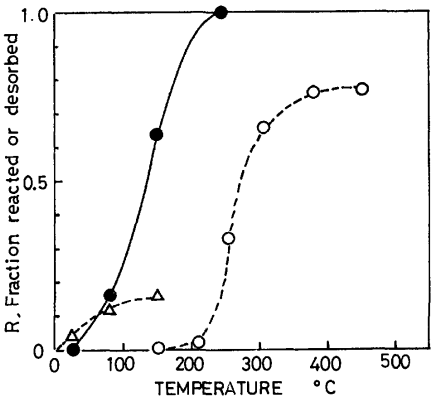

Fig. 2. Comparison of oxidation with desorption of propylene adsorbed on Co_3O_4.
—●—, CO_2 formed in the oxidation; ···○···, CO_2 formed in the desorption; —△—, C_3H_6 desorbed in the desorption. Experimental conditions in Figs. 2, 3, 4, and 5; Reaction time at each temperature in the oxidation, 3 h; oxygen pressure, 30 Torr; desorption time, 3 h; amounts of propylene adsorbed are shown in Fig. 1.

Symbols are the same as Fig. 2.

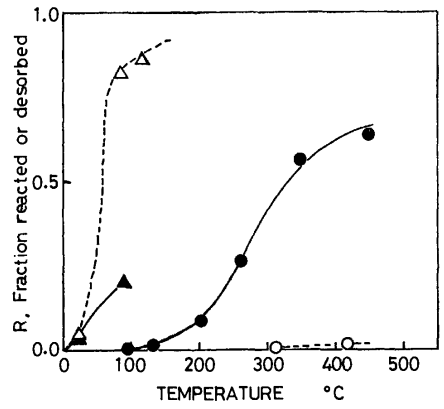

Fig. 4. Comparison of oxidation with desorption of propylene adsorbed on ZnO.
-▲-, C_3H_6 desorbed in the oxidation; other symbols are the same as Fig. 2.

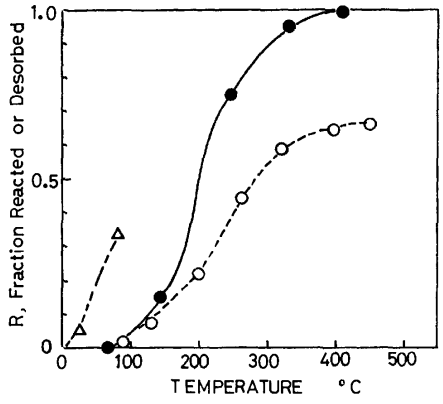

Fig. 5. Comparison of oxidation with desorption of propylene adsorbed on V_2O_5.
Symbols are the same as Fig. 2. Since in the case of V_2O_5 CO is formed in addition to CO_2, R values refer to formation of $CO+CO_2$. The amount of oxygen required for the oxidation of adsorbed propylene corresponded to about 30% of the surface oxygen layer.

with the case in the presence of oxygen where most part of adsorbed propylene was oxidized to CO_2 and H_2O (Fig. 4). Such a behavior suggests that surface lattice oxygen has no oxidizing power, *i.e.*, the oxidation proceeds *via* adsorbed oxygen alone.

For V_2O_5, the oxidation of adsorbed propylene in a vacuum occurs in about the same temperature range in the presence of oxygen (Fig. 5). The presence of gaseous oxygen has no effect on oxidation, *i.e.*, the surface lattice oxygen participates in the oxidation, in line with the conclusion reached by various workers.[10,11]

On the oxides which are effective for complete oxidation, active adsorbed oxygen is formed, which attacks olefins to form carboxylate ions, leading to the oxygen uptake by the catalysts. The absence of adsorbed oxygen on the catalysts for selective oxidation has been demonstrated by Seiyama,[14] who carried out the thermal desorption of oxygen adsorbed on various oxides. Haber and Grzybowska[15] reached similar conclusions from available data on the activity in oxygen isotopic exchange of various oxide catalysts. The general characteristic feature of the oxides effective for complete oxidation is that adsorbed oxygen plays a significant role in the oxidation because of its higher activity as compared with that of surface lattice oxygen.

Ionic Motion and Phase Transition in Potassium Hydrogendifluoride KHF_2 Studied by Pulsed NMR

Yoshihiro FURUKAWA* and Hideko KIRIYAMA

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita 565

(Received May 8, 1978)

Nuclear spin-lattice relaxation times, T_1 and $T_{1\rho}$, have been measured above room temperature for ^1H and ^{19}F nuclei in powdered KHF_2 and its deuterated analogue. Below 400 K and in the high-temperature β-phase (T_t=469.8 K), the magnetization recovery for both nuclei in KHF_2 is strongly non-exponential owing to the heteronuclear H–F interaction. In the low-temperature α-phase the T_1 *vs.* $1/T$ curves show broad minima ascribable to the 180°-flip motion of linear $[FHF]^-$ anions. The activation energy E_a of this motion was determined to be 50.5 ± 2 kJ/mol. The phase transition, which is defined by discontinuous changes in both T_1 and $T_{1\rho}$, is associated with diffusional disorder superimposed on rapid isotropic reorientation of the HF_2^- ion. The relaxational process in the β-phase is governed by self-diffusion of the anions with an E_a of 80 ± 6 kJ/mol deduced from the $T_{1\rho}$ data. In contrast to the earlier suggestion from electrical measurements, the NMR results indicate that the dominantly mobile species in the conducting high-temperature β-phase are not single F^- ions but complex $[FHF]^-$ anions.

Potassium hydrogendifluoride KHF_2 has been studied extensively by diffraction, spectroscopic and other physical methods, on account of its hydrogen bond forming unique difluoride ion $[F\cdots H\cdots F]^-$. In all cases, except for early infrared studies, the HF_2^- ion was found to be linear and centro-symmetric with an unusually short F–F distance of 2.29 Å.[1-6]

The compound KHF_2 is tetragonal with cell constants a=5.672, c=6.801 Å and Z=4 in the room-temperature α-phase.[3] The linear HF_2^- ions are arranged in planes (001). In these planes the $[FHF]^-$ ionic axes are directed alternately parallel to either [110] or [$\bar{1}$10]. At the transition temperature T_t (196.7 °C), the crystal transforms to the cubic β-phase. This is accompanied by large changes in volume and entropy, the cell constants being a=6.36 Å and Z=4.[1,7,8] In the high-temperature phase the F–F axis may orient parallel to any of the four body-diagonals [111] of the cubic cell with equal probability to attain higher symmetry. It seemed worthwhile to clarify whether such a disordered structure is dynamic or static by means of nuclear magnetic resonance (NMR) techniques.

Also of interest is the fact that the ionic conductivity of the compound increases sharply at T_t by about two orders of magnitude, when T_t is approached from a low temperature.[9,10] This strongly suggests that dynamical disorder or migration of ions takes place in the β-phase. Furthermore, electromotive force and electrolysis experiments show that the F^- ions contribute dominantly to the ionic conduction in the high-temperature phase.[11]

The purpose of this study is to determine the type of molecular motion associated with phase transition and ionic conduction by measuring proton and fluorine NMR relaxation times. Kriger *et al.* have reported the spin-lattice relaxation times, T_1, of KHF_2[12] and $CsHF_2$.[13] Our independent experiments, however, include a more detailed study of the temperature dependence of T_1 and the rotating-frame relaxation time, $T_{1\rho}$, in KHF_2 and its deuterated analogue. The results and discussion presented here disagree to some extent with those of Kriger *et al.*

Experimental

Commercial potassium hydrogendifluoride was twice recrystallized from water and dried over P_2O_5. Deuterated KDF_2 was prepared by repeated crystallization from saturated heavy-water solutions of the salt in a closed bottle. Polyethylene wares were used in order to avoid the reaction of HF acid with silicate glass. For the NMR measurement on the α-phase the powdered KHF_2 was placed in an 8 mm diam. glass tube, which was evacuated and then sealed. When the sample was kept below T_t for several days, the wall of the tube was hardly corroded at all by gaseous HF, but when the sample was transformed to the waxy β-phase, it became corroded at the contact surface. For the relaxation measurements on the β-phase, several pieces of single crystals with dimensions of about $4\times4\times1$ mm^3 were wrapped in Teflon tape and then sealed in a glass tube. It was thought that the use of Teflon would not interfere with the measurements since the ^{19}F FID (free induction decay) signal in the β-phase is long as compared with that in Teflon. Actually, the Teflon coated sample gave almost the same relaxation data as those of the sample coated with vacuum-pump-oil. The samples used were identified from the X-ray powder patterns at room temperature before and after NMR measurements. No extra diffraction peaks, especially those assignable to crystalline KF, were recognized after the sample had been heated at about 500 K for ten hours.

T_1 and $T_{1\rho}$ were measured with a Bruker pulsed NMR spectrometer B-KR 322s by the conventional methods. The Larmor frequencies were 20 and 18.814 MHz for ^1H and ^{19}F, respectively. Since the FID signal in the α-phase was very short, its height was obtained from the solid echo[14] and was averaged on a NIC 1074 signal averager. The sample temperature controlled within ±1 K was measured with a copper-constantan thermocouple.

Results and Discussion

The proton and fluorine relaxation times of KHF_2 are summarized in Fig. 1 as a semilogarithmic plot *versus* inverse temperature. Below 400 K the T_1 behavior for both nuclei was somewhat complicated by the presence of heteronuclear H–F interactions. In the region below the temperatures of the T_1 minima, the relaxations of ^1H and ^{19}F became markedly non-

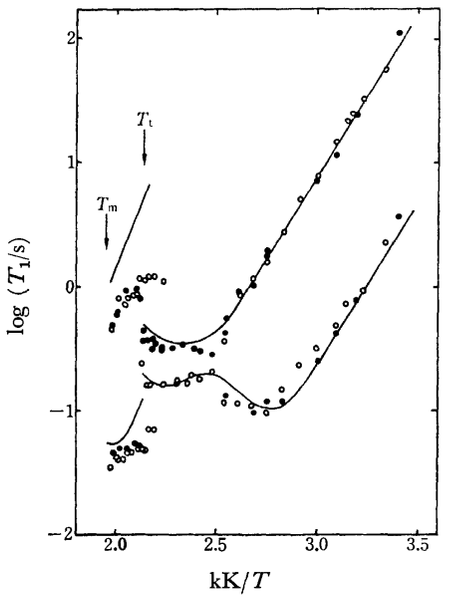

Fig. 1. Temperature dependences of the spin-lattice relaxation times, T_1, in KHF_2. ●: ^1H, ○: ^{19}F. Below 400 K and in the β-phase two components of T_1 are shown because of the non-exponential magnetization recovery. The solid lines in the α-phase are calculated on the basis of a model of 180°-flipping HF_2^- ions.

exponential. Each recovery curve of magnetization was manually resolved into two components, one of which (the short component) was characterized by a short relaxation time T_1', and the other by a long relaxation time T_1''.[15] As shown in Fig. 1, the relaxations for ^1H and ^{19}F have the same pair of T_1' and T_1'' below 400 K. On the other hand, at temperatures between 400 K and T_t (469.8 K), both relaxations are nearly exponential, the minimum value of $T_1(H)$ being about twice as long as that of $T_1(F)$. The results differ from those of Kriger *et al.*[12] as regards (1) the non-exponential behavior, (2) the absence of a temperature region in which $T_1(H)<T_1(F)$, and (3) the slope of log T_1 *vs.* $1/T$ curve in the high-temperature β-phase.

T_1 in the α-Phase of KHF_2. In this system, since the heteronuclear dipole interaction between ^1H and ^{19}F cannot be neglected, the observed relaxation rates of both nuclei are the eigenvalues of the following relaxation matrix:[15,16]

$$\begin{pmatrix} R_{HH}+R_{HF} & R_{HF}' \\ R_{FH}' & R_{FF}+R_{FH} \end{pmatrix} \quad (1)$$

The element R_{HF} represents the proton relaxation rate *via* the dipolar interaction between ^1H and ^{19}F spins. The relative magnitudes of these matrix elements are expected to govern the non-exponential behavior and the depths of the T_1 minima for ^1H and ^{19}F.[15]

$T_{1\,min}(F)<T_{1\,min}(H)$ indicates that $(R_{FF}+R_{FH})>(R_{HH}+R_{HF})$, suggesting that the two-fold reorientation or 180° flip of HF_2^- ions takes place rapidly in the α-phase. Look and Lowe derived a formula for the relaxation rate of flipping water molecules in a hydrated single crystal.[17] It is also applicable to R_{FF} in the case of 180°-flipping HF_2^- ions. Thus, we obtain

$$R_{FF}=\frac{3\gamma_F^4\hbar^2I_F(I_F+1)}{16N}\sum_{i\neq j}\left[\eta_{ij}^1\frac{\tau_f}{1+0.25\omega_{0F}^2\tau_f^2}+(2\xi_{ij}^1+\eta_{ij}^2)\frac{\tau_f}{1+\omega_{0F}^2\tau_f^2}+2\xi_{ij}^2\frac{\tau_f}{1+4\omega_{0F}^2\tau_f^2}\right], \quad (2a)$$

$$\eta_{ij}^q=\frac{1}{2}|\chi_{ij}^q(\beta\beta)+\chi_{ij}^q(\delta\delta)-\chi_{ij}^q(\beta\delta)-\chi_{ij}^q(\delta\beta)|^2, \quad (2b)$$

$$\xi_{ij}^q=|\chi_{ij}^q(\beta\beta)-\chi_{ij}^q(\delta\delta)|^2+|\chi_{ij}^q(\beta\delta)-\chi_{ij}^q(\delta\beta)|^2, \quad (2c)$$

where the symbols are those of Look and Lowe.[17] Since our sample was powdered, Eq. 2 was used after spatial averaging.[18]

On the other hand, the relaxation rate due to the heteronuclear H–F interactions was derived for a flipping model, in which the central H atom is fixed and each terminal F atom jumps between two equilibrium lattice sites. Only its spatially averaged form is presented here:

$$R_{HF}=\gamma_H^2\gamma_F^2\hbar^2/40\sum_F[r_{HF}(\beta)^{-6}+r_{HF}(\delta)^{-6}-r_{HF}(\beta)^{-3}r_{HF}(\delta)^{-3}\times(3\cos^2\Delta_{\beta\delta}-1)]g(\omega_{0H},\omega_{0F},\tau_f), \quad (3a)$$

$$R_{HF}'=\gamma_H^2\gamma_F^2\hbar^2/40\sum_F[r_{HF}(\beta)^{-6}+r_{HF}(\delta)^{-6}-r_{HF}(\beta)^{-3}r_{HF}(\delta)^{-3}\times(3\cos^2\Delta_{\beta\delta}-1)]g'(\omega_{0H},\omega_{0F},\tau_f), \quad (3b)$$

$$g(\omega_{0H},\omega_{0F},\tau_f)=\frac{\tau_f}{1+(\omega_{0H}-\omega_{0F})^2\tau_f^2}+\frac{3\tau_f}{1+\omega_{0H}^2\tau_f^2}+\frac{6\tau_f}{1+(\omega_{0H}+\omega_{0F})^2\tau_f^2}, \quad (3c)$$

$$g'(\omega_{0H},\omega_{0F},\tau_f)=-\frac{\tau_f}{1+(\omega_{0H}-\omega_{0F})^2\tau_f^2}+\frac{6\tau_f}{1+(\omega_{0H}+\omega_{0F})^2\tau_f^2}. \quad (3d)$$

Symbols β and δ denote the two possible sites for a given F atom and $\Delta_{\beta\delta}$ the angle between two H–F vectors of $r_{HF}(\beta)$ and $r_{HF}(\delta)$. It can readily be shown from the atomic arrangements that $R_{HH}=0$, whereas the other components are $R_{FH}=(1/2)R_{HF}$ and $R_{FH}'=(1/2)R_{HF}'$.[16]

The summation was taken over 14 neighboring HF_2^- ions about a central HF_2^- ion in Eq. 2, and over 6 neighbors in Eq. 3, within the tetragonal structure. Diagonalizing Eqs. 1—3 and using the Arrhenius relation, we can calculate the temperature dependences of $T_1(H)$ and $T_1(F)$. Simulated T_1 curves are represented by the solid lines in Fig. 1, with an activation energy E_a of 50.5 kJ/mol deduced from the linear region on the low-temperature side of the $T_{1\,min}$. Agreement between the observed and calculated $T_{1\,min}$ values indicates that the 180°-flip motion of the $[FHF]^-$ ion is responsible for the T_1 process in the α-phase. On the low-temperature side of $T_{1\,min}$, the off-diagonal elements in the relaxation matrix become comparable in magnitude with the diagonal elements, as anticipated from the non-exponential behavior. On the other hand, above and near the temperature of $T_{1\,min}$ both relaxations for ^1H and ^{19}F are exponential, since the off-diagonal elements can be neglected in comparison with the diagonal elements. The 180°-flip motion of linear $[FHF]^-$ ions was also found in $CsHF_2$.[13] The activation energy E_a of 50.5 kJ/mol for KHF_2 is much larger than that of 14.9 kJ/mol for $CsHF_2$. The room-temperature phase of $CsHF_2$ (T_t=61 °C) is isomorphous with

the α-phase of KHF_2, but the cell dimensions of the former are appreciably larger than those of the latter. Thus, the difference in E_a is attributable primarily to the cation-size effect.

T_1 and $T_{1\rho}$ in the β-Phase of KHF_2. At the phase transition both T_1 and $T_{1\rho}$ change abruptly, the FID signals of ^1H and ^{19}F becoming very long as in a liquid above T_t. The T_2 value defined as the time necessary for the FID to fall to 1/e of its initial value is of the order of a millisecond, demonstrating that the HF_2^- ions are very mobile. Thus, the static disordered model is excluded in view of motional narrowing. The T_1 and $T_{1\rho}$ data for the β-phase are given in Fig. 2 against an expanded scale of inverse temperature. The magnetization recovery for the T_1 process again becomes non-exponential, but not that for the $T_{1\rho}$ process. This is in line with the positive and negative slopes of the T_1 and $T_{1\rho}$ *vs.* $1/T$ curves, respectively. As shown in Fig. 2, the β-phase was often supercooled down to 445 K, some indication on the $T_{1\rho}$ minimum being recognized in the supercooled region.

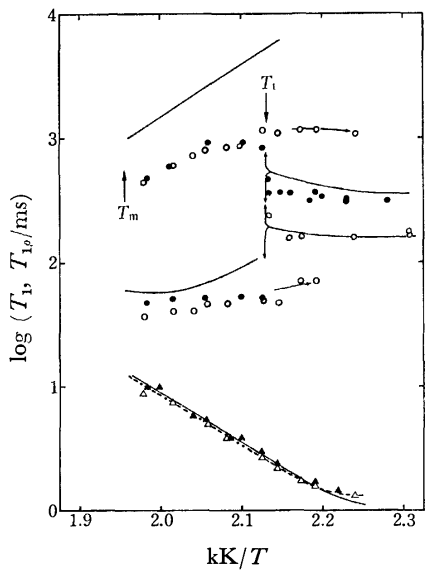

Fig. 2. The T_1 and $T_{1\rho}$ in the β-phase of KHF_2, plotted against an expanded scale of inverse temperature. ●: ^1H T_1, ○: ^{19}F T_1, ▲: ^1H $T_{1\rho}$ (H_1=10 G), △: ^{19}F $T_{1\rho}$ (H_1=10.6 G). The solid and broken lines represent the calculated ^1H and ^{19}F $T_{1\rho}$ curves, respectively. The self-diffusion of the HF_2^- ions is assumed. The phase transition and thermal hysteresis are indicated by arrows.

The dominant relaxation mechanism in the high-temperature phase cannot be assigned to isotropic reorientation of HF_2^- ions, since the experimental second moments estimated from the FID shapes are much smaller than the calculated ones for this model. The primary process is ascribable to the self-diffusion of HF_2^- ions. The rate of process is usually calculated by means of correlation functions derived and tabulated by Torrey[19] and Sholl.[20] Their derivations involve only the homonuclear dipole interactions for a random walk model, where jumping motion occurs between the nearest-neighbor sites. In the case of KHF_2, however, the interactions are complicated since they include the heteronuclear H–F as well as the H–H and F–F interactions, the magnitudes of which are comparable.

For the sake of simplicity, we start from an approximate expression to analyze the relaxation and correlation times for the diffusion process. In the temperature region where $T_1 > T_{1\rho}$, the $T_{1\rho}$ can be approximated by the following equation:[15]

$$T_{1\rho}(\mathrm{I})^{-1} = \frac{2}{3}\gamma_I^2 M_{II}\left(\frac{3}{2}\frac{\tau_d}{1+4\omega_{1I}^2\tau_d^2}\right) + \frac{1}{2}\gamma_I^2 M_{IS}\left\{\frac{2\tau_d}{1+\omega_{1I}^2\tau_d^2}+\frac{1}{2}\frac{\tau_d}{1+(\omega_{0I}-\omega_{0S})^2\tau_d^2}\right\}, \quad (4)$$

where subscripts I and S stand for H and F or *vice versa*, and M_{IS} is the second moment of the I-spin absorption spectrum due to I–S dipolar interaction prior to diffusional narrowing.

The motion of a linear $[FHF]^-$ ion would be expected to be thermally activated in the sequence of the 180° flip, the isotropic reorientation, and the diffusion with an increase in temperature. In the present case, however, the reorientational motion could not be separated from the other motions; it was probably prevented by the occurrence of the phase transition. On this supposition the values of the second moments in Eq. 4 were taken as those calculated for the rapid isotropic reorientation of the HF_2^- ions. The second moments were estimated on the basis of the NaCl-type structure of the β-phase and using the approximation that the two fluorine atoms of each HF_2^- ion are effectively located at the center of the ion; they are M_{HH}=0.626, M_{HF}=0.491, M_{FF}=1.105, and M_{FH}=0.278 G^2.

By substituting these values into Eq. 4 and by taking an activation energy of 80 kJ/mol from the experimental $T_{1\rho}$ *vs.* $1/T$ curve, the temperature dependence of the ^1H and ^{19}F $T_{1\rho}$'s was simulated. The results together with the corresponding T_1' and T_1'' are shown in Fig. 2. The agreement between the calculated and experimental curves for both $T_{1\rho}$'s supports the relaxation model used in the present analysis. On the other hand, the experimental curves for T_1' and T_1'' are significantly depressed from the calculated ones; the departure increases with decreasing temperature in the β-phase. This indicates that the rapid reorientation and the slow diffusional motion are superposed in this region. The correlation time for the reorientation is roughly estimated to be 10^{-12} s at the transition point. The motional parameters are summarized in Table 1.

Table 1. Summary of relaxational parameters

Phase	E_a/(kJ mol^{-1})	τ_0/s	Motion
α-Phase	50.5±2	6.4×10^{-15}	180° flip
β-Phase	80 ±6	5×10^{-16}	diffusion

T_1 and $T_{1\rho}$ in KDF_2. In order to confirm the relaxation mechanism, the T_1 and $T_{1\rho}$ of ^{19}F were measured on deuterated KDF_2 (Fig. 3). Since the isotope exchange of ^1H with ^2H nuclei almost extinguishes the heteronuclear dipole interaction, the relaxa-

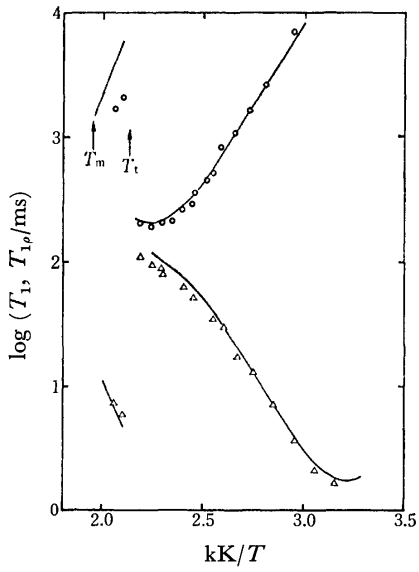

Fig. 3. Temperature dependences of T_1 and $T_{1\rho}$ for ^{19}F in KDF_2 ($H_1=10.6$ G). The solid lines represent the expected dependences based on relaxation processes similar to those in KHF_2 (see text).

tion becomes exponential for all temperatures studied. The T_1 value in the α-phase of KDF_2 is nearly equal to the long component T_1'' (Fig. 1). The $T_{1\,min}$ value is only 1.2 times that for ^{19}F in KHF_2. This shows that the T_1'' in KHF_2 is mainly due to the F–F dipolar interaction; of course both are modulated by 180°-flipping of the HF_2^- ion. Therefore, the T_1 and $T_{1\rho}$ values were calculated from Eq. 2 and the corresponding formulae derived by Look and Lowe,[17] respectively, using the same values as those found in KHF_2, except $\tau_0=7\times10^{-15}$ s. The results are shown by solid lines in Fig. 3. Agreement between the calculated and experimental T_1 and $T_{1\rho}$ curves furnishes additional evidence for the relaxation due to the flipping of the HF_2^- ion.

On the other hand, the ^{19}F relaxation times in the β-phase of KDF_2 were markedly affected by the isotope exchange, *viz.*, $T_1(KDF_2)\approx2\times T_1''(KHF_2)$ and $T_{1\rho}(KDF_2)\approx2\times T_{1\rho}(KHF_2)$. The calculation based on Eq. 4, taking $M_{FH}=0$, supports the results. However, the absolute value of the ^{19}F T_1 in the β-phase is in poor agreement with the experimental one, possibly for the same reason as that for KHF_2.

Phase Transition. At the phase transition the relaxation times change discontinuously with accompanying thermal hysteresis. This suggests a first-order phase transition. The compounds containing linear XY_2^- ions are often transformed into cubic phases at high temperatures. The azides of rubidium and caesium have the same structure as that of KHF_2 at room temperature, *viz.*, a tetragonally distorted CsCl-type structure with space group I4/mcm. On heating, the azides undergo phase transitions to cubic Pm3m phases.[21] Such I4/mcm-Pm3m transition involves a small displacement of the anion. The transition entropies of 7.9 for Rb- and 7.5 J/(K mol) for Cs-azides were interpreted in terms of random orienting N_3^- ions parallel to three cube-edges. Caesium hydrogendifluoride also shows an I4/mcm-Pm3m transition having a transition entropy of 8.4 J/(K mol), which is nearly equal to the expected $R\ln3$.[22]

On the other hand, the phase transition of KHF_2 is somewhat different from those described above. The high-temperature β-phase has an NaCl-type structure with space group Fm3m, and the HF_2^- ions are directed at random along four body-diagonals. The I4/mcm-Fm3m transition is associated with a large ionic displacement as well as disordering of the HF_2^- ions, as evidenced from the large increase in volume at the transition point.[8] The present NMR study on KHF_2 and KDF_2 suggests that the rapid flip motion triggers the phase transition and the spherical reorientation of the linear HF_2^- ion causes the symmetry of the anion to be effectively cubic in the β-phase. However, the diffusive motion of the HF_2^- ion can also be correlated with the I4/mcm-Fm3m transition, since the transition entropy of 23.8 J/(K mol),[7] is much larger than $R\ln4$ expected for pure orientational disorder in the β-phase.

Mobile Ions in the β-Phase. A number of hydrogen-bonded crystals have been studied as proton conductors with special interest centering on the identity of charge carriers and the mechanism of ionic migration.[23] The ionic conduction in KHF_2, where the hydrogen atom is located inside an isolated anion, becomes substantial only in the high-temperature β-phase. Bruinink and Kosmeijer determined the ionic transport numbers from changes in chemical composition on electrolysis as follows: $t_F\approx0.75$, $t_K\approx0.25$, and $t_H\approx0$ in the β-phase, while $t_H\approx1$ in the α-phase.[11] They explained the relatively high conductivity in the β-phase in terms of the migration of F^- (and to a smaller extent K^+) ions but not of H^+ ions.

The results of ^1H and ^{19}F T_1 are evidence for self-diffusion of the ions in the conducting β-phase, affording valuable information on the mobile ion-species. If the hydrogen ions are essentially immobile in this phase, as suggested from the electrolysis experiments, then the calculated $T_{1\rho}$ for ^1H should be about two times that for ^{19}F except near the $T_{1\rho}(H)$ minimum. The estimation is not compatible with the observation that $T_{1\rho}(H)\approx T_{1\rho}(F)$. Thus, the HF_2^- ion diffuses as a whole; at least H^+ and F^- ions move with almost equal correlation times, which is not in agreement with the results of electrolysis. On the other hand, the activation energy (80 kJ/mol) for the self-diffusion found from the NMR study is in fairly good agreement with the value of 86 kJ/mol deduced from the electric conductivity measurements.[10] Both values are much smaller than the hydrogen-bond energy, 240 kJ/mol, estimated for $[F\cdots H\cdots F]^-$ ions.[24] It can be concluded that the most mobile charge carriers in the conducting high-temperature β-phase are not single F^- ions but complex $[FHF]^-$ anions.

The authors are grateful to Professor Emeritus Ryôiti Kiriyama for his continued interest and stimulating discussions. This work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 047076).

(Received May 11, 1978)

The CNDO/2 and INDO calculations were performed on three azines: pyridazine, pyrimidine, and pyrazine. In order to check the validity of the lone-pair orbital energies, the calculated orbital energies were compared with those obtained by *ab initio* calculations. These molecules have two lone-pairs, which can be transformed into symmetric and antisymmetric combinations. In pyridazine and pyrimidine, the symmetric one is lower than the antisymmetric one in energy, while in pyrazine the reverse is true. These results were subjected to an analysis from the standpoint of the through-bond interaction. That is, we transformed the canonical molecular orbitals obtained by the CNDO/2 method into localized molecular orbitals. By the use of the localized molecular orbitals thus obtained, the variation in the lone-pair orbital energies of these molecules was estimated in terms of the through-bond (and/or the through space) interaction according to a method which selectively considered the particular interaction between the specified localized molecular orbitals in a molecule. As a result of this analysis, it was found that the relative order of the lone-pair orbital energies was determined by the different types of interactions from molecule to molecule, and the energy variation in the lone-pair orbitals was elucidated in terms of the specified through-bond and through-space interactions.

From the early days of the molecular orbital theory, such azines as pyridazine, pyrimidine, and pyrazine have been studied. Most of the previous works were examined by the semi-empirical methods.[1] Recently, *ab initio* molecular orbital methods have also been applied to these molecules.[2]

These molecules are characterized by their two lone-pair orbitals (LPO). These two LPO should be classified into symmetric and antisymmetric combinations on the basis of their symmetry properties. Hoffmann and his coworkers attempted to explain the separation between two lone-pair orbital energies (LPOE)[3] generally in terms of the "through-space" and the "through-bond" interactions in the cases of benzyne and its related compounds.[4] Many researches in this direction have been reported. However, the explicit calculations of the through-bond interactions have never been carried out, although data have been accumulated for the through-space interactions.[5] In the present article, we attempted to evaluate quantitatively the through-bond interactions by using the localized molecular orbitals (LMO) transformed from the canonical molecular orbitals (CMO). There is an advantage for chemists to understanding chemical phenomena in using the LMO- rather than the usual CMO-bases wave function, since the LMO can often be chosen so as to be localized in a certain space region, whereas the CMO are delocalized in most cases.

There are two LPO, n_1 and n_2, in the molecules treated here. These two LPO n_1 and n_2 can be classified into a symmetric or an antisymmetric combination from their symmetry properties, as was mentioned in the previous paragraph. There is an interest in the order of these LPOE, since there are intimate relations between this order and the assignments of the ionization potentials (IP's) and the $n\rightarrow\pi^*$ transition in the photoelectron or absorption spectra. For the IP's and the spectra of these molecules, there are many references available.[6] In connection with this, the order of the LPOE is different from molecule to molecule. Therefore, we have investigated the dominant factors in determining the order of the LPOE by using the LMO; that is, the order of the LPOE was successfully explained in terms of the through-space and the specified through-bond interactions.

Method of Calculations

There are fifteen occupied orbitals in the azines now under consideration. Among them, three are π-molecular orbitals. As a result, twelve occupied σ-orbitals were localized by minimizing the off-diagonal exchange energy according to the procedure of Edmiston-Ruedenberg.[7] The occupied π and all of the virtual orbitals were not transformed into the LMO. The original CMO were obtained from the CNDO/2

a) From Ref. 6c. b) Recalculated in the light of Ref. 10. c) From Ref. 2c.

calculations,[8] since an *ab initio* calculation consumes a lot of computation time. The INDO calculations[9] were also carried out in order to compare the order of the LPOE with the *ab initio* one. The atomic coordinates used are summarized in Table 1.[2c,6c,10]

Pyridazime, pyrimidine, and pyrazine belong to the C_{2v}, C_{2v}, and D_{2h} point groups respectively. In order to express the symmetric character of the LPO, only the two-fold axis, which bisects the LPO and interchanges n_1 and n_2 with the symmetry operation, is used. The two symbols, S(Symmetric) and A(Antisymmetric), are named according to their symmetry properties in terms of the transformation around the two-fold axis.

When there is no interaction between n_1 and n_2, the two LPOE should be equal. If there are some interactions between them, S and A should be separated into two different energy levels; the separation width $\Delta = |E(S)-E(A)|$ expresses the magnitude of the interactions between them.

Now we will attempt to explain the procedure for estimating the effect of a particular through-bond interaction in the molecule. For the purpose of this procedure, the atomic orbital, χ_r, is represented by a linear combination of the LMO in the CNDO or INDO approximation, as is shown below. That is, the LMO, ϕ_i, is given by

$$\phi_i = \sum_s c_{is}\chi_s. \tag{1}$$

Equation 1 is multiplied by the coefficient, c_{ir}, for all the i and the equations are added:

$$\sum_i c_{ir}\phi_i = \sum_i c_{ir}\sum_s c_{is}\chi_s = \sum_s \chi_s \sum_i c_{ir}c_{is} = \sum_s \chi_s \delta_{rs}. \tag{2}$$

Thus,

$$\chi_r = \sum_i c_{ir}\phi_i. \tag{3}$$

By using Eq. 3, we can represent a core resonance integral between atomic orbitals, χ_r and χ_s, as the summation of the core resonance integrals between the LMO, ϕ_i and ϕ_j:

$$I^\circ_{rs} = \int \chi_r h^\circ \chi_s d\tau = \sum_i \sum_j c_{ir}c_{js}\int \phi_i h^\circ \phi_j d\tau = \sum_i \sum_j c_{ir}c_{js}I_{ij}, \tag{4}$$

where I°_{rs} and I_{ij} are the core resonance integral between the atomic orbitals, χ_r and χ_s, and that between the LMO, ϕ_i, and ϕ_j, respectively, and where h° denotes a one-electron Hamiltonian. By modifying Eq. 4, we can obtain the value of the core resonance integral between the atomic orbitals which gives zero for the core resonance integrals between the specified LMO, and which gives the core resonance integral between the other LMO correctly. That is,

$$I_{rs} = I^\circ_{rs} - \sum_{(i_1-j_1)} (c_{i_1,r}c_{j_1,s} + c_{i_1,s}c_{j_1,r})I_{i_1,j_1}, \tag{5}$$

where $(i_1\text{-}j_1)$ means that the summation should cover only definite pairs of the specified LMO. It can easily be proved that the core resonance integral, I_{rs}, obtained by Eq. 5 gives zero for the core resonance integral between the specified LMO, $I_{i_1j_1}$, and the correct values for the others as is shown below.

$$\begin{aligned} I'_{ij} &= \sum_r \sum_s c_{ir}c_{js}\int \chi_r h^\circ \chi_s d\tau = \sum_r \sum_s c_{ir}c_{js}I_{rs} \\ &= \sum_r \sum_s c_{ir}c_{js}I^\circ_{rs} - \sum_r \sum_s c_{ir}c_{js}\sum_{(i_1-j_1)} (c_{i_1,r}c_{j_1,s} \\ &\quad + c_{i_1,s}c_{j_1,r})I_{i_1,j_1} \\ &= I_{ij} - \sum_{(i_1-j_1)} I_{i_1,j_1}[(\sum_r c_{ir}c_{i_1,r})(\sum_s c_{js}c_{j_1,s}) \\ &\quad + (\sum_r c_{ir}c_{j_1,r})(\sum_s c_{js}c_{i_1,s})] \\ &= I_{ij} - \sum_{(i_1-j_1)} I_{i_1,j_1}(\delta_{ii_1}\delta_{jj_1} + \delta_{ij_1}\delta_{ji_1}), \\ &\begin{cases} = 0 & (i = i_1,\ j = j_1 \text{ or } i = j_1,\ j = i_1) \\ = I_{ij} & (\text{otherwise}). \end{cases} \end{aligned} \tag{6}$$

Equation 6 indicates that I'_{ij} is equal to zero when $i = i_1$, $j = j_1$, or $i = j_1$, $j = i_1$, and is equal to the correct value otherwise. Consequently, when the LMO, ϕ_i and ϕ_j, which specified the bonds i and j, are picked up in Eq. 5, the core resonance integral between ϕ_i and ϕ_j should be cut off; that is, the through-bond interaction between the bonds i and j can be considered to be cut off.[11] Thus, the SCF calculations using the core resonance integrals in Eq. 5 give the total energy without the appropriate through-bond interactions. The difference between the total energies calculated with and without the specified through-bond interactions should be a measure of the specified through-bond interactions.[12]

Previously, in order to describe the π-hyperconjugative interactions, the through-space and the through-bond interactions were treated separately by removing the core resonance integrals by the use of the semi-empirical method;[5] the present procedure is the first attempt to analyze the LPO interactions including a σ-system quantitatively.

Results and Discussion

The LPOE of these molecules, as calculated by the CNDO/2 and INDO methods, together with an *ab initio* calculation,[2f] are summarized in Table 2. From this table we can see that the order of S and A, and the separation width between them as calculated by the semi-empirical method, correspond with the results of the *ab initio* calculations. The tendencies of the separation width between S and A are also very similar to each other in the cases of the semi-empirical and non-empirical methods. Therefore, we can recognize that

a) S: Symmetric; A: Antisymmetric; $\Delta = |E(S)-E(A)|$.
b) From Ref. 2f.

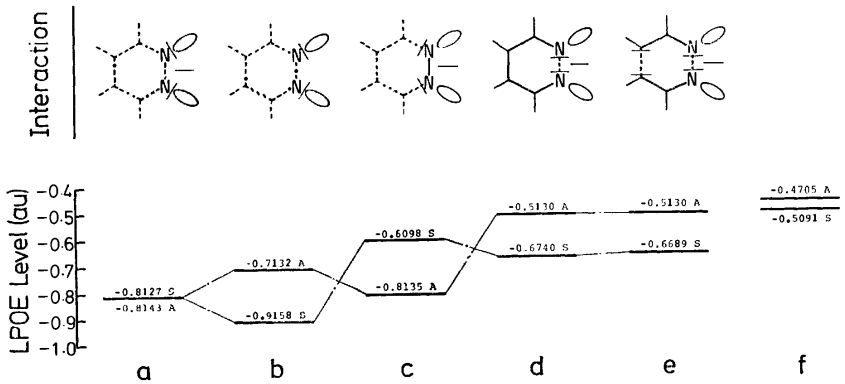

Fig. 1. LPO interaction diagram for pyridazine.
a: LPO are "cut off", **b**: LPO are "cut off" and N···N direct-through space interaction is allowed, **c**: short path is allowed, **d**: long path is allowed, **e**: short path is "cut off" and long path is "cut off" at the C–C bond parallel to the N–N bond, **f**: CMO level.

the semi-empirical method used here is sufficient to explain the energy variation in the LPOE or the change in the symmetry property of the LPO in these molecules.

Figure 1 shows the variation in the LPO energy levels of pyridazine.

a. When both LPO n_1 and n_2 were cut off from the interactions, S and A go to considerably lower energy levels. In this case, the N···N direct through-space interaction is not allowed. From the LPOE we can see that there is no interaction between n_1 and n_2.

b. Then the N···N direct through-space interaction was added to the **a** state; under these circumstances, A goes up about 0.1 au, while S lowers. This gives the magnitude of the direct through-space interaction between the LPO.

c. When the through-bond interaction *via* the N–N direct path (short path) was taken into consideration, S was found to go drastically up, but A scarcely varies from the **a** state. From the consideration of the orbital symmetry, it seems that this type of through-bond interaction does not have any effect on the energy level of A, as has already been pointed out by Hoffmann *et al.*[4]

d. When the interaction through the path N–C–C–C–C–N (long path) is taken into consideration, A goes up to around the CMO level, but S does not. The order of S and A is reversed from the **c** state.

e. In addition to the **d** state, the long path is cut off at the C–C bond parallel to the N–N bond; both S and A levels scarcely vary from the **d** state. Accordingly, it is obvious that the LPOE in the **d** state are not due merely to the through-bond interaction, but to a combination of the through-bond and through-space interactions, as will be discussed later in detail.

Figure 2 shows the variation in the LPO energy levels of pyrimidine.

a. Two LPO, n_1 and n_2, were cut off from the interactions; when this happens the energy levels of the LPO go lower, and S and A degenerate.

b. When we added the N···N direct through-space interaction to the **a** state, there were no variations in the energies of S and A from the **a** state. This shows that the N···N direct through-space interaction between two N atoms at the meta-position is almost zero. The same is true in pyrazine, as will be shown later.

c. Only the short path is allowed; S and A go upper,

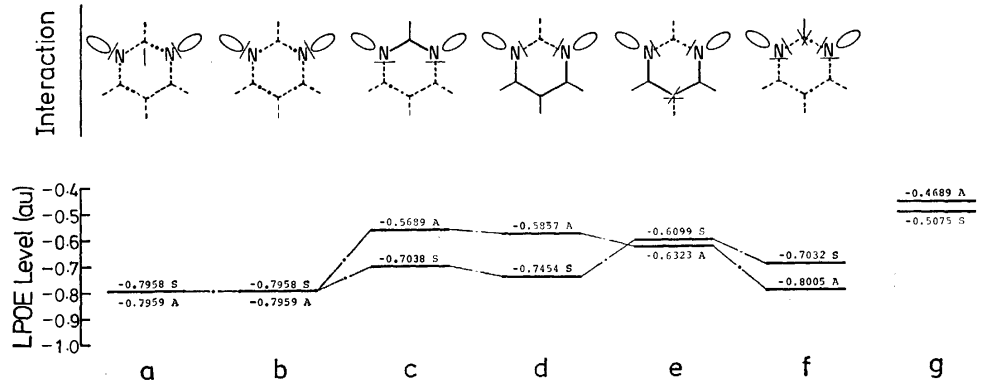

Fig. 2. LPO interaction diagram for pyrimidine.
a: LPO are "cut off", **b**: LPO are "cut off" and N···N direct through-space interaction is allowed, **c**: short path is allowed, **d**: long path is allowed, **e**: short path is "cut off" and long path is "cut off" at its central point, moreover C–H bond bonded at this point is "cut off", **f**: long path is "cut off" and short path is "cut off", but one C–H interaction with two LPO in the short path is allowed, **g**: CMO level.

but the variation is larger in A than in S. Therefore, it is noteworthy that the present situation is quite different from that in pyridazine.

d. The long path is allowed; both S and A vary from the **b** state. However, the variation in this case is less than that of the **c** state. One of the differences between the **c** and **d** states may be a result of the difference of the through-bond interactions *via* two and four bonds.

e. The short path is cut off, and the long path is cut off at its central point; moreover, the C–H bond combined at this point is cut off from the interactions. With this state, A goes lower than the **d** state, but S goes up. The energy difference between S and A becomes fairly small, and the order of S and A is reversed from the **d** state. From the **d** and **e** states, it is obvious that the energy variation in the LPO of the **e** state from the **d** state is caused by the through-bond interaction itself. This situation is also quite different from that of the **d** and **e** states in pyridazine.

f. The long path is cut off, as is the short path, but in the short path one C–H interaction is allowed. Therefore, in this state, only the through-space interaction between the two LPO (indirect through-space interaction) is allowed *via* the central C–H bond. With this interaction, S goes up from the **b** state; this new S level is nearly the same in energy as that of the **c** state. By comparing the energy levels in the **c** and **f** states, the variation in energy of S should mainly be derived not from the through-bond interaction (short path), but from the through-space interaction *via* the central C–H bond, while the variation of A is mostly the result of the through-bond interaction.

Figure 3 shows the variation in the LPO energy levels of pyrazine.

a. Two LPO on N atoms are cut off from the interactions; the energy levels of two LPO then go to lower levels and degenerate.

b. Even when we added the N···N direct through-space interaction to the **a** state, S and A showed no change in energy. The same phenomena had already been seen in pyrimidine.

c. When we cut off the right-hand side of C–C bond from the interactions (the same is true on the left-hand side), A goes up to the CMO level, but S does partly.

d. When the C–C bonds on both sides are cut off from the interactions, A does not vary from the **c** state, but S goes lower. The energy difference between the **c** and **d** states shows the magnitude of the C–C direct through-bond interaction. The order of S and A is reversed from the **c** state. From the **c** and **d** states, the energy level of S depends much on the through-bond interaction, while that of A does not, as is predicted from the consideration of the orbital symmetry. It is also noteworthy that the through-space interaction is not responsible for the energy difference between S and A, since the energy difference in the **d** state is rather small. This situation is quite different from that shown in pyridazine.

e. When the interactions were permitted only between the "cut-off" LPO and their neighboring four N–C bonds, A goes beyond the CMO level, but S still retains much below the CMO level. This result indicates that the energy level of S is determined not only by the direct through-bond interaction, but also by the through-space interaction combined with the through-bond interaction, since the energy level for S in the **e** state is much different from that of CMO, and the **e** state can be considered to include only the direct through-bond interaction.

Now we will discuss the roots of the LPO interactions. In the case of pyridazine, S is mainly destabilized through the short path, whereas A mainly interacts with the long path. Moreover in this molecule, the direct through-space interaction between n_1 and n_2 is larger than that of pyrimidine or pyrazine. Let us examine in more detail the **c**, **d**, and **e** states of Fig. 1. A indeed goes up by means of interactions *via* the long path. However, in comparison with the **d** and **e** states, both S and A retain nearly the same levels in spite of their different interactions. Therefore, in this molecule, it may be concluded that the interactions between the upper half and the lower half of a molecule *via* the through-space interaction are very important, as was

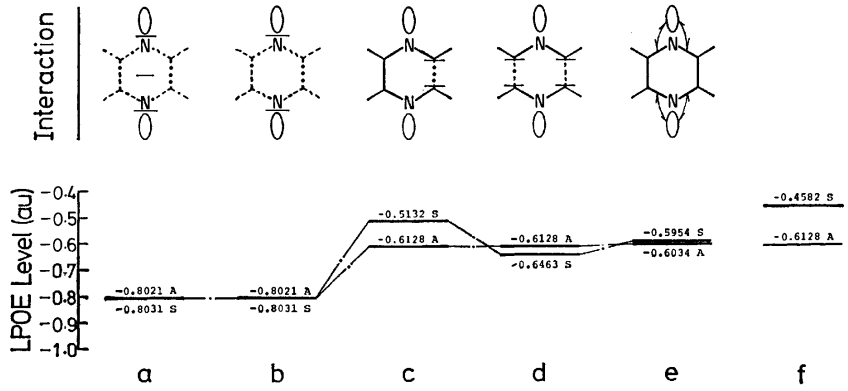

Fig. 3. LPO interaction diagram for pyrazine.
a: LPO are "cut off", **b**: LPO are "cut off" and N···N direct through-space interaction is allowed, **c**: one path is allowed but the other path is "cut off" at the C–C bond, **d**: both C–C bonds are "cut off", **e**: LPO are "cut off" and interactions between LPO and four N–C bonds are allowed, **f**: CMO level.

a b

Fig. 4. **a**: Through-space interaction, and **b**: through-bond interaction, in pyridazine. After combining **a** and **b**, it becomes the "through-space interaction after through-bond" or "through-bond interaction after through-space".

mentioned above. In the case, the through-bond interaction is also included, of course. That is, in other words, this may be named the "through-space after through-bond" or "through-bond after through-space" interaction. Some of interaction courses are shown in Fig. 4.

We shall now return to the discussion of pyrimidine by examining the **d**, **e**, and **f** states of Fig. 2 in more detail. In the case of pyridazine, we have already shown that the LPOE in the **d** and **e** states do not vary very much, as is shown in Fig. 1. However, in the case of pyrimidine, the LPOE are different in the **d** and **e** states, as is shown in Fig. 2. From this we can conclude that, in pyrimidine, the through-bond interaction *via* the N–C–C–C–N course is one of the most important interaction courses, unlike the case of pyridazine. That is, by cutting off the interactions between the C_1–C_2 and C_2–C_3 bonds, and the interaction of C_2–H in the N–C_1–C_2–C_3–N group, the LPO become less interactive.

With pyrazine from the **c** and **d** states shown in Fig. 3, we can recognize that S interacts intimately with the central C–C bonds. Usually the LPO energy order is S<A, but in pyrazine this order is reversed. Hoffmann *et al.*[4] have explained that this reverse order is attributable to the destabilization of the S level as a result of the interaction with the parallel σ C–C levels. Hackmeyer and Whitten[2c] have described that, in the case of the $n\rightarrow\pi^*$ transition, the two combinations of LPO n_1 and n_2 correspond to the $S\simeq n_1+n_2+\lambda\sigma$ and $A\simeq n_1-n_2$ relations. They have also concluded that the higher energy of S is attributable to the interaction with the pyrazine-ring σ system. The case in which the LPO do not interact with the σ C–C bond is shown by, for example, **d** of Fig. 3. In this case the energy order is S<A, indicating that the lack of interaction between the LPO and the central σ C–C bonds leads to a reversion of the levels of S and A. Therefore, the reverse order of S and A in pyrazine is explained quantitatively by the present analysis, and the present analysis confirms the previous hypotheses. In the **d** state, the LPOE are −0.6463 S and −0.6128 A (au), with a difference Δ= 0.0335 (au). The order of the difference agrees well with those of the CMO levels of pyridazine and pyrimidine, although the reason for it remains obscure.

The reversion of S and A is, of course, to be seen in pyridazine and pyrimidine also. In these molecules, however, the reversion cannot be explained only by the hypotheses of Hoffmann and his coworkers.[4] For example, with a pyridazine-type molecule, they proposed that the "through-space" interaction between LPO is dominant and that this lowers the S combination. According to the present analysis, it was found that the N–N direct through-bond interaction also plays an important role (the **c** state in Fig. 1), and in the **d** and **e** states of Fig. 1, the order is S below A even though the N···N direct through-space interaction is cut off.

Palmer *et al.* have reported on the photoelectron spectra of oxygen, sulfur, and nitrogen heterocycles, and they have discussed the variations in the LPOE at O, S, and N atoms.[13] In their paper they suggested that the "through-bond" interactions may play an important role in azines. In that paper, however, we cannot obtain a clear image of the interactions. The present investigation showed that the interactions between LPO are indeed very complicated. However, the interactions can be investigated very simply and clearly using the present procedure.

In conclusion, the present procedure for analyzing orbital interactions is very helpful to analyze the interactions between or among LPO in other molecules with very clear chemical images. The procedure is also applicable to analyzing the orbital interactions in such diradicals as benzynes. For such molecules the analyses are now in progress. This method will also be applied in an *ab initio* calculation. The details will be published elsewhere in the near future.

This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, for which we express our gratitude. We would like to acknowledge the continuing encouragement of Professor Hiromu Murata. The computations were carried out on a FACOM M190 of the Data Processing Center, Kyoto University.

11) Strictly speaking, the through-space and through-bond interactions, as defined in the present article, do not include the exchange energy, but include only the effect due to the core resonance intergrals. Although the through-space and through-bond interactions usually involve the exchange energy, the through-bond interaction with the exchange energy is dufficult to define by using the LMO; moreover, the problem treated in the present article is not essentially affected by omitting the exchange energy in the definitions of the though-space and through-bond interactions.

12) The through-space and/or through-bond interactions used in the present article are named on the basis of the LMO. Therefore, the definition used here is one of convenience.

(Received May 4, 1978)

The absorption and the fluorescence spectra of four [2.2]anthracenophanes were investigated at low temperatures. A theoretical calculation of the energy levels was performed by including the charge resonance and the exciton type interactions. The fluorescence excitation polarization spectra were recorded for all absorption bands at low temperatures, the directions of the transition moment of the excimer type emission bands being estimated by the *p*-values and the established transition directions of anthracene chromophores. The assignments of the absorption bands are presented based on these results.

The sandwich dimer is formed by photocleavage of dianthracene in rigid glass at low temperatures. Chandross *et al.*[1] and Ferguson *et al.*[2] found that the dimer shows excimer type emission at low temperatures but the absorption spectra slightly differ from a monomer spectrum and are correlated by a weak coupling vibronic theory. Ferguson and Mau[3] found the absorption of the anthracene sandwich pairs in dianthracene crystal.[3] In studies on the emission spectra of 9,10-dichloroanthracene crystal, Tanaka and Shibata[4] found that only the β crystalline form emits an excimer type emission, suggesting that a favorable geometrical arrangement of molecules in the crystal is necessary for formation of the excimer.

As a next step it is important to study the dimer interaction with a rigid molecule, *viz.*, anthracenophanes. Anthracenophanes have two anthracene chromophores separated by two ethylene bridges with a fixed or limited motion of composite rings; thus the inter-ring interaction should be more precisely investigated. Recently accurate X-ray crystal structure analyses of two anthracenophanes were carried out, the geometry and interatomic distances of these molecules being determined.[5,6] We have investigated the absorption and fluorescence spectra of four anthracenophanes at room temperature and low temperatures, and recorded the polarization of the fluorescence excitation spectra. A part of the emission work was published.[7] A theoretical calculation of the excited levels of these molecules was performed, and the assignments of the spectra are presented. It has been shown that the exciton type and the charge resonance type interactions between two chromophores are very important in molecules of close ring contact.[8–10] The structure of the excimer of anthracene is discussed from the reslults of the absorption and emission spectra of anthracenophanes.

Experimental

The materials were synthesized by the methods reported.[11,12] The shape and name of molecules are shown in Fig. 1. The solvent 2-methyltetrahydrofuran of spectrograde was distilled with sodium metal after treatment with potassium hydroxide.

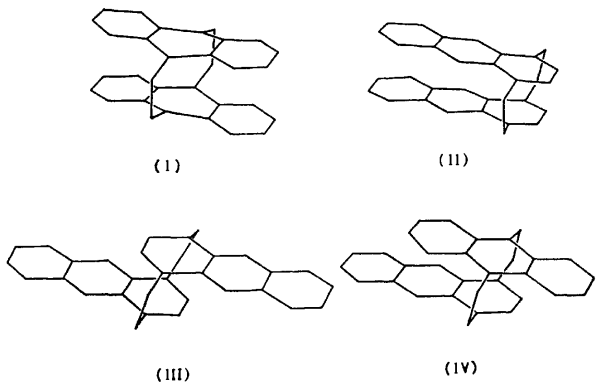

Fig. 1. [2.2]Anthracenophanes: (I) [2.2](9,10)anthracenophane; (II) *syn*-[2.2](1,4)anthracenophane; (III) *anti*-[2.2](1,4)anthracenophane; (IV) [2.2](1,4)(9,10)-anthracenophane.

The absorption spectra were recorded with a Cary 15 spectrophotometer with a Cryo-tip refrigerator for the low temperature measurement. A Cary 17 spectrophotometer at Australian National University was also used with a flow type cryostat. The fluorescence spectra were measured on a Carl-Zeiss M4QIII spectrofluorometer with a HTV R446 photomultiplier tube. The sample was excited with a 1 kW Xe lamp through a Carl-Zeiss monochromator set at right angles to the entrance slit of the fluorometer. Measurements of emission were also made with a 3/4 m Spex spectrometer, a cooled ITT-FW130 photomultiplier being used. The light from a 150W Varian xenon illuminator dispersed by a Carl-Zeiss MM 12 double monochromator was used as exciting source.[2,3] The intensity of fluorescence was corrected by comparison with that of quinine bisulfate solution in 0.1 N H_2SO_4 and of *o*-dichlorobenzene solution of 4-dimethylamino-4′-nitrostilbene. The polarization of the emission (PF) and the excitation (APF) was measured with the same system combined with calcite and pola-coat polarizers, the polarization character of the system

being cheked beforehand. The lifetime of the emission band was measured with a pulsed nitrogen gas laser combined with a Tektronix synchroscope of 465 type or a Tektronix sampling scope 564-3S2-3T77A system. The NMR spectra were recorded on JEOL JNM-TS-100 at 23, −50, −95, and −100 °C.

Theoretical Calculation

A SCF MO of each anthracene chromophore was calculated by the P-P-P method[13,14] with Nishimoto-Mataga potential.[15] The calculation was based on the structures determined by X-ray crystal analysis.[5,6] For molecules whose structures have not been determined by the X-ray method, model structures were constructed from the known forms.

The ground state wavefunctions of each ring are written as follows.

$$\begin{aligned} \Phi_0 &= |\varphi_1\bar{\varphi}_1 \cdots \varphi_7\bar{\varphi}_7| \\ \Theta_0 &= |\theta_1\bar{\theta}_1 \cdots \theta_7\bar{\theta}_7| \end{aligned} \tag{1}$$

The energies of the excited states were calculated from configuration interactions, where the intergroup charge resonance (CR) and the exciton interactions are included. The matrix elements between the locally excited (LE) and CR states were calculated by using the following formulas.

$$\begin{aligned} &\langle\varphi_m\varphi_n|H|\varphi_m\theta_n\rangle \\ &\quad= \frac{1}{2}\langle\{|\cdots\varphi_m\bar{\varphi}_n\cdots|+|\cdots\varphi_n\bar{\varphi}_m\cdots|\} \\ &\qquad||H||\{|\cdots\varphi_m\bar{\theta}_n\cdots|+|\cdots\bar{\theta}_n\varphi_m\cdots|\}\rangle \\ &\quad= \langle\varphi_n|F|\theta_n\rangle + 2(\varphi_m\theta_n|\varphi_m\varphi_n) - (\varphi_m\varphi_m|\varphi_n\theta_n), \\ &\langle\varphi_m\varphi_n|H|\theta_m\varphi_n\rangle \\ &\quad= \frac{1}{2}\langle\{|\cdots\varphi_m\bar{\varphi}_n\cdots|+|\cdots\varphi_n\bar{\varphi}_m\cdots|\} \\ &\qquad||H||\{|\cdots\theta_m\bar{\varphi}_n\cdots|+|\cdots\varphi_n\bar{\theta}_m\cdots|\}\rangle \\ &\quad= -\langle\varphi_m|F|\theta_m\rangle + 2(\varphi_m\varphi_n|\theta_m\varphi_n) - (\varphi_m\theta_m|\varphi_n\varphi_n), \end{aligned} \tag{2}$$

where Coulomb hybrid integrals are denoted by

$$(\varphi_m\theta_m|\varphi_n\varphi_n) = \int\varphi_m(1)\theta_m(1)\frac{1}{r_{12}}\varphi_n(2)\varphi_n(2)dv_1dv_2.$$

The hybrid integrals are calculated by using Mulliken's approximation

$$(\varphi_m\theta_m|\varphi_n\varphi_n) = \frac{1}{2}S_{mm}\{(\varphi_m\varphi_m|\varphi_n\varphi_n)+(\varphi_n\varphi_n|\theta_m\theta_m)\},$$

$$S_{mm} = \langle\varphi_m|\theta_m\rangle = \int\varphi_m(1)\theta_m(1)dv_1.$$

The one-electron integrals extending over two rings are taken as proportional to the overlap integrals:

$$\langle\varphi_n|F|\theta_n\rangle = kS_{nn}. \tag{4}$$

The proportionality constant, k, was so chosen as to obtain the best fit of calculated results with the observed values of transition energies and set to −14.0 eV. All computations were carried out on a Facom 230-60 computer at Nagoya University Computation Center.

Feature of Anthracenophane Excited State. Anthracene monomers have three excited states in the 25000—48000 cm^{-1} region, two of which are observed as allowed transitions. The lower energy transition in the 25000 cm^{-1} region is the short-axis polarized band ($^1B_{2u}$ state, ^1L_a band). It is composed of the electronic excitation from the highest occupied MO (φ_7, HOMO) to the lowest unoccupied MO (φ_8, LUMO). We can abbreviate the wavefunction of this state to

$$\Phi_1 = \frac{1}{\sqrt{2}}\{|\cdots\varphi_7\bar{\varphi}_8|+|\cdots\varphi_8\bar{\varphi}_7|\}. \tag{5}$$

The higher and stronger absorption is the long-axis polarized transition to the $^1B_{3u}$ state (^1B_b band); the wavefunction of the state is described by a linear combination of the excitation of an electron from the second HOMO (φ_6) to the LUMO (φ_8) and from the HOMO (φ_7) to the second LUMO (φ^9) as

$$\begin{aligned} \Phi_2 = \frac{1}{2}\{&|\cdots\varphi_6\bar{\varphi}_8\cdots|+|\cdots\varphi_8\bar{\varphi}_6\cdots| \\ &+|\cdots\varphi_7\bar{\varphi}_9|+|\cdots\varphi_9\bar{\varphi}_7|\}. \end{aligned} \tag{6}$$

A forbidden transition (^1L_b band) is composed of antisymmetric combination of the same excitation orbitals and is expected in the region of the first band, however, it has never been observed in the anthracene molecule.

When two anthracenophane chromophores approach each other, the CR configuration and the exciton type interaction become significant. The wavefunction of the exciton type state of the short-axis polarized first band is written as

$$\begin{aligned} \mathrm{ER}_1(+) &= \frac{1}{\sqrt{2}}\{\Phi_1\Theta_0+\Phi_0\Theta_1\}, \\ \mathrm{ER}_1(-) &= \frac{1}{\sqrt{2}}\{\Phi_1\Theta_0-\Phi_0\Theta_1\}. \end{aligned} \tag{7}$$

If the two chromophores are related by an inversion symmetry, the $ER_1(+)$ state is forbidden and the $ER_1(-)$ state allowed.

The CR configuration of the same symmetry type are given by

$$\begin{aligned} \mathrm{CR}_1(+) &= \frac{1}{\sqrt{2}}\{\Phi_1^+\Theta_1^- + \Phi_1^-\Theta_1^+\} \\ \text{and} \\ \mathrm{CR}_1(-) &= \frac{1}{\sqrt{2}}\{\Phi_1^+\Theta_1^- - \Phi_1^-\Theta_1^+\}. \end{aligned} \tag{8}$$

The energies of these configurations may be nearly degenerate, and the configuration interaction between the same symmetry levels should be considered. The resultant states can be approximately written as

$$\begin{aligned} \text{forbidden states} &\begin{cases} \mathrm{ER}_1(+) + \mathrm{CR}_1(+) \\ \mathrm{ER}_1(+) - \mathrm{CR}_1(+) \end{cases} \\ \text{allowed states} &\begin{cases} \mathrm{ER}_1(-) + \mathrm{CR}_1(-) \\ \mathrm{ER}_1(-) - \mathrm{CR}_1(-). \end{cases} \end{aligned} \tag{9}$$

The exciton states of the long-axis polarized transition are given by a linear combination of each LE state as

$$\begin{aligned} \mathrm{ER}_2(+) &= \frac{1}{\sqrt{2}}(\Phi_2\Theta_0+\Phi_0\Theta_2), \\ \mathrm{ER}_2(-) &= \frac{1}{\sqrt{2}}(\Phi_2\Theta_0-\Phi_0\Theta_2). \end{aligned} \tag{10}$$

The charge resonance excited levels of the same orbital type are written as $\Phi_2^+\Theta_2^-$. They are combined to give two CR states as

$$CR_2(+)=\frac{1}{\sqrt{2}}(\Phi_2^+\Theta_2^-+\Phi_2^-\Theta_2^+),$$
$$CR_2(-)=\frac{1}{\sqrt{2}}(\Phi_2^+\Theta_2^--\Phi_2^-\Theta_2^+). \quad (11)$$

Since the energy levels of the ER_2 and the CR_2 states do not differ a great deal, the same symmetry levels are coupled to give new states as given by Eq. 9.

The calculated results on the energy levels for each molecule are given in Tables 1—4. Only allowed transtions are compiled, assignments by abbreviated notations being given in the first column. The results show that the excited levels of anthracenophanes are described by a complex linear combination of LE and CT transitions of each anthracene chromophore. Actually the structure of the molecule deviates from an inversion symmetry, so that the calculated MO and the state functions lose symmetric properties. Lowering of molecular symmetry makes some transitions allowed, which were originally forbidden in anthracene molecule. Weak transitions appear as a result of the inter-chromophore interactions.

In spite of these complication the feature of anthracenophane absorption bands is characterized by the allowed states of Eq. 9 and allowed combinations of $ER_2(-)\pm CR_2(-)$. The excimer emission state is related to the lowest forbidden state of Eq. 9, which includes nearly a half $CR_1(+)$ state.

Results and Discussion

[2.2](9,10)Anthracenophane (I). The absorption spectra measured at room temperature and 77 K are shown in Fig. 2. A number of absorption peaks were found, at least six excited levels being discerned. The lowest energy transition was found in the range 19000—23000 cm^{-1} with weak intensity and broad band shape. Since the intensity is very weak and the level is much lower than other levels, the band is assigned to a forbidden transition to a mixed state of the $CR_1(+)$ and $ER_1(+)$. Murrell and Tanaka[8] represented this excited level as a mixed state of $^1E_g-{}^1R_g$, where ^1E_g and ^1R_g correspond to $ER_1(+)$ and $CR_1(+)$, respectively. In earlier studies on anthracene dimer or anthracene crystals, no such forbidden band had been observed in this region. Recently such transitions have been observed in bridged anthracene derivatives.[3] The

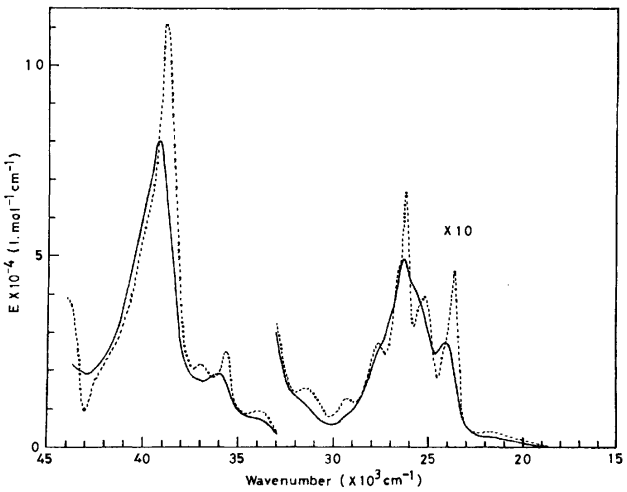

Fig. 2. Absorption spectra of I at 298 K (full line) and at 77 K (broken line) in MTHF.

inter-ring contact of this molecule is very close in the ground state, hence such type band is observed. The absorption band may be correlated with the excimer type emission of anthracene dimer, but the molecule gives no fluorescence even at 4 K. The absence of emission is ascribed to an efficient photochemical reaction and radiationless transitions.[7,16]

In the allowed transitions observed in the succeeding

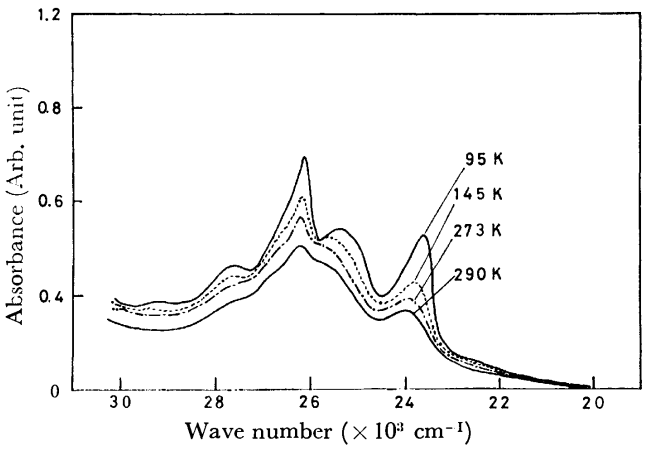

Fig. 3. Absorption spectra of I at various temperaures in MTHF.

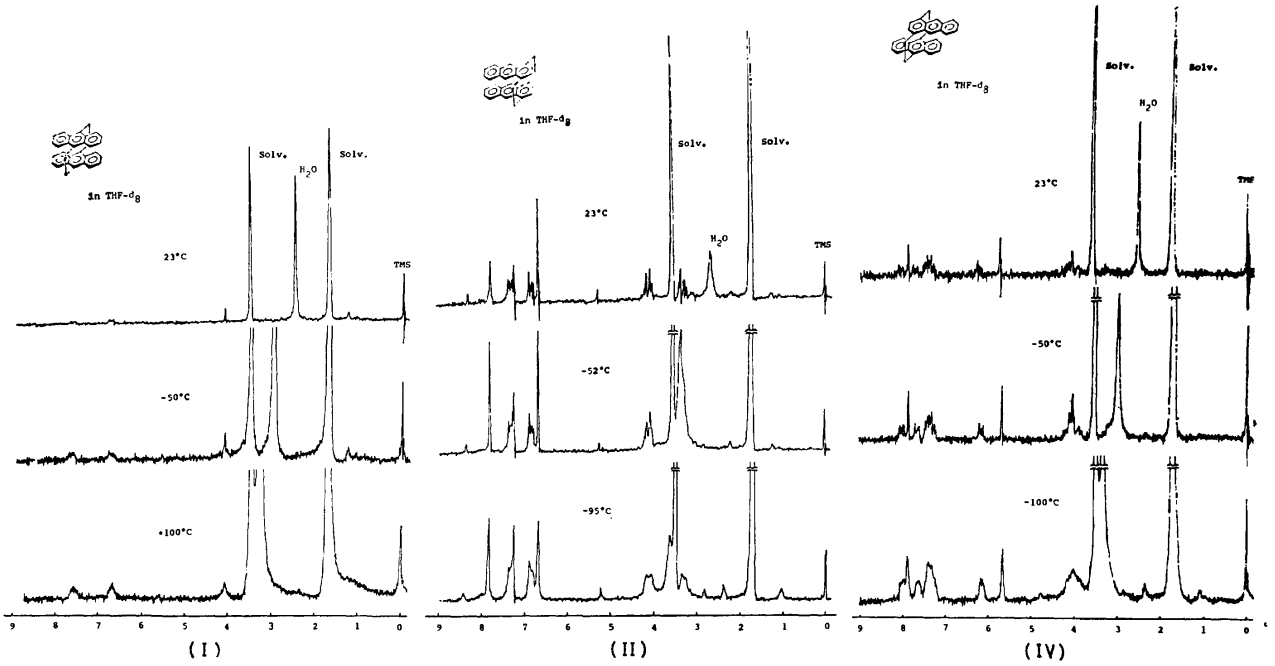

Fig. 4. NMR spectra of I, II, and IV at various temperatures.

region, the band at 24000 cm^{-1} is assigned to the transition of $ER_1(-)+CR_1(-)$. The next band at 25510 cm^{-1} shows strange spectral behavior with lowering in temperature; its intensity does not increase as compared to nearby transitions which are enhanced significantly. The intensity of this band is recorded as a guest in the single crystal of the photoisomer host, its intensity being much larger at 10 K as compared to that at 206 K.[17] The temperature change of solution spectra in this region shows that the 25510 cm^{-1} band behaves differently as compared to the neighboring bands (Fig. 3). Such unusual spectral behavior may be accounted for by assigning the band to the conformational isomer whose spectrum differs from that of the major conformer in this region.[18] The X-ray data on *syn*-[2.2](1,4)anthracenophane show the presence of two conformational isomers in the crystal.[5] Moreover, the NMR spectra of (I) (δ=4.05) at low temperature (Fig. 4) indicate that the methylene proton signals are broadened. It seems that a twisting around the methylene bridges causes the conformers.

The next peak at 26247 cm^{-1} is due to the transition to the $ER_1(-)-CR_1(-)$ state. The band shows regular vibrational progressions at 27624 and 29412 cm^{-1}. The appearance of sharp vibrational progressions indicates that the molecule has a relatively rigid structure. In the following region, several absorption bands were found at 31300, 33800, and 35600—37000 cm^{-1}. The 31300 cm^{-1} band may be due to a transition to the forbidden state of the coupled long-axis transition, $ER_2(+)+CR_2(+)$. The bands at 34000 and 35600 cm^{-1} region are assigned to the CR_2 type bands. The strongest absorption band observed at 38800 cm^{-1} is assigned to the strongly allowed long-axis transition of the coupled dimer, namely to the $ER_2(-)\pm CR_2(-)$ state. It appears from the calculation that two closely situated levels exist in this region.

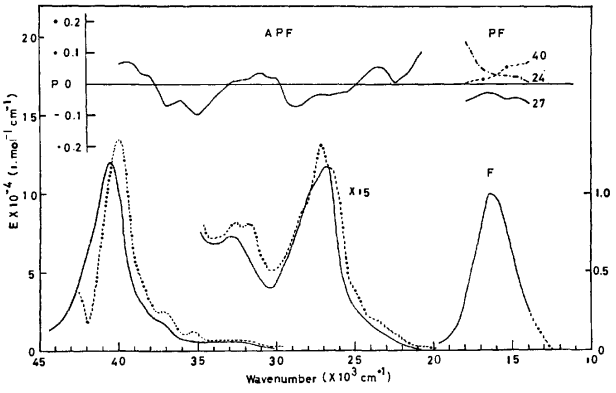

Fig. 5. Absorption spectra of II at 298 K (full line) and at 77 K (broken line) in MTHF with emission spectrum, PF, and APF measured at 77 K. APF monitored at 16000 cm^{-1}.

syn-[*2.2*]*(1,4)Anthracenophane (II).* The absorption spectra measured at room temperature and 77 K are shown in Fig. 5. There are at least seven transitions in the region 20000—45000 cm^{-1}. The lowest band is assigned to a forbidden transition to the $ER_1(+)+CR_1(+)$ state. No absorption related to the excimer emission has been observed in anthracene dimer prepared by photolysis at low temperature. The band can be assigned to the transition to the Franck-Condon state of the excimer level from the ground state. The excimer type fluorescence appears at 16000 cm^{-1}.

Several strong absorption bands were found in the range 24000—29000 cm^{-1} where there are at least three transitions. They are assigned to the coupled $^1B_{3u}$ state (forbidden long-axis polarized band in anthracene, ^1L_b band), $CR_1(-)$ and $ER_1(-)$ bands, respectively. The vibrational progressions are blurred off since the anthracene rings are hinged at the terminal benzene rings and the molecular structure seems to be flexible.

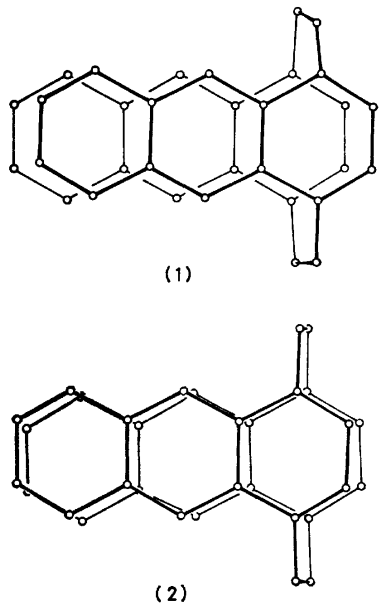

Fig. 6. Molecular structures of II at 124 K.
(1) Slipped form; (2) eclipsed form.

Toyoda and Misumi[5] determined the crystal structure of this molecule at −149 °C and found that two independent molecules are included in a unit cell, taking noticeably different conformations as shown in Fig. 6. One has an approximately symmetric faced conformation, while the other has a displaced or slipped conformation. NMR spectra at low temperature indicate that the methylene protons at $\delta=4$ ppm are broadened in (II) (Fig. 4). This indicates that the methylene bridges are not completely rigid and different conformers may exist at this temperature. The fluorescence spectra of (II) produced by the photocleavage of the photoisomer at 80 K show a peak at 16130 cm^{-1}. It turns into two peaks at 16130 and 16670 cm^{-1} at 140 K and finally is transformed into a single peak centered at 16580 cm^{-1} with enhancement of an intensity of three times. The results also show the presence of conformers at low temperatures.

In the higher energy region several absorption bands were found at 31000—34000, 35000—37000, and 39000—41000 cm^{-1}. The 31000—34000 cm^{-1} band is assigned to the $ER_2(-)$—$CR_2(-)$ band, which may have long-axis polarization. The band at around 37000 cm^{-1} is calculated to be the mixed higher CR and ER states. The strongest band in the 39000—41000 cm^{-1} region corresponds to the transition to the $ER_2(-)+CR_2(-)$ state.

For assignment of the absorption bands, the analysis of fluorescence polarization spectra would be of most value. The fluorescence spectra were measured at room temperature and 77 K as shown in Fig. 5, the broad excimer type emission band being observed with a peak at 16500 cm^{-1}. The excitation spectra for the red emission are consistent with the absorption spectra of (II), and the excitation efficiency is particularly large at 22000 cm^{-1} where the transition is to the Franck-Condon excimer state of $ER_1(+)+CR_1(+)$. The fluorescence excitation polarization spectra (APF) were measured by observing the fluorescence at 16500 cm^{-1}. The result is shown in Fig. 5 together with the absorption spectra. The first absorption band in the range 21000—22000 cm^{-1} shows the highest positive p value of 0.1. This indicates that the Franck-Condon excited state has nearly the same character as that of the excimer emission, but still the p-value is not high enough to show parallelism of the absorption and emission transition moments. It is very probable that the molecule is deformed in the excited state and the polarization direction of the emission is not exactly the same as of the absorption band. The emissive transition is originally forbidden; it might thus borrow the transition moment from other allowed transitions.

Although the internal molecular motion may occur in the excited state, we can estimate the direction of the transition moment of the emission band based on the p-value of APF for each absorption band at low temperature where the translational molecular motion is frozen. If the excimer state has the strict symmetry of D_{2h}, a radiative transition to the ground state is forbidden, and no emission can be expected. As a matter of fact the fluorescence is observed, hence the symmetry of the excited state should be lowered. However, no polarization study has been published on the excimer state formed by the encounter process in solution. Subudhi, Kanamaru and Lim[19] measured the polarization property on anthracene sandwich dimer and found that the excimer state includes both the short axis component of anthracene $^1B_{2u}(^1L_a)$ type state and the out of plane constituent of CR_1 type state.

In anthracenophanes the emission might appear as a result of the deformation of the molecule in the excited state. Several levels might be mixed to make the transition allowed with a definite polarization direction. The direction might be estimated by correlating the p-value to the long and the short axes polarized transition of anthracene chromophore in anthracenophane. We use the relation of angles between the transition moments of the absorption and the emission:[20]

$$p=\frac{3\cos^2\alpha-1}{3+\cos^2\alpha}, \tag{12}$$

where α is the angle between the emission and the absorption bands.

The direction of the transition moment of the strongest band at 40000 cm^{-1} is certainly along the long-axis; the excimer emission shows positive p-value to the long-axis polarized band. This can occur since the emission state involves the long-axis polarization component. The angle between the transition moment of the emission band and the long-axis is estimated at 48° by Eq. 12. The absorption band in the range 27300—29000 cm^{-1} may have the short-axis polarization (Table 2). The p-value is −0.08 and the angle is found as 60° to the short-axis. The direction of the excimer emission band is thus estimated by using these angles as shown in Fig. 7. In the 26500 cm^{-1} region the p-value is −0.04 and the angle between the absorption and emission transition moments is estimated to be 57° by Eq. 12. The transition of $CR_1(-)$ type may have the polarization in the out of plane direction, and the direction

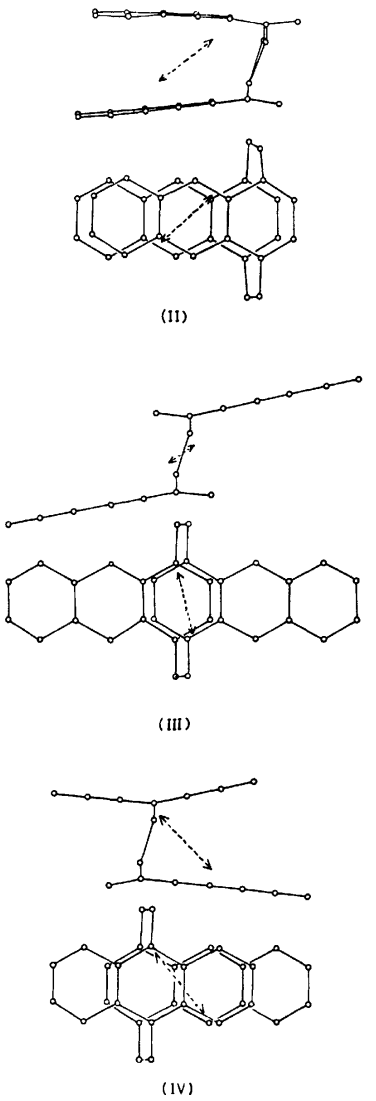

Fig. 7. The directions of the transition moment of emission bands of II, III, and IV estimated from polarization measurements.

makes 56° with the estimated direction of the excimer transition moment. The agreement seems satisfactory.

A positive hump of *p*-value was observed in the 23000—25000 cm^{-1} range, weak shoulders being detected in the absorption spectra. According to theoretical calculation, these weak transitions are attributed to the forbidden transition of the long-axis polarized band originated from anthracene $^1B_{3u}^-$ state (^1L_b type). The 31000 cm^{-1} band shows positive *p*-value, consistent with the assignment of $ER_2(-)+CR_2(-)$, since ER_2 component may have large contribution. In the range 35000—38000 cm^{-1}, the *p*-value is negative. This is reasonable since the transition takes place toward higher CR and the short-axis polarized ER states.

The polarization of the fluorescence band (PF) was measured with excitations fixed at 40000, 27000 and 24000 cm^{-1}, respectively, and the *p*-values were found nearly constant for the 27000 cm^{-1} excitation, varying slightly for the 24000 and 40000 cm^{-1} excitations. This indicates that the excited state involved for the emission band has a mixed character.

The lifetime of the emission was 70 ns, which may be short because of photochemical reaction. It seems that the molecule in the excited state is so deformed that a mixing of an allowed component occurs extensively and both the radiative and the radiationless transitions are enhanced.

anti-[*2.2*]*(1,4)Anthracenophane (III).* The absorption spectra measured at room temperature and 77 K are shown in Fig. 8. The first absorption band consisting of three different bands starts at 23000 cm^{-1} and extends to 31000 cm^{-1}. By lowering the temperature to 77 K, the lowest transition is red-shifted to 23900 cm^{-1}. This is assigned to the $ER_1(+)+CR_1(+)$ state. Several vibrational progressions are observed in the succeeding region. They are classified into two series at 24750, 26180, and 27620 cm^{-1} and 25250, 26740 and 28170 cm^{-1}. Theoretical calculation showed that these are the transitions to the $ER_1(-)\pm CR_1(-)$ states. The splitting of these levels was experimentally estimated as 500 cm^{-1}, while theoretical calculation showed a much larger value. For the molecule with a weak coupling, the present treatment should be modified considering the vibronic effect. The origin of the succeeding band series is not clear and the band at 30000 cm^{-1} is assigned to the higher CR state.

The strongest absorption band is found at 35300 cm^{-1}. This is an allowed long-axis polarized transition which is red-shifted from monomer transition by the exciton type interaction. The red shift as compared to I and II occurred because the arrangement of chromophore is of a head to tail type. The result of calculation shows that two allowed transitions coexist in the 35000—37000 cm^{-1} region, which are regarded to be of $ER_2(-)+CR_2(-)$ type. Another transition was observed at 39500 cm^{-1}, which is ascribed to the long-axis polarized transition of $ER_2(-)-CR_2(-)$.

The fluorescence and the APF spectra measured at 77 K are shown in Fig. 8. The Stokes shift for the

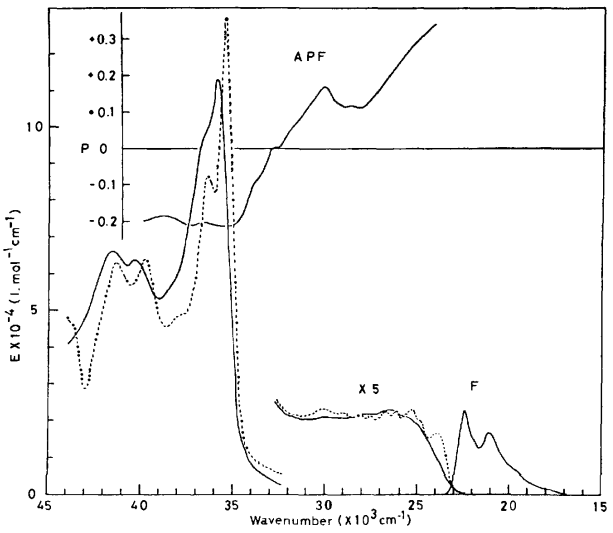

Fig. 8. Absorption spectra of III at 298 K (full line) and at 77 K (broken line) along with emission spectrum and APF at 77 K. APF monitored at 22000 cm^{-1}.

emission is 1500 cm^{-1}, which is smaller than in II and IV but fairly large to indicate the contribution of the CR interaction in the excited state. The APF spectra were measured at 22000 cm^{-1} emission band and the first absorption band at 26000 cm^{-1} shows a high p-value of 0.4. The angle between the emission and the first absorption is estimated to be 23° by Eq. 12, but actually it may be nearly parallel because of inherent experimental error. The bands at 25000—29000 cm^{-1} show positive p-values and the angle is estimated to be about 40°. The two band series are derived from the $ER_1(-)\pm CR_1(-)$ states; the mixing of the CR state with ER state makes the transition moments have an appreciable deviation from the short-axis. In the region of the long-axis polarized transitions, the p-values are all negative, being in line with the assignment of the transitions. The angle between the emission and the long-axis is estimated to be about 71°. By using these angles the direction of the transition moment is estimated as shown in Fig. 7. The lifetime of the emission is 8 ns which is very close to the value of anthracene derivatives. It is consistent with a relatively small shift of the energy level by the dimer type interaction.

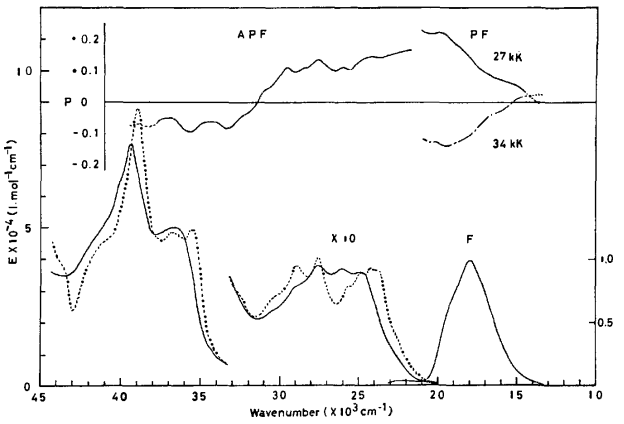

Fig. 9. Absorption spectra of IV at 298 K (full line) and at 77 K (broken line) with emission spectrum, PF, and APF mesured at 77 K. APF monitored at 17500 cm^{-1}.

[2.2](1,4)(9,10)Anthracenophane (IV). The absorption spectra measured at room temperature and 77 K are shown in Fig. 9. The spectra show a conspicuous change at 77 K as compared to that at room temperature, particularly in the lowest energy region. At 22500 cm^{-1} a faint shoulder is observed, but it is not clear whether it is correlated to the lowest calculated level of $ER_1(+)+CR_1(+)$. The strong bands observed at 23800, 24200, 24800, and 25600 cm^{-1} are assigned to the transitions to the $ER_1(-)+CR_1(-)$ state. The succeeding bands found at 27600, 29000, and 30500 cm^{-1} are considered as the transition to the $ER_1(-)-CR_1(-)$ state. The red-shift of the 23800—25600 cm^{-1} bands at low temperature can be explained by a conformational change of the molecule. The NMR spectra (Fig. 4) at low temperature show a broadening of the methylene protons at $\delta=4$ ppm which may be due to the conformational changes. According to a theoretical calculation, a slight change in molecular conformation may cause a significant change in energy levels, therefore a slight change in molecular structure may induce a conspicuous change in absorption spectra. The state which involves the CR configuration will be particularly influenced by a conformational change. The red shift of the 24000 cm^{-1} band can be reasonably understood by a contribution of the CR state to this level.

In the ranges 31500—34000 and 35500—37000 cm^{-1}, the absorption bands detected are ascribed to the $ER_2(-)+CR_2(-)$ state and the higher CR states. The strongest absorption band observed in the 39000—40000 cm^{-1} region is assigned to the $ER_2(-)-CR_2(-)$ state, which is polarized along the long-axis.

The fluorescence and APF spectra measured at room temperature and 77 K are shown in Fig. 9. At low temperature the fluorescence is of a typical excimer type, the Stokes shift being *ca.* 5000 cm^{-1}. APF spectra show positive p-values in the ranges 21500—26000 and 27000—31000 cm^{-1} for the emission band detected at 17500 cm^{-1}.

The results indicate that the polarization of the emission is inclined to the short-axis. In the higher energy region above 32000 cm^{-1}, the p-value is negative. By using Eq. 12 and these p-values, the direction of the transition moment of emission band is estimated as shown in Fig. 7.

The polarization of the fluorescence (PF) is not constant for the whole range of emission bands; the p-value is much more positive in the higher than the lower energy region. A similar result was reported by Subudhi *et al.*[19] for the sandwich dimer formed by the photocleavage of dianthracene in a rigid media. The lifetime of this emission at 77 K is 150—170 ns, typical of the excimer type emission.

Concluding Remarks

The absorption spectra of anthracenophanes show a remarkable change as compared to the sandwich dimer prepared by the photolysis of dianthracene at low temperature. This implies that the inter-ring interaction between anthracene chromophore is much stronger than in the sandwich dimer because the inter-ring distance is shorter than that of normal van der Waals contact. Moreover the planes of the anthracene rings in anthracenophanes are so deformed by ethylene bridges that some fordidden transitions in anthracene appear with lowering in molecular symmetry.

Relative arrangement of the faced rings greatly affects the pattern of the absorption spectra. The charge resonance and exciton type interactions are found to be most important for the interaction between the faced aromatic rings. The absorption bands corresponding to the excimer emission state were observed with weak intensities at the lowest energy region.

The excimer type fluorescence spectra of *syn*-[2.2](1,4)anthracenophane and [2.2](1,4)(9,10)anthracenophane do not differ much from that of the sandwich dimer. A large electron overlap is necessary for the stabilization of the excited state. An overlap of more than two benzene rings is sufficient for the excimer type emission to appear. A large Stokes shift from the

absorption to the fluorescence maximum suggests that the molecules are further deformed in the excited state to cause the stabilization of the excited level and the destabilization of the ground state. The excimer emission state was found to involve nearly a half CR state besides the lowest exciton states of the short- and the long-axis polarization.

(Received May 15, 1978)

Electronic absorption spectra of tetra-*t*-butylbisdehydro[14], [18], [22], [26], and [30]annulenes were investigated experimentally and theoretically. SCF MO calculations were carried out by the P-P-P method and random phase approximation (RPA). An assignment of spectra is presented. Fluorescence excitation polarization spectra of tetra-*t*-butylbisdehydro[14]annulene and the crystalline reflection spectra of tetra-*t*-butylbisdehydro[18]annulene were studied in order to determine the polarization of the spectra. The assignment was confirmed by these methods.

Recently a series of bisdehydroannulenes were synthesized by Nakagawa and coworkers.[1,2] The molecules were shown to have a symmetrical conjugated system. Among interesting physicochemical properties of these molecules, the electronic absorption spectra and fluorescence spectra are of particular interest, since they show a characteristic pattern of conjugated system.

In this paper we will present the assignment of the electronic transitions for bisdehydro[14], [18], [22], [26], and [30]annulenes based on the polarization analyses of the absorption bands with the aid of a crystalline reflectance measurement. The fluorescence polarization technique was also used for determination of the polarization direction. A theoretical calculation of the excited state has been performed, the effect of the bond alternation being examined.

Experimental

The synthesis of the compounds used in this investigation has been described elsewhere.[2] The visisble and UV absorption spectra were measured with a Carl Zeiss spectrophotometer PMQ II, and the fluorescence spectra were recorded with a Carl Zeiss spectrofluorometer. The polarization of the fluorescence was measured with a pola-coat polarizer placed parallel and perpendicular to the fluorescence cell, which was excited by light passed through a calcite polarizer. Reflectivity of a crystal was measured with a reflecting microscope constructed in this laboratory. Calculation of the energy levels of the excited states was carried out by the standard method of Pariser and Parr[3] and Pople[4] with CI calculation and the RPA method developed by Tanaka and Tanaka.[5] All the calculations were performed at Nagoya University Computation Center.

Results and Discussion

Absorption Spectra. The electronic spectra of tetra-*t*-butylbisdehydro[14], [18], [22], [26], and [30]-annulenes were measured in THF solutions in the range 10000—50000 cm^{-1}, four or five allowed transitions being found (Fig. 1). The intensities of these bands are weak, medium, very strong, and strong in the order of increasing energy. Although the location and shape of bands differ for each compound, a common spectral pattern conformable to the spectrum of naphthalene is observed.

We will use the notations used in the classification of polyacene spectra, and call the transitions ^1L_b, ^1L_a, ^1B_b, and ^1B_a bands in the order of increasing energy. A group theoretical classification of the states is also used assuming that the molecule has a D_{2h} symmetry.

Molecular Structure and Theoretical Calculation of Energy Levels. The electronic energy level of a large conjugated system is critically dependent on the precise structure of the molecule. According to the X-ray crystal analysis of Bailey and Mason,[6] and of Kabuto *et al.*[7] the crystals of bisdehydro[14] and [18]annulenes have symmetrical structures, where the center of the molecule is situated in the ceneter of the symmetry of the crystal. Although this does not necessarily indicate a symmetrical structure of the molecule, it is very probable that the molecules have a fully conjugated double bond system. However, according to Kabuto *et al.*[8] bisdehydro[22]annulene shows bond alternation in the crystal which suggests that the larger ring system is stable for the alternate bond structure. A theoretical calculation was carried out for all bisdehydroannulenes assuming that the symmetrical D_{2h} structure has cyclic delocalized double bonds. For bisdehydro[30]annulene, calculation was also carried out with alternate double bond lengths. The results are given in Table 1 together with the observed transition energies and intensities. A comparison of the calculated and observed values gives the following results:

(1) For bisdehydro[14] and [18]annulenes results obtained by the P-P-P and RPA methods are in excellent agreement except that the ^1B_b and ^1B_a transitions are reversed in sequence. The RPA method gives better results with respect to intensity. The ^1B_b and ^1B_a bands are assigned with reference to absorption intensity. The assignment for the ^1B_a band of bisdehydro[18]-annulene is based on the crystalline absorption measurement.

(2) For bisdehydro[22]annulene the agreement is not so good as comapred to small ring molecules. The ^1B_a band is calculated to be low in energy as compared to the observed 33000 cm^{-1} peak. A shoulder around 25000 cm^{-1} region can be assigned to the ^1B_a band.

(3) For bisdehydro[26]annulene the calculated values

are smaller than the observed values. The ^1B_a band is calculated to be too low in energy; it might be buried under the strong band around 24000 cm^{-1} region. If this is the case the 30200 cm^{-1} band should be assigned to another origin.

(4) For bisdehydro[30]annulene the calculated results are also lower in energy than the observed bands; the symmetrical model gives much lower energies than the alternate deformed model. It appears that the molecule has actually an alternate bond structure.

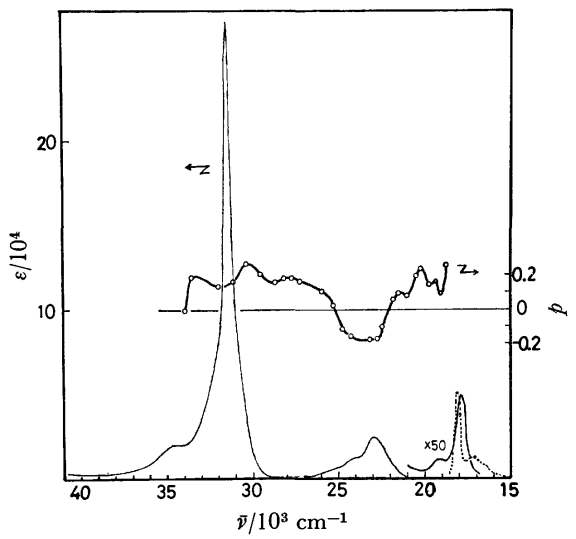

Fig. 2. Electronic absorption (——), fluorescence (……), and fluorescence excitation polarization (APF) spectra (-∘-∘-) of bisdehydro[14]annulene. p-Values are in the middle of the figure.

Fluorescence Excitation Polarization Spectra. The fluorescence excitation polarization (AFP) of bisdehydro[14]annulene was measured in 2-methyltetrahydrofuran solution at 77 K. The fluorescence was detected at 17100 cm^{-1}. The result is shown in Fig. 2. The fluorescence peak at 77 K was noticeably blue shifted as compared to the absorption peak at room temperature. The polarization of the excitation band defined by $p=I_{//}-I_{\perp}/I_{//}+I_{\perp}$ is also shown. The p-value for the first absorption band is positive (0.25—0.10), while that for the second band (^1L_a band) around 22000 cm^{-1} is negative (−0.19). For the strongest absorption region around 30000 cm^{-1}, the p-value is positive (0.25—0.13), becoming zero at around 33000 cm^{-1}. A theoretical calculation showed the polarization character; the first and the strongest bands are long-axis polarized, the second band is short-axis polarized and another short-axis polarized transition exists at above 30000 cm^{-1}. The result from AFP measurement confirms the theoretical assignment of polarization if we assume that the lowest transition is long-axis polarized. This was confirmed by the crystalline spectra of bisdehydro[18]annulene, and we use this result for bisdehydro[14] and other bisdehydro annulenes. A preliminary result on di-*t*-butyldiphenylbisdehydro[14]-annulene was reported.[1)]

Crystalline Spectra of Bisdehydro[18]annulene. In order to find a more reliable assignment of the spectra,

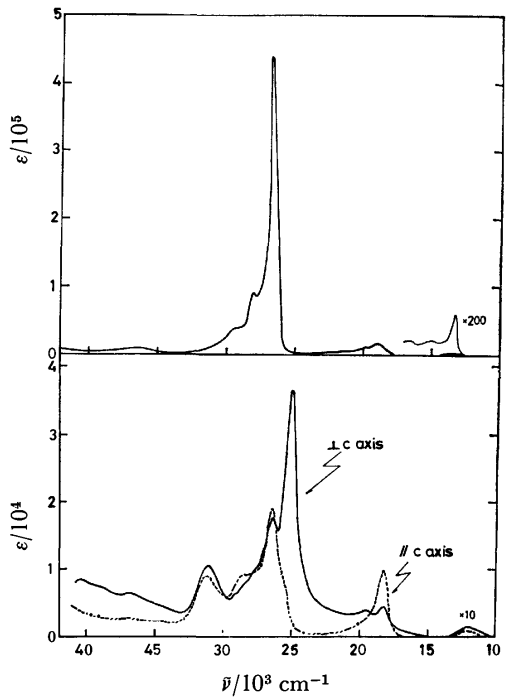

Fig. 3. Solution and the crystalline (110) face spectra of bisdehydro[18]annulene

the single crystal polarization spectra of bisdehydro[18]-annulene were measured by a reflection method. The solution spectra in 2-methyltetrahydrofuran and the crystalline spectra of bisdehydro[18]annulene are shown in Fig. 3; the crystalline spectra were obtained for the (110) face by the Kramers-Kronig transform of reflectivity. For the first absorption region the absorption was too weak to be measured by means of reflectivity and the transmission measurement was employed.

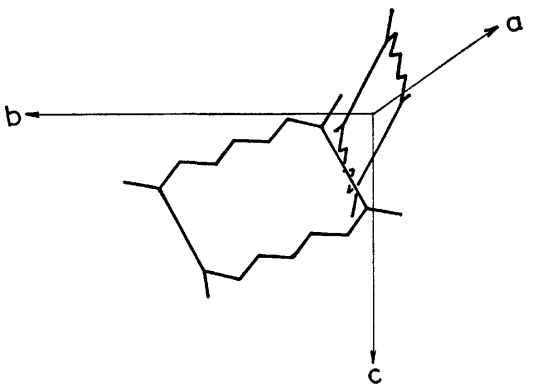

Fig. 4. Projection of molecules onto the (110) face of bisdehydro[18]annulene obtained from Ref. 7.

The projection of molecules onto the developed (110) face is shown in Fig. 4. From the crystalline projection it is easily seen that the short molecular axis of two molecules in a unit cell has a larger component along the c-axis than along the ⊥ c-axis. The long-axis of one of the molecules has a larger component along the ⊥ c-axis on this face, while another molecule has a smaller component. Thus the long-axis polarized transition will

appear mainly along the ⊥ c-direction.

The observed spectra clearly show the polarization character of each transition. The first absorption band in the 12000 cm^{-1} region is the weakest one. Such a transition is easily perturbed by the nearby transition. However, the first band shows its own polarization character in which its intensity is stronger along the ⊥ c-axis than along the // c-axis. This means that the first band has long-axis polarization. The second absorption band at 18200 cm^{-1} shows stronger absorption along the // c-axis than along the ⊥ c-axis. Thus it is assigned to the short-axis polarized transition. The third transition, which is the strongest of all transitions, shows peaks at 25000 (0-0), 26400 (0-1) and 27600 (0-2) cm^{-1} along the ⊥ c-axis, and at 26400 (0-0) and 27900—28400 (0-1, 0-2) cm^{-1} along the // c-axis. The splitting of 1400 cm^{-1} for the 0-0 band is due to a Davydov type crystalline splitting. The intensity is stronger along the ⊥ c-axis than along the // c-axis, hence it is assigned to the long-axis polarized band. The fourth absorption band appearing around 31000 cm^{-1} is considered to be the shifted one of 29400 cm^{-1} band in solution. It shows similar strengths of intensity along the ⊥ c and // c directions, and the ⊥ c band may be intensified since the tail of the third band is overlapped with the fourth band. Thus the fourth band is assigned to the short-axis polarized transition. The polarization of transitions was determined from these results (Table 1).

Concluding Remarks

Recently Kolc, Michl, and Vogel[9] studied the electronic spectra of bridged [14]annulenes and calculated excited energies of hypothetical planar [14]annulene. They obtained a similar result similar to ours which shows that the polarization of transitions are along long-, short-, short-, and long-axis in the order of increasing energy. Our theoretical results show a similar tendency, but it is not in harmony with experiment as regard to the third and fourth bands. A reason for this discrepancy may be that the valence state energies of the sp hybridized carbon atoms in the conjugated triple bonds are much larger than those of the sp^2 hybridized carbon atoms; this point was not considered in the present calculation.

Electrical Properties of Langmuir Films of Fatty Acid Salts and Carotenoic Acid

Naoto YAMAMOTO, Toshihiro OHNISHI, Masahiro HATAKEYAMA, and Hiroshi TSUBOMURA*

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received May 26, 1978)

Electric conductivities have been studied for Langmuir molecular layers of barium salt of fatty acids and for the layers of barium arachidate mixed with *all-trans-β-apo-8'*-carotenoic acid. These results have been interpreted based on an electron tunneling model taking account of the mirror image force. The conduction levels of the layers have thereby been estimated to be 1.00 eV for barium stearate, 1.31 eV for barium arachidate and 1.45 eV for barium behenate below vacuum level. The conduction level of the carotenoic acid has been derived to be 1.9 eV from these results. The structure of these layers has been discussed from the above mentioned experimental results, together with those on surface pressure, absorption spectrum and electric capacitance.

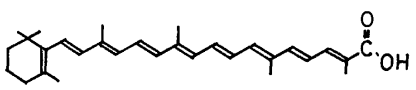
Recently, the physicochemical properties of Langmuir films were extensively investigated by Kuhn *et al.*[1,2] They showed from electric conductivity measurements of fatty acid layers that electron tunneling predominantly contributes to the conductivity through the monomolecular layers. They estimated the conduction levels of these fatty acid salts from a theoretical equation for the tunneling current and their experimental results.[3,4]

We have investigated electrical and spectroscopic properties of molecular layers of fatty acid mixed with *all-trans-β*-carotene.[5] It has been shown that, contrary to our expectation, *β*-carotene molecules lie parallel to the plane of the molecular layer and are aggregated.

All-trans-β-apo-8'-carotenoic acid is expected to form a stable mixed monolayer with fatty acids in which the molecules are perpendicular to the layer because of its hydrophobic chain and the hydrophilic end group. It is of interest to investigate the electrical properties of the surfaces, where long π-conjugated chain molecules are perpendicularly aligned, in connection with the action of carotenoids in biological electron transport. We have studied the surface pressure, the absorption spectrum and the electric conductivity of the monolayers of fatty acid salts with and without the carotenoic acid in order to clarify the structure of these layers and the mechanism of their electric conduction.

Experimental

The method for the preparation of aluminum/Langmiuir film/aluminum junctions was described in detail in a previous paper.[5] The surface pressure of monolayer spread at an air–water interface was kept constant at 30 dynes/cm during transferring the monolayer onto a substrate by use of a compression barrier automatically driven by a servomotor combined with a Wilhelmy balance.



carotenoic acid

All-trans-β-apo-8'-carotenoic acid (carotenoic acid) ethyl ester was obtained from F. Hoffmann-La Roche and Co.† Carotenoic acid was prepared by hydrolysis of the ester, followed by recrystallization from a benzene solution according to Isler *et al.*[6] Absorption spectrum of the purified carotenoic acid in hexane was confirmed to agree with that reported in benzene solution.[7] No band ascribable to the cis-isomer was found in the spectrum.[8] Arachidic acid from P-L Biochemicals, Inc. was purified by recrystallization twice from an ethanol solution. Other materials were prepared and purified in the same procedures as described previously.[5]

The dc conductivity was measured with a Keithley 414S picoammeter and a Shimadzu VM101 voltmeter. The dc voltage was applied by coupling a potentiometer and a dry cell. Capacitance measurement was made with a Yokogawa-Hewlett-Packard 4265B bridge at 1 kHz, 20 mV peak-to-peak. The visible-UV absorption spectra of the films were measured with an ultra sensitive spectrophotometer constructed in our laboratry.[9]

All measurements and preparation of the mixed layers of the carotenoic acid were performed in an atmosphere of nitrogen under red light.

Results and Discussion

Structure of the Mixed Layers. Figure 1 shows the surface pressure (π) *versus* the area per molecule (A) of the monolayers of carotenoic acid mixed with arachidic acid in various molar fractions at the air–water interface. The π-A curves consist of two components: the slow rising part below 10—20 dyn/cm and the steep part in the higher pressure region. The limiting areas per molecule, A_0, were derived by extrapolating the steep part in the curves at zero-pressure. The value of A_0 was obtained to be 28 Å^2 for the pure carotenoic acid monolayer, which was between the polyene chain cross section (about 20 Å^2) and the *β*-ionone ring cross section (about 50 Å^2). This result strongly suggests that carotenoic acid molecules are standing perpendicularly at the water surface. A linear relationship between the A_0 value and the molar fraction was found for the mixed monolayers, also implying that carotenoic acid molecules are perpendicularly standing in the mixed monolayers.

Figure 2 shows the electronic absorption spectra of carotenoic acid dissolved in hexane and those incorporated in cadmium arachidate monolayers at various molar ratios deposited on slide glass. The absorption spectra of the carotenoic acid in the mixed layers are somewhat broader than that of the solution. The

† The authors wish to express their gratitude to F. Hoffmann-La Roche and Co. for the kind donation of *all-trans-β-apo-8'*-carotenoic acid ester.

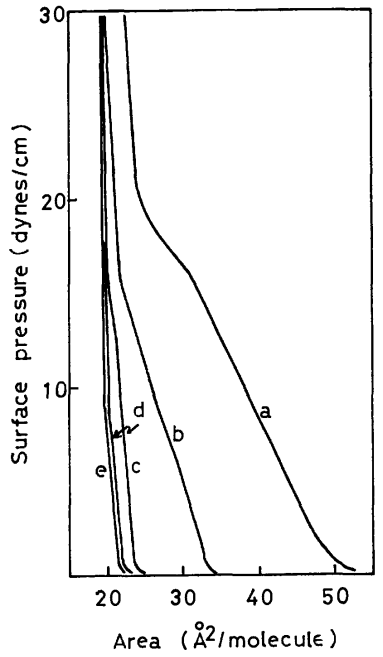


Fig. 1. The surface pressure-area curves for mixed layers of carotenoic acid and arachidic acid on the surface of solution containing 3×10^{-5} mol/l barium chloride and 4×10^{-4} mol/l potassium bicarbonate. The molar fractions of carotenoic acid were 1.0 for a, 0.464 for b, 0.0709 for c, 0.017 for d, and 0 for e, respectively.

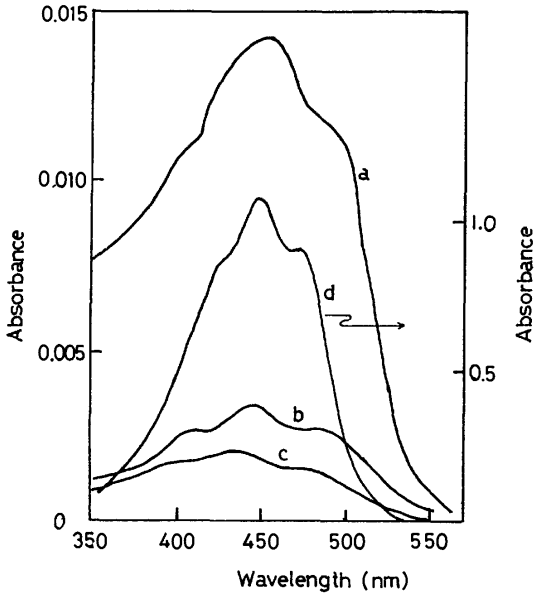

Fig. 2. Absorption spectra of the mixed monolayers of carotenoic acid and cadmium arachidate at normal incidence. The molar fractions of carotenoic acid are 1.0 for curve a, 0.194 for curve b, and 0.0973 for curve c. Curve d is for the 10^{-5} mol/l hexane solution of carotenoic acid.

spectra of the films show a slight blue-shift with decreasing molar fraction of carotenoic acid.

The "molar" extinction coefficient of carotenoic acid in the layers at the absorption peak may be defined by $\varepsilon_m=A/\Gamma$ mol^{-1} cm^2 where A is the absorbance of the monolayer and Γ is the number of moles of carotenoic acid per 1 cm^2 of the film. Taking A to be 0.014 from the maximum of curve a in Fig. 2 and Γ to be 5.9×10^{-10} mol cm^{-1}, corresponding to the value of 28 Å^2/molecule obtained for pure carotenoic acid layer, we obtain $\varepsilon_m=2.4\times10^7$ mol^{-1} cm^2. If the carotenoic acid molecules were to lie randomly in the pure carotenoic acid monolayer, ε_m would take the value of *ca.* 1.1×10^8 mol^{-1} cm^2, corresponding to the maximum molar extinction coefficient measured in the hexane solution. The experimental ε value obtained is 5 times as small as the latter. As the direction of the transition moment for the absorption band is thought to be parallel to the polyene chain, no absorption band should be observed in the wavelength region measured if the molecules are aligned in an exactly perpendicular array in the film. Simple calculation by use of our result leads to the conclusion that the carotenoic acid molecules in the pure film on an average make an angle of 20° with the line normal to the film plane. Curves b and c in Fig. 2 also indicate that the molecules are similarly oriented in the mixed films as well.

The capacitance measurements for the mixed films with various number of monolayers revealed that a good linear relationship between the reciprocal of capacitance and the number of the monolayers was observed. The value of thickness of the mixed monolayer divided by its relative permittivity was obtained to be 11.2 Å from the slope. Assuming that the electric polarization of the film is a simple sum of those due to the fatty acid and the carotenoic acid and taking the relative permittivities for the fatty acid and carotenoic acid to be 2.41[5] and 3.6[10] respectively, the thickness of carotenoic acid array was estimated to be 28 Å, corresponding to the length of the molecule, by the same methods as employed for the layers of fatty acid salt mixed with β-carotene.[5] This result also confirms that the carotenoic acid molecules are perpendicularly standing in the mixed monolayers deposited on the solid substrate. The conclusion on the molecular orientation of carotenoic acid in the layers agrees with that reported by Reich[11] and Engelsen.[7]

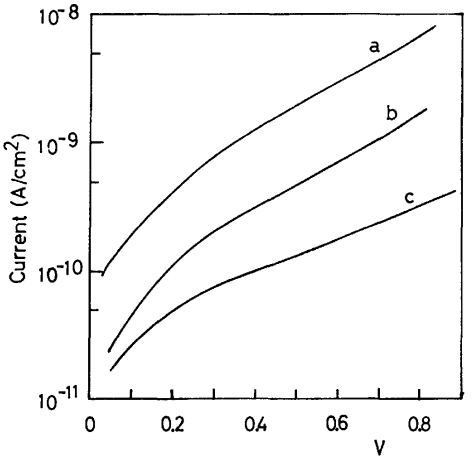

Fig. 3. The current-voltage curves for the monolayers of fatty acid salts: (a) barium stearate, (b) barium arachidate, and (c) barium behenate.

Conductivity Measurements. The current-voltage (j-V) curves obtained for the fatty acid salt monolayers at room temperature are shown in Fig. 3. The magnitude of current decreased with increasing fatty acid chain length, *i.e.*, in the order of barium stearate, barium arachidate and barium behenate. Each of the currents was proportional to the applied voltage in the low voltage region ($V<0.1$ V), but increased exponentially above 0.3 V. The currents obtained were about 100 times as small as those measured for Al/fatty acid salt/metal junctions by Kuhn *et al.*,[3,4] though the shapes of our j-V curves were very similar to theirs. The currents for 3-, 5-, 7-, and 9-layer films were much smaller than that for the monolayer, and proportional to the voltage up to about 0.8 V. The dc conductivity, σ_0, calculated from this ohmic behavior of the multilayer films was 2.3×10^{-16} Ω^{-1} cm^{-1} for barium stearate, 1.1×10^{-16} Ω^{-1} cm^{-1} for barium arachidate and 4.8×10^{-17} Ω^{-1} cm^{-1} for barium behenate. The σ_0 values fall into the range of conductivities of paraffin in the solid state.[12] This fact indicates that the fatty acid multi-layer films prepared have no substantial pinholes.

TABLE 1. TUNNELING CONDUCTIVITY, POTENTIAL BARRIER HEIGHT AND CONDUCTION LEVEL OF FATTY ACID SALT MONOLAYERS AND CAROTENOIC ACID ARRAY IN THE MIXED MONOLAYER

Material	σ_t (Ω^{-1} cm^{-1})	$\bar{\phi}$(eV)	V_0(eV)	d(Å)
Barium stearate	2.7×10^{-16}	2.53	1.00	25.8[a]
Barium arachidate	8.7×10^{-17}	2.26	1.31	28.0[a]
Barium behenate	1.96×10^{-17}	2.05	1.45	30.2[a]
Carotenoic acid	1.95×10^{-14}	1.7	1.9	28

a) Taken from Ref. 4.

The j-V curves obtained for the monolayers are reasonably explained by the electron tunneling model given for thin oxide films by Simmons.[13] The tunneling conductivity, σ_t, for the fatty acid salt monolayers was derived by subtracting σ_0 from the conductivity obtained for the monolayers at low voltage region and listed in Table 1. According to a Simmons' equation for a rectangular potential barrier in the low voltage region,[13] the tunneling current, j_t, can be expressed as a function of potential barrier height, $\bar{\phi}$, as follows:

$$j_t = [(2m\bar{\phi})^{1/2}/d](e/h)^2 \cdot V \cdot \exp[-4\pi d/h \cdot (2m\bar{\phi})^{1/2}], \quad (1)$$

where m and e are the electron mass and charge, respectively, h is Planck's constant and d the thidkness of monolayer. The $\bar{\phi}$ values calculated from the σ_t values using Eq. 1 are listed in Table 1. Assuming that $\bar{\phi}$ is simply represented by the difference between the work function of the metal electrode and the electron conduction level of the monolayer, V_0, the V_0 values of 1.7—2.1 eV were calculated for these fatty acid salts taking 4.2 eV as the work function of aluminum.[14] On the other hand, if one takes account of a mirror image force due to the metal electrodes, the V_0 values as listed in Table 1 were obtained with the aid of Simmons' method (Eqs. 48 and 49 in Ref. 13).

Figure 4 shows j-V curves measured for mono- and multi-layer films of barium arachidate with and without carotenoic acid at room temperature. The current measured for the mixed monolayer was much higher than that for the barium arachidate monolayer. The electric conductivity of the mixed monolayers is considered to be a sum of those by the barium arachidate array and the carotenoic acid array, so that the current in the mixed monolayer is caused mainly by electron flowing through the carotenoic acid array. The σ_0 and V_0 values were roughly estimated to be 1.1×10^{-13} Ω^{-1} cm^{-1} and 1.73 eV for the mixed monolayer, respectively.[15]

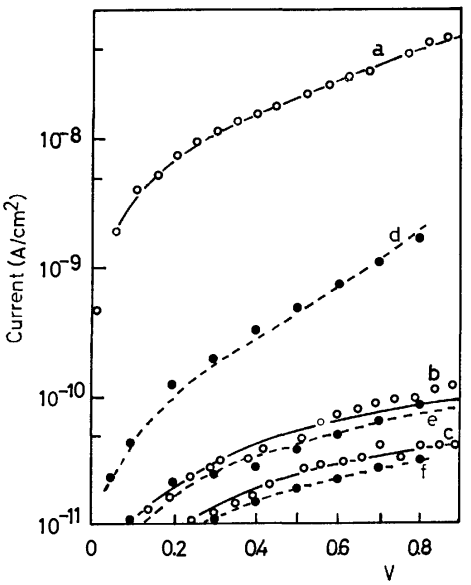

Fig. 4. The current-voltage curves for mono- and multilayer films of arachidic acid salt with and without carotenoic acid. Curves a, b, and c; for 1-, 5-, and 7-layer films of arachidic acid salt mixed with carotenoic acid, respectively (○). Curves d, e, and f; for 1-, 5-, and 7-layer films of arachidic acid salt, respectively (●). Solid and dotted lines are calculated curves (Ref. 15). Molar fraction of carotenoic acid in the mixed layers is 0.0709.

In the case of multi-layer films, the increase in the current due to the addition of carotenoic acid was small. The conductivity of the multi-layer films of barium arachidate mixed with carotenoic acid was obtained to be 1.3×10^{-16} Ω^{-1} cm^{-1} from the j-V curves shown in Fig. 3.

The conduction band level of a dry electron has been estimated to be almost zero for alkanes,[16,17] and the depth of electron trap in alkane matrices and benzene matrices have been obtained to be 0.26 eV[17-19] and 0.5 eV,[19] respectively. Our V_0 values are somewhat larger than either of these values.

The Simmons' equations have been derived for the tunneling current at 0 K.[13] At higher temperatures, the metal electrons should be populated in the higher electronic states of the electrode metal according to the Fermi distribution. It is, therefore, expected that part of the metal electrons are allowed to have kinetic energies much more than the average thermal energy ($kT\approx0.03$ eV) at room temperature. Though the number of

electrons in such highly excited states are relatively few according to the Fermi distribution, they can contribute largely in the tunnel current by the exponential dependence of the effective barrier height. Consequently, it becomes likely that our room temperature experiment brings about the larger V_0 value.

Inelastic electron tunneling process coupled with vibrational excitation and polarization of molecules has been investigated at low temperature.[20] It has been pointed out that an inelastic process for a monolayer of simple organic molecules adsorbed on metal oxide surface changes the conductance by *ca.* 1%,[21] and that the inelastic tunneling channels increase with applied voltage. In the inelastic processes, the electrons either lose or gain energy by interactions with the film material. In the first case, electrons should have excess energy to compensate the energy loss due to the inelastic processes in order to reach another electrode. In the second case, the film material should be in a higher lattice vibration-rotation states. Therefore, in either case, the probability of the inetastic tunneling is increased at higher temperature. It is, therefore, suggested that such an inelastic process, giving more important contributions at higher temperature, makes the experimental V_0 values larger than those corresponding to the conduction band levels for the alkane matrices obtained by other experimental methods.

NMR Studies on Zerovalent Metal π-Complexes of Dibenzylideneacetone. I. Ligand Conformation and Bonding in the Binuclear Palladium Complex

Hiroshi KAWAZURA,* Hisao TANAKA, Koh-ichi YAMADA, Toshio TAKAHASHI,** and Yoshio ISHII**

Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-02
***Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa, Nagoya 464*

(Received June 9, 1978)

To elucidate the ligand conformation and the metal–olefin bonding nature in the binuclear palladium complex of dibenzylideneacetone, $Pd_2[(C_6H_5CH{=}CH)_2CO]_3$, ^1H NMR studies have been performed on the deuteriated complexes $Pd_2[(C_6D_5CH{=}CH)_2CO]_3$, $Pd_2[(C_6D_5CD{=}CH)_2CO]_3$, and $Pd_2[(C_6D_5CH{=}CD)_2CO]_3$. Examination of the spectra has revealed that the three dibenzylideneacetone ligands which triply bridge the two Pd atoms are all in the *s-cis,trans* conformation. The most probable bonding scheme of the three ligands to the two Pd atoms is as follows: one Pd atom is ligated by one *s-trans* and two *s-cis* olefinic moieties and hence the other by one *s-cis* and two *s-trans* to yield a metal–olefin bonding stronger in the former combination than in the latter. A linear correlation between the couplings and the mean chemical shifts of the *trans* olefinic protons suggests a dominant role of metal to olefin π-back donation in differentiating the olefinic moieties in their bonding strength to the metal atoms and in retaining the characteristic rigid structure of the complex.

Concurrently reported X-ray structural analyses[1–3] of the binuclear Pd complexes of dibenzylideneacetone (dba), $(C_6H_5CH{=}CH)_2CO$, of the formula $Pd_2(dba)_3$(solvent) showed an interesting disparity in the conformations of the dba ligands. Pierpont and Mazza[1,2] conducted a structural analysis on a crystal of $Pd_2(dba)_3(CH_2Cl_2)$ and found two dba molecules in the *s-cis,trans* conformation and one in the more symmetric *s-trans,trans* conformation, whereas the analysis[3] of a crystal of $Pd_2(dba)_3(CHCl_3)$ indicated all three to be in the *s-cis,trans* conformation. The $Pd_2(dba)_3$ molecule in both crystals possesses essentialy the same configurational arrangement, *i.e.*, the two olefinic double bonds of a given dba ligand coordinate separately to Pd atoms (Pd–Pd distance 3.24 Å) to form a binuclear complex in which each of the Pd atoms exhibits trigonal coordination. The fact that the solvent molecules of crystallization in the $Pd_2(dba)_3$ molecule play a decisive role in changing the conformation of the dba ligand in the crystals prompted us to elucidate the ligand conformation of $Pd_2(dba)_3$ in solutions.

Another motive of this study emerged from a desire to elucidate the metal to olefin bonding nature. The $Pd_2(dba)_3$ molecule can provide genuine information on the π-olefin–metal bonding since the molecule contains a ligand in which only the olefinic portions are involved in bonding to the metal atoms.

With the above interests, we have performed a ^1H NMR study on the $Pd_2(dba)_3$ molecule. Examination of the NMR parameters for the olefinic moieties of the ligands has led to a clarification of the ligand conformation and suggested the bonding nature of the ligands to the Pd atoms.

Results and Discussion

Analysis of the ^1H NMR Spectrum of $Pd_2(dba)_3$.
As earlier reported,[3] the signals of the olefinic protons in $Pd_2[(C_6H_5CH{=}CH)_2CO]_3(CHCl_3)$ are partially obscured by those of the phenyl protons, although they are spread considerably to high field as a direct consequence of coordination. The whole pattern of olefinic protons was observed in the spectrum of $Pd_2[(C_6D_5CH{=}CH)_2CO]_3(CHCl_3)$ in $CDCl_3$ (Fig. 1A). The interpretation of this intricate spectrum was assisted by the availability of the spectra of $Pd_2[(C_6D_5CD{=}CH)_2CO]_3(CHCl_3)$ and $Pd_2[(C_6D_5CH{=}CD)_2CO]_3(CHCl_3)$ in $CDCl_3$ (Fig. 1C and D). These well resolved spectra were obtained through a number of pattern accumulations carried out by a pulsed 100 MHz NMR system in the Fourier transform mode. The fast pulsed scans greatly reduced the measurement time, so that liberation of the coordinated dba was minimized. The resonances

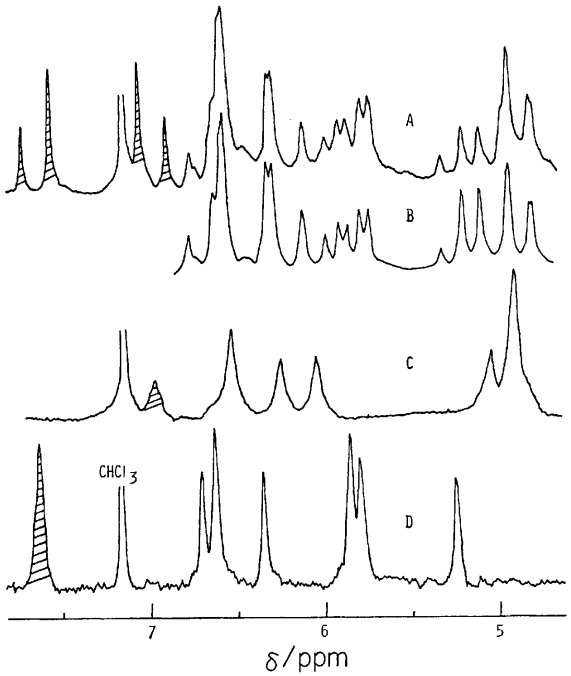

Fig. 1. ^1H NMR spectra measured in $CDCl_3$ at 25 °C. A: $Pd_2[(C_6D_5CH{=}CH)_2CO]_3$, C: $Pd_2[(C_6D_5CD{=}CH)_2CO]_3$, and D: $Pd_2[(C_6D_5CH{=}CD)_2CO]_3$ and B: the computer-simulated spectrum of $Pd_2[(C_6D_5CH{=}CH)_2CO]_3$.

originating from the free dba are shown with striped lines in Fig. 1. The spectra of Fig. 1C and D explicitly gave the resonance positions of the olefinic protons on the carbonyl side (H_A) and those of the olefinic protons on the phenyl side (H_B), respectively, in the coordinated dba. The chemical shifts of H_A and H_B (δ_A and δ_B) were used to assign the olefinic AB quartet families by spin decoupling in the spectrum of Fig. 1A, and then to simulate the spectrum by providing the coupling constants (J_{AB}) as small variables. An optimal simulation spectrum (Fig. 1B) was obtained to give the ^1H NMR parameters of the six olefinic moieties in the dba ligands (Table 1).

Table 1. ^1H NMR parameters of the olefinic protons of dba in $Pd_2(dba)_3$ in $CDCl_3$ at 25 °C

Olefin	J_{AB}/Hz	δ_A/ppm	δ_B/ppm	δ_{AB}/ppm	$\bar{\delta}_H$/ppm
a	14.2	6.619	6.688	0.069	6.654
b	13.7	6.134	6.765	0.631	6.450
c	13.8	6.322	6.422	0.100	6.372
d	12.7	4.935	5.900	0.965	5.418
e	12.7	4.916	5.853	0.937	5.385
f	12.3	5.057	5.243	0.186	5.150

δ_A and δ_B; in ppm with tetramethylsilane. $\delta_{AB}=\delta_B-\delta_A$ and $\bar{\delta}_H=(\delta_A+\delta_B)/2$. For free dba (in $CDCl_3$ at 25 °C): J_{AB}; 16.0 Hz, δ_A; 7.090, δ_B; 7.750, δ_{AB}; 0.660, and $\bar{\delta}_H$; 7.420 ppm.

From the Table, it can be seen that the six olefinic moieties which manifest various AB quartet patterns divide into two distinct and separate groups of three with respect to either the coupling J_{AB} or mean chemical shift $\bar{\delta}_H[=(\delta_A+\delta_B)/2]$ of the olefinic protons in the *trans* configuration; the three olefinic moieties **a**, **b**, and **c** with J_{AB} of *ca.* 14.0 Hz are located on the low field side ($\bar{\delta}_H$; *ca.* 6.5 ppm) and the other three **d**, **e**, and **f** with J_{AB} of *ca.* 12.5 Hz on the high field side ($\bar{\delta}_H$; *ca.* 5.3 ppm). The high field shift of the olefinic proton signals upon coordination has been observed for many metal–olefin π-complexes, especially for low valency transition metal complexes[4] and has been directly related to the amount of metal to olefin π-back donation.[5,6] It follows that the olefinic moieties **d**, **e**, and **f** are stronger in the π-bonding with the Pd atom than the other olefinic moieties **a**, **b**, and **c**.[10]

The six olefinic moieties can also be divided into another two distinct groups of three with respect to the internal chemical shift $\delta_{AB}(=\delta_B-\delta_A)$; the three olefinic moieties **a**, **c**, and **f** with δ_{AB} smaller than 0.2 ppm and the other three **b**, **d**, and **e** with δ_{AB} larger than 0.6 ppm. It should be noted that the former group contains two of the olefinic moieties with $\bar{\delta}_H$ of *ca.* 6.5 ppm and so the latter contains only one of them. Therefore the separation of the olefinic moieties with respect to δ_{AB} must differ in its origin from the separation with respect to $\bar{\delta}_H$.

Conformation of the dba Ligands. In the preceding paper[12] it has been shown that the parameter δ_{AB} is a good measure of the conformation of the olefinic moiety of dba. Thus it has been fully proven that the *s-cis* form of the olefinic moiety must have a minimum value of δ_{AB} (0.5 ppm) which increases slightly by a deformation towards the *s-skew* form, while the *s-trans* form must have a maximum value of δ_{AB} (1.5 ppm) which decreases rapidly even by a small deformation towards the *s-skew* form. From the above relation between the δ_{AB} value and the form of the olefin, it can be said that the six olefinic moieties of the coordinated dba molecules consist of three in the *s-cis* form (olefins **a**, **c**, and **f**) and three in the *s-trans* form (olefins **b**, **d**, and **e**).[13]

The existence of an equal number of both forms in the olefinic moieties necessarily demands at least one of the dba ligands with *s-cis,trans* conformation. In mutual allocation between H_A of one of the two olefinic portions of dba and H_B of the other, only the allocation between H_A of the *s-cis* olefin and H_B of the *s-trans* olefin in the *s-cis,trans* conformation brings about the closest proximity between H_A and H_B (Fig. 2); hence an intramolecular NOE will be a maximum for one of

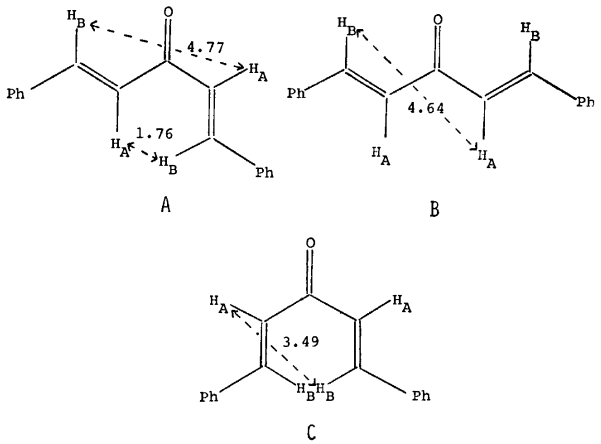

Fig. 2. Three basic conformations of dba. A: *s-cis, trans* B: *s-cis, cis*, and C: *s-trans, trans* and distances (in Å), between H_A and H_B in the different olefinic moiety in a given dba, estimated from the bond lengths and angles assumed in the preceding paper.[12]

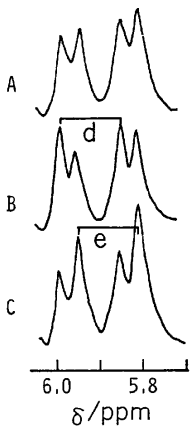

Fig. 3. NOE effects. A: Ordinary signals of H_B's of olefins **d** and **e** near 5.9 ppm in the spectrum of $Pd_2[(C_6D_5CH{=}CH)_2CO]_3$, B: enhancement of H_B signal of olefin **d** on an irradiation of H_A of olefin **a**, and C: enhancement of H_B signal of olefin **e** on an irradiation of H_A of olefin **c**. These spectra were successively taken under identical conditions.

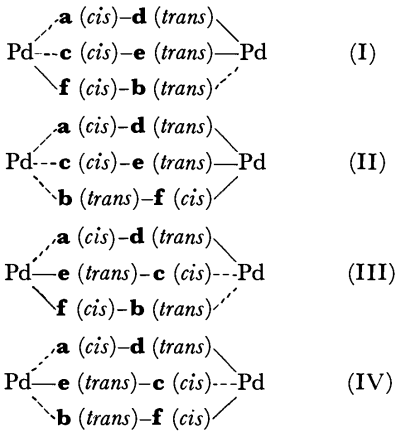
these proton signals when the other is saturated. Figure 3 shows the results of irradiation of the H_A protons in the olefinic moieties. As expected, the irradiation of H_A in the *s-cis* olefin **a** caused an appreciable enhancement of the signal intensity of H_B in the *s-trans* olefin **d**. This indicates that the *s-cis* olefin **a** and *s-trans* olefin **d** are linked to constitute one *s-cis,trans* dba ligand. The signal enhancement of H_B in olefin **e** was also observed on irradiation of H_A in olefin **c** to show the existence of another dba ligand of *s-cis,trans* conformation. Thus the remainder, the *s-trans* olefin **b** and *s-cis* olefin **f** should combine to give the third *s-cis,trans* ligand. Thus it may be concluded that the $Pd_2(dba)_3$ molecule in solution retain the three dba ligands in a *s-cis,trans* conformation as in the crystalline state.

If the conformations of the dba ligands in the crystal could be conserved in solution as in $Pd_2(dba)_3(CHCl_3)$, for $Pd_2(dba)_3(CH_2Cl_2)$ an ^1H NMR spectrum differing from that of $Pd_2(dba)_3(CHCl_3)$ would be expected. The ^1H NMR spectrum of $Pd_2[(C_6D_5CH{=}CH)_2CO]_3$-$(CH_2Cl_2)$ prepared by the recrystallization of Pd_2-$[(C_6D_5CH{=}CH)_2CO]_3(CHCl_3)$ in CH_2Cl_2 was measured in CD_2Cl_2. The spectrum showed that the resonance pattern of the olefinic protons was completely identical with that of $Pd_2[(C_6D_5CH{=}CH)_2CO]_3(CHCl_3)$ in $CDCl_3$, implying that in solution, the sterically repulsive *s-trans,trans* dba ligand[12] in the crystalline $Pd_2[(C_6D_5$-$CH{=}CH)_2CO]_3(CH_2Cl_2)$ changes to the less repulsive *s-cis,trans* form. The appearance of the *s-trans,trans* form in the crystal may be due to a packing requirement on the crystallization involving the solvent molecule.

In consideration of the bonding scheme of the three dba ligands to the two Pd atoms, the three ligands may be denoted as **a**(*cis*)–**d**(*trans*), **c**(*cis*)–**e**(*trans*), and **f**(*cis*)–**b**(*trans*) according to the binding manner of the olefinic moieties as already determined. The following four bonding schemes will be considered:



Here, the π-bonding strengths, as estimated already, between the olefinic moieties and the Pd metal are indicated by the solid line for the stronger bonds and by the broken line for the weaker ones. Although there is no direct method for determining the ligand allocation because of an absence of spin interaction between the ligands, schemes III or IV would be prefered from circumstantial evidence: the first scheme in which each Pd atom is attached by three *s-cis* or three *s-trans* olefins is improbable since the allocation differs from that[3] in the crystalline $Pd_2(dba)_3(CHCl_3)$. Indeed in scheme I the three olefinic moieties around each Pd atom must be equivalent in all the NMR parameters contrary to the experimental results. The remaining three all satisfy the allocation of the ligands in the crystalline complex. Some differences in the δ_{AB} values of ligand **b**–**f** from those of the other two ligands may be considered to come from a difference in the spatial location of the olefinic protons towards the carbonyl group[17] of the neighbouring ligand. In this respect scheme II is not compatible, since a molecular model indicates that the two ligands in inverse conformational allocation, *e.g.* **b**–**f** and **a**–**d** or **b**–**f** and **c**–**e** in II, must be similar to each other in spatial location.[18] The results of the decomposition process of the complex are against scheme II. Figure 4 shows the spectra of $Pd_2[(C_6D_5CD{=}$

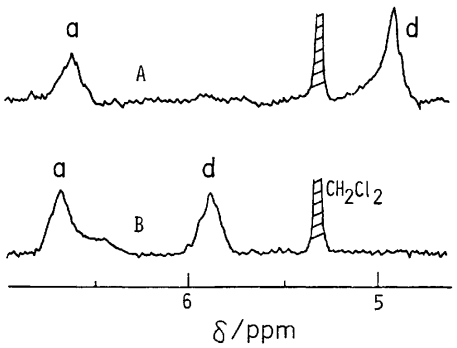


Fig. 4. ^1H NMR spectra of $Pd_2[(C_6D_5CD{=}CH)_2CO]_3$ (A) and $Pd_2[(C_6D_5CH{=}CD)_2CO]_3$ (B) measured in CD_2Cl_2 at 40 °C.

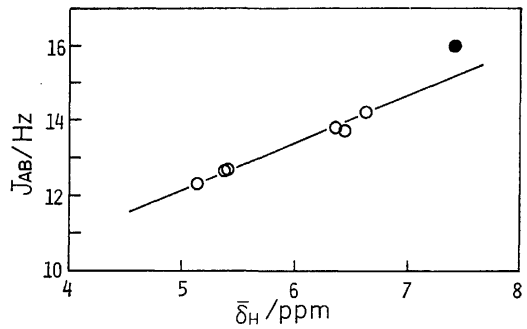
$CH)_2CO]_3$ and $Pd_2[(C_6D_5CH{=}CD)_2CO]_3$ in CD_2Cl_2 at 40 °C, where the broadened signals resulting from only the ligand **a**–**d** can be observed. This may indicate a slower elimination of the one specific ligand in the complex in accordance with the results of the thermogravimetric analysis.[3] The above behaviour of ligand **a**–**d** is difficult to understand in scheme II where ligands **a**–**d** and **c**–**e** are similar in both bonding and conformational allocation to the two Pd atoms. In the scheme III or IV the ligand **a**–**d** is different from the other two in either bonding or conformational allocation. Thus it may be justifiably said that the allocation of the three ligands in the complex is that in III or IV. Both schemes lead to the conclusion that the Pd atom coordinated by one *s-trans* and two *s-cis* olefins binds the olefins more strongly than does the one coordinated by one *s-cis* and two *s-trans* olefins. It should be reasonable to expect a difference in the Pd–olefin bonding between the conformation of *cis-trans-trans* and that of *cis-cis-trans*.

Pd–Olefin Bonding Nature. It has been already shown that either the chemical shift $\bar{\delta}_H$ or coupling J_{AB} classifies the six olefinic moieties into two groups of three with respect to their π-bonding strengths to the metal atoms. The parallel correlation between J_{AB} and $\bar{\delta}_H$ can be seen in Fig. 5 where the correlation is embodied in a line passing near the point for the free dba molecule (J_{AB}; 16.0 Hz and $\bar{\delta}_H$; 7.42 ppm in $CDCl_3$ at 25 °C) showing that the reduction of J_{AB} causes



Fgi. 5. A correlation between J_{AB} and δ_H of olefinic protons of dba. ○: $Pd_2(dba)_3$ and ●: free dba.

the high field shift of $\bar{\delta}_H$. This suggests[19] that the coupling is mainly influenced by the same source as that for the chemical shift $\bar{\delta}_H$, *i.e.* the amount of π-back donation. A similar result has also been discussed with the divalent Pt–olefin complexes.[20]

The reason for differing degrees of π-back donation in the olefinic moieties requires discussion. In $Pd_2(dba)_3$, the factors affecting the strength of π-bonding may be limited to the geometries around the metal–olefin bond. Two geometrical factors emerge from the structural data[2] on a crystal of $Pd_2(dba)_3(CH_2Cl_2)$.[21] The first one is the tilt angle of the olefinic double bond to the trigonal plane which the metal atom makes with the centers of the three olefinic double bonds. These angles are 9, 17, 21, and 37° for the *s-trans* olefins as compared to 67 and 80° for the *s-cis* olefins. The molecular models of the binuclear systems generally suggest that the double bonds of the *s-trans* and those of the *s-cis* olefin are forced parallel and perpendicular to the trigonal plane, respectively, due to conformational constraints. The recent molecular orbital treatment[22] of tris-(ethylene)nickel $Ni(C_2H_4)_3$ has shown that the "in plane" configuration is more effective in the π-back donation than the "up right" configuration. If this rule could be immediately applied to the present case the *s-trans* olefin would form the stronger π-bonding with the Pd atom than the *s-cis* olefin. However, as already seen it was not always so. Therefore the double bond tilting may not be the main factor in determining the strength of each metal–olefin π-bonding in $Pd_2(dba)_3$. The second factor, the distance between the olefinic double bond and the Pd atom, may be responsible for the π-bonding strength. The distances measured with the average of the metal–olefinic carbon distances fall into two ranges of 2.19—2.22 Å for the three *s-trans* and 2.28—2.30 Å for the one *s-trans* and two *s-cis* olefins. It is to be expected that the shorter ones cause better π-back donation through the improved overlapping of the metal hybridized orbital with the olefin π^*-orbital. For example, in the complexes such as $[PtCl_3(olefin)]^+$,[23] $PtCl_2$(4-methylpyridine *N*-oxide)(olefin),[24] and PtX-(acac)(olefin)(X=Cl, Br)[25] stronger shielding of the olefinic proton has been observed in ethylene as compared with the substituted ethylenes. This may be explained in terms of an easing of approach of the small ethylene molecule to the metal atom.[4] Thus it may be infered that the same mechanism operates for the present binuclear complex in solution, where the olefinic moieties **d**, **e**, and **f** with the stronger π-back bonding are closer and the olefinic moieties **a**, **b**, and **c** are more distant from the Pd atom.

The asymmetric allocation, probably forced by the minimal potential requirement, in the conformations of the dba molecules to the Pd atoms results in a slight distortion of the trigonal symmetry, and makes the olefinic moieties maintain their individual characteristics even in solution. The characteristics in the π-bonding occur from the geometry around each metal–olefin bond, especially the metal–olefin distance settled by the total configuration of the complex rather than the direction of the olefinic double bond to the trigonal plane.

Experimental

Materials. 1,5-Di(phenyl-d_5)-1,4-pentadien-3-one $(C_6D_5CH{=}CH)_2CO$, 1,5-di(phenyl-d_5)-1,4-pentadien-3-one-1,5-d_2 $(C_6D_5CD{=}CH)_2CO$, and 1,5-di(phenyl-d_5)-1,4-pentadien-3-one-2,4-d_2 $(C_6D_5CH{=}CD)_2CO$ were prepared by the same method as described elsewhere.[12] Tris[1,5-di(phenyl-d_5)-1,4-pentadien-3-one]dipalladium(chloroform) $[(C_6D_5CH{=}CH)_2CO]_3Pd_2(CHCl_3)$ was prepared according to the procedure in the preceding paper.[3] Tris[1,5-di(phenyl-d_5)-1,4-pentadien-3-one]dipalladium(dichloromethane) $[(C_6D_5CH{=}CH)_2CO]_3Pd_2(CH_2Cl_2)$ was prepared by allowing a dichloromethane solution of $[(C_6D_5CH{=}CH)_2CO]_3Pd_2(CHCl_3)$ to deposit deep violet needle-like crystals; mp 137—138 °C. Tris[1,5-di(phenyl-d_5)-1,4-pentadien-3-one-1,5-d_2]dipalladium(chloroform) $[(C_6D_5CD{=}CH)_2CO]_3(CHCl_3)$ and tris[1,5-di(phenyl-d_5)-1,4-pentadien-3-one-2,4-d_2]dipalladium(chloroform) $[(C_6D_5CH{=}CD)_2CO]_3Pd_2(CHCl_3)$ were also prepared by a method similar to that used to prepare $[(C_6D_5CH{=}CH)_2CO]_3Pd_2(CHCl_3)$. These gave deep violet needle-like crystals; mp 126—128 °C and 125—127 °C in 85 and 95% yield, respectively.

^1H NMR Measurements. A NMR sample was prepared as a solution containing a saturated amount of a deuteriated complex (smaller than 1%) and a trace of tetramethylsilane in the respective deuteriated solvent. The ^1H NMR spectrum was recorded on a JEOL PS-PFT 100/EC 100 pulsed Fourier transform system operating at 100 MHz with an internal deuterium lock. Typically, 8192 data points were taken over a 1 kHz spectral width at a tilt angle 45°, repeated at 4.2 s intervals. An EC 100 computer was also used, in addition to its ordinary use for the Fourier transformation, pattern accumulation, and data reduction, to simulate an observed spectrum by following a program written by JEOL. The sample used for the NOE experiment was degassed by repeated freezing and thawing under vacuum and measured at low temperature (−50 °C) set by a variable temperature unit VT-3C attached to the spectrometer.

The authors are grateful to Professors P. M. Maitlis of the University, Sheffield and J. A. Ibers of Northwestern University for helpful discussions.

6) A high field shift of olefinic proton signals on coordination may be attributed to π-back bonding[7] rather than σ-dative bonding in the Dewar-Chatt-Duncanson model:[8,9] the high field shift is remarkable (2—3 ppm) in Pd^0 and Pt^0 complexes where the π-bonding plays a major role in the overall metal–olefin bond, while the shift is relatively small (0.5—1.5 ppm) in Pd^{II} and Pt^{II} complexes showing nearly equal contribution of the π and σ-bonding. There is almost no shift or a slightly low field shift in Ag^I and Au^I adducts of olefin where the σ-bonding is operative.

10) Although the amount of up field shift of the $\bar{\delta}_H$ values thus varies significantly, the average up field shift is 1.51 ppm, being small in comparison with the shifts (*loc. cit.*) in the other zerovalent Pd-olefin complexes.[11] This implies that the Pd–olefin bonding, as a whole, in $Pd_2(dba)_3$ is comparatively weak. It explain well the comparatively long Pd-olefin distance averaged as 2.25 Å.[2]

13) This criterion may be a generality for other dba complexes. For example, in (pentamethylcyclopentadienyl) (dibenzylideneacetone) rhodium (C_5Me_5) (dba) Rh the δ_{AB} value has been found to be 1.30 ppm,[14] indicating an *s-trans* form for the olefinic moiety of the dba ligand. Indeed X-ray analysis[15] of the complex has shown the dba ligand to be in the *s-trans, trans* conformation. As indicated by the above example and observed for the other dba complexes,[16] both the δ_{AB} values of the coordinated *s-cis* and *s-trans* olefin, in most cases, tend to become somewhat small compared with the corresponding values for the free dba (0.5 for *s-cis* and 1.5 ppm for *s-trans*). Probably this is because the intrinsic term[12] of δ_{AB} which is independent of the conformational change is reduced as a consequence of the decrease of the π-bond nature in the olefinic double bond upon coordination.

Solution Properties of Phycocyanin. V. Studies of the Self-association Reaction of Phycocyanin in a pH 5.4 Solution†

Takahide SAITO, Naomichi Iso, Haruo MIZUNO,* and Ichiro KITAMURA

Department of Food Science and Technology, Tokyo University of Fisheries, Konan, Minato-ku, Tokyo 108

(Received June 16, 1978)

The self-association of phycocyanin in a buffer solution of pH 5.4 with an ionic strength of 0.1 has been studied by sedimentation equilibrium measurements in the temperature range from 5.0 to 25.0 °C. The thermodynamical treatment is also presented. The self-association of phycocyanin molecules proceeds with a decrease in the temperature. The concentration dependence of the apparent weight-average molecular weight of phycocyanin is interpreted in terms of a monomer⇌hexamer equilibrium system. It is clear from the thermodynamic parameters, ΔG^0, ΔH^0, and ΔS^0, that the self-association reaction is spontaneous in the solution of pH 5.4. In the association process, the formation of hydrophobic bonds is suggested by the large positive entropy change accompanying association reaction of phycocyanin molecules.

The dissociation-association properties of phycocyanin have been studied by many investigators. Some investigations in regard to the dissociation-association reaction system have also been reported in publications from this laboratory. Especially, it was suggested that the dissociation-association reacting state was precisely a monomer⇌hexamer system at pH 5.4, and also a monomer⇌trimer at pH 6.8 in relatively low concentrations.[1,2] In the higher concentration region, however, the existence of various aggregates higher than trimer was presumed from the osmotic pressure measurements under pH 6.8. The molecular weight of phycocyanin has been obtained as 2.56×10^5 from the osmotic pressure measurements at pH 5.4. The value was considered to be the molecular weight of the higher aggregate(hexamer) of phycocyanin.[3] The electron micrographic pattern of phycocyanin showed that the phycocyanin molecule was homogeneous and quite stable in the pH region 4.0—5.6, while, in contrast, it was unstable at a higher pH region.[4]

In the previous paper,[5] we postulated, from the results of the sedimentation equilibrium measurements under various temperature conditions at pH 6.8 and at the ionic strength of 0.1, that the dissociation-association behavior of phycocyanin could be explained by assuming a monomer⇌trimer⇌tetramer equilibrium system at this pH and ionic strength. Moreover, it was suggested from an analysis of the thermodynamic parameters, such as the Gibbs free energy change, ΔG^0, the enthalpy change, ΔH^0, and the entropy change, ΔS^0, that the associating reaction was analogous to the ordinary crystallization.

This work was undertaken in order to study the dissociation-association behavior of phycocyanin in solution at pH 5.4 and at the ionic strength of 0.1. In order to determine the equilibrium constants of phycocyanin under various temperature conditions, sedimentation equilibrium measurements in an acetate buffer solution at the ionic strength of 0.1 were performed at 5.0, 15.0, 20.0, and 25.0 °C. From the thermodynamic quantities, the ΔG^0, ΔH^0, ΔS^0 values, accompanied with the dissociation-association reaction, were estimated, and the mechanism of the dissociation-association of phycocyanin was discussed based on these quantities.

† Some of the experimental results in this paper were presented at the 26th Annual Meeting of The Society of Polymer Science, Japan, Kyoto, May 25, 1977.

Experimental

Protein Preparation. The crystalline phycocyanin from *Porphyra tenera* used in this study was isolated and purified as has been described previously.[1] The acetate buffer solution was used as a solvent, and the ionic strength was limited to 0.1. The ionic strength was the same as that previously used in the sedimentation equilibrium measurements performed at pH 6.8. The purity of the phycocyanin was ascertained from the measurements of the absorbance at 620 nm and at 280 nm in a phosphate buffer solution. The ratio of absorbance at 620 nm to that at 280 nm has usually been used as a criterion for judging the purity of phycocyanin; when the ratio is greater than 4.0, the protein has been considered to have a high purity.[6] The value of the ratio measured was greater than 4.7 for the phycocyanin obtained in this work. Therefore, the phycocyanin used in this study was a highly purified sample.

Sedimentation Equilibrium Measurements. Sedimentation equilibrium experiments were performed on the phycocyanin-buffer solutions at 5.0, 10.0, 20.0, and 25.0 °C respectively, using a Hitachi Model UCA-1 ultracentrifuge with an interference optics. The rotor speeds were set at approximately 8000—9000 rpm. All the runs were made at a given speed for approximately 24 h so as to ensure that an equilibrium was established in about a 2-mm liquid column. The apparent weight-average molecular weights at several radial positions in the solution column were evaluated by the method reported previously.[5] The solvent densities at 15.0, 20.0, and 25.0 °C were deterined in a 10-ml pycnometer. Since it was difficult to determine the solvent densities at low temperatures, the densities at 5.0 and 10.0 °C were estimated by the linear extrapolation of the values of the densities at 15.0, 20.0, and 25.0 °C repectively. By the same method, the solution densities at 5.0 and 10.0 °C were estimated. The partial specific volume of phycocyanin, $\bar{v}$, was calculated by the usual method from the densities of the solvents and solutions at 25.0 °C; the value of 0.749 ml/g was thus obtained. The variation in the partial specific volume with the temperature was very small;[7] therefore, the value of 0.749 ml/g was used in all the calculations of the molecular weight of phycocyanin in this work. This value is in good agreement with that of 0.744 ml/g(pH 5.3—7.0) reported by Hattori *et al.*[8]

Results and Discussion

Figure 1 shows a plot of the apparent weight-average molecular weight *versus* the concentration of protein in the solution column of the ultracentrifuge cell for the sedimentation experiment at 25.0 °C. As shown in this figure, the apparent weight-average molecular weights increase with an increase in the solute concentration in the low concentration region, and the molecular weight reaches a saturated value in the higher concentration region. This behavior is characteristic of a self-association system. Similar results were obtained from the measurements performed under the other temperature conditions; the saturated values of the molecular weight in the higher concentrations obtained from these measurements increased slightly as the temperature fell.

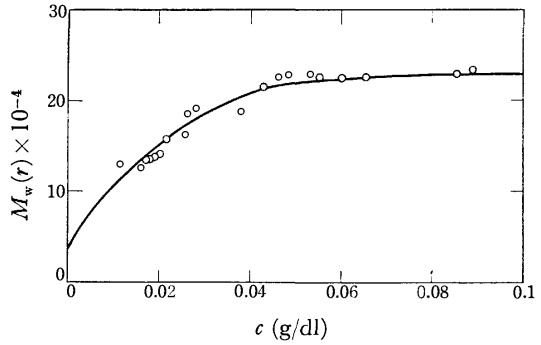

Fig. 1. Plot of apparent weight-average molecular weight as a function of concentration for phycocyanin solution at pH 5.4, $\mu=0.1$, and 25 °C.

In the equilibrium mixture system, the apparent weight fraction of the monomer, f_a, is related to $M_w^{app}(r)$ as follows:[9]

$$\ln f_a = \int_0^c \left(\frac{M_1}{M_w^{app}(r)} - 1\right)\frac{dc}{c}, \quad (1)$$

where

$$\ln f_a = \ln f_1 + BM_1c. \quad (2)$$

In these relations, $M_w^{app}(r)$ represents the apparent weight-average molecular weight at a radial position, r, in the sedimentation equilibrium cell; M_1 is the molecular weight of the monomer; f_1, the weight fraction of the monomer, and B, the non-ideal parameter. The value for M_1 was assumed to be 4.20×10^4 from the previous result of the osmotic pressure measurements performed at pH 5.4, which was about one-sixth of the molecular weight of the phycocyanin hexamer.[3] It becomes clear from previous works that the phycocyanin solution may be considered to be a pseudo-ideal solution.[3,5] Therefore, the non-ideal parameter, B, in relation (2) may be neglected, Therefore, f_a can be replaced by f_1. Once f_1 is determined, the concentration of the monomer in solution, c_1, is obtained from the following relation:

$$c_1 = c\cdot f_1. \quad (3)$$

In the monomer$\rightleftharpoons$$n$-mer type of self-association, the concentration of n-mer, c_n, is expressed as follows:

$$c_n = c - c_1. \quad (4)$$

This relation can be rewritten as

$$c - c_1 = K_n\cdot c_1^n, \quad (5)$$

where K_n represents the equilibrium constant on the weight-concentration scale of the monomer$\rightleftharpoons$$n$-mer system. If the value of n arbitrarily chosen is suitable, the plot of $(c-c_1)$ versus c_1^n will give a straight line which passes through the point of origin. In this study, such a plot could be obtained over the whole temperature range when the n-value was assumed to be 6, as is shown in Fig. 2. It may be concluded from the result described just above that the type of self-association of phycocyanin used in this study is a monomer$\rightleftharpoons$hexamer system at pH 5.4.

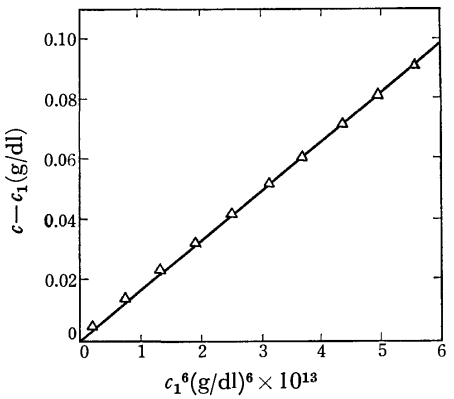

Fig. 2. Plot of $c-c_1$ *versus* c_1^6. The slope of this plot gives the equilibrium constant, K_6.

Table 1. Equilibrium constants at different temperatures

Temp (°C)	K_6(dl/g)^5	k_6(1/mol)^5
25.0	2×10^{11}	4×10^{28}
20.0	6×10^{11}	1×10^{29}
15.0	5×10^{11}	1×10^{29}
10.0	10×10^{11}	2×10^{29}
5.0	23×10^{11}	5×10^{29}

The molar equilibrium constant, k_6(1/mol)^5, was calculated by means of this relation: $k_6=\frac{1}{6}\cdot\left(\frac{M_1}{10}\right)^5\cdot K_6$.

Figure 2 shows the plot of $(c-c_1)$ *versus* c_1^6 at 25.0 °C. The equilibrium constant, K_6, can be evaluated from the slope of such a plot. Thus, the equilibrium constants at 5.0, 10.0, 20.0, and 25.0 °C were obtained. These values are summarized in Table 1. From the value of K_6, it is reasonable to say that the self-associating reaction of phycocyanin is practically hexamerization at pH 5.4 and the ionic strength of 0.1; this tendency becomes more outstanding with the decrease in the temperature. As is shown in Fig. 3, the characteristic dependence of the self-association on the temperature is clear from the van't Hoff plot, which is the relationship between the logarithm of the equilibrium constant on the molar scale and the reciprocal of the absolute temperature. The value of the equilibrium constant on the molar scale, k_6, is calculated from that on the weight-concentration scale by using the following relation:

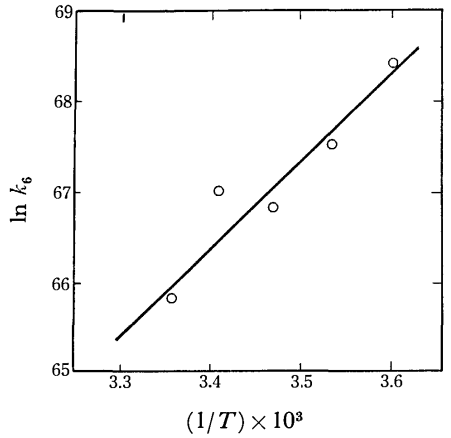

Fig. 3. The van't Hoff plot, $\ln k_6$ *versus* $1/T$, for the phycocyanin systems at five temperatures. The slope of this plot, calculated by a linear regression analysis, is $-\Delta H^0/R$.

$$k_6 = \frac{1}{6}\cdot\left(\frac{M_1}{10}\right)^5\cdot K_6 .$$

The ΔH^0 is evaluated as -19 kcal/mol from the van't Hoff plot, and the association reaction of phycocyanin is exothermic. It was concluded in a previous report[5] that the association reaction of phycocyanin at pH 6.8 was exothermic and that the value of ΔH^0 for the monomer⇌tetramer was -3.8 kcal/mol. Therefore, the difference in the enthalpy change shows that, from the viewpoint of energetics, the polymerization to a hexamer at pH 5.4 is more favorable than that to a tetramer at pH 6.8.

Table 2. Thermodynamic parameters at different temperatures

Temp (°C)	ΔG^0 (kcal/mol)	ΔS^0 (cal/K mol)
25.0	−39	67
20.0	−39	68
15.0	−38	66
10.0	−38	67
5.0	−38	68

$\Delta H^0 = -19$(kcal/mol).

The Gibbs free energy change, ΔG^0, and the entropy change, ΔS^0, accompanied by the dissociation-association of phycocyanin, can be calculated by using the following relations:

$$\Delta G^0 = -RT\ln K, \tag{6}$$

$$\Delta S^0 = \frac{\Delta H^0 - \Delta G^0}{T}. \tag{7}$$

The ΔG^0 and ΔS^0 values are calculated to be -38——-39 kcal/mol and 66—68 cal/K mol respectively. These values are listed in Table 2. If the aggregate at pH 5.4 is assumed to be a hexamer, the ΔG^0 value for the monomer unit is evaluated to be -6.5 kcal/mol from one-sixth of ΔG^0 for the hexamer. This result is not so different from the value of ΔG^0 reported for the monomer unit of phycocyanin at pH 6.8 (-5.0——5.3 kcal/mol).[5]

In other proteins, similar values have been reported for the ΔG^0 — for example, α-amylase (pH 7, 20 °C), -6.3 kcal/mol, and hemerythrine (pH 7, 5 °C), -5.8 kcal/mol.[10]

In the previous report,[5] the value of ΔS^0 for the monomer⇌tetramer at pH 6.8 was calculated to be 59—60 kcal/K mol. The value of ΔS^0 for the monomer ⇌hexamer at pH 5.4 in this study is 66—68 cal/K mol, almost the same order as that for the monomer⇌ tetramer.

From the negative values of ΔH^0 and ΔG^0 and the positive value of ΔS^0 for the phycocyanin aggregation obtained in this study, it is clear that the self-association reaction of phycocyanin is spontaneous under the solution conditions of pH 5.4 and an ionic strength of 0.1.

In the association reaction, the loss in entropy is expected to be quite high because of the increase in the restriction for the motion of molecules. However, the value of the entropy change of the phycocyanin obtained in this work is a large positive one. Scherga and his co-workers have studied the thermodynamic properties of hydrophobic bonds in protein.[11–13] They suggested that the positive entropy change accompanying the association reaction of protein is due to the changes in the water structure around the side chain which are caused by the formation of hydrophobic bonds, and that the hydrophobic bonds can contribute to the stabilization of protein structures. Cann has observed a large entropy change caused by the antigen-antibody reaction, and suggested that it is a result of the release of bound water from antigen and antibody molecules.[14]

As described above, the formation of a hydrophobic bond produces a reduction of the water in contact with the protein molecules and the destruction of that structure, and the freedom of water molecules increases. This brings about an increase in the entropy of the reaction system. The positive changes of entropy accompnying the association are currently interpreted as being due to the formation of a hydrophobic bond between monomers and also to the change in the water structure around a polymer. Scott and Berns have suggested that the hydrophobic bonding force and electrostatic force are involved in the interaction of phycocyanin molecules.[15] MacColl *et al.* have reported that the phycocyanin hexamer appears to be more stabilized by hydrophobic force than the trimer.[16]

Although it does not necessarily mean that the positive change of entropy is wholly attributable to the formation of the hydrophobic bond and the change in the water structure, the large value of ΔS^0 observed in this study suggests a change in conformation, with the cooperative formation of many bonds between monomers.

Nagasawa and Holtzer proposed an interesting method for the estimation of the non-electrostatic part of the standard free energy change accompanying the dissociation reaction of protein from the experimental potentiometric curve.[17] Their method will be of great help in attacking the aggregation mechanism of phycocyanin.

Depolarized Rayleigh Wings of the Liquids and Solutions of Some Symmetric Top Molecules

Keiji KAMOGAWA

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980

(Received July 17, 1978)

Spectra of depolarized Rayleigh wings were observed for the liquids and CCl_4 solutions of C_6H_6, CH_3CN, and $CHCl_3$. The spectral band shape can be reproduced very well by a Lorentz function for the low frequency wing component and a Gauss function for the far wing component. The functions for neat liquids gave the relaxation times for orientational motion, which support free rotation models. The relaxation times of the solutions were found to be independent of concentration, the integrated intensities showing a linear dependence on concentration. The results for the wing component are in marked contrast to those found for the central component of the spectra. The difference is discussed in terms of dynamical structure of the liquids.

The depolarized Rayleigh scattering spectrum of liquids usually appears in the frequency region less than 100 cm^{-1}, consisting of a sharp line at the exciting frequency and a broad wing spread over a wide frequency region. The spectrum is caused by fluctuations in the polarizability anisotropy of the molecules and provides information on the molecular motion and local structure of the liquid. The sharp line arises from the fluctuation caused by rotational diffusion motion of time scale $\approx$1 ps. The broad wing reflects the fluctuation of shorter time scale of 0.1 ps which is probably due to librational motion (rotational oscillation)[1-3] or collisional motion of the molecules.[4,5] Thus, the sharp line and broad wing correspond to the diffusional motion and bounded motion, respectively.

In order to clarify the dynamical behavior of molecules in the usual liquid, it is important to study the concentration (N) dependence of the Rayleigh scattering spectrum. For the liquids of symmetric top molecules, the concentration dependence has been studied theoretically and experimentally for the sharp line component and for the total Rayleigh intensity, the results being interpreted in terms of the rotational diffusion and the pair correlation.[6-13] However, there seems to be no study on the concentration dependence of the broad wing. In the present work, the concentration dependence of the wing components of several symmetric top molecules, C_6H_6, CH_3CN, and $CHCl_3$, was studied in their carbon tetrachloride solutions. The results provide information on the orientational correlation function between the solute molecules of the short time scale of 0.1 ps. By combining the results with the information of the longer time scale motions available from the analysis of the central component, the whole aspect of the dynamical structure of the liquid can be made clear.

Experimental

The experimental arrangement for Rayleigh scattering is almost the same as that for Raman spectral measurements. An argon ion laser operating at 514.5 nm was used as a light source. The incident light was chopped by a rotating sector at 20 Hz to avoid thermal lensing effect. After being passed through a Glan-Thomson prism, the light was focused with a long focusing lens into a sample cell kept at 30.0±0.1 °C. The light scattered at 90° with a small solid angle of 10^{-4} radian was observed along the direction parallel to that of the electric polarization of incident light and collected to a Nalumi double monochromator scanning with instrumental width of 1 cm^{-1}. The signal detected by an HTV R585 or cooled R649 photomultiplier was counted with an ORTEC Model 9315 photoncounter with time constant 5—10 s and digitally recorded with an interval of 0.6—1.2 cm^{-1}. The signals were averaged after several repeated measurements. The whole scattering intensity of solution was determined relative to the intensity of the neat liquid which was taken to be 100. The observed intensities thus obtained were not corrected for spectral sensitivity of the detection system because of the narrow frequency region. The spectra obtained were usually symmetric except for the Boltzmann factor, the intensity maxima being taken as $\omega=0$. The measurements were carried out from the intensity maxima to lower frequency region. The samples were neat liquids of C_6H_6, CH_3CN, $CHCl_3$, and CS_2 and their mixtures with CCl_4. They were of spectral grade and used without further purification. Just before the spectral measurements, the samples were filtered with 0.2 μm millipore membrane filter to remove suspended dusts. The refractive indices of the solutions were measured with an Abbe refractometer.

Results and Band Shape Analysis

The depolarized Rayleigh scattering spectrum of liquid CH_3CN is shown in Fig. 1. The spectrum consists of a sharp component at the center and a broad

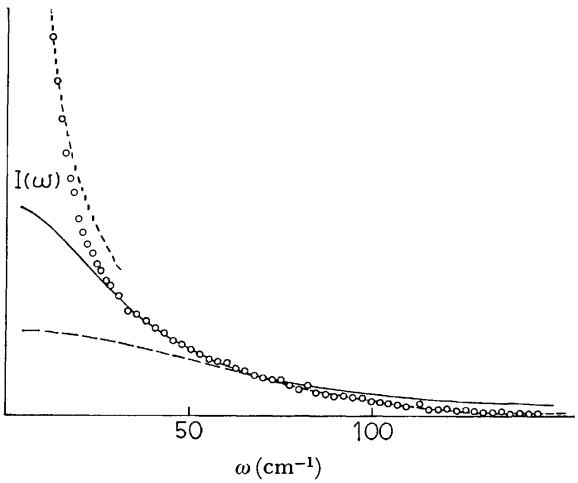

Fig. 1. The observed spectrum of liquid CH_3CN (circles) and analysis of the band shape by wing Lorentzian (full line), wing Lorentzian plus center Lorentzian (dotted line) and far wing Gaussian (broken line).

wing. In order to analyze the band shape, it is useful to assume reasonable analytical function.

Depolarized Rayleigh scattering originates from fluctuation in the local polarizability anisotropy α. Three kinds of fluctuations; rotational diffusion, libration (rotational oscillation in a potential well) and collision of the molecules; seem to contribute to the intensity $I(\omega)$ through the polarizability correlation function $<\alpha(t)\alpha(0)>$. According to Keyes and Kivelson[6] and Alms *et al.*,[7] the rotational diffusion of symmetric top molecule gives the spectrum expressed by the Lorentz function

$$I_r(\omega) = \frac{A}{15n^2\pi}\left[\frac{n^2+2}{3}\right]^4\beta^2N(1+fN)\frac{6D'}{\omega^2+(6D')^2},$$
$$D' = \left(\frac{(1+gN)}{(1+fN)}\right)D, \qquad (1)$$

where n, N, β, and D are the refractive index,[12] density of liquid, optical anisotropy of the molecule and rotational diffusion constant, respectively. f is the static orientational pair correlation function given by

$$f = \frac{<\alpha_o^i(0)\alpha_o^i(0)>}{<\alpha_o^i(0)\alpha_o^i(0)>}, \qquad (2)$$

where $\alpha_o^i(0)$ and $\alpha_o^j(0)$ are the polarizability anisotropies of the rigid rotating molecules i and j at $t=0$. g is the dynamical pair correlation function (Eq. B6, Ref. 6). The integrated intensity of Eq. 1 is given by

$$I_r = \frac{A}{15n^2}\left[\frac{n^2+2}{3}\right]^4\beta^2N(1+fN). \qquad (3)$$

It is well established that the rotational diffusion contributes to most of the intensities of narrow wave number region around the center of the Rayleigh scattering, giving rise to the sharp band of Lorentzian shape.

On the other hand, based on the librational scattering models, Starunov[1] obtained a modified Lorentzian spectrum expressed by

$$I(\omega) = \frac{I^0}{(1-I_\perp\omega^2/\mu)^2+\zeta^2\omega^2/\mu^2}, \qquad (4)$$

while Prorvin[2] and Sechkarev and Nikolaenko[3] gave on nearly the same model a squared Lorentzian

$$I(\omega) = \frac{I^0}{(1+\tau_2^2\omega^2)^2} \qquad \tau_2^2 = \frac{1}{1/\tau_0^2+z^2}. \qquad (5)$$

In Eqs. 4 and 5, I^0 is the peak intensity at $\omega=0$, ζ the internal friction constant of the molecule in the liquid, μ the elastic constant, $I_\perp$ the moment of inertia of the molecule perpendicular to the principal axis, τ_0 the average half-period of the libration, and z an average frequency of intermolecular interactions. Although it is assumed in both models that the scattering comes from the librational motion of individual molecules ($f=0$), Starunov's model is based on the stable librators of different sites in the liquid. Thus, different molecules contribute to the central and wing components. On the other hand, Sechkarev and Nikolaenko assumed that the librator is a temporary one appearing and disappearing by jump diffusion from one potential well to another and the two components of the spectrum come from the same molecules in different time periods. Thus, the band shape of the modified Lorentzian (Eq. 4) or the squared Lorentzian (Eq. 5) is expected if the librational fluctuations are predominant.

The collisional motion of the pairing molecules is known to give the spectrum of a modified exponential type[4] of Eq. 6 or a sum or a combination of exponential functions.[5,14]

$$I(\omega) = \omega^{2(m-7)/7}\exp(-\omega/\omega_0). \quad (\omega>\omega_0) \qquad (6)$$

ω_0 is an average frequency of translational oscillation and m has the value of 9 or 13 according to whether the fluid is an atomic or molecular fluid. Equation 6 holds on the assumption that collisionally induced polarizability $\Delta\alpha$ depends on the intermolecular distance r as follows:

$$\Delta\alpha \propto r^{-m}. \qquad (7)$$

In many liquids the librational and collisional motions give a broad spectrum, the Rayleigh wing, spread over a wide frequency region. In liquids composed of symmetric top molecules, both the modified Lorentzian and the squared Lorentzian reproduce the observed wing better than the modified exponential type.[15,16] We thus start analysis of the observed wing on the basis of the librational models. Both Eqs. 4 and 5 give a Lorentzian in the low frequency region. First we look for the low frequency region of the wing component where the spectrum can be expressed by a Lorentzian $I_L(\omega)$. Second, the central component obtained by subtraction of $I_L(\omega)$ from the observed intensities will be examined by another Lorentzian $I_r(\omega)$ corresponding to Eq. 1. A typical example of the analysis is shown in Fig. 1 for neat CH_3CN liquid. In the low frequency wing region 25—60 cm^{-1}, the spectrum can be reproduced by a Lorentzian $I_L(\omega)$ (called wing Lorentzian in this study). The spectral region less than 20 cm^{-1} can be reproduced by addition

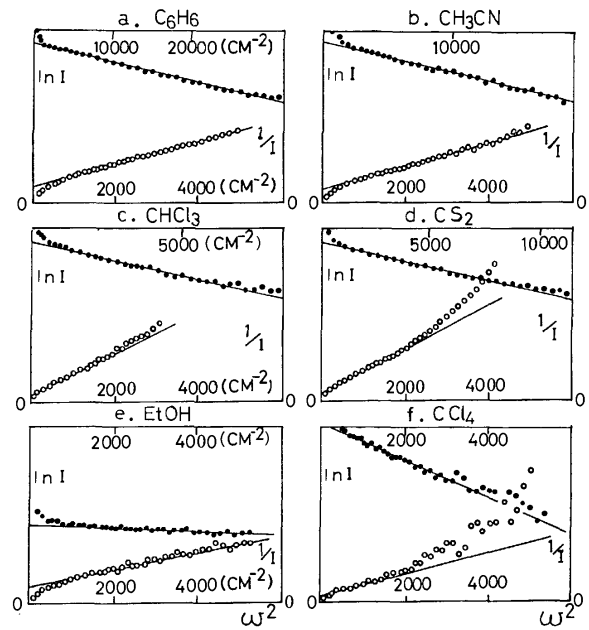

Fig. 2. Band shape analyses for neat liquids. A line drawn for the plots ○ of $1/I$ against ω^2 corresponds to the wing Lorentzian and a line drawn for the plots ● of ln I against ω^2 to the far wing Gaussian.

of the Lorentzian $I_L(\omega)$ plus another Lorentzian $I_r(\omega)$. The observed points for this frequency region are few and $I_r(\omega)$ involves a considerable ambiguity. No attempt was made to deduce physical quantities from $I_r(\omega)$. In this way, for all the liquids except for CCl_4, the spectra over the central and low frequency wing regions can be reproduced by a Lorentzian $I_L(\omega)$ and the central component which has a form close to that of Lorentzian $I_r(\omega)$. The results of the analysis are shown in Fig. 2.

However, the spectrum of the far wing region cannot be reproduced by the above analysis. As seen in Fig. 1, the spectrum deviates appreciably "downward" from the Lorentzian $I_L(\omega)$ in the frequency region higher than 65 cm^{-1}. The "downward" deviation cannot be reproduced by addition of another Lorentzian. As far as the spectral region is concerned, the spectrum can be expressed very well by a Gauss function. The Gauss function changes smoothly to the Lorentzian $I_L(\omega)$. The same is true for the far wing regions of all the liquids studied here (Fig. 2). The Gauss function is called far wing Gaussian $I_g(\omega)$ in this study. The central region of the Rayleigh scattering spectrum is explained by overlapping of the central component lying close to the Lorentzian $I_r(\omega)$ given by Eq. 1 and the wing Lorentzian $I_L(\omega)$. The low frequency wing region is expressed practically by $I_L(\omega)$, since the contribution from the central component is negligibly small in this region. For the far wing region, the spectrum can be reproduced very well by the far wing Gaussian $I_g(\omega)$ only. We assume that $I_L(\omega)$ does not necessarily extend to the far wing region.

Band shape analysis by the above method is successful for the symmetric top molecules, C_6H_6, CH_3CN, $CHCl_3$, and CS_2 (Figs. 2a—2d), and also for EtOH which is an asymmetric top and highly associative molecule (Fig. 2e). For these molecules, the deviation of the observed intensities from the analytical ones were within $\pm 2\%$ for the whole wing region. On the other hand, the Lorentzian analysis for the low frequency wing of CCl_4 shows appreciable deviation from the observed shape while a Gaussian for the far wing gives a good fit (Fig. 2f). The inadequacy of the Lorentzian analysis for the low frequency wing seems to be characteristic of isotropic molecules, for which only the collisional mechanism gives depolarized Rayleigh scattering.

We should compare the present analysis for the wing with the analysis based on the single function of the squared Lorentzian proposed by Prorvin[2] and Sechkarev and Nikolaenko.[3] Figure 3 shows the plots of $I(\omega)^{-1/2}$ *vs.* ω^2 for the wings of C_6H_6 and CH_3CN. The frequency

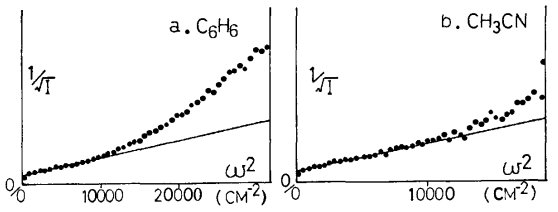

Fig. 3. Band shape analyses for liquid C_6H_6 and CH_3CN. A line drawn corresponds to the squared Lorentzian.

Table 1. Frequency regions of the wing (cm^{-1}) for which the observed spectrum is reproduced by the assumed functions

	CH_3CN	C_6H_6	CS_2	$CHCl_3$
Lorentzian	27—65	36—73	17—46	15—41
Gaussian	57—146	44—163	46—86	42—76
Squared Lorentzian	32—94	30—105	16—66	20—57

regions where the observed band shape is well described by the squared Lorentzian are summarized in Table 1 together with the regions of the good fit obtained by the present analysis. Although the squared Lorentzian reproduces the observed band shape fairly well over a wide wing region, considerable deviation occurs in the far wing region especially for C_6H_6. Measurements of Rayleigh scattering carried out by many workers are usually limited in the frequency region up to 100 cm^{-1}.[2,3,17] In this frequency region, the spectra can be reproduced fairly well by a single function of the squared Lorentzian. However, it is evident from our data that it is impossible to have a good fit with a single function for wider frequency region. It seems adequate to adopt a combination of a Lorentzian and a Gaussian for the wing in a wide frequency region.

From the slopes and the intercepts of the straight lines (Fig. 2) band widths and integrated intensities can be obtained for the low frequency wing and for the far wing. When the functions are given by

$$I_L(\omega) = \frac{1}{a_L + b_L\omega^2},$$
$$I_g(\omega) = \exp(a_g - b_g\omega^2), \tag{8}$$

the widths and the integrated areas for them are

$$\omega_L = \sqrt{\frac{a_L}{b_L}}, \quad \omega_g = \sqrt{\frac{1}{b_g}},$$
$$\int_0^{\omega_c} I_L(\omega)d\omega = \frac{1}{\sqrt{a_L b_L}} \tan^{-1}\left[\frac{\omega_c}{\omega_L}\right],$$
$$\int_{\omega_c}^{\infty} I_g(\omega)d\omega = \exp[a]\int_{\omega_c}^{\infty} \exp[-b_g\omega^2]d\omega, \tag{9}$$

where the two functions are joined at $\omega = \omega_c$. Although ω_c is arbitrary, the value does not affect the total wing intensity as far as $I_L(\omega)$ smoothly changes to $I_g(\omega)$ around the region $\omega \approx \omega_c$ (Fig. 1). Integration of $I_g(\omega)$ can be carried out by use of a numerical table for the error function. The relaxation time τ_L can be calculated from the half band width ω_L of the wing Lorentzian by $\tau_L = 1/2c\pi\omega_L$, while the relaxation time

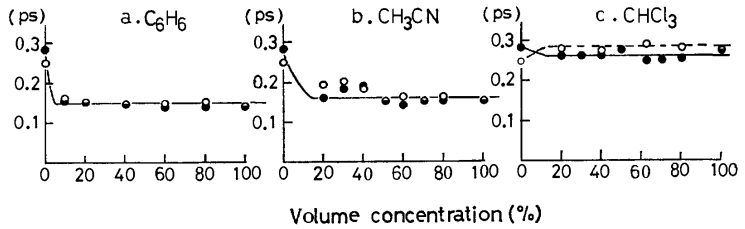

Fig. 4. Experimental relaxation times τ_g (●) and τ_L (○) for carbon tetrachloride solutions of C_6H_6, CH_3CN, and $CHCl_3$ at various volume concentrations.

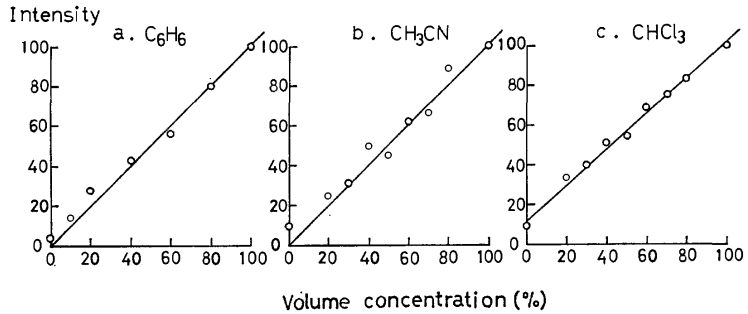

Fig. 5. Concentration dependence of the integrated intensity $\left(I/\frac{1}{n^2}\left(\frac{n^2+2}{3}\right)^4\right)$ for carbon tetrachloride solutions of C_6H_6, CH_3CN, and $CHCl_3$ (I is given by I_L+I_g).

τ_g can be calculated from the band width ω_g of the far wing Gaussian by means of $\tau_g=1/c\pi\omega_g$. The widths and relaxation times obtained are given in Table 2. Both τ_L and τ_g are as short as the order of 0.1 ps for all the liquids. τ_g corresponds to the time in which the correlation function $<\alpha(t)\alpha(0)>$ decays to $1/e$ according to

$$\langle\alpha(t)\alpha(0)\rangle \propto 1-t^2/\tau_g^2+O(t^4) \approx \exp[-t^2/\tau_g^2]. \quad (10)$$

τ_L is the time in which the correlation function decays exponentially to $1/e$.

The above are the results for the neat liquids. The relaxation times were also obtained from the analysis of the solution spectra at various concentrations. The observed τ_g and τ_L of the carbon tetrachloride solutions of C_6H_6, CH_3CN, and $CHCl_3$ at various concentrations are plotted against the concentrations in Fig. 4. We see that τ_g and τ_L remain unchanged over all the concentrations except for the region less than 10%. The sudden increases for C_6H_6 and CH_3CN at concentrations less than 10% are due to the appearance of CCl_4 spectrum whose relaxation time is 0.29 ps. According to Alms *et al.*,[7] in contrast to τ_L and τ_g, the relaxation time for the central component τ_c varies depending on the concentration and kind of the solvent. They found that τ_c varies from 2.91 to 1.79 ps for C_6H_6 in isopentane and from 2.95 to 1.74 ps for $CHCl_3$ in CCl_4 with change in volume concentration from 100 to 20%. They also found that the relaxation time obtained from NMR of $CHCl_3$ in CCl_4 remains constant at 1.5 ps over a wide concentration range, which is also close to the time obtained from NQR. The concentration independence of τ_g and τ_L is similar to the concentration behavior of the relaxation times obtained from NMR and NQR but differs from the concentration dependence of the central component.

The observed integrated intensities of the wing components I_L+I_g at various concentrations are given for the carbon tetrachloride solutions of C_6H_6, CH_3CN, and $CHCl_3$ in Fig. 5. The wing components of C_6H_6 show almost linear dependence on the concentration. The observed points lie near the straight line passing through the origin. This indicates that there is no orientational correlation ($f=0$) among the solute molecules, if Eq. 3 is applied to the wing component, I_L+I_g. The wing components of CH_3CN and $CHCl_3$ also show similar concentration dependence.†

On the other hand, the central component seems to show a concentration dependence differing from that of the wing component. $f=-0.2$ for the central component of C_6H_6 and $f=+0.9$ for that of $CHCl_3$ reported by Bauer *et al.*,[12,18] are different from $f\approx 0$ obtained for the wing components.

Discussion

Collisional Scattering. Let us first examine the possibility of the collisional process as a cause of the wing component. The collisional process can be tested by the observed relaxation time, its concentration dependence and the integrated intensity of the spectrum.

† In contrast, ethanol solution of CCl_4 shows quite different solute concentration dependence of the integrated intensity, which is non-linear in concentration. The non-linear dependence seems to be expressed by the sum of the part proportional to the square of the CCl_4 concentration and that of linear concentration dependence of EtOH.

The collisional interval time τ_{BC} is considered to be an average time interval between collisions and given by[19]

$$\tau_{BC} = 1/\bar{v}[V_m^{1/3} - \sigma], \quad (11)$$

where V_m is the average molecular volume, σ the collision diameter and $\bar{v}$ the average velocity of the molecules. τ_{BC} is not the exact relaxation time for collisional scattering determined by the correlation function for the intermolecular separation and its orientation of a pair molecule. However, τ_{BC} corresponds to the librational half period of the pair molecules so that it will be a measure of the collisional relaxation time. τ_{BC} given by Bartoli and Litovitz[19] are compared with τ_g obtained in the present study in Table 3. Although qualitative correlation seems to exist between them, τ_{BC} differes from τ_g by a factor of 5. The collisional interval time τ_{BC} should be dependent on the concentration, since τ_{BC} (Eq. 11) changes with the changes in the reduced mass of the colliding pair and $V^{1/3}$. Actually, such a change was experimentally confirmed by Dill *et al.*[20] for the angular velocity correlation time (τ_j) which is a measure of τ_{BC}. However, τ_g as well as τ_L are found to be almost independent of concentration. If the spectrum is caused by the binary collision process, the integrated intensity of the wing should change with the square of the concentration. However, the intensity of the wing component has linear dependence on the concentration for C_6H_6, CH_3CN, and $CHCl_3$.

Thus, the observed relaxation time, its concentration dependence and the integrated intensity do not support the collisional scattering process. It seems that the wing component comes from dynamical process of the single molecule rather than collision process between pairing molecules.

Librational Scattering. The observed spectra of the far wing region are reproduced by a Gauss function. The far wing spectrum corresponds to the motion of short time period which seems to be inertial. There are two types of rotational motions in liquids according to the classification by Atkins,[21] conditional and unconditional free rotations, which give a Lorentzian shape and a Gaussian shape, respectively. The former exists in the first stage of orientational motion of the molecule in homogeneous media having weak intermolecular torque. The correlation function for this process was given by Steel,[22] Gordon,[23] and Atkins[21] as follows.

$$\langle \alpha_o(t)\alpha_o(0)\rangle \propto 1 - \frac{l(l+1)kT}{2I_\perp}t^2 + O(t^4) \approx \exp\left[-\frac{l(l+1)kT}{2I_\perp}t^2\right], \quad (12)$$

where $l=2$ for light scattering and NMR process. The relaxation time, τ_{FR}, for Eq. 12, is given by $\sqrt{I_\perp/3kT}$, corresponding to Gaussian relaxation time. Another definition of the relaxation time for the unconditional free rotation was given by Bartoli and Litovitz[19] as the time in which a molecule rotates 41° based on the fact that the correlation function is the second Legendre polynomial. It is given by $41/360 \cdot 2\pi\sqrt{I_\perp/kT}$. Both τ_{FR} should be proportional to $I_\perp^{1/2}$. Figure 6 shows the plot of τ_g *vs.* $I_\perp^{1/2}$, which gives a straight line with zero intercept. This provides strong evidence that the far wing component arises from the unconditional free rotation of the molecule. However, τ_{FR} calculated by $\sqrt{I_\perp/3kT}$ differs from τ_g by a factor of 2 as shown in Table 3.

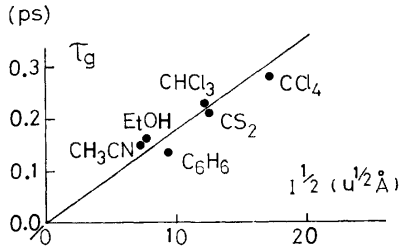

Fig. 6. Correlation between the relaxation time τ_g and $I_\perp^{1/2}$ ($I_\perp$: moment of inertia of the molecule).

τ_{LC} ps	0.19	0.19	0.17	0.32	0.22	0.36

a) Bartoli and Litovitz.[19] b) "Landolt-Börnstein," ed by K. H. Hellwege, Springer-Verlag, Berlin (1976), New Series II 7. c) lamu = 1.66056×10^{-27} kg.

The conditional free rotation would be of importance in the media where the intermolecular torques are appreciable. In such circumstances, free rotation occurs only in the local part of the media such as lattice defect, but it is inhibited in other parts of the liquid. The orientational correlation function for such conditional free rotation shows an exponential decay[21] on the assumption that the free rotation is caused by fast formation and destruction of the lattice defects, the rates being proportional to time t. The relaxation time of this model is given by

$$\tau_{LC} = \sqrt{\frac{I_\perp}{3kT}}\left(\frac{\alpha}{1+2\alpha}\right)^{1/2} P_d^{-1}, \quad (13)$$

where α is given by $I_\perp/I_\parallel$, a ratio of the moments of inertia perpendicular and parallel to the principal axis of the related symmetric top molecule, and P_d is the probability of finding the molecule in the lattice defects, being equal to 1 at the limit of weak intermolecular torques. The observed τ_L values obtained from the wing Lorentzian $I_L(\omega)$ are compared with τ_{LC} calculated by means of Eq. 13 at the limit of $P_d=1$, in Table 3. We see that the correlation between τ_L and τ_{LC} is fairly good. It seems that the orientational motions of the molecules are mostly free in the first stage to give the far wing Gaussian, the free rotation undergoing weak intermolecular interactions in the next stage to give the wing Lorentzian. This is the reason why the wing component can be separated into the Lorentzian and Gaussian parts as shown in the band analysis. The

concentration independence of τ_g and τ_L is important. In the orientational diffusion process, the concentration dependence of the relaxation time is determined by the pair correlation as shown by Eq. 1. If the process is of single molecular nature, the relaxation time should be independent of the concentration as found in NMR and NQR for the mixture of $CHCl_3$ and CCl_4. Our result confirms the view that the motion corresponding to the broad wing should be of single molecular nature with no correlation between different molecules. The orientational pair correlation f is expressed by[24]

$$f = \frac{1}{2}\langle 3\cos^2 \Psi_{ij}(0) - 1\rangle, \tag{14}$$

where $\Psi_{ij}(0)$ is the angle between the principal axis of molecule i and that of molecule j at arbitrary instant. From Eq. 14 we see that a negative value of f indicates perpendicular orientation of the two molecules, a positive value of f parallel orientation and $f=0$ random orientation. The concentration dependence of integrated intensities suggests that f is nearly zero in the short time period of 0.1 ps; the random orientation is realized in this short time scale. This is quite in contrast to the appreciable correlation in the long time period $\approx$2 ps known for C_6H_6[25] and $CHCl_3$,[26] showing perpendicular and parallel correlations, respectively.

Origin of Different f Values. We obtained $f\approx 0$ for the wing component from both the relaxation times and the integrated intensity, while $f\neq 0$ is shown by many workers for the central component. We should consider the cause of this difference, since f should be independent of time according to Eq. 2. The orientational pair correlation function f is as follows.[24]

$$\langle \alpha_0(t)\alpha_0(0)\rangle = \sum_{i,j}\langle \alpha_0^i(t)\alpha_0^j(0)\rangle$$
$$\propto \sum_i \langle P_2[\cos\theta_i(t)]P_2[\cos\theta_i(0)]\rangle \sum_j \langle 3\cos^2\Psi_{ij}(0) - 1\rangle \frac{1}{2}, \tag{15}$$

where $P_2[\cos\theta]$ is the second Legendre polynomial and $\Psi_{ij}(0)$ is given by Eq. 14. The ensemble average $1/2\langle 3\cos^2\Psi_{ij}(0) - 1\rangle$ should be replaced by a time average for finite time T as follows.

$$\bar{f}^T = \frac{1}{2}(3\cos^2\Psi_{ij}(0) - 1)^T = \frac{\frac{1}{2}\int_0^T (3\cos^2\Psi_{ij}(t) - 1)\mathrm{d}t}{T}, \tag{16}$$

where T is the duration time of the motion.

We assume that T can be replaced by relaxation time. The central and the wing component have different relaxation time τ_c and τ_L or τ_g, respectively. The pair correlation function for the central component might differ from that for the wing component. The different pair correlation function (f) indicates that the molecules in the different time scale are in different non-stationary states with regard to orientation. There should be a finite time τ_r in which the molecule has a preferential orientation in average relative to the neighbors. τ_r should be at least the period of libration in a potential well ($2\tau_0$, Eq. 5) and also a few times greater than τ_g (Eq. 5 and Table 2). Since the central component reflects the rotational diffusion, τ_c should be greater than τ_r. Thus, we have

$$\tau_c > \tau_r > \tau_g.$$

The rapid process with the relaxation time τ_g cannot reflect the stationary state, since the stationary state requires a relaxation time greater than τ_r.[27] In other words, the relaxation process for the wing scattering is too rapid for a molecule to follow average orientation of neighboring molecules. Such a rapid process gives random orientation corresponding to non-correlation ($f=0$).

Another interpretation for the different f values is possible when the liquid consists of two different portions, one giving the center spectrum and the other the broad wing spectrum. Transition from one portion to another may be fast or slow depending on the stability of the inhomogeneous liquid structure. The most unstable structure corresponds to the conditional free rotation model. The different orientational pair correlations will be obtained by assuming an inhomogeneous model. For the portion giving the wing scattering, intermolecular torques are weak enough to allow free rotation, the molecules taking random orientation without pair correlation. However, in another portion, the molecules are packed to the extent that they undergo diffusional motion as a whole. The pair correlation function for this portion will be positive or negative depending on the orientation of the pairing molecules. So far we have not sufficient evidence to make a choice from the two models.

The author sincerely thanks Prof. Mitsuo Ito and Dr. Yasuo Udagawa for their valuable advice, and Assist. Prof. Tohru Azumi for his help in the experimental setup.

Photoelectron Angular Distribution Measurements for Some Pyridines

Chikatoshi UTSUNOMIYA,† Tsunetoshi KOBAYASHI,†† and Saburo NAGAKURA*,†,††

†*The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106*

††*The Institute of Physical and Chemical Research, Wako, Saitama 351*

(Received July 20, 1978)

The angular distributions for the He I photoelectron spectra of pyridine, pentafluoropyridine, and 2,6-lutidine have been measured in order to solve the ambiguities on the band assignment of pyridine. It has been concluded that the first band of pyridine is assigned to the a_1n orbital and the fifth band to the lowest occupied $b_1\pi$ orbital.

The photoelectron differential cross-section $(d\sigma/d\Omega)$ for an unpolarized light and an ensemble of randomly oriented molecules or atoms is given by

$$d\sigma/d\Omega \propto 1 + 0.5\beta(1.5\sin^2\theta - 1), \quad (1)$$

where β is an asymmetry parameter and θ is the angle between the direction of an ejected photoelectron and that of an incoming photon.[1,2] The asymmetry parameter β depends on the kinetic energy of the photoelectron and the character of the molecular orbital from which the photoelectron is ejected. Therefore, the determination of the β value is useful for interpretation of photoelectron spectra. Especially, it is useful for the assignments of the overlapping bands which are difficult to be assigned solely by analysis of the ionization energies.

We reported in a previous paper[3] that the second and third bands of benzene, the assignments of which were in dispute, were assigned to the $e_{2g}\sigma$ and $a_{2u}\pi$ orbitals, respectively, by the comparison of the β values of benzene with those of hexafluorobenzene. In this paper the He I photoelectron angular distributions for pyridine, pentafluoropyridine, and 2,6-lutidine are reported and the assignments of the photoelectron spectral bands of pyridine are discussed.

Historically, concerning the assignments of the first three photoelectron spectral bands of pyridine there have been some conflicting proposals[4–12] (see also references 13—16). At present, however, there is no doubt that the broad band around 9.7 eV contains the a_1n and $a_2\pi$ bands and that the third band around 10.6 eV is related with the $b_1\pi$ orbital.[7,9–12,16] As for the band order of the first and second bands Heilbronner and co-workers assigned the first band to the a_1n orbital and the second band to the $a_2\pi$ orbital on the basis of band shape consideration and also of the methyl and trimethylsilyl-substituent effect.[7,9–11] On the other hand, King and co-workers prefer the reverse order on the basis of the fluoro-substituent effect.[12] In order to solve this problem we compare the photoelectron angular distributions for pyridine with those for 2,6-lutidine the band assignments of which are definite.[11] In addition to this, we examine the photoelectron angular distributions for the fourth and fifth bands of pyridine to certify their assignments by comparison with those of pentafluoropyridine.

Concerning the photoelectron angular distribution measurement for pyridine, Ames *et al.* presented crude data for the first three bands without giving the asymmetry parameter values.[17] Their data will be compared later with the present results.

Experimental

The details of the photoelectron spectrometer used for the photoelectron angular distribution measurements in this study were described in the previous paper.[3] The β values were obtained according to formula (1) using the intensities measured at the two angles, $\theta = 45°$ and 90°. The measurements were carried out at room temperature and the vapour pressure of the samples was kept constant at 4×10^{-4} Torr.

Results and Discussion

The ionization potentials (IP) and the β values of pyridine, pentafluoropyridine, and 2,6-lutidine are summarized in Table 1. The error limits for β values in Table 1 denote mean square errors. The first, second, and third bands of the photoelectron spectra of pyridine and 2,6-lutidine are shown in Figs. 1(a) and (b), respectively, with the β values plotted against IP.

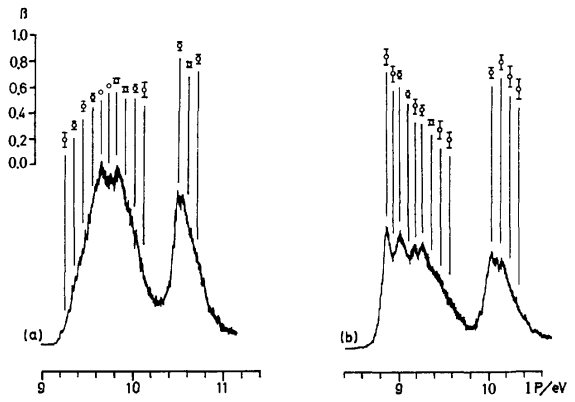

Fig. 1. The first, second, and third bands of the photoelectron spectra of pyridine (a) and 2,6-lutidine (b) and their β values.

We can see from Fig. 1 and Table 1 that the β values of the first and second bands of pyridine increase with increasing IP while the reverse is the case for 2,6-lutidine. This suggests that the order of the first and second bands of pyridine is reverse to that of 2,6-lutidine. The first band of 2,6-lutidine is the $a_2\pi$ band and the second band is the a_1n band.[11] Therefore, the first band of pyridine is assigned to the a_1n orbital and the second band to the $a_2\pi$ orbital. The β values of the first and second bands of pyridine estimated from the values in the regions in which the band overlap is small are $\approx$0.2 and $\approx$0.6, respectively (see Fig. 1(a) and Table 1), while those of 2,6-lutidine are $\approx$0.8 and

a) The IP's underlined are the vertical ionization potentials.

≈0.2, respectively (see Fig. 1(b) and Table 1). The β value of the first band of pyridine corresponds to that of the second band of 2,6-lutidine and the β value of the second band of pyridine is nearly equal to that of the first band of 2,6-lutidine. This fact also supports the above assignments.

Ames *et al.* presented crude photoelectron angular distribution data for pyridine and diazabenzenes without giving β values.[17] Their data indicate a general tendency that the band assignments for the first two bands of pyridine are consistent with the present conclusion.

IP (I) and IP (II) in Table 1 have so far been adopted as the vertical ionization potentials of the a_1n and $a_2\pi$ orbitals, respectively.[7,9–11,18] The β value of band peak (I) or (II) largely deviates from that for the a_1n band (≈0.2) and is nearly equal to the value for the $a_2\pi$ band. This indicates that IP (I) in Table 1 corresponds to the vertical ionization potential of the $a_2\pi$ band. The vertical ionization potential of the a_1n band may be smaller than IP (I) although it can not be decided precisely on account of the overlap of the bands.

We can see from Fig. 1 and Table 1 that the β values of the third bands of pyridine and 2,6-lutidine are ≈0.8 and ≈0.7, respectively, and are nearly equal to each other. This supports Heilbronner and co-workers' assignments of the third bands of pyridine and 2,6-lutidine.[7,9–11]

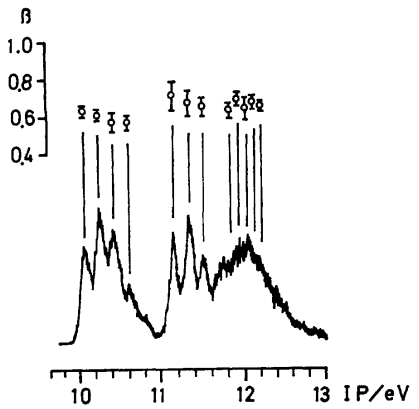

Fig. 2. The first, second, and third bands of the photoelectron spectrum of pentafluoropyridine and their β values.

The first three bands of the photoelectron spectrum of pentafluoropyridine are shown in Fig. 2 and the β values in Table 1 are also plotted against IP in Fig. 2. Brundle and co-workers assigned the first, second, and

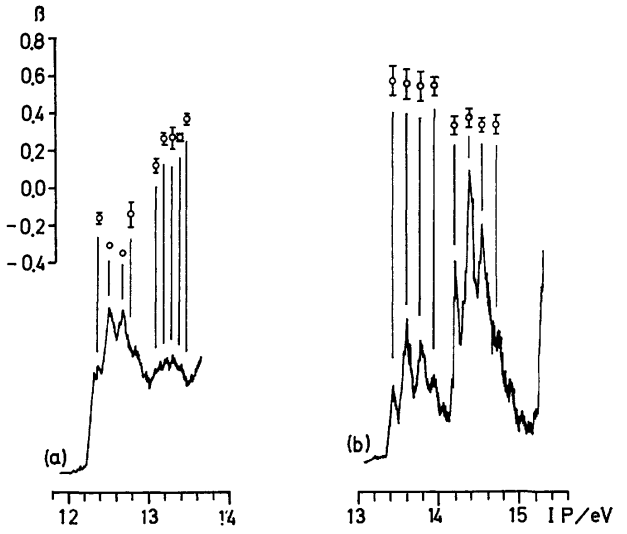

Fig. 3. The fourth and fifth bands of the photoelectron spectra of pyridine (a) and pentafluoropyridine (b) and their β values.

third bands to the $a_2\pi$, $b_1\pi$, and a_1n orbitals, respectively.[18] As is seen in Fig. 2 and Table 1, the β values of the $a_2\pi$ and $b_1\pi$ bands are $\approx$0.6 and $\approx$0.7, respectively. These values are nearly equal to those of the corresponding bands of pyridine, respectively. This also supports the above assignments. The β value ($\approx$0.6) of the a_1n band of pentafluoropyridine, however, differs largely from that ($\approx$0.2) of the corresponding a_1n band of pyridine (see Figs. 1(a), 2, and Table 1). This suggests that the character of the a_1n orbital of pyridine has been considerably changed by the perfluorination.

The fourth and fifth bands of the photoelectron spectra of pyridine and pentafluoropyridine are shown in Figs. 3(a) and (b), respectively, and the β values in Table 1 are also plotted against IP in Fig. 3. Brundle and co-workers assigned the fifth band of pyridine and the fourth band of pentafluoropyridine to the lowest occupied $b_1\pi$ orbitals and the fourth band of pyridine and the fifth band of pentafluoropyridine to the $b_2\sigma$ orbitals mainly from the perfluoro effect.[18] The result of our angular distribution measurements supports this assignment as described below.

The β value of the $b_1\pi$ band (fourth band) of pentafluoropyridine is $\approx$0.6 while the β values of the fourth and fifth bands of pyridine are —0.14——0.35 and 0.12—0.37, respectively. Comparing these β values, the $b_1\pi$ band of pentafluoropyridine should be correlated with not the fourth band but the fifth band of pyridine. Therefore, the fifth band of pyridine is assigned to the lowest occupied $b_1\pi$ orbital. The fourth band of pyridine is necessarily assigned to the $b_2\sigma$ orbital.

We can see that the β value of the $b_2\sigma$ band of pyridine is largely different from that of pentafluoropyridine (see Fig. 3 and Table 1). This indicates that the character of the $b_2\sigma$ orbital of pyridine has been changed by the perfluorination.

In conclusion, the five lower-energy bands of the photoelectron spectrum of pyridine can be assigned to the a_1n, $a_2\pi$, $b_1\pi$, $b_2\sigma$, and $b_1\pi$ orbitals from the lower IP side, respectively, and it is found that the β values of the a_1n and $b_2\sigma$ bands of pyridine are considerably changed by perfluorination while those of the π bands of pyridine are scarcely changed by it.

Studies on the Ammonium Form of Crystalline Zirconium Phosphate. III.[1,2] Ammonium-Hydrogen Ion-exchange on α-Zirconium Phosphate Prepared by the Direct Precipitation Method

Yoshitsugu HASEGAWA* and Motomasa KUWAYAMA**

Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Nakamachi, Koganei, Tokyo 184

(Received November 7, 1977)

The ammonium-hydrogen ion-exchange on α-zirconium phosphate prepared by the direct precipitation method has been investigated by means of pH titration and X-ray diffractometry. In the forward process (α-zirconium phosphate to the ammonium form) the ion-exchange reaction took place in one stage at the equilibrium pH of 5.9—6.0 and the α-zirconium phosphate exchanger was directly converted into the ammonium form. In the reverse process (the ammonium form to α-zirconium phosphate) the reaction proceeded in three stages, that is, the ammonium form→ a half-exchanged form→ an intermediate form→ α-zirconium phosphate. The chemical composition of the half-exchanged form has been represented as $Zr(NH_4PO_4)(HPO_4)\cdot nH_2O$ ($n>0.5$). A small amount of ammonium ions in the exchanger could not be easily replaced with protons in the solution.

The properties of α-zirconium phosphate as an ion-exchanger have been studied by several workers in recent years. It is well known that the ion-exchange reaction on α-zirconium phosphate is strongly affected by its crystal structure, since the largest opening into the crystal would allow a spherical cation with a diameter of 2.63 Å to diffuse into the crystal. Experimentally, Li^+, Na^+, and K^+ exchanged in acidic solution.[3] Although the ionic radius of the ammonium ion is larger than 1.32 Å, the ammonium-hydrogen ion-exchange took place on α-zirconium phosphate.[4,5] In the hydrogen–lithium ion-exchange system the titration curve exhibited two clear inflections at 50 and 66% exchange on α-zirconium phosphate prepared by the direct precipitation (d.p.) and the long refluxing,[6,7] while only one inflection was observed at 66% exchange on α-zirconium phosphate prepared by the ordinary reflux method.[8] Thus the ammonium-hydrogen ion-exchange on α-zirconium phosphate depends on the degree of crystallinity.

To date the ordinary reflux method has been employed in the course of a survey of ammonium form exchangers, but α-zirconium phosphate of high crystallinity could not be obtained by this method.[9] The present investigation has been undertaken using α-zirconium phosphate prepared by the d.p. method in order to avoid the gelatinous characteristics of the compound.

While the manuscript of this paper was in preparation, Alberti *et al.*[10] have reported the ammonium ion and ammonia uptake on α-zirconium phosphate prepared by the d.p. method.

Experimental

Preparation of the α-Zirconium Phosphate Ion-exchanger. α-Zirconium phosphate, $Zr(HPO_4)_2\cdot H_2O$, was prepared by a modification of Horsley and Nowell's method.[11] Zirconium dichloride oxide octahydrate (32 g) was dissolved in water (1050 ml), and hydrofluoric acid (40%, 22 ml) added slowly followed by orthophosphoric acid (about 85%, 77 ml) under continuous stirring. When gelatinous zirconium phosphate precipitated, a small amount of hydrofluoric acid was added until the precipitate was redissolved. The mixture was placed in a water bath (50 °C) and prehumidified air passed through it for 24—30 h. The precipitated α-zirconium phosphate was decantated with distilled water and separated by centrifugation.

pH *Titrations.* The titrations were carried out in batch. A weighed amount of α-zirconium phosphate (100 mg) was placed in contact with the solution of ammonium chloride–aqueous ammonia (10.0 ml) in a thermostat regulated at 25 °C in the forward titration. The composition of the solution was adjusted so that the total ammonium ion was equal to 0.1 M with a varying ratio of NH_4Cl to aqueous NH_3 in the range from 1 to 0. After the mixture was shaken continuously for a specified period of time, the value of the supernatant solution was measured using a pH meter with a glass electrode. Since the chemical composition of the ammonium form is represented as $Zr(NH_4PO_4)_2\cdot H_2O$, the ammonium form (112 mg) was placed in contact with NH_4Cl–HCl solution (10.0 ml) in the reverse titration. The concentration of ammonium chloride was kept constant (3.36×10^{-2} M) and the amount of hydrochloric acid varied.

For the forward process, the titration was also carried out with ammonium acetate–aqueous ammonia solution.

Analytical Procedure. The structural change of the exchanger during the ion-exchange process was measured by X-ray diffractometry. The powder patterns of the exchangers were obtained with a Geigerflex X-ray diffractometer with nickel filtered copper radiation. To avoid obscurity due to overlap and instability of peaks the powder pattern of one sample was recorded under wet and dry conditions. The wet sample was covered with a Mylar film to prevent evaporation after mounting on a glass holder. The dried sample was prepared over a saturated sodium chloride solution (relative humidity about 75% at room temperature). Thermogravimetric and differential scanning calorimetric data were obtained on a Rigaku scanning calorimetric balance TG-DSC standard unit. The chemical analysis of the exchanger was carried out according to the methods described previously.[4]

Results and Discussion

Characterization of the α-zirconium phosphate ion-exchanger was made by X-ray diffraction pattern, TG, DSC data, pH titration with LiCl-LiOH solution, and chemical analysis. The interplanar spacings (*d*-values)

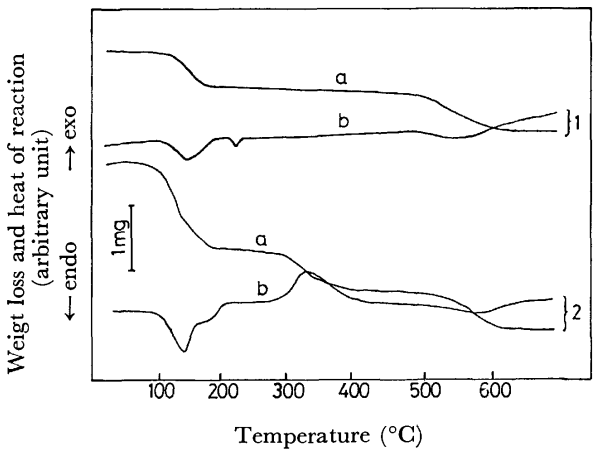

Fig. 1. Thermoanalytical curves. 1: α-Zirconium phosphate in H^+ form, 2: the ammonium form, (a) thermogravimetric and (b) scanning calorimetric curve.

agreed with those given in the literature.[11] The results of thermal analysis are shown in Fig. 1(1). The titration curve for the lithium ion agreed with those reported previously.[6,7] The chemical composition was as follows; Found: Zr, 30.2; PO_4, 63.7; ignition loss, 12.0%. Calcd for $Zr(HPO_4)_2 \cdot H_2O$: Zr, 30.0; PO_4, 63.0; ignition loss, 12.0%. The above results show that the α-zirconium phosphate ion-exchanger used was highly crystalline and essentially identical to that prepared by long refluxing.[5]

The chemical composition of the ammonium form was as follows: Found: Zr, 27.2; PO_4, 57.6; NH_4, 10.8; ignition loss, 20.9%. Calcd for $Zr(NH_4PO_4)_2 \cdot H_2O$: Zr, 27.2; PO_4, 56.7; NH_4, 10.8; ignition loss, 20.9%. The results of thermal analysis for the ammonium form are shown in Fig. 1(2). The curves agreed with those reported for the reflux method.[12] The exothermic peak at about 400 °C might be caused by the oxidation of the evolved ammonia on platinum surface of a crucible.[13]

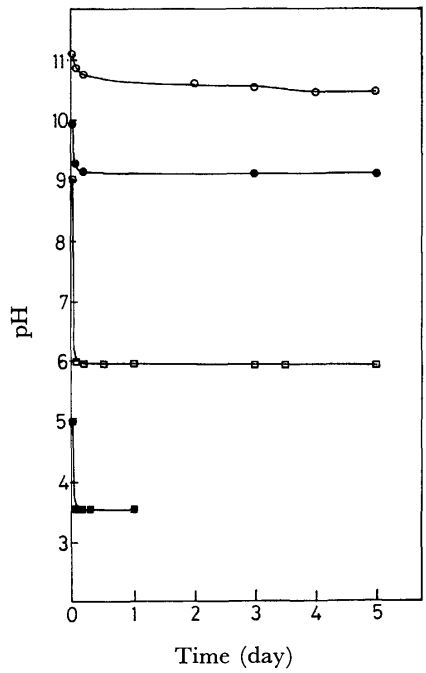

Fig. 2. pH dependence on time.
OH^- meq/g α-zirconium phosphate; ■ 0, □ 3, ● 7, ○ 10.

pH *Titrations.* To determine the equilibration time the pH values of the solutions were measured at specific intervals of time. Figure 2 shows that the ion-exchange reaction proceeded rapidly initially and then the pH value gradually fell to an equilibrium value. It took about 5 days to attain equilibrium for 0.1 M aqueous ammonia, compared to 6 h for 0.1 M ammonium chloride solution. In the reverse titration the pH values were measured at 6.00 and 3.00 meq H^+/g α-zirconium phosphate. The observed equilibrium was attained within one day for both solutions. Thus, a reaction time of 2—5 days was chosen in the forward process and 2 days in the reverse one.

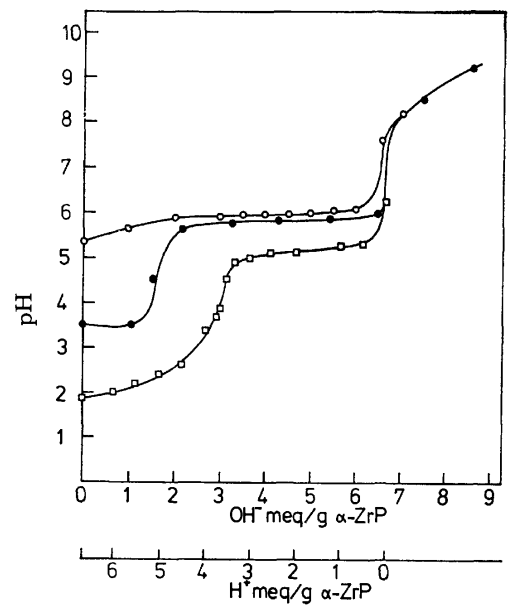

Fig. 3. pH titration curves.
(a) ● Forward titration NH_4Cl–NH_3(aq), (b) ○ forward titration NH_4CH_3COO–NH_3(aq), (c) □ reverse titration NH_4Cl–HCl.

The pH titration curves obtained are shown in Fig. 3. The curve (a) shows that in the forward process the ammonium–hydrogen ion-exchange reaction took place at a pH of about 3.5 until approximately $OH^- = 1.0$ meq, whereupon the pH rose sharply to the equilibrium pH of 5.9. The lowering of the pH in the initial stage may be ascribed to the selective uptake of the ammonium ion on α-zirconium phosphate. Figure 3(b) demonstrates that in ammonium acetate–aqueous ammonia solution the equilibrium pH and the ion-exchange capacity were almost equal to those observed for the chloride solution. In the initial stage of curve (b) compared with the curve (a) higher pH values are due to the bufferring action of the ammonium acetate solution. The α-zirconium phosphate ion-exchanger behaved as a monobasic exchanger with a capacity of 6.64 meq/g. The equilibrium pH was found to be approximately 5.9—6.0.

The titration curve of the reverse process is shown in

Fig. 3(c). It appears that the ion-exchange reaction took place in two stage, that is, in the first stage 50% of the ammonium ions in the exchanger were replaced with hydrogen ions and in the second stage the remaining ammonium ions were involved in the reaction. The reaction proceeded in a more acidic solution than for the forward titration, especially in the second stage. At the hydrogen ion addition of 6.0 and 6.6 meq the pH values of the solutions were found to be 2.03 and 1.88. The low pH value indicates that some hydrogen ions remained in the solution phase and the ionic mole fraction of the ammonium ion in the exchanger, $\bar{X}_{NH_4^+}$, was higher than expected from the forward process. Assuming that the apparent value of pH on a pH meter is equal to $-\log [H^+]$, the hydrogen ion concentration can be calculated to be 9.3×10^{-3} and 1.3×10^{-2} mol/l and this corresponds to the fact that hydrogen ions of 5.2 and 5.4 mmol/g α-zirconium phosphate exchanged with the ammonium ions in the exchanger. Consequently, $\bar{X}_{NH_4^+}$ is estimated to be 0.22 and 0.19. This demonstrates that the α-zirconium phosphate exchanger has a strong affinity for the ammonium ion especially when the exchanger is loaded by a small amount of ammonium ion. A similar behavior has been observed in another system.[14]

The titration curves, (a) and (c) in Fig. 3, indicate the irreversible ion-exchange reaction for the ammonium–hydrogen ion-exchange system.

Since the α-zirconium phosphate exchanger and its salt form have a layered structure, the structural change of solid phase is revealed in comparison with the reflections of the powder patterns at lower diffraction angles.[15] A similar phenomena may be expected, because the ammonium form also has a layered structure.[16]

Table 1. Phases present in the forward titration

OH^- meq/gZrP	Medium	
	Cl^-	CH_3COO^-
0	H	H
1.0	H	H + A
2.2	H + A	H + A
3.2	H + A	H + A
4.3	A + H	A + H
5.4	A + H	A + H
6.4	A + H	A + H
6.5		A
7.6	A	

H=Hydrogen form $Zr(HPO_4)_2 \cdot H_2O$,
A=Ammonium form $Zr(NH_4PO_4)_2 \cdot H_2O$.

Table 1 shows the structural change in the exchanger in the forward process. At the beginning of the ion-exchange reaction only the α-zirconium phosphate phase was present. Two phases, the α-zirconium phosphate and the ammonium phase, coexisted in the range of $\bar{X}_{NH_4^+}$=0.33—0.91. The intensity of the diffraction peak of α-zirconium phosphate decreased with an increase in $\bar{X}_{NH_4^+}$. Table 1 also shows that the structural change of the exchanger was similar in the chloride and acetate solution. At the initial stage of the ion-exchange the reaction proceeded further in the acetate solution than in the chloride solution, because the solution phase of acetate had higher pH value. α-Zirconium phosphate was directly converted into the ammonium form. These data support the validity of the interpretation of the titration curves given above.

Table 2. Phases present in the reverse titration

H^+ meq/gZrP	Phase
0	A
0.05	A + A′
2.00	A + A′
2.50	A′ + A
3.30	A′ + A
3.50	A′

A=Ammonium form, A′=A phase having peaks at 11.5 and 10.5° ($I_{11.5}/I_{10.5}$=8/5).

A complicated change was observed on the X-ray diffraction patterns of the solid phases during the reverse titration. In the first stage, 0—50% of the ion-exchange, four peaks were observed for the wet samples at a range of lower angles. The intensity of the peak at 2θ=8.6° was strongly affected by the water content of the sample. When the same sample was dried over a saturated sodium chloride solution, three peaks were observed on the powder pattern. On the assumption that the number of phases does not change on drying out of the solid sample, assignment of the peaks was conducted. The peak at 9.4° originated from the ammonium form and its intensity decreased with an increase in the mole fraction of hydrogen ion in the exchanger, $\bar{X}_{H^+}$. This peak was found in both wet and dry samples up to H^+=3.30 meq/g α-zirconium phosphate. The intensity of other two peaks at 11.5° and 10.5° increased as the ion-exchange process proceeded. In consideration of the inflection point of the titration curve (Fig. 3(c)) and the phase rule,[9] only two phases must be present in this region. Hence, the two peaks may be assigned as one phase, namely the half-exchanged form. A similar change was reported for α-zirconium phosphate prepared by long refluxing.[5] The ammonium ion and water contents of the half-exchanged form were determined by elemental analysis after drying. Found: N, 4.32; H, 1.84; ignition loss at 950 °C (100—ash), 13.4%. Calcd for $Zr(NH_4PO_4)(HPO_4) \cdot 0.5H_2O$: N, 4.53; H, 1.96; ignition loss, 14.3%. The half-exchanged form had more waters of hydration in solution than in the dry condition.

In the second stage of the reverse titration, the dried exchanger had two peaks at 11.5 and 10.5°. The intensity of the peak at 11.5° decreased with increase in $\bar{X}_{H^+}$ and the peak was observed as a shoulder of the peak at 10.5°. Subsequently the intensity of the peak at 11.5° increased again with the reaction above the hydrogen ion addition of 4.5 meq suggesting that a half-exchanged and an intermediate form were present in the region of H^+=3.6—4.5 meq. An intermediate and α-zirconium phosphate coexisted above H^+=4.5 meq (Table 3). At the final stage of the reverse titration an intermediate form was still present. This indicates

TABLE 3. CHANGE OF THE INTENSITY RATIO IN THE SECOND STAGE OF THE REVERSE TITRATION

H^+ meq/gZrP	$I_{11.5}/I_{10.5}$	Phase
3.50	8/5	A′
4.00	5/6	A′, A″
4.50	1/20	A′, A″ or A″, H
5.00	4/11	A″, H
6.00	5/3	A″, H
6.60	11/7	A″, H

A″=A phase deduced having a peak only at 10.5°, H=Hydrogen form.

that the ion-exchange reaction does not proceed stoichiometrically and that the ammonium ion was held by the exchanger.

The conclusion drawn are as follows. (1) Highly crystalline zirconium phosphate ion-exchanger was prepared under the mild conditions employed and the exchanger was essentially identical to that prepared by long refluxing. (2) The α-zirconium phosphate ion-exchanger behaved as a monobasic acid to aqueous ammonia and was converted into the ammonium form. In the reverse process the ion-exchange reaction took place in three stages. (3) A small amount of ammonium ion in the exchanger could not be replaced easily with hydrogen ion.

The authors are grateful to Professor Shuji Abe for his continuing interest and encouragement. They also wish to thank Mrs. Michiko Asuke for her assistance in the elemental analysis.

Syntheses and Electronic Spectra of 2,2′-Isopropylidenedi-8-quinolinol, Its Nickel(II), and Copper(II) Chelates

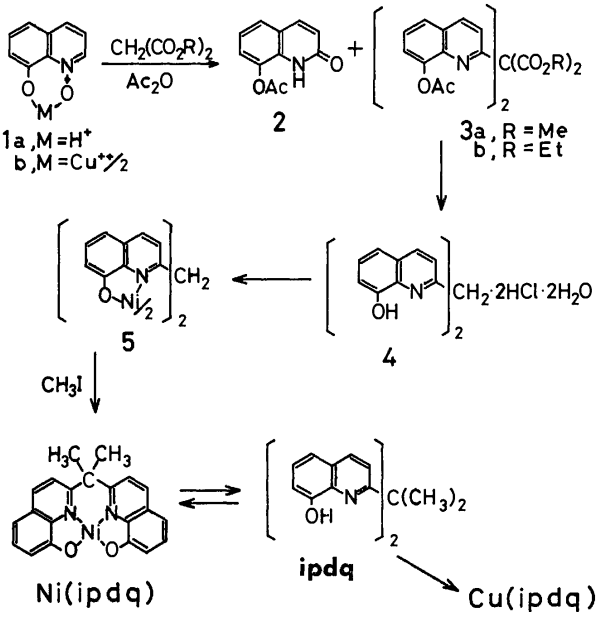
Yoshinori YAMAMOTO,* Akira MIURA, Akira KAWAMATA, Masayoshi MIURA, and Shinsuke TAKEI

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Nakanarusawa-cho, Hitachi 316

(Received November 14, 1977)

The title ligand, which contains two 8-quinolinol (oxine) functions in one molecule, and the Ni(II) and Cu(II) chelates have been synthesized and characterized. Visible and ultraviolet spectra of the chelates and the ligand in several solvents have been measured. Square-coordination of the ligand to the metal has been revealed by a comparison of the d-d bands between the chelates and quadridentate Schiff base chelates in the literature. Intra-ligand transition bands of the title chelates and the solvent effects on the frequency shifts have been compared with those of the ligand, 8-hydroxy-1-methylquinolinium hydroxide, bis(8-quinolinolato)palladium(II), -copper(II), and -nickel(II), and have been discussed.

The quadridentate ligand, 2,2′-isopropylidenedi-8-quinolinol, abbreviated as ipdq, has been prepared in our laboratory, in expectation of forming such type of stable metal chelates as *cis*-bis(8-quinolinolato)metal. The synthetic pathway is outlined in Scheme 1. It has been shown that ipdq readily reacts with both nickel(II) and copper(II) to give the crystalline compounds, Ni(ipdq) and Cu(ipdq), respectively. These chelates are sufficiently soluble in many organic solvents to examine the d-d absorption bands, which provide significant information regarding the coordinating structure. This paper presents the absorption data of Ni(ipdq) and Cu(ipdq) in eight solvents in the ultraviolet and visible regions, and the spectra have been compared with those of related compounds.



Scheme 1.

The chief purpose of this work was to determine the effect of the metal ion on the spectra of the 8-quinolinol-type ligand, of value from the viewpoint of the development of analytical colorimetric reagents, and in connection with the spectra of the corresponding 8-quinolinol chelates, NiQ_2 and CuQ_2.[1] It is known that the position of the lowest energy intra-ligand band of CuQ_2 is highly dependent upon the solvent[2] and the spectrum of NiQ_2 changes drastically with solvent.[3-7] The low solubility, however, restricts the elucidation of the relationship among the spectra, coordinating structure, and nature of solvent.

Results

Preparations. As shown in Scheme 1, Ni(ipdq) has been obtained from 8-quinolinol *N*-oxide (**1a**) or its copper(II) complex (**1b**) in a four-step process. The intermediate compounds (**3**—**5**) have also been isolated and characterized, the detailed procedures and results of which are given in the experimental section.

The malonates, **3a** and **3b**, have been prepared by a method similar to that reported by Hamana and Yamazaki[8] for the synthesis of diethyl di-2-quinolylmalonate by the treatment of quinoline *N*-oxide with diethyl malonate in the presence of acetic anhydride (Ac_2O). It is known that the treatment of **1a** with Ac_2O at room[9] or bath-temperature[10,11] affords 8-acetoxy-2-

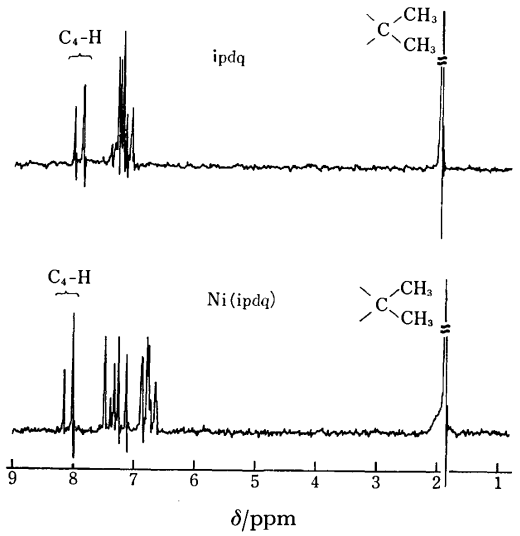


Fig. 1. The 60 MHz PMR spectra of ipdq and Ni(ipdq) in $CDCl_3$. For the spectrum of Ni(ipdq) (29 mg/0.6 cm³), the relative intensity are 3 (siglet), 4 (multiplet), and 1 (doublet). For the spectrum of ipdq (40 mg/0.6 cm³), those are 3, 4.4, and 1.2, respectively, and the latter two contain probably the phenolic proton.

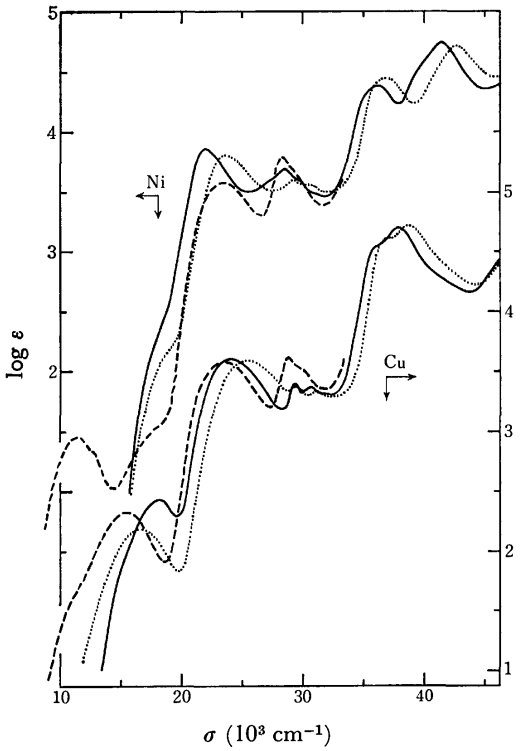

Fig. 2. The absorption spectra of Ni(ipdq) in MeOH (·····), in THF (——), and in pyridine (------), and the spectra of Cu(ipdq) in MeOH (·····), in 1,2-dichloroethane (——), and in pyridine (------).

quinolone (**2**) in high yield. It has been found, however, that the addition of dimethyl or diethyl malonate to the above system gives a mixture of **3** (**a** or **b**) and **2**, and that, on lowering the temperature, the yield of **3** increases at the expense of **2** as given in Table 4 in the experimental section.

The chelate, **5**, is not suitable for the present purpose, since in many common solvents it is not sufficiently soluble. However, **5** readily reacts with two moles of methyl iodide to yield a higher soluble chelate, Ni(ipdq). The PMR spectra of Ni(ipdq) and the metal-free ligand, ipdq, are shown in Fig. 1. The similarity of these spectra to those of 2-methyl-8-quinolinol and its Al(III) complex[12] supports the structure shown in Scheme 1.

Absorption Spectra. Absorption data obtained are set out in Tables 1—3. The spectra of some representative species are shown in Fig. 2. The intra-ligand transition bands have been divided into three parts, in an analogy with those of the 8-quinolinolate.[2,3,13] In this paper these bands have been denoted by A-, B-, and C- in the order of decreasing frequency.

The spectra of ipdq (Table 1) are comparable to those of 8-quinolinol[2,3,14] and its 2-methyl derivative.[3,15] A weak shoulder near 450 nm for ipdq in methanol (MeOH) is similar to a band for 8-quinolinol at 430 nm (ε: 51)[14c,f,h,i] in water or at 450 nm in MeOH (shoulder, log ε: −0.34),[14f] which is known to be due to the presence of the zwitter ionic form.[14c,h,i]

The spectrum of the 8-hydroxy-1-methylquinolinium salt in basic solvent is known to be a good model for the absorption characteristics of the zwitter ionic form of 8-quinolinol.[14c,g,i,j] The 8-hydroxy-1-methylquinolinium hydroxide (the isomer of 1-methylquinolinium-8-

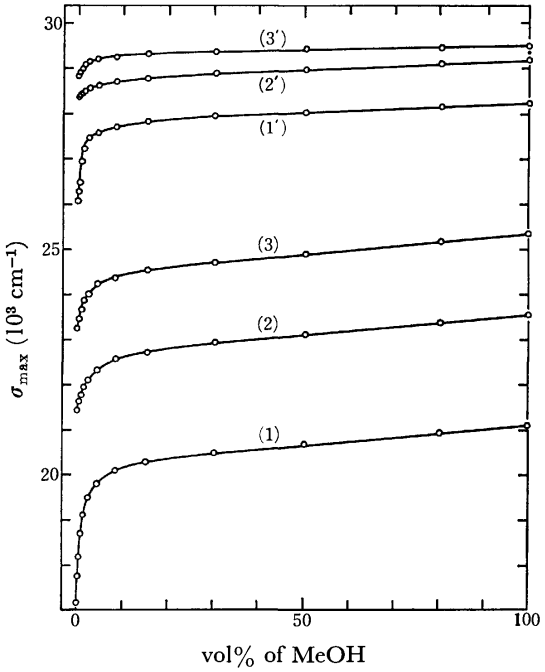

Fig. 3. Variation of the positions of the C- (1—3) and B-bands (1'—3') of the compounds in benzene–MeOH mixtures as a function of the vol% of MeOH; (1) 8-hydroxy-1-methylquinolinium hydroxide, (2) Ni-(ipdq), and (3) Cu(ipdq).

TABLE 1. THE ABSORPTION DATA[a,b] OF ipdq AND 8-HYDROXY-1-METHYLQUINOLINIUM CHLORIDE (N–CH_3)

Compound	Solvent	A-band σ_{max} (log ε)	B-band σ_{max} (log ε)	C-band σ_{max} (log ε)
ipdq	Cyclohexane	39.18 (4.94)	32.13 (3.83)	31.1 (sh 3.77)

After one day standing considerable amounts of ppt were deposited.

olate monohydrate) is known as one of the solvatochromic compounds exhibiting large color changes with solvent polarity.[16,17] The band positions of this hydroxide in MeOH (Table 2) are seen to be almost the same as that of the corresponding chloride salt in MeOH–KOH (Table 1). From these results, the chloride in a basic solvent and the hydroxide in an organic solvent can best be utilized to establish the spectral behavior of the zwitter ionic form of ipdq.

The plots of the positions of the B- and C-bands of the hydroxide, Ni(ipdq), and Cu(ipdq) in benzene–MeOH mixtures *vs.* the vol% of MeOH are shown in Fig. 3.

Discussion

The coordinating structure of Cu(ipdq) in eight solvents can be classified into three groups according to the positions and the shapes of the d-d bands (Fig. 2 and Table 2). On the basis of the data of (*N,N'*-disalicylidene-1,2-propanediaminato)copper(II) which has been shown to be square-planar in chloroform

TABLE 3. THE d-d ABSORPTION DATA[a] OF THE NICKEL CHELATES[b,c]

Chelate	Solvent	Band I σ_{max} (log ε)	Singlet band σ_{max} (log ε)	Band II σ_{max} (log ε)
$NiQ_2 \cdot 2H_2O$	MeOH	9.71 (1.12)	13.0 (0.50)	16.3 (0.97)
NiQ_2	MeOH[d]	9.8	13.0	16.3
	solid(mull)	9.76	13.0 (sh)	16.0
	Pyridine[e]	10.70 (1.03)	12.8 (sh 0.72)	18.3 (1.44)
Ni(ipdq)[c]	Pyridine	11.43 (1.45)	12.8 (sh 1.35)	18.5 (sh 1.54)

a) The wave numbers are given in 10^3 cm^{-1} unit, and sh means a shoulder band. b) *Cf.* Ref. 21, the data of $KNiQ_3$. c) The d-d data of Ni(ipdq) in the other seven solvents are omitted. The spectra in MeOH and in THF shown in Fig. 2 are representative. d) A saturated soln, and a 10 cm cell was used. e) *Cf.* Refs. 3, 5, and 6.

(d-d_{max}: 17760 cm^{-1}) and forming a five-coordinated monoadduct in pyridine (max: 16860),[18] it can be deduced that the benzene, chloroform, and 1,2-dichloroethane solutions of Cu(ipdq) involve a planar monomeric species; the tetrahydrofuran, *N,N*-dimethylformamide, and two alcoholic solutions involve a five-coordinated copper(II); and the pyridine solution involves a six-coordinated copper(II). The five-coordination in the solutions does not mean a dimeric structure since even in such an inert solvent as benzene the chelate is a monomer. Any relationship between the solvent-induced frequency shifts of the d-d band of Cu(ipdq) and those of the A-, B-, or C-band could not be found. The position of the C-band shifts linearly with the E_T value known as a solvent polarity parameter[19] with small deriation for the pyridine solution.

By comparing the d-d bands of Ni(ipdq) (Fig. 2 and Table 3) with those of the quadridentate Schiff base chelates of nickel(II),[20] it has been concluded that the pyridine solution involves a solvent-coordinated species and the other seven solutions involve a planar monomeric species. The difference in band position and intensity between the first d-d band of NiQ_2 in pyridine and that of Ni(ipdq) may be correlated with the difference in coordinated environment between *trans*-O_2N_4 and *cis*-O_2N_4 with a similar discussion of the d-d bands for *mer*- and *fac*-$KNiQ_3$.[21] From the band positions of the nickel chelates (Table 3), the form of NiQ_2 in MeOH and in the solid state have been assigned as solvent-coordinated O_4N_2 and oxygen-bridged polymeric O_4N_2, respectively. The latter is consistent with previous conclusions[22] of one form in an equilibrium mixture of NiQ_2 in inert solvent.

The shapes of the A-, B-, and C-bands of planar Ni(ipdq), and possibly those of planar NiQ_2 also, differ markedly from those of the copper chelates and the six-coordinated nickel chelates, which are similar to those of the ligand cation[3,13,14a] and the zwitter ion (Fig. 2 and Table 2). The bands of the planar nickel chelates, however, may be correlated to those of the other chelates by an inspection of the spectra of PdQ_2 (Table 2), since PdQ_2 has intermediate spectral properties between the copper chelates and the planar nickel chelates. Thus, with change from the copper chelates to PdQ_2 or the planar nickel chelates, the A-band appears to be split into two strong bands and the C-band becomes sharper and more intense, shifting to the red. Planar Ni(ipdq) shows an additional band near $27—28 \times 10^3$ cm^{-1}, and there is no corresponding band in the spectra of PdQ_2. In this sence, the band is clearly a new one.

It has been noted that the frequency shifts of the C-band of planar Ni(ipdq) induced by the solvents are almost the same as those of Cu(ipdq). These shifts may be correlated to the solvatochromism of the *N*-methyl compound, in regard to the strong blue shift by the addition of a small amount of MeOH in the benzene solutions (Fig. 3) and to the approximately linear relationship with the E_T value[19] (Table 2). These facts suggest that the nature of the C-bands, *i.e.* the first π-π^* bands, of these species are similar to each other, and throw doubt upon the explanation[3] for the C-band of planar NiQ_2 in terms of a strong mixing of charge transfer from the metal to the ligand with the intra-ligand transition.

Burton and Davis have studied the spectrum of 8-quinolinol and explained that the lowest energy band of the neutral molecule involves a movement of the electronic charge from the phenol ring to the pyridine ring, and that an increase in the electron density in the phenol ring (*e.g.* by the formation of the dissociated anion) or a decrease in the electron density in the pyridine ring (*e.g.* by the formation of the protonated cation) will move the transition to lower energies.[23] Hence the strong red shift of the C-band of the zwitter ion is explained.

In CuQ_2 *etc.*, the considerable delocalization of the negative charge on the phenol ring has been suggested from the bond-length between the carbon at 8-position and the phenolic oxygen[24] and the electrophilic reaction.[25] The delocalization and good σ-bonding character[3,13] of the metal–nitrogen bond can bring the C-band positions of the chelates listed in Table 2 between those of the zwitter ion and protonated cation of the ligand. As suggested from the study of the hydroxide,[17] the sensitivity of the C-band to the protic solvent, shown in Fig. 3, may be ascribed in most part to a decrease in the degree of delocalization of the negative charge to the phenol ring, possibly due to the formation of the H-bond between the protic solvent and the anionic oxygen in the chelates.

While the position of the C-band of the copper chelates is near to that of the solvent-coordinated nickel chelates, a blue shift of the C-band of the polymeric NiQ_2 relative to CuQ_2 (*e.g. ca.* 2000 cm^{-1}, in benzene) has been observed. In analogy with the formation of

the H-bond, the blue shift may be explained on the basis that the delocalization of the negative charge decreases due to the bonding of the phenolic oxygen to the two metal ions.

On changing from solvent-coordinated NiQ_2 to planar Ni(ipdq), the C-band is displaced to the red (*e.g. ca.* 2000 cm^{-1}, in MeOH). Although detailed analysis is not yet possible, the better σ-bonding character of the N–Ni (low spin) bond in the planar chelate may contribute much to this shift.

Experimental

Preparation of the Compounds. The spectral sample of NiQ_2 was obtained by heating $NiQ_2 \cdot 2H_2O$ at 140—150 °C for 10 h, which showed the bands (IR: KBr, in part) at 744, 737 (sh), and 731 cm^{-1}. A sample dehydrated by heating at lower temperature showed the single and somewhat broader peak at 730 cm^{-1} in this region.[26] The other MQ_2 were prepared by the usual method.[27]

8-Hydroxy-1-methylquinolinium chloride was prepared in a manner similar to the preparation of its perchlorate salt[14j] and recrystallized.[28] Mp 237—238 °C (lit,[28] 233 °C) (lit,[16] 197 °C). Found: C, 61.44; H, 5.27%. 8-Hydroxy-1-methylquinolinium hydroxide was prepared by the reported method.[17] Mp(dec) 117 °C (lit,[17] 115 °C) (lit,[16] 119 °C).

8-Quinolinol N-*Oxide (**1a**)*: The reported methods[29,30] were modified in the following way. To a hot solution of 8-quinolinol (73 g) dissolved in AcOH (200 cm^3), 30% aq H_2O_2 was added (50 cm^3). The mixture was heated at 75—80 °C, for 6 h. Additional peroxide (100 cm^3) was added in five equal portions, while heating, at hourly intervals. After cooling, the reaction mixture was concentrated with a rotary evaporator at 40—50 °C, and water (50 cm^3) added when the residue decreased. The resulting solution was concentrated again, and this procedure repeated three or four times until a solid separated. The resulting mixture was extracted with 150-, 100-, 100-, and 50 cm^3 of $CHCl_3$ and the combined extracts were washed with 2 M aq NH_3 (200- and 200 cm^3), water, 1 M aq HCl (200 cm^3), and finally water. The solvent of the organic layer, without drying, was distilled and the residual yellow solids were recrystallized from 50 vol% aq EtOH (210 cm^3) to give 47 g (58%) of **1a** as fine yellow needles; mp 138—139 °C (lit,[29] 138 °C) (lit,[30] 139 °C).

Bis(8-quinolinol N-*oxidato)copper(II) (**1b**)*: The reported method[10] was modified for large scale preparation. To a hot solution of $Cu(NO_3)_2 \cdot 3H_2O$ (25 g) dissolved in water (500 cm^3), concd aq NH_3 (24 cm^3) was added, followed by **1a** (32 g) dissolved in 50 vol% aq EtOH (300 cm^3) with vigorous stirring. After continued heating and stirring at *ca.* 60 °C for 4 h, the resulting suspension was allowed to stand overnight at room-temperature. The light-green product was collected, washed with 1.5 M aq NH_3 (*ca.* 200 cm^3) and water, and dried at 110 °C until the color changed to a yellowish brown to give 37 g (97%) of **1b**; mp (dec) 257—262 °C. IR(KBr): 3100, 3060, 1584, 1567, 1510, 1453, 1388, 1350, 1313, 1301, 1052, 1034, 821, 789, 745, 715, and 512 cm^{-1}. Found: C, 55.77; H, 3.11; Cu, 16.56%. This complex was slightly soluble in aq NH_3.

*Dimethyl and Diethyl Bis(8-acetoxy-2-quinolyl)malonate (**3a** and **3b**)*: See text. The following procedure is representative. A suspended mixture of **1b** (19 g), $CH_2(COOMe)_2$ (12 g), and Ac_2O (40 cm^3) in a flask equipped with a $CaCl_2$ tube, was stirred for periods and bath-temperature's as given in Table 4. To the resulting deep-green suspension, MeOH (25 cm^3) was added, and after stirring for 2 h at room-temperature, water (50 cm^3) was added in limited amounts with continuous stirring for complete precipitation of the desired products. The collected precipitate was washed with 50 vol% aq AcOH (*ca.* 100 cm^3) and water to remove the AcOH and the copper salt, and dried at 110 °C. The solids were suspended in hot $CHCl_3$ (50 cm^3), and the crude quinolone (**2**) filtered off. The filtrate was distilled off and the pale brown residual solids were dissolved in boiling acetone (150 cm^3 per 10 g). After cooling a small amount of **2** separated. The new filtrate was warmed, and an equal volume of hot water added portionwise to separate the crystalline powder of **3a**. After cooling, the collected powder was washed with water and dried. Concentration and cooling of the mother liquor yielded a small amount of a mixture of **2** and **3a**, which were separated by acetone. The combined crude quinolone (**2**) was recrystallized from AcOH by adding water (30- and 30 cm^3 per 10 g) to give light-tan leaflets; mp 247—249 °C, the yield of which is given in Table 4. Recrystallization from EtOH gave pale yellow leaflets; mp 249—251 °C (lit,[11] 252—254 °C), whose IR spectrum was virtually identical with that given in the lit.[9] The combined crude malonate (**3a**) was recrystallized from $CHCl_3$ by adding MeOH (25- and 75 cm^3 per 10 g) to give colorless needles; mp 211.5—213 °C, the yield of which is given in Table 4. Recrystallization from MeOH (100 cm^3 per 0.8 g) gave an analytical sample of the colorless needles; mp 211.5—213 °C. IR(KBr): 1759 and 1741 cm^{-1} (C=O); PMR ($CDCl_3$): δ=2.49 (6H, s, $-OCOCH_3$), 3.91 (6H, s, $-COOCH_3$), 7.29—8.10 (10H, m). Found: C, 64.47; H, 4.43%. Calcd for $C_{27}H_{22}N_2O_8$: C, 64.54; H, 4.41%. The estimated solubility of **2** and **3a** in hot $CHCl_3$ were 0.7 g and 20 g per 50 cm^3, and in acetone at a room-temperature were 0.07 g and 3.5 g per 50 cm^3, respectively.

The treatment of **1a** (16 g) with the methyl ester and the treatment of **1a** or **1b** with $CH_2(COOEt)_2$ (14 g) in a similar manner gave the results given in Table 4. The two samples of **3a** obtained from **1a** and **1b** had identical IR spectra with each other and the mp of a mixture of the two samples was not depressed. The same was found with the two samples of **3b**.

The colorless leaflets of **3b** recrystallized from MeOH; mp 237.5—239 °C. IR(KBr): 1763 and 1736 cm^{-1} (C=O); PMR ($CDCl_3$): δ=1.30 (6H, t, J=7 Hz, $-CH_3$ of the ethyl ester), 2.49 (6H, s, $-OCOCH_3$), 4.43 (4H, q, J=7 Hz, $-CH_2-$), 7.24—8.13 (10H, m). Found: C, 65.96; H, 4.73%. Calcd for $C_{29}H_{26}N_2O_8$: C, 65.65; H, 4.94%.

Table 4. The yields of **3** and **2**

N-oxide	Malonic ester	Temp[a] (°C)	Time (days)	Yield (%) **3**	Yield (%) **2**

a) Bath temp, ±3 °C.

2,2'-Methylenedi-8-quinolinol Dihydrochloride Dihydrate (4): This was prepared in a similar way to the conversion of di-2-quinolylmalonate into 2,2'-methylenediquinoline.[8] A suspension of **3a** (10.1 g) in 20% aq HCl (700 cm³) was heated under reflux for 2 h producing a yellow solution. While hot, a small amount of reddish material was filtered off, and the filtrate allowed to stand overnight at room-temperature. The separated yellow solid was collected, washed with acetone, dried at room-temperature under reduced pressure, and recrystallized from MeOH (150 cm³) containing concd HCl (1.5 cm³) by adding concd HCl (15 cm³) to give the yellow crystals of **4**, which were washed with 20% HCl and then with acetone. The yield was 7.8 g (95%). Further recrystallization from 20% HCl (100 cm³ per 2.5 g) gave an analytical sample of the yellow plates, salmon-pink above 110 °C, dec at 255—270 °C. IR(KBr): 3360, 3180—2500, 1631, 1599, 1502, 1422, 1391, 1302, 1090, 863, 848, 837, 821, 748, 574, and 564 cm⁻¹. Found: C, 55.27; H. 4.80%. Calcd for $C_{19}H_{20}N_2O_4Cl_2$: C, 55.49; H, 4.90%. The weight loss after heating at 110 °C for 15 h was 17.64%, corresponding to the release of one molecule of HCl and two molecules of H_2O (Calcd: 17.63%). The treatment of **3b** was effected also with 20% HCl (10.6 g per 700 cm³) under reflux for 3 h, resulting in a 95% yield of **4**. The IR spectrum was identical with that prepared from **3a**.

(2,2'-Methylenedi-8-quinolinolato)nickel(II) (5): To a hot solution of $Ni(OAc)_2 \cdot 4H_2O$ (4.7 g) dissolved in MeOH (100 cm³), **4** (7.8 g) was added with stirring and heating at *ca.* 60 °C. When the reddish brown precipitate disappeared producing a sky-blue precipitate and deep-green mother liquor (after *ca.* 30 min), a hot solution of $NaOAc \cdot 3H_2O$ (7.8 g) dissolved in water (200 cm³) was added portionwise. After heating and stirring for 2 h, the resulting yellowish brown solid was collected, washed with hot water, and dried at 110 °C to give 6.8 g (quantitative) of **5**; mp above 280 °C. IR(KBr): 3040, 2870, 1574, 1502, 1458, 1439, 1395, 1369, 1333, 1302, 1279, 1138, 1108 (C–O),[31] 904, 828, 818, 768, 743, 729, 631, 536, and 525 cm⁻¹. Found: C, 63.84; H, 3.18; Ni, 16.37%. Calcd for $C_{19}H_{12}N_2O_2Ni$: C, 63.56; H, 3.27; Ni, 16.35%.

The structure of **5** was deduced from its characteristic visible spectra. This yellowish brown powder showed similar visible spectra (mull method, max: 445 nm, sh: 540 nm) to that of Ni(ipdq) discussed in the text. However, the solution spectra (*ca.* 4×10^{-4} M, a 0.1 cm cell) showed three sharp peaks near 500 nm (Scheibe's A-band).[32] Thus in DMF at 452.5 nm (ε: 4700), 482 (9400), 515 (17600), and in 0.01 M methanolic NaOH at 447.5 (6400), 477 (15600), 511 (33200), these are similar to the metal chelates with 2,2'-methylenediquinoline.[32] A spectral change with time was observed, probably due to air-oxidation.

(2,2'-Isopropylidenedi-8-quinolinolato)nickel(II), Ni(ipdq): To a warmed suspension of **5** (1.8 g) in MeOH (100 cm³), CH_3I (5 cm³) was added, followed by NaOH (0.5 g) dissolved in water (45 cm³) with stirring and heating at 45—50 °C under reflux, to give a reddish black mixture. Soon a brown solid separated out. After continuous stirring and heating for 30 min, the reaction mixture was poured into hot water (200 cm³) with stirring with caution against the remaining iodide. The precipitated reddish brown solids were collected, washed with hot water, dried at 110 °C (yield: 1.9—1.8 g), extracted with boiling MeOH (250 cm³), and the residual solids (0.3—0.2 g) filtered off. After cooling the filtrate for some time, a small amount of the precipitated black material was filtered off, and the new filtrate allowed to stand at *ca.* 5 °C overnight. The crystals separated were collected, washed with MeOH, and dried to give 1.0 g (and 0.3 g from the mother liquor, total 67%) of Ni(ipdq). Repeated recrystallizations from MeOH (100 cm³ per 0.8 g) gave an analytical and spectral sample as reddish brown leaflets (sometime gave needles having a virtually identical IR spectrum). PMR and UV: see in the text. TGA-DTA (5 °C/min, in air): a sharp endothermic peak at 336 °C, followed by a weight loss. IR(KBr): 3040, 2970, 1567, 1501, 1468, 1447, 1395, 1334, 1296, 1110 (C–O),[31] 832, 772, 740, 638, and 551 cm⁻¹. Found: C, 65.21; H, 4.04; Ni, 15.16 %. Calcd for $C_{21}H_{16}N_2O_2Ni$: C, 65.16; H, 4.17; Ni, 15.17%.

2,2'-Isopropylidenedi-8-quinolinol, ipdq: To a suspension of Ni(ipdq) (2.0 g) in EtOH (20 cm³), concd HCl (4 cm³) was added with swirling to give a clear deep-green solution, to which hot water (80 cm³) was added in limited amounts, separating out the yellow leaflets (probably the hydrochloride of ipdq). The mixture was allowed to stand at *ca.* 5 °C overnight. The crystals were collected, washed with 1 M aq HCl, air-dried at room-temperature, and dissolved in hot EtOH (40 cm³). To this solution a half portion of a hot solution of $NaOAc \cdot 3H_2O$ (2 g) in water (40 cm³) was added to produce turbidity which was followed by crystallization. With continuous warming, the remaining portion of the acetate solution was added portionwise with swirling, followed by the addition of water (20 cm³). After cooling, the crystals were collected, washed with water, air-dried, and recrystallized from hexane (40 cm³) to give 1.4 g (and 0.1 g from the mother liquor, total 88%) of ipdq as colorless plates; mp 101.5—102.7 °C. Recrystallization from MeOH by adding water (40- and 100 cm³ per 1.4 g) gave an analytical and spectral sample as colorless leaflects; mp 102.0—102.7 °C. IR(KBr): 3460, 3425, 3040, 2975, 2925, 1599, 1568, 1498, 1470, 1454, 1433, 1317, 1252, 1230, 1193, 1098, 1077, 838, 756, 719, 607, and 560 cm⁻¹. PMR and UV: see in the text. Found: C, 76.22; H, 5.33%. Calcd for $C_{21}H_{18}N_2O_2$: C, 76.35; H, 5.49%.

(2,2'-Isopropylidenedi-8-quinolinolato)copper(II), Cu(ipdq): To a hot solution of ipdq (1.0 g) dissolved in EtOH (40 cm³), a warmed solution of $Cu(OAc)_2 \cdot H_2O$ (0.6 g) in water (40 cm³) was added to give a clear deep-green solution. Very soon green crystals separated out. After heating at *ca.* 60 °C for 30 min, the mixture was allowed to stand at *ca.* 5 °C overnight. The crystals were collected, washed with water, and dried at 110 °C to give 1.2 g (quantitative) of Cu(ipdq). Repeated recrystallizations from MeOH (100 cm³ per 0.75 g) gave an analytical and spectral sample as deep-green needles. TGA-DTA (5 °C/min, in air): a sharp exothermic peak at 346 °C, accompanied by a weight loss. IR(KBr): 3040, 2980, 1601, 1552, 1494, 1432, 1383, 1343, 1333, 1309, 1272, 1107 (C–O),[31] 826, 746, 605, 535, and 521 cm⁻¹. UV: see in the text. Found: C, 63.91; H, 4.18; Cu, 16.23%. Calcd for $C_{21}H_{16}N_2O_2Cu$: C, 64.36; H, 4.12; Cu, 16.21%.

Ni(ipdq) from ipdq: To a hot solution of ipdq (1.0 g) dissolved in MeOH (30 cm³), a hot solution of $Ni(OAc)_2 \cdot 4H_2O$ (0.75 g) in water (30 cm³) was added to make the solution turbid. Soon the crystals separated out. After heating at *ca.* 60 °C for 1 h, the mixture was worked up in a manner similar to that of Cu(ipdq). The sample obtained had an identical IR spectrum with that prepared from **5**.

Measurements. All the melting points were uncorrected. The IR and PMR spectra were recorded with a JASCO IRA-2 and a Hitachi R-20 spectrometer respectively. The TGA-DTA measurements were carried out with a Rigaku-denki TG-DSC apparatus. The electronic spectra were measured with a Simadzu MPS-50L spectrometer at room-temperature, using a 0.1 cm cell for the ultraviolet region, a 1.0 cm cell for the near-ultraviolet and visible region, except PdQ_2 in MeOH (a 2.0 cm cell), and a 1.0 or 5.0 cm cell for the d-d region, unless otherwise stated. The solvents used were dried and distilled except DMF, THF, 1,2-dichloroethane, and cyclohexane which were of spectroscopic grade and used without further purification.

Analyses: A Shimadzu UM-3B apparatus was used for the elemental analyses. The metal contents in the complexes were determined gravimetrically, after the complete decomposition with H_2SO_4–HNO_3.

The authors wish to thank Mr. Masahiko Takahashi for the elemental analyses and Dr. Masatoshi Hirayama for the PMR measurements.

Photometric Determination of a Trace Amount of Nitrite by Its Kinetic Effect†

Satori UTSUMI, Tadao OKUTANI, Akio SAKURAGAWA,* and Akira KENMOTSU**

College of Science and Technology, Nihon University, 1-8, Kanda-Surugadai, Chiyoda-ku, Tokyo 101

(Received January 30, 1978)

A new photometric method has been developed for determining nitrite ions. This method is based on the kinetic effect of nitrite ions on the color-fading of the iron(III) thiocyanate complex in dilute nitric acid solution in the presence of iodide ions. The reaction is initiated by adding an ammonium iron(III) sulfate solution to the sample solution containing a mixture of potassium thiocyanate and potassium iodide at 25 °C. A concentration of nitrite ions, ranging from 0.0005 to 10 ppm can be determined by measuring the absorbance at 460 nm at a given time after the initiation using four appropriate calibration curves. Silver, mercury(II), iron(II), sulfide, sulfite, thiosulfate, chromate and cyanide ions in the concentration range from 0.1 to 1 ppm level interfered with the determination.

It has been established that the orange color of iron(III) thiocyanate, which was formed by the reaction with potassium thiocyanate and an excess of iron(III) salt in dilute nitric acid solution, faded more rapidly in the presence of iodide than in its absence.[1] The catalytic action of iodide ions on this reaction has been studied colorimetrically, and a new micro-determination method for iodide ions established.[1,2] It was also found that the catalytic reaction was characterized by an induction period, the length of which depended on the nitrite ion concentration.[2,3] This kinetic effect has been utilized to determine the amounts of iodide ions in the presence of nitrite ions.[4] Iodides in silicate rocks,[5] and iodide and iodate ions in sea water[6] have also been determined.

Successive investigations on the behavior of nitrite ions have shown that the kinetic effect can be applied to the determination of nitrite ions. This paper proposes a new method for the determination of nitrite ions on the basis of the kinetic effect mentioned above.

The proposed method gives accurate results for nitrite ions ranging from 0.0005 to 10 ppm. The determination can be made by measuring the absorbance at a given time after the addition of an ammonium iron(III) sulfate solution using calibration curves obtained under identical conditions.

Experimental

Apparatus. A Hirama IIC type photometric colorimeter with a 460 nm filter and 10 mm glass cells was used to measure the absorbance. The reaction was performed at 25.00±0.05 °C using a water bath with a Komatsu-Yamato Coolnicks circulator Model CTE/CTR-120 unit.

Reagents. All of the chemicals used were of guaranteed reagent grade. The ion-exchanged water was distilled in a borosilicate still prior to use.

Standard Nitrite Solution: Sodium nitrite (1.4997 g) was dissolved in distilled water, diluted to exactly 1 litre (1000 ppm NO_2^-), and stored in a brown glass bottle. The working solution was diluted as required.

Potassium Thiocyanate Solution (0.01 M): A potassium thiocyanate solution(0.1 M), standardized by Volhard's method, was diluted to 0.01 M and stored in a brown glass bottle.

Potassium Iodide Solution (2×10^{-3} M): A potassium iodide solution (0.1 M), standardized by Volhard's method, was diluted to 2×10^{-3} M and stored in a brown glass bottle.

Potassium Thiocyanate–Potassium Iodide Mixed Reagent Solution (Mixed Reagent Solution): The mixed reagent solution was prepared by mixing potassium thiocyanate solution (0.01 M) with an equal volume of potassium iodide solution (2×10^{-3} M) just before the experiment was started.

Ammonium Iron(III) Sulfate–Nitric Acid Solution (Iron(III) Reagent Solution): The iron(III) reagent solution was prepared by dissolving ammonium iron(III) sulfate (6.0 g) in nitric acid (7.0 M), and then diluting to 100 ml with 7.0 M nitric acid. After urea (10 mg) was added to the solution, it was heated in boiling water with a reflux condenser for 10 min and then cooled rapidly in water. This reagent solution was stored in a brown glass bottle at room temperature, and could be used for approximately 30 days.

Procedure and Calibration Curves. The sample solution (10 ml) was placed in a 20 ml glass tube fitted with a stopper. The mixed reagent solution (1 ml) was then added and the glass tube placed in a water bath at 25.00±0.05 °C for 10

† Presented at the 21th National Meeting of the Chemical Society of Japan, Osaka, April 1968, and at the 25th Annual Meeting of the Japan Society for Analytical Chemistry, Niigata, October 1976.

** Present address: Nippon Electronics Engineering College, 5-23-22, Nishi-Kamata, Ohta-ku, Tokyo 144.

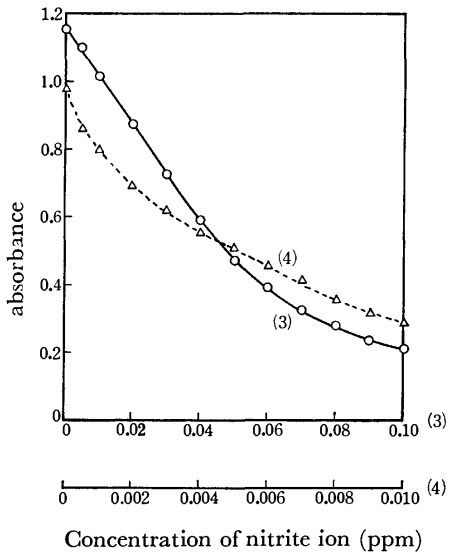

Fig. 2. Calibration curves 2.
(reaction temperature: 25 °C)
(3) Reaction time: 19 min, (4) reaction time: 24 min.

min. The reaction was initiated by adding the iron(III) reagent solution (2 ml, at the same temperature), mixing thoroughly and then replacing the glass tube in the water bath. The absorbance was measured at 460 nm using water as a reference at a given time after the addition of the iron(III) reagent solution. It is recommended that the solution in the glass tube is removed from the water bath and poured into the cell 20 s before measurement of the absorbance. By employing 7, 13, 19, or 24 min of reaction time, nitrite ions in the concentration range of 0.5—10, 0.05—1, 0.005—0.1, or 0.0005—0.01 ppm, respectively, could be determined. The calibration curves shown in Figs. 1 and 2 were obtained by the procedure described above.

Results and Discussion

The Reaction Rate Curves. The kinetic reactions were examined for each solution (10.0 ml) containing 10, 1, 0.1, or 0.01 ppm nitrite ions, and for distilled water. The curves shown in Fig. 3 were obtained by measuring the absorbances of these solutions at various reaction times. In the absence of nitrite ions (curve 5 in Fig. 3), the color-fading of the iron(III) thiocyanate complex began approximately 20 min after the initiation and after 32 min, the solution became almost colorless. In the presence of nitrite ions, the color-fading was accelerated with an increase in the concentration of nitrite ions. These results indicate that the length of the induction period is greatly affected by the concentration of nitrite ions, and that nitrite ions ranging in concentration from 0.0005 to 10 ppm can be determined by measuring the absorbances at different reaction times.

The Effect of Iodide Ion Concentration in the Mixed Reagent Solution. The concentration of potassium thiocyanate in the mixed reagent solution was chosen as 5×10^{-3} M, which was the same value as in a previous paper.[4] Three concentrations of iodide ion (5×10^{-4}, 1×10^{-3}, and 2×10^{-3} M) were adopted to examine the effect of the iodide ion concentration in the mixed reagent solution on the color-fading. It was found that, as the concentration of iodide ion increased, the start of the color-fading was delayed, but once initiated the speed of the color-fading increased. For example, in the reagent blank, the color-fading of the iron(III) thiocyanate complex began approximately 19 min after the initiation at a concentration of 5×10^{-4} M of iodide ions, whereas it began approximately 24 min after the initiation at 2×10^{-3} M of iodide ions. In the present work, the concentration of iodide ions was adjusted to 1×10^{-3} M to make four calibration curves effective for the concentration range from 0.0005 to 10 ppm of nitrite ions. Consequently, the mixed reagent solution used was of 5×10^{-3} M potassium thiocyanate and 1×10^{-3} M potassium iodide.

The Effect of the Concentration of Nitric Acid in Iron(III) Reagent Solution. This effect was studied using the three reagent solutions in which ammonium iron(III) sulfate was dissolved in 6.00, 7.00, or 8.00 M nitric acid, the experimental results of which are shown in Fig. 4. With regard to the sensitivity and the length of time required to determine the amounts of nitrite ions, the iron(III) reagent solution prepared from 7.00 M of nitric acid was selected. Figure 4 illustrates the effect of nitric acid on the color-fading which is remarkable. Therefore, it is necessary to accurately adjust the concentration of nitric acid.

10 mg urea/100 ml iron(III) reagent solution, heated for 10 min in boiling water.
a) Super Special Grade. b) Guaranteed Reagent of Japanese Industrial Standards. c) Extra Pure Japanese Industrial Standards.

The Effect of Temperature. Measurements were made at temperatures 20, 25, and 30 °C to study the effect of temperature. The induction period of the color-fading decreased with an increase in temperature. For example, in the reagent blank, the color-fading of the iron(III) thiocyanate complex began approximately 20 min after the initiation at 25 °C, and 36 min after the initiation at 20 °C (Fig. 5). A temperature of 25.00±0.05 °C was used throughout this work.

The Removal of Nitrite Ions in Nitric Acid. Commercially available nitric acid usually contains trace amounts of nitrite ions as impurity. If such nitric acid is used as a reagent, nitrite ion concentration of less than 0.01 ppm in the sample will prove impossible to determine. Thus, several attempts were made to remove the trace amounts of nitrite ions in the iron(III) reagent solution. It was found that the nitrite ion was readily decomposed

Table 4. Effect of various ions on the determination of nitrite

Ion	Added as	Concn (ppm)	Absorbance (19 min) Blank	Absorbance (19 min) 0.05 ppm NO_2^-

by the addition of urea. Therefore urea was added to the iron(III) reagent solution, and the solution heated in boiling water under different conditions. As Table 1 illustrates, the absorbance of the reagent blank increases with an increase in the amount of urea. As shown in Table 2, maximum absorbance was obtained after a heating period of 10 min. Heating of the solution over 10 min, causes the complete decomposition of urea, which is succeeded by the decomposition of nitric acid to produce the nitrite ion. By using 10 mg of urea and a heating period of 10 min, nitrite ions can be almost completely decomposed (Table 3). Less than 0.1 ppm of the nitrite ion in the iron(III) reagent solution can also be removed by treating the solution in the same way. The iron(III) reagent solution thus treated could be used for at least 30 days.

The Effect of Various Ions. To establish the effect of various ions on the proposed method, experiments were conducted, both in the presence of nitrite ion (0.05 ppm) and its absence. The experimental results are given in Table 4.

Metal ions, such as silver, mercury(II), and iron(II) interfered with the determination of nitrite ion. Oxidizing or reducing anions, such as sulfide, sulfite, thiosulfate, chromate, and cyanide at 0.1 to 1 ppm level also interfered.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Kinetic Studies on the Stability Enhancement of Mixed Ligand Copper(II) Complexs with 2,2′-Bipyridyl and Acetylacetonate

Megumu MUNAKATA* and Katsumi YAMADA

Department of Chemistry, Kinki University; Kowakae, Higashi-Osaka-Shi, Osaka 577

(Received March 9, 1978)

The rate constants for the formation and dissociation of the binary Cu^{2+}-acetylacetonate($acac^-$) complex and the ternary 2,2′-bipyridyl(bpy)-Cu^{2+}-$acac^-$ complex have been determined by the temperature-jump method. For the reactions $Cu^{2+}+acac^- \underset{k_{-1b}}{\overset{k_{1b}}{\rightleftharpoons}} Cu(acac)^+$, $Cu(acac)^+ + acac^- \underset{k_{-2b}}{\overset{k_{2b}}{\rightleftharpoons}} Cu(acac)_2$, and $Cu(bpy)^{2+} + acac^- \underset{k_{-1t}}{\overset{k_{1t}}{\rightleftharpoons}} Cu(bpy)(acac)^+$, the rate constants are $k_{1b}=9.0\times10^8\ M^{-1}\ s^{-1}$, $k_{-1b}=3.2\ s^{-1}$, $k_{2b}=7.0\times10^7\ M^{-1}\ s^{-1}$, $k_{-2b}=13\ s^{-1}$, $k_{1t}=1.1\times10^9\ M^{-1}\ s^{-1}$ and $k_{-1t}=1.9\ s^{-1}$. A comparison of the reactions shows that the forward rate for the Cu(bpy)(acac)$^+$ formation is larger than that for $Cu(acac)^+$ and, subsequently, the rate of the complex formation between $Cu(bpy)^{2+}$ and $acac^-$ is enhanced by the coordinating bpy. On the other hand, the reverse rate for the ternary complexation reaction is smaller than for the binary. This illustrates that the dissociation of $acac^-$ of Cu(bpy)(acac)$^+$ becomes more difficult owing to the coordination of the bpy. The above two effects of the bpy may be driving forces producing high stability, *i.e.*, a positive value of $\Delta \log K$ $\left(K=\dfrac{[Cu(bpy)[L]}{[Cu(bpy)][L]}\right)$ for the ternary copper(II) complexes with bpy and other ligands containing O as donor atoms.

It has been reported[1-9] that ligands containing O as donor atoms form stabler complexes with 2,2′-bipyridyl copper(II) ion (Eq. A) than with the hydrated Cu^{2+} ion (Eq. B).

$$Cu(bpy) + L \rightleftharpoons Cu(bpy)L$$

$$K^{Cu(bpy)}_{Cu(bpy)L} = \frac{[Cu(bpy)L]}{[Cu(bpy)][L]} \quad (A)$$

$$Cu + L \rightleftharpoons CuL \quad K^{Cu}_{CuL} = \frac{[CuL]}{[Cu][L]} \quad (B)$$

$$\Delta \log K = \log K^{Cu(bpy)}_{Cu(bpy)L} - \log K^{Cu}_{CuL} \quad (C)$$

The value of $\Delta \log K$ is, therefore, positive for ligands containing O donor atoms. This is especially noticeable in view of the fact that the value expected for $\Delta \log K$ is generally negative, since more coordination positions are available for bonding of the first ligand than for the second ligand to a given metal ion. Table 1 shows the $\Delta \log K$ values for some ternary complexes. The most important driving force for stabilization of the ternary complex (*i.e.*, the positive value of $\Delta \log K$) is considered to be the electronic effect due to π bonding formation in the complex.[3] However, little evidence is available which clarifies the electronic effect.

TABLE 1. STABILITIES OF SOME TERNARY Cu^{2+} COMPLEXES (25 °C, I=0.1)

Complex	$\Delta \log K$[a]

One method of elucidating the high stability of ternary bpy-Cu^{2+}-O ligand complexes is a kinetic study of the complexation reaction of the ternary complexes. No kinetics on the complexation reaction of Cu^{2+}-O ligand complexes have however been reported. In this paper the relaxation effects of the complexation of bpy-Cu^{2+}-acetylacetone and Cu^{2+}-acetylacetone (Hacac) have been investigated using temperature-jump techniques. On the basis of the kinetic data the high stability for the ternary bpy-Cu^{2+}-$acac^-$ complex has been discussed.

Experimental

Kinetic experiments were conducted using a Union Giken co-axial cable temperature-jump apparatus RA-1200. A discharge of 30 KV, through two electrodes in 1.0 ml sample solution, from a 0.05 μF condenser, corresponding to an increase in temperature of about 5 °C was used in all experiments. Wako Pure Chemical reagent grade $Cu(NO_3)_2\cdot 3H_2O$, KNO_3, 2,2′-bipyridyl, acetylacetone, Chlorophenol Red, and Protein Research Foundation glycine were used without further purification. The concentration of a copper stock solution was determined by an EDTA titration. Experimental solutions containing 1.00×10^{-4} M Chlorophenol Red were maintained at 0.1 ionic strength using KNO_3 and adjusted to the desired pH value with NaOH and/or HNO_3 solution. The temperature of this study was 25 °C. Each relaxation time was estimated from the relaxation graph which was the accumulation of five oscilloscope traces recorded using a Union Giken kinetic data processer RA-450 equipped with an X-Y recorder. The relative error for these measurements was ±5%. The analysis of the temperature-jump data required the appropriate equilibrium constants, which were determined by the titration technique. The titration procedure was essentially the same as in a previous paper.[9] The equilibrium constants obtained are given in Table 2.

TABLE 2. EQUILIBRIUM CONSTANTS (25 °C and μ=0.1)

Symbol	log K
K_a	−9.33
K_{1b}	8.45
K_{2b}	6.73
K_{1t}	8.77
K_{1n}	−6.00[a]

a) HIn=Chlorophenol Red (Kolthoff, *J. Phys. Chem.*, **34**, 1466 (1930)).

Results

Ternary Complex. No relaxation effect was observed for solutions containing equal concentrations of Cu^{2+} and bpy under the conditions of these experiments, as had been reported.[10] In the pH range which was studied here, 5.50—5.80, the reaction

$$Cu^{2+} + bpy \rightleftharpoons Cu(bpy)^{2+} \quad (1)$$

is effectively complete and a 5 °C temperature-jump does not appreciably perturb it. It the complexation reactions 2—4 of the ternary bpy-Cu-acetylacetone system, no complexation reaction 4 needs to be considered, since the copper(II) ion is square planar and not a distorted octahedron as in the complex with acetylacetone (Hacac).[10]

$$Cu(bpy)^{2+} + acac^- \underset{k_{-1t}}{\overset{k_{1t}}{\rightleftharpoons}} Cu(bpy)(acac)^+, \quad (2)$$

where

$$k_{1t}/k_{-1t} = K_{1t} = \frac{[Cu(bpy)(acac)^+]}{[Cu(bpy)^{2+}][acac^-]},$$

$$Cu(bpy)^{2+} + Hacac \underset{k'_{-1t}}{\overset{k'_{1t}}{\rightleftharpoons}} Cu(bpy)(acac)^+ + H^+, \quad (3)$$

$$Cu(bpy)(acac)^+ + acac^- \rightleftharpoons Cu(bpy)(acac)_2, \quad (4)$$

where K_{1t} is the stability constant of the ternary $Cu(bpy)(acac)^+$ complex. These reactions are coupled to the more rapid protonation processes 5 and 6.

$$Hacac \underset{}{\overset{K_a}{\rightleftharpoons}} acac^- + H^+,$$

$$K_a = [acac^-][H^+]/[Hacac], \quad (5)$$

$$HIn \underset{}{\overset{K_{In}}{\rightleftharpoons}} In^- + H^+,$$

$$K_{In} = [In^-][H^+]/[HIn], \quad (6)$$

where HIn, K_{1n} and K_a are the acidic form of Chlorophenol Red and the dissociation constants of H_{In} and Hacac, respectively.

By applying the standard techniques[10-12] for deriving relaxation time τ expressions, it can be shown that

$$1/\tau = Ak_{1t} + Bk'_{1t}, \quad (7)$$

where

$$A = \frac{[Cu(bpy)^{2+}]}{1+\alpha} + [acac^-] + \frac{1}{K_{1t}}, \quad (8)$$

$$B = \frac{\alpha[Cu(bpy)^{2+}]}{1+\alpha} + [Hacac] + \frac{1}{K_{1t}K_a}\left([H^+] + \frac{\alpha\beta[Cu(bpy)(acac)^+]}{1+\alpha}\right), \quad (9)$$

$$\alpha = \frac{[H^+]}{K_a + \beta[acac^-]}, \quad (10)$$

$$\beta = \frac{K_{In} + [H^+]}{K_{In} + [In^-] + [H^+]}. \quad (11)$$

The experimental conditions, equilibrium concentrations and observed relaxation times for the bpy-Cu^{2+}-acetylacetone system are shown in Table 3 and $(\tau B)^{-1}$ plotted against A/B is shown in Fig. 1, where the data was handled on the assumption that

$$[Cu^{2+}]_{total} = [bpy]_{total} = [Cu(bpy)^{2+}] \quad (12)$$

The assumption of complete formation of Cu^{2+}-bpy 1 : 1 complex has been demonstrated.[10] The slope of the line in Fig. 1 represents k_{1t} and the intercept k'_{1t} and from the plots, $k_{1t} = 1.1 \times 10^9\ M^{-1}\ s^{-1}$ and $k'_{1t} = 0—2 \times 10^{-4}\ M^{-1}\ s^{-1}$. This demonstrates that Hacac is remarkably unreactive towards $Cu(bpy)^{2+}$ and possibly towards Cu^{2+}.

Binary Complex. Two complexation reactions

80.0	80.0	1.39	1.98	6.68	198	780	108

All concentrations are molar. $\mu = 0.1M(KNO_3)$. Temperature = 25 °C.

between Cu^{2+} and acetylacetonate have been considered:

$$Cu^{2+} + acac^- \underset{k_{-1b}}{\overset{k_{1b}}{\rightleftharpoons}} Cu(acac)^+,$$

$$K_{1b} = \frac{[Cu(acac)^+]}{[Cu^{2+}][acac^-]}, \quad (13)$$

$$Cu(acac)^+ + acac^- \underset{k_{-2b}}{\overset{k_{2b}}{\rightleftharpoons}} Cu(acac)_2,$$

$$K_{2b} = \frac{[Cu(acac)_2]}{[Cu(acac)^+][acac^-]}. \quad (14)$$

A general treatment for obtaining relaxation time expressions in metal-ligand systems represented by Eqs. 13 and 14 has already been given.[13,14] The reciprocals of the two relaxation time are

$$\frac{1}{\tau_{+,-}} = \frac{1}{2}\{a_{11}+a_{22} \pm \sqrt{(a_{11}+a_{22})^2 - 4(a_{11}a_{22}-a_{21}a_{12})}\}, \quad (15)$$

where

$$a_{11} = k_{1b}\left([acac^-] + \frac{[Cu^{2+}]}{1+\alpha} + \frac{1}{K_{1b}}\right), \quad (16)$$

$$a_{12} = k_{1b}\left(\frac{1}{K_{1b}} - \frac{[Cu^{2+}]}{1+\alpha}\right), \quad (17)$$

$$a_{21} = k_{2b}\left([acac^-] - \frac{[Cu(acac)^+]}{1+\alpha}\right), \quad (18)$$

$$a_{22} = k_{2b}\left([acac^-] + \frac{[Cu(acac)^+]}{1+\alpha} + \frac{1}{K_{2b}}\right). \quad (19)$$

The plus and minus signs give the short and long relaxation times, respectively. Generally the short relaxation time, τ_+, was observed.[14] Equations 5, 6, and 10—19 were applied to the data of Table 4. The values of τ_{calc}^{-1} were fitted to the best values of k_{1b} and k_{2b} by inserting a large number of combinations for the two unknown constants into a computer program and comparing predicted values for τ_+^{-1} with those (τ_{obsd}^{-1}) observed experimentally. The best fit was determined by minimizing the quantity σ,[15]

$$\sigma = \sum\{(\tau_{calcd}^{-1} - \tau_{obsd}^{-1})/\tau_{obsd}^{-1}\}^2. \quad (20)$$

The best fit forward rate constants are given in Table 4.

Discussion

The kinetics of the complexation reactions of nickel(II), cobalt(II), and copper(II) ions have been extensively studied using a variety of rapid reaction techniques.[16] It has been concluded that the substitution reactions of nickel(II), cobalt(II), and copper(II) ions proceed *via* the rate determining mechanism in which a water molecule dissociates from the inner coordination sphere of a thermodynamically stable species. There have been some reports in which the rate-determining is chelate ring closure, when there is steric hindrance of the ligand to the chelate ring closure.[14] In the case of the fully hydrated copper(II) ion and a normal bidentate ligand, A–B, such as $acac^-$, the complexation reactions may be written as follows:

$$M_{aq} + A\text{-}B_{(aq)} \overset{K_{01}}{\rightleftharpoons} \underset{\text{ion pair}}{W_2MW_1, A\text{-}B}, \quad \text{very rapid,}$$

$$W_2MW_1, A\text{-}B \underset{k_{-01}}{\overset{k_{01}}{\rightleftharpoons}} W_2M\text{-}A\text{-}B + H_2O, \quad \text{slow,}$$

$$W_2M\text{-}A\text{-}B \underset{k'_{-01}}{\overset{k'_{01}}{\rightleftharpoons}} M\begin{matrix}A\\|\\B\end{matrix} + H_2O, \quad \text{fast.}$$

where W_1 and W_2 represent the two water molecules in the inner coordination sphere replaced by A–B. The rate-determining step in the transition from the ion pair to the final complex is the dissociation of a water molecule from the inner coordination sphere of the metal ion. The rate constant for complex formation is then

$$k_{1b} = K_{01}k_{01}, \quad (21)$$

where K_{01} is the ion pair formation constant (Eq. 22) and k_{01} is the rate constant for water dissociation.

$$K_{01} = \frac{[W_2MW_1, A\text{-}B]}{[W_2MW_1][A\text{-}B(aq)]}. \quad (22)$$

Theoretical values of K_{01} can be estimated from Eq. 23,[13] where $U(a)$ is the Debye-Hückel interaction potential and a is the distance between the centers of the ion-pair partners.

TABLE 4. EQUILIBRIUM CONCENTRATIONS AND RELAXATION TIMES FOR Cu^{2+}-ACETYLACETONE SOLUTIONS

1.00	2.00	3.29	8.12	1.16	2.24	0.730	0.453	9.79	8.95
2.00	3.00	1.94	11.1	2.67	2.08	1.57	2.25	9.29	8.83
3.00	4.00	1.69	10.5	2.91	2.87	2.35	3.66	20.2	17.4
4.00	4.00	1.94	5.75	1.39	7.68	3.01	2.25	17.5	18.0
5.00	5.00	2.55	7.43	1.36	9.77	3.75	2.74	20.5	21.5
5.00	4.00	2.22	3.75	0.789	15.1	3.35	1.42	17.3	18.8
5.00	6.00	2.03	9.84	2.27	6.12	3.91	4.77	22.0	25.3
6.00	6.00	3.00	8.80	1.37	11.6	4.50	3.32	27.1	25.2
7.00	7.00	1.98	7.08	1.67	11.4	5.38	4.82	23.6	26.9
$k_{1b}=9.0\times10^8\ M^{-1}\ s^{-1}$					$k_2=7.0\times10^7\ M^{-1}\ s^{-1}$			$\sigma=0.188$	
$k_{-1b}=3.2\ s^{-1}$					$k_{-2b}=13\ s^{-1}$				

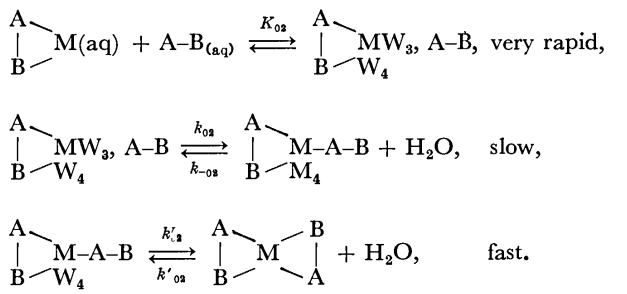
All concentrations are molar. $\mu=0.1M(KNO_3)$. Temperature=25 °C.

$$K_{01} = \frac{4\pi Na^3}{3000} \exp\left(-\frac{U(a)}{kT}\right). \quad (23)$$

Choosing $a=5$ Å (under the conditions $\mu=0.1$ and 25 °C) leads to a value of $K_{01}=0.8$ for +1, −1 interactions; 2 for +2, −1 and +1, −2; 0.3 when one of the reactants is uncharged.

The values of the forward rate constant, k_{1b}, for the binary complex formation between Cu^{2+} and acetylacetonate (O, O ligand) is 9.0×10^8 M^{-1} s^{-1} and is smaller than the value for glycinate (N, O ligand)[10] 4.0×10^9 M^{-1} s^{-1} and ethylendiamine (N, N ligand)[17] 3.8×10^9 M^{-1} s^{-1}. This can be interpreted as the easier entrance of the N-donor atom of the ligand in the ion pair into the inner coordination sphere than the O-donor atom.

A similar mechanism may be proposed for the formation of ternary complexes with bpy and higher order complexes.[10]



The observed forward rate constant, k_{1t}, is given by

$$k_{1t} = SK_{02}k_{02}, \quad (24)$$

where S is a statistical factor which can be computed from the number of independent attacking sites available for the ligand. For the first bidentate $acac^-$ substituting on the distorted octahedron of hydrated copper(II) ion there are 12 edges. This is because the rate constant[18] for the internal inversion between the axial water molecules and the equatorial water molecules, 10^{11} s^{-1}, is about two orders of magnitude greater than the rate constant of water dissociation, 4.5×10^8 s^{-1} (calculated for the complexation reaction between Cu^{2+} aq and acac from Eq. 21) and subsequently the six coordinating waters are equally attacked by the ligand. The attacking sites of $Cu(bpy)^{2+}$ for the second bidentate ligand is one, since $Cu(bpy)^{2+}$ is square planar rather than a distorted octahedron. A more satisfactory statistical factor therefore may be 1/12 rather than 1/8 as described in Ref. 10.

It is surprising that the forward rate for the ternary copper complexation reaction 2 is larger than for the binary complexation reaction 13. Furthermore, from a consideration of the statistical factors, the forward rate for the ternary complex formation should be about 15 times that for the binary, where the ion pair formation constants are assumed to be the same in both cases. It has been reported[10] that the forward rate for the $Cu(bpy)(gly)^+$ formation (Eq. 26) is also larger than that for the $Cu(gly)^+$ (Eq. 25) by a factor of about 3 (for $S=1/8$) and by a factor of about 5 if $S=1/12$.

$$Cu^{2+} + gly^- \underset{22\ s^{-1}}{\overset{4\times10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} Cu(gly)^+ \quad (25)$$

$$Cu(bpy)^{2+} + gly^- \underset{19\ s^{-1}}{\overset{1.4\times10^9\ M^{-1}\ s^{-1}}{\rightleftharpoons}} Cu(bpy)(gly)^+ \quad (26)$$

These facts suggest that the forward rate for the ternary copper(II) complexation reaction between $Cu(bpy)^{2+}$ and a ligand is increased by the bpy coordinating to the copper(II). The enhancement ratio of the forward rate for the $Cu(bpy)(acac)^+$ formation is larger than that for the $Cu(bpy)(gly)^+$ formation. This corresponds to the increasing order in the $\Delta \log K$ values: $\Delta \log K=-0.35$ for $Cu(bpy)(gly)^+$; 0.32 for $Cu(bpy)(acac)^+$.

The most important factor for the possitive values of $\Delta \log K$ for the ternary copper(II) complexes with bpy and $acac^-$ with O as donor atoms is apparently the remarkable increase in the forward rate for the complexation reaction. The increase indicates that the activation energy of formation of the ternary complex is smaller than that of the binary complex. If the square planar $Cu(bpy)^{2+}$ easily leads to a transition state, *i.e.*, the five coordination state,[19] in which the d-orbitals of the copper(II) ion combine more preferably with O donor atoms than the hydrated copper(II) ions, the forward rate for the reaction between $Cu(bpy)^{2+}$ and a ligand with O donor atoms must be larger than that between hydrated Cu^{2+} and the ligand.

Both reverse rate constants for the ternary $Cu(bpy)L^+$ and binary CuL^+ complexation reactions are statistically the same, since in both cases there is only one way to remove L and the charges are the same. In fact, both the constants for $Cu(bpy)^+$ and $Cu(bpy)(gly)^+$ are the same.[10] On the other hand, the value of the reverse rate constant, 1.9 s^{-1}, for the ternary $Cu(bpy)(acac)^+$ complexation reaction is smaller than 3.2 s^{-1} for the binary $Cu(acac)^+$. The ratio of the former to the latter is 0.6. This illustrates the greater difficulty of dissociation of the Cu-acac bond in the ternary complex than that in the binary complex. The copper-ligand bond may be stabilized by the π-bond interaction between the two ligands through the copper(II).[3,20] The stability constant of the ternary copper(II) complex is slightly enhanced by a small decrease in the dissociation rate. In conclusion, the high stability of the mixed ligand copper(II) complex with 2,2′-bipyridyl and acetylacetonate is largely attributed to the remarkable enhancement of the forward rate for the complexation reaction.

Circular Dichroism Spectra of Cobalt(III) Complexes of the $[Co(O,O)_2(N)_2]^-$-Type[1]

Satoru MURAMOTO, Kenji KAWASE, and Muraji SHIBATA*

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received March 31, 1978)

The $[Co(O,O)_2(N)_2]^-$-type complexes, $[Co(ox)(mal)(en)]^-$, *cis*-$[Co(CO_3)(mal)(NH_3)_2]^-$, *cis*-$[Co(ox)(mal)(NH_3)_2]^-$ and *cis*-$[Co(mal)_2(NH_3)_2]^-$, have been prepared and resolved. The CD spectra of various complexes of this type including these new complexes have been measured. The assignments of the absolute configurations have been carried out by means of the CD comparison. The CD patterns in the first absorption band region have revealed regular change with the varied O,O ligands (O,O=CO_3^{2-}, ox^{2-}, and mal^{2-}), and from this fact a criterion for the assignments of the absolute configurations for the complexes of the present type has been established.

It is known[2,3] that in the $[Co(O,O)_2(N,N)]^-$-type complexes, which contain two of a bidentate O-donor ligand such as oxalato (ox) or malonato (mal) and one of a bidentate N-donor ligand such as ethylenediamine (en) or trimethylenediamine (tn), the variations of the O-donor ligands cause marked changes in the CD spectra; the CD spectra of the $(+)_{546}[Co(ox)_2(en)]^-$ [2] and $(+)_{546}[Co(ox)_2(tn)]^-$ [3] complexes show two CD peaks of the same sign, (—, —), in the first absorption band region, while the spectra of the $(-)_{546}[Co(mal)_2(en)]^-$ [2] and $(-)_{546}[Co(mal)_2(tn)]^-$ [3] complexes show three CD peaks of alternating sign, (+, —, +), in the first absorption band region. On account of this change, it is difficult to correlate the absolute configurations of these complexes with the observed CD spectra. Thus, it was thought that the CD spectrum of a complex such as $[Co(ox)(mal)(en)]^-$, which is a transient intermediate between the bis(oxalato) and bis(malonato) complexes, would help in the understanding of such CD spectral changes.

From this standpoint, the preparation and optical resolution of the $[Co(O,O)_2(en)]^-$-type complexes containing a variety of O,O ligands (CO_3^{2-}, ox^{2-}, and mal^{2-}) have been conducted. The work was then extended to the corresponding diammine complexes, *cis*-$[Co(O,O)_2(NH_3)_2]^-$, and the bis(pyridine) complexes, *cis*-$[Co(O,O)_2(py)_2]^-$. The present paper deals with the CD studies of the complexes of the $[Co(O,O)_2(N)_2]^-$-type ($(N)_2$=en, $2NH_3$, and 2py).

Experimental

Preparation and Resolution. *a) Sodium Ethylenediaminemalonatooxalatocobaltate(III) Monohydrate, Na[Co(ox)(mal)(en)]·H_2O*: To a solution of $K[Co(CO_3)(ox)(en)]\cdot H_2O$[4] (32 g, 0.1 mol, in 150 cm³ H_2O) was added dropwise a solution of malonic acid (15 g, 0.15 mol, in 50 cm³ H_2O) with stirring at room temperature. The mixed solution was stirred at 40 °C for 2 h. The final product was filtered and the filtrate charged on a column containing Dowex 1-X 8 resin in Cl^- form (100—200 mesh, 7×20 cm). By elution with a 0.1 M NaCl aqueous solution, three bands colored red-violet descended and the three fractions were collected. The second desired fraction was concentrated under reduced pressure and, after filtration, kept in a refrigerator. The product obtained was recrystallized from a minimum amount of warm water (*ca.* 40 °C) and the yield was 3 g. The products from the first and third fractions were $Na[Co(mal)_2(en)]$ and $Na[Co(ox)_2(en)]$, respectively. Found: C, 23.84; H, 3.36; N, 8.07%. Calcd for $Na[Co(C_2O_4)(C_3H_2O_4)(C_2H_8N_2)]\cdot H_2O$: C, 24.04; H, 3.45; N, 8.00%.

The iodide complex, $(-)_{589}[Co(ox)(en)_2]$ I (4 g, 0.01 mol) was converted into the acetate with silver acetate (2.0 g, 0.012 mol) according to the literature.[5] To a solution of this resolving agent in H_2O (40 cm³, 40 °C) was added the above racemate (7.2 g, 0.02 mol) with constant stirring. A pink diastereoisomer containing the $(-)_{589}$-form of the malonatooxalato complex crystallized out on cooling the solution in an ice-bath (*ca.* 30 min). The crude product was recrystallized from a minimum amount of warm water (40 °C) producing fine scale-like crystals (yield 1.5 g). Found: C, 21.33; H, 4.91; N, 18.08%. Calcd for $[Co(C_2O_4)(C_2H_8N_2)_2]\cdot[Co(C_2O_4)(C_3H_2O_4)(C_2H_8N_2)]\cdot 2H_2O$: C, 21.44; H, 4.91; N, 18.19%.

When $(-)_{589}[Co(NO_2)_2(en)_2](C_2H_3O_2)$ was used as a resolving agent,[5] the same form of the complex formed the less soluble diastereoisomer.

b) Potassium Carbonatoethylenediamineoxalatocobaltate(III) Monohydrate, K[Co(CO₃)(ox)(en)]·H_2O: This complex was prepared by the literature method,[4] and resolved with $(-)_{589}[Co(ox)(en)_2](C_2H_3O_2)$. The less soluble diastereoisomer containing the $(-)_{589}$-form of the carbonatooxalato complex was recrystallized from water by the addition of ethanol. Found: C, 22.85; H, 4.98; N, 14.54%. Calcd for $[Co(C_2O_4)(C_2H_8N_2)_2]\cdot[Co(CO_3)(C_2O_4)(C_2H_8N_2)]\cdot 2.5H_2O$: C, 22.81; H, 5.05; N, 14.51%.

c) cis-*Diaquaethylenediamineoxalatocobalt(III) Nitrate*, cis-*[Co(ox)(en)(H₂O)₂]NO₃*: To a solution of $K[Co(CO_3)(ox)(en)]\cdot H_2O$ (13 g, 0.04 mol, in 30 cm³ H_2O) was carefully added 6 M HNO_3 until the evolution of CO_2 ceased. The resulting solution was kept in a refrigerator overnight. The crude product thus obtained was recrystallized from warm water yielding 8 g. Found: C, 15.98; H, 3.93; N, 13.69%. Calcd for *cis*-$[Co(C_2O_4)(C_2H_8N_2)(H_2O)_2]NO_3$: C, 15.75; H, 3.96; N, 13.77%.

To a solution of this racemate (9.2 g, 0.03 mol, in 50 cm³ H_2O, *ca.* 40 °C) was added $(+)_{546}Na[Co(ox)_2(en)]$[2] (5 g, 0.015 mol) as the resolving agent. The mixture was cooled in an ice-bath for 1 h, whereupon the less soluble diastereoisomer containing the $(+)_{589}$-form of the diaqua complex precipitated. Recrystallization from water yielded 2 g. Found: C, 20.89; H, 3.97; N, 9.93%. Calcd for $[Co(C_2O_4)(C_2H_8N_2)(H_2O)_2]\cdot[Co(C_2O_4)_2(C_2H_8N_2)]\cdot 2H_2O$: C, 20.92; H, 4.21; N, 9.76%.

The complex, $(+)_{546}Na[Co(edta)]$[2] was also useful for the resolution of this complex, where the $(+)_{589}$-isomer also formed the less soluble diastereoisomer.

d) Potassium Dicarbonatoethylenediaminecobaltate(III) Monohydrate, K[Co(CO₃)₂(en)]·H_2O: This complex was prepared by a modification of the procedure reported previously.[4] To a cold, green solution of tricarbonatocobaltate(III) ($Co(NO_3)_2\cdot 6H_2O$, 30 g, 0.1 mol scale) was added ethylenediamine (9 cm³,

0.13 mol), and the mixture was then stirred at *ca.* 5 °C for half an hour. Ethanol (*ca.* 100 cm³) was added to the solution, and the solution cooled in an ice-bath for half an hour. The solution, once filtered, was kept in a refrigerator and powdery purple crystals separated out. The material was recrystallized from warm water yielding 8 g.

This racemate was resolved with $(-)_{589}$[Co(ox)(en)$_2$]($C_2H_3O_2$). The less soluble diastereoisomer containing the $(+)_{589}$-form of the dicarbonato complex was recrystallized from a minimum amount of cold water (*ca.* 10 °C). The yield was 1 g. Found: C, 21.08; H, 5.59; N, 14.64%. Calcd for [Co(C_2O_4)($C_2H_8N_2$)$_2$]·[Co(CO_3)$_2$($C_2H_8N_2$)]·3H_2O: C, 21.06; H, 5.30; N, 14.74%.

e) Lithium cis-*Diamminedicarbonatocobaltate(III)*, cis-*Li*[Co(CO_3)$_2$(NH_3)$_2$]: The preparation of this complex and the isolation of its active lithium salt have been reported in an earlier communication.[6] The active complex, $(-)_{589}$Li[Co(CO_3)$_2$(NH_3)$_2$] was precipitated from a mixed solution of the racemic lithium salt and $(-)_{589}$[Co(ox)(en)$_2$]($C_2H_3O_2$), while the $(+)_{589}$ complex was precipitated in the presence of $(+)_{589}$-[Co(ox)(en)$_2$]($C_2H_3O_2$).

f) Potassium cis-*Diamminecarbonatooxalatocobaltate(III) Monohydrate*, cis-*K*[Co(CO_3)(ox)(NH_3)$_2$]·H_2O: This complex was prepared according to the literature.[4] A solution of the racemate (6 g, 0.02 mol, in 50 cm³ H_2O) was poured into a column of Dowex 50W-X 8 resin in Li^+ form (100—200 mesh, 5×10 cm) in order to convert the potassium salt into the lithium one. The effluent was added to a solution of $(-)_{589}$-[Co(ox)(en)$_2$]($C_2H_3O_2$) (4 g, 0.01 mol, in 20 cm³ H_2O) and the mixed solution evaporated to reduce the volume (*ca.* 15 cm³). The concentrated solution was kept in a refrigerator until the less soluble diastereoisomer containing the $(-)_{589}$-form of the carbonatooxalato complex precipitated. Recrystallization was carried out from water. Found: C, 20.03; H, 4.40; N, 15.50%. Calcd for [Co(C_2O_4)($C_2H_8N_2$)$_2$]·[Co(CO_3)-(C_2O_4)(NH_3)$_2$]·1.5H_2O: C, 20.19; H, 4.71; N, 15.71%.

g) Potassium cis-*Diamminebis(oxalato)cobaltate(III) Monohydrate*, cis-*K*[Co(ox)$_2$(NH_3)$_2$]·H_2O: This was prepared by the method in the literature.[4] The racemate was resolved with $(-)_{589}$[Co(ox)(en)$_2$]($C_2H_3O_2$). The less soluble diastereoisomer containing the $(+)_{589}$-form of the bis(oxalato) complex was recrystallized from a minimum amount of warm water. Found: C, 19.45; H, 5.21; N, 13.57%. Calcd for [Co(C_2O_4)-($C_2H_8N_2$)$_2$]·[Co(C_2O_4)$_2$(NH_3)$_2$]·4.5H_2O: C, 19.45; H, 5.06; N, 13.62%.

h) Sodium cis-*Diamminemalonatooxalatocobaltate(III) 2.5-Hydrate*, cis-*Na*[Co(ox)(mal)(NH_3)$_2$]·2.5H_2O: This was prepared and resolved in the same manner as that for the corresponding ethylenediamine complex. Found: C, 17.11; H, 3.73; N, 7.98%. Calcd for Na[Co(C_2O_4)($C_3H_2O_4$)(NH_3)$_2$]·2.5H_2O: C, 17.25; H, 3.75; N, 8.13%. Found: C, 22.18; H, 4.95; N, 14.32%. Calcd for [Co(C_2O_4)($C_2H_8N_2$)$_2$]·[Co(C_2O_4)(C_3H_2-O_4)(NH_3)$_2$]·2.5H_2O: C, 22.02; H, 4.91; N, 14.12%.

i) Potassium cis-*Diamminebis(malonato)cobaltate(III) 2.5-Hydrate*, cis-*K*[Co(mal)$_2$(NH_3)$_2$]·2.5H_2O: To a solution of *cis*-K[Co(CO_3)$_2$(NH_3)$_2$]·H_2O (28 g, 0.1 mol, in 150 cm³ H_2O) was added dropwise a solution of malonic acid (25 g, 0.25 mol, in 100 cm³ H_2O) with mechanical stirring in ice. The solution was then stirred at *ca.* 40 °C until the evolution of CO_2 ceased. The solution was neutralized with an aqueous KOH solution and further stirred at *ca.* 50 °C for half an hour. The resulting solution was evaporated to *ca.* 100 cm³ and the concentrated solution kept in a refrigerator overnight. The crude product thus obtained was recrystallized from warm water yielding 10 g. Found: C, 18.90; H, 3.83; N, 7.38%. Calcd for K[Co($C_3H_2O_4$)$_2$(NH_3)$_2$]·2.5H_2O: C, 18.96; H, 3.97; N, 7.37%.

The complex was resolved with $(-)_{589}$[Co(ox)(en)$_2$](C_2H_3-O_2). The less soluble diastereoisomer containing the $(+)_{589}$-form of the bis(malonato) complex was recrystallized from warm water. Found: C, 23.55; H, 4.91; N, 13.77%. Calcd for [Co(C_2O_4)($C_2H_8N_2$)$_2$]·[Co($C_3H_2O_4$)$_2$(NH_3)$_2$]·2.5H_2O: C, 23.69; H, 5.14; N, 13.81%.

j) Bis(ethylenediamine)oxalatocobalt(III) cis-*Diamminecarbonatomalonatocobaltate(III) Dihydrate*, [Co(ox)(en)$_2$]·cis-[Co(CO_3)-(mal)(NH_3)$_2$]·2H_2O: An appropriate amount of 30% $HClO_4$ was added dropwise to a solution of K[Co(CO_3)$_2$(NH_3)$_2$]·H_2O (28 g, 0.1 mol, in 100 cm³ H_2O) in order to adjust the pH to 5.0 in ice. After filtration, potassium malonate (20 g, 0.1 mol) was added to the filtrate and the mixture stirred at 40 °C for 1 h. Perchloric acid (30%) was again added to adjust the pH to 1.0. The solution was then filtered and the filtrate chromatographed on a column of Dowex 50W-X 8 resin in H^+ form (100—200 mesh, 7×15 cm) using 0.2 M NaCl as the eluting solution. Two red-violet bands came out from the column and were collected in fractions. The first fraction was concentrated to *ca.* 50 cm³ with simultaneous removal of NaCl precipitated by filtration. To the filtrate was added $NaHCO_3$ in order to adjust the pH to 9.0. To this solution was added an aqueous solution of [Co(ox)(en)$_2$]($C_2H_3O_2$) and the mixture kept in a refrigerator until reddish brown crystals precipitated. The crude product was recrystallized from water yielding 2 g. Found: C, 21.51; H, 5.05; N, 15.05%. Calcd for [Co(C_2O_4)-($C_2H_8N_2$)$_2$]·[Co(CO_3)($C_3H_2O_4$)(NH_3)$_2$]·2H_2O: C, 21.36; H, 4.87; N, 15.10%.

This complex (3 g, 0.005 mol) was ground in a mortar with water (10 cm³) and sodium iodide (0.83 g, 0.005 mol) added. The mixture was then filtered to remove the sparingly soluble [Co(ox)(en)$_2$]I. To this filtrate was added a solution of $(-)_{589}$[Co(ox)(en)$_2$]($C_2H_3O_2$) (1.0 g, 0.0025 mol, in 15 cm³ H_2O), and the mixture kept in a refrigerator. The less soluble diastereoisomer containing the $(+)_{589}$-form of the carbonatomalonato complex recrystallized yielding 0.1 g. Found: C, 20.99; H, 4.90; N, 14.90%. Calcd for [Co(C_2O_4)($C_2H_8N_2$)$_2$]·[Co(CO_3)($C_3H_2O_4$)(NH_3)$_2$]·2.5H_2O: C, 21.17; H, 5.15; N, 14.81%.

k) Potassium cis-*Dicarbonatobis(pyridine)cobaltate(III) Trihydrate*, cis-*K*[Co(CO_3)$_2$(*py*)$_2$]·3H_2O: This complex was prepared according to the method in the literature.[7] The optical resolution was performed with $(-)_{589}$[Co(ox)(en)$_2$]($C_2H_3O_2$). The less soluble diastereoisomer containing the $(+)_{589}$-form of the dicarbonato complex was recrystallized from cold water. Found: C, 32.82; H, 4.99; N, 12.60%. Calcd for [Co(C_2O_4)-($C_2H_8N_2$)$_2$]·[Co(CO_3)$_2$(C_5H_5N)$_2$]·3H_2O: C, 32.83; H, 4.89; N, 12.77%.

l) Lithium cis-*Bis(oxalato)bis(pyridine)cobaltate(III) Monohydrate*, cis-*Li*[Co(ox)$_2$(*py*)$_2$]·H_2O: This salt was prepared by the method in the literature.[8] The resolution was carried out in the same manner as that for the corresponding dicarbonato complex. The less soluble diastereoisomer contains the $(+)_{589}$-form of the bis(oxalato) complex. Found: C, 31.67; H, 4.85; N, 11.02%. Calcd for [Co(C_2O_4)($C_2H_8N_2$)$_2$]·[Co-(C_2O_4)$_2$(C_5H_5N)$_2$]·5.5H_2O: C, 31.63; H, 4.91; N, 11.07%.

Measurements. The absorption spectra in aqueous solution were recorded with a Hitachi 323 recording spectrophotometer. In the case of the *cis*-[Co(CO_3)(mal)(NH_3)$_2$]$^-$ complex, the spectrum was measured with a solution treated with a cation exchange resin in Na^+ form in order to remove the counter [Co(ox)(en)$_2$]$^+$ ion. The spectrum of the diaqua complex, after the corresponding carbonato complex was acid-hydrolyzed with 10% perchloric acid, was measured.

For the circular dichroism (CD) spectra and optical rotation measurements, a JASCO J-40CS automatic recording spectropolarimeter with a JASCO Model J-DPZ data processor for

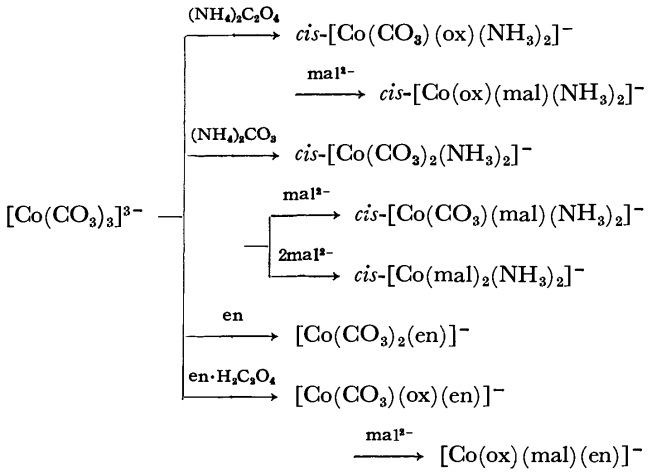
CD, and a JASCO Model DIP-SL automatic polarimeter were used, respectively, with samples converted into the same cations as those of the corresponding racemates by means of ion-exchange techniques.

Solubility measurements of the *cis*-Li[$Co(CO_3)_2(NH_3)_2$] complex were conducted as follows; a 0.2 M aqueous solution of $(-)_{589}[Co(ox)(en)_2](C_2H_3O_2)$ (20 cm^3) containing an excess of the complex to be measured was mechanically stirred at 25 °C for a minute and, after filtering, an appropriate volume of the filtrate was withdrawn with a pipet. The solution was passed through a column containing cation exchange resin (Na^+ form) and the effluent diluted to the appropriate volume. The concentration of the complex was measured at the maximum wavelength of the first absorption band (587 nm).

Gaussian Analysis. Some of the CD spectra measured were fitted to the two best gaussian on a wavelength scale using a computer. The expression of the gaussian formula employed was $E \cdot e^{-\delta(\Delta\lambda)^2}$, where E stands for the intensity of a calculated gaussian, δ a measure of the curve band-width, and $\Delta\lambda$ the difference in wavelength between the peak position of the gaussian and an arbitrary position.

Results and Discussion

Preparation and Resolution. In a previous paper,[9] it was reported that the *cis*(a),*cis*(N)-[$Coa_2(O,O)(N)_2$]$^-$-type complexes (a=CN^- or NO_2^-, $(N)_2$=en or $2NH_3$) could be prepared based on the *cis* substitution of the ligating carbonate ion in a starting complex by the desired ligand. The synthesis of the present *cis*-[$Co(O,O)_2(N_2)$]$^-$-type complexes ($(N)_2$=en or $2NH_3$) is analogous and Scheme 1 represents the pathway.



Scheme 1. Preparation of bis(dicarboxylato) complexes.

For the optical resolution of the complexes synthesized in this work, two kinds of resolving agents, $(-)_{589}$-$[Co(ox)(en)_2]^+$ and $(-)_{589}[Co(NO_2)_2(en)_2]^+$ were successfully used. The $[Co(CO_3)_2(NH_3)_2]^-$ complex, however, was an exceptional case; its active lithium salt, $(-)_{589}$Li[$Co(CO_3)_2(NH_3)_2$] being precipitated from a mixed aqueous solution of the racemic lithium salt and $(-)_{589}[Co(ox)(en)_2](C_2H_3O_2)$. In the presence of $(+)_{589}[Co(ox)(en)_2](C_2H_3O_2)$, the $(+)_{589}$ lithium salt was precipitated. The fact[6] that the yield of the active lithium salt was about 70% suggests that an asymmetric synthesis is achieved in the system. The complex obtained was optically labile such that its optical rotation decreased, in aqueous solution, with a half-life *ca.* 3 min at room temperature. The solubilities of the

racemic, $(+)_{589}$ and $(-)_{589}$ lithium salts in 0.2 M $(-)_{589}[Co(ox)(en)_2](C_2H_3O_2)$ aqueous solution were found to be approximately 0.35, 0.26, and 0.24 mol/l, respectively. From these facts, the poorer solubilities of the active salts than that of the racemate, the different solubilities between the enantiomeric salts, and the rapid racemization of the more soluble enantiomer are assumed as the conditions for the present asymmetric synthesis. For the documented asymmetric synthesis of metal complexes, the essential conditions are optical lability and the formation of the less soluble diastereoisomer in the presence of a resolving agent.[10]

CD Spectra. The absorption spectra of the new complexes are shown in Fig. 1 and the CD spectra for the $[Co(O,O)_2(en)]^-$-type, $[Co(O,O)_2(NH_3)_2]^-$-type, and $[Co(O,O)_2(py)_2]^-$-type complexes are shown in Figs. 2—4, the spectral data being summarized in Tables 1 and 2. The observed CD spectra may be grouped into four types from the patterns in the first absorption band ($\bar{\nu}_I$) region; 1) only one peak, 2) two peaks of opposite sign, 3) two peaks of the same sign, and 4) three peaks of alternating sign.

The $(+)_{589}[Co(CO_3)_2(en)]^-$, $(-)_{589}[Co(CO_3)_2(NH_3)_2]^-$ and $(+)_{589}[Co(CO_3)_2(py)_2]^-$ complexes exhibit the patterns of type 1. These peaks are almost symmetrical and the maximum position of each peak shifts to the higher-frequency-side compared with the corresponding absorption maximum ($\bar{\nu}_{I\,max}$). The $(-)_{589}[Co(CO_3)(ox)(en)]^-$ and $(-)_{589}[Co(CO_3)(ox)(NH_3)_2]^-$ complexes also have only one peak, which is unsymmetrical.

The $(+)_{589}[Co(CO_3)(mal)(NH_3)_2]^-$ complex exhibits the pattern of type 2. The acid hydrolysis of this carbonato complex to give the $(-)_{589}[Co(mal)(NH_3)_2(H_2O)_2]^+$ species brings about a reversal of the signs. Similar changes in CD sign has been reported with such diaqua complex species as $(+)_{589}[Co(ox)(NH_3)_2$-

$(H_2O)_2]^+$, $(+)_{589}[Co(CN)_2(NH_3)_2(H_2O)_2]^+$, and $(+)_{589}$-$[Co(NO_2)_2(NH_3)_2(H_2O)_2]^+$.[9,11]

The $(-)_{546}[Co(ox)_2(en)]^-$ [2] and $(+)_{589}[Co(ox)_2$-$(NH_3)_2]^-$ complexes have the patterns of type 3, whereas the $(+)_{589}[Co(ox)_2(py)_2]^-$ complex has that of type 1, but its peak position is compatible with the observed $\bar{\nu}_{I\,max}$.

The $(-)_{589}[Co(ox)(mal)(en)]^-$ and $(+)_{589}[Co(ox)$-$(mal)(NH_3)_2]^-$ complexes have the patterns of type 4, where the dominant peak in each pattern is at the lowest-frequency-side (that is, the first peak). The patterns of $(-)_{546}[Co(mal)_2(en)]^-$,[2] $(+)_{589}[Co(mal)_2$-$(NH_3)_2]^-$ also belong to type 4, but in these cases the middle peaks have greater intensities than the first peak intensities, or comparable ones to those.

The CD spectra in the second absorption band ($\bar{\nu}_{II}$) region also reveal patterns of the four types; the spectra of $(+)_{589}[Co(CO_3)_2(py)_2]^-$ and $(+)_{589}[Co(ox)_2(py)_2]^-$ show one peak, the spectrum of $(-)_{589}[Co(CO_3)_2$-$(NH_3)_2]^-$ show two peaks of opposite sign, those of $(+)_{589}[Co(ox)(mal)(NH_3)_2]^-$ show two peaks of the same sign, and those of $(+)_{589}[Co(ox)_2(NH_3)_2]^-$, $(+)_{589}[Co(CO_3)_2(en)]^-$ and $(-)_{589}[Co(ox)(mal)(en)]^-$ show three peaks of alternating sign. Further discussion can not be given about the CD spectra in the $\bar{\nu}_{II}$ region, but it may be noted that the sign of the lowest frequency peak in this region is consistent with that of the lowest one in the $\bar{\nu}_I$ region for complexes of the type $[Co(O,O)_2$-$(N)_2]^-$ except for the bis(pyridine) and diaquaoxalato complexes.

Absolute Configurations. Since the absolute configuration of the $(+)_{546}[Co(ox)_2(en)]^-$ complex has been known to be *Δ*,[2] the absolute configuration of the $(+)_{589}[Co(ox)_2(NH_3)_2]^-$ complex is determined to be *Δ*, since both complexes have CD patterns of type 3. As for the complexes whose CD patterns belong to type 1, the absolute configurations are assumed to be that the (−) sign refers to *Δ* and the (+) sign to *Λ* compared with the *Δ*$(+)_{546}[Co(ox)_2(en)]^-$ complex exhibiting the (−, −) signs. The $(+)_{589}[Co(ox)(mal)$-$(NH_3)_2]^-$, $(+)_{589}[Co(mal)_2(NH_3)_2]^-$, and $(-)_{589}[Co$-$(ox)(mal)(en)]^-$ complexes are assigned with *Δ*, *Δ*, and *Λ* configurations, respectively, from a comparison of the CD patterns with that of the $(-)_{546}[Co(mal)_2(en)]^-$ complex whose absolute configuration has been shown to be *Λ*.[12] Douglas *et al.*[2] used the $(-)_{546}[Co(edta)]^-$ complex for the assignment of the $(+)_{546}[Co(ox)_2(en)]^-$ and $(-)_{546}[Co(mal)_2(en)]^-$ complexes as the reference. In the same manner, the $(+)_{589}[Co(CO_3)(mal)(NH_3)_2]^-$ complex has tentatively been assigned to be the *Δ* configuration. The $(-)_{589}[Co(mal)(NH_3)_2(H_2O)_2]^+$ species derived from the above $(+)_{589}[Co(CO_3)(mal)$-$(NH_3)_2]^-$ complex may have an *S*[13] configuration, which is equivalent to the *Δ* configuration of the parent complex, since the acid hydrolysis should proceed with retention of configuration. The CD pattern of the $(+)_{589}[Co(ox)(en)(H_2O)_2]^+$ species derived from the $(-)_{589}[Co(CO_3)(ox)(en)]^-$ complex is the same as that of the $(+)_{589}[Co(ox)(en)(H_2O)_2]^+$ complex resolved using the $(+)_{546}[Co(ox)_2(en)]^-$ complex. Hence the *Λ* configuration is assigned to this diaqua complex. All the absolute configurations thus assigned are summarized in Tables 1 and 2.

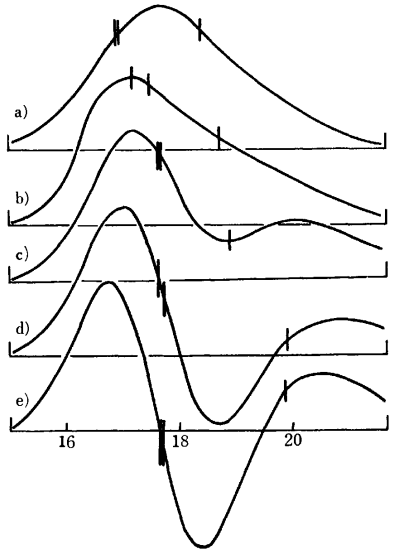

Fig. 5. CD spectral change in the $[Co(O,O)_2(en)]^-$-type complexes of *Λ* configuration.
a) $(-)_{589}[Co(CO_3)_2(en)]^-$, b) $(-)_{589}[Co(CO_3)(ox)$-$(en)]^-$, c) $(-)_{546}[Co(ox)_2(en)]^-$, d) $(-)_{589}[Co(ox)$-$(mal)(en)]^-$, e) $(-)_{546}[Co(mal)_2(en)]^-$. c) and e) Ref. 2.

In order to illustrate the changes of the CD patterns, in the $\bar{\nu}_I$ region, with the varied O,O ligands, the patterns of the complexes having *Λ* configuration have been collected and are shown in Fig. 5. The peak intensity, however, is arbitarily taken in each pattern, because the discussion is limited only to the shape of the pattern. The short vertical lines on each CD curve indicate the band positions calculated by means of Yamatera's predictions:[14] δ_I(en-CO_3)=5800, δ_I(en-ox)=4730, and δ_I(en-mal)=4830 cm^{-1}.

It is clear that there are regular changes of the shapes of the patterns over the range of complexes. The CD peak for the *Λ*-$[Co(CO_3)_2(en)]^-$ complex is situated in a middle position of the predicted band positions, the peak for the *Λ*-$[Co(CO_3)(ox)(en)]^-$ complex being apart considerably from a mean position of the predicted band positions. The two CD peaks for the *Λ*-$[Co(ox)_2$-$(en)]^-$ complex lie on both sides of the predicted two positions. With respect to the *Λ*-$[Co(ox)(mal)(en)]^-$ and *Λ*-$[Co(mal)_2(en)]^-$ complexes, their three CD peaks correspond incorrectly to the calculated components.

A similar change in CD pattern can be observed in the case of the *Λ*-$[Co(O,O)_2(NH_3)_2]^-$-type complexes, and also of the corresponding bis(pyridine) complexes although the bis(oxalato) complex exhibits only one peak.

In order to understand these regular changes of the CD patterns, an attempt has been made to analyze the patterns into Gaussian curves. Douglas *et al.*[2] resolved the CD curve of the $[Co(O,O)_2(en)]^-$ complex (O,O= ox or mal) into three components with respect to both the $\bar{\nu}_I$ and $\bar{\nu}_{II}$ regions, and claimed an effective rhombic field for each of the complexes. In this computation, the CD curve in $\bar{\nu}_I$ region was resolved into two com-

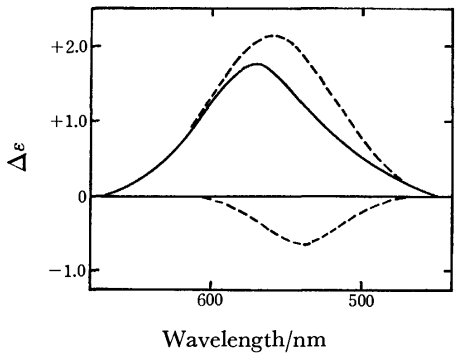

Fig. 6. Gaussian resolution of the CD spectrum of $(+)_{589}[Co(CO_3)(ox)(NH_3)_2]^-$.

——: Observed CD spectrum, ------: calculated gaussian curves.

ponents with opposite signs. The results obtained are shown in Figs. 6—8 with respect to the *Λ*-$[Co(O,O)_2(NH_3)_2]^-$-type complexes.

It is seen, from the Gaussian analysis, that every pattern is a resultant curve from the mutual cancellation of a (+) component at a lower frequency and a (−) component at a higher frequency. The separation between the two components is very small, unfortunately the correspondences of the peak positions of the Gaussians with the predicted band positions being too poor. However, the observed regular change in the CD spectra can be qualitatively understood from these results. It is evident that the CD sign at the shorter-wavelength is altered by the mutual cancelation, but the sign at the longest-wavelength remains unchanged. On the basis of this the absolute configurations of the $[Co(O,O)_2(N)_2]^-$-type complexes can be assigned from

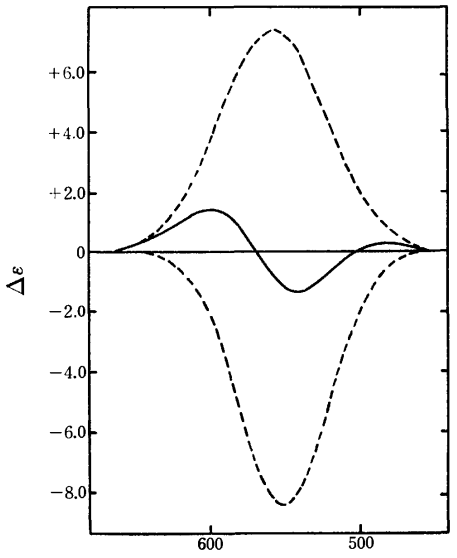

Fig. 8. Gaussian resolution of the CD spectrum of $(-)_{589}[Co(ox)(mal)(NH_3)_2]^-$.
——: Observed CD spectrum, ------ calculated gaussian curve.

the sign of the lowest-frequency peak; the (+) sign refers to *Λ* and the (−) sign to *Δ*. The results of the assignments from this criterion agree with those in Tables 1 and 2. However, this criterion is inapplicable to the $[Co(O,O)(N)_2(H_2O)_2]^+$-type complexes, where the (−) sign of the lowest-frequency peak relates to the *Λ* configuration of the corresponding $[Co(O,O)(CO_3)(N)_2]^-$ complex.

Syntheses and Properties of Some Trimethylantimony(V) Complexes of Dithiocarbonate Derivatives

Akira OUCHI,* Mamoru SHIMOI, Fujio EBINA, Takashi UEHIRO, and Yukichi YOSHINO

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro, Tokyo 153

(Received April 7, 1978)

New stable trimethylantimony(V) complexes of some dithiocarbonate derivatives, $(CH_3)_3SbL_2$, where HL= secondary amine-*N*-carbodithioic acid or *O*-alkyl dithiocarbonic acid, have been synthesized by the metathetical reaction between dibromotrimethylantimony(V) and the alkali salts of ligands. In these compounds, the antimony is kept quinquevalent. The ^{1}H-NMR peak of the methyl protons of all of these compounds appears as a singlet even at −60 °C. Therefore, the most probable structure for these compounds is the trigonal bipyramidal one, where two unidentate dithiocarbonate derivative ligands bond to antimony from the apical directions.

The R_3SbL_2 type quinquevalent organoantimony compounds, where R=alkyl or aryl, and HL= carboxylic acid, are well-known compounds, and are obtained by the metathetical reaction from dibromo- or dichlorotrialkyl(or triaryl)antimony(V).[1,2] However, the same type compounds where the antimony bonds to the ligands through sulfur atoms are not easily synthesized. Although the organoantimony(V) compounds, such as thioglycolates,[3] monothiocarboxylates,[4] alkanethiolates,[5] and thiophenolates,[5] where the ligands bond to antimony through sulfur, have already been synthesized, their complexes of dithiocarbonate derivatives, such as dialkyldithiocarbamates, and *O*-alkyl dithiocarbonates, have not been reported yet. Meinema and Noltes[6] reported about the dialkyldithiocarbamato derivatives of the types $RSbL_2$ and R_2SbL (where R= phenyl or alkyl, and HL=dialkyldithiocarbamic acid), but they are all tervalent antimony compounds.

The authors have investigated the metathetical reaction of R_3SbBr_2 (R=methyl or phenyl) with some alkali salts of secondary amine-*N*-carbodithioic acids as well as with *O*-alkyl dithiocarbonic acids, and obtained some stable trimethylantimony(V) compounds of dithiocarbonate derivatives, although the corresponding complexes of triphenylantimony(V) could not be isolated. They are not air sensitive, and do not decompose after several weeks in a refrigerator (5 °C).

During an attempt to synthesize trialkyl(or triaryl)-antimony(V) complexes of dithiocarboxy derivatives, the antimony(III) compounds of the type R_2SbL, where R=phenyl or methyl, were obtained when a little excess of the ligand was used. This fact shows that trialkyl(or triaryl)antimony(V) is readily reduced by such sulfur-containing ligands. Therefore when dibromo- or dichlorotriarylantimony(V) was treated with a large excess of dialkyldithiocarbamates, some of the aryl groups bonded to antimony were removed.

Experimental

Dibromotrimethylantimony(V) was obtained by the standard technique found in the references.[7–9] Sodium salts of piperidine- and pyrrolidine-*N*-carbodithioic acids were synthesized from each amine, carbon disulfide, and sodium hydroxide by the literature method.[10] Sodium *O*-benzyl dithiocarbonate was synthesized from benzyl alcohol, carbon disulfide, and sodium hydroxide applying the synthetic technique for other *O*-alkyl dithiocarbonates.[11,12] Potassium salts of *O*-propyl, isopropyl, and isobutyl dithiocarbonic acids were the GR of Tokyo Kasei Kogyo Co., Ltd., and other reagents were all GR of Wako Pure Chemicals Ltd. They were used without further purification.

Infrared and ^{1}H-NMR spectra were obtained using a JASCO 403G infrared spectrophotometer and a JEOL JNM-MH-100 (100 MHz) NMR spectrometer.

*Synthesis of Bis(pyrrolidine-*N*-carbodithioato)trimethylantimony(V).* To 0.96 g (3 mmol) of dibromotrimethylantimony(V) and 1.02 g (6 mmol) of soduim pyrrolidine-*N*-carbodithioate was added 20 ml of benzene–acetonitrile mixture (5/1= v/v). The mixture was stirred for about 1 h at room temperature (about 20 °C). Special air shielding was not necessary. The precipitated sodium bromide was filtered off, and the filtrate was evaporated using a water jet pump, at a temperature lower than 60 °C. After the residue thus obtained was dissolved in 7 ml of chloroform, 20 ml of petroleum ether was added, and the mixture was ice cooled. The product precipitated slowly. The yield was, on the average, 0.6 g (50%). The piperidine-*N*-carbodithioato complex was obtained by almost the same technique.

Synthesis of Bis(O-benzyl dithiocarbonato)trimethylantimony(V). To 20 ml of an isopropyl alcohol–water (1/1=v/v) mixture were added 0.96 g (3 mmol) of dibromotrimethylantimony(V) and 1.24 g (6 mmol) of sodium *O*-benzyl dithiocarbonate. The mixture was stirred for 2 h. The solvent was removed and sodium bromide was washed away with cold water. The residue was recrystallized from diethyl ether. The yield after the recrystallization was 0.9 g (58%). Other *O*-alkyl dithiocarbonates of trimethylantimony(V) were obtained by almost the same technique. However, the *O*-methyl and *O*-ethyl dithiocarbonates obtained by this process were hardly purified even by the repeated recrystallizations. As the products thus obtained decompose easily at high temperature, they must not be heated beyond 60 °C.

It should be noted that the synthetic technique used for the secondary amine-*N*-carbodithioates could not be applied for *O*-alkyl dithiocarbonates, and *vice versa*.

Results and Discussion

The elementary analyses, the calculated values from the expected chemical formulae, and melting points of these trimethylantimony(V) complexes of dithiocarbonate derivatives are shown in Table 1. All of them have the general formula $(CH_3)_3SbL_2$. These products were colorless or slightly yellow crystalline powders. All of them were soluble in organic solvents such as acetone, chloroform, and benzene, but insoluble in water.

The wave numbers of some infrared spectral bands of

dithiocarboxy derivatives (organoantimony complexes and alkali salts) are shown in Table 2. In the infrared spectra of secondary amine-*N*-carbodithioates, a strong band assigned as ν(C=N) appears at about 1460 cm^{-1}, which is an intermediate wave number between 1600 cm^{-1} (for ν(C=N)) and 1100 cm^{-1} (for ν(C–N)). The wave numbers of the bands of the trimethylantimony(V) derivatives are about 20—50 cm^{-1} lower than those of the 3d transition metal dialkyldithiocarbamates,[13,14] and are almost the same as those of the alkali salts. This fact shows that the double bond character of C=N bond does not increase much when the ligand bonds to antimony.

The ν(C–N) band of both these types of compounds easily mixes with other vibrational modes. Consequently, the assignments of the bands are difficult and the opinions of many authors are controversial.[15-18] A pure ν(C=S) band should appear at about 1200 cm^{-1},[19] but, in the infrared spectra of these products, three strong bands are found in 1250—980 cm^{-1} region. The ν(C=S) bands of these complexes are easily mixed with those from other modes. The band seems to be mixed with the ν(COC) mode one in the *O*-alkyl dithiocarbonates, and with some amine ring deformational modes in the piperidine- and pyrrolidine-*N*-carbodithioates. As a result, very little information about the bond type or its strength could be obtained from the data, although the general features of these spectra clearly show that these compounds are the complexes of dithiocarbonate derivatives.

The ν(Sb–S) band is expected to appear in the 350—410 cm^{-1} region, judging from the data about trialkyl(or triaryl)antimony(V) thiocarboxylates[4] as well as about tris(alkanethiolato)antimony(III).[20] In the cases of these complexes, however, the intensity of this band is not high. The wavenumbers of the tentatively assigned peaks are about 405 cm^{-1} for secondary amine-*N*-carbodithioates and about 360 cm^{-1} for *O*-alkyl dithiocarbonates, as shown in Table 2.

A characteristic band of dibromotrimethylantimony(V) at about 867 cm^{-1}, which is assigned as the skeletal vibration $\nu(C_3Sb)$, shifts to about 850 cm^{-1} in the complexes of dithiocarbonate derivatives.

The ^{1}H-NMR spectra of trimethylantimony(V) secondary amine-*N*-carbodithioates and *O*-alkyl dithiocarbonates, as well as their alkali salts, are shown in Table 3.

The methyl proton peak of all of these complexes was a sharp singlet at room temperature, and even at —60 °C; no broadening of the peak was found during the temperature lowering. Therefore, neither the coexisting of isomers nor the existence of nonequivalent methyl groups in a organoantimony complex are probable, provided that the exchange rates of the bonding groups are low enough.

Consequently, for these complexes, the most probable structure is the penta-coordinated trigonal bipyramidal one, where three methyl groups bond from equatorial directions, and two unidentate dithiocarboxy derivative ligands from apical directions. In penta-coordinate complexes, however, Berry's pseudo-rotation may occur,[21] and in such a case the exchange of ligands in a different positions is too rapid to be distinguished by NMR, even at low temperature.[22,23] Therefore, the

possibility of other penta-coordinate structures cannot be denied.

If the dithiocarboxy derivative ligands, one or both, work as the bidentates, the central antimony must be hexa- or hepta-coordinated. In such a case, the complex is expected to be rigid enough, and the exchange rate of the bonding bidentates should be low. Consequently, three methyl groups in the complex must be in unequal positions, and some splitting of the peak is expected. Some hexa-coordinated organoantimony(V) derivatives show fast pseudo-rotation even at low temperature, but even in such a case, some broadening of the peak is expected at −60 °C.[24]

When pyrrolidine was added to a $CDCl_3$ solution of dibromotrimethylantimony(V) containing carbon disulfide, a new peak appeared at about 2.49 ppm, besides the original 2.69 ppm one, due to the formation of the pyrrolidine-*N*-carbodithioate. This peak did not disappear even when the solution was dried up and redissolved into the same solvent. On the other hand, when pyrrolidine was added to a $CDCl_3$ solution of dibromotriphenylantimony(V) containing carbon disulfide at 25 °C, one new peak at 7.30 ppm, which is likely the peak of the triphenylantimony(III) proton, appeared. When more than three times the amounts of the amine (in moles) was added to the dibromotriphenylantimony(V), the original phenyl proton peaks at 8.23 and 7.58 ppm dissapeared. This change is probably due to the reduction of organoantimony(V) to (III), owing to the instability of secondary amine-*N*-carbodithioates of triphenylantimony(V).

Studies on Mixed Valence Complexes of Platinum and Palladium. II.[1] The Crystal Structures of $[Pt(tn)_2][PtCl_2(tn)_2](BF_4)_4$, $[Pt(tn)_2][PtBr_2(tn)_2](ClO_4)_4$, and $[Pt(tn)_2][PtBr_2(tn)_2](BF_4)_4$

Naohide MATSUMOTO, Masahiro YAMASHITA, and Sigeo KIDA*

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Fukuoka 812

(Received February 6, 1978)

The crystal structures of Pt(II)-Pt(IV) complexes, $[Pt(tn)_2][PtCl_2(tn)_2](BF_4)_4$ (**1**), $[Pt(tn)_2][PtBr_2(tn)_2](ClO_4)_4$ (**2**), and $[Pt(tn)_2][PtBr_2(tn)_2](BF_4)_4$ (**3**) have been determined by the single-crystal X-ray diffraction method, where tn denotes trimethylenediamine. The crystals of these complexes are isomorphous with one another and the space group is A222 with $a=10.790(2)$, $b=13.872(2)$, $c=10.287(1)$ Å for **1**, $a=11.003(6)$, $b=13.979(6)$, $c=10.355(4)$ Å for **2**, and $a=10.925(3)$, $b=13.862(3)$, $c=10.291(1)$ Å for **3**. The structures were determined by the heavy atom method and refined by the block-diagonal least-squares method to give the disagreement factor 0.082, 0.089, and 0.086 for **1**, **2**, and **3**, respectively. Each crystal comprises infinite $Pt^{II}\cdots X-Pt^{IV}-X\cdots$ chains running parallel to the a-axis. In the chain, tetragonal bipyramidal $[Pt^{IV}X_2(tn)_2]^{2+}$ (X=Cl or Br) and square planar $[Pt^{II}(tn)_2]^{2+}$ units are stacked alternately. Two of the fluorine or oxygen atoms of the counter anion are hydrogen-bonded to the nitrogen atoms of the ligand, contributing to the formation of an infinite chain.

In the preceding paper,[1] we reported the preparation of a number of mixed-valence complexes, $[Pt(AA)_2][PtX_2(AA)_2]Y_4$, $[Pd(AA)_2][PtX_2(AA)_2]Y_4$, and $[Pd(AA)_2][PdX_2(AA)_2]Y_4$, (AA = ethylenediamine(en), propylenediamine(pn), trimethylenediamine(tn); X= Cl, Br, I; Y=ClO_4, BF_4). In the visible region, the complexes show a characteristic broad band assigned to the charge-transfer transition from Pt(II) to Pt(IV). They are of interest in connection with the oxidation states of the platinum atoms and the charge-transfer mechanism between platinum atoms.

In this work, the crystal structures for three complexes, $[Pt(tn)_2][PtCl_2(tn)_2](BF_4)_4$, $[Pt(tn)_2][PtBr_2(tn)_2](ClO_4)_4$, and $[Pt(tn)_2][PtBr_2(tn)_2](BF_4)_4$ have been determined by the single-crystal X-ray diffraction method in order to verify the mixed valence state and to discuss the oxidation state of each platinum atom in more detail.

Experimental

Single-crystals for X-ray work were obtained by recrystallization from a dilute perchloric acid or tetrafluoroboric acid solution at room temperature. Red needle crystals of $[Pt(tn)_2][PtCl_2(tn)_2](BF_4)_4$ show remarkable dichroism; they are dark-red for polarized light along the needle axis and almost colorless for polarized light perpendicular to the axis. $[Pt(tn)_2][PtBr_2(tn)_2](ClO_4)_4$ and $[Pt(tn)_2][PtBr(tn)_2](BF_4)_4$ are lustrous dark-green needle crystals, and also show strong dichroism; they are dark-green parallel to, and light-green perpendicular to the needle axis.

Rotation and Weissenberg photographs about the needle axis (a-axis) were taken for each compound. In contrast to the even layer lines, the odd layer lines are weak in intensity. Similar phenomena were found in Wolffram's red salt,[2] $PtBr_3en$,[3] and related compounds,[4-7] consisting of infinite chains, $\cdots Pt^{II}\cdots X-Pt^{IV}-X\cdots$.

Approximate unit-cell parameters were obtained from the Weissenberg photographs, and refined later by a least-squares procedure using 2θ values of 15 high-angle reflections ($25° < 2\theta < 45°$) measured on a Syntex P$\bar{1}$ diffractometer. Bond's method[8] was applied to ground the crystals. However, no spherical crystals favorable for X-ray work could be obtained owing to the brittleness of the crystals. Hence, a nearly cubic crystal with dimensions *ca.* $0.3\times0.3\times0.3$ mm was used for the intensity measurement. Intensity data were collected on a Syntex P$\bar{1}$ automated four-circle diffractometer by the 2θ-θ scan technique with a variable scan rate in the range 4.0°—24.0°/min using Mo $K\alpha$ radiation monochromoated by a

graphite plate. Three standard reflections were monitored after each measurement of 50 reflections, their intensities showing good stability. The Lorentz and polarization corrections were applied to the intensity data. Since the present structure analysis was focussed on the determination of the arrangement of heavier atoms and their interatomic distances, no correction was made for absorption. The crystal data are given in Table 1.

Structure Determination and Refinement

The structures were determined by the heavey-atom method, and refined by the block-diagonal least-squares method. The function minimized was $\sum\omega(|F_o|-k|F_c|)^2$, where k is a scale factor and $\omega=1$ for $|F_o|>5.0$ and $\omega=0$ for $|F_o|<5.0$. The space group, in each case, was determined as A222 unequivocally based on the Patterson maps. Atomic scattering factors were taken from International Tables for X-Ray Crystallography.[9] Anomalous dispersion corrections were applied to Pt and Br atoms. All calculations were carried out on a FACOM 230-75 computer in the Computer Center of Kyushu University, the UNICS Program System being used.[10] The final positional and thermal parameters with their estimated standard deviations are given in Table 2. The tables of observed and calculated structure factors are deposited in the office of the Chemical Society of Japan as a Document No. 7842.

$[Pt(tn)_2][PtCl_2(tn)_2](BF_4)_4$. The Patterson function gave the positions of platinum and chlorine atoms. The minimum function based on the platinum and chlorine positions revealed the positions of the nitrogen and boron atoms. In this stage the space group was unequivocally determined to be A222 on the basis of restrictions on crystal packing of the counter ions. Successive Fourier synthesis revealed all the remaining non-hydrogen atoms. The atomic positions and isotropic temperature factors were refined by the block-diagonal least-squares method, the disagreement factor (R) being reduced to 9.3%. Refinement was carried out with anisotropic temperature factors for the Pt and Cl atoms and isotropic ones for all the remaining non-hydrogen atoms, the final R value being 8.2%.

$[Pt(tn)_2][PtBr_2(tn)_2](ClO_4)_4$. The structure was determined by a procedure similar to that for $[Pt(tn)_2][PtCl_2(tn)_2](BF_4)_4$, the final R value being 8.9%.

$[Pt(tn)_2][PtBr_2(tn)_2](BF_4)_4$. Since this compound was thought to be isomorphous with $[Pt(tn)_2][PtBr_2(tn)_2](ClO_4)_4$, the positional parameters of the perchlorate and the over-all temperature factor calculated from Wilson's plot were used as the initial parameters of the refinement. After 5 cycles of the refinement, the R value was reduced to 10.5%. Refinement was then

Table 2. Positional and thermal parameters with their estimated standard deviations in parentheses ($\times 10^4$) (Anisotropic thermal parameters are expressed in the form $\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)]$.)

carried out with anisotropic temperature factors for the Pt and Br atoms, the final R value being 8.6%.

Description of the Structure

The crystal structure of $[Pt(tn)_2][PtCl_2(tn)_2](BF_4)_4$ and the atom numbering systems are shown in Fig. 1. Bond distances and bond angles with their estimated standard deviations are given in Table 3, hydrogen bond distances in Table 4.

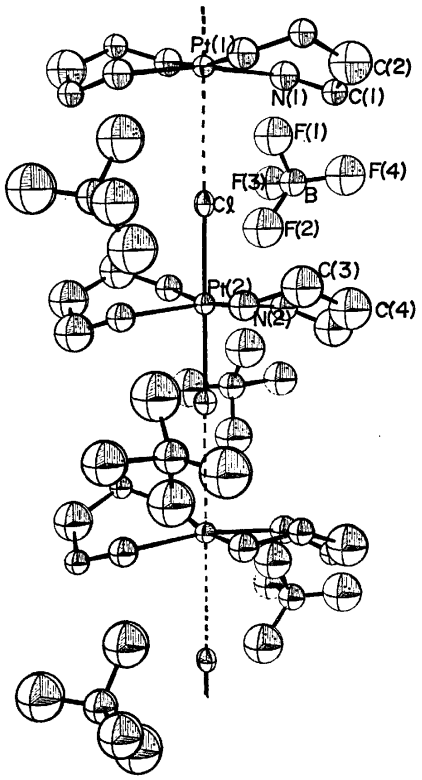

Fig. 1. A perspective view of $[Pt(tn)_2][PtCl_2(tn)_2](BF_4)_4$ and the numbering system of atoms. The vibrational spheres and ellipsoids are drawn at the 50% probability.[14]

$[Pt(tn)_2][PtCl_2(tn)_2](BF_4)_4$. The crystal contains infinite ···Pt(1)···Cl–Pt(2)–Cl··· chains running parallel to the a-axis. Pt(1) and Pt(2) occupy (0,0,0) and (1/2,0,0), respectively. Hence, the Pt(1)–Pt(1) and Pt(2)–Pt(2) distances correspond to the length of the a-axis.

Each platinum atom is coordinated with four nitrogen atoms of diamines in a square planar configuration with normal Pt–N distances of Pt(II) and Pt(IV) complexes. However, the Pt(1)–Cl (3.096(6) Å) and Pt(2)–Cl (2.299(6) Å) distances are quite different. The latter is close to the value (2.32 Å) of the Pt–Cl distance in *trans*-$[PtCl_2(NH_3)_4]Cl_2$,[11] which is a discrete Pt(IV) complex, and is also near the value (2.27 Å) calculated from atomic radii.[12] On the other hand, the former distance is greater than the normal covalent Pt–Cl distance, though it is still small enough to bring about some interaction between Pt(1) and Pt(2), as evidenced by the characteristic visible absorption.[13] Thus, the compound can be regarded to comprise square planar $[Pt^{II}(tn)_2]^{2+}$ and tetragonal bipyramidal $[Pt^{IV}Cl_2(tn)_2]^{2+}$ units which are stacked alternately in the chain.

The distances N(1)–F(1) (or –O(1)), N(2)–F(2) (or –O(2)), and N(2)[b]–F(2) (or –O(2)) (Table 4 and Fig. 2) indicate that the atoms are hydrogen-bonded. These hydrogen bonds seem to serve for the formation of the complexes of this type.

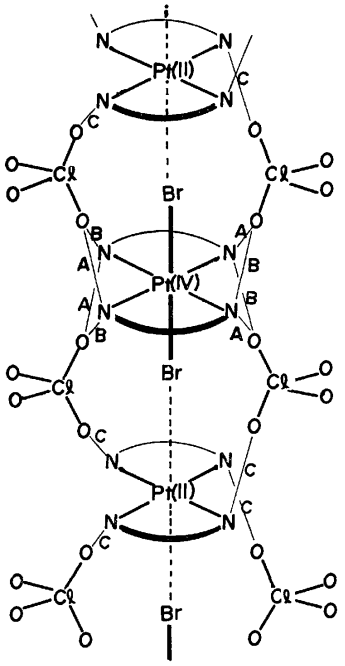

Fig. 2. A schematic representation of the hydrogen bonds. (A, B, and C refer to Table 4.)

$[Pt(tn)_2][PtBr_2(tn)_2](ClO_4)_4$ and $[Pt(tn)_2][PtBr_2(tn)_2](BF_4)_4$. The crystal structures are essentially the same as that of $[Pt(tn)_2][PtCl_2(tn)_2](BF_4)_4$. The Pt–Br distances are 2.546(7) and 2.955(7) Å for $[Pt(tn)_2][PtBr_2(tn)_2](ClO_4)_4$, and 2.541(5) and 2.921(5) Å for $[Pt(tn)_2][PtBr_2(tn)_2](BF_4)_4$, respectively. The Pt(2)–Br bond distances (2.546(7), 2.541(5) Å) are greater than the sum of the covalent bond radii 2.43 Å.[12] They are also greater than the corresponding distances in the related compounds, $[Pt(ea)_4][PtBr_2(ea)_4]Br_4\cdot 4H_2O$ (2.447 Å)[5] and $[Pt(ea)_4][PtBr_2(ea)_4]Br_4$ (2.42 Å),[4] where ea denotes ethylamine. The Pt(1)–Br distances (2.955(7), 2.921(5) Å) are smaller than those in the related complexes $[Pt(ea)_4][PtBr_2(ea)_4]Br_4\cdot 4H_2O$ (3.107, 3.139 Å)[5] and $[Pt(ea)_4][PtBr_2(ea)_4]Br_4$ (3.19, 4.07 Å).[4]

Discussion

The crystal structure is exactly in accord with what we had expected.[1] The fact that the ···Pt^{II}···X–Pt^{IV}–X··· chains array along the needle axis of crystal is also in line with our prediction deduced from the consideration of the polarization of the visible absorption.[1]

The relation between ν_{max} of the visible absorption and the Pt–halogen distances has not been clarified. The difference in Pt–Br distances between the per-

TABLE 5. ABSORPTION MAXIMUM AND PLATINUM-HALOGEN DISTANCES

Compound	ν_{max}(kcm^{-1})	Pt^{IV}–X(Å)	Pt^{II}–X(Å)	a(Å)	$\rho=(Pt^{IV}–X)/(Pt^{II}–X)$
$[Pt(tn)_2][PtCl_2(tn)_2](BF_4)_4$	20.62	2.299(6)	3.096(6)	10.790(2)	0.74
$[Pt(tn)_2][PtBr_2(tn)_2](ClO_4)_4$	16.53	2.546(7)	2.955(7)	11.003(6)	0.86
$[Pt(tn)_2][PtBr_2(tn)_2](BF_4)_4$	14.08	2.541(6)	2.921(5)	10.925(3)	0.87

chlorate and the tetrafluoroborate seems to be too small to account for the remarkable red-shift of the visible band (Table 5).

It is of interest to examine the oxidation states of the platinum atoms in the crystal in terms of the ratio of interatomic distances between platinum and halogen, $\rho=$(Pt(IV)–X)/(Pt(II)–X). In the case $\rho<1$, there is a difference in oxidation state between platinum atoms. When ρ approaches unity, the difference decreases to zero; the oxidation states of platinum atoms being leveled out at $\rho=1$. All the ratios are less than unity, and the ρ value of the bromo-complexes is larger than that of the chloro-complex (Table 5). This indicates that the extent of leveling of oxidation states of platinum atoms is greater in bromo-complexes than in the chloro-complex, as a result of the stronger Pt(II)$\cdots$ Br–Pt(IV) interaction. In this connection, it is of interest to consider the ρ value of the iodo-homologs expected to assume a value greater than that of bromo-homologs. The single-crystal X-ray analysis of $[Pt(tn)_2][PtI_2(tn)_2](ClO_4)_4$ is in progress, preliminary data showing $\rho\approx0.91$.

The authors are grateful to Prof. I. Ueda and Assoc. Prof. S. Kawano, Kyushu University, for their valuable advice and for use of their programs. Thanks are also due to Prof. T. Komori for use of the Syntex $P\bar{1}$ automated diffractometer.

On the Behavior of Mercury in Some Polluted Seawater

(Received March 17, 1978)

Most of the mercury in coastal seawater polluted with waste water including mainly organic suspended matter is associated with suspended matter, especially particulate organic matter. The amount of mercury adsorbed on a given amount of particulate organic matter nearly obeys Freundlich's adsorption isotherm at mercury concentrations less than 15 ppm in particulate organic matter. The mercury in suspended matter is not much reduced by the addition of tin(II) chloride. Thus, to get the total value of the mercury concentration, the water samples must be heated with the addition of a sulfuric and nitric acid mixture to decompose the suspended matter.

Measurements of the mercury concentration in seawater have been made by several investigators; the values, however, are widely scattered. It may be most significant that almost all the samples were kept in polyethylene bottles after acidification. Matsunaga[1] has found that mercury at the nanogram level is given off from such bottles during sample storage, increasing the initial mercury level by a factor of 2 to 100, even if the container has been acid-rinsed. The mercury concentrations in uncontaminated natural waters are generally lower than 5 ng dm^{-3},[2-6] and that in the oceans was found to be constant at 5 ng dm^{-3}.[2,3] In studying the behavior of mercury in contaminated seawater, Carr and Wilknis[7] have reported a desorption rate of mercury from suspended matter. They added ^{197}Hg into seawater including a high concentration of suspended matter (7 mg dm^{-3}) and adjusted the pH of the water to 1.

Here we report on the behavior of mercury in coastal seawater polluted with waste water including mercury and fish meal.

Experimental

Reagents. 1000 ppm $HgCl_2$ stock solution: 1.345 g $HgCl_2$ was dissolved in distilled water; the volume was filled up to 1 dm^3. NaCl: To eliminate any contaminant mercury in the sodium chloride, the reagent was heated in a furnace at 500 °C for 2 h. 10 ppb $HgCl_2$ solution: Sodium chloride and sulfuric acid were added into the adequate amounts of the stock solution to become 3.5% and 0.2 mol dm^{-3}, respectively. This solution is stable for at least 3 months. Tin(II) chloride solution: 50 g $SnCl_2 \cdot 2H_2O$ was dissolved in 1 dm^3 of 1 mol dm^{-3} hydrochloric acid. The mercury in tin(II) chloride solution was eliminated by passing nitrogen gas at a flow rate of 1.4 dm^3 min^{-1} for 1 h. H_2SO_4 and HNO_3: Both the chemicals are of the analytical special reagent grade for measurements of toxic metals produced by Wako Chemicals Inc. Mercury contents in both acids were below 0.1 ppb in most cases, but we had to determine the amount before using because there is a difference of mercury concentration between lots.

Apparatus. Absorbances were measured on a Jarrell-Ash atomic absorption spectrophotometer, AA-780, with a quartz cell (2.0-cm diameter, 20-cm length).

Sampling and Analytical Methods. *Sampling Method*: About 30 samples of surface seawater were collected in the Hakodate Bay with a plastic bucket during a period from June to September 1976 at a station shown by the star mark in Fig. 1. Immediately after collection the sample was acidified to 0.2 mol dm^{-3} with sulfuric acid, and stored in a glass bottle. The mercury contents in the samples were analysed at the laboratory within 1 h. Samples were also collected vertically in the bay with a Van Dorn bottle on 12 August, 1976 at stations shown by a circle mark in Fig. 1.

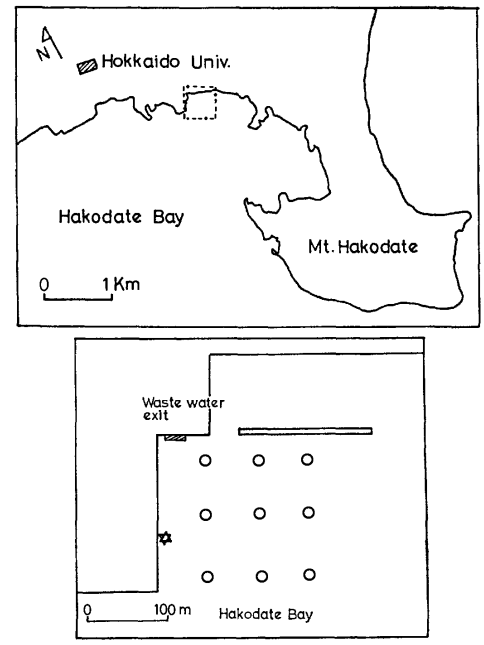

Fig. 1. Sampling stations for polluted seawater. Sampling station ☆: about 30 surface seawater samples were collected from Jun. to Sep. 1976, ○: samples were vertically collected at 12 Aug. 1976.

Analytical Method. *Ionic Mercury*: The outline of the analytical method is as follows:[8] Ionic mercury in 0.2—0.8 dm^3 sample is reduced with tin(II) chloride and the mercury vapor generated is transferred to gold particles, packed in a glass tube, by a stream of nitrogen gas. The metal is then heated to 500 °C in a furnace, and the vaporized mercury is determined with an atomic absorption spectrophotometer.

Total Mercury: To a 0.5 dm^3 sample solution, sulfuric acid (2 cm^3) and nitric acid (5 cm^3) are added, and the solution is heated with a reflux condenser for 2 h to decompose particulate phases. The leached mercury is determined according to the procedure of ionic mercury determination. The acid decomposition method was compared with the decomposition method with potassium permanganate for the same samples. Table 1 shows that there is no significant difference between two methods for the significance level $(1-\alpha)=95\%$, $(\alpha=0.05)$.

Mercury in Suspended Matter: The sample was filtered through an HA type Millipore filter with a 0.45 μm pore size, and then

TABLE 1. THE COMPARISON OF TOTAL MERCURY CONCENTRATIONS DETERMINED BY TWO OXIDATION METHODS

Batch	Oxidant	
	NHO_3–H_2SO_4	$KMnO_4$
	[Hg] (ng dm^{-3})	
1	64.3	54.5
2	11.5	9.6
3	420	414
4	9.3	15.8
5	44.4	44.5
6	12.0	13.5
7	5.8	5.3
8	4.4	3.5
9	23.3	19.3
10	15.1	12.9

$t_0 = 1.25 < t(9, 0.05) = 2.26$.

the residue was decomposed with sulfuric and nitric acid mixture by heating. The mercury was determined by AAS, following the procedure described above.

Suspended Matter and Loss on Ignition: After the sample solution was filtered using the Millipore filter, the filter paper was rinsed with 100—150 cm^3 H_2O to remove sea salt, and dried in a desiccator until the weight of each filter reached a constant value within $\pm$0.2 mg. After weighing, the total weight of suspended matter was obtained using the difference in weight before and after filtration, and then the filter was ignited at 500 °C for 2 h. After weighing, the loss on ignition, assumed to be a measurement of the particulate organic matter, was determined from the difference in the values of the weight.

Results and Discussion

Student's *t*-test is useful to compare the data obtained by the use of two different methods. As already mentioned above, there is no significant difference between the two sets of data given in Table 1, for $\alpha = 0.05$. Therefore, the method with sulfuric and nitric acid mixture can be applied to decompose suspended matters present in the samples in a simple and easy way. Some results on different forms are shown in Table 2. For the samples containing more than 10 mg dm^{-3} of suspended matter, quantities of mercury less than 11% of total mercury were detected in ionic form. Judging from the concentrations of mercury in suspended matters, evidently the rest of the mercury in those samples is adsorbed on, or coagulated with, suspended matter. Figure 2 shows the relationship between ionic mercury concentration and total mercury concentration. A remarkable deviation form the line which indicates the 1 : 1 relationship is observed with increasing the amounts of suspended matters. This means that the concentrations of ionic mercury decreased with

increasing the amounts of suspended matters. Figure 3 shows the relationship between mercury concentrations in ionic form and in particulate organic matters. The amount of mercury adsorbed on particulate organic matters per unit weight nearly obeys Freundlich's adsorption isotherm at the concentrations lower than 15 ppm mercury.

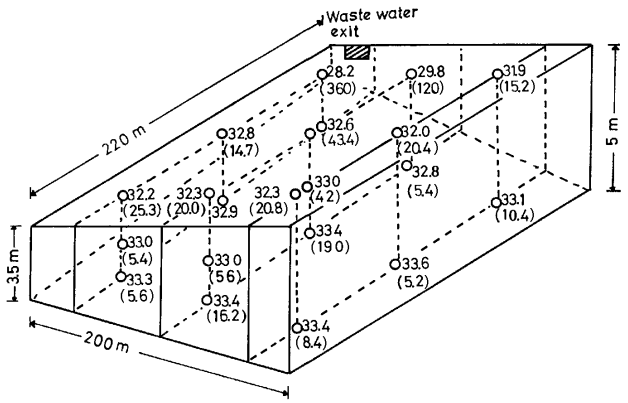

Fig. 4. Salinity, ‰ and the amount of suspended matter (mg dm^{-3}).

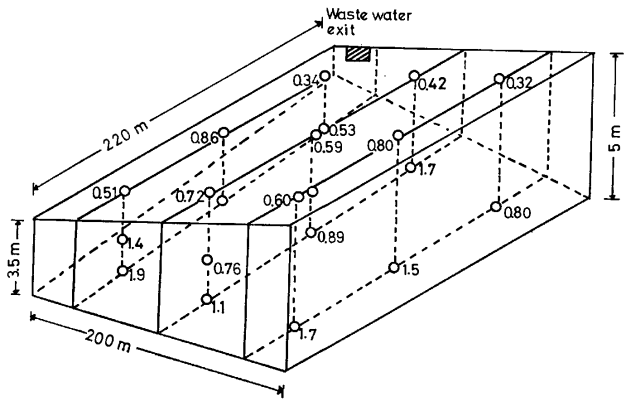

Fig. 5. The amount of mercury in suspended matter.

The salinity and the amount of suspended matter, and the amount of mercury in the suspended matters are shown in Figs. 4 and 5, respectively, for the samples at different depths collected in the area shown in Fig. 1. In the area, waste water diffuses from east to south, as is seen in the salinity distribution (Fig. 4) around the waste water exit. However, the salinity near the bottom is scarcely affected by waste water, except for the area adjacent to the discharge. The same tendency is observed in the suspended matter distribution, though suspended matters settle downward. The mercury concentration in suspended matters is about 0.1 ppm level in samples near the surface, while the concentration occasionally approaches 1 ppm level with increasing depth. This suggests that suspended matters adsorb and remove mercury from the water. The concentrations of ionic mercury in seawater samples are below 2 ng dm^{-3} in all of the samples measured; such values are about half of the values in unpolluted sewater at Hakodate Bay. The present results suggest that most of mercury in highly polluted waters is associated with suspended matter. As mentioned above, the determination of mercury can be simplified by treating water samples with a nitric and sulfuric acid mixture. For samples with salinity higher than 30‰ and acidified to 0.2 ml dm^{-3} with sulfuric acid, no adsorption of mercury on the walls of the glass container was observed. But significant adsorption of mercury occurred for samples with salinity less than 30‰, even if they were acidified to more than 0.2 mol dm^{-3}. Generally coastal seawater has a salinity lower than 30‰. Therefore, sodium chloride preheated at 500 °C must be added to the sample solutions to bring its salinity up higher than 30‰, unless the samples are quickly processed after sampling. By these procedures, adsorption of mercury on the walls of the container was avoided.[1] For open seawater samples, acidification to 0.2 mol dm^{-3} with sulfuric acid for a month at room temperature was found to be sufficient for quantitative determination of mercury.[1] However, this treatment yielded only 40% of the total mercury for samples with suspended matters concentration higher than 30 mg dm^{-3}. For polluted seawater samples, the treatment with sulfuric and nitric acid mixture is necessary for quantitative determination of mercury.

The authors wish to thank Prof. M. Nishimura for his advice and the Ministry of Education for the financial support granted for this research.

Nickel(II) Complexes of Schiff Bases Derived from Salicylaldehyde and Glycyl-aspartate or -glutamate. Application to a Selective Hydrolysis Reaction of Dimethyl Glycylaspartate and Glycylglutamate

Yasuo NAKAO*,† and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received May 6, 1978)

Nickel(II) complexes of Schiff bases derived from salicylaldehyde and glycylaspartate or glycylglutamate were prepared and their structures were determined on the basis of electronic absorption and ^{1}H NMR spectra. The relationship between structure of the chelates and stability of fused-ring systems was discussed in some detail, and was applied to a selective hydrolysis reaction of dimethyl glycylaspartate and glycylglutamate. Nickel(II) complexes of Schiff bases derived from salicylaldehyde and β-methyl glycylaspartate or γ-methyl glycylglutamate were obtained by a reaction between dimethyl glycylaspartate or glycylglutamate and bis(salicylaldehydato)-nickel(II) in methanol containing sodium or potassium hydroxide.

In a previous paper,[1] we reported as the result of a comparative study on copper(II) and nickel(II) complexes (**1**, **2**) of Schiff bases derived from salicylaldehyde and glycylglycine or glycyl-β-alanine that the fused-ring system of **1** (6-5-5) is more stable than that of **2** (6-5-6).[2] In connection with such delicate difference in the stability of fused-ring systems, we have extended the study to the preparation and structural determination of nickel(II) complexes of Schiff bases composed of salicylaldehyde and glycyl-aspartate and -glutamate. As an application of the result concerning the structure-stability relationship, we have also attempted selective hydrolysis reactions of dimethyl glycylaspartate and glycylglutamate.

Experimental

Dibenzyl L-*Aspartate Hydrochloride* was prepared by the method of Miller *et al.*[3]

Glycyl-L-*aspartic Acid* was obtained by catalytic reduction of dibenzyl *N*-benzyloxycarbonylglycyl-L-aspartate, which had been prepared from *N*-benzyloxycarbonylglycine and dibenzyl L-aspartate hydrochloride according to the direction of Miller *et al.*[3]

Dibenzyl L- *and* DL-*Glutamate Benzenesulfonates* were prepared by a similar procedure to that for benzyl glycinate benzenesulfonate.[4] The L-compound was identified by comparing the melting point with that in literature.[5] Melting point and analytical data of dibenzyl DL-glutamate benzenesulfonate, which was recrystallized from ethanol are as follows: mp 118—119 °C. Found: C, 61.40; H, 5.63; N, 3.07%. Calcd for $C_{25}H_{27}O_7NS$: C, 61.83; H, 5.62; N, 2.89%.

Dibenzyl L- *and* DL-*Glutamate Hydrochlorides* were obtained from the corresponding benzenesulfonate described above.[6]

Dibenzyl N-*Benzyloxycarbonylglycyl*-L- *and* -DL-*glutamates* were prepared by the same method as that for the corresponding dibenzyl *N*-benzyloxycarbonylglycyl-L-aspartate, using dibenzyl L- and DL-glutamate hydrochlorides instead of dibenzyl L-aspartate hydrochloride.[3] These compounds were obtained as oily products, which were used for the subsequent reaction without further purification.

Glycyl-L- *and* -DL-*glutamic Acids.* These were obtained by the catalytic reduction of the corresponding dibenzyl *N*-benzyloxycarbonylglycyl-L- and -DL-glutamates by using palladium black as a catalyst. In all cases, methanol was used as solvent with a small amount of acetic acid. These peptides were recrystallized from water-ethanol. H·Gly·DL-Glu·OH: mp 184—187 °C (dec). Found: C, 40.78; H, 5.81; N, 13.71%. Calcd for $C_7H_{12}O_5N_2$: C, 41.17; H, 5.94; N, 13.72%.

Glycyl-L-glutamic Acid was identified from the melting point.[5]

Dimethyl DL-*Aspartate and* DL-*Glutamate Hydrochlorides* were prepared according to the ordinary method.[7]

Dimethyl N-*Benzyloxycarbonylglycyl*-DL-*aspartate.* This was prepared in a similar procedure as that reported by Winitz *et al.*[8] To a solution of 13.7 g of *N*-benzyloxycarbonylglycine, 13.0 g of dimethyl DL-aspartate hydrochloride and 9.2 cm^3 of triethylamine in 135 cm^3 of chloroform was added 14.1 g of dicyclohexylcarbodiimide. The reaction mixture was stirred at room temperature overnight. After removal of precipitated

N,N'-dicyclohexylurea, the filtrate was washed with water, 1 mol/dm³ HCl, saturated aqueous solution of $NaHCO_3$, and water. After the chloroform fraction had been dried over anhydrous magnesium sulfate, the filtrate was evaporated to dryness. The oily products obtained were recrystallized from ethyl acetate and petroleum benzine. Mp 93—95 °C. Found: C, 54.53; H, 5.75; N, 7.97%. Calcd for $C_{16}H_{20}O_7N_2$: C, 54.53; H, 5.75; N, 7.95%.

Dimethyl N-*Benzyloxycarbonylglycyl*-DL-*glutamate.* This was prepared from *N*-benzyloxycarbonylglycine and dimethyl DL-glutamate hydrochloride in the same way as described for dimethyl *N*-benzyloxycarbonylglycyl-DL-aspartate. Mp 64—65 °C. Found: C, 56.01; H, 6.18; N, 7.59%. Calcd for $C_{17}H_{22}O_7N_2$: C, 55.72; H, 6.06; N, 7.65%.

Hydrochlorides of Dimethyl Glycyl-DL-*aspartate and Glycyl*-DL-*glutamate.* These were obtained by catalytic reduction of dimethyl *N*-benzyloxycarbonylglycyl-DL-aspartate and -DL-*glu*tamate using palladium black catalyst. Methanol containing a small volume of concentrated hydrochloric acid was used as solvent. These compounds were obtained as oily products, which were recrystallized from methanol-ether. Gly·DL-Asp(OMe)$_2$·HCl: mp 146—148 °C. Found: C, 37.35; H, 5.88; N, 10.83%. Calcd for $C_8H_{15}O_5N_2Cl$: C, 37.72; H, 5.95; N, 11.00%. Gly·DL-Glu(OMe)$_2$·HCl: mp 139—141 °C. Found: C, 40.00; H, 6.38; N, 10.43%. Calcd for $C_9H_{17}O_5N_2Cl$: C, 40.22; H, 6.39; N, 10.43%.

Benzyl γ-Aminobutyrate p-*Toluenesulfonate* was prepared by the same method as that for the corresponding benzyl β-alaninate *p*-toluenesulfonate.[9] Recrystallization was carried out by using ethanol–ether. Mp 107—107.5 °C. Found: C, 59.29; H, 6.39; N, 3.91%. Calcd for $C_{18}H_{23}O_5NS$: C, 59.15; H, 6.36; N, 3.83%.

Benzyl N-*Benzyloxycarbonylglycyl-γ-aminobutyrate.* This was prepared in a similar method as that reported by Winitz *et al.*[8] To a solution of 14.6 g of *N*-benzyloxycarbonylglycine, 24.6 g of benzyl γ-aminobutyrate *p*-toluenesulfonate and 9.8 cm³ of triethylamine in 160 cm³ of chloroform was added 14.5 g of dicyclohexylcarbodiimide. The reaction mixture was stirred at 25 °C overnight. After removal of precipitated *N,N'*-dicyclohexylurea, the filtrate was washed with water, 1 mol/dm³ HCl, saturated aqueous solution of $NaHCO_3$, and water. After the chloroform fraction had been dried over anhydrous magnesium sulfate, the filtrate was evaporated to dryness. The crystalline materials obtained were recrystallized from ethyl acetate and petroleum benzine. Mp 83—84 °C. Found: C, 65.49; H, 6.39; N, 7.24%. Calcd for $C_{21}H_{24}O_5N_2$: C, 65.60; H, 6.30; N, 7.29%.

Glycyl-γ-aminobutyric Acid. This was obtained by catalytic reduction of benzyl *N*-benzyloxycarbonylglycyl-γ-aminobutyrate using palladium black catalyst. Methanol containing a small volume of glacial acetic acid was used as solvent. Recrystallization was carried out by using water and ethanol. Mp 198—202 °C (dec). Found: C, 44.50; H, 7.48; N, 17.09%. Calcd for $C_{13}H_{18}O_3N$: C, 44.98; H, 7.57; N, 17.49%.

Bis(salicylaldehydato)nickel(II) and Barium N-*Salicylideneglycyl-β-alaninatonickelate(II)*, **2** were prepared according to the direction described previously.[1]

Potassium N-*Salicylideneglycyl-γ-aminobutyratonickelate(II)*, **6**. Into 30 cm³ of a water: ethanol mixture (2: 1 by volume) were dissolved 0.8 g of glycyl-γ-aminobutyric acid and 1.5 g of bis(salicylaldehydato)nickel(II). The resulting mixture was adjusted to pH 9—10 with concentrated KOH solution and stirred at 40 °C for 3 h. After it had been filtered, the solution was evaporated to dryness *in vacuo* to give a yellowish green powder. The powder was recrystallized from hot ethanol. Found: C, 41.21; H, 4.59; N, 7.03%. Calcd for K[Ni($C_{13}H_{13}O_4N_2$)]·H_2O: C, 41.40; H, 4.02; N, 7.43%.

Dipotassium N-*Salicylideneglycyl*-L-*aspartatonickelate(II)*, **3a**. A mixture of 0.50 g of glycyl-L-aspartic acid and 0.79 g of bis(salicylaldehydato)nickel(II) was dissolved in 15 cm³ of water–ethanol (2: 1 by volume). The reaction mixture was adjusted to pH 9—10 by concentrated KOH solution and stirred at room temperature for 1 h. After it had been filtered, ethanol was added to the filtrate to give orange crystals, which were recrystallized from water–ethanol. Found: C, 35.36; H, 2.48; N, 6.33%. Calcd for K_2[Ni($C_{13}H_{10}O_6N_2$)]·H_2O: C, 35.07; H, 2.72; N, 6.29%.

Dipotassium N-*Salicylideneglycyl*-L- *and* -DL-*glutamatonickelates-(II)*, **4a** were prepared in the same way as for chelate **3a**. K_2[Ni(Sal=Gly·L-Glu)]·2.5H_2O: Found: C, 34.69; H, 4.04; N, 5.77%. Calcd for K_2[Ni($C_{14}H_{12}O_6N_2$)]·2.5H_2O: C, 34.58; H, 3.53; N, 5.76%. K_2[Ni(Sal=Gly·DL-Glu)]·3.5H_2O: Found: C, 33.33; H, 3.64; N, 5.67%. Calcd for K_2[Ni($C_{14}H_{12}O_6N_2$)]·3.5H_2O: C, 33.34; H, 3.81; N, 5.56%.

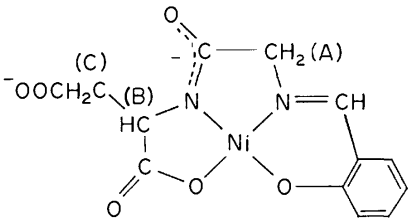
The Reaction between Dimethyl Glycyl-DL-*aspartate and Bis(salicylaldehydato)nickel(II) in Methanol.* To a mixture of 0.75 g (0.0025 mol) of bis(salicylaldehydato)nickel(II) and 0.64 g (0.0025 mol) of dimethyl glycyl-DL-aspartate hydrochloride in 10 cm³ of methanol was added a concentrated KOH methanol solution, until the color of the solution became completely orange. The reaction mixture was then stirred at room temperature for 2 h, being allowed to stand for a few more hours in a refrigerator; hereupon orange crystals were obtained in 70% yield. The products were filtered and recrystallized from methanol. Found: C, 41.35; H, 3.39; N, 6.88%. Calcd for K[Ni($C_{14}H_{13}O_6N_2$)], **7**: C, 41.71; H, 3.26; N, 6.95%.

The Reaction between Dimethyl Glycyl-DL-*glutamate and Bis(salicylaldehydato)nickel(II) in Methanol.* A mixture of 0.67 g (0.0025 mol) of dimethyl glycyl-DL-glutamate hydrochloride and 0.75 g (0.0025 mol) of bis(salicylaldehydato)nickel(II) was dissolved in 15 cm³ of methanol. To the solution was added 0.27 g of sodium hydroxide and 0.42 g of barium perchlorate. The mixture was stirred at room temperature for 2 h to give an orange crystalline material, yield 75%. This was filtered and washed several times by methanol. Found: C, 40.18; H, 3.79; N, 6.07%. Calcd for Ba/2[Ni($C_{15}H_{15}O_6N_2$)], **9**: C, 40.33; H, 3.39; N, 6.27%.

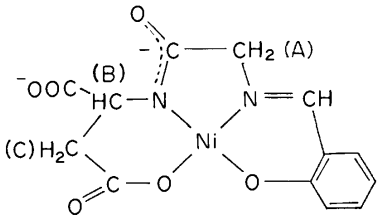
Measurements. Melting points were determined on a micro melting point apparatus and uncorrected. The PMR spectra were recorded by using a JEOL MH-100 spectrometer with sodium 2,2-dimethyl-2-silapentane-5-sulfonate as an internal standard and deuterium oxide was used as a solvent. The pD-adjustment was carried out by the addition of concentrated NaOD-heavy water solution. A Yanagimoto pH-66A pH meter equipped with a MGR-11A combined electrode was used after standardization with a Wako standard buffer solution (pH 6.86 and 9.18 at 25 °C). The visible and ultaviolet absorption spectra were obtained with a 323 Hitachi Recording Spectrophotometer. The IR spectra were recorded with a Hitachi EPI-2 Infrared Spectrophotometer. The measurements were carried out at room temperature using the pressed KBr disk technique in the wave number range 700—4000 cm^{-1} with a rock-salt prism.

Results and Discussion

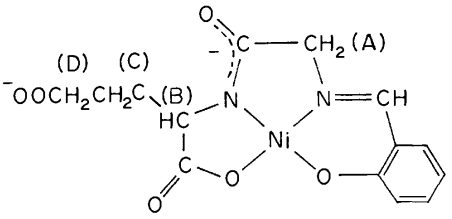
Nickel(II) Complexes of Schiff Bases Derived from Salicylaldehyde and Glycylaspartate or Glycylglutamate. These nickel(II) complexes were prepared by reactions of each dipeptide with bis(salicylaldehydato)nickel(II) in the pH range 9—10. Since the complexes do not exhibit any absorption peak in the visible and near infrared region, they are expected to have such square-planar



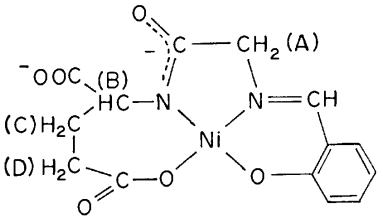
3a



3b



4a



4b

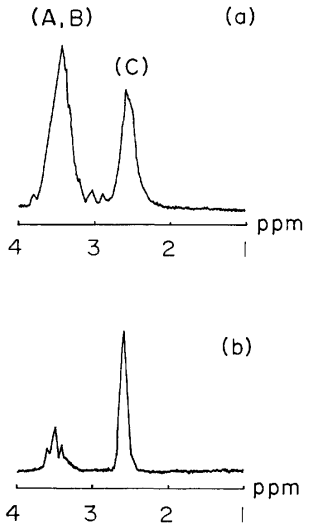


Fig. 1. PMR spectra of $[Ni(Sal{=}Gly\cdot L\text{-}Asp)]^{2-}$: (a) pD 7.8, room temp, after 2 h; (b) pD 13.1, 40 °C, after 8 days.

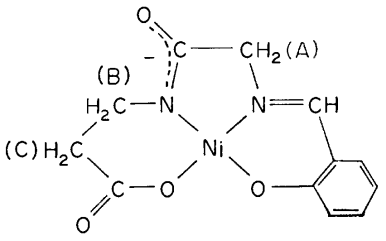
structures as **3**- and **4**-**a** or -**b**. In the structural formulas, the symbol (A) indicates the methylene group of glycinate residue, while (B), (C), and (D) indicate the methylene or methine groups of α-, β- and γ-position in the C-terminal amino acid residues. In order to confirm the structure of glycyl-L-aspartate-Schiff base complex, the PMR spectra were measured in D_2O under various conditions (Fig. 1). Inspection of the PMR spectrum represented in Fig. 1(a) reveals that signals for the methylene or methine protons of (A), (B), and (C) are not separated in three but two peaks, of which the ratio of absorption intensity at 3.56 and 2.60 ppm is 3:2. It was clealy observed that the peak at 3.56 ppm turned out triplet together with decrease in intensity after 8 days at pD 13.1, 40 °C, while the peak at 2.60 ppm remained unchanged (Fig. 1(b)). From the fact, the nickel(II) complex of Schiff base composed of salicylaldehyde and glycyl-L-aspartate may be reasonably accepted as the structure **3a** rather than as **3b**, since the deuteration of (A) methylene and (B) methine groups in **3a**, can be understood by taking into account the results obtained through the deuteration in *N*-salicylideneglycylglycinato- and -glycyl-L-α-alaninatonickelates(II).[10] In other words, (A) methylene protons of glycyl-L-aspartate residue in **3a** are entirely replaced by deuterons, whereas the (B) methine proton is not so entirely replaced as (A) under the same conditions. On the other hand, if *N*-salicylideneglycyl-L-aspartatonickelate(II) had the structural formula **3b**, only the



5

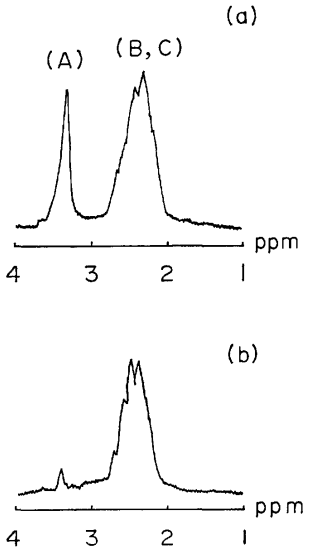


Fig. 2. PMR spectra of $[Ni(Sal{=}Gly\cdot\beta\text{-}Ala)]^{-}$: (a) pD 9.3, room temp, after 1 h; (b) pD 13.2, 40 °C, after 8 days.

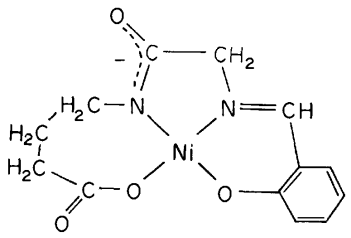
deuteration of (A) methylene protons would take place. This is because of the fact that the deuteration of (A) methylene protons in *N*-salicylideneglycyl-β-alaninatonickelate(II), **5** occurs easily, whereas that of (B) and (C) methylene protons does not at all (Figs. 2(a) and (b)). Preferential formation of **3a** instead of **3b** suggests that the stability of fused-ring system decreases in the order 6-5-5>6-5-6, showing good agreement with the previous conclusion established for copper(II) and nickel(II) complexes, **1** and **2**.[1)]



6

The *N*-salicylideneglycyl-L- or -DL-glutamatonickelate(II) is orange, while *N*-salicylideneglycylglycinato- and *N*-salicylideneglycyl-γ-aminobutyratonickelates(II) (**1** and **6**), are orange and brownish green, respectively. The d-d transition band of the complex, **6** was observed at 950 nm. On the basis of these facts, potassium *N*-salicylideneglycyl-γ-aminobutyratonickelate(II) is not supposed to be the square-planar type. This may be attributed to a rather weak ligand field of the *N*-salicylideneglycyl-γ-aminobutyrate, whose fused-ring structure involves a 7-membered ring. On the other hand, the square-planar structure of *N*-salicylideneglycylglycinato- and -glycylglutamato-nickelates(II) have been inferred from the absence of absorption peak in the visible and near infrared region. Thus, the nickel(II) complex of Schiff base

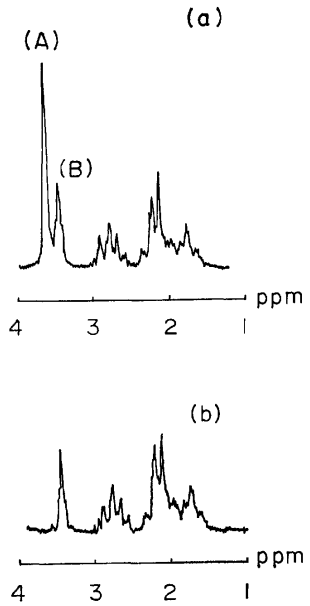


Fig. 3. PMR spectra of $[Ni(Sal{=}Gly\cdot L\text{-}Glu)]^{2-}$: (a) pD 9.6, room temp, after 1 h; (b) pD 13.8, 40 °C, after 9 days.

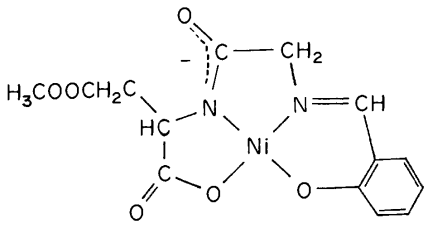
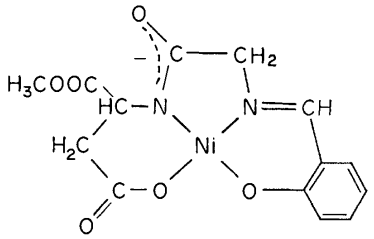
derived from salicylaldehyde and glycyl-L- or -DL-glutamate can be represented as the structure **4a**. The PMR spectrum shown in Fig. 3(a) also indicates that *N*-salicylideneglycyl-L-glutamatonickelate(II) is diamagnetic, and probably is planar. On the basis of the result of deuteration in *N*-salicylideneglycyl-L-aspartatonickelate(II), **3a**, it is expected that (A) methylene and (B) methine protons in **4a** are deuterated in D_2O solution. In fact, the peak at 3.64 ppm arising from the (A) methylene protons disappears on allowing the solution to stand at 40 °C, pD 13.8 for 9 days, as is clear from Figs. 3(a) and (b). On the other hand, the peak due to the (B) methine proton remains unchanged under the same conditions; the corresponding (B) methine proton of *N*-salicylideneglycyl-L-aspartatonickelate(II), **3a** was fairly deuterated under similar conditions. This may be correlated to the extent of the upfield shift of (B) methine peak in **3a** and **4a**. The (B) methine peak in **3a** and **4a** appeared at 3.58 and 3.47 ppm, respectively. We described previously that the methylene protons, of which the signal is observed at the lowest field in PMR spectra of a series of tripeptide-nickel(II) chelates, were most easily deuterated in D_2O solution.[11)] Therefore, the difficulty of deuteration of (B) methine in **4a** is thus understandable.

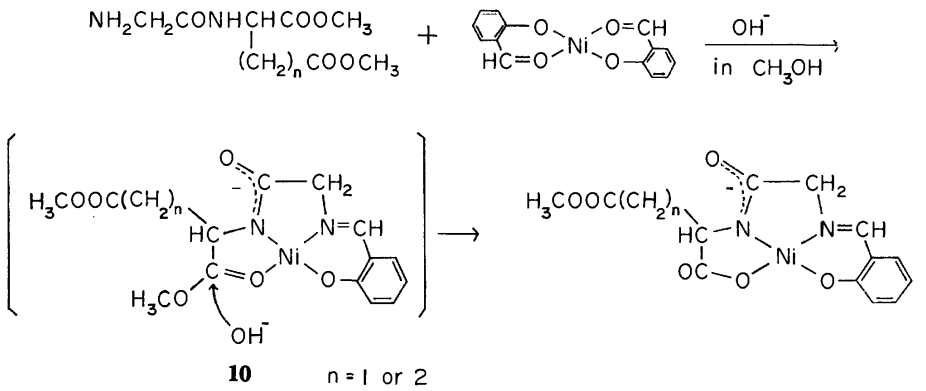
Selective Hydrolysis of Dimethyl Glycyl-DL-aspartate or Glycyl-DL-glutamate by Bis(salicylaldehydato)nickel(II) in Methanol. The reaction between dimethyl glycyl-DL-aspartate hydrochloride and bis(salicylaldehydato)-nickel(II) in methanol containing potassium hydroxide gave an orange nickel(II) complex. Inspection of the IR spectrum of the complex reveals the band characteristic of ester group at around 1720 cm^{-1}. The electronic spectrum in methanol-dimethyl sulfoxide solution resembles those observed for *N*-salicylideneglycyl-L-aspartato- and -glycyl-L-glutamato-nickelats(II) which are estimated to have the square planar structure. Thus, the structure of the nickel(II) complex obtained is considered as shown in formula **7** or **8**. The result of elemental analysis also supports the above presumption. Further, we are more in line with the structure **7**, since the 6-5-5-fused ring structure is supposed to be more



7

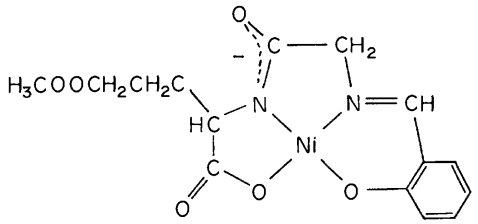


8



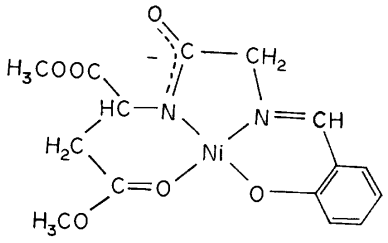
10 n = 1 or 2

Scheme 1.

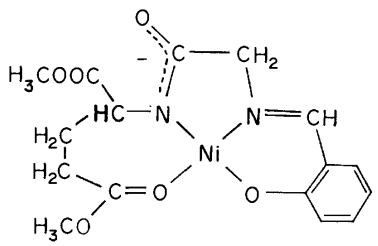


9

stable than the 6-5-6-fused ring structure. Accordingly, it can be concluded that the hydrolysis of ester groups occurred preferably at the α-position in the dimethyl glycyl-DL-aspartate. Likewise, the α-ester group in dimethyl glycyl-DL-glutamate is also selectively hydrolyzed under similar conditions. Since the isolation of potassium salt of γ-methyl *N*-salicylideneglycyl-DL-glutamatonickelate(II), **9** was a little more difficult, we obtained the same chelate as the barium salt. The selective hydrolysis of peptide ester of this kind can well be explained by a mechanism involving the intermediate **10** as illustrated in Scheme 1. In **10**, the carbon atom of the α-ester group would be readily attacked by hydroxide ion. Of course, there is a possibility for the ester group coming into coordination at the β- or γ-position as indicated in **11** or **12**. However, the coordination of the β- or γ-ester group is supposed to be much more difficult than that of the α-ester group. This is because of the foregoing argument that the 6-5-5-fused chelate ring is more stable than the 6-5-6 or 6-5-7 ring in the nickel(II) chelates of Schiff bases derived from salicylaldehyde and glycyl-aspartate or -glutamate.



11



12

We thank Mr. Teruhisa Morishita for technical assistance. We are also indebted to Mr. Yoshio Terawaki of the Faculty of Engineering Science for PMR measurements and to Miss Teruko Kuroe for the elemental analyses. Expenses for this work were defrayed in part by a grant from the Ministry of Education.

Reaction Process between Iron(II) Chloride and Oxygen

Yuzo Saeki,* Ryoko Matsuzaki, and Seiki Fujiwara

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received May 11, 1978)

The product formed by heating $FeCl_2$ in an oxygen stream has been examined in detail. The reaction processes of gaseous $FeCl_3$ and FeOCl, formed during the reaction between $FeCl_2$ and oxygen, with oxygen were also examined. The reaction process between $FeCl_2$ and oxygen can be represented as follows: $FeCl_2$ reacts with oxygen above about 250 °C to form FeOCl and gaseous $FeCl_3$, $2FeCl_2(s)+1/2O_2(g)\rightarrow FeOCl(s)+1/2Fe_2Cl_6(g)$. Subsequently, the resulting FeOCl reacts with oxygen to form α-Fe_2O_3 and chlorine, $2FeOCl(s)+1/2O_2(g)\rightarrow Fe_2O_3(s)+Cl_2(g)$. Above about 320 °C, the decomposition of the FeOCl to α-Fe_2O_3 and gaseous $FeCl_3$, $3FeOCl(s)\rightarrow Fe_2O_3(s)+1/2Fe_2Cl_6(g)$, also occurs. Above about 370 °C, the reaction between gaseous $FeCl_3$ formed and oxygen to form η-Fe_2O_3 and chlorine, $Fe_2Cl_6(g)+3/2O_2(g)\rightarrow Fe_2O_3(s)+3Cl_2(g)$, occurs in addition to the above reactions.

During the chlorination of ilmenite and many ores, iron(II) chloride($FeCl_2$) is usually formed in addition to the main products. This work was undertaken to obtain fundamental information on the chemical process for dechlorinating the $FeCl_2$ with oxygen(air) to produce a non-polluting iron oxide product and chlorine for recycle.

It has been reported in the early literature[1] that on heating $FeCl_2$ in a stream of air or oxygen, the reaction, $6FeCl_2+3/2O_2\rightarrow 2Fe_2Cl_6+Fe_2O_3$, occurs. Teterevkov *et al.*[2] have examined the relationship between the amount of chlorine evolved upon heating $FeCl_2$ in an oxygen stream and the heating time in the temperature range of 300—500 °C, and have conducted the experiment on the recovery of chlorine from $FeCl_2$. However, the reaction process between $FeCl_2$ and oxygen was not clarified.

In this paper, the product formed by heating $FeCl_2$ in an oxygen stream has been examined in detail. The reaction processes of gaseous iron(III) chloride($FeCl_3$) and iron chloride oxide(FeOCl), which were formed during the reaction between $FeCl_2$ and oxygen, with oxygen were also examined. From these experimental results, the reaction process between $FeCl_2$ and oxygen was revealed.

Experimental

The $FeCl_2$ used was prepared by the reaction between pure iron (Fe 99.98%) and HCl at 850 °C, and confirmed as $FeCl_2$ by X-ray analysis.[3] The chemical analysis gave Fe, 44.0; Cl, 55.9% (calcd for $FeCl_2$: Fe, 44.06; Cl, 55.94%). $FeCl_3$ was prepared by the reaction between pure iron and chlorine at 500 °C, and confirmed as $FeCl_3$ by X-ray analysis.[4] The chemical analysis gave Fe, 34.3; Cl, 65.5% (calcd for $FeCl_3$: Fe, 34.43; Cl, 65.57%). FeOCl was prepared from guaranteed reagent $FeCl_3\cdot 6H_2O$ and $FeCl_3$ by the method based on the report of Schäfer,[5] and confirmed as FeOCl by X-ray analysis.[6] The chemical analysis gave Fe, 52.0; Cl, 32.9% (calcd for FeOCl: Fe, 52.05; Cl, 33.04%). Oxygen was dried by passing it through conc. sulfuric acid and over phosphorus(V) oxide.

The Fe content of the sample was determined by chelatometric titration[7] after dissolving the sample in dilute hydrochloric acid followed by oxidation of Fe^{2+} ion to Fe^{3+} ion with aqueous H_2O_2 solution. The Cl content of the sample was gravimetrically determined as AgCl after dissolving the sample in dilute nitric acid. The chlorine evolved during the reaction was passed through KI solution and determined by iodometry.

X-ray analysis of the sample was performed with an X-ray powder diffractometer, equipped with a proportional counter, using Mn filtered Fe radiation. The sample chamber of the diffractometer was maintained under dry nitrogen atmosphere to prevent the contamination of the sample with moisture in the air during the irradiation.

Thermogravimetry (TG) was performed in an oxygen stream at 50 ml/min. The sensitivity of the quartz helix used was approximately 0.14 mg/0.01 mm. The heating rate was 2.5 °C/min.

Throughout this work, the chlorides and chloride oxide of iron were handled in an argon atmosphere to prevent any contamination with moisture in the air.

Results and Discussion

Reaction Products between $FeCl_2$ and Oxygen. The TG curves of $FeCl_2$ in an oxygen and an argon stream are shown in Fig. 1.

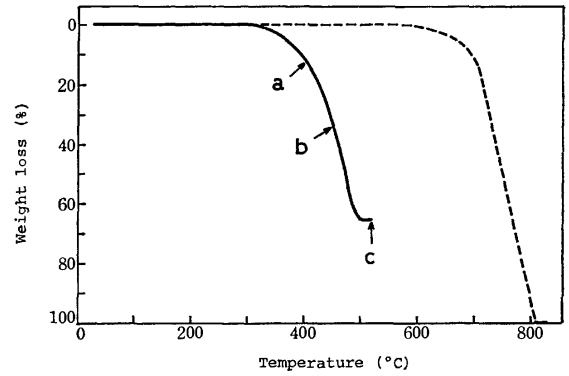

Fig. 1. TG curves of $FeCl_2$ in oxygen and argon streams. —— in O_2, ---- in Ar.

The results showed that $FeCl_2$ reacted with oxygen before vaporizing. The samples heated up to Points a(400 °C), b(450 °C), and c(520 °C) in Fig. 1 were found by X-ray analysis to be a mixture of $FeCl_2$ and FeOCl, a mixture of $FeCl_2$ and α-Fe_2O_3,[8] and α-Fe_2O_3, respectively. It was also observed that the weight loss was accompanied by the evolution of chlorine and gaseous $FeCl_3$.

To obtain more detailed information on the reaction between $FeCl_2$ and oxygen, $FeCl_2$ (4.0 g) in a quartz

Table 1. Reaction products between $FeCl_2$ and oxygen at various temperatures

Temp (°C)	Product: In the boat (%)	Product: Outside the heating zone (%)	Amount of Cl_2 formed (mg)	Unreacted $FeCl_2$ (%)
250	FeOCl (<0.1)	$FeCl_3$ (0.1)	0.1	99.8
280	FeOCl (0.8)	$FeCl_3$ (1.3)	0.9	97.8
300	FeOCl ≫ α-Fe_2O_3 (2.1)	$FeCl_3$ (3.0)	3.1	95.1
320	FeOCl ≫ α-Fe_2O_3 (4.1)	$FeCl_3$ (6.2)	6.6	90.1
350	FeOCl ≫ α-Fe_2O_3 (9.9)	$FeCl_3$ (15.8)	18	75.4

450	α-Fe_2O_3 (23.5)	$FeCl_3$ (77.6), η-Fe_2O_3 ≒ FeOCl (1.2)	190	0

boat (70 mm length, 15 mm width, 7 mm depth) was placed in a straight reaction tube (28 mm i.d., 1000 mm length). Oxygen was introduced into the reaction tube at a flow-rate of 100 ml/min. The sample part was then placed in the centre of an electric furnace (300 mm heating length) maintained at a specified temperature for 2 h. The temperature of the sample part was controlled to within ±2 °C. The temperature of the reaction tube outside the heating zone was below 50 °C.

At 230 °C, no reaction product was observed. The reaction products obtained at various temperatures above 250 °C are summarized in Table 1. The value in parentheses is the weight percentage of the product to the initial $FeCl_2$. The product obtained in the boat was identified by X-ray analysis after dissolving the unreacted $FeCl_2$ in ethyl alcohol. Small amounts of η-Fe_2O_3 and FeOCl formed outside the heating zone above 370 °C in addition to $FeCl_3$ were identified by X-ray analysis[9] after dissolving the $FeCl_3$ in ethyl alcohol.

At 250—280 °C, FeOCl, $FeCl_3$, and a small amount of chlorine were formed as shown in Table 1. Calculations showed that FeOCl and $FeCl_3$ were the main products and that the molar ratio of FeOCl: $FeCl_3$ was approximately 1 : 1. From this result, the formation of FeOCl and $FeCl_3$ was considered to be due to the reaction,

$$2FeCl_2(s) + 1/2O_2(g) \longrightarrow FeOCl(s) + 1/2Fe_2Cl_6(g). \quad (1)$$

It was assumed that the formation of chlorine was due to the reaction,

$$2FeOCl(s) + 1/2O_2(g) \longrightarrow Fe_2O_3(s) + Cl_2(g), \quad (2)$$

from the observation that the FeOCl obtained in the boat contained a small amount of insoluble product after dissolving the FeOCl in 1 M-H_2SO_4.[5,10]

The possible reactions which gave α-Fe_2O_3 in the boat were considered to be Reaction 2 and the thermal decomposition of FeOCl in oxygen,

$$3FeOCl(s) \longrightarrow Fe_2O_3(s) + 1/2Fe_2Cl_6(g).^{10} \quad (3)$$

Above 370 °C, a small amount of η-Fe_2O_3 was obtained outside the heating zone in addition to $FeCl_3$. It appeared that η-Fe_2O_3 was formed by the reaction,

$$Fe_2Cl_6(g) + 3/2O_2(g) \longrightarrow Fe_2O_3(s) + 3Cl_2(g).^{9} \quad (4)$$

Above 420 °C, a small amount of FeOCl was obtained outside the heating zone in addition to $FeCl_3$ and η-Fe_2O_3. The amount of chlorine evolved, shown in Table 1, indicated that Reaction 1 proceeded markedly above about 420 °C to form a large amount of gaseous $FeCl_3$. Consequently, the reaction between gaseous $FeCl_3$ and oxygen has been thought to proceed under a low ratio of oxygen to gaseous $FeCl_3$ to form FeOCl in addition to η-Fe_2O_3.

To clarify the possible reactions occurring between $FeCl_2$ and oxygen, experiments on the reaction processes of gaseous $FeCl_3$ and FeOCl with oxygen were carried out.

Reaction Process between Gaseous $FeCl_3$ and Oxygen. A transparent quartz reaction tube with an inner concentric tube was used. Gaseous $FeCl_3$ was formed by heating $FeCl_3$ placed in the inner tube at 250 °C and carried by a stream of argon (30 ml/min) to the reaction zone of 28 mm i.d. and 250 mm length, held at a specified temperature. The mean flow-rate of gaseous $FeCl_3$ was about 1.5 ml Fe_2Cl_6/min. Oxygen was simultaneously introduced through a separate tube into the reaction zone at a flow-rate of 100 ml/min. The reaction was allowed to proceed for 2 h.

The products were only obtained outside the heating zone and the experimental results are summarized in Table 2.

The vaporization of $FeCl_3$ is accompanied by the decomposition of $FeCl_3$ to $FeCl_2$ and chlorine.[11]

Table 2. Reaction products between gaseous $FeCl_3$ and oxygen at various temperatures

Temp (°C)	Product: Outside the heating zone (g)	Product: Amount of Cl_2 formed (mg)	Unreacted $FeCl_3$ (%)
350	Not detectable	40	100
370	η-Fe_2O_3 0.02	63	99.8
400	η-Fe_2O_3 0.04	99	96.5
450	η-Fe_2O_3 0.12	213	89.7
500	η-Fe_2O_3 0.21	330	82.8
550	η-Fe_2O_3 0.43	621	65.7
600	η-Fe_2O_3 0.83	1156	34.3
650	η-Fe_2O_3 1.11	1521	11.0
700	η-Fe_2O_3 > α-Fe_2O_3 1.25	1710	0

Consequently, the amount of chlorine evolved by heating $FeCl_3$ in the inner tube at 250 °C was examined in the same manner as described above, except that argon was introduced into the reaction zone instead of oxygen at the same flow-rate as that of oxygen. The amount of chlorine evolved was always approximately 40 mg.

The molar ratio of the amount of Fe_2O_3 to the amount of chlorine obtained by subtracting the amount of chlorine evolved by heating $FeCl_3$ in the inner tube from the total amount of chlorine was calculated to be approximately 1 : 3 above 370 °C.

From these results, the reaction between gaseous $FeCl_3$ and oxygen proceeds above about 370 °C according to Reaction 4. The Fe_2O_3 formed was η-Fe_2O_3 at 370—650 °C, and a mixture of η-Fe_2O_3 and α-Fe_2O_3 at 700 °C.

The effect of the molar ratio of $FeCl_3$: O_2 on the reaction product between gaseous $FeCl_3$ and oxygen was examined at 450 °C. The molar ratio was changed by raising the heating temperature of $FeCl_3$. The results are shown in Table 3.

Table 3. Effect of $FeCl_3$: O_2 molar ratio on reaction product between gaseous $FeCl_3$ and oxygen

$FeCl_3$: O_2 (molar ratio)	Product
1 : 33	η-Fe_2O_3
1 : 19	η-$Fe_2O_3 \gg$ FeOCl
1 : 11	η-$Fe_2O_3 >$ FeOCl
1 : 7	FeOCl $> \eta$-Fe_2O_3

This confirms the estimation on the formation of FeOCl obtained outside the heating zone by heating $FeCl_2$ in an oxygen stream above 420 °C, described in the preceding paragraph.

Reaction Process between FeOCl and Oxygen. The products obtained by heating FeOCl (2.0 g) at various temperatures in an oxygen stream were examined in the same manner as described in the previous paragraph.

At 230 °C, no reaction product was observed. The products obtained at various temperatures above 250 °C are shown in Table 4. The product in the boat was identified by X-ray analysis after dissolving the unreacted FeOCl in 1 M-H_2SO_4. Identification of the product in the boat below 300 °C was carried out using 20 g of FeOCl, because of the small amount of the product formed.

The results indicated that the reaction between FeOCl and oxygen proceeded according to Reaction 2 at 250—300 °C. Above 320 °C, $FeCl_3$ was obtained in addition to α-Fe_2O_3 and chlorine. The molar ratio of the amount of $FeCl_3$ to the amount of α-Fe_2O_3 obtained by subtracting the amount of α-Fe_2O_3 formed by Reaction 2 from the total amount of α-Fe_2O_3 was calculated to be approximately 1 : 1. This result indicated that Reaction 3 also occurred besides Reaction 2. It may be considered that the formation of a small amount of η-Fe_2O_3 obtained outside the heating zone in addition to $FeCl_3$ at 400 °C was due to the reaction between gaseous $FeCl_3$ formed by Reaction 3 and oxygen, Reaction 4, from the result described in the preceding paragraph.

From these results, FeOCl reacts with oxygen above about 250 °C according to Reaction 2. Above about 320 °C, Reaction 3 also occurs besides Reaction 2.

Reaction Process between $FeCl_2$ and Oxygen. From the experimental results, the reaction process between $FeCl_2$ and oxygen may be represented as follows: $FeCl_2$ reacts with oxygen above about 250 °C according to Reaction 1. Subsequently, the resulting FeOCl reacts with oxygen according to Reaction 2. Above about 320 °C, the decomposition of the FeOCl also occurs according to Reaction 3. Above about 370 °C, the reaction between gaseous $FeCl_3$, formed by Reactions 1 and 3, and oxygen occurs according to Reaction 4 (under a low ratio of O_2: $FeCl_3$, FeOCl is formed in addition to Fe_2O_3) in addition to the above reactions.

Kinetics and Mechanism of the Oxidation Reaction of Bis(μ-dibutyldithiocarbamato-*S*,*S*′)-digold(I) by Halogens

Hidetoshi KITA, Kazuyuki ITOH, Koji TANAKA, and Toshio TANAKA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received June 2, 1978)

Kinetics of the reaction of bis(μ-dibutyldithiocarbamato-*S*,*S*′)-digold(I), [Au(*n*-Bu_2dtc)]$_2$, with I_2, IBr, and Br_2 in dichloromethane was studied by the stopped-flow technique. A 1 : 1 charge-transfer (CT) complex, [Au(*n*-Bu_2dtc)]$_2$·X_2 (X_2=I_2, IBr, and Br_2), formed in the initial process of reaction was identified spectrophotometrically at −50 °C. The rates of reaction were almost the same for I_2, IBr, and Br_2, and independent of the both [Au(*n*-Bu_2dtc)]$_2$ and halogen concentrations. The reaction has been interpreted to proceed *via* the charge-transfer complex, [Au(*n*-Bu_2dtc)]$_2$·X_2, which decomposes in a rate-determining step to give the final product, [Au^{III}(*n*-Bu_2dtc)$_2$][$Au^{I}X_2$]. The activation parameters for the reactions were determined: ΔH^*(kJ/mol)=43.7 (I_2), 26.0 (IBr), and 12.3 (Br_2); ΔS^*(J/(mol K))=−91.5 (I_2), −156 (IBr), and −201 (Br_2).

Reactions of dithiocarbamato metal complexes with halogens[1-4] are classified into two types; one of them is that the dithiocarbamato ligand is oxidized by halogen to give thiuram disulfide, and the other is the oxidation of the central metal by halogen. The authors previously reported the kinetic studies on the reactions of bis(diethyldithiocarbamato)dimethyltin(IV)[5] and bis(dibutyldithiocarbamato)zinc(II)[6] with iodine in cyclohexane, which belong to the former type of reaction. No kinetic study for the latter type of reaction, however, has been reported so far.

This paper describes a kinetic study on the oxidation reaction of bis(μ-dibutyldithiocarbamato-*S*,*S*′)-digold(I) by iodine, iodine bromide, and bromine in dichloromethane by the stopped-flow method. This reaction is known to give bis(dibutyldithiocarbamato)gold(III) dihalogenoaurate(I).[7,8]

Experimental

Materials. Bis(μ-dibutyldithiocarbamato-*S*,*S*′)-digold(I), [Au(*n*-Bu_2dtc)]$_2$ (*n*-Bu_2dtc=S_2CN(*n*-C_4H_9)$_2$), was prepared by the literature method[9] and recrystallized twice from 1,2-dichloroethane. Found: C, 26.70; H, 4.52; N, 3.29%. Calcd for $C_{18}H_{36}N_2S_4Au_2$: C, 26.93; H, 4.52; N, 3.49%.

Iodine and iodine bromide were purified by sublimation and bromine by distillation prior to use. A dichloroethane solution of Br_2 was standardized by 0.01 N $Na_2S_2O_3$ containing 0.1 M KI using starch as an indicator before use. Dichloromethane used as a solvent was purified in the usual method.[10]

Reactions of [Au(n-Bu_2dtc)]$_2$ with Halogens. A solution of X_2 (X_2=I_2, IBr, and Br_2) (0.5 mmol) in CH_2Cl_2(15 ml) was mixed with [Au(*n*-Bu_2dtc)]$_2$ (0.5 mmol) in CH_2Cl_2(15 ml) at room temperature to give a dark green (I_2 and IBr) or a red (Br_2) solution, followed by rapid decoloration. The solution was evaporated to dryness under reduced pressure. The resulting solid was recrystallized from acetonitrile to afford yellow needles of [Au^{III}(*n*-Bu_2dtc)$_2$][$Au^{I}X_2$] (95% based on the amount of gold). X_2=I_2: mp 135 °C (lit,[8] 135 °C). Found: C, 20.45; H, 3.44; N, 2.57%. Calcd for $C_{18}H_{36}N_2S_4I_2Au_2$: C, 20.46; H, 3.44; N, 2.65%. X_2=IBr: mp 139 °C. Found: C, 21.07; H, 3.49; N, 2.88%. Calcd for $C_{18}H_{36}N_2S_4BrIAu_2$: C, 21.41; H, 3.60; N, 2.78%. X_2=Br_2: mp 143 °C (lit,[8] 143—144 °C). Found: C, 22.31; H, 3.74; N, 2.91%. Calcd for $C_{18}H_{36}N_2S_4Br_2Au_2$: C, 22.46; H, 3.78; N, 2.91%.

The stoichiometry of reaction of [Au(*n*-Bu_2dtc)]$_2$ with halogens is, therefore, expressed as follows:

$$[Au(n\text{-}Bu_2dtc)]_2 + X_2 \longrightarrow [Au(n\text{-}Bu_2dtc)_2][AuX_2].$$

Spectra. Electronic spectra were recorded on a Hitachi 124 (at 25 °C) or a Hitachi 356 (at −50 °C) spectrophotometer, the latter of which was equipped with a glass Dewar. Rapid scanning spectra were measured with a Union RA-1300 stopped-flow rapid scan analyzer.

Kinetic Measurements. Kinetic runs were carried out under the conditions where equimolar amounts of the reactants were used and either one of those was used excessively relative to the other. The rate of reaction was followed by monitoring the absorbance at a fixed wavelength in the electronic spectra of the reaction mixture, using a Union RA-413 stopped-flow spectrophotometer equipped with a 0.2 cm quartz cell in a cell holder thermostated within ±0.2 °C. Absorbance-time data were accumulated at least five times on a Union System-71 data processor and average absorbance-time curves were recorded using a National VP-6421A X-Y recorder. Plots of $\ln|A_t-A_\infty|$ *vs.* time were found to be linear to at least 70% completion, where A_t and A_∞ are absorbances at a given wavelength at a time t and the end of the reaction, respectively. Observed first-order rate constants, k_{obsd}, were obtained by performing the least-squares analysis on the linear region of $\ln|A_t-A_\infty|$ *vs.* time plots.

Results and Discussion

Rapid Scanning Spectra and a Reaction Intermediate. Figure 1 shows a typical example of rapid scanning spectra for the [Au(*n*-Bu_2dtc)]$_2$–I_2 system. Four absorp-

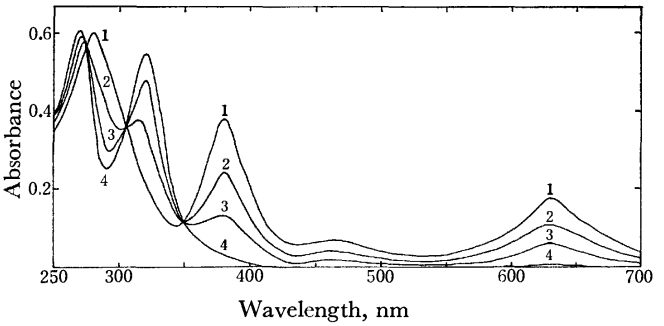

Fig. 1. Rapid scanning spectra of the reaction of [Au(*n*-Bu_2dtc)]$_2$ (2.11×10^{-4} M) with I_2 (2.08×10^{-4} M) in CH_2Cl_2 at 25 °C; scanning speed=150 nm/5 ms, cell length=0.2 cm.
1: 0.08 s, 2: 0.48 s, 3: 1.28 s, 4: the end of reaction.

tion peaks at 280, 380, 460, and 630 nm are observed immediately after mixing of the reactants. These bands are weakened with intensifying of the bands newly appeared at 270 and 320 nm, which are assigned to $[Au(n\text{-}Bu_2dtc)_2][AuI_2]$.[8] Then, isosbestic points are found at 275, 305, and 350 nm. This spectral change clearly indicates the occurrence of a transient species as a reaction intermediate. The transient species has been frozen at −50 °C; when a dichloromethane solution of $[Au(n\text{-}Bu_2dtc)]_2$ was mixed with iodine in the same solvent at −50 °C, the solution immediately displayed green color, which did not disappear over 10 h at this temperature, though a decoloration took place almost instantly above −15 °C. The absorption spectrum at −50 °C was quite similar to that immediately after mixing at 25 °C and the green color can be associated with the 630 nm band. It has been reported that $Au^{II}(Et_2dtc)_2$ exhibits an absorption near 600 nm.[11] No ESR signal has, however, been detected for the green solution obtained here, indicating that the transient species is not $Au^{II}(n\text{-}Bu_2dtc)_2$. By analogy with kinetic studies of the $Me_2Sn(Et_2dtc)_2$-I_2[5] and $Zn(n\text{-}Bu_2dtc)_2$-I_2[6] systems, the 380 nm band can be assigned to the charge-transfer (CT) transition from sulfur of the dithiocarbamato ligand to I_2 and the weak absorption at 460 nm to a blue-shifted band of the iodine moiety of the CT complex. The composition of the CT complex was determined by the mole ratio method in the visible spectrum at −50 °C. Figure 2 shows plots

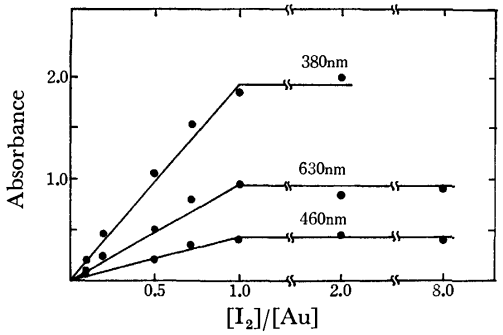

Fig. 2. Mole ratio study of $[Au(n\text{-}Bu_2dtc)]_2$-I_2 system in CH_2Cl_2 at −50 °C; $[Au(n\text{-}Bu_2dtc)]_2 = 5.0\times10^{-5}$ M.

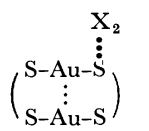
of the absorbance at three different wavelengths against the mole ratio of I_2 to the gold(I) complex, indicating the composition of 1 : 1. It is to be noted that the band characteristic of $[Au(n\text{-}Bu_2dtc)]_2$ underwent only a little shift upon CT complexation (287→280 nm). This fact indicates that the CT complex may retain the parent dimeric structure of $[Au(n\text{-}Bu_2dtc)]_2$. The gold-gold distance in $[Au(n\text{-}Pr_2dtc)]_2$ was reported to be shorter than that in metallic gold,[12] however the valence state of Au(I), $5d^{10}$, predicts the presence of no metal-metal bondings. In spite of this, the fact that



1: $\overset{\frown}{S\ \ S} = S_2CN(n\text{-}Bu)_2$.

$[Au(n\text{-}Bu_2dtc)]_2\cdot I_2$ exhibited the absorption band at 630 nm suggests the CT complex involving the skeleton with a gold-gold interaction shown in **1**. The Au(I)–Au(I) interaction would account for the absorption band at 630 nm observed in the CT complex.

The $[Au(n\text{-}Bu_2dtc)]_2$-IBr and $-Br_2$ systems also exhibited absorption maxima due to the CT transition at 380 nm. No blue-shifted band of halogens has, however, been observed in these systems (Table 1).

Table 1. Electronic spectra of $[Au(n\text{-}Bu_2dtc)]_2$, $[Au(n\text{-}Bu_2dtc)]_2\cdot X_2$, and $[Au(n\text{-}Bu_2dtc)_2]$-$[AuX_2]$ in CH_2Cl_2 at 25 °C

	λ_{max} / nm	ε[a] / $M^{-1}cm^{-1}$
$[Au(n\text{-}Bu_2dtc)]_2$	287	4.0×10^4
$[Au(n\text{-}Bu_2dtc)]_2\cdot X_2$		
$X_2=I_2$	280	b)
	380	(3.9×10^4)
	460	(8.3×10^3)[c]
	630	(1.8×10^4)
IBr	280	b)
	380	
	600	
Br_2	280	
	380	
	560	
$[Au(n\text{-}Bu_2dtc)_2][AuX_2]$		
$X_2=I_2$	270	4.0×10^4
	320	3.9×10^4
IBr	270	3.5×10^4
	320	3.0×10^4
Br_2	270	3.8×10^4
	320	3.1×10^4

a) Values in parentheses were calculated from the visible spectrum at −50 °C. b) Not measured. c) Uncorrected for the contribution from the overlap with the CT band.

This is probably due to the masking of it by the tail of the intense CT band at 380 nm, because of small molar extinction coefficients of IBr and Br_2 compared with that of I_2; $\varepsilon_{486nm}=3.7\times10^2$, $\varepsilon_{406nm}=2.6\times10^2$, and $\varepsilon_{505nm}=9.0\times10^2$ M^{-1} cm^{-1} for IBr, Br_2, and I_2 in CH_2Cl_2, respectively.

Molar extinction coefficients of the absorptions arising from the CT complex were determined from the visible spectra of dichloromethane solutions containing a fixed amount of the gold(I) complex and large excess I_2 or *vice versa* at −50 °C. The result is listed in Table 1 together with the ε values of absorptions due to $[Au(n\text{-}Bu_2dtc)]_2$ and $[Au(n\text{-}Bu_2dtc)_2][AuX_2]$. The ε value of the 380 nm band is very close to those of CT bands of the I_2 complexes with methyl dimethyldithiocarbamate ($\varepsilon_{347nm}=3.0\times10^4$ M^{-1} cm^{-1}) and tetraethylthiuram disulfide ($\varepsilon_{356nm}=3.8\times10^4$ M^{-1} cm^{-1}).[13] On the other hand, the value of the blue-shifted band of iodine (460 nm) is larger than those of other known iodine complexes ($\varepsilon_{max}=(2.7—4.2)\times10^3$ M^{-1} cm^{-1}).[13-17] This is due to an overlapping of this band with the tail of the CT band.

TABLE 2. OBSERVED RATE CONSTANTS FOR THE REACTION OF $[Au(n\text{-}Bu_2dtc)]_2$ WITH I_2 IN CH_2Cl_2 AT 25 °C

$\frac{I_2}{M}$	$\frac{[Au(n\text{-}Bu_2dtc)]_2}{M}$	$\frac{k_{obsd}}{s^{-1}}$

Kinetics and Mechanism. The rate of reaction was determined by following the decomposition of $[Au(n\text{-}Bu_2dtc)]_2\cdot X_2$ and the formation of $[Au(n\text{-}Bu_2dtc)_2][AuX_2]$. Observed first-order rate constants, k_{obsd}, obtained from the decay of three band maxima of the CT complex and the rise of a band maximum of the product for the reaction of $[Au(n\text{-}Bu_2dtc)]_2$ with I_2 in CH_2Cl_2 at 25 °C are listed in Table 2, which indicates that the k_{obsd} values obtained from the different wavelengths are consistent with one another within experimental error. They are also essentially the same in various concentrations and varying mole ratios of the reactants, indicating that the reaction is independent of both concentrations of $[Au(n\text{-}Bu_2dtc)]_2$ and I_2 in the measured range. Similar kinetic results were obtained in the $[Au(n\text{-}Bu_2dtc)]_2$–IBr and $-Br_2$ systems. It is therefore suggested that the reaction of $[Au(n\text{-}Bu_2dtc)]_2$ with halogens proceeds *via* a CT complex, which decomposes to give the final product as follows:

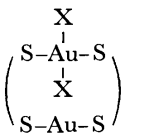
$$[Au(n\text{-}Bu_2dtc)]_2 + X_2 \xrightarrow{\text{fast}} [Au(n\text{-}Bu_2dtc)]_2\cdot X_2 \downarrow k \rightarrow [Au(n\text{-}Bu_2dtc)_2][AuX_2],$$

where k is equal to k_{obsd}. According to this scheme, the rate law can be written as

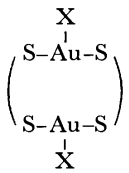
$$\frac{d[[Au(n\text{-}Bu_2dtc)_2][AuX_2]]}{dt} = -\frac{d[[Au(n\text{-}Bu_2dtc)]_2\cdot X_2]}{dt} = k[[Au(n\text{-}Bu_2dtc)]_2\cdot X_2].$$

Rate constants and activation parameters obtained from the Eyring plots of $\ln(k/T)$ against $1/T$ are summarized in Table 3.

Although there is no direct evidence for another transient species, at least two possible intermediates,

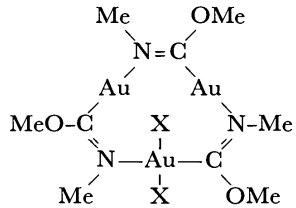


2

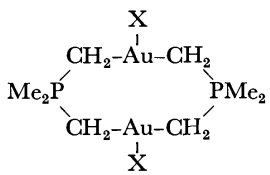


3

2 and **3**, can be envisaged in the decomposition pathway. Intermediate **2** which is a mixed valence gold(III)–gold(I) complex may be formed by the attack of iodine at a single gold atom. Alternatively, the simultaneous attack of iodine at both gold atoms will afford the gold(II) complex, **3**. The existence of both **2** and **3** may be supported from the fact that analogous gold complexes, **4** and **5**, were isolated in the oxidation



4



5

reactions of trimeric[18] and dimeric[19] gold(I) complexes with halogen, respectively. Of the two possible inter-

a) Errors quoted are standard deviations.

mediates, however, **2** is more appealing since it requires a less reorganization of atoms, followed by reductive elimination at the gold(III) center to afford the final product, $[Au(n\text{-}Bu_2dtc)_2][AuX_2]$.

Crystal Structure and Absolute Configuration of (+)$_{546}$-*cis*(*O*)-Triammine(sarcosinate-*N*-propionato)cobalt(III) (+)$_{546}$-(Ethylenediaminetetraacetato)cobaltate(III) Monohydrate

(Received June 8, 1978)

The crystal structure of (+)$_{546}$-*cis*(*O*)-triammine(sarcosinate-*N*-propionato)cobalt(III) (+)$_{546}$-(ethylenediaminetetraacetato)cobaltate(III) monohydrate was solved by single crystal X-ray diffraction techniques. The crystal is orthorhombic, space group $P2_12_12_1$, with $a=10.792$, $b=26.816$, $c=8.203$ Å, and $Z=4$. The final R value was 0.054. The absolute configurations of two complex ions were determined by means of anomalous dispersion using Cu $K\alpha$ radiation. The coordinated asymmetric nitrogen atom of sarcosinate-*N*-propionate ligand takes an *R* configuration, and the (+)$_{546}$-(ethylenediaminetetraacetato)cobaltate(III) ion Δ one.

Sarcosinate-*N*-propionate ($sarmp^{2-}$) forms a five- and six-membered chelate ring by coordination of an α-amino carboxylate foot and an *N*-propionate one, respectively. *cis*(*O*)-Triammine(sarcosinate-*N*-propionato)cobalt(III) cation is a model complex, which contains only one asymmetrically coordinated nitrogen atom, and was optically resolved through its diastereomeric salt formation with (+)$_{546}$-(ethylenediaminetetraacetato)-cobaltate(III) anion, $[Co(edta)]^-$.[1] The absolute configuration of (+)$_{546}$-*cis*(*O*) isomer was presumed to be an *R* one from the consideration of its CD spectra, referring to the stereochemistry of several kinds of analogous complexes.[1-4]

This paper deals with the crystal structure of the diastereomeric salt, and the absolute configurations of (+)$_{546}$-*cis*(*O*)-$[Co(sarmp)(NH_3)_3]^+$ and (+)$_{546}$-$[Co(edta)]^-$ ions are established concurrently. A preliminary report has been presented.[5]

Experimental

Preparation of the Crystals. The diastereomer (+)$_{546}$-*cis*(*O*)-$[Co(sarmp)(NH_3)_3]\cdot$(+)$_{546}$-$[Co(edta)]\cdot H_2O$ was isolated first in the course of the study on the stereochemistry of cobalt(III) complexes with *O*,*N*,*O*-tridentate ligand.[1] Silver acetate (0.30 g) was added to a solution of 0.54 g of racemic $[Co(sarmp)(NH_3)_3]Cl$ in a small amount of water and the resulting silver chloride was filtered off. The filtrate was added to a solution of 0.375 g of (+)$_{546}$-$K[Co(edta)]\cdot 2H_2O$[6] in a minimum amount of water. After the mixed solution had been evaporated by a stream of air at room temperature, the concentrated solution was kept in a refrigerator. The violet needle crystals crystallized out as less soluble diastereomer were collected by filtration. The optically active chloride (+)$_{546}$-*cis*(*O*)-$[Co(sarmp)(NH_3)_3]Cl$ obtained from the diastereomer showed $\Delta\varepsilon_{346}=+0.35$.

Crystal Data. Preliminary Weissenberg and oscillation photographs established the fact that the crystals are orthorhombic with b axis along the needle axis. The systematic extinction restricts the space group to $P2_12_12_1$. The crystal data are listed in Table 1.

Data Collection. The intensity data were collected on a Rigaku Denki Computer-controlled four-circle diffractometer employing Mo $K\alpha$ radiation. A single crystal of size *ca.* 0.45 $\times$0.31$\times$0.41 mm was used for the intensity measurement of 2440 independent non-zero reflections. The ω-2θ scan technique was employed with a scan speed 2° min^{-1} by ω, and the background was measured for each 10.0 seconds at the start and end points of a scan range. A scan range of ω for each reflection was calculated by the formula $\Delta\omega=0.08°+0.35°\tan\theta$. Attenuators were automatically inserted when the maximum counting rate exceeded 9000 cps. The measurement of two reference reflections (0 0 2) and (0 10 0) was repeated every thirty reflections.

Table 1. Crystal data

$Co_2C_{16}H_{32}N_6O_{13}$	$M_r=634.33$	
Orthorhombic	$P2_12_12_1$	
$a=10.792(9)$Å	$b=26.816(4)$Å	$c=8.203(12)$Å
$\alpha=90.0°$	$\beta=90.0°$	$\gamma=90.0°$
$D_{calcd}=1.775$ g cm^{-3}		$Z=4$.
$D_{obsd}=1.766$ g cm^{-3} (by flotation)		

For the determination of absolute configurations of both complex ions, the intensities of pairs of reflections, *hkl* and $\bar{h}\bar{k}\bar{l}$, were measured by use of Cu $K\alpha$ radiation.

Structure Determination and Refinement. The structure was solved by the usual heavy-atom method. The positions of two cobalt atoms were determined by means of the Patterson synthesis, and all the non-hydrogen atoms were located by the subsequent Fourier synthesis. The trial structure was refined by a diagonal least-squares procedure with the positional and isotropic thermal parameters. The atomic scattering factors were taken from International Tables for X-ray Crystallography.[7] Further refinement was carried out by the least-squares method of a block-diagonal matrix approximation with the positional and anisotropic thermal parameters for all the non-hydrogen atoms (a program by Dr. T. Ashida was used). After several cycles of refinement, the R value ($R=\sum||F_o|-|F_c||/\sum|F_o|$) decreased to 0.054.

The final parameters of all atoms (except hydrogen atoms) are listed in Table 2. These positional parameters are normal within the estimated standard deviations: 0.0011 and 0.0015 Å for cobalts, 0.006—0.009 Å for oxygens, 0.008—0.010 Å for nitrogens, and 0.009—0.013 Å for carbons. Table 3 containing the observed and calculated structure factors is kept as Document No. 7841 at the Chemical Society of Japan.

Results and Discussion

Description of the Structure. The numbering schemes

within the $[Co(sarmp)(NH_3)_3]^+$ ion are given in Tables 4 and 5. In the complex cation, the sarcosinate-*N*-propionate tridentate ligand coordinates facially giving a *cis*(*O*) configuration of the CoN_4O_2 octahedron. It is interesting that the bond length from cobalt to the coordinated nitrogen atom of this ligand, 2.013 Å, is the longest of all the Co–N bonds; the other three Co–NH_3 bonds are in the range 1.968—1.987 Å. Furthermore, this Co–N bond is significantly longer than that of an analogous *O*,*N*,*O*-tridentate ligand, iminodiacetate, which makes two five-membered chelate rings.[8] The bond lengths and angles in the six-membered chelate ring differ markedly from those in the five-membered chelate ring. This is in line with the tendency known for several α- and β-amino carboxylato complexes.[9–11] Though the bond lengths and angles of the five-membered chelate ring are similar to those of simple α-amino carboxylato or *O*,*N*,*O*-tridentato complexes, the bond angles of the six-membered chelate ring differ significantly from those

of simple β-amino carboxylato complexes: *e.g.*, <O6–Co1–N6=96.1° (90° for $[Co^{II}(\beta\text{-alaninato})_2(H_2O)_2]$,[10] and 93.4° for *trans*-dinitro(β-alaninato)(1,3-propanediamine)cobalt(III),[11] <Co1–N6–C12=110.6° (115 and 116.2°, *vide ante*), and <N6–C12–C16=115.4° (111 and 113°, *vide ante*).

The bond lengths and angles within the $[Co(edta)]^-$ ion (Tables 6 and 7) agree well with the data for ammonium and rubidium salts.[12]

The oxygen atom O11 of the water molecule seems to have four nearest neighbor atoms, N5, O2, O5, and O10 (Fig. 3). Several hydrogen bonds are recognized between the complex ions; *e.g.*, N5–O13, N5–O12, N1–O12, and so on.

Absolute Configuration. The absolute configuration was determined by anomalous dispersion. The atomic scattering factors were taken from literature;[7] those of cobalt atoms were collected for real and imaginary parts of anomalous dispersion: $\Delta f' = -2.2$ and $\Delta f'' = 3.8$.

The intensities of the reflections, $|F_c(hkl)|$ and $|F_c(\bar{h}\bar{k}\bar{l})|$, were calculated by use of both sets of atomic parameter values given in Table 2, (X, Y, Z) and $(X, -Y, Z)$. The values calculated by $(X, -Y, Z)$ fit the observation satisfactorily (Table 8). Thus, it is confirmed that the nitrogen atom of the tridentate ligand takes *R* configuration in the $(+)_{546}$-*cis*(*O*)-[Co(sarmp)$(NH_3)_3$]$^+$ ion, which is in line with the assignment from its CD spectra.[1] This shows that the nitrogen atom has the same absolute configuration as the stereospecifically coordinated *R* nitrogen atom of *cis*(*O*)-*R*-triammine(L-prolinate-*N*-propionato)cobalt(III) ion. On the other hand, the absolute configuration of $(+)_{546}$-$[Co(edta)]^-$ ion can be designated as *Δ*. The complex ion has been assigned to this configuration from a comparison of its ORD[13] and CD[9] spectra with those of *Δ*-$(+)_{546}$-(*R*-propylenediaminetetraacetato)-cobaltate(III) formed stereospecifically.

Conformation of the Chelate Rings. In order to examine the conformation of chelate rings, the displacements of relevant atoms from the chelate ring plane, which is defined by the central cobalt atom and the two coordinating atoms in the chelate ring, were calculated. The results are given in Table 9. It is concluded that the six-membered chelate ring in the cation has an asymmetric skew-boat form with *δ* conformation taking C13 and C16 on the same side of the O6–Co–N6 plane. This type of conformation has been recognized in a few cobalt(III) complexes with β-alaninate.[11,14] The five-membered chelate ring in the present complex cation has an asymmetric envelope form with *λ* conformation.

The diamine chelate ring in the anion has an asymmetric gauche form with *λ* conformation. This is in line with the case of diamines such as ethylenediamine.[9] One of the two out-of-plane glycinate chelate rings has a strained asymmetric envelope form with *λ* conformation, and the other *δ* one. Both of the in-plane glycinate chelate rings have an asymmetric envelope form with *δ* conformation.

Resonance Energies of Nonbenzenoid Hydrocarbons†

Jun-ichi AIHARA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received October 21, 1977)

Resonance energies of 30 conjugated hydrocarbons and their molecular ions have been calculated on the basis of the graph-theoretical theory of aromaticity. No difficulty was found in extending the aromaticity theory to ionic conjugated species. In general, the resonance energies obtained correlated well with typical chemical features of the compounds.

The chemistry of nonbenzenoid hydrocarbons has occupied the interest of many organic chemists to an increasing extent. The synthetic accessibility of a number of nonbenzenoid hydrocarbons has given rise to a new field of organic chemistry.[1,2] In parallel with this, a theoretical understanding of their electronic structures, centered on their aromaticity, has been attempted in a variety of sophisticated manners.[3]

The classical concept of aromaticity, based primarily upon the Hückel (4n+2) rule, has been adequately applied to benzenoid hydrocarbons.[4] However, it appears less effective in predicting aromaticities of nonbenzenoid hydrocarbons.[4] Recently, the classical concept of aromaticity has been replaced by a graph-theoretical theory of aromaticity.[5–8] This theory has proven quite suitable for describing aromaticities of nonbenzenoid hydrocarbons as well as those of the other kinds of conjugated compounds.[5] There has been a qualitative idea that aromatic compounds should be unusually stable.[9] In this paper, I would like to further examine the stabilities of typical nonbenzenoid hydrocarbons by means of the graph-theoretical theory of aromaticity.

Results and Discussion

Resonance energies of 30 conjugated hydrocarbons **1**—**30** and their molecular ions have been calculated. They are mostly non-alternant pyrene-like compounds of synthetic importance. For the other types of nonbenzenoid hydrocarbons, see Ref. 5. The method used for calculating resonance energies is the graph-theoretical one previously presented by the author.[5,8] The HMO theory used is the simplest one. Resonance energies obtained are all listed in Table 1. As shown in this table, a comparative study is made for the neutral and ionic species with an even number of π-electrons. Conjugated hydrocarbons with an even number of π-electrons have been of prime interest to synthetic organic chemists.[1,2] Free radicals are hence omitted from consideration. In fact, it is not easy to rationalize their stability in terms of an HMO model.

Pyrene-like tetracycles constitute the most attractive group of non-alternant hydrocarbons. It is interesting to see how these compounds are like or unlike the parent compound pyrene (**1**). Figure 1 shows the relative resonance energies of pyrene and its eight isomers (**2**—**9**) with the same formula of $C_{16}H_{10}$. First of all, pyrene (**1**) is quite a stable compound. Its resonance energy is almost twice as large as that of benzene (0.273β).[5] Most compounds cited in Fig. 1 have the largest resonance energy in the neutral 16-π-electronic state. They are Compounds **2**, **3**, **4**, **6**, **7**, and **8**. Stabilities of these compounds can roughly be justified by the fact that they have so far been synthesized.[10–15] One should here note that in general the easiness of synthesis is one of the most realistic measures of stability (or aromaticity) of a conjugated compound.[9,16]

Compound **5** has not been prepared yet. For this

† Presented at the Symposium on Molecular Structures, Sapporo, Japan, August 1977.

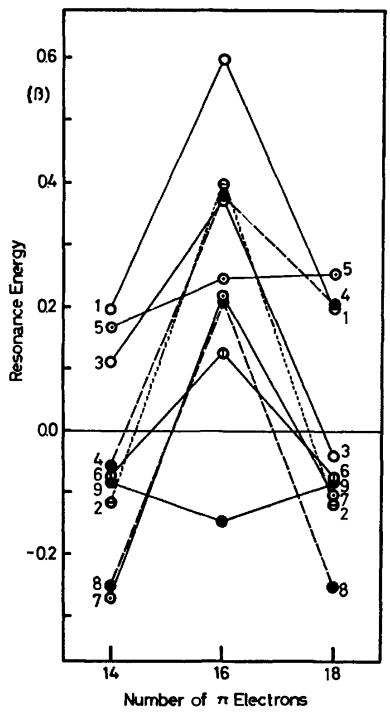

Fig. 1. Resonance energies of pyrene and its structural isomers.

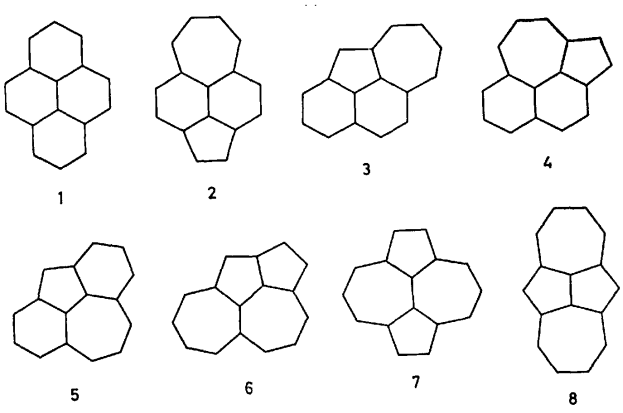

compound, the resonance energy of the neutral species is not so large and is comparable to that of the dianion. Such a situation may be less favorable to the exclusive existence of either species. Aromaticity of this compound may be depicted by means of a perimeter model,[17] since a central double bond in the canonical structure is fixed there. The resonance energy of Compound **6** is small even in the neutral state. This compound appears to gain additional stability by locally introducing bond alternation.[18] The resulting system is an azulene conjugated with a triene unit. The resonance energy is comparable to that of azulene (0.151 β).[5]

An alternant isomer of pyrene (**9**) is antiaromatic because of its negative resonance energy. This compound, however, has been synthesized by Wilcox *et al.*,[19] but the NMR spectrum shows it to be paratropic, in accord with the resonance energy. Compound **10** is essentially nonaromatic, since a conjugated system of Compound **9** is stabilized by the third benzene ring. It has also been synthesized by Wilcox *et al.*[20]

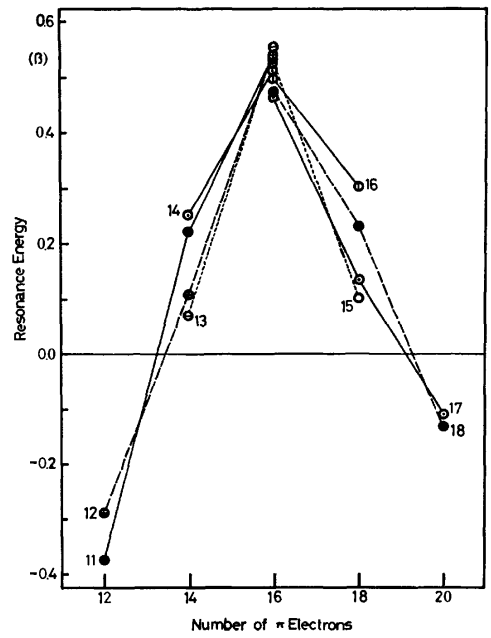

Fig. 2. Resonance energies of pyrene-like hydrocarbons.

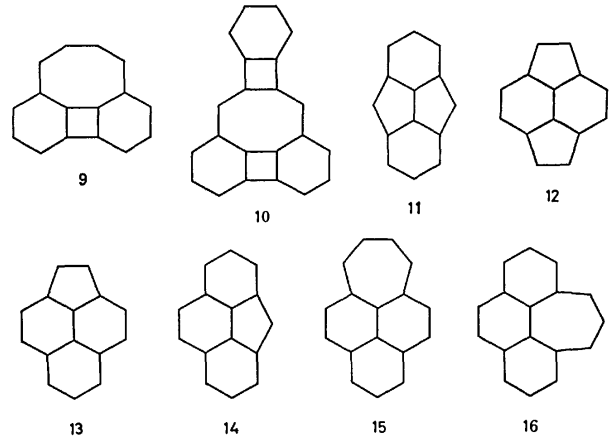
Next, let us consider the aromaticities of eight conjugated hydrocarbons which are iso-π-electronic with pyrene (**1**); these are necessarily ionic species. The resonance energies are compared with each other in Fig. 2. One may notice at once that each of these compounds has the largest resonance energy when it has 16 π-electrons. Furthermore, it is noteworthy that the resonance energies of these 16-π-electronic species lie within a relatively narrow energy range of 0.46—0.56 β.

Compound **11** in its neutral state has not been prepared yet, although its dianion has been prepared by Trost *et al.*[21] This fact is quite consistent with the resonance energy of the dianion, which is twice as large as that of the neutral species. Compound **12** has also been prepared by Trost *et al.*[22] Its half-wave reduction potential is anomalously low, suggesting that this compound is not obviously aromatic. It readily reacts with butyllithium to form a dianion.[23] These aspects of the compound suggest reasons for the increased resonance energy of the dianion.

The anion of Compound **13** has been prepared by



Murata *et al.*[24] The NMR spectrum indicates that the charge is delocalized over the entire conjugated system. This result is in marked contrast to the anion of Compound **14**, which has been prepared by Cox *et al.*,[25] in that the latter ion appears from an NMR viewpoint to be a phenanthrene derivative. The two anions likewise have resonance energies as large as pyrene (**1**). The cationic species of these compounds have not been prepared. Cationic species of Compounds **15** and **16** have so far been synthesized by Murata *et al.*[26,27] It should be stressed that the synthetic accessibility thus correlates very well with the large resonance energies. Two compounds (**17** and **18**) have not been prepared, nor have their ions.

The methyl derivative of Compound **19** has been prepared by Hafner *et al.*[28] It is thermally unstable, protonates easily, and has a relatively high-field proton. These facts evidently reflect the olefinic character shown by the small resonance energy. A mononegative anion of Compound **20** has been synthesized by Wilner and Ravinovitz.[29] The positive resonance energy is again in line with its synthesis.

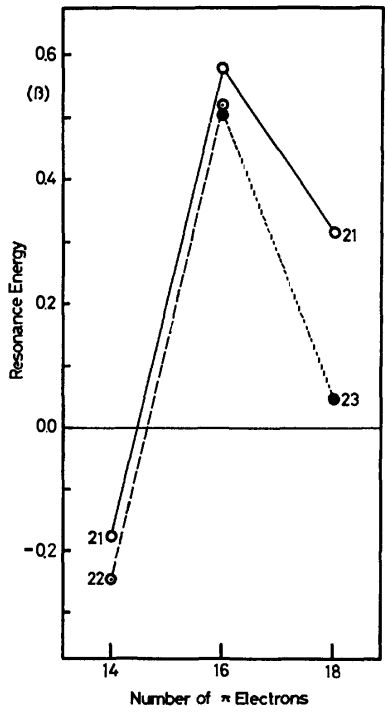


Fig. 3. Resonance energies of fluoranthene-like hydrocarbons.

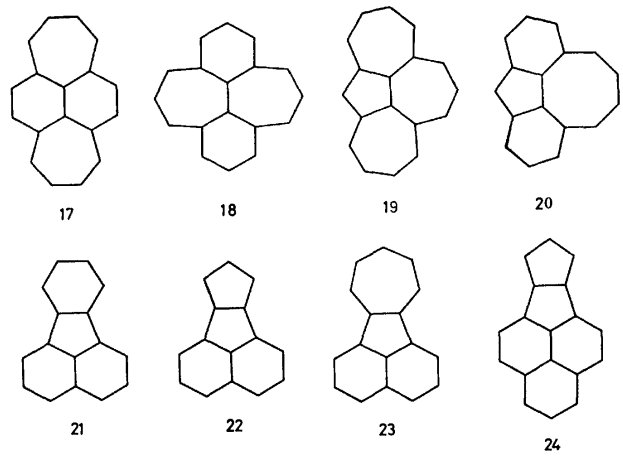
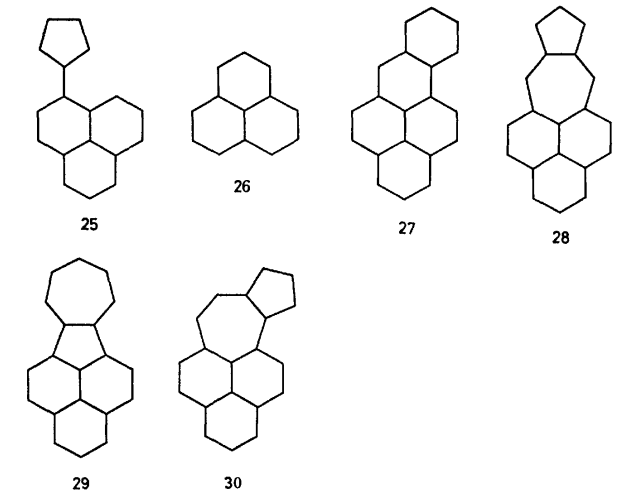
Fluoranthene (**21**) is a structural isomer of pyrene (**1**). It is a stable nonbenzenoid hydrocarbon composed of two benzenoid units. The two iso-π-electronic species **22** and **23** have been synthesized by Murata and his coworkers.[30,31] In each of the 16-π-electronic ions, the charge is delocalized over the entire conjugated system. As shown in Fig. 3, these compounds likewise have the largest resonance energy in the 16-π-electronic state.

Derivatives of Compounds **24** and **25** have been prepared in their neutral state.[32,33] Every proton NMR signal of Compound **25** exhibits a downfield shift of 1—2 ppm compared with the corresponding signal of



Compound **24**. This trend is in parallel with the order of magnitude of their resonance energies. In relation to these compounds, phenalene (**26**) is remakable in that it gives rise to a relatively stable anion and cation.[34] These mononegative and monopositive ions have the same resonance energies, which are seemingly large enough to justify the stability.



Compounds **28**—**30** are a set of benzo[*a*]pyrene isomers, benzo[*a*]pyrene (**27**) being famous for its carcinogenicity. Benzo[*a*]pyrene is stable in our chemical sense. All the isomers considered here have been prepared.[2,35,36] Our resonance energies predict these isomers to be fairly stable in the neutral state, in accord with their chemical properties.[2] Figure 4 shows this aspect of the benzo[*a*]pyrene isomers.

As has been seen above, our definition of resonance energy has proven very effective in predicting the stability of a non-alternant hydrocarbon with or without electric charges. This supports a view that the same approach can be used for designing novel conjugated systems. For example, appropriate attempts to prepare dications of Compounds **17** and **18** are quite promising because of their large resonance energies.

It goes without saying that some other effects must be considered at the same time when one attempts to design a new conjugated system. The strain of a molecular framework is of course a destabilizing factor. When

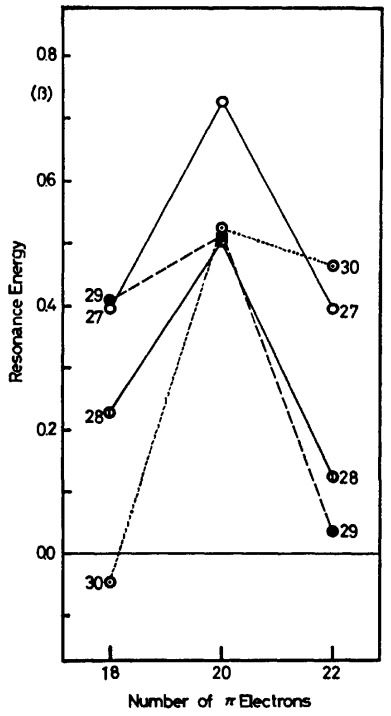


Fig. 4. Resonance energies of benzo[*a*]pyrene and its structural isomers.

a conjugated system is polycyclic, the resonance energy distribution is non-uniform in the system.[7] This may diversify the reactivity of the conjugated system. The least aromatic sites in the compound might be preferentially attacked by reagents even if the entire conjugated system has a large resonance energy.

The use of facilities of the Hokkaido University Computing Center is gratefully acknowledged. This work was motivated by a comprehensive review of Profs. I. Murata and K. Yamamoto on the condensed polycyclic conjugated systems (Ref. 2).

8) The definition of resonance energy presented in a recent paper [J. Aihara, *Bull. Chem. Soc. Jpn.*, **50**, 2010 (1977)] is not used here because the original definition proposed in Ref. 5 always appears most suitable for describing stability of a conjugated system. Note that the reference energy in Ref 5 defines the lowest energy of the reference structure. For all the conjugated hydrocarbons investigated here, however, both definitions of resonance energy give the same results. In such a case, the overrall resonance energy can be assigned to every occupied π-molecular orbital on the basis of the 1977 definition of resonance energy.

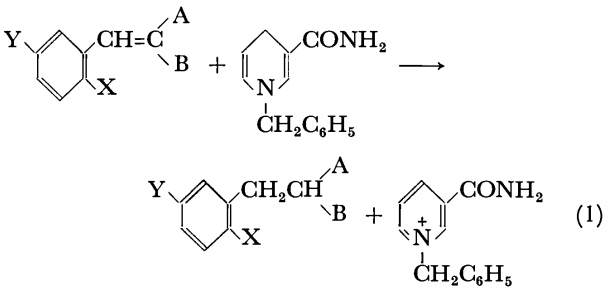
(Received December 17, 1978)

Nonenzymatic dihydronicotinamide reduction of carbon-carbon double bonds occurs with the aid of Mg^{2+} ion or acetic acid. The role of Mg^{2+} ion and acetic acid is discussed on the basis of spectral studies, kinetic measurements, and product analyses. The addition of Mg^{2+} ion caused the shift of the NMR peak of substrate α-proton to lower field, and the magnitude was parallel to the yield of reduced methylene derivatives. Kinetic studies suggested that the dihydronicotinamide reduction in the presence of Mg^{2+} ion is most reasonably understood by assuming a competitive complexation of dihydronicotinamide and substrate with Mg^{2+} ion. On the other hand, acetic acid aids the reduction by means of general acid catalysis, but an alternative mechanism is suggested for the reduction of benzylidenemalononitrile.

It has been established that the metal ion and the ortho hydroxyl group greatly assist the nonenzymatic dihydronicotinamide reduction of >C=O, >C=S, and >C=N double bonds.[1-3] The findings in nonenzymatic systems are considerably important in connection with the fact that most of NADH dependent enzymes employ metal ion (*e.g.*, Zn^{2+} ion) and/or Brönsted acid (*e.g.*, imidazolium ion) in the active sites.[4,5] From the mechanistic point of view, however, the reductions of these double bonds seem somewhat complicated because of (i) the possible interaction of substrates with the metal ion or the ortho hydroxyl group both in the initial state and in the transition state[6,7] and (ii) the equilibrium of substrate hydration which is catalyzed by acid and base.[8,9] In this respect, C=C double bonds are convenient substrates to assess the influence of added metal ions and Brönsted acids, since they are not subjected to hydration equilibria[10] and interact very weakly with added acids.[11]

We selected several styrene derivatives (Table 1) and performed the reduction by *N*-benzyl-1,4-dihydronicotinamide (BzlNicH) in a few solvents. The results are discussed on the bases of spectral studies, kinetic measurements, and product analyses.



Experimental

Materials. The following styrene derivatives were prepared according to the literature and identified by spectroscopic (NMR and IR) methods and elemental analysis: benzylidenemalononitrile (**1**), mp 83—85 °C (lit,[12] 87 °C); β-nitrostyrene (**2**), mp 57—59 °C (lit,[13] 58—59 °C); diethyl benzylidenemalonate (**3**), bp 132—133 °C/2 mmHg (lit,[14] 160—163 °C/7 mmHg); isopropylidene benzylidenemalonate (**4**), mp 80—84 °C (lit,[15] 80—84 °C); 3,β-dinitrostyrene (**2NO$_2$**), mp 122—124 °C (lit,[16] 125 °C). 2-Hydroxy-β-nitrostyrene (**2OH**) was prepared from nitromethane and salicylaldehyde according to the method of Gairand and Lappin.[13] The product is a mixture of yellow solid and black oil. The mixture was heated to 60—70 °C on a steam bath, and the oily layer was decanted. Recrytallization of the residual yellow solid from methanol and water gave yellow needles, mp 130—133 °C. IR: ν_{OH} 3460 cm^{-1}, $\nu_{C=C}$ 1620 cm^{-1}, nitro group 1330 cm^{-1}. Found: C, 58.06; H, 4.31; N, 8.46%. Calcd for $C_8H_7NO_3$: C, 58.17; H, 4.28; N, 8.48%. The preparation of *N*-benzyl-1,4-dihydronicotinamide (BzlNicH) was described.[17]

Product Analyses. 1.0 mmol of a substrate and 1.2 mmol of BzlNicH were dissolved in 10 ml of dry solvent (acetonitrile or methanol), and the solution was gently refluxed in the dark for 2 h. The reaction was also carried out in the presence of acid (1.4 mmol $Mg(ClO_4)_2$ or 1.0 M acetic acid). In order to evaluate the relative reactivity of substrates, the reaction period was unified in 2 h. The solvent was evaporated at room temperature *in vacuo*, the residue being extracted with aqueous HCl (0.1 M) and chloroform. The chloroform layer was separated, dried over Na_2SO_4, and evaporated to dryness. The sample thus obtained was subjected to the NMR analysis (JEOL JNM-MH-100; solvent, Me_2SO-d_6 or $CDCl_3$). The reduced compounds provided doublet (for **1** and **3**) or triplet (**2**, **2OH**, and **2NO$_2$**) peaks at around 3.3 ppm which are characteristic of product α-methylenes. The yield of the reduced products was determined from integral intensity of the peaks with acetone oxime as internal standard. The reaction was repeated two to four times and the average value is recorded in Table 2. The solid product from **1** was recrystallized from ethanol, which gave benzylmalononitrile in 42% yield; mp 88—91 °C (lit,[18] 87 °C).

In the presence of acetic acid, the yield of the reduced product was not improved largely by elongation of the reaction period. For example, the reaction with **2** in methanol–acetic acid (1.0 M) for 24 h gave corresponding reduced product in 26% yield. This is probably due to the competing decomposition of BzlNicH.

The analysis of by-products was carried out mainly by the mass spectroscopic method. Black, viscous oil recovered from the reaction of BzlNicH and **2** in acetonitrile gave a M^+ peak at 306. If the dimer of **2**, $(C_6H_5C_2H_3NO_2)_2$, is formed, the M^+ peak is expected at 300. The reaction of BzlNicH and **4** in acetonitrile resulted in reddish-yellow solid, and the peak of the dimer (462 for $[C_6H_5C_2H_2(COO)_2C(CH_3)_2]_2$) could not be found in the mass spectrum. These results indicate that the dimer is not contained in the recovered solid. Since the

IR spectrum of the oily product from **2** showed strong absorptions due to nitro group, the nitro group of **2** is not reduced by BzlNicH under the present reaction conditions. Further investigation of the by-products is now continued in our laboratory.

Kinetics. The kinetic measurements were carried out at 30 °C in dry acetonitrile or ethanol. The progress of the reaction was followed spectrophotometrically by monitoring the decrease in the absorption of BzlNicH at 380 nm. Since excess substrate was used in all the cases, the pseudo first-order behavior was observed except in the presence of acetic acid. The rate of disappearance of BzlNicH(v_{obsd}) in the presence of acetic acid (AcOH) is described by

$$v_{obsd} = -\frac{[\text{BzlNicH}]}{dt} = v_r + k_d[\text{BzlNicH}][\text{AcOH}], \quad (2)$$

where k_d is the second-order rate constant for acid-catalyzed decomposition of BzlNicH and v_r is the disappearance rate of BzlNicH other than the acid-catalyzed decomposition. The k_d term was separately evaluated in the absence of substrate, and v_r was determined by substracting this value from v_{obsd}. The detail of the method has been described.[20]

Results and Discussion

Substituent Effect. The BzlNicH reduction of six styrene derivatives was carried out in acetonitrile or in methanol, and the yield of the reduced product was estimated by the NMR method (Table 2: for the detail of the method, see Experimental). The reaction rates were estimated from disappearance of the UV absorption band of BzlNicH at 30 °C, and the apparent second-order rate constants ($k_r = k_{obsd}$ (pseudo first-order rate constants)/[substrate]) are summarized in Table 3.

Table 1. Structure of substrates

Abbreviation	A	B	X	Y
1	CN	CN	H	H
2	NO_2	H	H	H
3	$COOC_2H_5$	$COOC_2H_5$	H	H
4[a]				
2OH	NO_2	H	OH	H
2NO$_2$	NO_2	H	H	NO_2

a) **4**, $C_6H_5CH{=}C(COO)(COO)C(CH_3)_2$.

Table 3. Apparent second-order rate constants ($k_r \times 10^2$, $M^{-1}s^{-1}$) for the BzlNicH reduction and third-order rate constants ($k_{AcOH} \times 10^2$, $M^{-2}s^{-1}$) for added acetic acid[a]

Substrate	CH_3CN		C_2H_5OH	
	k_r	k_{AcOH}	k_r	k_{AcOH}
1	3.8	0	6.3	0
2	0.5	22.3	0	6.3
2OH	16.7		23.3	
2NO$_2$	6.0	18.3	0.5	2.7

a) 30° C, pH 8.5, μ=0.02 with KCl, [BzlNicH]=1.00×10^{-4} M, [substrate]=5.00×10^{-3} M.

As shown in Table 2, the reduction of **1** in methanol gave the corresponding reduced products in 10% yield. On the other hand, **2** was not reduced by BzlNicH under the similar reaction conditions. Base on the σ° value,[21] the C=C double bond of **1** is presumed to be more electron-deficient than that of **2** ($2\sigma^\circ_{CN}=1.12$, $\sigma^\circ_{NO_2}=0.63$), and is more sensitive to BzlNicH reduction. The electron-withdrawing group on benzene ring (*e.g.*, **2NO$_2$**) also enhanced the yield. Evidently, the BzlNicH reduction without the aid of acids is limited to very electron-deficient C=C double bonds.

Interestingly, **1** is not reduced in acetonitrile (Table 2). The result may be rationalized based on the proposition by van Eikeren and Grier[22] that protic media greatly lower the free energy of activation for the dihydronicotinamide reduction of carbonyl compounds: in the present system, for example, solvent alcohol may provide a means of stabilizing the developing negative charge on the substrate β-carbon in the transition state through hydrogen bonding. However, **3** ($2\sigma^\circ_{COOEt}=0.60$), a less electron-deficient olefin is reduced in acetonitrile in 10% yield. Therefore, it is difficult to provide a consistent elucidation on the yield based on the proposition of van Eikeren and Grier.[22]

Here, it is worth mentioning that the disappearance rate of BzlNicH in the presence of **1** in acetonitrile is almost comparable with that in ethanol, despite the difference in the yield. Since the reduced product of **1** was not found in acetonitrile, the disappearance of BzlNicH should be attributed to the formation of some

Table 2. Product analyses of the BzlNicH reduction[a] and the influence of $Mg(ClO_4)_2$ on NMR chemical shift of α-proton of substrates[b]

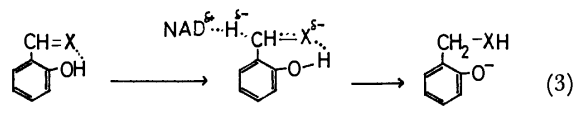
by-products.

2OH is a suitable substrate to evaluate the effectiveness of the ortho hydroxyl group in the reduction of C=C double bonds. The NMR coupling constant between two olefinic protons (16 Hz) is compatible with *trans*-configuration, so that the steric hindrance between ortho hydroxyl group and β-nitro group would be almost disregarded. Table 3 indicates that the relatively fast disappearance of BzlNicH occurs on the addition of **2OH**, but the corresponding reduced product was neither detected by NMR nor isolated by extraction with chloroform. It would appear, therefore, that the fast disappearance of BzlNicH should be ascribed to the decomposition catalyzed by the ortho hydroxyl group.[19] In fact, the NMR spectrum of the reaction mixture showed that 20—40% of **2OH** were left unreacted. These results endorse that the ortho hydroxyl group is not effective in the reduction of the C=C double bond of **2OH** (and probably C=C double bonds in general). The finding provides a striking contrast to a number of precedents that the ortho hydroxyl group plays a crucial role in the dihydronicotinamide reduction of double bonds attached to aromatic rings.[23-26] The role of the ortho hydroxyl group has been ambiguous due to two undistinguishable effects: that is, the ortho hydroxyl group can activate the carbonyl (and its analogs) in the initial state through hydrogen bonding and, at the same time, it can stabilize the developed negative charge in the transition state by means of specific solvation (or intramolecular general acid catalysis).[20,22,26]



(3)

initial state transition state

We consider that the contribution of the ortho hydroxyl group in the initial state is less significant in the reduction of C=C double bonds, because it is well-known that C=C double bonds (as π bases) very weakly interact with the phenolic hydroxyl group.[11] On the other hand, the stabilization of the developing carbanion by the hydroxyl group in the transition state is still probable. The claim is supported by an example of the intermolecular reaction that BzlNicH reduction of **2** is general acid catalyzed by added acetic acid (*vide post*). Thus, the ineffectiveness of the ortho hydroxyl group suggests that, in the reduction of C=X (X: hetero atom) double bonds, hydrogen bonding with the ortho hydroxyl group in the initial state plays an indispensable role for the subsequent hydrogen transfer.

Influence of Added Mg^{2+} Ion. Prior to kinetic and product analyses, the possible interaction between substrates (**1**—**4**) and $Mg(ClO_4)_2$ (1.4 equivalents of substrate) was dissected. The UV spectrum of these four substrates (0.1 mM) in dry acetonitrile was hardly affected by added Mg^{2+} ion. The IR absorption band based on $\nu_{C=O}$ of **3** and **4** (solvent, acetonitrile) did not change appreciably in the presence of Mg^{2+} ion. On the other hand, added Mg^{2+} ion caused a significant change in the NMR chemical shifts of α-protons of **1** and **3** to lower field (Table 2), while those of **2** and **4** scarcely shifted. It is implicated, therefore, that the metal-substrate interaction does exist in **1** and **3** at least at the concentration used for the NMR measurements (*ca.* 1.0 M). On the contrary, the interaction with **2** and **4** is almost disregaded. It is expected that **3** would bahave as a bidentate ligand (*e.g.*, ), while the similar interaction between metal and **4** would be accompanied by condsiderable difficulty due to energetically-unfavorable conformational change (*e.g.*, chair form or other non-planar conformations between carbonyl and C=C double bond).

The reduction of **1**, **2**, and **3** was remarkably facilitated by added Mg^{2+} ion (Table 2). In particular, **3** was reduced quantitatively to the corresponding methylene compound within 2 h. It is interesting that the yield in the presence of Mg^{2+} ion shows a trend parallel to the NMR chemical shift. On the other hand, **4** which hardly interacts with Mg^{2+} ion was not subject to the Mg^{2+}-assisted reduction at all. Conceivably, the steric factor markedly suppresses the reactivity of **4**.

Ohno *et al.*[7,27] found that BzlNicH strongly interacts with Mg^{2+} ion. We also confirmed in the present study that the λ_{max} of BzlNicH in acetonitrile (345 nm) shifts to 352 nm on the addition of 2.0 equivalents of $Mg(ClO_4)_2$. The result substantiates, together with the absence of the spectral change of the substrates (*vide supra*), that BzlNicH preferentially interacts with Mg^{2+} ion. The parallel relation between the NMR shift and the yield suggests, however, that the interaction with the substrates is not necessarily meaningless: for example, the interaction could occur at least in the transition state. It is expected, of course, that, when the coordination ability of substrate is relatively superior,[6,28] the interaction with substrate occurs predominantly.

The kinetic measurements in the presence of Mg^{2+} ion were carried out at 30 °C in dry acetonitrile. Since **1** and **2** are not reduced by BzlNicH in the absence of Mg^{2+} ion, the decay of BzlNicH at $[Mg(ClO_4)_2]=0$ is attributed to the production of some by-products. The

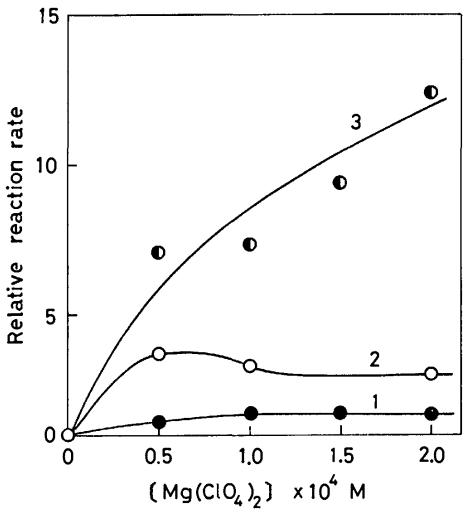


Fig. 1. $[Mg(ClO_4)_2]$ *vs.* relative reaction rate in acetonitrile.
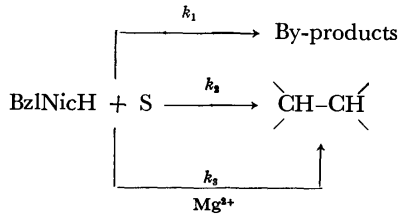
[BzlNicH] = 1.00×10^{-4} M, [substrate] = 5.00×10^{-3} M.

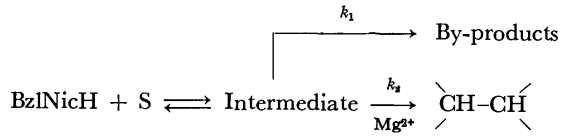
reaction rates were determined by varying the concentration of Mg^{2+} ion while maintaining the concentration of BzlNicH constant. The relative reaction rates thus obtained were plotted as a function of the concentration of Mg^{2+} ion in Fig. 1. A small rate augmentation of 1.4—3.3 fold was observed for the reaction with **1** and **2**, and the reaction with **3** was further enhanced (7—12 fold). The largest rate increase in **3** is consistent with the expectation that **3** interacts with Mg^{2+} ion most strongly among three substrates employed. The reaction rates showed saturation tendencies with increasing Mg^{2+} concentration, but the clear rate maximum which was reported for the reaction with 2-benzoylpyridine[6] was not found.

Scheme 1 may be proposed for the reduction of **3**, where the k_3 term involves the reaction of Mg^{2+}-coordinated BzlNicH and substrate ($k_{Mg^{2+}-BzlNicH}$) and the reaction of BzlNicH and Mg^{2+}-coordinated substrate ($k_{Mg^{2+}-S}$). If a relation, $k_2 < k_{BzlNicH}, k_{Mg^{2+}-S}$, is assumed, the experimental results for **3** is explained consistently by Scheme 1.



Scheme 1.

The reaction with **1** and **2** may be also rationalized by Scheme 1, but a question arises whether or not the drastic change in the yield (Table 2) can be explained by such small rate augmentations (for example, only 1.7 fold for **1**). It seems as if scheme 2 is more plausible for the reaction with **1** and **2** which features the rate-limiting formation of an intermediate followed by a Mg^{2+} dependent partition.



Scheme 2.

According to Scheme 2, the discrepancy between the slight rate enhancement and the dramatic improvement of the yield can be readily explained. It becomes difficult, however, to rationalize the saturation phenomena, for Mg^{2+} ion is not involved in the rate-limiting step in Scheme 2. Thus, both Schemes may be concurrent in the reduction of **1** and **2**.

Influence of Added Acetic Acid. The role of metal ion in dihydronicotinamide reduction is complicated because of its potential interaction with dihydronicotinamide and substrate both in the initial and transition states. In contrast, the role of Brösted acid is fairly simplified, since the interaction with dihydronicotinamide is offset as acid-catalyzed decomposition by the blank reaction in the absence of substrate. In addition, the interaction with substrate in the initial

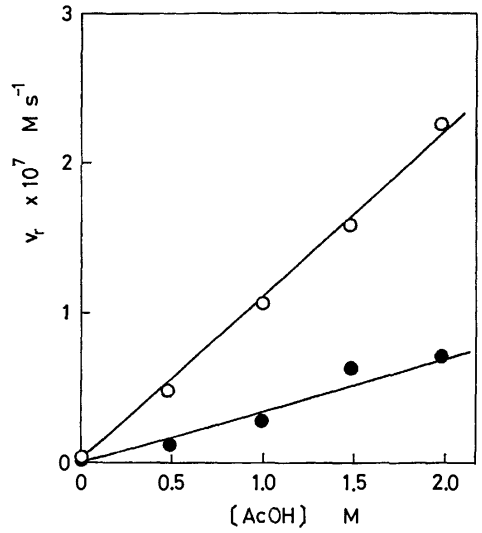


Fig. 2. v_r for the reaction of BzlNicH and **2** in acetonitrile (○) and in ethanol (●) plotted as a function of the concentration of acetic acid. [BzlNicH] = 1.00×10^{-4} M, [**2**] = 5.00×10^{-3} M.

state (*i.e.*, specific acid catalysis) is hardly conceivably. Thus, the interaction occurs only in the transition state.

As shown in Fig. 2, plots of v_r *vs.* [AcOH] gave good linear relations ($r > 0.98$), and Eq. 4 follows,

$$v_r = k_r[\text{BzlNicH}][\text{S}] + k_{\text{AcOH}}[\text{BzlNicH}][\text{S}][\text{AcOH}], \quad (4)$$

where k_{AcOH} is the third-order rate constant for acetic acid assisted rate acceleration which can be calculated from the slope in Fig. 2. The results are summarized in Table 3.

The reaction of BzlNicH and **2** is very slow without acetic acid, and the corresponding reduced product is not obtained. The addition of acetic acid brought forth the enhancement of the rate and the yield simultaneously. Evidently, acetic acid is involved in the rate-limiting step, and the role is reasonably designated as a general acid catalysis.[20,22] Thus, the reaction mechanism analogous to Scheme 1 is in effect for **2**.

The reduction of **1** is not the case, however. As shown in Tables 2 and 3, added acetic acid does not accelerate the disappearance of BzlNicH at all despite the fact that the yield is remarkably enhanced.[18] The discrepancy cannot be explained by Scheme 1 in which the improvement in the yield *must be* accompanied by the rate enhancement. Alternatively, Scheme 2 may be adopted as a possible mechanism for **1**. Although it is difficult to specify "intermediate" at present, the formation of some radical species is expected.[18,29,30]

Concluding Remark. The various kinds of electron-deficient C=C double bonds are reduced by the aid of metal ion or acetic acid, as has been reported by some groups.[18,31,32] However, the combination of kinetic studies with product analyses clarified that the role of added acids is not simple. We believe that the clear understanding of the behavior of metal ions and Brönsted acids would bear further application of nonenzymatic dihydronicotinamide reductions.

We thank Professor Toyoki Kunitake (Kyushu University) for helpful discussion.

Reaction of Organic Tin(II) Compound with Phenyl Isothiocyanate and Carbon Disulfide

Ikuko WAKESHIMA,* Yoshihiro SAITOH, and Ichiro KIJIMA

Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received December 22, 1977)

Reaction of organic tin(II) compounds, $Sn(OR)_2$[R=C_2H_5, $CH_2CH_2N(CH_3)_2$, C_6H_5, *o*-$CH_3C_6H_4$], with phenyl isothiocyanate and carbon disulfide have been investigated. The reaction of di(ethoxo)tin(II) with phenyl isothiocyanate in benzene at room temperature gave the corresponding addition product. The reaction at 80—81 °C however gave diethyl *N*-phenylcarbonimidate. Phenyl isothiocyanate reacted exothermically with bis[2-(dimethylamino)ethoxo]tin(II) to yield the 1:1 addition product. In the reaction with bis(2-methylphenoxo)-tin(II), a compound containing one molecule of phenyl isothiocyanate per two molecules of the tin(II) compound was isolated, but the reaction with di(phenoxo)tin(II) did not occur. Di(ethoxo)tin(II) reacted with carbon disulfide to give diethyl thiocarbonate, diethyl carbonate, and tetraethyl orthocarbonate. Bis(*o*-methylphenoxo)-tin(II) and di(phenoxo)tin(II) however did not react with carbon disulfide.

Since P. G. Harrison and J. J. Zuckerman reported the reaction between di(methoxo)tin(II) and multiple-bond compounds,[1] there have been many investigations concerning the reactivity of organic and organotin(II) compounds.[2-6] The reaction of alkylalkoxotin(IV) with phenyl isothiocyanate led to the corresponding *S*-stannyl derivatives[7-8] and di(methoxo)tin(II) reacted with phenyl isothiocyanate to give the corresponding *N*-stannyl derivative.[1] In the reaction of alkylalkoxotin-(IV) and di(ethoxo)tin(II) with carbon disulfide, S. Sakai and coworkers reported that alkylalkoxotin(IV) reacted with carbon disulfide to give the corresponding orthocarbonate, dithiocarbonate or carbonate. However di(ethoxo)tin(II) did not react.[9]

In this paper, the reaction of organic tin(II) compounds, $Sn(OR)_2$[R=C_2H_5, $CH_2CH_2N(CH_3)_2$, C_6H_5, *o*-$CH_3C_6H_4$], with phenyl isothiocyanate and carbon disulfide will be described.

Results and Discussion

Reaction of Organic Tin(II) Compound with Phenyl Isothiocyanate. The reaction of di(ethoxo)tin(II) (**1**), bis[2-(dimethylamino)ethoxo]tin(II) (**2**), bis(*o*-methyl-phenoxo)tin(II) (**3**), and di(phenoxo)tin(II) (**4**) with phenyl isothiocyanate (PhNCS) were conducted in

Table 1. Reactions of $Sn(OR)_2$ with PhNCS

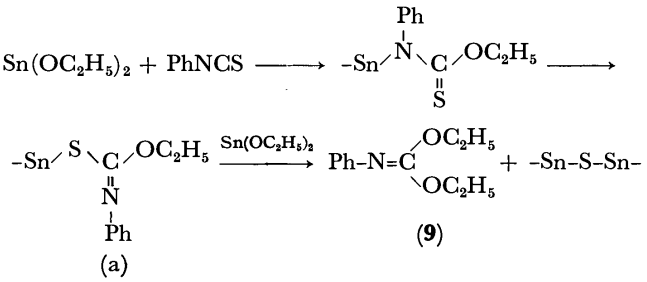
benzene and the results are summarized in Table 1.

Compound **1** reacted with two equivalents of PhNCS in benzene at 30—32 °C to give the 1 : 2 addition product (**6**) in good yield. However, in the case of 1 : 1 molar ratio, the reaction was sluggish and brought to completion by heating at 48—50 °C. The reaction between compound **2** and one or two equivalents of PhNCS was exothermic and proceeded smoothly below 20 °C to afford only the 1 : 1 addition product (**7**). In the case of compound **3** with PhNCS, the resulting product was found to be a compound containing one molecule of PhNCS per two molecules of compound **3**. Compound **4** did not react. All of the isolated products **5**—**8** were sensitive to atmospheric moisture, exhibiting a new characteristic absorption band assigned to $\nu_{C=S}$ at 1148—1225 cm^{-1}. These results suggest the formation of an Sn–N bond. In addition, the *N*-phenylthiocarbamate derivatives were isolated as the hydrolysis products of compounds **5**—**8**. On the basis of these results, the aryloxotin(II) compounds **3** and **4** may be considered less reactive than the alkoxotin(II) compounds **1** and **2**. This difference may be attributed to the decrease in nucleophilicity of oxygen by the R-effect of the aryl group on the Sn–O–Ar bond.

When compound **1** was treated with PhNCS under reflux in benzene, a transparent liquid and black-brown solid were formed. The liquid was assinged as diethyl *N*-phenylcarbonimidate (**9**) according to elemental analysis, IR and NMR spectra. The carbonimidate was also obtained by heating the addition product **5** in benzene at 80—81 °C. Therefore, it is thought that the intermediate **a** results from a rearrangement of the tin atom from nitrogen to sulfur which further reacts with $Sn(OC_2H_5)_2$ to give the elimination products as shown in Scheme 1.



Scheme 1.

Reaction of Organic Tin(II) Compounds with Carbon Disulfide. The reaction of the compound **1** with carbon disulfide (CS_2) in benzene afforded diethyl thiocarbonate (**10**) ($\nu_{C=S}$ 1235 cm^{-1}), tetraethyl orthocarbonate (**11**) (ν_{C-O} 1185, 1115 cm^{-1}), and diethyl carbonate (**12**) ($\nu_{C=O}$ 1750 cm^{-1}). The yields depended on the reaction temperatures; the reaction at 69—71 °C for 20 h afforded compounds **10**, **11**, and **12** in 8, 16, and 48% yields, respectively, whereas the reaction at room temperature (below 22 °C) for one month lead to the formation of compound **10**, **11**, and **12** in 3, 42, and 4% yields, respectively. In each reaction, the NMR spectra of the benzene removed indicated the presence

of a slight amount of diethyl sulfide (**13**).

Scheme 2 suggests the following reaction route; first, the nucleophilic attack of compound **1** on carbon disulfide produces the intermediate **b**. Subsequently, the attack of compound **1** on the carbon atom of >C=S group on the intermediate **b** results in the formation of compound **10** and tin sulfide. Furthermore, the attack of $Sn(OC_2H_5)_2$ on compound **10** gives the intermediate **c** which may undergo either the nucleophilic attack of compound **1** with the formation of compound **11** or intramolecular elimination followed by the formation of compound **12** (path A). This path is supported from the proton NMR spectra data; CH_3 8.76 (t) and CH_2 7.50 (q) ppm.[10] Assuming path B is a possible route, then diethyl ether should be derived from compound **11** (path B). However, no direct evidence for the presence of diethyl ether has been obtained.

The reaction of compounds **3** and **4** with CS_2 at 69—71 °C in benzene, showed no appreciable change occured. These results are summarized in Table 2.

Experimental

Experiments were carried out in a nitrogen atmosphere dried with liquid nitrogen. The melting and boiling points are uncorrected. IR spectra were recorded with a Hitachi EPI-2S spectrometer and ^{1} NMR spectra on a Hitachi R-24 (60 MHz) using TMS as an internal standard. The elemental analysis were carried out with a Yanagimoto MT-2 CHN corder. Liquid chromatographic determinations were performed on a Nippon Bunseki LC-08, using a polystyrene–divinylbenzene copolymer GPC column.

PhNCS was dried with the azeotropic distillation method using benzene which was freshly distilled before use. Carbon disulfide was purified according to the method of Pestermer[11] and distilled after dehydration over P_2O_5.

Reaction of Compound 1 with PhNCS in a 1: 1 Molar Ratio. In a flask equipped with a mechanical stirrer, a condenser, and a dropping funnel, were placed compound **1** (11.6 g, 56 mmol) and benzene (28 ml). PhNCS (7.5 g, 55 mmol) was slowly added so that the temperature did not exceed 24—24.5 °C. After stirring at room temperature for 2 h, the flask was allowed to stand overnight, followed by heating at 48—50 °C for 10 min with stirring. During this time, the heterogeneous solution became almost clear together with a small amount of black solid. After suction filtration, the filtrate was concentrated *in vacuo* to about one-half of the volume, and hexane (30 ml) was added to the residue. The resulting white precipitates were collected by filtration, washed with benzene, and dried to give 12.8 g (66%) of product **5**. Analytical and physical data are summarized in Table 1.

Reaction of Compound 1 with PhNCS in a 1: 2 Molar Ratio. In a similar procedure, PhNCS (21.2 g, 157 mmol) was slowly added to the suspension of compound **1** (16.2 g, 78 mmol) in benzene and heated at 29—30 °C for 3 h. During this time, the heterogeneous solution became clear without any formation of the black solid. After concentration to one-half volume, hexane (30 ml) was added to the residue. The white powdery precipitates were isolated in a 96% yield (25.9 g).

Reaction between Compound 4 and PhNCS. After compound **4** was treated with PhNCS under the conditions described in Table 1, the unreacted compound **4** was recovered in a 85% yield.

Reaction of Compound 1 with PhNCS in Boiling Benzene. Compound **1** (12.5 g, 60 mmol) was refluxed in benzene for 5 h. After separation of the resultant black solid, ditillation of the filtrate under reduced pressure gave diethyl *N*-phenylcarbonimidate (**9**) in 50% yield (5.8 g): bp 117 °C at 8 mmHg (lit,[12] 122 °C at 12 mmHg); IR (liquid film), $\nu_{C=N}$ 1660cm^{-1}; NMR (CCl_4, τ), 8,85 (t, CH_3), 5.89 (q, CH_2), and 2.7—3.3 (m, C_6H_5) ppm; Found, C, 68.51; H, 7.91; N, 7.28%, Calcd for $C_{11}H_{15}NO_2$, C, 68.37; H, 7.82; N, 7.25%. The treatment of compound **9** with 2 M-HCl ethanolic solution lead to the formation of a compound having a characteristic band at 1745 cm^{-1}.

Reaction of Compound 1 with CS_2. CS_2 (10.2 g, 34 mmol) was added dropwise to a suspension of compound **1** (13.3 g, 63 mmol) in benzene (31 ml) with stirring, and the mixture refluxed for 20 h. The heterogeneous reaction mixture changed gradually from a semi-transparent mixture to yellowish transparent solution with the formation of a black suspension. After the insoluble solids were removed by filtration, the benzene solution was distilled to afford two fractions; bp 35—50 °C at 28 mmHg, bp 50—75 °C at 28 mmHg. Each fraction was subjected to liquid chromatography (eluant, $CHCl_3$): the former gave compound **12** and the latter a mixture of **10**, **11**, and **12**.

Compound **10**: IR (CCl_4 soln); 1235 cm^{-1} (C=S). NMR (τ); 8.57 (CH_3), 5.67 (CH_2) ppm.

Compound **11**: IR (liquid film); 1185, 1115 cm^{-1} (C–O), NMR (τ); 8.85 (CH_3), 6.48 (CH_2) ppm.

Compound **12**: IR (liquid film); 1750 cm^{-1} (C=O), 1260 cm^{-1} (C–O), NMR (τ); 8.75 (CH_3), 5.99 (CH_2) ppm.

Compound **3** and **4** were treated with CS_2 according to a similar procedure, and the unreacted tin(II) compounds were recovered in quantitative yields.

General Procedure of Hydrolysis. Compound **5**—**8** were hydrolyzed with a solution of water (5—6 ml) and acetone (100 ml) at room temperature. After separation of inorganic tin with a centrifugal separator, the organic layer was concentrated under reduced pressure and cooled with an ice bath. The resulting white crystals were filtered off and dried. Physical and analytical data were as follows:

$PhNHC(S)OC_2H_5$: Mp 68—70 °C (lit,[13] 71—72 °C), IR; 1205 cm^{-1} ($\nu_{C=S}$), Found, C, 59.4; H, 6.10; N, 7.60%. Calcd for $C_9H_{11}NOS$, C, 59.6; H, 6.12; N, 7.73%.

$PhNHC(S)OCH_2CH_2N(CH_3)_2$: A pale yellow viscous liquid, IR; 1115 cm^{-1} ($\nu_{C=S}$), Found, C, 58.1; H, 7.22; N, 12.2%. Calcd for $C_{11}H_{16}N_2OS$, C, 58.9; H, 7.14; N, 12.5%.

$PhNHC(S)O$-*o*-$CH_3C_6H_4$: Mp 146—148 °C, IR; 1150 cm^{-1} ($\nu_{C=S}$) Found, C, 69.2; H, 5.34; N, 5.86%, Calcd for $C_{14}H_{13}NOS$, C, 69.1; H, 5.35; N, 5.67%.

Chemical Transformation of Seldomycin 5 into 3′-Deoxyseldomycin 5 and Related Compounds[1)]

Hideo MATSUSHIMA,* Yasuki MORI, and Kozo KITAURA**

Tokyo Research Laboratory, Kyowa Hakko Kogyo Co., 3-6-6, Asahimachi, Machida, Tokyo 194

***Pharmaceuticals Research Laboratory, Kyowa Hakko Kogyo Co., Nagaizumimachi, Suntogun, Shizuoka 411*

(Received January 24, 1978)

3′-Deoxyseldomycin 5 (**2**), 2′-deamino-3′-epiamino-3′-deoxyseldomycin 5 (**14**), and 2′,3′-epimino-2′-deamino-3′-deoxyseldomycin 5 (**15**) were prepared from seldomycin 5 (**1**). Treatment of hexa-*N*-ethoxycarbonyl (ecb)-3′-*O*-tosylseldomycin 5 with sodium borohydride in DMSO gave the corresponding *N*-ecb-derivatives of **2**, **14**, and **15**. Removal of the ecb groups of these compounds with aq potassium hydroxide gave the free bases **2**, **14**, and **15**, respectively. Structure determination of the products was performed by means of MS, CMR, PMR, and chemical reactions. It was found that **2** exhibits a more potent and broader antibacterial activity than the parent compound **1**, and **14** shows unique antibacterial spectrum against resistant strains, whereas **15** has almost no activity.

Synthesis of 3′-deoxy derivatives of aminoglycoside antibiotics has been studied extensively, since it was disclosed by H. Umezawa and S. Umezawa that resistance of certain clinically isolated bacteria against kanamycin is due to enzymatic 3′-*O*-phosphorylation of the antibiotic, and that 3′-deoxykanamycin, designed rationally upon this mechanism of resistance, exhibits strongly recovered antibacterial activity against the resistant strains.[2)] Seldomycin 5 (SLD-5) (**1**), a new aminoglycoside antibiotic found in our institute, is inactivated, like other aminoglycoside antibiotics, by various resistant strains including those bacteria which produce aminoglycoside 3′-phosphotransferase.[3)] In a previous paper, we reported that the inactivation of SLD-5 by enzymatic 3′-*O*-phosphorylation is inhibited by the change of configuration of the 3′-hydroxyl group of **1**.[4)] In this paper, we describe the synthesis of 3′-deoxy-SLD-5 (**2**) and related compounds as a modification to enhance and broaden the antibacterial activity of **1**. We expected **2** to exhibit more potent activity than the parent compound since **2** has a pseudodisaccharide unit, 3′,4′-dideoxyneamine (**3**), which constructs the common partial structure of gentamicin C_{1a} (GM-C_{1a}) (**4**)[5)] and 3′,4′-dideoxykanamycin B (DKB) (**5**).[6)] The latter two compounds are well-known aminoglycoside antibiotics that have very strong intrinsic activity against various bacteria.

Results and Discussion

Synthesis and Identification of the Products. Attempts were made to convert hexa-*N*-ethoxycarbonyl(ecb)-3′-*O*-tosyl-SLD-5 (**6**)[4)] into 3′-iodo derivative by the usual procedure using sodium iodide, but TLC of the reaction mixture indicated that the reaction is complicated. S_N2 substitution reaction of a tosyloxy group by a nucleophile does not occur smoothly when an approaching nucleophile and a substituent at γ position are in 1,3-diaxial relationship. 1,2,4,6-Tetra-*O*-benzoyl-3-*O*-tosyl-α-D-glucopyranose is recovered on the nucleophilic displacement reaction with sodium benzoate.[7)] 1,2:5,6-Di-*O*-isopropylidene-3-*O*-tosyl-α-D-glucofuranose is recovered in a 90% yield on reaction with azide ion.[8)] Steric and polar factors affecting reactivity of a sulfonyloxy group of carbohydrate have been summarized[9)] and such steric hindrance has been reported in the field of steroid chemistry.[10)] The results suggest that the α-glycosidic linkage at the 1′ position of **6** blocks the approach of an iodide ion from side α to the 3′ position in our case also. However, penta-*N*-ecb-3′-*O*-tosylkanamycin B was successfully converted into 3′-iodo derivative in an exceptionally good yield.[11)] Successful iodination was attributed to the neighboring group participation of the 2′-ethoxycarbonylamino group.[11)] However, an alterna-

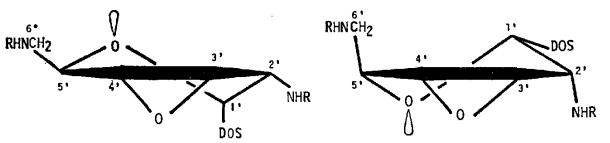
tive explanation might be given by the present result.***

*** In the case of kanamycin B, the smooth displacement of the 3′-tosyloxyl group by iodide ion might occur with the aid of the neighboring 4′-hydroxyl group participation to form a 3′,4′-anhydro derivative as an intermediate, followed by dieq-uatorial opening of the epoxide ring [N. R. Williams, *Adv. Carbohydr. Chem. Biochem.*, **25**, 109 (1970)] due to the regio-specific attack of iodide ion at the 3′ position. The cause of regiospecifity can be explained as follows. The epoxide is considered to adopt one of the conformers (i) or (ii). If the epoxide exists as conformer (i), the attack of iodide ion at 4′ position might be hindered by the 1,3-diaxial electrostatic repulsion between the approaching iodide ion and the lone pair electrons of the pyranose-ring oxygen. If the epoxide



(i) (ii)

exists as conformer (ii), the attack of iodide ion at 4′ position might sterically be hindered by the adjacent *quasi*-axial 5′-ethoxycarbonylaminomethyl group, thus resulting in the regiospecific formation of the 3′-iodo derivative. In the case of compound **6**, no such epoxide intermediate can be formed since **6** has no 4′-hydroxyl group.

Bell *et al.* reported that treatment of several sulfonates with sodium borohydride in dimethyl sulfoxide (DMSO) or diglyme gives deoxygenated products.[12] Application of this method to carbohydrate derivatives has been reported.[13,14] We have adopted the reaction to reduce **6**.

Treatment of **6** with sodium borohydride in DMSO afforded the following four products after chromatographic separation; hexa-*N*-ecb-3′-deoxy-SLD-5 (**7**) (20.1%), hexa-*N*-ecb-2′-deamino-3′-epiamino-3′-deoxy-SLD-5 (**8**) (23.3%), 1,3,6′,2″,3″-penta-*N*-ecb-2′,3′-*N*-ecb-epimino-2′-deamino-3′-deoxy-SLD-5 (**9**) (21.8%), and 1,3,6′,2″,3″-penta-*N*-ecb-2′,3′-epimino-2′-deamino-3′-deoxy-SLD-5 (**10**) (14.8%). The structure of **7** was elucidated by comparison of its CMR spectrum with that of penta-*N*-ecb-GM-C_{1a}[15] (**11**) (Table 1). The chemical shifts for C-1′—C-6′ and C-1—C-5 of **7** correspond to those for the carbons of **11** which has a common disaccharide unit, 1,3,2′,6′-tetra-*N*-ecb-3′,4′-dideoxyneamine (**12**). The ecb groups of **7** were removed by aq methanolic potassium hydroxide to give 3′-deoxy-SLD-5 free base (**2**). Its structure was confirmed by MS, PMR, and CMR spectra.[1] Compound **2** consumed 1.00 mol/mol periodate (theoretical value: 1.00); **1** consumed 2.90 (theoretical value: 2.00) under carefully controlled conditions. Although we have tentatively attributed the excess uptake of periodate

by **1** to non-Malapradian oxidation of vicinal amino and methoxyl groups,[16] the present result together with another result concerning periodate oxidation of 6′-*N*-benzyloxycarbonyl-SLD-5 (**13**)[17] (consumption: 1.52, theoretical value: 2.00), indicate that our previous speculation was incorrect. The over-oxidation seems to take place only when both the 3′-hydroxyl and 6′-amino groups exist in the molecule.

The structure of **8** was determined retrospectively on the basis of the following spectroscopic data for deethoxycarbonylated compound, 2′-deamino-3′-epi-amino-3′-deoxy-SLD-5 free base (**14**). i) High resolution mass spectrum indicates that the molecular weight of **14** is 434.2816, which is isomeric with **2**. The deoxygenated structure was supported by the appearance of a prominent peak at *m/e* 129.[18] ii) In PMR spectrum of **14**, the H-1′ signal appeared at τ 4.68 as a broad double doublet with J=*ca.* 5 and *ca.* 2 Hz, which indicates that the 2′ position has no substituent. iii) In CMR (Table 2), the signal of C-2′ appeared at 36.6 ppm as a triplet by off-resonance and that of C-3′ at 42.9 ppm as a doublet. Protonation-β-shift of the spectrum was in line with the structure. No evidence was obtained that 3′-amino group is axially oriented. However, its orientation was suggested from the reaction mechanism.

Compounds **9** and **10** gave the same product, 2′,3′-epimino-2′-deamino-3′-deoxy-SLD-5 free base (**15**), by alkaline hydrolysis to remove ecb groups. The structure of **15** was determined by the following data. i) Mass spectrum of **15** gives a (M+1) and M peak at *m/e* 433 and 432, respectively. ii) PMR spectrum of **15** shows no signal of an olefinic proton. iii) In CMR spectrum of **15** (Table 2), two signals attributable to C-2′ and C-3′ appear at 29.2 and 31.2 ppm (or *vice versa*) as doublets, respectively. These signals shifted *ca.* 5—7 ppm downfield by acidifying the media, C-1′ and C-4′ signals shifted *ca.* 5 ppm upfield.

Elemental analyses of **9** and **10** indicate that **9** has

six ecb groups whereas **10** has five. This is supported by the fact that **10** was converted into **9** by treatment with ethyl chloroformate. A comparison of the CMR spectra of both compounds (Table 1) reveals that the 2′,3′-aziridine ring of **10** bears no ecb group. The C-2′ and C-3′ signals of **9** appear at 36.5 and 36.1 ppm, those of **10** at 27.7 and 29.4 ppm accompanied by slight downfield shifts of C-1′ and C-4′. The peak appearing at 162.5 ppm in the spectrum of **9** is attributable to the carbonyl carbon of ecb group attached at the aziridine nitrogen. The fact that treatment of **9** with sodium borohydride in DMSO afforded **7** and **8** leads to the conclusion that, in the reaction of **6** with sodium borohydride, **9** was initially formed and then transformed into **7** and **8** by ring-opening of the aziridine due to an attack of hydride ion. It is not obvious whether **7** was formed, besides this mechanism, directly by the replacement of the 3′-tosyloxyl group with hydride. The course of formation of **10** remains unclarified. The formation might take place by hydrolysis of the ecb group attached to the aziridine nitrogen due to basic property of sodium borohydride. Recently, Okutani *et al.* reported that 2′,3′-epimino derivatives play the role of intermediate during the course of synthesis of 3′-deoxy and related compounds from butirosin 3′-phosphate *etc.*[19]

Antibacterial Activities of **2**, **14**, *and* **15**. The *in vitro* antibacterial activities of **2**, **14**, and **15** were measured and compared with those of SLD-5 (**1**), GM-C_{1a} (**4**), and DKB (**5**) (Tables 3 and 4). Compound **2** exhibits, as compared with **1**, both enhanced activity against gram-negative sensitive strains and strongly recovered potency against resistant strains which produce aminoglycoside 3′-phosphotransferase [APH(3′)]. Activity of **2**, however, is less potent than that of the two reference compounds, **4** and **5**, against both sensitive and resistant strains except aminoglycoside 2″-nucleotidyltransferase [ANT(2″)]-producing strains. The result

TABLE 5. ED_{50} VALUES OF COMPOUND **2** AGAINST EXPERIMENTAL INFECTIONS IN MICE (mg/kg)[a]

Organism	**1**	**2**	**5**
Escherichia coli Juhl	6.75	3.9	0.62
R-20	200	4.5	2.8
Pseudomonas aeruginosa BMH#1	265	150	18.8
R-5	180	52.5	—

a) Acute systemic infections in mice were produced by intraperitoneal inoculation. The dosage regimen for all infections was 1 or 2 h post-infection, all the compounds being administered subcutaneously.

of the test *in vivo* (Table 5) showed a similar tendency to that in the *in vitro* experiment. The difference in activity seems to arise from the structure of the monosaccharide attached to the 6 position of the deoxystreptamine core, since other portions of the molecules of these compounds are quite the same. We infer that, as compared with 2″-equatorial hydroxyl group, the 2″-equatorial amino group characteristically involved in the structures of **1** and **2** does not function to strengthen antibacterial activity.

It seems that **1** is inactive against four of the six ANT-producing resistant strains tested in spite of its lack of a 2″-hydroxyl group in the structure. The four strains which are moderately resistant to **1** inactivate streptomycin[20] (MIC: >100 mcg/ml, data not given in Table 4). The other two strains which are sensitive to **1** do not inactivate streptomycin (MIC: 3.12—12.5 mcg/ml). It should be noted that this inactivation of **1** was inhibited by deoxygenation or epimerization[4] at the 3′ position of **1**. The results suggest that in **1** the 3′-hydroxyl group might function as a substrate for the ANTs, or these four strains might produce, besides ANT, other enzymes which modify the 3′-hydroxyl group of **1**.

Compound **15** lacks antibacterial activity. It is

considered that construction of the aziridine ring deforms chair conformation of the 2,6-diaminohexose unit, causing the loss of activity.

The potency of **14** against sensitive strains is less strong than that of **1** except against *Pseudomonas*. However, the antibacterial spectrum of **14** against resistant strains was found to be interesting. Although less potent than **2**, it exhibits recovered activity against resistant strains which produce APH(3′)-I or aminoglycoside 2′-acetyltransferase [AAC(2′)]. This is understandable since the targets of these enzymes have been removed from the substrate. Compound **14** is active against AAC(3)-I-producing strains, indicating that 2′-deamino-3′-epiamino-3′-deoxygenation offers a new mode of modification to the established methods, such as 1-*N*-ω-amino-α-hydroxyalkanoylation,[21] 1-*N*-ethylation,[22] and 1-*N*-ω-amino-α-hydroxyalkylation,[23] for recovering activity of aminoglycoside antibiotics against AAC(3)-I-producing strains. Against the four ANT-producing strains, **14** shows improved activity than **1**. Compound **14** is an unique aminoglycoside antibiotic both in its structure and its width of antibacterial spectrum against resistant strains.

The LD_{50} value of **2** was estimated to be 300 mg/kg (mice, intraveneously).

Experimental

General. Melting points were determined with a Yanaco micro melting point apparatus and are uncorrected. Varian T-60, JEOL JNM-FX 100, or JEOL PS-100 was employed for NMR measurements with TMS or DSS as an internal reference. Samples of the free bases were decarbonated in the usual way[24] just before the NMR measurements. Thin layer chromatography (TLC) was carried out with Merck TLC plate and spots were located by iodine vapor and/or ninhydrin. Mass spectra were obtained with JEOL JMS-01SG-2 at 75 eV using direct insertion probe. Optical rotations were measured with a Hitachi-Perkin-Elmer 141 polarimeter at ambient temperature. Commercial DMSO and sodium borohydride were used without further purification. Quantitative determination of periodate uptake was made as reported.[16] No effort was made to crystallize the products. Antibacterial activity was determined by the agar dilution method at pH 7.2 specified by the Japan Society of Chemotherapy.

*Reaction of **6** with Sodium Borohydride.* To a solution of **6** (25.0 g) in DMSO (500 ml) was added sodium borohydride (12.5 g) in one portion and the solution was stirred at 65 °C for 17 h. DMSO was evaporated *in vacuo* and water (600 ml) was added to the residue. The mixture was extracted with chloroform (300 ml×10) and the organic layer was washed with water (50 ml×3), dried with anhydrous sodium sulfate and evaporated to give white powder. The residue was charged to a silica gel column (Merck, 2.2 kg, 8 cm×128 cm) and the column was washed with chloroform (7 liter), followed by elution with a mixture of chloroform–methanol (fraction *ca.* 200 ml each); eluent: Frs. 1—101, chloroform–methanol 30: 1; Frs. 102—199, 20: 1; Frs. 200—269, 10: 1. Fractions were monitored by TLC.

Fractions 102—110 were rechromatographed on CG-50 to give 0.57 g of pure **2** and a trace amount of a compound supposed to be 6-*O*-(2,3-diamino-2,3-dideoxy-4-*O*-methyl-α-D-xylopyranosyl)-2-deoxystreptamine (DOS-seldamine). Mp 142—149 °C, $[\alpha]_D^{17}$ +59.9 (*c* 0.302, water). PMR (D_2O): τ 5.00 (d, J=3 Hz, H-1″), 6.53 (s, OCH_3); CMR (D_2O): C-1, 51.1; C-2, 36.8; C-3, 51.1; C-4, 78.8; C-5, 74.9; C-6, 87.4; C-1″, 100.1; C-2″, 56.2; C-3″, 54.7; C-4″, 80.2; C-5″, 60.8; OCH_3, 58.7. MS: 307 (1, MH), 306 (0.5, M), 289 (3, A8), 203 (37, unknown), 173 (7, A10), 163 (10, A11), 145 (100, Cl and A12). This compound is considered to be formed by hydrolysis of the glycosidic linkage under drastic conditions used for the removal of ecb groups. This compound exhibits no antibacterial activity.

*2′-Deamino-3′-epiamino-3′-deoxy-SLD-5 Free Base (**14**).* The ecb groups of **8** (2.50 g) was removed in a similar manner as described above and the product was purified by CG-50 to afford pure **14** (0.70 g), as slightly yellow powder. Mp 134—137 °C, $[\alpha]_D^{22}$ +106 (*c* 0.356, water).

Found: C, 44.75; H, 8.08; N, 16.55%. Calcd for $C_{18}H_{38}N_6O_6 \cdot H_2O \cdot H_2CO_3$: C, 44.34; H, 8.24; N, 16.33%.

PMR (D_2O): τ 4.68 (br dd, J=*ca.* 5, *ca.* 2 Hz, H-1′), 5.04 (d, J=3 Hz, H-1″); MS: 435 (1, MH), 307 (7, A7), 289 (5, A8), 274 (18, F2), 273 (29, A4), 258 (8, F1), 173 (13, A10), 163 (31, A11), 145 (100, Cl and A12), 129 (64, B1), 112 (25, F4).

*2′,3′-Epimino-2′-deamino-3′-deoxy-SLD-5 Free Base (**15**).* *From **9**:* Alkaline hydrolysis of **9** (2.00 g) and purification of

the crude product were carried out in a similar way to that mentioned above. Pure **15** was obtained as white powder, 0.54 g. Mp 120—149 °C, $[\alpha]_D^{23}$ +100 (*c* 0.667, water).

Found: C, 48.43; H, 8.80; N, 18.57%. Calcd for $C_{18}H_{36}N_6O_6 \cdot H_2O$: C, 47.97; H, 8.52; N, 18.65%.

PMR (D_2O): τ 4.42 (d, J=3 Hz, H-1′), 5.06 (d, J=3 Hz, H-1″), at pD 2: τ 3.83 (d, J=4 Hz, H-1′), 4.46 (d, J=*ca.* 0 Hz,[16] H-1″); MS: 433 (1, MH), 432 (0.5, M), 307 (20, A7), 289 (72, A8), 274 (4, F2), 163 (20, A11), 145 (100, Cl and A12), 127 (32, B1). Characteristics of the MS: no fragment peaks attributable to the species arising from the 4-*O*-glycosyl-2-deoxystreptamine were observed, peaks at *m/e* 347 (25) and 203 (10) appearing. These two fragments probably correspond to D9 and D10 fragments,[18] though hydrogen shift is needed in this case.

From ***10***: De-ethoxycarbonylation of **10** (0.45 g) and chromatography were carried out as described above. Compound **15** was obtained as white powder, 0.12 g. MS, PMR, and antibacterial activity of this material were identical with those obtained with a sample prepared from **9**. A small amount of DOS-seldamine (0.03 g) was also isolated.

Reaction of ***9*** *with Sodium Borohydride.* Sodium borohydride (13 mg) was added to a solution of **9** (25 mg) in DMSO (0.5 ml) and the solution was kept at 65 °C for 13 h. DMSO was evaporated *in vacuo* and the residue was extracted with chloroform (10 ml), washed with water (3 ml×2), and dried. The chloroform solution was then concentrated to *ca.* 1 ml. TLC (chloroform–methanol 10: 1) of the concentrate indicated that the starting material (R_f 0.61) had disappeared and the following products were formed; **7** (R_f 0.74), **8** (R_f 0.64), a trace of **10** (R_f 0.36), and an unidentified product (R_f 0.31).

Reaction of ***10*** *with Ethyl Chloroformate.* To a solution of **10** (50 mg) in DMF (2 ml) were added anhyd. sodium carbonate (16 mg) dissolved in water (0.5 ml) and ethyl chloroformate (17 mg). The solution was stirred overnight. Solvents were removed *in vacuo* and the residue was extracted with chloroform (10 ml), washed with water (2 ml), and dried with anhyd. sodium sulfate. TLC of the chloroform solution showed a single spot of **9**. Chloroform was evaporated to give white powder of **9** (55 mg); mixed mp with the material obtained above: 234—235 °C.

The authors wish to thank Mrs. Mayumi Yoshida and Mr. Noboru Kojima for the NMR measurements, Mrs. Kazuko Yamaguchi for the elemental analyses, and Miss Yuriko Adachi for obtaining the Mass spectra. The authors are also indebted to Sagami Chemical Research Center for the elemental analysis of sulfur.

Enantioface-Differentiating (Asymmetric) Hydrogenation of β-Ketoester with Modified Raney Nickel Catalyst (MRNi). XXXI. A Comparative Study of Reaction Rates and Optical Yields

Hiroshi OZAKI,* Akira TAI, Shinzo KOBATAKE, Hironobu WATANABE, and Yoshiharu IZUMI

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Suita, Osaka 565

(Received February 3, 1978)

Enantioface-differentiating hydrogenations of methyl acetoacetate over (*S*)-alanine-, (*S*)-2-aminobutyric acid, (*S*)-valine-, (*S*)-leucine-, (*S*)-malic acid-, and (*R,R*)-tartaric acid-MRNi were carried out under atmospheric pressure of hydrogen and the effects of the modifying reagent on the rates of the formation of enantiomer, v_S and v_R, were investigated. The rates of hydrogenation, $v=v_S+v_R$, were the same for all the amino acid-MRNi and also for all the hydroxy dicarboxylic acid-MRNi. However, the v_R/v_S ratios were different. These results are explained in terms of the independence of the rate-determining and enantioface-differentiating steps in the reaction pathway of hydrogenation. The rate-determining step of hydrogenation was shown to be the hydrogen addition to the adsorbed substrate, while the enantioface-differentiating step was expected to occur prior to the rate-determining step.

Modified Raney nickel catalyst (MRNi) is the most intensively studied catalyst for the enantioface-differentiating hydrogenation of the C=O double bond.[1]

As reported in the preceding paper,[2] the features of the hydrogenation of methyl acetoacetate (MAA) to methyl 3-hydroxybutyrate (MHB) over MRNi have been summarized as follows. 1) The Arrhenius plots with respect to the initial rate of hydrogenation over various MRNi were parallel to one another and the resulting apparent activation energies were 10.5±0.5 kcal/mol in all cases. That is, the reaction mechanism of the rate-determining step was not influenced by the modifying reagent. 2) The rate of hydrogenation followed the equation: $v=k[\mathrm{MAA}]^{0.2-0.3}$. Taking the value of activation energy into consideration, the rate-determining step of hydrogenation was supposed to be the hydrogen addition to the adsorbed substrate (surface reaction). 3) The initial rate of hydrogenation linearly increased with the decrease in the amount of modifying reagent adsorbed on the catalyst, and the amounts of adsorption were found to be similar in so far as the structures of the modifying reagents were homologous. However, there was no systematic relation between the rate and the optical yield. Thus the roles of the modifying reagent were divided into two independent functions: one is to regulate the rate of reaction by occupying a part of the active sites of the catalyst and the other is to make the catalyst differentiate the enantioface of the substrate. We have pointed out[2] that these features of the enantio-differentiating reaction are not explained by the simple kinetic controlled enantio-differentiation usually claimed in the literature[3] and have proposed that the enantio-differentiation should take place elsewhere than in the rate-determining step. Recently, many experimental results favoring our proposal have been reported in the reaction with chiral homogeneous catalyst[4] and the proposal has gradually become general. In this report, the validity of our previous proposal in the reaction with MRNi will be verified on the basis of the detailed studies of the relations between the rate and the optical yield.

Results

Raney nickel catalyst suited for the kinetic studies was prepared by a newly developed method and was modified with α-amino acid or α-hydroxy acid under the conditions reported before.[5]

The resulting time courses of the hydrogenation and optical yields at 20% of conversion are shown in Fig. 1 (α-amino acid-MRNi) and Fig. 2 (α-hydroxy dicarboxylic acid).

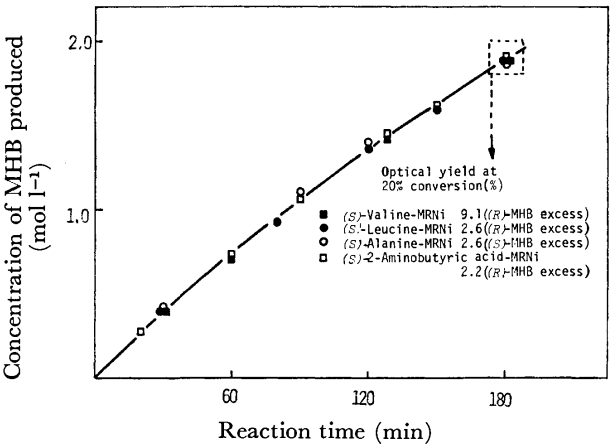

Fig. 1. Time courses of hydrogenation with α-amino acid MRNi.

All the plots in Fig. 1 overlapped one another, that is, all kinetic features of the hydrogenations with α-amino acid-MRNi appeared to be identical. On the other hand, the optical yields were intrinsic to each catalyst. As found in Fig. 2, similar results were obtained in the hydrogenations with α-hydroxy dicarboxylic acid-MRNi.

Figures 3 and 4 show the time courses of (*S*)- and (*R*)-MHB formations calculated from the optical yield of the product with α-amino acid-MRNi ((*S*)-valine and (*S*)-leucine) and α-hydroxy dicarboxylic acid-MRNi ((*S*)-malic acid and (*R,R*)-tartaric acid) respectively.

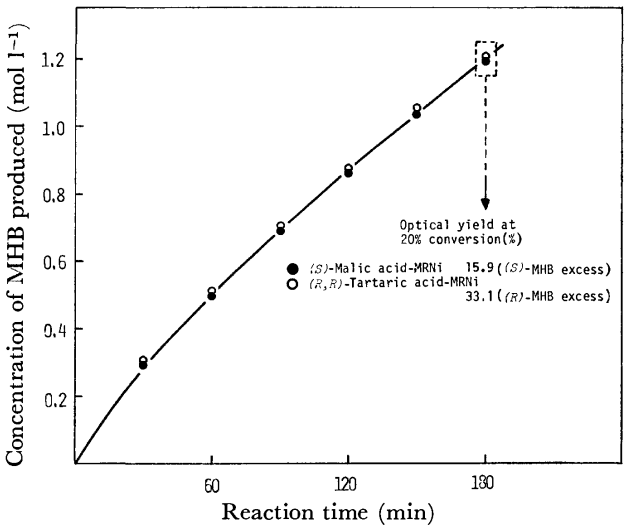

Fig. 2. Time courses of hydrogenation with α-hydroxy dicarboxylic acid-MRNi.

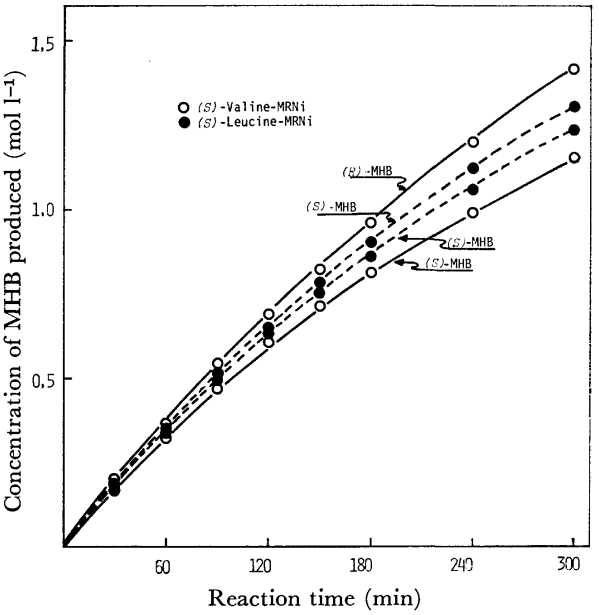

Fig. 3. Time courses of (*S*)- and (*R*)-MHB formation.

The rates of formations of *S*- and *R*-isomers, v_R and v_S, were determined graphically from the figures. The results are listed in Table 1.

From all these data, it became evident that the overall rates, $v=v_R+v_S$, at each reaction time were identical where the modifying reagents were of homologous structure, despite the difference in the rates of formation of each enantiomer, v_R and v_S, with respect to each catalyst.

The rate law of the hydrogenations with MRNi was determined in the usual manner. Initial rates, v_0, at different initial concentrations of MAA, [MAA], were determined by independent experiments. As shown in Fig. 5, plots of $1/v_0$ against 1/[MAA] gave straight lines and the plots corresponding to valine- and leucine-MRNi overlapped each other. Thus, the rates of the hydrogenations with α-amino acid-MRNi and α-hydroxy dicarboxylic acid-MRNi were found to follow the equation

$$v_0 = \beta^\circ[\mathrm{MAA}]/(1+\alpha^\circ[\mathrm{MAA}]) \quad (1)$$

and the following relations were expected to hold between valine- and leucine-MRNi:

$$\alpha^\circ_{(\mathrm{valine})} = \alpha^\circ_{(\mathrm{leucine})}, \quad \beta^\circ_{(\mathrm{valine})} = \beta^\circ_{(\mathrm{leucine})}. \quad (2)$$

The rates, v, determined in a single experiment (shown in Table 1), however, gradually deviated from the relations shown in Eq. 1 with increase of the conversion, owing to the decay of the catalyst.

Since all the α-amino acid-MRNi gave the same initial rates, as expected from Fig. 1, Eq. 2 was expected to hold among all the α-amino acid-MRNi examined.

The relations $\alpha^\circ_{(\mathrm{malic\ acid})}=\alpha^\circ_{(\mathrm{tartaric\ acid})}$ and $\beta^\circ_{(\mathrm{maric\ acid})}=\beta^\circ_{(\mathrm{tartaric\ acid})}$ were also expected to hold between malic acid- and tartaric acid-MRNi.

Table 1. The rates of the formations of (*S*)- and (*R*)-MHB

Catalyst (Reaction temp)		Reaction time (min) 30	60	90	120	150	180	240	300
(*S*)-Valine-MRNi (70 °C)	v_R (mol l^{-1} min^{-1}) × 10^3	6.15	5.90	5.32	4.81	4.51	4.33	3.73	3.62
	v_S	5.75	5.11	4.59	4.00	3.38	3.16	2.81	2.55
	v	11.90	11.01	9.91	8.81	7.89	7.49	6.54	6.17
	$(\lvert v_R-v_S\rvert/v)\times 10^2$	3.4	7.2	7.4	9.2	14.3	15.6	14.1	17.3
(*S*)-Leucine-MRNi (70 °C)	v_R (mol l^{-1} min^{-1}) × 10^3	6.01	5.37	5.10	4.55	4.24	4.00	3.42	3.21
	v_S	5.77	5.26	4.89	4.35	3.96	3.58	3.13	2.90
	v	11.78	10.63	9.90	8.90	8.20	7.58	6.55	6.11
	$(\lvert v_R-v_S\rvert/v)\times 10^2$	2.0	1.0	1.2	2.3	3.4	5.5	4.4	5.1
(*S*)-Malic acid-MRNi (60 °C)	v_R (mol l^{-1} min^{-1}) × 10^3	4.54	3.77	3.54	3.38	3.28	3.11	2.87	2.77
	v_S	3.98	2.99	2.54	2.51	2.38	2.27	1.94	1.63
	v	8.52	6.76	6.08	5.89	5.66	5.38	4.81	4.40
	$(\lvert v_R-v_S\rvert/v)\times 10^2$	6.6	11.5	16.4	14.8	15.9	15.6	19.3	25.9
(*R*,*R*)-Tartaric acid-MRNi (60 °C)	v_R (mol l^{-1} min^{-1}) × 10^3	5.16	4.52	4.18	4.01	3.94	3.63	3.47	3.32
	v_S	3.36	2.35	2.05	1.94	1.84	1.68	1.52	1.60
	v	8.52	6.87	6.23	5.95	5.78	5.31	4.99	4.93
	$(\lvert v_R-v_S\rvert/v)\times 10^2$	21.1	31.6	34.2	34.8	36.3	36.7	39.1	34.7

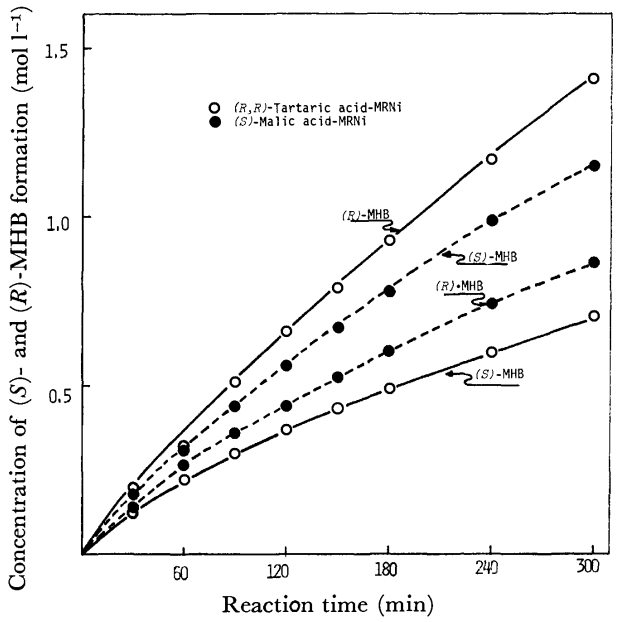

Fig. 4. Time courses of (*S*)- and (*R*)-MHB formation.

The relations mentioned above are also applicable to the values α and β at any reaction times, because the overlapping of the time courses shown in Figs. 1 and 2 indicated that all kinetic constants at each reaction time possess the same value within the same class of MRNi.

Discussions

The rate law shown in Eq. 1 can be derived from the following reaction Scheme, in which the adsorption of MAA to the modified and unmodified parts of catalyst is in competition and each adsorbed species is convertible with the others under the pre-equilibrium condition:

$$\begin{array}{ccccc} & \overset{K_S}{\longrightarrow} & (\mathrm{MAA}^*\cdot C)_S & \overset{H_2^*}{\underset{k_S}{\longrightarrow}} & (S)\text{-MHB} + C \\ \mathrm{MAA} + C & \overset{K_R}{\rightleftharpoons} & (\mathrm{MAA}^*\cdot C)_R & \overset{H_2^*}{\underset{k_R}{\longrightarrow}} & (R)\text{-MHB} + C \\ & \underset{K_O}{\longrightarrow} & (\mathrm{MAA}^*\cdot C)_O & \overset{H_2^*}{\underset{k_O}{\longrightarrow}} & \end{array} \qquad (3)$$

$$((S)\text{-MHB}+(R)\text{-MHB})/2 + C$$

C: Amount of adsorption site of MAA in given weight of catalyst.

K_S and K_R: Adsorption constants of MAA to be hydrogenated to (*S*)- and (*R*)-MHB under the influence of the modifying reagent.

K_O: Adsorption constant of MAA which did not interact with the modifying reagent.

k_S and k_R: Rate constants of the formations of (*S*)- and (*R*)-MHB from the $(\mathrm{MAA}^*\cdot C)$ interacted with the modifying reagent.

k_O: Rate constant of the formation of racemic MHB from the $(\mathrm{MAA}^*\cdot C)$ which did not interact with the modifying reagent.

Since the adsorption of hydrogen and MAA was not competitive[6] and all reactions were carried out under the same hydrogen pressure, the concentration of active hydrogen on the catalyst, $[H_2^*]$, would be constant under the experimental conditions.

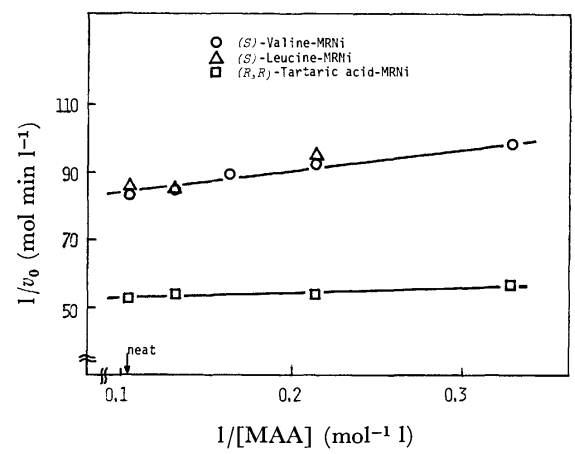

Fig. 5. Relation between initial rate (v_0) and initial concentration of substrate ([MHB]).

The rate of the reaction can be reduced to

$$v_R = \frac{(k_O K_O/2 + k_S K_S)[\mathrm{MAA}]C[\mathrm{H}^*]}{1+(K_O+K_S+K_R)[\mathrm{MAA}]}, \qquad (4)$$

$$v_S = \frac{(k_O K_O/2 + k_R K_R)[\mathrm{MAA}]C[\mathrm{H}^*]}{1+(K_O+K_S+K_R)[\mathrm{MAA}]}, \qquad (5)$$

$$v = \frac{(k_O K_O + k_S K_S + k_R K_R)[\mathrm{MAA}]C[\mathrm{H}^*]}{1+(K_O+K_S+K_R)[\mathrm{MAA}]}. \qquad (6)$$

When Eq. 6 was compared with Eq. 1, the following relations were deduced:

$$\alpha = K_R + K_S + K_O, \qquad (7)$$

$$\beta = (k_R K_R + k_S K_S + k_O K_O)\cdot C\cdot[\mathrm{H}^*]. \qquad (8)$$

If we simply assume that the enantio-differentiation takes place only at the rate-determining step of the hydrogenation and does not depend on the relative amounts of adsorption species, $[\mathrm{MAA}^*\cdot C]_R$, $[\mathrm{MAA}^*\cdot C]_S$, and $[\mathrm{MAA}^*\cdot C]_S$, the rates of formation of enantiomers, v_R and v_S should be proportional to $(k_S+k_O/2)$ and $(k_R+k_O/2)$. When the common adsorption constant of MAA is expressed by K, the relation $\beta=(k_O+k_R+k_S)\text{-}K\cdot C\cdot[\mathrm{H}^*]$ is expected to hold. In such a case, k_O is a common value for all the modified catalysts, while k_R and k_S should be independent values with respect to each catalyst. Therefore, the catalysts with different v_R and v_S values no longer give the same β value.

Thus this assumption would not be adequate to elucidate the present experimental results that the same class of MRNi gave the same β value but different v_R and v_S values.

The alternative assumption that the rates of formation of enantiomers are related to the amounts of $[\mathrm{MAA}^*\cdot C]_R$, $[\mathrm{MAA}^*\cdot C]_O$, and $[\mathrm{MAA}^*\cdot C]_S$ but not related to k_S, k_R, and k_O, leads to the equation

$$\beta = k(K_S+K_R+K_O)\cdot C\cdot[\mathrm{H}^*]. \qquad (9)$$

Here, k is the common rate constant of the all adsorption species $(k=k_R=k_S=k_O)$.

From the linear relation between the rate of hydrogenation and the amount of the adsorbed modifying reagent on the catalyst,[2] it is expected that the modifying reagent makes the adsorption site of MAA change by

occupying the adsorption site as a simple competitive adsorption species, but the exsistence of the modifying reagent on the catalyst does not affect the equilibrium constant between MAA and vacant adsorption sites. It has also been confirmed that the same class of modifying reagent was adsorbed on the catalyst in the same amount. Therefore, the same adsorption sites of MAA and C, and the same adsorption constants, K, are expected in the same class of MRNi. Hence the total amounts of the adsorbed MAA, that is $[MAA^*\cdot C]_S+[MAA^*\cdot C]_R+[MAA^*\cdot C]_O$, are the same for the same class of MRNi and only the molar fractions of the adsorption species, γ_S, γ_R, and γ_O, are determined by the chiral influence of the modifying reagent. Under these conditions, β can be reduced to

$$\beta = (K_O+K_R+K_S)\cdot C\cdot[H^*] = (\gamma_O+\gamma_R+\gamma_S)\cdot K\cdot C\cdot[H^*] = K\cdot C\cdot[H^*] = \alpha\cdot C\cdot[H^*],$$

where K is an adsorption constant of MAA and γ_O, γ_R, and γ_S are fraction coefficients of the adsorbed MAA. In this manner, the experimental result that the same class of MRNi gave the same β and α was justified.

Although the kinetic studies do not give any direct indications of the relations, $k_O=k_S=k_R=k$ and $K_O+K_R+K_S=(\gamma_O+\gamma_R+\gamma_S)K$, the present experimental results can only be rationalized without conflicting with the kinetic law under the assumption that the ratios of formation of enantiomers are determined by γ_O, γ_R, and γ_S. The function of the modifying reagent can be reduced to interacting with the substrate on the catalyst; such interaction results in the disproportionate formations of the diastereomeric adsorption species. The conclusion of the present studies is that the ratio of formation of enantiomers depends principally on the term, $(\gamma_O/2+\gamma_R)/(\gamma_O/2+\gamma_S)$, and that the enantioface-differentiating step occurs before the rate-determining step.

Another important finding of this study is that $|v_R-v_S|/v$ increased with the progress of the decay of the catalytic activity, as shown in Table 1. This may be caused by either the specific inactivation of the catalytic site at which the modifying reagent is absent and R- and S-isomers are produced at equal rates (decrease of γ_O), or the change of the adsorption mode of the modifying reagent with the change of the surface of the catalyst by the decay of the catalyst. Further detailed studies on this line are underway.

Experimental

Preparation of Modified Raney Nickel Catalyst. Into an alkaline solution (52 g of sodium hydroxide in 260 ml of water) whose temperature has been adjusted to 19 °C, 19.5 g of well-pulverized Raney alloy (Ni 42%, Al 58%, Kawaken Finechemical Co.) was added in portions at such a rate that the temperature of the mixture was maintained at 19±1 °C with vigorous shaking and cooling on an ice bath. It took 18 min to complete the addition of the alloy. The resulting suspension of Raney nickel was kept at 75—78 °C for 45 min, then allowed to stand at room temperature for 1.5—3 h. After the removal of the alkaline solution by decantation, the Raney nickel (RNi) was washed with eight 300 ml-portions of deionized water.

The modification of RNi was carried out in a 1% solution of modifying reagent. The pH of the modifying solution was adjusted to 5.1 for tartaric acid and malic acid with sodium hydroxide, and to an isoelectric point for each monoamino monocarboxylic acid.

Into 400 ml of the modifying solution, a 2.4 g-portion of the catalyst was immersed at 0 °C for 15 min. During that time, the solution was gently stirred for a few seconds every 5 min. After the removal of the solution, the catalyst was washed with a 40 ml-portion of water and three 200 ml-portions of methanol.

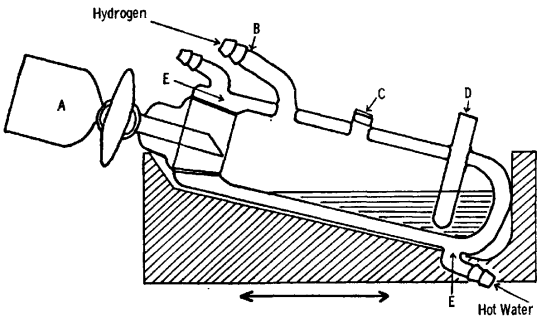

Fig. 6. Frask for hydrogenation.

Hydrogenation. The liquid-phase hydrogenation under atmospheric pressure was carried out with a specially designed 400 ml flask having a liquid inlet funnel (A), a gas inlet side-tube (B), a serum capped hole for sampling (C), a case for the thermometer (D), and a heating jacket with hot water (Fig. 6). Into the flask which had been filled with hydrogen and connected with a graduated hydrogen reservoir through the side-tube B, the modified catalyst suspended in 70 ml of

a) 2-Aminobutyric acid. b) Tartaric acid. c) Malic acid.

MAA (or solution of MAA in MHB) was introduced. The flask was fixed to a reciprocating shaker and the jacket was connected with a hot water circulation system. The heating and shaking of the reaction mixture were started simultaneously. The hydrogen uptake was followed by measurement taken every 10 min. The hydrogen uptake of each catalyst is listed in Table 2; from this the concentration of MHB at each stage was calculated. The concentration of MHB thus calculated matched with that determined by GLPC. The plots of time against concentration of MHB in the reaction mixture are shown in the text (Figs. 1 and 2).

Determination of Optical Yield. The optical yield was determined from the optical purity of the MHB dissolved in MAA. After the removal of the catalyst from the reaction mixture by filtration, the filtrate was distilled under reduced pressure. The optical rotation and the ratio, MAA/MHB, in the distillate were determined by means of polarimetry (Perkin-Elmer Model 241 Polarimeter with a 1 dm cell) at 20 °C and GLPC (Shimadzu GC-3HA, 300×0.5 cm stainless-steel column packed with PEG 20 M (20%) on Chromosorb W) at 100 °C respectively. The optical purity of MHB was determined by means of a calibration chart prepared by the plotting of α_D against the concentrations of MHB of different optical purities in MAA.

Time Course of the Formations of (S)- and (R)-MHB. The hydrogenation was carried out in the apparatus described above. A 2 ml portion of the reaction mixture was taken out through the serum capped sampling hole, using an injection syringe, at the times shown in Figs. 3 and 4. The concentration of MAA and the optical rotation of each sample were determined by the procedures mentioned above.

The plots of time against concentrations of (*S*)-and (*R*)-MHB are shown in the text (Figs. 4 and 5).

Initial Rates of Hydrogenation. The hydrogenations of MAA diluted with DL-MHB ranging in concentration from 1.86 to 9.29 (neat) mol/l were carried out at 70 °C. The initial rates of each experiment was determined graphically from the plot of hydrogen uptake against reaction time.

The authors wishes to thank Professors S. Teranishi and T. Imanaka of Osaka University for advice on the kinetic problems. The authors are happy to acknowledge the support of a Scientific Research Grant from the Ministry of Education, Japan (110308), for part of this work.

Activation of Carbon Dioxide by Tetraphenylporphinatoaluminium Methoxide. Reaction with Epoxide

Norikazu TAKEDA and Shohei INOUE*

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113

(Received March 27, 1978)

α,β,γ,δ-Tetraphenylporphinatoaluminium methoxide reacts reversibly with carbon dioxide in the presence of 1-methylimidazole, and this carbon dioxide is activated to react with propylene oxide to produce propylene carbonate under atmospheric pressure and at room temperature.

In the course of our studies on the reaction of carbon dioxide with organometallic compounds,[1-3] we have found that carbon dioxide reacts with tetraphenylporphinatoaluminium ethyl in the presence of 1-methylimidazole only in visible light, but not in the dark.[4] Further studies on the reaction of porphinatoaluminium complex with carbon dioxide have led to an interesting finding that tetraphenylporphinatoaluminium methoxide can be a carrier of carbon dioxide which is activated enough to easily react with propylene oxide.

Experimental

Materials. α,β,γ,δ-Tetraphenylporphine ($TPPH_2$) was synthesized from pyrrole and benzaldehyde in propionic acid.[5-6] Propylene oxide was purified by refluxing over potassium hydroxide, then fractional distillation. 1-Methylimidazole (Im) was purified by distillation over calcium hydride under reduced pressure. Dichloromethane was washed with sulfuric acid followed by water, dried over calcium chloride and then calcium hydride, and distilled over calcium hydride in a nitrogen atmosphere.

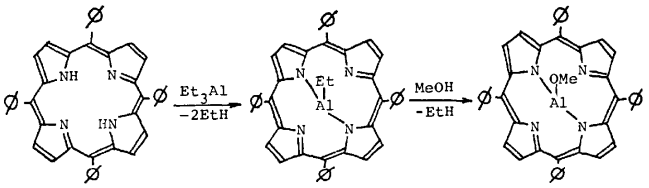
Carbon dioxide was purified by passing through a series of columns packed with copper(II) sulfate, potassium hydrogen carbonate, reduced copper, phosphorus pentaoxide and activated copper(II) oxide. Triethylaluminium was purified by distillation in a nitrogen atmosphere under reduced pressure (111 °C/24 mmHg).

Measurement. Infrared spectra were measured in a fixed cell (0.1—1.0 mm) using a Hitachi EPI-G3 spectrophotometer. Ultraviolet and visible spectra were measured in a quartz cell of length 0.1 cm using Shimadzu RSP-7B spectrophotometer. ^1H NMR spectra were measured using a JEOL 4H-A type spectrometer.

Gas chromatographic analysis was carried out using a Yanagimoto Model G80 gas chromatograph with the column of 1—1.5 m packed with silica gel with helium as the carrier gas. The composition of propylene oxide–carbon dioxide copolymer was determined by the ^1H NMR spectrum of its chloroform solution.[7]

Average molecular weight of the polymer was measured by using Toyo Soda HLC-802UR high speed liquid chromatograph.

Procedure. Formation of Tetraphenylporphinatoaluminium Methoxide (TPPAlOMe) by the Reaction of Tetraphenylporphinatoaluminium Ethyl (TPPAlEt) with Methanol: A 200 ml two-necked Pyrex flask containing tetraphenylporphine ($TPPH_2$; 3.07 g, 5.0 mmol) was purged with nitrogen, and dichloromethane (150 ml) was added to dissolve $TPPH_2$. Triethylaluminium (0.69 ml, 5.0 mmol) was added slowly to the solution in a nitrogen stream at room temperature to give a solution of TPPAlEt in a few minutes.[4] The solvent was removed under reduced pressure from this system, the purple residue was dissolved in methanol (100 ml), and the solution was refluxed for three hours in a nitrogen atmosphere. After removing most of methanol under reduced pressure, remaining trace of methanol was removed as benzene azetrope. The resulting product was dark reddish-purple powder (about 3.3 g). Found C, 80.18; H, 4.81; N, 8.15%. Calcd for $C_{45}H_{31}N_4OAl$: C, 80.58; H, 4.66; N, 8.35%.



When dry hydrogen chloride was bubbled in the dichloromethane solution of the resulting product, the liberation of an equivalent amount of methanol to aluminium was detected in the solution by gas chromatography.

Reaction of Carbon Dioxide with TPPAlOMe: Reactions of tetraphenylporphinatoaluminium methoxide (TPPAlOMe) with carbon dioxide were carried out in a 20 ml quartz cell at 20 °C. The cell containing TPPAlOMe (0.168 g, 0.25 mmol), synthesized by the aforesaid method, was purged with nitrogen, and dichloromethane (20 ml) was added to dissolve TPPAlOMe. After the addition of 1-methylimidazole (0.033 g, 0.40 mmol), carbon dioxide was bubbled in the solution for one minute, and the reaction was followed by the infrared spectral measurement of the reaction mixture.

Reaction of Carbon Dioxide and Propylene Oxide with TPPAlOMe:

Reaction in Dichloromethane: Carbon dioxide was bubbled into the dichloromethane solution (20 ml) of TPPAlOMe (0.168 g, 0.25 mmol) with 1-methylimidazole (0.033 g, 0.40 mmol), and after two hours propylene oxide (0.35 ml, 5.0 mmol) was added to the solution in a carbon dioxide stream.

The solvent was removed from the solution after 45 h under reduced pressure at room temperature, followed by the addition of 5% hydrochloric acid (about 30 ml). After the insoluble materials were filtered off, sodium chloride (about 1 g) and diethyl ether (about 100 ml) were added to the aqueous filtrate, and the reaction product was extracted into the ether layer. After the evaporation of diethyl ether, the product was isolated by distillation under reduced pressure as a colorless oily liquid (0.2 g), which was identified as propylene carbonate by infrared spectral measurement and gas chromatography. The yield was directly determined by gas chromatography of the reaction mixture.

Reaction in Propylene Oxide in the Presence of 1-Methylimidazole:

The cell containing TPPAlOMe (0.168 g, 0.25 mmol) was purged with nitrogen and propylene oxide (8.3 g, 140 mmol) was added to dissolve TPPAlOMe. After the addition of 1-methylimidazole (0.033 g, 0.40 mmol), carbon dioxide was bubbled in the solution for one minute every 24 h.

After 96 h the reaction product was isolated by the same procedure as described above. In this case, about 1.2 g of propylene carbonate was obtained.

Reaction in Propylene Oxide in the Absence of 1-Methylimidazole: Carbon dioxide was bubbled in the propylene oxide solution (10 ml) of TPPAlOMe (0.12 or 0.25 mmol) for 1 min every 24 h. After 11 days, unreacted propylene oxide was removed from the reaction mixture under reduced pressure at room temperature. Diethyl ether was added to the residual viscous product, and the solvent was removed from the ether soluble part to obtain 9.3 g of propylene oxide–carbon dioxide copolymer.

Results and Discussion

Reaction of Carbon Dioxide with Tetraphenylporphinatoaluminium Methoxide (TPPAlOMe). When carbon dioxide was bubbled in a dichloromethane solution of TPPAlOMe in the presence of 1-methylimidazole (Im), a new carbonyl absorption band immediately appeared at 1697 cm^{-1} in the infrared spectrum of the reaction mixture (Fig. 1). If nitrogen gas was bubbled in this

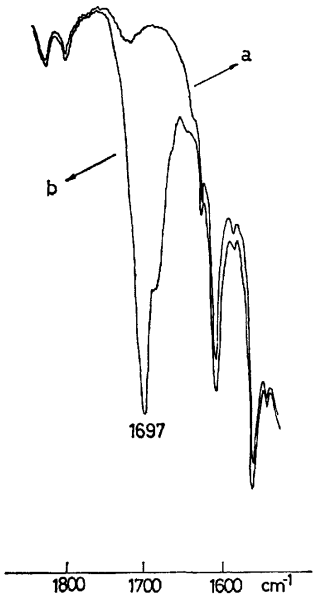


Fig. 1. Infrared spectra of the reaction mixture of tetraphenylporphinatoaluminium methoxide (TPPAlOMe) with carbon dioxide (CO_2) in the presence of 1-methylimidazole, TPPAlOMe; 0.25 mmol, 1-methylimidazole; 0.40 mmol, CH_2Cl_2; 20 ml, temp; 20 °C, a: before bubbling of CO_2, b: 20 min after bubbling of CO_2.

reaction mixture, this absorption band disappeared, and it appeared again by the introduction of carbon dioxide in the solution, indicating carbon dioxide reversibly reacted with TPPAlOMe in the presence of Im. In the absence of Im, no carbonyl absorption band was observed in the spectrum, in the reaction in 1 atm CO_2 at 20 °C for 120 h as well as in the reaction in 40 atm CO_2 at 60 °C for 20 h. No remarkable effect of irradiation of visible light was recognized in this reaction.

Figure 2 shows the visible spectra of TPPAlOMe and

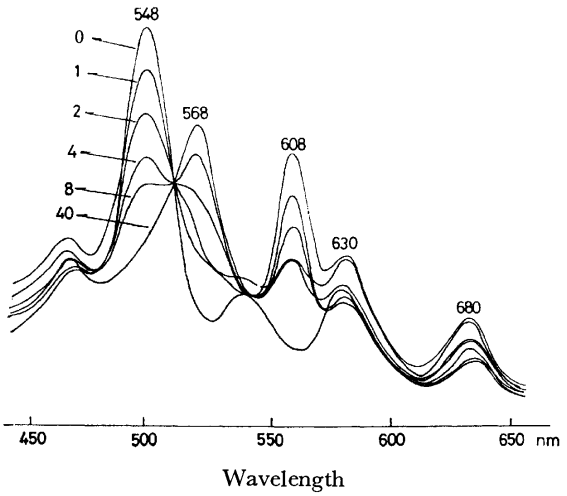

Fig. 2. Visible spectra of tetraphenylporphinatoaluminium methoxide (TPPAlOMe) and tetraphenylporphinatoaluminium methoxide–1-methylimidazole system in dichloromethane, TPPAlOMe; 7.0×10^{-3} mmol, CH_2Cl_2; 20 ml, 1-methylimidazole; 0, 7.0×10^{-3}, 1.4×10^{-2}, 2.8×10^{-2}, 5.6×10^{-2}, 2.8×10^{-1} mmol. The number in the figure represents the mole ratio of 1-methylimidazole to TPPAlOMe.

TPPAlOMe–Im (1 : 0.5—1 : 40) systems in dichloromethane at room temperature. The absorption maximum of the TPPAlOMe spectrum shifted from 548 to 568 nm in the presence of a sufficient amount of Im, and an isosbestic point was observed at 557 nm, which indicates the coordination of Im to TPPAlOMe probably as an axial ligand on the opposite side of methoxyl group with respect to the porphine ring.

As to the reactivity of other aluminium alkoxides with carbon dioxide, diethylaluminium ethoxide does not react with carbon dioxide even at 100 °C in the presence of several tertiary amines.[8] Thus, the reversible reaction with carbon dioxide at room temperature and under atmospheric pressure is very characteristic of the present system.

Reaction of Carbon Dioxide and Propylene Oxide with TPPAlOMe. Reaction in Dichloromethane in the Presence of 1-Methylimidazole: When the solution of TPPAlOMe with 1-methylimidazole (Im), saturated with carbon dioxide, was added by propylene oxide, the absorption at 1697 cm^{-1}, which was already observed in the TPPAlOMe–Im–CO_2 system, increased immediately (Fig. 3(A)). After three hours, a new carbonyl absorption band centered at 1805 cm^{-1} appeared, assigned to C=O stretching vibration of cyclic carbonate (propylene carbonate). And then after about 25 h other carbonyl absorption bands appeared at 1675 and 1750 cm^{-1}, which did not disappear by bubbling nitrogen gas or by removing the solvent. The band at 1750 cm^{-1} is considered due to linear carbonate as mentioned in the latter part of this paper, but the assignment of the band at 1675 cm^{-1} is not made at present.

The behavior of the absorption band at 1697 cm^{-1} is particularly interesting as shown in Fig. 3(B). As long as sufficient carbon dioxide existed in the solution as indicated by the absorption at 2340 cm^{-1}, the band at

Infrared spectra of the reaction mixture of tetraphenylporphinatoaluminium methoxide (TPPAlOMe), carbon dioxide (CO_2) and propylene oxide in the presence of 1-methylimidazole, TPPAlOMe; 0.25mmol, 1-methylimidazole; 0.40 mmol, PO; 5.0 mmol, CO_2; bubbling, (A); a: before addition of propylene oxide, b: 3 h after addition c: 25 h, d: 43 h, (B); e: when free CO_2 exists in the reaction mixture, f: when there remains no free CO_2 in the system.

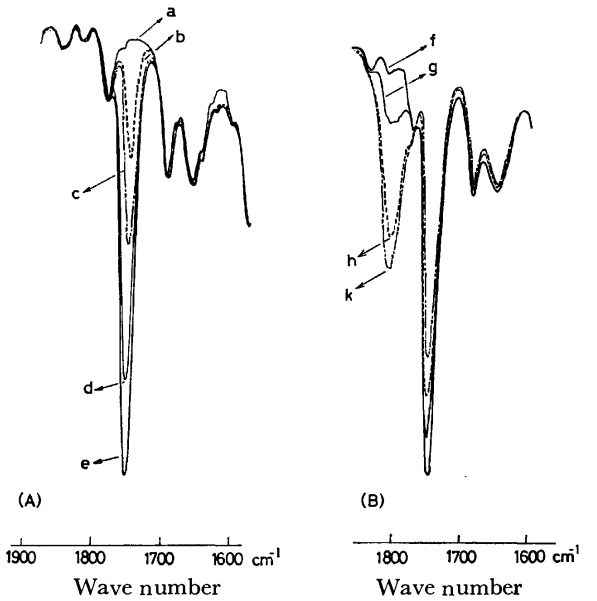

Fig. 4. Infrared spectra of the reaction mixture of tetraphenylporphinatoaluminium methoxide (TPPAlOMe), carbon dioxide (CO_2) and propylene oxide, (A); TPPAlOMe; 0.25 mmol, propylene oxide; 10 ml, CO_2; bubbling every 24 h, a: before bubbling of CO_2, b: 18 h after bubbling of CO_2, c: 44 h, d: 92 h, e: 167 h, (B) when there exists no free CO_2. Added 1-methylimidazole; 0.40 mmol, f: 20 min after addition of 1-methylimidazole, g: 2 h, h: 33 h, k: 49 h.

1697 cm^{-1} did not change its intensity. When the solution became deficient in carbon dioxide, it diminished rapidly, while the absorption band at 1805 cm^{-1} increased. Supply of carbon dioxide here in the solution made absorption band at 1697 cm^{-1} strong again. Thus, the absorption band at 1697 cm^{-1} is due to carbon dioxide activated by the TPPAlOMe–Im complex, which reacts immediately with propylene oxide to produce propylene carbonate at room temperature and under atmospheric pressure.

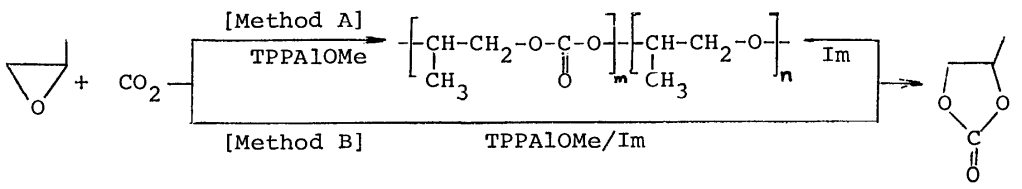
The formation of propylene carbonate proceeded catalytically with respect to TPPAlOMe: for example, 2.7 equivalent in dichloromethane and 4.0 equivalent in propylene oxide under 1 atm CO_2 at 20 °C, after 2.5 h, respectively.

As to other amines than Im, pyridine behaved similarly, showing a reversible absorption band at 1695 cm^{-1} in the infrared spectrum of the reaction system TPPAlOMe–pyridine–CO_2. In contrast, no new carbonyl absorption band was observed when carbon dioxide was bubbled in the TPPAlOMe–triethylamine system. However, when propylene oxide was added to the solution, a reversible absorption band appeared at 1697 cm^{-1}. Similar results were obtained in the case of *N,N*-dimethylbenzylamine or *N,N*-dimethylaniline. Nevertheless, propylene carbonate could be produced from propylene oxide and carbon dioxide under mild reaction conditions by using TPPAlOMe coupled with amine, such as 1-ethylimidazole, pyridine, picolines, *N,N*-dimethylbenzylamine, triethylamine, tributylamine, triethylenediamine and hexamethylenetetraamine.

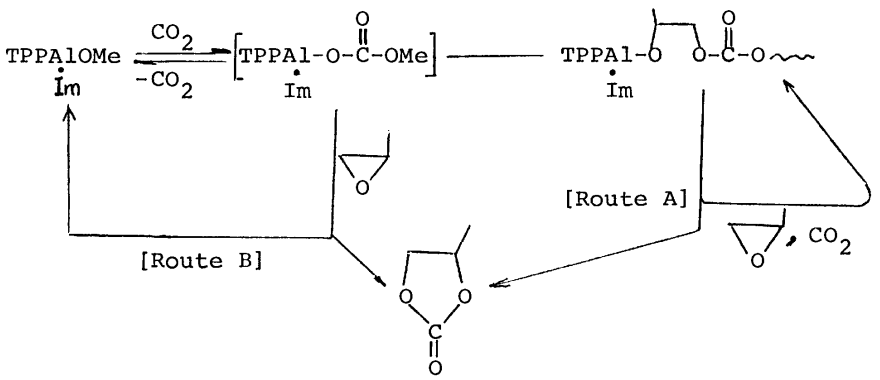
However, under atmospheric pressure and at room temperature, a mixture of only carbon dioxide, propylene oxide and tertiary amine, without TPPAlOMe, could not produce propylene carbonate.

Reaction in Propylene Oxide in the Absence of 1-Methylimidazole: When TPPAlOMe, carbon dioxide and propylene oxide reacted in the absence of amine, the infrared spectra of the reaction mixture showed a carbonyl absorption band only at 1750 cm^{-1} (Fig. 4(A)) which was assigned to C=O stretching vibration of linear carbonate. In fact, from this reaction mixture was obtained 9.3 g of propylene oxide–carbon dioxide copolymer, which consisted of 15 mol % of oxycarbonyl and 85 mol % of oxy(2-methylethylene) units, and the average molecular weight was about 4000.[9]

By the removal of carbon dioxide perfectly from this



Scheme 1.



Scheme 2.

system, followed by the addition of Im or *N,N*-dimethylbenzylamine, the intensity of the absorption band at 1750 cm^{-1} decreased and an absorption at 1805 cm^{-1} appeared (Fig. 4(B)).

Therefore, propylene carbonate may be formed from the cyclization of carbon dioxide–propylene oxide copolymer (linear polyether–carbonate) by the effect of amine (Scheme 1).

However, as the formation reaction of propylene carbonate (PC) in the TPPAlOMe–Im–CO_2–propylene oxide system (Method B; 2.7 mol PC/mol TPPAlOMe/2.5 h) proceeds much faster than that *via* carbon dioxide–propylene oxide copolymer (Method A; 0.1 mol PC/mol TPPAlOMe/2.5 h), there seems to be another route than that *via* the copolymer, in which TPPAlOMe–Im–CO_2 complex reacts with propylene oxide to produce propylene carbonate directly.

Conclusion

Possible routes for the reaction in TPPAlOMe–Im–CO_2–propylene oxide system are shown in Scheme 2. In route A, carbon dioxide inserts between Al–OMe bond reversibly, propylene oxide reacts into the Al–carbonate bond thus formed, and the repeating reaction of propylene oxide and CO_2 results in the formation of copolymer. This copolymer may be gradually cyclized to propylene carbonate in the presence of amine, as actually confirmed. However, there still remains the possibility of the existence of another direct route, B, because of the difference in the rates of the formation of propylene carbonate in two methods of Scheme 1 (directly from TPPAlOMe–amine–CO_2–propylene oxide system, and *via* copolymer). Although TPPAlOMe–Im–CO_2 complex, having infrared absorption at 1697 cm^{-1}, would be an aluminium alkyl carbonate as shown in Scheme 2, the structure has not yet been confirmed, because of its highly reversible, unstable nature.

As the conclusion, TPPAlOMe–1-methylimidazole complex is a carrier of activated carbon dioxide which is able to react readily with propylene oxide to give propylene carbonate even under atmospheric pressure of carbon dioxide and at room temperature.

The authors wish to express their thanks to Professor Teiji Tsuruta for his valuable discussion, and to Mr. Hiroshi Yokoyama for his carrying out some of the preliminary experiments.

The Chlorination of Norbornene and Cyclooctadienes with Sulfuryl Chloride and Phosphorus(V) Chloride. Ionic *vs.* Radical Chlorination with Each Reagent

Sakae UEMURA,* Hajime OKAZAKI, Akira ONOE, and Masaya OKANO

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

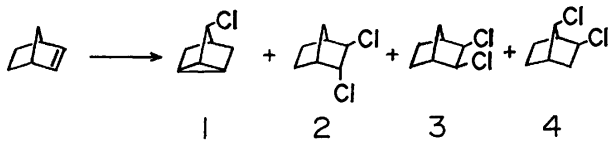
(Received March 31, 1978)

The chlorination of norbornene and cyclooctadienes with sulfuryl chloride and phosphorus(V) chloride has been investigated mainly in carbon tetrachloride under various conditions. From the studies of the product distributions and the effect of radical scavengers, the following facts have been revealed for the first time in olefin chlorination: chlorination with sulfuryl chloride proceeds through an ionic pathway at room temperature or in the presence of silica gel and that with phosphorus(V) chloride through a radical pathway at elevated temperature, and an ionic chlorination with phosphorus(V) chloride in nonpolar solvents does not seem to involve C–P bond formation through the reaction.

Sulfuryl chloride has generally been known to chlorinate olefin through a radical pathway,[1] while it is also known as the effective electrophile in nuclear chlorination of some aromatic compounds.[2] Phosphorus(V) chloride, on the other hand, can usually chlorinate olefin *via* an ionic mechanism,[3] while it also works as the effective catalyst[4] or the reagent[3] for the radical chlorination of alkanes. In order to know whether each chlorinating agent shows both an ionic and a radical nature in olefin chlorination, we have carried out the chlorination of norbornene and cyclooctadienes under various conditions; these olefins have already been shown to be good substrates to study the nature of chlorination because of clear-cut different distributions in the products between radical and ionic reactions.[5,6] We will describe the results and discuss the nature of both reagents.

Results and Discussion

Treatment of norbornene with sulfuryl chloride and phosphorus(V) chloride afforded four products: nortricyclenyl chloride (**1**) and *trans*-2,3- (**2**), *exo-cis*-2,3- (**3**), and *exo*-2-*syn*-7-dichloronorbornane (**4**); their distributions depended very much on reaction conditions. The results are summarized in Table 1, together with



the data of typical ionic (Runs 13 and 15) and radical chlorination (Runs 14 and 16) by use of chlorine[7] and

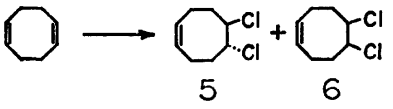
a) Determined by GLC. b) *m*-Dinitrobenzene. c) Silica gel, Wakogel C-300, 2.35 g, 100 wt % to norbornene. 2-Chloronorbornane (*ca.* 10%) and a small amount of unidentified compound were also formed. d) Ref. 7. The amounts of olefin and chlorine were not described. e) Ref. 8. Olefin (0.15—0.8 M) and $PhICl_2$ (0.13—0.2 M) were used. The yields of the products were not stated.

(dichloroiodo)benzene.[8] The chlorination with sulfuryl chloride in carbon tetrachloride gave a mixture of **1** and **4** or of **2** and **3** as the main products at room (Run 1) or reflux (Run 2) temperature, respectively. The comparison of the product distribution with that of Runs 13—16 reveals that the reaction has a radical nature at reflux temperature as expected, while it has an ionic nature at room temperature. In fact, when *m*-dinitrobenzene (*m*-DNB) was added as a radical scavenger in the reaction at reflux temperature (Run 3), the yields of the products decreased profoundly and the isomer distribution became similar to that in an ionic reaction, showing that the radical reaction was almost completely suppressed. A quite similar phenomenon was observed using phenol or *t*-butylcatechol instead of *m*-DNB. Under irradiation of UV light (Run 4) or in the presence of benzoyl peroxide, an almost complete radical reaction occurred even at room temperature. The reaction in benzene under reflux also showed a radical nature, as expected (Run 5). Since olefin chlorination with sulfuryl chloride has already been recognized as a radical reaction, as described above, the finding described here seems to be the first clear-cut example of ionic chlorination of olefins with sulfuryl chloride. The attempts of the chlorination in more polar solvents such as acetonitrile and nitromethane, in which the result of a more ionic reaction is expected, resulted in the low yield of products and/or the formation of various unidentified compounds. It has been found that electrophilic chlorination of aromatic compounds by sulfuryl chloride occurs if silica gel is added to the reaction system.[9] When we applied such a reaction to norbornene by using silica gel (Wakogel C-300, 300 mesh), the products whose distribution was clearly characteristic of an ionic reaction were obtained even in the reaction at refluxing temperature (Run 6).

The product distributions in the chlorination of norbornene by phosphorus(V) chloride in carbon tetrachloride, chloroform, and benzene suggest that all reactions proceeded mainly through an ionic pathway (Runs 7, 8, 11, and 12). Considering the results of Runs 8 and 10, however, it may be possible to say that the reaction has a slightly radical nature at refluxing temperature or under UV irradiation in carbon tetrachloride. In fact, the addition of *m*-DNB to a reaction system at refluxing temperature in carbon tetrachloride suppressed the formation of **2** and **3** (Run 9). These results revealed that both a homolytic and a heterolytic chlorination were operative at 76 °C (refluxing temperature of CCl_4) by use of phosphorus(V) chloride. Wyman *et al.*[3] have suggested the presence of a radical nature in the chlorination of *trans*-stilbene at more elevated temperatures (at 124 °C in chlorobenzene as solvent).

Treatment of 1,5-cyclooctadiene with sulfuryl chloride and phosphorus(V) chloride gave *trans*- (**5**) and *cis*-5,6-dichlorocyclooctene (**6**), together with a small amount (<1%) of an unidentified compound. Typical results are shown in Table 2. It has already been clarified



5 6

that an ionic reaction favored the formation of

Table 2. Chlorination of 1,5- and 1,3-cyclooctadienes

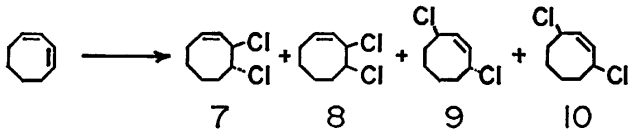
a) Determined by GLC. The yield is based on the chlorinating agent charged. b) 1,5-Cyclooctadiene. c) *m*-Dinitrobenzene. d) Silica gel, Wakogel C-300, 5.41 g, 100 wt % to 1,5-COD. Two unidentified compounds, probably HCl addition products, were also formed (*ca.* 5%). e) Ref. 6. Radical reaction. f) Ref. 6. Ionic reaction. g) 1,3-Cyclooctadiene.

5 (Run 28), while a radical reaction preferred that of **6** (Run 27).[6] The reaction with sulfuryl chloride at reflux temperature in carbon tetrachloride (Run 17) gave mainly **6**, as expected, while that at room temperature (Run 20) gave mainly **5**, although the yield was very low. The addition of silica gel promoted the ionic chlorination profoundly (Run 19), as in the case of norbornene. On the other hand, the reaction with phosphorus(V) chloride afforded mainly **5** in almost all cases (Runs 23—26), except in carbon tetrachloride in which the formation of **6** predominated (Runs 21 and 23). This result seems to be another and much clearer example of a homolytic olefin chlorination with phosphorus(V) chloride. In all cases where a radical reaction seems to prevail, the addition of *m*-DNB suppressed the yield of **6** markedly and increased that of **5** (Runs 18 and 22).

Although a detailed study was not carried out, the results of some reactions of 1,3-cyclooctadiene with both chlorinating agents were worth noting. The products were four dichlorocyclooctenes, **7**—**10**. Typical results are shown in Table 2, together with the results under



7 8 9 10

ionic (Run 33) and radical conditions (Run 32).[6] If we compare the isomer distributions in Runs 30 and 31 with those in Runs 32 and 33, it seems that chlorination with phosphorus(V) chloride has a radical nature in carbon tetrachloride at refluxing temperature, while it proceeds mainly through ionic pathway in dichloromethane.

Contrary to the case of radical chlorination with sulfuryl chloride, where it has already been clarified that sulfuryl chloride decomposed to chlorine atoms and chlorosulfonyl radicals, both acting as chain carriers,[1] there should be the polarization of sulfuryl chloride shown below in an ionic olefin chlorination. The

$$SO_2Cl_2 \longrightarrow SO_2\overset{\delta-}{Cl}\overset{\delta+}{Cl} \rightleftarrows SO_2Cl^- + Cl^+$$

addition of silica gel clearly enhances such polarization. On the other hand, in the radical chlorination of olefin with phosphorus(V) chloride the dissociation shown below seems to occur at elevated temperatures in carbon tetrachloride; such a dissociation was proposed by Olah *et al.*[4] in the phosphorus(V) chloride catalyzed radical chlorination of several alkanes.

$$PCl_5 \rightleftarrows PCl_4\cdot + Cl\cdot$$
$$PCl_5 \rightleftarrows PCl_3 + Cl_2$$
$$PCl_5 + Cl_2 \rightleftarrows PCl_4\cdot + Cl_3\cdot \quad (Cl\cdot + Cl_2)$$

For an ionic olefin chlorination with phosphorus(V) chloride, it has been proposed[3] that phosphorus(V) chloride (in the form of $PCl_4^+PCl_6^-$) added across the double bond to afford the β-chlorophosphorus(V) compound,[10] followed by the S_Ni attack of the chlorine of the PCl_4 moiety and the elimination of phosphorus(III) chloride. Although phosphorus(V) chloride is known to exist in two competing equilibria, (1) $2PCl_5 \rightleftarrows PCl_4^+ + PCl_6^-$ and (2) $PCl_5 \rightleftarrows PCl_4^+ + Cl^-$, in polar solvents, it exists as a monomer in nonpolar solvents such as benzene and carbon tetrachloride.[11] Therefore, a mechanism which does not involve C–P bond formation should also be conceivable in the ionic chlorination of olefins with phosphorus(V) chloride in nonpolar solvents. By comparing the product distribution in the case of phosphorus(V) chloride with that in an ionic chlorination with chlorine, one possible scheme may be the ionic attack of chlorine which may be formed by the equilibrium $PCl_5 \rightleftarrows PCl_3 + Cl_2$.[3,4]

The following two points were revealed. The chlorination with sulfuryl chloride proceeds through a radical pathway at elevated temperature, as has been reported, but also through an ionic pathway at lower temperature or in the presence of silica gel. The chlorination with phosphorus(V) chloride is mainly an ionic reaction, but it showed some radical nature in carbon tetrachloride at refluxing temperature.

Experimental

All organic materials and sulfuryl chloride were commercial products and distilled just before use. Commercial phosphorus(V) chloride was used without further purification. The reactions were carried out by mixing all the reagents at room temperature and then keeping the mixture at reaction temperature for appropriate times under the presence of atmospheric oxygen unless otherwise stated. After reaction the mixture was cooled and washed with water and then the organic layer was separated and dried over $MgSO_4$. The identifications of each product, **1**—**4**[5,12] and **5**—**10**[6] were described previously. The product mixtures were analyzed by GLC by the use of Shimadzu 4BMPF apparatus on EGSS-X (15%)-Chromosorb-W (1 or 3 m) column (carrier gas, N_2; ethyl benzoate as internal standard).

Volatile Components of *Meratia praecox*

Yoko NAYA* and the late Munio KOTAKE
The Institute of Food Chemistry, Shimamoto-cho, Mishima-gun, Osaka 618
(Received April 10, 1978)

The major volatile constituents present in different parts of a deciduous tree, *Meratia praecox*, have been identified by combination of GC-MS and spectral analysis of the isolated compounds. From the results, some biogenetic implications were discussed.

The family Calycanthaceae consists of two genera, *Meratia* (Chinese origin) and *Calycanthus* (American origin). *Meratia praecox* Rehd. et Wils. (*Chimonanthus praecox*) is a small deciduous tree producing fragrant flowers during a period of two months in midwinter. Early works on the essential oils of Chimonanthus fragrance were reviewed by Louveau.[1] Among the compounds reported were benzyl alcohol, linalool, terpineol, farnesol, and indole. By means of recent techniques, we have made an exhaustive study of the oils isolated from the different parts of *M. praecox*, and determined the relative amounts of various components as a function of growing season. This paper presents the results of investigation and a discussion on biogenetic implications.

Experimental

Of many samples collected, the results for six characteristic specimens will be described. Samples were flower bud bursting flower, fresh flower, faded flower, leaf and fresh branch (Table 1). All the specimens were collected from the same tree. Each specimen was steam-distilled under atmospheric pressure. The distillates were saturated with sodium chloride and extracted with ether; the ether extract was dried over anhydrous sodium sulfate, and the ether was removed to give the essential oil. The yields of essential oils are also given in Table 1. Characterization of the components was carried out by a combination of GC-MS and spectral analysis after their isolation by adsorption chromatography (silica gel or silver nitrate-impregnated silica gel) and preparative gas chromatography (Carbowax-20M). The identity of the major constituents was confirmed by a comparison of their IR and NMR spectra with those of authentic samples.

TABLE 1. ANALYTICAL SAMPLES FROM THE DIFFERENT PARTS OF *M. praecox* AND THE CONTENTS OF VOLATILE COMPOUNDS

Sample No.	Plant part	Harvested date (1977)	Yield (%)
I	Flower bud	17/Jan.	0.082
II	Bursting flower	5/Feb.	0.087
III	Fresh flower	10/Feb.	0.19
IV	Faded flower	1/March	0.012
V	Leaf	7/June	0.04
VI	Fresh branch	1/March	0.02

Apparatus and Operating Conditions. Preparative GLC was carried out with a Varian Aerograph 920 fitted with a thermal conductivity detector, using a 10 ft.×3/8 in. aluminum column containing 20% Carbowax-20M on 60—80 mesh Diasolid-L. Helium was used as a carrier gas, the column temperature being set at 100—200 °C.

For quantitative analytical GLC, a Hitachi K-53 apparatus equipped with a flame ionization detector and a computer system was used. The capillary column used for the analysis was 45 m×0.25 mm, made of stainless steel and coated with HB 2000; the column temperature was 150 °C, isothermal. The inlet pressure for nitrogen carrier gas was set at 1.5 kg/cm^2.

The GC-MS spectra were measured by combination of GLC fitted with a Golay column (45 m×0.25 mm, HB 2000) and mass spectrometry using a Hitachi RMU-6 mass spectrometer with operating conditions: ionization energy, 70 eV; acceleration voltage, 2000 V. The column temperature was programmed non-linearly at 100—150 °C with a gas inlet pressure of 0.6 kg/cm^2.

The IR spectra were measured with a Hitachi EPI-G2 spectrometer. The PMR spectra were taken with a Hitachi R-20B spectrometer at 60 MHz in CCl_4 with TMS as internal standard.

Results and Discussion

The components identified in six specimens, together with their contents as determined with the GC/computer system are given in Table 2. The major compound common to the oils of the flower bud and the bursting flower was found to be elemol, corresponding to more than 80% of the volatile oils. However, hedycaryol, instead of elemol, was isolated from ether extracts obtained without steam distillation by preparative TLC on silica gel. Hedycaryol, identified by its NMR spectrum, was converted into elemol on being injected into a gas chromatograph. Elemol is known to be an artifact caused by thermal isomerization. Thus, its biosynthetic equivalent, hedycaryol, appears to be one of the basic products of sesquiterpene biosynthesis. The data for bursting flower oil indicate that benzyl alcohol is produced at an early stage in the flowering. In the fresh flower oil, bicyclogermacrene and related compounds, δ-, β-, γ-elemenes, and germacrene-B, were found to be the major components. Considerable amounts of benzyl alcohol, its acetate, and linalool (possibly responsible for the flowery odor) were detected. Because of the marked increase of volatiles in the fresh flower, the detection of elomol or its equivalent would be masked by the post-products. In the faded flower oil, elemol was found to be the main compound, the level of components predominant when the flower was in full bloom decreasing. The characteristic compounds of the flower odor might have evaporated into the air, only sesquiterpens remaining. The leaf oil was similar to the faded flower oil, but not to the woody branch oil. In the woody branch oil, major components were humulene, caryoph-

yllene and its oxides (*t,t*-farnesyl-pp type), together with considerable amounts of compounds of *c,t*-farnesyl-pp type such as germacrene-D, cadinenes, and cadinols.

The contents (%) of some distinctive components are given in Table 3. Linalool, its oxides and aromatic compounds such as benzyl alcohol, its acetate and indole are distinctive components of the fresh flower oil, appearing to have been translocated or partly lost by evaporation in the faded flower. These compounds were formed before the leaf emerged, thus before the start of vigorous assimilation. Sesquiterpenes of the germacrene-B type, such as hedycaryol and related hydrocarbons, amounted to 35—88% of the flower oils (I—IV) and the leaf oil (V). The branch oils did not contain nearly as much, while germacrene-D and related hydrocarbons and oxygenated compounds, in addition to humulene and caryophyllene, were major components of the woody branch oils. All these components were absent or present in only small quantities in the oils of flowers and the leaf. The difference in biosynthetic pathways is thus distinct.

Vinyl Polymerization. 375.[1] Radical Polymerization of Vinyl Monomer in Water Initiated with Tin Mercaptides and Iron(III) Ion

Yoshiaki NAKAMURA, Tatsuro OUCHI, and Minoru IMOTO*

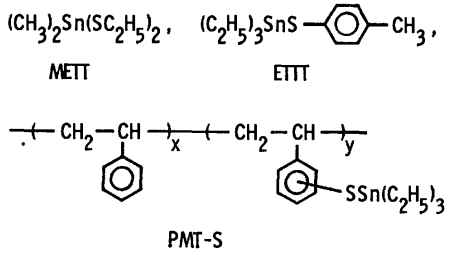
Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita-shi, Osaka 564

(Received April 12, 1978)

The polymerization of the vinyl monomer was carried out in water, using either dimethylbis(ethylthio)tin or triethyl(*p*-tolylthio)tin as an initiator. The polymerization required the coexistence of the iron(III) ion. The initiating species was concluded to be a thiyl radical. Macromolecular tin mercaptide was much more effective than monomeric tin mercaptide.

The present authors[2-4] have reported that dibutyltin dilaurate containing metal-oxygen bonds and tetrabutyltin or dimethylmercury bearing metal-carbon bonds are able to polymerize vinyl monomers in the presence of various metal chlorides. The present paper reports the polymerization in water, using either dimethylbis(ethylthio)tin (METT) or triethyl(*p*-tolylthio)tin (ETTT) as the organotin compound containing the metal-sulfur bond. Furthermore, in order to study the polymeric effects of organotin compounds, the polymerization of the monomer with macromolecular tin mercaptide has been conducted.

Tin mercaptides are used as stabilizers for poly(vinyl chloride) resins, and as catalysts for the ring-opening polymerization of epoxides and the reaction of isocyanate with alcohol. Ayrey *et al.*[5] conducted the radical polymerization of vinyl monomers initiated with α,α′-azobisisobutyronitrile in the presence of dibutylbis(ethylthio)tin. However, the radical polymerization of vinyl monomers initiated with tin mercaptide in the absence of the usual initiator has not been reported.



Experimental

Materials. METT, ETTT, and partially tin mercaptidated polystyrene (PMT-S) were prepared from dimethyltin dichloride (MTC) and ethanethiol, from triethyltin chloride (ETC) and *p*-toluenethiol, and from ETC and partial mercapto polystyrene, respectively, according to Abel *et al.*[6] Partially mercaptidated polystyrene was prepared by Ogawara's method[7] from polystyrene whose degree of polymerization was about 30. PMT-S was assumed to be wholly composed of units having para-substituted $SSnEt_3$, according to the IR spectrum and elemental analysis; δ_{C-H}: 1290, 1165, 1115, 1025, 815 cm^{-1}; Found: C, 49.51; H, 6.96%. Calcd for $(C_{14}H_{22}SSn)_n$: C, 49.30; H, 6.50%. ETC and 1,3,5-triphenylverdazyl (TPV) were synthesized by Grignard's[8] and Kuhn's methods,[9] respectively. *N,N′*-diphenylpicrylhydrazil (DPPH), metal chlorides and iron(III) compounds were of special grade, and used without further purification. Methyl methacrylate (MMA), styrene (St) and acrylonitrile (AN) were purified by the usual methods. The water was ion-exchanged and distilled.

Polymerization Procedure. The required amounts of monomer, tin mercaptide, metal compound and water were placed in a tube. The tube was cooled in a Dry Ice/methanol bath, thawed three times with nitrogen, and sealed under vacuum. The tube was shaken in a thermostat at 85 °C. After a specific interval, the contents were poured into a large amount of methanol to precipitate the polymer. The polymer was dried under vacuum until constant weight and the conversion determined from the polymer weight. In the case of PMT-S, the conversion was calculated by the following equation.

$$\text{Conversion (\%)} = \frac{\left(\begin{array}{c}\text{Weight of}\\ \text{precipitate (g)}\end{array}\right) - \left(\begin{array}{c}\text{Added weight}\\ \text{of PMT-S (g)}\end{array}\right)}{\text{Initial weight of monomer (g)}} \times 100$$

The number-average molecular weight ($\overline{M}_n$) of poly-MMA was calculated by the GPC method (Toyo Soda Co., Ltd., Model HLC-801A).

Results and Discussion

Polymerization of Vinyl Monomer Initiated with METT. Effect of Various Metal Chlorides: Table 1 shows the results of the polymerization of MMA in the presence of various metal chlorides. It was found that the polymerization of MMA was accelerated particularly with $FeCl_3$. As METT was immediately decomposed by the aqueous solution of $SnCl_4$, $HgCl_2$, $CuCl_2$, or CuCl, these chlorides were not applied to the polymerization system.

Table 1. Effect of various metal chlorides on the polymerization of MMA

(MMA 5 cm^3, METT 0.5 cm^3, H_2O 3 cm^3, metal chloride 5.32×10^{-4} mol; 85 °C, 6h.)

Metal chloride	Conversion (%)
None	1.5
$FeCl_3$	74.6
$FeCl_2$	3.3
$CdCl_2$	2.8
$MnCl_2$	1.8
$NiCl_2$	1.9
$CoCl_2$	1.6
$CeCl_3$	1.3

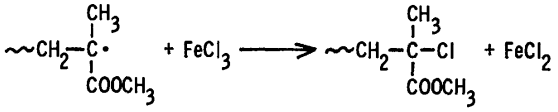
Selectivity of Vinyl Monomer: In order to observe the selectivity of METT for vinyl monomer, three kinds of vinyl monomer were used and the observed data are

Table 2. Polymerization of vinyl monomer initiated with METT in the presence of iron(III) chloride (Monomer 5 cm³, $FeCl_3$ 5.32×10^{-4} mol, H_2O 3 cm³; 85 °C, 6h.)

METT (cm³)	Conversion (%)		
	MMA	AN	St
0	1.8	2.3	4.8
0.5	74.6	7.8	12.7

shown in Table 2. The polymerizations of the three monomers were promoted by the chlorides.

Effect of Amount of Iron(III) Chloride on the Polymerization: The effect of added iron(III) chloride on the polymerization was studied, by keeping the amounts of water, monomer and METT constant and varying the amount of $FeCl_3$. The conversion of MMA and the molecular weight ($\bar{M}_n$) of poly-MMA were remarkably affected by the added amount of $FeCl_3$, as shown in Fig. 1. After exceeding a certain limit, $FeCl_3$ inhibited the polymerization of MMA through the following mechanism;[10]



The inhibition was supported by the rapid decrease of $\bar{M}_n$ with the increase of added $FeCl_3$, as shown in Fig. 1.

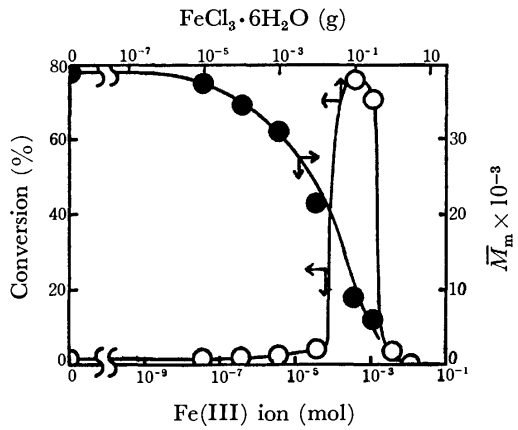


Fig. 1. Effect of the amount of iron(III) ion on the polymerization. MMA 5 cm³, METT 0.5 cm³, H_2O 3 cm³: 85 °C, 6 h.

Effect of the Kind of Anionic Part of the Iron(III) Compound: MMA 5 cm³ was polymerized with METT 0.5 cm³ and Fe(III) ion (5.32×10^{-4} mol) in water 3 cm³. The relationship between pK_a[11] of the protic acid (H_mX) of the anionic part (X^{m-}) and the conversion of MMA are shown in Table 3 and Fig. 2. It was found that the polymerization of MMA was promoted with iron(III) compounds, having the anion whose protic acid has a pK_a value less than 2 and the conversion was directly proportional to the pK_a. Iron(III) compounds having a pK_a value less than 2 were soluble, but those more than 2 were insoluble in water and ineffective in promoting the polymerization.

Table 3. Polymerization of MMA with iron(III) compound (MMA 5 cm³, METT 0.5 cm³, Fe(III) ion 5.32×10^{-4} mol, H_2O 3 cm³; 85 °C, 6h.)

Iron(III) compound	Anion part (X^{m-})	pK_a of H_mX[11]	Conversion (%)
None	—	—	1.5
$FeBr_3$	Br^-	−7.74	86.0
$FeCl_3$	Cl^-	−4.74	74.6
$Fe(NO_3)_3$	NO_3^-	−1.34	45.1
$Fe_2(SO_4)_3$	SO_4^{2-}	2.00[a]	11.6
$FePO_4$	PO_4^{3-}	—	1.5
FeF_3	F^-	3.16	1.0
$Fe(OH)_3$	OH^-	15.74	0.4
Fe_2O_3	O^{2-}	—	0

a) First equivalent point.

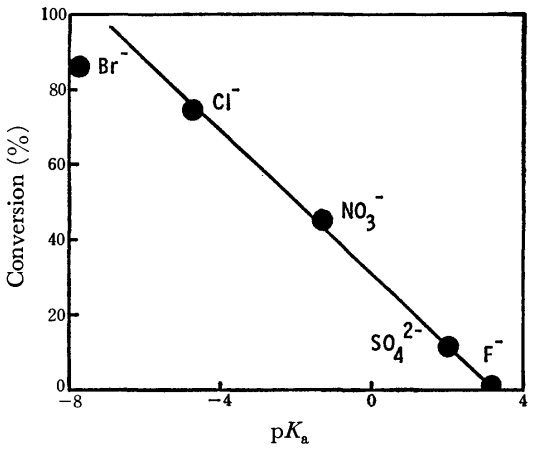

Fig. 2. Relationship between pK_a of H_mX and conversion of MMA.

Subsequent experiments were carried out, using iron(III) chloride.

Effect of Amount of Water on the Polymerization: Since it became clear that the dissociation of iron(III) ion was playing an important role in the polymerization, it was reasonable that the polymerization was required to be carried out in water. As shown in Fig. 3, the conversion of MMA increased with increasing amounts of water, and water was found to be indispensable for the polymerization.

Proof of Radical Mechanism: As shown in Table 1, the conversion of MMA amounted to 74.6%. Alternatively,

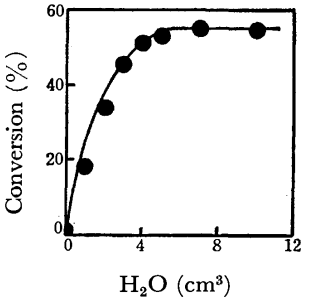

Fig. 3. Effect of the amount of water on the polymerization. MMA 5 cm³, METT 0.5 cm³, $FeCl_3$ 5.32×10^{-4} mol; 85 °C, 4 h.

0.1 g of DPPH or TPV, as radical scavenger, was added to the polymerization mixture. The polymerization was retarded with DPPH and inhibited with TPV, thus, it was concluded that the polymerization proceeded through a radical mechanism. Furthermore, the radical mechanism was verified by the method of copolymerization of MMA (M_1) with St (M_2) as shown in Fig. 4. By the Fineman-Ross method, r_1 and r_2 were estimated as 0.45 and 0.63, respectively (lit,[12] 0.46 and 0.57).

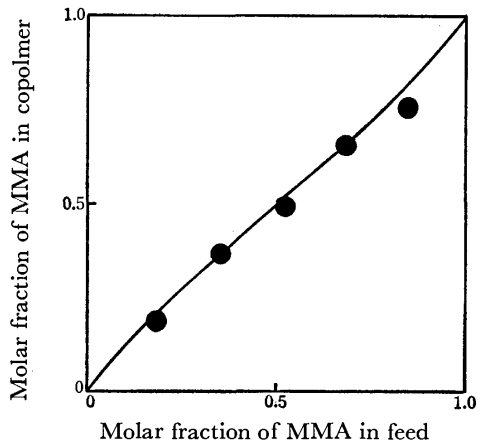

Fig. 4. Monomer-copolymer composition curve. (MMA+St) 6 cm³, METT 0.5 cm³, H_2O 3 cm³, $FeCl_3$ 5.32×10^{-4} mol, 85 °C, 6 h.

Polymerization of Vinyl Monomer Initiated with ETTT. In order to compare the activity of the aliphatic mercaptide with that of the aromatic one, the polymerization was carried out with triethyl(*p*-tolylthio)tin (ETTT).

MMA 5 cm³ was reacted with ETTT 0.1 cm³ and a varied amount of iron(III) chloride in water 3 cm³ at 85 °C for 6 h (Fig. 5). ETTT gave similar results to those obtained with METT. The molar quantity of $FeCl_3$ which gave maximum conversion was equal to the amount of ETTT applied and consequently, it was concluded that the reaction of ETTT and $FeCl_3$ took place by a 1: 1 molar ratio.

Maintaining the amounts of monomer, ETTT, $FeCl_3$, and water constant, the polymerizations of three kinds of vinyl monomer were carried out at 85 °C for 6 h.

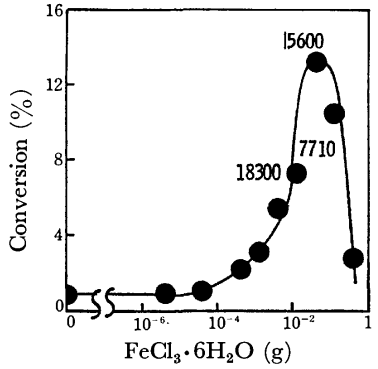

Fig. 5. Effect of the amount of iron(III) chloride on the polymerization of MMA. MMA 5 cm³, ETTT 0.1 cm³, H_2O 3 cm³; 85 °C, 6 h. (The numbers in the figure indicate mol wt of poly-MMA.)

Table 4. Polymerization of vinyl monomer initiated with ETTT
(Monomer 5 cm³, $FeCl_3\cdot6H_2O$ 0.06 g, H_2O 3 cm³; 85 °C, 6h.)

ETTT (cm³)	Conversion (%)		
	MMA	AN	St
0	0.6	0.7	0.6
0.1	13.2	43.5	7.2

By the present initiating system, all monomers could be polymerized as shown in Table 4.

As shown in Table 4, the conversion of MMA amounted to 13.2%. However, when 0.1 g of DPPH or TPV was added as a radical scavenger to this system, the polymerization did not proceed. Furthermore, the copolymerization of MMA (M_1) with St (M_2) was carried out. The composition curve obtained is shown in Fig. 6. By the Fineman-Ross method, r_1 and r_2 were estimated as 0.50 and 0.52, respectively (lit,[12] 0.46 and 0.57). From these results, it was concluded that the polymerization proceeded through a radical mechanism.

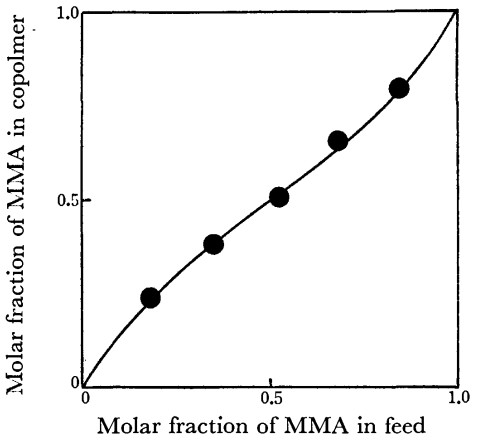

Fig. 6. Monomer-copolymer composition curve. (MMA +St) 6 cm³, ETTT 0.1 cm³, H_2O 3 cm³, $FeCl_3\cdot6H_2O$ 0.06 g; 85 °C, 6 h.

Determination of the Initiating Radical Species. The Reaction of METT with $FeCl_3$: In a tube, METT (1.06×10^{-2} mol), iron(III) chloride (2.13×10^{-2} mol) and water 8 cm³ were placed. The tube was evacuated and warmed at 85 °C for 8 h under shaking. The reaction mixture was fractionated into three portions by the procedure shown in Fig. 7.

Organic Layer I: The organic layer I gave a distillate having a boiling point of 41.5 °C/10 mmHg and a yield

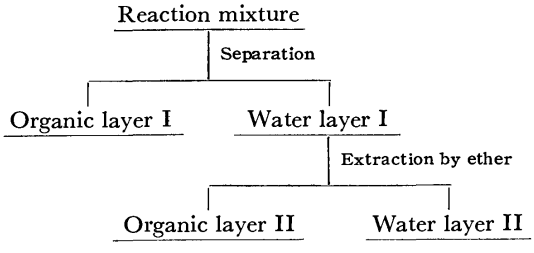

Fig. 7. Separation of the reaction mixture of METT with iron(III) chloride.

of 0.838 g. The IR spectrum and the gas chromatogram (GLC) of the distillate agreed completely with the reference diethyl disulfide (EDS) (bp 40 °C/10 mmHg[13]). Accordingly, the distillate was identified as EDS.

Organic Layer II: The ether extract was evaporated and a white solid residue was obtained. A white needle crystalline compound was obtained by the recrystallization from toluene (1.7 g). Mp and molar weight were 107—107.5 °C and 220.1 (by VPO-method in benzene at 37 °C), respectively. In the literature,[14] mp of dimethyltin dichloride (MTC) is 106 °C. The mixed mp of the crystals with the reference MTC was 107—108 °C. The organic layer II was identified as MTC; Found: C, 10.89; H, 2.74%. Calcd for $C_2H_6SnCl_2$: C, 10.93; H, 2.75%; mol wt 219.7.

Water Layer II: The water layer II was evaporated and the residue recrystallized from methanol to give blue-green powder-like crystals (3.85 g). The aqueous solution of the crystals gave a white precipitate of AgCl by adding a drop of $AgNO_3$ solution and a deep blue precipitate by potassium ferricyanide solution. Consequently, the crystalline compound from water layer II were concluded to be iron(II) chloride.

The Reaction of ETTT with $FeCl_3$: ETTT reacted with iron(III) chloride in a manner similar to METT. The reaction mixture was treated as shown in Fig. 8 and separated into the residue, the organic layer and the water layer.

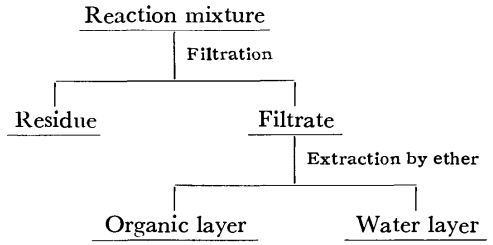

Fig. 8. Separation of the reaction mixture of ETTT with iron(III) chloride.

Residue: The residue was recrystallized from methanol and gave white needle-like crystals. Mp, mol wt and elemental analysis of the crystals were compared with those of di-*p*-tolyl disulfide (TDS), as shown in Table 5. Thus, the compound was identified as TDS.

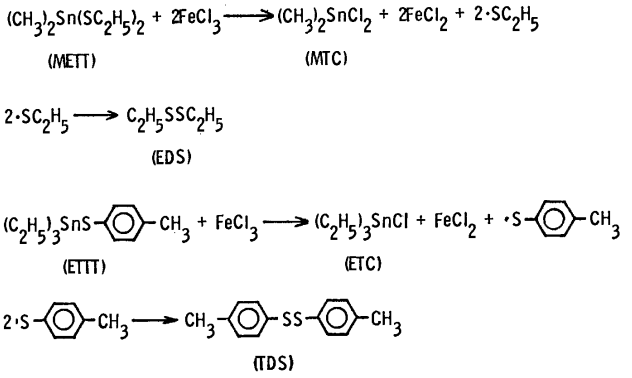
Table 5. Crystals from the residue

	Found	Theor. values of TDS[15]
Mp (°C)	46.5—47	47—48
Mol wt	245.7	246.4
Elemental analysis (%)	C, 68.72	C, 68.25
	H, 5.69	H, 5.73

Organic Layer: The ether-extract was evaporated, distilled under reduced presure, and the middle fraction (bp 90—91 °C/10 mmHg) separated. From the IR spectrum, the GLC and elemental analysis of the distillate, the fraction was identified as triethyltin chloride (ETC). Found: C, 29.81; H, 6.27%. Calcd for $C_6H_{15}SnCl$: C, 29.86; H, 6.27%; bp of ETC was 91 °C/10 mmHg.[16]

Water Layer: The water layer was similarly treated as in the case of METT and $FeCl_2$ identified.

From these results, the reactions were concluded to proceed as follow:



It was concluded that the initiating radical species for the polymerization were thiyl radicals, *i.e.*, $\cdot SC_2H_5$ or $\cdot S-C_6H_4-CH_3$, *i.e.*, the initiation reaction took place by a redox reaction; an electron transfered from tin to iron(III) ion. Fe(II), Cd(II), Co(II), Mn(II), Ni(II), and Ce(II) ions accept electrons with difficulty, so they were inactive to polymerization, as shown in Table 1.

Polymerization of Vinyl Monomer Initiated with PMT-S. In order to observe the polymer effect of the initiator, PMT-S was used. MMA 5 cm³ was polymerized in water 3 cm³ in the presence of PMT-S 0.1 g and various amounts of iron(II) chloride. The results are shown in Fig. 9. The polymerization proceeded in a similar fashion as in the cases of METT and ETTT.

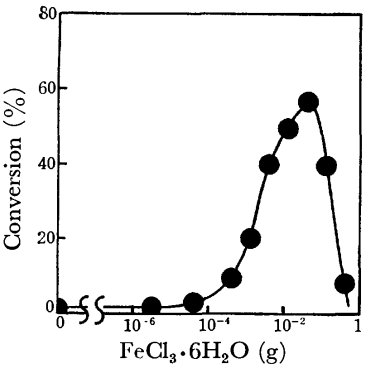


Fig. 9. Effect of the amount of iron(III) chloride on the polymerization of MMA. MMA 5 cm³, PMT-S 0.1 g, H_2O 3 cm³; 85 °C, 1 h.

Table 6. Polymerization of vinyl monomer initiated with PMT-S

(Monomer 5 cm³, $FeCl_3 \cdot 6H_2O$ 0.06 g, H_2O 3 cm³; 85 °C, 1h.)

PMT-S (g)	Conversion (%)		
	MMA	AN	St
0	0.3	0.3	0.5
0.1	56.3	30.7	13.7

Table 6 shows the results of the polymerizations of three kinds of vinyl monomers initiated with PMT-S in the presence of water and $FeCl_3$. The results were the same as in the above cases. From Tables 2, 4, and 6 and Figs. 1, 5, and 9, it may be seen that the rate of polymerization by PMT-S was larger than that by METT and ETTT. Thus the polymer effect of the initiator was clearly observed.

TABLE 7. EFFECT OF RADICAL SCAVENGER ON THE POLYMERIZATION OF MMA
(MMA 5 cm³, PMT-S 0.1 g, $FeCl_3 \cdot 6H_2O$ 0.06 g, H_2O 3 cm³, radical scavenger 0.1 g; 85 °C, 1h.)

Radical scavenger	Conversion (%)
None	56.3
DPPH	4.7
TPV	0

In order to confirm the radical mechanism, DPPH or TPV 0.1 g was added to the reaction system and the results are shown in Table 7. The polymerization was retarded with DPPH and inhibited with TPV. Thus, it was concluded that the polymerization proceeded through a radical mechanism.

It may be concluded that the polymerization with PMT-S was initiated through the same initiation mechanism as in the cases with METT and ETTT.

Synthesis of 6-Hydroxy-12-methyl-7,12-dihydrobenzo[6,7]-cyclohept[1,2-*b*]indol-7-one

Kunihide FUJIMORI and Kameji YAMANE*

Department of Chemistry, Faculty of Science, Shinshu University, Matsumoto 390

(Received April 26, 1978)

5,6,7,12-Tetrahydrobenzo[6,7]cyclohept[1,2-*b*]indol-7-ones were obtained by the oxidation of 5,6,7,12-tetrahydrobenzo[6,7]cyclohept[1,2-*b*]indoles with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in wet dioxane. The α,α-dibromo compound, obtained by bromination of 12-methyl-5,6,7,12-tetrahydrobenzo[6,7]cyclohept-[1,2-*b*]indol-7-one with phenyltrimethylammonium tribromide (PTAB), was hydrolyzed to give the diketone (**5**). By treatment with alkali, compound **5** was converted to 6-hydroxy-12-methyl-7,12-dihydrobenzo[6,7]cyclohept-[1,2-*b*]indol-7-one.

Many troponoid compounds which contain a tropone ring fused with a heterocyclic ring have been found. In a previous paper,[1,2] the preparation of fused tropones containing indole ring was reported. We now report the synthesis of 7,12-dihydrobenzo[6,7]cyclohept[1,2-*b*]-indol-7-ones.

Results and Discussion

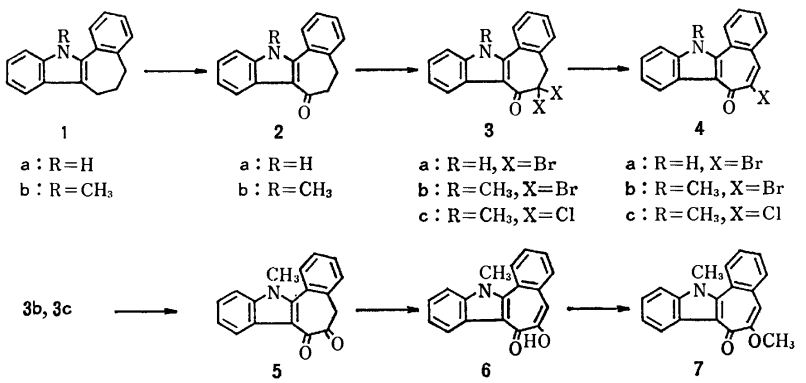
5,6,7,12-Tetrahydrobenzo[6,7]cyclohept[1,2-*b*]indole (**1a**) and its 12-methyl derivative (**1b**) obtained from the reaction of benzosuberone (5*H*-6,7,8,9-tetrahydrobenzocyclohepten-5-one) with phenylhydrazine or *N*-methylphenylhydrazine underwent oxidation with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone[3,4] (DDQ) in wet dioxane to give 5,6,7,12-tetrahydrobenzo[6,7]cyclohept-[1,2-*b*]indol-7-one (**2a**) and its 12-methyl derivative (**2b**) respectively. The IR and PMR spectra of compounds **2a** and **2b** supported the structure described above (Experimental section). Compound **2b** was also obtained by the treatment of **2a** with dimethyl sulfate.

Compounds **2a** and **2b** were brominated with phenyltrimethylammonium tribromide (PTAB) in dry tetrahydrofuran to give their 6,6-dibromo derivatives (**3a** and **3b**). Dichloro derivative (**3c**) was obtained by the treatment of **2b** with copper(I) chloride in 50% dioxane–water. The dehydrobromination of compounds **3a**—**c** with lithium chloride in boiling *N*,*N*-dimethylformamide (DMF) gave 6-halo-7,12-dihydrobenzo[6,7]cyclohept-[1,2-*b*]indol-7-ones (**4a**—**c**). Compound **3a** also gave **4a** when refluxed in ethanol with 2 M sodium hydroxide.

Compounds **3b** and **3c**, on the other hand, gave yellow prisms (mp 182—184 °C) upon being heated with dilute sodium hydroxide in ethanol. The analytical data revealed a composition with the formula $C_{18}H_{13}O_2N$. The mass spectrum showed a parent peak at *m/e* 275. On the basis of the spectral data (IR, PMR, and CMR: experimental section), the compound may be considered to have the structure of 12-methyl-5,6,7,12-tetrahydrobenzo[6,7]cyclohept[1,2-*b*]indole-6,7-dione (**5**).

Furthermore, compound **5**, when treated with 2 M sodium hydroxide and ethanol (1 : 2 vol%), was converted into yellow plates (mp 235—237 °C). The analytical data revealed a composition with the formula of $C_{18}H_{13}O_2N$, which is the same as that of **5**. The mass spectrum showed a parent peak at *m/e* 275. The IR and PMR spectral data support the assertion that the compound has the structure of 6-hydroxy-12-methyl-7,12-dihydrobenzo[6,7]cyclohept[1,2-*b*]indol-7-one (**6**). These spectral data are shown in the experimental section. Compound **5** was also converted into **6** in trifluoroacetic acid. Compound **6** produced a brown color with iron(III) chloride reagent and gave a complex by the treatment with copper(II) sulfate. The reaction of **6** with dimethyl sulfate gave the methyl ether of **6** as pale yellow plates.

The structure of **5** corresponds to a diketo form of **6**. But its enolization was not as easy as that described above. The unexpected stability of **5** is thought to be due to the steric interaction between the fused benzene and the indole ring, which are prevented from arranging in the same plane on enolization. However, no attempts to achieve the reverse change, from **6** to **5**, were successful. It has been reported[5] that the diketone type tautomer was isolated on monocyclic tropolone.



Experimental

All the melting points are uncorrected.

5,6,7,12-Tetrahydrobenzo[6,7]cyclohept[1,2-b]indol-7-one (2a). To a solution of 5,6,7,12-tetrahydrobenzo[6,7]cyclohept-[1,2-*b*]indole (2.0 g) obtained by the reaction of 5*H*-6,7,8,9-tetrahydrobenzocyclohepten-5-one with phenylhydrazine in dioxane (100 ml) and water (10 ml), we added 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) (3.88 g) at 5 °C. The mixture was stirred for 10 min, the resulting precipitate was filtered off, and the filtrate was concentrated. The residue was extracted with chloroform. The organic layer was washed with 2 M sodium hydroxide, dried on anhydrous sodium sulfate, and concentrated. The residue was recrystallized from benzene–ethanol to give colorless plates (1.5 g, 71%); mp 246—246.5 °C. IR(KBr): ν_{NH} 3210; $\nu_{C=O}$ 1610 cm^{-1}. Found: C, 82.44; H, 5.37; N, 5.29%. Calcd for $C_{17}H_{13}ON$: C, 82.57; H, 5.30; N, 5.66%.

12-Methyl-5,6,7,12-tetrahydrobenzo[6,7]cyclohept[1,2-b]indol-7-one (2b). *(a)*: Into a solution of **1b** (2.0 g) in dioxane (100 ml) and water (10 ml), we added DDQ (3.6 g). The reaction mixture was treated by a method similar to that used for the preparation of **2a**. Colorless plates (1.4 g, 66%); mp 214–216 °C. PMR (100 MHz, $CDCl_3$): δ 8.62 (1H, m, H-8), 7.3—7.6 (7H, m, benzenoid), 3.89 (3H, s, N–CH_3), and 2.7—3.2 (4H, m, 2×CH_2). The H-8 signal can be compared with that of **1b** (δ 7.73). IR(KBr): $\nu_{C=O}$ 1628 cm^{-1}. Found: C, 82.66; H, 5.61; N, 5.48%. Calcd for $C_{18}H_{15}ON$: C, 82.73; H, 5.79; N, 5.36%.

(b): A mixture of **2a** (3.0 g), dimethyl sulfate (5.0 g), and 2 M sodium hydroxide (25 ml) in acetone (150 ml) was refluxed for 2 h. The reaction mixture was concentrated and diluted with water, followed by extraction with chloroform. The extract was dried with anhydrous sodium sulfate and the solvent was removed. The residue was recrystallized from acetonitrile to give colorless plates (2.8 g, 89%); mp 214—216 °C. The IR spectrum was identical with that of the sample prepared by means of Method (a) and the mixed melting point with the sample was not depressed.

Dibromo Compound (3a) of 2a. To a solution of **2a** (1.43 g) in dry tetrahydrofuran (60 ml), we added phenyltrimethylammonium tribromide (PTAB) (4.35 g) at room temperature. The mixture was stirred for 4 h. The resulting precipitate was filtered off, the filtrate was evaporated, and the residue was recrystallized from methanol to give **3a** as yellowish green micro needles (1.87 g, 80%); mp 204—205 °C (dec). IR(KBr): ν_{NH} 3255, $\nu_{conjugated\ C=O}$ 1606 cm^{-1}. Found: C, 49.97; H, 2.90; N, 3.63; Br, 39.46%. Calcd for $C_{17}H_{11}ONBr_2$: C, 50.41; H, 2.74; N, 3.46; Br, 39.32%.

Dibromo Compound (3b) of 2b. To a solution of **2b** (1.28 g) in dry tetrahydrofuran (90 ml), we added PTAB (3.68 g). The mixture was then treated by a method similar to that used for the preparation of **3a**. Yellow micro needles (from methanol) (1.64 g, 80%); mp 183—184 °C. IR(KBr): $\nu_{C=O}$ 1649 cm^{-1}. Found: C, 51.29; H, 3.48; N, 3.77; Br, 38.34%. Calcd for $C_{18}H_{13}ONBr_2$: C, 51.58; H, 3.13; N, 3.34; Br, 38.14%.

Dichloro Compound (3c) of 2b. A mixture of **2b** (0.2 g) and copper(I) chloride dihydrate (2.61 g) in dioxane (35 ml) and water (35 ml) was refluxed for 24 h on the oil bath. The reaction mixture was concentrated and extracted with chloroform. The extract was dried with anhydrous sodium sulfate and the solvent was removed. The oily residue was recrystallized from cyclohexane to give pale yellow needles (0.15 g, 59%); mp 167—168 °C. IR(KBr): $\nu_{C=O}$ 1621 cm^{-1}. PMR (100 MHz, in $CDCl_3$): δ 8.40 (1H, m, H-8), 7.2—7.7 (7H, m, benzenoid), 3.97 (2H, s, methylene), and 3.90 (3H, s, N–CH_3). Found: C, 65.50; H, 3.91; N, 4.15; Cl, 21.31%. Calcd for $C_{18}H_{13}ONCl_2$: C, 65.47; H, 3.97; N, 4.24; Cl, 21.48%.

6-Bromo-7,12-dihydrobenzo[6,7]cyclohept[1,2-b]indol-7-one (4a). *(a)*: A mixture of dibromo compound (**3a**) (0.6 g) and lithium chloride (0.13 g) in *N,N*-dimethylformamide (20 ml) was refluxed under nitrogen for 4 h. The solvent was removed under reduced pressure, after which the residue was diluted with water. The resulting precipitate was collected, dried under reduced pressure, and chromatographed on a silica gel. The product obtained from the acetone effluent was recrystallized from acetone to give pale yellow micro needles (0.45 g; 94%); mp>290 °C. IR(KBr): $\nu_{conjugated\ C=O}$ 1597 cm^{-1}. Found: C, 62.80; H, 3.02; N, 4.32; Br, 24.70%. Calcd for $C_{17}H_{10}ONBr$: C, 62.97; H, 3.11; N, 4.32; Br, 24.65%.

(b): A mixture of **3a** (0.27 g) and 2 M sodium hydroxide (2 ml) in ethanol (10 ml) was refluxed for 30 min. The reaction mixture was concentrated and made slightly acid with 6 M sulfuric acid. The resulting precipitate was treated by a method similar to that used for Method (a). Pale yellow micro needles (0.2 g, 93%); mp>290 °C. The IR spectrum was identical with that of the sample prepared by means of Method (a).

6-Bromo-12-methyl-7,12-dihydrobenzo[6,7]cyclohept[1,2-b]indol-7-one (4b). A mixture of dibromo compound (**3a**) (0.6 g) and lithium chloride (0.12 g) in *N,N*-dimethylformamide (20 ml) was refluxed under nitrogen atmosphere for 4 h. The reaction mixture was treated by a method similar to that used for the preparation of **4a**. Yellow prisms (0.48 g, *ca.* 100%); mp 195—196 °C. IR(KBr): $\nu_{conjugated\ C=O}$ 1591 cm^{-1}. Found: C; 63.93; H, 3.52; N, 4.33%. Calcd for $C_{18}H_{21}ONBr$: C, 63.99; H, 3.58; N, 4.15%.

6-Chloro-12-methyl-7,12-dihydrobenzo[6,7]cyclohept[1,2-b]indol-7-one (4c). A mixture of dichloro compound (**3c**) (0.5 g) and lithium chloride (0.1 g) in *N,N*-dimethylformamide (20 ml) was refluxed under nitrogen atmosphere. The reaction mixture was treated by a method similar to that used for the preparation of **4a**. Yellow micro needles (0.38 g, 85%); mp 163—164 °C. IR(KBr): $\nu_{conjugated\ C=O}$ 1601 cm^{-1}. Found: C, 73.58; H, 4.01; N, 4.92; Cl, 12.07%. Calcd for $C_{18}H_{12}ONCl$: C, 73.59; H, 4.12; N, 4.77; Cl, 12.07%.

12-Methyl-5,6,7,12-tetrahydrobenzo[6,7]cyclohept[1,2-b]indole-6,7-dione (5). *(a)*: A mixture of dibromo compound (**3b**) (1.43 g) and 2 M sodium hydroxide (5 ml) in ethanol (50 ml) was refluxed for 30 min on the water bath. The mixture was concentrated, diluted with water, and made acid by adding 2 M sulfuric acid. The resulting precipitate was collected and dried under reduced pressure. It was chromatographed on silica gel. From the benzene effluent, **5** was obtained as pale yellow needles (0.55 g, 59%); mp 182—184 °C. IR(KBr): $\nu_{C=O}$ 1641 cm^{-1}. UV: λ_{max}^{MeOH} 244 (log ε=4.40), 250 (4.45), 269 (4.51), 291 (4.37), 363 (4.12), and 379 (4.18) nm. Found: C, 78.62; H, 4.63; N, 5.01%. Calcd for $C_{18}H_{13}O_2N$: C, 78.53; H, 4.76; N, 5.09%. MS: *m/e* 275 (M^+), 247 (M^+-CO), and 218 (M^+-2CO, base). PMR (100 MHz, in $CDCl_3$): δ 8.17 (1H, m, H-8), 7.2—7.8 (7H, m, benzenoid), 4.47 (1H, d, J=4.5 Hz, C_5-methylene Ha), 4.19 (1H, d, J=4.5 Hz, C_5-methylene Hb), and 3.96 (3H, s, N–CH_3). ^{13}C NMR (DMSO-d_6): δ 61.3 (N–$\underline{C}H_3$), 67.6 (C-5), 111.0, 119.9, 122.6, 123.9, 125.1, 127.1, 128.9, 131.4, 132.9, 138.5, and 192.1 (C=O). These signals at δ 67.6 and 61.3 were assigned to C-5 and N–$\underline{C}H_3$ respectively, using the off-resonance coherent proton spin-decoupling technique.

From the chloroform effluent, trace amounts of reddish brown micro needles was obtained; mp 278 °C (dec). The structure of this material has not been clarified yet. IR(KBr): 1634, 1592, and 1489 cm^{-1}.

(b): A mixture of dichloro compound (**3c**) (0.2 g) a 2 M sodium hydroxide (1 ml) in ethanol (20 ml) was refluxed for 1 h. The reaction mixture was treated by a method similar to that used for Method (a). Yellow needles (0.12 g, 72%); mp 182—184 °C. The IR spectrum was identical with that of a sample prepared by Method (a) and the mixed melting point was not depressed.

*6-Hydroxy-12-methyl-7,12-dihydrobenzo[6,7]cyclohept[1,2-*b*]indol-7-one (**6**).* *(a)*: A mixture of **5** (0.3 g) and 2 M sodium hydroxide (30 ml) in ethanol (60 ml) was refluxed for 1 h. The reaction mixture was concentrated and diluted with water. It was made slightly acid by adding 2 M sulfuric acid, and then extracted with chloroform. The solvent was removed and the residue was chromatographed on silica gel. From benzene effluent, **6** was obtained as yellow plates (0.14 g, 47%); mp 235—237 °C. IR(KBr): ν_{OH} 3272 and $\nu_{conjugated\ C=O}$ 1636 cm^{-1}. PMR (100 MHz, in DMSO) δ 7.3—9.1 (m) and 4.18 (s, N-CH_3). UV: λ_{max}^{MeOH} 233 (log ε=4.34); 312 (4.67); and 422 (3.86) nm. Found: C, 78.64; H, 4.70; N, 5.38%. Calcd for $C_{18}H_{13}O_2N$: C, 78.53; H, 4.76; N, 5.09%. MS: *m/e* 275 (M^+); 247 (M^+-CO, base), and 218 (M^+-2CO).

(b): Compound **5** was dissolved in trifluoroacetic acid, followed by dilution with water to give **6**.

*6-Methoxy-12-methyl-7,12-dihydrobenzo[6,7]cyclohept[1,2-*b*]indol-7-one (**7**).* A mixture of **6** (0.2 g); dimethyl sulfate (0.48 g); and 2 M sodium hydroxide (2.4 ml) in acetone (20 ml) was refluxed for 2 h. The reaction mixture was poured into water and extracted with chloroform. The extract was dried and the solvent was removed. The residue was chromatographed on silica gel. The product obtained from the benzene effluent was recrystallized from ethanol to give yellow needles (0.13 g, 62%); mp 211—213 °C. IR(KBr): 1593, 1581, and 1130 cm^{-1}. UV: λ_{max}^{MeOH} 244 (log ε=4.30); 266 (4.12), and 295 (4.72) nm. PMR (100 MHz, in $CDCl_3$): δ 8.74 (1H; m, H-8), 7.2—7.9 (7H, m, benzenoid), 6.80 (1H, s, H-5), 3.97 (3H, s, N-CH_3 or O-CH_3), and 3.93 (3H, s, C-CH_3 or O-CH_3). Found: C, 78.79; H, 5.19; N, 4.83%. Calcd for $C_{19}H_{15}O_2N$: C, 78.87; H, 5.23; N, 4.84%.

The authors wish to express their thanks to Dr. Masafumi Yasunami and Professor Kahei Takase of Tohoku University for their helpful suggestions and for obtaining the ^{13}C NMR spectrum. We also would like to thank Professor Yasuo Iwanami of Keio University and Dr. Takeshi Inagaki of Nitto Chemical Industry Co., Ltd, for measurements and analyses of the mass spectra. The authors are grateful to the Sankyo Co., Ltd., for doing a part of the elemental analyses.

Studies of the Azulenes. V.[1] Condensation Products of Guaiazulene and 4,6,8-Trimethylazulene with Active Methylene Compounds by Means of Selenium Dioxide. Molecular Asymmetry Induced by Chelate Ring and Its Anisotropy Effect†

Kazuko KOHARA

Konan Chemical Industry, Co., Ltd., 5-21, Nakagawa-cho, Takatsuki, Osaka 569

(Received May 1, 1978)

In the presence of selenium dioxide, guaiazulene and 4,6,8-trimethylazulene condensed with the active methylene compounds, ethyl acetoacetate and acetylacetone, to give ethyl α-(3-guaiazulenyl)acetoacetate (**3a**), α-(3-guaiazulenyl)acetylacetone, ethyl α-(4,6,8-trimethyl-1-azulenyl)acetoacetate (**5a**), and α-(4,6,8-trimethyl-1-azulenyl)acetylacetone. These α-substituted β-diketones exist exclusively in their corresponding enol forms, as evidenced by their NMR spectra. In the NMR spectra of **3a** and **5a**, the ethyl protons of the ester group show an ABX_3 pattern; the observed nonequivalence of the methylene protons is attributable to the restricted rotation between azulene and the substituent carbon atoms. From an inspection of the chemical shifts of the methyl group of metal chelate compounds of azulene derivatives, it is now reasonably concluded that there is no aromaticity associated with the chelate ring, providing further support for Musso's proposal.

It has previously been reported[2] that guaiazulene (**1**) condensed with active methyl compounds such as acetone and ethyl methyl ketone in the presence of selenium dioxide to give the di-3-guaiazulenylmethyl ketones. The experiments described in this paper deal with similar reactions of **1** and 4,6,8-trimethylazulene (**4**) with active methylene compounds (**2**) to give the corresponding α-(3-guaiazulenyl) and α-(4,6,8-trimethyl-1-azulenyl) derivatives. The condensation products (**3a**, **3b**, **5a**, and **5b**) involve an identical structural moiety, *e.g.*, a β-dicarbonyl substituent is located at peri-position to the methyl group attached to the seven-membered ring of the azulene skeleton.

In this paper we wish to report the molecular asymmetry of **3a** and **5a** induced by restricted rotation around the bond between the azulene skeleton and 3- and 1-substituted chelate ring. The anisotropy effect of the 6π chelate ring is also discussed.

Results and Discussion

We have recently found that guaiazulene (**1**) condensed with active methylene compounds (**2**) in the presence of selenium dioxide to give the corresponding α-guaiazulenyl derivatives (**3**).[3] Furthermore, 4,6,8-trimethylazulene (**4**) can also be condensed with the active methylene compounds (**2**) to produce similar products (**5**).

Although there are several possible mechanisms for the formation of **3a**, **3b**, **5a**, and **5b** from the reaction of guaiazulene and 4,6,8-trimethylazulene with active methylene compounds, the most likely one is *via* formation of the half ester (A) of selenious acid with the enol form of the active methylene compounds, followed by [2.3]sigmatropic shift to the intermediate (B).[4] A final nucleophilic attack of the azulene and elimination of the elements of hyposelenious acid (H_2SeO_2)[5] would account for the formation of the observed products.

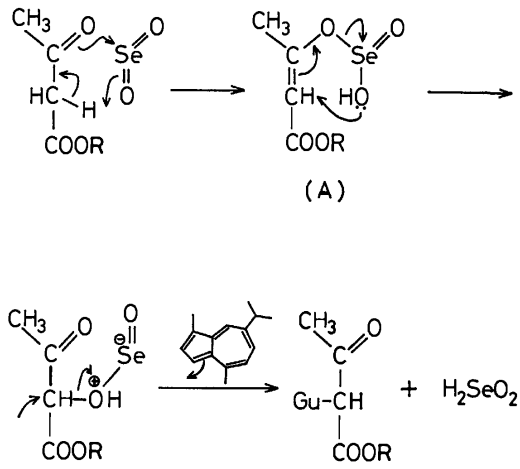
Scheme 1.



Scheme 2.

The structure of **3a** was established through its spectroscopic properties. Thus, in the NMR spectrum of **3a** (Fig. 1), the proton at C-2 of the azulene skeleton appears as a singlet at δ 7.34, indicating that it must be a 3-substituted guaiazulene. The singlet at δ 13.11 is assignable to a hydroxyl proton incorporated into a strong hydrogen bonding. This is also proved by its IR spectrum, which exhibits bands at 1608 cm^{-1} (C=C) and 1640 cm^{-1} (C=O) characteristic of a chelate ring. These findings accord well with the known linear relationship[6] between the chemical shift of the chelate hydroxyl proton and the stretching frequency of the carbonyl group associated with the hydrogen bonding.

† A preliminary report of this work was presented at the 7th International Congress of Essential Oils, Kyoto, Japan, October 1977.

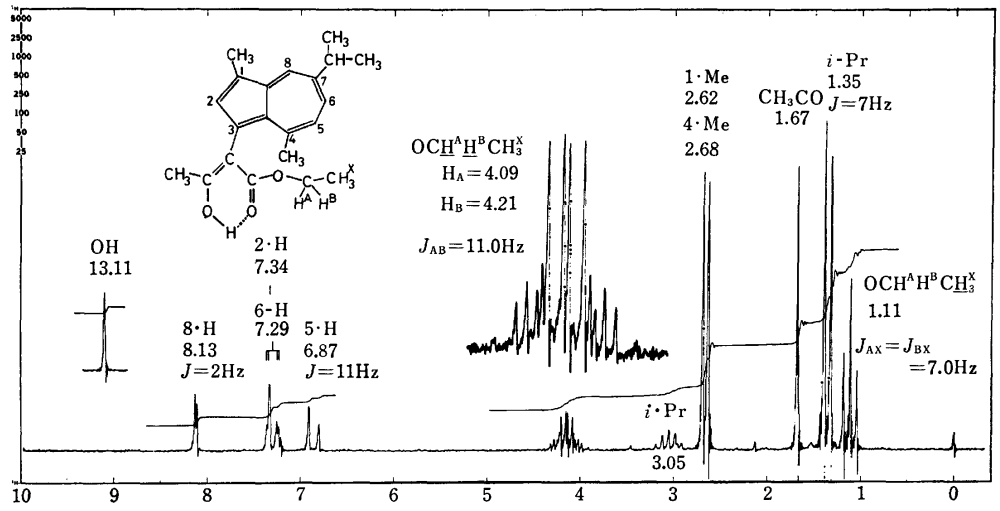


Fig. 1. 100 MHz NMR spectrum of **3a**.

The expanded spectrum of the methylene protons of **3a** is shown in Fig. 1; it could easily be analyzed as an AB-part of an ABX_3 spin system arising from the ethyl ester. The spectral parameters thus obtained are δ_A= 4.09, δ_B=4.21, δ_X=1.11 ppm, $J_{AX}=J_{BX}$=7.0, and J_{AB}=11.0 Hz. These assignments are fully confirmed by the comparison with the computer simulated spectrum, which agreed well with the experimental spectrum. Furthermore, irradiation at the site of the X-part signal at δ 1.11 assigned to the methyl protons changed the methylene protons multiplet to a broad AB-quartet, as illustrated in Fig. 2.

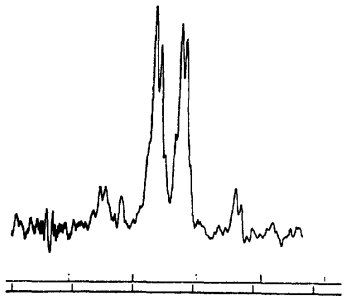

Fig. 2. Decoupled Spectrum of $-O-CH_2-$ region of **3a**.

Since the ethyl protons of the ester group of **3a** show an ABX_3 pattern, it is reasonable to assume that the nonequivalence of the methylene protons is attributable to the molecular asymmetry induced by restricted rotation about the bond between C-3 of the azulene nucleus and the substituent carbon atoms.[7-9] This is also the case for the corresponding derivative (**5a**) derived from 4,6,8-trimethylazulene (**4**). As can be seen from the NMR spectrum depicted in Fig. 3, the magnetic nonequivalence of the methylene protons is also observed.

The electronic spectrum of **3a** is illustrated in Fig. 4 and compared with that of guaiazulene (**1**). No appreciable differences between the spectra of **1** and **3a** could be discerned in intensities or in absorption maxima. These phenomena can reasonably be interpreted by the postulate that the six-membered chelate ring is oriented perpendicular to the plane of the azulene skeleton. This presumption is fully consistent with the afore-mentioned magnetic nonequivalence of the meth-

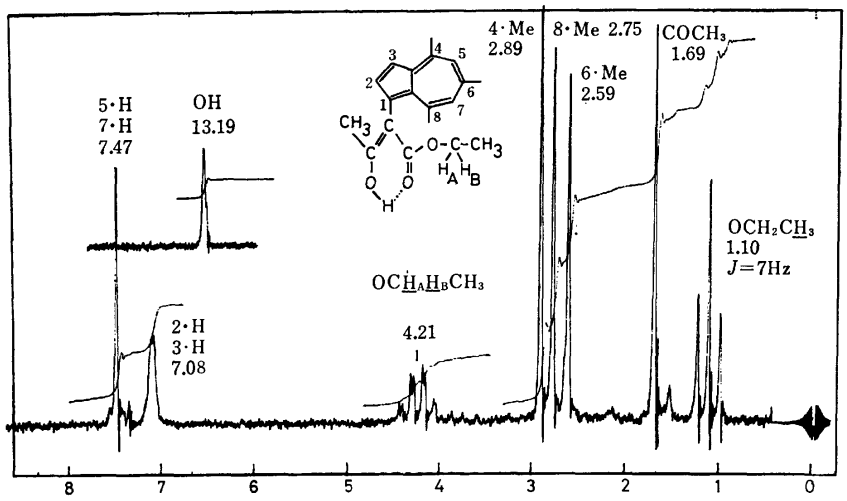

Fig. 3. 60 MHz NMR spectrum of **5a**.

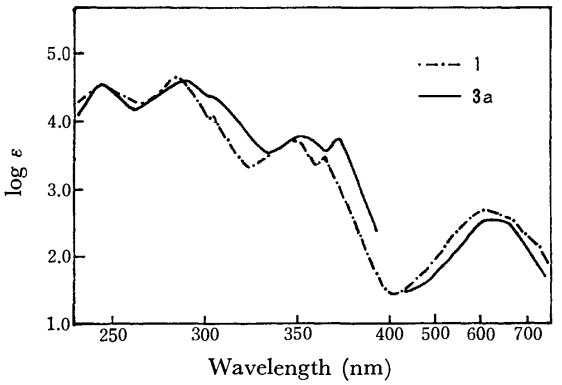

Fig. 4. Electronic spectra of **1** and **3a** in hexane.

ylene protons.

With these findings in mind, the series of compounds: **3a**, **3b**, **5a**, and **5b** provides a good model for the examination of the shielding effect of a chelate ring,[10] because one of the methyl groups attached to the azulene nucleus must be situated in a position just above the plane of the chelate ring, as shown schematically in Fig. 5.

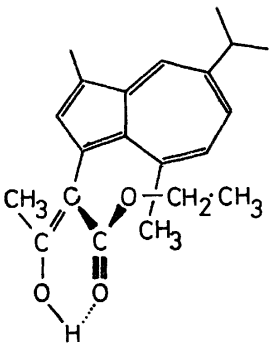

Fig. 5.

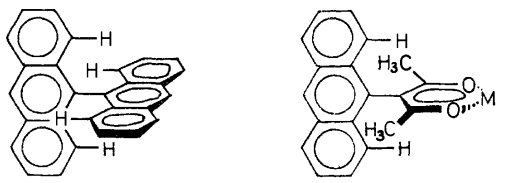
About a decade ago, Musso and coworkers[11] reported that in 9,9-bianthryl (**6**) the chemical shift of the 1- and 8-protons is more than 1 ppm higher than those at positions 4 and 5, while in the *C*-(9-anthryl)acetylacetonate salts (**7**) this difference is much smaller. Thus, these authors concluded that there is no ring current and no aromaticity in the chelate ring.



6 **7**

Fig. 6.

Our compounds (**3a**, **3b**, **5a**, and **5b**) possess several advantages over the model compounds reported by Musso *et al.*: *e.g.*, i) the methyl protons singlet in our compounds might more easily be recognized than the aromatic hydrogen multiplet in **7**; ii) the location of the methyl hydrogens of our compounds is above the plane of the chelate ring more precisely than that of the aromatic hydrogens of **7**.

TABLE 1. CHEMICAL SHIFTS OF 4-METHYL (GUAIAZULENE SERIES) AND 8-METHYL (TRIMETHYLAZULENE SERIES)

	R=H	R = 3a	3b	8	9
4-CH_3	2.76	2.68	2.67	2.72	2.80
$\Delta\delta$[a]		+0.08	+0.09	+0.04	−0.04
	R=H	R = 5a	5b	10	
8-CH_3	2.82	2.75	2.73	2.77	
$\Delta\delta$[a]		+0.07	+0.09	+0.05	

a) + and − denote upfield and downfield shifts, respectively.

In order to gain further evidence for the aromaticity of the chelate ring, we have examined the chemical shifts of the methyl groups being considered. These values are summarized in Table 1. Although the chemical shifts of the 4-methyl protons of **3a** and **3b** are shifted upfield compared with that of guaiazulene,[12] the difference (0.08—0.09 ppm) in chemical shifts cannot be regarded as significant. The same is true for compounds **5a** and **5b**. No appreciable upfield shift can be observed even in the palladium and beryllium salts of **3b** and the palladium salt of **5b**.

These results provide further confirmation of Musso's proposal.

Experimental

IR spectra were obtained on a Hitachi Model EPI-G2 spectrophotometer. NMR spectra were taken in $CDCl_3$ or CCl_4 solution with a Varian XL-100-15, A-60D, or T-60 spectrometer and are reported in δ-values with tetramethylsilane as the internal standard.

4,6,8-Trimethylazulene (**4**) was prepared according to the literature.[13]

Reaction of Azulenes with Ethyl Acetoacetate or Acetylacetone. General Procedure: To a solution of azulene (4 g) in 60 g of ethyl acetoacetate or acetylacetone was added a solution containing 2 g of selenium dioxide in 4 ml of water. The solution was stirred for 3 days at room temperature. Work-up was made in a similar manner with that of the literature.[2] All products, obtained in 15—20% yield, were recrystallized from methanol. These condensation products are sensitive to air and are converted gradually to unidentified, variously colored products.

*Ethyl α-(3-guaiazulenyl)acetoacetate (**3a**)*: Blue needles; mp 70—72 °C. IR (Nujol): 1608 (C=C), 1640 (C=O) cm^{-1}. UV (hexane): λ_{max} (log ε) 247 (4.51), 287 (4.61), 306[sh] (4.30), 354 (3.79), 372 (3.78), 612 (2.62), 666[sh] nm (2.51). NMR ($CDCl_3$, 100 MHz): δ 1.11 (3H, t, X_3-part of an ABX_3, $J_{AX}=J_{BX}=7.0$ Hz, $CH_2\underline{CH_3}$), 1.35 and 3.05 (6H, d, and 1H, septet, $J=7.0$ Hz, 7-*i*-Pr), 1.67 (3H, s, $COCH_3$), 2.62 (3H, s, 1-Me), 2.68 (3H, s, 4-Me), 4.15 (2H, m, AB-part of an ABX_3, $J_{AX}=J_{BX}=7.0$, $J_{AB}=11.0$ Hz; $\delta_A=4.09$, $\delta_B=4.21$, $C\underline{H_2}CH_3$), 6.87 (1H, d, $J=11.0$ Hz, 5-H), 7.29 (1H, dd, $J=11.0$, 2.0 Hz, 6-H), 7.34 (1H, s, 2-H), 8.13 (1H, d, $J=2.0$ Hz, 8-H), 13.11

ppm (1H, s, chelate OH). Found: C, 77.28; H, 7.96%. Calcd for $C_{21}H_{26}O_3$: C, 77.27; H, 8.03%.

*α-(3-Guaiazulenyl)acetylacetone (**3b**)*: Blue needles; mp 58 °C. IR (Nujol): 1600, br (C=O, C=C) cm^{-1}. UV (hexane): λ_{max} (log ε) 245 (4.42), 287 (4.65), 307^{sh} (4.34), 354 (3.82), 372 (3.76), 612 (2.69), 666^{sh} nm (2.60). NMR (CCl_4, 100 MHz): δ 1.39 and 3.05 (6H, d, and 1H, septet, J=7.0 Hz, 7-*i*-Pr), 1.75 (6H, s, $COCH_3$), 2.63 (3H, s, 1-Me), 2.67 (3H, s, 4-Me), 6.82 (1H, d, J=11.0 Hz, 5-H), 7.26 (1H, dd, J=11.0, 2.0 Hz, 6-H), 7.30 (1H, s, 2-H), 8.04 (1H, d, J=2.0 Hz, 8-H), 16.36 ppm (1H, s, chelate OH). Found: C, 80.80; H, 8.09%. Calcd for $C_{20}H_{24}O_2$: C, 81.04; H, 8.16%.

*Ethyl α-(4,6,8-Trimethyl-1-azulenyl)acetoacetate (**5a**)*: Purple needles; mp 86 °C. UV (cyclohexane): λ_{max} (log ε) 246 (4.54), 291 (4.64), 339 (3.70), 349^{sh} (3.74), 353.5 (3.76), 557 (2.70), 604^{sh} (2.60), 661 nm (2.13). NMR ($CDCl_3$, 60 MHz): δ 1.10 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 1.69 (3H, s, $COCH_3$) 2.59 (3H, s, 6-Me), 2.75 (3H, s, 8-Me), 2.89 (3H, s, 4-Me), 4.21 (2H, m, $C\underline{H}_2CH_3$), 7.08 (2H, br s, 2- and 3-H), 7.47 (2H, s, 5- and 7-H), 13.19 ppm (1H, s, chelate OH). Found: C, 76.02; H, 7.30%. Calcd for $C_{19}H_{22}O_3$: C, 76.48; H, 7.43%.

*α-(4,6,8-Trimethyl-1-azulenyl)acetylacetone (**5b**)*: Purple needles; mp 106—108 °C. UV (cyclohexane): λ_{max} (log ε) 246.5 (4.48), 293 (4.70), 339 (3.78), 349^{sh} (3.76), 354 (3.73), 556 (2.72), 603^{sh} (2.63), 660 nm (2.14). NMR ($CDCl_3$, 60 MHz): δ 1.80 (6H, s, $COCH_3$), 2.61 (3H, s, 6-Me), 2.73 (3H, s, 8-Me), 2.89 (3H, s, 4-Me), 6.99 and 7.04 (each 1H, s, 2- and 3-H), 7.38 (1H, s, 5-H), 16.52 ppm (1H, s, chelate OH). Found: C, 80.13; H, 7.46%. Calcd for $C_{18}H_{20}O_2$: C, 80.56; H, 7.51%.

*Metal Chelates **8**, **9**, and **10***. Preparation of **8**, **9**, and **10** was carried out according to Musso's procedure[10b] at room temperature.

*α-(3-Guaiazulenyl)acetylacetonate Palladium(II) (**8**)*: Blue crystals; mp >280 °C. NMR ($CDCl_3$, 60 MHz): δ 1.37 and 3.08 (6H, d, and 1H, septet, J=7 Hz, 7-*i*-Pr), 1.77 (6H, s, $COCH_3$), 2.66 (3H, s, 1-Me), 2.72 (3H, s, 4-Me), 6.90 (1H, d, J=11 Hz, 5-H), 7.33 (1H, s, 2-H), 7.34 (1H, dd, J=11, 2 Hz, 6-H), 8.16 ppm (1H, d, J=2 Hz, 8-H).

*α-(3-Guaiazulenyl)acetylacetonate Beryllium(II) (**9**)*: Blue crystals; mp 213—214 °C. NMR ($CDCl_3$, 60 MHz): δ 1.37 and 3.08 (6H, d, and 1H, septet, J=7 Hz, 7-*i*-Pr), 1.85 (6H, s, $COCH_3$), 2.68 (3H, s, 1-Me), 2.80 (3H, s, 4-Me), 6.95 (1H, d, J=11 Hz, 5-H), 7.40 (1H, dd, J=11, 2 Hz, 6-H), 7.48 (1H, s, 2-H), 8.21 ppm (1H, d, J=2 Hz, 8-H).

*α-(4,6,8-Trimethyl-1-azulenyl)acetylacetonate Palladium (II) (**10**)*: Purple crystals; mp 269 °C. NMR ($CDCl_3$, 60 MHz): δ 1.77 (6H, s, $COCH_3$), 2.60 (3H, s, 6-Me), 2.77 (3H, s, 8-Me), 2.88 (3H, s, 4-Me), 7.05 (2H, br s, 2- and 3-H), 7.42 ppm (2H, s, 5- and 7-H).

The author wishes to express her thanks to Professor Shuichi Hayashi of Hiroshima University for valuable discussions.

Oxidation of 2,5-Dimethoxyacetophenone Derivatives with Thallium(III) Nitrate in Trimethyl Orthoformate-Methanol. I

Kazuhiro MARUYAMA* and Tadashi KOZUKA

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received May 6, 1978)

Alkyl-substituted 2,5-dimethoxyacetophenones were oxidized with thallium(III) nitrate in methanol–trimethyl orthoformate (TMOF) to give methyl alkyl-substituted 2,5-dimethoxyphenylacetates in a good yield. A simple modification of separating method from the reacting mixture allowed us to obtain the corresponding methyl (alkyl-substituted 3,6-dioxo-1,4-cyclohexadienyl)acetates.

Oxidations of alkyl-substituted 2,5-dimethoxyacetophenones **1** with thallium(III) nitrate were investigated. Using an acidified methanol with perchloric acid as the solvent, we obtained methyl esters of alkyl-substituted-3,6-dioxo-1,4-cyclohexadienylacetic acids **4** by the oxidation in a high yield. By the oxidation we expected to have methyl esters of alkyl-substituted 2,5-dimethoxyphenylacetic acids **2**, but every effort to yield **2** ended without success. However, changing the solvent from MeOH–$HClO_4$ to absolute MeOH–trimethyl orthoformate (TMOF), we obtained **2** in excellent yields at last. In this paper the oxidation method will be described in detail.

Results and Discussion

Alkyl-substituted 2,5-dimethoxyacetophenones **1** dissolved in absolute MeOH–TMOF were oxidized with thallium(III) nitrate trihydrate at 0 °C. After approximately 10 min the oxidation was completed, and the resulting mixture was passed through a short column filled with basic alumina. Then, evaporation of the solvent gave us an excellent yield of methyl esters of alkyl-substituted 2,5-dimethoxyphenylacetic acids **2**. However, if we save the basic alumina treatment other products will be obtained; that is, **4**, oxidation product of **2**, instead of **2**. Recently, use of $Tl(NO_3)_3 \cdot 3H_2O$ in MeOH–TMOF, or anhydrous $Tl(NO_3)_3$ on solid support has been reported to allow a high conversion of acetophenones to the corresponding methyl esters of α-methoxyphenylacetic acids, $C_6H_5CH(OMe)CO_2Me$.[1,2]

On the contrast, the present work showed that oxidation of **1** with $Tl(NO_3)_3 \cdot 3H_2O$ in absolute MeOH–TMOF gave an excellent yield of **2** together with only a small amount of the corresponding α-methoxylated phenylacetates **3**. Thus, by our procedure **2** was obtained predominantly. If we saved the basic alumina treatment, **4** was the major product. The results of representative reactions are summarized in Table 1.

Oxidation of 2,5-dimethoxy-4-methylpropiophenone **6** with $Tl(NO_3)_3 \cdot 3H_2O$ in MeOH–TMOF gave a quantitative yield of methyl ester of 2-(2,5-dimethoxy-4-methylphenyl)propionic acid **7**, although the oxidation of **6** in MeOH–$HClO_4$ scarcely gave **7** or its oxidized product; methyl ester of 2-(4-methyl-3,6-dioxo-1,4-cyclohexadienyl)propionic acid **8**. Without the basic alumina treatment we obtained **8** as the single product (96%). 2,4,5-Trimethoxyacetophenone **1g** is also smoothly oxidized to yield methyl ester of 2,4,5-trimethoxyphenylacetic acid **2g**. Without basic alumina treatment we obtained a complex mixture composed of intractable substances.

Concerned to the oxidation of acetophenone in MeOH–TMOF, Taylor *et al.* have reported a smooth production of methyl ester of α-methoxyphenylacetic acid. However, they did not obtained any methyl ester of phenylacetic acid, and excluded the possible intermediacy of it in the oxidation. As the evidence they gave the fact that methyl phenylacetate was recovered unchanged in the oxidation with $Tl(NO_3)_3 \cdot 3H_2O$ in MeOH–TMOF. In spite of the Taylor's work, our investigation indicates a possible intermediacy of methyl ester of alkyl-substituted 2,5-dimethoxyphenylacetic acid **2**. Table 2 shows clearly the gradual change of **2b** to **3b** on standing the reacting mixture. The discrepancy between Taylor's work and ours might be due to the absence and presence of NO_3^-, HCO_2CH_3, and thallium(I) nitrate in the reacting mixture. As the oxidation proceeds, these three species can be produced in the reacting mixture. Taylor's blank test was performed in

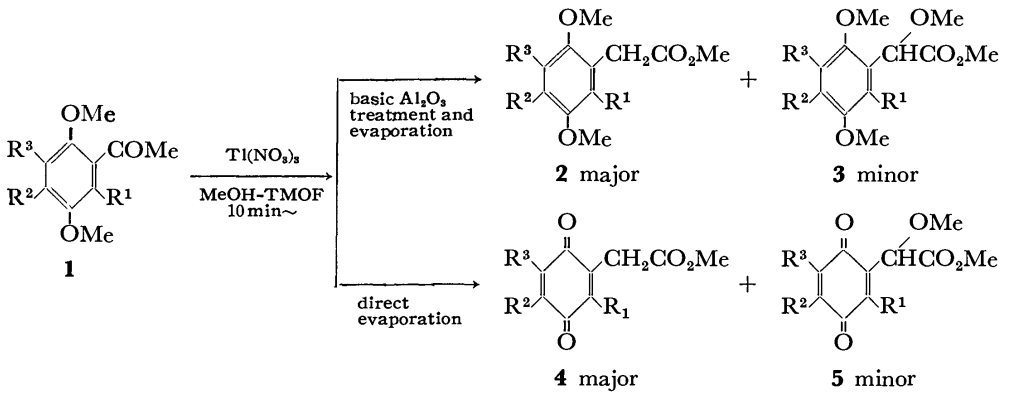

Table 1.

24	13/87	9	61

a) The relative product ratio **2b**/**3b** were determined by GLPC analysis. b) At that time the oxidation was completed.

the absence of the above species in the reacting mixture.

Experimental

Melting points were taken on a Yanagimoto micro-melting apparatus and are uncorrected. ^{1}H NMR spectra were recorded in deuteriochloroform solutions with a JEOL PS-100 instrument using tetramethylsilane as an internal standard. IR spectra were measured with a JASCO IR-S spectrometer in KBr disk or liquid film techniques. Mass spectra were determined on a Hitachi M-52 mass spectrometer. Microanalyses were performed by the Microanalytical Laboratory of Kyoto University. GLPC analyses were performed using JEOL JGC-20K gas chromatographs equipped with a 2 m silicon SE-30 (5%) column. The analyses were reconfirmed with the use of another column; *i.e.*, 1 m silicon DC-550 (10%). Column chromatography was performed over basic alumina, silica gel (Wako Pure Chem. Ind.) and Florisil 100—200 mesh (Floridin Com., U.S.A). The ratio of isomeric products (**2**/**3** and **4**/**5**) was determined by integration of GLPC signals, and/or of the NMR signals (see Tables 1 and 2).

Starting Materials. All of the compounds **1a**—**g** were prepared by the Friedel-Crafts acylation of the corresponding hydroquinone dimethyl ethers with acetyl chloride in the presence of titanium tetrachloride in carbon disulfide. 2,5-Dimethoxy-4-methylpropiophenone **6** was prepared by the similar methods. All were purified by either distillation or recrystallization. 2,5-Dimethoxyacetophenone **1a**, bp 114—116 °C/5 mmHg (lit,[3] bp 156—158 °C/15 mmHg), 2,5-dimethoxy-4-methylacetophenone **1b**, mp 73—75 °C, 4-*t*-butyl-2,5-dimethoxyacetophenone **1c**, mp 64—65 °C, 2,5-dimethoxy-3,4-dimethylacetophenone **1d**, bp 123—130 °C/3 mmHg, 3,6-dimethoxy-2,4-dimethylacetophenone **1e**, bp 123—125 °C/3 mmHg, 2-acetyl-1,4-dimethoxynaphthalene **1f**, mp 59—60.5 °C, 2,4,5-trimethoxyacetophenone **1g**, mp 102 °C, 2,5-dimethoxy-4-methylpropiophenone **6**, mp 78 °C.

General Procedure for the Oxidation of 2,5-Dimethoxyacetophenones. To a solution of TMOF (1 ml) and $Tl(NO_3)_3 \cdot 3H_2O$ (1 g) in abs methanol (5 ml) 2,5-dimethoxyacetophenone **1** (2 mmol) was added at once with stirring at 0 °C, and then the resulting mixture was allowed to stand at room temperature for 5 min. The reaction was continued till the white precipitates of thallium(I) nitrate crystallized out. After filtration of thallium(I) nitrate the filtrate was worked up in the following two methods; A and B. Work-up method A: the filtrate was diluted with petroleum ether (50 ml), and passed through a short column of basic alumina (20 g) by eluting with dichloromethane (200 ml). Evaporation of dichloromethane gave a mixture of **2** and **3**. Work-up method B: the filtrate was concentrated directly *in vacuo* (<40 °C). The residure was passed through a short column of Florisil (20 g) using dichloromethane (200 ml) as an eluent. Evaporation of dichloromethane gave a mixture of **4** and **5**. The analytical samples **2** and **3** were separated by preparative GLPC. The pure product **4** was isolated by chromatography on silica gel using benzene or dichloromethane as an eluent.

Methyl 2,5-Dimethoxyphenylacetate ***2a*** *and Methyl α,2,5-Trimethoxyphenylacetate* ***3a***. Followed to the work-up method A oxidation of **1a** with $Tl(NO_3)_3$–TMOF–MeOH (reaction time: 15 min) gave a mixture of products **2a** and **3a** (**2a**: **3a**=85: 15) in 84% yield. Compound **2a**, mp 46—47 °C; MS, *m/e*, 210; IR(KBr) 1742 cm^{-1}; NMR($CDCl_3$) δ=3.59 (s, 2H, CH_2), 3.67 (s, 3H, CO_2CH_3), 3.73 (s, 3H, OCH_3), 3.75 (s, 3H, OCH_3), 6.75 (s, 3H, ArH); Found: C, 63.08; H, 6.75%. Calcd for $C_{11}H_{14}O_4$: C, 62.84, H, 6.71%. Compound **3a**, oil; MS, *m/e*, 240; IR(NaCl) 1752 cm^{-1}; NMR ($CDCl_3$) δ=3.40 (s, 3H, OCH_3), 3.71 (s, 3H, CO_2CH_3), 3.76 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3), 5.17 (s, 1H, CH), 6.82, 6.84, and 6.95 (m, 3H, ArH); Found: C, 59.73; H, 6.92%. Calcd for $C_{12}H_{16}O_5$: C, 59.99; H, 6.71%.

Methyl 2,5-Dimethoxy-4-methylphenylacetate ***2b*** *and Methyl α,2,5-Trimethoxy-4-methylphenylacetate* ***3b***. Oxidation of **1b** with $Tl(NO_3)_3$–TMOF–MeOH (reaction time: 15 min) applied

with the work-up method A gave a mixture of products **2b** and **3b** (**2b**: **3b**=90: 10) in 90% yield. Compound **2b**, mp 69—70 °C; MS; *m/e*, 224; IR(KBr) 1735 cm^{-1}; NMR($CDCl_3$) δ=2.26 (s, 3H, CH_3), 3.63 (s, 2H, CH_2), 3.72 (s, 3H, CO_2CH_3), 3.79 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3), 6.71 (s, 2H, ArH); Found: C, 64.32; H, 7.06%. Calcd for $C_{13}H_{18}O_5$: C, 64.27; H, 7.14%. Compound **3b**, mp 70—71 °C; MS, *m/e*, 254; IR(KBr) 1750 cm^{-1}; NMR($CDCl_3$) δ=2.23 (s, 3H, CH_3), 3.38 (s, 3H, OCH_3), 3.71 (s, 3H, CO_2CH_3), 3.78 (s, 3H, OCH_3), 3.80 (s, 3H, OCH_3), 5.20 (s, 1H, CH), 6.74 (s, 1H, ArH), 6.85 (s, 1H, ArH); Found: C, 61.29; H, 7.25%. Calcd for $C_{13}H_{18}O_5$: C, 61.40; H, 7.14%.

Methyl 4-t-Butyl-2,5-dimethoxyphenylacetate ***2c*** *and Methyl α,2,5-Trimethoxyphenylacetate* ***3c***. Oxidation of **1c** with $Tl(NO_3)_3$–TMOF–MeOH for 30 min resulted a reacting mixture. Immediate application of the work-up method A gave a mixture of products **2c** and **3c** (**2c**: **3c**=85: 15) in 93% yield. Compound **2c**, mp 52.5—54.5 °C; MS, *m/e*, 266; IR(KBr) 1741 cm^{-1}; NMR ($CDCl_3$) δ=1.36 (s, 9H, *t*-Bu), 3.57 (s, 2H, CH_2), 3.67 (s, 3H, CO_2CH_3), 3.76 (s, 6H,OCH_3), 6.70 (s, 1H, ArH), 6.81 (s, 1H, ArH); Found: C, 67.47; H, 8.37%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%. Compound **3c**, mp 46.5—47 °C, MS, *m/e*, 296; IR(KBr) 1760 cm^{-1}; NMR ($CDCl_3$) δ=1.36 (s, 9H, *t*-Bu), 3.38 (s, 3H, OCH_3), 3.71 (s, 3H, CO_2CH_3), 3.77 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3), 5.17 (s, 1H, CH), 6.84 (s, 1H, ArH); Found: C, 64.74; H, 8.29%. Calcd for $C_{16}H_{24}O_5$: C, 64.84; H, 8.16%.

Methyl 2,5-Dimethoxy-3,4-dimethylphenylacetate ***2d*** *and Methyl α,2,5-Trimethoxy-3,4-dimethylphenylacetate* ***3d***. Oxidation of **1d** with $Tl(NO_3)_3$–TMOF–MeOH for 30 min resulted a reacting mixture. Subsequent application of the work-up method A gave a mixture of products **2d** and **3d** (**2d**: **3d**= 80: 20) in 96% yield. Compound **2d**, oil; MS, *m/e*, 238; IR(NaCl) 1740 cm^{-1}; NMR ($CDCl_3$), δ=2.12 (s, 3H, CH_3), 2.20 (s, 3H, CH_3), 3.63 (s, 2H, CH_2), 3.65 (s, 3H, CO_2CH_3), 3.70 (s, 3H, OCH_3), 3.78 (s, 3H, OCH_3), 6.60 (s, 1H, ArH); Found: C, 65.33; H, 7.67%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%. Compound **3d**, oil; MS, *m/e*, 268; IR(NaCl) 1750 cm^{-1}; NMR ($CDCl_3$) δ=2.13 (s, 3H, CH_3), 2.22 (s, 3H, CH_3), 3.38 (s, 3H, OCH_3), 3.73 (s, 3H, CO_2CH_3), 3.73 (s, 3H, OCH_3), 3.78 (s, 3H, OCH_3), 5.15 (s, 1H, CH), 6.72 (s, 1H, ArH); Found: C, 62.66; H, 7.54%. Calcd for $C_{14}H_{20}O_5$: C, 62.67; H, 7.51%.

Methyl 3,6-Dimethoxy-2,4-dimethylphenylacetate ***2e*** *and Methyl α,3,6-Trimethoxy-2,4-dimethylphenylacetate* ***3e***. Oxidation of **1e** with $Tl(NO_3)_3$–TMOF–MeOH for 20 h application of the work-up method A gave a mixture of products **2e** and **3e** (**2e**: **3e**=92: 8) in 80% yield. Compound **2e**, mp 50—52 °C; MS, *m/e*, 238; IR(KBr) 1732 cm^{-1}; NMR ($CDCl_3$) δ=2.20 (s, 3H, CH_3), 2.28 (s, 3H, CH_3), 3.64 (s, 2H, CH_2), 3.67 (s, 3H, CO_2CH_3), 3.67 (s, 3H, OCH_3), 3.76 (s, 3H, CH_3), 6.56 (s, 1H, ArH); Found: C, 65.49; H, 7.57%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%. Compound **3e**, oil, MS, *m/e*, 268; IR(NaCl) 1745 cm^{-1}; NMR ($CDCl_3$) δ=2.25 (s, 3H, CH_3), 2.28 (s, 3H, CH_3), 3.39 (s, 3H, OCH_3), 3.65 (s, 3H, CO_2CH_3), 3.72 (s, 3H, OCH_3), 3.77 (s, 3H, OCH_3), 5.31 (s, 1H, CH), 6.59 (s, 1H, ArH); Found: C, 62.56; H, 7.59%. Calcd for $C_{14}H_{20}O_5$: C, 62.67; H, 7.51%.

Methyl (1,4-Dimethoxy-2-naphthyl)acetate ***2f*** *and Methyl α-Methoxy-α-(1,4-dimethoxy-2-naphthyl)acetate* ***3f***. Oxidation of **1f** with $Tl(NO_3)_3$–TMOF–MeOH for 5 h resulted a reacting mixture. Applying the work-up method A we obtained a mixture of products **2f** and **3f** (**2f**: **3f**=81: 19) in 84% yield. Compound **2f**, oil; MS, *m/e*, 260; IR(NaCl) 1730 cm^{-1}; NMR ($CDCl_3$) δ=3.71 (s, 3H, CO_2CH_3), 3.82 (s, 2H, CH_2), 3.88 (s. 3H, OCH_3), 3.96 (s, 3H, OCH_3), 6.65 (s, 1H, ArH), 7.47 (m, 2H, ArH), 8.00 (m, 1H, ArH), 8.19 (m, 1H, ArH); Found: C, 69.18; H, 6.35%. Calcd for $C_{15}H_{16}O_4$: C, 69.21; H, 6.20%. Compound **3f**, oil, MS, *m/e*, 290; IR(NaCl) 1750 cm^{-1}; NMR ($CDCl_3$) δ=3.41 (s, 3H, OCH_3), 3.73 (s, 3H, CO_2CH_3), 3.97 (s, 3H, OCH_3), 3.98 (s, 3H, OCH_3), 5.41 (s, 1H, CH), 6.77 (s, 1H, ArH), 7.51 (m, 2H, ArH), 8.04 (m, 1H, ArH), 8.21 (m, 1H, ArH); Found: C, 66.70; H, 6.14%. Calcd for $C_{16}H_{18}O_5$: C, 66.19; H, 6.25%.

Methyl 2,4,5-Trimethoxyphenylacetate ***2g*** *and Methyl α,2,4,5-Tetramethoxyphenylacetate* ***3g***. Oxidation of **1g** with $Tl(NO_3)_3$–TMOF–MeOH for 30 min gave a reacting mixture. After treating it with work-up method A a mixture of products **2g** and **3g** (**2g**: **3g**=93: 7) was obtained in 98% yield. Compound **2g**, mp 44—46 °C; MS, *m/e*, 240; IR(KBr) 1735 cm^{-1}; NMR ($CDCl_3$) δ=3.56 (s, 2H, CH_2), 3.67 (s, 3H, CO_2CH_3), 3.78 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3), 3.86 (s, 3H, OCH_3), 6.49 (s, 1H, ArH), 6.70 (s, 1H, ArH); Found: C, 59.99; H, 6.75%. Calcd for $C_{12}H_{16}O_5$: C, 59.99; H, 6.71%. Compound **3g**, mp 47—49 °C, MS, *m/e*, 270; IR(KBr) 1758 cm^{-1}; NMR ($CDCl_3$) δ=3.37 (s, 3H, OCH_3), 3.72 (s, 3H, CO_2CH_3), 3.84 (s, 6H, $OCH_3\times2$), 3.89 (s, 3H, OCH_3), 5.19 (s, 1H. CH). 6.52 (s, 1H, ArH), 6.91 (s, 1H, ArH); Found: C, 57.77; H, 6.77%. Calcd for $C_{13}H_{18}O_6$: C, 57.77; H, 6.71%.

Methyl 2,5-Dimethoxy-4-nitrophenylacetate. Treatment of **1a** with $Tl(NO_3)_3$–TMOF–MeOH for 15 min according to the general procedure, followed by work-up method B, gave the methyl 2,5-dimethoxy-4-nitrophenylacetate in 85% yield: mp 80—81 °C; MS, *m/e*, 255; IR(KBr) 1735 and 1519 cm^{-1}; NMR ($CDCl_3$) δ=3.66 (s, 2H, CH_2), 3.69 (s, 3H, CO_2CH_3), 3.83 (s, 3H, OCH_3), 3.91 (s, 3H, OCH_3), 6.94 (s, 1H, ArH), 7.35 (s, 1H, ArH); Found: C, 51.76; H, 5.17; N, 5.43%. Calcd for $C_{11}H_{13}O_6N$: C, 51.76; H, 5.13; N, 5.49%.

Methyl 4-Methyl-3,6-dioxo-1,4-cyclohexadienylacetate ***4b***. Oxidation of **1b** with $Tl(NO_3)_3$–TMOF–MeOH for 15 min according to the general procedure, followed by work-up method B, gave a mixture of products **4b** and **5b** (**4d**: **5b**= 84: 16) in 93% yield. Compound **4b**, mp 74—75 °C; MS, *m/e*, 194; IR(KBr) 1730 and 1675 cm^{-1}; NMR ($CDCl_3$) δ=2.03 (d, J=1.6 Hz, 3H, CH_3), 3.42 (d, J=1.2 Hz, 2H, CH_2), 3.69 (s, 3H, CO_2CH_3), 6.60 (q, J=1.6 Hz, 1H, =CH), 6.65 (t, J=1.2 Hz, 1H, =CH); Found: C, 61.60; H, 5.12%. Calcd for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19%.

Methyl 4-t-Butyl-3,6-dioxo-1,4-cyclohexadienylacetate ***4c***. Oxidation of **1c** with $Tl(NO_3)_3$–TMOF–MeOH for 30 min according to the general procedure resulted a reacting mixture. Subsequent application of the work-up method B we obtained a mixture of products **4c** and **5c** (**4c**: **5c**=88: 12) in 95% yield. Isolation of the product **4c** was carried out as described above and gave oil; MS, *m/e*, 208; IR(NaCl) 1735 and 1670 cm^{-1}; NMR ($CDCl_3$) δ=2.02 (s, 6H, $CH_3\times2$), 3.45 (d, J=1.2 Hz, CH_2), 3.72 (s, 3H, CO_2CH_3), 6.67 (t, J=1.2 Hz, 1H, =CH); Found: C, 63.71; H, 5.99%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

Methyl 4,5-Dimethyl-3,6-dioxo-1,4-cyclohexadienylacetate ***4d***. Oxidation of **1d** with $Tl(NO_3)_3$–TMOF–MeOH for 30 min according to the general procedure, follwed by work-up method B, gave a mixture of products **4d** and **5d** (**4d**: **5d**= 90: 10) in 52% yield. Compound **4d**, oil; MS, *m/e*, 208; IR(NaCl) 1735 and 1670 cm^{-1}; NMR ($CDCl_3$) δ=2.02 (s, 6H, $CH_3\times2$), 3.45 (d, J=1.2 Hz, 2H, CH_2), 3.72 (s, 3H, CO_2CH_3), 6.67 (t, J=1.2 Hz, 1H, =CH); Found: C, 63.71; H, 5.99%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

Methyl 2,4-Dimethyl-3,6-dioxo-1,4-cyclohexadienylacetate ***4e***. Oxidation of **1e** with $Tl(NO_3)_3$–TMOF–MeOH for 20 h according to the general procedure resulted a reacting mixture. Applying the work-up method B we obtained a mixture of products **4e** and **5e** (**4e**: **5e**=70: 30) in 47% yield. Compound **4e**, oil; MS, *m/e*, 208; IR(NaCl) 1740 and 1652 cm^{-1}; NMR

($CDCl_3$) δ=2.05 (d, J=1.6 Hz, 3H, CH_3), 2.04 (s, 3H, CH_3), 3.54 (s, 2H, CH_2), 3.68 (s, 3H, CO_2CH_3), 6.56 (q, J=1.6 Hz, 1H, =CH), Found: C, 63.79; H, 6.02%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

Methyl 1,4-Dioxo-1,4-dihydro-2-naphthylacetate ***4f***. Oxidation of **1f** with $Tl(NO_3)_3$–TMOF–MeOH for 5 h according to the general procedure application of the work-up method B gave a mixture of products **4f** and **5f** (**4f**: **5f**=80: 20) in 35% yield. Compound **4f**, mp 123—125 °C; MS, *m/e*, 230; IR(KBr) 1735 and 1665 cm^{-1}; NMR ($CDCl_3$) δ=3.58 (d, J=1.5 Hz, 1H, CH_2), 3.72 (s, 3H, CO_2CH_3), 6.91 (t, J=1.5 Hz, 1H, =CH), 7.70 (m, 2H, ArH), 8.04 (m, 2H, ArH); Found: C, 67.55; H, 4.20%. Calcd for $C_{13}H_{10}O_4$: C, 67.82; H, 4.38%.

Methyl 2-(2,5-Dimethoxy-4-methylphenyl)propionate ***7***. Oxidation of **6** with $Tl(NO_3)_3$–TMOF–MeOH for 12 h gave a reacting mixture. Treatment of it with the work-up method A afforded a pure product **7** in 92% yield. Compound **7**, oil. MS, *m/e*, 238; IR(NaCl) 1735 cm^{-1}; NMR ($CDCl_3$) δ=1.42 (d, J=7 Hz, 3H, CH_3), 2.19 (s, 3H, CH_3), 3.64 (s, 3H, CO_2CH_3), 3.77 (s, 6H, $OCH_3\times2$), 4.03 (q, J=7 Hz, 1H, CH), 6.70 (s, 2H, ArH); Found: C, 65.39; H, 7.65%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%.

Methyl 2-(4-Methyl-3,6-dioxo-1,4-cyclohexadienyl)propionate ***8***. Treatment of **6** with $Tl(NO_3)_3$–TMOF–MeOH for 12 h according to the general procedure, followed by work-up method B, gave a pure product **8** in 96% yield. Compound **8**, mp 59—60 °C; MS, *m/e*, 208; IR(KBr) 1735 and 1655 cm^{-1}; NMR ($CDCl_3$) δ=1.41 (d, J=7.2 Hz, 3H, CH_3), 2.08 (d, J=1.6 Hz, 3H, CH_3), 3.70 (s, 3H, CO_2CH_3), 3.79 (dq, J=7.2 Hz, J=1.2 Hz, 1H, CH), 6.60 (m, 2H, $=CH\times2$); Found: C, 63.27; H, 6.11%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

A Synthesis of (±)-β-Vetivone and Its Related Spirovetivanes *via* the Base-catalyzed Spiroannelation of Phenolic Tosylates

Sigeru TORII,* Kenji UNEYAMA, and Kaoru OKAMOTO
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700
(Received May 10, 1978)

(±)-β-Vetivone was synthesized by the base-catalyzed spiroannelation of 2-[2-(4-hydroxy-2-methylphenyl)-ethyl]-3-methyl-3-butenyl *p*-toluenesulfonate followed by methylation and subsequent isomerization of the side chain double bond. The reactivities of the related tosylates, 4-(4-hydroxy-2-methylphenyl)-2-isopropylbutyl *p*-toluenesulfonate, 3-hydroxy-2-[2-(4-hydroxy-2-methylphenylethyl]-3-methylbutyl *p*-toluenesulfonate, and 2,3-epoxy-2-[2-(4-hydroxy-2-methylphenyl)ethyl]-3-methylbutyl *p*-toluenesulfonate have been discussed.

β-Vetivone (**1**),[1] a fragrance principle of vetiver oil, solavetivone (**2**),[2] hinesolone (**3**),[3] and the related alcohols **4** and **5**,[4] aroma substances from flue-cured Virginia tobacco, are spirovetivane-type sesquiterpenes bearing a 2-cyclohexenone group. Reported attempts to synthesize these sesquiterpenes[5] involve complex intermediates and many steps. Therefore, adequate use of promising intermediates for the synthesis of the desired terpenes would be important.

One of the attractive approaches to the spirovetivane may involve the preparation of 2-alkyl-6-methylspiro-[4.5]deca-6,9-dien-8-one *via* the base-catalyzed annelation of the corresponding phenols by the Winstein's method.[6] The spiroannelation has often been used for the synthesis of spiro[*n*.5]dienones,[7] but has not been employed yet for the spirovetivane synthesis.[8]

Phenolic tosylates **6a**—**c** and **7a** are considered to be promising precursors in obtaining **8** and **9**, which can be transformed to (±)-**1** and its related compounds **10a**—**c** by introducing methyl group at C-10. The isopropenyl group at C-2 of **8b** may be modified to isopropylidene, 1-(hydroxymethyl)vinyl, and 1,2-dihydroxy-1-methylethyl groups, leading to **1**, **4**, and **5**, respectively.

2 R; $C(CH_3)=CH_2$
3 $C(OH)(CH_3)_2$
4 $C(OH)(CH_2OH)CH_3$
5 $C(CH_2OH)=CH_2$

In this paper, we describe spiroannelation of 2-substituted butyl tosylates **6a**—**c** and **7a** leading to the corresponding spirodienones **8a**—**c** and **9** as well as a synthesis of (±)-β-vetivone (**1**).

Results and Discussion

*Preparation of Phenolic Tosylates **6a**—**c** and **7a**.*
The lactone **11**, prepared from 3-(4-methoxy-2-methylbenzoyl)propanoic acid[9] by reduction and following lactonization, was treated with lithium diisopropylamide (LDA) in THF at −78 °C followed by addition of acetone, affording a C-2 epimeric mixture of **12** in

The arrow (⇐) indicates a reverse-synthesis.

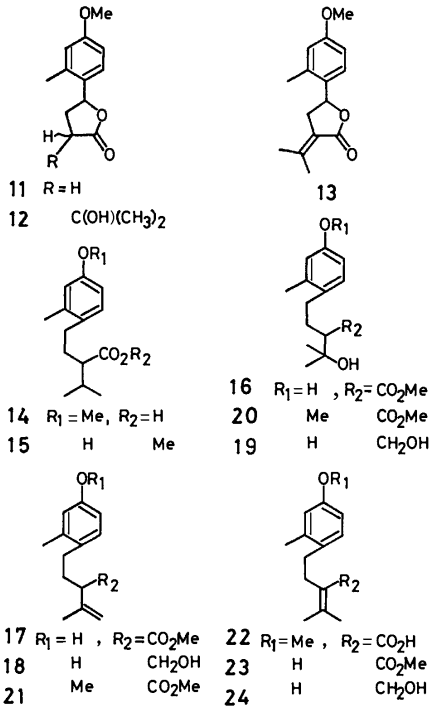
quantitative yield. Dehydration of the alcohol **12** with thionyl chloride and subsequent hydrogenation of the resultant isopropylidene derivative **13** with Pt and then Pd on charcoal gave the carboxylic acid **14** in 98% yield. Treatment of **14** with boron tribromide in dichloromethane and next with diazomethane provided **15** in 87% yield. The desired **6a** was obtained by reduction of **15** with lithium aluminum hydride (LAH) followed by tosylation in 92% yield.

Similarly, methyl 4-(4-hydroxy-2-methylphenyl)-butanoate was converted into **16** in 86% yield. Dehydration of **16** with thionyl chloride afforded β,γ-unsaturated ester **17** as a sole product, which was then reduced with LAH to give **18**. Subsequent tosylation of **18** provided **6b** in 68% yield (from **16**).

On the other hand, the monotosylate **6c** was prepared by selective tosylation of the primary hydroxyl group of **19**, obtained by reduction of **16** with LAH in THF, on treatment with tosyl chloride in dry pyridine at −30 °C for 6 h in 86% yield.

The alcohol **20**, prepared by coupling reaction of methyl 4-(4-methoxy-2-methylphenyl)butanoate with acetone, was dehydrated with thionyl chloride to give **21** in 89% yield. The olefin **21** was isomerized to the α,β-unsaturated acid **22** using wet potassium *t*-butoxide in *t*-butylalcohol. Successful conversion of the acid **22**

into the phenolic ester **23** was carried out by demethylation with boron tribromide followed by esterification with diazomethane in 78% yield (from **21**). Thus, another tosylate **7a** was obtained in 82% yield by reduction of **23** with LAH followed by epoxidation of **24** with monoperoxyphthalic acid.

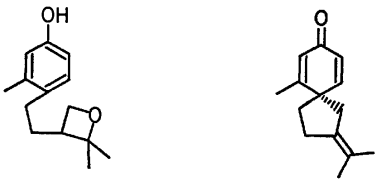


Spiroannelation of Phenolic Tosylates ***6a—c*** *and* ***7a***. The base-catalyzed spiroannelation of **6a** was performed by treatment with *t*-BuOK in refluxing *t*-butyl alcohol, providing C-2 epimers of **8a** in 83% yield after chromatography (SiO_2). Similarly, the tosylate **6b** gave **8b** in 74% yield.[10]

On the other hand, the hydroxy tosylate **6c** could lead to the corresponding spiro compound **8c** only in 17% yield, but it gave the oxetane **25** (67%) as a major product. Treatment of **6c** with sodium methoxide in methanol resulted in **8c** (7%) and **25** (74%). Other combinations of solvents and bases such as NaH–benzene, *t*-BuOK–DMSO, *t*-BuOK–THF, K_2CO_3–acetone, and BuLi–THF did not improve the yield of **8c**. The predominant formation of oxetane may be due to the faster intramolecular S_N2 reaction of the tertiary hydroxyl group toward the tosyloxyl group. The epoxy tosylate **7a** was similarly spiroannelated with *t*-BuOK in refluxing *t*-butyl alcohol, providing **9** in 45% yield. The low yield of **9** would arise from instability of the dienone in high temperature and strong base.

Conversion of ***8a—c*** *to (±)-β-Vetivone and Its Related Compounds.* The dienones **8a**, **8b**, and **8c** underwent methylation at the C-10 carbon with lithium dimethylcuprate(I). However, the epoxy dienone **9** did not afford the desired methylated compound, but it gave complex mixtures.[11] Thus, **8a** was allowed to react with lithiumdimethylcuprate(I) at −25 °C to give **10a** in 85% yield. Similarly, **8b** and **8c** provided **10b** and **10c** in 75 and 63% yield, respectively. The compound **10b** was subsequently converted into (±)-β-vetivone and (±)-10-epi-β-vetivone (1:1 by HPLC) in 80% yield by isomerization of the terminal double bond with rhodium trichloride[12] in ethanol at 110 °C. The pure (±)-**1** was separated by HPLC and identified by the spectroscopic comparison with the authentic data.[5f]

The compound **10c** as an epimeric mixture at C-2 and C-10 was converted into (±)-**1** and (±)-10-epi-**1** (1:1 by HPLC) in 72% yield by dehydration with thionyl chloride.[3,5a,5b,5j,5k] Similarly, the alcohol **8c** was transformed to the olefinic dienone **26** in 75% yield, which had been converted into (±)-**1** by Pesaro.[5h]



Experimental

Boiling points are indicated by an air-bath temperature and uncorrected. Melting points are taken on a Thomas-Hoover capillary melting point apparatus and uncorrected. IR spectra were obtained on a JASCO IRA-1 spectrometer. ^1H NMR spectra were measured at 60 MHz with a Hitachi R-24 or at 100 MHz with a JEOL FX-100. The chemical shift values are expressed in δ (ppm) downfield from Me_4Si as an internal standard.

*4-(4-Methoxy-2-methylphenyl)butanolide (**11**).* The mixture of 3-(4-methoxy-2-methylbenzoyl)propanoic acid (669 mg, 3 mmol) dissolved in 6.5 ml of 2% aq NaOH and $NaBH_4$ (65 mg, 1.7 mmol) was stirred at room temperature for 24 h, acidified with 10% H_2SO_4 under cooling with an ice bath, and then heated at 80 °C for 15 min. The organic phase was extracted with $CHCl_3$. The extract was washed with saturated $NaHCO_3$ and brine, dried (Na_2SO_4), and concentrated *in vacuo* to give a residue which was chromatographed (SiO_2, hexane:benzene=5:1) to provide **11** (608 mg, 98%) as colorless crystals: mp 52—54 °C (hexane–benzene); IR (neat) 1777 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ 2.27 (s, 3H, CH_3), 1.6—2.8 (m, 4H, CH_2), 3.72 (s, 3H, CH_3O), 5.4—5.8 (m, 1H, CH), 6.5—7.3 (m, 3H, ArH). Found: C, 69.87; H, 6.58%. Calcd for $C_{12}H_{14}O_3$: C, 69.89; H, 6.84%.

*2-(1-Hydroxy-1-methylethyl)-4-(methoxy-2-methylphenyl) butanolide (**12**).* The lactone **11** (722 mg, 3.5 mmol) was added dropwise to a THF solution of LDA, which was prepared by treatment of $NH(CHMe_2)_2$ (1 ml, 7 mmol) dissolved in 4.5 ml of THF with BuLi (5.3 mmol) at −78 °C under N_2. After stirring at −78 °C for 30 min, acetone (0.25 ml, 3.5 mmol) was added and stirred for 30 min. The mixture was quenched with 2 ml of saturated NH_4Cl and the organic phase was taken up in AcOEt. The extract was washed with saturated $NaHCO_3$ and water, dried (Na_2SO_4), and concentrated *in vacuo* to give a residue (970 mg), which was chromatographed (SiO_2, benzene:hexane:AcOEt=10:2:1), providing **12** (970 mg, quant) as a colorless liquid: bp 115—117 °C (0.01 mmHg); IR (neat) 3466 (OH), 1761 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.32 (s, 6H, CH_3), 2.29 (s, 3H, CH_3), 1.8—3.0 (m, 3H, CH_2, CH) 3.41 (s, 1H, OH), 3.77 (s, 3H, CH_3O), 5.4—5.8 (m, 1H, CH), 6.5—7.3 (m, 3H, ArH). Found: C, 68.06; H, 7.53%. Calcd for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63%.

*2-Isopropylidene-4-(4-methoxy-2-methylphenyl)butanolide (**13**).* Thionyl chloride (0.09 ml, 1.3 mmol) was added dropwise to a solution of **12** (300 mg, 1.1 mmol) dissolved in 0.5 ml of pyridine and 1.5 ml of CH_2Cl_2. The reaction mixture was stirred at 0 °C for 20 min and then at room temperature for 4 h. After addition of a few pieces of ice, the organic phase was extracted with ether. The extract was washed with 5% HCl and water, dried (Na_2SO_4), and concentrated under reduced pressure, providing 275 mg of the residue which was chromatographed (SiO_2, hexane: benzene: AcOEt=10: 4: 1) to give **13** (275 mg, 98%): bp 105—107 °C (0.003 mmHg); IR (neat) 1745 (C=O), 1668 (C=C) cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.84 (s, 3H, CH_3), 2.29 (s, 6H, CH_3), 2.4—3.6 (m, 2H, CH_2), 3.75 (s, 3H, CH_3O), 5.51 (dd, $J_1=7$ Hz, $J_2=8$ Hz, 1H, CHO). 6.5—7.4 (m, 3H, ArH). Found: C, 73.19; H, 7.57%. Calcd for $C_{15}H_{18}O_3$: C, 73.15; H, 7.37%.

*2-Isopropyl-4-(4-methoxy-2-methylphenyl)butanoic Acid (**14**).* The lactone **13** (400 mg, 1.6 mmol) dissolved in 20 ml of MeOH was hydrogenated with PtO_2 (40 mg) at room temperature for 12 h and then Pd/C (40 mg) for 6 h to give **14** (388 mg, 96%): bp 111—113 °C (0.01 mmHg); IR (neat) 3500—2400 (CO_2H), 1702 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.96 (d, $J=6$ Hz, 6H, CH_3), 1.4—2.9 (m, 6H, CH_2, CH) 2.26 (s, 3H, CH_3), 3.74 (s, 3H, CH_3O), 6.4—7.3 (m, 3H, ArH), 9.3—10.4 (br s, 1H, CO_2H). Found: C, 71.97; H, 9.03%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

*Methyl 4-(4-Hydroxy-2-methylphenyl)-2-isopropylbutanoate (**15**).* Boron tribromide (0.25 ml, 2.64 mmol) was added dropwise to a solution of **14** (335 mg, 1.32 mmol) dissolved in 3.5 ml of dry CH_2Cl_2 at −70 °C. The mixture was stirred for 1 h at −70 °C and 0 °C for 1 h, quenched with water, and extracted with AcOEt. The usual work-up gave yellow liquid, which was subsequently esterified with diazomethane and chromatographed (SiO_2, benzene: hexane: AcOEt=6: 2: 1) to afford **15** (283 mg, 86%) as an oil: bp 92—94 °C (0.005 mmHg); IR (neat) 3380 (OH), 1732, 1710 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.88 (d, $J=6$ Hz, 6H, CH_3), 2.14 (s, 3H, CH_3), 1.4—2.6 (m, 6H, CH_2, CH), 3.63 (s, 3H, CH_3O), 6.3—6.9 (m, 4H, ArH, OH). Found: C, 71.99; H, 9.06%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

4-(4-Hydroxy-2-methylphenyl)-2-isopropylbutyl p-*Toluenesulfonate (**6a**).* A solution of sublimated *p*-TsCl (309 mg, 1.62 mmol) in 1.5 ml of dry pyridine was added dropwise to a solution of 4-(4-hydroxy-2-methylphenyl)-2-isopropyl-1-butanol (240 mg, 1.08 mmol) dissolved in 1.5 ml of dry pyridine at −30 °C. After stirring at −30 °C for 10 min and at 0 °C for 6 h, the mixture was quenched with water and then worked up to give an oil, which was chromatographed (SiO_2, benzene: AcOEt=2: 1) to yield **6a** (381 mg, 94%) as a pale yellow oil: IR (neat) 3470 (OH), 1354, 1175 (SO_2) cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.82 (d, $J=7$ Hz, 6H, CH_3), 1.2—2.0 (m, 4H, CH_2, CH), 2.14 (s, 3H, CH_3), 2.41 (s, 3H, CH_3), 2.2—2.6 (m, 2H, CH_2), 4.04 (d, $J=4$ Hz, 2H, CH_2O), 5.11 (br s, 1H, OH), 6.4—7.0 (m, 3H, ArH), 7.28 (d, $J=8$ Hz, 2H, ArH), 7.77 (d, $J=8$ Hz, 2H, ArH). Found: C, 67.09; H, 7.58%. Calcd for $C_{21}H_{28}O_4S$: C, 66.99; H, 7.50%.

*Methyl 3-Hydroxy-2-[2-(4-hydroxy-2-methylphenyl)ethyl]-3-methylbutanoate (**16**).* The compound **16** was obtained as a colorless oil in 86% yield by alkylation of methyl 4-(4-hydroxy-2-methylphenyl)butanoate in the same reaction conditions as employed for **12** using a mixed solvent (HMPA: THF=1: 10); bp 123—126 °C (0.01 mmHg); IR (neat) 3320 (OH), 1707 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.22 (s, 6H, CH_3), 2.19 (s, 3H, CH_3), 1.5—2.7 (m, 7H, CH_2, CH, OH), 3.73 (s, 3H, CH_3O), 6.4—7.1 (m, 3H, ArH). Found: C, 67.49; H, 8.08%. Calcd for $C_{15}H_{22}O_4$: C, 67.65; H, 8.33%.

*Methyl 2-[2-(4-Hydroxy-2-methylphenyl)ethyl]-3-methyl-3-butenoate (**17**):* Bp 123—125 °C (0.009 mmHg); IR (neat) 3440 (OH), 1733 (C=O), 1644 (C=C) cm^{-1}; NMR ($CDCl_3$) δ 1.75 (br s, 3H, CH_3), 2.29 (s, 3H, CH_3), 1.5—2.8 (m, 5H, CH_2, OH), 3.09 (t, $J=7$ Hz, 1H, CH), 3.68 (s, 3H, CH_3O), 4.8—5.0 (m, 2H, $CH_2=$), 6.8—7.2 (m, 3H, ArH). Found: C, 72.56; H, 8.25%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

*2-[2-(4-Hydroxy-2-methylphenyl)ethyl]-3-methyl-3-buten-1-ol(**18**).* Reduction of **17** with $LiAlH_4$ in dry THF provided **18** as an oil in 90% yield: bp 118—121 °C (0.015 mmHg); IR (neat) 3320 (OH), 1644 (C=C) cm^{-1}; NMR ($CDCl_3$) δ 1.69 (s, 3H, CH_3), 1.1—1.8 (m, 2H, CH_2), 2.16 (s, 3H, CH_3), 2.0—2.8 (m, 5H, CH_2, CH, OH), 3.54 (d, $J=7$ Hz, 2H, CH_2O), 4.8—5.1 (m, 2H, $CH_2=$), 6.4—7.1 (m, 3H, ArH). Found: C, 76.26; H, 9.00%. Calcd for $C_{14}H_{20}O_2$: C, 76.33; H, 9.15%.

2-[2-(4-Hydroxy-2-methylphenyl)ethyl]-3-methyl-3-butenyl p-*Toluenesulfonate (**6b**):* IR (neat) 3460 (OH), 1649 (C=C), 1358, 1178 (SO_2) cm^{-1}; NMR ($CDCl_3$) δ 1.58 (s, 3H, CH_3), 1.2—1.8 (m, 2H, CH_2), 2.12 (s, 3H, CH_3), 2.38 (s, 3H, CH_3), 2.0—2.7 (m, 3H, CH_2, CH), 3.96 (d, $J=7$ Hz, 2H, CH_2O), 4.7—5.0 (m, 2H, $CH_2=$), 5.67 (br s, 1H, OH), 6.4—7.0 (m, 3H, ArH), 7.23 (d, $J=8$ Hz, 2H, ArH), 7.70 (d, $J=8$ Hz, 2H, ArH). Found: C, 67.43; H, 7.07%. Calcd for $C_{21}H_{26}O_4S$: 67.35; H, 7.00%.

*2-[2-(4-Hydroxy-2-methylphenyl)ethyl]-3-methyl-1,3-butanediol (**19**):* Mp 111—113 °C (benzene: AcOEt=5: 1); IR (neat) 3320 (OH); NMR (acetone-d_6) δ 1.16 (s, 3H, CH_3), 1.21 (s, 3H, CH_3), 1.3—1.9 (m, 3H, CH_2, CH), 2.23 (s, 3H, CH_3), CH_3), 2.3—2.8 (m, 2H, CH_2), 2.88 (br. s, 1H, OH), 3.7—4.0 (m, 2H, CH_2O), 4.0—4.2 (m, 1H, OH), 6.4—7.1 (m, 3H, ArH), 7.89 (br s, 1H, OH). Found: C, 70.61; H, 9.53%. Calcd for $C_{14}H_{22}O_3$: C, 70.56; H, 9.30%.

3-Hydroxy-2-[2-(4-hydroxy-2-methylphenyl)ethyl]-3-methylbutyl p-*Toluenesulfonate (**6c**):* IR (neat) 3400 (OH), 1352, 1177 (SO_2) cm^{-1}; NMR ($CDCl_3$) δ 1.15 (s, 6H, CH_3), 1.3—2.0 (m, 3H, CH_2, CH), 2.12 (s, 3H, CH_3), 2.39 (s, 3H, CH_3), 2.2—2.8 (m, 2H, CH_2), 3.90 (br s, 2H, OH), 4.19 (d, $J=3$ Hz, 2H, CH_2O), 6.3—6.9 (m, 3H, ArH), 7.27 (d, $J=8$ Hz, 2H, ArH), 7.54 (d, $J=8$ Hz, 2H, ArH). Found: C, 64.13; H, 7.23%. Calcd for $C_{21}H_{28}O_5S$: C, 64.26; H, 7.19%.

*Methyl 3-Hydroxy-2-[2-(4-methoxy-2-methylphenyl)ethyl]-3-methylbutanoate (**20**):* Bp 103—105 °C (0.01 mmHg); IR (neat) 3460 (OH), 1728 (C=O) cm^{-1}; NMR ($CDCl_3$) δ 1.20 (s, 6H, CH_3), 1.5—2.1 (m, 2H, CH_2), 2.23 (s, 3H, CH_3), 2.2—2.7 (m, 3H, CH_2, CH), 2.78 (br s, 1H, OH), 3.69 (s, 3H, CH_3O), 3.71 (s, 3H, CH_3), 6.5—7.1 (m, 3H, ArH). Found: C, 68.48; H, 8.50%. Calcd for $C_{16}H_{24}O_4$: C, 68.55; H. 8.63%.

*Methyl 2-[2-(4-methoxy-2-methylphenyl)ethyl]-3-methyl-3-butenoate (**21**):* Bp 81—83 °C (0.003 mmHg); IR (neat) 1733 (C=O), 1646 (C=C) cm^{-1}; NMR ($CDCl_3$) δ 1.75 (br s, 3H, CH_3), 1.7—2.2 (m, 2H, CH_2), 2.26 (s, 3H, CH_3), 2.3—2.7 (m, 2H, CH_2), 3.07 (t, $J=7$ Hz, 1H, CH), 3.67 (s, 3H, CH_3O), 3.73 (s, 3H, CH_3O), 4.8—5.0 (m, 2H, $CH_2=$), 6.5—7.1 (m, 3H, ArH). Found: C, 73.29; H, 8.64%. Calcd for $C_{16}H_{22}O_3$: C, 73.25; H, 8.45%.

*2-[2-(4-Methoxy-2-methylphenyl)ethyl]-3-methyl-2-butenoic Acid (**22**).* The mixture of **21** (1.37 g, 5.22 mmol) and *t*-BuOK (2.59 g, 23.1 mmol) in 8 ml of dry *t*-BuOH and 18 ml of dry THF was refluxed for 30 h. After evaporation of the solvent *in vacuo*, the residue was mixed with 10 ml of water and then acidified with 5% HCl. The usual work-up gave 1.32 g of a solid, which was recrystallized from hexane/benzene (10/1) affording **22** (1.25 g, 96%) as colorless crystals: mp 108—110 °C; IR (nujol) 3400—2000 (CO_2H), 1687 (C=O), 1652 (C=C) cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.77 (s, 3H, CH_3), 2.11 (s, 3H, CH_3), 2.31 (s, 3H, CH_3), 2.58 (br s, 4H, CH_2), 3.73 (s, 3H, CH_3O), 6.5—7.2 (m, 3H, ArH), 11.16 (br s, 1H, CO_2H).

Found: C, 72.55; H, 8.12%. Calcd for $C_{15}H_{20}O_3$: C, 72.55: H, 8.12%.

Methyl 2-[2-(4-Hydroxy-2-methylphenyl)ethyl]-3-methyl-2-butenoate (23): Mp 81—82 °C (hexane: benzene=15: 1); IR (Nujol) 3330 (OH), 1682 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.74 (s, 3H, CH_3), 1.98 (s, 3H, CH_3), 2.24 (s, 3H, CH_3), 2.54 (br s, 4H, CH_2), 3.70 (s, 3H, CH_3O), 6.40 (br s, 1H, OH), 6.5—7.1 (m, 3H, ArH). Found: C, 72.56; H, 8.19%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

2-[2-(4-Hydroxy-2-methylphenyl)ethyl]-3-methyl-2-buten-1-ol (24): Mp 119—121 °C (CH_2Cl_2); IR (Nujol) 3340 (OH), 1653 (C=C) cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.67 (s, 3H, CH_3), 1.75 (s, 3H, CH_3), 2.26 (s, 3H, CH_3), 1.9—2.9 (m, 6H, CH_2, OH), 4.13 (s, 2H, CH_2O), 6.4—7.1 (m, 3H, ArH). Found: C, 76.33; H, 9.20%. Calcd for $C_{14}H_{20}O_2$: C, 76.33; H, 9.15%.

2,3-Epoxy-2-[2-(4-hydroxy-2-methylphenyl)ethyl]-3-methyl-1-butanol (7b). An ethereal solution of monoperoxyphthalic acid (0.5 ml, *ca.* 0.5 mmol) was added to an ice-cooled solution of **24** (43 mg, 0.2 mmol) in 0.5 ml of ether with stirring. After stirring at 5 °C for 10 h, the reaction mixture was quenched with saturated $NaHCO_3$ and then extracted with ether. The extract was washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to give an oil, which was chromatographed (SiO_2, benzene: AcOEt=5: 1) affording **7b** (42 mg, 91%) as a colorless oil: bp 112—114 °C (0.009 mmHg); IR (neat) 3340 (OH) cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.27 (s, 3H, CH_3), 1.34 (s, 3H, CH_3), 2.22 (s, 3H, CH_3), 1.5—2.9 (m, 6H, CH_2, OH), 3.78 (s, 2H, CH_2O), 6.4—7.1 (m, 3H, ArH). Found: C, 71.16; H, 8.31%. Calcd for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53%.

2,3-Epoxy-2-[2-(4-hydroxy-2-methylphenyl)ethyl]-3-methylbutyl p-Toluenesulfonate (7a): Mp 79—81 °C (hexane: benzene=5: 1); IR (Nujol) 3250 (OH), 1365, 1168 (SO_2) cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.27 (s, 6H, CH_3), 2.16 (s, 3H, CH_3), 2.40 (s, 3H, CH_3), 1.5—2.8 (m, 4H, CH_2), 4.15 (s, 2H, CH_2O), 6.00 (br s, 1H, OH), 6.4—7.1 (m, 3H, ArH), 7.30 (d, J=9 Hz, 2H, ArH), 7.79 (d, J=9 Hz, ArH). Found: C, 64.63; H, 6.60%. Calcd for $C_{21}H_{26}O_5S$: C, 64.59; H, 6.71%.

2-Isopropyl-6-methylspiro[4.5]deca-6,9-dien-8-one (8a). Sublimated *t*-BuOK (16 mg, 0.14 mmol) in 1.2 ml of dry BuOH was added dropwise to a solution of **6a** (45 mg, 0.12 mmol) in 0.8 ml of dry *t*-BuOH under N_2 and the mixture was refluxed for 12 h. After cooling to room temperature, the mixture was quenched with water and then worked up to afford a yellow oil, which was chromatographed (SiO_2, benzene: AcOEt=10: 1) to give **8a** (21 mg, 86%) as a pale yellow oil: bp 60—61 °C (0.01 mmHg); IR (neat) 1660 (C=O), 1625, 1604 (C=C) cm^{-1}; NMR ($CDCl_3$) δ 0.92 (d, J=6 Hz, 3H, CH_3), 0.96 (d, J=6 Hz, 3H, CH_3), 1.99, 2.01 (2s, 3H, CH_3), 1.1—2.3 (m, 8H, CH_2, CH), 5.9—6.2 (m, 2H, CH=), 6.87 (d, J=10 Hz, 1H, CH=). Found: C, 82.24; H, 9.92%. Calcd for $C_{14}H_{20}O$: C, 82.30; H, 9.87%.

2-Isopropenyl-6-methylspiro[4.5]deca-6,9-dien-8-one (8b): Bp 65—68 °C (0.007 mmHg); IR (neat) 1659 (C=O), 1624, 1602 (C=C) cm^{-1}; NMR ($CDCl_3$) δ 1.77 (br s, 3H, CH_3), 2.02, 2.04 (2s, 3H, CH_3), 1.5—2.3 (m, 6H, CH_2), 2.4—3.2 (m, 1H, CH), 4.7—4.9 (m, 2H, CH_2=), 5.9—6.2 (m, 2H, CH=), 6.91 (d, J=10 Hz, CH=). Found: C, 83.15; H, 9.12%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.97%.

2-(1-Hydroxy-1-methylethyl)-6-methylspiro[4.5]deca-6,9-dien-8-one (8c): IR (neat) 3380 (OH), 1650 (C=O), 1614 (C=C) cm^{-1}; NMR ($CDCl_3$) δ 1.25 (s, 3H, CH_3), 1.27 (s, 3H, CH_3), 2.00, 2.02 (2s, 3H, CH_3), 1.4—2.4 (m, 7H, CH_2, CH), 2.73 (br s, 1H, OH), 5.9—6.2 (m, 2H, CH=), 6.99 (d, J=10 Hz, 1H, CH=). Found: C, 76.21; H, 8.97%. Calcd for $C_{14}H_{20}O_2$: C, 76.33; H, 9.15%.

3-[2-(4-Hydroxy-2-methylphenyl)ethyl]-2,2-dimethyloxetane (25): Mp 78—80 °C (hexane: benzene=15: 1); IR (neat) 3280 (OH) cm^{-1}; NMR ($CDCl_3$) δ 1.34 (s, 3H, CH_3), 1.43 (s, 3H, CH_3), 1.6—2.0 (m, 2H, CH_2), 2.20 (s, 3H, CH_3), 2.1—3.0 (m, 3H, CH_2, CH), 4.09 (dd, J_1=6 Hz, J_2=7 Hz, 1H, CH_2O), 4.51 (dd, J_1=7 Hz, J_2=8 Hz, 1H, CH_2O), 6.4—7.0 (m, 3H, ArH), 7.60 (br s, 1H, OH). Found: C, 76.34; H, 9.17%. Calcd for $C_{14}H_{20}O_2$: C, 76.33; H, 9.15%.

2,2,6-Trimethyl-1-oxadispiro[2.1.5.2]dodeca-6,9-dien-8-one (9): Bp 75—77 °C (0.008 mmHg); IR 1662 (C=O), 1624, 1603 (C=C) cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.32 (s, 3H, CH_3), 1.38 (s, 3H, CH_3), 2.01, 2.04 (2s, 3H, CH_3), 1.5—2.9 (m, 6H, CH_2), 6.0—6.3 (m, 2H, CH=), 6.90 (d, J=11 Hz, 1H, CH=). Found: C, 77.02; H, 8.37%. Calcd for $C_{14}H_{18}O_2$: C, 77.03; H, 8.13%.

2-Isopropyl-6,10-dimethylspiro[4.5]dec-6-en-8-one (10a). An ethereal solution of lithium dimethylcuprate (I) (1.0 mmol) was added to a solution of **8a** (70 mg, 0.34 mmol) in 1.5 ml of dry ethre over 20 min period under N_2 at −20——25 °C. The mixture was stirred for 1.5 h and quenched with water and 5% HCl. The usual work-up gave an oil, which was chromatographed (SiO_2, benzene: AcOEt=10: 1) providing **10a** (61 mg, 81%) as a slightly yellow oil: bp 56—57 °C (0.01 mmHg); IR (neat) 1669 (C=O), 1614 (C=C) cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.92 (d, J=7 Hz, 6H, CH_3), 0.96—1.03 (m, 3H, CH_3), 1.93, 1.95, 1.96, 1.97 (4s, 3H, CH_3), 1.1—2.8 (m, 11H, CH_2, CH), 5.70 (br s, 1H, CH=). Found: C, 81.84; H, 10.98%. Calcd for $C_{15}H_{24}O$: C, 81.76; H, 10.98%.

2-Isopropenyl-6,10-dimethylspiro[4.5]dec-6-en-8-one (10b): Bp 65—67 °C (0.008 mmHg); IR (neat) 1667 (C=O), 1612 (C=C) cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.00, 1.04 (2d, J=7 Hz, 3H, CH_3), 1.78 (br s, 3H, CH_3), 1.99, 2.00, 2.01, 2.02 (4s, 3H, CH_3), 1.30—2.80 (m, 10H, CH_2, CH), 4.75 (br s, 2H, CH_2=), 5.75 (br s, 1H, CH=). Found: C, 82.49; H, 10.35%. Calcd for $C_{15}H_{22}O$: C, 82.52; H, 10.16%.

2-(1-Hydroxy-1-methylethyl)-6,10-dimethylspiro[4.5]dec-6-en-8-one (10c): IR (neat) 3420 (OH), 1654 (C=O), 1612 (C=C) cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.90—1.07 (m, 3H, CH_3), 1.25 (s, 6H, CH_3), 1.92—2.00 (m, 3H, CH_3), 1.30—2.62 (m, 11H, CH_2, CH, OH), 5.73 (br s, 1H, CH=). Found: C, 76.19; H, 10.24%. Calcd for $C_{15}H_{24}O_2$: C, 76.23; H, 10.24%.

2-Isopropylidene-6,10-dimethylspiro[4.5]dec-6-en-8-one (dl-β-Vetivone) (1) and Its C-10 Epimer. A mixture of **10b** (14 mg, 0.064 mmol) and $RhCl_3 \cdot 2H_2O$ (1.3 mg, 0.05 mmol) in 0.05 ml of dry EtOH was heated in a glass tube at 110 °C for 8 h. The mixture was filtered and the precipitate was rinsed several times with ether. The combined filtrates were concentrated *in vacuo* and the residue was chromatographed (SiO_2, benzene: AcOEt=10: 1) to give (±)-**1** and its C-10 epimer (11 mg, 80%). HPLC separation of the epimeric mixture (μ-Porasil, 4φ-30 cm, ether: hexane=1: 10, flow rate 2 ml/min, 1000 psi) and further purification through a short silica gel column to remove a paraffin provided (±)-**1** (3 mg, retention time 10.8 min) as an oil and 10-epi-(±)-**1** (3 mg, retention time 12.7 min); (±)-**1**: IR (CCl_4) 1670, 1658 (shoulder), 1612 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.96 (d, J=7 Hz, 3H, CH_3), 1.73—1.51 (m, 6H, CH_3), 1.89 (d, J=1.5 Hz, 3H, CH_3), 2.2—1.8 (m, 3H, CH, CH_2), 2.6—2.2 (m, 5H, CH_2), 2.63 (dd, J_1=17 Hz, J_2=5 Hz, 1H, CH_2CO), 5.78 (br s, 1H, CH=). 10-epi-(±)-**1**: IR (CCl_4) 1670, 1657 (shoulder), 1612 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.97 (d, J=7 Hz, 3H, CH_3), 1.62 (br s, 6H, CH_3), 1.90 (d, J=1.5 Hz, 3H, CH_3), 2.0—1.7 (m, 3H, CH, CH_2), 2.6—2.0 (m, 5H, CH_2), 2.59 (dd, J_1=17 Hz, J_2=6 Hz, 1H, CH_2CO), 5.78 (br s, 1H, CH=).

2-Isopropylidene-6-methylspiro[4.5]deca-6,9-dien-8-one (26). Thionyl chloride (0.014 ml, 0.19 mmol) was added to an ice-cooled solution of **8c** (35 mg, 0.16 mmol) in 0.15 ml of dry pyridine and 0.3 ml of dry CH_2Cl_2 under N_2. After 10 min stirring, the reaction mixture was warmed to room temperature for 3.5 h. The mixture was quenched with a few pieces

of ice and the organic substances were worked up to give an oil, which was chromatographed (SiO_2, benzene: AcOEt=5: 1) providing **26** (24 mg, 75%) as colorless crystals: mp 80—82 °C (pentane) (lit. 82—83 °C)[5h]; IR (neat) 1662 (C=O), 1627, 1605 (C=C) cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.67 (br. s, 6H, CH_3), 2.00, 2.02 (2s, 3H, CH_3), 1.5—2.8 (m, 6H, CH_2), 5.9—6.3 (m, 2H, CH=), 6.92 (d, J=10 Hz, 1H, CH=).

We wish to thank Dr. M. Ueda and Mr. I. Akuta, Central Research Lab., Kuraray Co., Ltd., for their support of HPLC analysis.

Synthetic Studies on Pyridomycin. III.[1] Chiral Synthesis of (2*R*,2*S*)-(−)-2,3-Dihydroxy-3-methylpentanoic Acid from Sugar Derivative

Mitsuhiro KINOSHITA,* Hiroshi HAMAZAKI, and Masaki AWAMURA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received May 10, 1978)

The Grignard reaction of 3-*O*-benzyl-6-deoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hexofuranos-5-ulose (**5**) with ethylmagnesium bromide yielded 3-*O*-benzyl-6-deoxy-5-*C*-ethyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**6**) as a major product in 91% stereoselectivity. Hydrolysis of **6** followed by successive periodate oxidation and lithium aluminium hydride reduction gave 2-*O*-benzyl-5-deoxy-4-*C*-ethyl-D-arabinitol. Selective benzoylation of **9** followed by successive 3,4-*O*-isopropylidenation, debenzoylation, hydrogenolysis, and two-stage oxidation with periodate-hypoiodite afforded (4*R*,5*S*)-(+)-5-ethyl-2,2,5-trimethyl-1,3-dioxolane-4-carboxylic acid (**15**) in 24.6% overall yield from **5**. Hydrolysis of **15** gave (2*R*,3*S*)-(−)-2,3-dihydroxy-3-methylpentanoic acid. The acetonide **15** is usefull as a synthon for pyridomycin synthesis.

The structure of pyridomycin (**1**) contains (*Z*)-2-acyloxy-3-methyl-2-pentenoic ester (unit **A**) which corresponds to the unique exocyclic *s*-butylidene side chain moiety in the twelve-membered ring system.[2] For the total synthesis of pyridomycin, it was desirable for the precursor of **1** to contain an appropriate 2-*O*-acylated dihydroxy ester (unit **2**) derived from *threo*-2,3-dihydroxy-3-methylpentanoic acid such as structure **3**, since dehydration of unit **2** is expected to afford predominantly unit **A** in **1** by *trans*-elimination.[3]

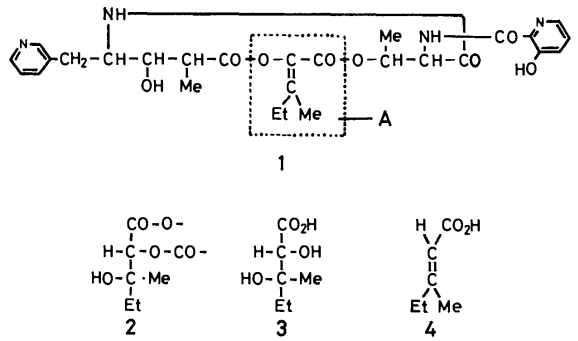

Fig. 1.

The (±)- and (−)-*threo*-2,3-dihydroxy-3-methylpentanoic acids have been prepared from (*E*)-3-methyl-2-pentenoic acid (**4**) by *cis*-hydroxylation[4,5] and by optical resolution of the (±)-*threo*-acid,[5] respectively. This synthetic method seems less promising since the isomerically pure key substance **4** can not be easily prepared on a large scale. On the other hand, a mixture of the *threo*- and *erythro*-dihydroxy acids has easily been prepared from ethyl 3-methyl-2,3-epoxypentanoate.[6,7] However, attempts to isolate the *threo*-isomer from the isomeric mixture have not yet been successful.

This paper presents a chiral synthesis of (2*R*,3*S*)-2,3-dihydroxy-3-methylpentanoic acid (**3**)[8] *via* its acetonide (2,3-*O*-isopropylidene derivative) **15** from 3-*O*-benzyl-6-deoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hexofuranos-5-ulose (**5**)[9,10] through the route shown in Fig. 2. In the first step, the desired product **6** in which the configuration of the C-5 carbon is identical with that of the C-3 carbon in the target compound **3**, was obtained in high stereoselectivity by the asymmetric Grignard reaction.[11–13] The isomerically pure acetonide **15** derived from **6** substantially contributed to the configurational assignment of **6**. The acetonide **15** is useful not only as a precursor for **3** but also as a synthon for synthesis of a precursor of **1**. This synthesis is advantageous for all the optically active diastereo- and enantio-isomers of **3**. the (3*R*)-epimer **3'** (Fig. 2), which has been established[5–8] to be an intermediate in the biosynthesis of isoleucine, will be synthesized *via* **6'** by the use of the ulose **5'** as a starting material instead of **5**. The enantiomer of **5** will be converted into the optical antipode of **3** which is also useful in the pyridomycin synthesis.

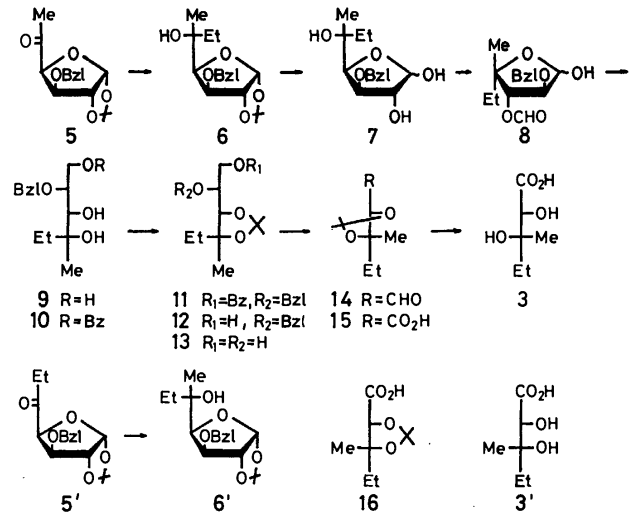

Fig. 2.

Results and Discussion

The Grignard reaction of **5** with an eight-fold excess of ethylmagnesium bromide in ether afforded a crystalline condensation product in 80.1% yield after recrystallization from pentane. A thorough examination of this product by PMR spectroscopy revealed that it is a *ca.* 91 : 9 mixture of the desired 3-*O*-benzyl-6-deoxy-5-*C*-ethyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**6**) and its 5-epimer **6'**. Further purification of the product by recrystallization gave no isomerically pure major isomer **6**. For the PMR analysis a pure sample of **6** was isolated

from the product by silica gel column chromatography in a poor yield. A pure sample of the minor isomer **6'** was obtained by column chromatography of a product containing mainly **6'** (91%) prepared by the Grignard reaction of 3-*O*-benzyl-6,7-dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-heptofuranos-5-ulos (**5'**)[10] and methylmagnesium iodide. The PMR spectra of **6** and **6'** showed a characteristic singlet at δ 1.15 and 1.26 ascribed to the methyl protons of each isomer, respectively. The assignment of the (5*S*)-configuration for **6** was rationalized on the basis of the results of asymmetric Grignard reactions of free carbonyl sugar derivatives reported by Wolfrom and Hanessian,[11] Inch,[12] and Inch *et al.*[13] The assumed configuration was verified by PMR study of the acetonide **15** derived from **6** (see below). Hydrolysis of **6** (the aforesaid isomeric mixture) in a boiling 50% aqueous acetic acid afforded free sugar in 92% yield, to which the furanose structure **7** was given, because it could be smoothly converted into the subsequent product **8**. Periodate oxidation of **7** gave 2-*O*-benzyl-5-deoxy-4-*C*-ethyl-3-*O*-formyl-D-arabinofuranose (**8**) in 87.6% yield after treatment by silica gel chromatography. The PMR spectrum of **8** showed signals in line with the furanose structure. Lithium aluminium hydride reduction of **8** in THF afforded 2-*O*-benzyl-5-deoxy-4-*C*-ethyl-D-arabinitol (**9**) as colorless prisms in 98.3% yield. This sample appeared to be isomerically homogeneous as judged from its PMR spectrum. Selective benzoylation of **9** with benzoyl chloride in pyridine gave the 1-*O*-benzoate **10** in 86.3% yield after being subjected to silica gel chromatography. Treatment of **10** with 2,2-dimethoxypropane containing a small amount of *p*-toluenesulfonic acid yielded 3,4-acetonide **11** in 96.6% yield. Debenzoylation of **11** with sodium methoxide afforded 2-*O*-benzyl-5-deoxy-4-*C*-ethyl-3,4-*O*-isopropylidene-D-arabinitol (**12**) in 81.7% yield after being subjected to chromatography. Hydrogenolysis of **12** followed by periodate oxidation of the resulting diol **13** gave the crude aldehyde **14** in 71.9% yield. The aldehyde was then oxidized with potassium hypoiodite[14] to afford the crystalline acetonide **15** in 79.2% yield (24.6% overall yield from **5**). The sample of **15** was shown to be isomerically homogeneous by its PMR spectrum.

Hill and Yan[7] reported on the acetonide **16** corresponding to (2*R*,3*R*)-(—)-2,3-dihydroxy-3-methylpentanoic acid (**3'**).[5,7] A comparison of the PMR data of **15** with those of **16** shows significant differences between the chemical shifts of the corresponding 5-methyl and 5-ethyl protons on the 1,3-dioxolane ring of each acetonide (see Table). Thus acetonide **15** was proved to be the (5*S*)-epimer of **16**, the (5*S*)-configuration of **6** being verified.

Treatment of **15** with 50% trifluoroacetic acid yielded the title compound **3** as a syrup in quantitative yield. The PMR spectrum showed signals in line with the structure. The hydroxy acid **3** exhibited a weak positive CD Cotton effect at 235 nm in addition to the strong negative Cotton effect at 205 nm in water. The result is also consistent with the (2*R*)-configuration of **3**.[5,15]

Experimental

Melting points were determined on a micro hot-stage and are uncorrected. PMR spectra were taken on a Varian A-60D spectrometer using TMS and DSS as internal standards. Specific rotations were determined with a Zeiss Photoelectric Polarimeter. TLC and column chromatography were performed in Wakogel B-5 and C-200, respectively. Concentration was carried out under reduced pressure below 40 °C.

3-O-Benzyl-6-deoxy-5-C-ethyl-1,2-O-isopropylidene-α-D-glucofuranose (6). The starting material, 3-*O*-benzyl-6-deoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hexofuranos-5-ulose (**5**)[9,10] was prepared in 91% yield by Jones oxidation[10] of 3-*O*-benzyl 6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose[9,10,12] which was derived *via* 5,6-anhydro-3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose[16] from 3-*O*-benzyl-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose[17] in 83% overall yield. A solution of **5** (30 g, 0.1026 mol) in dry ether (900 ml) was added dropwise under stirring to an ether solution of ethylmagnesium bromide prepared from magnesium turnings (20.0 g, 0.8235 mol) and ethyl bromide (61.8 ml, 0.8227 mol) in dry ether (900 ml). The mixture which was stirred at room temperature for 3 h was treated with a cold saturated aqueous NH_4Cl solution (800 ml) under cooling. The aqueous layer was extracted with ether, and the combined ether layer were washed with saturated aqueous NaCl solution, dried and evaporated to afford a pale yellow crystalline solid (32.7 g, mp 51—60 °C). The solid was recrystallized from pentane to give needles of the condensation product (26.8 g, 80.1%, mp 64—64.5 °C) which was shown by PMR analysis to be a 91:9 mixture of the title compound **6** and its 5-epimer **6'**. The product (1 g) was recrystallized from pentane to afford colorless needles (0.79 g); mp 64—65 °C, $[\alpha]_D^{20}$ −68° (*c* 2.06, $CHCl_3$). The PMR spectrum showed no appreciable change in the proportion of **6** to **6'**. The product (1.00 g) was chromatographed on silica gel (180 g) with benzene–ethyl acetate (6:1). By PMR inspection, the effluent containing the pure isomer **6** was collected in the fore-run, giving a pure sample (82 mg, 8.2%) of **6**: colorless needles, mp 64.3—65 °C; $[\alpha]_D^{20}$ −72° (*c* 0.6, $CHCl_3$); δ ($CDCl_3$) 0.92 (t, 3H, 5-$CH_2\underline{CH_3}$, J=7 Hz, 1.15 (s, 3H, H-6), 1.34 and 1.50 [each s, 3H, C-$(CH_3)_2$], 1.72 (m, 2H, 5-$C\underline{H_2}CH_3$), 3.71 (s, 1H, OH), 4.01

Table 1. Comparison of 60 MHz PMR data (δ, $CDCl_3$) of **15** with the published PMR data (60 MHz, δ, $CDCl_3$)[7] of (4*R*,5*R*)-5-ethyl-2,2,5-trimethyl-1,3-dioxolane-4-carboxylic acid (**16**)

3-O-Benzyl-6-deoxy-5-C-ethyl-1,2-O-isopropylidene-α-D-idofuranose (6′). 3-*O*-Benzyl-6,7-dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-heptofuranos-5-ulose (**5′**)[10] (475 mg) was allowed to react with an eight-fold excess of methylmagnesium iodide in ether (29 ml) at room temperature for 3 h. Work-up as in the preparation of **6** followed by purification of the crude product through a silica gel column (27 g) with benzene–ethyl acetate (6: 1) afforded a syrup of the condensation product (471 mg, 94.1%) which was shown by PMR analysis to be a 91: 9 mixture of **6′** and **6**. The sample (422 mg) was again chromatographed on silica gel (76 g) with the same solvent system to give a pure sample (90 mg, 21.4%) of **6′** as colorless syrup: $[\alpha]_D^{19}$ −58° (*c* 1.0, $CHCl_3$); δ ($CDCl_3$) 0.92 (t, 3H, 5-$CH_2C\underline{H}_3$, $J=7$ Hz), 1.26 (s, 3H, H-6), 1.33 and 1.49 [each s, 3H, $C(CH_3)_3$], *ca.* 1.5 (m, 2H, 5-C$\underline{H}_2CH_3$), 3.40 (s, 1H, OH), 4.00 and 4.18 (each d, H-3, H-4, $J_{3,4}=3$ Hz),** 6.69 (d, 1H, H-2, $J_{1,2}=4$ Hz), 4.57 and 4.78 (each d,OC$\underline{H}_2$Ph, $J_{gem}=11.5$ Hz),** 6.11 (d, 1H, H-1), and 7.44 (s, 5H, Ph).

Found: C, 66.76; H, 8.13%. Calcd for $C_{18}H_{26}O_5$: C, 67.06; H, 7.91%.

2-O-Benzyl-5-deoxy-4-C-ethyl-D-arabinitol (9). Treatment of the Grignard reaction product (10.0 g) containing *ca.* 91% of **6** with 50% aqueous acetic acid (60 ml) at 115 °C for 6 h, followed by evaporation afforded a brown syrup, which was dissolved in ethyl acetate (200 ml). The solution was washed successively with saturated $NaHCO_3$ and saturated NaCl solutions, dried and evaporated. The residual pale brown syrup (10.5 g) was chromatographed on silica gel (300 g) with benzene–ethyl acetate (1: 1) to give 3-*O*-benzyl-6-deoxy-5-*C*-ethyl-D-glucofuranose (**7**) (8.06 g, 92%). A sample of the free sugar **7** (7.96 g) was dissolved in acetone (240 ml) and treated with a solution of sodium metaperiodate (12.06 g) in water (120 ml) at room temperature for 3 h. A solution of the periodate (6.03 g) in water (60 ml) was added to the reaction mixture, which was stirred at room temperature overnight and filtered. Acetone was removed from the filtrate by evaporation and the aqueous residue was extracted with ethyl acetate. The extract was washed with saturated NaCl solution, dried and evaporated. The residual syrup (7.64 g) was chromatographed on silica gel (300 g) with benzene–ethyl acetate (6: 1) to afford a colorless syrup of 2-*O*-benzyl-5-deoxy-4-*C*-ethyl-3-*O*-formyl-D-arabinofuranose (**8**) as an anomeric mixture, yield 6.92 g (87.6%); δ ($CDCl_3$) 0.96 (dt, 3H, 4-$CH_2C\underline{H}_3$), 1.36 and 1.45 (each s, 3H, H-5), 1.76 (m, 2H, 4-C$\underline{H}_2CH_3$), 3.8—4.2 (br, 2H, H-2 and OH), 4.78 (d, 2H, OC$\underline{H}_2$Ph), 5.3—5.6 (m, 2H, H-1 and H-3), 7.48 (s, 5H, Ph), and 8.25 (s, 1H, OC$\underline{H}$O). A sample of **8** (5.56 g, 19.84 mmol) was dissolved in dry THF (209 ml) and cooled in an ice-bath. Powdered $LiAlH_4$ (1.50 g, 39.67 mmol) was added slowly to the stirred solution and then refluxed for 6 h. Ethyl acetate (150 ml) and water (5 ml) were added to the cooled reaction mixture and stirred at room temperature overnight. The mixture was filtered and the filter cake was washed with ethyl acetate. The filtrate and washings were combined and washed with saturated NaCl solution, dried and evaporated to give **9** as colorless needles (4.96 g, 98.3%). Recrystallization from ether–petroleum ether afforded an analytical sample: prisms, mp 58—59 °C; $[\alpha]_D^{23}$ −60° (*c* 1.00, $CHCl_3$); δ ($CDCl_3$) 0.96 (t, 3H, 4-$CH_2C\underline{H}_3$), 1.13 (s, 3H, 5-H), 1.56 (q, 2H, 4-C$\underline{H}_2$-CH_3), 2.86 (s, 3H, OH), 3.51 (d, 1H, H-3, $J_{2,3}=2$ Hz), 3.6—4.2 (m, 3H, H-1,1′ and H-2), 4.48 and 4.75 (each d, 2H, OC$\underline{H}_2$Ph, $J_{gem}=11$ Hz),** and 7.30 (s, 5H, Ph).

1-O-Benzoyl-2-O-benzyl-5-deoxy-4-C-ethyl-D-arabinitol (10). Benzoyl chloride (6.17 ml, 53.0 mmol) was added to a solution of **9** (12.26 g, 48.19 mmol) in dry pyridine (245 ml) cooled at −10 °C. The mixture was allowed to stand at 4 °C for 24 h and then poured into cold water (200 ml) and extracted with chloroform (300 ml × 3). The concentrated extract was diluted with chloroform (300 ml); this was washed with 50% aqueous $KHSO_4$ solution, saturated $NaHCO_3$ and saturated NaCl solutions successively, dried and evaporated to yield a syrup (18.73 g), which was chromatographed on silica gel (360 g) with benzene–ethyl acetate (6: 1) to afford a colorless syrup of **10** (14.9 g, 86.3%): $[\alpha]_D^{20}$ −19° (*c* 1.04, $CHCl_3$); IR $(CCl_4)_{max}$ 3500 (OH) and 1710 cm^{-1} (ester); δ ($CDCl_3$) 0.92 (t, 3H, 4-$CH_2C\underline{H}_3$, $J=7$ Hz), 1.16 (s, 3H, H-5), 1.66 (m, 2H, 4-C$\underline{H}_2$-CH_3), 3.30 (s, 2H, OH), 3.62 (d, 1H, H-3, $J_{2,3}=2$ Hz), 4.22 (dt, 1H, H-2, $J_{1,2}=5.5$ Hz), 4.79 (d, 2H, H-1), 4.74 and 5.00 (each d, 2H, OC$\underline{H}_2$Ph),** 7.48 (s, 5H, $OCH_2\underline{Ph}$), 7.60 (m, 3H, benzoyl), and 8.26 (m, 2H, benzoyl).

1-O-Benzoyl-2-O-benzyl-5-deoxy-4-C-ethyl-3,4-O-isopropylidene-D-arabinitol (11). A solution of **10** (14.90 g, 41.57 mmol) and *p*-toluenesulfonic acid (515 mg) in 2,2-dimethoxypropane (204 ml) was kept at room temperature for 2 h and then diluted with ether (500 ml). The mixture was washed with saturated $NaHCO_3$ and saturated NaCl solutions, dried and evaporated to afford the crude acetonide **11** (16.00 g, 96.6%). Analytical sample of **11** was obtained by chromatograpy of the crude **11** through a silica gel column with benzene–ethyl acetate (12: 1): $[\alpha]_D^{21}$ +29° (*c* 1.03, $CHCl_3$); IR $(CCl_4)_{max}$ 1710 cm^{-1} (ester); δ ($CDCl_3$) 0.98 (t, 3H, 4-$CH_2C\underline{H}_3$, $J=7$ Hz), 1.24 (s, 3H, H-5), 1.40 and 1.51 [each s, 3H, $C(CH_3)_3$], 1.66 (m, 2H, 4-C$\underline{H}_2$-CH_3), 3.8—4.8 (m, 4H, H-3, H-2, and H-1), 4.91 (s, 2H, OC$\underline{H}_2$Ph), 7.46 (d, 5H, OCH_2Ph), 7.64 (m, 3H, benzoyl), and 8.22 (m, 2H, benzoyl).

2-O-Benzyl-5-deoxy-4-C-ethyl-3,4-O-isopropylidene-D-arabinitol (12). The crude acetonide **11** (16.00 g) was dissolved in dry methanol (320 ml). A solution of 2.5 M sodium methoxide in methanol was added under ice-cooling and kept at room temperature for 1 h. The resulting mixture was poured into ice–water (230 ml) and extracted with chloroform (200 ml × 3). The extract was washed with saturated NaCl solution, dried and evaporated. The residual syrup (16.38 g) was chromatographed on silica gel (500 g) with benzene–ethyl acetate (6: 1) to afford a colorless syrup of **12** (9.66 g, 81.7%): $[\alpha]_D^{22}$ +35° (*c* 1.14, $CHCl_3$); δ ($CDCl_3$) 1.00 (t, 3H, 4-CH_2-$C\underline{H}_3$, $J=7$ Hz), 1.26 (s, 3H, 5-H), 1.38 and 1.51 [each s, 3H, $C(CH_3)_2$], 1.60 (m, 2H, 4-C$\underline{H}_2CH_3$), 3.4—4.2 (m, 4H, H-3, H-2, and H-1), 4.77 and 5.10 (each d, 2H, OC$\underline{H}_2$Ph, $J_{gem}=12$ Hz),** and 7.50 (s, 5H, Ph).

Found: C, 69.09; H, 8.74%. Calcd for $C_{17}H_{26}O_4$: C, 69.36; H, 8.90%.

(4R,5S)-(+)-5-Ethyl-2,2,5-trimehyl-1,3-dioxolane-4-carboxylic Acid (15). A solution of **12** (2.30 g) in methanol (70 ml) was stirred with palladium black for 1 h under bubbling with hydrogen gas. The filtered solution was evaporated to a colorless syrup of 5-deoxy-4-*C*-ethyl-3,4-*O*-isopropylidene-D-arabinitol (**13**) (1.60 g, 100%) which appeared to be homogeneous on TLC with benzene–ethyl acetate (1: 1). A sample of **13** (6.70 g, 32.8 mmol) was dissolved in acetone (200 ml)

** The chemical shifts for the protons of system AB were calculated.

and treated with a solution of sodium metaperiodate (14.04 g, 65.6 mmol) in water (140 ml). After being stirred in a dark place at room temperature for 1 h, the reaction mixture was filtered and the acetone was removed by concentration of the filtrate. The resulting aqueous residue was extracted with chloroform (100 ml×2). The extracts were washed with saturated NaCl solution, dried and evaporated to give (4*R*, 5*S*)-5-ethyl-2,2,5-trimethyl-1,3-dioxolane-4-carbaldehyde (**14**) (4.07 g, 71.9%) as a colorless liquid; δ($CDCl_3$) 1.02 (t, 3H, 5-$CH_2C\underline{H}_3$, J=7 Hz), 1.20 (s, 3H, 5-CH_3), 1.42 and 1.58 [each s, 3H, $C(CH_3)_2$], 1.74 (m, 2H, 5-$C\underline{H}_2CH_3$), 4.22 (d, 1H, H-4, $J_{5,CHO}$=2 Hz), and 9.98 (d, 1H, CHO). The aldehyde **14** (4.06 g, 23.6 mmol) was dissolved in dioxane (100 ml). The solution was diluted with water (37 ml), and a solution of K_2CO_3 (20.55 g, 148.7 mmol) and $KHCO_3$ (14.89 g, 148.7 mmol) in water (160 ml) was added. A solution of iodine (17.62 g, 69.4 mmol) and KI (23.04 g, 138.8 mmol) in water (20 ml) was added, and the mixture was stirred at room temperature for 2 h. The cooled mixture was reduced by the addition of solid sodium thiosulfate. The resulting colorless solution was washed with ether to remove the unchanged aldehyde and impurities. The aqueous solution was made acid (pH 2—3) with 10% sulfuric acid under ice-cooling, and immediately extracted with chloroform (100 ml×3). The extracts were washed with saturated NaCl solution, dried and evaporated to yield colorless crystals of **15** (3.52 g, 79.2%), whose PMR spectrum showed no signals indicating the presence of the (4*R*)-epimer **16**. The crude crystals (20 mg) were subjected to sublimation at 49 °C (bath temp) under reduced pressure (1 Torr) to afford a pure sample (18.8 mg) as hygroscopic colorless needles: mp 46.5—49 °C (subl); $[\alpha]_D^{20}$ +26° (*c* 0.84, $CHCl_3$).

Found: C, 57.58; H, 8.44%. Calcd for $C_9H_{16}O_4$: C, 57.43; H, 8.57%.

(2R3,S)-(−)-2,3-Dihydroxy-3-methylpentanoic Acid (3). A sample of **15** (200 mg) was dissolved in 50% aqueous trifluoroacetic acid (2 ml). After being kept at room temperature for 4 h, the solution was evaporated to afford **3** as a pale yellow syrup. The crude acid (217 mg) was purified by silica gel chromatography with chloroform–methanol–acetic acid (80: 10: 1) and the resulting colorless syrup was again chromatographed with chloroform–ethyl acetate (1: 1) to give a pure sample of **3** (155 mg, 98.2%): $[\alpha]_D$ −28°, $[\alpha]_{436}$ −63°, $[\alpha]_{365}$ −106° (*c* 1.48, $CHCl_3$, at 20°); $[\alpha]_D$ −16°, $[\alpha]_{436}$ −34°, $[\alpha]_{365}$ −55° (*c* 1.32, H_2O, at 20°); CD, $[\theta]_{235}$ +290 and $[\theta]_{205}$ −5460 (*c* 0.115, H_2O); δ (D_2O, DSS) 0.90 (t, 3H, H-5, J=7 Hz), 1.21 (s, 3H, 3-CH_3), *ca.* 1.6 (m, 2H, H-4), 4.10 (s, 1H, H-2), and 4.62 (s, DOH); δ ($CDCl_3$) 0.94 (t, 3H, H-5, J=7 Hz), 1.27 (s, 3H, 3-CH_3), *ca.* 1.6 (m, 2H, H-4), 4.07 (s, 1H, H-2), and 5.82 (s, 3H, CO_2H, OH).

Found: C, 48.47; H, 8.35%. Calcd for $C_6H_{12}O_4$: C, 48.64; H, 8.16%.

We thank Mr. Saburo Nakada for carrying out the microanalyses and Dr. Shimpei Aburaki for the CD spectral measurement.

Thermal Curtius Rearrangement of *N*-Acyl-*S*,*S*-diphenylsulfilimine

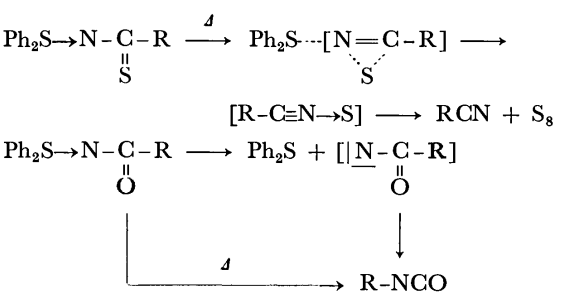
Naomichi FURUKAWA,* Mitsuo FUKUMURA, Takehiko NISHIO, and Shigeru OAE
Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31
(Received May 13, 1978)

Several *N*-acyl-*S*,*S*-arylphenylsulfilimines were prepared and subjected to thermal decomposition. They decomposed readily at 130—190 °C to give isocyanates together with diphenyl sulfide, quantitatively. However, *N*-tosyl-*S*,*S*-diphenylsulfilimine did not decompose even upon heating at 200 °C for 24 h. A kinetic study revealed that the rates of pyrolysis of *N*-aroyl-*S*,*S*-arylphenylsulfilimines (*p*-Y-C_6H_4(Ph)S→$NCOC_6H_4$-X-*p*) are nicely correlated with the Hammett σ-values, $\rho_X=-1.2$ and $\rho_Y=+0.92$, respectively, being obtained. The activation enthalpies and entropies were $\Delta H^{\neq}=38.7$ kcal/mol and $\Delta S^{\neq}=6.0$ e.u. for Ph_2S→NCOPh and $\Delta H^{\neq}=32.3$ kcal/mol and $\Delta S^{\neq}=5.5$ e.u. for Ph_2S→NCO-  -, respectively. The rearrangement was accelerated considerably by *o*-methyl substituent in the aryl group. The effect of solvent on the rate of pyrolysis was small. The results indicate that the pyrolysis of sulfilimine proceeds *via* a concerted migration of the R group from carbonyl carbon to imino nitrogen similar to the Curtius type rearrangement of acid azide.

N-Tosylsulfilimines each having at least one β-hydrogen atom undergo facile intramolecular elimination (Ei) to afford olefin stereoselectively in high yields.[1] Meanwhile, *N*-tosylsulfilimines having no β-hydrogen atom, such as *N*-tosyl-*S*,*S*-dimethyl and *N*-tosyl-*S*,*S*-methylphenylsulfilimines are stable under the usual Ei conditions (benzene reflux) but decompose upon heating in DMSO or DMF at *ca.* 200 °C to afford interesting products as shown below.[2] In contrast, *N*-tosyl-*S*,*S*-diphenylsulfilimine is quite stable even upon heating at 200 °C and recovered almost quantitatively.[3]

Yoshida *et al.*[4] found that *N*-thiocarbonyl-*S*,*S*-diphenylsulfilimines undergo pyrolysis at 70 °C to afford the corresponding nitriles, diphenyl sulfide and sulfur. They proposed that the pyrolysis proceeds *via* the initial migration of the thione sulfur to the imino nitrogen to form incipiently the nitrile sulfide which decomposes rapidly to afford the nitrile and sulfur. Thermally stable *N*-acyl-*S*,*S*-diphenylsulfilimines were found to undergo facile photolysis, resulting in the photochemical Curtius rearrangement *via* an incipient formation of the corresponding nitrene.[5] Synthetic utilization of the thermolysis of sulfilimines has recently been shown by Gilchrist *et al.*[6] and Tamura *et al.*[7]

In the course of a preliminary study on the sulfilimines, we found that *N*-benzoyl-*S*,*S*-diphenylsulfilimine decomposes quite readily when heated at 200 °C *in situ* and also in such solvents as DMF, tetralin and even EtOH in a sealed tube.[3] The products obtained in high yields by the pyrolysis were found to be diphenyl sulfide, phenyl isocyanate and *N*,*N*′-diphenylurea. The facile thermal decomposition of *N*-benzoyl-*S*,*S*-diphenylsulfilimine prompted us to investigate the thermolysis of various *N*-acyl-*S*,*S*-diarylsulfilimines, all of which have been found to afford the corresponding isocyanates and diaryl sulfides almost quantitatively. Thus, we carried out a kinetic study on the pyrolysis of *N*-acyl-*S*,*S*-diarylsulfilimines and found that these rearrangements proceed through the Curtius type rearrangement as in the ordinary thermal Curtius rearrangement in the thermolysis of *N*-acyl azides.



Scheme 2.

This paper describes detailed analysis of products, results of kinetic experiments on the Curtius type rearrangement of *N*-acyl-*S*,*S*-arylphenylsulfilimines and a plausible mechanism of the reaction in comparison with those of other reactions involving alkyl or aryl group migration from carbonyl group to electron deficient nitrogen or oxygen terminus.

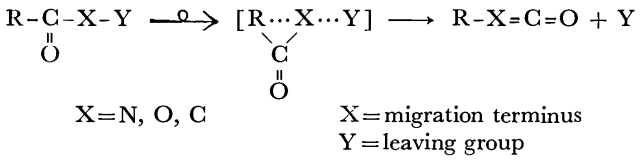
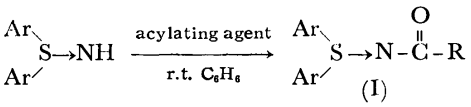


Scheme 3.

Results and Discussion

Preparation of N-*Acyl*-S,S-*diphenylsulfilimine.* *N*-Acyl-*S,S*-diphenylsulfilimines were prepared by acylating unsubstituted diphenylsulfilimine with appropriate acylating agents.[7] The yields and mp(°C) of sulfilimines thus prepared are summarized in Table 1 together with spectral data.

Pyrolyses of N-*Acyl*-S,S-*diphenylsulfilimines.* The pyrolysis of *N*-acyl-*S,S*-diphenylsulfilimines (Ia—f) was carried out by heating *in situ* or in such solvents as tetralin, DMF, toluene and EtOH. After the pyrolysis,



Scheme 4.

the products were separated by column chromatography or preparative GLC and identified by spectroscopic analysis by comparing their spectra with those of the authentic samples. The products thus obtained are summarized in Table 2. We see that the pyrolysis proceeds cleanly to afford the corresponding isocyanate-(II) and diphenyl sulfide nearly quantitatively except in the case of the *N*-benzoyl (R=Ph) derivative which gives a small amount of the isocyanate and a substantial portion of the dimerized product which is similarly obtained by photolysis; thus the total yield of phenyl isocyanate incipiently formed by the thermolysis of Ia is also quantitative.

Kinetic Studies. A kinetic study of the pyrolysis of

N-acyl-*S*,*S*-arylphenylsulfilimines (Ia—r) was carried out in DMF at around 130—190 °C. The rate of the pyrolysis followed the first order kinetic equation. The dependence of rate on concentration shows that the reaction is of the first order in sulfilimine. The rate constants of the pyrolysis of *N*-acyl-*S*,*S*-arylphenylsulfilimines are summarized in Table 3, together with the relative rates, assuming the rate of the *N*-benzoyl-*S*,*S*-diphenylsulfilimine at 190 °C as the standard. The rate constants can be correlated nicely with the Hammett σ-values, ρ-values of −1.20 (X-substituents) and +0.92 (Y-substituents) being obtained (except *p*-nitro group), (Fig. 1). Pyrolysis of the *p*-nitro derivatives also gave the corresponding isocyanates in low yields and some uncharacterized products. The effect of temperature on the rate is given in Table 4. The activation enthalpies and entropies of both sulfilimines (Ia, e) are calculated to be $\Delta H^{\neq}=38.7$ kcal/mol, $\Delta S^{\neq}=6.0$ e.u. ($E_a=39.5$

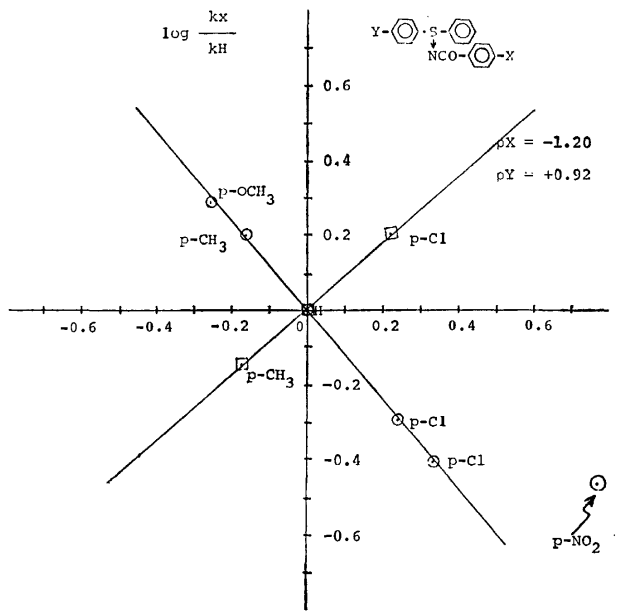

Fig. 1. Hammett plots of *p*- or *m*-substituted sulfilimine.

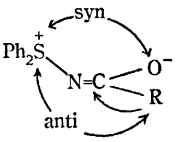
kcal/mol) for Ia, $\Delta H^{*}=32.3$ kcal/mol, $\Delta S^{*}=5.5$ e.u. ($E_a=33.0$ kcal/mol) for Ie. The effect of solvent on the rate of pyrolysis was examined with *N*-2,4,6-trimethylbenzoyl-*S*,*S*-diphenylsulfilimine in benzene, DMF and ethanol. The results are given in Table 4. The rate increases in a nonpolar aprotic solvent such as benzene but decreases in a polar protic solvent such as EtOH. However, difference in the rate is not large unlike the reaction in which the transition state is more polarized than the ground state.

In contrast to the thermal stability of *N*-tosyl-*S*,*S*-diphenylsulfilimine, *N*-acyl derivatives decompose readily giving the corresponding isocyanates in high yields as shown in Table 2. The facile thermolysis of *N*-acyl-*S*,*S*-diphenylsulfilimines reflects on their IR S–N stretching band which appears at *ca.* 800 cm^{-1} (*e.g.*, *N*-benzoyl-*S*,*S*-diphenylsulfilimine 805 cm^{-1}) and also on that of the carbonyl band of the *N*-acyl group which appears at 1500—1600 cm^{-1} (*e.g.*, *N*-benzoyl-*S*,*S*-diphenylsulfilimine 1595—1535 cm^{-1}). The IR absorptions are in sharp contrast to those of the *N*-tosyl derivatives in which the S–N stretching band appears at 930—970 cm^{-1} (*e.g.*, *N*-tosyl-*S*,*S*-diphenyl, 960 cm^{-1}). A comparison of the S–N bond of the *N*-benzoyl with that of the *N*-tosyl group indicates that the S–N bond of the former can be cleaved more readily. The low frequency shift of the absorption due to the carbonyl group of the *N*-acyl derivatives as compared to the corresponding amide group suggests that the carbonyl bond in the *N*-acylsulfilimines is markedly stretched and the contribution of structure B is greater than that of structure A in the resonance hybrid.

$$Ph_2\overset{+}{S}-\overset{-}{N}-\underset{\underset{O}{\|}}{C}-R \longleftrightarrow Ph_2\overset{+}{S}-N=\underset{\underset{O^-}{|}}{C}-R$$

(A) (B)

X-Ray crystallographic analysis of the *N*-acylsulfilimine indicates structure B to be more favored than structure A (*N*-dichloroacetylsulfilimine)[8] while the S–N–C–O atoms in the molecule are arranged nearly in a coplanar geometry, Ph_2S group and the R group being at the anti arrangement. This molecular



geometry suggests that in *N*-acylsulfilimine, the R group can readily migrate to the imino nitrogen from the back of the leaving group, *i.e.*, diphenyl sulfide, in keeping with the stereochemistry of the Curtius,[9] the Hoffman[10,11] the Lossen,[12] and the Schmidt[13] rearrangements.

The rearrangement of the *N*-acyl-*S*,*S*-arylphenylsulfilimines proceeds *via* simultaneous migration of the R group and cleavage of the S–N bond, since the effect of substituents on the phenyl ring of the migrating group shows a negative ρ-value ($\rho=-1.2$) against Hammett σ-values, while that of the leaving group shows a positive ρ-value ($\rho=+0.92$). The Hammett ρ-values

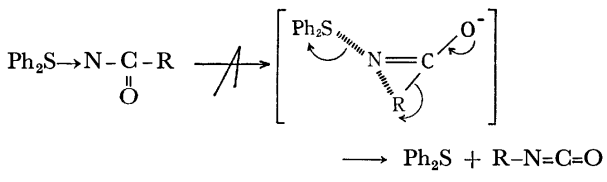
strongly suggest the concerted nature of C–N bond formation and S–N bond breaking in the transition state.

In the [1,2]-shift of the aryl group from carbon to an electron deficient hetero atoms such as nitrogen and oxygen, the Hammett plot with σ^+-values sometimes gives a better correlation than with σ-values.[10,14] However, in the pyrolysis of *N*-acyl-*S,S*-arylphenylsulfilimines the Hammett plot can be correlated better with σ-values than σ^+-values except in the NO_2 derivatives. This suggests that the charge separation in the transition state is rather small. This seems to be supported by the fact that the rate of reaction does not increase markedly in polar solvent; the rate of Ie varies from 3.2 in benzene to 1.0 in DMF and to 0.80 in EtOH.

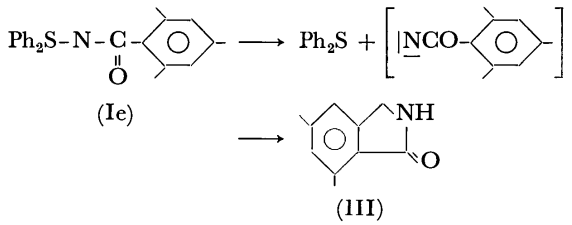
In the pyrolysis of *N*-acyl-*S,S*-arylphenylsulfilimines, the migratory aptitude of the alkyl group lies in the order, *tert*$\simeq$*sec*>*prim*>Me. As compared to this the phenyl group does not accelerate the rate of rearrangement. This effect on the migratory aptitude is in contrast to other similar rearrangements such as Schmidt,[13] Lossen[12] or Bayer-Villiger[16] reactions. As seen from the data in Table 1, the ortho methyl group accelerates the rate of rearrangement enormously; one *o*-methyl group accelerates 70 times and two *o*-methyl groups increase the rate 2200 times. This is probably due to the steric inhibition of resonance between the phenyl group and N–C or carbonyl group, which prevents the planar conformation of the –NCOR group.[8,17,18] In the *N*-benzoylsulfilimine, the acylamide group would be in the same plane as the phenyl ring, a strong conjugation between the phenyl group and C=O and N=C group retarding the cleavage of the C–Ar bond. Two ortho methyl groups in *N*-2,4,6-trimethylbenzoyl derivative would prevent the conjugation between the phenyl ring and the N–CO– group, facilitating migration of the 2,4,6-trimethylbenzoyl group to the nitrogen atom. The same effect of *o*-substituent was observed in other Curtius type rearrangements.[9]

The activation parameters in the rearrangements are of interest. Despite the large rate difference in the pyrolysis of benzoyl and 2,4,6-trimethylbenzoyl derivatives, the values of activation entropies are similar. Thus, the large rate difference is due solely to that of the enthalpy values. The activation parameters in DMF and benzene are also similar. Similar values of both enthalpies and entropies of activation suggest that the transition states of the rearrangements in both solvents are nearly identical.

All these observations indicate that pyrolysis of the *N*-acyl-*S,S*-diphenylsulfilimine proceeds *via* a similar mechanistic path to that of the Curtius rearrangement



Scheme 5.



Scheme 6.

of acid azides involving the rate determining migration of alkyl or aryl group and the concomitant departure of the diaryl sulfide group eventually affording diphenyl sulfide and the isocyanate as shown below.

A similar rearrangement was observed in the photolysis of *N*-acylsulfilimine. The photolysis of *N*-2,4,6-trimethylbenzoyl-*S,S*-diphenylsulfilimine affords not only the rearrangement product but also a C–H insertion product which arises *via* the initial formation of a singlet nitrene as shown above. Singlet multiplicity of the nitrene thus generated has also been confirmed by other trapping experiments with an olefin. In the pyrolysis of the sulfilimine, the possibility of the formation of nitrene as intermediate should also be considered. However, no aziridine derivative was detected when pyrolysis of the *N*-benzoyl-*S,S*-diphenylsulfilimine in the presence of a large excess of diphenylacetylene was carried out. Furthermore, pyrolysis of *N*-2,4,6-trimethylbenzoylsulfilimine gave neither a trace amount of the inserted product such as 4,6-dimethyl-1-isoindolinone-(III) nor H-abstraction product such as 2,4,6-trimethylbenzoyl amide. Thus the pyrolysis of *N*-acyl-*S,S*-diphenylsulfilimines does not seem to involve the initial formation of a nitrene from which alkyl or aryl group migrates subsequently to afford the isocyanates but is considered to be a concerted process. The yields of both the isocyanate and diaryl sulfide are much higher in the pyrolysis than the photolysis of the same *N*-acyl-*S,S*-diarylsulfilimine. Thus, pyrolysis is a convenient method for preparation of isocyanates.

Experimental

Preparation of N-*Acyl*-S,S-*arylphenylsulfilimine.* *N*-Acyl-*S,S*-arylphenylsulfilimines were prepared according to the known method starting from free *S,S*-arylphenylsulfilimines and appropriate acylating agents. A typical example is shown below.

N-*2,4,6-Trimethylbenzoylsulfilimine.* Free *S,S*-diphenylsulfilimine (1.0 g, 4.98 mmol) was dissolved in 5 ml benzene. To this was added 1.1 g (5.99 mmol) of 2,4,6-trimethylbenzoyl chloride in 5 ml benzene at room temperature. Benzene was removed *in vacuo* and the residual solid was recrystallized from benzene–hexane. *N*-2,4,6-Trimethylbenzoyl-*S,S*-diphenylsulfilimine 0.9 g was obtained in 52.0% yield, mp 143—144 °C. Other *N*-acyl-*S,S*-arylphenylsulfilimines were similarly prepared. Their yields, spectral data and elemental analyses are given in Table 1.

Pyrolysis of N-*Acyl*-S,S-*arylphenylsulfilimine.* The pyrolysis of *N*-acyl-*S,S*-arylphenylsulfilimine was carried out *in situ* or such solvents as DMF, benzene, tetralin at *ca.* 120—200 °C for 0.3—3 h. A typical experiment is shown below.

Pyrolysis of N-*2,4,6-Trimethylbenzoyl*-S,S-*diphenylsulfilimine.* The sulfilimine, 60 mg, was heated in a sealed tube *in situ* at 190 °C for 20 min. After the usual work-up, diphenyl sulfide

and 2,4,6-trimethylbenzoyl isocyanate were obtained quantitatively by gas chromatography. 2,4,6-Trimethylbenzoyl isocyanate was isolated by GLC (TCD column SE-30, 2 m×2 mm, column temp 130 °C, He 1.6 kg/cm²) in 95.5% yield. All the isocyanates thus obtained are summarized in Table 2 together with their spectral data.

Kinetics of N-*Acyl*-S,S-*arylphenylsulfilimine*. A typical kinetic procedure is as follows; to a 0.1 mol/l solution of *N*-acyl-*S*,*S*-arylphenylsulfilimine in DMF, benzene and ethanol (10 ml) was added 170 mg of benzyl phenyl sulfide (0.085 mol/l) as an internal standard at room temperature. The solution (0.2 ml was taken in a 1 ml ampoule by a 1 ml syringe. Several ampoules were then immersed in an oil-bath maintained at the desired temperature. Ampoules were taken out at various time intervals. The solution was quenched immediately with 0.5 ml of water in an ampoule. After addition of 0.2 ml of hexane, it was shaken vigorously for a while. The hexane layer was then separated and 2 μl of the hexane solution was injected directly into a gas chromatography column. Gas chromatography was carried out under the following conditions; column SE-30, 1 m×2 mm, column temp 140 °C, He 0.7 kg/cm². The rate constants of the reaction were calculated by the first order kinetic equation, where a concentration change of diphenyl sulfide is calculated from the relative peak-height of benzyl phenyl sulfide (internal standard) each time. The activation parameters were calculated as usual and the Hammett plots were made against σ-values. The data obtained are summarized in Tables 3 and 4 and Fig. 1.

Study on Zinc *O,O*-Diisobutyl Dithiophosphate as Antioxidant

Yasukazu OHKATSU,* Kazumi KIKKAWA, and Tetsuo OSA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received May 15, 1978)

Cumyl hydroperoxide has been decomposed using zinc *O,O*-diisobutyl dithiophosphate. The decomposition reaction consisted of three stages including the first homolytic decomposition and the last heterolytic decomposition. These decomposition modes depended considerably on the relative concentration of the complex to the hydroperoxide and the total concentration. From these results and on the basis of decomposition reaction in the presence of both zinc *O,O*-diisobutyl dithiophosphate and bis(*O,O*-diisobutoxyphosphonothioyl) disulfide, it has been shown that the formation of sulfuric acid was most important for heterolytic decomposition.

The zinc *O,O*-diisoalkyl dithiophosphates are widely used as antioxidants, especially as hydroperoxide-decomposers. However it is not easy in practice to determine the kind and effective amount of such antioxidants, because the activities of decomposition of the hydroperoxides are very complicated, and considerably affected by the circumstances. Elucidation of the complicated action mechanism of such decomposes would clarify the mechanisms.

Burn *et al.*[1] found that the decomposition reaction of cumyl hydroperoxide with zinc *O,O*-diisopropyl dithiophosphate consisted of three stages: 1) a first homolytic decomposition, 2) an induction period, and 3) a fast heterolytic decomposition. However, they did not satisfactorily explain what kind of species induced the third stage which was the most important action expected of the complex. Other investigators[2-4] have proposed such species.

The decomposition reaction of cumyl hydroperoxide with bis(*O,O*-diisobutoxyphosphonothioyl) disulfide[5] (referred to as "the disulfide"), which is reported[1,6] to be formed during the decomposition reaction of a hydroperoxide with zinc *O,O*-diisoalkyl dithiophosphate. It was also found[5] that sulfuric acid from the disulfide was most effective for heterolytic decomposition. In this paper, the action mechanism of zinc *O,O*-diisobutyl dithiophosphate and the role of the disulfide in the decomposition of cumyl hydroperoxide are discussed.

Experimental

Materials. Zinc *O,O*-diisobutyl dithiophosphate (Zn–Bu^i_2–DTP),[6] and copper and nickel *O,O*-[3-(3,5-di-*t*-butyl-4-hydroxyphenyl)-propyl] phosphorodithioate (Cu and Ni–P–C_3–DTP)[7] were synthesized according to known procedures. Bis(*O,O*-diisobutoxyphosphonothioyl) disulfide was also prepared by a known method.[5]

Cumyl hydroperoxide and chlorobenzene were purified by convertional methods.

Procedure. Decomposition of cumyl hydroperoxide (CHP) was carried out using a reaction flask fitted with stirrer and sampling neck. For hydroperoxide analyses, an iodometric method was used.[1]

Decomposition products of cumyl hydroperoxide were analyzed by a GLC method (10% Silicone rubber on Diasolid S). ESR measurements were conducted on a JEOL Model JES-PE-1X spectrometer.

Results and Discussion

Decomposition of Cumyl Hydroperoxide. Cumyl hydroperoxide (0.1 M) was decomposed by Zn–Bu^i_2–DTP in chlorobenzene under a nitrogen or oxygen atmosphere at 70 °C. The results are shown in Figs. 1 and 2. The decomposition reactions, regardless of the kind of atmosphere, proceeded as reported by Burn *et al.*,[1] and consisted of three stages,** an initial fast homolytic decomposition, a slow reaction (induction period), and a last fast heterolytic decomposition. With decresing concentration of Zn–Bu^i_2–DTP, the induction period decreased. The presence of oxygen in the reaction system shortened the induction period and accelerated the final decomposition.

The formation of the cumylperoxyl radical during the initial stage of the decomposition of cumyl hydroperoxide with *O,O*-dialkyl dithiophosphates, such as Zn, Cu, and Ni *O,O*-[3-(3,5-di-*t*-butyl-4-hydroxyphenyl)-propyl]-phosphorodithioates (Me–P–C_3–DTP) was indirectly observed; the signal of the phenoxy radical derived from the secondary reaction of the phenolic moiety of

Me-P-C_3-DTP with cumylperoxyl radical, which is formed by the decomposition reaction of cumyl hydroperoxide with Me-P-C_3-DTP, being observed.[7] Figures 3 and 4 show the peak heights of the ESR signal of the phenoxy radical observed in the decomposition reactions of cumyl hydroperoxide with Ni-P-C_3-DTP and Cu(II)-P-C_3-DTP, respectively. The figures also include the

titration curves of cumyl hydroperoxide against time in decomposition reactions. When the titration curves are compared with the corresponding curves for the phenoxy radical, it is clearly seen that homolytic decomposition occurs in the initial stage as proposed by Burn *et al.*[1] Furthermore, cupric sulfate begins to form at the same time as the homolytic decomposition (Fig. 4). These results indicate that an acid, probably sulfuric acid, forms cupric sulfate by reacting with Cu-P-C_3-DTP during homolytic decomposition. The results with respect to Me-P-C_3-DTP may be employed to determine the decomposition activity of Zn-Bu$_2^i$-DTP, since the effect of the phenolic moieties of Me-P-C_3-DTP on the decomposition activity of cumyl hydroperoxide is negligible.[7]

The initial rates were found to be first order dependent on both Zn-Bu$_2^i$-DTP and cumyl hydroperoxide (CHP) (Table 1):

$$-d[CHP]/dt = k_D[Zn\text{-}Bu_2^i\text{-}DPT][CHP].$$

The rate constant, k_D, has been calculated to be 2.07×10^{-2} M^{-1} s^{-1} at 70 °C. This value seems somewhat

higher than that for zinc *O,O*-diisopropyl dithiophosphate[1] and considerably higher than that for zinc *N,N*-diisobutyl dithiocarbamate (Zn–Bu^i_2–DTC) and isopropyl dithiocabonate (Zn–Pr^i–X) studied for comparison (Table 1 and Fig. 5).

Products Derived from Decomposition of Cumyl Hydroperoxide with Zinc O,O-*Diisobutyl Dithiophosphate.* When cumyl hydroperoxide (1 M) was completely decomposed with Zn–Bu^i_2–DTP ($1—1\times10^{-4}$ M) in chlorobenzene at 70 °C, several decomposition products were obtained (Table 2). The results shown in Table 2 suggest† the heterolytic decomposition of cumyl hydroperoxide in the presence of Zn–Bu^i_2–DTP above 1.0×10^{-1} M. When the ratio of cumyl hydroperoxide to Zn–Bu^i_2–DTP exceeded 100, cumyl hydroperoxide decomposed heterolytically. This suggests that one mole of Zn–Bu^i_2–DTP is able to decompose at least 10 mol of cumyl hydroperoxide homolytically.†† Cosequently, it appears that the decomposition modes (homolytic or heterolytic) are drastically dependent on the relative ratio of cumyl hydroperoxide to Zn–Bu^i_2–DTP.

It was found, however, that the decomposition modes were also affected by the total concentration of Zn–Bu^i_2–DTP and cumyl hydroperoxide, even though they coexist in the relative ratio of unity (Table 3). A total concentration above 2×10^{-1} M was preferable for homolytic decomposition; this was also supported by the increase in amount of α,α-dimethylbenzyl alcohol formed in the presence of 2,6-di-*t*-butyl-4-methoxyphenol. The total concentration below 2×10^{-2} M, on the other hand, was preferable for heterolytic decomposition.

In the decomposition reactions mentioned above, Zn–Bu^i_2–DTP itself was also decomposed into compounds, such as zinc sulfate, bis(*O,O*-diisobutoxyphosphonothioyl) disulfide and sulfuric acid, depending on the concentrations of Zn–Bu^i_2–DTP and the hydroperoxide. Zinc sulfate and bis(*O,O*-diisobutoxyphosphonothioyl) disulfide were separated from the reaction solution after the homolytic decomposition (for example, cumyl hydroperoxide, 1.0 M and Zn–Bu^i_2–DTP, 1×10^{-1} M), while sulfuric acid was obtained from the decomposition reaction (for example, cumyl hydroperoxide, 1×10^{-2} M and Zn–Bu^i_2–DTP, 1×10^{-2} M). These results support the formation of the disulfide, as reported by Burn *et al.*,[1] as follows:

$$(Bu^iO)_2P(S)(S)Zn(S)(S)P(OBu^i)_2 \xrightarrow{PhCMe_2OOH}$$

$$(BuO^i)_2P(S^{\ddagger})(S)P(OBu^i)_2 + PhCMe_2O + {}^-OH,$$

$$(Bu^iO)_2P(S^{\ddagger})(S)P(OBu^i)_2 \xrightarrow{PhCMe_2O\cdot}$$

$$(Bu^iO)_2P(S-S)P(OBu^i)_2 + Zn(OH)(OCMe_2Ph).$$

the disulfide

† It is well documented that the homolytic decomposition of cumyl hydroperoxide gives α,α-dimethylbenzyl alcohol, acetophenone and α-methylstyrene, while the heterolytic decomposition gives phenol and acetone.

†† J. A. Howard reported[8] that nickel diisopropyl dithiophosphate decomposed about 25 times of cumyl hydroperoxide homolytically.

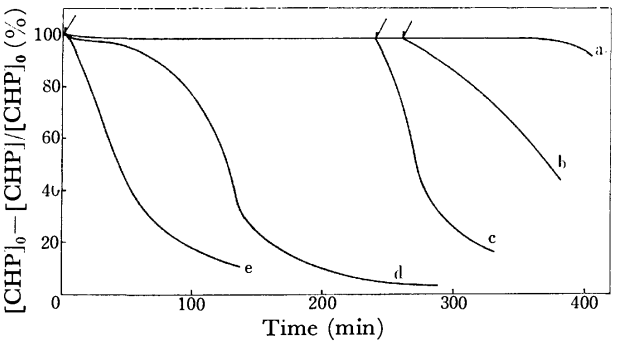

Fig. 6. Decomposition of cumyl hydroperoxide (0.1 M) with Zn-Bu^i_2-DTP and/or bis(*O,O*-diisobutylphosphonothioyl)disulfide in chlorobenzene at 70 °C.

	a	b	c
Zn-DTP	1×10^{-3} M	1×10^{-3} M	1×10^{-3} M
Disulfide	0	1×10^{-2} M	3×10^{-2} M
	d	e	
Zn-DTP	1×10^{-3} M	0	
Disulfide	1×10^{-2} M	1×10^{-2} M	

The resulting disulfide will react rapidly with the hydroperoxide and/or a free radical to form the sulfate ion,[5] which may be converted into zinc sulfate and free sulfuric acid.

Decomposition of Cumyl Hydroperoxide Using Zinc O,O-*Diisobutyl Dithiophosphate with Bis(*O,O-*diisobutoxyphosphonothioyl) Disulfide.* Cumyl hydroperoxide was decomposed in the presence of Zn-Bu^i_2-DTP and the disulfide. The result is shown in Fig. 6, in which the decompositions by either Zn-Bu^i_2-DTP or the disulfide are also shown for comparison. Only the Zn-Bu^i_2-DTP decomposed a little of the hydroperoxide after the start of decomposition (Curve a), while only the disulfide did considerably without any induction period (Curve e). When both decomposers co-existed in the same concentration (1×10^{-3} M) of Zn-Bu^i_2-DTP (Curve a) and in the same concentration (1×10^{-2} M) of the disulfide (Curve e), however, the curve of decomposition (Curve d) was not unexpectedly comparable to Curve e. This may be interpreted assuming that sulfuric acid, which is most effective for ionic decomposition and is derived from the decomposition of cumyl hydroperoxide with the disulfide,[5] is rapidly trapped by Zn-Bu^i_2-DTP present to form zinc sulfate as seen in Fig. 4 for Cu(II)-P-C_3-DTP. Sulfuric acid formed, therefore, is not an effective catalyst till all of the Zn-Bu^i_2-DTP is consumed as zinc sulfate, resulting in the induction period as shown by Curve d.

The assumption made may be supported by the result of Curves b and c. When the disulfide was added during decomposition started with the same concentration of Zn-Bu^i_2-DTP as in Curve a, no induction periods were observed (Curves b and c). This indicates that the addition of the disulfide, at the time of which almost all of the Zn-Bu^i_2-DTP is presumably converted into zinc sulfate, decomposes cumyl hydroperoxide immediately, as if only the disulfide were added at the beginning of decomposition reaction, for example, as shown in Curve e.

Conclusion

The present study has clarified the effects of the relative concentration of the complex to cumyl hydroperoxide (Table 2) and the total concentration of the complex and cumyl hydroperoxide (Table 3) on the decomposition activity of the complex.

It was also found that zinc *O,O*-dialkyl dithiophosphate was not an effective decomposer for the heterolytic decomposition till free sulfuric acid was formed. These results must contribute to select an useful amount of the zinc complex.

The authors would like to express their to Prof. Teiji Tsuruta for his fruitful discussion on this study.

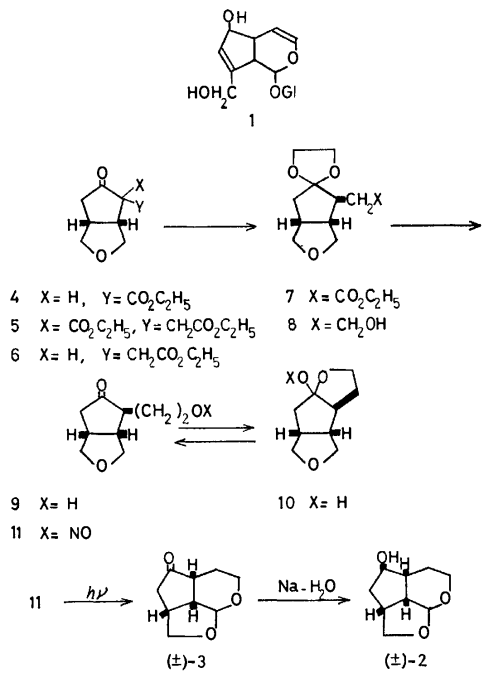
Synthesis of (±)-Tetrahydroanhydroaucubigenone and (±)-Tetrahydroanhydroaucubigenin[1)]

Heitaro OBARA,* Hiroshi KIMURA, Masanobu SUZUKI, and Jun-ichi ONODERA
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992
(Received May 15, 1978)

The racemate of tetrahydroanhydroaucubigenone (**3**), one of the related compounds of aucubin, was synthesized by the photoirradiation of 6-[2-(nitrosooxy)ethyl]-3-oxabicyclo[3.3.0]octan-7-one. (±)-Tetrahydroanhydroaucubigenin was also obtained by reduction of (±)-**3** with sodium in moist ether.

Tetrahydroanhydroaucubigenin (**2**), mp 85 °C, $[\alpha]_D^{19.6}$ +51.5° (ethanol), and its oxidation product, tetrahydroanhydroaucubigenone (**3**), mp 77—78 °C, $[\alpha]_D^{17}$ −41.3° (ethanol), have been known to be the key compounds for the determination of aucubin (**1**).[2)] These compounds have been already obtained by Karrer[3)] and Fujise[4)] in 1946 and 1953, independently, and the correct structures were established by Fujise *et al.*[5)] in 1960. However, the synthesis of **2** and **3** have not been accomplished yet. In this paper, we wish to report the synthesis of the racemates of **2** and **3** by the following scheme.



Scheme 1

6-Ethoxycarbonyl-6-ethoxycarbonylmethyl-3-oxabicyclo[3.3.0]octan-7-one (**5**) was obtained with a small amount of *O*-alkylated compound by alkylation of the sodio derivative of *cis*-6-ethoxycarbonyl-3-oxabicyclo[3.3.0]octan-7-one (**4**) with ethyl bromoacetate in toluene. Hydrolysis and decarboxylation of **5** with 6 M hydrochloric acid, followed by esterification, afforded 6-ethoxycarbonylmethyl-3-oxabicyclo[3.3.0]octan-7-one (**6**) in a 50% yield. This compound does not change by treatment with sodium ethoxide, so it is assumed that it has a more stereochemically favorable *cis-trans* (1,5- and 5,6-position) configuration. After acetalization of **6** with ethylene glycol, the acetal (**7**) was reduced into the alcohol (**8**) with lithium aluminium hydride in tetrahydrofuran in a 89% yield. Deacetalization of **8** by treatment with dilute hydrochloric acid or *p*-toluenesulfonic acid in acetone afforded a mixture of 6-(2-hydroxyethyl)-3-oxabicyclo[3.3.0]octan-7-one (**9**) and its intramolecular hemiacetal (**10**) in a 76% yield. The hemiacetal (**10**) is easily converted into the keto alcohol (**9**) by treatment with dilute hydrochloric acid. 6-[2-(Nitrosooxy)ethyl]-3-oxabicyclo[3.3.0]octan-7-one (**11**), a pale green unstable viscous oil, was obtained by the nitrosation of **9** with a mixture of sodium nitrite and dilute sulfuric acid in a 30% yield.

The irradiation of **11** was carried out in a benzene solution under a nitrogen atmosphere at 0 °C using a high-pressure 500 W mercury arc. After irradiation, the benzene was removed *in vacuo* and the residue was chromatographed on silica gel to give (±)-tetrahydroanhydroaucubigenone ((±)-**3**), colorless prisms, mp 57—57.5 °C. The IR spectrum of this compound in carbon tetrachloride was identical with that of the natural sample. Since the *cis-cis* configuration of the ring junction of **3** is already confirmed,[6)] it can be assumed that the photoisomerization at 6-position occurred simultaneously with the photochemical ring closure of **11**. The reduction of (±)-**3** was carried out by considering the configuration of the hydroxyl group of **2**. Fujise *et al.*[7)] previously reported that the epimer of **2** was obtained as an oil by reduction of **3** with lithium aluminium hydride in ether, and they have referred to the mechanism of its stereospecific reduction. We achieved the synthesis of ((±)-**2**), mp 74.5—75 °C, in a 46% yield by reduction of (±)-**3** with sodium in moist ether instead of lithium aluminium hydride. The IR spectrum was identical with that of the natural sample.

Experimental

All the boiling and melting points are uncorrected.

6-Ethoxycarbonyl-6-ethoxycarbonylmethyl-3-oxabicyclo[3.3.0]octan-7-one (5). To a suspension of 11.5 g of sodium metal in 240 ml of dry toluene was added 92.5 g of *cis*-6-ethoxycarbonyl-3-oxabicyclo[3.3.0]octan-7-one (**4**)[8)] dropwise with efficient stirring. The stirred mixture was heated on an oil bath until all the sodium was consumed. Then 83.5 g of ethyl bromoacetate was added to the solution at room temperature, and the mixture was refluxed for 4 h. Upon cooling, the mixture was poured into 150 ml of aqueous 10% acetic acid and the toluene layer was washed with aqueous $NaHCO_3$ and water, dried over Na_2SO_4, and freed from toluene to give a viscous liquid. Distillation of the residue under reduced pressure afforded 113.8 g (85%) of **5** containing a small amount of

O-alkylated by-product, bp 163—169 °C/6 mmHg, MS *m/e* 284 (M^+); IR (neat) 1755 and 1730 cm^{-1} (C=O). The additional absorption bands at 1635 and 1685 cm^{-1} can be attributed to an *O*-alkylated by-product. Found: C, 58.72; H, 7.08%. Calcd for $C_{14}H_{20}O_6$: C, 59.14; H, 7.09%.

6-Ethoxycarbonylmethyl-3-oxabicyclo[3.3.0]octan-7-one (6). The keto ester (**5**) (50 g), containing a small amount of the *O*-alkylated product, was hydrolyzed in 150 ml of aqueous 6 M HCl under boiling for 5 h. After removal of most of the HCl and water under reduced pressure, a mixture of 100 ml of ethanol, 50 ml of toluene, and 0.1 ml of concd H_2SO_4 was added to the oily residue, and the mixture was distilled slowly at atmosphere pressure. The esterification was completed by the redistillation with 100 ml of ethanol and 50 ml of toluene. After the solvent was removed *in vacuo*, the oily residue was extracted with ether, and the ether layer was washed with aqueous $NaHCO_3$ and water, dried over Na_2SO_4, and freed from ether to give a viscous oil. Distillation of the residue in reduced pressure afforded **6**, bp 140—144 °C/4 mmHg, in a 75% yield. MS *m/e* 212 (M^+); IR (neat) 1730 cm^{-1} (C=O). Found: C, 61.89; H, 7.44%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%. 3-Oxabicyclo[3.3.0]octan-7-one (0.5 g), bp 107—109 °C/14 mmHg (lit,[8] bp 118—119 °C/17 mmHg), 2,4-dinitrophenylhydrazone, mp 144—145 °C (lit,[8] mp 144—145 °C), was obtained as a minor fraction, which was derived from the *O*-alkylated product.

6-(2-Hydroxyethyl)-3-oxabicyclo[3.3.0]octan-7-one (9). A mixture of 30 g of 6-ethoxycarbonylmethyl-3-oxabicyclo[3.3.0]-octan-7-one (**6**), 9.7 g of ethylene glycol, 160 ml of dry benzene, and 60 mg of *p*-toluenesulfonic acid was refluxed on an oil bath for 3 h. Then, most of the water was removed azeotropically at atmospheric pressure. After removal of the solvent, the residue was taken up in ether and worked up in the usual manner to afford 28.1 g (78%) of ethylene acetal (**7**), bp 150—153 °C/3 mmHg, MS *m/e* 256 (M^+). To a mixture of 80 ml of dry THF and 2.5 g of $LiAlH_4$ was added 28.1 g of the ethylene acetal (**7**) over a period of 1 h with stirring on an ice bath and warmed at 40—50 °C for 2 h. Then, 20 ml of water was added cautiously to decompose the unreacted $LiAlH_4$. The THF layer was separated by decantation and freed from THF to give an oily residue. Distillation of the residue in diminished pressure afforded 6-(2-hydroxyethyl)-3-oxabicyclo[3.3.0]octan-7-one ethylene acetal (**8**) (18.9 g, 80%), bp 146—151 °C/2 mmHg, MS *m/e* 214 (M^+). A mixture of 18.2 g of **8** and 60 ml of aqueous 0.2 M HCl was warmed at 50—60 °C for 2 h. After neutralization with solid $NaHCO_3$, it was concentrated to about one-fifth of its original volume and extracted with ether. The ether layer was worked up by the usual manner and distilled to give 10.8 g (75%) of 6-(2-hydroxyethyl)-3-oxabicyclo[3.3.0]octan-7-one (**9**), bp 145—146 °C/3 mmHg, MS *m/e* 170 (M^+), IR (neat) 3450 cm^{-1} (OH) and 1736 cm^{-1} (C=O). Found: C, 62.72; H, 8.40%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%. 2,4-Dinitrophenylhydrazone, mp 151—152 °C. Found: C, 51.26; H, 5.21; N, 15.72%. Calcd for $C_{15}H_{17}O_6N_4$: C, 51.57; H, 4.91; N, 16.04%.

6-[2-(Nitrosooxy)ethyl]-3-oxabicyclo[3.3.0]octan-7-one (11). To a mixture of 2.0 g of **9**, 7.5 g of $NaNO_2$, and 10 ml of water, was added a mixed solution of 2.5 ml of concd H_2SO_4 and 1 ml of water dropwise with efficient stirring in an ice–salt bath over a period of 1 h. The reaction mixture was then extracted with ether and the ether layer was worked up in the usual manner. Distillation of the residue in reduced pressure afforded 0.7 g (30%) of **11**, bp 100—102 °C/2 mmHg, IR (neat) 1735 cm^{-1} (C=O), 1640, 1600, and 790 cm^{-1} (N=O and N–O). This green unstable oil was used immediately in the subsequent photoirradiation.

(±)-Tetrahydroanhydroaucubigenone ((±)-3). A solution of 0.4 g of **11** in 110 ml of dry benzene was irradiated with stirring for 15 h under a nitrogen atmosphere at 0 °C by a high-pressure 500 W mercury arc using a CS-054 filter (corning glass works). After irradiation, the solvent was removed *in vacuo*, and the residue was chromatographed on a column of silica gel. Elution with CCl_4–ethyl acetate gave crude (±)-**3** (36 mg) as an oil. Recrystallization from benzene–petroleum ether afforded (±)-**3** (21 mg, 5.7%), mp 57.5 °C. MS, *m/e* 168 (M^+), 139, 110, 83, 69 (base), 55, and 41; IR (CCl_4), ν_{max} 2970, 2900, 1748 (strong), 1175, 1148, 1100, 1065, 1040, 980, and 945 cm^{-1}. The IR spectrum of this compound in CCl_4 was identical with that of the natural sample.

(±)-Tetrahydroanhydroaucubigenin ((±)-2). To a mixture of 12.2 mg of (±)-**3**, 0.02 ml of water, and 3 ml of ether, was added slowly 20 mg of sodium metal in limited amounts over a period of 15 min at 0 °C. The subsequent alternate addition of 0.02 ml of water and 20 mg of sodium metal was continued until the disappearance of the spot of (±)-**3** has been confirmed by TLC. Then water was cautiously added to the reaction mixture and the ether layer was thoroughly washed with saturated brine, dried, and evaporated to leave a crystalline residue, which on recrystallization from petroleum ether–benzene yielded (±)-**2** (5.6 mg, 46%) as colorless prisms, mp 74.5—75 °C. IR (CCl_4), ν_{max} 3600, 3450, 1403, 1153, 1138, 1077, 1060, 1040, 1004, and 972 cm^{-1}. The IR spectrum of this compound in CCl_4 was identical with that of the natural sample.

One of the authors (H. O) is grateful to the late Professor Emeritus Shin-ichiro Fujise of Tohoku University for his encouragement during his lifetime.

Synthesis of 4-Cinnamylidene-2,5-cyclohexadien-1-ones

Kazu KUROSAWA,* Atsuko HASHIBA, and Hirobumi TAKAHASHI
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860
(Received May 24, 1978)

Lithium aluminium hydride (LAH) reduction of 4′-hydroxychalcones, followed by dehydration, yielded 4-cinnamylidene-2,5-cyclohexadien-1-ones in 19—42% yields. The LAH reduction of 4′-acetoxychalcones also gave the same products in improved yields.

It has been reported that the oxidations of 2- and 4-alkylphenols with manganese dioxide,[1] lead dioxide,[2] silver oxide,[3] potassium hexacyanoferrate(III),[4] and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone[5] (DDQ) gave 2-alkylidene-3,5-cyclohexadien-1-ones and 4-alkylidene-2,5-cyclohexadien-1-ones. Dehydrochlorination of *p*-(chloromethyl)phenol[6] and the elimination reaction of *p*-(methoxymethyl)phenols also yielded 4-methylene-2,5-cyclohexadien-1-ones, but have a limited value.[7] The lithium aluminium hydride (LAH) reduction of 2′-hydroxychalcones has been reported to give 2-phenyl-2*H*-1-benzopyrans,[8] and 2-cinnamylidene-3,5-cyclohexadien-1-one was postulated as a reaction intermediate. This was proved by obtaining pure 2-cinnamylidene-3,5-cyclohexadien-1-one and by converting the latter to 2-phenyl-2*H*-1-benzopyran[3b] (Fig. 1). We have investigated the synthesis of 4-cinnamylidene-2,5-cyclohexadien-1-ones by dehydration of 1-(*p*-hydroxyphenyl)-3-phenyl-2-propen-1-ols (III), which can be obtained by the LAH reduction of 4′-hydroxychalcones (Ia—i), and found that these reactions indeed yielded the desired compounds (IVc—i) in 19—42% yields (Fig. 1 and Table 1).

4′-Hydroxychalcones (Ia—i) were obtained by the condensation of *p*-hydroxyacetophenones and benzaldehydes with aqueous alkali. The structures of these new chalcones were determined by examining their IR and NMR spectra and by elemental analyses. All chalcones have a *trans*-double bond; this was shown by the large coupling constant (J=15—17 Hz) of the ethylenic hydrogens in their NMR spectra.

When 4′-hydroxy-3′,5′-dimethylchalcone (Ic) was treated with LAH in tetrahydrofuran, followed by the treatment with 1 M sulfuric acid, an orange-red crystalline product was separated by column chromatography on alumina. The NMR spectrum (CCl_4) of this compound indicates the presence of two methyl groups {δ=1.98 (3H, broad singlet) and δ=2.04 (3H, doublet, J=1.0 Hz)}, vinylic protons {δ=6.60 (1H, d, J=11.0 Hz), δ=6.78 (1H, multiplet), and δ=6.98 (1H, d, J=11.0 Hz)}, and seven protons {δ=7.1—7.5 (m)}. The multiplet at δ=6.78 becomes a doublet with a small coupling constant, J=2.5 Hz, when irradiated at the methyl signals. The IR spectrum showed multiple absorptions at 1570, 1592, 1612, and 1625 cm.$^{-1}$ These spectroscopic results are consistent with the structure of 4-cinnamylidene-2,5-cyclohexadien-1-one (IVc). A *cis*-configuration of the ethylenic double bond in the cinnamyl group in IVc is suggested by the coupling constant, J=11.0 Hz, of the ethylenic protons. However, the chalcone has a *trans*-configuration, as already mentioned, and isomerization from *trans* to *cis* is not likely to occur during the reaction. Further study would be neccessary to clarify the matter.

Phenolic products (V, VI, and VII) were separated from the ethyl acetate fraction of the chromatography (Fig. 3). Based on the NMR spectrum, the structure of the product V is 4-*trans*-cinnamyl-2,6-dimethylphenol; this was confirmed by a synthesis. The spectral properties of VI suggest that the structure of this compound

TABLE 1. SYNTHESIS OF 4-*trans*-CINNAMYLIDENE-2,5-CYCLOHEXADIEN-1-ONES (IV)

Entry	Chalcone	Reaction conditions				IV (% yield)
		Molar ratio of I: $LiAlH_4$	Solvent	Time (h)	Temp (°C)

7	Ie	1:2	THF	2.0	20	IVe (21)
8	If	1:2	THF	2.0	20	IVf (19)
9	Ig	1:2	THF	1.0	20	IVg (30)
10	Ih	1:2	THF	2.0	20	IVh (26)
11	Ii	1:2	THF	0.5	20	IVi (42)
12	Ij	1:2	THF	1.0	20	IVg (42)
13	IIc	1:2	THF	2.0	20	IVc (46)
14	IId	1:2	THF	2.0	20	IVd (58)
15	IIe	1:2	THF	2.0	20	IVe (28)

is 1-(3,5-dimethyl-4-hydroxyphenyl)-3-phenyl-1-propanone (VI). The structure of VII was determined to be 1-(3,5-dimethyl-4-hydroxyphenyl)-3-phenyl-1-propanol (VII).

The LAH reduction of Ic in ether gave IVc in a slightly decreased yield (22%, entry 5). Five other chalcones (Id—h) gave the corresponding 4-cinnamylidene-2,5-cyclohexadien-1-ones (IVd—h) (entries 6, 7, 8, 9, and 10), but no effort was made to isolate the phenolic products in these cases.

The methyl ether of Obtsusaquinone,[9] which is the first naturally occurring 4-cinnamylidene-2-hydroxy-5-methoxy-2,5-cyclohexadien-1-one, was also synthesized by the reaction of Ii (entry 11) and found to be identical

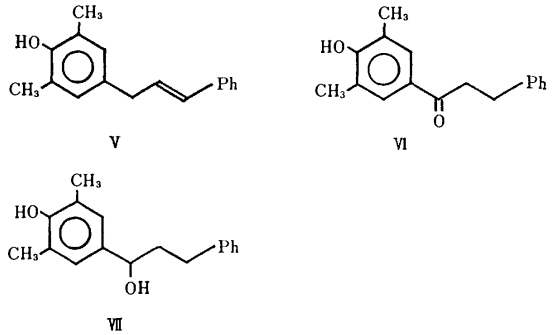
Fig. 2. a: $R_1=R_2=R_3=R_4=R_5=H$, b: $R_1=R_4=R_5=H$, $R_2=R_3=Br$, c: $R_1=R_4=R_5=H$, $R_2=R_3=CH_3$ d: $R_1=R_4=H$, $R_2=R_3=CH_3$, $R_5=OCH_3$, e: $R_1=H$, $R_2=R_3=CH_3$, $R_4=R_5=OCH_3$, f: $R_1=R_4=R_5=H$, $R_2=R_3=OCH_3$, g: $R_1=R_4=H$, $R_2=R_3=R_5=OCH_3$, h: $R_1=H$, $R_2=R_3=R_4=R_5=OCH_3$, i: $R_2=R_4=R_5=H$, $R_1=R_3=OCH_3$.



V VI VII

Fig. 3.

with the methyl ether by comparison of their spectral properties (the configuration of the styryl group in IVi could be reversed in Fig. 2).

The LAH reductions of 4'-hydroxychalcone (Ia) and 4'-hydroxy-3',5'-dibromochalcone (Ib) were also carried out, but pure compounds were not isolated due to the decomposition during chromatography. When 4'-acetoxychalcones (IIc—e) were reduced with LAH in tetrahydrofuran, followed by the treatment with 1 M sulfuric acid, IVc, IVd, and IVe were obtained in improved yields (46% (entry 13), 58% (entry 14), and 28% (entry 15)).

It seemed reasonable to assume that a chalcone having a hydroxyl group at the position 4 would also give a 4-cinnamylidene-2,5-cyclohexadien-1-one by the LAH reduction and the dehydration. This proved to be the case. The LAH reduction of 4-hydroxy-3,4',5-trimethoxychalcone (Ij) yielded IVg, identical with that obtained from Ig, but in a better yield (entry 12).

It is thus concluded that the LAH reductions of 4- and 4'-hydroxy-, and 4'-acetoxychalcones can be utilized as a convenient method for the synthesis of 4-cinnamylidene-2,5-cyclohexadien-1-ones.

Experimental

All ^1H NMR spectra were recorded with a Hitachi R 24 NMR spectrometer with TMS as an internal standard. The IR spectra were recoreded with a JASCO IRA-1 IR spectrometer, while the UV spectra were recorded with a Hitachi EPS-3T spectrophotometer. Melting points were determined on a Yanagimoto hot-stage and are uncorrected.

Preparations of Acetophenones. 4-Hydroxy-3,5-dimethoxyacetophenone was synthesized by partial demethylation of 3,4,5-trimethoxyacetophenone with aluminium chloride. 3,4,5-Trimethoxyacetophenone[13] (2.1 g) was dissolved in hot benzene (300 ml) containing anhydrous aluminium chloride (2.66 g) and heated under reflux for 2 h. 2 M hydrochloric acid (100 ml) was added to the solution and the benzene layer was separated. After removal of the benzene, the resulting solid was recrystallized from ether, giving colorless prisms (1.19 g, 61%), mp 119—120 °C (lit,[14] mp 120—121 °C).

4-Hydroxy-3,5-dimethylacetophenone was prepared by the modified Nencki reaction. 2,6-Dimethylphenol (1.22 g) was heated with boron trifluoride–acetic acid complex (5 ml) at 100 °C for 2 h. The reaction mixture was poured into 2 M hydrochloric acid (50 ml) and the precipitates were collected. The crude product was recrystallized from benzene to give colorless plates (623 mg, 38%), mp 150—151 °C(lit,[15] mp 150.5—151.2 °C).

4-Hydroxy-2,5-dimethoxyacetophenone was prepared similarly in 91% yield (mp 128—129 °C (lit,[16] mp 117—118 °C)).

Preparations of 4'-Hydroxy- and 4-Hydroxychalcones (Id—j). A typical preparation of 4'- and 4-hydroxychalcones was as follows. A mixture of an aldehyde (10 mmol) and an acetophenone (10 mmol) in ethanol (20 ml) was treated with 20—40% aqueous potassium hydroxide at an appropriate temperature overnight. The reaction mixture was poured into iced hydrochloric acid (10 ml), and the precipitates were collected and recrystallized.

4'-Hydroxy-3',5'-dimethyl-4-methoxychalcone (Id): Mp 146—147 °C (EtOH), 34% yield; IR ($CHCl_3$) 1656, 1670, and 3440 cm^{-1}. NMR ($CDCl_3$) $\delta=2.30$ (6H, s, $2\times CH_3$), 3.82 (3H, s, OCH_3), 5.7 (1H, broad s, OH), 6.90 (2H, m, $H_{(3)}$ and $H_{(5)}$), 7.41 (1H, d, $J=15.0$ Hz, H_a), 7.57 (2H, m, $H_{(2)}$ and

$H_{(6)}$), 7.73 (1H, d, J=15.0 Hz, H_β), and 7.71 (2H, s, $H_{(2')}$ and $H_{(6')}$). Found: C, 76.02; H, 6.63%. Calcd for $C_{18}H_{18}O_3 \cdot 1/10\ H_2O$: C, 76.08; H, 6.46%.

4'-Hydroxy-3,4-dimethoxy-3',5'-dimethylchalcone (Ie): Mp 184—186 °C (EtOH); 26% yield; IR ($CHCl_3$) 1668, 1675, and 3590 cm.$^{-1}$ NMR ($CDCl_3$) δ=2.33 (6H, s, 2×CH_3), 3.89 (3H, s, OCH_3), 3.91 (3H, s, OCH_3), 5.7 (1H, broad s, OH), 6.75—7.3 (3H, m, $H_{(2)}$, $H_{(5)}$, and $H_{(6)}$), 7.36 (1H, d, J=15.0 Hz, H_α), 7.67 (1H, d, J=15.0 Hz, H_β), and 7.67 (2H, s, $H_{(2')}$ and $H_{(6')}$). Found: C, 72.78; H, 6.55%. Calcd for $C_{19}H_{20}O_4$: 73.06; H, 6.45%.

4'-Hydroxy-3',5'-dimethoxychalcone (If): Mp 106—107 °C (aq EtOH); 55% yield; IR ($CHCl_3$) 1650 and 3500 cm^{-1}. NMR ($CDCl_3$) δ=3.98 (6H, s, 2×OCH_3), 6.0 (1H, s, OH), 7.30 (2H, s, $H_{(2')}$. and $H_{(6')}$), 7.48 (1H, d, J=16.0 Hz, H_α), 7.78 (1H, d, J=16.0 Hz, H_β), 7.3—7.7 (5H, m, Ph). Found: C, 71.64; H, 5.74%. Calcd for $C_{17}H_{16}O_4$: C, 71.82; H, 5.67%.

4'-Hydroxy-3',4,5'-trimethoxychalcone (Ig): Mp 79 °C (EtOH); 29% yield; IR ($CHCl_3$) 1650 and 3530 cm^{-1}. NMR ($CDCl_3$) δ=3.83 (3H, s, OCH_3), 3.95 (6H, s, 2×OCH_3), 6.0 (1H, broad s, OH), 6.95 (2H, m, $H_{(3)}$ and $H_{(5)}$), 7.35 (2H, s, $H_{(2')}$. and $H_{(6')}$), 7.43 (1H, d, J=16.0 Hz, H_α), 7.61 (2H, m, $H_{(2)}$ and $H_{(6)}$), and 7.78 1H, d, J=16.0 Hz, H_β). Found: C, 67.96; H, 5.85%. Calcd for $C_{18}H_{18}O_5 \cdot 1/5H_2O$: C, 68.00; H, 5.83%.

4'-Hydroxy-3,3',4,5'-tetramethoxychalcone (Ih): Mp 90 °C (EtOH); 49% yield; IR ($CHCl_3$) 1650 and 3520 cm^{-1}. NMR ($CDCl_3$) δ=3.90 (3H, s, OCH_3), 3.91 (3H, s, OCH_3), 3.95 (6H, s, 2×OCH_3), 6.1 (1H, s, OH), 6.89 (1H, m, $H_{(5)}$), 7.17 (2H, m, $H_{(2)}$ and $H_{(6)}$), 7.30 (2H, s, $H_{(2')}$ and $H_{(6')}$), 7.33 (1H, d, J=17.0 Hz, H_α), and 7.67 (1H, d, J=17.0 Hz, H_β). Found: C, 65.80; H, 5.92%. Calcd for $C_{19}H_{20}O_6 \cdot 1/10H_2O$: C, 65.92; H, 5.88%.

4'-Hydroxy-2',5'-dimethoxychalcone (Ii): Mp 162—163 °C (EtOH); 56% yield; IR ($CHCl_3$) 1630, 1660, and 3530 cm^{-1}. NMR ($CDCl_3$) δ=3.88 (3H, s, OCH_3), 3.89 (3H, s, OCH_3), 6.25 (1H, s, $H_{(3')}$), 6.62 (1H, s, $H_{(6')}$), 7.3—7.8 (6H, m, Ph and OH), and 7.69 (2H, s, H_α and H_β). Found: C, 71.23; H, 5.79%. Calcd for $C_{17}H_{16}O_4 \cdot 1/10H_2O$: 71.31; H, 5.71%.

4-Hydroxy-3,4',5-trimethoxychalcone (Ij): Mp 132 °C (EtOH); 28% yield; IR ($CHCl_3$) 1672 and 3540 cm^{-1}. NMR ($CDCl_3$) δ=3.88 (3H, s, OCH_3), 3.94 (6H, s, 2×OCH_3), 5.8 (1H, broad s, OH), 6.87 (2H, s, $H_{(2)}$ and $H_{(6)}$), 6.97 (2H, m, $H_{(3')}$ and $H_{(5')}$), 7.38 (1H, d, J=15 Hz, H_α), 7.70 (1H, d, J=15.0 Hz, H_β), and 8.00 (2H, m, $H_{(2')}$ and $H_{(6')}$). Found: C, 62.85; H, 5.40%. Calcd for $C_{18}H_{18}O_5 \cdot 4/5\ H_2O$: 62.71; H, 5.73%.

Preparation of 4'-Acetoxychalcones (IIc—e). A typical procedure for the preparation of 4'-acetoxychalcone was as follows. A 4'-hydroxychalcone (4 mmol) was treated with a mixture of acetic anhydride (1 ml), acetic acid (1 ml), and pyridine (6 ml) at room temperature overnight. The reaction mixture was poured into iced water and the precipitates were collected.

4'-Acetoxy-3',5'-dimethylchalcone (IIc): Mp 102 °C (EtOH); 92% yield; IR ($CHCl_3$) 1680 (C=O) and 1765 cm^{-1} (OAc). NMR ($CDCl_3$) δ=2.22 (6H, s, 2×CH_3), 2.33 (3H, s, OAc), 7.2—7.8 (5H, m, Ph), 7.43 (1H, d, J=15.0 Hz, H_α), 7.72 (2H, s, $H_{(2')}$ and $H_{(6')}$), and 7.75 (1H, d, J=15.0 Hz, H_β). Found: C, 77.32; H, 6.23%. Calcd for $C_{19}H_{18}O_3$: C, 77.53; H, 6.16%.

4'-Acetoxy-3',5'-dimethyl-4-methoxychalcone (IId): Mp 125—126 °C (EtOH); 65% yield; IR ($CHCl_3$) 1670 (C=O) and 1765 cm^{-1} (OAc). NMR ($CDCl_3$) δ=2.22 (6H, s, 2×CH_3), 2.35 (3H, s, OAc), 3.84 (3H, s, OCH_3), 6.91 (2H, m, $H_{(3)}$ and $H_{(5)}$), 7.36 (1H, d, J=15.0 Hz, H_α). 7.60 (2H, m, $H_{(2)}$ and $H_{(6)}$), 7.72 (2H, s, $H_{(2')}$ and $H_{(6')}$), and 7.80 (1H, d, J=15.0 Hz, H_β). Found: C, 73.75; H, 6.36%. Calcd for $C_{20}H_{20}O_4$: C, 74.05; H, 6.22%.

4'-Acetoxy-3,4-dimethoxy-3',5'-dimethylchalcone (IIe): Mp 135—136 °C (EtOH); 58% yield; IR ($CHCl_3$) 1680 (C=O) and 1770 cm^{-1} (OAc). NMR ($CDCl_3$) δ=2.23 (6H, s, 2×CH_3), 2.35 (3H, s, OAc), 3.92 (3H, s, OCH_3), 3.94 (3H, s, OCH_3), 6.8—7.3 (3H, m, $H_{(2)}$, $H_{(5)}$ and $H_{(6)}$), 7.30 (1H, d, J=16.0 Hz, H_α), 7.69 (1H, d, J=16.0 Hz, H_β), and 7.69 (2H, s, $H_{(2')}$ and $H_{(6')}$). Found: C, 70.92; H, 6.36%. Calcd for $C_{21}H_{22}O_5$: C, 71.17; H, 6.26%.

Lithium Aluminium Hydride Reduction of 4- and 4'-Hydroxychalcones (Ia—j) and 4'-Acetoxychalcones (IIc—e). A typical procedure of the LAH reduction of chalcones was as follows. To a stirred THF solution of LAH (2 mmol), a chalcone (1 mmol) was added and stirred for the time shown in the table. The color of the chalcones disappeared within 5—10 min. After the removal of the THF *in vacuo*, 1 M sulfuric acid (20 ml) was added to the residue and the mixture was extracted with chloroform. The chloroform solution was concentrated to a small volume and then passed through an alumina column (5—10 g) by eluting with chloroform. The chloroform was removed and the resulting orange-red colored substance was allowed to crystallize. In the case of Ic, the reaction mixture was extracted with benzene and passed through a silicagel column by eluting with chloroform and ethyl acetate successively. The chloroform fraction was again passed through an alumina column by eluting with benzene to give IVc. The ethyl acetate fraction was further purified by TLC effected with chloroform, yielding V, VI, and VII. The LAH reduction in ether was carried out similarly. Yields were based on the amount of chalcones used.

Ic gave IVc, mp 115—116 °C (cyclohexane); 27% yield THF and 22% yield (ether); IR ($CHCl_3$) 1570, 1592, 1612, and 1625 cm^{-1}; UV (MeOH) λ_{max} (ε) 260 (10800) and 406 nm (4530) (Found: C, 86.34; H, 6.88%. Calcd for $C_{17}H_{16}O$: C, 86.40, H, 6.83%); V: mp 56—57 °C (light petroleum); 1% yield; IR ($CHCl_3$) 3600 cm^{-1} (OH); UV (MeOH) λ_{max} (ε) 258 nm (20300); NMR ($CDCl_3$) δ=2.11 (6H, s, 2×CH_3), 3.25 (2H, m, $-CH_2-$), 4.4 (1H, broad s, OH), 5.85—6.5 (2H, m, $-CH=CH-$), 6.65 (2H, s, aromatic), and 7.15 (5H, m, Ph) (Found: C, 85.71; H, 7.77%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%); VI: liquid; 8% yield; IR ($CHCl_3$) 1690 (C=O) and 3580 cm^{-1} (OH); NMR ($CDCl_3$) δ=2.25 (6H, s, 2×CH_3), 2.7—3.4 (4H, m, $-CH_2-CH_2-$), 5.8 (1H, s, OH), 7.21 (5H, s, Ph), and 7.60 (2H, s, aromatic); and VII: liquid; 4% yield; IR ($CHCl_3$) 3400 (OH) and 3580 cm^{-1} (OH); NMR ($CDCl_3$) δ=2.21 (6H, 2×CH_3), 1.6—3.0 (5H, m, $-CH_2-CH_2-$, OH), 4.52 (1H, t, J=6.0 Hz, $-CHOH$), 4.65 (1H, broad s, OH), 6.92 (2H, s, aromatic), and 7.18 (5H, s, Ph). IIc gave IVc in a 46% yield.

2,6-Dimethyl-4-(4-methoxycinnamylidene)-2,5-cyclohexadien-1-one (IVd): Mp 141—142 °C (ethyl acetate); 33% yield; IR ($CHCl_3$) 1560, 1586, 1615, and 1650 cm^{-1}; UV (MeOH) λ_{max} (ε) 273 (15700) and 442 nm (20800); NMR ($CDCl_3$) δ=2.03 (3H, s, CH_3), 2.10 (3H, s, CH_3), 3.79 (3H, s, OCH_3), 6.6—7.6 (9H, m). Found: C, 81.18; H, 6.78%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%. IId yielded IVd in a 58% yield.

4-(3,4-Dimethoxycinnamylidene)-2,6-dimethyl-2,5-cyclohexadien-1-one (IVe): Mp 142—143 °C (benzene); 21% yield; IR ($CHCl_3$) 1575, 1595, 1615, and 1650 cm^{-1}; UV (MeOH) λ_{max} (ε) 275 (12700) and 450 nm (41400); NMR ($CDCl_3$) δ=2.05 (3H, s, CH_3), 2.11 (3H, s, CH_3), 3.89 (3H, s, OCH_3), 3.92 (3H, s, OCH_3), 6.7—7.5 (7H, m), and 7.55 (1H, m). Found: C, 76.80; H, 6.87%. Calcd for $C_{19}H_{20}O_3$: C, 77.00; H, 6.80%. IIe gave IVe in a 28% yield

4-Cinnamylidene-2,6-dimethoxy-2,5-cyclohexadien-1-one (IVf): Mp 113—114 °C (benzene); 19% yield; IR ($CHCl_3$) 1570,

1590, 1600, and 1635 cm^{-1}; UV (MeOH) λ_{max} (ε) 275 (shoulder) (4440) and 424 nm (3410) (the ε values could not be accurate as they decreased rapidly); NMR ($CDCl_3$) δ=3.75 (3H, s, OCH_3), 3.82 (3H, s, OCH_3) 6.23 (1H, d, J=2.0 Hz), 6.75 (1H, broad s), 6.74 (1H, d, J=12.7 Hz), 7.07 (1H, d, J=12.7 Hz), and 7.2—7.7 (6H, m). Found: C, 77.12; H, 6.05%. Calcd for $C_{17}H_{16}O_3 \cdot 1/5\ C_6H_6$: C, 76.99; H, 6.11%.

2,6-Dimethoxy-4-(4-methoxycinnamylidene)-2,5-cyclohexadien-1-one (IVg): Mp 142 °C (benzene); 30% yield (from Ig) and 42% yield (from Ij); IR ($CHCl_3$) 1572, 1588, and 1632 cm^{-1}; UV (MeOH) λ_{max} (ε) 245 (10300), 280 (shoulder) (6240), 300 (6240), and 456 nm (41900); NMR ($CDCl_3$) δ=3.77 (3H, s, OCH_3), 3.81 (3H, s, OCH_3), 3.96 (3H, s, OCH_3), 6.31 (1H, m), 6.5—7.2 (5H, m), 7.33 (1H, s), and 7.48 (2H, m). Found: C, 73.92; H, 6.15%. Calcd for $C_{18}H_{18}O_4 \cdot 1/4\ C_6H_6$: C, 73.68; H, 6.18%.

2,6-Dimethoxy-4-(3,4-dimethoxycinnamylidene)-2,5-cyclohexadien-1-one (IVh): Mp 149—151 °C (ethyl acetate); 26% yield; IR ($CHCl_3$) 1570, 1590, and 1632 cm^{-1}; UV (MeOH) λ_{max} (ε) 235 (shoulder) (13100), 280 (8450), 300 (shoulder) (5830), and 466 nm (40800); NMR ($CDCl_3$) δ=3.80 (3H, s, OCH_3), 3.88 (3H, s, OCH_3), 3.91 (3H, s, OCH_3), 3.93 (3H, s, OCH_3), 6.32 (1H, d, J=2.0 Hz), 6.6—7.5 (7H, m). Found: C, 69.30; H, 6.18%. Calcd for $C_{19}H_{20}O_5$: C, 69.50; H, 6.14%.

4-Cinnamylidene-3,6-dimethoxy-2,5-cyclohexadien-1-one (IVi): Mp 165 °C (primarily softening at 130—140 °C, lit,[9] mp 169 °C), 42% yield.

Preparation of 4-trans-Cinnamyl-2,6-dimethylphenol. trans-Cinnamyl 2,6-Dimethylphenyl Ether: A mixture of 2,6-dimethylphenol (15 g), *trans*-cinnamyl chloride (15 g), anhydrous potassium carbonate (15 g), and acetone (100 ml) was heated under reflux for 4 days. After the removal of the acetone, water was added to the residue. The mixture was extracted with benzene and the benzene layer was washed with 1 M sodium hydroxide. Evaporation of the benzene gave *trans*-cinnamyl 2,6-dimethylphenyl ether (21.5 g, 91%) as an oil, bp 180 °C (bath temp)/0.03 mmHg. UV (MeOH) λ_{max} (ε) 257 nm (19400); NMR ($CDCl_3$) δ=2.23 (6H, s, 2×CH_3), 4.34 (2H, d, J=4.5 Hz), 6.30 (1H, d t, J=16.0, 4.5 Hz), 6.66 (1H, d, J=16.0 Hz), 6.83 (3H, m, aromatic), and 7.20 (5H, m, Ph). Found: C, 85.72; H, 7.76%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

4-trans-Cinnamyl-2,6-dimethylphenol: *trans*-Cinnamyl 2,6-dimethylphenyl ether (5.0 g) was heated in *N,N*-dimethylaniline (20 ml) for 2 h at 200 °C under nitrogen atmosphere. The reaction mixture was dissolved into 2 M hydrochloric acid (100 ml) and then extracted with benzene. After the removal of the benzene, the resulting mixture was chromatographed through an alumina column (100 g) by eluting with benzene, giving colorless needles (2.95 g, 59%), mp 56—57 °C (light petroleum) identical with those obtained by the LAH reduction of Ic.

5,9-Dihydroxy-4,8,11,11-tetramethyltricyclo[6.3.0.0^{2,4}]undecane. Acid-catalyzed Cyclization Product of 6,7-Epoxyhumula-2,9-diene[1]

Misuzu NAMIKAWA, Tatsushi MURAE, and Takeyoshi TAKAHASHI*

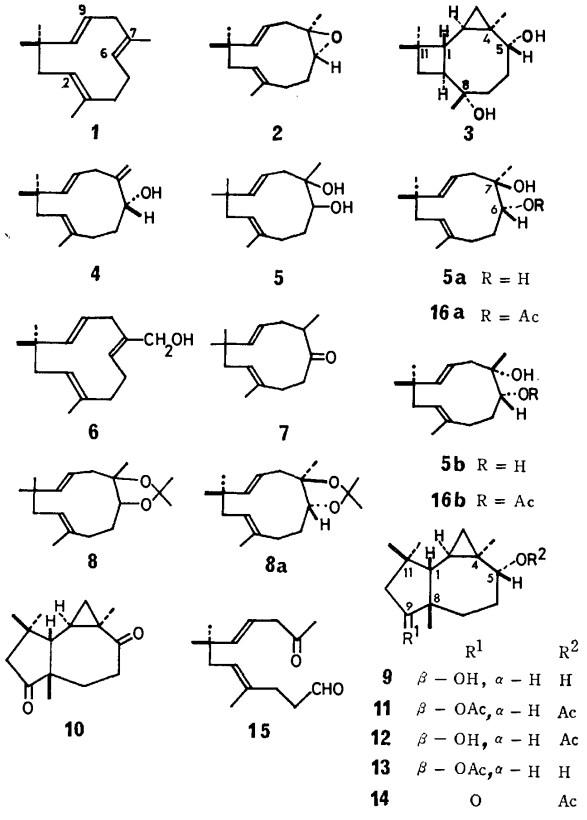
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received June 8, 1978)

6,7-Epoxyhumula-2,9-diene (**2**) was treated with 1.8 M sulfuric acid–acetone (1 : 1) to yield a new tricyclic diol, 5,9-dihydroxy-4,8,11,11-tetramethyltricyclo[6.3.0.0^{2,4}]undecane (**9**; diol B), together with tricyclohumuladiol (**3**; diol A), humulenol-II (**4**), a diol C (**5b**), a diol D (**5a**), and an acetonide (**8a**). The same reaction at 0° gave only **3**. Tricyclohumuladiol (**3**) was shown to be a key intermediate in the reaction of **2** to form **4**, **5a**, **5b**, **8a**, and **9**.

Cyclization of humulene (**1**) and its derivatives has been the subject of a number of studies in connection with the biogenesis of sesquiterpenes.[2] Treatment of 6,7-epoxyhumula-2,9-diene[3] (**2**; 1,2-humulene epoxide;[4] humulene epoxide-II[5]) with 20% sulfuric acid in acetone at room temperature has been reported[4] to give a complex mixture of products containing tricyclohumuladiol (**3**),[6-9] humulenol-II (**4**),[5,6b] and an unsaturated diol (**5**).[4] In this reaction, **4** was suggested to be formed directly from **2** or by acid-catalyzed decyclization of **3**.[4] It has also been reported[7] that tricyclohumuladiol (**3**) affords humulenol-II (**4**), an alcohol (**6**), humuladienone (**7**),[9] and an acetonide (**8**) on treatment with sulfuric acid in acetone at room temperature. In the present paper, the formation of a diol (**9**) with a new skeletal structure of 4,8,11,11-tetramethyltricyclo[6.3.0.0^{2,4}]undecane in the cyclization of **2** is described.

Treatment of 6,7-epoxyhumula-2,9-diene (**2**)[3-5,11] with 1.8 M sulfuric acid and acetone (1 : 1) at 0 °C for 30 min gave tricyclohumuladiol (**3**;[6-9,11] diol A) as a sole product (yield: >95%). Further continuation of the reaction at room temperature for 7 h resulted in the formation of a mixture of at least seven products, which was subjected to separation by crystallization, column chromatography, and/or preparative gas chromatography to give the acetonide (**8**;[7,11] y: 10%), humulenol-II (**4**;[5,6b,11] y: 9%), tricyclohumuladiol (**3**; y: 4%), a diol B (**9**;[11] y: 25%), a diol C (**5b**;[11] y: *ca.* 4%), a diol D (**5a**;[11] y: 7%), and a diol E (y: *ca.* 4%). The same mixture of products was formed when tricyclohumuladiol (**3**) was treated with 1.8 M sulfuric acid in acetone (1 : 1) (at room temperature, 7 h).



The elementary analysis of the diol B (**9**; mp 171.5—172 °C) fitted best for the molecular formula $C_{15}H_{26}O_2$ (M^+ at *m/e* 238.1861). The PMR and IR spectra showed the presence of four tertiary methyl groups, a trisubstituted cyclopropane ring, and hydroxyl group(s). A diol nature with two secondary hydroxyl groups was shown for **9** by oxidation with chromium trioxide–pyridine complex in dichloromethane (Ratcliffe's procedure[12]) to yield a diketone (**10**). The IR (1740 and 1680 cm^{-1}; no hydroxyl absorption) and UV (λ_{max} 212 nm, ε 2200) spectra of **10** suggested the presence of a five-membered ring ketone and a six- or larger-membered ring ketone conjugated with the cyclopropane ring.[6] Acetylation of **9** with acetic anhydride in pyridine at room temperature gave a diacetate (**11**) and two monoacetates (**12** and **13**). One (**12**) of the monoacetates was treated with chromium trioxide in pyridine to yield a keto acetate (**14**), whose IR spectrum (1742 cm^{-1}) indicated the presence of a five-membered ring ketone. The hydroxyl and acetoxyl groups of the monoacetate (**12**) must be located on a five-membered ring and on a carbon adjacent to the cyclopropane ring, respectively. Lanthanide induced shift (LIS) technique using Eu(fod)$_3$-d_{27} as a shift reagent coupled with double irradiation was applied for PMR measurements of **12** to show the presence of the partial structures **A**, **B**, and **C** (*cf.* Table 1). It was suggested from the large LIS value observed for the proton (H_h) that the hydroxyl group in **A** and the proton (H_h) in **C** are located closely to each other. The results described above

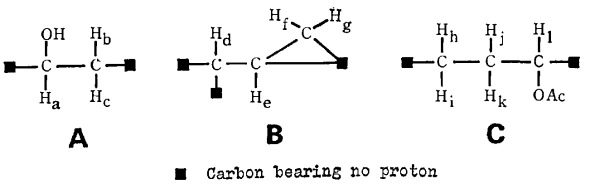


Table 1. Lanthanide induced shift values and coupling constants for the protons of the diol B monoacetate (**12**)

Protons	a	b	c	d	e	f	g	h	i	j	k	l
S[a]	24.7	19	13.7	6.3	5	3	3	15.5	8	8	5	6.3
Coupling constants (Hz)	$J_{a,b}=11$ $J_{a,c}=8$ $J_{b,c}=13$			$J_{d,e}=10$ $J_{e,f}=J_{e,g}=9$ $J_{f,g}=6$				$J_{h,i}$ or $J_{h,j}=10$ $J_{k,l}$ and/or $J_{k,j}=12$ $J_{h,k}=0$; $J_{j,l}=7$ $J_{k,l}=10$				
Methyls	$C_{(4)}$–CH_3		$C_{(8)}$–CH_3	$C_{(11)}$–CH_3		$C_{(11)}$–CH_3		$C_{(5)}$–$OCOCH_3$

a) S: the slopes of shift values plotted against the molar ratio of [Eu(fod)$_3$-d_{27}]/**12** for a *ca.* 2%w/v soln of **12** in $CDCl_3$.

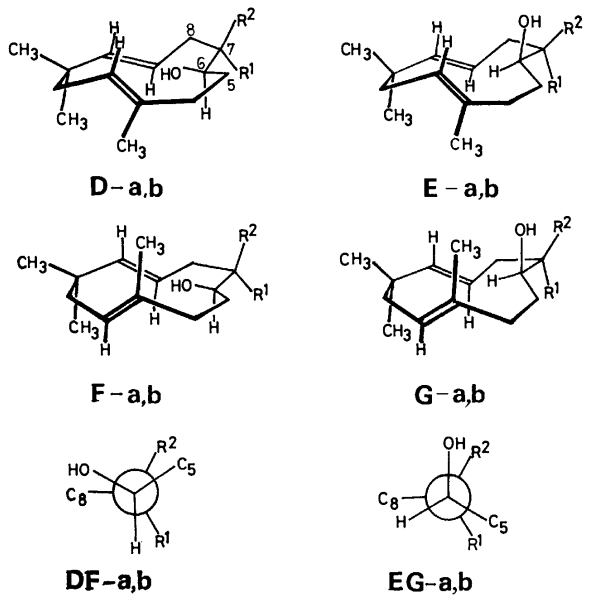
along with the evidence that the diol B was formed by acid-catalyzed rearrangement of tricyclohumuladiol (**3**) led to the structure of 5,9-dihydroxy-4,8,11,11-tetramethyltricyclo[6.3.0.0^{2,4}]undecane for the diol B (**9**). The large LIS value observed for the methyl group at C-8 of **12** showed that the C-9 hydroxyl group and the C-8 methyl group are in *cis* relationship for **9** and **12**.

The molecular formula of $C_{15}H_{26}O_2$ was given for both the diol C (**5b**; mp 182—183 °C) and the diol D (**5a**; a colorless oil). The diol D was treated with acetone in the presence of cupric sulfate to yield the known acetonide (**8**).[7] Acid hydrolysis of **8** gave the diol D. The diol D was also obtained on treatment of humulene [**1**; (2*E*,6*E*,9*E*)-3,7,11,11-tetramethylcycloundeca-2,6,9-triene)][3,13] with osmium tetroxide.[14] When the diol D as well as the diol C was oxidized with periodate, the same keto aldehyde (**15**) was formed. Therefore, the structure of (2*E*,9*E*)-6,7-dihydroxyhumula-2,9-diene[3] was confirmed for both the diols C (**5b**) and D (**5a**), which must be the diastereomers at C-7.

The presence of four preferred conformational isomers (**D**—**G**) could be suggested for each of the diols (**5a** and **5b**) based on an examination by the Dreiding model. The Newman projection about the bond axis $C_{(6)}$–$C_{(7)}$ for **D** and **F** is shown as in **DF**, and that for **E** and **G** as in **EG**. The presence of an intramolecular O–H···π hydrogen-bonding[15] could be expected for **D** and **F** for both the *trans*-diol (R^1=CH_3, R^2=OH) and the *cis*-diol (R^1=OH, R^2=CH_3). An intramolecular O–H···O hydrogen-bonding could be formed in **E** and **G** for the *trans*-diol; no formation of this hydrogen-bonding is expected for **D**—**G** for the *cis*-diol. The IR spectrum of the diol C (2.6 mM soln in carbon tetrachloride) showed the absorptions at 3640, 3625, and 3605 cm^{-1} due to a free secondary hydroxyl, a free tertiary hydroxyl, and an intramolecular O–H···π hydrogen-bonded hydroxyl group,[15] respectively, while the spectrum of the diol D (2.6 mM soln in carbon tetrachloride) indicated an absorption at 3588 cm^{-1} due to an intramolecular O–H···O hydrogen-bonded hydroxyl group in addition to the bands at 3642, 3627, and 3603 cm^{-1} (Fig. 1). The *trans*-diol (**5a**) and the *cis*-diol (**5b**) structures are suggested for the diol D and the diol C, respectively. The structure (**8a**) follows for the acetonide (**8**) of the diol D.

These results received support from the following observations. (i) The rate of the periodate cleavage of the *trans*-diol (**5a**) was found to be greater than that of the *cis*-diol (**5b**). This could be interpreted by the proximity of the two hydroxyl groups for **5a** shown as in **E-a**, **G-a**, and **EG-a**; the two hydroxyl groups are rather alienated to each other in **D**—**G** for **5b**. (ii) The formation of the acetonide (**8a**) from the *trans*-diol (**5a**) can be explained on the basis of the conformations **E-a** and **G-a**, while the corresponding acetonide could not be obtained from the *cis*-diol (**5b**). (iii) The R_f value on TLC for **5a** was observed higher than that for **5b**; this could be due to the formation of an intramolecular hydrogen-bonding in **5a**. (iv) In the IR spectrum of the monoacetate (**16a**) prepared from **5a**, the carbonyl absorption due to the acetoxyl group appears at the lower wave-number (1710 cm^{-1}). The presence of an intramolecular hydrogen-bonding between the C-7 hydroxyl group and the acetoxyl group at C-6 is suggested for **16a** which could adopt the conformations **E-a** and **G-a** (OAc in place of $C_{(6)}$–OH). (v) A *cis*-addition of osmium tetroxide to the (6*E*)-olefinic linkage of humulene (**1**) would lead to the *trans*-diol (**5a**).

In the mass spectra of the diol B (**9**) and its related compounds (**11**—**14**), the peaks due to cleavages **a**, **b**,



a R^1= CH_3, R^2= OH (**5a**: *trans*-diol)
b R^1= OH, R^2= CH_3 (**5b**: *cis*-diol)

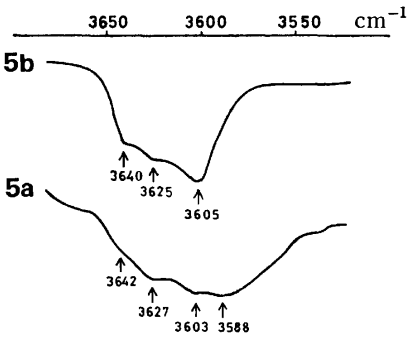


Fig. 1. IR Spectra of the diol D (**5a**) and the diol C (**5b**) in CCl_4 (2.6 mM soln for both compounds).

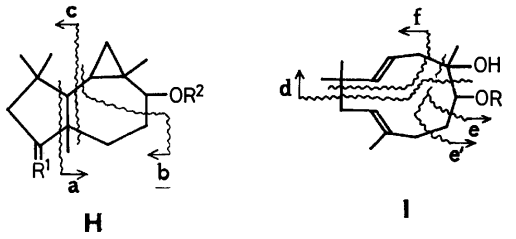
and **c** were observed (*cf.* **H**). The fragment ions due to fissions **d**, **e**, **e'**, and **f** were observed for the diols C (**5b**), D (**5a**), and their derivatives (**16a**, **b**) (*cf.* **I**).



Finally, both the reaction of the epoxide (**2**) (Fig. 2) and the rearrangement of tricyclohumuladiol (**3**) (Fig. 3) were examined by a time-dependent product analysis (GLC). An initial formation of **3** and the subsequent

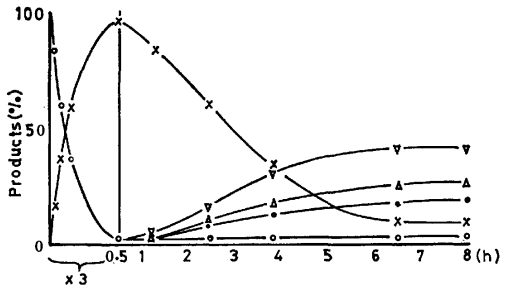


Fig. 2.

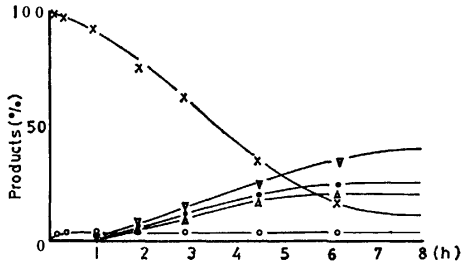

Fig. 3.

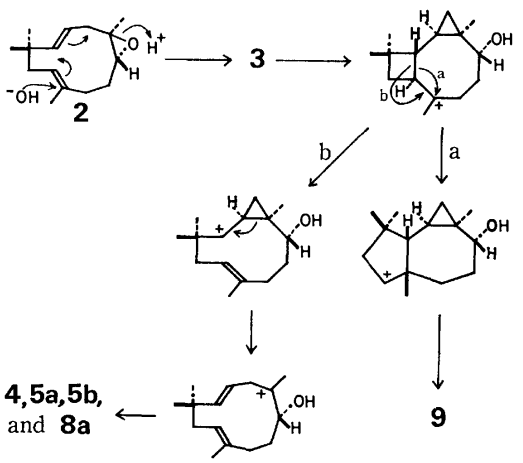
Figs. 2 and 3. Time-dependent product analysis for the reaction of the epoxide (**2**) (Fig. 2) and the rearrangement of tricyclohumuladiol (**3**) (Fig. 3): **2** (-○-), **3** (-×-), **4** (-△-), **8a** (-▽-), and **9** (-●-). The formation of the diol C (**5b**) was detected. However, this could not be registered in Figs. 2 and 3 due to a small quantity of **5b** formed. The diol D (**5a**) could not be detected due to decomposition of this compound under the conditions employed [column: SP-1000 (10%); 180—220 °C].



Scheme 1.

formation of a series of products (**4**, **5b**, **8a**, and **9**) in consumption of **3** were shown (Fig. 2). These results and the product isolation experiments (*vide supra*) indicate that tricyclohumuladiol (**3**) is a key intermediate in the reaction of **2** to form **4**, **5a**, **5b**, **8a**, and **9**. The sequence of the acid-catalyzed cyclization and the subsequent rearrangement of 6,7-epoxyhumula-2,9-diene (**2**) could be interpreted as in Scheme 1.[16]

Experimental

All mps were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and uncorrected. IR spectra were measured on Hitachi EPI-G2, JASCO IRA-2, JASCO DS-402G spectrometers, and UV spectrum on a Hitachi EPS-2 spectrometer. Mass (MS) spectra were run on a Hitachi RMU-6-Tokugata mass spectrometer and high resolution mass spectra on a Hitachi RMH-2 mass spectrometer operating at 70 eV. The relative intensity observed in low resolution mass spectra was expressed in % in the parentheses. PMR spectra were taken using a Hitachi R-20B (60 MHz), or a JEOL FX-60 spectrometer, using TMS as an internal standard. Gas chromatography (GLC) was carried out using Shimadzu GC-6A equipped with a hydrogen flame ionization detector. Analytical TLC was carried out on Kieselgel GF_{254} (Merck) in 0.25 mm thickness and preparative TLC on Kieselgel PF_{254} (Merck) in 0.5 mm thickness. Wakogel C-200 (Wako) was used for column chromatography.

6,7-Epoxyhumula-2,9-diene (2). 6,7-Epoxyhumula-2,9-diene (**2**)[11] was prepared from humulene (**1**) by treatment with pervanadic acid (H_2O_2–V_2O_5)[17] in acetone according to the procedure described by Damodaran *et al.*[5]

Treatment of 6,7-Epoxyhumula-2,9-diene (2) with Sulfuric Acid in Acetone. To a solution of the epoxide (**2**; 100 mg) in acetone (10 ml) cooled to 0 °C was added 1.8 M sulfuric acid (10 ml) with stirring. The solution was stirred at 0 °C for 1 h and then at room temperature for 7 h. The reaction mixture was neutralized with aqueous sodium hydroxide solution and extracted thrice with ether after acetone was removed. The combined ethereal solutions were washed with brine, dried over sodium sulfate, and evaporated. Crystals (17 mg; **9**; *diol B*) separated from the residual oil (98 mg) were filtered and washed with a small amount of ether. The filtrate gave another crop of crystals [6 mg; a mixture of diols B, C, and E], which was collected by filtration. Evaporation of the filtrate gave a residue (75 mg), which was dissolved in hexane–ether (4: 1), passed through a column of silica gel (7 g), and

eluted with the following solvents (each fraction, 5 ml). Hexane–ether (7: 3), frs 1—4; hexane–ether (1: 1), frs 5—14; ether, frs 15—50. On evaporation, fractions 9—14 gave a *diol D* (**5a**; 4 mg), fractions 17—23 a mixture of diols B, C, and E (12.5 mg), fractions 24—30 a *diol C* (**5b**; 1 mg), fractions 31—36 a mixture (*ca.* 1: 1) of diols C and A (2 mg), fractions 37—43 a *diol A* (**3**; *tricyclohumuladiol*;[6-9] 2 mg), and fractions 44—47 a mixture (*ca.* 1: 1) of diol A and an unidentified product (2 mg). Fractions 3—8 were combined and the solvents were distilled off. The residue (44 mg) was dissolved in hexane and further chromatographed on a column of silica gel (8 g) using the following solvents as eluent (each fraction, 8 ml). Hexane, frs 1—6; hexane–ether (19: 1), frs 7—14; hexane–ether (9: 1), frs 15—31; ether, frs 32—36. On removal of the solvents, fractions 10—12 afforded an *acetonide* (**8a**; 14 mg; yield 10%), fractions 13—15 the starting material (**2**; 1 mg), fractions 25—28 *humulenol-II* (**4**;[5,6,11] 9 mg; y: 9%), and fraction 34 a mixture (*ca.* 1: 1) of diol D and another unidentified product (6 mg). From the mixture containing diols B, C, and E mentioned above, the diol C (R_t 15 min) and the *diol E* (R_t 10.3 min) were separated by means of preparative GLC [column, SP-1000 (10%), 4 (mm)×2 (m); 220 °C; N_2 flow rate, 50 ml/min]. The total yields for each of the diols A—E were estimated to be 4, 25, 4, 7, and 4%, respectively.

When the reaction (at 0 °C) was interrupted after 30 min, the diol A (**3**) was obtained as a sole product (y: >95%); a part of the starting material (**2**; <5%) left unchanged.

Characterization of the diols B, C, D, and E and the acetonide are as follows. *5,9-Dihydroxy-4,8,11,11-tetramethyltricyclo[6.3.0.0^{2,4}]undecane (**9**; Diol B).* The diol B (**9**) crystallized from benzene as colorless needles, mp 171.5—172 °C; IR (Nujol) 3280, 3050, 1380, 1365, 1350, 1260, 1055, 1045, 1035, 925, 910, and 880 cm^{-1}; PMR ($CDCl_3$) δ 0.16—0.63 (3H, m), 0.90, 1.03, 1.05, 1.12 (each 3H, s), 3.4 and 3.8 (each 1H, m); Found: C, 75.31; H, 11.02%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 10.99%; MS *m/e* 238.1861 (9%; M^+; calcd for $C_{15}H_{26}O_2$: 238.1931), 223.1684 [11%; $(M-CH_3)^+$], 220.1795 [13%; $(M-H_2O)^+$], 205.1585 [20%; $(M-H_2O-CH_3)^+$], 202.1658 [9%; $(M-2\times H_2O)^+$], 152.1229 [22%; **a** and/or (**b**−2H); $C_{10}H_{16}O$], 150.1083 [38%; (**a**−2H); $C_{10}H_{14}O$], 138.0976 (84%; $C_9H_{14}O$), 125.0963 [71%; (**c**−H); $C_8H_{13}O$], 121.1014 (73%; C_9H_{13}), 109.0886 (100%; C_8H_{13}), and 107.0833 (91%; C_8H_{11}).

*Diol C (**5b**).* The diol C (**5b**) crystallized from ethyl acetate as colorless needles, mp 182—183 °C; IR (Nujol) 3380, 1150, 980, and 860 cm^{-1}; PMR (CD_3OD) δ 1.04, 1.09, 1.31, and 1.66 (each 3H, s); MS *m/e* 238.2004 (3%; M^+; calcd for $C_{15}H_{26}O_2$: 238.1931), 220.1765 [3%; $(M-H_2O)^+$], 205.1450 [2%; $(M-H_2O-CH_3)^+$], 138.1037 (53%; $C_9H_{14}O$), 125.0959 [35%; (**d**−H); $C_8H_{13}O$], 109.0951 (57%; C_8H_{13}), 95.0853 (53%; C_7H_{11}), 87.0419 [23%; (**e′**−H); $C_4H_7O_2$], and 83.0831 [100%; (**f**+H); C_6H_{11}].

*Diol D (**5a**).* The diol D (**5a**) is a colorless oil, IR (liquid) 3400, 1040, 980, 910, 875, and 860 cm^{-1}; PMR ($CDCl_3$) δ 1.05 (3H, s), 1.11 (6H, s), 1.60 (3H, s), 3.68 (1H, *t*-like, *J*=*ca.* 4.5 Hz), and 4.8—5.6 (3H); MS *m/e* 238.2026 (4%; M^+; calcd for $C_{15}H_{26}O_2$: 238.1931), 220.1813 [6%; $(M-H_2O)^+$], 205.1552 [5%; $(M-H_2O-CH_3)^+$], 138.1053 (35%; $C_9H_{14}O$), 125.0946 [36%; (**d**−H); $C_8H_{13}O$], 109.1018 (74%; C_8H_{13}), 95.0853 (87%; C_7H_{11}), 87.0421 [19%; (**e′**−H); $C_4H_7O_2$], 83.0848 [100%; (**f**+H); C_6H_{11}], and 74.0359 [46%; **e**; $C_3H_6O_2$].

Diol E. The diol E is a crystalline compound, mp 131.5—132 °C; IR (Nujol) 3320, 1380, 1362, 1110, 1080, 928, and 868 cm^{-1}; PMR ($CDCl_3$) δ 0.82, 0.97, 1.11, 1.15 (each 3H, s), and 3.77 (1H, m); MS M^+ at *m/e* 238. The structure of the diol E remains undetermined due to paucity of this compound.

*Acetonide (**8a**).* The acetonide (**8a**) was obtained as a colorless oil, IR (liquid) 1250, 1095, 1085, 1050, 995, 970, and 860 cm^{-1}; PMR (CCl_4) δ 1.03, 1.06, 1.10, 1.28, 1.33 (each 3H, s), 1.63 (3H, br s), 3.88 (1H, dd, *J*=2, *J*=7 Hz), and 4.8—5.5 (3H) [lit,[7] 1.04 (6H, s), 1.08 (3H, s), 1.28, 1.34 (each 3H, s), 1.60 (3H, d, *J*=1 Hz), 3.92 (1H, m), and 5.10 (3H, m)], PMR ($CDCl_3$) δ 1.07 (3H, s), 1.11 (6H, s), 1.37, 1.44 (each 3H, s), 1.64 (3H, d, *J*=1 Hz), 4.01 (1H, dd, *J*=2, *J*=7 Hz), and 4.8—5.5 (3H); MS[7] (indirect) M^+ at *m/e* 278 ($C_{18}H_{30}O_2$).

*Time-dependent Product Analysis of the Reaction of 6,7-Epoxyhumula-2,9-diene (**2**) with Sulfuric Acid in Acetone by Means of GLC.* Sulfuric acid (8 ml; 1.8 M soln) was added to a solution of the epoxide (**2**: 60 mg) in acetone (8 ml) at 0 °C, and the reaction was allowed to proceed at 0 °C for 30 min and then at room temperature for 7.5 h. Product analysis was carried out as follows. A part of the solution (0.5 ml) was separated from the reaction mixture. To this solution was added a 10% aqueous sodium hydroxide solution (0.4 ml) and the resulting mixture was extracted four times with dichloromethane (total 5 ml). The dichloromethane solution was washed with brine, dried over magnesium sulfate, and evaporated to give a residue, which was dissolved in acetone (1.5 ml) and subjected to an examination by GLC [column, SP-1000 (10%), 4 (mm)×2 (m); 180—220 °C (temperature elevated at the rate of 5 °C/min); N_2 flow rate, 55 ml/min] (Fig. 2). The retention times under these conditions for **2**, **3**, **4**, **5b**, **8a**, and **9** were 5.6, 15.2, 8.2, 17.4, 4.8, and 24.6 min, respectively.

*Product Analysis of the Reaction of Tricyclohumuladiol (**3**) with Sulfuric Acid in Acetone by Means of GLC.* To a solution of tricyclohumuladiol (**3**: diol A; 71 mg) in acetone (9 ml) was added 1.8 M sulfuric acid (9 ml) with stirring at 0 °C. The reaction was allowed to proceed at room temperature for 8 h. Product analysis was effected as mentioned above. The result is shown as in Fig. 3.

*Oxidation of the Diol B (**9**).* Chromium trioxide (52 mg) was added to a mixture of pyridine (75 mg) and dichloromethane (1.3 ml) with stirring for 15 min. To the solution, the diol B (20 mg) in dichloromethane (2 ml) was added. The reaction mixture was stirred at room temperature for 40 min. The organic solution was separated by decantation and the residue was washed thoroughly with ether. The combined solution was evaporated *in vacuo* and the residue was extracted with ether. The ethereal layer was washed with 1% aqueous sodium hydroxide solution, brine, and dried over sodium sulfate. Evaporation of the solvent gave a residue which was dissolved in hexane, passed through a column of silica gel (5 g), and eluted with hexane–ether (2: 3) (each fraction, 3 ml). Fractions 5 and 6 gave a dione and fractions 8—13 a crude mixture of monoketones and the dione. This mixture was further subjected to separation by preparative TLC to afford the dione and a mixture of monoketones. *5,9-Dioxo-4,8,11,11-tetramethyltricyclo[6.3.0.0^{2,4}]undecane* (10; total 7.5 mg), a colorless oil; IR (CCl_4) 1740, 1710, 1680, 1380, and 1345 cm^{-1}; IR (liquid) 1735, 1700, 1670, 1380, 1345, 1275, 1230, and 895 cm^{-1}; UV (EtOH) λ_{max} 212 nm (ε 2200); PMR ($CDCl_3$) δ 1.11, 1.20, 1.22, 1.34 (each 3H, s), 2.30 (2H, d, *J*=*ca.* 1 Hz), and 2.56 (2H, dd, *J*=5, *J*=7 Hz); MS *m/e* 234.1612 (35%; M^+; calcd for $C_{15}H_{22}O_2$: 234.1618), 219.1394 [9%; $(M-CH_3)^+$], 151.1130 [94%; (**a**+H) and/or (**b**−H); $C_{10}H_{15}O$], 123.0805 [31%; (**c**−H); $C_8H_{11}O$], 109.1031 (100%; C_8H_{13}), and 69.0335 (66%; C_4H_5O); GLC R_t=10.8 min [column, SP-1000 (10%); 220 °C; N_2 flow rate 90 ml/min], R_t=4.0 min [column, Dexsil-300GC (5%); 170 °C; N_2 flow rate, 50 ml/min].

*Acetylation of the Diol B (**9**).* A solution of the diol B (**9**; 33 mg) in pyridine was treated with acetic anhydride at room temperature for 30 min. Methanol was added to decompose an excess of acetic anhydride. The solvents were evaporated under reduced pressure to give an oily residue, which was dissolved in hexane–ether. Crystals (7 mg; diol B) separated from the solution were removed by filtration and the filtrate was passed through a column of silica gel (5 g). Elution with hexane–ether (3: 2; each fraction, 5 ml) gave a *diacetate* (**11**; 8 mg; from frs 1—4), mp 88.5—90.5 °C (crystallized from hexane), IR (Nujol) 3050, 1735, 1245, 1040, and 980 cm^{-1}; PMR ($CDCl_3$) δ 0.35—0.63 (3H), 1.02, 1.04, 1.10, 1.16, 2.02, 2.05 (each 3H, s), 4.50 (1H, dd, J=7.5, J=10 Hz; H–C–OAc), and 4.82 (1H, dd, J=7.5, J=11 Hz; H–C–OAc); MS *m/e* 322.2155 (1%; M^+; calcd for $C_{19}H_{30}O_4$: 322.2142), 280.2031 [5%; $(M-CH_3CO+H)^+$], 263.2007 [17%; $(M-AcOH+H)^+$], 262.1904 [5%; $(M-AcOH)^+$], 220.1824 [17%; $(M-AcOH-CH_3CO+H)^+$], 205.1581 [18%; $(M-AcOH-CH_3CO-CH_3+H)^+$], 203.1774 [23%; $(M-2\times AcOH+H)^+$], 202.1709 [46%; $(M-2\times AcOH)^+$], 187.1482 [46%; $(M-2\times AcOH-CH_3)^+$], 162.1407 (100%, $C_{12}H_{19}$), 135.1164 [49%; (**a**−AcOH+H) and/or (**b**−AcOH−H); $C_{10}H_{15}$], 133.1015 [51%; (**a**−AcOH−H); $C_{10}H_{13}$], 109.1020 (66%; C_8H_{13}), and 107.0861 [80%; (**c**−AcOH−H); C_8H_{11}]. Fractions 5 and 6 yielded a *monoacetate* (**12**; 5 mg), a colorless oil, IR (liquid) 3420, 3050, 1735, 1720 (sh), 1380, 1365, 1250, and 1030 cm^{-1}; PMR ($CDCl_3$) δ *ca.* 0.4 (2H, m), 0.62 (1H, br s), 1.00 (3H, s), 1.06 (6H, s), 1.15, 2.05 (each 3H, s), 3.88 (1H, dd, J=8, J=11 Hz; H–C–OH), and 4.53 (1H, dd, J=7, J=10 Hz; H–C–OAc); MS *m/e* 280.2032 (3%; M^+; calcd for $C_{17}H_{28}O_3$: 280.2036), 265.1812 [2%; $(M-CH_3)^+$], 262.1926 [2%; $(M-H_2O)^+$], 238.1912 [7%; $(M-CH_3CO+H)^+$], 220.1818 [22%; $(M-AcOH)^+$], 205.1585 [33%; $(M-AcOH-CH_3)^+$], 202.1696 [23%; $(M-AcOH-H_2O)^+$], 180.1513 (54%; $C_{12}H_{20}O$), 162.1414 (60%; $C_{12}H_{18}$), 135.1109 [75%; (**a**−AcOH+H) and/or (**b**−H_2O−H); $C_{10}H_{15}$], 133.1002 [43%; (**a**−AcOH−H); $C_{10}H_{13}$], 125.0967 [75%; (**c**−H); $C_8H_{13}O$], 121.0984 (83%; C_9H_{13}), 109.1017 (83%; C_8H_{13}), and 107.0859 [100%; (**c**−H_2O−H); C_8H_{11}]. Fractions 7—11 were combined and the solvents were evaporated to give a residue, which was subjected to separation by silica gel dry column chromatography [9 g; elution with hexane–ether (1: 1); each fraction 2.3 ml]. Fractions 16—18 gave **12** (5 mg) and fractions 22—30 afforded another *monoacetate* (**13**; 3.8 mg), an amorphous solid, IR (Nujol) 3300, 1730, 1245, and 1030 cm^{-1}; PMR ($CDCl_3$) δ 0.2—0.7 (3H), 0.97, 1.02, 1.10, 1.15, 2.04 (each 3H, s), 3.38 (1H,m), and 4.82 (1H, dd, J=8, J=11 Hz); MS *m/e* 280.2120 (0.2%; M^+; calcd for $C_{17}H_{28}O_3$; 280.2036), 262.1938 [1%; $(M-H_2O)^+$], 220.1823 [5%; $(M-AcOH)^+$], 205.1591 [5%; $(M-AcOH-CH_3)^+$], 202.1722 [5%; $(M-AcOH-H_2O)^+$], 187.1482 (8%; $C_{14}H_{19}$), 135.1128 [16%; (**a**−H_2O+H) and/or (**b**−AcOH+H); $C_{10}H_{15}$], 133.1013 [16%; (**a**−H_2O−H); $C_{10}H_{13}$], 109.1027 (26%; C_8H_{13}), and 107.0866 [30%; (**c**−AcOH−H); C_8H_{11}], and 55.0563 (100%; C_4H_7).

*Oxidation of the Monoacetate (**12**).* The monoacetate (**12**; 4.7 mg) in dichloromethane (*ca.* 0.1 ml) was added to a solution prepared from chromium trioxide (11.1 mg), pyridine (18.5 mg), and dichloromethane (0.25 ml). The mixture was stirred at room temperature for 1 h. The reaction mixture was worked up as before to give a keto acetate (**14**; 2.1 mg), a colorless oil; IR (liquid) 3050, 1742, 1736, 1380, 1370, and 1250 cm^{-1}; MS *m/e* 278.1859 (15%; M^+; calcd for $C_{17}H_{26}O_3$: 278.1879), 236.1759 [8%; $(M-CH_3CO+H)^+$], 221.1534 [19%; $(M-CH_3CO-CH_3+H)^+$], 218.1654 [20%; $(M-AcOH)^+$], 203.1439 [22%; $(M-AcOH-CH_3)^+$], 152.1211 (43%; **b**; $C_{10}H_{16}O$), 134.1094 [99%; (**a**−AcOH); $C_{10}H_{14}$], 123.0855 [47%; (**c**−H), $C_8H_{11}O$], 119.0861 [87%; (**a**−AcOH−CH_3); C_9H_{11}], 109.1013 (79%; C_8H_{13}), and 94.0782 (100%; C_7H_{10}).

*Acetonization of the Diol D (**5a**).* To a solution of the diol D (**5a**; 19.5 mg) in acetone (0.5 ml) containing a trace of sulfuric acid, was added anhydrous cupric sulfate (40 mg) and the mixture was stirred vigorously at room temperature for 18 h. Cupric sulfate was separated by filtration and washed with acetone. The combined acetone solution was neutralized with powdered calcium hydroxide. After filtration, the solvent was removed to give a residue, which was chromatographed on a column of silica gel (5 g). Elution with hexane–ether (17: 3; each fraction, 2.5 ml) gave an acetonide (8.7 mg; from frs 4—7), whose spectral data were identical with those of the acetonide (**8a**).

*Acid Hydrolysis of the Acetonide (**8a**).* A mixture of the acetonide (**8a**; 52 mg), methanol (3 ml), and 0.5 M hydrochloric acid (1.5 ml) was stirred at room temperature for 7 h. The reaction mixture was neutralized with aqueous sodium hydroxide solution and extracted with ether after methanol was removed. The ethereal solution was washed with brine, dried over sodium sulfate, and evaporated to give a residue (37 mg), which was chromatographed on a column of silica gel (5 g; elution with hexane–ether (1: 2); each fraction, 5 ml). Fractions 13—21 yielded the diol D (**5a**; 26 mg).

*Treatment of Humulene (**1**) with Osmium Tetroxide.* To a solution of humulene (**1**; 54 mg) in dry ether (5 ml) was added osmium tetroxide (67 mg) in dry ether (1.5 ml) under nitrogen atomosphere and the reaction mixture was left for 14 h at room temperature in the dark. A solution of sodium sulfite (470 mg) in water (5 ml) and ethanol (2.5 ml) was added to the reaction mixture and refluxed for 4 h under nitrogen atmosphere in the dark. The precipitate was removed by filtration and washed with hot ethanol. The combined solution was concentrated under reduced pressure, and extracted with ether. The ethereal solution was washed with brine, dried over sodium sulfate, and the solvent was evaporated to give a residue (40 mg), which was chromatographed on a column of silica gel (5 g; elution with hexane–ether (1: 2); each fraction 2.5 ml). Fractions 7—11 gave a diol (27.3 mg) which was identified to be the diol D (**5a**).

*Periodate Oxidation of the Diol C (**5b**).* A solution of the diol C (**5b**; 5.3 mg) in methanol (5 ml) was treated with 22.6 mM aqueous potassium periodate solution (2 ml) at room temperature for 28 h. Aqueous sodium arsenite solution (5 ml; 26.3 mM soln) and 20% aqueous potassium iodide solution (1 ml) were added and the resulting mixture was titrated with iodine solution; it was shown that *ca.* 0.65 equivalent mole of periodate was consumed. After the titration was effected, the mixture was extracted with dichloromethane. The organic layer was washed with brine, dried over sodium sulfate, and the solvent was evaporated. Crystals (2.6 mg; **5b**; diol C) separated from the residual oil were filtered. The residue was then passed through a column of silica gel (1 g) and eluted with hexane–ether (1: 1) to give a *keto aldehyde* (**15**; 0.4 mg), a colorless oil, IR (liquid) 2720, 1720, 1380, 1360, 1160, and 975 cm^{-1}; PMR ($CDCl_3$) δ 0.99 (6H, s), 1.62 (3H, br s), 1.98 (2H, d, J=7 Hz), 2.14 (3H, s), 2.43 (4H), 3.11 (2H, d, J=6 Hz), 5.18 (1H, t, J=7 Hz), 5.49 (2H, d, J=2 Hz), and 9.75 (1H, br s); MS *m/e* 218 [0.3%; $(M-H_2O)^+$], 207 [0.3%; $(M-CHO)^+$], 193 [0.6%; $(M-CH_3CO)^+$], 178 (15%), 125 (45%), and 43 (100%); GLC R_t=6.2 min [column, SP-1000 (10%); 220 °C; N_2 flow rate, 55 ml/min], R_t=7.7 min [column, Dexsil-300GC (5%); 200 °C; N_2 flow rate, 53 ml/min].

*Periodate Oxidation of the Diol D (**5a**).* A solution of the diol D (**5a**; 6.5 mg) in methanol (3 ml) was treated with

24.2 mM aqueous potassium periodate solution (2 ml) at room temperature for 24 h; *ca.* 1.1 equivalent mole of periodate was consumed. Treatment of the reaction mixture as described above afforded a keto aldehyde (**15**; 5 mg), whose spectral data and chromatographic (TLC and GLC) properties were identical with those of the keto aldehyde obtained from the diol C (**5b**).

Acetylation of the Diol C (5b). A solution of the diol C (**5b**; 11.7 mg) in pyridine was acetylated with acetic anhydride at room temperature for 2 days. Treatment as usual gave an oily product, which was passed through a silica gel dry column [5 g; elution with hexane–ether (2: 3)] to yield a *monoacetate* (**16b**; 7.4 mg), an amorphous solid, IR (liquid) 3450, 1730, 1710 (sh), 1380, 1373, 1260 (sh), 1245, 1025, 980, 875, and 800 cm^{-1}; PMR ($CDCl_3$) δ 1.07, 1.16, 1.23, 1.64, 2.10 (each 3H, s), and 4.9—5.5 (4H); MS *m/e* 280 (1%; M^+; $C_{17}H_{28}O_3$), 262 [1%; $(M-H_2O)^+$], 220 [5.5%; $(M-AcOH)^+$], 202 [4%; $(M-AcOH-H_2O)^+$], 138 (18%), 129 [1.5%; (**e**′−H)], 125 [100 %; (**d**–H)], 116 (40%; **e**), 109 (36%), 95 (73%), 83 [50%; (**f**+H)], 74 (30%), and 68 (70%). Further purification was not effected due to paucity of the material.

Acetylation of the Diol D (5a). The diol (**5a**; 15.5 mg) in pyridine was acetylated with acetic anhydride at room temperature for 16 h. The usual treatment gave a product which was passed through a silica gel dry column (5 g) and eluted with hexane–ether (2: 3) to afford a *monoacetate* (**16a**; 6.2 mg), mp 132.5—133.0 °C (crystallized from hexane); IR (Nujol) 3450, 1740 (sh), 1710, 1260, 1240 (sh), 1035, 990, 965, and 880 cm^{-1}; PMR ($CDCl_3$) δ 1.07, 1.14, 1.18, 1.63, 2.11 (each 3H, s), and 4.7—5.7 (4H); MS *m/e* 280 (1%; M^+; $C_{17}H_{28}O_3$), 262 [2%; $(M-H_2O)^+$], 220 [5%; $(M-AcOH)^+$], 205 [2%; $(M-AcOH-CH_3)^+$], 202 [5%; $(M-AcOH-H_2O)^+$], 138 (32%), 129 [16%; (**e**′−H)], 125 [65%; (**d**−H)], 116 (71 %; **e**), 109 (45%), 95 (100%), 83 [59%; (**f**+H)], and 68 (96%).

The authors wish to thank Dr. Nobuo Nakamura, the University of Tokyo, for decoupling experiment by FT-NMR.

Preparation of Alkylthio- and Phenylthio(triphenylphosphine)copper(I) Complexes and Their Catalytic Activity for Transesterification of *S*-Alkyl Ethanethioates and Thiols

Minoru KUBOTA and Akio YAMAMOTO*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama, 227

(Received June 9, 1978)

Alkylcopper complexes, $RCu(PPh_3)_2$ (R=methyl, ethyl, propyl, isobutyl)reacted with sulfur smoothly at low temperatures to produce dialkyl disulfides. This indicates the insertion of sulfur to alkyl-Cu bond taking place followed by coupling of the two alkylthio-Cu bonds. Methylcopper complex, $CH_3Cu(PPh_3)_2 \cdot 0.5Et_2O$ reacted with thiols to produce alkylthio- and phenylthiocopper complexes having one or two triphenylphosphine ligands. The reactions of these alkylthiocopper complexes with acyl halides and acid anhydrides produced *S*-alkyl ethanethioates in high yields, whereas the reactions of alkylthiocopper complexes with alkyl halides produced dialkyl sulfides. Alkylthio- and phenylthiocopper complexes were found to catalyze the transesterification reactions between *S*-alkyl ethanethioates and thiols. The exchange reactions also take place between the alkylthiocopper complex and benzenethiol producing phenylthiocopper complex with liberation of alkanethiol.

As part of the project for studying the chemistry of organic copper complexes we have been investigating the properties of alkylcopper and alkoxocopper complexes containing tertiary phosphine ligands.[1-9] Natural extension of our study of alkoxocopper complexes[8,9] has led us to investigation of the chemistry of copper complexes containing organic sulfur moiety. Survey of the literature revealed that the chemistry of organic sulfur-copper complexes has been scarcely explored. Copper(I) alkanethiolates have been prepared by the reaction of copper(II) sulfate and thiols,[10] from copper(II) acetoacetate and sulfocyanate,[11] and from copper(II) acetate and thiols.[12] Phenylthiocopper complex also has been prepared from $ClCu(PPh_3)_3$ and NaSPh.[13] The copper(I) alkane- and benzenethiolates thus obtained are insoluble except for copper(I) alkanethiolates of higher secondary thiols in organic solvents, but their characterization is far from satisfactory.

Some reactions of the copper(I) alkane- and benzenethiolates have been examined sporadically, including the reactions of the complexes with carbon disulfide,[12] alkenyl halides,[14] phenyl acetylene,[15] sulfur dioxide.[16] Since most of the works concerning the copper(I) alkanethiolates have been done in rather old days and in none of the works the well defined copper(I) alkanethiolates have been prepared and their behavior examined, we consider it worthwhile to prepare a series of alkylthiocopper and phenylthiocopper complexes and examine their properties as chemical reagents which might be used for organic syntheses, particularly for catalytic reactions.

Our previous work on alkylcopper and alkoxocopper complexes having tertiary phosphine ligands[1-9] revealed the remarkable stabilizing effects of the tertiary phosphine ligands and employment of the tertiary phosphine ligands led to isolation of various well-characterized organic copper complexes. This paper deals with the preparation of new alkylthio- and phenylthiocopper complexes starting from the methylcopper complex having triphenylphosphine ligands and their properties including catalytic transesterification reactions of *S*-alkyl ethanethioate with thiols.

Results and Discussion

Preparation of Alkylthio- and Phenylthiocopper Complexes with Triphenylphosphine Ligands. As our previous studies on the properties of alkylcopper complexes having tertiary phosphine show, they have some similarities to Grignard reagents. Grignard reagents are known to react with sulfur giving magnesium alkanethiolates which on hydrolysis yield thiols.[17] Therefore we first attempted to prepare the alkylthiocopper complexes by reactions of sulfur with alkylcopper complexes having triphenylphosphine ligands in tetrahydrofuran below −10 °C. The reaction did not give isolable alkylthiocopper complexes but yielded dialkyl disulfides accompanied by small amounts of dialkyl sulfides as shown in Table 1. As our later study showed the alkylthiocopper complex once formed can be readily converted into dialkyl disulfide in high yields on reaction with sulfur. The small amount of dialkyl sulfide may have been produced by the reaction of alkylthiocopper

TABLE 1. REACTION OF ALKYLCOPPER COMPLEXES WITH SULFUR[a]

$$RCu(PPh_3)_2 \xrightarrow[\text{in THF}]{\text{Sulfur}} R\text{–}S\text{–}S\text{–}R + R\text{–}S\text{–}R$$

Alkylcopper complex (mmol)	Sulfur (g)	Products (yield %)[b] RSSR	RSR
$CH_3Cu(PPh_3)_2 \cdot 0.5Et_2O$ (1.00)	2.00	43	1
$CH_3CH_2Cu(PPh_3)_2$ (0.45)	1.50	30	7
$CH_3CH_2CH_2Cu(PPh_3)_2$ (0.89)	2.00	31	3
$(CH_3)_2CHCH_2Cu(PPh_3)_2$ (3.02)	2.50	48	2

a) The reactions were carried out in tetrahydrofuran for 5 h at −40 to −10 °C in a vacuum or under N_2 atmosphere. b) Yields were calculated based on alkyl group in alkylcopper complexes. Alkanes were also evolved in these reactions.

Table 2. Characterization data of alkylthio- and phenylthiocopper complex

b) Measured in vacuum-sealed capillaries.

complexes with remaining alkylcopper complexes or by the reaction of the dialkyl disulfide with triphenylphosphine which was present in the reaction mixture by dissociation from the copper complex.

Upon failure of our attempts to prepare an alkylthiocopper complex using sulfur powder we have tried reactions of thiols with a methylcopper complex having triphenylphosphine ligands and found that the reactions at 0 °C in diethyl ether gave a series of alkylthiocopper complexes and phenylthiocopper complex in considerably high yields evolving one mole of methane per mol of the copper complex.

$$CH_3Cu(PPh_3)_2\cdot 0.5Et_2O + RSH \xrightarrow[Et_2O]{0\,^\circ C} RSCu(PPh_3)_n + CH_4$$

The phenylthiocopper complex could be also prepared by the reaction of PhSH with Cu_2O in the presence of PPh_3 in a high yield (92%) as well as from the methylcopper complex with PhSH. The alkylthio- and phenylthiocopper complexes were characterized by elemental analysis, molecular weight determination (cryoscopic in benzene), chemical reactions, and IR and NMR spectroscopy. Table 2 shows relevant data for characterization together with yields and melting points with decomposition of alkylthio- and phenylthiocopper complexes. Infrared spectra of the alkylthiocopper complexes (shown in Experimental section) showed a band in the range of 1220 to 1260 cm^{-1} which may be related to alkylthio group, in addition to other bands due to triphenylphosphine. The molecular weights of the alkylthiocopper complexes having one triphenylphosphine ligand (complexes **2** and **3**) were found to be slightly higher than the theoretical values, whereas those of complexes having two triphenylphosphine ligands were slightly lower. The possible explanation for the former cases is the association of the alkylthiocopper complexes whereas in the latter the partial dissociation of the triphenylphosphine ligands might be taking place as have been observed in other alkylcopper complexes.[1-2,6] The melting points (with decomposition) of the isolated alkylthiocopper complexes showed a considerable variance and no reasonable explanation for this was found. Although the complexes have relatively high thermal stabilities and are relatively insensitive to air when heated rapidly, they are gradually decomposed at room temperature even under nitrogen.

Reactions of Alkylthiocopper Complexes. Pyrolysis of the ethylthiocopper complex at 150 °C liberated diethyl sulfide (54%), diethyl disulfide (31%) and a

Table 3. Reactions of alkylthiocopper complexes with various reagents[a]

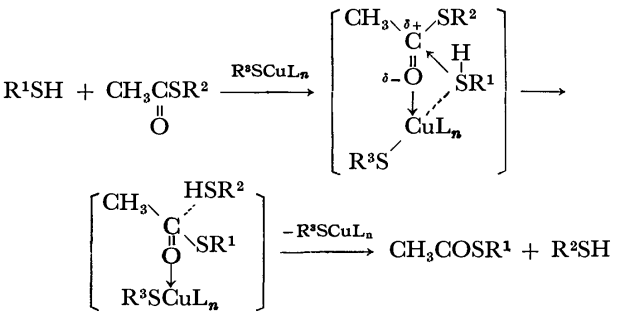
a) These reactions were carried out at room temperature for 12 h. b) At 32 °C for 2 h.
c) In 2 ml of THF.

small amount of ethane (7%) and a trace of ethylene, the yields being based on the ethyl group. Pyrolysis of the phenylthiocopper complex at 150 °C similarly gave diphenyl sulfide (43%), diphenyl disulfide (52%), and benzene (2%). The formation of disulfides may be accounted for by assuming the homolytic splitting of the RS–Cu bond yielding RS radicals which are known to give the disulfide on recombination. On the other hand, the sulfide may have been formed either from the disulfide on reaction with triphenylphosphine which is known to convert the disulfide into sulfide with concomitant conversion of the triphenylphosphine to triphenyl phosphine sulfide,[18,19)] or by the recombination of R radical and RS radical produced on pyrolysis of these complexes. The small amount of RH (ethane and benzene) seems to be produced by the abstraction of *o*-hydrogen of the PPh_3 ligand by the R radical. A part of the ethyl radical seems to participate into the disproportionation to afford ethylene. For further characterizing the alkylthiocopper complexes and for getting information of their chemical properties the alkylthiocopper complexes were subjected to various chemical reactions. The main features of the chemical properties of the alkylthiocopper complexes parallel with those of the alkoxocopper complexes as shown in Table 3. They afford *S*-alkyl ethanethioate on reaction with acetic anhydride and acetyl chloride, dialkyl sulfide on treatment with alkyl halide under mild conditions, whereas vinyl acetate was polymerized with the alkylthiocopper complex. Propylthiocopper complex **2** reacts with benzenethiol at 0 °C to produce the more thermally stable phenylthiocopper complex **6** in a high yield.

Catalytic Transesterification Reactions Promoted by the Alkylthiocopper Complexes. Our previous study on the alkoxocopper complexes revealed their excellent catalytic activities for transesterification of carboxylic esters with alcohols under mild conditions. In the light of the importance of the thiol esters such as exemplified by coenzyme A in biosynthesis, the catalytic transesterification reactions of *S*-alkyl ethanethioates with thiols promoted by the alkylthiocopper complexes under mild conditions were examined. As Table 4 shows, the alkylthiocopper complexes were found to serve as the transesterification catalyst in a similar manner to the alkoxocopper complexes which catalyzed the transesterification of carboxylic esters with alcohols.[9)] In view of the reluctane for the exchange of the alkylthio group bound to copper with that in the other alkanethiol, a stepwise mechanism involving the exchange of RSCu entity with R'SH is not likely and attack of an ester carbonyl group, which is polarized on coordination to copper, by thiol in a nucleophilic manner as shown below seems to provide a reasonable explanation for the transesterification catalyzed by the copper complexes:



A similar S_N2 type mechanism has been proposed for the transesterification of carboxylic esters with alcohols catalyzed by alkoxocopper and phenoxocopper complexes.[9)]

Whereas the transesterification between the *S*-alkyl ethanethioates and thiols were catalyzed by the alkylthiocopper complexes, attempted transesterification of carboxylic esters with thiols has been so far unsuccessful. On the other hand transesterification of *S*-*t*-butyl ethanethioate with ethanol was found to be catalyzed by the ethoxocopper complex, $EtOCu(PPh_3)_2$. A related activation of thiol esters by copper, silver, and mercury compounds have been examined by Masamune and utilyzed for organic synthesis.[20,21)]

Experimental

General. All preparations and reactions of copper complexes were carried out in Schlenk type flasks under deoxygenated nitrogen, argon or in a vacuum. Solvents were dried by usual procedures, distilled, and stored under argon or nitrogen. IR spectra were recorded on a Hitachi Model

295 using KBr discs under nitrogen. ^{1}H-NMR spectra were recorded with a Japan Electron Optics Lab. JNM-PS-100 spectrometer. Evolved gas was analyzed with a Hitachi RMU 5B mass-spectrometer and a Shimadzu GC 5B gas chromatograph, and its volume was measured with a Toepler pump. The microanalysis of carbon, hydrogen, and nitrogen was performed by Mr. T. Saito of our labolatory with a Yanagimoto CHN Autocorder Type MT-2.

Reactions of Alkylcopper Complexes with Sulfur. Sulfur (2.0 g) was added into a Schlenk-type flask containing methylcopper complex, $CH_3Cu(PPh_3)_2 \cdot 0.5Et_2O$ (1 mmol) in THF (5 ml) and the yellow emulsion was stirred at -40 °C to -10 °C for 5 h to give a red solution. Analysis of the products in the solution by means of gas chromatography showed that dimethyl disulfide (yield 43%) and dimethyl sulfide (yield 1%) were produced (yields are based on the methyl group of the methylcopper complex). The other reactions between alkylcopper complexes and sulfur were carried in a similar way to the above reaction.

Preparation of Ethylthiobis(triphenylphosphine)copper (1). Ethanethiol (0.28 ml, 3.62 mmol) was added to a yellow suspension of $CH_3Cu(PPh_3)_2 \cdot 0.5Et_2O$ (1.932 g, 3.02 mmol) in 5 ml of Et_2O at -10 °C, and the mixture was stirred at -10 °C for about 10 min until the yellow emulsion turns to white. A quantative amount of methane (yield 98% on the basis of Cu) was evolved. The white complex produced was separated and recrystallized from toluene to give white crystals of $CH_3CH_2SCu(PPh_3)_2$ (**1**) (1.535 g, yield 78%). IR(KBr): 2950 w, 2900 w, 2840 w, 1235 w, 1235 m and other absorption bands due to PPh_3.

Preparation of Propylthiotriphenylphosphinecopper (2). The reaction of $CH_3Cu(PPh_3)_2 \cdot 0.5Et_2O$ (2.085 g, 3.26 mmol) with propanethiol (3.26 mmol) in 10 ml of Et_2O at -10 °C to 0 °C for 1 h produced a light yellow precipitate and methane (0.99 mol per Cu). The yellow precipitate was recrystallized from a mixture of Et_2O and toluene. Light yellow crystals of **2** (1.095 g, yield 84%) were obtained. IR(KBr): 2950 w, 2900 w, 2860 w, 1200 m cm^{-1} and other absorption bands due to PPh_3.

Preparation of Isopropylthiotriphenylphosphinecopper (3). The reaction of $CH_3Cu(PPh_3)_2 \cdot 0.5Et_2O$ (1.475 g, 2.3 mmol) with 1-methyl-ethanethiol (2.76 mmol) in 5 ml of Et_2O at -10 °C to 0 °C for 1 h produced a white precipitate from the yellow emulsion. Methane (0.94 mol per Cu) was evolved. The white precipitate was recrystallized from a mixture of Et_2O and toluene to give white crystals of **3** (0.795 g, yield 86%). IR(KBr): 2930 w, 2900 w, 2840 w, 1220 w, 1140 w cm^{-1} and other absorption bands due to PPh_3.

Preparation of Isobutylthiobis(triphenylphosphine)copper (4). To a yellow suspension of the methylcopper complex (1.832 g, 2.86 mmol) in Et_2O (5 ml) at -20 °C 2-methylpropanethiol (3.44 mmol) was added. After stirring the mixture at -20 to 0 °C for 3 h a yellow solution was produced. On concentrating the solution, a white complex precipitated and it was recrystallized from a mixture of Et_2O and hexane to give white crystals of **4** (1.572 g, yield 81%). IR(KBr): 2950w, 2920w, 2900w, 2860w, 1370w, 1350w, 1225w cm^{-1} and other absorption bands due to PPh_3.

Preparation of Phenylthiobis(triphenylphosphine)copper (5). The reaction of the methylcopper complex (0.941 g, 1.31 mmol) with benzenethiol (1.57 mmol) in diethyl ether (5 ml) at -10 °C for 10 min produced a white precipitate from a yellow heterogeneous system. The precipitate was recrystallized from a mixture of diethyl ether and toluene and was dried in a vacuum to give crystals of **5** (0.835 g, yield 92%). IR(KBr): 1570s, 1260w, 1075m cm^{-1} and absorption bands due to PPh_3.

Thermal Decomposition of Complex 1 and 5. Complex **1** (0.5 mmol) was decomposed by heating at 150 °C under nitrogen atmosphere and diethyl ether (2 ml) was added to the cooled thermolysis residue. After stirring the solution the amount of products formed on thermolysis was measured by means of gas chromatography.

Reactions of Alkylthiocopper Complexes with Alkyl Halide, Acyl Halide, Acid Anhydride, Vinyl Acetate, and Benezenethiol. Propyl bromide (2 ml) was introduced into a Schlenk type flask containing **3** (0.722 mmol) by a trap-to-trap distillation in a vacuum. After stirring the white emulsion at room temperature for 1 h a yellow solution was produced and finally a colorless supernatant and a white precipitate of bromocopper(I) complex were produced with further stirring the solution for 11 h. The mixture was filtered and the filtrate was introduced into another flask by distillation to remove copper compounds. The distillate was analyzed by means of gas chromatography to confirm the formation of dipropyl sulfide (yield 39% on the basis of Cu). Other products in the reactions of alkylthiocopper complexes with reagents were analyzed similarly.

Acetyl chloride (1.15 mmol) was added to a white emulsion of **3** (0.382 mmol) in diethyl ether (2 ml) and the mixture was stirred at room temperature overnight under nitrogen atmosphere to give *S*-propyl ethanethioate (yield 92% on the basis of Cu).

Acetic anhydride (0.5 ml) was added to a white emulsion of **2** (0.204 mmol) in diethyl ether (2 ml) and the mixture was stirred at room temperature overnight to produce *S*-propyl ethanethioate (yield 95% on the basis of Cu) and a white precipitate of $CH_3CO_2Cu(PPh_3)_2$ (yield 90%).

Vinyl acetate (2 ml) was introduced into a Schlenk type flask containing **4** (0.355 mmol) by a trap-to-trap distillation in a vacuum. The yellow solution was stirred at -10 to 0 °C for a day to give polyvinylacetate.

One ml of benzenethiol was added to complex **2** (0.20 g, 0.5 mmol) in diethyl ether (3 ml) and the mixture was stirred at 10 min to give a yellow solution. Further stirring it for 20 min gave a white precipitate. The precipitate was crystallized from toluene to give white crystals identified as PhSCu-PPh_3 (**6**) (191 mg, yield 88%). Complex **6**, mp 115—117 °C (dec.). Found: C, 67.0; H, 4.91; S, 7.27%. Calcd for $C_{24}H_{20}PSCu$: C, 66.3; H, 4.60; S, 7.36%. IR(KBr): 1570s, 1260w, 1075s cm^{-1} and absorption bands due to PPh_3. ^{1}H-NMR (C_6D_6): δ 6.7 (m, 5H, phenyl); δ 7.0 (m, 9H, *m,p*-phenyl of PPh_3); δ 7.5 (m, 6H, *o*-phenyl of PPh_3).

Transesterification Reactions between S-Alkyl Ethanethioates and Thiols with Alkylthiocopper Catalysts. *S*-Ethyl ethanethioate (4.86 mmol) was added into a flask containing propanethiol (11 mmol) and **2** (0.25 mmol). The yellow solution was stirred at room temperature overnight and the mixture was passed through a column of Wakogel C-200 (5 g) with diethyl ether to remove copper compounds. The solution was condensed under reduced pressure and the condensate was analyzed by means of gas chromatography to confirm the formation of *S*-propyl ethanethioate (yield 64% on the basis of starting *S*-ethyl ethanethioate) and thiol. The other transesterification reactions were carried in a similar way.

Reaction between S-Alkyl Ethanethioate and Alcohol with Alkoxocopper Catalyst. *S-t*-Butyl ethanethioate (10 mmol) was added to a solution containing ethanol (40 mmol) and EtOCu-$(PPh_3)_2$ (0.3 mmol). The mixture was stirred at room temperature overnight to produce ethyl acetate (yield 14% on the basis of thiol ester) and 1,1-dimethylethanethiol (yield 13%).

Synthesis of 2′,3′,4,4′,6′-Pentahydroxychalcone, an Aglycone of Carthamin, and Its Isomerization into 4′,5,6,7- and 4′,5,7,8-Tetrahydroxyflavanone, Carthamidin and Isocarthamidin[1)]

Heitaro OBARA,* Jun-ichi ONODERA, Yuji KURIHARA, and Fumitada YAMAMOTO
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992
(Received June 10, 1978)

2′,3′,4,4′,6′-Pentahydroxychalcone (**4**), an aglycone of carthamin, was synthesized by the demethoxymethylation of 2′,3′,4,4′,6′-pentakis(methoxymethoxy)chalcone prepared by the condensation of 2,3,4,6-tetrakis(methoxymethoxy)acetophenone with *p*-methoxymethoxybenzaldehyde. **4** was converted into 4′,5,6,7- and 4′,5,7,8-tetrahydroxyflavanone (**5** and **6**) by boiling with methanolic hydrochloric acid. On the basis of the comparisons of the properties of **5** and **6** with those of carthamidin (**A**) and isocarthamidin (**B**) derived from natural product, the structures originally assigned for **A** and **B** should be reversed.

In 1930, Kuroda[2)] obtained two flavanones, carthamidin (**A**) and isocarthamidin (**B**), by the hydrolysis of carthamin, the red coloring matter of the flowers of Safflower (*Carthamus tinctorius* L.) and proposed the structures of 4′,5,7,8- and 4′,5,6,7-tetrahydroxyflavanone (**6** and **5**) for **A** and **B**, respectively. However, the identification of **A** and **B** has not yet been accomplished synthetically. In 1949, Seshadri *et al.*[3)] reported the synthesis of **5** and **6** by the demethylation of the corresponding tetramethoxyflavanones in the presence

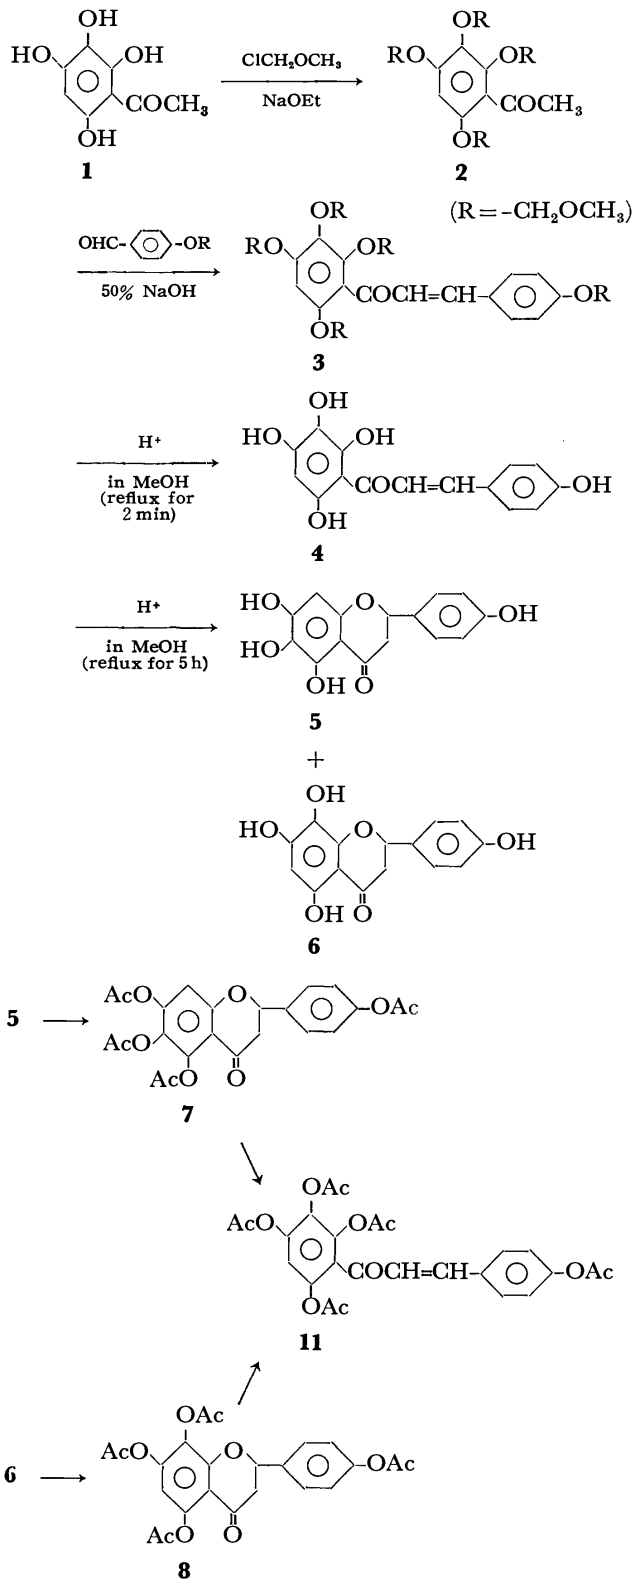
a) In DMSO-d_6. b) In $CDCl_3$.

of anhydrous aluminium chloride in benzene solution, but the direct comparisons with the natural products were not undertaken.

In this paper, we wish to report the synthesis of 2′,3′,4,4′,6′-pentahydroxychalcone (**4**) and its isomerization into 4′,5,6,7- and 4′,5,7,8-tetrahydroxyflavanone (**5** and **6**) and, furthermore, the new fact that the structures originally assigned for **A** and **B** should be reversed from the comparisons of the properties of **5** and **6** with those of **A** and **B** derived from the natural product.



Scheme 1.

The alkaline condensation of 2,3,4,6-tetrakis(methoxymethoxy)acetophenone (**2**) prepared by the methoxymethylation of 2,3,4,6-tetrahydroxyacetophenone (**1**) with *p*-methoxymethoxybenzaldehyde afforded 2′,3′,4,-4′,6′-pentakis(methoxymethoxy)chalcone (**3**) as a pale yellow viscous oil. The subsequent demethoxymethylation of **3** with dilute hydrochloric acid in methanol gave 2′,3′,4,4′,6′-pentahydroxychalcone (**4**). The structure of this chalcone was identified by its conversion into 2′,3′,4,4′,6′-pentamethoxychalcone, which was identified by a comparison of the melting point, UV, and IR spectrum with those of an authentic sample.[2]

A mixture of 4′,5,6,7- and 4′,5,7,8-tetrahydroxyflavanone (**5** and **6**) was obtained by boiling **4** with dilute hydrochloric acid in methanol; it was chromatographed on a column of silica gel to give **5** and **6**, both in 25% yields. 4′,5,6,7- and 4′,5,7,8-Tetraacetoxyflavanone (**7** and **8**) were obtained by acetylation of **5** and **6** with acetic anhydride–sulfuric acid and both **7** and **8** afforded 2′,3′,4,4′,6′-pentaacetoxychalcone (**11**) by heating with a mixture of acetic anhydride and sodium acetate.

The structure of **5** and **6** were confirmed by the elemental analyses, by the studies of their UV, IR, and PMR spectra, and by the comparison of their tetramethyl ethers with the authentic samples of 4′,5,6,7-[4] and 4′,5,7,8-tetramethoxyflavanone[5] (**9** and **10**), prepared in a manner similar to that in the literature. The PMR spectral data of **5**, **6**, **7**, **8**, **9**, and **10** are shown in Table 1.

While Kuroda[2] proposed the structures **6** and **5** for carthamidin (**A**), mp 220 °C, and isocarthamidin (**B**), mp 240 °C, on the basis of the color phenomena of their hydroxyl groups, the IR spectra of **A** and **B** obtained from carthamin according to Kuroda's method[2] were identical with those of the synthetic **5** and **6**, respectively. Accordingly, it was proved that the old structures assigned for carthamidin (**A**) and isocarthamidin (**B**) should be reversed, as mentioned above. Finally, the comparison of the melting points of the synthetic **5**, **6**, **7**, **8**, and **11** with those of the derivatives of carthamin reported by Kuroda[2] are shown in Table 2.

Table 2. The melting points of the synthetic and reported **5**, **6**, **7**, **8**, and **11**

Compound	Synthesized (°C)	Reported (°C)
4′,5,6,7-Tetrahydroxyflavanone (**5**)	218	240
4′,5,7,8-Tetrahydroxyflavanone (**6**)	248	220
4′,5,6,7-Tetraacetoxyflavanone (**7**)	160	180
4′,5,7,8-Tetraacetoxyflavanone (**8**)	178	158
2′,3′,4,4′,6′-Pentaacetoxychalcone (**11**)	142	142

Experimental

All the melting points were uncorrected. The UV and IR spectra were recorded with a Hitachi 135 spectrophotom-

eter and Hitachi EPI-S2 spectrophotometer, respectively. The PMR spectra were measured with a Hitachi R-22 spectrometer (90 MHz), using tetramethylsilane as an internal standard. The mass spectra were obtained on a Hitachi RMU-6M mass spectrometer.

2,3,4,6-Tetrahydroxyacetophenone (1). Into a mixture of 20 g of 1,2,3,5-benzenetetrol,[6] 10 g of acetonitrile, and 7 g of anhydrous zinc chloride in 200 ml of dry ether, dry hydrogen chloride gas was passed for 3 h under cooling with ice water, and the reaction mixture was left to stand overnight at 0 °C. After the solvent was removed by decantation, the residue was refluxed with 600 ml of water for 3 h. The reaction mixture was decolored with charcoal and filtered. After cooling, **1** was obtained from the filtrate as light yellow needles (16.8 g, 65%), mp 236—238 °C (lit,[7] 206—208 °C); MS *m/e* 184 (M^+); IR (KBr) 1630 cm^{-1} (C=O); PMR (DMSO-d_6) δ 2.60 (3H, s, -OAc), 6.02 (1H, s, C_5-H), 9.98, 11.18, and 12.18 (4H, -OH). Found: C, 52.39; H, 4.63%. Calcd for $C_8H_8O_5$: C, 52.18; H, 4.38%. Tetramethyl ether, mp 55—56 °C (lit,[2] 54 °C). Found: C, 60.33; H, 6.95%. Calcd for $C_{12}H_{16}O_5$: C, 59.99; H, 6.71%. Tetraacetate, mp 110—111 °C. Found: C, 54.61; H, 4.70%. Calcd for $C_{16}H_{16}O_9$: C, 54.55; H, 4.58%.

2,3,4,6-Tetrakis(methoxymethoxy)acetophenone (2). Into a solution of **1** (5 g) in 100 ml of absolute ethanol was added one fifth volume of a solution of sodium (8.8 g) in 140 ml of absolute ethanol with stirring at 15—20 °C. After 30 s, one fifth volume of chloromethyl ether (31 g) was added to the above solution over a 5 min interval with stirring at 15—20 °C, this operation was repeated four times under the same conditions. After the addition was completed, the reaction mixture was stirred for 10 min at 40 °C. The solvent was removed *in vacuo* and 100 ml of water was added to the residue and extracted with ether. The ether was evaporated to give an oily residue, which was chromatographed over silica gel. Elution with benzene–ethyl acetate (4: 1) afforded **2** as a light yellow oil (2.9 g, 30%). IR ($CHCl_3$) 1963 cm^{-1} (C=O); PMR ($CDCl_3$) δ 2.53 (3H, s, -OAc), 3.49, 3.51, 3.53, and 3.62 (8H, s, $-CH_2-\times 4$), 5.12, 5.16, 5.17, and 5.24 (12H, s, $-CH_3\times 4$), 6.86 (1H, s, C_5-H). Found: C, 52.99; H, 6.61%. Calcd for $C_{16}H_{24}O_9$: C, 53.33; H, 6.71%.

2′,3′,4,4′,6′-Pentakis(methoxymethoxy)chalcone (3). To a mixed solution of **2** (600 mg) and *p*-methoxymethoxybenzaldehyde (510 mg) in 12 ml of methanol was added 6 ml of 50% aqueous sodium hydroxide solution with stirring at room temperature. After standing overnight, the reaction mixture was poured into cold water and extracted with ether. The evaporation of the solvent gave an oily residue, which was chromatographed over silica gel. Elution with benzene–ethyl acetate (4: 1) afforded **3** as a viscous light yellow oil (830 mg, 98%). IR ($CHCl_3$) 1640 cm^{-1} (C=O); PMR ($CDCl_3$) δ 3.34, 3.36, 3.42, 3.49, and 3.57 (15H, s, $-CH_3\times 5$), 5.05, 5.07, and 5.18 (6H, s, $-CH_2-\times 3$), 5.13 (4H, s, $-CH_2-\times 2$), 6.78 (1H, s, $C_{5'}$-H), 6.99 (2H, d, J=8.5 Hz, $C_{3,5}$-H), 7.43 (2H, d, J=8.5 Hz, $C_{2,6}$-H), 6.85 (1H, d, J=16.0 Hz, C_α-H), 7.32 (1H, d, J=16.0 Hz, C_β-H). Found: C, 59.44; H, 6.65%. Calcd for $C_{25}H_{32}O_{11}$: C, 59.05; H, 6.34%.

2′,3′,4,4′,6′-Pentahydroxychalcone (4). A mixture of **3** (400 mg) and 6 M hydrochloric acid (6 ml) in 16 ml of methanol was refluxed for 2 min. After cooling, the reaction mixture was poured into 30 ml of cold brine and extracted with ether. The ether layer was dried over anhydrous sodium sulfate and concentrated to about 10 ml *in vacuo*. A small quantity of petroleum ether was added to the concentrated solution to give **4** as yellow crystals (170 mg, 74%), mp 181 °C. UV (EtOH) max: 375 nm (log ε=4.47); IR (KBr) 1625 cm^{-1} (C=O); PMR (acetone-d_6) δ 6.07 (1H, s $C_{5'}$-H), 6.96 (2H, d, J=8.5 Hz, $C_{3,5}$-H), 6.73 (2H, d, J=8.5 Hz, $C_{2,6}$-H), 7.83 (1H, d, J=16.0 Hz, C_α-H), 8.24 (1H, d, J=16.0 Hz, C_β-H), 8.95, 11.36, and 11.54 (4H, s, OH). Found: C, 62.15; H, 4.54%. Calcd for $C_{15}H_{12}O_6$: C, 62.50; H, 4.20%.

Methylation of 4. A mixture of **4** (100 mg), potassium carbonate (2 g), and dimethyl sulfate (0.3 ml) in 20 ml of acetone was refluxed for 8 h. The reaction mixture was worked up in the usual manner and the crude product was chromatographed on a column of silica gel with benzene–ethyl acetate (4: 1) to give the methyl ether of **4** (50 mg, 40%), mp 92—93 °C. UV (EtOH) max: 326 nm (log ε=4.47); IR (KBr) 1640 cm^{-1} (C=O); PMR (acetone-d_6) δ 3.70 (6H, s, $-OMe\times 2$), 3.74, 3.77, and 3.87 (9H, s, $-OMe\times 3$), 6.52 (1H, s, $C_{5'}$-H), 6.77 (1H, d, J=16.0 Hz, C_α-H), 7.22 (1H, d, J=16.0 Hz, C_β-H), 6.90 (2H, d, J=8.5 Hz, $C_{3,5}$-H), 7.53 (2H, d, J=8.5 Hz, $C_{2,6}$-H). Found: C, 66.82; H, 6.31%. Calcd for $C_{20}H_{22}O_6$: C, 67.01; H, 6.19%. The UV, IR, and PMR spectra of this methyl ether were completely identical with those of 2′,3′,4,4′,6′-pentamethoxychalcone, mp 92—93 °C (lit,[2] 112 °C), which was prepared by the condensation of 2,3,4,6-tetramethoxyacetophenone with *p*-anisaldehyde.

Isomerization of 4 into 4′,5,6,7- and 4′,5,7,8-Tetrahydroxyflavanone (5 and 6). A mixture of **4** (500 mg) and 6 M hydrochloric acid (5 ml) in 40 ml of methanol was refluxed for 5 h. The reaction mixture was evaporated *in vacuo* and the resulting residue was extracted with ethyl acetate. The ethyl acetate solution was dried over anhydrous sodium sulfate, the solvent was removed *in vacuo*,and the residue was chromatographed on a column of silica gel. Elution with ether–petroleum ether–formic acid (24: 16: 1) afforded a mixture of **5** and **6**. The subsequent silica gel column chromatography with carbon tetrachloride–ether–acetic acid (8: 1: 1) afforded **5** (100 mg, 20%) and **6** (100 mg, 20%), respectively.

4′,5,6,7-Tetrahydroxyflavanone (5): Mp 218 °C (from chloroform); UV (EtOH) max: 300 nm (log ε=4.13) and 368 nm (log ε=3.18); IR (KBr) 1643 cm^{-1} (C=O). Found: C, 62.31; H, 4.40%. Calcd for $C_{15}H_{12}O_6$: C, 62.50; H, 4.20%.

Tetraacetate (7): Mp 158 °C; UV (EtOH) max: 313 nm (log ε=4.04) and 327 nm (log ε=3.63); IR (KBr) 1685 and 1775 cm^{-1} (C=O). Found: C, 60.22; H, 4.36%. Calcd for $C_{23}H_{20}O_{10}$: C, 60.52; H, 4.42%.

4′,5,7,8-Tetrahydroxyflavanone (6): Mp 248 °C; UV (EtOH) max: 299 nm (log ε=4.17) and 370 nm (log ε=3.52); IR (KBr) 1642 cm^{-1} (C=O). Found: C, 62.22; H, 4.68%. Calcd for $C_{15}H_{12}O_6$: C, 62.50; H, 4.20%.

Tetraacetate (8): Mp 178 °C; UV (EtOH) max: 264 nm (log ε=4.03) and 322 nm (log ε=3.52); IR (KBr) 1684 and 1770 cm^{-1} (C=O). Found: C, 60.22; H, 4.35%. Calcd for $C_{23}H_{20}O_{10}$: C, 60.52; H, 4.42%.

Methylation of 5. A mixture of **5** (50 mg), potassium carbonate (3 g), and dimethyl sulfate (2 ml) in 15 ml of dry acetone was refluxed for 1 h. The reaction mixture was worked up in the usual manner and the crude product was chromatographed on a column of silica gel with ether–petroleum ether (3: 1) to afford light yellow crystals. Recrystallization from methanol gave tetramethyl ether of **5** (27 mg, 46%), mp 120—121 °C; UV (EtOH) max: 280 nm (log ε=4.22) and 330 nm (log ε=3.68); IR (KBr) 1670 cm^{-1} (C=O). Found: C, 66.27; H, 5.85%. Calcd for $C_{19}H_{20}O_6$: C, 66.27; H, 5.85%. The IR spectrum of this compound was completely identical with that of the authentic sample of 4′,5,6,7-tetramethoxyflavanone (**9**) (mp 121 °C, lit,[4] 119.5—120.6 °C) prepared by the literature method.[4]

Methylation of 6. Tetramethyl ether of **6**, mp 114—116 °C (37%), was obtained in a similar manner to that

described above. UV (EtOH) max: 286 nm (log ε=4.23) and 332 nm (log ε=3.66); IR (KBr) 1673 cm^{-1} (C=O). Found: C, 66.09; H, 5.93%. Calcd for $C_{19}H_{20}O_6$: C, 66.27; H, 5.85%.

The IR spectrum of this compound was completely identical with that of the authentic sample of 4',5,7,8-tetramethoxyflavanone (**10**) (mp 114—115 °C, lit,[5] 138—140 °C) prepared by the literature method.[5]

*2',3',4,4',6'-Pentaacetoxychalcone (**11**).* This pentaacetate, mp 142 °C (lit,[2] mp 142 °C), was obtained by acetylation of **7** and **8** in a manner similar to that described by Kuroda.[2] UV (EtOH) max: 313 nm (log ε=4.47); IR (KBr) 1640 and 1770 cm^{-1} (C=O); PMR ($CDCl_3$) δ 2.09, 2.11, and 2.27 (9H, s, -OAc×3), 2.22 (6H, s, -OAc×2), 7.12 (1H, s, $C_{5'}$-H), 6.83 (1H, d, J=16.0 Hz, C_α-H), 7.43 (1H, d, J=16.0 Hz, C_β-H), 7.11 (2H, d, J=8.5 Hz, $C_{3,5}$-H), 7.54 (2H, d, J=8.5 Hz, $C_{2,6}$-H).

*Carthamidin (**A**) and Isocarthamidin (**B**).* Both **A**, mp 218 °C (lit,[2] 220 °C), and **B**, mp 248 °C (lit,[2] mp 240 °C), were obtained by hydrolysis of carthamin according to Kuroda's method.[2] The IR spectra of **A** and **B** were identical with those of **5** and **6**, respectively.

The present work was partly supported by a Grant-in Aid for Scientific Research from the Ministry of Education.

The Hydrocracking of Alkyl-substituted Polynuclear Aromatic Hydrocarbons over $ZnCl_2$/CuCl Molten Salt Catalyst[1)]

Yohji NAKATSUJI,* Yasuhiko IKKAKU, Masakatsu NOMURA, and Shōichi KIKKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received April 13, 1978)

The hydrocracking of alkyl derivatives of polynuclear aromatic hydrocarbons (naphthalene, anthracene, dihydroanthracene, phenanthrene, and dihydrophenanthrene) over $ZnCl_2$/CuCl molten salt was examined at 400 °C for 3 h in a batch autoclave system. The kinds of alkyl groups, the positions of the alkyl groups, and the types of condensed rings were changed in order to clarify the decomposition process of the polynuclear aromatic hydrocarbons. On the basis of the detailed product distribution obtained by using GC-MS, the behavior of the alkyl group attached to the condensed ring under these reaction conditions was found to be different. Generally, in this investigation, the alkyl group was not completely dealkylated in the initial stage and remained in the products as monocyclic aromatics; the extent of dealkylation was found to be dependent upon the type of starting materials. In the hydrocracking of 9,10-dihydroanthracene, dehydrogenation occurred in preference to the opening of the central ring.

Hydrocracking is one of the important methods of obtaining liquid fuels from coal. In order to obtain the fundamental data with regard to the hydrocracking of coal, we have already employed the following model substances: 1) A pure substance:[2)] The properties of the starting material are known and the reaction process will be easily deduced. 2) A heavy anthracene oil:[3)] The NMR analyses can be applied, and the main components can be determined by using analytical methods (ex. GC-MS). 3) Solvent refined coal (SRC):[4)] This is considered to be representative of the structure of coal. The NMR analyses can be applied, but the constituents cannot be determined.

Previously,[2)] we used polynuclear aromatic hydrocarbons (anthracene, phenanthrene, pyrene, chrysene, and fluoranthene), which were supposed to be structural units of bituminous coal, as the model substances. The detailed product distributions and the differences of the catalytic activities among some molten salts were presented and discussed. The $ZnCl_2$/CuCl molten salt was found to be one of the superior hydrocracking catalysts for polynuclear aromatic hydrocarbons.

In the study of structural units of coal, one of the major problems is to understand the behavior of the substituents which attach to the condensed aromatic rings in the hydrocracking reaction. From this standpoint, we will apply the findings reported in the previous paper[2)] to interprete the results obtained in the hydrocracking of alkyl-substituted polynuclear aromatic hydrocarbons, in order to clarify the effect of the alkyl substituents on the product distributions. The characteristic behavior of the alkyl groups on the starting material and the decomposition process will be described in this paper.

Experimental

General Procedure. A stainless steel vessel containing 8 g of feed (in the case of the unsubstituted aromatic hydrocarbon) and an equimolar amount of the catalyst ($ZnCl_2$: CuCl=60 mol %: 40 mol %) was placed in a stainless steel (SUS 32) autoclave with a capacity of 200 ml. In the hydrocracking of an alkyl-substituted or dihydro aromatic hydrocarbon, the quantity of feed used was equimolar with the unsubstituted derivative containing the same condensed ring. Hydrogen was introduced into the autoclave to achieve a pressure of 100 kg/cm^2; then the autoclave was heated up to the desired temperature. This took from 60 to 70 min. The reaction system was shaken in a horizontal direction (68 strokes/min) and maintained at 400 °C for 3 h. No attempts were made to maintain the hydrogen pressure at a constant level during the reaction. The identification and the determination of the products were carried out according to the methods described previously.[2)]

Materials. The naphthalene (Ia), 2,6-dimethylnaphthalene (Id), and fluorene (VII) were obtained from Wako Pure Chemical Industries, Ltd. The 1-methylnaphthalene (Ib), 2-methylnaphthalene (Ic), anthracene (IIa), and 9,10-dihydroanthracene (Va) were obtained from Nakarai Chemicals, Ltd. The phenanthrene (IIIa) and chrysene (IV) were obtained from the Tokyo Kasei Kogyo Co., Ltd. 9-Methylanthracene (IIb) and 9-propylanthracene (IIc) were prepared by the reaction of anthrone with methylmagnesium iodide and propylmagnesium bromide respectively.[5)] 2-Methylanthracene (IId) was prepared by the reduction of 2-methylanthraquinone with zinc dust in NaOH aqueous solution and toluene.[6)] 9,10-Dihydro-9-methylanthracene (Vb) was prepared from Va and methyl iodide by using BuLi.[7)] Similarly, 9,10-dihydro-9,10-dimethylanthracene (Vc) was synthesized by using Vb as the starting material. 9-Methylphenanthrene (IIIb) was prepared from 9-bromophenanthrene and methyl iodide in the presence of BuLi.[8)] 9-Bromophenanthrene was prepared by the addition of bromine to IIIa, followed by thermal elimination of hydrogen bromide. 9,10-Dihydro-9-methylphenanthrene (VI) was prepared by the reduction of IIIb by using Li in liquid NH_3 in the presence of iron(III) chloride.[8)] All the purities of these compounds, determined by GC, were more than 95%. The zinc chloride and copper(I) chloride were obtained from Nakarai Chemicals, Ltd. The mixture of $ZnCl_2$ and CuCl was dried before use at 400 °C for 1 h in nitrogen.

Classification of Products. In order to clarify the reactivity of the starting material over the molten salt, it is necessary to know the product distribution. The products were classified for convenience into seven groups as follows: **1**, C_1-C_4 gases; **2**, C_5-C_7 alkanes; **3**, cycloalkanes; **4**, monocyclic aromatics; **5**, indans, tetralins, and bicyclic aromatics; **6**, dihydrobenzindenes, tricyclic aromatics, and their hydrogenated compounds; **7**, coke.

Results and Discussion

Table 1 shows the product distributions according to the classification described in the experimental section. The reaction conditions were decided by considering the extent of the progress of the hydrocracking, because a high conversion is required in order to discuss the reaction process of hydrocracking based on the product distribution.

Influence of the Number of Rings in the Condensed Aromatic Hydrocarbon. Table 1 shows that the yield of cycloalkanes(**3**) increases with increasing number of rings, from the comparison of the results of naphthalene (Run 1), phenanthrene(Run 9), and chrysene(Run 11). Here, the yield of **3** in the hydrocracking of naphthalene is much lower than that in the hydrocracking of anthracene, phenanthrene, and chrysene. This finding strongly indicates that the cleavage of the C–C bonds of the central rings in highly hydrogenated polynuclear aromatic hydrocarbons containing more than three rings (ex. *unsym*-octahydroanthracene, *unsym*-octahydrophenanthrene, and so on) is one of the main decomposition pathways. Actually, the decomposition of *unsym*-octahydrophenanthrene to 1-cyclohexyl-2-phenylethane in the hydrocracking of phenanthrene and a similar cleavage in the hydrocracking of chrysene were found and reported in the previous paper.[2] This finding also demonstrates that the contribution of the pathway *via* decalin to the decomposition process of naphthalene is minor,[9] and that this type of catalyst is relatively inactive for the hydrogenation and hydrocracking of monocyclic aromatics. The latter seems to be desirable for obtaining a high yield of gasoline.[10]

Influence of Kinds of Alkyl Groups in the Hydrocracking of Anthracenes. Tables 2 and 3 describe the compositions of gases(**1**) and monocyclic aromatics(**4**) respectively. The behavior of the alkyl group can be deduced by using these results, because the difference in the composition of **1** or **4** between the alkyl polynuclear aromatic hydrocarbon and the corresponding unsubstituted compound is apparent. First we will discuss the results for anthracene derivatives and compare the reactivity of IIb with that of IIc. Two experiments(Runs 6 and 7) were carried out to investigate the difference of the composition of the products in accordance with the change in the alkyl group. The relative content of methane in Run 6 is higher than that in Run 5. Similarly the relative content of propane in Run 7 is quite a bit higher than that in Run 5. These findings show that the alkyl group is eliminated in the course of hydrocracking. In the case of methyl-substituted polynuclear aromatics, the ratio of benzene to toluene(R) is supposed to indicate the extent of demethylation, because the

value may increase with increasing demethylation according to the main reaction scheme, as shown later (*cf.* Fig. 1), and we used this ratio as a convenient measure of demethylation. The comparison of R in Run 6 with R in Run 5 shows that the methyl group of IIb is conserved in monocyclic aromatics in the course of hydrocracking. The ratio of the yield of unsubstituted tricyclic compounds to that of alkylated tricyclic compounds was 8.9 in the case of IIc and 2.3 in the case of IIb. In addition, the composition of monocyclic aromatics in Run 7 was very similar to that in Run 5. All of these findings indicate that the propyl group is dealkylated more easily than the methyl group. Similar phenomena were observed in the hydrocracking of alkylbenzenes in the presence of acidic catalysts.[11] These findings may be explained by considering that propylanthracene possesses the possibility of isomerization to isopropylanthracene and that the secondary alkyl group can be dealkylated in preference to the primary alkyl group.[11,12] The similarity between IIa and IIc in the composition of monocyclic aromatics would demonstrate that the propyl group of IIc is mainly dealkylated in the initial decomposition stage. On the other hand, the decomposition process of the marginal hydrogenated rings prior to dealkylation is also considered to be of importance in the case of IIb.

Influence of Positions of Alkyl Groups and Types of Condensed Rings. Since the presence of methyl group remarkably influenced the decomposition of the polynuclear aromatics, the methyl derivatives were used for the following experiments. The experiments of IIb and IId were carried out to clarify the effect of the position of methyl group attached to the anthracene skeleton on the composition of the decomposed products. The value of R in IId is lower than that in IIb; this finding suggests that the methyl group of IId is well conserved in monocyclic aromatics in comparison with that of IIb. This result is interpreted by the idea that the demethylation prior to the hydrocracking of the condensed ring has a minor contribution to the reaction process in the hydrocracking of IId, that is, the methyl group of IIb is eliminated more easily than that of IId. The experiments of IIb and IIIb were carried out to clarify the difference of the type of condensed rings. The ease of demethylation in the initial decomposition process differs in these two cases. The methyl group of IIIb is conserved in monocyclic aromatics much more frequently than that of IIb. It is noteworthy that the composition of monocyclic aromatics of IV is fairly similar to that of IIIa. The effect of the presence of the methyl group on the composition of monocyclic aromatics (Run 10) is observed more dramatically than that of the increase of the number of the aromatic rings(Run 11).

Hydrocracking of Naphthalenes. It is noteworthy that a remarkable difference in the R values was observed

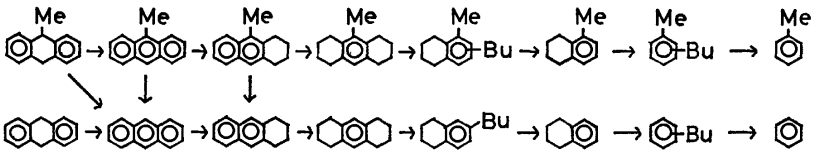

Fig. 1. Main reaction scheme of dihydroanthracene derivatives.

in the hydrocracking of naphthalene derivatives(Runs 1—3). This finding suggests that the unsubstituted ring is more easily hydrogenated than the methylated ring. This fact is the basis for asserting that the alkyl groups on the polynuclear aromatic hydrocarbons influence the composition of monocyclic aromatics in this hydrocracking. The effect of the position of the methyl group on the composition of monocyclic aromatics was hardly observed in the case of Ib and Ic(Runs 2 and 3). The experiment of Id (Run 4) seems to be most suitable for investigating the demethylation. If Id never undergoes the demethylation, the yield of benzene should become zero. The presence of a little quantity of benzene demonstrates the occurence of demethylation; however, the contribution of the demethylation in the initial stage to the composition of monocyclic aromatics seems rather insignificant.

Hydrocracking of Dihydro Tricyclic Aromatics. The hydrocracking of Va is of importance for clarifying the decomposition process of IIa.[13–15] If the central methylene bridge of Va is ruptured, the yield of monocyclic aromatics should increase remarkably compared with IIa. However, the product distributions of these two hydrocracking reactions are similar: Va seems to undergo dehydrogenation, followed by the decomposition process, in a way similar to IIa. The experiments of Vb and Vc were carried out in anticipation of the specific reaction caused by introducing the methyl group(s) to the central carbon atom(s) of 9,10-dihydroanthracene. The product distribution of Vb(Run 13) is successfully explained by considering that the dehydrogenation and demethylation occurred in the initial stage; that is, Vb was mainly decomposed *via* IIa or IIb. Vc is also considered to be decomposed in a manner similar to Vb, and so the opening of the central ring of this type of compound is considered to be small in this hydrocracking reaction. Fig. 1 shows the main decomposition scheme of 9,10-dihydroanthracene derivatives. The ease of dealkylation of the butyl group compared with the methyl group is considered to govern this decomposition process. If the C_{8a}–C_9 bond of VI is fairly well cleaved, the yield of biphenyl derivatives in the hydrocracking of VI should be higher than that in the hydrocracking of IIIb. However, no such increase of the yield of biphenyl derivatives could be observed, and so VI seems to undergo demethylation and dehydrogenation in the initial decomposition process. On the other hand, the pathway to the biphenyl derivatives becomes very important in the case of VII, because VII has no pathway of dehydrogenation to the stable aromatic compounds. In this case, the lowering of the reactivity was observed.

Conclusion

The hydrocracking of alkyl-substituted polynuclear aromatic hydrocarbons was carried out to clarify the decomposition scheme and the behavior of the alkyl group. The findings are outlined as follows: 1) The decomposition route *via* highly hydrogenated compounds becomes important with increasing numbers of rings of the polynuclear aromatics. 2) The alkyl group substituted on the polynuclear aromatic hydrocarbon is not completely dealkylated in the initial stage and remains in the products as monocyclic aromatics. The extent of dealkylation depends on the properties (that is, kinds and positions of alkyl groups, and types of condensed rings) of the starting materials. 3) In the hydrocracking of 9,10-dihydroanthracene, the dehydrogenation occurs in preference to the opening of the central ring; in the hydrocracking of the methylated 9,10-dihydroanthracenes and 9,10-dihydrophenanthrene, the dehydrogenation and demethylation take place in preference to the opening of the central ring; but in the hydrocracking of fluorene, the pathway to the biphenyls becomes important. These findings are expected to be useful for understanding the hydrocracked mechanism and the composition of the resulting products of coal.

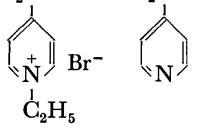
Optical Spectra of the Picrate Ion in Micellar and Polymer Micellar Systems. Comment on the Solvation of Anions

Seiji SHINKAI,* Toyoko IDE, and Osamu MANABE
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received January 27, 1978)

Synopsis. The optical spectra of the picrate ion in a micellar solution indicate that slightly below the CMC of CTAB surfactant the anion is relatively free and exists as an ion pair above the CMC. The hydrophobic aggregate of TMAC invariably gives free ion. The polymer micelle of quaternized poly(4-vinylpyridine) results in a tight ion pair.

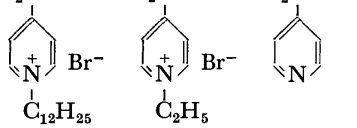
Anionic nucleophiles are activated to a great extent in cationic hydrophobic aggregates such as micelles and polymer micelles.[1] The unusual activation is mainly attributed to the formation of hydrophobic ion pairs which are relatively "desolvated" in the hydrophobic domain.[2-6] Thus, it would be valuable to estimate the degree of solvation as a function of surfactant concentrations. According to Bourgoin *et al.*,[7] bathochromic shifts observed in the optical spectra of alkali picrates can be rationalized in terms of the formation of the free ion, and the apolar environment is characterized by a shoulder at around 400 nm. The spectrum of the picrate ion would thus be most useful for confirmation. We have measured the optical spectra of the picrate ion in the presence of hexadecyltrimethylammonium bromide (CTAB), sodium dodecyl sulfate (SDS), Brij-35, trioctylmethylammonium chloride (TMAC), and the following quaternized poly(4-vinylpyridine) polymers (4VP-D-0 and 4VP-D-22).[6] Typical results are summarized in Table 1.

4VP-D-0: —CH_2CH——CH_2CH—



85 mol % 15 mol %

4VP-D-22: —CH_2CH——CH_2CH——CH_2CH—



22 mol % 42 mol % 36 mol %

The λ_{max} of the picrate ion in an aqueous solution appeared at 355 nm. Addition of CTAB caused marked bathochromic shifts, the largest shift to 380 nm being observed at [CTAB]$=1.0\times10^{-4}$ M. This is comparable with the λ_{max} value of triethylammonium picrate in dimethyl sulfoxide (377 nm)[8] or of potassium picrate in tetrahydrofuran containing excess crown ether (380 nm).[7] Since the critical micelle concentration (CMC) of CTAB (determined by use of 2,6-dichlorophenolindophenol) is 4.0×10^{-4} M, the picrate ion is relatively free slightly below this. Further increase in CTAB concentration caused hypsochromic shifts to 350 nm with a new absorption maximum at 422 nm. The final spectrum at [CTAB]$=2.0\times10^{-3}$ M (λ_{max}, 350 and 412 nm) was similar to that in tetrahydrofuran (357 and 420 nm for the K^+ ion pair[7]) and 354 and 432 nm for the $HNEt_3^+$ ion pair). The results indicate that the nature of the picrate ion changes with increase in CATB concentration: hydrated (with hydrogen-bond)→dehydrated (without hydrogen-bond) and free→dehydrated and ion-paired.

Table 1. Absorption maxima and shoulders of picrate ions in the presence of surfactants[a]

	0.04	375	(4.35)	+	
	0.06	377	(4.38)	+	
	0.08	374	(4.38)	+	
	0.10	374	(4.37)	+	

a) 30 °C, pH 7.1 with 0.02 M phosphate (KH_2PO_4–K_2HPO_4) buffer, [picrate ion (added as picric acid)]$=3.90\times10^{-5}$M. b) "+" indicates that distinct shoulder appears but the absorption maximum cannot be determined clearly. c) The polymer concentration stands for the total concentration of monomeric units.

No appreciable shift was observed in the presence of SDS and Brij-35 above their CMC's (Table 1).

TMAC, a typical phase transfer catalyst, forms aggregates at very low concentrations (10^{-5}—10^{-4} M). They seem to be much smaller than the conventional globular micelles and enhance the nucleophilicity of the bound anions more than the conventional cationic micelles.[9] The λ_{max} values at [TMAC]$=0.04$—0.1 mM always appear in the range 374—377 nm (Table 1), indicating that the TMAC aggregate provides a relative-

ly free picrate ion. The result indicates that the nucleophilic reactivity of the anion bound to the TMAC aggregate is enhanced due to the desolvation to a greater extent than that bound to the conventional cationic micelle.[9]

It has been established on the basis of absorption and emission spectra of dye molecules that 4VP-D-0 is classified as a simple polyelectrolyte and 4VP-D-22 as a polymer micelle which possesses the hydrophobic domain.[6,10,11] The spectrum of the picrate ion was scarcely affected by 4VP-D-0, while addition of 4VP-D-22 caused appreciable bathochromic shifts to 360 nm accompanied by the appearance of a shoulder at around 400 nm. Further increase in the concentration of 4VP-D-22 did not change the spectrum. This indicates that the picrate ion pair formed in the polymer micelle is relatively tight.

Free, dehydrated picrate ion is formed at slightly below the CMC of CTAB. On the other hand, once the micelle formation takes place, the ion pair becomes relatively tight probably due to the apolar environment. It is suggested that the local hydrophobic domain is preferred to the globular hydrophobic domain of the micelle to produce the free ion. The TMAC aggregate may be the case.

Although the multi-phase dependence of the bimolecular reaction rate in the micellar catalysis has been rationalized in terms of concentration and dilution of reactants by micelles,[12–14] the present study indicates that the reactivity of the anion may be also dependent on surfactant concentrations.

Optical and Magnetic Properties of Crystalline Phenothiazine Cation Radical Salts

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 10, 1978)

Synopsis. Crystalline phenothiazine cation radical salts show charge-transfer transition between cation radicals in the low-energy region. These salts have antiferromagnetic exchange interaction between cation radicals. Their optical and magnetic properties were discussed in terms of one-dimensional Hubbard model.

The prominent magnetic, electrical and optical properties of a number of crystalline ion radical salts have been the subject of many theoretical and experimental investigations over the past fifteen years.[1-8] In such ion radical salts, the ion radical molecules are known to form, in themselves, a segregated stacking into infinite one-dimensional columns so as to make a large overlap between their half-occupied molecular orbitals.[1-8] In this case, since any individual radical molecule interacts through charge-transfer most strongly with two other neighboring radicals, the electronic spectrum of the solid salt differs distinctly from the monomer spectrum of the radical ion in solution but shows a charge-transfer transition between ion radicals in the low-energy region.[1-4] In a previous paper,[6] we applied one-dimensional Hubbard model to the columns of ion radical molecules, and investigated the optical properties of solid ion radical salts. In the present paper, we examined the optical and magnetic properties of several crystalline phenothiazine cation radical salts on the basis of such a model.

Phenothiazine (PT) is a strong electron donating molecule and forms chemically stable cation radical salts with various counter anions. Several years ago,[2] we prepared such cation radical salts as $PT^{+\cdot}Br^-$, $PT^{+\cdot}HSO_4^-\cdot H_2O$, and $PT^{+\cdot}C_6H_2(NO_2)_3O^-$ (picrate). Moreover, Sato *et al.* synthesized the salts with antimony pentachloride anions.[3] The absorption spectrum of the phenothiazine cation radical monomer dissolved in dilute hydrochloric acid has a weak band around 13500 cm^{-1} composed of several vibrational structures at 15000, 13500, and 12200 cm^{-1}, a strong band at 19300 cm^{-1} with a shoulder at 19900 cm^{-1} and a band at 22800 cm^{-1}.[2] On the other hand, the solid-state spectra of $PT^{+\cdot}Br^-$, $PT^{+\cdot}HSO_4^-\cdot H_2O$, and $PT^{+\cdot}C_6H_2(NO_2)_3O^-$ differ markedly from the monomer spectrum of the cation radical.[2] For example, the solid-state spectrum of $PT^{+\cdot}HSO_4^-\cdot H_2O$ is reproduced in Fig. 1, together with the absorption spectrum of the cation radical monomer. The solid-state spectrum shows a strong low-energy band at 12000 cm^{-1}, high-energy bands at 21100 and 23300 cm^{-1}, and a shoulder around 28000 cm^{-1}. The low-energy band at 12000 cm^{-1} has been assigned to the charge-transfer transition between the phenothiazine cation radicals in their segregated stacks, while the high-energy bands at 21100 and 23300 cm^{-1}, to the shifted bands of the cation radical monomer

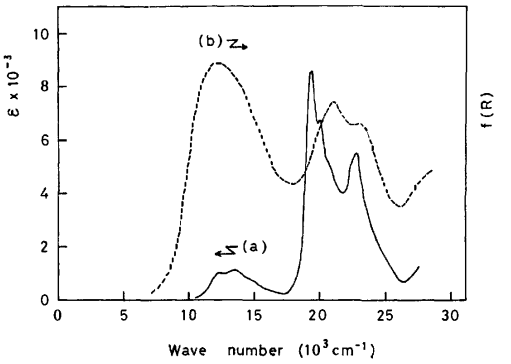

Fig. 1. (a) The absorption spectrum of the cation radical salt of phenothiazine hydrogen-sulfate monohydrate dissolved in hydrochloric acid and (b) the solid-state spectrum of the same salt. The solid-state spectrum was obtained by plotting the diffuse reflection spectrum using the Kubelka-Munk function, $f(R)=(1-R)^2/2R$, where R is the reflectance. See Ref. 2.

at 19300 and 22800 cm^{-1}, respectively.[2] The line shape of the charge-transfer absorption is almost symmetrical with respect to the axis of peak energy. The solid-state spectra of the bromide and the picrate are found to be very similar to that of the hydrogen-sulfate monohydrate salt. The charge-transfer absorptions of the bromide and picrate salts are located at 12900 and 12800 cm^{-1}, respectively.[2] On the other hand, according to Sato *et al.*,[3] the solid-state spectra of $PT^{+\cdot}SbCl_4^-$ and $PT^{+\cdot}SbCl_5^-$ salts are rather similar to the absorption spectrum of the phenothiazine cation radical monomer. The charge-transfer absorptions of these solid salts appear at 9350 and 10000 cm^{-1}, respectively. However, these absorptions have weak intensity and appear as a shoulder in the monomer spectrum of the cation radical.

In a previous paper,[6] we presented the theoretical line shape of the charge-transfer absorption on the basis of non-alternant one-dimensional Hubbard model. The shape of the absorption spectrum is given by

$$\sigma(\omega) \propto \frac{e^2}{4}\frac{I^2}{\omega^2\sqrt{\omega^2-I^2}}\sqrt{4T^2-\omega^2+I^2}. \quad (1)$$

Here, a δ-function was assumed for each elementary transition in which the spin and the wave vector of an electron are conserved; I is the intra-site Coulomb repulsion energy, and $T(<0)$ the transfer matrix element between nearest neighbor ion radicals in one-dimensional column of the phenothiazine cation radicals. A schematic representation of the absorption line shape of Eq. 1 has been given in Fig. 1 of Ref. 6. The theoretical charge-transfer absorption has a sharp divergent peak at $\omega=I$. The spectrum has no absorption in the region $\omega<I$, but has a distinct shoulder in the region $I<\omega<\sqrt{I^2+4T^2}$. Actually, however, the

elementary absorption is not a δ-function but involves a finite width, and the spectrum will become more smoothed,[6,7] so that the observed charge-transfer absorption has an intensity even in the energy region lower than the peak position. Then, the absorption peak of the observed charge-transfer band corresponds to $\omega=I$, and its band width comes partly from the width due to the elementary absorptions but partly from the width due to non-zero transfer matrix element, $\sqrt{I^2+4T^2}-I$. We divide the two contributions of the widths in a way similar to the previous work,[7] where the width, $\sqrt{I^2+4T^2}-I$, could be estimated by subtracting with respect to $\omega=I$, the lower-energy side from the higher-energy side of the observed charge-transfer absorption. For example, in the case of the $PT^{+\cdot}\cdot HSO_4^-\cdot H_2O$ salt (see Fig. 1, (b)), the observed peak energy of the charge-transfer absorption, 12000 cm^{-1}, thus corresponds to $I=12000$ cm^{-1}. From the observed line shape of the absorption, the width due to the transfer matrix element, $\sqrt{I^2+4T^2}-I$, is estimated to be of the order of 1500 cm^{-1}. This relation, together with $I=12000$ cm^{-1}, leads to the magnitude of the transfer matrix element, $|T|$, of the order of 3000 cm^{-1} or less in the hydrogen-sulfate monohydrate salt. In a similar way, from the observed solid-state spectra, the magnitudes of I for the bromide and the picrate are estimated to be 12900 and 12800 cm^{-1}, respectively. In both salts, the values of the transfer matrix element, $|T|$, again seem to be smaller than 3000 cm^{-1}. As for the $PT^{+\cdot}\,SbCl_4^-$ and $PT^{+\cdot}\,SbCl_5^-$ salts, from the observed charge-transfer absorptions, the I values are estimated to be 9350 and 10000 cm^{-1}, respectively, and the magnitudes of $|T|$ seem to be of the order of 1000 cm^{-1} or less. However, since those charge-transfer absorptions appear as a shoulder in the monomer spectrum of the phenothiazine cation radical, the estimated values of I and $|T|$ should be taken only as an indication.

In order to obtain more exact information on the magnitudes of the transfer matrix elements, we further examined the magnetic properties of solid phenothiazine cation radical salts. In a region of small $|T|$ limit, the Hubbard model leads to a stabilization of the antiferromagnetic state between ion radical molecules. For a pair of nearest neighbor ion radicals, if the small direct exchange is neglected, the energy gap between the parallel and antiparallel spin states is given by $2J=4T^2/I$. Therefore, we can well consider our solid phenothiazine cation radical salts as one-dimensional antiferromagnet with an exchange interaction, J.[8] By measuring the static magnetic susceptibility and its temperature dependence, Sato *et al.* reported the J values for $PT^{+\cdot}\,SbCl_5^-$, $PT^{+\cdot}\,SbCl_4^-$, and $PT^{+\cdot}\,Br^-$ to be 34, 270, and $\approx$970 cm^{-1}, respectively.[3] We also measured the magnetic susceptibility of the hydrogen-sulfate monohydrate.[2] It was found to be almost diamagnetic, indicating the J value of $\approx$800 cm^{-1}. Therefore, by using the relation $J=2T^2/I$, together with the I values determined previously, the $|T|$ values for $PT^{+\cdot}\,SbCl_5^-$, $PT^{+\cdot}\,SbCl_4^-$, and $PT^{+\cdot}\,Br^-$ are estimated to be 410, 1120, and $\approx$2500 cm^{-1}, respectively, while that for the hydrogen-sulfate monohydrate, to be of the order of 2200 cm^{-1}. Although the $|T|$ values estimated previously from the line shape of the charge-transfer absorptions include some uncertainties, for each of the salts the magnitude of the $|T|$ value obtained from the $|T|=\sqrt{J\,I/2}$ relation is found to agree with that estimated only from the spectroscopic data.

Turning back to the optical properties of those phenothiazine cation radical salts, we discuss how the intensity of the charge-transfer absorption is related to the $|T|$ value. According to our preliminary work,[9] the intensity of the charge-transfer absorption is roughly proportional to $|T|^2$. In this respect, the intensities of the charge-transfer absorptions of the bromide and the hydrogen-sulfate monohydrate should be the greatest, that of $PT^{+\cdot}\,SbCl_4^-$ should be intermediate, and that of $PT^{+\cdot}\,SbCl_5^-$, the weakest. In accordance with this prediction, the solid-state spectra observed with the former two compounds differ markedly from the phenothiazine cation radical monomer spectrum and show strong charge-transfer absorptions,[2] while the latter two compounds show only weak charge-transfer absorptions.[3] In particular, the solid-state spectrum of $PT^{+\cdot}\,SbCl_5^-$ is very similar to the monomer spectrum of the phenothiazine cation radical in solution.

On the basis of these considerations, we conclude that the phenothiazine cation radicals in the solid salts of the bromide, the hydrogen-sulfate monohydrate and the picrate stack, in themselves, very closely, while the intermolecular interaction between the phenothiazine cation radicals is weak in the solid $PT^{+\cdot}\,SbCl_4^-$ and $PT^{+\cdot}\,SbCl_5^-$ salts.

(Received March 20, 1978)

Synopsis. 2,3-(2,2′-Biphenylylene)-5-phenyltetrazolium chloride has been prepared. The ESR spectra of 2,3,5-triphenyltetrazolyl and 2,3-(2,2′-biphenylylene)-5-phenyltetrazolyl have been measured and their ESR coupling constants determined.

Since Deguchi and Takagi reported that 2,3,5-triphenyltetrazolium chloride with silver amalgam in 1,2-dimethoxyethane (DME) shows an ESR spectrum consisting of nine broad lines due to the hyperfine coupling of four equivalent N^{14} nuclei,[1] a few papers have been published concerning radicals of this type.[2]

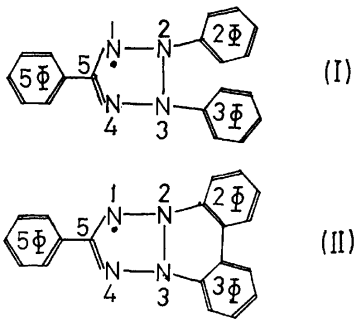

Fig. 1. Moleculer structure of 2,3,5-triphenyltetrazolyl radical (I) and 2,3-(2,2′-biphenylylene)-5-phenyltetrazolyl radical (II).

In this paper we will report the more detailed analyses of ESR spectra of radicals produced by alkali metal reduction from 2,3,5-triphenyltetrazolium chloride (TTC) and its photo-illuminated derivative; 2,3-(2,2′-biphenylylene)-5-phenyltetrazolium chloride (Photo-TTC).

Experimental

Commercial TTC was recrystallized from absolute ethanol by addition of dried ether. Photo-TTC was synthesized from the purified TTC following the photo-illumination method of Kuhn *et al.*[3] and the elementary analyses of carbon, hydrogen, nitrogen, and chlorine agreed with the values of the literature.

Found: H, 3.79; C, 68.38; N, 16.59; Cl, 10.56%. Calcd for $C_{19}H_{13}N_4Cl$: H, 3.91; C, 68.57; N, 16.84; Cl, 10.67%.

Each free radical was prepared *in vacuo* by contact reduction with alkali metal at −30——40 °C, the contact time being 1—2 s.

ESR spectra were observed using a X-band ESR apparatus equipped with 100 kHz field modulation.

Results and Discussion

2,3,5-Triphenyltetrazolyl (I). The ESR spectrum of 2,3,5-triphenyltetrazolyl obtained by reduction with potassium in DME is shown in Fig. 2a. In this spectrum the third line from the center is slightly flat and broader than the others. Thus the spectrum is satisfactorily analyzed if we assume the presence of two unequivalent pairs of N^{14} nuclei summarized in Table 1 from which the simulated spectrum (Fig. 2b) was calculated.

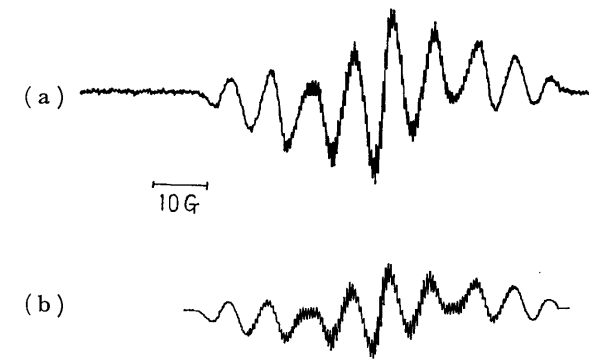

Fig. 2. ESR spectrum of radical (I) (2a) and its simulation (2b).

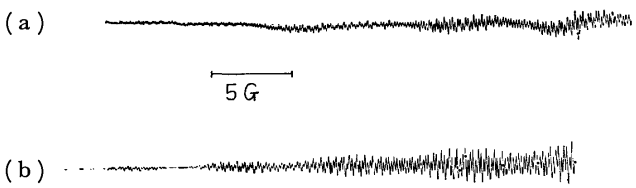

Fig. 3. Slightly more than one-half of ESR spectrum of radical (I) (better resolved than Fig. 2a) (3a) and its simulation (3b).

The better resolved spectrum is shown in Fig. 3a, and the simulated one using the coupling constant in the Table in Fig. 3b.

When the solution is kept in contact with alkali metal further, the color turns red and the ESR signal disappears. This suggests the formation of formazane in the solution, since formazane treated with alkali metal in the etheric solvent such as DME gives no ESR signal.

2,3-(2,2′-Biphenylylene)-5-phenyltetrazolyl (II). This radical was obtained by the same procedure as that for radical (I). The ESR spectrum of radical (II) (Fig. 4a) consists of twenty nine absorption lines were observed. Figure 4b shows the better resolved spectrum of radical (II) and Fig. 4c its simulated one calculated by the data in Table 1. The result reveals that *o,o′*-bridging between the two phenyl rings attached to the nitrogens at 2- and 3-positions of tetrazolium ring causes more conjugation of the two phenyl rings than in the case of TTC. The unpaired electron is, however,

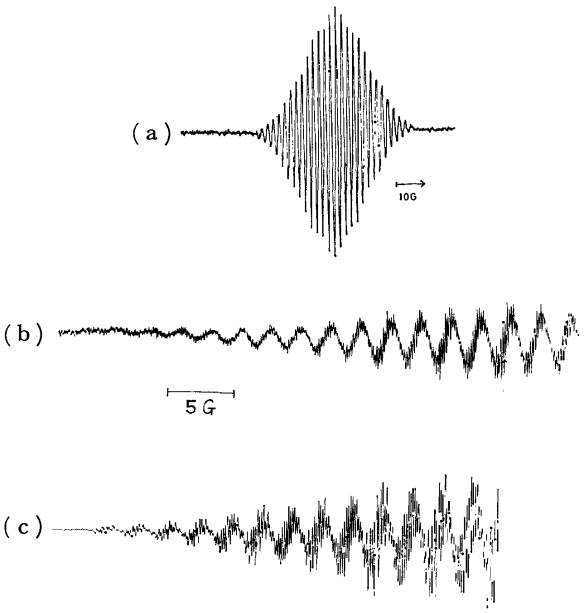

Fig. 4. ESR spectrum of radical (II) (4a), slightly more than one-half of ESR spectrum of radical (II) (better resolved than Fig. 4a) (4b), and its simulation (4c).

distributed to a greater extent to the tetrazolium ring rather than to the biphenylene ring. Both the results of Neugebauer[4] and the present MO calculation show that the distribution of the unpaired electron on the nitrogens does not differ remarkably between radicals (I) and (II).

Long contact of the solution with alkali metal, however, gives rise to the spectrum of benzo[*c*]cinnoline radical anion, the overall-width of which is about a half of that of radical (II). This result offers another evidence for the moleculer structure of Photo-TTC.[5]

The spectra of both radicals (I) and (II) do not change from 20 to —50 °C during observation. The same is true for those produced by sodium metal. Both experimental and calculated (by McLachlan method) data for radicals (I) and (II) are summarized in Table 1.

Table 1. Hyperfine splitting constants of radical (I) and radical (II)

	Radical (I)		Radical (II)	
	Found[a]	Calcd[b]	Found[a]	Calcd[b]
a_1^N	5.25G	4.61G	4.03G	4.00G
a_2^N	7.35	7.97	7.80	7.94
$a_{2\phi.o}^H$	0.90	1.63	1.95	1.74
$a_{2\phi.p}^H$	0.90	1.58	1.95	1.46
$a_{2\phi\ m}^H$	0.45	(−)0.63	0.39	(−)0.38
$a_{5\phi.o}^H$	0.30	(−)0.12	0.26	(−)0.11
$a_{5\phi.p}^H$	0.30	(−)0.10	0.26	(−)0.09
$a_{5\phi.m}^H$	—	0.0043	—	0.004

a) The values were determined by the analyses of the observed spectra referring to the simulated spectra. b) The values were estimated with the relations: $a_N=32.0\cdot|\rho_N^\pi|$ and $a_H=22.5|\rho_C^\pi|$. c) Parameters used in MO calculations are $h_{N1}=1.20$, $h_{N2}=1.50$, $k_{CN}=1.20$ and $k_{NN}=1.0$.

The authors appreciate the helpful discussions of Professors K. Ishizu and K. Mukai. Thanks are also due to Hideo Fujita for his help.

Hydrogenation and Dehydrogenation of 4-Isopropenyl-1-methylcyclohexene Catalyzed by MgO, CaO, La_2O_3, ThO_2, and ZrO_2

Yasutaka TANAKA, Hideshi HATTORI,* and Kozo TANABE*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 20, 1978)

Synopsis. 4-Isopropenyl-1-methylcyclohexene undergoes hydrogenation over ZrO_2 and ThO_2 to 4-isopropyl-1-methylcyclohexene, while it undergoes mainly dehydrogenation over MgO, CaO, and La_2O_3 to 1-isopropyl-4-methylbenzene. The activity variation of catalysts with pretreatment temperature and the reaction of 4-isopropyl-1-methyl-1,3-cyclohexadiene suggest that selectivity is determined by relative activity for hydrogenation to that for double bond isomerization.

In hydrogenation of diolefins, certain metal oxide catalysts exhibit characteristic selectivity which distinguishes the metal oxides from metallic hydrogenation catalysts. One characteristic of a metal oxide catalyst is partial hydrogenation to produce monoolefins selectively. Another is the 1,4-addition of hydrogen atoms to conjugated diolefins such as 1,3-butadiene and 2-methyl-1,3-butadiene. MgO,[1] ThO_2,[2] and ZrO_2[3] have been found to be active for hydrogenation as well as double bond isomerization of olefins. We have studied the hydrogenation of 4-isopropenyl-1-methylcyclohexene having two kinds of double bonds in a molecule over MgO, CaO, La_2O_3, ThO_2, and ZrO_2 in order to examine the selectivity-determining factor of each catalyst.

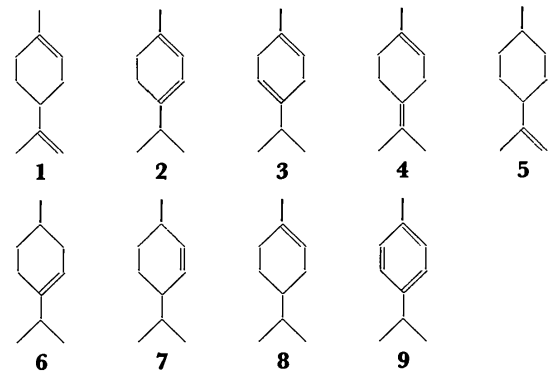
Experimental

Magnesium oxide and CaO were obtained by heating *in situ* $Mg(OH)_2$ and $Ca(OH)_2$, respectively. Lanthanum sesquioxide was obtained by heating *in situ* $La(OH)_3$ prepared by the hydrolysis of $La(NO)_3$. Zirconium oxide was obtained by calcination of $Zr(OH)_4$ in air. The $Zr(OH)_4$ was prepared by hydrolysis of $ZrOCl_2$. Thorium oxide was prepared by pyrolysis of $Th(NO_3)_4$ in air. 4-Isopropenyl-1-methylcyclohexene and 4-isopropyl-1-methyl-1,4-cyclohexadiene were supplied by Takasago Perfumery Co., Ltd.

For the reaction, a microcatalytic pulse reactor directly combined with a gas chromatographic column was employed. The oxides or hydroxides were heated at desired temperatures under a helium stream (flow rate, 80 ml/min) for 2 h. Eight μl of a reactant was injected into a hydrogen stream ahead of the catalyst. The reaction was carried out at room temperature, the flow rate of hydrogen stream being 60 ml/min. The reaction products were trapped in liquid nitrogen and then flash evaporated into a gas chromatographic column. A column (5 m, 6 mm o.d.) was packed with PEG 20 M on Celite 545, which was operated at 100 °C with a flow rate of 60 ml/min.

Results and Discussion

The reaction products of 4-isopropenyl-1-methylcyclohexene (**1**) were 4-isopropyl-1-methyl-1,3-cyclohexadiene (**2**), 4-isopropyl-1-methyl-1,4-cyclohexadiene (**3**), 4-isopropylidene-1-methylcyclohexene (**4**), 1-isopropenyl-4-methylcyclohexane (**5**), 1-isopropyl-4-methylcyclohexene (**6**), 3-isopropyl-6-methylcyclohexene (**7**), 4-isopropyl-1-methylcyclohexene (**8**) and 1-isopropyl-4-methylbenzene (**9**).



The composition of products over each catalyst is given in Table 1. In the reaction of **1** over CaO, dehydrogenation occurred producing **9** exclusively. Hydrogenated products **7** and **8** were formed over MgO in addition to the main product **9**. Formation of **4** increased with decrease in the conversion of the reactant. Over La_2O_3, product distribution was similar to that for MgO except that **6** was formed instead of **7**. In the reactions of **1** over ThO_2 and ZrO_2, the main product was **8** formed by the selective hydrogenation of the double bond in

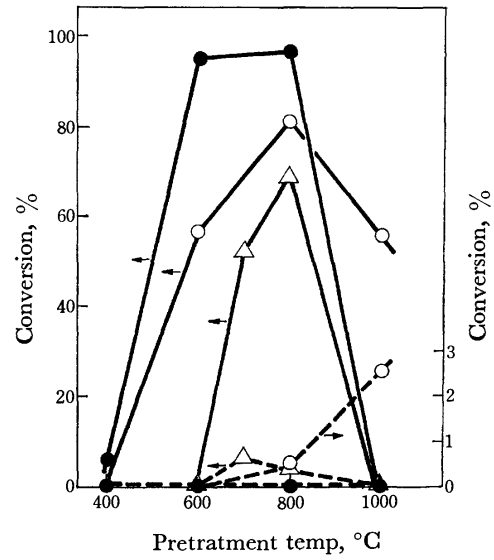


Fig. 1. Variations in conversions to 4-isopropyl-1-methylcyclohexene **8** and 1-isopropyl-4-methylbenzene **9** at the second pulse with pretreatment temperature of catalysts.
○, MgO (0.050 g); ●, CaO (0.050 g); △, La_2O_3 (0.050 g). Broken line, for **8**; solid line, for **9**.

Table 1. Composition of product in reactions of 4-isopropenyl-1-methylcyclohexene **1** and 4-isopropyl-1-methyl-1,3-cyclohexadiene **2** in hydrogen stream at room temperature

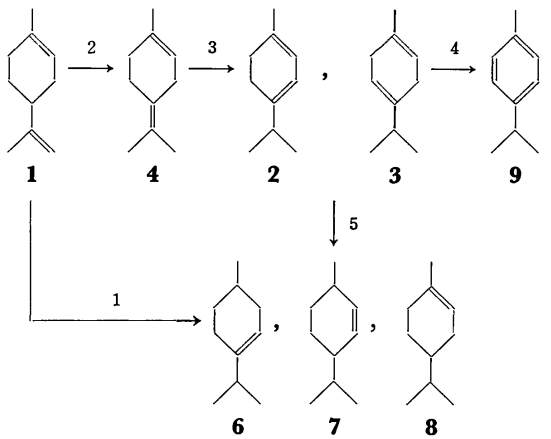
Catalyst	Weight g	Pretreatment temp °C	Pulse No.	Reactant	Mol % each product								
					1	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**
MgO	0.050	1000	2	**1**	30	<1	0	29	0	0	2	3	36
			3	**1**	54	<1	<1	46	0	0	<1	<1	1
MgO	0.10	1000	3	**1**	0	0	0	0	0	0	7	13	80
			4	**2**	0	0	0	0	0	0	7	12	81
CaO	0.050	800	2	**1**	2	0	0	0	0	0	0	0	98
			4	**1**	8	0	0	0	0	0	0	0	92
La_2O_3	0.10	700	1	**1**	0	0	0	0	0	15	0	8	77
			3	**2**	0	2	3	0	0	18	0	8	69
ThO_2	0.20	650	3	**1**	34	0	0	0	<1	4	0	59	3
			5	**2**	0	19	<1	0	<1	19	0	21	41
ZrO_2	0.20	700	2	**1**	81	0	0	0	0	0	0	15	4
			4	**2**	0	80	1	0	0	0	0	<1	19

the isopropenyl group of the reactant.

In the reaction of **2**, MgO and La_2O_3 gave almost the same product composition as in the reaction of **1**. Over ZrO_2 and ThO_2, however, the product compositions differed from those in the reaction of **1**. Zirconium oxide gave mainly **9** and ThO_2 gave **6** and **8** in addition to **9**.

In Figs. 1 and 2, the conversion into **8** and **9** in the reaction of **1** is plotted against pretreatment temperature of catalysts. Magnesium oxide exhibited maximum activity for dehydrogenation at pretreatment temperature, 800 °C, while for hydrogenation, the activity increased with a rise in pretreatment temperature up to 1000 °C. Calcium oxide showed only dehydrogenation activity over the whole range of pretreatment temperature and maximum activity at pretreatment temperatures 600—800 °C. Over La_2O_3, dehydrogenation and hydrogenation changed nearly parallel with pretreatment temperature, the maximum activities being observed at pretreatment temperatures 700—800 °C. Over ThO_2 and ZrO_2, hydrogenation was predominant over the entire pretreatment temperature range, the maximum activities being obtained at pretreatment temperature 700 °C.

The reaction scheme might be as follows.



The catalytic feature of each catalyst could be explained as follows.

Over ZrO_2 and ThO_2, **1** undergoes hydrogenation by step 1 before it undergoes double bond migration by steps 2 and 3 to form **2** which would easily be converted into **9**. Step 5 is negligible with ZrO_2 but fast with ThO_2.

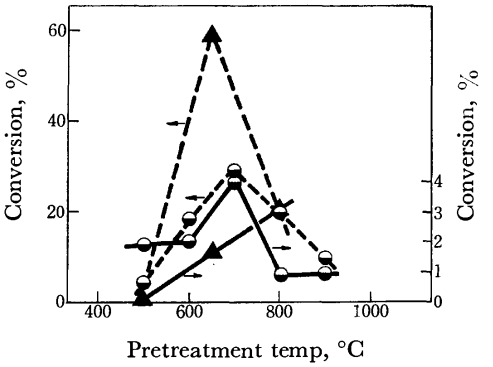


Fig. 2. Variations in conversions to 4-isopropyl-1-methylcyclohexene **8** and 1-isopropyl-4-methylbenzene **9** at the second pulse with pretreatment temperature of catalysts. ◒, ZrO_2 (0.20 g); ▲, ThO_2 (0.20 g). Broken line, for **8**; solid line, for **9**.

Over MgO, CaO, and La_2O_3, hydrogenation step 1 should be slower than steps 2, 3, and 4. Double bond isomerization by steps 2 and 3 quickly occurs to produce **2** or **3** which undergoes fast dehydrogenation to **9**. Since the product distribution of **6**, **7**, and **8** from **1** was practically the same as from **2**, step 5 is much faster than step 1.

Variations in the activities of MgO and CaO were reported for the isomerization of butenes and hydrogenation of olefins as a function of pretreatment temperature.[4–6] The activity of MgO for isomerization exhibited a maximum at 600 °C, while that for hydrogenation did not appear at 600 °C and reached a maximum around 1100 °C. The activity for dehydrogenation of **1** to **9** correlates better with that for isomerization of butenes.

Since the hydrogenation step in the reaction of **1** to **9** is considered to proceed on the hydrogenation sites, a correlation of dehydrogenation activity to **9** with isomerization activity suggests that dehydrogenation to **9** involves an isomerization step which is slower than the dehydrogenation step. This is in line with the proposed reaction scheme.

High selectivity of ThO_2 and ZrO_2 for hydrogenation is considered to be due to a relatively high activity for hydrogenation as compared with that for double bond isomerization, as actually observed in hydrogenation and isomerization of butenes.[2,3]

Intramolecular Dimer and Excimer Phosphorescence of Poly(2-vinylnaphthalene) and Copolymers of 2-Vinylnaphthalene and Phenyl Vinyl Ketone

Masayuki AIKAWA, Takeshi TAKEMURA,* Hiroaki BABA, Masahiro IRIE,** and Koichiro HAYASHI**

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

***Institute of Scientific and Industrial Research, Osake University, Suita, Osake 565*

(Received July 25, 1978)

Synopsis. Phosphorescence spectra and lifetimes of poly(2-vinylnaphthalene) and copolymers of 2-vinylnaphthalene and phenyl vinyl ketone have been measured as a function of the composition ratio between the constituent benzoyl and naphthyl groups in both rigid and fluid solutions.

In a previous paper[1] it was shown that poly(vinylnaphthalene)s exhibit fluorescence emissions ascribable to the monomer, dimer, and excimer of the constituent naphthyl groups. The purpose of the present study is to examine whether such a polymer emits the intramolecular dimer and excimer phosphorescence. Copolymers of 2-vinylnaphthalene and phenyl vinyl ketone have been employed in addition to poly(2-vinylnaphthlene). Since the formation of the intramolecular dimer or excimer is expected to depend on the naphthyl group content of copolymer, the ratio between the components of the copolymer was varied to a considerable extent. The phosphorescence spectra of these compounds were measured in both rigid and fluid solutions.

Poly(2-vinylnaphthalene) (PVN) and copolymers of 2-vinylnaphthlene and phenyl vinyl ketone (VN–PVK) were synthesized in benzene with use of azobisisobutyronitrile. The compositions of copolymer I, II, III, and IV are 9/91, 16/84, 35/65, and 75/25, respectively, in mole fraction of 2-vinylnaphthalene-phenyl vinyl ketone. Spectro-grade THF and reagent-grade MTHF were passed through an activated alumina column and distilled repeatedly (4 or 5 times) over lithium aluminium hydride or phosphorus pentaoxide.

The concentrations of the copolymer solutions were so adjusted that the absorbance at the $n\rightarrow\pi^*$ transition band was less than 0.1. The sample solutions were carefully degassed by freeze-thaw cycles. The apparatus and techniques for measuring emission spectra and monitoring the time-dependent behavior of the emissions were the same as those reported.[2,3]

Results and Discussion

Phosphorescence Spectra in Rigid Glass. Figure 1 shows the phosphorescence spectra of VN–PVK copolymers in MTHF at 77 K. Excitation was carried out at 350 nm, where there is only the $n\rightarrow\pi^*$ absorption band of the constituent benzoyl group. The spectrum of copolymer I consists of two phosphorescence emissions. One located in the region of 400—460 nm is similar to the phosphorescence spectrum of acetophenone and ascribed to the triplet state of the benzoyl group; the other located in the region of 470—600 nm has an origin at 468 nm and is very similar to the phosphorescence spectrum of naphthalene, and is assigned to the naphthyl group. The appearance of the phosphorescence

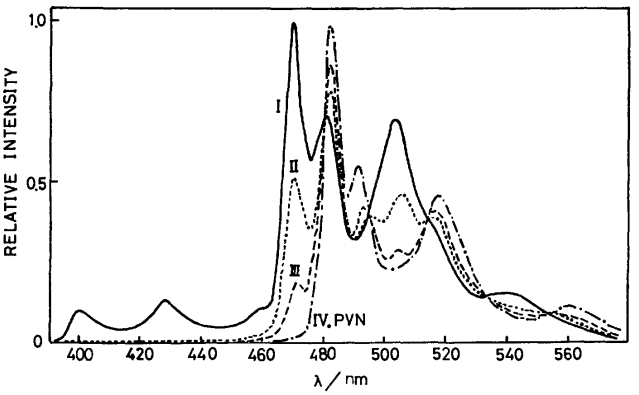

Fig. 1. The phosphorescence spectra (uncorrected) of VN–PVK copolymer I, II, III, and IV and of PVN in MTHF at 77 K obtained by exciting at 350 nm. The spectra of copolymer-IV and PVN were almost the same.

of the naphthyl group by excitation at 350 nm indicates that intramolecular triplet-triplet (T-T) energy transfer from the benzoyl group to the naphthyl group occurs effectively in the copolymer. This is supported by the fact that the emission due to the benzoyl group disappears with increase in content of the naphthyl group, which acts as an acceptor in the T-T energy transfer.

With increase in content of the naphthyl group in the copolymer the intensity of the 0-0 band at 468 nm in the phosphorescence spectrum decreases, while a new band grows at 482 nm. The intensity of the band at 482 nm is comparable to that at 468 nm for copolymer II, dominating over the latter intensity for copolymer III. On the other hand, copolymer IV and PVN give predominantly phosphorescence spectra with an origin at 482 nm which are very similar to the spectrum of the naphthalene dimer with a 0-0 band at 485 nm reported by Chandross and Dempster.[4] From the composition dependence of the phosphorescence spectra of the copolymer and PVN, the phosphorescence spectrum with the 0-0 band at 482 nm for the copolymers and PVN can be assigned to the dimer formed between the naphthyl groups in the ground state. This leads to the conclusion that the phosphorescence spectrum of PVN in rigid glass consists almost of the dimer phosphorescence in disagreement with a previous assignment of the monomer.[5]

The decay of the phosphorescence observed at 480 nm of copolymer I in MTHF at 77 K gives a single exponential curve with a lifetime 2.7 s. However, two exponential decays are observed in each of the copolymers II—IV. A relatively fast decaying component

appears in addition to the slowly decaying component corresponding to the component of copolymer I. The contribution of the fast decaying component increases with increase in content of the naphthyl group. Since copolymer I shows mainly the monomer phosphorescence and the intensity ratio of the dimer to monomer phosphorescence in copolymers II—IV increases with the content of the naphthyl group, it is obvious that the fast and slow components correspond to the dimer and monomer phosphorescence of the naphthyl groups, respectively. The lifetimes of the triplet monomer and dimer are 2.1 and 0.6 s for copolymer II, 2.3 and 0.5 s for copolymer III, and 2.0 and 0.5 s for copolymer IV.

With the change of copolymer from I to IV, the lifetime of the monomer decreases from 2.7 to 2.0 s, while that of the triplet dimer remains 0.5 s. The decrease in lifetime of the monomer phosphorescence can be explained in terms of the quenching of the monomer emission by the dimer species through T-T energy transfer.

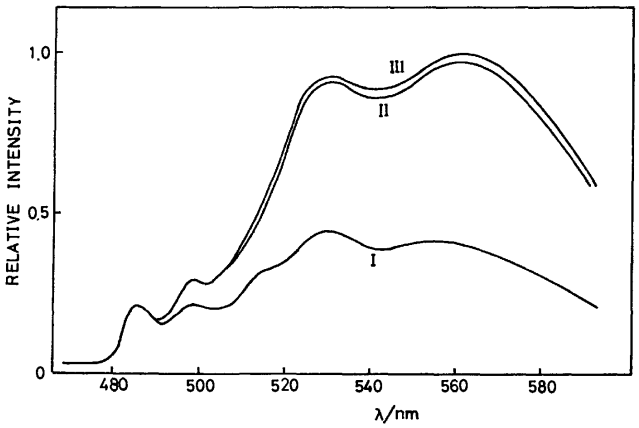

Fig. 2. The phosphorescence spectra (corrected) of VN-PVK copolymer I, II, and III in fluid THF solution at 187 K obtained by exciting at 350 nm.

Phosphorescence Spectra of the Copolymers in Fluid Solution. Figure 2 shows corrected phosphorescence spectra of the copolymers in fluid THF solution at 187 K. Each of these spectra consists of a structured spectrum with a 0-0 band at 485 nm and a broad, structureless spectrum with intensity maximum at *ca.* 550 nm. The former phosphorescence spectrum is attributable to the emission of the dimer of the naphthyl groups in the polymer since it is similar in position to the spectrum of the dimer of the naphthalene nuclei in rigid glass,[4] and in general $\pi \leftarrow \pi^*$ phosphorescence spectra of compounds such as naphthalene, phenanthrene, and quinoxaline remain almost unchanged in the position of the 0-0 band when the sample is changed from rigid glass solution to fluid.[2,3,6]

The broad emission spectra are attributed to the phosphorescence from the excimer of the naphthyl group in the polymers. This assignment is in line with the following experimental results: (1) The broad emission spectra of the copolymers correspond to the excimer phosphorescence spectra of naphthalene and its derivatives,[2,3] and 1,3-di(1-naphthyl)propane[7,8] in fluid solution. (2) The excitation spectra obtained by monitoring the emission at 560 nm of the copolymers agree with the absorption spectra. (3) No broad emission spectra are observed in rigid glass at 77 K. (4) The lifetimes of the emissions are of the order of 10^{-4} s.

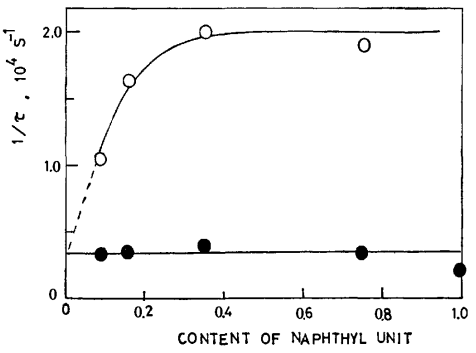

Fig. 3. The reciprocal lifetimes of the phosphorescence of VN-PVK copolymers as a function of VN-PVK composition. The measurements were carried out in fluid THF solution at 187 K. ○ corresponds to the reciprocal lifetime of the excimer and ● that of the dimer.

In the fluid solution at 187 K, the decay curves of the phosphorescence emissions of all the copolymers obtained by monitoring at 500 nm consist also of two exponentiallg decaying components. The results are shown in Fig. 3 where the reciprocal lifetimes of the two decaying components are plotted as a function of the composition of the copolymer. The monitoring wavelength dependence and VN-PVK composition dependence of the contribution of the two components indicate that the two components, fast and slow, are attributable to excimer and dimer phosphorescence, respectively. The lifetime of the dimer phosphorescence with a relatively slow decay, 3×10^{-4} s, is independent of the composition of the copolymer, while that of the excimer phosphorescence decreases rapidly, reaching a constant value of 5×10^{-5} s as the content of the naphthyl group increases.

(Received January 9, 1978)

Synopsis. Rare Earth orthophosphates have been synthesized and examined by X-ray diffraction, DTA and TGA. Six types have been found: a) the monazite type RPO_4, b) the xenotime type RPO_4, c) the hexagonal form $RPO_4 \cdot 0.5H_2O$, d) the weinschenkite type $RPO_4 \cdot 2H_2O$, e) the orthorhombic form $DyPO_4 \cdot 1.5H_2O$ and f) the amorphous phosphate.

In preceding papers,[1-4] the synthesized monazite type $CePO_4$, the hexagonal form $CePO_4 \cdot 0.5H_2O$, the xenotime type YPO_4, and the weinschenkite type $YPO_4 \cdot 2H_2O$ have been reported. The present study reports the syntheses and thermal stability of various rare earth orthophosphates RPO_4 (R=La, Ce, Pr, Nd, Sm, Gd, Y, Dy, Er, or Yb).

Experimental

Starting Materials. RCl_3 of 99.9% purity (R=La, Ce, Pr, Nd, Sm, Gd, Y, Dy, Er, or Yb) and H_3PO_4, $(NH_4)H_2PO_4$, $(NH_4)_2HPO_4$, $(NH_4)_3PO_4 \cdot 3H_2O$ or $NaPO_3$ were used as starting materials.

Synthesis by Solid State Reactions. Mixtures of RCl_3 and $NaPO_3$ with a mole ratio (P/R) of 2.5 were heated in the temperature range 200—1000 °C for 5 h in an electric furnace using a platinum crucible. After heating, the hot crucible was removed from the furnance and quenched to room temperature. The products were taken out from the crucible and washed successively with (1+10)HNO_3 solution, distilled water and acetone.

Synthesis by Precipitation. A solution of RCl_3 (0.05 mol/l) was rapidly added to dilute H_3PO_4 or phosphate solution and magnetically stirred. After one hour, the pH of the mixed solution was measured by a pH meter and the solution transfered to a conical flask, which was tightly stoppered. The mixed solutions were maintained at 20, 50, and 90 °C for 1 to 900 days in an air bath. The pH of the mixed solution was adjusted to a constant value with H_3PO_4 or phosphate solution. The solution was suction-filtered with a filter paper and washed five times with distilled water and finally with acetone. The precipitate was kept in a desiccator (drying agent: H_2SO_4) at room temperature.

Results and Discussion

Phases Obtained by Solid State Reaction. Feigelson[5] synthesized anhydrous RPO_4 by the fusion of rare earth oxides with excess $Pb_2P_2O_7$ at 1300 °C in a refractory (mullite) crucible in an electric furnace.

In the present investigation, the anhydrous phosphates of monazite type RPO_4 (R=La, Ce, Pr, Nd, Sm, or Gd) and xenotime type RPO_4 (R=Y, Dy, Er, or Yb) were first synthesized by the solid state reactions in air of RCl_3 with $NaPO_3$ at temperatures as low as 200 °C. No hydrated phosphates were detected in the heated samples. The intensity of the X-ray diffraction powder lines of the anhydrous phosphates increased with increasing preparation temperature.

Phases Obtained by Precipitation. Anthony[6] synthesized the monazite type $CePO_4$ by the hydrothermal treatment of mixtures of cerium hydroxide gel, H_3PO_4 and water at *ca.* 300 °C. Hydrated phosphates were not observed in the products.

In the present investigation, various types of phosphates were synthesized below 90 °C in solution. The crystalline phases obtained by precipitation from mixed solutions in the temperature range 20—90 °C for 1 to 900 days were the hexagonal form $RPO_4 \cdot 0.5H_2O$ (R=La, Ce, Pr, Nd, Sm, or Gd), the weinschenkite type $RPO_4 \cdot 2H_2O$ (R=Y, Dy, Er, or Yb), the orthorhombic form $DyPO_4 \cdot 1.5H_2O$, the monazite type RPO_4 (R=La, Ce, Pr, Nd, Sm, or Gd) and the xenotime type RPO_4 (R=Y, Dy, Er, or Yb). Table 1 illustrates the phases obtained by X-ray diffraction analysis under various experimental conditions.

The hexagonal form $RPO_4 \cdot 0.5H_2O$ was synthesized in the pH range 1—3 at 20 °C and was stable in the mother liquor for 900 days. Above 50 °C, however, the hexagonal form gradually changed into the monazite type RPO_4 in the solution. The rate of transformation from the hexagonal form to the monazite type by ageing in solution increased with decreasing pH and increasing preparation temperature. The weinschenkite type $RPO_4 \cdot 2H_2O$ was synthesized in the pH range 1—3 at 20 °C and was stable in solution for 900 days. When aged above 50 °C the weinschenkite type gradually changed to the xenotime type RPO_4. Amorphous phosphate was detected in the precipitate from the mixed solution above pH 3 at 20 °C. After ageing in solution above 50 °C, the amorphous phosphate became the crystalline hydrated or anhydrous phosphates of the hexagonal form, weinschenkite type, orthorhombic form, monazite type or xenotime type, depending on the kind of rare earth.

Thermal Stability. It has been established that monazite and xenotime are stable in air at high temperatures. Ueda and Korekawa,[7] and Ueda[8] found that the cone of natural monazite from Nogisawa-mura, Fukushima Pref. did not melt when fired at 1950 °C, and that natural xenotime from Ishikawa-cho, Fukushima Pref. did not decompose at 1800 °C. The thermal stability of the hydrated rare earth orthophosphates has been reported only for $CePO_4 \cdot 0.5H_2O$[9] and $YPO_4 \cdot 2H_2O$.[3]

The DTA curves of the hexagonal form $RPO_4 \cdot 0.5H_2O$ showed two endothermic peaks and the TGA curves showed a weight loss corresponding to $0.5H_2O$ at 204—234 °C. This weight loss appeares to correspond to the first endothermic DTA peak (204—234 °C).

Table 1. Synthetic runs and phases detected

R	Aging time (day)	Detected phases: 20 °C (pH) 0.5	1	3	5	50 °C (pH) 0.5	1	3	5	90 °C (pH) 0.5	1	3	5

	900	—	W	W	A	X	X	X	X	X	X	X	X

—: No precipitate, H: hexagonal form $RPO_4 \cdot 0.5\ H_2O$, M: monazite type RPO_4, W: weinschenkite type $RPO_4 \cdot 2H_2O$, A: amorphous phosphate, X: xenotime type RPO_4, O: orthorhombic $DyPO_4 \cdot 1.5H_2O$.

Dehydrated RPO_4 had a hexagonal form and was easily rehydrated to form $RPO_4 \cdot 0.5H_2O$ when kept at ordinary humidity. Therefore this water corresponding to $0.5H_2O$ was concluded to be zeolitic water. The anhydrous hexagonal form RPO_4 gradually transformed into the monazite type at 500—600 °C. The DTA curves of the synthesized weinschenkite type $RPO_4 \cdot 2H_2O$ showed one endothermic peak and the TGA curves showed a weight loss corresponding to $2H_2O$ at 273—276 °C. This weight loss appeares to correspond to the endothermic DTA peak (273—276 °C). Anhydrous RPO_4 was xenotime type. The weinschenkite type $RPO_4 \cdot 2H_2O$ appeared to convert to the xenotime type in air in the temperature range 273—276 °C. The orthorhombic form $DyPO_4 \cdot 1.5H_2O$ converted to the xenotime type $DyPO_4$ at 270 °C in air.

(Received June 21, 1978)

Synopsis. Oxidative dehydrogenation of three kinds of the title compounds, *meso*[1*R*(*S*), 3*S*(*R*), 8*S*(*R*), 10*R*(*S*)]-, *rac*[1*S*(*R*), 3*R*(*S*), 8*S*(*R*), 10*R*(*S*)]-, and optically active[1*S*, 3*R*, 8*S*, 10*R*]-forms produced the complexes with four isolated imine groups. Some spectroscopic data of the tetraimine complexes are presented.

It has been found that some nickel(II) complexes of cyclic ligand containing secondary amine donors are chemically oxidized to forms containing a higher unsaturation in the ligand.[1-4] The *meso*-, *rac*-, and optically active-forms of the title complex **1**[5] underwent oxidative dehydrogenation of the ligand in concentrated nitric acid to give the respective tetraimine complexes **2**. The elemental analyses of each oxidation product indicated the presence of two additional sites of unsaturation. The IR spectra of the oxidation products showed no absorption for N–H stretching modes ($\approx$3200 cm^{-1}). These two results lead to the isolated tetraimine structure **2**.

The proton noise decoupling ^{13}C NMR spectra of the *meso*- and *rac*-complexes show nine resonance lines, respectively, indicating that each carbon atom within each isomer is pairwise equivalent. The *meso*- and *rac*-complexes have C_i and C_2 symmetry, respectively. The off-resonance spectrum of each isomer consists of four quartets, one triplet, two doublets, and two singlets. This spectral pattern is as expected from the structure **2**. The resonance lines were assigned in the way similar to that for the complex **1**.[6] The ^{1}H NMR spectra of the products also support the structure. The ^{1}H and ^{13}C NMR spectral data are listed in Tables 1 and 2, respectively.

Table 1. ^{1}H NMR spectral data for tetraimine complexes[a]

C_6	(50.9) t	(50.1) t
C_7	185.1 s	185.2 s
C_8	69.1 d	69.2 d
C_9	177.4 d	175.6 d

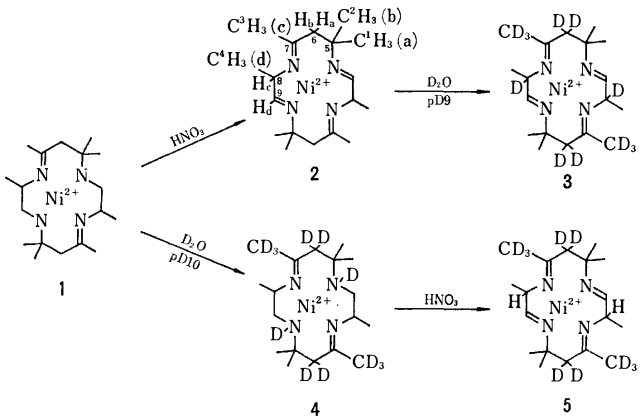
a) Data for the perchlorate salts in DMSO-d_6. The signals, whose chemical shifts are given in parentheses, disappear substantially upon d_{10}-deuteration. The abbreviations, q, t, d, and s, denote quartet, triplet, doublet, and singlet, respectively, which are signal shape upon off-resonance decoupling. b) See the structure **2** for numbering. c) Axial. d) Equatorial.

The perchlorate salts of the tetraimine complexes are square planar and diamagnetic in most solvents (H_2O, MeOH, DMSO, CH_3CN, Py) as revealed by the ligand field spectra. The optically active isomer in H_2O has a d-d electronic absorption band at 23000 cm^{-1} with an ε_{max} of 86 and an absorption at 34100 cm^{-1} (ε_{max}= 5580) associated with the isolated imine functions. The corresponding CD peaks appear at 20800 ($\Delta\varepsilon$= −0.29) and 24300 ($\Delta\varepsilon$=+2.62), and 33800 cm^{-1} ($\Delta\varepsilon$=−5.75). The *meso*-isomer shows a similar electronic spectrum; $\tilde{\nu}_{max}(\varepsilon_{max})$=23400 (58), 34400 cm^{-1} (5860).[7] These features of the electronic spectra and the circular dichroism spectrum demonstrate a square planar structure for these complexes in water.[1]

The tetraimine complexes are stable in neutral or acidic solutions but decompose in basic solutions.

It is well known for analogous marcrocyclic nickel(II) complexes that the protons α to the imine carbon atom can be exchanged for deuterium atoms in basic D_2O solution.[3-5,8] Recrystallization of **1** from basic D_2O deuterates selectively the methylene protons of the six-membered chelate rings and the protons of the imine methyl groups (CH_3(c)), giving the d_{12}-derivative **4**.[5] Oxidation of the d_{12}-derivatives **4** of the *rac*- and the *meso*-diene complexes with nitric acid produced the d_{10}-derivative of their respective tetraimine complexes **5**. The ^{1}H and ^{13}C NMR spectra of the deuterated,

† Present address: Institute for Molecular Science Okazaki 444.



oxidized species indicate the deuterated sites remain intact upon oxidation.

Attempts to prepare d_{12}-derivatives **3** by recrystallization of **2** from basic D_2O solution were partly successful. The ^1H and ^{13}C NMR spectra of the *meso*-tetraimine complex recrystallized from weakly basic D_2O solution indicated that the desired deuteration accomplished. However, the resonance lines of the ^1H and ^{13}C NMR spectra were broad, indicating the presence of the paramagnetic species. All attempts to prepare the d_{12}-derivative **3** of the *rac*-tetraimine complexes in the same way were unsuccessful. As was mentioned before, the tetraimine complexes are unstable in basic solutions as compared with the parent diene complexes.

Experimental

Materials. meso[*1*R(S),*3*S(R),*8*S(R),*10*R(S)]-, rac-[*1*S(R),*3*R(S),*8*S(R),*10*R(S)]-, *and Optically Active*[*1*S,*3*R,*8*S,*10*R]-*form of 3,5,7,7,10,12,14,14-Octamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-dienenickel(II) Perchlorates* (**1**): These complexes were prepared as reported in the previous papers.[5,6]

Oxidation of **1**: Ten grams of the *meso*-diene complex was dissolved in 30 ml of concentrated nitric acid. Dissolution was immediate and a deep orange solution was produced. This solution was heated on a water bath (80 °C) for 2 h. After cooling, 150 ml of cold acetone was added. A yellow product precipitated. This material was removed by filtration and recrystallized from hot water; yield 6.4 g. This was identified as the *meso*-isomer of **2** (see text). The *rac*- and optically active tetraimine complexes were prepared in a similar way. However, since these isomers were more soluble than the *meso*-isomer, an acetone–diethyl ether mixture (1:2 (v/v)) was used instead of acetone to obtain the precipitates. Found for the *meso*-isomer: C, 38.44; H, 5.70; N, 10.03%. Found for the *rac*-isomer: C, 38.77; H, 5.64; N, 10.17%. Found for the optically active isomer: C, 38.41; H, 5.98; N, 10.21%. Calcd for $NiC_{18}H_{32}N_4Cl_2O_8$: C, 38.46; H, 5.74; N, 9.97%.

The d_{10}*-Derivatives* **5**: The d_{12}-derivatives **4** of the *meso*-, *rac*-, and optically active dienes[5,6] were used as strating materials and oxidized with concentrated nitric acid in the same way.

Measurements. Instruments used for the spectral measurements were as follows: ^{13}C NMR spectra, a JEOL NMR Spectrometer, Model JNM-PFT-60, operating at 15.09 MHz; ^1H NMR spectra, a JEOL NMR Spectrometer, Model PS-100; Electronic spectra, a Hitachi EPS-3T Recording Spectrophotometer; Circular dichroism spectra, a JASCO ORD/UV-5 Spectrometer with CD attachment; Infrared spectra, a JASCO IR-G Spectrophotometer.

Preparation of Shark Powder and Shark Paste as Biological Standard Reference Materials

Yukiko DOKIYA, Satoru KUROSAWA, Shozo TODA,* and Keiichiro FUWA**

Department of Agricultural Chemistry, Faculty of Agriculture, The University of Tokyo, Yayoi, Bunkyo-ku, Tokyo 113

***Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received July 4, 1978)

Synopsis. As a possible biological standard reference material for metal analysis, shark powder has been prepared from the muscle of sharks (*Squalus mitsukurii*) and compared with shark paste which was prepared from the same raw material adopting the procedure of Japanese fish paste production. With respect to the homogeneity of metal contents and to the stability during storage, both samples were found to be similar.

As a possible biological standard reference for metal analysis the authors have suggested the preparation of powdered Japanese tea leaves.[1] Since there has been no fish reference material available, a search for a suitable fish reference material was commenced. A wet fish reference material, shark paste, has been proposed by the present authors as a possible candidate for a new biological reference material.[2] In this report, a comparison is made between the wet fish reference material and the dry powder, shark powder, prepared from the same raw material, from the standpoint of practical utilization.

Experimental

Preparation of Shark Powder. The procedure for preparation of shark powder in comparison with shark paste, is outlined in Fig. 1. Two equal amounts of the white muscle was dissected from eight sharks (*squalus mitsukurii*) and one was used for shark powder and the other was used for shark paste. The freeze-dried muscle was pulverized with an agate ball mill (Fritsch Co., Ltd.) followed by sieving with a polyvinylidene chloride fiber sieve (50 mesh). The powder obtained was bottled in polystyrene bottles of 20 ml and kept in a desiccator containing silica gel.

Other Reference Material. Tuna powder was obtained from NBS. This material is packed in a polyethylene pouch which is sealed in an aluminium can and it is necessary to use immediately after opening the can. The metal contents are not certified yet for this material.

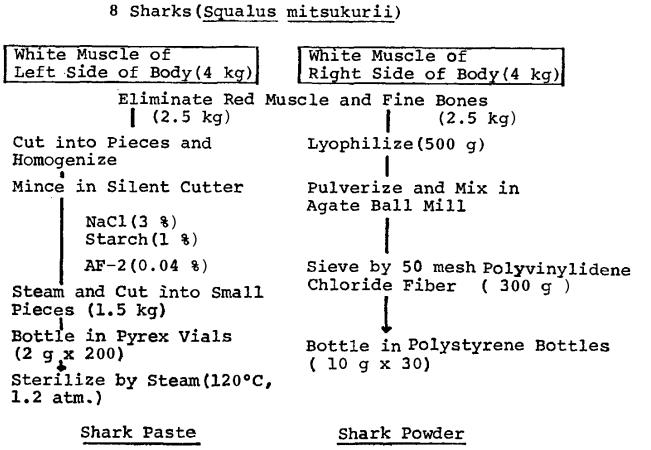

Fig. 1. Procedure for the preparation of shark paste and shark powder.

Determination of Water and Metal Content. Five lots of 0.1—0.5 g were taken from the bottles and dried at 90 °C in dry oven for 24 h to determine the water content. The powder was then used for the determination of metals by atomic absorption and flame emission spectrometry.

For mercury determination, 5 additional portions were taken and digested with HNO_3 and H_2O_2 in the same manner as previously reported.[3]

Results and Discussion

Homogeneity of Shark Powder. The content of metals in the shark powder and NBS-tuna is shown in Table 1. The homogeneity with respect to K, Na, Mg, and Hg is similar for both samples. However, with respect to Ca, the results for shark powder indicated a better homogeneity compared to NBS-tuna. According to Rook,[4] the comparatively poor homogeneity of Tuna with respect to Ca might be attributed to the bone meals in tuna meat. In this study, the raw materials, shark meat, which contains less bones than tuna meat was utilized. In addition, sieving with the polyvinylidene chloride fiber would eliminate the comparatively heterogeneous part which was considered to be mainly the fisca containing a higher amount of Ca than the muscle part.

According to Barnes,[5] the variation in calcium determinations for NBS-tuna can be controlled to within

Table 1. Metal content in shark powder and tuna powder (μg/g-dry)

	Shark powder	NBS-tuna[a]		Shark powder	NBS-tuna[a]
K	17300	12300	Ca	185	253
	17100	12000		208	385
	17400	12000		210	331
	17100	12700		200	493
	17300	12000		199	338
Na	4000	1240	Hg	7.68	0.59
	4080	1280		7.72	0.60
	4090	1310		7.88	0.57
	4080	1290		8.29	0.57
	4070	1270		7.75	0.50

	1080	1080			
	1090	1060			
	1070	1100			
	1100	1110			

a) Determined by present authors.

5% relative standard deviation. Since the calcium determination by flame spectrometry tends to be subjected to chemical interferences, these values obtained in this study might be improved by adopting a more accurate method such as isotope dilution mass spectrometry. In any case it is considered that homogeneity of the prepared shark powder is higher with respect to calcium compared to that for NBS-tuna.

Preservation of Shark Powder. Preservation is one of the most important problems when a biological material is handled. With respect to shark powder and more particularly shark paste, changes of organic constituents by both chemical and biological activities during the preservation period should be considered. ^{60}Co irradiation which is often adopted in plant materials, however, is not suitable for this material, since chemical changes of some trace organic compounds are suspected during the irradiation.

As an index of preservation, the chang of weight was measured in a three month period during summer. The powders were kept in the same polystyrene bottles in a desiccator containing silica gel. The water and ash contents of both samples are shown in Table 2.

Table 2. Change of water and ash contents during storage

	June, 1977		September, 1977	
	Water	Ash	Water	Ash
Shark powder	7.34%	5.46%	5.27%	5.35%
NBS-tuna	1.04	4.28	1.64	4.04

Shark powder lost a little moisture during storage whereas NBS-tuna powder gained a little moisture. In plant samples, less change of weight was observed as previously reported.[1] This fact indicates that care should be taken in the preservation of these powders. With respect to the ash content in dry matter, little weight change was observed for shark powder and tuna powder. In addition, no change in flavor was observed with shark powder, which indicated that oxidation of oily materials did not take place during the storage. These observations suggest that NBS-tuna powder should be preserved in a can until it is used as stated by NBS. Shark powder, however, could be preserved in a desiccator for at least 3 months without any significant change of chemical components, provided the dry weight is measured prior to utilization.

Table 3. Metal contents in shark paste and shark powder

Comparison of Shark Powder and Shark Paste. In Table 3, the metal contents of shark powder and shark paste are shown. The values of shark paste are shown for a wet weight as well as a dry weight basis (dry weight are calculated from the values on the wet weight basis using the water content of 68.5%).

The Na content is ten times higher in shark paste than in shark powder, due to the addition of NaCl in the preparation process of shark paste. The contents of K and Mg are about 30% smaller in shark paste which might be caused by the addition of starch and by the loss during the steaming process. The high content of Fe in shark paste might be due to contamination from the material of the silent cutter.

Fundamentally, shark powder which was less processed in the preparation step, must be subjected to less contamination and loss of elements. Thus, its elementary composition represents that of the natural shark meat. Shark paste, a manufactured product is somewhat different from the natural fish meat, but the difference in metal contents is sufficiently small for Hg, K, Ca, and Mg (within 30%) to enable to be used as a standard reference material for the metal analysis of fish, because the metal contents are the same order as the natural ones.

With respect to the homogeneity of elements, both samples provided similar result, when 0.5 g, dry lots (*ca.* 2 g wet lots in shark paste) were analyzed.

The preservation test indicated that both samples can be preserved for at least 3 months at room temperature. Longer preservation is now under investigation, and it is thought that they will be preserved for one year or longer.

As a conclusion, both shark powder and shark paste are good candidates for new standard reference materials. Since most of the actual field determinations of metals in fish are performed with "wet" or "fresh" samples, shark paste might be a more suitable standard reference material, for example, in the determination of Hg in fish meat by the combustion-gold trap atomic absorption technique. On the other hand, when metal analysis is performed by X-ray fluorescence spectrometry, shark powder would be more suitable than shark paste. Therefore, these two samples can be utilized according to the fields and requirements of analysis.

Preparation and Properties of Cobalt(III) Complexes Containing *meso*-1,2-Diphenyl-1,2-ethanediamine

Masaaki KOJIMA, Momoyo ISHIGURO, and Junnosuke FUJITA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received July 20, 1978)

Synopsis. Two new complexes, $[Co(meso\text{-dpen})_3]^{3+}$ and $[Co(NH_3)_4(meso\text{-dpen})]^{3+}$ have been obtained, where *meso*-dpen denotes *meso*(*R*,*S*)-1,2-diphenyl-1,2-ethanediamine. The former is stable in the solid state, but decomposes slowly in solution at room temperature, while the latter is stable in solution.

Williams and Bailar[1] reported that *meso*(*R*,*S*)-1,2-diphenyl-1,2-ethanediamine (dpen) did not form a tris-chelate complex with a cobalt(III) ion, although the corresponding optically active (*R*,*R* or *S*,*S*) dpen complex was easily obtained. A *meso*-dpen chelate ring in the gauche conformation has one axially disposed phenyl group. Such an axial group may cause steric interactions with other ligands in an octahedral complex, and hence the tris-*meso*-dpen complex will be unstable compared with the tris-(*R*,*R* or *S*,*S*)-dpen complex in which both phenyl groups of the ligand can take the equatorial disposition. This note reports the preparation of $[Co(meso\text{-dpen})_3]^{3+}$ together with *trans*-$[CoCl_2(meso\text{-dpen})_2]^+$ and $[Co(NH_3)_4(meso\text{-dpen})]^{3+}$ and compares their properties with those of the corresponding *S*,*S*-dpen complexes.

Experimental

Ligand. *meso*-1,2-Diphenyl-1,2-ethanediamine (*meso*-dpen) was prepared by the method of Irving and Parkins.[2]

trans-$[CoCl_2(meso\text{-}dpen)_2]Cl\cdot 3H_2O$. To a solution of $CoCl_2\cdot 6H_2O$ (0.29 g, 1.2 mmol) in methanol (10 cm^3) was added a solution of *meso*-dpen (0.51 g, 2.4 mmol) in methanol (15 cm^3). The solution was aerated for 4 h at room temperature and then mixed with concd hydrochloric acid (1 cm^3) to yield green crystals. After standing the mixture overnight in a refrigerator, the crystals were filtered and recrystallized from methanol. Yield: 45%. Found: C, 51.81; H, 6.17; N, 8.90%. Calcd for $CoC_{28}H_{38}N_4Cl_3O_3$=*trans*-$[CoCl_2(meso\text{-dpen})_2]Cl\cdot 3H_2O$: C, 52.22; H, 5.95; N, 8.70%.

$[Co(meso\text{-}dpen)_3]Cl_3\cdot 6H_2O$. To a solution of *trans*-$[CoCl_2(meso\text{-dpen})_2]Cl\cdot 3H_2O$ (0.25 g, 0.39 mmol) in methanol (10 cm^3) was added a solution of *meso*-dpen (0.10 g, 0.47 mmol) in methanol (20 cm^3). Orange crystals which formed on standing the resulting solution for 2 days at room temperature were filtered and washed with methanol. Recrystallization was not carried out because of decomposition of the complex. Yield: 31%. Found: C, 55.92; H, 6.15; N, 9.45%. Calcd for $CoC_{42}H_{60}N_6Cl_3O_6$=$[Co(meso\text{-dpen})_3]Cl_3\cdot 6H_2O$: C, 55.97; H, 6.71; N, 9.32%.

$[Co(NH_3)_4(meso\text{-}dpen)]Cl_3\cdot 2.5H_2O$. This complex was prepared from $[Co(NH_3)_5(H_2O)](ClO_4)_3$ and *meso*-dpen in dimethyl sulfoxide (DMSO) by a method similar to that for the corresponding (*R*,*R*)-2,4-pentanediamine complex.[3] Yield: 30%. Found: C, 34.34; H, 6.81; N, 17.05%. Calcd for $CoC_{14}H_{33}N_6Cl_3O_{2.5}$=$[Co(NH_3)_4(meso\text{-dpen})]Cl_3\cdot 2.5H_2O$: C, 34.26; H, 6.78; N, 17.13%.

Measurements. Absorption spectra were recorded on a Hitachi 323 spectrophotometer. FT ^{13}C-NMR spectra were obtained in DMSO at 15.04 MHz on a JEOL FX-60 spectrometer using dioxane as an external reference, the chemical shift of which is at 67.6 ppm downfield from TMS sealed in an external capillary.

Results and Discussion

Williams and Bailar[1] prepared *trans*-$[CoCl_2(dpen)_2]^+$ by oxidizing a mixture of the diamine and $CoCl_2\cdot 6H_2O$ (molar ratio of 2:1) in ethanol with H_2O_2. They found that the *S*,*S*-dpen complex was prepared easily in good yield (62%), while the *meso*-dpen one was formed in very poor yield (*ca.* 1%). They also attempted to prepare $[Co(dpen)_3]^{3+}$ from the diamine and $CoCl_2\cdot 6H_2O$ (molar ratio of 4:1) by a similar method. The $[Co(S,S\text{-dpen})_3]^{3+}$ complex was obtained in good yield (81%), but the products from the *meso*-dpen were *trans*-$[CoCl_2(meso\text{-dpen})_2]^+$ and *trans*-$[CoCl(H_2O)(meso\text{-dpen})_2]^{2+}$. As stated previously, one of the phenyl groups of the *meso*-dpen ligand is forced to take the axial position upon coordination, regardless of the conformation assumed by the chelate ring, δ- or λ-gauche, while the *S*,*S*-dpen ligand should adopt the δ-gauche conformation with both phenyl groups in the equatorial disposition. The axial phenyl group may cause steric interactions with other ligands in a complex, and hence the *meso*-dpen complexes will be less stable than the *S*,*S*-dpen ones.

In the present study, we have obtained *trans*-$[CoCl_2(meso\text{-dpen})_2]^+$ in fairly good yield (45%) by oxidizing the cobalt(II) ions in methanol with air in place of ethanol and H_2O_2, respectively. By the reaction between this complex and *meso*-dpen in methanol, we have succeeded in preparing $[Co(meso\text{-dpen})_3]^{3+}$ in 31% yield. It is known that a reaction of a *trans*-dichloro-bis(diamine) complex with a diamine in organic solvents is very useful for obtaining an unstable tris(diamine) complex.[4] The $[Co(meso\text{-dpen})_3]Cl_3\cdot 6H_2O$ complex isolated is highly soluble in *N*,*N*-dimethylformamide (DMF) and DMSO, but hardly soluble in water, methanol, and ethanol. In the former solvents, the complex decomposes gradually to give unknown brown precipitate.

The $[Co(NH_3)_4(meso\text{-dpen})]^{3+}$ complex was prepared by the reaction between $[Co(NH_3)_5(H_2O)]^{3+}$ and *meso*-dpen in DMSO. Such a reaction is also known to be very useful for obtaining tetraammine complexes containing a diamine.[3] The complex is stable in water, methanol, ethanol, DMF, and DMSO.

Yano *et al.*[5] suggested by PMR study of $[Pt(en)(meso\text{-dpen})]Cl_2$ (en=ethylenediamine) that the *meso*-dpen chelate ring changes its conformation ($\delta \rightleftharpoons \lambda$-gauche) rapidly on the NMR time scale in solution at room

Fig. Proton-decoupled ^{13}C-NMR(15.04 MHz) spectra of (a) [$Co(NH_3)_4$(*meso*-dpen)]$Cl_3\cdot 2.5H_2O$ and (b) [Co-*meso*-dpen)$_3$]$Cl_3\cdot 6H_2O$ in DMSO.

temperature. In the present study, we have utilized ^{13}C-NMR spectroscopy. The spectrum of [$Co(NH_3)_4$-(*meso*-dpen)]$Cl_3\cdot 2.5H_2O$ gives one and four resonances for the methine and the phenyl carbons, respectively, indicating rapid inversion of the chelate ring (Fig. a).

The [Co(*meso*-dpen)$_3$]$^{3+}$ complex ion can give two geometric isomers, *mer* and *fac*, by the alignment of asymmetric carbons (*R* and *S*). If the conformational change were also rapid in this complex, the *mer*(C_1 symmetry) isomer would show six and twenty-four signals for the methine and the phenyl carbons, respectively, while the *fac*(C_3 symmetry) isomer two and eight signals for the corresponding carbons, respectively. The appearance of the multiplet due to the methine carbons indicates the presence of the *mer* isomer (Fig. b). Although the presence of the *fac* isomer is not clear, the complex seems to be a mixture of the *mer* and *fac* isomers, since the less crowded *fac* isomer should be formed to a greater extent than the more crowded *mer* one. Attempts to separate the geometric isomers by column chromatography were unsuccessful because of decomposition of the complex.

The absorption spectral data for the dpen complexes are listed in the Table. The first absorption maxima of the *meso*-dpen complexes shift to longer wavelengths compared with those of the corresponding *S,S*-dpen complexes. The shift may be caused by the crowded and strained structure due to the axial phenyl group of the *meso*-dpen ligand. A similar shift is observed for the 2,3-butanediamine (2,3-bn) complexes, as shown in the Table. The *meso*- and *S,S*-2,3-bn chelate rings have similar structures to those of the *meso*- and *S,S*-dpen ligands, respectively. The differences in the first absorption maxima between the *meso*- and *S,S*-dpen complexes are larger than those between the corresponding 2,3-bn complexes. This result may be correlated with larger steric interactions caused by the more bulky phenyl group than the methyl one.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (12), 3653—3654 (1978)

The Reaction of Thio-substituted Cyclopropenium Ions with Iminopyridinium and Sulfonium Ylides

Shinichi INOUE,* Gorou YASUDA, and Takuya HORI

Department of Applied Chemistry, Aichi Institute of Technology, Yagusa-cho, Toyoda-shi, Aichi 470-03

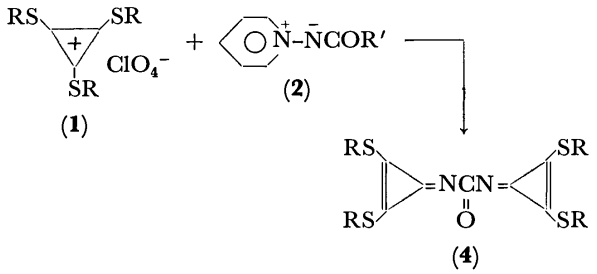
(Received October 31, 1977)

Synopsis. The reaction of several thio-substituted cyclopropenium ions with iminopyridinium and sulfonium ylides in organic solvents at reflux and room temperature under N_2 gave *N,N'*-dicyclopropenylidene urea derivatives, together with some unidentified compounds.

Amino-substituted cyclopropenium ions react with iminopyridinium ylides to give only cyclopropenimine derivatives.[1] It would be of interest to investigate what reaction takes place between heteroatom-substituted cyclopropenium ions[2] and ylides. As regards the reactions of cyclopropenium ions substituted with heteroatom, Yoshida *et al.* reported that tris(alkylthio)-cyclopropenium ion reacts with trialkylphosphite to afford phosphonic acid esters and with hexamethylphosphorous triamide to give phosphonium salts and pyrrole derivatives, and with alkali to produce cyclopropenone and allene derivatives.[3]

Results and Discussion

When tris(ethylthio)cyclopropenium perchlorate (**1a**) was heated with three molar amount of *N*-benzoyliminopyridinium ylide (**2a**) in DMSO at 80 °C for 8 h under nitrogen atmosphere, *N,N'*-bis[bis(ethylthio)-cyclopropenylidene]urea (**4a**) was formed in 60% yield; 7% of **1a** was recovered. The reaction of **1a** with *N*-(ethoxycarbonyl)iminopyridinium ylide (**2b**) under the same conditions gave **4a** in 39% yield.



R : Et for **1a** and **4a**, *t*-Bu for **1b** and **4b**, *p*-*t*-BuC_6H_4 for **1c** and **4c**
R′: Ph for **2a**, EtO for **2b**

Reactions of tris(*t*-butylthio)cyclopropenium perchlorate (**1b**) with **2a** and **2b** under the same reaction conditions afforded *N,N'*-bis[bis(*t*-butylthio)cyclopropenylidene]urea (**4b**) in 75 and 31% yields, respectively.

The reactions of tris(*p*-*t*-butylphenylthio)cyclopropenium perchlorate (**1c**) with **2a** in DMSO and **2b** in THF gave *N,N'*-bis[bis(*p*-*t*-butylphenylthio)cyclopropenylidene]urea (**4c**) in 87 and 89% yields, respectively.

The structures of **4a**, **4b**, and **4c** were confirmed by elemental analyses and spectroscopy.

When **1c** was reacted with *S,S*-dimethyl-*N*-acetylsulfimide (**3a**) in chloroform at room temperature for 8 h under nitrogen atmosphere with stirring, **4c** was formed in 89% yield.

$$\mathbf{1a}\text{—}\mathbf{c} + (CH_3)_2\overset{+}{S}\text{–}\overset{-}{N}COR'' \longrightarrow \mathbf{4a}\text{—}\mathbf{c}$$

(**3**)

R″: **3a**=Me, **3b**=EtO

However, reactions of **1a** and **1b** with **3a** under the same conditions did not give the corresponding ureas **4a** and **4b**, **1a** and **1b** being recovered quantitatively.

Reactions of **1a**, **1b**, and **1c** with *S,S*-dimethyl-*N*-(ethoxycarbonyl)sulfimide (**3b**) under the same conditions gave **4a**, **4b**, and **4c** in 42, 43, and 73% yields, respectively.

Experimental

All the melting points were uncorrected. IR spectra were determined with a Hitachi Model 215 spectrophotometer, UV spectra with a Hitachi Model EPS-3T spectrophotometer, and NMR spectra with a JEOL Model JNM-C-60H spectrometer with use of tetramethylsilane as an internal standard. Mass spectra were determined with a Hitachi RMU-6E spectrometer.

Materials. Tris(*p*-*t*-butylphenylthio)cyclopropenium perchlorate (**1c**) was prepared by a modification of the method of Yoshida and Tawara.[4] **1c**, mp 180 °C (from ether); UV max (CH_3CN) 232 (ε 32300) and 290 nm (19900); IR (KBr) 3010, 2970, 1242, and 824 cm^{-1}; NMR (acetone-d_6) δ 7.85 (m, 6H), 7.65 (m, 6H), and 1.75 (s, 36H, *t*-Bu); MS *m/e* 534 (M^+). Found: C, 62.66; H, 6.17%. Calcd for $C_{33}H_{39}S_3O_4Cl$: C, 62.78; H, 6.24%. The ylides were synthesized according to the reported procedures[5] and identified by elemental analyses as well as by comparison of IR and melting points. The solvents were purified before use.[6]

*Reactions of Tris(ethylthio)-(**1a**), Tris(t-butylthio)-(**1b**), and Tris(p-t-butylphenylthio)cyclopropenium Perchlorate (**1c**) with N-Benzoyliminopyridinium Ylide (**2a**).* A mixture of **1a** (7 mmol) and **2a** (5.1 mmol) in freshly distilled DMSO (30 ml) was stirred at 80 °C for 8 h under nitrogen atmosphere. After the reaction mixture had been allowed to stand overnight, the solvent was removed under reduced pressure. Urea (**4a**), dark brown oil, was obtained in 60% yield by column chromatography (silica gel) of the residue. The reactions of **1b** and **1c** with **2a** under the same conditions afforded the corresponding ureas (**4b**), pale yellow powder, and (**4c**), pale yellow needles, in 75 and 89% yields, respectively.

*Urea (**4a**).* IR (neat) 2930, 1795, 1635 (N–CO–N), and 790 cm^{-1}. UV max (EtOH) 319.5 nm (ε 22400). NMR (CCl_4) δ 1.50 (t, 12H, J=7.4 Hz) and 3.12 (q, 8H, J=7.4 Hz). MS *m/e* 372 (M^+). Found: C, 48.15; H, 5.82; N, 7.57%. Calcd for $C_{15}H_{20}N_2OS_4$: C, 48.35; H, 5.42; N, 7.52%.

*Urea (**4b**).* Mp 113—114.5 °C (from MeOH–H_2O). IR (KBr) 2960, 1800, 1630 (N–CO–N), 1360, 1090, and 770 cm^{-1}. UV max (EtOH) 327 nm (ε 34100). NMR (CCl_4) δ 1.50 (s, 36H, *t*-Bu). MS *m/e* 484 (M^+). Found: C, 56.74;

H, 7.77; N, 5.54%. Calcd for $C_{23}H_{36}N_2OS_4$: C, 56.97; H, 7.50; N, 5.78%.

Urea (4c). Mp 120—121 °C (from chloroform–ether). IR (KBr) 2900, 1805, 1640 (N–CO–N), 1470, 820, and 760 cm^{-1}. UV max (CH_3CN) 247 (ε 18600) and 238 nm (10200). NMR (CD_3CN) δ 1.31 (s, 36H, *t*-Bu) and 7.26—7.35 (m, 16H). MS *m/e* 788 (M^+). Found: C, 71.86; H, 6.43; N, 3.87%. Calcd for $C_{47}H_{52}N_2OS_4$: C, 71.52; H, 6.65; N, 3.55%.

Reactions of **1a**, **1b**, *and* **1c** *with* N-*(Ethoxycarbonyl)iminopyridinium Ylide (2b).* By application of the same procedure as that for urea (**4a**), **1c** (2 mmol) was treated with **2b** (6 mmol) in dry THF (30 ml). The reaction mixture was worked up to give a crude oil, which was extracted with benzene. The solvent was then removed. The residue was extracted with ether to give **4c** in 89% yield. The reactions of **1a** and **1b** with **2b** were carried out by a similar procedure to give **4a** and **4b** in 39 and 31% yields, respectively.

Reactions of **1a**, **1b**, *and* **1c** *with* S,S-*Dimethyl*-N-*(ethoxycarbonyl)sulfimide (3b).* By a procedure similar to that described above, **1b** (2 mmol) was treated with **3b** (8 mmol) in dry THF (30 ml) at room temperature for 8 h under nitrogen atmosphere. The reaction mixture was worked up to give a hygroscopic residue. The residue was crystallized from MeOH–H_2O to give **4b** in 43% yield. The reactions of **1a** and **1c** with **3b** were carried out in the same manner to give **4a** and **4c** in 42 and 73% yields, respectively.

Reactions of **1a**, **1b**, *and* **1c** *with* S,S-*Dimethyl*-N-*acetylsulfimide (3a).* A mixture of **1c** (2.8 mmol) and **3a** (8.4 mmol) in chloroform (30 ml) was kept at room temperature for 8 h under nitrogen atmosphere with stirring. The reaction mixture was allowed to stand overnight and then the solvent was removed. The residual materials were dissolved in acetonitrile and the solution was extracted with petroleum ether. After removal of petroleum ether, the residue was recrystallized from chloroform–ether to afford **4c** in 84% yield. However, **1a** and **1b** did not react with **3a** and were recovered quantitatively.

Synopsis. The 1,4-dihydronicotinamide reduction of isoalloxazines and acridinium ion was examined in cationic (CTAB, CPyB), anionic (SDS), and nonionic (POOA, Brij-35) micelles. The micellar effect is accounted for by micellar stabilization (or destabilization) of the micelle-bound species.

Micellar catalysis provides suitable model systems of enzymatic catalysis, since micelles can influence rates and equilibria of biologically important reactions.[1-4] Very recently, Hadju and Sigman[5,6] reported that *N*-(2-carboxybenzyl)-1,4-dihydronicotinamide and *N*-(*cis*-2-carboxycyclopentyl)-1,4-dihydronicotinamide where the carboxylate moiety is closely fixed near the nicotinamide moiety nonenzymatically reduce *N*-methylacridinium ion in acetonitrile 150—300 times faster than corresponding dihydronicotinamides, but the significant difference cannot be found in an aqueous solution. The result prompted us to investigate the NADH (and model) dependent reactions in micellar systems, since micelles can provide charged environment on the surface and apolar environment in the core. This paper deals with micellar catalysis of 1,4-dihydronicotinamide reduction of isoalloxazines and acridinium ion (Eqs. 1 and 2). We found that the reactions are subject to micellar catalysis, especially to micellar rate inhibition.

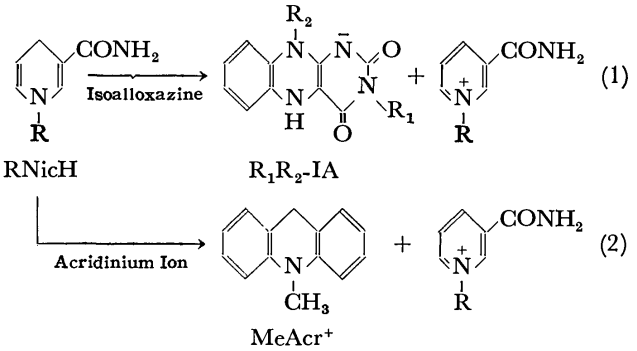

Figure 1 shows the second-order rate constants (k_2) for the reaction of BzlNicH ($R=CH_2C_6H_5$) and MeEt-IA ($R_1=CH_3$, $R_2=C_2H_5$) plotted against surfactant concentrations. The plots for three ionic surfactants (CATB, CPyB, and SDS)** gave sigmoidal curves followed by gradual rate suppression. Since the surfactant concentration where a considerable rate enhancement occurs is almost equal to the CMC for each surfactant (4×10^{-4} M for CTAB, 3×10^{-4} M for CPyB, and 3×10^{-3} M for SDS), the rate enhancement observed is attributable to the micelle formation. It is seen from Fig. 1 that the rate enhancement is transient and the magnitude is of 1.4—2.3 fold at optimal surfactant concentrations. On the other hand, the reaction rate

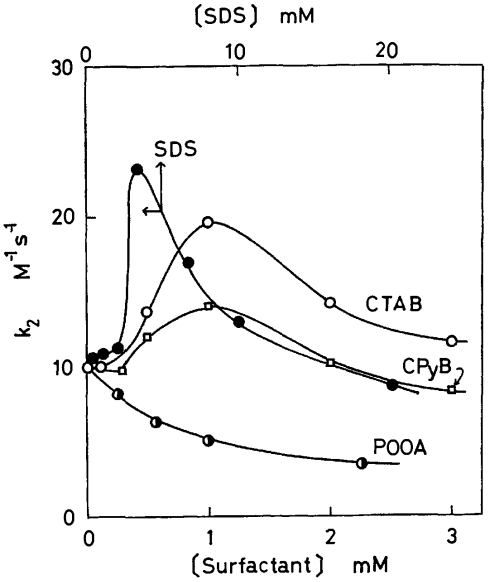

Fig. 1. Second-order rate constants for the reaction of BzlNicH and MeEt-IA plotted as a function of surfactant concentrations. pH 8.5 with 0.02 M phosphate, $\mu=0.02$ with KCl.

was simply retarded with increasing POOA** concentration. The contrasting influence observed between the ionic micelles and the nonionic micelle implies that the ionic environments (both cationic and anionic) are favorable to the reaction.

The micellar catalysis is substantiated more clearly by the reactions involving HxdecBu-IA ($R_1=C_{16}H_{33}$, $R_2=C_4H_9$) and DodNicH ($R=C_{12}H_{25}$), for these

Table 1. Second-order rate constants ($M^{-1}s^{-1}$) for the reaction of 1,4-dihydronicotinamides with isoalloxazines[a]

Surfactant	BzlNicH+ MeEt-IA	BzlNicH+ HxdecBu-IA	DodNicH+ MeEt-IA
None	10.0	10.0[b]	48.2[c]
CTAB	20—11	9.92 (3 mM)	4.00 (3 mM)
CPyB	14—8	14.1 (3 mM)	2.86 (3 mM)
SDS	23—9	1.16 (10 mM)	99.5 (10 mM)
POOA	10—3	7.36 (3.3 mM)	18.6 (3.3 mM)

a) 30 °C, $\mu=0.02$, pH 8.5 with 0.02 M phosphate, 3 vol% ethanol, [dihydronicotinamide] = $(2.2-5.0)\times10^{-4}$ M, [isoalloxazine] = $(2.1-4.0)\times10^{-5}$ M. The numbers in parentheses indicate surfactant concentrations. b) MeEt-IA was used instead of HxdecBu-IA. c) PrNicH was used instead of DodNicH.

** CATB: cetyltrimethylammonium bromide, CPyB: cetylpyridinium bromide, SDS: sodium dodecylsulfate, POOA: polyoxyethylene ($n=10$) oleyl alcohol.

compounds are bound to the micellar phase as shown by their spectral changes.[7,8] The second-order rate constants determined at a given surfactant concentration above the CMC are listed in Table 1. The reaction of BzlNicH with HxdecBu-IA (hydrophobic isoalloxazine) was markedly retarded on the addition of 10 mM SDS, while the addition of other surfactants was less significant. On the contrary, the reaction of DodNicH (hydrophobic dihydronicotinamide) with MeEt-IA was suppressed by the cationic micelles, and the SDS micelle accelerated the reaction by a factor of *ca.* 2. Evidently, the micellar effect in these systems reflects the electrostatic influence on the micelle-bound reactant. The examination of Table 1 also reveals that micelles result in the profound inhibitory effect on the dihydronicotinamide reduction, while the accelerative effect is rather small.

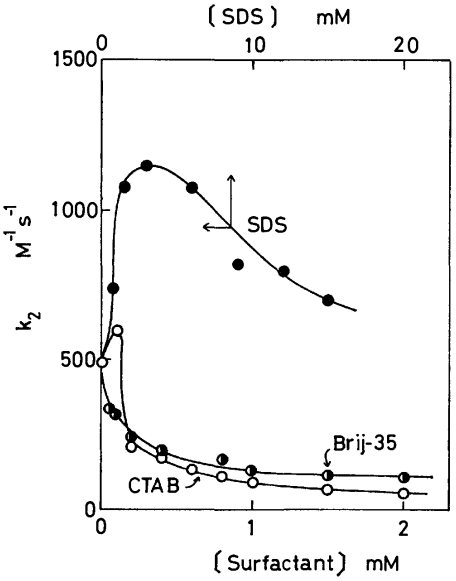

Fig. 2. Second-order rate constants for the reaction of Cl_2BzlNicH and MeAcr$^+$ plotted as a function of surfactant concentrations. pH 7.1 with 0.02 M phosphate, μ=0.02 with KCl.

Figure 2 shows the second-order rate constants for the reaction of Cl_2BzlNicH (R=2,4-dichlorobenzyl) and *N*-methylacridinium ion plotted against surfactant concentration. Plots of k_2 against the concentration of SDS gave the accelerative dependence upon the surfactant concentration, giving rise to the largest rate augmentation of 2.7 fold at the optimal SDS concentration (3 mM). In contrast, k_2 in CTAB and Brij-35 simply descended with increasing surfactant concentrations. The greatest rate suppression caused by the CTAB micelle was 8.7 fold.

The foregoing results establish that the micellar effect in the present system is attributable to the stabilization (or destabilization) of developed charge in the micellar phase. This suggests that NADH dependent reactions which involve the change in the transition state can be controlled by the ionic microenvironments.

Experimental

Materials. *N*-(2,4-Dichlorobenzyl)-1,4-dihydronicotinamide was prepared from *N*-(2,4-dichlorobenzyl)-nicotinamide according to the method of Kim and Chaykin;[9] mp 125—128 °C. Found: C, 54.87; H, 4.24; N, 9.91%. Calcd for $C_{13}H_{12}N_2OCl_2$: C, 55.12; H, 4.24 N, 9.89%. Preparations of other compounds were previously described.[7,8]

Kinetics. All the kinetic measurements were carried out at 30±0.1 °C at a calculated ionic strength (μ=0.02 with KCl) unless otherwise stated. The kinetic runs involving isoalloxazines were performed under strictly anaerobic(N_2) conditions in order to avoid air reoxidation of the reduced products. The progress of the reaction was followed spectrophotometrically by monitoring the disappearance of isoalloxazines (433 nm for MeEt-IA and 440 nm for HxdecBu-IA) and MeAcr$^+$ (420 nm). The reactions were first-order both in dihydronicotinamides and in oxidizing agents.

(Received February 6, 1978)

Synopsis. Photoreaction of ethyl chloroacetate with cumene gives ethyl cumenylacetates (17.5%) in the ratio *o*: *m*: *p*=17: 46: 37. The same reaction with *t*-butylbenzene gives ethyl *t*-butylphenylacetate (23%) in the ratio *o*: *m*: *p*= trace: 65: 35. Addition of BF_3 increases the total yield of the substitution products. Orientations together with those for toluene and anisole in ethoxycarbonylmethylation were discussed in terms of INDO-type MO calculation of the lowest singlet excitation energies.

Reports were given on the ethoxycarbonylmethylation of aromatic compounds with haloacetate.[2-4)] Irradiation of a 0.3 M ethyl chloroacetate solution in toluene gave ethyl tolylacetate with isomer distribution: ortho, 33%; meta, 61%; and para, 6%; total yields 16%.[4)] Irradiation of a 0.1 M ethyl chloroacetate solution in anisole gave ethyl methoxyphenylacetates with isomer distribution: ortho, 59%; meta, 28%; and para, 13%; total yields 17%.[5)] The mechanism may involve an attack of radical species $\cdot CH_2COOEt$ on the aromatic ring in view of the by-products of dimerized $\cdot CH_2COOEt$, *i.e.*, diethyl succinate, but the yields of meta isomer are higher than those of para isomer. This is abnormal on the basis of the ground state π-electron densities.[6,7)]

We wish to report on the product distribution in the photo-reaction of ethyl chloroacetate and cumene or *t*-butylbenzene, where the yield of meta-substituted product is higher than that of para-substituted one as observed with toluene and anisole. The results including previous ones will be rationalized by the molecular orbital consideration.

Results and Discussion

Irradiation of 0.1 M ethyl chloroacetate in cumene for 60 h gave an isomeric mixture of ethyl cumylacetates. The isomer distribution of produced ethyl cumylacetates was as follows: ortho (Ia), 17%; meta (IIa), 46%; and para (IIIa), 37%, in a total yield of 54% based on the consumed ethyl chloroacetate. Ethyl 2-methyl-2-phenylpropionate (IVa) (7.5%) and dimeric cumene (V) were obtained, no β-ethoxycarbonylmethylation taking place. Addition of $BF_3 \cdot Et_2O$ (a Lewis acid) (0.1 M) to the same mixture gave higher yields with an analogous distribution of ethyl cumylacetates: ortho (Ia), 21%; meta (IIa), 45%; para (IIIa), 34%, in a total yield of 65% based on the consumed ethyl chloroacetate along with (IVa) (8.0%). In addition, isomeric bicumenyls were obtained.

Similar irradiation of a 0.1 M ethyl chloroacetate solution in *t*-butylbenzene for 60 h gave ethyl *t*-butylphenylacetates: ortho (Ib), trace; meta (IIb), 65%; and para (IIIb), 35%, in a total yield of 82% based on the consumed ethyl chloroacetate. In this case, the yield of dimeric *t*-butylbenzene was low. Addition of $BF_3 \cdot Et_2O$ (0.1 M) to the same mixture gave higher yields of ethyl *t*-butylphenylacetates composed of ortho (Ib), 5%; meta (IIb), 50%; and para (IIIb), 45%, in a total yield of 89% based on the consumed ethyl chloroacetate.

$$R\text{-}C_6H_5 + ClCH_2COOEt \xrightarrow{h\nu}$$

$$\begin{cases} o\text{-}R\text{-}C_6H_4\text{-}CH_2COOEt & (I) \\ m\text{-}R\text{-}C_6H_4\text{-}CH_2COOEt & (II) \\ p\text{-}R\text{-}C_6H_4\text{-}CH_2COOEt & (III) \\ C_6H_5\text{-}C(CH_3)_2COOEt & (IVa) \\ C_6H_5\text{-}C(CH_3)_2\text{-}C(CH_3)_2\text{-}C_6H_5 & (V) \end{cases}$$

a: $R=CH(CH_3)_2$ b: $R=C(CH_3)_3$

As apparent from the above data, isopropyl- and *t*-butylbenzenes afford lower yields of ortho isomers than toluene and anisole because of steric hindrance.

The yields of meta isomers, (IIa) and (IIb), are higher than those of the corresponding para isomers, (IIIa) and (IIIb), which are similar to the yield reported for toluene. Since the attacking species $\cdot CH_2COOEt$ would be cationic by the electron-withdrawing effect of carbonyl, it is difficult to explain the results in terms of ground state electron density. In the reactions of proton (H–D exchange), the π-π^* singlet excited aromatics react with the electrophile, giving ortho and meta orientation with toluene and anisole.[7,8)] A similar phenomenon, observed with solvolysis of methoxybenzylacetates is called "meta-transmission".[9)]

Calculations were made on the electronic structures of these alkylbenzenes by the INDO-type method.[10)] The calculated lowest singlet excitation energies and their transition moments are summarized in Table 1 together with the experimental ones. The calculated

Table 1. Excitation energy and transition moment of alkylbenzenes and anisole

R	Calcd by CI method		Obsd	
	Excitation energy (mm)	Transition moment[a)]	λ_{max} (mm)	$\log_{max}$
CH_3	224	−0.011	261	2.25[b)]
OCH_3	226	0.229	277	3.15[c)]
$CH(CH_3)_2$	223	0.037	261	2.31[b)]
$C(CH_3)_3$	224	−0.076	258	2.36[b)]

a) All transition moments are in the direction of short axis. b) A.P.I. Research Project, No. 44, I (1945). c) A.B. Raway and J.T. Chanberlain, *J. Chem. Soc.*, **1952**, 2310.

energy values are somewhat larger than the observed ones, the parallelism between the calculated and the observed values of excitation energy and their moments being fairly good.

Since the lowest excited states of alkylbenzenes are constructed by two important configurations, the frontier electron density of rth position is given by

$$f_r^R = C_1^2[(C_{ir})^2+(C_{kr})^2] + C_2^2[(C_{jr})^2+(C_{lr})^2],$$

where indices i and j denote the occupied MO's, k and l the vacant MO's in the ground state of alkylbenzene, and C_1 and C_2 are the CI coefficients of the i→k and j→l excited states, respectively.

Table 2. The frontier electron densities of aromatic compounds calculated by CI method and observed composition of products in the photoreaction of aromatic compounds with ethyl chloroacetate

R	Lowest excited state frontier electron density				Ethoxycarbonyl-methylation products composition		
	1	2(*o*)	3(*m*)	4(*p*)	2(*o*)	3(*m*)	4(*p*)
CH_3	0.309	0.340	0.321	0.309	33	61	6
OCH_3	0.238	0.350	0.314	0.267	59	28	13
$CH(CH_3)_2$	0.289	0.335	0.311	0.287	17	46	37
$C(CH_3)_3$	0.260	0.327	0.295	0.258	trace	65	35

In all cases, the frontier electron densities of lowest excited states decrease in the order: ortho>meta>para (Table 2). The difference in the calculated frontier electron densities can be used for an examination of the difference in relative reactivities for electrophilic attack. For example, in the case of toluene, the ground state π-electron densities calculated by a similar INDO-type MO calculation are: ortho, 1.012; meta, 1.000; and para, 1.016,[11] and those by the Hückel MO calculation are: ortho, 1.0044; meta, 0.9999; and para, 1.0037,[6] whereas the orientation in the nitration of toluene is: ortho 58; meta 4; para 38. The similar small difference in the ground-state π-electron densities of anisole (*o*, 1.056; *m*, 0.982; *p*, 1.020) gives rise to the observed large difference in *o*, *m*, and *p*-orientations.[11]

The calculated frontier electron densities in the lowest excited states coincide with the observation with anisole but not ground state electron densities. The yields of meta isomers in alkylbenzenes, however, are higher than the yields of ortho isomers. The lower yields of ortho isomers can be ascribed to the steric requirement, since the yields of ortho isomer decrease in the order: toluene>cumene>*t*-butylbenzene in spite of the small difference in the calculated frontier electron densities. As shown in Table 2 the reactivity of para position is higher than that expected from calculation. This might reflect the electrophilic nature of $\cdot CH_2COOEt$ radical which is increased by the presence of BF_3. The isomeric ratio in toluene, at least, (meta: para=10: 1) cannot be explained by statistical attack (2: 1) of neutral molecules on the ground state toluene. In the case of the other aromatic compounds, the isomeric distribution can be explained by the statistical ratio (meta: para=2: 1). However, on the basis of electrophilic nature of $\cdot CH_2COOEt$ the para attack should be preferred to the meta attack, if the attack were to occur on ground states.

Since the lowest energy for excitation of alkyl chloroacetate (4.56 eV) is lower than that of alkylbenzens (5.5—5.6 eV), the dissociation of C–Cl bond would be preferred to the excitation of alkylbenzenes. However, the very low concentration of chloroacetates would result in the simultaneous excitation of both reactants.

The attempted reaction of 0.1 M ethyl chloroacetate with chlorobenzene gave self-condensation products (biphenyl and diethyl succinate) together with ethyl phenylacetate (23%) but no ethoxycarbonylmethylation product. Nitrobenzene did not react with ethyl chloroacetate on irradiation. The results show the electrophilic nature of $\cdot CH_2COOEt$ radical.

Experimental

Materials. Isopropylbenzene (bp 152—153 °C) and *t*-butylbenzene (bp 167—169 °C) of guaranteed grade were used after washing with H_2SO_4 and distillation. Ethyl chloroacetate (bp 51—52 °C/20 Torr) was distilled before use.

A Typical Procedure. A Halos high-pressure 300 W Hg lamp was used as a light source. The sample solution was placed in a cylindrical quartz vessel (25×200 mm). The vessel and the lamp were immersed in a water bath (20 °C) at a distance of 5 cm. The sample solution was irradiated for 60 h.

Identification of the products was carried out by means of GLC using a column (1.2 m×4 mm) packed with Silicone OV-17 (5 wt %) on Shimalite W of 80—100 mesh and a column (1.2 m×4 mm) packed with PEG 20 M (10 wt %) on Chromosorb WAN of 60—80 mesh in comparison with the authentic specimen. The yields of products were determined also by means of GLC using a column (1.2 m×4 mm) packed with Silicone OV-17 (5 wt %) on Shimalite W of 80—100 mesh using N_2 as a carrier gas (20 cm³/min) at 80—270 °C (8 °C/min) using naphthalene as an internal standard.

UV Spectra. Following UV spectra peaks (λ_{max}) were observed for reactants: Ia, 262 nm; IIa, 259 nm, ethyl chloroacetate, 236 nm; Ia–BF_3, and IIa–BF_3 mixtures had the same peaks as those of Ia and IIa, respectively. Systems Ia–$ClCH_2CO_2Et$ and IIa–$ClCH_2CO_2Et$ showed no extra peak besides those of the component materials.

(Received May 17, 1978)

Synopsis. ^{13}C NMR spectra of the title compounds were measured. The relationship between their chemical shifts and reactivity is discussed.

In the course of studies on the 2,3-unsaturation of 4,6-*O*-benzylidene-2,3-di-*O*-sulfonylhexopyranosides[1] and of 4′,6′-*O*-benzylidene-2,2′-anhydro-3′-*O*-sulfonylhexopyranosyl nucleosides,[2] it was found that the configuration and conformation of a sugar ring mainly control unsaturation. This led us to study the C-13 NMR spectra of these compounds, since the C-13 chemical shift is highly susceptible to configurational and conformational changes.[3] The C-13 NMR spectra of some compounds in the present study were studied by Conway *et al.*,[4] and we have compared our results with theirs.

All methyl 4,6-*O*-benzylidenehexopyranosides (**1**—**10**) and 4′,6′-*O*-benzylidenehexopyranosyl nucleosides (**11**—**18**) showed almost the same phenyl carbon signals of benzylidene moiety, 126, 127.8, 128.6 (para), and 137.8 ppm (quarternary). Signals at 100.7 ± 0.6 ppm in these spectra should be assigned to C-7 of benzylidene moiety because of the same environment throughout the series of compounds. The shift values of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**1**), its β-anomer (**2**), and methyl 4,6-*O*-benzylidene-α-D-mannopyranoside (**3**) are the results of the study of Conway *et al.*[4]

The anomeric signal of methyl 4,6-*O*-benzylidene-β-D-mannopyranoside (**4**) can be assigned to 101.9 ppm, since the anomeric signal of methyl β-mannoside shows a slightly lower chemical shift than that of the α-anomer;[5] those of 2,3-di-*O*-tolylsulfonyl derivatives (**9** and **10**) show the same tendency (Table 1). The signals at 78.4, 66.6, and 67.8 ppm of **4** can be assigned to C-4, -5, and -6, respectively, by comparison with those of **1**, **2**, and **3**. The signals at 70.8 and 69.8 ppm should be attributed to C-2 and -3, respectively, since 4,6-*O*-benzylidenation makes 3.0—4.2 ppm upfield shift on C-3 and 0.1—1.1 ppm upfield shift on C-2 of **1**, **2**, and **3**.[4,5]

The assignment of methyl 4,6-*O*-benzylidene-2,3-di-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (**5**) and its 2,3-di-*O*-methylsulfonyl substituent (**7**) is the same as the assignment by Conway *et al.*[4] However, there are slight differences due to the difference in solvent. In the cases of methyl 4,6-*O*-benzylidene-2,3-di-*O*-*p*-tolylsulfonyl-β-D-glucopyranoside (**6**) and its 2,3-di-*O*-methylsulfonyl substituent (**8**), the chemical shifts of *O*-methyl, C-5 and -6 can be assigned by a comparison with those of **2**, since sulfonation causes no noticeable effect on these carbons. Disulfonation makes 4.0—4.8 ppm downfield shift on C-2 and 5.2—5.5 ppm downfield shift on C-3 of **5** and **7**. The signals at 79.0 and 79.5 ppm of **6** can thus be assigned to C-2 and -3, respectively. Sulfonation effect on C-1 and -4 of **5** and **7** shows 0.6—3.7 ppm upfield shift, C-1 and -4 chemical shifts

a) Data from Conway *et al.*[4]

being assigned as in Table 1. A similar procedure was used for the assignment of methyl 4,6-*O*-benzylidene-2,3-di-*O*-*p*-tolylsulfonyl-α-D-mannopyranoside (**9**) and its β-anomer (**10**).

In the cases of nucleosides 1-(4′,6′-*O*-benzylidene-β-D-glucopyranosyl)thymine (**11**), its 2′,3′-di-*O*-methylsulfonyl derivative (**13**), 1-(4′,6′-*O*-benzylidene-2′,3′-di-*O*-methylsulfonyl-β-D-glucopyranosyl)uracil (**12**), 1-(4′,6′-*O*-benzylidene-3′-*O*-methylsulfonyl-β-D-mannopyranosyl)uracil (**14**), its 2′,3′-di-*O*-methanesulfonate (**15**), 1-(4′,6′-*O*-benzylidene-2′,3′-di-*O*-methylsulfonyl-β-D-mannopyranosyl)thymine (**16**), 2,2′-anhydro-1-(4′,6′-*O*-benzylidene-3′-*O*-methylsulfonyl-β-D-mannopyranosyl)uracil (**17**), and 2,2′-anhydro-1-(4′,6′-*O*-benzylidene-3′-*O*-methylsulfonyl-β-D-mannopyranosyl)thymine (**18**), it is easy to assign the chemical shift of a sugar moiety, since the displacement of methyl by nucleoside base on C-1′ gives no serious effect on the chemical shifts of a sugar moiety except that of C-1′. It is easy to assign those of a sugar moiety of cyclic nucleosides **17** and **18**. The assignment of a base moiety is as the same as in previous reports.[6]

Predicted Δ' [a] (mannoside)	−2.1	9.2	9.2	−1.8	−1.3	

a) Predicted from Duddeck's results.[7] Negative sign represents upfield difference.

Duddeck has shown with adamantane derivatives that the effect of substitution hydroxyl group for sulfonyloxyl one is 10.9 ppm downfield shift on α-carbon, 1.7 ppm upfield shift on β-carbon, and less than 1 ppm upfield shift on γ- and δ-carbons.[7] Usually the substitution effect on carbon chemical shift is additive and predictable.[8] However, our results can hardly be predicted by Duddeck's results. This discrepancy can be attributed mainly to steric effect.[8,9] The sum of absolute values of these differences ($\Delta-\Delta'$) (Table 2) suggests the dgree of the steric compression due to sulfonylation. The order of reactivity of unsaturation of 2,3-disulfonates is **6**>**10**>**5**>**9**.[1] As seen in Table 2, there is no relationship between the sum of $\lvert\Delta-\Delta'\rvert$ and reactivity. Thus, the steric interaction of the starting static state is not important and the steric and electrostatic effects of the dynamic intermediates are important as regards unsaturation.[1]

Experimental

NMR Spectra. The spectra were obtained at 25.15 MHz on a JEOL JNM-MH-100 instrument with JNM-MFT-100 Fourier transform accessory and a JEC-6 computer. Saturated solution was used as a sample in $(CD_3)_2SO$. The deuterium signal provided a field frequency lock, the carbon signal being used as an internal standard (39.5 ppm downfield from Me_4Si). Measurement conditions were as follow: pulse width, 27.5 μs (*ca.* 45°); repetition time, 4 s; spectral width, 6.25 KHz; data points, 8192; acquisition time 0.655 s; noise modulated proton decoupling power, 20 W. All the chemical shifts are expressed in ppm downfield from Me_4Si.

Materials. Compounds **3**—**10**,[1] thymine nucleosides (**11**), (**13**), (**16**), and (**18**)[2] and uracil nucleosides (**12**), (**14**), (**15**), and (**17**)[10] were prepared according to the methods reported.

The authors thank Drs. T. Imanari and N. Esumi, JEOL, Tokyo, for measuring the spectrum of compound **18** with a JEOL FX-60 instrument at 15 MHz.

Reactions of Benzyl 2-Benzyloxycarbonylamino-2-deoxy-3-*O*-mesyl-α-D-gluco- and -α-D-allopyranoside Derivative with Iodide

Hiroshi SANO, Seiji IIMURA, Tsutomu TSUCHIYA,* and Sumio UMEZAWA
Institute of Bioorganic Chemistry, 1614 Ida, Nakahara-ku, Kawasaki 211

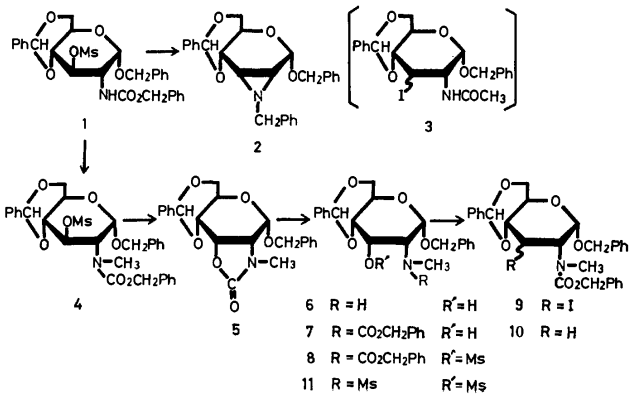
(Received June 5, 1978)

Synopsis. The reactions of benzyl 4,6-*O*-benzylidene-2-benzyloxycarbonylamino-2-deoxy-3-*O*-mesyl-α-D-glucopyranoside (**1**), its *N*-methyl derivative (**4**) and 3-epimer (**8**) with sodium iodide in DMF were studied. Compound **1** gave several products including 2,3-alloepimine, **4** an oxazolidinone and **8** a 3-iodo derivative.

A number of synthetic C-3′ and C-3″ deoxy derivatives of aminoglycoside antibiotics were found to be active against resistant bacteria.[1-3] As reported,[4] 3-iodination of a kanamycin B derivative having 2,6-dideoxy-2,6-bis(ethoxycarbonylamino)-3-*O*-tosyl-α-D-glucopyranosyl moiety was successfully performed in the synthesis of tobramysin in spite of the presence of syn-diaxial interaction[5] between axial anomeric oxygen and a nucleophile approaching axially to C-3. We are interested in a similar iodination of sulfonyloxy derivatives of related aminosugars. We have studied the displacement reaction at C-3 of benzyl 4,6-*O*-benzylidene-2-benzyloxycarbonylamino-2-deoxy-3-*O*-mesyl-α-D-glucopyranoside[6] (**1**) and related compounds with iodide ion.

Treatment of **1** with 50% (W/V) sodium iodide in *N*,*N*-dimethylformamide (DMF) at 100 °C for 48 h gave three products. The major product (14% yield) was not the corresponding 3-iodo derivative but *N*-benzyl-2,3-epimino-α-D-allopyranoside (**2**). Its structure was evidenced by identity with the compound prepared by benzylation of benzyl 4,6-*O*-benzylidene-2,3-epimino-α-D-allopyranoside. Since the starting material was recovered by a similar treatment of **1** without sodium iodide, it is apparent that iodide ion plays an important role in this reaction though the mechanism of this reaction remains equivocal. One of the other two minor products was found to be an iodo derivative (2-amino-3-iodo derivative) on the basis of IR and NMR spectra and microanalysis of its acetylated product (**3**).

In order to examine the effect of *N*-methyl group on the above reaction, the *N*-methyl derivative (**4**) was prepared by methylation of **1** and treated with sodium iodide in DMF in a similar manner to that described for **1**. In this case, an oxazolidinone (**5**) was the sole product isolated (71% yield), identical with the specimen obtained by alkaline treatment[7] of **4**.



In order to examine the configurational effect at C-3, 3-epimer of **4**, *i.e.* 3-*O*-mesyl-α-D-allopyranoside derivative (**8**) was prepared from **5**. Basic hydrolysis of **5** gave the allo-aminol (**6**), which was *N*-benzyloxycarbonylated to give **7**. Mesylation of **7** gave **8**. Treatment of **8** with sodium iodide in DMF afforded the 3-iodo derivative (**9**) in 33% yield. Its structure was characterized by reduction with Raney nickel, giving 3-deoxy compound (**10**).

Since the direct iodination at C-3 is more or less restricted by syn-diaxial interaction in both reactions of epimeric 3-mesylates (**4** and **8**), it is suggested that the neighboring 2-*N*-benzyloxycarbonyl group plays an important role in the reaction of iodide ion,[8] participating in the elimination of the mesyloxy group. For the sake of confirmation, we have prepared a 2-*N*-mesyl derivative (**11**), which is assumed to take no such participation. By treatment of **11** with sodium iodide the starting material was mainly recovered along with some minor products containing no iodine.

Experimental

*Reaction of **1** with Sodium Iodide in DMF.* Dry sodium iodide (3.0 g) was added to a solution of **1** (300 mg) in dry DMF (4.5 ml) and the mixture was heated at 100 °C for 48 h. The chloroform extracts of the reaction mixture were concentrated by addition of toluene. The solution of the residue in chloroform was washed with 5% sodium thiosulfate solution and water, dried (Na_2SO_4), and concentrated. The thick syrup (287 mg) was chromatographed with silica gel (Wakogel C-200) with benzene–ethyl acetate (30: 1→1: 1, gradual change). From the earlier fractions, a solid (74 mg; TLC, R_f 0.75 with benzene–ethyl acetate 9: 1) was obtained, which was further purified by chromatography with hexane–benzene (1: 5→1: 10). Recrystallization from ethanol gave needles of **2**, 32 mg (14%), mp 165—166 °C, $[\alpha]_D^{25}$ + 120° (*c* 0.2, chloroform). Found: C, 75.53; H, 6.70; N, 2.98%. Calcd for $C_{27}H_{47}NO_4$: C, 75.50; H, 6.34; N, 3.26%.

1 (27 mg, R_f 0.5) was recovered from the middle fractions described above; a solid (24 mg; TLC, R_f 0.13) from the latest fractions. Acetylation of the solid gave a solid (13 mg) [IR (KBr): 1740, 1700, 1650, 1540 cm^{-1}] and another solid (**3**, 14 mg), IR (KBr): 1660, 1560 cm^{-1}; PMR (pyridine-d_5): δ 2.15 (3H s, Ac). Found: C, 52.18; H, 4.85; N, 2.76; I, 24.42%. Calcd for $C_{22}H_{24}NO_5I$: C, 51.88; H, 4.75; N, 2.75; I, 24.91%.

*Benzyl N-Benzyl-4,6-O-benzylidene-2,3-dideoxy-2,3-epimino-α-D-allopyranoside (**2**).* Sodium (10.3 mg) dissolved in 2-propanol (0.45 ml) was added to a solution of **1** (103 mg) in dry dioxane (1.4 ml), and the mixture was treated in a similar

way to that reported by Rhoads and Gross.[9] To a solution of the crude epimine (51 mg) in DMF (1.0 ml) were added benzyl bromide (0.06 ml) and silver oxide (70 mg) and the mixture was stirred at room temperature for 14 h. Usual purification gave a solid. Recrystallization from ethanol gave needles, 49 mg (32%), mp 165—166 °C, $[\alpha]_D^{25}+120°$ (*c* 0.2, chloroform). PMR ($CDCl_3$): 2H unresolved q centered at δ 2.18 (H-2,3) (J=6 Hz), which sharpened on irradiation at δ 5.05. Found: C, 75.24; H, 6.51; N, 2.97%. Calcd for $C_{27}H_{27}NO_4$: C, 75.50; H, 6.34; N, 3.26%.

Benzyl 4,6-O-Benzylidene-2-benzyloxycarbonylamino-2-deoxy-3-O-mesyl-2-N-methyl-α-D-glucopyranoside (4). Methyl iodide (0.22 ml) and silver oxide (408 mg) were added to a solution of **1** (503 mg) in dry DMF (10 ml) and the mixture was stirred vigorously at room temperature for 15 h. Work-up in the usual manner gave a solid. Recrystallization from ethyl acetate–hexane gave rods (496 mg, 97%), mp 160—162 °C, $[\alpha]_D^{21}+67°$ (*c* 2, chloroform). IR (KBr): 1690 cm^{-1} (amide I); the peak at 1540 cm^{-1} (amide II) was not observed. PMR ($CDCl_3$): δ 2.91 and 3.12 (each 3H s, SO_2CH_3 and NCH_3). Found: C, 61.88; H, 5.80; N, 2.46; S, 5.21%. Calcd for $C_{30}H_{33}NO_9S$: C, 61.74; H, 5.70; N, 2.40; S, 5.49%.

Benzyl 4,6-O-Benzylidene-2-N:3-O-carbonyl-2-deoxy-2-methylamino-α-D-allopyranoside (5). By Use of Sodium Iodide in DMF: Dry sodium iodide (0.83 g) was added to a solution of **4** (83 mg) in dry DMF (1.2 ml) and the mixture was heated at 100 °C for 48 h. Work-up in the usual manner gave a solid. Recrystallization from ethyl acetate gave rods, 40 mg (71%), mp 229—230 °C, $[\alpha]_D^{21}+190°$ (*c* 2, chloroform). IR (KBr): 1775 cm^{-1} (cyclic carbamate). PMR ($CDCl_3$): δ 2.82 (3H s, NCH_3), 5.06 (1H d, J=5 Hz, H-1), 5.64 (1H s, C_6H_5CH=). Found C, 66.69; H, 5.98; N, 3.54%. Calcd for $C_{22}H_{23}NO_6$: C, 66.49; H, 5.83; N, 3.52%.

By Use of Sodium Acetate: Sodium acetate trihydrate (431 mg) was added to a solution of **4** (431 mg) in 2-methoxyethanol (8.6 ml), and the mixture was refluxed for 45 h. Work-up in the usual manner gave a solid. Recrystallization from ethyl acetate gave rods, 256 mg (85%), mp 229—230 °C.

Benzyl 4,6-O-Benzylidene-2-deoxy-2-methylamino-α-D-allopyranoside (6). A solution of **5** (232 mg) in ethanolic 0.5 M potassium hydroxide (6.9 ml) was refluxed for 24 h. Work-up in the usual manner gave a solid. Recrystallization from ethyl acetate gave needles, 181 mg (85%), mp 210—211 °C, $[\alpha]_D^{31}+99°$ (*c* 1, chloroform). PMR ($CDCl_3$): δ 2.28 (1H m, H-2) which collapsed to a triplet (J=3.5 Hz) on deuteration; 2.48 (3H s, NCH_3), 5.08 (1H d, J=3.5 Hz, H-1). Found: C, 67.80; H, 6.80; N, 3.71%. Calcd for $C_{21}H_{25}NO_5$: C, 67.91; H, 6.78; N, 3.77%.

Benzyl 4,6-O-Benzylidene-2-N-benzyloxycarbonyl-2-deoxy-2-methylamino-α-D-allopyranoside (7). Work-up in the usual manner gave a thick syrup (86%), $[\alpha]_D^{26}+79°$ (*c* 2, chloroform). PMR ($CDCl_3$): δ 3.32 (3H s, NCH_3). Found: C, 68.90; H, 6.22; N, 2.73%. Calcd for $C_{29}H_{31}NO_7$: C, 68.91; H, 6.18; N, 2.77%.

Benzyl 4,6-O-Benzylidene-2-N-benzyloxycarbonyl-2-deoxy-3-O-mesyl-2-methylamino-α-D-allopyranoside (8) was prepared from **7** in the usual manner; a thick syrup (97%), $[\alpha]_D^{30}+88°$ (*c* 2, chloroform). PMR ($CDCl_3$): δ 2.97 (3H s, SO_2CH_3), 3.32 (3H s, NCH_3), 5.07 (1H d, J=3.5 Hz, H-1), 5.45 (1H t, J=2.5 Hz, H-3). Found: C, 61.90; H, 5.80; N, 2.47; S, 5.41%. Calcd for $C_{30}H_{33}NO_9S$: C, 61.73; H, 5.70; N, 2.40; S, 5.49%.

Benzyl 4,6-O-Benzylidene-2-N-benzyloxycarbonyl-2-deoxy-3-iodo-2-methylamino-α-D-gluco or allopyranoside (9). Dry sodium iodide (1.32 g) was added to a solution of **8** (132 mg) in dry DMF (2.6 ml) and the mixture was heated at 100 °C for 48 h. The solution contained at least 6 components (TLC, R_f 0, 0.1, 0.4, 0.45 (weak, **8**), 0.55 and 0.6 (major, **9**), with benzene–ethyl acetate=15:1). Separation of the products in a similar manner to that for the reaction of **1** with NaI gave a thick syrup of **9**, which crystallized on standing; 46 mg (33%). Recrystallization from benzene–hexane gave needles, mp 180—183 °C, $[\alpha]_D^{29}+28°$ (*c* 2, chloroform). PMR ($CDCl_3$): δ 3.02 and 3.04 (each s, 3H in total, NCH_3). Found: C, 56.55; H, 4.83; N, 2.20; I, 20.25%. Calcd for $C_{29}H_{30}NO_6I$: C, 56.59; H, 4.91; N, 2.28; I, 20.62%.

Benzyl 4,6-O-Benzylidene-2-N-benzyloxycarbonyl-2,3-dideoxy-2-methylamino-α-D-ribohexopyranoside (10). Hydrogenation of **9** (11.4 mg) in dioxane (0.2 ml) with Raney nickel (0.2 ml) and triethylamine (trace) gave a syrup, 5.6 mg (62%), $[\alpha]_D^{25}+132°$ (*c* 1, chloroform); PMR ($CDCl_3$): δ 1.8—2.5 (2H m, H-3, 3′), 3.01 (3H s, NCH_3). Found: C, 71.40; H, 6.49; N, 2.96%. Calcd for $C_{29}H_{31}NO_6$: C, 71.14; H, 6.38; N, 2.86%.

Benzyl 4,6-O-Benzylidene-2-deoxy-3-O-mesyl-2-methylsulfonylamino-2-N-methyl-α-D-allopyranoside (11). Hydrogenation of **8** (40 mg) in dioxane (1.5 ml) with palladium black gave a syrup (29 mg, 96%); PMR ($CDCl_3$): δ 2.49 (3H s, NCH_3), 2.29 (3H s, SO_2CH_3). Mesylation of the syrup in the usual manner gave a syrup, 17 mg (97%), $[\alpha]_D^{24}+58°$ (*c* 1, chloroform); PMR ($CDCl_3$): δ 2.87 and 2.93 (each 3H s, NSO_2CH_3 and NCH_3), 3.25 (3H s, SO_2CH_3). Found: C, 52.85; H, 5.65; N, 2.45%. Calcd for $C_{23}H_{29}NO_9S_2$: C, 52.36; H, 5.54; N, 2.65%.

Oxidation of Thujopsene with Metal Acetate in Acetic Acid

Haruo SEKIZAKI,* Masaaki ITO, and Shoji INOUE**

Chemistry Laboratory, Department of General Education, Higashi Nippon Gakuen University, Onbetsu-cho, Hokkaido 088-01

***Faculty of Pharmacy, Meijo University, Tenpaku-ku, Nagoya 468*

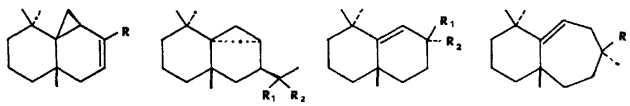
(Received June 23, 1978)

Synopsis. Thujopsene has been oxidized with lead tetraacetate, cobalt triacetate and manganese triacetate, to different kinds of products being 4β-acetyl-6β,10,10-trimethyltricyclo[4.4.0.0^{1,3}]decane (**3**) and its diacetate; 2β-acetoxymethyl-2α,4aβ,8,8-tetramethyl-2,3,4,4a,5,6,7,8-octahydronaphthalene (**7**) and widdryl acetate; **3**, **7**, and widdrol, respectively.

In the oxidation of thujopsene (**1**) with metal acetates[1-3] much attention has been focused on the acetate of Pb(IV), Co(III), and Mn(III). The reactions with metal acetates are summarized in Table 1.

Results and Discussion

*Oxidation of **1** with Lead Tetraacetate.* Thujopsene (**1**) was oxidized with lead tetraacetate in acetic acid at 30 °C for 3 h. Workup and purification gave a stereospecifically ring-contracted ketone (**3**) in 60—65% yield, and the diacetate (**6**) in 16—20% yield. The structure of **3** was identical with that already reported by



1: R=CH_3 **3**: R_1=R_2=O **5**: R_1=CH_3, **8**: R=OAc
2: R=CH_2OAc **6**: R_1=R_2=OAc R_2=CH_2OAc **9**: R=OH
4: R=CHO **7**: R_1=CH_2OAc, R_2=CH_3
10: R_1=CH_2OH, R_2=CH_3

Nagahama *et al.*[3] The configuration of the acetyl group of **3**[2] was determined and the structure of **6** deduced from the spectral data. The IR absorptions of **6** at 1753 cm^{-1} show the presence of an acetyl group and the presence of a methyl and two acetyl groups is indicated by the NMR signals at 1.91 and 2.06. Hydrolysis of **6** gave **3** in quantitative yield. Thus the minor product (**6**) on this reaction was identified as the stereospecifically ring-contracted diacetate.

*Oxidation of **1** with Cobalt Triacetate.* Onopchenko *et al.*[4] have reported that the preparation of cobalt triacetate and oxidation of cyclohexene with cobalt triacetate gave the 3-cyclohexenyl acetate in high yield. However, a similar reaction with **1** shows different results. After stirring the acetic acid solution of **1** and cobalt triacetate for 45 h, the usual workup yielded no oxidation product and gave the acid-catalyzed isomerization-acetoxylation products **7** and **8** in poor yields. Compound **7** was purified by column chromatography and the structure of **7** confirmed by comparing the IR and NMR spectra of an authentic sample.[5] The configuration of the acetoxymethyl group in **7** was the reverse of the acetate (**5**) prepared by the mercury diacetate oxidation.[1] The structure of the product **8** was determined from following chemical evidence. Hydrolysis of a mixture of **7** and **8** with ethanolic KOH at room temperature for 1 h afforded alcohols **9** and **10**, the spectral data of which were identical with authentic specimens.[6,7] These results indicate that product **8** is widdryl acetate.

*Oxidation of **1** with Manganese Triacetate.* The acetic acid solution of **1** and manganese triacetate was stirred at 80 °C for 54 h. The usual workup and purification gave the acetate (**7**), widdrol (**9**) and the ring-contracted ketone (**3**) in 13.8, 10.3, and 4.3% yields, respectively. The same reaction on general olefins (*e.g.* α-methylstyrene, octene-1 *etc.*) affords the corresponding γ-lactone.[8]

Experimental

The melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. The NMR spectra were recorded on a JEOL PMX-60 spectrometer at 60 MHz, using Me_4Si as an internal standard. The IR spectra were determined on a Shimadzu IR-400 spectrometer.

*Oxidation of Thujopsene (**1**) with Lead Tetraacetate.* To the stirred solution of **1** (5.1 g, 25 mmol) in acetic acid (20 ml), kept at 5 °C, was added solid lead tetraacetate (9.0 g, 20 mmol) in portions for 30 min. The mixture was stirred for 3 h at 30 °C, then poured into ice-water and extracted with

ether. The ether solution was washed with aqueous $NaHCO_3$ solution, water, dried (Na_2SO_4), and evaporated to give an oily residue (7.3 g). The products were separated by column chromatography using silica gel. Elution with benzene gave **3** (3.6 g) as a colorless liquid and **6** (914 mg) as colorless crystals. The pure sample of **3** was obtained by distillation under reduced pressure. **3**: Bp 117—119 °C/5 mmHg. NMR ($CDCl_3$) δ 0.75 (s, 3, CH_3), 1.05 (s, 3, CH_3), 1.10 (s, 3, CH_3), 2.20 (s, 3, Ac), and 3.07 (t, 1, J=10.0 and 4.0 Hz); 2,4-dinitrophenylhydrazone: mp 168—169 °C (lit,[3] mp 170—170.5 °C). The pure sample of **6** was obtained by recrystallization from hexane. **6**: Mp 67—71 °C. IR (KBr) 3075, 3045 (cyclopropyl) and 1753 cm^{-1} (OAc); NMR ($CDCl_3$) δ 0.57 (s, 3, CH_3), 1.00 (s, 3, CH_3), 1.03 (s, 3, CH_3), 1.90 (s, 3, CH_3), 2.03 (s, 6, OAc), 3.17 (t, 1, J=10.0 and 4.0 Hz).

Hydrolysis of ***6***. The compound (**6**) (322 mg, 1 mmol) was hydrolyzed in ethanol (3 ml) with 5% HCl (1 ml) for 1 h at 50 °C. After the usual workup a crude product (**3**) (217 mg) was obtained.

*Oxidation of Thujopsene (****1****) with Cobalt Triacetate.* A mixed solution of cobalt triacetate[4] (prepared from $Co(OAc)_2 \cdot 4H_2O$ (25 g)) and **1** (20.4 g, 0.1 mol) was heated to 80 °C. Reaction was continued for 45 h, then the solution was poured into ice–water and extracted with benzene. The benzene solution was washed with aqueous $NaHCO_3$ solution, water, dried (Na_2SO_4) and evaporated to give an oily residue (22.7 g). The products were separated by column chromatography using silica gel. Elution with benzene gave **7** (1.25 g) as a colorless liquid and a mixture of **7** and **8** (1.45 g). **7**: IR (neat) 1743 cm^{-1} (OAc); NMR ($CDCl_3$) δ 0.93 (s, 3, CH_3), 1.05 (s, 6, $2CH_3$), 1.17 (s, 3, CH_3), 2.03 (s, 3, OAc), 3.81 (m, 2, $-\underline{CH_2}OAc$), and 5.10 (s, 1, olefinic). Accordingly, compound (**8**) could not be isolated by repeated column chromatography, a mixture of **7** and **8** was used for the following reaction.

Hydrolysis of Mixture of ***7*** *and* ***8***. To the stirred solution of the mixture of **7** and **8** (1.45 g) in ethanol (15 ml), kept at 10 °C, powdered KOH (56 mg, 10 mmol) was added. The solution was stirred for 1 h at room temperature, then the the solvent was evaporated under reduced pressure and the residue diluted by water and extracted with ether. The ether solution was washed with water, dried (Na_2SO_4), and evaporated to give an oily residue (1.17 g). The products were separated by column chromatography using silica gel. Elution with benzene and ether (5: 1) gave **10** (532 mg), colorless crystals. **10**: mp 70—72 °C (lit,[6] 71—72 °C); IR (KBr) 3230 cm^{-1} (–OH); NMR ($CDCl_3$) δ 0.92 (s, 3, CH_3), 1.07 (s, 3, CH_3), 1.10 (s, 3, CH_3), 3.27 (s, 2, $-\underline{CH_2}OAc$), 5.05 (s, 1, olefinic), and **9** (528 mg), colorless crystals. **9**: mp 83—85 °C (lit,[7] 86—87 °C); IR (KBr) 3255 cm^{-1} (–OH); NMR ($CDCl_3$) δ 1.10 (s, 6, $2CH_3$), 1.23 (s, 6, $2CH_3$), 5.52 (dd, 1, J=9.0 and 6.0 Hz, olefinic).

*Oxidation of Thujopsene (****1****) with Manganese Triacetate.* To a stirred solution of **1** (5.10 g, 25 mmol) in acetic acid (50 ml) was added solid manganase triacetate (13.6 g, 30 mmol) in portions for 10 min. The mixture was stirred for 54 h at 80 °C, then poured into ice–water and extracted with ether. The extract was washed with aqueous $NaHCO_3$ solution, water, dried (Na_2SO_4), and evaporated to give an oily residue (6.5 g). The products were separated by column chromatography using silica gel. Elution with benzene gave **7** (903 mg), **9** (549 mg), and **3** (344 mg).

The authors are grateful to Takasago Perfumery Co., Ltd. for providing the crude sample of thujopsene.

Synthesis of *cyclo*(-L-Leucyl-L-lysyl-glycyl-)$_2$ and Its Hydrolysis by Trypsin

Nobuo Kosui, Tetsuo Kato, and Nobuo Izumiya*

Laboratory of Biochemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812

(Received July 10, 1978)

Synopsis. A protected cyclic hexapeptide, *cyclo*-(-L-Leu-L-Lys(ε-benzyloxycarbonyl)-Gly-)$_2$ (**6**), was synthesized by doubling cyclization of the corresponding tripeptide azide. Compound **6** was converted by hydrogenolysis into a cyclic hexapeptide, *cyclo*(-L-Leu-L-Lys-Gly-)$_2$, which was hydrolyzed by trypsin to a tripeptide, H-Gly-L-Leu-L-Lys-OH.

A few studies have been carried out on the enzymatic hydrolysis of cyclic peptides. Three cyclic hexapeptides, *cyclo*(-Gly$_5$-L-Lys-),[1] *cyclo*(-Gly$_2$-L-Lys-)$_2$,[2] and *cyclo*-(-Gly$_2$-L-Phe$_2$-Gly-L-Lys-),[3] all of which contain the -Gly-L-Lys-Gly- sequence, were hydrolyzed by trypsin at the L-Lys-Gly bond. Izumiya *et al.*[4] observed that the rate of tryptic hydrolysis of H-L-Leu-L-Lys-NH_2 is higher than that of H-Gly-L-Lys-NH_2. It thus seemed of interest to synthesize *cyclo*(-L-Leu-L-Lys-Gly-)$_2$ (**7**) and see if it is hydrolyzed by trypsin faster than *cyclo*-(-Gly$_2$-L-Lys-)$_2$.

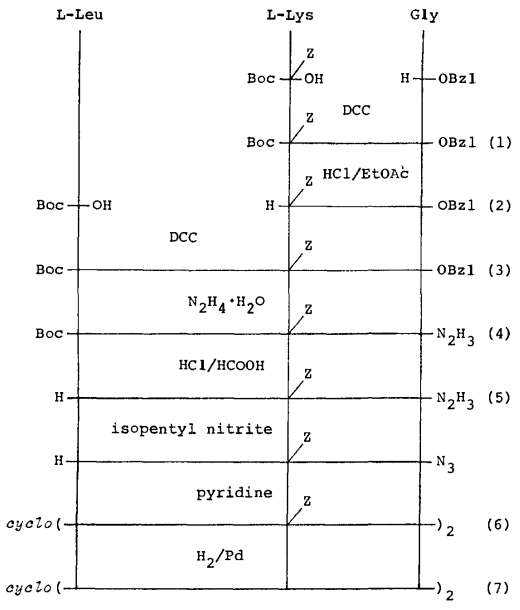

Fig. 1. Synthesis of cyclic hexapeptides, **6** and **7**.

The synthetic route[5] is shown in Fig. 1. A key intermediate, *cyclo*(-L-Leu-L-Lys(Z)-Gly-)$_2$ (**6**) was obtained in 30% yield by the cyclization of the tripeptide azide in pyridine (concentration, 5×10^{-3} M) at 0 °C. Compound **6** was hydrogenolyzed to give the final product **7** as crystalline dihydrochloride. The dimeric nature of **7** was confirmed by FD-mass spectrometry; M^+ 597 was observed, the calculated molecular weight corresponding to the cyclic hexapeptide being 596.7. The homogeneity of **7** was confirmed by TLC and paper chromatography.

Compound **7** was hydrolyzed by trypsin, giving a peptide (R_f^3 0.48) in Tris buffer at pH 7.8. No other spot except for the peptide with R_f^3 0.48 could be observed on a paper chromatogram during the course of incubation of **7**. The peptide with R_f^3 0.48 was assigned to a tripeptide, H-Gly-L-Leu-L-Lys-OH (**11**), by comparison with an authentic **11**, which was synthesized by the hydrogenation of Z-Gly-L-Leu-L-Lys-(Z)-OBzl (**10**). Compound **10** was prepared from Z-Gly-OH and H-L-Leu-L-Lys(Z)-OBzl (**9**) which was derived from Boc-L-Leu-L-Lys(Z)-OBzl (**8**). The result of tryptic digestion is similar to that obtained for *cyclo*-(-Gly$_2$-L-Lys-)$_2$.[2] This indicates that the rate-determining step is the conversion of **7** into a linear hexapeptide H-Gly-L-Leu-L-Lys-Gly-L-Leu-L-Lys-OH, which is cleaved to **11** immediately. It was observed, however, that tryptic hydrolysis of **7** proceeds slowly as compared to *cyclo*(-Gly$_2$-L-Lys-)$_2$. Steric effect of the bulky side chain in leucyl residues in the rigid backbone of **7** seems to hinder tryptic digestion.

Experimental

TLC was carried out on Merck silica gel G with the following systems: R_f^1, $CHCl_3$–MeOH (5: 1); R_f^2, *n*-BuOH–AcOH–pyridine–H_2O (4: 1: 1: 2). The ratio in parentheses is given in terms of vol. Paper chromatography was performed on Toyo Roshi No. 52 paper with the solvent system: R_f^3, the same solvent as used for R_f^2. Mass spectrum was taken on a Hitachi mass spectrometer Model JMS-01SG 2 equipped with combined sources: the sample was charged by emitter dipping technique; anode heating current, 18 mA. Crystalline trypsin (Nutritional Biochemicals, Cleveland, U.S.A.) was used without further purification.

Boc-L-Lys(Z)-Gly-OBzl (1). DCC (2.06 g, 10 mmol) was added to a solution of dicyclohexylamine salt[2] (5.62 g, 10 mmol) of Boc-L-Lys(Z)-OH and H-Gly-OBzl·TosOH (3.37 g, 10 mmol) in CH_2Cl_2 (20 ml) at 0 °C. The reaction mixture was stirred at 0 °C for 1 h and at room temperature overnight. After removal of *N,N'*-dicyclohexylurea, the filtrate was evaporated and the residue was diluted with EtOAc. The solution was successively washed with 0.5 M citric acid, 0.5 M $NaHCO_3$, and water, and then dried (Na_2SO_4). After evaporation under reduced pressure, the residue was solidified by the addition of ether. It was recrystallized from EtOAc–ether–petroleum ether; yield, 4.48 g (85%); R_f^1 0.86. Physical constants and results of elemental analyses of all crystalline compounds are given in Table 1.

H-L-Lys(Z)-Gly-OBzl·HCl (2·HCl). Compound **1** (1.32 g, 2.5 mmol) was dissolved in 2.57 M HCl in EtOAc (19.4 ml, 50 mmol), and the solution was left to stand at room temperature for 1 h and then evaporated. The resulting crystals were collected with the aid of ether; yield, 1.13 g (96%); R_f^1 0.50.

Boc-L-Leu-L-Lys(Z)-Gly-OBzl (3). This was prepared from Boc-L-Leu-OH and **2**·HCl as described for **1**;

a) MeOH (*c* 2) used. b) AcOH (*c* 0.2) used.

yield, 82%; R_f^1 0.72.

*Boc-L-Leu-L-Lys(Z)-Gly-N_2H_3 (**4**).* A solution of **3** (640 mg, 1 mmol) and $N_2H_4\cdot H_2O$ (0.95 ml, 20 mmol) in DMF (10 ml) was left to stand for 3 days at 38 °C, and then evaporated. The residue was dissolved in $CHCl_3$ (50 ml), washed with water, and dried (Na_2SO_4). After removal of the solvent, the residue was solidified by the addition of ether. Recrystallization from MeOH–ether–petroleum ether yielded 468 mg (83%); R_f^1 0.60.

*H-L-Leu-L-Lys(Z)-Gly-N_2H_3·2HCl (**5**·2HCl).* This was prepared from **4** by use of a mixture of 0.0925 M HCl (2.2 eq) in HCOOH and CH_2Cl_2 (1: 1) in place of HCl in EtOAc as described for **2**·HCl; yield, 92%; R_f^1 0.10.

cyclo(*-L-Leu-L-Lys(Z)-Gly-*)$_2$ (**6**). Compound **5**·2HCl (860 mg, 1.6 mmol) was dissolved in DMF (20 ml) containing a few drops of glacial AcOH, and the solution was cooled to −50 °C. To the solution were added 2.7 M HCl in EtOAc (1.78 ml, 4.8 mmol) and isopentyl nitrite (0.237 ml, 1.76 mmol). The solution was stirred for 20 min at −30 °C, and then added dropwise to pyridine (300 ml) at 0 °C. The reaction mixture was stirred for 3 days at 0 °C, and then evaporated. The residue was dissolved in a mixture of MeOH (6 ml) and water (1 ml), and passed successively through columns (each 10.5×1.8 cm) of Dowex 50 (H^+ form) and Dowex 1 (OH^- form). The columns were washed with the same solvent, and the combined effluent (*ca.* 200 ml) was evaporated to dryness. The residue was collected with water. Recrystallization from MeOH-ether yielded 210 mg (30%); R_f^1 0.72, R_f^2 0.87.

cyclo(*-L-Leu-L-Lys-Gly-*)$_2$·2HCl (**7**·2HCl). Compound **6** (86.5 mg, 0.1 mmol) was suspended in a mixture of MeOH (1.5 ml) and AcOH (1.5 ml), and hydrogenated in the presence of palladium black. The suspension turned clear with the progress of reaction. In the course of the reaction, the solution showed 3 spots on TLC with R_f^2 values of 0.87 (A), 0.73 (B), and 0.55 (C). Spot A was of the starting material **6**, while spot C was of the final product **7**. Spot B was assumed to be a cyclic hexapeptide in which one of the Z group had been cleaved and another remained. When hydrogenation completed after 4 h, only one spot C was observed on TLC. To this solution was added 2.7 M HCl in EtOAc (0.081 ml, 0.22 mmol) and the filtrate from the catalyst was evaporated to dryness. It was recrystallized from MeOH–EtOAc; yield, 52 mg (75%); R_f^2 0.55, R_f^3 0.66. Found: M^+, 597. Calcd for $C_{28}H_{52}O_6N_8$ (**7**): M, 597.

*Boc-L-Leu-L-Lys(Z)-OBzl (**8**).* Isobutyl chloroformate (0.13 ml, 1 mmol) was added at −10 °C to a chilled solution of Boc-L-Leu-OH (231 mg, 1 mmol) and Et_3N (0.14 ml, 1 mmol) in tetrahydrofuran (2 ml). After 5 min, a chilled mixture of H-L-Lys(Z)-OBzl·TosOH[2] (543 mg, 1 mmol) and Et_3N (0.14 ml, 1 mmol) in $CHCl_3$ (2 ml) was added. The reaction mixture was stirred for 1 h at 0 °C and overnight at room temperature, and then evaporated. The residual oil was then dissolved in EtOAc, washed successively with 0.5 M citric acid, 0.5 M $NaHCO_3$, and water, and dried (Na_2SO_4). After evaporation, the residue was solidified by the addition of ether. It was recrystallized from EtOAc–ether–petroleum ether; yield, 425 mg (73%); R_f^1 0.85.

*H-L-Leu-L-Lys(Z)-OBzl·HCl (**9**·HCl).* This was prepared from **8** as described for **2**·HCl; yield, 93%; R_f^2 0.75.

*Z-Gly-L-Leu-L-Lys(Z)-OBzl (**10**).* This was prepared from Z-Gly-OH and **9**·HCl as described for **8**; yield, 89%; R_f^1 0.90.

*H-Gly-L-Leu-L-Lys-OH·2HCl (**11**·2HCl).* This was prepared from **10** as described for **7**; yield of hygroscopic crystals, 100%; R_f^2 0.43, R_f^3 0.48.

*Action of Trypsin on **7**.* Tryptic hydrolysis on the substrate **7** was carried out at pH 7.8 and at 30 °C. A solution of **7**·2HCl (6.7 mg, 0.01 mmol) in dimethyl sulfoxide (0.05 ml) was diluted with 0.2 M Tris buffer (0.50 ml) and with water to a total volume of 1 ml and incubated upon addition of trypsin (2 mg). The progress of the reaction was followed by paper chromatography in the course of time. A spot of **11** appeared after 10 min and the spot of **7** diasppeared after 24 h. In a similar experiment, *cyclo*(-Gly$_2$-L-Lys-)$_2$ was completely hydrolyzed within 4 h.

The authors wish to express their thanks to Mr. Akio Hashimoto, Kitakyushu Municipal Institute of Environmental Health Science, for his help in the measurement of mass spectroscopy.

Liquid-phase Oxidation of Anthracene in Acetic Acid by Copper(II) Chloro Complexes

Jinya KOSHITANI,* Masayoshi HIRAMATSU, Yoshio UENO, and Takatoshi YOSHIDA

Department of Industrial Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received September 5, 1977)

Synopsis. Copper(II) chloro complexes contribute to the liquid-phase oxidation of anthracene in acetic acid. Products of the oxidation were anthrone, anthraquinone, 9-acetoxyanthracene, and 9-chloroanthracene.

It is known that the copper(II) chloro complexes[1-4] are formed by the reactions of copper(II) salts with alkali chlorides both in aqueous and nonaqueous solutions. Although the catalytic activities of copper(II) salts in liquid-phase oxidation are generally low, it was observed that the addition of lithium chloride highly improved the activity of copper(II) acetate in liquid-phase oxidation. No chain reaction in liquid-phase oxidation of a polynuclear aromatic hydrocarbon had been reported before the work[5] of Mahoney. There appears to be general agreement that a polynuclear aromatic hydrocarbon is not readily oxidized in liquid-phase oxidation. In this paper, the activities of copper-(II) chloro complexes and the reaction products in the liquid-phase oxidation of anthracene are reported.

Experimental

Materials. Acetic acid was distilled after refluxing with $KMnO_4$. The water content in the distllate was determined by the Karl-Fischer method and the water removed with the equivalent amount of acetic anhydride. Copper(II) acetate (reagent grade) and lithium chloride (reagent grade) were dried at 115 and 120 °C in vacuum respectively. Lithium acetate (reagent grade) was used without further purification. Commercial oxygen was purified by passing through 30% aqueous potassium hydroxide solution and concd sulfuric acid. Anthracene was dissolved in xylene, the solution poured into methanol and the precipitated anthracene dried in vacuum.

Oxidation Procedure. Oxidation was performed in a closed system using an apparatus equipped with a gas burette and oxygen absorption was followed by a manually controlled gas burette filled with mercury. The reaction was performed under the partial pressure of oxygen by which the rate of the oxidation was not affected.

Measurements. UV and visible absorption spectra were recorded with a Hitachi spectrophotometer model 124. The water content in acetic acid was determined with a Karl-Fischer apparatus, Kyoto Electronic Industry Ltd. MK-SS.

Analyses of Reaction Products. The reaction mixture was diluted with water and extracted with benzene which was removed in vacuum. The extracts were analyzed with a Yanagimoto model 550-TF gas chromatograph using a 2.25 m column of 30% Apieason grease L on Celite 545 at 190 °C and a 2 m column of 10% Silicone OV-17 on Chromosorb WAW at 230 °C. Gas-mass spectral analysis was performed with a JEOL model JMSD100-JGC20K spectrometer equipped with a 2 m column of 10% Silicone OV-17 on Chromosorb WAW.

Results and Discussion

Effect of Copper(II) Chloro Complexes. The following equilibrium exists in a mixture of acetic acid and lithium chloride.

$$AcOH + LiCl \rightleftarrows LiOAc + HCl \quad (1)$$

In a mixture of copper(II) acetate and hydrogen chloride, the following equilibria[4] have been proposed.

$$Cu_2(OAc)_4 + 2HCl \rightleftarrows 2CuCl(OAc) + 2AcOH \quad (2)$$

$$Cu_2(OAc)_4 + 4HCl \rightleftarrows 2CuCl_2 + 4AcOH \quad (3)$$

Further, the following equilibria[4] in a mixture of lithium chloride and copper(II) chloride in acetic acid have also been reported.

$$CuCl_2 + LiCl \rightleftarrows LiCuCl_3 \quad (4)$$

$$LiCuCl_3 + LiCl \rightleftarrows Li_2CuCl_4 \quad (5)$$

It is also known that copper(II) acetate exists mainly as the dimer[6] in acetic acid. In these experiments, the absorption maximums at 685 and 365 nm which were observed when copper(II) acetate was dissolved in acetic acid decreased and disappeared upon addition of lithium chloride respectively. This suggests that a part of the dimer of copper(II) acetate is converted into the monomer by the addition of lithium chloride and that copper(II) chloro complexes are formed. No oxygen absorption was detected when the oxidation of anthracene without any additive was performed at 90 °C in acetic acid. The rate of oxygen absorption in the oxidation of anthracene with copper(II) acetate was low but improved on addition of lithium chloride. However, without copper(II) acetate in the oxidation of anthracene, no oxygen absorption was observed either on adding lithium chloride or lithium acetate. A part of these results is shown in Table 1. Accordingly lithium chloride, lithium acetate and hydrogen chloride formed by the reaction of lithium chloride with acetic acid were not effective in the oxidation of anthracene directly. Moreover, the rate of oxygen absorption in the oxidation

Table 1. Effects of copper(II) acetate and lithium chloride addition on the oxidation of anthracene at 90 °C

Anthracene mol/l	Copper(II) acetate $Cu_2(OAc)_4$ mol/l	Lithium chloride mol/l	Initial rate of oxygen absorption mol/l·s
0.05	—	0.01	0 (reaction time 240 min)
0.05	0.01	—	1.3×10^{-7}
0.05	0.005	0.01	2.9×10^{-6}
0.05	0.01	0.01	4.2×10^{-6}

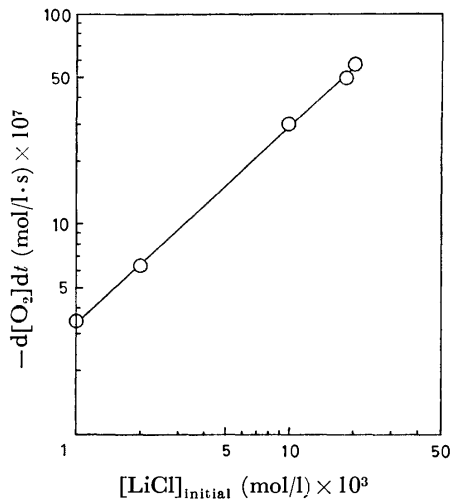

Fig. 1. Effect of $[LiCl]_{initial}$ at 90 °C under conditions, $[LiCl]_{initial}=2\times[Cu_2(OAc)_4]_{initial}$.
$[LiCl]_{initial}$: initial concentration of added lithium chloride.
$[Cu_2(OAc)_4]_{initial}$: initial concentration of added copper (II) acetate dimer.

of anthracene with copper(II) acetate and lithium acetate was low. Thus the increase of oxygen absorption rate is presumed to be related to the formation of copper(II) chloro complexes.

Effect of Added Amount of Copper(II) Acetate and Lithium Chloride on Oxygen Absorption Rate. When the molar ratio of copper(II) acetate dimer to lithium chloride is 0.5, the effect of various amounts of added copper(II) acetate and lithium chloride is shown in Fig. 1. Initial rates of oxygen absorption increase as concentrations of added copper(II) acetate and lithium chloride increase. That is, some copper(II) chloro complexes formed from copper(II) acetate and lithium chloride effectively work for the liquid-phase oxidation. The rates of oxygen absorption are approximately proportional to the added amounts of copper(II) acetate and lithium chloride under the experimental conditions.

Reaction Products. Anthraquinone, anthrone, 9-acetoxyanthracene, and 9-chloroanthracene were identified as reaction products by gas chromatography and gas-mass spectrometry. Formation of 10,10′-bianthrone was not observed. No generation of carbon dioxide from the reaction solution was detected. Typical

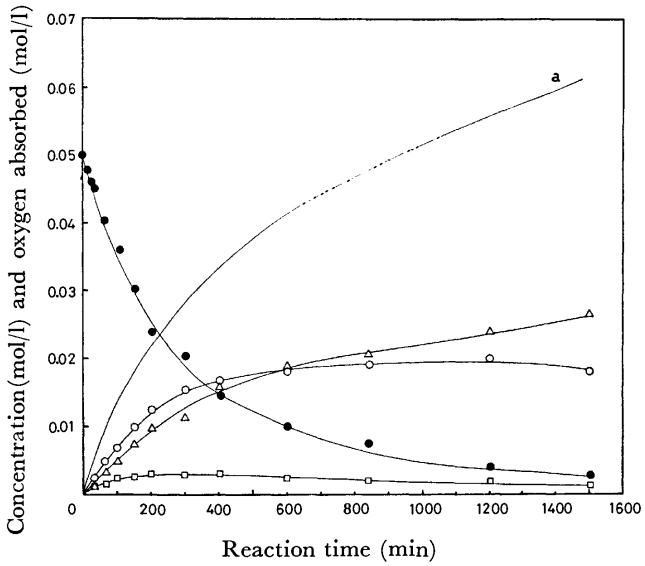

Fig. 2. Time course of oxidation of anthracene at 90 °C.
anthracene : 0.05 mol/l
copper(II) acetate $Cu_2(OAc)_4$: 0.005 mol/l
lithium chloride : 0.01 mol/l
●: Anthracene, □: 9-acetoxyanthracene, ○: anthrone, △: anthraquinone, a: oxygen absorbed.

patterns of production of anthraquinone, anthrone, and 9-acetoxyanthracene, decrease of anthracene, and oxygen absorption are shown in Fig. 2. 9-Chloroanthracene was detected in trace amounts. At the initial stage of oxidation, anthrone was a main product. 9-Acetoxyanthracene was produced at the initial stage of oxidation and then remained nearly constant in the reaction solution.
