The Pd–P bond lenghts [2.320(2) and 2.349(2) Å] are not equal, and these values are slightly longer than those of 2.232(3) Å in $[Pd(C_2H_2O_2)(PPh_3)(py)]$,[2] 2.235(1) Å in $[Pd(CH_2COOH)(acac)(PPh_3)]$,[7] and 2.258(4) Å in $[Pd(acac)_2(PPh_3)]$.[5] The P(1)–Pd–P(2) angle of 98.05(7)° is larger than 90° because of steric interaction between two triphenylphosphine ligands.

In the chelate ring of acetic anhydride, the C(1)–C(2) and C(3)–C(4) bond lenghts of 1.473(18) and 1.479(19) Å are compared with those ovserved in C–C=O moieties in many organic compounds [av 1.506(5) Å].[10] The C(2)=O(2) and C(3)=O(3) bond lengths are 1.192(18) and 1.202(17) Å, respectively, which are equal to those in aldehydes and ketones [av 1.215(5) Å],[10] and that in α-oxalic acid [1.207(1) Å].[11] The C(2)–O(1) and C(3)–O(1) bond lengths [1.412(16) and 1.386(17) Å] have intermediate values between those observed in saturated [av 1.426(5) Å] and conjugated heterocyclic C–O bonds [1.371(16) Å (in furan)].[12] The C(1)–C-(2)–O(1) and C(4)–C(3)–O(1) angles [113.6(11) and 113.2(11)°] are much smaller, whereas the C(1)–C(2)–O(2) and C(4)–C(3)–O(3) angles [129.6(13) and 128.3-(12)°] are much larger than 120°. However, the C(1), C(2), O(1), and O(2) atoms and C(3), C(4), O(1), and O(3) atoms respectively lie on a plane: the dihedral angles between these planes being 69.8°. The dihedral angles between these planes and the coordination plane are 64.0 and 65.4°, respectively: the O(2) and O(3) atoms being above and below the coordination plane

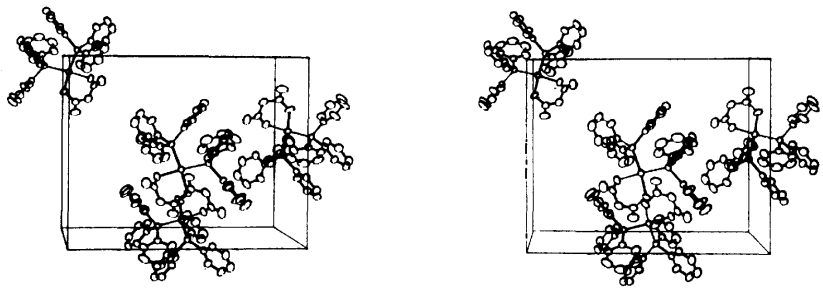

Fig. 4. A stereoscopic drawing of the molecular packing in the unit cell.

TABLE 5. INTERMOLECULAR ATOMIC CONSTANTS WITHIN 3.5 Å

O(2)–C(53)[a]	3.48(2) Å	Code for superscript
O(1)–C(64)[b]	3.44(2)	a) $0.5-x, \quad -y, -0.5+z$
O(3)–C(63)[b]	3.41(2)	b) $0.5+x, 0.5-y, \quad -z$

(Fig. 3(b)). The Pd–C(1)–C(2) and Pd–C(4)–C(3) angles [109.2(9) and 107.3(8)°] have normal tetrahedral values.

Both phosphorus atoms show deviations from the tetrahedral geometry: the C(11)–P(1)–C(21) and C(21)–P(1)–C(31) [102.5(4), and 100.8(4)°] and C(41)–P(2)–C(51), C(41)–P(2)–C(61), and C(51)–P(2)–C(61) angles [104.0(4), 99.6(4), and 105.6(4)°] being much smaller, whereas Pd–P(1)–C(21) and Pd–P(1)–C(31) [118.7(3) and 113.0(3)°] and Pd–P(2)–C(41) angle [122.8(3) Å] being larger than the tetrahedral angle. Six phenyl rings attached to the phosphorus atoms heve normal structure [C–C (av)=1.395 Å and C–C–C (av)=120.0°].

Crystal Structure. Figure 4 shows a stereoscopic view of the molecular packing in the unit-cell along the c axis. The intermolecular atomic contacts less than 3.5 Å are listed in Table 5: no short interatomic distance being found.

Computations throughout the present study were carried out on a NEAC 2200-700 computer at the Osaka University. Figures 2 and 4 were drawn on the NUMERICON 7000 system at Osaka University with a local version of ORTEP.[13]

The authors wish to express their deep thanks to Professor Shinichi Kawaguchi and co-workers of the Osaka City University for supplying crystals and helpful discussions.

Fluorescence Lifetime Measurements of Morin-Metal Ion Complexes

Tsuguo SAWADA, Takeshi SHIBAMOTO, and Hitoshi KAMADA
Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received June 8, 1977)

Fluorescence lifetimes of morin complexes of Be(II), Zn(II), Al(III), Ga(III), In(III), Th(IV), Zr(IV), and Sn(IV) extracted into isopentyl alcohol from the acid solution at various pH values were investigated. The result indicates that the Al(III), Ga(III), and In(III) complexes change their compositions according to the change of pH. More detailed investigations by the use of mole ratio method suggest that Al(III), Ga(III), and In(III) form complexes having two different mole ratios of 1 to 1 and 1 to 2 (metal ion: morin). Fluorescence lifetimes were changed according to the changes of the composition of the complex and the differences of the metal ion.

Morin (3,5,7,2′,4′-pentahydroxyflavone) has been widely used as an analytical reagent for fluorometric determinations.

It reacts with Be(II), Zn(II), Al(III), Ga(III), In(III), Sn(IV), Th(IV), Zr(IV), and so on to form fluorescent complexes. The Al(III),[1] Zr(IV),[2] and Be(II)[3] complexes exhibit especially intense green fluorescence, and morin has been utilized very often for the determination of trace amounts of these metal ions. The fluorescence system resulting from the reaction between Al(III) and morin has been applied also to the determination of inorganic ions such as F^- by the use of its quenching ability.[4]

Katyal[5] discussed summarily the analytical utilities of flavonoid compounds including morin. The compositions of complexes formed between morin and metal ions have been investigated by several workers. Biryuk and Rabitskaya[6] reported that In(III)-morin complex with the mole ratio of 1 : 1 is formed at pH 3.6. Recently Katyal and Prakash[7] reported that Al(III) and Ga(III) give the morin complexes with the same composition as the In(III) complex at pH 3.6. In the case of Th(IV) complex, two different results were obtained by Fletcher *et al.*[8] and by Blank *et al.*[9]: that is, 1 : 2 and 1 : 3 complexes, respectively.

In the present paper, we report the new results that complexes with two different mole ratios are formed in Al(III)-, Ga(III)-, In(III)-, and Be(II)-morin systems, while Zn(II), Th(IV), Zr(IV), and Sn(IV) react with morin to give the complexes with a single mole ratio by the measurement of the fluorescence lifetime of these complexes. Although these complexes showed very similar fluorescence spectra, explicitly different fluorescence lifetimes were determined.

Experimental

Reagents and Procedure. Aluminium(III) and gallium(III) stock solutions were obtained by dissolving each metal in concentrated hydrochloric acid. An indium(III) solution was prepared by dissolving indium(III) hydroxide in boiling hydrochloric acid. Other metal ion solutions were prepared by dissolving each salt in hydrochloric acid. Working solutions of each metal ion were prepared by diluting the stock solutions with distilled water to about 10 mM.

Morin of high purity was purchased from Merck. Solutions of morin were prepared by dissolving the solid material in methanol. Spectral grade methanol and high purity isopentyl alcohol were purchased from Wako Junyaku, Co., Ltd. All the reactions of complexation were done in hydrochloric acid solutions at various pH values, and the complexes obtained were almost extracted into isopentyl alcohol, as described elsewhere.[10] After the extraction solutions were degassed by bubbling with high purity nitrogen for 5 min, fluorescence and excitation spectra and fluorescence lifetimes were measured.

Apparatus. Fluorescene and excitation spectra were measured with a Hitachi MPF-4 fluorometer. Fluorescence lifetimes were measured by the use of a home-made time-correlated single photon counting apparatus.[11] Although the time-resolution is 0.1 ns, the exciting light pulse has a time-duration of 1.6 ns. Therefore, the values of fluorescence lifetimes shorter than 2.0 ns were corrected by the deconvolution method.

Results and Discussion

Aluminium(III)-Morin Complex. Figure 1 shows fluorescence and excitation spectra of the aluminium-morin complex in isopentyl alcohol. The complex was formed in hydrochloric acid solutions at pH 1.0 and 3.0. Morin itself does not fluoresce in acid solutions. As is seen in this figure, the maximum fluorescence wavelengths are 495 nm at pH 1.0 and 503 nm at pH 3.0.

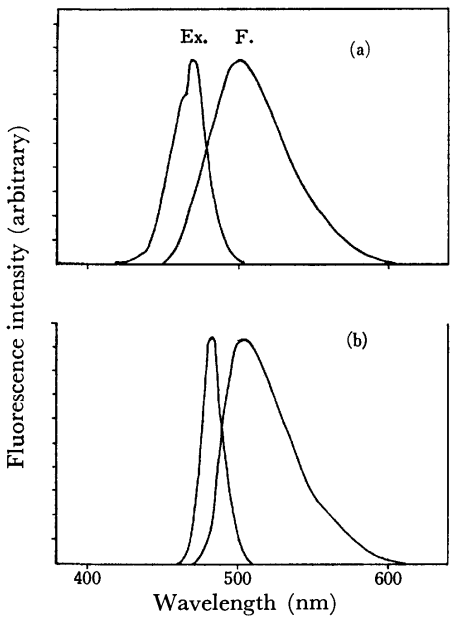

Fig. 1. Fluorescence and excitation spectra of Al(III)-morin complex in isopentyl alcohol; (a) pH 1.0 and (b) pH 3.0.

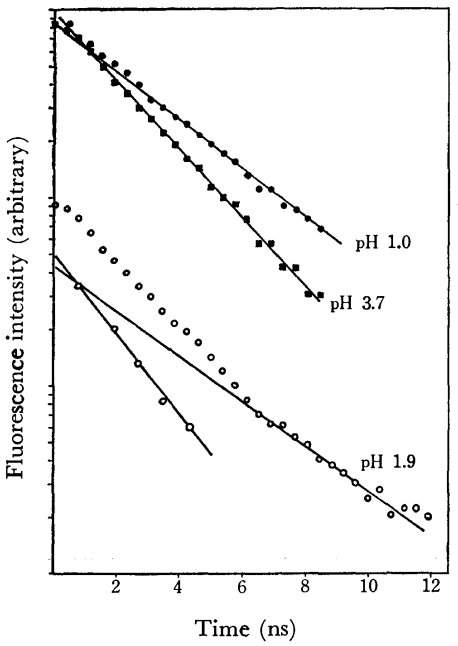

Fig. 2. Semilogarithmic plots of the decay time of the fluorescence of Al(III)–morin complex.

There is little difference between the fluorescence spectra at pH 1.0 and 3.0, while the excitation spectra are very different.

Figure 2 shows a semilogarithmic plot of the fluorescence intensity *vs.* time in order to obtain the fluorescence lifetime of the aluminium complex. As shown in Fig. 2, the decay time of fluorescence of the complex extracted at pH 1.9 has two different exponential features. On the contrary, the plots for those extracted both at pH 1.0 and 3.7 give single exponential decay times. Moreover, the component with the longer lifetime in the two fluorescence decays at pH 1.9 agrees with that at pH 1.0, and the component with the shorter lifetime with that at pH 3.7, within experimental errors. The value of the longer lifetime component is (3.3 ± 0.1) ns and that of the shorter lifetime component is (2.0 ± 0.3) ns. These results suggest that the composition of aluminium-morin complex changes near pH 2. The composition of aluminium to morin was estimated by the mole ratio method. The result is shown in Fig. 3,

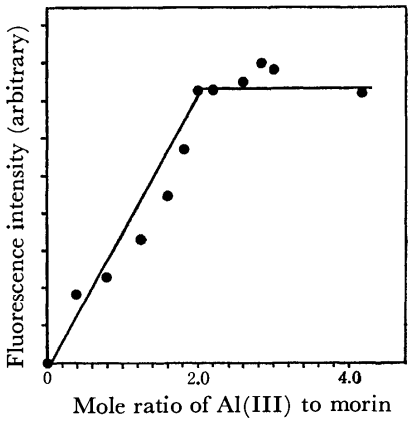

Fig. 3. The mole ratio method for Al(III)–morin complex formed at pH 1.3.

which confirms the aluminium-morin ratio of 1 : 2 for the complex formed at pH 1.0. The composition of complex at pH 3.0 was also investigated and the result obtained was in good agreement with that in the literature.[7] The structure of the complex has not been established yet, but the metal ion is assumed to be substituted for the hydrogen of the hydroxyl group at the 3- or 5-position.[10]

Gallium(III)- and Indium(III)–Morin Complexes. Figures 4 and 5 show fluorescence spectra of gallium-

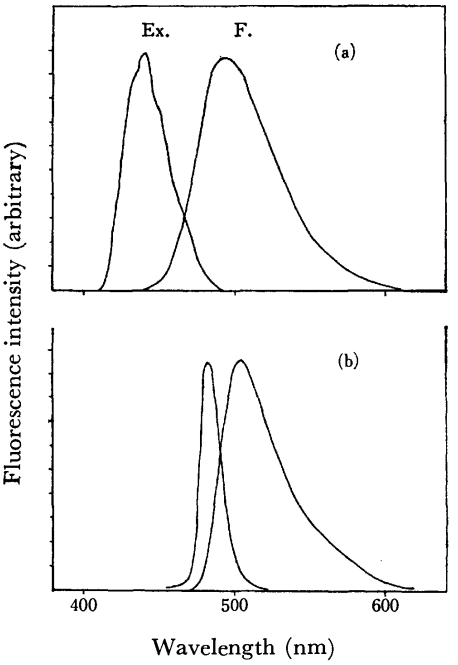

Fig. 4. Fluorescence and excitation spectra of Ga(III)–morin complex in isopentyl alcohol; (a) pH 1.0 and (b) pH 3.0.

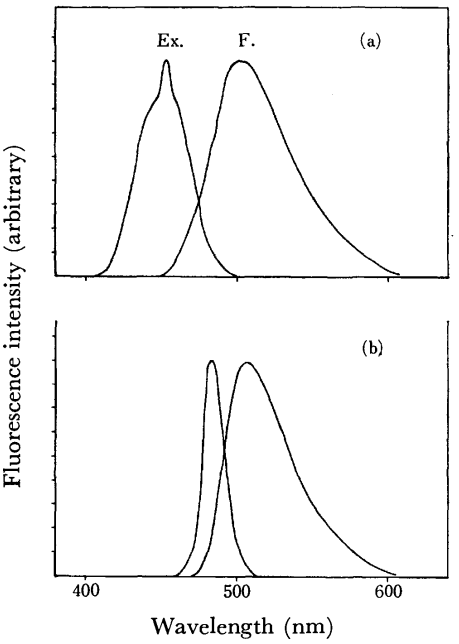

Fig. 5. Fluorescence and excitation spectra of In(III)–morin complex in isopentyl alcohol; (a) pH 1.3 and (b) pH 3.6.

and indium–morin complexes and their excitation spectra at two different pH values. The decay curve of the fluorescence showed a single exponent at each pH value. The results of the fluorescence lifetime measurement were that the longer lifetime component of the gallium complex is (2.7±0.1) ns and the shorter one is (1.6±0.4) ns. As for the indium complex, the longer lifetime component is (4.6±0.1) ns and the shorter one is (3.5±0.1) ns. Dependencies of the shape and wavelength of fluorescence and excitation spectra on pH were in good agreement with those in the case of the aluminium complex. However, the fluorescences of the gallium and indium complexes were unstable in comparison with that of the aluminium complex. Therefore, no reliable composition of these complexes has been determined by the mole ratio method. However, the same conclusion about the composition as that obtained in the aluminium complex is predictable, because aluminium, gallium, and indium belong to the same group IIIb.

Beryllium(II)-Morin Complex. Beryllium ion reacted with morin to form a stable complex in both acid and basic solutions. If forms a complex with the mole ratio of 1 : 2 (beryllium: morin) in hydrochloric acid at pH 2.0 and its fluorescence lifetime was estimated to be (2.1±0.1) ns. Some differences in fluorescence and excitation spectra can be seen between the complexes obtained at pH>3.4 and at pH 2.0. The fluorescence lifetime obtained at pH 4.3 is (4.8±0.3) ns, although the mole ratio has not been determined because of the poorness of experimental reproducibility.

Thorium(IV)–, Zirconium(IV)–, Tin(IV)–, and Zinc-(IV)-Morin Complexes. These complexes obtained in acid media are considered to have a single mole ratio, since the fluorescence lifetime values showed no change in the pH range of 1–5. As for the thorium and zirconium complexes, the mole ratio of metal ions to morin was estimated to be 1 : 2. However, the mole ratio of tin– and zinc–morin complexes has not been determined, because the complexes were unstable.

The fluorescence lifetime values obtained in this work are summarized in Table 1.

TABLE 1. FLUORESCENCE PROPERTIES OF METAL ION–MORIN COMPLEXES IN ISOPENTYL ALCOHOL

Metal ion	Mole ratio (metal ion: morin)	F_{max} (nm)	E_x (nm)	Fluoresence lifetime (ns)
Al(III)	1 : 2	495	438	3.3±0.1
	1 : 1	503	483	2.0±0.3
Ga(III)	1 : 2	500	468	2.7±0.1
	1 : 1	503	483	1.6±0.4
In(III)	1 : 2	500	452	4.6±0.1
	1 : 1	506	483	3.5±0.1

Reactions between PbO and TiO_2 under Hydrothermal Conditions

Shoji KANEKO and Fumio IMOTO

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432

(Received July 29, 1977)

The phase relation of products obtained by the reaction between PbO and TiO_2 under hydrothermal conditions up to 500 °C and 500 kg/cm² for 5h has been investigated. The yield and crystallographic properties of purified $PbTiO_3$ depend upon the PbO/TiO_2 mole ratio (Pb/Ti ratio) in raw mixtures as well as the reaction temperature. Both $PbTiO_3$ and $PbTi_3O_7$ are synthesized at a remarkably low temperature under hydrothermal conditions, as compared with the ignition process in air. Pure and well-crystallized $PbTiO_3$ is obtained by heat-treating above 400 °C at Pb/Ti ratios greater than 1.0 and by dissolving excess PbO with acetic acid. $PbTi_3O_7$ coexists occasionally with $PbTiO_3$ to some extent at Pb/Ti ratios less than 1.0, but appears as a single phase in the temperature range 100—450 °C at the Pb/Ti ratio 0.33. The unit cell volume of $PbTiO_3$ prepared at lower temperature is considerably large, suggesting a loosely-packed structure. The compound is always of tetragonal form containing no metastable cubic form.

Three compounds, Pb_2TiO_4,[1] $PbTiO_3$,[2] and $PbTi_3O_7$[3] have been reported in the system PbO–TiO_2, although the phase diagram has not been completed so far. The existence of Pb_2TiO_4 was denied by Matsuo and Sasaki.[4] Aykan[3] found a novel compound $PbTi_3O_7$ by the reaction between PbO and TiO_2 in the TiO_2-rich region. Kato *et al.*[5] analyzed the structure in detail using a single crystal prepared by a flux method. Lobachev[6] also found a new phase in the system PbO–TiO_2–KF–H_2O under hydrothermal conditions and determined the composition as $PbTi_3O_7$ by chemical analysis. His X-ray data, however, were insufficient, differing from those of other investigators.[3,5]

$PbTiO_3$ has a tetragonal form at room temperature, the axial ratio (c/a=1.065) being the largest of perovskite-type compounds. It is transformed reversibly from tetragonal to cubic around 490 °C (Curie point),[7] and is important as a component of complex perovskite-type compounds, especially piezoelectrics such as PZT ceramics.[8]

In previous papers[9,10] dealing with the reaction of oxides under hydrothermal conditions, it was shown that the crystallization and anatase-rutile transformation of TiO_2 was markedly accelerated, and fine-grained (below 200 Å) $BaTiO_3$ of tetragonal form easily synthesized. A hydrothermal reaction seems to be suitable for the preparation of inorganic powders containing a volatile component such as PbO.

We have investigated the phase relation of the products by the reaction between PbO and TiO_2 in order to find the optimum conditions for the preparation of pure $PbTiO_3$ under hydrothermal conditions.

Experimental

Starting Materials and Procedures. Hydrous titanium dioxide (TiO_2: 83.6 wt%, H_2O: 10.8 wt%, SO_3: 5.6 wt%) was prepared by the neutralization of titanium sulfate with aqueous ammonia (sulfate-process). This compound (TiO_2: 91.9 wt%, H_2O: 8.1 wt%) was also prepared by the hydrolysis of titanium tetrachloride with heating at about 100 °C (chloride-process). Both of them were considered to be the most reactive source of TiO_2.

Hydrous titanium dioxide and guaranteed reagent lead monoxide (purity 99.0 wt%, Koso Chemical Co., Ltd.) were weighed to prepare a mixture of a certain PbO/TiO_2 mole ratio (Pb/Ti ratio). A gold vessel containing raw materials and water was placed in a cylindrical autoclave of 100 cm³ volume, and subjected to various conditions up to 500 °C and 500 kg/cm² for 5 h. Products were washed several times with 5% acetic acid and distilled water by decantation in order to remove excess PbO, then dried at 80 °C in an oven.

Chemical Analysis. Dried products were analyzed by the following method. About 0.6 g of a sample is accurately weighed and dissolved in 20 ml of hot sulfuric acid with 6 g of ammonium sulfate. After cooling, lead sulfate is precipitated by addition water and filtered off for weighing. Hydrous titanium dioxide is precipitated from the filtrate by addition of aqueous ammonia. After filtration and ignition, the precipitate is weighed as total TiO_2, *i.e.*, unreacted TiO_2 and TiO_2 in $PbTiO_3$. The yield of $PbTiO_3$ is calculated by

$$\text{Yield (\%)} = \frac{\text{Weight of } TiO_2 \text{ in } PbTiO_3 \text{ equimolar to } PbSO_4}{\text{Weight of total } TiO_2} \times 100. \quad (1)$$

X-Ray Diffraction. The products were identified by means of X-ray diffraction using Geigerflex, Type D-2* with nickel-filtered Cu $K\alpha$ radiation. The crystallite size was calculated from Scherrer's equation[11] with Warren's correction, employing half value widths of $PbTiO_3$ (110) and Si (111) reflections. Lattice constants of tetragonal $PbTiO_3$ were determined by (110) and (200) reflections using Si as an internal standard.

Results and Discussion

Reaction Products under Various Conditions. Poorly-crystallized $PbTiO_3$ was formed at Pb/Ti ratio 1.0 and 200 °C, with an unknown phase X and a small amount of lead sulfate attributed to the sulfate ion contained in hydrous titanium dioxide[9] (Fig. 1). Above 300 °C, the unknown phase disappeared with increase of $PbTiO_3$. $PbTiO_3$ appeared as a single phase in a considerably wide temperature range. Under hydrothermal conditions, the synthesis of $PbTiO_3$ was initiated at a temperature as low as 170 °C, which was much lower than 550 °C in the ignition process reported by Okazaki *et al.*[12] and somewhat higher than 60 °C in the wet synthesis of $BaTiO_3$.[13] Figure 2 shows a similar

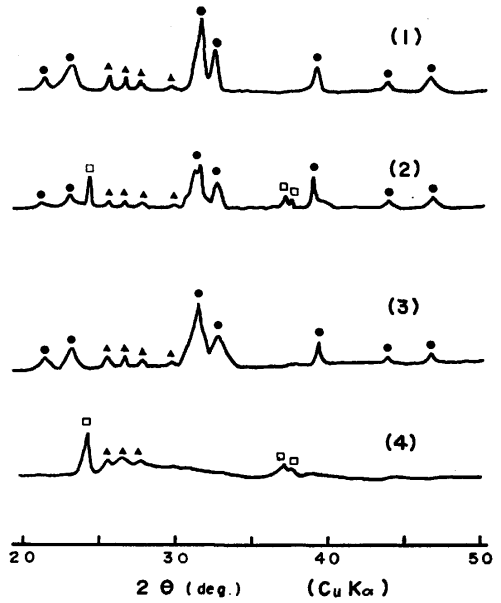

Fig. 1. X-Ray diffraction patterns of the products. (1) Pb/Ti ratio=1.0, 300 °C, (2) Pb/Ti ratio=1.0, 200 °C, (3) Pb/Ti ratio=0.8, 300 °C, (4) Pb/Ti ratio=0.8, 200 °C. ●: $PbTiO_3$, ○: $PbTi_3O_7$, ▲: $PbSO_4$, □: unknown phase.

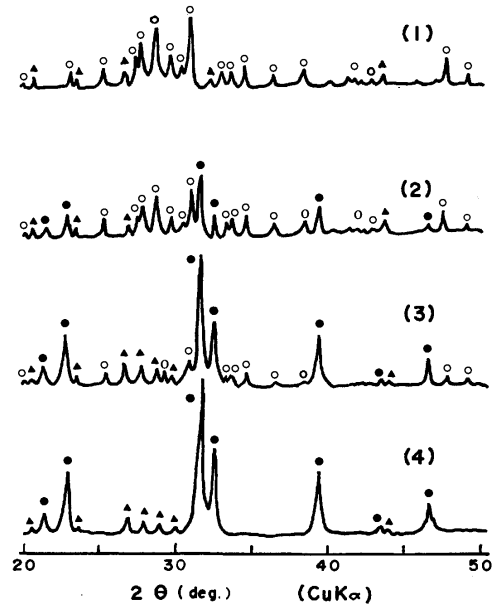

Fig. 2. X-Ray diffraction patterns of the products at various Pb/Ti ratios and 400 °C. (1) Pb/Ti ratio=0.33, (2) Pb/Ti ratio=0.5, (3) Pb/Ti ratio=0.7, (4) Pb/Ti ratio=1.0. ●: $PbTiO_3$, ○: $PbTi_3O_7$, ▲: $PbSO_4$.

phase relation at 400 °C. $PbTi_3O_7$ was observed as a single phase at Pb/Ti ratio 0.33. $PbTi_3O_7$ and $PbTiO_3$ coexisting at Pb/Ti ratios 0.45—0.7, the latter predominated high Pb/Ti ratio.

The relationship between Pb/Ti ratio, temperature and phase is shown in Fig. 3. The diagram is divided into four zones: (1) coexistence of amorphous and unknown phases, (2) $PbTiO_3$, (3) $PbTi_3O_7$, and (4)

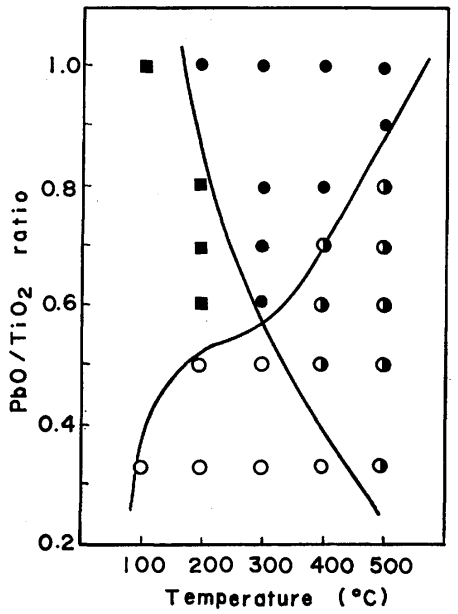

Fig. 3. Phase relation in the reaction between PbO and TiO_2 under hydrothermal conditions. ■: Amorphous and unknown phase, ●: $PbTiO_3$, ○: $PbTi_3O_7$, ◑: $PbTiO_3+PbTi_3O_7$.

coexistence of $PbTiO_3$ and $PbTi_3O_7$. It is remarkable that $PbTi_3O_7$ was solely obtained in a wide and low temperature range 100—450 °C under hydrothermal conditions, as compared with the narrow temperature range 800—850 °C in the ignition process in the air.[3]

Crystallographic Properties of $PbTiO_3$. In the lattice constants of $PbTiO_3$, *a* for the specimens treated at lower temperatures is slightly smaller than the value

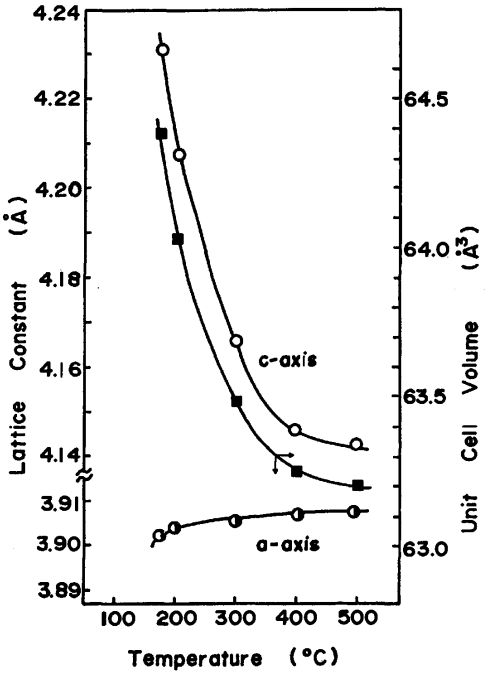

Fig. 4. Variations of lattice constants and unit cell volume of hydrothermal $PbTiO_3$ with reaction temperature.

reported** whereas c is relatively larger (Fig. 4), indicating that the unit cell expands to the direction of c-axis by loose packing of each ion. With increase in temperature, c decreases markedly and the axial ratio (c/a) gradually approaches the value 1.065,** the unit cell volume (a^2c) changing in a similar way to c. In contrast, hydrothermal $BaTiO_3$, as well as wet-synthesized $BaTiO_3$,[13,14] are of cubic form presumed to be a metastable state, being transformed into tetragonal form with increase in temperature.[11] The difference between $PbTiO_3$ and $BaTiO_3$ seems to arise primarily from the difference in ionic properties of lead and barium. The tolerance factor, or the fraction of ion packing, in $PbTiO_3$ is smaller than that in $BaTiO_3$; each ion in the former moves more easily around than that in the latter in the crystal lattice. In addition, lead ion is more readily polarized than barium ion. The anisotropy of the crystal structure is more enhanced in $PbTiO_3$.

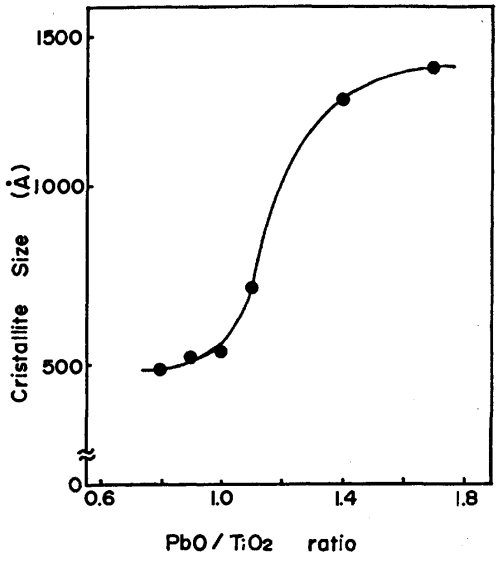

Fig. 5. Crystallite size of hydrothermal $PbTiO_3$ at 500 °C as a function of Pb/Ti ratio.

The crystallite size of $PbTiO_3$ increases from 500 to 1400 Å with increase in the Pb/Ti ratio (Fig. 5). The size of starting hydrous titanium dioxide is about 80 Å, the reaction temperature being too low to expect crystal growth by the solid state reaction. Thus the crystal growth suggests that the hydrothermal reaction proceeds through the solution-precipitation mechanism based on the large dissolving power of hydrothermal media.

TiO_2 obtained by the chloride-process was also examined as a starting material to avoid the formation of the by-products resulting from impurities. As shown in Fig. 6, the specimens prepared from TiO_2 by the chloride-process generally give sharper X-ray profiles than those for the specimens prepared from TiO_2 by the sulfate-process. No preheating TiO_2 by the sulfate-process contains both H_2O and SO_3. It loses almost H_2O at about 570 °C, then releasing SO_3 and crystallizes completely. On the other hand, no preheating TiO_2 by the chloride-process contains H_2O alone and loses it at 300 °C.[9] When used no preheating TiO_2 or TiO_2 preheated at 600 °C, the X-ray profiles of $PbTiO_3$ were sharp [Fig. 6(1)], but when used TiO_2 preheated at 400 °C, the profile was broad. When used no preheating TiO_2, the profile was very sharp, but when used TiO_2 preheated over 400 °C, the profiles were rather broad [Fig. 6(2)]. If we assume that the sharper X-ray profile

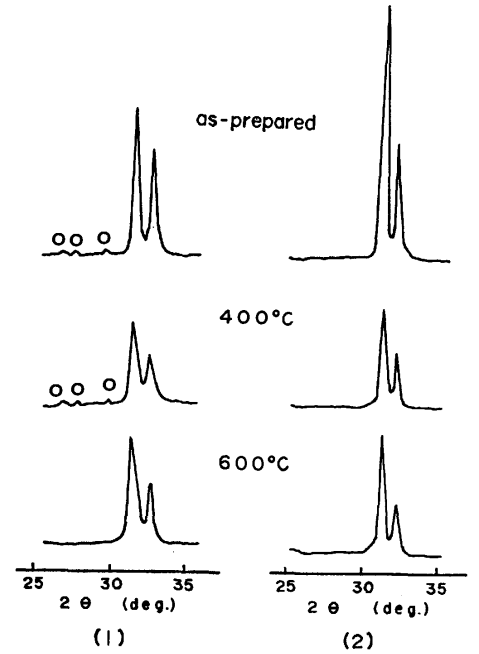

Fig. 6. X-Ray profiles of hydrothermal $PbTiO_3$ prepared from two kinds of TiO_2 pre-heated at various temperatures. (1) TiO_2 prepared by the sulfate-process, (2) TiO_2 prepared by the chloride-process. ○: $PbSO_4$.

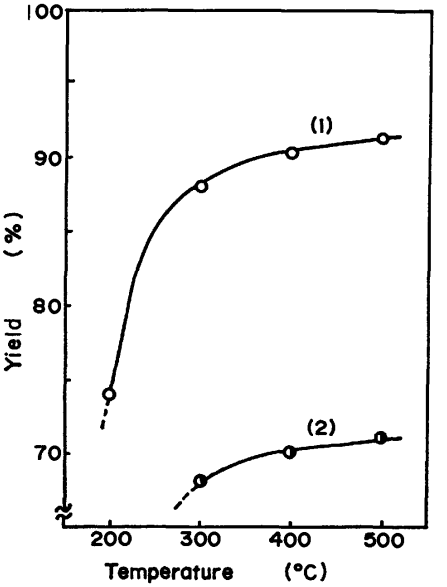

Fig. 7. Relationship between yield of hydrothermal $PbTiO_3$ and reaction temperature. (1) Pb/Ti ratio= 1.0, (2) Pb/Ti ratio=0.8.

** From "Powder Diffraction File, Card No. 4-0477," lattice constants a and c of $PbTiO_3$ are 3.899 Å and 4.153 Å, respectively. Unit cell volume, a^2c=63.138 Å^3 and axial ratio, c/a=1.065 are calculated from these values.

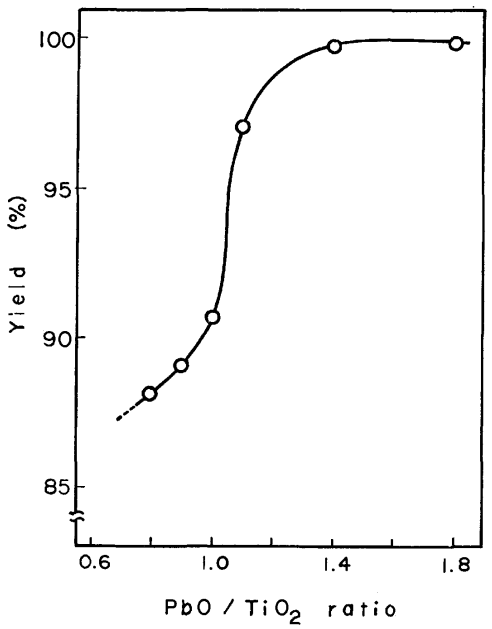

Fig. 8. Relationship between yield of hydrothermal $PbTiO_3$ and Pb/Ti ratio at 500 °C.

is related to better crystallinity, OH or H_2O on the surface of TiO_2 promotes crystallization, while the sulfate ion retards it. For the preparation of pure and well-crystallized $PbTiO_3$ it is advantageous to use no preheating TiO_2 by the chloride-process containing much H_2O and no sulfate ion.

Yield of $PbTiO_3$. At the Pb/Ti ratios 0.8—1.0, the yield increases with in temperature, the reaction proceeding almost completely up to 400 °C (Fig. 7). The yield was 90.7% at the Pb/Ti ratio 1.0 and 400 °C. However it is estimated to be over 95% after the correction for the consumption of PbO by the preferential reaction with sulfate ion contained in hydrous titanium dioxide converting to lead sulfate. Figure 8 shows the relation between yield and the Pb/Ti ratio at 500 °C. When the Pb/Ti ratio exceeds 1.0, the yield reaches 100% after the correction described above. The yield changes considerably with the Pb/Ti ratio and reaction temperature.

The authors wish to thank Mr. Kenji Kamo and Mr. Tohru Yamamoto for technical assistence throughout the course of this work.

Bivalent and Tervalent Cobalt Complexes of 4-(2-Pyridylazo)resorcinol, 1-(2-Pyridylazo)-2-naphthol, and their Thiazolyl Analogs in Aqueous and Aqueous Dioxane Media. Rapid-scan Spectral and Kinetic Studies*

Katsura MOCHIZUKI, Taira IMAMURA, Tasuku ITO, and Masatoshi FUJIMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received August 29, 1977)

The reactions of Co^{2+} with 4-(2-pyridylazo)resorcinol (PAR), 1-(2-pyridylazo)-2-naphthol (PAN), and their thiazolyl analogs TAR and TAN in aqueous or aqueous dioxane media are followed by a rapid-scan spectroscopic method combined with stopped-flow technique. The step of the fast formation of cobalt(II) complexes is clearly discriminated from the subsequent slower step of oxidation to the cobalt(III) state. Formation and redissolution of transient insoluble intermediates are observed in the stopped-flow signals for the light scattered by the reaction mixture. The metal-to-ligand ratio in the short-lived intermediate cobalt(II) complex of PAR and PAN is determined to be 1 : 2 by applying the method of continuous variation to the fast change in stopped-flow signals. The rate constants k_1 and k_2 for the step of formation of 1 : 1 cobalt(II) complex with the species LHH* and LH^- of PAR in aqueous solution and with the species LH_2^+ and LH of PAN in 5%(v/v) dioxane–water are determined to be $k_1 = 4.8 \times 10^4$ and $k_2 = 9.8 \times 10^4$ dm^3 mol^{-1} s^{-1}, and $k_1 < 10^3$ and $k_2 = 4.6 \times 10^3$ dm^3 mol^{-1} s^{-1}, respectively.

Some *ortho*-hydroxy azo compounds shown in Fig. 1 are reported to behave as terdentate ligands[1,2] forming colored chelates with many metal ions.[3] PAN and PAR have been used as sensitive analytical reagents for the spectrophotometric determination of cobalt.[4,5]

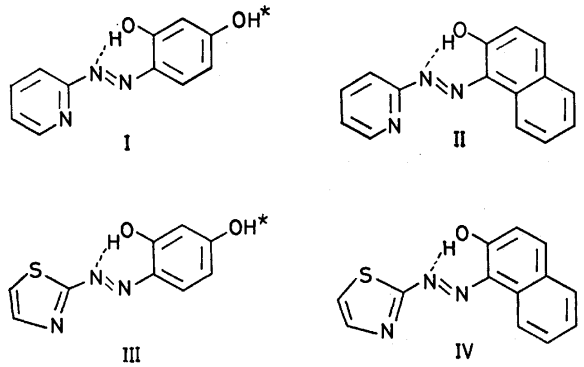

Fig. 1. Structural formulae of the ligands. I: 4-(2-pyridylazo)resorcinol (PAR), II: 1-(2-pyridylazo)-2-naphthol (PAN), III: 4-(2-thiazolylazo)resorcinol (TAR), IV: 1-(2-thiazolylazo)-2-naphthol (TAN).

As regards the cobalt chelates of PAN and PAR, a number of data have been reported on the composition and the stability constants.[3,6,7] On the basis of the measurements of magnetic susceptibility, Iwamoto and Fujimoto provided an evidence for the formation of cobalt(III) complexes in a solution prepared from Co^{2+} and PAR or PAN.[8] This result has been supported by the studies on the substitution reaction with EDTA[5,9] and also by the proton magnetic resonance studies of the isolated complex.[10,11] Although the cobalt(III) complexes of these heterocyclic *ortho*-hydroxy azo compounds have been well characterized, no studies on cobalt(II) chelates have been reported so far.

In the present study, we have confirmed the formation of transient intermediate cobalt(II) complexes in the course of the reaction between Co^{2+} and the ligands I—IV using a rapid-scan spectrophotometer equipped with a stopped-flow cell. The formation and redissolution of hardly visible fine precipitates in the course of the reaction between Co^{2+} and PAN or TAN were also revealed by applying the stopped-flow technique to the measurements of the change in intensity of the scattered light.[12] The metal-to-ligand ratio in the transient cobalt(II) complexes, the mechanisms and the kinetic data for the step of formation of 1 : 1 cobalt(II) complexes, and some results on the cobalt(III) complexes are discussed.

Experimental

Materials. Deionized water was distilled. Reagent grade materials were used unless otherwise specified.

The cobalt(II) perchlorate solution was prepared by heating cobalt(II) chloride with a small excess of perchloric acid until no trace of chloride ion was detected. The solution was standardized titrimetrically with EDTA using Xylenol Orange as an indicator.

PAR was synthesized by the usual method,[13] and recrystallized several times from 1 : 1(v/v) ethanol–water to yield reddish yellow needles of the monohydrate of the monosodium salt. Found: C, 51.34; H, 3.97; N, 16.26%. Calcd for $C_{11}H_8N_3O_2Na \cdot H_2O$: C, 51.77; H, 3.95; N, 16.47%. The concentration of PAR in the aqueous stock solution (*ca.* 10^{-4} mol dm^{-3}) was calculated from its weight.

Commercial PAN, TAR, and TAN (Dojindo, Kumamoto) were used without further purification. The purity was confirmed by elemental analyses. Stock solutions of these compounds (1×10^{-4} mol dm^{-3}) were prepared by dissolving the reagent in 50%(v/v) dioxane–water. The concentrations were calculated from the weighed amount.

A neutral 1 : 2 cobalt(III) complex of PAR, [$Co^{III}L(LH^*)$] was prepared as follows, where LH* stands for the ligand with an undissociated *para*-hydroxyl group.† The stoichio-

* Prensented in part at the 1977 Winter Meeting in Hokkaido of the Chemical Society of Japan and the Japan Society for Analytical Chemistry, Sapporo, February 2, 1977, Abstracts, p. 11, and at the 36th National Meeting of the Chemical Society of Japan, Osaka, April 1, 1977, Abstracts Vol. 1, p. 18.

† Hereafter "PAR" stands for L^{2-}, LH^-, LH^{*-}, and/or LHH*, where H* denotes the proton of the *para*-hydroxyl group (Fig. 1).

metric amounts of cobalt(II) perchlorate and PAR were slowly mixed with vigorous stirring at pH 6.0—6.5. Precipitates formed gradually. Then the pH of the solution was lowered to 4.0 by adding dropwise dilute perchloric acid in order to complete the precipitation. The solution was allowed to stand for 24 h. Precipitates were filtered off, washed thoroughly with water and ethanol, and dried at 80 °C. The content of cobalt was determined titrimetrically with EDTA using Cu–PAN as an indicator after decomposition of the complex by heating with hydrogen peroxide and sulfuric acid. Found: C, 52.87; H, 3.66; N, 16.58; Co, 11.38%. Calcd for $C_{22}H_{15}N_6O_4Co \cdot H_2O$: C, 52.39; H, 3.20; N, 16.66; Co, 11.69%.

A pale-colored anion-exchange resin QAE-Sephadex A-25 in the Cl-form and a pale-colored cation exchanger SP-Sephadex C-25 in the Na-form were used in order to discern the sign of the net charge on the final cobalt(III)–PAR species formed in the reaction at various pH by the sensitive coloration on the resin grains.

Measurements. The absorption spectra were measured with a Hitachi recording spectrophotometer model EPS-3T.

Fast changes in the absorption spectra and the rate of complex formation were measured with a Union Giken rapid-scan spectrophotometer model RA-1300 equipped with a stopped-flow cell.

The stopped-flow signal for the scattered light[12] was also observed with this apparatus.

All measurements were carried out at 25.0±0.2 °C. The ionic strength was maintained at 0.1 mol dm^{-3} with sodium perchlorate. The pH of the solution was adjusted with acetate or hexamine buffers and measured with a Radiometer pH-meter 4d (Copenhagen) equipped with a glass electrode type G 202B and a reference calomel electrode type 401. The pH-meter readings for the 5 or 10% (v/v) dioxane–water solutions were used without correction.[14]

Results and Discussion

I. Rapid-scan Spectral Studies. Cobalt–PAR. Rapid-scan Spectra: Figure 2(a) shows a typical example of the spectral change for the reaction of Co^{2+} and PAR in aqueous solution at pH 5.46. Each spectrum was rapidly scanned at appropriate time intervals after the solution containing cobalt(II) perchlorate in excess was rapidly mixed with a PAR solution by the stopped-flow technique. The figure clearly indicates that two steps are involved in the reaction.

At the initial stage, the spectrum of the reaction mixture changed rapidly with an isosbestic point at 450 nm. The absorption around 400 nm due to the free ligand PAR decreased with the increase of a new absorption around 500 nm due to the complex. The rapid spectral change ceased in *ca.* 40—50 ms after mixing. Then a relatively slow spectral change occurred with other isosbestic points at 330 and 435 nm. The final equilibrium was attained in *ca.* 3 min under the given conditions.

The change in the rapid-scan spectra for the reaction of Co^{2+} and PAR at pH 2.72 (Fig. 2(b)) differs from that at pH 5.46 (Fig. 2(a)), but it is still evident that two steps with two sets of isosbestic points are involved in the reaction.

In each case, the final spectrum coincides with the spectrum of $[Co^{III}(par)_2]$, which was obtained under the same conditions either with an equilibrated solution

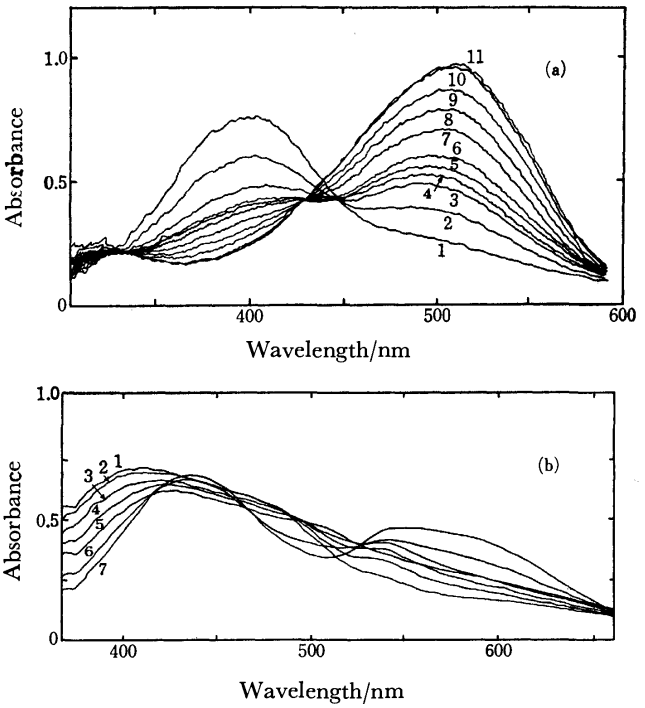

Fig. 2. (a) Rapid-scan spectra for the reaction of 7.64 × 10^{-4} mol dm^{-3} cobalt(II) perchlorate and 3.31 × 10^{-5} mol dm^{-3} PAR at pH 5.46, I=0.1 ($NaClO_4$), and 23 °C, measured at 0 (1), 10 (2), 25 (3), 50 (4), 100 ms (5), 0.5 (6), 5 (7), 20 s (8), 1 (9), 2 (10), and 3 min (11) after mixing. Scan rate: 300 nm/5 ms.

(b) Rapid-scan spectra for the reaction of 1.53 × 10^{-3} mol dm^{-3} cobalt(II) perchlorate and 3.57 × 10^{-5} mol dm^{-3} PAR at pH 2.72, I=0.1 ($NaClO_4$), and 25 °C, measured at 0 (1), 10 (2), 25 (3), 50 (4), 100 ms (5), 1 s (6), and 3 min (7) after mixing. Scan rate: 300 nm/5 ms.

prepared by mixing Co^{2+} and PAR in the molar ratio of 1 : 2 or with an aqueous solution of the isolated 1 : 2 cobalt(III) complex $[Co^{III}L(LH^*)]$ (Fig. 7).

Stopped-flow Signal: Figure 3 shows the change in absorbance with time at 510 nm in the course of the reaction under the same conditions as in Fig. 2(a). The stopped-flow signal also discriminates the fast reaction from the slower one. The rate of the first step

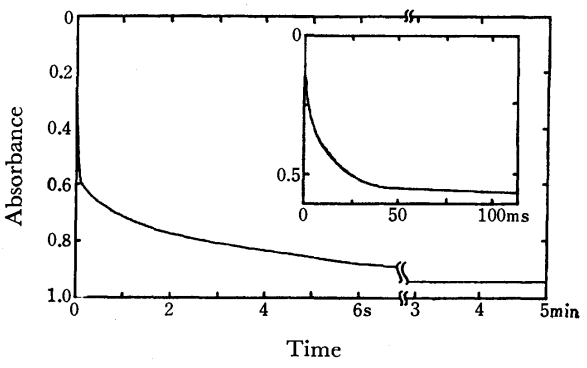

Fig. 3. Stopped-flow signal at 510 nm for the reaction of Co^{2+} and PAR. The experimental conditions are the same as those for Fig. 2(a). Inset shows an expanded signal for the initial stage of the reaction.

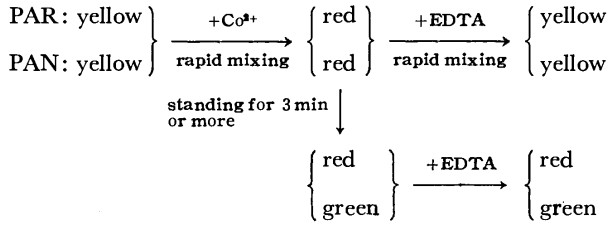
was found to be enhanced under the same conditions with the increase in the initial concentration of Co^{2+} ion (*vide infra*). This result indicates that the first step is the complex formation process. On the other hand, the effects of hydrogen peroxide on the reaction between Co^{2+} and PAR reveal that the second step involves the oxidation of cobalt(II)–PAR complex. When the solution of PAR containing 6% H_2O_2 was mixed with a Co^{2+} solution under the same conditions as in Fig. 3, only the second step was accelerated several-fold, leaving the first step essentially unaffected.

Substitution Reaction with EDTA: The results on the substitution reaction of cobalt–PAR complexes with EDTA also provide a further evidence for the presence of the Co(II) state in the initial stage of the present reaction and of the Co(III) state in the final stage. The solution containing Co^{2+} ion in excess was rapidly mixed with a yellow PAR solution at pH 5 with a microsyringe. The red color of the solution thus formed turned orange by the subsequent rapid addition of EDTA. The color change indicates the liberation of yellow ligand PAR, suggesting the presence of labile Co(II) state immediately after the rapid mixing of Co^{2+} and PAR.[15]

However, when once the final equilibrium is attained, the red color of the solution never changes on addition of even a large excess of EDTA. This fact suggests the formation of inert cobalt(III)–PAR complexes and the absence of labile cobalt(II)–PAR complexes in this stage of the reaction. The observed color changes are summarized in Scheme 1 together with those for the cobalt–PAN system.



Scheme 1. Color change at pH *ca.* 5.

Ion-exchange Behavior of the Final Products: The nature of the final products was also proved by their ion-exchange behavior. The final product obtained at pH 2.72 was strongly adsorbed on the cation-exchange resin but not on the anion-exchange resin. On the other hand, the final product at pH 5.46 was strongly adsorbed on the anion-exchange resin but not on the cation-exchange resin. These facts lead to the conclusion that the final product is a tervalent cobalt complex with two ligand molecules having dissociated or undissociated *para*-hydroxyl groups with respect to the azo group; the final products at pH 2.72 and 5.46 are a cationic species $[Co^{III}(LH^*)_2]^+$ and an anionic species $[Co^{III}L_2]^-$, respectively. The net charge on the final product is supported by the pK_a value of the *para*-hydroxyl group of the ligand in $[Co(par)_2]$ (*vide infra*). It should be noted that 1:2 complexes are finally formed even though a large excess of Co^{2+} reacts with the ligand PAR.

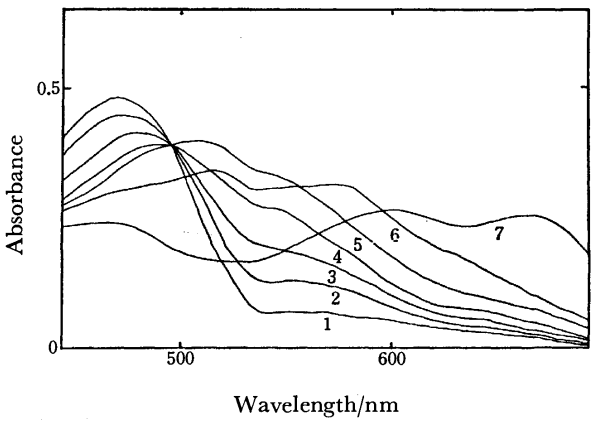


Fig. 4. Rapid-scan spectra for the reaction of 7.65×10^{-4} mol dm^{-3} cobalt(II) perchlorate and 2.99×10^{-5} mol dm^{-3} PAN in 5%(v/v) dioxane–water mixture at pH 4.72, I=0.1 ($NaClO_4$), and 25 °C, measured at 0 (1), 0.04 (2), 0.1 (3), 0.2 (4), 0.4 (5), 4 s (6), and 4 min (7) after mixing. Scan rate: 300 nm/20 ms.

Cobalt–PAN. Rapid-scan Spectra: Figure 4 shows the change of rapid-scan spectra for the reaction of Co^{2+} ion and PAN at pH 4.72. The experiments were carried out in 5%(v/v) dioxane–water solutions because of the very low water-solubility of PAN. At the initial stage, the spectrum of the reaction mixture changes rapidly with an isosbestic point at 490 nm. The absorption around 470 nm due to the free ligand PAN decreases in 400 ms with the increase of a new absorption around 540 nm due to a red-colored complex. This absorption in turn decreases in a few minutes with the increase of an absorption around 650 nm due to the formation of a green-colored complex.

The lability of the cobalt in the red and the green complex was confirmed by means of the substitution reaction with EDTA. The results shown in Scheme 1 indicate the formation of a red-colored labile cobalt(II) complex immediately after the rapid mixing of Co^{2+} and PAN and the subsequent slow formation of a green-colored inert cobalt(III) complex. These observations, together with the results of the kinetic study, indicate that the two-step reaction in Fig. 4 corresponds to the fast formation of cobalt(II)–PAN complex and the subsequent slow oxidation to a cobalt(III)–PAN complex $[Co^{III}(pan)_2]$.

However, no isosbestic point was observed for the oxidation step in contrast to the observation for the corresponding step of the cobalt–PAR system. For the reaction of Co^{2+} with PAN the formation of a neutral insoluble intermediate $[Co^{II}(pan)_2]^0$ was expected, as observed for the Ni^{2+}–PAN system.[12] In order to confirm this expectation, the stopped-flow signal of the scattered light was measured for the reaction of the Co^{2+}–PAN system.

Stopped-flow Signals for Scattered Light: Figure 5 shows the change in intensity of scattered light in the course of the reaction. The intensity increases after a short induction period and then decreases gradually. The feature is essentially independent of the wavelength of the incident monochromatic light in the range 400—600 nm. The induction period appearing at the initial

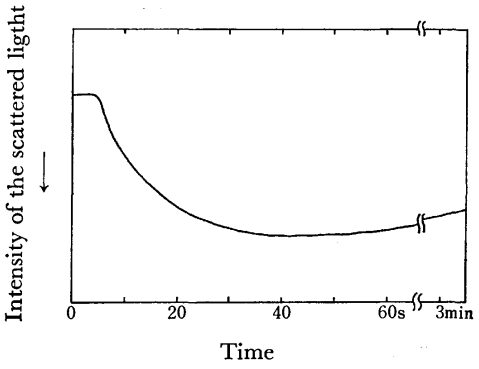

Fig. 5. Stopped-flow signal of the scattered light for the reaction of 1.91×10^{-5} mol dm^{-3} cobalt(II) perchlorate and 2.99×10^{-5} mol dm^{-3} PAN in 5%(v/v) dioxane–water mixture at pH 4.72, I=0.1 ($NaClO_4$) and 25 °C.

stage of the reaction corresponds to the formation of the cobalt(II)–PAN complex prior to the crystal growth. The subsequent increase in the intensity of the scattered light is due to the formation and the growth of the insoluble crystals of $[Co^{II}(pan)_2]^0$. The final decreasing portion of the signal indicates the process of redissolution of the insoluble intermediate. This corresponds to the step of oxidation of $[Co^{II}(pan)_2]^0$ forming a more soluble $[Co^{III}(pan)_2]^+$ complex. The lack of an isosbestic point in the spectra for the second step of the present reaction shown in Fig. 4 is due to the formation of an insoluble intermediate $[Co^{II}(pan)_2]^0$.

Cobalt–TAR and Cobalt–TAN. Similar spectral changes were observed for the reactions of Co^{2+}–TAR and –TAN. The ligands TAR and TAN, which have a thiazolyl group instead of pyridyl group in PAR and PAN, are insoluble in water. The experiments were, therefore, carried out in a 5 or 10%(v/v) dioxane–water solution. The spectral change for these systems also consists of a fast and a subsequent slower step. Two sets of distinct isosbestic points were observed in the spectra for the reaction of Co^{2+} and TAR, while no isosbestic point was observed for the second step of the Co^{2+}–TAN system.

Experiments on the substitution reactions of the intermediates and the final products with EDTA were carried out for both the cobalt-TAR and the cobalt–TAN system in the same way as described for the PAR and the PAN system. Stopped-flow signals for the scattered light similar to the signal shown in Fig. 5 were observed for the Co^{2+}–TAN reaction.

It is concluded that the reactions of Co^{2+}–TAR and –TAN proceed by the same mechanism as for the Co^{2+}–PAR and –PAN systems, respectively. In each system, the first and the second step correspond to the formation of cobalt(II) complex and subsequent oxidation, respectively. The reaction of cobalt(II) with TAN involves the formation of insoluble intermediate, $[Co^{II}(tan)_2]^0$.

Effect of Oxygen on the Oxidation of Cobalt(II) Complexes. In order to ascertain if the cobalt(II) complexes are stable in deoxygenated media, we carried out spectrophotometric measurements for the cobalt(II)–PAN and the cobalt(II)–PAR system with a device connected to a vacuum system (Fig. 6). In this device the solutions of Co^{2+} and the ligand were separately degassed beforehand by freezing several times. Then the solutions were mixed and introduced into the optical cell *in vacuo*. This approach succeeded in detection of the cobalt(II)–PAN and the cobalt(II)–PAR complex even with an ordinary spectrophotometer, since in the measurements with this device the rate of oxidation was lowered by 50—60 times for both systems as compared with that in undegassed solutions. Spectra thus obtained were identical with those of the cobalt(II) complexes observed transiently by the rapid-scan spectrophotometer. It is concluded that $[Co^{II}(pan)_2]$ and $[Co^{II}(par)_2]$ complexes are oxidized by oxygen in the solution and that even a trace amount of oxygen takes part in the oxidation to cobalt(III) complexes.

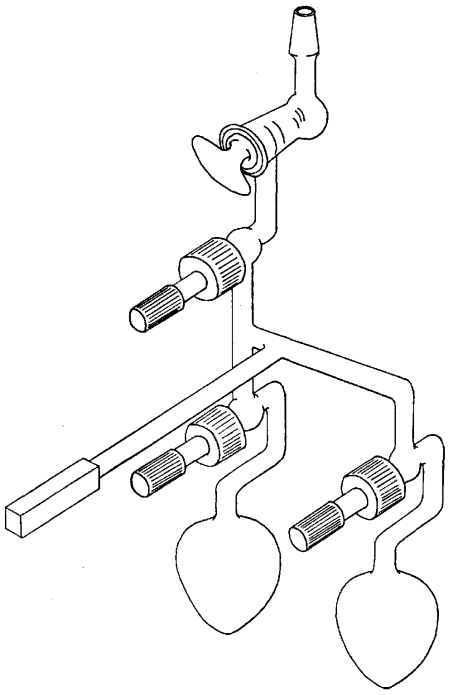

Fig. 6. Evacuable mixing device for measurements of absorption spectra in deoxygenated systems.

II. Equilibrium and Kinetic Studies. Composition of the Cobalt–PAR and –PAN Complexes. The Composition of the short-lived intermediate cobalt(II) complexes was determined to be 1 : 2 by applying the method of continuous variation to the first rapid change of the stopped-flow signals as shown in the inset of Fig. 3. The composition of the cobalt(III) complexes of PAR and PAN in the aqueous and the 50%(v/v) dioxane–water solutions, respectively, was determined also to be 1 : 2 by the usual continuous variation method.

Protonation-Deprotonation of $[Co^{III}(par)_2]$. Figure 7 shows the pH-dependence of the spectrum of an aqueous solution of the isolated cobalt(III)–PAR complex $[Co^{III}L(LH^*)]$. The same pH-dependence of the spectrum was also observed with an equilibrated solution prepared from Co^{2+} and PAR in a molar ratio of 1 : 2. It is attributed to the protonation-deprotonation of the *para*-hydroxyl group of the coordinated

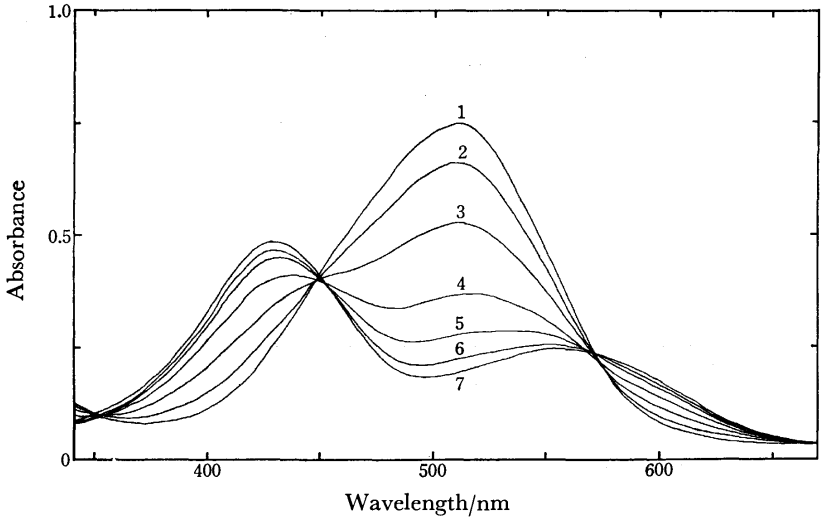

Fig. 7. Absorption spectra of the aqueous solution of $[Co^{III}(par)_2]$ as a function of pH at 25 °C and I=0.1 ($NaClO_4$). $[Co^{III}(par)_2]$= 1.26×10^{-5} mol dm^{-3}. pH=9.29 (1), 5.05 (2), 4.39 (3), 3.73 (4), 3.26 (5), 2.77 (6), and 1.88 (7).

PAR in the inert cobalt(III) complex.

Acid-dissociation constants for

$$[Co^{III}(LH^*)_2]^+ \overset{K_{a1}}{\rightleftharpoons} [Co^{III}L(LH^*)] + H^+$$

and

$$[Co^{III}L(LH^*)] \overset{K_{a2}}{\rightleftharpoons} [Co^{III}L_2]^- + H^+$$

were determined from the result shown in Fig. 7. The plots of absorbance *vs.* pH at 420, 510, and 600 nm indicate that the values of pK_{a1} and pK_{a2} are not quite different from each other, the average value being 4.1.[16]

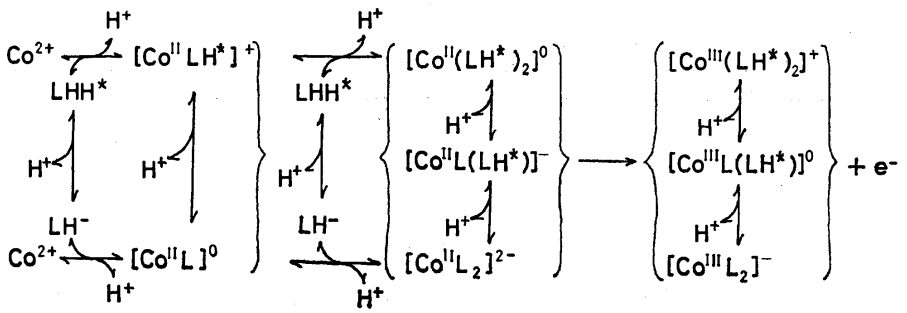
From these results and the ion-exchange behavior the cobalt(III)–PAR complexes are found to be in the form of an anionic $[Co^{III}L_2]^-$ (λ_{max}=510 nm, ε_{max}=57000) at pH 6 or higher, and a cationic $[Co^{III}(LH^*)_2]^+$ (λ_{max}=430 nm, ε_{max}=37500; λ_{max}=558 nm, ε_{max}= 18300) at pH 2 or lower. Features of the spectral change depicted in Fig. 7 suggest the formation of a neutral species $[Co^{III}L(LH^*)]^0$, since two sets of isosbestic points are observed at 452 and 568, and 448 and 574 nm.[17]

Overall Reaction Mechanisms for the Formation of Cobalt(III) Complexes. On the basis of the results given above the overall reaction mechanisms for the formation of 1:2 cobalt(III) complexes with the ligands PAR and PAN are summarized in Schemes 2 and 3, respectively. It should be noted that cobalt(II) complexes are oxidized only *via* formation of 1:2 complexes, $[Co^{II}(par)_2]$ or $[Co^{II}(pan)_2]$.

Kinetics on the Formation of Cobalt(II) Complexes. Kinetic measurements were carried out under the conditions of Co^{2+} ion in large excess over the ligand. For the calculation of rate constants, the first rapid change in the stopped-flow signal was analyzed after subtracting the part of slower oxidation step involved in the signal. The stopped-flow signals were followed at the absorption maxima for the 1:2 cobalt(II) complexes and for the free ligands PAR or PAN as well. Both signals for the fast complex formation gave a single exponential curve characterized by the same pseudo-first-order rate constant, k_{obsd}. The result and the values of k_{obsd} suggest that the coordination of the first ligand is the rate-determining step, the coordination of the second ligand molecule proceeding very fast.

Cobalt(II)–PAR: The rate of formation of cobalt(II)–PAR complex was determined in aqueous solution at pH 3—6 with 10—100 fold excess of Co^{2+} ion over the ligand. The absorbance change at 510 nm was used for the calculation of rate constants. The pseudo-first-order rate constant k_{obsd} showed first-order dependence on the total concentration of Co^{2+}, [Co], at constant pH as shown by

$$k_{obsd} = k_f[Co] + k_d. \quad (1)$$



Scheme 2. Overall reaction mechanism for the formation of $[Co^{III}(par)_2]$.[1]

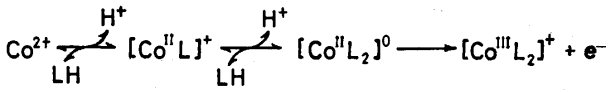

Scheme 3. Overall reaction mechanism for the formation of $[Co^{III}(pan)_2]$.

Forward and backward rate constants, k_f and k_d, were evaluated from the slope and the intercept of the linear plot of k_{obsd} against [Co] (Table 1). Under the experimental conditions the mechanism for the step of formation of 1 : 1 cobalt(II)–PAR complex was postulated as follows, the hydrolysis of Co^{2+} being neglected.[18]

$$\begin{array}{ccc} Co^{2+} + LHH^* & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & CoLH^{*+} + H^+ \\ K_a \uparrow\downarrow & & K_G \uparrow\downarrow \\ Co^{2+} + LH^- + H^+ & \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} & CoL + 2H^+ \end{array}$$

According to this mechanism, the overall formation rate constant k_f is expressed by

$$k_f = \frac{k_1[H] + k_2K_a}{[H] + K_a} \quad (2)$$

or

$$k_f(1 + K_a[H]^{-1}) = k_1 + k_2K_a[H]^{-1}, \quad (3)$$

where K_a denotes the acid-dissociation constant of *para*-hydroxyl proton of PAR. The plot of $k_f(1+K_a[H]^{-1})$ against $[H]^{-1}$ gives a straight line. The rate constants k_1 and k_2 were determined from the intercept and the slope to be 4.8×10^4 and 9.8×10^4 dm^3 mol^{-1} s^{-1}, respectively, using the value pK_a=5.6.[7]

Cobalt(II)–PAN: The rate of formation of the cobalt(II)–PAN complex was measured with 5%(v/v) dioxane–water solutions at pH 3—5 with 10—100 fold excess of Co^{2+} ion over the ligand. For the calculation of rate constants, the stopped-flow signal at 540 nm, the absorption maximum of the 1 : 2 complex, was used. The pseudo-first-order rate constant, k_{obsd}, at constant pH showed first-order dependence on [Co], as shown by Eq. 1 (see Table 1). The k_f values obtained from the linear plot show a slight dependence of [H]. The pH-dependence of k_{obsd} is interpreted by the following reaction scheme.

$$\begin{array}{ccc} Co^{2+} + LH_2^+ & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & Co^{II}L^+ + 2H^+, \\ K_a' \uparrow\downarrow & & k_2 \nearrow\swarrow k_{-2} \\ Co^{2+} + LH + H^+ & & \end{array}$$

where LH_2^+ denotes a unipositive species of PAN protonated on the pyridyl nitrogen having $K_a'=10^{-2.9}$.[19] According to this mechanism the overall formation rate constant k_f is expressed by

$$k_f = \frac{k_1[H] + k_2K_a'}{[H] + K_a'} \quad (4)$$

or

$$k_f(1 + K_a'[H]^{-1}) = k_1 + k_2K_a'[H]^{-1}. \quad (5)$$

The plot of $k_f(1+K_a'[H]^{-1})$ against $[H]^{-1}$ gives a straight line. The rate constants k_1 and k_2 were determined from the intercept and the slope to be $<10^3$ and 4.6×10^3 dm^3 mol^{-1} s^{-1}, respectively.

The rate constants k_f and k_d were also evaluated for the TAR and the TAN complex. The data obtained for the cobalt(II)–TAR and –TAN systems would be explained by the mechanisms for the PAR and the PAN complex, respectively.

The rate constants are summarized in Tables 1 and 2. It is noticeable in Table 2 that the protonated cationic species of PAN is inert for the complex formation of Co^{2+} as was found in the reaction of Ni^{2+} and PAR,[21] suggesting that the first coordinating group in PAR and PAN is the pyridyl group in the ligands.

Wilkins reported the kinetic data on the reactions of a neutral ligand 4-(2-pyridylazo)-*N*,*N*-dimethylaniline

Table 2. Rate constants for the formation of cobalt(II) complexes at 25 °C and I=0.1 ($NaClO_4$)

Ligand		Rate constant	
PAR	LH_2	k_1/dm^3 mol^{-1} s^{-1}	4.8×10^4
	LH^-	k_2/dm^3 mol^{-1} s^{-1}	9.8×10^4
PAN	LH_2^+	k_1/dm^3 mol^{-1} s^{-1}	$<10^3$
	LH	k_2/dm^3 mol^{-1} s^{-1}	4.6×10^3
PAD[a]		k_f/dm^3 mol^{-1} s^{-1}	4.0×10^4
H_2O[b]		k_{H_2O}/s^{-1}	1.1×10^6

a) Ref. 22. b) Ref. 27.

(PAD) with Co^{2+} or Ni^{2+} ion.[22] PAD is a bidentate ligand having a structure similar to that of PAR except for the absence of intramolecular hydrogen-bond. In his paper, the values of the formation constant of the outer-sphere complex for the neutral ligand species, K_{os},[23] and the distance of closest approach of the reactant molecules, a, are estimated to be 0.1 dm^3 mol^{-1} and 5 Å, respectively. Since the rate constants reported for the reactions of Co^{2+} and PAD are in the same order of magnitude as the rate constants for the reactions of Co^{2+} and the neutral species of PAR, LH_2 (see Table 2), it would be reasonable to assume that the reaction of PAR and Co^{2+} also proceeds by the same mechanism as in the case of PAD and that the internal rotation of the resorcinol moiety around the C–N axis in PAR preceded by the rupture of the stable intramolecular hydrogen-bond does not eventually lower the overall rate of complex formation.

However, in the reaction of Co^{2+} and PAN the formation rate constant is smaller by one order of magnitude than that of the corresponding reaction of PAR. This difference observed in similar ligands might be explained by the following: (a) the difference in values of K_{os}[23] for the two systems, (b) the effect of small amounts of dioxane added in the case of PAN on the rate constants, (c) retardation of complex formation by the relative slowness of the internal rotation of the bulky naphthol moiety in PAN for the formation of the terdentate complex,[1] and (d) steric hindrance caused by the shape of a bulky ligand PAN on the first coordination site in the ligand.

As regards (a), if the relatively small rate constants for the Co^{2+}–PAN system as compared with the case of Co^{2+}–PAR were attributed to the lower values of K_{os}, the reaction distance a for the complex formation of PAN would be evaluated to be 2—3 Å.[25] This is about a half of the value of a estimated by Funahashi and Tanaka for the Ni^{2+}–PAR system,[25] and would be too small as the reaction distance for the Co^{2+}–PAN system. The second possibility (b) is also not essential, since the rate constant of complex formation of a similar ligand TAR is in the same order of magnitude even in dioxane–water media as that of PAR observed in aqueous media. Therefore, it would be reasonable to infer that the intervening step of internal rotation of the bulky naphthol moiety around the C–N axis (c) and a steric hindrance caused by the particular shape of the bulky PAN molecule on the site of the first coordination at the pyridyl nitrogen atom (d) would essentially be responsible for the retardation of the overall reaction in PAN. The smaller rate constants observed for the reaction of Ni^{2+} and PAN as compared with those of Ni^{2+} and PAR would also be attributed to the difference in character of these ligands.[26]

Copper(II)-2,2′-Bipyridine-Eriochrome Cyanine R Ternary Complex and Its Application to the Spectrophotometric Determination of Copper(II)

Ryoei Ishida, Hifumi Narita, and Koichi Tonosaki

Department of Chemistry, Faculty of Science, Hirosaki University, Hirosaki, Aomori 036

(Received September 26, 1977)

Copper(II) ion reacted with 2,2′-bipyridine (bpy) and Eriochrome Cyanine R (ECR) to give one of two kinds of ternary complexes according to the amount of reagents in a weakly basic medium. The combining ratios of three components in the complexes were estimated to be Cu(II): bpy: ECR=1: 1: 2 and 1: 1: 1, respectively, the former having an absorption maximum at 515 nm and the latter at 550 nm. The color development of the 1: 1: 2 complex was utilized in the spectrophotometric determination of copper(II) at microgram level. The ternary complex gave a maximum absorbance at 515 nm in the pH range 10.2—10.6. Under optimum pH, 2,2′-bipyridine and Eriochrome Cyanine R concentrations, a linear relationship holds between the absorbance of the complex and copper(II) concentration up to 6×10^{-5} mol dm^{-3}. The apparent molar absorption coefficient at 515 nm is about 20400 dm^3 mol^{-1} cm^{-1}, corresponding to Sandell's sensitivity index of 0.003_1 μg cm^{-2}.

Eriochrome Cyanine R (ECR), sodium 2″-sulfo-5,5′-dimethyl-4-hydroxyfuchsone-3,3′-dicarboxylate, a dyestuff of the triphenylmethane series like Chromazurol S, has been used for the spectrophotometric determination of aluminium(III),[1-3] beryllium(II)[4,5] and scandium(III),[6] and others. While 2,2′-bipyridine (bpy) is a sensitive and selective reagent for iron(II),[7,8] it has been reported to form a 1: 2 complex with copper(I), and a 1: 3 complex with copper(II).[9]

In a previous paper, the formation reaction of Cu(II)–bpy–Chromazurol S mixed ligand complex and its application to the spectrophotometric determination of copper(II) was reported.[10]

The present paper deals with studies on the color reaction forming the ternary complex composed of copper(II), 2,2′-bipyridine and Eriochrome Cyanine R, which has a structure similar to that of Chromazurol S, and on the spectrophotometric determination of copper(II) by means of this ternary complex. The composition of the ternary complex as well as the fundamental conditions for the determination of copper(II) are discussed.

Experimental

Reagents. Copper(II) Standard Stock Solution (1.00×10^{-2} mol dm^{-3}): Copper metal (Purity: 99.99%) was dissolved in a small amount of dilute nitric acid, with heating, and the solution was evaporated nearly to dryness on a water bath. The residual contents were dissolved in water containing nitric acid, and the solution was diluted with water in a volumetric flask (nitric acid was added to make the final acidity 0.01 mol dm^{-3}).

Standard Solution: The stock solution was diluted as required.

2,2′-Bipyridine Solution (1.00×10^{-3} mol dm^{-3}): 2,2′-Bipyridine (Wako Pure Chemical Industries, Ltd.) was dissolved in water containing hydrochloric acid (final concentration of hydrochloric acid: 0.002 mol dm^{-3}).

Eriochrome Cyanine R Solution (2.00×10^{-3} mol dm^{-3}): Eriochrome Cyanine R (Merck & Co., Inc.) was dissolved in water containing hydrochloric acid (final concentration of hydrochloric acid: 0.008 mol dm^{-3}). The acidified Eriochrome Cyanine R solution was stable for at least 1 year.

Buffer Solution: A borate buffer solution was prepared by mixing 0.1 mol dm^{-3} solution of borax and 0.2 mol dm^{-3} solution of hydrochloric acid or sodium hydroxide.

Triton X-100 Solution (1%, v/v): This was prepared by diluting polyethylene glycol mono[*o*-(1,1,3,3-tetramethylbutyl)phenyl]ether (BDH Chemicals Ltd.) with water.

All the other reagents were of analytical reagent grade. Doubly distilled water was used.

Apparatus. A Hitachi model 124 double-beam recording spectrophotometer and a Hitachi 139 spectrophotometer were used for measuring absorbance in glass cells of 10-mm pathlength. Measurements were carried out at 25±0.1 °C.

A Hitachi-Horiba model F-7 glass electrode pH meter was used for pH measurements.

Standard Procedure. An aliquot of a standard copper(II) solution was transferred to a 25-cm^3 volumetric flask, and then 2,2′-bipyridine and Eriochrome Cyanine R solutions were added. The flask was filled up to about 10 cm^3 by adding water. The pH value was adjusted with a buffer solution, the ionic strength of the solution being controlled to 0.1 with the amount of buffer solution. The total volume of the solution was made up to the mark with water. After gentle mixing, the absorbance of the resulting solution was measured against the reagent blank obtained in the same way.

Results and Discussion

Absorption Spectra. Suk and Mikeťuková[11] reported that Eriochrome Cyanine R dissociates in aqueous solution as follows:

$$H_5ECR^+ \rightleftarrows H_4ECR^0 \rightleftarrows H_3ECR^- \rightleftarrows H_2ECR^{2-} \rightleftarrows HECR^{3-} \rightleftarrows ECR^{4-}$$

The absorption spectra of each species caused by the acid dissociation of Eriochrome Cyanine R in aqueous medium are shown in Fig. 1. No spectrum of the neutral species H_4ECR^0 is shown, since it is almost insoluble in water. In the reaction, mainly the $HECR^{3-}$ species takes part in the color development.

The absorption spectra of the reagent blank (bpy and ECR) and the ternary complex with copper(II) at pH 10.4 are shown in Fig. 2. For the sake of comparison the spectrum of Cu(II)–ECR binary complex at the same pH value is also given. The absorption spectrum of the reagent blank (Curve 1) coincides with that of Eriochrome Cyanine R itself. Thus it seems that there is no interaction between Eriochrome Cyanine R and 2,2′-bipyridine. The maximum absorption wavelengths of both the binary and the ternary complexes are found

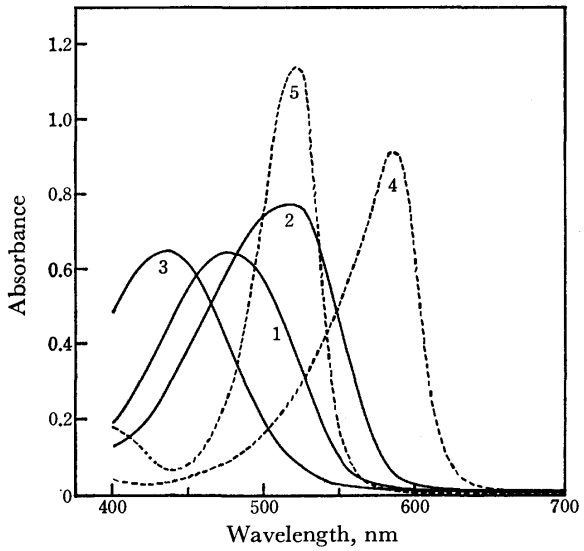

Fig. 1. Absorption spectra of Erichrome Cyanine R at various acidities.
Concn of ECR—1, 2 and 3: 6.0×10^{-5} mol dm^{-3}, 4 and 5: 3.0×10^{-5} mol dm^{-3}; acidity—1: pH 1.35 (H_3ECR^-), 2: pH 3.50 (H_2ECR^{2-}), 3: pH 9.00 ($HECR^{3-}$), 4: pH 13.5 (ECR^{4-}), 5: 9 mol dm^{-3} H_2SO_4 (H_5ECR^+).

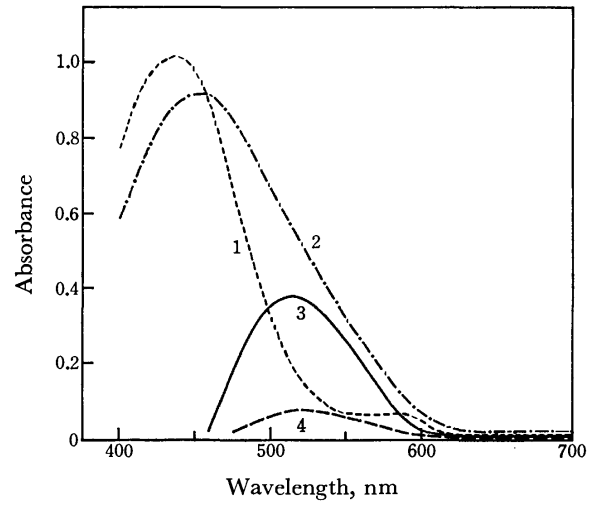

Fig. 2. Absorption spectra of Cu(II)-bpy-ECR complex and binary Cu(II)-ECR complex.
Concn of Cu(II), bpy and ECR: 2.0×10^{-5} mol dm^{-3}, 4.0×10^{-5} mol dm^{-3} and 1.0×10^{-4} mol dm^{-3}, respectively; pH: 10.4, ionic strength: 0.1; 1: reagent blank *vs.* water, 2: Cu(II)-bpy-ECR *vs.* water, 3: Cu(II)-bpy-ECR *vs.* reagent blank, 4: Cu(II)-ECR *vs.* ECR.

at about 515 nm. The addition of 2,2′-bipyridine to the Cu(II)-ECR complex gives rise to a large hyperchromic shift at the maximum absorption wavelength. The hyperchromic effect is probably due to the increment of molecular cross section caused by the combination with 2,2′-bipyridine. It follows that the sensitivity of the color development increases remarkably (about 5-fold).

The absorption spectra of colored solutions at different pH values were measured against the reagent blanks

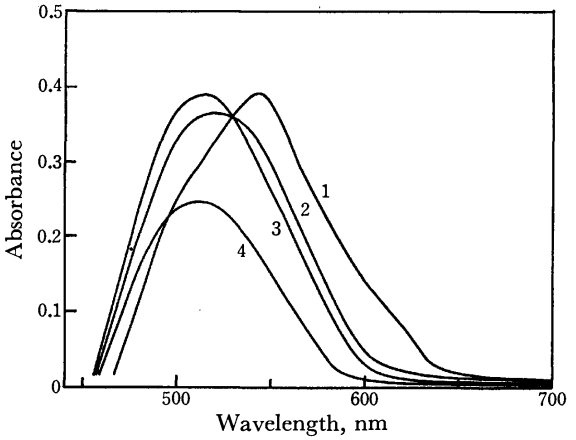

Fig. 3. Absorption spectra of Cu(II)-bpy-ECR complex at various pH values.
Concn of Cu(II), bpy and ECR: 2.0×10^{-5} mol dm^{-3}, 4.0×10^{-5} mol dm^{-3} and 1.0×10^{-4} mol dm^{-3}, respectively; Triton X-100: 0.04%, ionic strength: 0.05; 1: pH 9.60, 2: pH 10.00, 3: pH 10.31, 4: pH 11.15.

(Fig. 3). At pH above 10, the maximum absorption wavelength is found at 515 nm, the spectra showing similar shapes. At pH below 10, each peak is shifted toward a longer wavelength, and at pH below 9.5, a part of the formed complex precipitates, even in the presence of Triton X-100 (0.04%).

The concentration of Eriochrome Cyanine R was kept constant and varying amounts of an equimolar mixed solution of copper(II) and 2,2′-bipyridine were added. The absorption spectra were measured against the water blank. The results for pH 10.4 are shown in Fig. 4.

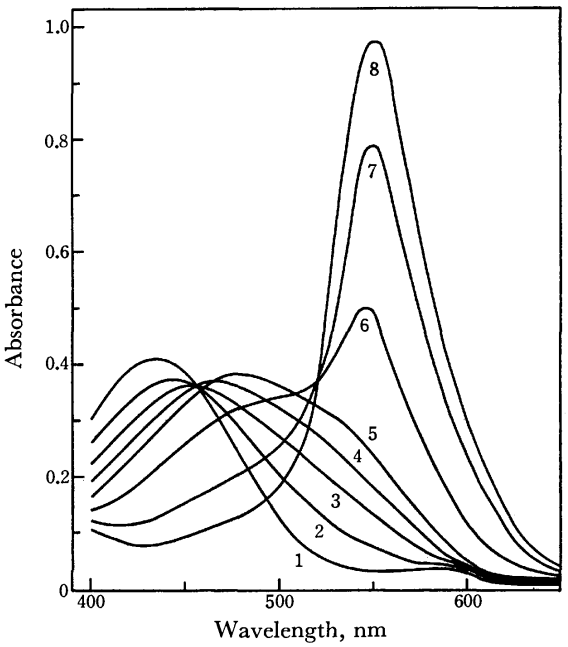

Fig. 4. Absorption spectra of Cu(II)-bpy-ECR system.
Concn of ECR: 4.0×10^{-5} mol dm^{-3}; pH: 10.4, Triton X-100: 0.04%, ionic strength: 0.05; each concn of Cu(II) and bpy (mol dm^{-3})—1: 0, 2: 5.0×10^{-6}, 3: 1.0×10^{-5}, 4: 1.5×10^{-5}, 5: 2.0×10^{-5}, 6: 3.0×10^{-5}, 7: 4.0×10^{-5}, 8: 5.0×10^{-5}.

Under the conditions of excess copper(II), a part of the complex formed precipitate. However, by addition of Triton X-100 the complex existed in a homogeneous dispersed state without formation of any precipitate. An absorption band appears with a maximum at 550 nm in accordance with the increasing amounts of the mixed solution of copper(II) and 2,2′-bipyridine, indicating that there are two absorbing species under these conditions (Fig. 4).

Composition of the Ternary Complexes. From the results given in Figs. 2 and 4, it seems that two kinds of complexes can be formed in a weakly basic pH medium (pH 10.4), according to the concentration ratio of the reagents.

A triangular coordinate method extended to three-component system of the continuous variation plot was applied to the determination of the composition of ternary complexes. The sum of the initial concentrations of copper(II), 2,2′-bipyridine and Eriochrome Cyanine R in the solution was kept constant, and preparation of the colored solution was carried out with 45 different compositions. The absorbance of the solution was measured against the reagent blank at 515 and 550 nm. The results are shown in Figs. 5 and 6, respectively. The contour lines in both figures show various compositions of equal absorbance. At 515 nm, maximum absorbance is obtained at the mole ratio of Cu(II) : bpy : ECR=0.25 : 0.25 : 0.5, namely 1 : 1 : 2 (Fig. 5). Similarly, at 550 nm, maximum absorbance is obtained at the mole ratio of Cu(II) : bpy : ECR= 1 : 1 : 1 (Fig. 6).

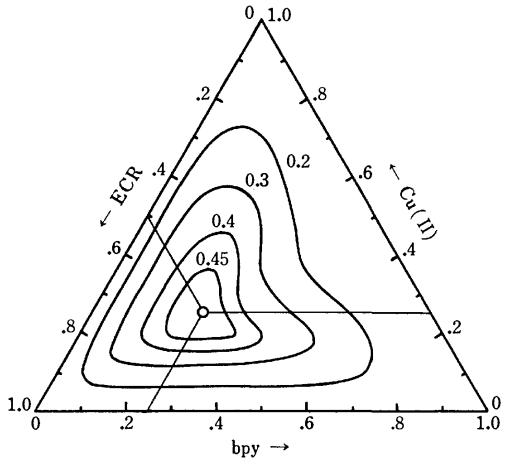

Fig. 5. Continuous variation method applied to three-component system of Cu(II)-bpy-ECR complex.
Total concn of Cu(II), bpy and ECR: 1.5×10^{-4} mol dm^{-3}; pH: 10.4, Triton X-100: 0.04%, ionic strength: 0.05, wavelength: 515 nm.

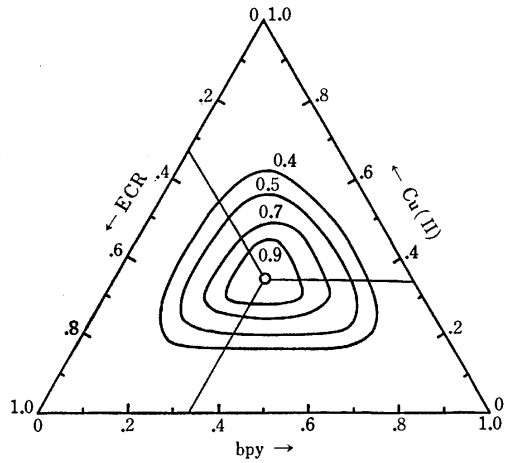

Fig. 6. Continuous variation method applied to three-component system of Cu(II)-bpy-ECR complex.
Wavelength: 550 nm; the other conditions except wavelength are the same as those in Fig. 5.

In the above experiments (Figs. 3, 4, 5, and 6) nonionic surfactant Triton X-100 was used as a solubilizing agent of the ternary complex. Addition of Triton X-100, however, had no effect on the light absorption of solutions.

From the results (Figs. 4, 5, and 6) it is evident that two types of ternary complex are formed successively, according to the amount of reagent, at pH 10.4, the combining ratio of Cu(II): bpy: ECR being confirmed to be 1 : 1 : 2 in one and 1 : 1 : 1 in the other. The maximum absorption wavelengths of the 1 : 1 : 2 and 1 : 1 : 1 complexes were 515 and 550 nm, respectively. In Cu(II)–bpy–Chromazurol S ternary complex[10] only the 1 : 1 : 2 species is formed.

The color development of the 1 : 1 : 2 complex with absorption maximum at 515 nm in a weakly basic pH medium was utilized in the spectrophotometric determination of copper(II). Conditions for the color development were investigated.

Effect of pH. The effect of pH on the color development of the ternary complex was studied with solutions adjusted to various pH values. The results are shown in Fig. 7. The maximum and nearly constant absorbance is obtained over the pH range 10.2—10.6.

Effect of 2,2′-Bipyridine and Eriochrome Cyanine R Concentrations. With the concentration of copper(II) kept constant, varying amounts of reagent were added, and the absorbances of the resulting solutions were measured against the reagent blanks. The results are shown in Fig. 8. When the concentration of 2,2′-bipyridine was varied and the concentrations of copper(II) and Erio-

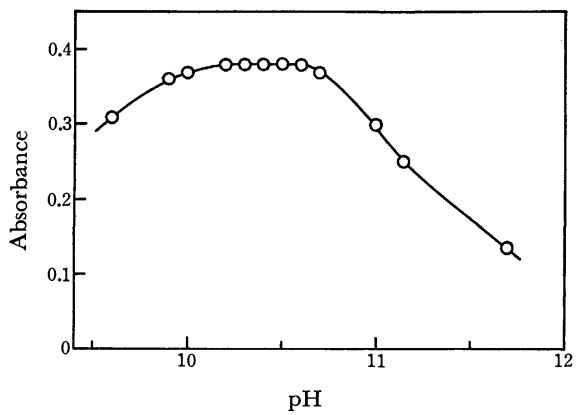

Fig. 7. Effect of pH on the absorbance of Cu(II)-bpy-ECR complex.
Concn of Cu(II), bpy and ECR: 2.0×10^{-5} mol dm^{-3}, 4.0×10^{-5} mol dm^{-3} and 1.0×10^{-4} mol dm^{-3}, respectively; ionic strength: 0.1, wavelength: 515 nm.

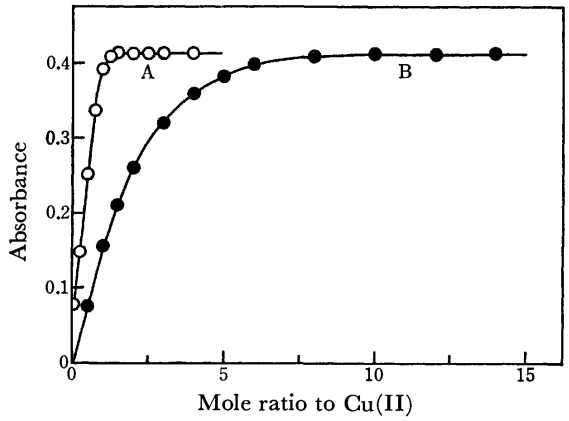

Fig. 8. Effect of 2,2′-bipyridine and Eriochrome Cyanine R concentrations on the absorbance of Cu(II)-bpy-ECR complex.
Concn of Cu(II): 2.0×10^{-5} mol dm^{-3}, pH: 10.4, ionic strength: 0.1, wavelength: 515 nm; A: [bpy]/[Cu(II)], ECR: 2.0×10^{-4} mol dm^{-3}, bpy varying; B: [ECR]/[Cu(II)], bpy: 4.0×10^{-5} mol dm^{-3}, ECR varying.

chrome Cyanine R were kept constant, the constant and maximum absorbance was obtained with a concentration ratio higher than 1.5-fold of 2,2′-bipyridine to copper(II) (Curve A). The absorbance at mole ratio of zero in curve A corresponds to that of the binary Cu(II)–ECR complex. In the same way, the effect of various Eriochrome Cyanine R concentrations is shown by curve B. More than 10-fold excess of Eriochrome Cyanine R over the copper(II) concentration is necessary in order to obtain the maximum color intensity.

Effect of Time. Color development of the ternary complex was almost instantaneous, the absorbance remaining unchanged for several hours.

Calibration Curve. A calibration curve was made under optimum conditions. A linear concentration-absorbance relationship is obtained in the copper(II) concentration up to 6×10^{-5} mol dm^{-3}. The regression equation of the calibration curve obtained by a least squares method is as follows:

$$\log (I_0/I) = 20433[\mathrm{Cu(II)}] + 0.005_5 \qquad (1)$$

Experimental conditions:
- bpy: 2.0×10^{-4} mol dm^{-3}
- ECR: 5.0×10^{-4} mol dm^{-3}
- pH: 10.4
- Ionic strength: 0.1
- Wavelength: 515 nm

Here, $\log(I_0/I)$ and [Cu(II)] are the absorbance of ternary complex against the reagent blank as reference and the concentration (mol dm^{-3}) of copper(II) in the solution, respectively. As is evident from Eq. 1, the apparent molar absorption coefficient of the complex is about 20400 dm^3 mol^{-1} cm^{-1}, corresponding to Sandell's sensitivity index of 0.003_1 μg cm^{-2}. When this is compared with indices of other similar ternary systems, its sensitivity is lower than that of the method using Neocuproine and Chromazurol S (0.002_2 μg cm^{-2}),[12] but comparable to that of the method using 2,2′-bipyridine and Chromazurol S (0.003_1 μg cm^{-2}).[10]

Effect of Diverse Ions. The influence of several cations which might introduce a large error in the determination of copper(II), and that of a few anions as masking agents were examined. The results are given in Table 1. All the cations interfere with the copper(II) determination. Beryllium(II), cobalt(II), nickel(II), and manganese(II) give high positive error, and iron(III) gives negative error. Tartrate, citrate and cyanide ions inhibit color formation of the ternary complex. Fluoride and phosphate ions, however, have almost no influence on the ternary complex formation, even in large amounts. Sodium fluoride and sodium phosphate can, therefore, serve as excellent masking agents. Among the coexisting cations in Table 1, metal cations except beryllium(II) and cobalt(II) can be effectively masked by using appropriate amounts of either fluoride or phosphate.[12,13]

Table 1. Influence of several foreign ions

Foreign ion	Ion added (μmol)	Absorbance[a] (515 nm)	Relative error (%)
	Nil	0.414	
Beryllium(II)	0.5	1.022	146.9
Cobalt(II)	0.5	0.542	30.9
Nickel(II)	0.5	0.484	16.9
Manganese(II)	0.5	0.457	10.4
Thorium(IV)	0.5	0.444	7.2
Aluminium(III)	0.5	0.417	0.7
Iron(III)	0.5	0.392	−5.3
Fluoride	50	0.416	0.5
	150	0.412	−0.5

(Received September 28, 1977)

A new chemical precipitation process utilizing CaS_x solution as a single coagulant was tested for the removal of heavy metals from a batch stirred vessel. The precipitation of heavy metals from the simulated wastewater was investigated under varing conditions of pH, temperature, and heavy metal concentrations. Several agitating speeds were studied for the gases (atmospheric air and CO_2 gas) blown into the water to decompose the coagulant (CaS_x). The findings are as follows: Heavy metal removal in keeping with the water quality standards in Japan was achieved for the simulated wastewater having pH's between 3 and 11, and the temperatures from 10 to 85 °C. The agitating speed for optimum removal was found to be 10 Hz. More than 250 ppm of the initial heavy metal concentration gives sufficient removal at stoichiometric quantities of coagulant, while less than 50 ppm of the initial concentration results in rather poor removal owing to the colloidal properties of the metal sulfide or hydroxide. For low concentrations of heavy metals, several units of the coagulant over stoichiometric amount are necessary for sufficient precipitation to achieve the water quality standards.

The effluent from the industry and the cities known as wastewater has various pH's, temperatures and concentrations of contaminants. Therefore, in designing and operating wastewater treatment plants, information about the properties of the wastewater to be treated and the precipitating conditions are of great importance. For the removal of heavy metals, there have been many processes with high efficiency.[1] Among these, the chemical precipitation processes are most widely put into practice.[2,3] The temperature and pH of the wastewater, the initial concentration of heavy metals, the amount of coagulant to be injected, and the agitating speed of the stirrer are known to adversely affect the heavy metal removal by chemical precipitation.[1]

In the previous work,[4] a new chemical precipitation process has been developed to cope with the severe water quality standards in Japan for Hg^{2+}, Cd^{2+}, and Cr(VI). This process utilizes "Lime Sulfurated Solution" as a single coagulant to precipitate the heavy metals from wastewater as metal sulfides or hydroxides. Kinetic studies on this process have already been done for the removal of heavy metals: Hg^{2+}, Cd^{2+}, Cu^{2+}, Zn^{2+}, Pb^{2+}, Cr^{3+}, and Cr(VI).[4,5]

In the present study, optimum precipitating conditions have been discussed. The conditions for effective coagulation were investigated experimentally in a batch stirred vessel for the removal of Cd^{2+} and Cr(VI) from simulated wastewater at various pH's, temperatures, and initial concentrations of the heavy metals.

Lime Sulfurated Solution (Calcium Polysulfide) Process

According to previous studies on the apparent kinetics,[4,5] the principal reactions for the precipitation of heavy metals by this process may be summarized as follows.

$$CaS_x + \frac{3}{2}O_2 \longrightarrow CaS_2O_3 + (x-2)S, \quad (1)$$

$$CaS_x + CO_2 + H_2O \longrightarrow CaCO_3 + H_2S + (x-1)S. \quad (2)$$

CaS_x which is the main component of the lime sulfurated solution reacts with O_2 or CO_2 which is blown into the wastewater, and this liberates CaS_2O_3, H_2S, and S (solid sulfur particles), as shown in Eqs. 1 and 2. Bivalent heavy metals denoted by M^{2+} are precipitated as metal sulfides by CaS_2O_3 and H_2S according to Eqs. 3 and 4.

$$M^{2+} + CaS_2O_3 + H_2O \longrightarrow MS + CaSO_4 + 2H^+, \quad (3)$$

$$M^{2+} + H_2S \longrightarrow MS + 2H^+. \quad (4)$$

Trivalent heavy metals, the sulfides of which are usually unstable in water as is the case of Cr^{3+}, may be precipitated as metal hydroxides by the alkaline base of the lime sulfurated solution. Sexi-chromium Cr(VI) (dichromate) is reduced to Cr^{3+} by H_2S or CaS_2O_3 and precipitated as $Cr(OH)_3$.

$$Cr(VI) + \frac{3}{2}H_2S \longrightarrow Cr^{3+} + \frac{3}{2}S + 3H^+, \quad (5)$$

$$Cr(VI) + \frac{3}{2}CaS_2O_3 + \frac{3}{2}H_2O \longrightarrow Cr^{3+} + \frac{3}{2}CaSO_4 + \frac{3}{2}S + 3H^+. \quad (6)$$

The experimental findings of previous studies[4,5] may be summarized as follows;

(1) Heavy metals, especially Hg^{2+}, Cd^{2+}, and Cr(VI) may be treated below the water quality standards in Japan within 60 min of processing time (fixed temperature of 25 °C, initial pH of 5.0, initial heavy metal concentration of 25 ppm with the amount of the coagulant: $R_m=25$). R_m is defined as the mole ratio of sulfur in CaS_x per M^{2+}.

2) The processing time is dependent on the kinds of

** Present address: Ataka Kogyo Co. Ltd., Sueyoshibashi, Minamiku, Osaka 542.

heavy metals and gases (air and CO_2) used for the decomposition of CaS_x, and varies from 5 to 60 min. The rate of precipitation for the bivalent heavy metals is determined by that of the CaS_x decomposition, which is accelerated by CO_2 blowing. The rate of $Cr(OH)_3$ floc formation can be favored by aeration. The pH values of the water treated with aeration or CO_2 blowing were found to change to 7 and 6, respectively.

Experimental

The precipitation of heavy metals at various conditions by CaS_x solution was carried out in a batch stirred vessel with gas (air or CO_2) blowing. The vessel was made of glass and cylindrical in shape and had a flat bottom. The diameter and height of the vessel were, respectively, 15 and 22 cm. Four baffles were positioned symmetrically on the inside wall of the vessel. The vessel contents were agitated by a six-bladed turbine driven by a variable speed electric motor. The vessel was immersed in a constant temperature bath, maintained between 10 and 85 °C by set of control systems consisting of a contact thermometer and a heater or cooler. The gas (air or CO_2) for the decomposition of CaS_x was blown through a pipe of 1 mm inner diameter attached just below the center of the turbine. Simulated wastewater containing heavy metals as soluble salts (nitrates were used for bivalent metals and potassium dichromate was used for sexi-chromium) was poured into the vessel. After ensuring steady state conditions in the vessel, removal of the heavy metals was started by injecting the coagulant (CaS_x solution). The sample liquor taken from the vessel at predetermined time intervals was filtered on a No. 5C filter paper and, if necessary, by a membrane filter and analyzed by an atomic absorption spectrophotometer according to JIS-K0102.

Results and Discussion

Effect of the Injected Amount of the Coagulant. Removal experiments were undertaken for Cd^{2+} as the representative of the bivalent heavy metals which were precipitated as metal sulfides, and for Cr(VI) as one of the multivalent heavy metals precipitated as metal hydroxides after reduction to the trivalent state.

Figure 1 shows the concentration of Cd^{2+} in the filtrate plotted against the processing time for the various mole ratios (R_m) of sulfur in CaS_x solution per metal (at 25 °C, agitating speed of 10 Hz, and initial heavy metal concentration (C_0) of 25 ppm). The CO_2 gas was blown in at the rate of 0.5 dm^3/min. The steady state concentration is likely to be realized after 80 to 120 min of the processing time and enough removal was found to be attained for R_m over 25. The steady state concentrations of Cd^{2+} after 120 min were measured for various values of C_0 and R_m (the same operating conditions as the data in Fig. 1). The result is shown in Fig. 2. For the highest value of C_0=1000 ppm, R_m=5.9 was found sufficient to achieve the water quality standard (criterion). Since x atoms of sulfur in the polysulfide are necessary to precipitate an ion of Cd^{2+} if the reactions proceed as described by Eqs. 1 to 4, then $R_m=x$ is the theoretical stoichiometric amount of the coagulant. x in CaS_x is reported as x=4.7 to 5.4.[6] The higher R_m value observed here, *i.e.*, R_m=5.9 is a little more than the stoichiometric amount for C_0=1000 ppm. One explanation for this may be that the sulfur from the CaS_x partly leaks as H_2S from the liquid phase to the exhaust gas phase, though the H_2S generated is in relatively smaller quantities under aeration than CO_2 blowing. Figure 3 illustrates the precipitation of Cd^{2+}, when CO_2 gas is used as the blowing gas instead of air. For the same values of C_0, R_m values increased a little with CO_2 blowing, in comparison with aeration. This increase may be due to the fact that CO_2 blowing generates H_2S which tends to leak from the liquid phase to the exhaust gas phase without any precipitating reaction with Cd^{2+}. Aeration generates mainly CaS_2O_3 which does not leak from the liquid phase. This leakage may explain the higher R_m values in Fig. 3 (CO_3 blowing) than that in Fig. 2 (aeration). CO_2 blowing had the advantage over aeration in that it shortened the processing time.[4] Aeration was found to utilize the sulfur from CaS_x more effectively than CO_2 blowing in the batch process. With decrease in C_0 from 1000 ppm, values of R_m (to achieve the same standard) increased gradually as shown in Figs. 2 and 3 for both cases of aeration and CO_2 blowing. A reason for this increase may be the generation of finer particles of metal sulfide for the lower values of C_0. These finer particles may pass the No. 5C filter paper and may be detected as apparent liquid phase concentration by atomic absorption to give high concentration of Cd^{2+} in the filtrate.

The behavior of these suspended fine particles was investigated by the following experiments. The sample liquors were filtered by membrane filters of various pore sizes. The filtrates were acidified with HCl to dissolve the metal sulfides and the atomic absorption was measured. Figures 4 and 5 show the apparent particle size distributions of the suspended colloidal CdS. These distributions are calculated from the filtrate concentrations based on the assumption that the membrane filter works like a standard mesh. As may be seen from

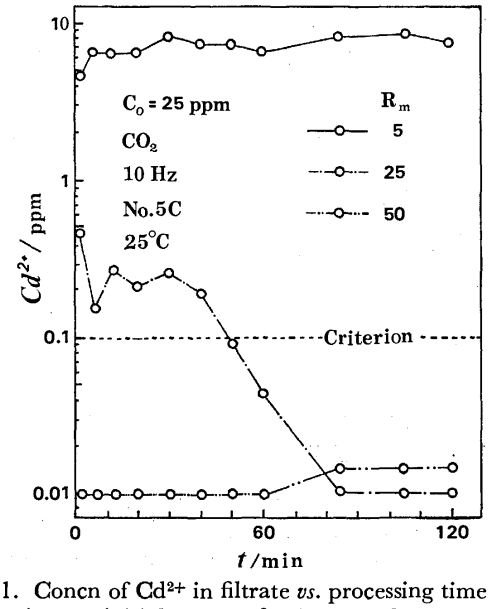

Fig. 1. Concn of Cd^{2+} in filtrate *vs.* processing time (CO_2 blowing, at initial concn of Cd^{2+}; C_0=25 ppm, agitating speed of 10 Hz, filtered on No. 5C, for mole ratio of coagulant to heavy metal; R_m=5, 25, and 50).

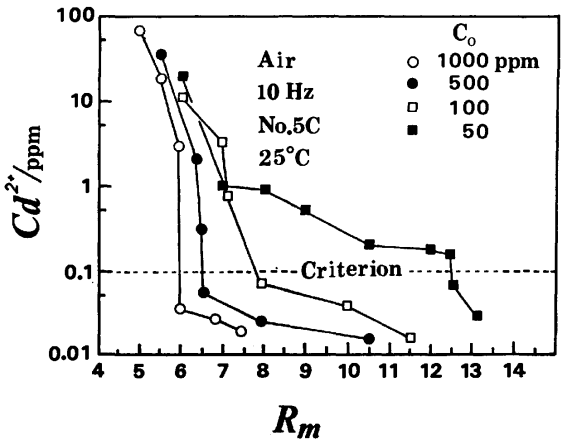

Fig. 2. Concn of Cd^{2+} in filtrate after 120 min of aeration *vs.* R_m (at 25 °C, 10 Hz, by No. 5C, for C_0=1000, 500, 100 and 50 ppm).

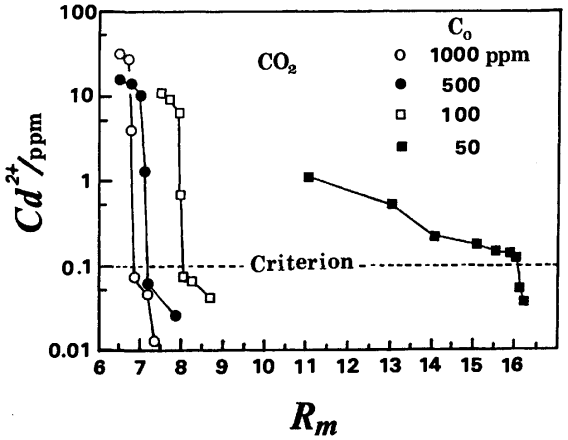

Fig. 3. Concn of Cd^{2+} after 120 min of CO_2 blowing *vs.* R_m.

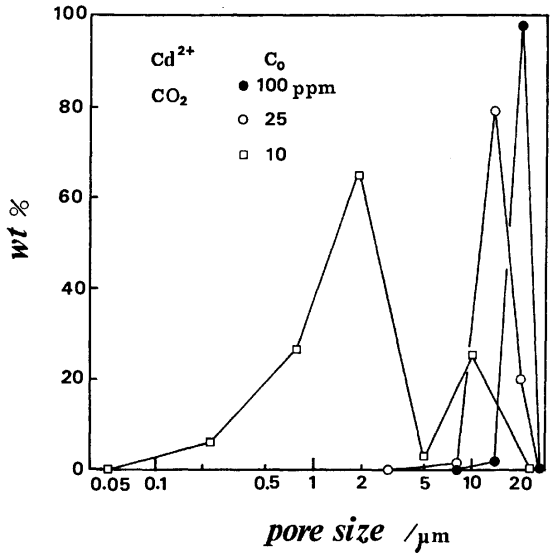

Fig. 4. Apparent particle size distribution of CdS, at 25 °C, R_m=25, with CO_2 blowing, for C_0=100, 25, and 10 ppm.

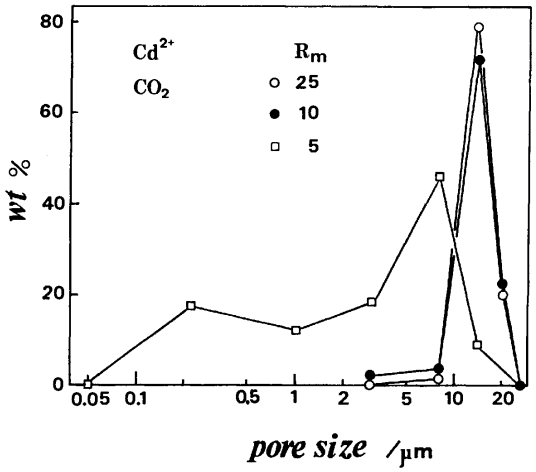

Fig. 5. Apparent particle size distribution of CdS, at 25 °C, C_0=25 ppm, with CO_2 blowing, for R_m=25, 10, and 5.

Fig. 4, decreases in C_0 gives rise to the generation of fine particles for R_m=25. Increase in R_m results in the generation of the big particles, as shown in Fig. 5. To separate the precipitated CdS completely for R_m=25 and C_0=25 ppm, a filter having a maximum pore size of 3 μm was suitable as may be seen from Figs. 4 and 5. The mean particle size of this process was found to be over 8 μm from Figs. 4 and 5, for R_m greater than 10 and C_0 greater than 25 ppm.

Processing results of Cr(VI) by CaS_x are shown in Fig. 6 with aeration and in Fig. 7 with CO_2 blowing. The residual concentration of total chromium in the filtrate after 180 min of the processing time is shown as the ordinate. As observed with Cd^{2+}, the concentration decreases critically near the theoretical stoichiometric injection of CaS_x only for aeration. If the reducing reactions follows Eqs. 1 to 5 or 6 and x is taken as 4.7 to 5.4,[6] the theoretical stoichiometric amount of CaS_x needed to treat Cr(VI) is $R_m=(3/2)x$, that is, R_m=7.1 to 9.1. Figure 8 shows the apparent particle size distribution of $Cr(OH)_3$ flocs. CO_2 blowing was found to give a finer particle size than aeration. On comparing Figs. 6 and 7, values of R_m (to achieve the standard) are observed to differ more evidently with aeration and CO_2 blowing than those with Cd^{2+} (see Figs. 2 and 3). CdS flocs have almost the same particle size distribution both for CO_2 blowing and aeration. On the other side, $Cr(OH)_3$ flocs formed by the CaS_x process with CO_2 blowing are relatively fine and need more processing time to flocculate than with aeration. This slow flocculation was observed as a gradual decrease in the amount of the light green particles ($Cr(OH)_3$) (the suspension was held in the filtrate for about 60 min with the CO_2 blowing).

Effect of Temperature. Figure 9 shows the concentration of Cd^{2+} in the filtrate (No. 5C) after 120 min of the processing time plotted against the temperature of the simulated wastewater (CO_2 blowing for C_0=25 ppm). For large values of R_m and C_0, the removal of Cd^{2+} is almost independent of the temperature. The temperature may not have such an effect on the precipitation of Cd^{2+} with large values of R_m and C_0 when

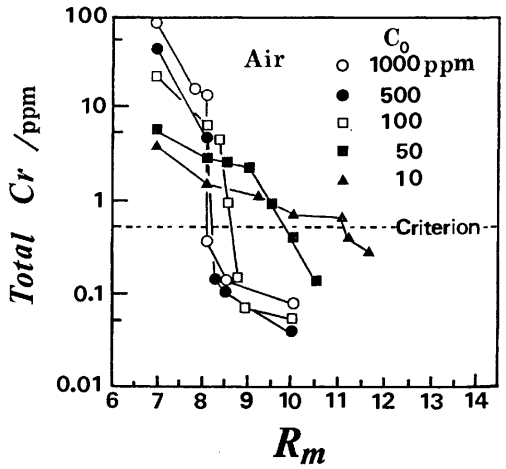

Fig. 6. Concn of total Cr after 180 min of aeration *vs.* R_m, at 25 °C, 10 Hz, by No. 5C, for C_0=1000, 500, 100, 50, and 10 ppm.

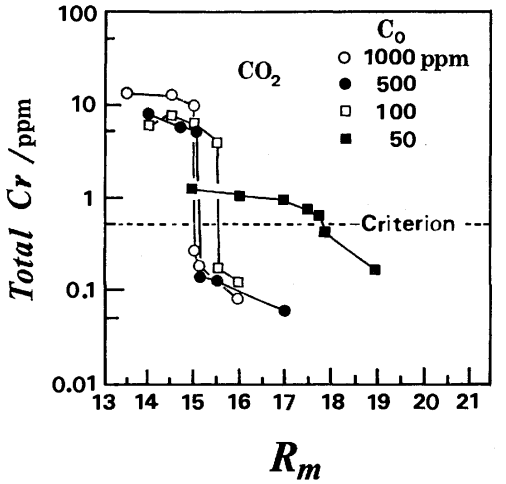

Fig. 7. Concn of total Cr after 180 min of CO_2 blowing *vs.* R_m.

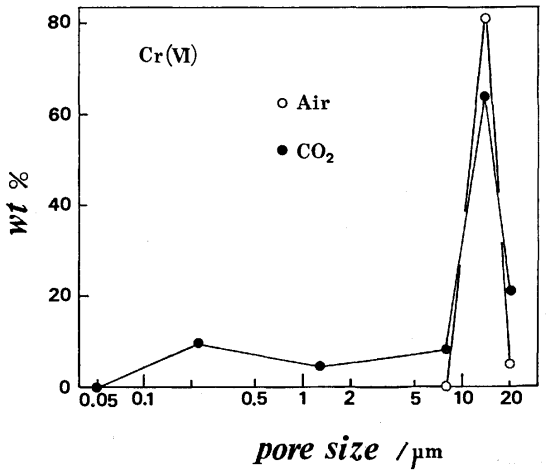

Fig. 8. Apparent particle size distribution of $Cr(OH)_3$, at 25 °C, C_0=25 ppm, after 15 min from the start of run with aeration or CO_2 blowing.

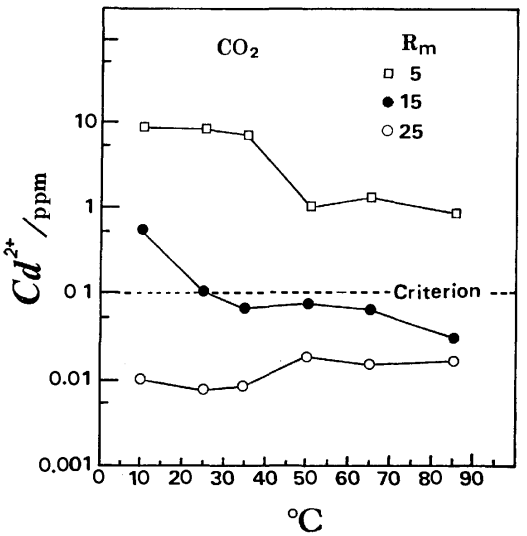

Fig. 9. Effect of temperature: Concn of Cd^{2+} *vs.* processing temperature, with CO_2 blowing, at 25 ppm, by No. 5C, for R_m=5, 15, and 25.

the particle size is large. The precipitation seems to be related to the temperature of the wastewater for R_m=5 which gives fine particles as shown in Fig. 5. Removal meets the criterion conditions for wastewater between 10 and 85 °C. Thus the CaS_x process is able to cope with variations in the temperature of the wastewater to be treated.

Effect of Agitating Speed. The removal of Cd^{2+} is shown plotted against the agitating speed of the impeller for C_0=1000 ppm and 50 ppm in Figs. 10 and 11, respectively. For C_0=1000 ppm which produces a precipitate of large particle size, the removal is almost independent of change in the agitating speed. For C_0= 50 ppm which generates the fine suspended particles, the agitation affects the removal. The removal is thought to be promoted by the agitation which accelerates the flocculation. However, removal at an agitation higher than 10 Hz results in adverse removal, and this may be due to the fragmentation of the flocs, once

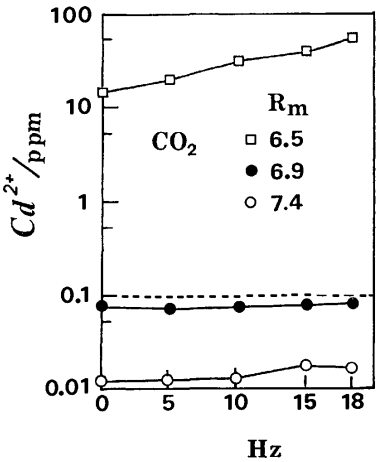

Fig. 10. Effect of agitating speed: Concn of Cd^{2+} after 120 min of CO_2 blowing *vs.* Hz, at C_0=1000 ppm, 25 °C, by No. 5C.

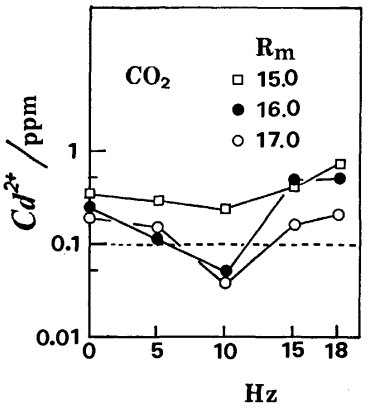

Fig. 11. Concn of Cd^{2+} with CO_2 blowing *vs.* Hz, at $C_0=50$ ppm.

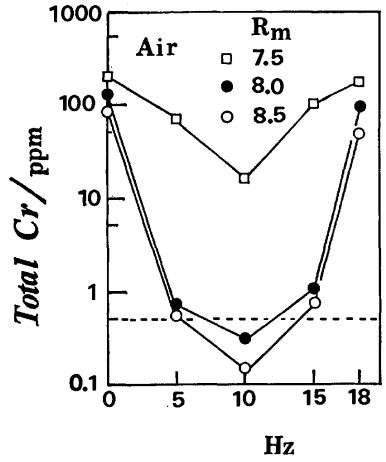

Fig. 12. Effect of agitating speed: Concn of total Cr after 180 min of aeration *vs.* Hz, at $C_0=1{,}000$ ppm, 25 °C, by No. 5C.

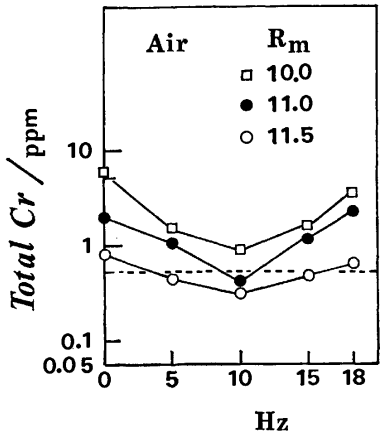

Fig. 13. Concn of total Cr with aeration *vs.* Hz, at $C_0=50$ ppm.

coagulated, by the vigorous mechanical agitation. The fragmentation may produce fine particles that pass through the No. 5C filter paper and detected as apparent Cd^{2+} concentration by atomic absorption measurements.

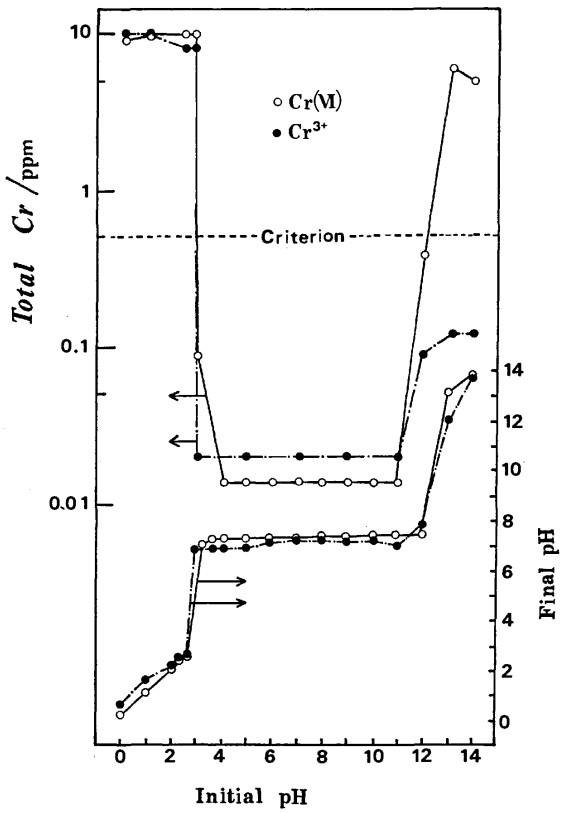

Fig. 14. Effect of pH: Concn of total Cr after 180 min of aeration *vs.* initial pH, at $C_0=25$ ppm, $R_m=25$, 25 °C, by No. 5C: Final pH *vs.* initial pH.

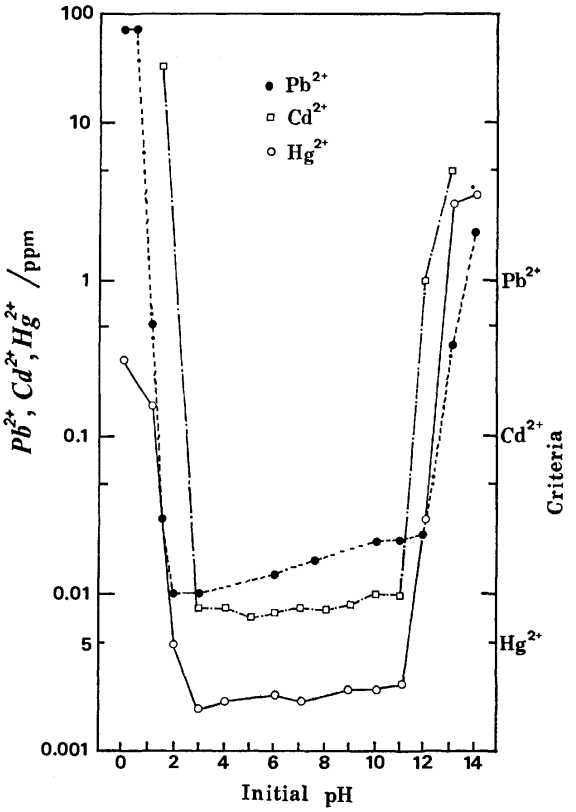

Fig. 15. Effect of pH: Concn of Pb^{2+}, Cd^{2+}, Hg^{2+} *vs.* initial pH at $C_0=25$ ppm, $R_m=25$, 25 °C, by No. 5C.

For the removal of Cr(VI), the effect of the agitating speed is shown in Fig. 12 with $C_0=1000$ ppm and Fig. 13 with $C_0=50$ ppm. In contrast to the Cd^{2+} removal, at $C_0=1000$ ppm the Cr(VI) removal was more affected by the aeration than at $C_0=50$ ppm. In the present, the reason for this is not so evident. Possibly, this may be due to the differences between metal sulfides and hydroxides in their mechanisms of flocculation.

Effect of pH. The results of removal with the wastewater having the initial pH from 0 to 14 are shown in Figs. 14 and 15. With a slightly acidic wastewater, the acid in the water may be neutralized by the strong alkaline base of the coagulant, *i.e.*, lime sulfurated solution. With alkaline water, it is neutralized by the acid of the blown gas (CO_2 in air or CO_2 gas) and by the protons liberated as stated in Eqs. 1 to 5. Figure 14 shows the removal of Cr^{3+} and Cr(VI) from simulated wastewater having pH's between 0 to 14. The final pH's are almost constant around pH=7.0, and the removal is satisfactory for the initial pH's between 3 and 11. Figure 15 shows the results of Pb^{2+}, Cd^{2+}, and Hg^{2+} removal from the wastewater of various initial pH's. The same pH range of removal is observed for these bivalent metals as that for Cr^{3+} and Cr(VI). For the other heavy metals Ni^{2+}, Zn^{2+}, and Cu^{2+}, approximately the same removal range of pH has been reported.[5]

Conclusion

The above experiments help to clarify the conditions of the CaS_x process for the removal of heavy metals from wastewater. The experimental findings are summarized as follows.

1) Almost stoichiometric amount of the coagulant is enough for the precipitation of heavy metals when their concentrations are more than about 100 ppm. When the concentrations are less than 100 ppm, several portions of coagulant are needed because of the colloidal properties of the precipitates.

2) The wastewater at wide temperature and pH range is expected to be treated far below the water quality standards for heavy metals in Japan.

The authors wish to thank Prof. Dr. Ryozo Ito of Osaka University, Profs. Drs. Takataro Suda and Yoshiki Sanoh of Shinshu University, and Assoc. Prof. Dr. Kei Miyanami of University of Osaka Prefecture for their useful discussions.

The authors wish to express their thanks to Messrs. Teruhisa Nakashiba, Kiyoshi Inoue, and Jun Akai for assistance in the experimental work.

Synthesis of Oxide-Chalcogenides. I. Hydrothermal Synthesis of Sarabauite $CaSb_{10}O_{10}S_6$ and Related Compounds*

Kozo Nagashima, Masataka Ogino, and Izumi Nakai
Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 300-31
(Received October 8, 1977)

Single crystals of a recently described metal oxide sulfide mineral sarabauite and three related oxide-sulfides of alkaline earths and antimony were hydrothermally synthesized. (1) $CaSb_{10}O_{10}S_6$: color, carmine red; crystal system, monoclinic; space group, C2/c. (2) Compound in Sr–Sb–O–S system (O<S), blackish silver, monoclinic, $P2_1/a$. (3) Compound in Ba–Sb–O–S system (O>S), reddish orange, triclinic P1 or $P\bar{1}$. (4) Compound in Ba–Sb–S–O system (O<S), blackish brown, monoclinic, $P2_1/a$.

A new oxide-sulfide of calcium and antimony with the formula $CaSb_{10}O_{10}S_6$ was first found as a beautiful scarlet colored mineral from the Sarabau mine, Malaysia, and reported as a mineral sarabauite.[1] The mineral and three compositionally related compounds in the M^{II}–Sb–O–S system (where M^{II} represents an alkaline earth metal), have been hydrothermally synthesized. This paper reports the preparation and chemical and physical properties of sarabauite and the three related oxide sulfide compounds. The three compounds have not been found in nature. Their preparation has not been reported.

Experimental

The following CP-grade reagents were used for the syntheses: CaO, $SrCO_3$, $BaCO_3$, Sb_2S_3, and Sb_2O_3. They were taken in the required ratios and mixed in an agate motor. Seventy milligrams of the mixture and 0.07 ml of water were sealed in either a gold or platinum tube: length 35 mm, inner diam. 2.7 mm. The conventional hydrothermal method, using stellite bombs of the test-tube type, was employed throughout the investigation. Syntheses were conducted under hydrothermal conditions in the temperature range 100—650 °C under 500—2000 kg/cm² pressure for 1—360 h.

The products were examined by means of the Weissenberg and precession methods, X-ray powder diffraction method, DTA, TGA, and microscope. Some were subjected to electron microprobe analysis.

Results and Discussion

Sarabauite. Single crystals up to 3 mm long have been synthesized by subjecting a mixture of the composition CaO: Sb_2S_3: Sb_2O_3 in the ratio 1:2:3 for three days at 400 °C and 1000 kg/cm² pressure. The crystals are transparent with a carmine red color similar to that of natural sarabauite. The twelve strongest X-ray powder reflections obtained by the diffractometer method are given in Table 1, together with the reflections for natural sarabauite for the sake of comparison. They are in good agreement. The unit cell dimensions for the synthesized $CaSb_{10}O_{10}S_6$ calculated from the powder data are a=25.39(4), b=5.655(5), c=16.92(3) Å and β=117.5(2)°. The values are very close to those for natural sarabauite: a=25.37(2), b=5.654(1), c=16.87(1) Å and β=117.58(4). The Weissenberg and precession photographs of the product reveal that it belongs to the same space group as sarabauite *i.e.* C2/c.[2] Thermal analyses (DTA and TGA) were performed at a heating rate of 2.5 °C/min. The DTA curve (Fig. 1) shows two exothermic peaks starting at 410 and 490 °C. The former is accompanied by weight loss. The corresponding peaks for natural sarabauite are found to start at 420 and 490 °C. The decomposition products at 490 °C

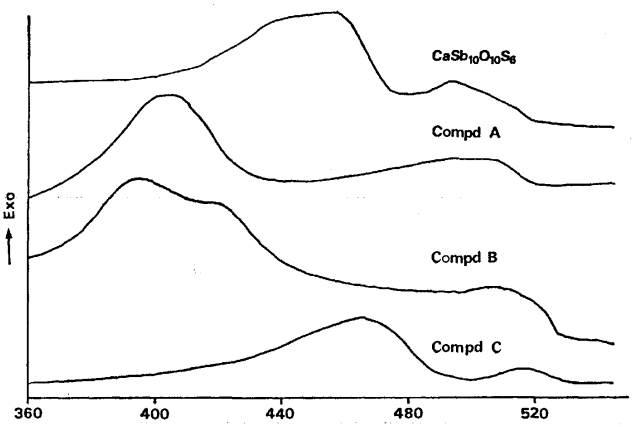

Fig. 1. DTA curves of $CaSb_{10}O_{10}S_6$, Compd A, Compd B, and Compd C.

* Presented at the 36th National Meeting of the Chemical Society of Japan, April 1977, and partly at the 1976 National Meeting of the Mineralogical Society of Japan, June 1976.

were found by X-ray analysis to be Sb_2O_3, Sb_2O_4, and $CaSb_2O_6$.

The density 4.9 g/cm³ determined by a Berman balance agrees with the calculated density 4.96 g/cm³ for $CaSb_{10}O_{10}S_6$ if we adopt the measured unit cell data and $Z=4$. The synthesized crystals have been identified as sarabauite $CaSb_{10}O_{10}S_6$.

Crystal habits of the synthesized sarabauite are tabular or columnar parallel to the b-axis. The former is characterized by the well developed {100} face.

The sarabauite phase was found to be formed in the temperature range 230—560 °C at a 1000 kg/cm² pressure. The product often included recrystallized acicular Sb_2S_3 and polygonal Sb_2O_3. The rate of sarabauite formation is scarcely influenced by variations in pressure up to 2000 kg/cm². One experiment carried out in a silica tube at 500 °C resulted in sarabauite formation at a 20 kg/cm² pressure. Formation of sarabauite proceeded so rapidly that the sarabauite phase appeared within 1 h at 500 °C and 1000 kg/cm². The presence of water is essential for the formation of sarabauite. Attempts at synthesis in a dry atmosphere at temperatures below 500 °C were unsuccessful.

Three compounds related to the above were prepared as follows: compound A, Sr–Sb–O–S system; compound B and compound C, Ba–Sb–O–S system. Their chemical compositions are given in Table 2. The analysis was carried out with an electron microprobe analyzer, measurements being made at 15 kV using Sb_2S_3, Sb_2S_2O, Sb_2O_3, $BaSO_4$, and $SrCO_3$ as standards. Since the correction procedures for the oxide–sulfide system are not well established in electron microprobe analysis, the values given should be considered approximate. The crystallographic data are summarized in Table 3. The crystal system and possible space group were determined by means of Weissenberg and precession photographs. The unit cell dimensions were obtained on an automated four-circle diffractometer using Mo $K_{\alpha 1}$ radiation for A and B and Cu $K_{\alpha 1}$ radiation for C. The 12 strongest X-ray powder lines are given in Table 4. Indexing is in line with the space groups, unit cell constants and X-ray intensity data of the single crystals.

Table 2. Electron microprobe chemical analysis of compounds A, B, and C

	Compd A		Compd B		Compd C	
	wt%	r[a)]	wt%	r[a)]	wt%	r[a)]
Sr	4.7	0.9

Total	101.9		100.7		99.3	

a) Atomic ratio, basis Sb=10.

Sr–Sb–O–S System: Compound A. A mixture of $SrCO_3$: Sb_2S_3: Sb_2O_3 in the ratio 1: 2: 3 was maintained for 214 h at 450 °C and 1030 kg/cm². The color of the crystal is blackish silver and by transmitted light red, giving a metallic luster and columnar shape elongated along the b-axis, and often showing parallel growth. The determined density is 4.6 g/cm³ which is slightly less than the 4.9 g/cm³ for sarabauite. The DTA and TGA curves are characterized by an exothermic peak starting at 380 °C, accompanied by weight loss, and one starting at 460 °C (Fig. 1). An X-ray powder study for the product at 460 °C showed that it consists of a mixture of Sb_2O_4 and $SrSb_2O_6$. Compound A is formed in the temperature range 460—540 °C under 1000 kg/cm².

Ba–Sb–O–S System: 1) Compound B. A mixture of $BaCO_3$: Sb_2S_3: Sb_2O_3 in the ratio 1: 2: 3 was maintained at 520 °C and 500 kg/cm² for 219 h. The crystals obtained are reddish orange and transparent, possessing resinous luster similar to that of sarabauite.

The habit is tabular or columnar parallel to the b-axis. The measured density is 5.4 g/cm³. Figure 1 shows the result of DTA. The curve consists of two exothermic peaks starting at 370 and 500 °C, the former being accompanied by weight loss resulting from thermal decomposition. The temperature range for the formation of compound B is similar to that for sarabauite: 290—550 °C under 1000 kg/cm².

2) Compound C. Crystals up to 1 mm in length have been prepared by heating the mixture for B at 500 °C and 1000 kg/cm² for 110 h. The color is blackish brown and by transmitted light, red, respectively. C is a sulfur rich oxide–sulfide as compared to B (Table 2). It is characterized by its extremely large unit cell (Table 3). It appears columnar in shape, showing parallel growth along the b-axis in many cases. The product usually contains some of compound B. The result of DTA, given in Fig. 1, shows two exothermic peaks, one starting at 420 °C with weight loss and the other at 500 °C. The optimum temperature range

Note added in proof

A new oxide-selenide of barium and antimony, Compound D, has been synthesized by heating a mixture of $BaO:Sb_2Se_3:Sb_2O_3$ in the ratio 1:2:3 with 5% NaOH solution for 110 h under hydrothermal conditions.

The crystals are red, and transparent having resinous luster and columnar shape. X-Ray data show them to be hexagonal, space group $P6_3$ or $P6_3/m$, with $a=14.41(1)$, and $c=5.552(3)$ Å. The strongest X-ray powder lines are: 12.62(30)(100), 4.168(40)(300), 3.601(30)(220), 3.333(50)(301), 3.124(40)(040), 3.027(90)(221), 2.943(60)(311), 2.727(100)(140). The DTA curve shows an exothermic peak starting at 495 °C, accompanied by weight loss. Compound D is formed in the temperature range 300—650 °C under 1000 kg/cm².

Synthesis and Spectroscopy of Acetato and Dithiocarbamate Complexes of Bis(cyclopentadienyl)zirconium(IV)

Hideo SUZUKI, Toshio TAKIGUCHI, and Yoshikane KAWASAKI*

Department of Synthetic Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376

(Received October 14, 1977)

Several acetato and dithiocarbamate complexes of bis(cyclopentadienyl)zirconium(IV), $Cp_2Zr(X)OAc$ (X= Me, Cl, OAc), $Cp_2Zr(X)dmtc$ (X=Me, Cl; dmtc=S_2CNMe_2), and $Cp_2Zr(X)detc$ (X=Me, Cl; detc=S_2CNEt_2) have been prepared. Infrared, ^1H NMR and mass spectra of these complexes suggest the chelation of acetato (except for one acetato group in $Cp_2Zr(OAc)_2$) and dithiocarbamate groups, affording 18-electron configuration of the zirconium atom. The infrared spectrum of diacetate bis(cyclopentadienyl)zirconium(IV) shows that one acetato group acts as bidentate ligand and the other as unidentate. Remarkable benzene- and hexafluorobenzene-induced shifts were observed in the ^1H NMR signal of methyl group attached to the zirconium atom and the dithiocarbamate group.

The structure and reactivity of bis(cyclopentadienyl)-zirconium(IV) complexes are of considerable interest in comparison with those of titanium analogs in view of the fact that the zirconium atom has larger ionic radius and smaller ionization potentials than the titanium atom.

Very few[1-3] 18-electron bis(cyclopentadienyl)zirconium complexes $Cp_2Zr\begin{matrix}X\\ \leftarrow L\\ Y\end{matrix}$, which are thought to be a reaction intermediate, have been reported. In these complexes the X, Y, and L groups take coplanar three coordinated configuration. Brainina *et al.*[4] reported the preparation of acetate chlorobis(cyclopentadienyl)zirconium(IV) but gave no spectral data. Wailes *et al.*[5] reported only ^1H NMR data of diacetate bis(cyclopentadienyl)zirconium(IV) in $CDCl_3$. Neither groups, however, made any suggestions for the structures.

This paper reports the preparation of several dithiocarbamate bis(cyclopentadienyl)zirconium(IV), with some spectroscopic discussion on their structures. No dithiocarbamate derivatives of bis(cyclopentadienyl)zirconium(IV) have been reported, except for monocyclopentadienylzirconium(IV) complex $CpZr(S_2CNMe_2)_3$.[6] The preparation of some acetate bis(cyclopentadienyl)-zirconium(IV) is also reported.

Experimental

General. Preparation and recrystallization were carried out under argon or nitrogen atmosphere. Solvents were dried in the usual manner and distilled. Chlorobis-(cyclopentadienyl)(methyl)zirconium(IV) and thallium(I) dimethyl and diethyldithiocarbamate were prepared by the procedures reported.[7,8] Thallium(I) acetate and thallium(I) dithiocarbamates were used as a fine powder stored over P_2O_5. Infrared and mass spectra were recorded on a Hitachi 225 spectrophotometer and a JEOL model JMS-07 spectrometer, respectively. ^1H NMR spectra were recorded on a JEOL model JNM-PS-100 spectrometer operating at 100 MHz and a Varian A60-D spectrometer operating at 60 MHz. Chemical shifts were measured relative to tetramethylsilane as an internal standard. Melting points were measured in sealed capillary tubes and are uncorrected.

Preparation. Acetato Bis(cyclopentadienyl)(methyl)zirconium(IV) **1**: Thallium(I) acetate (0.58 g, 2.2 mmol) was gradually added to a solution of chlorobis(cyclopentadienyl)(methyl)zirconium(IV) (0.54 g, 2 mmol) in 50 ml of dichloromethane and the mixture was stirred at room temperature for 4 h. The filtrate was evaporated *in vacuo*, and the yellow residue was recrystallized twice from benzene–hexane to give white crystals **1** (0.21 g, 35% yield). Am attempt to prepare **1** by the reaction of $(Cp_2ZrMe)_2O$[9] with Ac_2O was unsuccessful, although $Cp_2Zr(Cl)OAc$ was prepared[4] by the treatment of $(Cp_2ZrCl)_2O$ with Ac_2O.

Acetato Chlorobis(cyclopentadienyl)zirconium(IV) **2**: Dichlorobis(cyclopentadienyl)zirconium(IV) (0.58 g, 2 mmol) was treated with thallium(I) acetate (0.58 g, 2.2 mmol) to give **2** (0.40 g, 64% yield) after recrystallization twice from dichloromethane–hexane.

Diacetate Bis(cyclopentadienyl)zirconium(IV) **3**: Sodium acetate (0.36 g, 4.4 mmol) was added to a solution of dichloro bis(cyclopentadienyl)zirconium(IV) (0.58 g, 2 mmol) in 40 ml of benzene and the mixture was refluxed for 6 h with stirring. The yellow filtrate was evaporated *in vacuo*. The orange residue was recrystallized three times from benzene–hexane to give white crystals **3** (0.30 g, 45% yield).

Dimethyldithiocarbamate Bis(cyclopentadienyl)(methyl)zirconium(IV) **4**, *Dimethyldithiocarbamate Chlorobis(cyclopentadienyl)-zirconium(IV)* **5**, *Diethyldithiocarbamate Bis(cyclopentadienyl)-(methyl)zirconium(IV)* **6**, *and Diethyldithiocarbamate Chlorobis-(cyclopentadienyl)zirconium(IV)* **7**: Complexes **4**—**7** were obtained as white crystals in 45(for **4**)—85%(for **7**) yield by the reaction of $Cp_2ZrMeCl$ or Cp_2ZrCl_2 with thallium(I)-dimethyl- or diethyldithiocarbamate in a similar way to

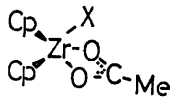
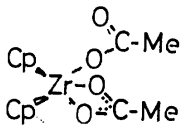
that for **1** and **2**.

Results and Discussion

Acetato Derivatives (1—3). In the monoacetato complexes **1** and **2**, ν_{as}(OCO) and $\Delta(\nu_{as}-\nu_s)$ values (Table 2) suggest that the acetato group belongs to the category of the chelating structure[10] in the solid state. On the other hand, in the diacetate derivative **3** one acetato group acts as the bidentate ligand and the other as unidentate in the solid state. Bridging and ionic structures of the acetate groups are excluded on the basis of molecular weight measurements and negligible molar conductivities (Table 3). In mass spectra of these complexes no ion heavier than the parent ion or the $(M-Me)^+$ ion was detected (Table 4). The results suggest the following structures I and II for complexes **1**—**3** in the solid state. The IR spectra of **1** and **2** in

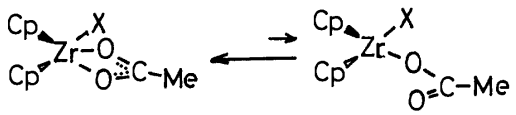


1 (X=Me)
2 (X=Cl)
(I)



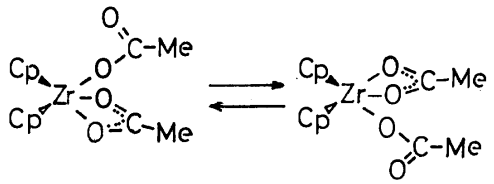
3
(II)

CH_2Cl_2, however, give additional weak bands at *ca.* 1640 and 1300 cm^{-1}. The results indicate that there is some portion of III in equilibrium with I in CH_2Cl_2.



(I) (III)

The structure of **3** is of interest as compared with that of analogous titanium(IV) complex $Cp_2Ti(OAc)_2$.[11] In the latter both acetate groups are unidentate, although the bidentate acetate group was reported for Cp_2Ti^{III}-OAc.[12] The difference in structure of these diacetate complexes might be mainly due to the difference in their ionic radii (Ti(IV) 0.62—0.65 Å, Zr(IV) 0.79—0.87 Å). In the ^1H NMR spectrum of **3** methyl signals of the two acetate groups were observed as a singlet resonance even at −91 °C in CH_2Cl_2. The IR spectrum of **3** in CH_2Cl_2 shows little difference from that in the solid state. The IR and ^1H NMR data suggest that there is a rapid interconversion process IIa—IIb between two acetate groups in CH_2Cl_2.



(IIa) (IIb)

Dithiocarbamate Derivatives (4—7). IR spectra: The νC=N frequency of complexes **4**—**7** together with that of methyl dialkyldithiocarbamate, tetraalkylthiuram disulfide, and sodium dialkyldithiocarbamate is summarized in Table 2. The IR spectra of complexes **4**—**7** in CH_2Cl_2 show little difference from those in the solid state. Complexes **4**—**7** exhibited the νC=N band at higher frequency than the corresponding unidentate dithiocarbamate compounds containing the same *N,N*-dialkyl group. The frequency of this band of **4**—**7** is nearly the same as that of $CpZr(S_2CNR_2)_3$,[6,17] in which chelation of the dithiocarbamate groups has been demonstrated by X-ray crystal analysis.[6] Thus the higher νC=N values suggest the chelation of dithiocarbamate groups in the complexes.

^1H NMR Spectra and the Structures: One sharp N–Me proton signal was observed at 23 °C in CH_2Cl_2 in complexes **4** and **5**, the latter showing two N–Me proton signals under 0 °C. One kind of sharp N–CH_2 and two

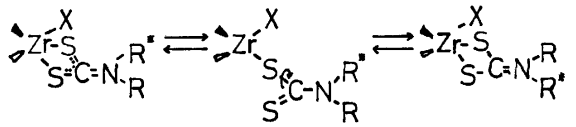
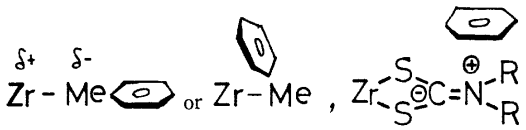
a) δ value (ppm); (q) quartet; (t) triplet; other, sharp singlet except as noted. b) Recorded on a JEOL model JNM-PS-100 spectrometer at 23 °C operating at 100 MHz. c) Recorded on a Varian A-60-D spectrometer at 40 °C operating at 60 MHz. d) $\Delta=\delta(CH_2Cl_2)-\delta(C_6D_6)$. e) $\Delta^*=\delta(CH_2Cl_2)-\delta(C_6F_6)$. f) Singlet even at −97 °C. g) Coalesces to doublet at 0 °C. h) Coalesces to triplet at about 34 °C. i) Ref. 7.

sorts of sharp C–Me proton signals were observed at 23 °C in complexes **6** and **7**. The C–Me proton signals coalesced at 34 °C. On the other hand, very broad N–Me and N–CH_2 proton signals were observed in Me_2NCS_2Me and Et_2NCS_2Me at 23 °C in CH_2Cl_2, due to the high rotational barrier around the S_2C=N bond.[13] The chemical shifts of *N*-alkyl protons of complexes **4**—**7** are nearly the same as those of $CpZr(S_2CNR_2)_3$. The IR and ^{1}H NMR data suggest that these dithiocarbamate groups complexes **4**—**7** are chelating in the solid state and in CH_2Cl_2. The two *N*-alkyl protons might be magnetically equivalent by the following equilibration IVa—IVc over −97 °C in **4**, 0 °C in **5**, and 34 °C in **6** and **7**.



(IVa) (IVb) (IVc)

Chemical Shifts of Cp Proton, and Solvent-induced Shifts. Table 5 shows ^{1}H NMR data for complexes **1**—**7** in CH_2Cl_2, C_6D_6, and C_6F_6 together with those for Cp_2Zr-Me_2, $Cp_2Zr(Me)Cl$, Cp_2ZrCl_2. In a series of $Cp_2Zr(X)$-OAc the order of high field shifts of Cp proton in CH_2Cl_2 is X=Me>Cl≥OAc (unidentate). Similarly in Cp_2Zr-(X)Me the order is X=dmtc>detc>OAc(chelating)>Me>Cl, and in $Cp_2Zr(X)Cl$ it is X=detc≥dmtc>OAc-(chelating)≥Me>Cl. Thus the overall order of high field shifts of the Cp proton in CH_2Cl_2 is as follows: dmtc≥detc>OAc(chelating)≥Me>Cl≥OAc(unidentate). The signals of Cp proton in bis(cyclopentadienyl)-zirconium(IV) complexes in $CDCl_3$ shift in general to high field in line with electron donating effect of ligands on the zirconium atom.[18] The order is in line with that of electron donating ability of ligands. Remarkably low field shifts for (Zr)–CH_3 proton signals and high field shifts for N–CH_3 proton signals in dithiocarbamate groups were observed in benzene (Tables 5). The specific benzene-induced solvent shifts are interpreted by the following benzene-solute stereospecific interaction. Benzene–dithiocarbamate interaction has been



reported by Hatton and Richards[19-20] and Honda *et al.*[21-22] Hexafluorobenzene[23-24] induces low field shifts of protons at the electron-deficient site in a solute molecule and high field shifts of protons at the electron-rich site, the direction of these shifts being reversed in ben-

zene. In our zirconium complexes appreciable hexafluorobenzene induced shifts were also observed in (Zr)–CH_3, N–CH_3, and N-CH_2CH_3 proton signals.

One of us (H. S) is grateful to Prof. Rokuro Okawara, Dr. Masanori Wada and Dr. Hideo Kurosawa, Osaka University, for their encouragement and valuable discussions.

Five-coordinate Bis(8-aminoquinoline) Nitrosylcobalt Complexes

Eiichi MIKI, Hiromichi OKAMURA,* Kunihiko MIZUMACHI, and Tatsujiro ISHIMORI

Department of Chemistry, College of Science, Rikkyo University, 3-Chome, Nishi-Ikebukuro, Toshima-Ku, Tokyo 171

(Received December 6, 1977)

$[Co(C_9H_8N_2)_2NO]X_2 \cdot nH_2O$ ($C_9H_8N_2$=8-aminoquinoline; X=Cl, Br, I, NO_3, ClO_4, and $SO_4/2$; n=0, 1, 1.5, and 2) was isolated by the reaction of nitrogen oxide with a mixture of the corresponding cobalt(II) salt and 8-aminoquinoline in methanol. The IR, UV, and molar conductivity measurements suggest that the geometry of the cation is a tetragonal pyramid with an apical NO^-.

Nast *et al.* reported that paramagnetic deep blue compounds formulated as $[Co(C_9H_8N_2)_2NO]X_2$ ($C_9H_8N_2$=8-aminoquinoline; X=Cl and NO_3) had been isolated by the reaction of nitrogen oxide with $CoX_2(C_9H_8N_2)_2$ in methanol, and that the geometry of the complex cation was a tetragonal pyramid with an apical NO^-, its N–O stretching vibration being assigned to a *ca.* 1170 cm^{-1} band.[1] Subsequently, it was established that N–O stretching vibrations for nitrosylcobalt complexes with this geometry can be observed in the region 1620—1710 cm^{-1} and most of the compounds are diamagnetic.[2,3] N–O stretching vibrations for compounds bridged by a NO group and those for compounds containing an anion of dimer of nitrosyl group such as a hyponitrite ion were observed in the region 1300—1550 and 920—1270 cm^{-1}, respectively.[4,5]

The authors reinvestigated the reaction of nitrogen oxide with $CoX_2(C_9H_8N_2)_2$ to make clear the detals. In this paper, they report the syntheses and characterization of some new five-coordinate mononitrosyl complexes which are different from the compounds isolated by Nast *et al.*[1]

Experimental

Preparations. The compounds were prepared by the use of a Schlenk apparatus under nitrogen atmosphere. Four mmol of 8-aminoquinoline was added to *ca.* 50 cm^3 of deoxygenated methanol solution containing 2 mmol of cobalt(II) salt to give a deep orange solution. Nitrogen oxide (of purity more than 99.0%) purchased from Seitetsu Kagaku Co., Ltd., after being further purified by passing it through a trap at −80 °C, was then passed into this solution at room temperature causing the solution to darken gradually with the formation of a precipitate. This precipitation was not reported by Nast *et al.*[1] After the nitrogen oxide had been replaced with nitrogen, the precipitate was collected by filtration, washed with methanol and diethyl ether, successively in air, and dried over anhydrous calcium chloride under vacuum. Yield, 500—700 mg. The elementary analyses are given in Table 1. The filtrate was wine red. The same compounds could also be prepared by the reaction of $CoX_2(C_9H_8N_2)_2$ with the nitrogen oxide in methanol, but could not be prepared by exposure of $CoX_2(C_9H_8N_2)_2$ in the solid state to the nitrogen oxide under *ca.* 1 atmosphere at room temperature. The ^{15}NO(^{15}N atom%=95.5) analogues were prepared in a vacuum system on a scale half of the ordinary one by the use of *ca.* 3 mmol of ^{15}NO derived from $K^{15}NO_3$.

The wine red filtrate was dropped into a large volume of petroleum ether or diethyl ether (*ca.* 500 cm^3), while being stirred, to give the paramagnetic deep blue precipitate reported by Nast *et al.*[1]

$[CoNO(diars)_2](ClO_4)_2$ (diars=1,2-bis(dimethylarsino)benzene), $[CoINO(diars)_2]ClO_4$, and their ^{15}NO-substituted compounds were synthesized by the use of a vacuum system in accordance with Ref. 6.

Measurements. The magnetic susceptibility was measured by the Gouy method. The IR spectra were measured as Nujol and hexachlorobutadiene mulls in the region 200—4000 cm^{-1} on JASCO 402G and JASCO IR-F spectrometers. The wave numbers of the observed bands were calibrated with polystyrene film and water vapor. The UV spectra in *N,N*-dimethylformamide were measured with a Hitachi 124 spectrometer and the diffuse reflection spectra with a Hitachi EPS-3T spectrometer. The molar conductivities in *N,N*-dimethylformamide were measured in the range $(2.5—10)\times10^{-3}$ M at 25 °C (±0.1 °C) with a universal bridge (Model 4225A of Yokogawa-Hewlett-Packard Ltd.). The *N,N*-dimethylformamide was purified by the standard method, its electrolytic conductivity being $(1.1—2.3)\times10^{-5}$ S m^{-1}.

Results and Discussion

Properties of the Compounds. All the compounds obtained were stable in air, and were soluble in water, methanol, and ethanol to give wine red solutions from which the deep blue compounds reported by Nast *et al.*

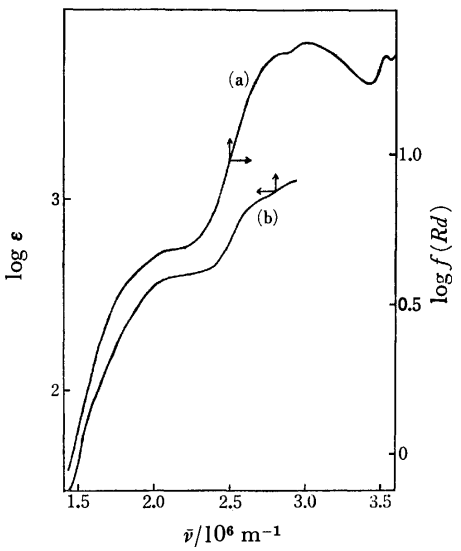

Fig. 1. UV spectra of $[Co(C_9H_8N_2)_2NO](NO_3)_2$; a: in *N,N*-dimethylformamide(1.266×10^{-4} M), b: in the solid state.

precipitate by addition of petroleum ether or diethyl ether. UV spectra of the wine red solutions were consistent with those of the deep blue compounds. All of the compounds except the chloride and sulfate were stable in *N,N*-dimethylformamide for a few hours. Although they could not be purified by recrystallization from *N,N*-dimethylformamide, they gave excellent results for the elementary analyses.

Magnetic susceptibilities, χ_g, for the chloride, bromide, iodide, perchlorate, and nitrate are -0.38, $+1.33$, -0.06, $+0.01$, and -0.14×10^{-6} cm^3 g^{-1}, respectively. Thus, all the compounds are essentially diamagnetic. The slight paramagnetism is probably due to contamination by a small amount of the deep blue compound (μ_B=3.45 and 2.95 B. M. for the chloride and nitrate, respectively) reported by Nast *et al.* considering the synthetic conditions.

UV Spectra and Molar Conductivities. The spectral figures in *N,N*-dimethylformamide are similar to those of the diffuse reflection as shown in Fig. 1. Hence, the structures of the cation in the solid state of the bromide, iodide, perchlorate, and nitrate may be the same as those in *N,N*-dimethylformamide. The UV spectra in *N,N*-dimethylformamide show a peak or shoulder at $(1.9—2.1)\times 10^6$ m^{-1} with log ε=2.7—2.8, which is a characteristic band of a tetragonal pyramid-type nitrosyl complex with an apical NO^- group.[2]

The measurement of the molar conductivity was carried out within *ca.* one hour after the compounds had been dissolved. The molar conductivities were compared with those of 3:1-, 2:1-, and 1:1-type electrolytes by the method of Feltham and Hayter.[7] The results in Table 2 show that the compounds are 2:1-type electrolytes.

IR Spectra. The wave numbers and their assignments due to the CoNO group are summarized in Table 2.

No isotopic shift upon ^{15}NO-substitution was observed in the bands at *ca.* 1100 cm^{-1}, while the bands at 1630—1720 cm^{-1} shifted downwards by 26—29 cm^{-1}. Hence, the latter can be assigned to the N–O stretching vibrations.

The isotopic shift in the region 200—700 cm^{-1} was carefully measured because a number of bands due to 8-aminoquinoline disturbed the assignments of skeletal vibrations due to the CoNO group. The 500—520 cm^{-1} bands showed the isotopic shift, its value being 4—8 cm^{-1}. The 305 cm^{-1} band for the bromide shifted to 301 cm^{-1}; however, no band in the region of 300 cm^{-1} was observed for the other compounds. This can be

explained from the fact that a very strong band at 290—300 cm^{-1} due to the coordinated 8-aminoquinolines overlapped the bands due to the CoNO group.

For nitrosylcobalt complexes, the N–O stretching vibration of the NO^- complex is observed in the region 1570—1710 cm^{-1}, while that of the NO^+ complex such as $[CoNO(diars)_2](ClO_4)_2$ at 1846 cm^{-1}.[2,3,6,8] The ^{15}N-isotopic shift of the N–O stretching vibration for $[CoNO(diars)_2](ClO_4)_2$ was 36 cm^{-1}, this value being quite similar to the isotopic shift, 35 cm^{-1}, calculated by a linear Co–N–O arrangement. On the other hand, the isotopic shift of the N–O stretching vibrations for the NO^- complexes such as $[Co(NH_3)_5NO]Cl_2$ (νNO, 1614 cm^{-1}), $[Co(OClO_3)(en)_2NO]ClO_4$ (νNO, 1661 cm^{-1}), $Co\{S_2CN(CH_3)_2\}_2NO$ (νNO, 1624 cm^{-1}), and $[CoINO(diars)_2]ClO_4$ (νNO, 1575 cm^{-1}) was in the range 25—29 cm^{-1}.[9] Thus, the value of the ^{15}N-isotopic shift for the N–O stretching vibration is sensitive to the metal–N–O bond angle.

Skeletal vibrations of the metal–N–O group are observed in the wide region 280—600 cm^{-1}, which have been established from the ^{15}NO-substitution.[9] For NO^+ complexes, the skeletal vibrations are observed in the limited region *ca.* 450—650 cm^{-1}. For example, those for $[CoNO(diars)_2](ClO_4)_2$ in the present work were observed at 477 and 501 cm^{-1}, the ^{15}N-isotopic shifts being 10 and 11 cm^{-1}, respectively. For NO^- complexes, the metal–N stretching and the metal–N–O bending vibrations are observed in the regions, 280—340 and 500—620 cm^{-1}, respectively, and the ^{15}N-isotopic shift for the former vibration is generally smaller than that for the latter one. Thus, the 500—520 cm^{-1} bands for the present compounds can be assigned to the Co–N–O bending and the *ca.* 300 cm^{-1} bands to the Co–N stretching vibrations. Similar vibrational frequencies are also observed in a strongly bent nitrosyl, XNO (X= F, Cl, and Br); the X–N–O bending vibrations appear in the region 550—780 cm^{-1}, the X–N stretching vibrations in the region 270—520 cm^{-1}. The ^{15}N-isotopic shift of the X–N–O bending vibration is 14—18 cm^{-1}, that of the X–N stretching one being 2.2—2.5 cm^{-1}.[10]

The position of the N–O stretching vibration, its ^{15}N-isotopic shift, and the far IR measurement suggest that the present compounds are formulated as NO^- complex.

IR bands due to the stretching vibration of Co–X (X=Cl, Br, and I) are usually observed in the region 170—350 cm^{-1}, and the bands due to the Co–O stretching vibration resulted from coordination of perchlorate, nitrate, and sulfate ions to the cobalt atom in the region 200—350 cm^{-1}.[11,12] Spectral figures in the region 200—350 cm^{-1} for the compounds were very similar to each other. This finding supports the contention that the anions are not in the coordination sphere, which is also suggested from the molar conductivity measurements.

It is well known that geometry of five-coordinate mononitrosyl complexes with a CoNO group, the formal oxidation state of which is II, is divided into two forms: a tetragonal pyramid with an apical NO^- and a trigonal bipyramid with an equatorial NO^+.[3] From the experimental results, the geometry of the cation of the present compounds is considered to be a tetragonal pyramid with an apical NO^-.

The compounds reported in this paper may be a precursor of the deep blue compounds isolated by Nast *et al.*[1] considering the synthetic conditions and the properties of the compounds.

The authous express their appreciation to Mr. Osamu Sakuma of Rikkyo University, for his technical assistance. The present work was supported in part by a Grant-in-Aid (No. 254208 in 1977) for Scientific Research from the Ministry of Education.

The Polymorphic Crystallization of Titanium(IV) Oxide under Hydrothermal Conditions. II.[1] The Roles of Inorganic Anions in the Nucleation of Rutile and Anatase from Acid Solutions

Fujio Izumi

National Institute for Research in Inorganic Materials, Sakura-mura, Niihari-gun, Ibaraki 300-31

(Received December 7, 1977)

Titanic acid was treated with hydrochloric, nitric, sulfuric, and hydrofluoric acids at 350 °C and 49 MPa to give titanium(IV) oxide. With increasing acid concentration, its polymorphic forms changed from anatase to rutile in hydrochloric and nitric acids, but from anatase to rutile, then back to anatase in sulfuric and hydrofluoric acids. Rutile and anatase crystals were grown from 1.7—9.5 mol dm^{-3} hydrofluoric acid at 360—560 °C by the temperature-drop method. Lower temperatures and higher concentrations of the acid favored anatase formation. The mechanisms for crystallization of the two forms are discussed by considering the chemical behavior of titanium(IV) complexes involved in their primary nucleation.

Titanium(IV) oxide occurs naturally in three minerals: rutile (tetragonal), brookite (orthorhombic), and anatase (tetragonal). Rutile and anatase can readily be prepared in a large variety of ways;[2] they are produced industrially for use as important white pigments. By contrast, brookite has rarely been synthesized by conventional methods.[3,4] On the basis of thermochemical data, Navrotsky and Kleppa[5] established that anatase is thermodynamically always unstable with respect to rutile. Anatase formation should, therefore, be regarded as metastable crystallization. Many reports have been published on the kinetics and mechanism of the irreversible anatase-rutile phase transition.[6]

There is some information in the literature regarding the crystallization and chemical reactivities of the two polymorphs under hydrothermal conditions. Osborn[7] was the first to find that, in pure water, anatase was converted into rutile above *ca.* 600 °C, which is a good deal lower than the temperatures of the anatase-rutile transformation in air. Hydrothermal treatment of hydrous titanium(IV) oxide (titanic acid) with pure water yielded rutile and/or anatase; lower temperatures, and to a lesser extent lower pressures, favored the unstable formation of anatase.[3,4,8,9] Single crystals of rutile have been grown from sulfuric acid[10] and from solutions of several fluorides.[11,12] The previous work in this series[1] has shown that anatase crystals can be successfully grown from potassium fluoride–dipotassium hydrogenphosphate solutions at less than 600 °C.

Few papers report the polymorphism of titanium(IV) oxide in acid solutions, apart from the formation of hydrated titanium(IV) oxide of poor crystallinity at temperatures below 100 °C and at atmospheric pressure.[2] The present investigation deals chiefly with the hydrothermal synthesis of rutile and anatase in four different mineral acids. Attention will be paid to the roles of dissolved anions in the nucleation of the oxide, as in the preceding paper.[1] Information of this type is indispensable for an understanding of the mechanisms by which rutile and anatase are crystallized under hydrothermal conditions.

Experimental

Materials. Titanium(IV) ethoxide obtained commercially was used without further purification. The single crystal of rutile-type titanium(IV) oxide produced by the Verneuil technique was a highly-purified product from Nakazumi Crystal, Ltd. Rutile powder of 99.99% purity was obtained from the Kojundo Kagaku Kenkyusho. All the other reagents used were of a GR grade.

Preparation of Amorphous Titanic Acid. Titanium(IV) ethoxide was poured into a large excess of pure water. The white precipitate which formed was washed several times with pure water by decantation, filtered off with suction, and then dried over phosphorus(V) oxide at ambient temperature under reduced pressure. Thermogravimetry showed that this sample contained *ca.* 23 wt% of water, which was released almost completely at 420 °C in static air.

Hydrothermal Treatment of Titanic Acid with Acid Solutions. Titanic acid (30 mg) and mineralizer solutions (0.1 cm^3) were sealed into welded gold capsules 4 mm in diameter and 30 mm in effective length. Four capsules were placed together in a cold-seal pressure vessel (Nikkiso NK-H25-III) with a capacity of 27 cm^3 and an i.d. of 12.7 mm. Most of the unoccupied space above the capsules was filled with a hastelloy rod to minimize the temperature differences both between the interior and exterior of the pressure vessel and between the capsule ends.[13] The vessel was then allowed to heat to 350 °C in a tubular furnace arranged vertically. The reaction temperature was measured with an external chromel-alumel thermocouple. The pressures generated within the capsules were balanced by water pumped into the pressure vessel and measured with a Bourdon gauge.

Recrystallization of Titanium(IV) Oxide in Fluoride Solutions by Means of a Double-capsule Technique. Small pieces (0.1—4 mm in size) of broken single crystals of rutile (Ru-I) and rutile powder (Ru-II) were used as starting materials. Either Ru-I (0.15 g) or Ru-II (0.1 g) was contained in a gold capsule 4 mm in diameter and 10 mm long, with a small hole. This nutrient capsule was fixed at one end of a larger gold capsule 5 mm in diameter and 60 mm in effective length. After 0.5 cm^3 of a mineralizer solution had been added, the larger capsule was sealed by crimping and welding the other end shut. This double capsule was placed in a conventional cold-seal pressure vessel (Nikkiso NK-H25-I: capacity, 5.5 cm^3; i.d., 6.4 mm), which was set horizontally in a tubular furnace. The temperature gradient between the capsule ends varied from 40 to 90 °C. The solid in the nutrient capsule was dissolved and then transported to the other end, where titanium(IV) oxide recrystallized spontaneously from supersaturated solutions.

The phases which formed were identified by X-ray powder diffraction using nickel-filtered Cu $K\alpha$ radiation. The relative amounts of rutile and anatase in their mixtures were

calculated from the X-ray intensities of the strongest reflections for rutile (d=0.3245 nm) and anatase (d=0.351 nm).[14] Acid solutions were standardized against a sodium hydroxide solution.

Chemical Analysis of Fluoride Ions Coprecipitated with Titanium(IV) Oxide. A sample ground into a powder was fused with about 2.5 g of potassium sodium carbonate in a platinum crucible at 900 °C. After the resulting cake had been transferred quantitatively to a distillation flask together with a small amount of water, 15 cm^3 of concentrated sulfuric acid was slowly added into the flask, which was cooled in an ice bath. The mixture was steam-distilled at 130—150 °C until *ca.* 80 cm^3 of distillate was collected. The total volume of the solution was then adjusted to 100 cm^3 with pure water. About 90% of fluorine could be recovered as hexafluorosilicic acid by following the above procedure. The fluoride ion concentration of the distillate was determined colorimetrically with Dotite Alfusone (lanthanum–alizarin complexone).[15]

Results

Titanic acid was treated isothermally with dilute acids of various concentrations as well as pure water for *ca.* 70 h at 350 °C and 49 MPa. Rutile and/or anatase were crystallized by the action of hydrochloric, nitric, sulfuric, and hydrofluoric acids on the amorphous reactant. Anatase was formed exclusively in pure water. These products were fully crystalline powders, white or yellow-tinged white except for those obtained by using 0.1—1.0 mol dm^{-3} hydrofluoric acid, in which bluish-gray powders formed. This exceptional coloration will later be discussed in some detail. An attempt to prepare titanium(IV) oxide in about 7.5 mol dm^{-3} phosphoric acid failed; only a highly insoluble, poorly crystallized phosphate of titanium(IV) was formed.

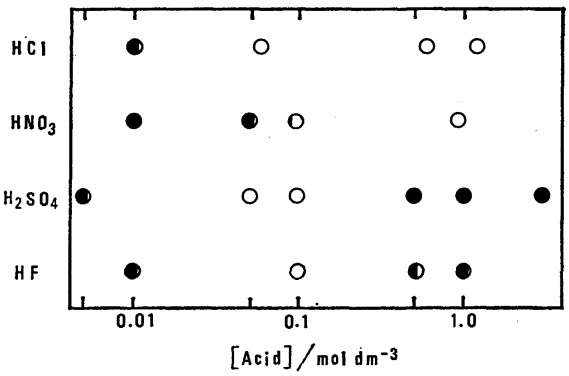

Fig. 1. Crystallization of rutile and anatase from titanic acid in four mineral acids at 350 °C and 49 MPa (t= 70 h). ○: Rutile, ●: anatase. Percentage of area of each circle shaded indicates percentage of anatase in the mixture.

Figure 1 shows the effects of the acid and its concentration on the relative amounts of rutile and anatase. With increasing acid concentration, the polymorphic forms of titanium(IV) oxide changed from anatase to rutile in hydrochloric acid and nitric acid, but from anatase to rutile, then to anatase again in sulfuric acid and hydrofluoric acid. The crystallization behavior of the oxide in the presence of hydrochloric acid is similar to that reported earlier by Matthews.[9] On the basis of experiments with only pure water, hydrochloric acid, and a sodium carbonate solution, he claimed that neutral, basic, and weakly acidic media were favorable for anatase formation, whereas more strongly acid environments resulted in the appearance of rutile. Judging from the conflicting results obtained by use of sulfuric acid and of hydrofluoric acid, his conclusion is highly questionable. The observations presented above support the idea that polymorphic crystallization of titanium(IV) oxide from aqueous solution is susceptible to the influence of not only the acid concentration but also the kind of acid.

Several representative specimens prepared hydrothermally were observed by scanning electron microscopy

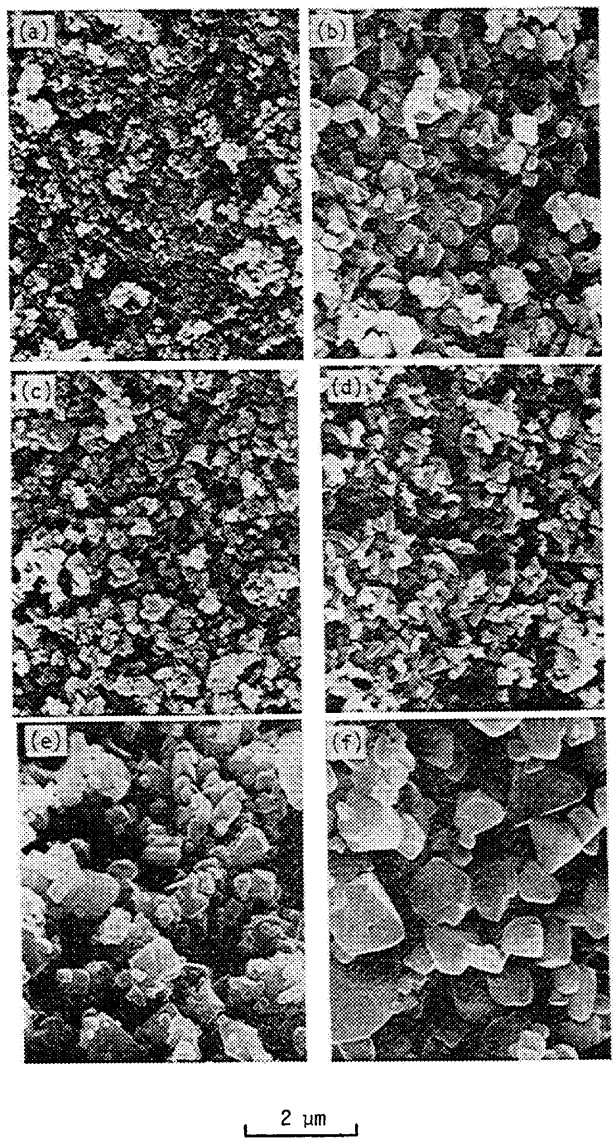

Fig. 2. Scanning electron micrographs of rutile and anatase prepared from titanic acid in dilute acids at 350 °C and 49 MPa.
(a) Anatase, pure water; (b) rutile, 0.058 mol dm^{-3} HCl; (c) rutile, 0.92 mol dm^{-3} HNO_3; (d) rutile, 0.049 mol dm^{-3} H_2SO_4; (e) anatase, 1.0 mol dm^{-3} H_2SO_4; (f) rutile, 0.10 mol dm^{-3} HF.

(Fig. 2). In pure water, anatase occurred as aggregates of reasonably equidimensional crystallites of the order of 0.1 μm in diameter [Fig. 2(a)]. The formation of the finely dispersed product is evidently due to the very low solubilities of titanic acid and the resulting anatase in pure water.

As pointed out by Matthews,[9] the anatase must be crystallized *via* the gradual structural rearrangement of the reactant with liberation of water. Dehydration probably precedes the structural rearrangement in the same way as in the crystallization of anatase by thermal dehydration of titanic acid in air. Titanic acid, which was amorphous to X rays, is assumed to have already a short-range order analogous in structure to anatase. Hence, anatase nucleation is readily induced in the reactive starting material and followed by a series of epitaxial growth processes. Practically the same reaction scheme as proposed above holds also for anatase formation in acids with concentrations lower than 50 mol m^{-3} (see Fig. 1).

By contrast, rutile and anatase grew into relatively large particles with characteristic crystal habits in acids of concentrations higher than 50 mol m^{-3} [Fig. 2 (b) to (f)]. The gross morphologies of their grains were quite different from those of the titanic acid grains from which they were obtained. Rutile crystallized in columns 0.07—0.2 μm in diameter from 49 mol m^{-3} sulfuric acid [Fig. 2(d)]. All the other products in acid solutions consisted of polygonal microcrystals with smooth faces. These observations are compatible with the dissolution and precipitation mechanism described below.

Amorphous titanic acid has much higher free energies of formation than has any polymorph of titanium(IV) oxide, with the result that mineralizer solutions equilibrated with titanic acid become supersaturated with respect to both rutile and anatase. Subsequently, rutile or anatase nucleates spontaneously and grows by transfer of material from titanic acid. Rutile growth at the expense of fully crystalline anatase seems to proceed to a very small extent, if at all, at a temperature as low as 350 °C.

Titanium(IV) oxide was more soluble in hydrofluoric acid than in any of the other mineral acids at relatively low temperatures, making it possible to grow crystals of rutile and anatase from the acid by the temperature-drop method.[16] It was transported from the cold to the hot zone (retrograde solubility) in 1.7—9.5 mol dm^{-3} hydrofluoric acid over the temperature range 320 to 600 °C under a constant pressure of 49 MPa. For this reason, its dissolution in hydrofluoric acid must be exothermic, at least under the above conditions.[17] Hydrofluoric acid enabled the oxide to be transported much more rapidly than did alkali fluoride solutions.[1,11,12] Unless otherwise stated, the reaction temperatures described below refer to those at the hot (crystallization) zone. Titanium(IV) compounds where fluorine is a dominant element were never formed, even in hydrofluoric acid at a concentration as high as 9.5 mol dm^{-3}, in disagreement with earlier work by Kuznetsov and Panteleev.[18]

Figure 3 gives the results of mole fraction of anatase in titanium(IV) oxide formed in the temperature range 360—560 °C *versus* concentration of hydrofluoric acid.

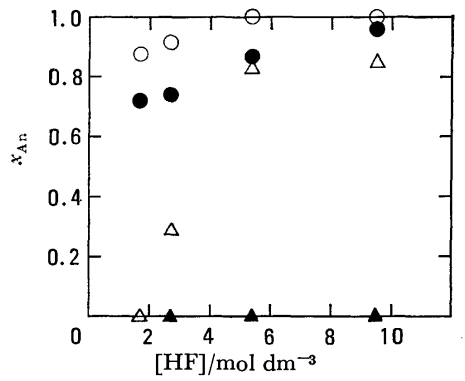

Fig. 3. Mole fraction of anatase in titanium(IV) oxide crystallized from hydrofluoric acid, x_{An}, *vs.* concentration of hydrofluoric acid. Nutrient, Ru-I; P=49 MPa; t=5—11 d. $x_{An}=w_{An}/(w_{Rn}+w_{An})$, where w_{Ru} and w_{An} are, respectively, the weights of rutile and anatase in the product. ○: 360 °C, ●: 400 °C, △: 480 °C, ▲: 560 °C.

As expected, higher concentrations of hydrofluoric acid and especially lower temperatures favored the precipitation of titanium(IV) oxide as anatase. Anatase was converted into rutile to a greater extent with rising reaction temperature; only rutile appeared at 560 °C or above. Anatase which was pure to X rays could be isolated at 360 °C from 5.4—9.5 mol dm^{-3} hydrofluoric acid.

Both rutile and anatase were obtained as almost opaque grains, blue or bluish black and less than 1 mm

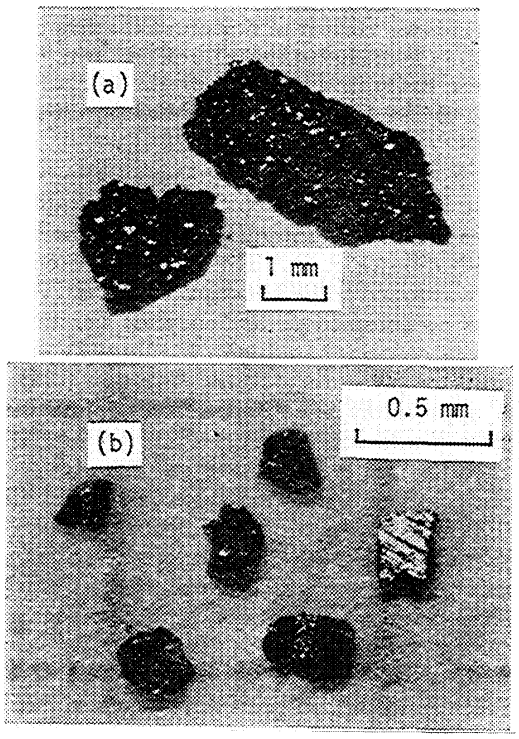

Fig. 4. Crystals of titanium(IV) oxide grown from hydrofluoric acid.
(a) Aggregates of rutile crystals. [HF]=1.7 mol dm^{-3}; θ=480 °C; t=258 h.

in size, or as their irregular aggregates (Fig. 4). Anatase was hardly distinguishable from rutile without the aid of X-ray analysis. Anatase grew at such high supersaturations that most crystals were anhedral and had rather rough surfaces. It was also found as subhedral plate crystals [Fig. 4(b)]. The Laue in conjunction with the oscillation methods showed these single-domain crystals to be tabular on {001}. The anatase which was prepared in 9.5 mol dm^{-3} hydrofluoric acid at 400 °C was submitted to high-temperature X-ray diffraction. When heated in air at a temperature-scan rate of 6.5 °C min^{-1}, it began to change into rutile at 970 °C and disappeared by 1210 °C.

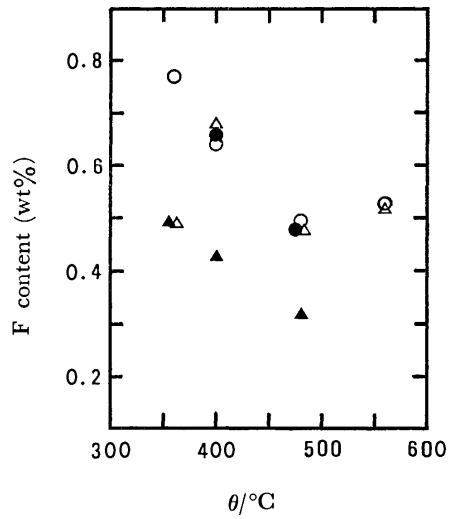

Fig. 5. Fluorine content of titanium(IV) oxide crystallized from hydrofluoric acid *vs.* reaction temperature. Nutrient, Ru-I; P=49 MPa; t=5—11 d. ○: 9.5 mol dm^{-3}, ●: 5.4 mol dm^{-3}, △: 2.7 mol dm^{-3}, ▲: 1.7 mol dm^{-3}.

Fluoride ions in parent solutions were readily taken up into the lattice of titanium(IV) oxide in the course of its crystallization (Fig. 5). The fluorine content of the products was found to lie between 3200 and 7700 ppm. There was no conspicuous tendency for the amount of fluoride ions coprecipitated with titanium(IV) oxide to vary with temperature. Rutile did not differ from anatase appreciably in the partition of fluoride ions between solid and aqueous phases.

Chamberland *et al.*[19,20] have successfully prepared the black compound titanium fluoride oxide, TiFO, in which titanium is formally in a valence state of +3. It is isostructural with rutile and characterized by its n-type semiconducting properties. Furthermore, they have established that, for the titanium fluoride oxides system, nonstoichiometry can easily be achieved to form a series of solid solutions with the general formula TiF_xO_{2-x} ($0<x<1$). As described previously, anatase and rutile were crystallized as bluish-gray powders only by the action of dilute hydrofluoric acid on titanic acid. The almost colorless, transparent crystals of rutile used as a starting material turned blue during hydrothermal reactions in hydrofluoric acid. These blue crystals of rutile contained about 330 ppm of fluorine and showed an ESR spectrum characteristic of the presence of titanium(III) ions at liquid helium temperature.

All these facts provide convincing evidence that titanium(IV) oxide prepared in hydrofluoric acid owes its intense color not to the nonstoichiometry, which is expressed as TiO_{2-x} ($x<8\times10^{-3}$),[11,21] but to point defects arising from the non-equilibrium incorporation of fluoride ions into the growing crystals of rutile and anatase. In fact, crystals of titanium(IV) oxide prepared in various solutions containing fluoride ions (see Table 1) became darker with increasing fluorine content. Fluoride ions presumably substitute oxide ions with similar size in a random way to form $[Ti(O,F)_6]$ octahedra; this substitution causes equal numbers of titanium(IV) ions to be replaced by titanium(III) ions to maintain electrical neutrality. Reduction of quadrivalent titanium to trivalent titanium in the absence of any powerful reducing agent is not surprising because reducing atmospheres usually predominate under hydrothermal conditions.

Discussion

The factors governing hydrothermal crystallization of rutile and anatase should be considered in the light of both the crystal structures of the two modifications and the chemical properties of titanium(IV) species in aqueous solution. Figure 6 illustrates the structures of rutile

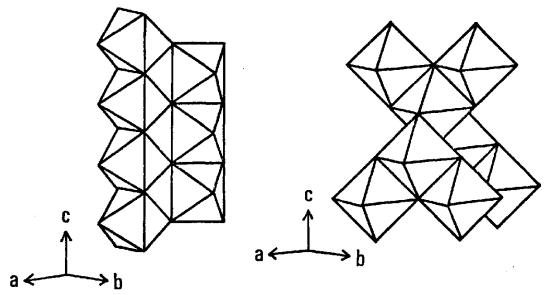

Fig. 6. Structures of rutile and anatase drawn as arrays of regular octahedra joined by common corners and edges.

and anatase. In both crystal lattices, every titanium(IV) ion is surrounded by six oxide ions arranged octahedrally (slightly distorted), and each oxide ion by three titanium(IV) ions. Rutile consists of $[TiO_6]$ octahedra linked by sharing two opposite edges to form chains parallel to the c-axis. In less dense anatase, each $[TiO_6]$ octahedron shares edges with four adjacent $[TiO_6]$ octahedra, which form spiral chains round each four-fold axis. It follows from the above structural consideration that the formation of linear polynuclear species containing bidentate oxo or hydroxo bridges between titanium(IV) ions will give rise to rutile nucleation, while nonlinear ones must pass into anatase nuclei.

We shall, for the moment, confine ourselves to speculating about the nucleation process in solutions containing fluoride ions. Table 1 summarizes the results of a series of experiments on crystallization of titanium(IV) oxide from fluoride solutions by the temperature-drop

method.[22] Strange to say, the polymorphic crystallization of the oxide from a 2 mol dm^{-3} solution of ammonium fluoride at 480 °C depended on the grain size of the original charge. A mixture of rutile and anatase separated out with Ru-I, whereas rutile alone was isolated by using Ru-II instead. The reasons for these reproducible phenomena have not been established. The crystallization behavior of titanium(IV) oxide in hydrofluoric acid was essentially uninfluenced by a change of the source material. Rutile was formed exclusively out of potassium fluoride solutions, regardless of the size of the starting rutile.[1]

The small, highly charged metals of Group IVA in the highest oxidation state of +4 are typical hard acids[23] and hence have strong affinities for hard bases such as fluoride,[24,25] sulfate (HSO_4^- and SO_4^{2-}),[26] and phosphate ($H_2PO_4^-$, HPO_4^{2-}, and PO_4^{3-}) ions. Since anatase was crystallizable from solutions containing fluoride ions with rutile as the nutrient in some instances, Ti–O–Ti and $Ti\langle^{O}_{O}\rangle Ti$ bonds in starting rutile are assumed to be thoroughly broken on dissolution in fluoride solutions. As a result, mononuclear titanium(IV) complexes are formed in which each titanium(IV) ion is octahedrally coordinated to hard bases including the fluoride ion, oxide ion, hydroxide ion, and water. The directions of transport of titanium(IV) oxide along temperature gradients show that it has negative partial molar enthalpies of solution in hydrofluoric acid and ammonium fluoride solutions, but positive ones in potassium fluoride solutions.[17] These experimental results indicate that the dissolved species in the above two types of fluoride solutions differ markedly from one another in composition and structure.

Mononuclear fluoro complexes of titanium(IV) are unstable toward hydrolysis at high supersaturations, where they are polymerized through fluctuation to afford polynuclear complexes (embryos) related structurally to either rutile or anatase. Further progress of polymerization leads to rutile or anatase nucleation, which is followed by the growth of the resulting crystal nuclei.

Phosphate ions dissolved in parent solutions were most effective in catalyzing anatase formation and/or retarding rutile formation (Runs No. 2 and No. 8).[1] On addition of an adequate amount of phosphate ions to fluoride solutions, titanium(IV) ions almost certainly form mixed-ligand complexes with fluoride and phosphate ions. In this case, phosphate ions bound coordinatively to titanium(IV) ions have a decisive influence on the selective nucleation of anatase. A crystalline phosphate of titanium(IV), together with anatase, precipitated from an ammonium fluoride–diammonium hydrogenphosphate solution (Run No. 2).[1] The concomitant formation of the phosphate undoubtedly reflects the strong complexation between titanium(IV) and phosphate ions. Duncan and Richards[27] have recently demonstrated that sulfate ions slow down the rate of hydrolysis of titanium(IV) ions by occupying a place in the first coordination sphere of each titanium(IV) ion.

Metal oxides in contact with air or water vapor are normally covered with a monomolecular hydroxide layer,[28,29] evidently because hydroxide ions can fit nearer to the centers of positive charge than half the quantity of oxide ions. Hydroxyl groups on the surface of titanium(IV) oxide are amphoteric; basic hydroxyl groups are readily exchangeable for foreign anions such as fluoride, sulfate, and phosphate ions in acidic or neutral media.[28,29] These facts suggest that the above anions are appreciably chemisorbed onto the surfaces of crystals (nuclei) of rutile and anatase under hydrothermal conditions as well.

The ease with which fluoride ions are incorporated into the lattice of titanium(IV) oxide is ascribable not only to the similarities in ionic radius and electronegativity between the fluoride and oxide ions, but also to the surface coverage by fluoride ions during crystal growth. As Table 1 and Fig. 5 show, the bulk uptakes of fluoride ions into titanium(IV) oxide crystallized from three different fluoride solutions (*ca.* 2 mol dm^{-3}) decreased in the order:

$$NH_4F > HF > KF$$

Anatase crystals grown from a potassium fluoride solution with addition of phosphate ions (Run No. 8) contained far fewer fluoride ions in solid solution than rutile crystals obtained in a potassium fluoride solution (Run No. 7). Very few phosphate ions were coprecipitated with anatase. These findings provide some indirect evidence for the adsorption (desorption) of phosphate ions on (from) the growing surface of anatase.

As the concentration of complexing anions is increased, their uptake at nucleus (crystal)/solution interfaces must also increase. When titanium(IV) oxide nucleates at high supersaturations through the hydrolytic polymerization of the dissolved species, anions initially bound to titanium(IV) ions are partly retained by the resulting polynuclear species on their surfaces and partly released into aqueous phases. Of course, the modes and extent of surface complexing by these ligands foreign to the titanium(IV) oxide lattice greatly affect the relative rates at which rutile and anatase nucleate, thus determining the structures of its crystal nuclei and macrocrystals.

In contrast with the three complexing anions already described, chloride and nitrate ions are known to be generally unattached to the surface of titanium(IV) oxide,[29] owing to their weak ability to complex the titanium(IV) ion. Those polymeric ions analogous in structure to rutile which contain as anions only oxide and hydroxide ions are formed selectively in hydrochloric and nitric acids.

The overall excess free energy, ΔG, between a crystal nucleus and the solute in solution is equal to the sum of the surface excess free energy, ΔG_s, and the volume excess free energy, ΔG_v:[30]

$$\Delta G = \Delta G_s + \Delta G_v$$

ΔG_s is the excess free energy between the surface of the nucleus and the bulk of the nucleus, and ΔG_v the excess free energy between a very large crystal and the solute in solution. Let us suppose that values of ΔG_s for anatase nuclei are smaller than those for rutile ones with comparable dimensions, as a result of the chemisorption of fluoride, sulfate, and phosphate ions. Then we find the possibility that the critical nucleus of anatase is more thermodynamically stable than that of rutile.[30,31] In other words, the relative stabilities for the two polymorphs of large particle size can be reversed in the nuclear state. The metastable formation of anatase in sulfuric and hydrofluoric acids with concentrations higher than 0.5 mol dm^{-3} (Fig. 1), as well as in fluoride solutions containing phosphate ions (Table 1), may be attributed to the pronounced stabilization of anatase nuclei by adsorption of sulfate, fluoride, or phosphate ions.

The details of the mechanisms whereby rutile and anatase are crystallized remain unknown, since we are technically incapable of observing the hydrothermal crystallization process *in situ*.

The author is much indebted to Michiko Kobayashi and Yoshiyuki Yajima for their experimental assistance in the chemical analyses and to Masayuki Tsutsumi for his cooperation in the scanning electron microscopy The author also benefited from stimulating discussions with the members of Seventh Research Group of this institute.

Nuclear Magnetic Resonance Study of Exchanging Systems. XI.[1] ^{13}C NMR Spectra of 9-Ethyltriptycene Derivatives and the Restricted Rotation of the Ethyl Group

Hiroshi NAKANISHI and Osamu YAMAMOTO

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received August 16, 1977)

9-Ethyl-1,4-dimethoxytriptycene, 1,5-dichloro-9-ethyltriptycene, and 9-ethyl-1,4-dimethyltriptycene were prepared. The ^{13}C NMR spectra of these compounds were measured at low temperatures in order to obtain information about the restricted rotation of the ethyl group. It was found that the former two compounds have the *meso* isomer as well as the *dl* isomer. Different chemical shifts of the methylene carbons in the ethyl group, C(2) and C(3) of the benzene A ring, and some quaternary carbons in the two isomers of 9-ethyl-1,4-dimethoxytriptycene indicate that the 120° rotation around C_{sp_3}–C_{sp_2} single bond in the ethyl group deforms the benzene or bicyclo-[2.2.2]octatriene skeleton. The complete line-shape analyses of the temperature-dependent ^{13}C NMR spectra of this compound were performed, and the thermodynamic static parameters and activation parameters of the ethyl rotation were determined. The correlation between the rotational barriers of the alkyl groups and their bulkiness was briefly discussed.

One of the most interesting recent topics in internal rotation studies using dynamic NMR spectroscopic methods is the restricted rotation around C_{sp_2}–C_{sp_2} single bond in sterically overcrowded molecules.[2–5] A number of the rotations of sterically larger groups, for example, *t*-butyl, isopropyl, and ortho-substituted aryl groups, have been investigated, becuase the rotational barriers of these groups are quite high as a result of the severe steric repulsion. Recently, even the rotation of a methyl group, the smallest alkyl group, was found to be strongly restricted on the NMR time scale in several compounds.[6–11] The restricted rotation around the C_{sp^3}–C_{sp^3} single bond in 9-alkyltriptycene derivatives has intensively studied by Ōki[5] and his co-workers, while the rotations of the methyl (**1**)[8,9] benzyl,[12,13] isopropyl (**2**),[14] *t*-butyl (**3**),[10] 1,1-dimethyl-2-phenylethyl,[15] aryl,[16,17] and chloromethyl[18] groups were investigated by the ^1H NMR spectroscopic methods. From these studies, it has been made clear that the rotational barriers of 9-alkyl or aryl groups in triptycene derivatives are strongly influenced by the bulkiness of these groups as well as by the substituents at the peri positions of the benzene rings. However, the rotation of an ethyl group in triptycene derivatives has not yet been studied, and it is important to study systematically how the barriers of the rotations of the alkyl groups at the 9-position in the triptycene derivatives (**1**—**6**) change when the bulkiness of the alkyl group changes in such an order as; methyl, ethyl, isopropyl, and *t*-butyl groups,.

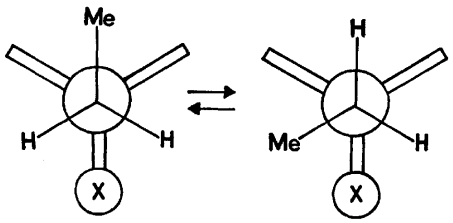
6: R=Et, X=Z=Me, Y=V=W=H

When the three groups or atoms bonded to α-carbon in the 9-substituent alkyl group are not all the same, there is a possibility for two rotational isomers (*i.e.*, *dl* and *meso* forms) to exist (see the Newman projection). In the case of 9-isopropyltriptycene derivatives, however, it was reported in an ^1H NMR spectral study[14] that only the *dl* isomer exists. This may be ascribed to a great destabilization in the *meso* isomer by the severe steric repulsion between the peri-substituent and the two methyl groups. Therefore, from the point of view of the steric repulsion, there may be a possibility for the meso isomer as well as the *dl* one to exist in 9-ethyltriptycene derivatives, for the repulsion in question in the ethyl compound is considered to be much smaller than in the isopropyl analogue. Thus, if this is so, the rotation of the 9-ethyl group in the triptycene derivatives is an isomerization process between the *dl* and *meso* isomers. Therefore, it will be interesting to study the stability of these isomers.

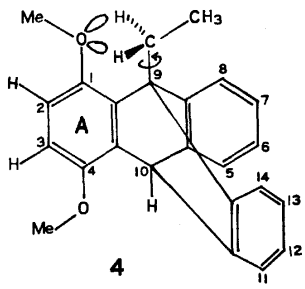


meso *dl*

It is well known that ^{13}C NMR chemical shifts are strongly influenced by the steric compression effect as well as by the electronic effects in sterically overcrowded molecules. Recently an interesting tendency in the ^{13}C NMR chemical shift was found in dibenzobicyclo[2.2.2]-octatriene derivatives.[19] Therefore, it may be worthwhile to study also the correlation between the ^{13}C chemical shifts and the steric repulsion in the sterically overcrowded 9-ethyltriptycene derivatives.

In this work, we chose to study 9-ethyl-1,4-dimethoxytriptycene (**4**), 1,5-dichloro-9-ethyltriptycene (**5**), and 9-ethyl-1,4-dimethyltriptycene (**6**), for the rotation of the ethyl group in these compounds was expected to be strongly restricted on the NMR time scale because of

the strong repulsion between the ethyl group and the peri-substitutents on the rigid triptycene skeleton. Moreover, since the rotational barriers of the methyl,[8,9] isopropyl,[14] and *t*-butyl[10] groups in triptycene derivatives with the same substituents (described above) have already been studied, it is convenient to know the barriers of the ethyl groups in **4**—**6** in order to discuss the correlation of the barriers with the bulkiness of the alkyl groups and the peri-substituents.



4

Experimental

Materials. **4** was prepared by means of a benzyne reaction between ethylanthracene[20] and 1,4-dimethoxybenzyne, which had been prepared from phenylsodium and 1-chloro-2,5-dimethoxybenzene under nitrogen according to a method similar to that in literature.[9] The purification was made three times by Al_2O_3 chromatography. Mp 179—181 °C, MS, Found: *m/e* 342.162. Calcd for $C_{24}H_{22}O_2$: M+, 342.162.

1,5-Dichloro-9-ethylanthracene (7). A solution of 28.0 g of 1,5-dichloroanthraquinone, 7.0 g of red phosphor, 57 ml of 57% aqueous hydroiodic acid, and 800 ml of acetic acid were heated and stirred at *ca.* 140 °C for 7 h. After cooling, the precipitant was filtered and dissolved in chloroform. After the chloroform solution had then been filtered again to exclude the red phosphor, the solution was dried with anhydrous potassium carbonate. Then, 18.3 g of 1,5-dichloroanthrone (**8**) was obtained by evaporating the solvent. 1,5-Dichloro-9-ethyl-9-hydroxy-10-dihydroanthracene (**9**) was prepared by the Grignard reaction of **8** and ethyl magnesium bromide in dry benzene. The yield was 65%. **7** was prepared by dehydration reaction of 15 g of **9** and 200 g of diphosphorus pentaoxide in 400 ml of benzene at room temperature for 10 h. The solution was decanted, washed with aqueous sodium hydrogencarbonate, and dried over potassium chloride. After the evaporation of the solvent, the residue was recrystallized three times from chloroform and methanol (1: 1) mixed solvent. The yield was 23%. Mp 100—102 °C.

1,5-Dichloro-9-ethyltriptycene (5). Into a refluxing solution of 1.3 g of butyl nitrite and 3.5 g of **7** in 150 ml of dry dichloromethane was added a solution of 1.8 g of anthranilic acid in 150 ml of dry ether over a period of 40 min with stirring. The solution was then refluxed for half an hour, washed with aqueous potassium carbonate, and dried over potassium chloride. The purification was made by Al_2O_3 chromatography and by three recrystallizations from a chloroform and methanol (1: 1) mixed solvent. The yield was *ca.* 30%. Mp 208—210 °C, MS, Found: *m/e* 350.072. Calcd for $C_{22}H_{16}Cl_2$: M+, 350.063.

9-Ethyl-1,4-dimethylanthracene (10). **10** was prepared from 1,4-dimethyl-anthraquinone of a commercial origin by a similar method. The yield was *ca.* 14% from the anthraquinone. Mp 63—64 °C.

9-Ethyl-1,4-dimethyltriptycene (6). **6** was prepared from **10** and anthranilic acid by a similar method. The purification was made by SiO_2 chromatography. The yield was *ca.* 20%. Mp 219—221 °C, MS, Found: *m/e* 310.176. Calcd for $C_{24}H_{22}$: M+, 310.172.

The purity of these compounds was checked by means of the ^{13}C-NMR spectra.

NMR Spectral Measurements. The ^{13}C-NMR spectra of these compounds were recorded by the pulsed FT method on NEVA NV-14 (15.087 MHz) and Varian XL-100-15 (25.162 MHz) spectrometers with Varian 620/L computers. The sample concentrations and solvents were as follows: 13 wt% in $CDCl_3+CS_2+CD_3COCD_3$ (5: 5:1) for **4**, 10 wt% in $CDCl_3+CS_2$ (1: 2) for **5**, and 21 wt% in $CDCl_3+CS_2$ (1: 2) for **6**. The temperature was read by means of a calibrated copper-constantan thermocouple.

Molecular-weight Determinations. High-resolution molecular-weight determinations were carried out on a CEC high-resolution mass spectrometer, Model 21-110 B, with a direct-inlet system and an ionization potential of 70 eV.

Spectral Calculations. The calculations of the theoretical spectra in the complete line-shape analyses were made using program EXNMR **1*** on a FACOM 270/30 computer.

Results and Discussion

The Temperature-dependence of the ^{13}C NMR Spectra and the Rotational Isomers of the Ethyl Groups in 4—6. The total spectrum of **4** at ambient temperature is shown in Fig. 1 (a). The spectrum shows that the signals of methyl and methylene carbons of the ethyl group are singlets and that the line broadening occurs in two signals at this temperature. An ^1H undecoupled ^{13}C spectrum

* A modified version of EXNMR 0.[21]

of **4** shows that the higher-field peak of the ethyl group can be assigned to the methyl carbon, as expected. The degree of the line broadening in the methyl signal is larger than that in the methylene signal. The line broadening indicates that the rotation of the ethyl group is quite rapid at room temperature. This is reasonable,

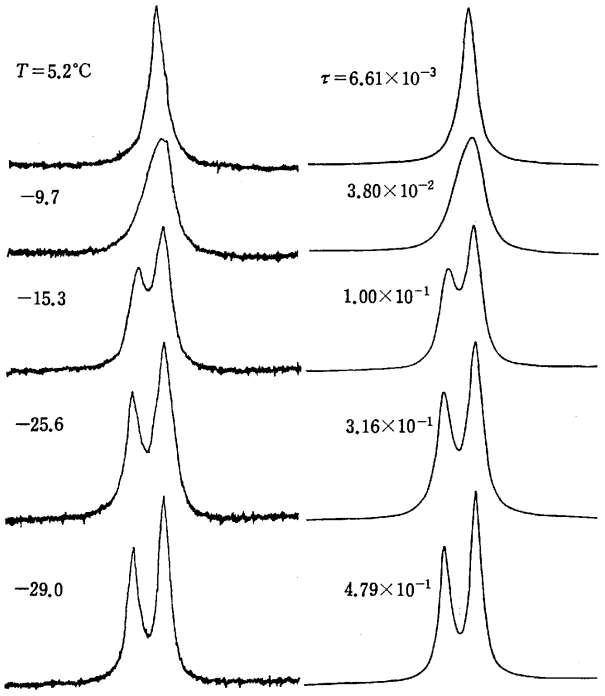

Fig. 2. The observed (left) and calculated (right) ^{13}C spectra of the methyl carbons of the ethyl groups in the *meso* and *dl* isomers of **4** at several temperatures. τ is a mean life time.

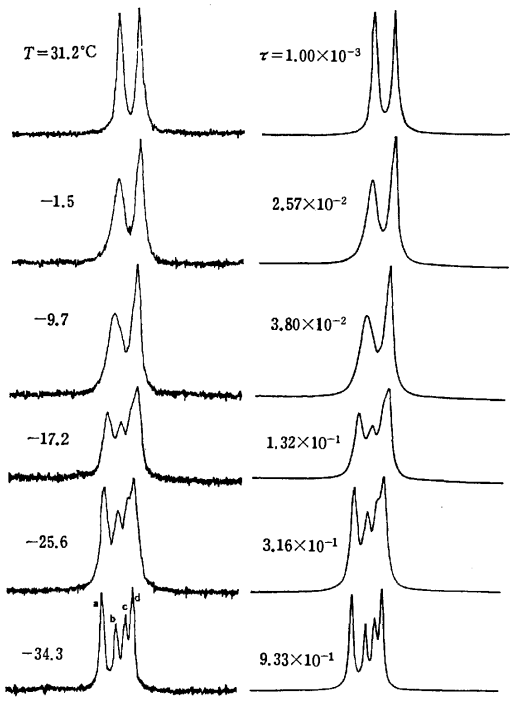

Fig. 3. The observed (left) and calculated (right) ^{13}C spectra of the aromatic CH carbons at 2 and 3 positions of **4** at several temperatures.

for it has been reported that , at room temperature, the rotation of the isopropyl group in 9-isopropyltriptycene derivatives is frozen,[14] while that of the methyl group in the methyl analogues is extremely rapid.[9] Then, in order to freeze the rotation, the ^{13}C spectra of **4** were measured at low temperatures (see Figs. 2 and 3). At −29.0 °C, the methyl signal of the ethyl group consists of two sharp peaks. This means a sufficiently slow rotation at this temperature. The intensity of the higher-field peak is stronger than that of the lower one: the intensity ratio of the former to the latter is 59/41 at −29.0 °C. Taking the steric repulsion between the ethyl and methoxyl groups into account (see the Newman projection), the *meso* isomer can be expected to be more stable than the *dl* isomer. Therefore, the strong peak at the higher filed is assigned to the *meso* isomer, and the weak peak at the lower field to the *dl* isomer.

The signal of the methylene carbon also shows line broadening when the temperature is lowered. At −28.1 °C, the signal consists of two sharp peaks. The intensity of the higher-field peak is stronger than that of the lower-field one, so the former peak is assigned to the *meso* isomer.

The signals of the methoxy carbons do not show any line broadening at low temperatures.

The signals of the aromatic CH carbons in **4** show unexpectedly simple spectral patterns (the higher- and lower-field parts) at ambient temperature (see Fig. 1 (a)). In the higher-field part, the two peaks at 109.6 and 110.5 ppm from TMS are assigned to C(2) and C(3) with reference to the CH signal of *p*-dimethoxybenzene (δ: 114.8). In the lower-field part, the signals of eight other CH carbons [C(5)–C(8), and C(11)–C(14)] apparently show a simple line shape (three peaks), as is shown in Fig. 1 (a), probably because of the signal overlapping and the signal averaging by a rapid rotation of the ethyl group at room temperature. As the temperature is lowered, the signals of these carbons become broader, until finally they consist of many sharp peaks at such conformationally frozen temperatures as −28.1 °C. This line-shape behavior is reasonable, because C(8) and C(14) are near the rotating ethyl group and the chemical shifts of these carbons in the *dl* isomer can be different from those in the *meso* isomer.

Surprisingly, it was found that the peaks of aromatic C(2) and C(3) also show line broadening at low temperatures, and the separate sharp peaks of the two isomers appear at −34.3 °C, as is shown in Fig. 3. The two stronger peaks are assigned to the *meso* isomer, and the intensity ratio of the *meso* isomer to the *dl* isomer is 60/40, which is the same as in the analysis of the methyl carbon signals.

The ^{13}C spectrum of **5** at room temperature is shown in Fig. 1 (b). The signals of the methyl and methylene carbons are singlets. Although the signal of the methylene carbon is a sharp singlet, the line-width of the methyl carbon signal is considerably large. The line broadening in the methyl signal is explained by the existence of both *meso* and *dl* isomers and the signal coalescence due to the rapid exchange between the two isomers. When the temperature is lowered, however, it was found that the methyl signal shows the following curious tempera-

ture-dependent behavior: as the temperature is lowered, the signal first shows little line broadening up to *ca.* −30 °C, but when the temperature is more deeply decreased, it becomes sharper instead of being separated into two peaks, until finally its peak height is almost the same as that of the bridge-head methine carbon at −62.5 °C. This interesting phenomenon can be accounted for as follows. When the temperature is lowered from 31.0 °C to *ca.* −30 °C, two contradictory phenomena, *i.e.*, the increased line broadening due to the slower exchange rate with the temperature decrease, and the decreased line broadening due to the smaller population of the less stabilized isomer (*dl* isomer) at the lower temperature, occur, causing the degree of the line broadening in the methyl signal to be almost unchanged. Then, at the lower temperatures, the population of the *dl* isomer becomes so small that the former effect becomes negligibly small, until at last the line broadening cannot be observed. These discussions lead to the conclusion that the population of the less stabilized *dl* isomer in **5** is much smaller than in **4**. This may be reasonable, because the steric repulsion between the ethyl group and the peri-substituted chlorine atom in **5** is larger than that between the ethyl group and the methoxy oxygen atom in **4**.

In extending the discussion, it may be expected that **6** with a methyl group at a peri position, has more of the *dl* isomer than **4** and **5**, because the bulkiness of a methyl group is smaller than those of the methoxyl group and the chlorine atom, so the steric repulsion in question in **6** is smaller than those in **4** and **5**. Contrary to expectations, the signals of the methyl and methylene carbons in the ethyl group of **6** show little line broadening in the temperature range from 31.0 °C to *ca.* −50 °C. This quite unexpected result may be explained by the absence for the *dl* isomer. However, there remains a possibility that the two rotational isomers do exist, but the chemical shift differences between the two isomers of the methyl and methylene carbons in the ethyl group are so small and/or the rotational barrier is so small that the line broadening does not occur at these temperatures. At present, we cannot conclude which is true in **6**. If the former case is true, we should consider, in addition to the steric factors, some unknown interaction in **4** which may stabilize the *dl* isomer for example, an interaction between the methylene group and the methoxy oxygen atom ($CH_2\cdots O$).

In this work, it has been made clear that the two rotational isomers around the C_{sp_3}–C_{sp_3} single bond at the 9-position of triptycene exist in **4** and **5**. The results make a clear constanst to the fact that, in 9-isopropyltriptycene derivatives (**2**), only the *dl* isomer exists; the *dl* isomer is the more stable isomer in this case.[14] This interesting contrast may be caused by the great unstability of the *meso* isomer in **2** due to the severe steric repulsion between the two methyl groups and the peri-substituent (see the Newman projections **11** and **12**).

a) Two other shoulder peaks are present in this region.

The ^{13}C NMR Chemical Shifts and the Conformations of the Two Isomers in 4. The ^{13}C chemical shifts of **4**—**6** are listed in Table 1. As has been described previously, the higher-field peak of the methyl carbon in the ethyl group of **4** is assigned to the *meso* isomer on the basis of the peak intensities and the degree of the unstability caused by the steric repulsion. The validity of the assignment is strongly suppoted by the steric compression shift. Since the steric repulsion between the methyl and methoxyl groups in the *dl* isomer is larger than in the *meso* isomer as has been described above, the signal of the methyl carbon in the *dl* isomer should be at a lower field than that in the *meso* isomer because of the large lower-field shift due to the steric compression.[22]

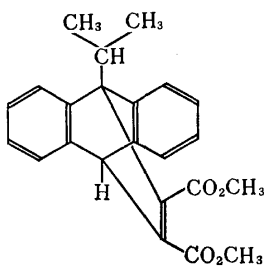
The fact that there is a difference between the chemical shifts of the methylene carbons in the two isomers of **4** is quite unexpected if we consider only the simple Newman projection model described above, for it is assumed in the model that all of the distances between the methylene carbon and the other atoms or groups are equal in the two isomers. It has been considered thus far that such carbons as the methylene carbons in **4**, which are positioned on the rotational axis, are all

equivalent. This remarkable fact may be explained, however, by different geometries of the methylene groups in the two isomers in the severely compressed environment around the ethyl group in **4**, or by an unknown interaction between the methylene group and the oxygen lone pair, an interaction which may be caused by the extreme proximity of the two groups. Previously, in dimethyl 9-isopropyl-9,10-ethenoanthracene-11,12-dicarboxylate (**13**), we found a similar interesting unequality in chemical shifts between the signals of the methine carbons in the isopropyl groups in the *dl* and *meso* isomers, which are both positioned on the rotational axis.

It is very interesting to find the unequality between the chemical shifts of C(2) and C(3) in the *dl* isomer and those in the *meso* isomer. Since the distances between these two carbons and the rotating ethyl group are very great, the steric and anisotropic effects on the chemical shifts of these carbons can be considered to be negligibly small. Therefore, the fact indicates that the electronic states of these carbons of the *dl* isomer are different from those of the *meso* isomer.

The determination of the pairs of the C(2) and C(3) in the two isomers was made by a careful investigation of the temperature-dependent line shape in the computer simulation analyses (Peaks a—b and c—d; see Fig. 3), although it could not be determined which signal in C(2) and C(3) is at the higher field. The chemical shift differences ($\Delta\delta$=4.9 and 10.7 Hz) are almost comparable to those of the methylene and methyl signals ($\Delta\delta$=8.3 and 12.5 Hz respectively). The large differences between the chemical shifts in the two isomers may be caused by the following two possibilities. The steric repulsion between the ethyl and methoxyl groups in the *dl* isomer is so severe that the angle between the C–OCH_3 bond and the 1,4-dimethoxy substituted benzene ring (A ring) is a little deformed. In the *meso* isomer, the steric repulsion is not so severe, and so the deformation is considered to be negligibly small (see the Newman projection). The deformation influences the conformation of the A ring and so has an effect on the electronic state of the ring. This causes the chemical shifts of C(2) and C(3) in the *dl* isomer to be different from those in the *meso* isomer. The second possibility is the deformation of the bicyclo[2.2.2]octatriene skeleton by the strong repulsion in the *dl* isomer, such as was found in **13**. If this happens, the signals of C(9), C(10), and other quaternary carbons would be different from each other in the two isomers.

The signal of the quaternary carbon C(9) is masked by the strong methoxy carbon signals at room temperature, but it appears as a separate peak at −25.6 °C (δ: 56.6), because the peaks of the methoxy carbon signals shift to a little higher field as the temperature is lowered. However, it cannot be immediately concluded that C(9) gives only one peak, for there remains a possibility that the other peak is masked by the methoxy carbon signals if the chemical shifts of the two isomers are different from each other.



13

The signal of C(10) methine carbon does not show line-broadening at low temperatures. However, this does not directly mean that there is the same conformation in the two isomers, because even if they are different, the chemical shift difference between the C(10) signals in the two isomers is not always large because of the long distance between C(10) and the ethyl group. It is worthwhile to point out that the signal of C(10) in **4** (δ: 47.3) is at a much higher field than those in **5** and **6** (δ: 51.4 and 51.0 respectively). It may be that the anomalous high-field shift of the C(10) signal in **4** indicates a conformation of the bicyclo[2.2.2]octatriene skeleton in **4** different from those in **5** and **6**.

The signals in the lowest field region (145—150 ppm from TMS) consist of three peaks at room temperature (see Fig. 1(a)). When the temperature is lowered, line broadening occurs in these peaks. At −34.3 °C, the signals consist of six peaks. The temperature-dependent signals should be assigned to quaternary carbons at the ring junction or to C(1) and C(4) carbons, judging from their long relaxation times (T_1) and the comparison with the chemical shifts of **5**—**6**, *p*-dimethoxybenzene, and 9-methyltriptycene. Unfortunately, however, more exact assignments cannot be made because of the closeness of their signals. At any rate, it is certain from the line-shape changes that the signals of some quaternary carbons are different between the two isomers.

Therefore, from the results and the discussion presented above, we cannot determine which possibility (*i.e.*, the deformation of the A ring or that of bicyclo[2.2.2]octatriene skeleton) is true here. In any case, it is a very important fact, from the point of view of structural chemistry, that a simple 120° rotation of the small ethyl group around the C_{sp_3}–C_{sp_2} single bond of the 9-position in **4** deforms the benzene ring or bicyclo[2.2.2]octatriene skeleton, both which are known to have very solid structures.

The Static and Dynamic Parameters of the Rotation of the Ethyl Group in 4. The populations of the two isomers in **4** were determined using a computer simulation in the trial-and-error method in the conformationally frozen temperature range, independently in the two regions of the methyl signals in the ethyl group and of C(2) and C(3) signals. The values obtained in the two regions were in good agreement with each other at all temperatures. The static thermodynamic parameters ($\Delta G°$, $\Delta H°$, and $\Delta S°$) of the isomerization between

the *meso* and *dl* isomers in **4** were determined from the Arrhenius plot of the populations of the two isomers. The result are shown in Table 2.

In order to obtain the activation parameters of the ethyl rotation in **4**, the computer similation of the temperature-dependent spectra was performed using the modified Bloch equation method, which has been described before.[21]

The complete line-shape analyses were carried out for the methyl and C(2) and C(3) signals independently, changing the rotational rate k and the population ratio between the two isomers at each temperature. Several calculated spectra thus obtained are shown in Figs. 2 and 3. The rotational rate obtained in the two regions were in excellent agreement with each other at all temperatures, within the experimental errors. The activation parameters were determined from the Arrhenius plots of k's and Eyrings's equations. The results are given in Table 3. In Table 3, the activation parameters of the R–C(9) rotations in 1,4-dimethoxy-9-methyltriptycene (**1a**),[9] 1,4-dimethoxy-9-isopropyltriptycene (**2a**),[14] and 1,4-dimethoxy-9-*t*-butyltriptycene (**3a**) are also listed in order to facilitate a comparison of rotational barriers.

The two activation energies E_a (Et1) and E_a (Et2) of **4**, which correspond to the two rotations from the conformation at the ground state to that at the transition state for the *meso* and *dl* isomers respectively, are larger than that of the methyl analogue (**1a**) and much smaller than that of the isopropyl one (**2a**). These data are reasonable considering the bulkiness of the alkyl group at the 9-position of the triptycene derivatives. It can be considered that the conformations of these compounds are *gauche* form at the ground states and *eclipsed* form at the transition states, as is shown in the Newman projections of Fig. 4. If we simply assume that the energies concerning the rotational barriers of the alkyl groups are mainly influenced by the steric repulsions between the three peri-substituents of the benzene rings and the methyl groups and/or hydrogen atoms in the 9-alkyl groups, and that the deformation of the geometries of the 9-alkyl groups in question is neglibibly small, and finally, that in the estimation of the steric repulsion energies between these groups and atoms in the ground and transition states, an additive nature is effective in **1a**, **2a**, and **4**, simple calculations of the activation energies in these compounds can be made. These calculation shows that the activation energy differences

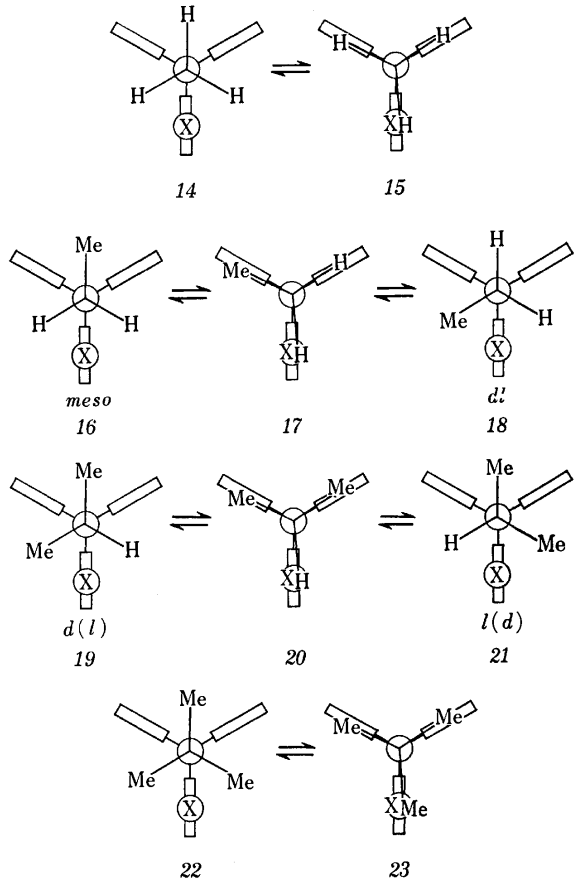

Fig. 4. The Newman projections of the conformations at the ground and transition states of the rotations of the 9-alkyl groups in 1,4-dimethyltriptycene derivatives (**1a**, **2a**, **3a**, and **4**). (X=OMe).

$\Delta E_a(1)$ and $\Delta E_a(2)$ [$\Delta E_a(1)=E_a(\text{Et1})-E_a(\text{Me})$, $\Delta E_a(2)=E_a(\text{Et2})-E_a(\text{Me})$] must be equal to $\Delta E_a(4)$, and $\Delta E_a(3)$ [$\Delta E_a(4)=E_a(^i\text{Pr})-E_a(\text{Et2})$, $\Delta E_a(3)=E_a(^i\text{Pr})-E_a(\text{Et1})$] respectively. In real, however, $\Delta E_a(3)$ and $\Delta E_a(4)$ (10.5 and 11.8 kcal/mol respectively) are much larger than $\Delta E_a(1)$ and $\Delta E_a(2)$ (7.1 and 5.8 kcal/mol respectively). This means that the steric repulsion energy between the two methyl groups in the isopropyl group and the benzene rings at the transition state of **2a** (*cf.* **20**) is not equal, but is much larger than twice the steric repulsion energy of one methyl group and the benzene ring in **4** (*cf.* **17**). The

results indicate much increased steric overcrowding of the isopropyl group against the three peri-substituents in **2a** in comparison with that in **4**. In this connection, it is reasonable that the rotational barrier of the *t*-butyl analogue (**3a**) is much larger than that in **2a**, for, at the transition state of **3a** (**23**), one methyl group must have an *eclipsed* conformation against the largest peri-subsituted methoxy oxygen atom, and the other two methyl groups, against the peri-hydrogen atoms, thus, the repulsion energy becomes extremely high, although, at the ground state, the steric repulsion in the *gauche* form (**22**) is considerably larger than that in **2a** (**19**).

The simple calculations beased on the above assumptions are not valid in the estimation of the steric repulsion energies of severely overcrowded molecules. In a sense, this is an expected result. It is very difficult to estimate quantitatively the correlation between the steric bulkiness of the alkyl groups and the rotational barriers of the alkyl groups in these overcrowded molecules.

The authors wish to express their hearty thanks to Professor Michinori Ōki and Dr. Fumio Suzuki of the University of Tokyo for their helpful discussions, and Mr. Nobuhide Wasada of our Laboratory for his kind measurements of the mass spectra of the compounds studied.

**Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo 112*

(Received August 16, 1977)

Six analogous new flavones with a skeleton similar to arthraxin, which is a light-stable, natural, new flavone, have been synthesized by the use of a modification of Allan-Robinson's flavone synthesis. The structures of these compounds were elucidated by means of the Gibbs reaction, NMR, and mass spectrometry. The light resistance of these flavones was then examined by means of UV spectrometry. The results indicate that these flavones, with a 4*H*,10*H*-benzo[1,2-*b*: 3,4-*b*'] dipyran-4,10-dione skeleton, in contrast with natural common flavonol and arthraxin, show a high resistance to light.

In a previous paper,[1] we reported the isolation and structure of a new flavone arthraxin (**1**) from the grass *Arthraxon hispidus*, which had been used as a source of natural dyestuff for the light-stable, yellow coloring "Kihachijo," produced on Hachijo Island, Japan. In our succesive studies,[2,3] arthraxin, in contrast with flavonol, was found to show a high resistance to light. This result suggests that the flavones which have a skeleton similar to arthraxin's 4*H*,10*H*-benzo[1,2-*b*: 3,4-*b*']dipyran-4,10-dione skeleton will be stable to light. To make clear this problem, we have synthesized a series of new flavones with skeletons similar to arthraxin and have examined the light resistance of these compounds by UV spectrometry.

Synthesis of Six Analogous New Flavones with a 4H,10H-Benzo[1,2-b: 3,4-b']dipyran-4,10-dione Skeleton. These compounds, **6**, **7**, **8**, **9**, **10**, and **11**, have been synthesized according to the annexed scheme.

2,4-Diacetylphloroglucinol (**2**) was prepared by saturating a glacial acetic acid solution of phloroglucinol with boron trifluoride gas.[4] The condensation of **2** with potassium benzoate and benzoic anhydride yielded 8-acetyl-5,7-dihydroxyflavone (**3**). By using

4b $R_1=H$, $R_2=OCH_3$
5b $R_1=R_2=OCH_3$

potassium *p*-anisate and *p*-anisic anhydride or potassium veratrate and veratric anhydride instead, 8-acetyl-5,7-dihydroxy-4'-methoxyflavone (**4**) or 8-acetyl-5,7-dihydroxy-3',4'-dimethoxyflavone (**5**) was obtained respectively. The alternative structures, 6-acetyl-5,7-dihydroxyflavone (**3b**), 6-acetyl-5,7-dihydroxy-4'-methoxyflavone (**4b**), and 6-acetyl-5,7-dihydroxy-3',4'-dimethoxyflavone (**5b**), were rejected after a study of the NMR spectra of Compounds **3**, **4**, and **5** indicated the presence of the C-6 proton and because the negative Gibbs reaction[5] indicated the presence of C substitution in the C-8 position. The signals at 6.40, 6.41, and 6.43 ppm of **3**, **4**, and **5** can be assigned to the C-6 proton in the A-ring, because the C-6 and C-8 protons of the 5,7-disubstituted flavones appear in the regions of 6.25—6.5 ppm for the C-6 proton and 6.5—6.9 ppm for the C-8 proton.[6,7] The Gibbs reaction with *N*-chloro-2,6-dichloro-*p*-benzoquinone 4-imine has been used for the

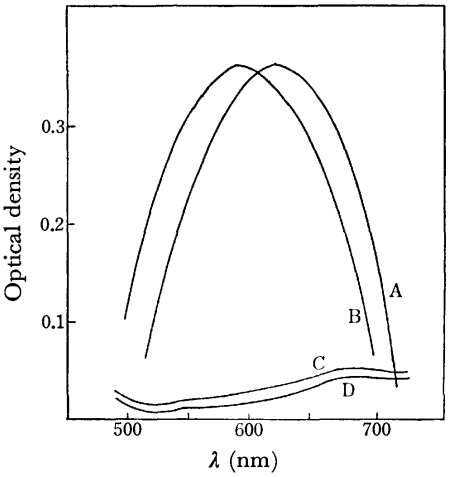

Fig. 1. UV spectra of the compounds treated with the Gibbs reagent.
A: Phenol, B: *o*-cresol, C: Compd **3**, D: Compd **4**.

detection of unsubstituted CH para to a phenolic hydroxyl group at the C-5 position. On treatment with the Gibbs reagent, a phenolic compound which is unsubstituted in the para position to the phenolic hydroxyl group gives the blue-green color of the indophenol derivative, with an absorption peak at 500—900 nm.[5] Compounds **3**, **4**, and **5** showed negative Gibbs reactions. This constitutes further evidence that **3**, **4**, and **5** do not have the C-8 proton which is in the para position to the C-5 hydroxyl group.

Heating **3** with potassium *p*-anisate and *p*-anisic anhydride yielded a new flavone, 2-phenyl,8-(4-methoxyphenyl)-4*H*,10*H*-benzo[1,2-*b*: 3,4-*b'*]dipyran-4,10-dione (**7**). By using potassium benzoate and benzoic anhydride or potassium veratrate and veratric anhydride instead, 2,8-diphenyl-4*H*,10*H*-benzo[1,2-*b*: 3,4-*b'*]dipyran-4,10-dione (**6**) or 2-phenyl,8-(3,4-dimethoxyphenyl)-4*H*,10*H*-benzo[1,2-*b*: 3,4-*b'*]dipyran-4,10-dione (**8**) was obtained. When **4** was used for the condensation with potassium veratrate and veratric anhydride, 2-(4-methoxyphenyl)-8-(3,4-dimethoxyphenyl)-4*H*,10*H*-benzo[1,2-*b*: 3,4-*b'*]dipyran-4,10-dione (**10**) was obtained.

According to the usual Allan-Robinson's flavone synthesis, Compound **6** is synthesized by heating a mixture of **3** which has been synthesized from **2**, potassium benzoate, and benzoic anhydride in a ratio of about 1: 2: 4 mol for several hours. However, we could synthesize **6** directly from **2** by heating a mixture of **2**, potassium benzoate, and benzoic anhydride in a ratio of about 1: 4: 8 mol for 10—12 h. In this way, Compounds (**9**) and (**11**) were also synthesized. The NMR and mass spectral data as well as the negative Gibbs reaction support the **6**, **7**, **8**, **9**, **10**, and **11** structures.

*Light Resistance of New Synthesized Flavones with a 4H,10H-Benzo[1,2-*b*: 3,4-*b'*]dipyran-4,10-dione Skeleton.* The light resistance of the following flavones, has been examined by means of the UV spectra; quercetin, morin, arthraxin (**1**), **7**, **9**, and **11**. The methanol solution of a sample prepared at a constant concentration was irradiated with a 200 W high-pressure mercury lamp

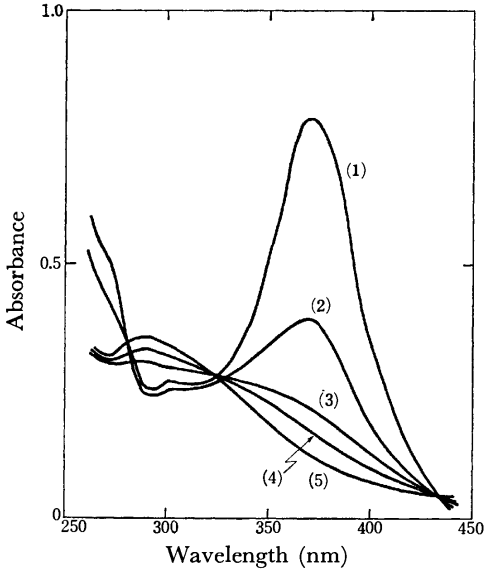

Fig. 2. Time change during irradiation of the spectrum of quercetin in methanol.

a) λ_{max} of Band I of the samples are shown in the respective parentheses.

through a quartz glass tube, with a water-cooled jacket, under bubbling air. The UV spectrum of an aliquot portion was then recorded at intervals of 3, 5, 8, 15, 22, and 50 h. The resistance to light was measured in terms of the decrease ratio of the concentration calculated from the intensity of Band 1, defined as the peak absorption intensity in the 350—450 nm region.

The results tabulated in Table 1 indicate that the synthesized flavones with a 4*H*,10*H*-benzo[1,2-*b*: 3,4-*b*']dipyran-4,10-dione skeleton, in contrast with flavonol and arthraxin, show a high resistance to light when air is bubbled into the methanol solution.

Experimental

The melting points are uncorrected. The NMR spectra were taken at 60 MHz with a Hitachi high-resolution nuclear magnetic resonance spectrometer, R-24 A. All the samples were run as 5—10% solutions in deuteriochloroform. The mass spectra were determined by a direct sample introduction using a Hitachi mass spectrometer, model RMU-6MG, under the following conditions: ionizing voltage; 70 eV, Samples **3**, **4**, and **5**; 20 eV, Samples **6**, **7**, **8**, **9**, **10**, and **11**; accelerating voltage; 3 kV, Samples **3**, **4**, and **5**; 3.2 kV, Samples **6**, **7**, **8**, **9**, **10**, and **11**; ion-source temperature; 170 °C, Samples **6**, **8**, and **10**, 200 °C, Samples **3**, **4**, and **5**; 220 °C, Samples **7**, **9**, and **11**.

2,4-Diacetylphloroglucinol (2). A solution of phloroglucinol (25 g) in warm glacial acetic acid (150 ml) was saturated with boron trifluoride gas and was then set aside for 1 h. The reaction mixture was poured into water (1300 ml), and the orange solid which separated was collected and recrystallized from aqueous ethanol to give nearly colorless needles (17 g); mp 164 °C (lit,[4] mp 168 °C).

8-Acetyl-5,7-dihydroxyflavone (3). A mixture of **2** (20 g), benzoic anhydride (88 g), and potassium benzoate (32 g) was heated at 170—175 °C for 6 h. The product was boiled for a short time with a mixture of ethanol (750 ml), water (90 ml), and potassium hydroxide (60 g). After the subsequent evaporation of the solvent under reduced pressure, the residue was redissolved in water (1000 ml). The solution was saturated with carbon dioxide, and the brown precipitate which separated was collected, washed, and dried (14 g). The product was purified on a silica gel column by eluting it successively with benzene, benzene–ethyl acetate (1: 1), and ethyl acetate. The fraction which was eluted with benzene–ethyl acetate was evaporated to dryness, and the residue was recrystallized from ethanol to give **3** (4.15 g) as yellow needles; mp 210 °C; NMR ($CDCl_3$), 2.81 (s, 3H, $COCH_3$), 6.40 (s, 1H, H-6), 6.66 (s, 1H, H-3), 7.4—8.0 (m, 5H, H-2′, 3′, 4′ 5′, 6′); M(mass spectrum), 296. $C_{17}H_{12}O_5$ requires M, 296.

The Gibbs Reaction. A small quantity (about 1 mg) of Samples **3**, **4**, **5**, **6**, **7**, **8**, **9**, **10**, and **11** was placed in a measuring cylinder and dissolved in pyridine (1 ml). To the solution we then added 5 ml of a freshly prepared Gibbs reagent solution (*N*-chloro-2,6-dichloro-*p*-benzoquinone diimine (10 mg) in pyridine (5 ml)), after which the mixture was diluted to 20 ml with a sodium borate buffer (pH 9.2). The absorption spectrum was determined between 10 and 20 min. All the samples, **3**—**11**, showed negative Gibbs reactions.

8-Acetyl-5,7-dihydroxy-4′-methoxyflavone (4). Compound **4** (15 g) was synthesized from **2** (18.7 g), *p*-anisic anhydride (90 g), and potassium *p*-anisate (35 g) by a way similar to that used in synthesizing **3**. Compound **4** was obtained as yellow needles; mp 181 °C; NMR ($CDCl_3$), 2.75 (s, 3H, $COCH_3$), 3.82 (s, 3H, OCH_3), 6.41 (s, 1H, H-6), 6.73 (s, 1H, H-3), 6.93, 7.09 (d, 2H, 3′, 5′-H), 7.79, 7.94 (d, 2H, 2′, 6′-H); M(mass spectrum), 326. $C_{18}H_{14}O_6$ requires M, 326.

8-Acetyl-5,7-dihydroxy-3′,4′-dimethoxyflavone (5). Compound **5** (7.5 g) was synthesized from **2** (8 g), veratric anhydride (35 g), and potassium veratrate (13 g) by a way imilar to that used in synthesizing **3**. Compound **5** was obtained as yellow needles; mp 251 °C; NMR ($CDCl_3$), 2.75 (s, 3H, $COCH_3$). 3.70 (s, 3H, OCH_3), 3.90 (s, 3H, OCH_3), 6.43 (s, 1H, H-6), 6.66 (s, 1H, H-3), 6.73—6.88 (m, 1H, H-5′), 7.40—7.58 (m, 2H, H-2′, 6′); M (mass spectrum), 356. $C_{19}H_{16}O_7$ requires M, 356.

*2-Phenyl-8-(4-methoxylhenyl)-4*H,*10*H-*benzo*[*1,2*-b: *3,4*-b′]-*dipyran-4,10-dione (7).* A mixture of **3** (1 g), *p*-anisic anhydride (17 g), and potassium *p*-anisate (3 g) was heated at 170 °C for 8 h. The product was boiled for 30 min with a mixture of ethanol (125 ml), water (30 ml), and potassium hydroxide (10 g). After the evaporation of the solvent, the residue was redissolved in water. The solution was saturated with carbon dioxide, and the precipitate which was thus separated was collected, washed, and dried (450 mg). The product was purified on a silica gel column by eluting it successively with benzene, benzene–ehytl acetate (15: 1), benzene–ethyl acetate (1: 1), and benzene–ethyl acetate (1: 5). The fraction which was eluted with benzene–ethy acetate (15: 1) was evaporated to dryness, and, the residue was recrystallzed from ethanol to give **7** (*ca.* 40 mg) as yellow needles; mp 139 °C; NMR ($CDCl_3$), 3.87 (s, 3H, OCH_3), 6.45 (s, 1H, H-6), 6.72 (s, 1H, H-3), 7.3—7.8 (m, 10H); M (mass spcetrum), 412. $C_{25}H_{16}O_6$ requires M, 412.

*2-Phenyl-8-(3,4-dimethoxyphenyl)-4*H,*10*H-*benzo*[*1,2*-b:*3,4*-b′]-*dipyran-4,10-dione (8).* Compound **8** (850 mg) was synthesized from **3** (1 g), veratric anhydride (20 g), and potassium veratrate (4 g) by a way similar to that used in synthesizing **7**. Compound **8** was obtained as yellow needles, mp 151 °C; NMR ($CDCl_3$), 3.85 (s, 3H, OCH_3), 3.91 (s, 3H, OCH_3), 6.45 (s, 1H, H-6), 6.73 (s, 1H, H-3), 6.9—7.9 (m, 9H); M (mass spectrum), 442. $C_{26}H_{18}O_7$ requires M, 442.

*2-(4-Methoxyphenyl)-8-(3,4-dimethoxyphenyl)-4*H,*10*H-*benzo*[*1,2*-b: *3,4*-b′]*dipyran-4,10-doine (10).* Compound **10** (700 mg) was syntheized from **4** (1.3 g), veratric anhydride (23.5 g), and potassium veratrate (4.1 g) by a way similar to that used in synthesizing **7**. Compound **10** was obtained as yellow needles; mp 168 °C; NMR ($CDCl_3$), 3.82 (s, 3H, OCH_3), 3.87 (s, 3H, OCH_3), 3.90 (s, 3H, OCH_3), 6.42 (s, 1H, H-6), 6.70 (s, 1H, H-3), 6.9—8.0 (m, 8H); M (mass spectrum), 472. $C_{27}H_{20}O_8$ requires M, 472.

*2,8-Diphenyl-4*H,*10*H-*benzo*[*1,2-b*: *3,4-b*′]*dipyran-4,10-dione (6).* A mixture of **2** (3 g), benzoic anhydride (25 g), and potassium benzoate (9 g) in a ratio of about 1: 4: 8 mol was heated at 170 °C for 11 h. The product was boiled for 30 min with a mixture of ethanol (200 ml), water (70 ml), and potassium hydroxide (43 g). After the evaporation of the solvent under reduced pressure, the residue was redissolved in water. The solution was saturated with carbon dioxide, and the precipitate which was thus separated was collected, washed, and dried (2.9 g). The product was purified on a silica gel column by eluting it successively with benzene–ethyl acetate (1: 1), ethyl acetate, ethyl acetate–acetone (1: 1), acetone, acetone–methanol (1: 1), and methanol. The fraction which was eluted with acetone was evaporated to dryness, and the residue was recrystallized from ethanol to give (**6**) as pale yellow needles; mp 272 °C; NMR ($CDCl_3$), 6.76 (s, 1H), 6.94 (s, 1H), 7.30—7.62 (m, 7H), 7.81—8.05 (m, 4H); M (mass spectrum), 382. $C_{24}H_{14}O_5$ requires M, 382.

*2-(4-Methoxyphenyl)-8-(4-methoxyohenyl)-4*H,*10*H-*benzo*[*1,2*-b:

3,4-b']*dipyran-4,10-dione* (*9*). Compound **9** (1.2 g) was synthesized from **2** (1 g), *p*-anisic anhydride (11 g), and potassium *p*-anisate (3.7 g) by a way similar to that used in synthesizing **6**. Compound **9** was thus obtained as yellow needles; mp 286 °C; NMR ($CDCl_3$), 3.71 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3), 6.40 (s, 1H), 6.80 (s, 1H), 6.9—8.1 (m, 9H); M (mass spectrum), 442. $C_{26}H_{18}O_7$ requires M, 442.

*2-(3,4-Dimethoxyphenyl)-8-(3,4-dimethoxyphenyl)-4*H,*10*H-*benzo*[*1,2*-b: *3,4*-b']*dipyran-4,10-dione* (*11*). Compound **11** (600 mg) was synthesized from **2** (1 g), veratric anhydride (13.5 g), and potassium veratrate (4.3 g) in a way similar to that used in synthesizing **6**. Compound **11** was thus obtained as yellow needles; mp 225 °C; NMR ($CDCl_3$), 3.65, 3.73, 3.88, 3.95 (all s, 3H, OCH_3), 6.43 (s, 1H), 6.70 (s, 1H), 6.9—8.1 (m, 7H); M (mass spectrum), 502. $C_{28}H_{22}O_9$ requires M, 502.

Aromaticity-Based Theory of Pericyclic Reactions

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 26, 1977)

The resonance energies of conjugated compounds in the electronically excited state were calculated on the basis of the aromaticity theory previously reported by us. The allowednesses of pericyclic reactions were predicted by means of these resonance energies. The predictions based on the resonance energy difference (RED) between the pericyclic transition state and the reactant(s) are in general agreement with the experiment.

Dewar-type resonance energy is an excellent aromaticity index for a conjugated compound.[1] It is defined as the difference between the energy of a conjugated compound and the energy of a "localized structure." Here, a "localized structure" signifies an olefinic reference structure which is hypothetically free from aromaticity. During the last three years we have been developing an analytical theory of aromaticity by means of the HMO theory, and have succeeded in formulating a characteristic polynomial for a "localized structure" of a conjugated compound.[2-5] A characteristic polynomial for the localized structure has been termed a "reference polynomial."[2] The π energy calculated from a reference polynomial can be interpreted as the π energy which a compound would possess if it were absolutely olefinic in nature.[2,3] On this basis, we could satisfactorily evaluate the aromatic resonance energy for any kind of conjugated compound and its ions.[2-5]

In this paper, we will show that the same definition of resonance energy can be applied to conjugated compounds in the excited state, and that it can be used as a new reactivity index for judging the allowedness of related pericyclic (*i.e.*, concerted) reactions.

Aromaticity in an Excited-State Species

A criterion of aromaticity in an electronically excited species is a comparison of the π energies of the compound and its localized structure (*i.e.*, its reference structure),[2] but in this case both structures must be in an equivalent excited state. We will here restrict our consideration to the lowest excited state, because, in most cases, any higher excited state will rapidly relax to the lowest excited state.[6] This means that, in most photochemical reactions, only the lowest excited state is important.

Let a characteristic polynomial for a conjugated compound and a corresponding reference polynomial be written respectively as

$$P(X) = X^N + \sum_{k=1}^{N} a_k X^{N-k} \tag{1}$$

and

$$R(X) = X^N + \sum_{k=1}^{N} b_k X^{N-k}, \tag{2}$$

where N is the number of atoms in the conjugated system. The coefficients, a_k and b_k, can be enumerated graphically with little difficulty.[2,3,7]

The roots of a secular equation, $P(X)=0$, are arranged in decreasing order as

$$X = X_1, X_2, \cdots, X_{N-1}, X_N. \tag{3}$$

The roots of a corresponding reference equation, $R(X)=0$, are arranged analogously in decreasing order as

$$X = X_1^*, X_2^*, \cdots, X_{N-1}^*, X_N^*. \tag{4}$$

The resonance energy of a conjugated system, RE, is then defined as

$$RE = \sum_{m}^{\text{occ.}} g_m(X_m - X_m^*), \tag{5}$$

where m runs over all the occupied π-molecular orbitals and where g_m is the number of electrons which occupy the m-th orbital. The resonance energy of any conjugated compound in any excited state can be calculated from this expression simply by adjusting the g_m values to its electronic configuration.

Resonance Energies of Annulenes in the Lowest Excited State

The resonance energies of ordinary annulenes (*i.e.*, Hückel annulenes) can be calculated straightforwardly from Eq. 5. The resonance energies of unrealistic Möbius annulenes (*i.e.*, singly twisted annulenes)[8] can also be calculated in the same manner. A reference polynomial for a Möbius annulene is identical with that for an ordinary annulene of the same size because the coefficients of the reference polynomials for both annulenes depend solely upon the connectivity of carbon atoms.[9] More accurately, each coefficient of a reference polynomial is a function of the bond (or heterobond) parameters squared (k^2).[3] Therefore, the coefficients of a reference polynomial are independent of the sign of any bond parameter. The π-orbital energies for the Hückel and Möbius benzenes, together with those for their reference structure, are shown in Fig. 1. Table 1 contains the resonance energies obtained for the Hückel and Möbius annulenes.

It is noteworthy that the aromaticity of a Möbius annulene in the ground state is determined by the converse of the Hückel (4n+2) rule, in agreement with a conclusion by Heilbronner.[8] The sign and the magnitude of the resonance energy for any ground-state annulene are essentially the same as those previously reported by us.[10] On the other hand, either conformation of any annulene in the excited state can be predicted to have an aromatic character opposite to that in the ground state. For example, a Hückel benzene (*i.e.*, an ordinary benzene) is the most stable annulene in the ground state, but the resonance energy becomes greatly negative when it is electronically excited. Such a situation is best represented by a high reactivity of

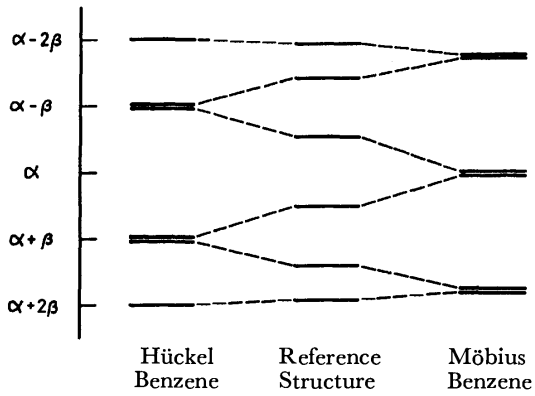

Fig. 1. Orbital correlations between benzenes and their reference structure.
Dashed lines indicate orbital correlations, which are drawn according to the principle described in J. Aihara, *Bull. Chem. Soc. Jpn.*, **50**, 2010 (1977). However, another definition of resonance energy given therein is not used in this paper, because the original definition (Ref. 2) is more practical and physically meaningful. Note that the reference energy in Ref. 2 defines the lowest energy of the reference structure.

Table 1. Resonance energies of annulenes

Species	Resonance energy (β)	
	Ground state	Excited state
Hückel cyclobutadiene	−1.226	0.305
Möbius cyclobutadiene	0.431	−0.867
Hückel benzene	0.273	−0.692
Möbius benzene	−0.799	0.236
Hückel cyclooctatetraene	−0.595	0.186
Möbius cyclooctatetraene	0.201	−0.550
Hückel[10]annulene	0.159	−0.451
Möbius[10]annulene	−0.474	0.152

this compound in the excited state. Benzene often forms benzvalene, Dewar benzene, and prismane when it is irradiated by ultraviolet light.[11]

Pericyclic Reactions with a Monocyclic Transition State

The above aspect of the aromaticity of annulene reminds us of the stereoselectivity of pericyclic reactions. Thus far, two principal approaches, the frontier orbital method[12] and the correlation diagram method,[13] have been widely employed to explain a number of pericyclic reactions. An alternative approach was made by Dewar[14] and Zimmerman,[15] who independently considered an aromatic property of a transition state as a determinant for the allowedness of pericyclic reactions.

Since, at any point along the reaction coordinate, a set of electrons are cyclically delocalized over the reacting centers, a transition state of the pericyclic reaction can be considered as a kind of cyclic conjugated system. For example, a transition state of a $[4_s+2_s]$ Diels-Alder reaction is isoconjugate with a Hückel benzene. According to an aromaticity-based theory of pericyclic reactions,[14,15] this reaction is thermally allowed because benzene is aromatic in the ground state. Dewar and Zimmerman thus showed that the problem of pericyclic reactions is identical in principle with that of aromaticity. The utility of this approach depends on the facility with which one can predict whether or not a given pericyclic transition state is aromatic. However, there has been no satisfactory theory of aromaticity for conjugated systems in the excited state. Their account of photochemical pericyclic reactions hence appeared less persuasive than that of thermal pericyclic reactions.

Now, we have an analytical theory of aromaticity[2-5] applicable to the excited-state species. By correlating the present resonance energies of annulenes (Table 1) with the pericyclic reactions whose transition states are monocyclic, we can safely predict that, if a pericyclic transition state is electronically equivalent to an annulene in an aromatic state, the reaction is allowed, while if it is not, the reaction is forbidden. Here, an aromatic state signifies a state in which the compound has a positive resonance energy, whether or not it is a ground-state species. On this basis, it can be predicted that a $[4_s+2_s]$ Diels-Alder reaction is photochemically forbidden, since a corresponding Hückel benzene has a negative resonance energy in the excited state. This is, of course, in harmony with the fact that such a reaction has not been reported.

Accordingly, an aromaticity-based theory of pericyclic reactions can be generalized into a single definitive rule: pericyclic reactions, both thermal and photochemical, take place *via* aromatic transition states. Since there are no exceptions to the Woodward-Hoffmann rules, there are no exceptions to this rule, either.

Pericyclic Reactions with a Polycyclic Transition State

Even though a pericyclic reaction has a polycyclic transition state, we can expect that an analogous consideration can be applied to it. In this case, the reactants are often cyclic conjugated compounds, and they may have an aromatic character. In order to take this new factor into account, we propose a new quantity, defined as the resonance energy difference (RED) between the pericyclic transition state and the reactants. This quantity reflects the relative aromatic stabilization of the transition state as compared with that of the reactants in an equivalent electronic state.

After extensive numerical analysis, the RED was found to give an excellent reactivity index for pericyclic reactions of any type. In Table 2 some typical pericyclic reactions with a polycyclic transition state are listed, together with their RED values. In calculating these RED values, some substituents, denoted therein as R_1 and R_2, were ignored for the sake of simplicity. As is shown in this table, the RED must be positive in order for the reaction to be allowed. The reaction is predicted to be allowed *via* a transition state with the largest RED value. When the RED is smaller than that, the reaction cannot be expected to occur, in accord with the experimental results.

Such a trend in reactivity strongly suggests that an

TABLE 2. RED VALUES FOR TYPICAL PERICYCLIC REACTIONS

Type of reaction	Stereochemistry	RED (β)	Allowedness
A	(4_s+2_a) or (4_a+2_s)	0.02	Yes[a]
	(4_s+2_s)[k] or (4_a+2_a)	−0.26	No

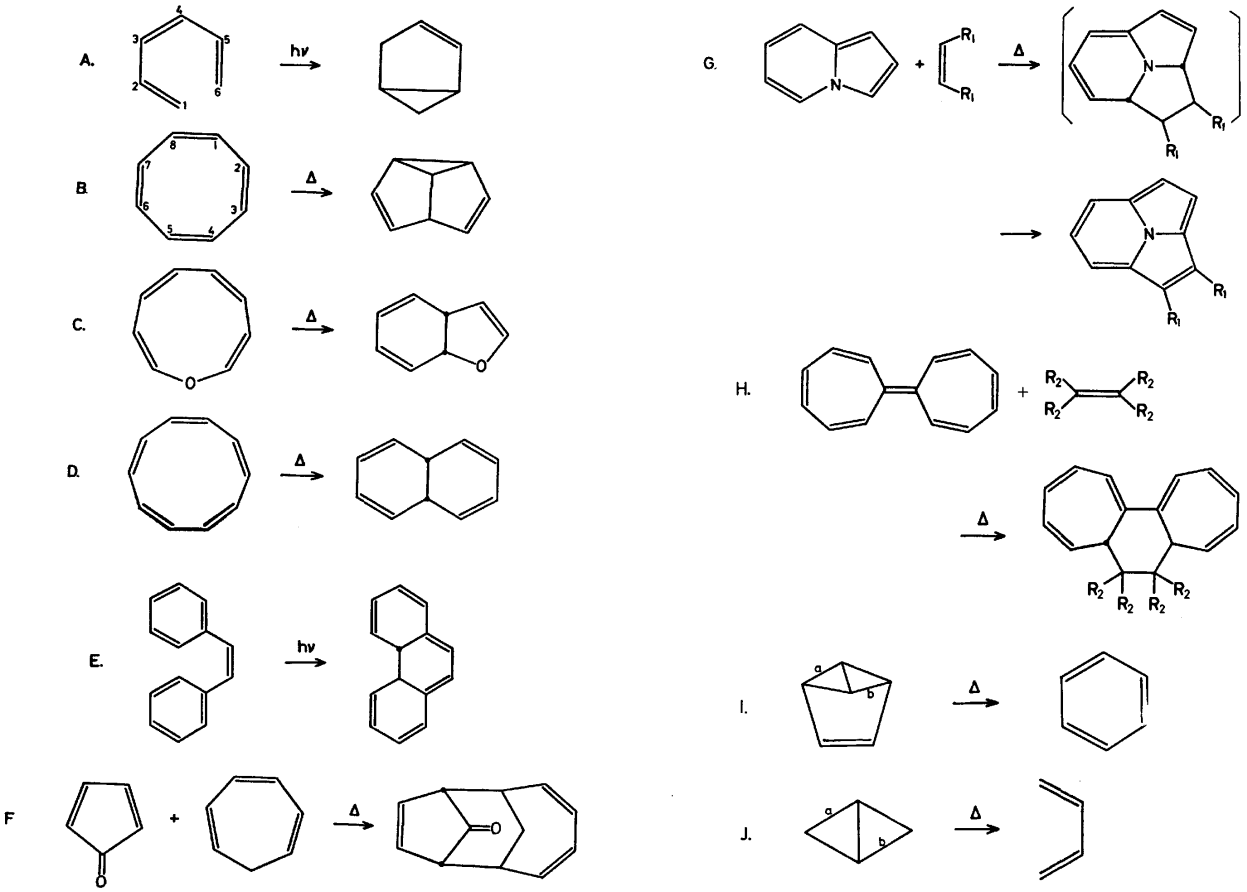
Phys Chem.*, **69**, 1775 (1965); Ref. 16. k) Heavy steric hindrance does not allow this reaction path, either.



The conformation of the product shown in each of these chemical equations is the one obtained from the allowed reaction path.

actual transition state of a pericyclic reaction must be more aromatic, or less antiaromatic, than the reactants and any other transition state imaginable in an equivalent electronic state. This trend appears to be justified by the view that a more aromatic state might more easily be reached in the course of the reaction. All the pericyclic reactions investigated can be explained in this manner.

Therefore, the definitive rule found above for pericyclic reactions with a monocyclic transition state must neccessarily be modified to include all kinds of pericyclic reactions as follows: Pericyclic reactions, both thermal and photochemical, take place *via* more aromatic transition states than the reactants. In the case of pericyclic reactions with a monocyclic transition state, the RED agrees exactly with the resonance energy of the transition state.

Above all, it should be noted that, on the basis of the present approach, we can avoid a certain ambiguity encountered in applying the Woodward-Hoffmann rules to pericyclic reactions with a polycyclic transition state. For example, the fact that the conversion of benzvalene to benzene is thermally allowed in a disrotatory-disrotatory manner (Reaction I in Table 2), whereas the same stereochemical conversion of bicyclobutane to butadiene is thermally forbidden (Reaction J in Table 2), cannot be explained in terms of orbital correlations between reactants and products.[16]

This problem can, in principle, be solved by means of the present aromaticity-based theory. The reason for the occurrence of the former reaction is that the resonance energy of the transition state, which is something like tricyclo[3.1.0.$0^{4,6}$]hexatriene, is positive. On the contray, the resonance energy of a transition state for the latter reaction, which is something like propalene, is negative. They are 0.253 and -0.473 respectively in units of β. Since the reactants for both reactions are nonaromatic, the RED for only the former reaction is positive. In agreement with a suggestion of Dewar and Kirschner,[16] a double bond in benzvalene obviously plays a significant role in determining both the aromaticity of the transition state and the allowedness of this reaction.

In this context, one comment must be made here. A thermal conrotatory-disrotatory conversion of benzvalene to benzene (Ia) can also be predicted to have a positive RED value (see Table 2). Unfortunately, this value is considerably larger than that for a thermal disrotatory-disrotatory conversion of the same compound (Ib). However, heavy steric hindrance forbids the occurrence of the former reaction (*i.e.*, Ia). It goes without saying that the steric effect is one of the crucial factors in determining the allowedness of any pericyclic reaction.

Apart from the steric effect, the suspicion that an actual reaction may not follow a reaction path with the maximum RED value seems to be related to a fault in the HMO model, rather than to one in the present approach to pericyclic reactions. According to our simplest HMO model, the energy of the transition state for Ia is estimated to be larger than that for Ib. This difficulty can be overcome simply by improving the HMO model so as to reproduce the actual transition states for both reactions (*i.e.*, Ia and Ib). Because any actual reaction occurs along the lowest-energy path, an actual transition state for Ib should be energetically lower than that for Ia. Logically, the RED for Ib is larger than that for Ia. For such a reason, the slight inconsistency found in Table 2 should be ascribed to a rather incomplete HMO model, in which bond alternation and the like are not taken into consideration.

Concluding Remarks

We now feel confident that the degree of aromaticity in a conjugated transition state is an important factor in determining the allowedness of pericyclic reactions. We might safely conclude that pericyclic reactions with the largest RED occur only thermally or photochemically, depending upon the electronic state concerned. It goes without saying that a heavy steric hindrance may forbid an electronically-allowed reaction. It is clear that the present approach complements and completes the aromaticity-based theory of pericyclic reactions, originally proposed by Dewar[14] and Zimmerman.[15] From this standpoint, the new concept of the aromaticity of the excited-state species also seems to have been explained fairly well, although it is not easy to estimate this aromaticity experimentally. The introduction of actual bond alternation would obviously improve the value of the RED as a reactivity index.[3]

The author would like to thank Professor Takashi Tsuji for his help in preparing Table 2. The use of the facilities of the Hokkaido University Computing Center is acknowledged.

Solvent Effects on the Photoamination of 1-Amino-2,4-dibromoanthraquinone. I. Photoamination in Benzene *via* Intramolecular Charge Transfer Excited Triplet State

Haruo INOUE and Mitsuhiko HIDA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received September 19, 1977)

The bromine atom at the 4 position of 1-amino-2,4-dibromoanthraquinone (**1**) was substituted by butylamine and aniline by the irradiation of visible light. In ethanol the dissolved oxygen promoted the reaction and anthracene, a triplet quencher, had little effect. In benzene, the dissolved oxygen retarded the reaction and anthracene had a considerable quenching effect. Kinetic analysis indicated that in ethanol the photoamination of **1** proceeds mainly through the interaction of **1** in $S_1(^1CT)$ with the ground state oxygen, while in benzene it does through the $T_1(^3CT)$ of **1** without the aid of oxygen. The detailed reaction mechanism in benzene has been discussed and the rate constant of each process including the deactivation constant of the upper excited $T_2(^3n\pi^*)$ level evaluated.

The photochemical behavior of anthraquinone derivatives has attracted attention for a long time in relation to the photofading of vat dyes and the photosensitized oxidation. Many intensive studies have been made on the photoreduction, the photoannelation, and the photosubstitution.[1] Anthraquinone derivatives have four $\pi\pi^*$ absorption bands in the region of the wavelength between 220 nm and 350 nm, and $n\pi^*$ band at the longer wavelength near 400 nm. When electron donating substituents such as hydroxyl, amino, and methylamino groups are introduced in to the nucleus, a new $\pi\pi^*$ absorption band, an intramolecular charge transfer band, appears in the visible region. It has been emphasized that the triplet excited $n\pi^*$ state is reactive in almost all the photochemical reactions of anthraquinones, while the excited CT state has little reactivity and the introduction of an electron donating substituent renders the excited anthraquinone extremely unreactive.[1] However, recently a new photosubstitution reaction of aminohaloanthraquinone has been reported: the bromine atom of sodium 1-amino-4-bromoanthraquinone-2-sulfonate **3** has been substituted by ammonia and alkylamine by the irradiation of visible light.[2] The oxygen molecule is indispensable for the photoamination and the mechanism has been postulated that the photoamination proceeds through an exciplex or an encounter complex formation between **3** in its excited ^1CT state and the ground sate oxygen, followed by an attack of amine to produce the aminated product as shown below.[3]

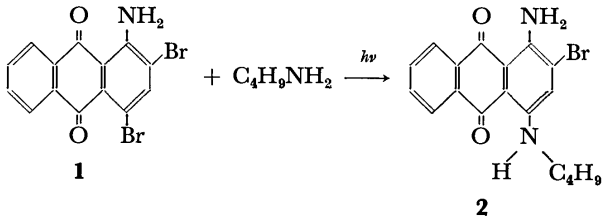
$$AQ^*(^1CT) + {}^3O_2 \longrightarrow [AQ^{\delta+} \cdots O_2^{\delta-}]$$

$$[AQ^{\delta+} \cdots O_2^{\delta-}] \swarrow \quad \downarrow \text{Amine}$$

$$AQ + O_2 \qquad \text{Amination}$$

This photoamination appears to be the first example of a reaction which proceeds *via* the excited CT state of anthraquinone derivatives.

In this paper the photoamination of 1-amino-2,4-dibromoanthraquinone **1** by butylamine has been investigated. Very large solvent effects were observed between the photoamination of **1** in benzene and that in ethanol: both the reactive state of the excited **1** and the reaction mechanism changed with the nature of the solvents used.



1 **2**

Experimental

1-Amino-2,4-dibromoanthraquinone **1** was prepared by the bromination of sodium 1-amino-4-bromoanthraquinone-2-sulfonate **3** with bromine and was purified by repeated recrystallizations from ethanol. Shimadzu UV-200 spectrophotometer was used for the measurement of the visible and UV spectra, and Hitachi MPF-4 spectroflurometer for the measurement of the fluorescence spectra. The quantum yield of the photoamination of **1** was determined by the potassium tris(oxalto)ferrate(III) chemical actinometer according to the method recommended by Hatchard and Parker.[4] The reaction mixture was irradiated by means of a 500 W xenon lamp (USHIO UXL-500 DXO) or a 100 W high-pressure mercury lamp (Eikosha) through the following filter system: soda glass for the irradiation of light of $\lambda > 300$ nm, a Toshiba interference filter KL-40 for monochromatic light of $\lambda = 400$ nm, and a Toshiba interference filter KL-47 and a glass filter VY-45 for monochromatic light of $\lambda = 470$ nm, respectively.

Results and Discussions

*The Photoamination of **1** in Benzene.* A solution of **1** (1.00×10^{-4} mol/dm^3) and butylamine (5.00×10^{-2} mol/dm^3) in benzene was irradiated by the light of $\lambda > 300$ nm, and a new absorption band appeared in the region between 500 and 700 nm which is characteristic of the aminated product **2**, having the isosbestic points at $\lambda = 390$ and 512 nm. TLC analysis (silica gel, eluent: 93: 7 benzene–acetone) of the irradiated mixture indicated that only **2** was produced in the reaction system. From these results it was concluded that the photoreaction of **1** with butylamine in benzene gave only the aminated product **2**. After evaporating the solvent from the irradiated mixture, the aminated product **2** was seperated by silica gel column chromatography and purified by repeated recrystallizations from

hexane. (Found: C, 58.02; H, 4.55; N, 7.56%).

Solvent Effects on the Photoamination of 1. The solvent effects on the photoamination of **1** with butylamine are shown in Table 1. Very large solvent effects were observed. In ethanol, 1) the dissolved oxygen promoted the photoamination of **1**, but **1** had a poor reactivity under a nitrogen atmosphere, 2) a little quenching effect was observed by the addition of anthracene, and 3) the yield (%) of **2** was not equivalent to the conversion (%) of **1** and the ratio (0.79) between them was unchanged during the photoreaction. The last result suggests that the simultaneous photodecomposition of **1** accompanied by the photoamination took place as observed in the photoamination of **3** in aqueous 2-propanol. In benzene, 1) the dissolved oxygen retarded the photoamination and **1** was rather reactive under a nitrogen atmosphere, 2) a considerable quenching effect was observed by the addition of anthracene, and 3) the yield of **2** was equal to the conversion of **1**, suggesting that the photoamination of **1** proceeded quantitatively.

TABLE 1. SOLVENT EFFECTS ON THE PHOTOAMINATION OF **1** BY BUTYLAMINE[a)]

Solvent	Φ_{N_2}[b)] / Φ_{Air}	Quenching effect by anthracene[c)]	Yield of **2** / conversion of **1**
Ethanol	0.13	△[d)]	0.79
Benzene	1.50	○[e)]	1.00

a) **1** (1.00×10^{-4} mol/dm^3); butylamine (5.00×10^{-2} mol/dm^3); in ethanol or benzene; light of $\lambda>420$ nm. b) Φ_{N_2} and Φ_{Air} are the quantum yield of the photoamination of **1** under nitrogen and air, respectively. c) [Anthracene] = 1.00×10^{-2} mol/dm^3. d) Little quenching. e) Considerable quenching.

Absorption and Fluorescence Emission Spectra of 1. The absorption and the fluorescence emission spectra of **1** shown in Fig. 1 have two distinct characteristics. 1) The λ_{max} of the first absorption band in ethanol exibits a red shift of 5 nm compared with that in benzene and the λ_{max} of the fluorescence spectrum exibits a red shift of 21 nm. This supports the theory that **1** in the excited state has an intramolecular CT nature. 2) Contrary to the usual solvent effect,[5)] the relative intensity of the fluorescence spectrum in benzene is weaker by a factor of ten than that in ethanol under the same conditions. This suggests that **1** in its ^{1}CT state in benzene is deactivated more than ten times as effectively as in ethanol, possibly by a process such as an enhanced intersystem crossing to the triplet state.

Energy Diagram of the Excited State of 1. An introduction of substituent to the anthraquinone nucleus is thought to have little effect on the position of the nπ^* level,[1b)] so that the ^{1}nπ^* and ^{3}nπ^* levels of **1** are supposed to lie in the neighborhood of those of anthraquinone, 280 kJ/mol and 259 kJ/mol respectively. As the absorption and the fluorescence spectra were still structureless even at 77 K, the 0-0 band in the first absorption band of **1** was estimated from the intersection of the absorption and the fluorescence spectra in a mirror image relation.[6)] The ^{1}CT level of **1** was supposed to be at 218 kJ/mol in ethanol and 228 kJ/mol in benzene, respectively.

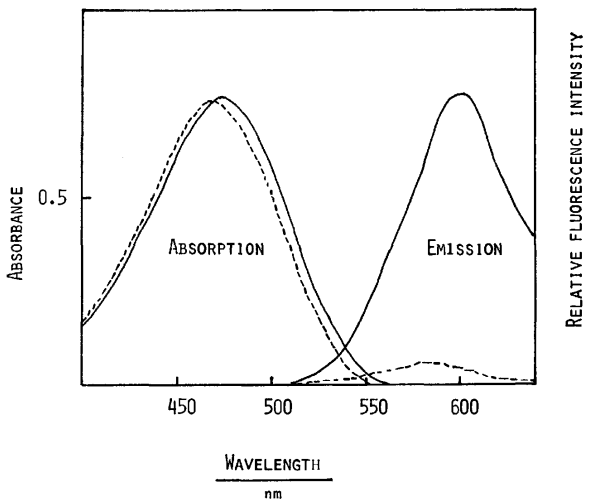


Fig. 1. Absorption and fluorescence spectra of **1**. [**1**] = 1.00×10^{-4} mol/dm^3, ——: in ethanol, ——: in benzene.

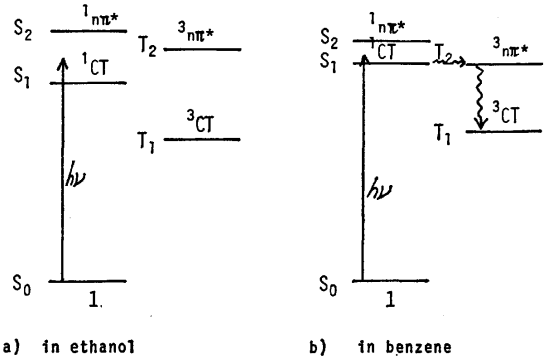

Fig. 2. Energy diagram of the excited state of **1**.

Thus, the ^{1}CT level of **1** in ethanol was considered to be a little lower than the ^{3}nπ^* level as illustrated in Fig. 2a. In benzene the absorption and the fluorescence spectra indicate the ^{1}CT level of **1** being situated at a higher position than that in ethanol. Moreover, the nπ^* level of **1** in a non-polar solvent such as benzene lies in a relatively lower position than that in a polar protic solvent such as ethanol, and it may be reasonably accepted that in benzene the ^{1}CT level lies in close contiguity to the ^{3}nπ^* level as shown in Fig. 2b. An inversion of the disposition between the ^{1}CT and the ^{3}nπ^* levels may take place by the variation of the solvent polarity. On the basis of the energy diagram of the excited states of **1** (Fig. 2a and b), the solvent effects on the photoamination can be discussed as follows. In ethanol **1** is excited to the ^{1}CT level by an irradiation of the first absorption band of **1** and the photoamination takes place in a similar manner to the case of **3** in aqueous 2-propanol. In benzene, because of a close contiguity or an inversion of the disposition between $S_1(^1CT)$ and the $T_2(^3n\pi^*)$ levels, both levels interact more strongly with each other than in ethanol, resulting in enhancement of the intersystem crossing process. Thus the relative fluorescence intensity of **1** in benzene becomes weaker by a factor of ten compared with that in ethanol. Consequently, the $T_1(^3CT)$ level

of **1** is supposed to be largely populated by the irradiation of the first absorption band of **1** in benzene by the dominant deactivation process of $S_1(^1CT) \rightsquigarrow T_2(^3n\pi^*) \rightsquigarrow T_1(^3CT)$. Then, the photoamination is supposed to proceed mainly from the $T_1(^3CT)$ without the aid of the dissolved oxygen.

Effect of Oxygen in Benzene. The quenching experiments by the dissolved oxygen in benzene gave a linear Stern-Volmer plot (Fig. 3), indicating that the dissolved oxygen acted as a quencher of the photoamination of **1** in benzene and the photoreaction proceeds through the one excited state of **1**. From the slope of the linear plot, $k_q \cdot \tau_1$ was found to be 513 dm³/mol, where k_q denotes the quenching rate constant by oxygen and τ_1 the lifetime of the excited state quenched by oxygen, respectively.

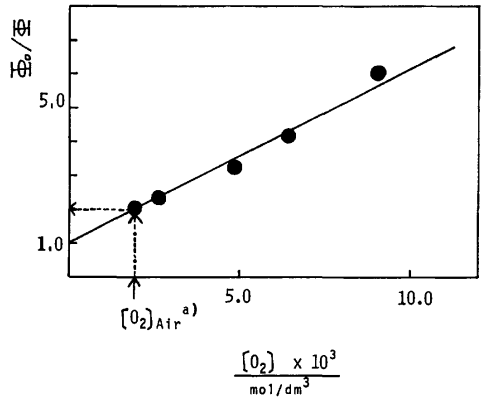

Fig. 3. Stern-Volmer plot for the quenching effect of oxygen on the photoamination of **1** (1.00×10^{-4} mol/dm³) by butylamine (5.00×10^{-2} mol/dm³) in benzene by the irradiation of the light of $\lambda = 470$ nm.
a) The concentration of the dissolved oxygen in the air saturated benzene.

Effect of the Triplet Sensitizer in Benzene. The benzene solution of **1** (1.00×10^{-4} mol/dm³) and butylamine (5.00×10^{-2} mol/dm³) with or without a triplet sensitizer (1.00×10^{-2} mol/dm³) was irradiated by monochromatic light of $\lambda = 400$ nm under nitrogen. In the presence of benzil ($E_T = 226$ kJ/mol) and fluorenone ($E_T = 226$ kJ/mol) as triplet sensitizers the reaction was promoted by a factor of 1.8 and 10, respectively. These results indicate that the photoamination proceeds through the triplet excited state of **1**. As the triplet levels of both benzil and fluorenone are lower than the $T_2(^3n\pi^*)$ of **1**, it is supposed that the photoreaction proceeds through the $T_1(^3CT)$ level.

Effect of the Triplet Quencher in Benzene. Cyclooctatetraene (COT) and anthracene did not affect the fluorescence intensity of **1**. Thus, they were expected to act as a triplet quencher but not as a singlet quencher. The Stern-Volmer plot was shown in Fig. 4 when COT ($E_T = 163$ kJ/mol) was used as a triplet quencher. A linear relationship between Φ_0/Φ and the concentration of COT was observed and its slope was 52 dm³/mol under nitrogen and 28 dm³/mol in aerated solution, respectively, that is, the lifetime of the excited state of **1**, quenched by COT, depended upon the presence of

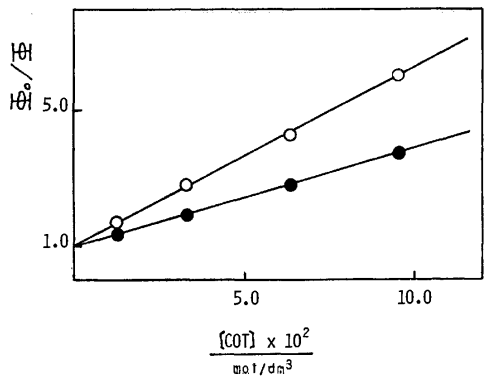

Fig. 4. Stern-Volmer plot for the quenching effect of cyclooctatetraene on the photoamination of **1** (1.00×10^{-4} mol/dm³) by butylamine (5.00×10^{-2} mol/dm³) in benzene by the irradiation of the light of $\lambda = 470$ nm.
○: Under nitrogen, ●: under air.

the dissolved oxygen, suggesting that the dissolved oxygen may interact with the same state as that quenched by COT. These results, in addition to the above sensitizing experiments, lead to the conclusion that the photoamination of **1** proceeded through the $T_1(^3CT)$ level of **1** which can be quenched by both the dissolved oxygen and COT.

In the presence of anthracene ($E_T = 176$ kJ/mol), the Stern-Volmer plot for the photoamination of **1** was also found to be linear (Fig. 5). A different result with COT was obtained. The slope of the Stern-Volmer plot was the same both under nitrogen and air, that is, the lifetime of the excited state of **1** quenched by anthracene was not affected by the presence of oxygen. This suggests that anthracene interacts in the quenching manner with the different excited state of **1** from the $T_1(^3CT)$ which is quenched by oxygen. It is been reported that the photoreduction of anthraquinone *via* the $^3n\pi^*$ level is efficiently quenched by anthracene.[7] Davies *et al.* reported the quenching of the $T_2(^3n\pi^*)$ level of 1-dimethylaminoanthraquinone by anthracene.[8] The quenching effect on the photoamination of **1** by anthracene in this study is understandable by

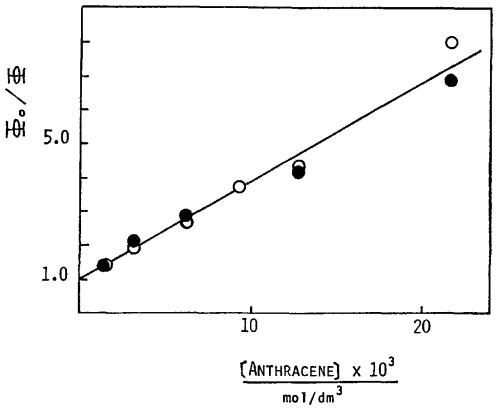

Fig. 5. Stern-Volmer plot for the quenching effect of anthracene on the photoamination of **1** (1.00×10^{-4} mol/dm³) by butylamine (5.00×10^{-2} mol/dm³) by the irradiation of the light of $\lambda = 470$ nm.
○: Under nitrogen, ●: under air.

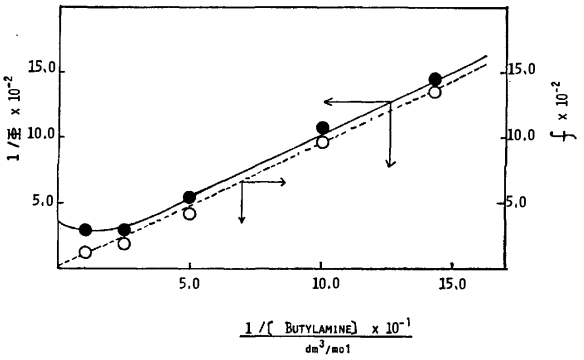

Fig. 6. Effect of the concentration of butylamine on the photoamination of **1** (1.00×10^{-4} mol/dm³) in benzene. -●-: $1/\Phi$ *vs.* 1/[Butylamine], -○-: f *vs.* 1/[Butylamine].

assuming that the $T_2(^3n\pi^*)$ level of **1** is quenched by anthracene. Thus, the $T_1(^3CT)$ level of **1** in benzene, which was quenched by COT (E_T=163 kJ/mol), but not by anthracene (E_T=176 kJ/mol), was supposed to lie in the range of 163—176 kJ/mol.

Effect of the Concentration of Butylamine in Benzene. The plot of the reciprocal of the quantum yield of the photoamination of **1** *versus* the reciprocal of the concentration of butylamine gave the curve as shown in Fig. 6. This curve may be explained by assuming that the amine molecule participates not only in the process leading to the aminated product **2**, but also in the quenching. Since anthraquinonesulfonic acids and aminoanthraquinones have been reported to be photoreduced *via* their $^3n\pi^*$ state by an electron transfer from amines or inorganic anions in polar solvents,[9,10] it may be possible that in non-polar benzene, butylamine as an electron donor interacts with **1** in the $T_2(^3n\pi^*)$ level in a quenching manner to the photoamination of **1** which proceeds through the $T_1(^3CT)$ level of **1**. If butylamine interacts with the $T_2(^3n\pi^*)$ level in a quenching manner to the photoamination, the lifetime of the $T_2(^3n\pi^*)$ level, τ_2, should be shortened by an increase in concentration of butylamine: the slope of the Stern-Volmer plot (Fig. 5) expressed as $k_q'\cdot\tau_2$, where k_q denotes the quenching rate constant of $T_2(^3n\pi^*)$ by anthracene and τ_2 the lifetime of $T_2(^3n\pi^*)$, should decrease with an increase in concentration of the amine. The slope of the Stern-Volmer plot in different concentration of the amine are listed in Table 2. It is seen that the slope of the Stern-Volmer plot,

TABLE 2. EFFECT OF THE CONCENTRATION OF BUTYLAMINE ON THE SLOPE OF THE STERN-VOLMER PLOT IN FIG. 5

$\frac{[\text{Butylamine}]\times10^2}{\text{mol/dm}^3}$	2.00	5.00	10.0
$\frac{\text{Slope } (k'_q\cdot\tau_2)}{\text{dm}^3/\text{mol}}$	380	290	210

$k_q'\cdot\tau_2$, decreased with an increase in concentration of the amine. Consequently, it may be concluded that butylamine interacts with **1** in the $T_2(^3n\pi^*)$ level in a quenching manner. The quenching effect by the amine may be explained by assuming an exciplex

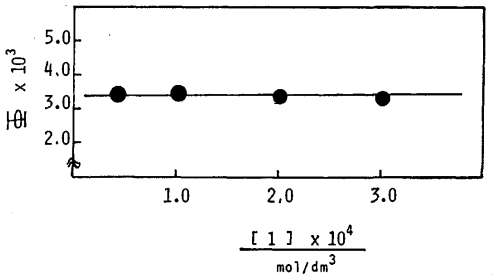

Fig. 7. Effect of the concentration of **1** on the photoamination of **1** by butylamine (5.00×10^{-2} mol/dm³) by the irradiation of the light of λ=470 nm.

formation such as $[AQ^{\delta-}\cdots Amine^{\delta+}]$ which whould not lead to the aminated product **2**, but be deactivated to the ground state of **1** and the amine in non-polar benzene.

Effect of the Concentration of 1 in Benzene. The quantum yield of the photoamination remained unchanged by the variation of the concentration of **1** (Fig. 7). This precludes the possibility that **1** participates in the photoamination as depicted below.

$$AQ^* + AQ \longrightarrow [AQ^{\oplus}\cdots AQ^{\ominus}]$$

$$[AQ^{\oplus}\cdots AQ^{\ominus}] \xrightarrow{\text{Amine}} \text{Amination}$$

$$[AQ^{\oplus}\cdots AQ^{\ominus}] \longrightarrow 2AQ$$

The Reaction Mechanism of the Photoamination of 1 in Benzene. On the basis of the above experimental results, the reaction scheme for the photoamination of **1** may be depicted as Fig. 8.

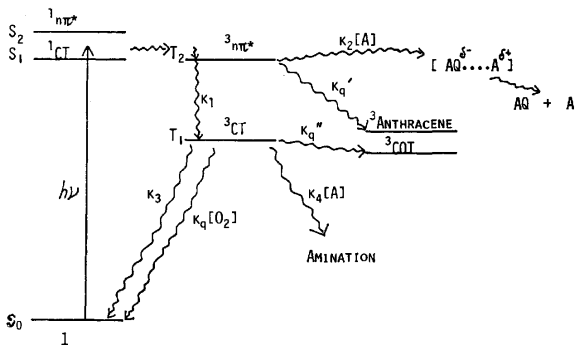

Fig. 8. Reaction scheme of the photoamination of **1** by butylamine in benzene.

The quantum yield for the production of **2** under nitrogen without a triplet quencher may be expressed by

$$\Phi = \Phi_{isc}\cdot\left(\frac{k_1}{k_1+k_2[A]}\right)\cdot\left(\frac{k_4[A]}{k_3+k_4[A]}\right)\cdot\alpha, \qquad (1)$$

where Φ_{isc} = the efficiency of the intersystem crossing of $S_1(^1CT) \rightsquigarrow T_2(^3n\pi^*)$,
k_i = the rate constant of each process indicated in Fig. 8,
A = butylamine,
and α = the yield of the aminated product **2** for every collision between the amine and **1** in its $T_1(^3CT)$ level.

The reciprocal of the quantum yield is thus expressed by

$$\frac{1}{\Phi} = \frac{1}{\Phi_{isc}\cdot\alpha}\cdot\left(1+\frac{k_2[A]}{k_1}\right)\cdot\left(1+\frac{k_3}{k_4[A]}\right). \quad (2)$$

Hence, a plot of the reciprocal of the quantum yield *versus* the reciprocal of the concentration of butylamine would be expected to show the result given in Fig. 6.

With dissolved oxygen present, the Stern-Volmer equation may be expressed by

$$\frac{\Phi_0}{\Phi} = 1 + \frac{k_q[O_2]}{k_3+k_4[A]}. \quad (3)$$

When COT was used as a triplet quencher,

$$\frac{\Phi_0}{\Phi} = 1 + \frac{k_q''[COT]}{k_3+k_4[A]+k_q[O_2]} \quad (4)$$

and in the case of anthracene,

$$\frac{\Phi_0}{\Phi} = 1 + \frac{k_q'[Anthracene]}{k_1+k_2[A]}. \quad (5)$$

A plot of Φ_0/Φ *versus* the concentration of each quencher used should give a linear relationship (Figs. 3, 4, and 5). Equation 4 indicates that the slope of the plot in Fig. 4 means to be $k_q''/(k_3+k_4[A]+k_q[O_2])$, which should be dependent upon the concentration of the dissolved oxygen as discussed before. The ratio between the slope of the plot (Fig. 4) for the results under nitrogen and air (52/28=1.9), corresponding to $1+k_q[O_2]_{air}/(k_3+k_4[A])$, agrees with the value of $\Phi_0/\Phi=1+k_q[O_2]_{air}/(k_3+k_4[A])=2.0$ obtained from Fig. 3 and Eq. 3 at the air saturated oxygen concentration. Equation 5 indicates that the slope of the plot, Φ_0/Φ *versus* [Anthracene] (Fig. 5), should be independent of the concentration of the dissolved oxygen.

By combining the values of the slopes of the lines represented by Figs. 3, 4, and 5 with Eqs. 3, 4, and 5, the following rate constants relationships were obtained;

$$\frac{k_q}{k_3+k_4[A]} = 513\ dm^3/mol, \quad (6)$$

where $[A]=5.00\times10^{-2}$ mol/dm^3,

$$\frac{k_q''}{k_3+k_4[A]} = 52\ dm^3/mol, \quad (7)$$

where $[A]=5.00\times10^{-2}$ mol/dm^3, and

$$\frac{k_q'}{k_1+k_2[A]} = 210, 290, \text{and } 380\ dm^3/mol, \quad (8)$$

where $[A]=1.00\times10^{-1}$, 5.00×10^{-2}, and 2.00×10^{-2} mol/dm^3, respectively.

Equation 8 gave the value of $k_1/k_q'=2.1\times10^{-3}$ mol/dm^3 and $k_2/k_q'=2.7\times10^{-2}$ mol/dm^3, respectively. Assuming that the quenching rate constant of $T_2(^3n\pi^*)$ by anthracene is $k_q'=1.6\times10^{10}$ dm^3/(mol·s) which is a diffusion controlled one, k_1 and k_2 may be calculated as $k_1=3.4\times10^7$ s^{-1} and $k_2=4.3\times10^8$ dm^3/(mol·s), respectively.

If Eq. 2 is rewritten using Eq. 9, the value of f calculated by using the k_1 and k_2 obtained above, with the reciprocal of the concentration of butylamine would be expected to exibit a linear relationship.

$$f = \frac{1}{\Phi}\left(\frac{k_1}{k_1+k_2[A]}\right) = \frac{1}{\Phi_{isc}\cdot\alpha}\cdot\left(1+\frac{k_3}{k_4[A]}\right) \quad (9)$$

A plot of f *versus* the reciprocal of the concentration of butylamine gave a linear relationship as indicated by the dotted line in Fig. 6. These results support the reaction scheme shown in Fig. 8. It may be seen from Eq. 9 that the ratio between the slope and the intercept in the plot of f *versus* the reciprocal of the concentration of the amine (Fig. 6) is equal to k_3/k_4. The value of k_3/k_4 was obtained as 0.50 mol/dm^3. Supposing the quenching rate constant of $T_1(^3CT)$ by oxygen k_q to be the diffusion controlled one (1.6×10^{10} dm^3/(mol·s)), k_3 and k_4 may be determined by substituting the value of k_3/k_4 into Eq. 6 as $k_3=2.8\times10^7$ s^{-1} and $k_4=5.7\times10^7$ dm^3/(mol·s), respectively. Moreover, the substitution of the value of k_3 and k_4 into Eq. 7 reveal the quenching rate constant of $T_1(^3CT)$ by COT, k_q'', to be 1.6×10^9 dm^3/(mol·s), which is one order of magunitude smaller than the diffusion controlled rate. It has been reported that the quenching rate by energy transfer drops very quickly from the diffusion controlled rate when the acceptor triplet level approaches that of the donor within 13—17 kJ/mol.[11] This may be valid in the case of $T_1(^3CT)$ (E_T=163—176 kJ/mol) of **1** as a donor level and COT (E_T=163 kJ/mol) as an acceptor. The rate constant in the reaction scheme of Fig. 8 determined by these kinetic analysis are tabulated in Table 3.

Table 3. Rate constants in the reaction scheme for the photoamination of **1** by butylamine in benzene[a]

k_1 / s^{-1}	k_2 / dm^3/(mol·s)	k_3 / s^{-1}	k_4 / dm^3/(mol·s)	k_q'' / dm^3/(mol·s)
3.4×10^7	4.3×10^8	2.8×10^7	5.7×10^7	1.6×10^9

a) They were determined on the assumption that k_q, $k_q'=1.6\times10^{10}$ dm^3/(mol·s) (diffusion controlled rate), respectively.

It is significant that these rate constants, especially the deactivation constant of the upper excited level $T_2(^3n\pi^*)$ can be determined kinetically, which is rarely possible in many cases because of the short lifetime of the upper excited level. The deactivation constant k_1 corresponding to the reciprocal of the lifetime of $T_2(^3n\pi^*)$ level was revealed to have a value of 3.4×10^7 s^{-1} comparable to that of the lowest excited triplet level $T_1(^3CT)$ ($k_3=2.8\times10^7$ s^{-1}). Davies *et al.* reported the photoreduction of 1-dimethylaminoanthraquinone by hydrogen abstraction *via* its upper excited level $T_2(^3n\pi^*)$ and pointed out that anthraquinone derivatives might have a lifetime long enough to photoreact in their upper excited $T_2(^3n\pi^*)$ level.[8] This has been demonstrated in this study. That the $T_2(^3n\pi^*)$ level of **1** has such a long lifetime of *ca.* 30 ns in contrast to those of T_2 of substituted anthracenes (*ca.* 0.3 ns) and naphthalene (*ca.* 10 ps) would be unusual. These values were kinetically determined by Liu *et al.*[12,13]

Previously it has been reported that in contrast to the aliphatic amines, aromatic amines appeared not to photoreact with sodium 1-amino-4-bromoanthraquinone-2-sulfonate **3** in polar medium. As stated above, in polar solvent the photoamination proceeds through the $S_1(^1CT)$ level interacting with the ground state oxygen along with the simultaneous production of the peroxide, probably derived from the superoxide ion O_2^-.[3] Consequently it was considered that the

aromatic amine was oxidized predominantly by the peroxide produced in the reaction system, resulting in the suppression of the photoamination in polar solvent. These considerations suggest that aromatic amines would be expected to photoreact with **1** in benzene, in which the photoamination proceeds without the aid of oxygen. In fact, in benzene under a nitrogen atmosphere effective photoamination of **1** with aromatic amine, aniline, was observed.

The Effects of Solvents on the IR and PMR Spectra of Intramolecular OH···π and OH···O Hydrogen Bonded Systems[1)]

Shinichi UEJI

Institute of Chemistry, College of General Education, Kobe University, Tsurukabuto, Nada, Kobe 657

(Received October 7, 1977)

The effects of solvents on the intramolecular OH···π and OH···O hydrogen bonding in 2-arylphenols and 2,6-diarylphenols have been studied by examining the OH stretching IR absorption spectra in a range of solvents. The solvent shifts of the hydrogen bonded bands, νOH···π and νOH···O, followed the *G* correlation and the BHW plot. The success of both correlations suggests that the solvent shifts are primarily due to a specific solvent-solute association, even in relatively non-polar solvents. The solvent sensitivity of the OH···π and OH···O hydrogen bonded bands depended on the stereo-chemical environment around the hydrogen bonded system rather than on such electronic factors as the strength of the hydrogen bonding. On the basis of the relationship between the solvent sensitivity and the structural changes over a group of phenols, a simplified model for the solvent-solute association is put forward. Furthermore, this simplified model is also discussed in terms of the aromatic solvent-induced shifts in the PMR spectra.

Since the first observation of the solvent sensitivity of the hydrogen bonded OH frequency,[2)] considerable attention has been focused on the solvent effects on IR frequency shifts.[3–6)] However, the problem is not yet completely settled.

In the IR study of the solvent effects on the hydrogen bonded bands, Bellamy, Morgan, and Pace[3)] attributed the origin of solvent shifts to the specific association of solvents with the hydrogen bonded complex;

$$\text{S–H} \cdots \text{O–H} \cdots \text{B(Base)},$$

where S–H denotes the solvent molecule. Later, Yoshida and Ōsawa[4)] interpreted the solvent shifts in terms of the dipolar association model, in which the solvent is preferentially oriented with its bond dipole toward the lone pair dipole of the hydroxyl group in the hydrogen bonded system. Furthermore, they assumed that the dipolar association exists as the following geometry.[4a)]

$$\begin{array}{l} \overset{\delta-}{\text{O}}\text{H} \cdots \overset{\delta+}{\text{B}} \\ \vdots \\ \underset{\delta+}{\text{H}}\text{–}\underset{\delta-}{\text{S}} \end{array}$$

Most of the studies in this field have been concerned with the intermolecular hydrogen bonding. However, there has been little systematic study of the intramolecular hydrogen bonding, primarily because of the complexity of the factors affecting the solvent sensitivity. In case of the intramolecular hydrogen bonding, the solvent shifts can be expected to be affected by the geometric effects as well as the electronic effects if the specific solvent-solute association is an important factor in determining the solvent shifts.

In this paper, the effects of solvents on the intramolecular OH···π and OH···O hydrogen bonding in 2-arylphenols (**1**—**7**) and 2,6-diarylphenols (**8**—**13**) are investigated by means of IR spectroscopy, and the solvent-solute association model is discussed through the geometric effects on the solvent sensitivity.

^{1}H NMR spectroscopy is also a powerful method for the study of the geometry for the solvent-solute association model. The aromatic solvent-induced shifts in the PMR spectra of Compound (**8**) are nicely explained in terms of the model derived from the IR study.

Results and Discussion

IR Spectra. In nonpolar solvents such as CCl_4, 2-arylphenols (**1**, **2**, **3**, **5**, and **7**) show the doublet νOH absorptions, corresponding to the free and the intramolecularly OH···π hydrogen bonded hydroxyl groups, while 2,6-diarylphenols (**8**—**13**) have only a singlet νOH due to the intramolecular OH···π hydrogen bonding. In addition to the observed doublet, the other 2-arylphenols (**4** and **6**) exhibit a broad third band centered at about 3450 cm^{-1}, indicating the presence of intramolecular OH···O hydrogen bonding. These assignments are based on the reported IR spectra of similar compounds.[7,8)] Some typical νOH absorption spectra are reproduced in Fig. 1.

Table 1 summarizes the intramolecularly OH···π and OH···O hydrogen-bonded OH stretching frequencies in the same set of solvents, together with the solvent constants. The OH···π and OH···O frequencies in the

vapor phase were estimated by interception at $G=0$ in the G correlations (see Fig. 2), according to the previously reported procedure.[2,4] The G value is the solvent constant empirically assigned to the solvent by Allerhand and Schleyer in order to explain the solvent sensitive IR bands.[2] The relative solvent shifts, $\Delta\nu/\nu$, of the νC=O of acetophenone are used as the reference value in the Bellamy-Hallam-Williams (BHW) plot.[9] The choice of solvents was limited to inert solvents which can not act as proton acceptors, because the proton acceptor solvents produce intermolecular hydrogen bonding.[10,11]

It is found from Table 1 that the frequencies of the hydrogen bonded bands, νOH···π and νOH···O, are fairly sensitive to the change of solvent. These solvent shifts correlate linearly with both the G and $\Delta\nu/\nu$ values. Figures 2 and 3 show the G correlation and the BHW plot respectively. The success of both correlations suggests that the operation of the solvation mechanism in the OH···π bonded system is similar to that in the

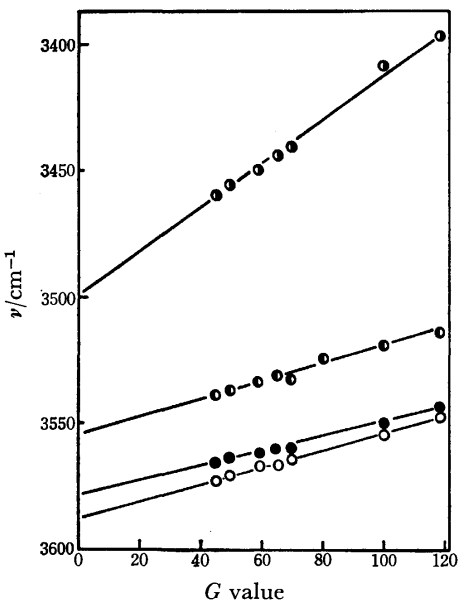

Fig. 2. Correlation of the OH stretching frequencies of OH···π and OH···O hydrogen bonds with the G values of the solvents.

carbonyl group[12] and that the solvent shifts are mainly produced by a specific solvent-solute association rather than by general dielectric effects, because (1) Bellamy *et al.* showed that the solvent dependency of the νC=O frequency is primarily due to a specific solvent-solute association,[9] and (2) the G value does not fit the KBM, Pullin, and Buckingham equations based on the dielectric theory.[2]

As can be seen from Figs. 2 and 3, the slopes in both correlations vary widely from compound to compound. It is known that the slope of the G correlation (a)[2] and the reciprocal slope of the BHW plot ($1/S$)[13] become direct measures of the solvent sensitivity.

Table 2 lists the a and $1/S$ values, the IR spectral data, and the dihedral angle between the phenol ring and the proton acceptor ring. In the IR data, both A_i/A_f and $\Delta\nu_{max}$ can indicate the strength of the hydrogen bonding in 2-arylphenols.[14] With 2,6-diarylphenols without a free hydroxyl group, both A_i and $\nu_{i\,max}$ are adopted as a measure of the strength of the OH···π bonding.[15] The dihedral angle was roughly estimated from the K-band maxima of these compounds in heptane in the UV spectra, according to the established method.[8,16] From the data in Table 2, the strength of the OH···π hydrogen bonding is found to increase with the increase in the dihedral angle. This trend is consistent with those reported by Ōki and Iwamura,[8] who studied the steric effects on the OH···π hydrogen bonding in 2-arylphenols.

For the intermolecular hydrogen bonding, Yoshida *et al.*[4] reported the parallelism between the $1/S$ value and the strength of the hydrogen bonding. This fact is consistent with the dipolar association theory, in which the bond dipole of the solvent associates with the lone pair dipole of the hydrogen bonded system, because the lone pair dipole increases with the strength of the hydrogen bonding.

In case of the OH···π hydrogen bonding, the component of the dipole electric field is in the $\overset{\delta-}{\text{O}}\text{H}\overset{\delta+}{\leftarrow}\pi$ direction, because the charge-transfer plays an important role in this hydrogen bonded system.[17] Furthermore, the oxygen lone pair dipole on the OH group reinforces the component of the dipole due to the charge-transfer. Therefore, the dipolar association theory can also be applied to the intramolecular OH···π hydrogen bonding now being studied, as with the ordinary hydrogen bonding.

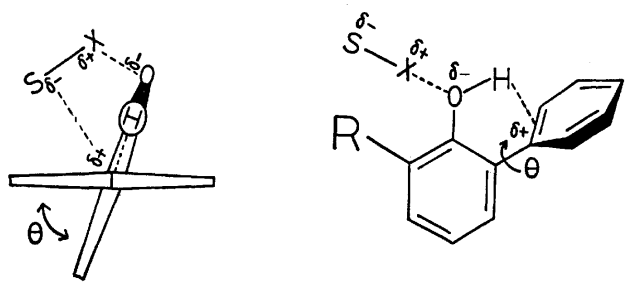
In contrast to Yoshida's result, it is clear from Table 2 that the proportional correlation between the solvent sensitivity and the strength of the OH···π bonding does not hold in this case; rather, both the a and $1/S$ values seem to be inversely proportional to the A_i, A_i/A_f, ν_i, and $\Delta\nu$ values. However, it seems that our

observation can be reconciled with Yoshida's dipolar association theory by considering the difference between inter- and intramolecular hydrogen bonded system.

For the intermolecular hydrogen bonding, such electronic effects as the strength of the hydrogen bonding are important factors in the dipolar association. On the other hand, for the intramolecular hydrogen bonding, the steric effects on the dipolar association seem to play a larger part than the electronic effects,[18] since the OH···π bonded system is fixed in the same molecule by the molecular geometry. Therefore, the lack of the correlation proposed by Yoshida *et al.* can be interpreted by assuming that the steric effects are so great that the electronic effects are masked.

By comparing the solvent sensitivity for the compound pairs of **1** and **7**, **8** and **10**, and **9** and **11**, it is noted that the nitrophenols (**7**, **10**, and **11**) show a and $1/S$ values larger than those for the corresponding phenols without the nitro group (**1**, **8**, and **9**) (see Table 2). The electron withdrawing nitro substituent produces a stronger OH···π hydrogen bonding, but does not greatly alter the stereochemical environment around the dipole of the OH···π bonded system. For these pairs of compounds, therefore, only the electronic effects can be operative in determining the solvent sensitivity. This result supports the dipolar association theory.

In order to investigate the steric effects on the dipolar association, both a and $1/S$ values are compared with the structural changes over a group of phenols. As can be seen from Table 2, both a and $1/S$ values appear to decrease with an increase in the dihedral angle; the observed order in the solvent sensitivity for the similar structural class is as follows; **7**>**1**>**2**>**3**, **4**>**5**, **8**>**9**, **10**>**11**, **10**≃**12**≃**13**. This suggests that the solvent sensi tivity is greatly affected by the steric factors, and supports the specific dipolar association mechanism in solvation to the OH···π bonded system.



geometry (I) R=H or aryl. geometry (II)

Fig. 4. Schematic representation of the dipolar association between the bond dipole of the solvent and the dipole of the OH···π bonded system. S–X; solvent, θ; dihedral angle.

From the dihedral angular dependence of the solvent sensitivity, we propose a simplified model with the geometry (I) for the dipolar association between the dipole of the OH···π bonded system (involving the lone pair dipole) and the bond dipole of the solvent molecule, as is shown in Fig. 4. This model is based on a specific 1:1 solvent-solute interaction. The geometry (I) indicates that the approach of the bond dipole of the solvent to the dipole of the OH···π bonded system is made difficult by the larger dihedral angle, since the steric repulsion between the solvent molecule and the proton acceptor ring becomes more severe with an increase in the dihedral angle.

As another model, the geometry (II), in which the positive end of the dipole of the solvent associates with negative end of the dipole (the lone pair electrons) of the OH···π bonded system, is also shown in Fig. 4. In this model, however, there are no steric effects on the solvent-solute association, and so Yoshida's correlation should be held throughout all the phenols studied here. It seems that this model is significant only in a protic solvent[19] because of the formation of hydrogen bonding.

In the competitive intramolecular hydrogen bond formation between the OH···π and OH···O systems in **4** and **6**, the latter system shows a remarkably large solvent sensitivity. The OH···O hydrogen bonding in the biphenyl skeleton is possible only in either a planar or nearly planar conformation,[7b] while the OH···π hydrogen bonding is favored for the conformation in which the dihedral angle becomes larger.[8] For example, 2-arylphenol (**5**), with a nearly perpendicular conformation, shows no OH···O bonding, but a strong OH···π interaction (see Table 2). Furthermore, in general, the strength of the OH···O bonding is greater than that of the OH···π bonding (see Table 2). Therefore, the trend in the observed solvent sensitivity can be interpreted in terms of both electronic and dihedral angular effects, supporting the model with the geometry (I).

Another steric factor which can affect the solvent sensitivity is the presence of alkyl substituents in the proton acceptor ring. In addition to the dihedral angular effects, an *ortho* methyl group in the proton acceptor ring also hinders the bond dipole of the solvent from approaching the dipole of the OH···π bonded system, as is anticipated from the geometry (I). Furthermore, the introduction of the alkyl group to the *para* position of the proton acceptor ring (**12** and **13**) produces little variation in the solvent sensitivity (see Table 2). If the dipolar association exists in the geometry (II), the dipolar association will be made difficult by the presence of the *para* alkyl group, because the *para* alkyl group on the opposite side of the OH···π bond is expected to hinder the approach of the solvent molecule (the positive end of the dipole) to the lone pair electrons on the oxygen atom (the negative end of the dipole). Therefore, the absence of any effects of the *para* alkyl group on the solvent sensitivity agrees with the geometry (I), because the alkyl group at the *para* position is well removed from the site of the dipolar association.

PMR Spectra. The chemical shifts (δ) of the PMR spectra of 2,6-diphenylphenol (**8**) in CCl_4, in benzene-d_6, and hexafluorobenzene and the solvent shifts ($\Delta\delta=\delta_{CCl_4}-\delta_{C_6D_6 \text{ or } C_6F_6}$) are given in Table 3. For comparison, this Table also includes the IR frequency shifts in these solvents. Compound (**8**) with a single polar site was selected for this study, because the aromatic solvent-induced shifts (ASIS) become more complex for a compound with multiple polar sites.[21] The observed ASIS are due to the dipolar association of the aromatic solvent with the OH···π bonded system,

Table 3. Proton chemical shifts (δ) and OH stretching frequencies (νOH) in CCl_4, C_6D_6, and C_6F_6 and solvent shifts ($\Delta\delta$ and $\Delta\nu$OH) of 2,6-diphenylphenol

Proton chemical shifts (ppm)			
	OH proton

a) Estimated from the δ value of the strongest peak.

not to the intermolecular OH···π bond formation,[22] since these IR shifts follow a common pattern obtained for other inert solvents studied here (see Figs. 2 and 3).

It is known[24] that the direction of the ASIS with C_6D_6 is opposed to that with C_6F_6. As may be seen in Table 3, however, both C_6D_6 and C_6F_6 produced more complex ASIS results. This seeming anomaly can be interpreted by assuming the asymmetric deformation of the geometry for the dipolar association caused by the steric requirement. In order to explain these ASIS results, the schematic representation of the dipolar association between the bond dipole of C_6D_6 and of C_6F_6 solvent molecules and the dipole of the OH···π bonded system is shown in Fig. 5; the direction of the bond dipole of the $\overset{\delta-}{C}\leftarrow\overset{\delta+}{D}$ bond in C_6D_6 shows a sign opposite to that of the $\overset{\delta+}{C}\rightarrow\overset{\delta-}{F}$ in C_6F_6.[24a]

In C_6D_6 solvent, a slight downfield shift for the OH proton and an upfield shift for the ring protons at the 2,6-positions of the phenol are observed. As is shown in model A, the π-electron cloud on the C_6D_6 molecule, which is attracted by the dipolar association, will be repelled by the π-electron cloud on the proton acceptor ring, thus increasing the angle, θ, between the dipole of the OH···π bonded system and the bond dipole of the overlying C_6D_6 solvent molecule. The large angle should cause a large remove of the OH proton from the center of the C_6D_6 molecule, so that the OH proton may be expected to lie near the edge of the aromatic shielding cone or the weak deshielding region of the C_6D_6 molecule. As another possible source of the ASIS effects, the charge polarization and variation in the bond order for the OH bond arising from a change in the solvent must be considered. On passing from CCl_4 to C_6H_6, the OH stretching frequency falls by 6.4 cm^{-1} (see Table 3). This electronic effect will cause the downfield ASIS of the OH proton. Thus, the slight deshielding of the OH proton in C_6D_6 can be explained in terms of the combination of the ring current and electronic effects. Furthermore, the upfield shifts for the ring protons must be considered in the same model. When the C_6D_6 solvent molecule approaches the proton acceptor ring (hereafter abbreviated as Ring I) with the positive end of the dipole, the other ring (hereafter Ring II) will be further removed from the same C_6D_6 solvent molecule. Therefore, the protons on Ring I will be strongly shielded, and those on Ring II, weakly deshielded. As the average ASIS effect, therefore, the upfield shift was observed in C_6D_6 solvent, supporting the model A.[25]

On the other hand, C_6F_6 gives a downfield shift in the OH proton and little variation in the ASIS of the ring protons. It is possible to expect the approach of the fluorine of the C_6F_6 periphery to the positive end of the dipole of the OH···π bonded system, since the van der Waals radius for fluorine (1.35 Å) is almost equal to that for hydrogen (1.2 Å). As is to be anticipated from the model B, the OH proton will be in the deshielding region of the C_6F_6 ring, in spite of the repulsion of the π-electron cloud on the C_6F_6 solvent molecule and the oxygen lone pair electrons. Accordingly, the OH proton should have a downfield shift, although the OH stretching frequency rises by 3.6 cm^{-1}. At the same time, this model shows that the protons on Ring I and II are in the deshielding and shielding region of the C_6F_6 solvent molecule respectively, since the C_6F_6 could be situated along the dipole of the OH···π bonded system. These ASIS, therefore, should cancel each other. In short, the direction of the ASIS can be nicely explained in terms of the model B.

Consequently, it is found that these ASIS results support the model derived from the IR study.

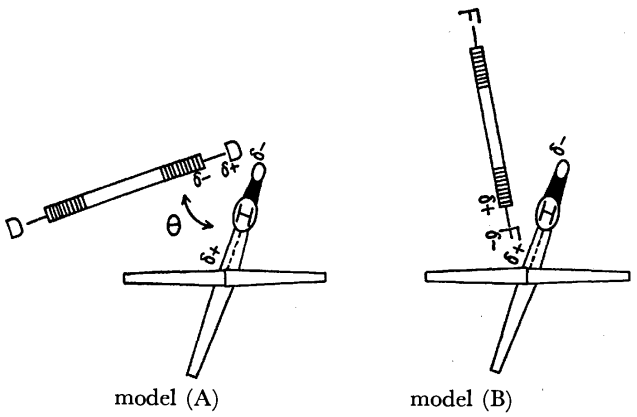

Fig. 5. Schematic representation of the dipolar association between the bond dipole of benzene and of hexafluorobenzene and the dipole of the OH···π bonded system.

Experimental

Measurement of the Spectra. The infrared spectra were recorded on a JASCO DS-701G grating spectrometer. The spectral slit width under high resolution conditions was 2 cm^{-1} in the region 3200—3700 cm^{-1}. Sodium chloride cells of 1 and 2 mm thicknesses were used. The concentration of phenols was about 5×10^{-3} M. The frequencies were calibrated by the standard absorption line of water vapor (3568.5 and 3447.2 cm^{-1}). The precision of the measure-

ments on νOH was about 2 cm^{-1} for the OH···π band and about 5 cm^{-1} for the broader OH···O band. All the measurements were carried out at 35 °C. Proton chemical shifts were measured on a JEOL PS-100 spectrometer operating at 100 MHz by using TMS as the internal standard at normal probe temperatures (*ca.* 35 °C). Frequency calibration was provided by the use of standard side-band techniques employing an audio-frequency counter. The measured relative chemical shifts are believed accurate to ±0.1 Hz. The ultraviolet absorption was obtained with a Hitachi 124 automatic recording spectrophtometer in 1.0 cm quartz cells at room temperature. The concentration of the samples in heptane was 10^{-5}—10^{-4} M.

Materials. Most of the solvents for spectra measurements were spectro-grade solvents and were used without further purification. Bromoform and decalin were purified by known methods.[27] Compound (**1**) was a commercial sample, recrystallized before use. Compounds (**2**),[8] (**3**),[8] (**4**),[28] (**5**),[29] (**6**),[28] (**7**),[7a] and (**12**)[30] were prepared according to the published procedures. Compounds (**8**)—(**11**) were prepared earlier.[10]

Preparation of ***13***. To a mixture of *t*-butyl chloride (4.3 g, 46.5 mmol) and **10** (2 g, 6.9 mmol) was added powered aluminium chloride (0.4 g, 3 mmol) at 40 °C. The mixture was then stirred for 5 h. A subsequent in the usual way gave a brown solid which was chromatographed on silica gel; elution with benzene–hexane (5: 1) afforded **13** (1.4 g, 52%). Recrystallization from benzene–hexane gave yellow plates; mp 162—164 °C. Found: C, 77.49; H, 7.29; N, 3.50%. Calcd for $C_{26}H_{29}O_3N$: C, 77.39; H, 7.24; N, 3.47%.

The author is indebted to Professor Emeritus Toshio Kinugasa of Kobe University for his valuable advice.

The Reactions of 2-Arylacetylene-1-sulfonamides with Heterocumulenes

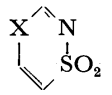
Kiyoshi HASEGAWA, Syuzi HIROOKA, Hiroshi KAWAHARA, Akihiko NAKAYAMA, Keiichi ISHIKAWA, Nobuyuki TAKEDA, and Hisakatsu MUKAI

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka-shi 933

(Received October 12, 1977)

The syntheses of new heterocyclic compounds by the reaction of 2-arylacetylene-1-sulfonamides **1**, (*Z*)-β-bromo- **12** or (*Z*)-α-chloro-β-styrenesulfonamides **13** with heterocumulenes are described. Weak base treatment of ureas $R^1C_6H_4C{\equiv}CSO_2NHC(=O)NHR^2$ prepared from **1** and isocyanates gave 2-amino-6-aryl-1,4,3-oxathiazine 4,4-dioxides, whereas strong base treatment of the ureas afforded 3-oxo-4,5-diphenyl-2,3-dihydro-1,2,4-thiadiazine 1,1-dioxides where R^2 is a phenyl group. The thiadiazines were also prepared by the strong base treatment of *N*-((*Z*)-α-bromo- or (*Z*)-β-chlorostyrylsulfonyl)-*N'*-phenylureas. The reaction of **1**, **12**, or **13** with isothiocyanates in the presence of weak base gave 3-amino-5-aryl-1,4,2-dithiazine 1,1-dioxides, but the major products produced were 3-amino-5-benzylidene-1,4,2-dithiazole 1,1-dioxides when **12a** was treated with isothiocyanates in the presence of strong base. The reaction of **1** with carbon disulfide and dimethyl sulfate in the presence of 5 M NaOH afforded 3-methylthio-5-benzylidene-1,4,2-dithiazole 1,1-dioxide with a small amount of 3-methylthio-5-aryl-1,4,2-dithiazine 1,1-dioxide. A mixture of both isomers was also prepared from **12a**. Possible mechanisms for the formation of the heterocycles from **1**, **12**, or **13** are suggested.

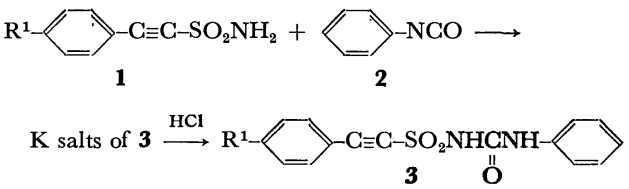
The syntheses of 5,6-dihydro-1,4,2-dithiazine 1,1-dioxide and 5,6-dihydro-1,2,4-thiadiazine 1,1-dioxide rings from β-styrenesulfonamides have been reported.[1-3] The synthesis of hitherto unknown 5,6-unsaturated heterocyclic systems is reported here. Since triple bonds are more susceptible to nucleophilic attack than double bonds,[4] reactions of 2-arylacetylene-1-sulfonamides **1**[5] with heterocumulenes such as isocyanate, isothiocyanate and carbon disulfide were investigated. This paper describes the syntheses of new 1,4,3-oxathiazine 4,4-dioxide, 2,3-dihydro-1,2,4-thiadiazine 1,1-dioxide, 1,4,2-dithiazine 1,1-dioxide and 1,4,2-dithiazole 1,1-dioxide derivatives. These heterocycles were also prepared from (*Z*)-β-bromo- **12**[5] and (*Z*)-α-chloro-β-styrenesulfonamides **13**.[5]



X=O, S

Results and Discussion

Reaction of the Sulfonamides with Isocyanates. A mixture of **1**, phenyl isocyanate **2** and K_2CO_3 in acetone was stirred for 30 min at 0—5 °C. Analytically pure potassium salts of *N*-(arylethynylsulfonyl)-*N'*-phenylureas **3** subsequently separated out. As the salts were immediately cyclized to 2-phenylamino-6-aryl-1,4,3-oxathiazine 4,4-dioxides **6** when dissolved in water,



the sulfonylureas **3** were prepared by suspending the salts in aqueous 9 M HCl. All of the ureas **3** thus

TABLE 1. LIST OF THE UREAS **3**, **11**, **14**, AND **15**, AND THE THIOUREA **19**

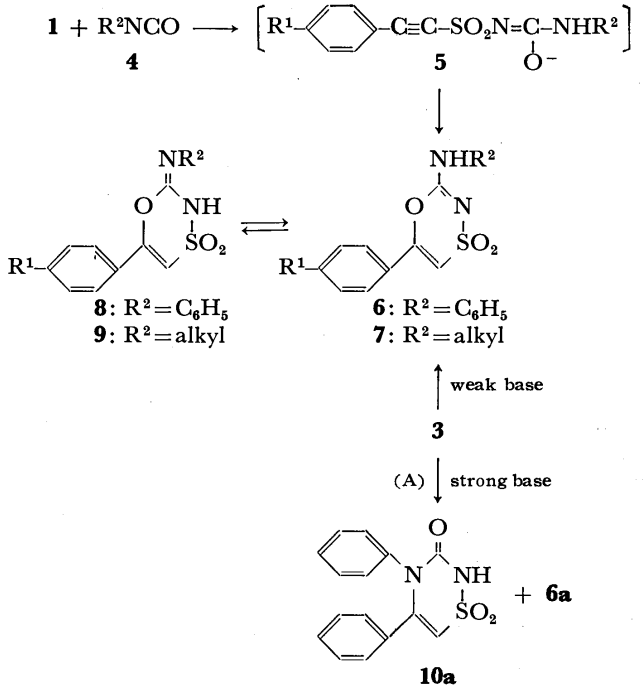
obtained was analytically pure. Recrystallization was not attempted because of ready cyclization to **6**. The results are summarized in Table 1. The IR spectra of **3a**—**d** displayed absorption bands at 1670—1680 (C=O) and 2185—2195 (C≡C) cm^{-1}. The NMR and mass spectra were identical with those of **6a**—**d**.

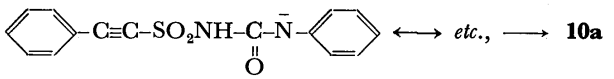
1 reacted with alkyl isocyanates **4** to give only 2-alkylamino-6-aryl-1,4,3-oxathiazine 4,4-dioxides **7** as shown in Scheme 1.



Scheme 1.

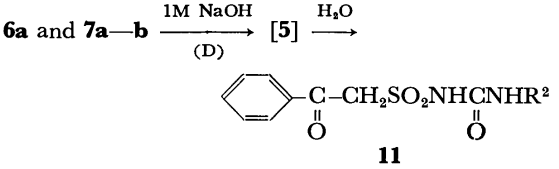
Treatment of **3a**—**d** with weak base (0.01—0.1 M K_2CO_3) gave a mixture of **6a**—**d** and their "imino" isomers **8a**—**c** (Table 2). Although "imino" isomers **9** were not isolated, the equilibrium between **7** and **9** (about 3: 1) in DMSO-d_6 was established by estimating the peak areas of the doublet due to NH**CH**$_3$ protons (δ=2.77, J=4.0 Hz) and the singlet due to NCH$_3$ protons (δ=2.76) in the NMR spectra of **7a**, **7d**, and **7e**.

Treatment of **3a** with strong base (1 M NaOH) at 45—50 °C for 4 h afforded a 96: 4 mixture of 3-oxo-4,5-diphenyl-2,3-dihydro-1,2,4-thiadiazine 1,1-dioxide **10a** and **6a**. **10a** was purified by fractional recrystallization (path A in Table 2). Aqueous 1 M NaOH has sufficient basicity to abstract a N'-proton from **3** and the resulting amide ion stabilized by a phenyl group seems to be responsible for the thiadiazine formation. The struc-

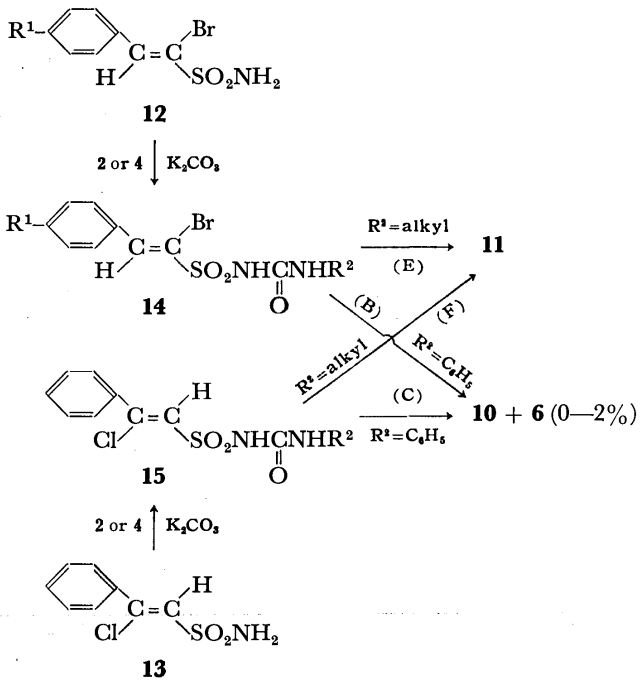


tures of **6**—**8** and **10a** were assigned on the basis of analytical and spectral data. The IR spectra of **6** and **7** showed C=N absorption bands adjacent to a SO_2 group at a lower frequency (1640 cm^{-1}) than those of **8** (1680 cm^{-1}). The IR spectrum of **10a** displayed absorption bands at 1680 (C=O) and 3080 (NH) cm^{-1}. These values are similar to the frequencies reported for 3-oxo-4-alkyl-5-aryl-2,3,5,6-tetrahydro-1,2,4-thiadiazine 1,1-dioxides.[3] The mass spectra of the oxathiazines **6**, **7** and **8** and **10a** showed fragment peaks assigned to $R^1C_6H_4CO^+$ and $C_6H_5CN^+C_6H_5$, respectively. The NMR spectra of **6**—**8** and **10a** displayed singlet CH signals in the region described in Table 2.

Strong base treatment of **6a** and **7a**—**b** gave N'-substituted N-(benzoylmethylsulfonyl)ureas **11** (path D in Table 1). A possible driving force for C–O fission is the abstraction of a vinyl proton on C_5 activated by an adjacent sulfonyl group.



The thiadiazines **10** were also prepared from **14** (path B) or **15** (path C) under reaction conditions similar to those described in path A. **11** was prepared when R^2 groups in **14** and **15** are alkyls. The paths are illustrated in Scheme 2 and the results summarized in Tables 1 and



Scheme 2.

2. Two mechanisms for the formation of **10** are conceivable: (a) dehydrohalogenation followed by addition, or (b) addition followed by dehydrohalogenation. The mechanisms are similar to those suggested in the cyclization of N-(α-bromostyrylsulfonyl)amidines.[6] The reaction of **7a**, **14**, or **15** with 1 M NaOH proceeds slowly even at 10—20 °C, but attempts to detect and isolate the intermediates by IR and high-speed liquid chromatography were unsuccessful. At present it has not been established whether the reactions in paths B, C, E, and F involve the mechanism (a) or (b). N-(Styrylsulfonyl)-N'-alkyl(or phenyl)ureas[7] gave no cycloadducts as compared with ready cyclization of **3**, **14**, and **15**.

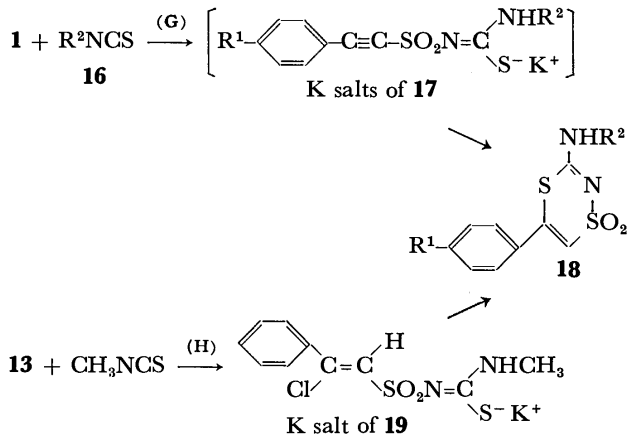
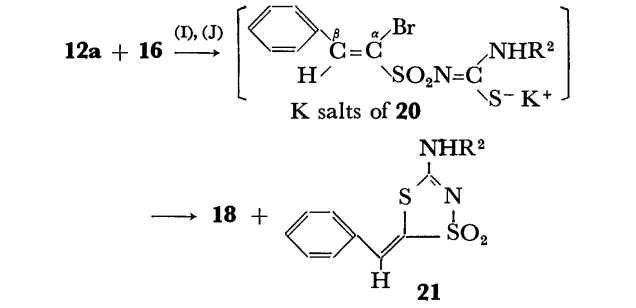
a) The NMR spectra could not be measured on account of the low solubility in usual solvent. b) Yield after recrystallization. c) The NMR spectra could not be measured on account of insufficient material. d) The CH proton is ambiguous because of overlapping with multiplet of phenyl protons. e) Dihydrate. f) Yield of a mixture of **25** and **26**, respectively.

Reaction of the Sulfonamides with Isothiocyanates. The reaction of **1**, isothiocyanates **16** and K_2CO_3 in acetone at 50—55 °C gave 3-alkylamino(or anilino)-5-aryl-1,4,2-dithiazine 1,1-dioxides **18**, which are the Michael cycloadducts of intermediate potassium salts of *N'*-substituted *N*-(arylethynylsulfonyl)thioureas **17** (path G). In contrast to the reaction of β-styrenesulfonamides



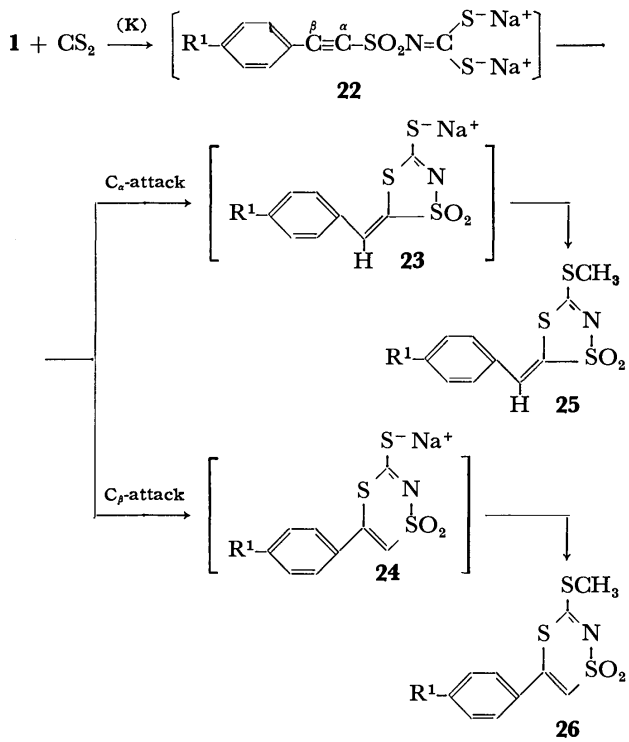
with **16**,[1] the potassium salts of **17** could not be isolated since they were soluble in warm acetone and their triple bonds were more susceptible to nucleophilic attack than their double bonds. Aqueous 5 M NaOH may be used in place of K_2CO_3.

The dithiazine **18a** ($R^2=CH_3$) was also prepared by the reaction of **13** with methyl isothiocyanate (path H) under conditions similar to those described for path G. The results are summarized in Table 2. The intermediate potassium salt of *N*-((*Z*)-β-chlorostyrylsulfonyl)-*N'*-methylthiourea **19** was isolated under ambient conditions (Table 1). The IR spectra of **18** showed typical C=N bands attached to a SO_2 group at 1570—1590 cm^{-1}. In the NMR spectra of **18**, a methine proton peak appeared as a singlet (Table 2). The mass spectra of **18** displayed fragment peaks assigned to $R^1C_6H_4CS^+$ and $R^1C_6H_4C(S)=CH^+$. The reaction of **12a** ($R^1=H$) with **16** in acetone in the presence of K_2CO_3 gave **18** along with small amounts of 3-alkylamino-5-benzylidene-1,4,2-dithiazole 1,1-dioxide **21** (path I in Table 2). The content ratios(%) of **18** were as follows: $R^2=CH_3$(96), C_2H_5(97), and C_6H_5(82).



Potassium carbonate is not sufficiently basic to eliminate HX from **12**—**15**, thus the formation of **18** from **19** and **20** may proceed by the Michael addition followed by dehydrohalogenation. A similar reaction carried out in DMF in the presence of 10 M NaOH gave **21** along with small amount of **18** (path J). The content ratios(%) of **21** were as follows: $R^2=CH_3$(96), C_2H_5(97), and C_6H_5(96). The formation of **21** by path J may be explained in terms of S_N attack of a thiolate anion on the C_α atom, and this is favored under strongly basic conditions. **18** and **21** were purified by fractional recrystallization of the crude products of paths I and J, respectively. The structure of **21** was determined by means of the IR (1620 cm^{-1} for C=N), NMR (δ: *ca.* 7.65 for CH), UV and mass spectra, and also by elemental analysis (Table 2). All mass spectra of **21** displayed peaks due to $C_6H_5CH=CS^+$ but no peaks due to $C_6H_5CS^+$.

Reaction of the Sulfonamides with Carbon Disulfide. The reaction of **1** with CS_2 in the presence of 5 M NaOH at 0—3 °C and subsequent methylation yielded 3-methylthio-5-benzylidene-1,4,2-dithiazole 1,1-dioxide **25** in low yield together with a small amount of 3-methylthio-5-aryl-1,4,2-dithiazine 1,1-dioxide **26** (path K). Possible mechanisms for the formation of **25** and **26** are shown in Scheme 3. The content ratios of **25** and

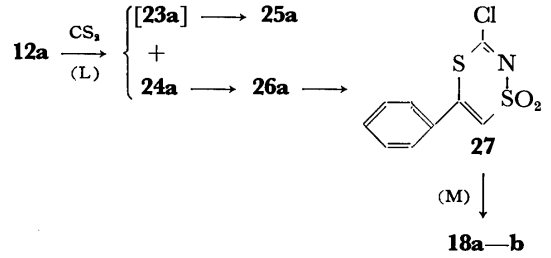


Scheme 3.

26 in the crude products were determined by evaluating the peak areas of the methyl protons and the results are as follows: R^1, yield % (ratio % of **25**)=H, 9(94), Cl, 31(92), and CH_3, 16(70). **25** was purified by fractional recrystallization of the crude products (Table 2), but **26** could not be purified.

The sulfonamide **12a** was reacted with CS_2 and dimethyl sulfate by a procedure similar to path K to give a 44: 56 mixture of **25a** and **26a** (91% yield). The mixture could not be separated into **25a** and **26a**, so intermediate **24a** was isolated and converted into **26a** by methylation (path L).

Chlorination of **26a** gave the 3-chloro derivative **27**



which was treated with amines to afford **18a** and **18b** (path M). The structure of **26a** was determined by the presence of $C_6H_5CS^+$ in the mass spectrum and also by the synthetic pathway **26a**→**18a**—**b**. The spectral data of **25a** differed from those of **26a** and **25a** displayed no peak due to $C_6H_5CS^+$.

3-Substituted 1,4,2-dithiazole 1,1-dioxide rings were previously prepared by the reaction of α-chloromethanesulfonamide with isothiocyanate or carbon disulfide.[9]

p-Substituent effect on the formation of **25** in path K was examined, but the results were not satisfactory as illustrated above (H≃Cl>CH_3). This may be due to low yield and formation of an unknown oily by-product. Further studies are required to clarify the mechanisms for paths K and L.

Experimental

The melting points were determined on a Yanagimoto micro melting-point measuring apparatus, MP-S2, and are uncorrected. The IR and UV spectra were recorded on a JASCO IRA-1 and Hitachi EPS-3T spectrometer, respectively. The NMR spectra were determined with a JEOL JNM-MH-100 spectrometer, with TMS as the internal standard and the mass spectra, with JEOL JNM-O1SG spectrometer. The high-speed liquid chromatographic (HLC) analysis was carried out using a JASCO FLC-150 apparatus equipped with a UV detector (254 nm) and a 0.5m×2.1 mm column packed with JASCO-DAC SV-02 (Solvent: methanol (20—50%)–water). Distribution of the isomers was determined by the results of NMR and HLC analyses. Spectral data are given only for a representative of each class.

N-(Arylethynylsulfonyl)-N'-phenylurea (3a). To a solution of **1a** (0.199 g, 0.0011 mol) in dry actone (3 ml) was added **2** (0.143 g, 0.0012 mol) and anhydrous K_2CO_3 (0.235 g, 0.0017 mol), and the mixture stirred for 30 min at 0—5° C. The resulting potassium salt of **3a** was filtered and suspended in aqueous 9 M HCl (5 ml). After standing for a night, the suspension was filtered to give 0.213 g (71%) of **3a** as analytically pure crystals: IR(KBr) 3340 (NH), 2180 (C≡C), 1620 (C=N), 1270 and 1140 (SO_2) cm^{-1}. *N,N'*-Diphenylurea (0.050 g) was obtained from the acetone filtrate, mp 238—239 °C (lit,[8] 235 °C).

2-Phenylamino-6-phenyl-1,4,3-oxathiazine 4,4-Dioxide (6a). When potassium salt of **3a** (0.102 g, 0.00030 mol) was dissolved in warm water (40—50 °C, 10 ml) or when **3a** (0.090 g, 0.00030 mol) was dissolved in warm aqueous 0.01—0.1 M K_2CO_3 (10 ml), **6a** began to separate out. After about 5 min, the reaction mixture was filtered to give 0.054 g (60%) of **6a**. The filtrate was acidified with conc HCl to afford 0.008 g (9%) of **8a**. Compound **6a** was recrystallized from CH_3OH and **8a** from CH_3OH–H_2O. When the reaction mixture was filtered after 12 h, 0.069 g (77%) of **6a** was obtained as shown in Table 2. **6a**: IR(KBr) 3260 (NH), 1640 (C=N), 1290 and 1160 (SO_2) cm^{-1}; NMR (DMSO-d_6) δ 7.20—7.70 (m, 10, $2C_6H_5$), 7.70 (s, 1, CH) and 7.96 ppm (broad, 1, NH); MS *m/e* 105 ($C_6H_5CO^+$), 118 (base peak, $C_6H_5C(O)=CH^+$), 236 (M^+-SO_2) and 300 (M^+). **8a**: IR (KBr) 3320 (NH), 1680 (C=N), 1330 and 1160 (SO_2) cm^{-1}. MS *m/e* 105 (base peak), 118, 236 and 300 (M^+). **8c** NMR (DMSO-d_6) δ 7.20—7.65 (m, 5, C_6H_5), 7.85—8.06 (dd, 4, C_6H_4), 8.10 (s, 1, CH) and 11.50 ppm (broad, 1, NH).

2-Methylamino-6-aryl-1,4,3-oxathiazine 4,4-Dioxides (7). To a solution of **1** (0.0010 mol) in acetone (4 ml) was added **4** (0.0011 mol) and anhydrous K_2CO_3 (0.0015 mol), and the solution stirred for 1 h at 20—25 °C. Oxathiazines **7a—c** were obtained by evaporation of the acetone filtrates, and **7d** and **7e**, which were almost insoluble in acetone, by filtration. **7e**: IR (KBr) 3300 (NH), 1650 (C=N), 1290 and 1130 (SO_2) cm^{-1}; NMR (DMSO-d_6) δ 2.76 (s, 0.7 H, $=NCH_3$), 2.77 (d, J_{NH-CH3}=4.0 Hz, 2.3H, CH_3), 7.60 (s, 1, CH), 7.72—7.78 (m, 4, C_6H_4), 8.40 (broad, 0.3H, SO_2NH) and 8.80 ppm (broad, 0.7H, NH); MS *m/e* 184±1 ($BrC_6H_4CO^+$), 197±1 (base peak, $BrC_6H_4C(O)=CH^+$), 253±1 (M^+-SO_2) and 317±1 (M^+).

3-Oxo-4,5-diphenyl-2,3-dihydro-1,2,4-thiadiazine 1,1-Dioxide (10a). *Path A*: A suspension of **3a** (0.060 g, 0.00020 mol) in aqueous 1M NaOH (2.0 ml, 0.0020 mol) was stirred at 45—50 °C for 4 h. The resulting clear solution was acidified with conc HCl to give 0.040 g of a 96: 4 mixture of **10a** and **6a**. Recrystallization of the crude mixture from benzene gave 0.024 g (40%) of **10a** and **6a** remained insoluble in warm benzene. **10a**: IR (KBr) 3080 (NH), 1680 (C=N), 1330 and 1160 (SO_2) cm^{-1}; NMR (DMSO-d_6) δ 6.85 (s, 1, CH), 7.12—7.30 (m, 10, $2C_6H_5$) and 8.60 ppm (broad, 1, NH), MS *m/e* 116, 145, 180 ($C_6H_5CN^+C_6H_5$), 193 (base peak, $C_6H_5C(NC_6H_5)=CH^+$), 236 (M^+-SO_2), 257 and 300 (M^+).

Path B: By using the way described in path A, 0.035 g (58%) of **10a** was obtained from **14d** (0.076 g, 0.00020 mol).

Path C: By using the way described in path A, 0.148 g (55%) of **10a** was obtained from **15d** (0.30 g, 0.00090 mol).

N-(Benzoylmethylsulfonyl)-N'-methylurea (11a). *Path D*: A solution of **7a** (0.238 g, 0.0010 mol) in aqueous 1M NaOH (10 ml, 0.0100 mol) was stirred at 50 °C for 4 h and acidified with conc HCl to give 0.217 g (85%) of **11a**. It was recrystallized from CH_3OH: IR (KBr) 3380 (NH), 1680 and 1660 (C=O), 1350 and 1160 (SO_2) cm^{-1}; NMR (DMSO-d_6)[10] δ 2.64 (d, J_{NH-CH3}=4.0 Hz, 3, CH_3), 5.20 (s, 2, CH_2), 6.35 (broad, 1, NH), 7.50—7.80 and 8.04—8.20 ppm (m, 5, C_6H_5), MS *m/e* 105 (base peak), 120, 131, 143, 174, 199, 225, and 238 (M^+-H_2O). The urea **11d** was obtained under the more drastic reaction conditions (20 equiv of 1M NaOH, 60—70 °C, 4h) because **6a** was almost insoluble in 10 equiv of 1M NaOH at 50 °C.

Path E: By using the way described in path D, 0.103 g (84%) of **11a** was obtained from **14a** (0.153 g, 0.00048 mol).

Path F: By using the way described in path D, 0.103 g (80%) of **11a** was obtained from **15a** (0.136 g, 0.00050 mol).

The ureas **11a** and **11d** were also prepared by stirring the acetone solution (3 ml) of benzoylmethanesulfonamide (0.0005 mol) with K_2CO_3 (0.00075 mol) and methyl and phenyl isocynate (0.00055 mol) for 2 h at 20—25 °C in 70 and 50% yields, respectively.

N-((Z)-α-Bromostyrylsulfonyl)-N'-methylurea (14a). To a solution of **12a** (0.40 g, 0.0015 mol) in dry acetone (4 ml) was added methyl isocynate (0.094 g, 0.00165 mol) and anhydrous K_2CO_3 (0.311 g, 0.00225 mol), and the mixture stirred for 2h at 55—60 °C. The resulting potassium salt was filtered and dissolved in water (20 ml). The solution was acidified with conc HCl to give 0.36 g (75%) of **14a**. An additional crop of **14a** (0.058 g, 12%) was obtained

from the acetone filtrate and recrystallized from CH_3OH: IR(KBr) 3360 (NH), 1660 (C=O), 1350 and 1160 (SO_2) cm^{-1}; NMR (DMSO-d_6)[10] δ 2.60 (d, J_{NH-CH3}=4.0Hz, 3, CH_3), 6.40 (broad, 1, NH), 7.48—7.60 and 7.80—7.96 (m, 5, C_6H_5) and 8.18 ppm (s, 1, CH); MS *m/e* 319±1 (M^+).

*N-((Z)-β-Chlorostyrylsulfonyl)-N'-methylurea (**15a**).* By using the way described in the synthesis of **14a**, 0.236 g (86%) of **15a** was obtained from the acetone filtrate of the reaction mixture of **13** (0.218 g, 0.0010 mol), methyl isocyanate (0.063 g, 0.0011 mol) and anhydrous K_2CO_3 (0.207 g, 0.0015 mol), and was recrystallized from CH_3OH–H_2O: IR (KBr) 3340 (NH), 1650 (C=O), 1340, 1175 and 1150 (SO_2) cm^{-1}; NMR (DMSO-d_6) δ 2.65 (d, J_{NH-CH3}=4.0 Hz, 3, CH_3), 3.90 (broad, 1, NH), 6.35 (broad, 1, SO_2NH), 7.30 (s, 1. CH) and 7.45—7.60 ppm (m, 5, C_6H_5); MS *m/e* 274±1 (M^+).

*3-Methylamino-5-phenyl-1,4,2-dithiazine 1,1-Dioxide (**18a**).* *path G*: To a solution of **1a** (3.0 g, 0.0165 mol) in acetone (23 ml) was added methyl isothiocyanate (1.33 g, 0.0182 mol) and anhydrous K_2CO_3 (3.42 g, 0.025 mol), and the mixture stirred for 3 h at 50—55 °C. The solution was filtered and the filtrate concentrated to dryness *in vacuo* to leave viscous oil. It was recrystallized three times from CH_3OH to give 1.47 g (35%) of **18a**: IR (KBr) 3240 (NH), 1590 and 1570 (C=N), 1280 and 1120 (SO_2) cm^{-1}; NMR (DMSO-d_6) δ 2.90 (s, 3, CH_3), 7.55 (s, 1, CH), 7.60 (s, 5, C_6H_5) and 9.50 ppm (broad, 1, NH): MS *m/e* 102, 121 ($C_6H_5CS^+$), 134 (base peak, $C_6H_5C(S)=CH^+$), 162, 190 (M^+–SO_2), and 254 (M^+).

Path H: By using the way described in path G, 0.085 g (34%) of **18a** was obtained from **13** (0.218 g, 0.0010 mol), methyl isothiocyanate (0.080 g, 0.0011 mol) and anhydrous K_2CO_3 (0.207 g, 0.0015 mol).

Path I: By using the way described in path G, 0.104 g (41%) of **18a** was obtained from **12a** (0.262 g, 0.0010 mol), methyl isothiocyanate (0.080 g, 0.0011 mol) and anhydrous K_2CO_3 (0.207 g, 0.0015 mol).

Path M: To a suspension of **27** (0.052 g, 0.00020 mol) in methanol (5 ml) was added 30% aqueous methylamine (0.21 g, 0.0020 mol), and the mixture stirred for 1 h at 50—55 °C. The clear solution was concentrated to dryness *in vacuo* to leave viscous oil. Water (2 ml) was added and the cooled precipitate was filtered to give 0.034 g (66%) of **18a**.

*3-Methylamino-5-benzylidene-1,4,2-dithiazole 1,1-Dioxide (**21a**).* *Path J*: To a solution of **12a** (0.262 g, 0.0010 mol) in DMF (2 ml) was added methyl isothiocyanate (0.080 g, 0.0011 mol) and aqueous 10 M NaOH (0.20 ml, 0.0020 mol), and the mixture stirred for 4h at 55—60 °C. Water (7 ml) was added to the solution and cooled precipitate filtered to afford 0.185 g of a 96: 4 mixture of **21a** and **18a**. It was recrystallized from CH_3OH to give 0.147 g (58%) of **21a**: IR (KBr) 3200 (NH), 1620 (C=N), 1290 and 1160 (SO_2) cm^{-1}; NMR (DMSO-d_6) δ 3.00 (s, 3, CH_3), 7.50 (s, 5, C_6H_5), 7.62 (s, 1, CH) and 9.50 ppm (broad, 1, NH); MS *m/e* 102, 108, 134 (base peak, $C_6H_5CH=CS^+$), 190 (M^+–SO_2) and 254 (M^+).

*3-Methylthio-5-benzylidene-1,4,2-dithiazole 1,1-Dioxide (**25a**).* *Path K*: To a solution of **1a** (0.72 g, 0.0040 mol) in DMF (4 ml) was added aqueous 5 M NaOH (1.60 ml, 0.0080 mol) and CS_2 (0.61 g, 0.0080 mol), and the mixture was stirred for 2 h at 0—3 °C. Dimethyl sulfate (0.55 g, 0.0044 mol) was then added to the red solution and the mixture stirred for 2 h at 0—3 °C. The resulting precipitate was filtered and washed with methanol to give 0.097 g (9%) of a 94: 6 mixture of **25a** and **26a**. It was recrystallized from CH_3OH to afford 0.078 g (7%) of **25a** as colorless columns: IR(KBr) 1510 (C=N), 1330 and 1160 (SO_2) 995, 960, 825 and 750 cm^{-1}; NMR (DMSO-d_6) δ 2.81 (s, 3, CH_3), 7.50—7.60 (m, 5, C_6H_5) and 7.87 ppm (s, 1, CH); MS *m/e* 102, 108, 134 (base peak, $C_6H_5CH=CS^+$), 207 (M^+–SO_2) and 271 (M^+).

*3-Methylthio-5-phenyl-1,4,2-dithiazine 1,1-Dioxide (**26a**).* *Path L*: To a solution of **12a** (1.00 g, 0.0038 mol) in DMF (8 ml) was added aqueous 10 M NaOH (0.76 ml, 0.0076 mol) and CS_2 (0.58 g, 0.0076 mol), and the mixture stirred for 2h at 15—20 °C. Evaporation of DMF *in vacuo* left a residue, which was recrystallized twice from aqueous 1M NaOH to give 0.50 g (42%) of **24a** as dihydrate: IR (KBr) 3550—3400 ($2H_2O$), 1350 and 1130 (SO_2) cm^{-1}; NMR (DMSO-d_6) δ 3.26 ($2H_2O$), 7.17 (s, 1, CH) and 7.54—7.58 ppm (m, 5, C_6H_5).

To a solution of **24a** (0.63 g, 0.0020 mol) in 2: 1 (v/v) CH_3OH–H_2O (10 ml) was added dimethyl sulfate (0.28 g, 0.0022 mol), and the mixture was stirred for 2h at 15—20 °C. The precipitate was filtered to give 0.43 g (80%) of **26a**. It was recrystallized from CH_3OH to give colorless needles: IR (KBr) 1510 (C=N), 1330 and 1150 (SO_2), 940 and 750 cm^{-1}; NMR (DMSO-d_6) δ 2.71 (s, 3, CH_3), 7.55–7.60 (m, 5, C_6H_5) and 7.83 (s, 1, CH); MS *m/e* 102 ,108, 121 ($C_6H_5CS^+$), 134 (base peak, $C_6H_5C(S)=CH^+$), 174, 198, 207 (M^+–SO_2) and 271 (M^+).

*3-Chloro-5-phenyl-1,4,2-dithiazine 1,1-Dioxide (**27**).* Excess chlorine was bubbled through a solution of **26a** (0.65 g, 0.0024 mol) in chloroform (10 ml) at 20—30 °C. The orange solution was concentrated to dryness *in vacuo* and the residue suspended in CCl_4 (5 ml). The mixture was filtered to give 0.33 g (53%) of **27** and recrystallized from CCl_4: IR (KBr) 1570 (C=N), 1330 and 1160 (SO_2) cm^{-1}; NMR (DMSO-d_6) δ 7.45—7.65 (m, 5, C_6H_5) and 7.90 ppm (s, 1, CH); MS *m/e* 102, 108, 121 ($C_6H_5CS^+$), 134 (base peak, $C_6H_5C(S)=CH^+$), 195 (M^+–SO_2) and 258 (M^+).

Photochemical Reactions of Aromatic Compunds. XXXI.[1] Exciplex Quenching by Pyridine, Methylated Pyridines, and Methylated Imidazoles and Termolecular Interaction in the Excited Singlet State

Tetsuro MAJIMA, Chyongjin PAC,* and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received October 24, 1977)

Pyridine, methylated pyridines, and methylated imidazoles quenched the exciplexes of aromatic nitrile–2,5-dimethylfuran or 2,5-dimethyl-2,4-hexadiene, and the rate constants for the exciplex quenching were obtained. The exciplex quenching by 2-methyl- and 2,6-dimethylpyridines was much less efficient than that by the other quenchers. The exciplex quenching was discussed in terms of the interaction of the n-orbital of the quenchers with the positive charge developed on the electron-donor side of the exciplexes. Curved Stern-Volmer plots were obtained in the quenching of aromatic nitrile fluorescence by 1-methylimidazole and/or 1,2-dimethylimidazole. On the basis of the kinetic results, the mechanism was discussed in terms of a termolecular interaction between excited singlet aromatic nitrile, the methylated imidazole as the π-donor, and the second one as the n-donor.

Exciplex formation has been recognized to be a general mechanistic pathway in fluorescence quenching[2,3] and has been suggested to precede photocycloadditions in a variety of reaction system.[4–6] We have also extensively investigated photocycloadditions of furan and olefinic compounds to aromatic nitriles, which have been suggested to occur *via* exciplexes.[7] In some exciplex-formation systems, the increase in the concentration of a precursor results in the formation of a termolecular excited complex (triplex), which arises from the interaction of a precursor with an exciplex.[8,9] This type of termolecular interaction can be considered to be rather general and has been suggested to be important in some photoreactions.[10] Caldwell and his co-workers reported a different type of termolecular interaction in the excited singlet state which occurs by means of the interaction of exciplexes with compounds which are not the precursors of the exciplexes and which possess either an electron-donor or an electron-acceptor nature.[11] In a previous paper,[12] we reported that pyridine quenches exciplexes which emit very weakly or which are not emissive at all. The exciplex quenching by pyridine provides a convenient method for establishing the existence of the exciplex intermediacy in our reaction systems. In the exciplex quenching, however, pyridine can act as either an n-donor or a π-acceptor, since it is weakly basic as well as π-deficient. In the present paper, we wish to report that pyridine, methylated pyridines, and methylated imidazoles quench the exciplexes of aromatic nitrile–2,5-dimethylfuran or 2,5-dimethyl-2,4-hexadiene by acting as n-donors, and that 1-methyl- and 1,2-dimethylimidazoles quench the fluorescence of aromatic nitriles by way of a termolecular process.

Results

Characteristics of Exciplexes. For exciplex-quenching experiments, we employed the exciplexes of 1- and 2-naphthonitriles (1- and 2-NN)–2,5-dimethylfuran (DF) and 9-cyanophenanthrene (9-CP)–2,5-dimethyl-2,4-hexadiene (DHD), since these exciplexes can be considered to be typical models of the supposed intermediates in our reaction systems and all are fairly emissive. Table 1 lists the lifetimes of the exciplexes in a benzene solution containing 0.3 mol dm^{-3} in DF or DHD, the exciplex emission maxima in benzene and ethyl acetate solutions containing 0.3 mol dm^{-3} in DF or DHD, the calculated dipole moments, and the apparent rate constants ($\gamma_0 k_e$) of the quenching of the aromatic nitrile fluorescence by DF or DHD.

Table 1. Characteristics of exciplexes

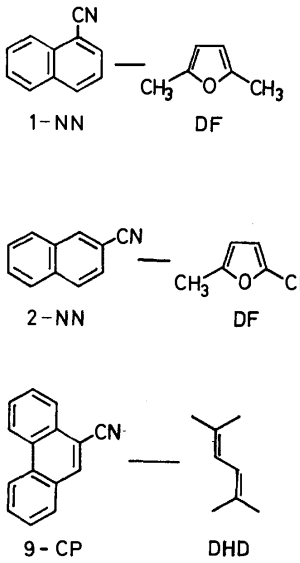
		Exciplex		
		1-NN–DF	2-NN–DF	9-CP–DHD
λ_{max}[a] (nm)	C_6H_6	435	413	440
	AcOEt	445	435	460
τ_{EX}[b] (ns)		32[c] (15)	28[c] (14)	21[d] (12)
Dipole moment[e] (D)		≈10	≈10	≈10
$\gamma_0 k_e$[f] (dm^3 mol^{-1} s^{-1}) $\times 10^{-9}$		8.1	2.6	8.1

a) Emission maxima of the exciplexes; 5×10^{-4} mol dm^{-3} in aromatic nitrile and 0.3 mol dm^{-3} in DF or DHD; ±2 nm. b) Lifetimes in degassed benzene; the numbers in parentheses are the lifetimes in air-saturated benzene; ±0.5 ns. c) Oxygen-quenching method. d) Determined by an N_2 laser-flash method. e) Calculated from the solvent shifts of the emission maxima. f) Apparent rate constants for the quenching of the aromatic nitrile fluorescence by DF or DHD.

The lifetime of the 9-CP–DHD exciplex was directly determined by monitoring the decay of the exciplex fluorescence at 440 nm using an N_2 laser. When the decay of the residual 9-CP fluorescence was monitored at 375 nm, two decays were observed; the lifetimes of the slow and rapid decay components were calculated to be 17 ns and less than 2 ns respectively. The slow-decay component apparently arises from the reversible dissociation of the exciplex into an excited singlet 9-CP and a ground-state DHD. However, the reversible dissociation can be considered to be not so significant, since the quenching of the 9-CP fluorescence by DHD occured at a diffusion-controlled rate. The lifetimes of

* To whom all correspondence should be addressed.

the 1-NN– and 2-NN–DF exciplexes were determined by the oxygen-quenching method proposed by Caldwell.[13]



These exciplexes are charge-transfer complexes in nature, as is shown by the dipole moment, which was obtained by a usual method using plots of the wave numbers of the emission maxima in various solvents *vs.* $[(\varepsilon-1)/(2\varepsilon-1)-(n^2-1)/2(2n^2-1)]$,[14] where ε and n represent the dielectric constant and the refractive index of the solvent respectively. The slopes of the plots are commonly $(10\pm1)\times10^3$ cm^{-1}, which corresponds to *ca.* 10 Debey units of the dipole moment. The 9-CP–DHD exciplex crosses over a $2\pi+2\pi$ cycloadduct,[7f] while the 1- and 2-NN–DF exciplexes do not result in the formation of any stable products at room temperature. The UV spectra showed no indication of the formation of charge-transfer complexes in the ground state.

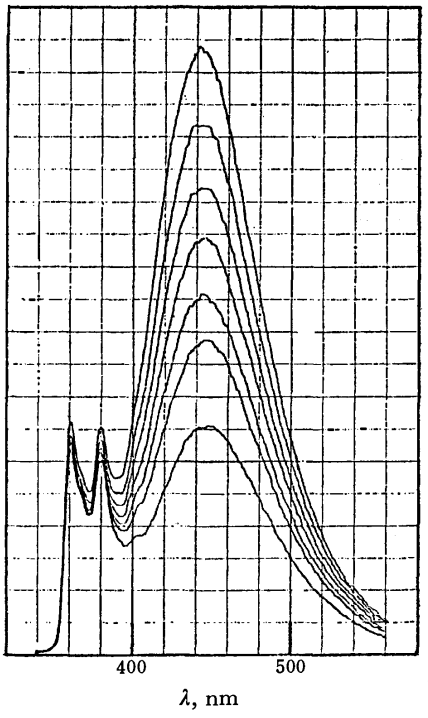


Fig. 1. Quenching of 9-CP–DHD exciplex by **1a** in deoxygenated benzene: $k_q\tau_{EX}=1.5$ dm^3 mol^{-1}.

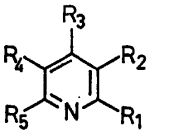
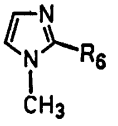
Exciplex Quenching by Pyridine and Imidazole Compounds. For the exciplex quenching, we used pyridine (**1a**), 2-, 3-, and 4-methylpyridines (**1b**, **1c**, and **1d**), 2,6- and 3,5-dimethylpyridines (**1e** and **1f**), 1-methylimidazole (**2a**), and 1,2-dimethylimidazole (**2b**) as quenchers. The exciplex-quenching experiments were carried out as usual. Figure 1, for example, shows the spectral change in the fluorescence from a benzene solution containing 5×10^{-4} mol dm^{-3} in 9-CP and 0.3 mol dm^{-3} in DHD on the addition of **1a**. The exciplex emission with the maximum at 440 nm was significantly quenched. The plot of the relative intensities at 440 nm in the absence of and in the presence of **1a** (I^0_{EX}/I^Q_{EX}) *vs.* the concentrations of **1a** gave a linear line, the slope of which was 1.5 dm^3 mol^{-1} (Fig. 4); the rate constant (k_q) of the exciplex quenching was calculated to be 7.1×10^7 dm^3 mol^{-1} s^{-1} by applying the slope to Eq. a, where τ_{EX} and Q represent the lifetimes of an exciplex and an exciplex quencher respectively. Similarly, the rate

$$I^0_{EX}/I^Q_{EX} = 1 + k_q\tau_{EX}[Q] \qquad (a)$$

constants of the quenching of the 1- and 2-NN–DF exciplexes by pyridine were calculated to be 3.5×10^8 and 2.6×10^8 dm^3 mol^{-1} s^{-1} respectively.





1a: $R_1=R_2=R_3=R_4=R_5=H$
1b: $R_1=CH_3$, $R_2=R_3=R_4=R_5=H$
1c: $R_2=CH_3$, $R_1=R_3=R_4=R_5=H$
1d: $R_3=CH_3$, $R_1=R_2=R_4=R_5=H$
1e: $R_1=R_5=CH_3$, $R_2=R_3=R_4=H$
1f: $R_2=R_4=CH_3$, $R_1=R_3=R_5=H$

2a: $R_6=H$
2b: $R_6=CH_3$

As is shown in Fig. 1, the residual 9-CP fluorescence at 360—380 nm was also slightly quenched by pyridine. Similarly, a slight quenching of the residual 1- and 2-NN fluorescence was also observed in the quenching of the 1- and 2-NN–DF exciplexes by pyridine. In contrast, the 2-NN or 9-CP fluorescence in the absence of DF or DHD was not quenched at all by pyridine, while the quenching of the 1-NN fluorescence by pyridine was relatively efficient, the rate constant being 3×10^8 dm^3 mol^{-1} s^{-1}. Therefore, the quenching of the residual 2-NN or 9-CP fluorescence can be ascribed to the decrease in the reversible dissociation of the exciplex because of the exciplex quenching. In the case of the 1-NN–DF exciplex, however, the slight quenching of the residual 1-NN fluorescence would be caused by either the exciplex quenching or the direct quenching of the excited singlet 1-NN by pyridine.

Table 2 lists the quenching constants ($k_q\tau^{air}_{EX}$) for each exciplex-quencher pair; they were obtained by the usual Stern-Volmer plots for air-saturated benzene and ethyl acetate solutions, using Eq. a but replacing τ_{EX} by τ^{air}_{EX}, the lifetime in air-saturated solutions. In order to avoid the quenching of excited-singlet aromatic

Table 2. Quenching of exciplex emission by exciplex quenchers[a)]

nitrile, the concentrations of the quenchers were kept as low as the quenching of excited-singlet aromatic nitrile, which was negligible except for the exciplex quenching by **1b** and **1e**. There was no indication of the formation of any charge-transfer complexes between A or D and Q in the ground state.

*Quenching of Aromatic Nitrile Fluorescence by **2a** and **2b**.* The fluorescence of 1- and 2-NN was quenched by **2a**. Interestingly, the Stern-Volmer plots were not linear (Fig. 2). In the fluorescence quenching, very weak exciplex emissions appeared, but no isoemissive points could be observed. The 9-CP fluorescence was not quenched by **2a** at all. The quenching of the 2-NN and 9-CP fluorescence by **2b** gave, again, slightly curved Stern-Volmer plots, while that of the 1-NN fluorescence was efficient and gave a linear Stern-Volmer plot (Fig. 3). In the latter quenching, a fairly strong exciplex emission with the maximum at 408 nm appeared without an isoemissive point; it revealed its maximum intensity at the concentration of 1.8×10^{-2} mol dm^{-3} of added **2b**. A further increase in the **2b** concentration

resulted in a decrease in the exciplex emission. Table 3 summarizes the relative intensities of 1-NN fluorescence at 340 nm (I_M^0/I_M^Q) and those of the exciplex emission at 408 nm ($\phi_{EX}/\phi_{EX}^{max}$), the atterl of which are corrected by subtracting the intensity of the 1-NN fluorescence at 408 nm from the total intensity at this wavelength. The curved Stern-Volmer plots could be caused by the formation of charge-transfer complexes in the ground state. However, UV measurements eliminated this posibility.

Discussion

Mechanism of Exciplex Quenching. Scheme 1 shows the reaction processes involving the exciplex formation and the quenching of the exciplex, where A, D, $[A^-D^+]^*$, and Q represent the aromatic nitriles, DF or DHD, the exciplexes, and the exciplex quenchers respectively. Processes 1 and 4 involve all the unimolecular physical

$$A \xrightarrow{h\nu} {}^1A^*$$

$${}^1A^* \xrightarrow{1/\tau_M} A + h\nu' \text{ (or heat)} \quad (1)$$

$${}^1A^* + Q \xrightarrow{k_q'} A + Q \quad (2)$$

$${}^1A^* + D \underset{k_{-e}}{\overset{k_e}{\rightleftharpoons}} [A^-D^+]^* \quad (3)$$

$$[A^-D^+]^* \xrightarrow{k_d} A + D + h\nu'' \text{ (or heat)} \quad (4)$$

$$[A^-D^+]^* \xrightarrow{k_p} \text{Product(s)} \quad (5)$$

$$[A^-D^+]^* + Q \xrightarrow{k_q} A + D + Q \quad (6)$$

Scheme 1.

decays of A and $[A^-D^+]^*$ respectively. Equations b and c are the Stern-Volmer equations for the quenching of the Nonomer (A) fluorescence by D in the absence of Q and of exciplex emission at a constant concentration of D (0.3 mol dm^{-3}) by Q respectively.

$$I_M^0/I_M^Q = 1 + \gamma_0 k_e \tau_M [D] \quad (b)$$

$$\gamma_0 = (k_d + k_p)/(k_{-e} + k_d + k_p) \approx 1$$

$$I_{EX}^0/I_{EX}^Q = \left(1 + \frac{k_q' \tau_M [Q]}{1 + k_e \tau_M [D]}\right)(1 + k_q \tau_{EX} [Q]) \quad (c)$$

The value of γ_0 is nearly unity, since the fluorescence of A was quenched by D at a diffusion-controlled rate *i.e.*, $k_{-e} \ll k_d + k_p$; the exciplexes are almost irreversibly formed. In the presence of 0.3 mol dm^{-3} in D, therefore, Eq. c can be reduced to Eq. a, since $1 \gg k_q' \tau_M [Q]/(1 + k_e \tau_M [D])$. The calculated k_q values for the quenching of the exciplexes by pyridine are one or two orders lower than the diffusion-controlled rate, showing that pyridine is an inefficient quencher for the exciplexes. Significantly, however, pyridine does not quench the 2-NN and 9-CP fluorescence at all; thus, it can be used as a selective quencher for the exciplexes involving nitriles.[12] The photocycloaddition of DHD to 9-CP[7f] was also quenched by pyridine; the Stern-Volmer plot gave the $k_q \tau_{EX}$ value of 1.95 ± 0.5 dm^3 mol^{-1}, which is very similar to that obtained from exciplex-emission-quenching experiments (Fig. 4). The results clearly

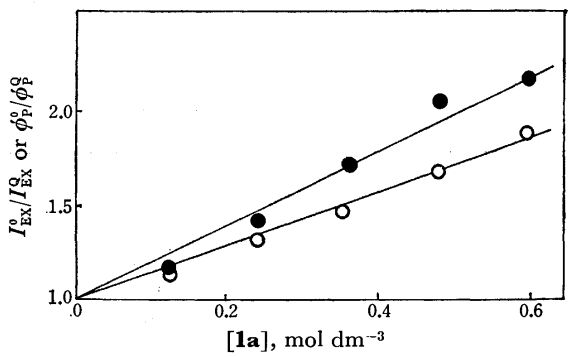

Fig. 4. Stern-Volmer plots for the quenching of 9-CP–DHD exciplex by **1a** in degassed benzene; fluorescence quenching (-○-) and product quenching (-●-) runs, [9-CP] = 5×10^{-4} mol dm^{-3} and [DHD] = 0.3 mol dm^{-3}.

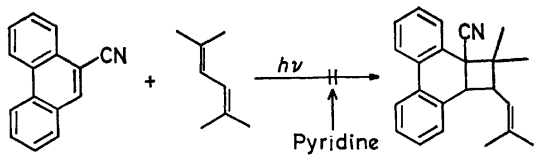
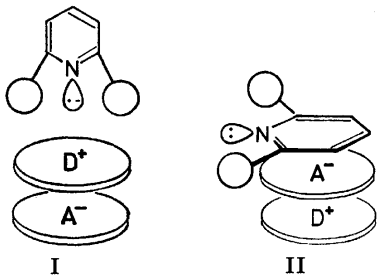
demonstrate the intermediacy of the exciplex in the photocycloaddition.



According to Caldwell's generalization of exciplex quenching,[11] an exciplex quencher possessing an electron-donor or electron-acceptor nature (Q_D or Q_A) interacts with an exciplex $[A^-D^+]^*$ on the D or A side *i.e.*, $A^{\delta-}\cdots D\cdots Q_D^{\delta+}$ or $Q_A^{\delta-}\cdots A\cdots D^{\delta+}$. This termolecular interaction results in exciplex quenching. Therefore, if pyridine acts as an n-donor in the exciplex quenching, the n-orbital of pyridine must perpendicularly approach to the molecular plane of the D side of exciplexes (I in Scheme 2). On the other hand, the pyridine which acts as a π-acceptor can interact with the A side of exciplexes with a sandwich type of configuration (II).



Scheme 2.

As is shown in Table 2, methyl substitution at the 2- and 2,6-positions of the pyridine ring commonly leads to a marked decrease in the quenching ability of the three exciplexes, while substitution at the other positions instead slightly enhances the quenching rate. The effect of the methyl groups at the 2- and 2,6-positions demonstrates the dominant n-donor character in the exciplex quenching. The methyl groups of **1b** and **1e** would sterically inhibit the approach of the n-orbital to the exciplexes within an effective distance for the

quenching. In the cases of the other methylated pyridines, such steric hindrance can not occur in the attack of the n-orbital on the exciplexes. Moreover, this mechanism is supported by the observation that the $k_q\tau_{EX}^{air}$ values increase with the increase in the base strength of the quenchers; methyl substitution in the pyridine ring enhances the base strength, and imidazole is much more strongly basic, but less π-defficient, than pyridine.[15] In line with this mechanism, **2a** is a much more efficient quencher than **1a**. Methyl substitution at the 2-position of the imidazole ring results, again, in a decrease in the quenching efficiency to some extent, though the steric effect is much smaller than that of the methyl group of **1b**; the difference in the steric effects can be easily predicted by molecular models. In conclusion, the exciplex quenching occurs by means of the attack of the n-orbital of the quenchers on the positive charge developed on the D side because of a high degree of charge-transfer contribution to the exciplexes. The ionic or charge-transfer nature of the exciplex quenching is supported by the observation that the $k_q\tau_{EX}^{air}$ values in ethyl acetate are greater than those in benzene.

Quenching of Aromatic Nitrile Fluorescence by 2a and 2b. The quenching of the 1- and 2-NN fluorescence by **2a** gave curved Stern-Volmer plots, which, it may be suggested, occur by way of a termolecular process involving the exciplexes of 1- and 2-NN–**2a**. The termolecular mechanism is further suggested by the observation that the emission of the 1-NN–**2b** exciplex increases up to the concentration of 1.8×10^{-2} mol dm^{-3} in **2b**, but decreases upon a further increase in the concentration of **2b**. In Scheme 3, therefore, the

$$A \xrightarrow{h\nu} {}^1A^* \tag{7}$$

$${}^1A^* \xrightarrow{1/\tau_M} A + h\nu' \text{ (or heat)} \tag{8}$$

$${}^1A^* + Q \underset{k_{-e}}{\overset{k_e}{\rightleftharpoons}} [AQ]^* \tag{9}$$

$$[AQ]^* \xrightarrow{k_f} A + Q + h\nu'' \tag{10}$$

$$[AQ]^* \xrightarrow{k_{it}} A + Q + \text{heat} \tag{11}$$

$$[AQ]^* + Q \xrightarrow{k_q} A + 2Q$$

Scheme 3.

reaction processes are shown, where A, Q, and [AQ]* denote the aromatic nitriles, **2a** or **2b**, and the exciplexes respectively. The process for the formation of stable products, [AQ]* and/or [AQ]*+Q→Products, can be discarded, since no products could be detected. Equation d represents the Stern-Volmer equation for the quenching of the aromatic nitrile fluorescence by Q, whereas Eq. e shows the quantum yield of the 1-NN–**2b** exciplex emission at a given concentration of Q.

$$I_M^0/I_M^Q = 1 + \left\{\frac{1+k_q\tau_{EX}^0[Q]}{1+(k_{-e}+k_q[Q])\tau_{EX}^0}\right\}k_e\tau_M[Q] \tag{d}$$

$$\tau_{EX}^0 = 1/(k_d+k_f)$$

$$\phi_{EX} = \left(\frac{I_M^Q}{I_M^0}\right)\left\{\frac{k_f\tau_{EX}^0}{1+(k_{-e}+k_q[Q])\tau_{EX}^0}\right\}k_e[Q] \tag{e}$$

If the reversible dissociation of the exciplex into $^1A^*$ and Q can be neglected (*i.e.*, $k_{-e}\ll k_d+k_f$), Eq. d can be reduced to a usual Stern-Volmer equation; thus, the fluorescence quenching would give a linear Stern-Volmer plot. The quenching of the 1-NN fluorescence by **2b** fits the case (Fig. 3); the k_e value was calculated to be $(9.3\pm1.0)\times10^9$ dm^3 mol^{-1} s^{-1} from the slope of the Stern-Volmer plot (71.0 dm^3 mol^{-1}) and the lifetime of the excited singlet 1-NN in air-saturated benzene (7.5 ± 0.5 ns). The occurrence of a diffusion-controlled fluorescence quenching demonstrates the negligible importance of the reversible dissociation.

If the reversible dissociation can not be neglected,

Eq. d predicts non-linear Stern-Volmer plots (Figs. 2 and 3). Equation d can be transformed into Eq. f; thus, the plots of $(I_M^0/I_M^Q-1)/[Q]$ *vs.* [Q] are shown in Figs. 5 and 6, using the data in Figs. 2 and 3. Equation f predicts that the plots will be linear at lower concentrations of Q, provided $k_q[Q]\ll k_d+k_f+k_{-e}$, while a deviation from the linearity occurs at higher concentrations of Q. The results are in good accord with this prediction.

$$(I_M^0/I_M^Q-1)/[Q]=\frac{k_e\tau_M}{1+(k_{-e}+k_q[Q])\tau_{EX}^0}+\frac{k_e\tau_M k_q\tau_{EX}^0[Q]}{1+(k_{-e}+k_q[Q])\tau_{EX}^0} \quad (f)$$

When the slopes and intercepts in Figs. 5 and 6 applied to Eq. f, one can obtain the values of $\{1/(1/\tau_{EX}^0+k_{-e})\cdot\tau_{EX}^0\}k_e$ and $k_q\tau_{EX}^0$ listed in Table 4. The former is the apparent rate constant for the formation of the exciplex, in which the reversible dissociation of the exciplex is taken into account. In the case of the 2-NN–**2a** exciplex, the rate constant is three orders lower than the diffusion-controlled rate, suggesting the dominant dissociation; the exciplex formation must be isothermal or only slightly exothermic. In the cases of all the other exciplexes except the 1-NN–**2b** exciplex, the dissociation is also important. The curved Stern-Volmer plots arise from the quenching of the exciplexes by **2a** or **2b**. The $k_q\tau_{EX}^0$ values can be obtained by dividing the slopes by the intercepts in Figs. 5 and 6.

In the case of the 1-NN–**2b** exciplex, the $k_q\tau_{EX}^0$ value should be calculated by another method, since the Stern-Volmer plot for the quenching of the 1-NN fluorescence by **2b** gives a linear line. If Eq. g represents the maximum quantum yield of the 1-NN–**2b** exciplex emission observed in the presence of 1.8×10^{-2} mol dm^{-3} in **2b** ($[Q]_{max}$), Eq. h can be finally obtained by dividing Eq. g by Eq. e and by a subsequent transformation:

$$\phi_{EX}^{max}=\left(\frac{I_M^Q}{I_M^0}\right)_{max}\left(\frac{k_f\tau_{EX}^0}{1+k_q\tau_{EX}^0[Q]_{max}}\right)k_e[Q]_{max} \quad (g)$$

$$L_{max}/L=\left(\frac{\phi_{EX}^{max}}{\phi_{EX}}\right)\left(\frac{[Q]}{[Q]_{max}}\right)\left\{\frac{(I_M^Q/I_M^0)}{(I_M^Q/I_M^0)_{max}}\right\}=\left(\frac{1}{1+k_q\tau_{EX}^0[Q]_{max}}\right)(1+k_q\tau_{EX}^0[Q]) \quad (h)$$

Since the 1-NN–**2b** exciplex is almost irreversibly formed, k_{-e} was omitted in Eqs. e, g, and h. Thus, L_{max}/L was plotted *vs.* [Q] using the data in Table 3; a good linear line was thus obtained (Fig. 7). The $k_q\tau_{EX}^0$ value was calculated to be 22.0 $dm^3\ mol^{-1}$ by dividing the slope by the intercept, or 24.1 $dm^3\ mol^{-1}$ from the intercept. Although the latter must include a greater error than the former, the agreement between the calculated values is good within the limits of experimental error.

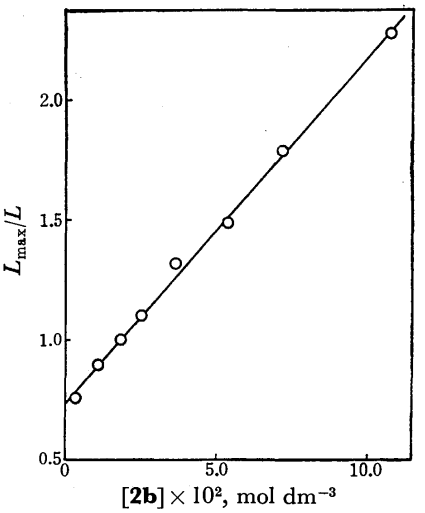

Fig. 7. Plots of L_{max}/L *vs.* [**2b**], using the data in Table 3.

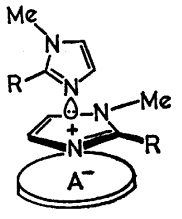
The apparent rate constants for the formation of the 1- and 2-NN–**2a** exciplexes are much lower than those for the exciplexes of **2b**. This suggests that **2a** and **2b** act as π-donors in the exciplex formation, since **2b** is apparently a stronger π-donor than **2a**. In contrast, the $k_q\tau_{EX}^0$ values for 1- and 2-NN–**2a** system are about ten times greater than those for the 1- and 2-NN–**2b** system respectively. The difference between the $k_q\tau_{EX}^0$ values for **2a** and **2b** suggests that **2a** and **2b** act as n-donors in Process 11, as is illustrated as III; the methyl group at the 2-position of **2b** sterically inhibits the interaction of the n-orbital with the 1- and 2-NN–**2b** exciplexes, leading to lower k_q values than those for **2a**, as has been discussed in the foregoing section.



III

Unfortunately, the k_q values which are essential for the discussion can not be calculated, since the τ^0_{EX} values are not available. However, the participation of the n-orbital in Process 11 is further supported by the fact that DF and 1-methylpyrrole, which are strong π-donors but are very weakly basic, do not interact with the respective exciplexes of 1- or 2-NN up to 0.1 mol dm^{-3}, though they do quench the 1- and 2-NN fluorescence at a diffusion-controlled rate.[16] In summary, the termolecular interactions in the exciplex quenching and the quenching of aromatic nitrile fluorescence by **2a**, **b** occur upon the attack of **1** and **2** as n-donor, Q_n, on the exciplexes, $[A^-_\pi D^+_\pi]^*$ or $[A^-_\pi Q^+_\pi]^*$, giving rise to a purturbation of the exciplexes, by which non-radiative decays may be assisted. The interaction of triplexes, $[A_\pi D_\pi Q_n]^*$ or $[A_\pi Q_\pi Q_n]^*$, provokes an interesting speculation, though triplex emission could not be observed; the triplexes may rapidly collapse into the precursors in the ground state without emission and/or into triplet-state species. Alternatively, the interaction of Q_n with the exciplexes may cause a complete electron transfer from D_π or Q_π to A_π, leading to such ion-pairs as $[A^-_\pi \cdots (D_\pi Q_n)^+]_{solv}$ or $[A^-_\pi \cdots (Q_\pi Q_n)^+]_{solv}$; the electron reversal in the ion-pairs may exclusively occur to result in the collapse in to the precursors in the ground-state or triplet-state species because of the low polarity of the solvent. However, it should be pointed out that the decay channels are still open to question.

Experimental

The 1- and 2 naphthonitriles (Tokyo Kasei Co., Ltd.) were distilled under a high vacuum, chromatographed on silica gel, and recrystallized three times from hexane. The 9-cyanophenanthrene was prepared by a known method,[17] distilled under a high vacuum, and recrystallized three times from methanol. The 2,5-dimethyl-furan and 2,5-dimethyl-2,4-hexadine (Tokyo Kasei Co., Ltd.) were distilled from sodium under a pure nitrogen stream before use. The pyridine, methylated pyridines, 1-methylimidazole, and 1,2-dimethylimidazole (Tokyo Kasei Co., Ltd.) were all distilled from anhydrous potassium hydroxide under a pure nitrogen stream before use. The benzene and ethyl acetate (spectrograde, Nakarai Chemicals) were distilled before use.

The measurements of the fluorescence spectra and the fluorescence-quenching experiments were carried out with a Hitachi MPF-2A spectrofluorometer. The product analysis were carried out with a Shimadzu GC-2C gas chromatograph using a column of SE-30 (5% on Celite 545, 0.75 m) at 140—170 °C, a Hitachi R-24 (60 MHz) NMR spectrometer, and a Hitachi 124 UV spectrometer.

The authors wish to thank Professor Noboru Mataga and Dr. Tadashi Okada, Osaka University, for their help and guidance in the determination of the lifetime of the 9-CP–DHD exciplex. They are also indebted to Professor Haruo Shizuka, Gunma University, for the fluorescence lifetimes of 1- and 2-NN.

The Reaction of Alkyl Halides with Mercury(II) and Potassium Thioacetates and Selenocyanates

Sakae UEMURA,* Nanao WATANABE,** Akio TOSHIMITSU, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received October 28, 1977)

The reactions of alkyl halides with mercury(II) and potassium thioacetates afford alkyl thioacetates (RSCOMe), S_N1 and S_N2 type reactions taking place. In neither case is ROCSMe formed. Reactions with mercury(II) selenocyanate usually give only small amounts of alkyl selenocyanates and/or isoselenocyanates as isolated products except the case of benzyl bromide from which benzyl selenocyanate was obtained almost quantitatively. The ambident reactivity of this salt was revealed to be not so strong as that of mercury(II) thiocyanate. The reaction with potassium selenocyanate is also reported for comparison.

Mercury(II) thiocyanate reacts with alkyl halides in less-polar solvents to afford both alkyl isothiocyanates and thiocyanates, the former being predominant, in contrast to the reaction with the corresponding potassium salt in *N,N*-dimethylformamide (DMF), where alkyl thiocyanates are the main products.[1] We have carried out a similar reaction using mercury(II) thioacetate and selenocyanate to confirm the ambident reactivity of mercury(II) salt. The results are given herewith. For the sake of comparison reactions with the corresponding potassium salts were also carried out. It should be noted that the ambident character of potassium selenocyanate in the reaction with alkyl halide is known to some extent.[2]

Results and Discussion

Reaction with Mercury(II) or Potassium Thioacetate. The reaction was carried out by stirring equimolar amounts of alkyl halide and mercury(II) thioacetate in hexane at room or refluxing temperature as in the case of the reaction with mercury(II) thiocyanate.[1] It was found to be heterogeneous. The products were only alkyl thioacetates (**1**)[3] (Scheme 1), their formation being restricted to the cases of *t*-butyl and arylalkyl halides which can form the stable carbonium ions, all the starting alkyl halides being recovered unreacted in the other cases.

$$RX + Hg(SCOMe)_2 \xrightarrow{\text{hexane}} RSCOMe\ (\mathbf{1}) + Hg(X)SCOMe \quad (1)$$

The results show that the S_N1 type reaction might be involved, but when the homogeneous reactions of alkyl halides with potassium thioacetate were carried out in DMF, **1** was obtained in almost all cases except *t*-butyl halide (Scheme 2), suggesting the occurrence of S_N2

$$RX + KSCOMe \xrightarrow{\text{DMF}} (\mathbf{1}) + KX \quad (2)$$

type reaction. In all cases no ROCSMe were obtained. This indicates that mercury(II) thioacetate shows no ambident character, reflecting the significant difference in nucleophilic reactivity toward carbocation between sulfur and oxygen.[4] The attack by only S-site in the case of potassium thiocarboxylate is known in several cases such as the reaction of potassium thioacetate with alkyl tosylate[5] and that of potassium thiobenzoate with butyl halides.[6] Typical results are given in Table 1. An appreciable amount of thioacetic anhydride was also formed in the reaction of *t*-butyl bromide with the mercury(II) salts. Although the exact pathway for this anhydride is still ambiguous, it could not be formed by stirring mercury(II) thioacetate in hexane at room temperature for 24 h in the presence or absence of **1** (R=*t*-Bu).

Table 1. Reaction of alkyl halides with $Hg(SCOMe)_2$ or KSCOMe[a]

Reaction with Mercury(II) or Potassium Selenocyanate. When benzyl bromide was reacted with equimolar amount of mercury(II) selenocyanate in hexane or dibutyl ether at refluxing temperature for 0.5—1 h, benzyl selenocyanate [**2**(R=$PhCH_2$)] was obtained almost quantitatively. In the cases of almost all other alkyl or arylalkyl halides, however, the yields of the products, the corresponding selenocyanate (**2**) and isoselenocyanate (**3**) (Scheme 3), were quite low because of the rapid formation of lots of sticky solids containing mercury(II) salt, about 60—80% of the starting alkyl or arylalkyl halides being recovered unreacted. The situation was not improved by changing the

solvent, reaction temperature, and molar ratio of the reactants. Although these solids were found to contain C and N, attempts to identify them were unsuccessful. The reason for the phenomena is not clear, but instability of the products, especially **3**, may be one cause.[7] In fact, when **3** (R=*t*-Bu), prepared separately,[7b] was heated in hexane for 1 h in the presence of an equimolar amount of mercury(II) selenocyanate and/or bromide, only half the amount of the starting material **3** was recovered. In the case of **2** (R=*i*-Pr), 75% of **2** was recovered by a similar treatment.

Formation of **3** from secondary and tertiary alkyl halides, although in low yield, suggests the ambident nature of mercury(II) selenocyanate. However, when the isomer ratio of **3**/**2** obtained from benzyl bromide[0 in hexane and $(n\text{-Bu})_2O$] is compared with that of $PhCH_2NCS/PhCH_2SCN$[0.56 in $(n\text{-Bu})_2O$][1] obtained in the reactions with mercury(II) thiocyanate, the ambident nature is clearly not so strong as in the case of mercury(II) thiocyanate. The exclusive formation of **2** ($R=PhCH_2$) indicates the predominant attack of the Se-site despite the fact that mercury is bonded with Se and not with N in mercury(II) selenocyanate.[8] This is probably due to the difference in nucleophilicity of Se and S. In this connection, the former is known to be a much stronger nucleophile than the latter in aliphatic nucleophilic substitution (S_N2).[9] Diphenylmethyl bromide reacts with potassium selenocyanate to give diphenylmethyl selenocyanate, while triphenylmethyl chloride gives only triphenylmethyl isoselenocyanate by a similar treatment.[2] In order to obtain authentic samples for alkyl selenocyanate and clarify the isomer distribution in the products, reactions with potassium selenocyanate were also carried out in acetone or DMF as solvent.[10] All alkyl halides except tertiary ones were found to give only the corresponding **2**, triphenylmethyl chloride affording only **3** and *t*-butyl bromide a small amount of a mixture of **2** and **3**.

Experimental

All the organic substrates except the solvents were used without further purification. Mercury(II) thioacetate[11] was prepared as follows. Thioacetic acid (10 g, 130 mmol) was slowly added to a chloroform (40 ml) suspension of mercury(II) oxide (yellow, 13 g, 6 mmol) at 5—10 °C with stirring for 1 h. The precipitated yellowish gray solid was collected and recrystallized from chloroform to give white leaflets; yield, 13.7 g (65%). Potassium thioacetate was prepared from thioacetic acid and $KHCO_3$.[12] Mercury(II) selenocyanate was prepared from mercury(II) nitrate and commercial potassium selenocyanate in water.[8] A sharp absorption at 2150 cm^{-1} ($\nu_{C\equiv N}$) in the IR spectrum (KBr disc) suggests the coordination of mercury with selenium.[8]

Gas chromatography (GLC) was used for detection of the isomer and determination of the isomer ratios, NMR analysis also being used in some cases. GLC analyses were carried out with a Shimadzu 5APTF apparatus using DEGS (1 m), Apiezon-L (1 m), and PEG-6000 (3 m) columns (carrier gas, N_2). The NMR and IR spectra were recorded on Varian EM-360 ($CDCl_3$, TMS, internal lock) and Hitachi EPI-S2 spectrometers, respectively.

All the products except **1** ($R=Ph_2CH$) and **2** (R=PhCHMe) are known compounds and were identified by NMR spectra and by comparison of their bp and mp with those in literature. The authentic samples of thioacetic anhydride,[13] **3** (R=*i*-Pr),[7a] and **3** (R=*t*-Bu)[7b] were prepared according to reported methods for identification of the products on GLC. **1** ($R=Ph_2CH$); bp 120—140 °C/5 mmHg, mp 39—40 °C (from EtOH); NMR δ 2.30 (s, 3H), 5.95 (s, 1H), 7.30 (s, 10H). **2** (R=PhCHMe); bp 120—125 °C/10 mmHg, NMR δ 2.30 (d, 3H), 4.90 (q, 1H), 7.39 (s, 5H).

Reaction of Benzyl Bromide with Mercury(II) Thioacetate in Hexane. Benzyl bromide (2.57 g, 15 mmol) was added to a stirred suspension of $Hg(SCOMe)_2$ (5.25 g, 15 mmol) in hexane (20 ml) at 30 °C, and the mixture was heated to 70 °C and kept for 8 h with stirring. The resulting red-brown suspension was cooled and filtered to remove

the red-brown precipitates which were found to contain C, H, and Br by analyses. The pale orange filtrate was washed with water and dried over Na_2SO_4. The GLC analysis of this filtrate showed the presence of one product and the absence of the starting benzyl bromide. Distillation afforded benzyl thioacetate [**1**(R=$PhCH_2$), 1.33 g, 53.4% yield, bp 100—102 °C/7 mmHg (lit,[5] bp 54 °C/0.05 mmHg)], leaving 0.14 g of residue. NMR δ 2.32 (s, 3H), 4.12 (s, 2H), 7.28 (s, 5H).

*Formation of Bis(diphenylmethyl) Sulfide (**4**).* Diphenylmethyl chloride (2.03 g, 10 mmol) was added to a stirred suspension of $Hg(SCOMe)_2$ (1.75 g, 5 mmol) in hexane (20 ml) at 40 °C and the resulting heterogeneous mixture was heated to 70 °C and kept for 2 h with stirring. After being cooled, the yellow orange precipitates were filtered and the filtrate was treated as above. GLC analysis of the filtrate showed the absence of diphenylmethyl chloride and the presence of **1** (R=Ph_2CH). Evaporation of the solvent left 2.10 g of an oil shown by NMR to consist of 1.20 g (5 mmol) of **1** (R=Ph_2CH) and 0.90 g (2.5 mmol) of **4**. The residue after distilling **1** (R=Ph_2CH) off was solidified and recrystallized from petroleum ether to afford 0.83 g of pure **4**; mp 63—65 °C (lit,[3] mp 66.5 °C), NMR δ 4.72 (s, 2H), 6.85—7.5 (m, 20H).

Reaction of Benzyl Bromide with Mercury(II) Selenocyanate in (n-Bu)$_2$O. Benzyl bromide (1.11 g, 6.5 mmol) was added to a stirred suspension of $Hg(SeCN)_2$ (2.68 g, 6.5 mmol) in (n-Bu)$_2$O (20 ml) at 85 °C, and the mixture was kept for 0.5 h with stirring. The reaction mixture was cooled and filtered in order to remove the orange sticky precipitates. Removal of (n-Bu)$_2$O from the filtrate gave white solids of crude benzyl selenocyanate [**2** (R=$PhCH_2$), 1.12 g, 94% yield] which were recrystallized from aqueous ethanol; mp 69—70 °C (lit,[10] mp 71.5 °C, 72 °C), NMR δ 4.25 (s, 2H), 7.33 (s, 5H).

This work was partly supported by a Grant-in-Aid from the Ministry of Education.

The Reactions of Olefins with Chloromethoxymethane or Dimethoxymethane in Nitriles

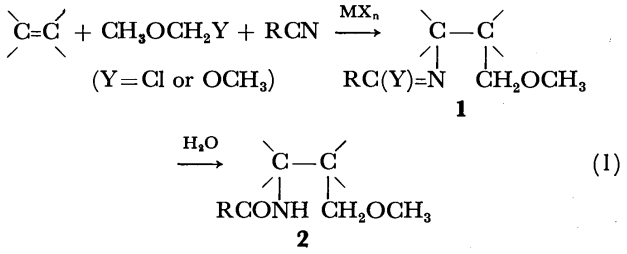
Yasuo WADA,* Takeshi YAMAZAKI,* Kazuo NISHIURA,* Shigeo TANIMOTO, and Masaya OKANO**

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received November 7, 1977)

The Lewis acid-catalyzed reactions of olefins with chloromethoxymethane (CM) or dimethoxymethane (DM) and aliphatic or aromatic nitriles afforded the 1 : 1 : 1 adducts and/or their hydrolysis products in various yields, together with the 1 : 1 olefin–CM (or DM) adducts. $AlCl_3$, $FeCl_3$, $ZnCl_2$, and $SnCl_4$ were effective catalysts for the reaction with CM, whereas BF_3 and $SnCl_4$ were effective for that with DM. In the case of cyclohexene, the addition proceeded in the *trans*-manner; *i.e.*, the methoxymethyl group and the nitrile molecule were added to the olefin from opposite sides.

Several modifications of the Ritter reaction with various positive halogen compounds (*e.g.*, Cl_2,[1] Br_2,[1] ClOH,[1] BrN_3,[2] $ClNHCONH_2$,[3] $Cl_2NCOOEt$,[4] and Cl_2NSO_2Ph[5]), a nitronium salt,[6] and a carbenium salt[7] have been reported. However, in the last case the reaction of styrene with a methoxycarbenium salt and acetonitrile to produce *N*-(2-methoxy-1-phenylpropyl) acetamide is the sole example thus far examined, and only a brief description on it has been given. In order to know the nature of such a reaction involving the attack of a carbenium ion and to save the trouble of pre-preparing a carbenium salt, we examined three-component reactions of olefins with readily available sources of a methoxymethyl cation, such as chloromethoxymethane (CM), dimethoxymethane (DM), or trimethoxymethane (TM), and nitriles in the presence of Lewis acid catalysts. Except for the case of TM, the reactions proceeded smoothly and afforded the desired adducts (**1**) and/or their hydrolysis products (**2**) in various yields (Eq. 1), together with other products, including the 1 : 1 olefin–CM(or DM) adducts. The present paper will be concerned with these results.



(1)

In this connection, the Lewis acid-catalyzed reactions of α-halo ethers,[8] 1,1-dialkoxymethanes,[9] or trialkoxymethanes[10] with olefins to yield the corresponding 1 : 1 adducts were known in the 1950's (Eqs. 2 and 3).

Results and Discussion

The treatment of cyclohexene with CM in acetonitrile in the presence of a Lewis acid catalyst at room temperature for 24 h, followed by a work-up procedure with aqueous Na_2CO_3, gave the following three compounds as the main products: a *N*-[2-(methoxymethyl)-cyclohexyl]acetamide (**2a**, R=CH_3), a 1-chloro-2-(methoxymethyl)cyclohexane (**3a**, Y=Cl), and probably 3-methoxymethyl-1-cyclohexene (**4'a**) (see Eq. 6). The first compound corresponds to the hydrolysis product of the 1 : 1 : 1 olefin–CM–nitrile adduct and the second one, to the 1 : 1 olefin–CM adduct, while the last one may come from the intermediate cation **5a** in the addition and/or from the 1 : 1 adduct, **3a**. However, a blank experiment revealed that the latter possibility (the dehydrochlorination of **3a**) can be excluded, at least during the work-up procedure. Further, it was confirmed by a separate experiment that **3a** (Y=Cl) does not react with acetonitrile to afford **2a** and either **4a** or **4'a**, even in the presence of equimolar amounts of $AlCl_3$ or $FeCl_3$, under the given reaction conditions. When propionitrile and some aromatic nitriles were used as solvents in place of acetonitrile, the corresponding 1 : 1 : 1 adducts were obtained similarly. Generally, the reactions were accompanied by a considerable formation of tarry materials (which were probably formed by further acid-catalyzed reactions of the products, **3a**, **4a** and/or **4'a**). Several results of the reaction of cyclohexene with CM are summarized in Table 1.

As can be seen from the table, $AlCl_3$, $FeCl_3$, $ZnCl_2$, and $SnCl_4$ were superior to $HgCl_2$ and BF_3 as catalysts. When equimolar amounts of these effective catalysts were used in acetonitrile, the combined yields of **2a**, **3a**, and **4'a** were nearly 55—60% (based on the consumed cyclohexene), and the proportions of **2a** (R=CH_3) changed appreciably with the nature of the catalysts. The best yield (41%) of **2a** was obtained by the use of one equivalent of $AlCl_3$. Though it is known that the basicity of benzonitrile is lower than that of acetonitrile, the former nitrile afforded the corresponding amide (**2a**, R=C_6H_5) in considerable yields with selectivities comparable to those of the case of acetonitrile (*e.g.*, $AlCl_3$-catalyzed, the **2a**/**2a**+**3a**+**4'a** ratio was 0.69/1 for CH_3CN and 0.71/1 for C_6H_5CN). Such a result may reflect a considerable stabilization through conjuga-

tion in the imidoyl cation, **6**, formed by the attack of benzonitrile on the cation **5** (see Eq. 6).

When the reaction was applied to three typical terminal olefins in acetonitrile, the yields of the 1: 1: 1 adducts varied significantly (Table 2). From 1-hexene, the expected adduct **2b** (R=CH_3), following Markovnikov's rule, was obtained in a yield similar to that in the case of cyclohexene. Although the successful addition of nitriles to 2-methylpropene has been known in the Ritter reaction (in H_2SO_4–HOAc),[1] our reaction gave a poor yield of the expected adduct **2c** (R=CH_3) and a large amount of a tarry product. In the case of styrene, the 1: 1 adduct **3d** (Y=Cl) became the principal product, and the yield of the desired adduct, **2d** (R=CH_3), was also quite poor.

Next, a similar treatment of cyclohexene with DM in place of CM in acetonitrile resulted in the formation of the following four products: a methyl *N*-[2-(methoxymethyl)cyclohexyl]ethanimidate (**1a**, Y=OCH_3, R=CH_3), the actamide **2a** (R=CH_3), a 1-methoxy-2-(methoxymethyl)cyclohexane (**3a**, Y=OCH_3), and the olefin **4'a** (see Eq. 6). The first and third compounds correspond to the 1: 1: 1 olefin–DM–nitrile adduct and the 1: 1 olefin–DM adduct respectively. For this reaction, the apparent effectiveness of catalysts decreased in this order: $BF_3 > SnCl_4 > AlCl_3 > FeCl_3 \gg ZnCl_2$ and $HgCl_2$ (both almost ineffective), in contrast to the case of CM. When two-thirds equivalents of $BF_3 \cdot Et_2O$ was used, the combined yield of **1a** and **2a** (R=CH_3 each) was found to be 39%; this value was comparable to the highest yield of **2a** (R=CH_3) in the reaction with CM. By a separate experiment, it was confirmed that **1a** (Y=OCH_3, R=CH_3) can be readily converted into **2a** (R=CH_3) by hydrolysis with 5% aqueous NaOH (under reflux, 2 h). Most of the **2a** product may arise from **1a** (Y=OCH_3) during the work-up procedure, but another route *via* **1a** (Y=Cl) can not be excluded when metal chlorides are used as catalysts. In addition, a controlled experiment revealed that **3a** (Y=OCH_3) does not react with acetonitrile in the presence of $BF_3 \cdot Et_2O$ to afford **1a** or **2a** under the given reaction conditions. Some typical data of the reaction with DM are given in Table 3.

1-Hexene and styrene can be used as the olefin component for this reaction, but 2-methylpropene failed to undergo the reaction (Table 4). Here, it would be worthwhile to note that the reaction with CM is somewhat preferable to that with DM for the one-step preparation of the 1: 1: 1 adducts, **2**, from cyclohexene or 1-hexene, but the latter reaction is prefered for the preparation of **2** (*via* **1**) from styrene.

The following pathway, which is analogous to that of the Ritter reaction, appears to be consistent with all

The attemped reaction using TM as the source of the methoxymethyl moiety under similar reaction conditions was unsuccesful. For example, when an equimolar mixture of cyclohexene and TM was treated with excess acetonitrile in the presence of $BF_3 \cdot Et_2O$ (2/3 equiv.) at room temperature for 48 h, only a small amount of a tarry product was formed, and most of the olefin was recovered.

Lastly, we wish to add a short comment on the stereochemical results of the reactions of cyclohexene in acetonitrile. When crude **2a** (R=CH_3) (obtained by the reaction with CM) was hydrolyzed by refluxing in aqueous HCl, *trans*-2- and probably *cis*-3-(methoxymethyl)cyclohexylamines (*trans*-**7** and *cis*-**8** respectively) were formed in a ratio of 9: 1, and no other products, including the *cis*-isomer of **7**, were found.[11] The configuration and conformation of **7** were deduced from the splitting of the C<u>H</u>(NH_2) proton in its NMR (100 MHz) spectrum, which indicates that this proton is in an *axial* position, coupled strongly to two adjacent *axial* protons and weakly to one adjacent *equatorial* proton (δ=2.42, d of t, J=4 and 10 Hz). In addition, the C<u>H</u>Cl proton of **3a** (Y=Cl) showed a quite similar splitting pattern at δ=3.74, indicating that its structure is also *trans* (diequatorial). An almost exclusive formation of *trans*-**7** was also observed when crude **1a** (Y=OCH_3) and crude **2a** (R=CH_3) (both obtained by the reaction with DM) were each subjected to hydrolysis in 10% aqueous HCl.[13] These results imply that the methoxymethyl cation and the nitrile molecule or Cl^- are added to cyclohexene from opposite sides. Since the absence of γ-methoxyl group participation in solvolytic reactions has been established by Winstein *et al.*,[14] the *trans*-addition *via* a four-membered cyclic oxonium ion intermediate is unlikely. The high stereoselectivity might be explained by assuming that, on the attack by the nucleophile upon the **5a** cation, the course leading to a thermodynamically more stable isomer becomes quite favorable for some reason.

Experimental

All the organic and inorganic materials were commercial products. The NMR spectra (in $CDCl_3$) were recorded with a Varian A-60 apparatus and a JEOL MH-100 apparatus. The GLC analyses were carried out on a Shimadzu 5APTF apparatus, using EGSS-X (30%)-Chromosorb-W(1 m) and PEG 6000 (3 m) columns (with N_2 as the carrier gas).

Reactions of Cyclohexene with CM or DM in Nitriles. Some typical examples are given below.

Method A: To a stirred mixture of cyclohexene (8.2 g, 100 mmol) and $FeCl_3$ (16.2 g, 100 mmol) in acetonitrile (41 g, 1000 mmol), CM (8.0 g, 100 mmol) was added, drop by drop, the temperature being maintained at near 5 °C by cooling with ice water. The mixture was stirred for 24 h at room temperature (20—25 °C) and then poured into a cooled solution of aqueous Na_2CO_3. After the basic mixture had then been stirred for 2 h at room temperature, the precipitated inorganic substance was filtered off and the filtrate was extracted with ether. Then the organic layer separated from the aqueous one was washed with aqueous NaCl and dried over anhydrous $MgSO_4$, and most of the solvent was evaporated. GLC analysis of the residue indicated the presence of **4'a** (probably) (1.0 g, 8 mmol), **3a** (Y=Cl) (2.1 g, 13 mmol), and **2a** (R=CH_3) (6.3 g, 34 mmol). Distillation afforded the following fractions: bp 65—95 °C/25 Torr [a mixture of **4'a** and **3a** (Y=Cl), 3 g], bp 119—123 °C/2—3 Torr [crude **2a** (R=CH_3), 6.5 g], and a brown, tarry residue (3.6 g).

Method B: To a stirred solution of cyclohexene (8.2 g, 100 mmol) and DM (7.6 g, 100 mmol) in acetonitrile (41 g, 1000 mmol), $BF_3 \cdot Et_2O$ (9.5 g, 67 mmol) was added slowly at near 5 °C; the resulting mixture was stirred for 24 h at room temperature. The work-up procedure was the same as above. GLC analysis showed the presence of unreacted cyclohexene (1.1 g, 13 mmol), **4'a** (1.0 g, 8 mmol), **3a** (Y=OCH_3) (0.1 g, 1 mmol), **1a** (Y=OCH_3, R=CH_3) (4.4 g, 22 mmol), and **2a** (R=CH_3) (1.8 g, 10 mmol). Distillation gave the following fractions: bp 65—95 °C/25 Torr [a mixture of **4'a** and **3a** (Y=OCH_3), 1.0 g], bp 103—108 °C/15 Torr [crude **1a** (Y=OCH_3, R=CH_3), 4.0 g], bp 119—123 °C/2—3 Torr [crude **2a** (R=CH_3), 1.6 g], and a tarry resudue (2.8 g).

In the reaction with CM or DM in benzonitrile, the **1a** adduct (Y=OCH_3, R=C_6H_5) could be separated by distillation, whereas the **2a** adduct (R=C_6H_5) was purely isolated from the residual solid by column chromatography [Wakogel, hexane–ether (1: 2)].

In GLC analysis, ethyl acetate, *p*-chlorotoluene, *p*-nitrotoluene, and benzophenone were used as internal standards for the estimation of cyclohexene, **4'a** and **3a** (Y=Cl), **3a** (Y=OCH_3) and **1a** (Y=OCH_3, R=CH_3), and **1a** (Y=OCH_3, R=C_6H_5) and **2a** (R=CH_3) respectively.

The physical properties of the products collected by means of the GLC technique, careful distillation, or recrystallization are as follows: **4'a**[15]: bp 77—78 °C/50 Torr (lit,[9b] bp 158 °C); NMR, δ=5.9—5.4 (m, 2H), 3.20 (s, 3H), 3.10

(d, 2H), 2.5—1.0 (m, 7H). *trans*-**3a** (Y=Cl): bp 95—97 °C/25 Torr (lit,[17,18] bp 109—113 °C/49 Torr); NMR (100 MHz), δ=3.74 (d of t, J=4 and 10 Hz, 1H), 3.50 (d, J=4 Hz, 2H), 3.30 (s, 3H), 2.3—1.0 (m, 9H). **3a** (Y=OCH_3): bp 106—108 °C/50 Torr (lit,[9b,18] bp 192—192.5 °C); NMR (100 MHz), δ=3.6—3.0 (m, 3H), 3.30 (s, 6H), 2.2—0.8 (m, 9H). The data on *trans*-**1a** (Y=OCH_3, R=CH_3), **1a** (Y=OCH_3, R=C_6H_5), *trans*-**2a** (R=CH_3), **2a** (R=C_2H_5), **2a** (R=C_6H_5), **2a** (R=*p*-$CH_3C_6H_4$), and **2a** (R=*p*-ClC_6H_4) are given in Table 5.

Hydrolysis of ***1a*** and ***2a***. When **1a** (Y=OCH_3, R=CH_3) (*ca.* 10 mmol) was heated in 5% NaOH under reflux for 2 h, **2a** (R=CH_3) was obtained in a *ca.* 95% yield. On the other hand, the hydrolysis of **1a** (*ca.* 10 mmol) with 10% HCl under reflux for 6 h afforded almost pure *trans*-**7** in a *ca.* 90% yield. When crude **2a** (R=CH_3) (prepared by the reaction with CM) (*ca.* 10 mmol) was hydrolyzed with 10% HCl under reflux for 6 h, a mixture of *trans*-**7** and *cis*-**8** (9: 1) was obtained in a high yield, whereas the acid-catalyzed hydrolysis of crude **2a** (R=CH_3) (obtained by the reaction with DM) afforded *trans*-7 almost exclusively. *trans*-**7**: bp 87—88 °C/19 Torr; Found (Calcd): C, 66.87 (67.09), H, 11.66 (11.96), N. 9.60 (9.78)%; NMR (100 MHz), δ=3.30 (d, J=4.5 Hz, 1H), 3.28 (d, J=4.5 Hz, 1H), 3.20 (s, 2H), 2.42 (d of t, J=4 and 10 Hz, 1H), 1.36 (s, 2H), 2.0—0.8 (m, 9H). *cis*-**8**: NMR (100 MHz), δ=3.25 (s, 3H), 3.15 (d, J=4.5 Hz, 1H), 3.31 (d, J=4.5 Hz, 1H), 2.60 (t of t, J=4 and 10 Hz, 1H), 1.25 (s, 2H), 2.1—0.7 (m,9H).

Reactions of Other Olefins with CM or DM in Nitriles The reactions were performed analogously to the cyclohexene experiment. The physical properties of the products (other than **1** and **2**, shown in Table 5) from other olefins are given below. *trans*-**4'b** (probably *trans*-1-methoxy-3-heptene): bp 78—79 °C/100 Torr (lit,[18,19] bp 58—59 °C/30 Totr); IR, 965 cm^{-1} (*trans*-CH=CH); NMR, 5.7—5.3 (m, 2H), 3.35 (t, J=6 Hz, 2H), 3.30 (s, 3H), 2.5—1.8 (m, 4H), 1.6—1.2 (m, 2H), 0.9 (t, 3H). **3b** (Y=Cl): bp 90—92 °C/23—25 Torr; Found (Calcd): C, 58.99 (58.35), H, 10.95 (10.40)%; NMR, δ=4.1—3.8 (m, 1H), 3.30 (t, J=5.5 Hz, 2H), 3.20 (s, 3H), 1.8—1.1 (m, 8H), 0.9 (t, 3H). **3b** (Y=OCH_3): bp 104—105 °C/100 Torr; Found (Calcd): C, 67.12 (67.45), H, 12.77 (12.58)%; NMR, δ=3.6—3.1 (m, 3H), 3.30 (s, 6H), 1.9—1.1 (m, 8H), 0.9 (t, 3H). **3d** (Y=Cl): bp 83—84 °C/3 Torr (lit,[20] bp 100—101.5 °C/6 Torr); NMR, δ=7.4—7.1 (m, 5H), 5.2—4.8 (m, 1H), 3.25 (s, 3H), 3.7—3.2 (m, 2H), 2.4—2.0 (m, 2H). **3d** (Y=OCH_3): bp 105 °C/11 Torr (lit,[9a] bp 151 °C/74 Torr); NMR, δ=7.4—7.2 (m, 5H), 4.4—4.1 (m, 1H), 3.30 (s, 3H), 3.20 (s, 3H), 3.6—3.2 (m, 2H), 2.2—1.75 (m, 2H).

We wish to thank Dr. Sakae Uemura, Institute for Chemical Research, Kyoto University, for his helpful discussions of the NMR data.

Synthesis of Stachyose Tetradecaacetate and An Isomer

Tetsuo SUAMI,* Toshiki OTAKE, Shigeru NISHIYAMA, Ryoichi ADACHI, and Katsumi NAKAMURA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 233

(Received November 9, 1977)

Condensation of 1′,2,2″,3,3′,3″,4,4′,4″,6′-deca-*O*-acetylraffinose (**1**) with 2,3,4,6-tetra-*O*-benzyl-D-galactopyranosyl chloride in the presence of tetraethylammonium chloride, followed by deacetylation, debenzylation and subsequent acetylation afforded stachyose tetradecaacetate. An isomer in which a terminal D-galctopyranosyl group is attached to the 6″-*O* of raffinose in β-anomeric linkage, was prepared by condensing **1** with 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide in the presence of mercury(II) cyanide. ^{13}C NMR spectra of stachyose tetradecaacetate and the isomer were discussed.

Stachyose was first discovered from a root of *Stachys tuberifera* (*Chorogi* in Japanese) by von Planta and Schulze in 1890.[1] Later this tetrasaccharide was found in other plants such as *Labiate*, *Pinuceae*, and *Leguminosae*.[2] The structure of stachyose was established by Onuki,[3] Laidlaw and Wylam,[4] and Hérissey and Courtois[5] as *O*-α-D-galactopyranosyl-(1→6)-*O*-α-D-galactopyranosyl-(1→6)-*O*-α-D-glucopyranosyl β-D-fructofuranoside.

In continuation of a previous study on sucrochemistry,[6] attempts were made to synthesize stachyose tetradecaacetate by condensing 1′,2,2″,3,3′,3″,4,4′,4″,6′-deca-*O*-acetylraffinose[6] (**1**) with 2,3,4,6-tetra-*O*-benzyl-D-galactopyranosyl chloride[7] (**2**). We now wish to report a successful synthesis of stachyose tetradecaacetate (**5**) by the condensation in the presence of tetraethyl ammonium chloride,[8–12] followed by deacetylation, debenzylation and subsequent acetylation.

Results and Discussion

When **1** was condensed with **2** in dichloromethane in the presence of tetraethylammonium chloride, *N,N*-diisopropylethylamine and molecular sieves at ambient temperature for a prolonged period, *O*-(2,3,4,6-tetra-*O*-benzyl-α-D-galactopyranosyl)-(1→6)-*O*-(2,3,4-tri-*O*-acetyl-α-D-galactopyranosyl)-(1→6)-*O*-(2,3,4-tri-*O*-acetyl-α-D-glucopyranosyl) 1,3,4,6-tetra-*O*-acetyl-β-D-fructofuranoside (**3**) was obtained as crystals. Deacetylation of **3** in methanolic sodium methoxide gave 2‴,3‴,4‴,6‴-tetra-*O*-benzylstachyose (**4**). Debenzylation of **4** in aqueous methanol in the presence of palladium catalyst under hydrogen atmosphere, followed by acetylation gave **5**. Compound **5** was identical with authentic stachyose tetradecaacetate.[3] Deacetylation of **5** gave stachyose (**6**) which was identical with an authentic sample.[3] The present synthesis substantiates the effectiveness and the high stereoselectivity of the Lemieux's condensation system.[8–11]

In contrast, when **1** was condensed with **2** in the presence of mercury(II) cyanide in benzene, the product was contaminated with an isomer (isostachyose derivative)[22]: *O*-(2,3,4,6-tetra-*O*-benzyl-β-D-galactopyranosyl)-(1→6)-*O*-(2,3,4-tri-*O*-acetyl-α-D-galactopyranosyl)-(1→6)-*O*-(2,3,4-tri-*O*-acetyl-α-D-glucopyranosyl) 1,3,4,6-tetra-*O*-acetyl-β-D-fructofuranoside. In this case, isolation of stachyose tetradecaacetate in a pure state was unsuccessful, owing to a similar chromatographic behavior of a contaminant in each step of the reactions. The contamination with isostachyose tetradecaacetate[22] (**7**) was demonstrated by measurement of ^{13}C NMR spectra of **5** and **7**. An authentic sample of **7** was prepared by condensing **1** with 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide[15] in the presence of mercury(II) cyanide in nitromethane.

^{13}C NMR spectra of sucrose octaacetate,[16] raffinose undecaacetate,[13] isoraffinose undecaacetate,[14] **5** and **7** have been determined. Assignments of the signals, obtained in accordance with the data for sucrose,[17–19] raffinose[19] and stachyose,[19] are given in Table 1.

The signals of the anomeric carbon atoms are readily recognized in the lower field (90.0—101.0 ppm). The chemical shift values for the anomeric carbon atoms of the α-D-glucopyranosyl moieties are almost the same in these cases (90.0—90.3 ppm). The anomeric carbon atoms of the α-D-galactopyranosyl groups (C-1″ and 1‴) reveal their signals at 95.9—96.2 ppm.

The signal of the anomeric carbon atom of the terminal β-D-galactopyranosyl group (C-1‴) in **7** (101.0 ppm) shifts downfield markedly from that of the corresponding α-D-galactopyranosyl group in **5** (96.2 ppm). This is in line with the fact that the C-1 of methyl α-D-glucopyranoside gives its signal in a 4.1 ppm higher field than that of the β-D-glucopyranoside.[20] This is also the

a) Chemical shifts are expressed in parts per million (ppm) downfield from the ^{13}C NMR resonance of tetramethylsilane.

case of the anomeric carbon atoms of the terminal D-galactopyranosyl groups in raffinose and isoraffinose undecaacetates (Table 1).

The presence of **7** as an impurity in stachyose tetradecaacetate was demonstrated by measuring its ^{13}C NMR spectrum and determining the optical rotation. The crude product of **5** showed a trace of the signal at 101.0 ppm and a slightly lower value of specific rotation as compared with that of an authentic sample.

Experimental

General Methods. Stachyose tetrahydrate (Aldrich Chemical Company, Inc., U. S. A.), mp 100—104 °C, $[\alpha]_D^{24}$ +133 °C (*c* 4, water), was used as an authentic sample. Melting points were determined in capillary tubes and are corrected. Solutions were concentrated under reduced pressure below 40 °C. Optical rotations were measured with a Japan Spectroscopic DIS-SL polarimeter. ^1H NMR spectra were recorded with a Varian XL-100 spectrometer at 100 MHz, peak positions being given in δ values. ^{13}C NMR spectra were determined with a Varian CFT-20 spectrometer at 20 MHz, the resonance signals being expressed in ppm downfield from the signal of tetramethylsilane. In both spectra, deuteriochloroform was used as a solvent and tetramethylsilane as an internal standard. IR spectra were recorded with a Hitachi 225 spectrophotometer in KBr disks. TLC was performed on Wakogel B-10 (Wako Pure Chemical Co. Ltd.) plates, silica gel (Wakogel C-300) being used for column chromatography. Acetylation was carried out with acetic anhydride in pyridine as usual.

*1′,2,2″,3,3′,3″,4,4′,4″,6′-Deca-O-acetylraffinose (**1**).* The compound was prepared by the method of Suami *et al.*[6] The product used in the present synthesis contained a trace amount of 1′,2,2″,3,3′,3″,4,4′,6′,6″-deca-*O*-acetylraffinose[6] which was detectable on TLC.

*O-(2,3,4,6-Tetra-O-benzyl-α-D-galactopyranosyl)-(1→6)-O-(2,3,4-tri-O-acetyl-α-D-galactopyranosyl)-(1→6)-O-(2,3,4-tri-O-acetyl-α-D-glucopyranosyl) 1,3,4,6-tetra-O-acetyl-β-D-fructofuranoside (**3**).* (a) Tetraethylammonium chloride (4.04 g), *N,N*-diisopropylethylamine (3.25 g) and molecular sieves 3A (5.2 g) were added to a solution of **1** (1.43 g) and 2,3,4,6-tetra-*O*-benzyl-D-galactopyranosyl chloride[7] (**2**, 12.1 g) in dichloromethane (40 ml). After 21 days at ambient temperature, the mixture was filtered and the filtrate was washed with cold water. The aqueous layer was extracted with chloroform, the chloroform layer being combined with the dichloromethane solution. After being dried over Na_2SO_4, the combined solution was concentrated. The residue was acetylated with acetic anhydride and pyridine in order to make the subsequent chromatographic separation easy. The acetylation product was purified on a silica gel column using 1:5 (v/v) 2-butanone–toluene. Fractions homogeneous on TLC (R_f 0.30) in the same solvent were combined and concentrated. The residue was recrystallized from 2-propanol to give 711 mg (32%) of **3**, mp 70—72 °C, $[\alpha]_D^{20}$ +91.9° (*c* 0.86, chloroform).

Found: C, 59.95; H, 5.98%. Calcd for $C_{72}H_{86}O_{31}$: C, 59.74; H, 5.99%.

Fractions homogeneous on TLC (R_f 0.17) in the same solvent were combined and concentrated. The residue was recrystallized from 3:2:5 (v/v) ethanol–methanol–water to give 349 mg (23%) of raffinose undecaacetate, mp 97—100 °C (Lit,[13] mp 99—101 °C).

(b) Mercury(II) cyanide (1.5 g) and drierite (3.0 g) were added to a solution of **1** (1.60 g) and **2** (3.51 g) in dry benzene (30 ml). The mixture was heated under reflux for 20 h with

mechanical agitation. The mixture was filtered and the filtrate was washed with sodium hydrogencarbonate solution and cold water. After being dried over Na_2SO_4, the solution was concentrated. The residue was purified on a silica gel column analogously as described in (a). Fractions practically homogeneous on TLC (R_f 0.30) in the same solvent as in (a) were combined and concentrated to dryness.
The residue was recrystallized from 2-propanol to give 1.12 g (45%) of crude **3**, mp 66—68 °C, $[\alpha]_D^{23}$ +88.2 ° (*c* 1.02, chloroform).

Found: C, 59.99; H, 5.87%. Calcd for $C_{72}H_{86}O_{31}$: C, 59.74; H, 5.99%.

Fractions homogeneous on TLC (R_f 0.54) in 20: 1 (v/v) chloroform-ethanol were combined and concentrated to give 205 mg (13%) of 1′,2,2″,3,3′,3″,4,4′,6′,6″-deca-*O*-acetylraffinose.[14]

Besides the products described above, 650 mg of a mixture of **3** and an isomer (isostachyose derivative)[22]: *O*-(2,3,4,6-tetra-*O*-benzyl-β-D-galactopyranosyl)-(1→6)-*O*-(2,3,4-tri-*O*-acetyl-α-D-galactopyranosyl)-(1→6)-*O*-(2,3,4-tri-*O*-acetyl-α-D-glucopyranosyl) 1,3,4,6-tetra-*O*-acetyl-β-D-fructofuranoside, was recovered from the column. The mixture showed two spots on TLC (R_f 0.30 and 0.29) in the same solvent system as described in (a) in an approximate ratio of 1: 1. An attempt to separate each component by repeated column chromatography was unsuccessful.

2‴,3‴,4‴,6‴-Tetra-O-benzylstachyose (4). (a) Compound **3** (669 mg) was deacetylated in 0.1 M methanolic sodium methoxide (10 ml) at ambient temperature overnight. After being neutralized with Amberlite IRA-120(H^+) resin, the solution was concentrated. The residue was purified on a silica gel column using 6: 18: 6: 1 (v/v) acetone–hlorocform–methanol–water. Fractions homogeneous on TLC (R_f 0.58) in 4: 9: 4: 1 (v/v) acetone–chloroform–methanol–water were combined and concentrated to give 471 mg (100%) of **4** as a glass, $[\alpha]_D^{20}$+81.7° (c 0.6, chloroform).

(b) Crude **3** (896 mg) was deaectylated analogously as described above to giv 596 mg (94%) of crude **4**, $[\alpha]_D^{20}$+96.2° (*c*, 1.04, chloroform).

1′,2,2‴,2‴,3,3′,3‴,3‴,4,4′,4‴,4‴,6′,6‴-Tetradeca-O-acetylstachyose (5). (a) Compound **4** (423 mg) was hydrogenated in 90% aqueous methanol (15 ml) in the presence of freshly prepared palladium black in hydrogen atmosphere (343 kPa) at 35 °C for a week in a Parr apparatus. During the course of hydrogenation, the pH of the solution was adjusted to 5 by adding a few drops of glacial acetic acid. The catalyst was filtered off and the filtrate was concentrated to dryness. The residue was acetylated, the product being purified on a silica-gel column using 1: 7 (v/v) acetone–benzene. Fractions homogeneous on TLC (R_f 0.62) in 1: 1 (v/v) 2-butanone–toluene were combined and concentrated. The residue was recrystallized from 2-propanol to give 248 mg (48%) of **5**, mp 93—95 °C, $[\alpha]_D^{21}$+123.0° (*c* 0.88, ethanol). The compound is identical with an authentic sample in ^1H NMR and IR spectra, showing no depression in mixed melting point determination with an authentic sample. Lit,[3] mp 95—96 °C, $[\alpha]_D^{22.5}$+120.2° (*c* 1.02, ethanol). ^1H NMR: δ 1.95 (s, 3, OAc), 2.02 (s, 3, OAc), 2.07 (s, 12, 4×OAc), 2.11 (s, 18, 6×OAc), 2.15 (s, 3, OAc), 2.19 (s, 3, OAc), 4.84 (dd, 1, $J_{1,2}$=4.2 Hz, $J_{2,3}$=10.0 Hz, H-2), 5.65 (d,1, H-1).

Found: C, 49.72; H, 5.62%. Calcd for $C_{52}H_{70}O_{35}$: C, 49.76; H, 5.62%.

(b) Crude **4** (600 mg) was worked up analogously as described above to give 236 mg (32%) of crude **5**, mp 93—95 °C, $[\alpha]_D^{22}$+117.9 ° (*c* 3.30, ethanol).

Found: C, 49.53; H, 5.47%. Calcd for $C_{52}H_{70}O_{35}$: C, 49.76; H, 5.62%.

Stachyose (6). Compound **5** (56 mg) was deacetylated in 0.1 M methanolic sodium methoxide (2 ml) at ambient temperature overnight. The solution was diluted with cold water and neutralized with Amberlite IR-120(H^+) resin. The solution was concentrated to dryness, and the residue was recrystallized from aqueous ethanol to give 14.2 mg (48%) of **6**. After 24 h in a vacuum desiccator with calcium chloride, the product melted at 122—123 °C, $[\alpha]_D^{20}$+140.2° (*c* 0.84, water). After being dried over phosphorus pentaoxide *in vacuo* at 45 °C for 72 h, the product gave correct analysis as a monohydrate, $[\alpha]_D^{20}$+147.3° (*c* 0.8, wster), its IR spectrum being superimposable on that of an authentic sample. Lit, $[\alpha]_D$+148.1° (*c* 9, water) (anhyd ous),[1] $[\alpha]_D^{20}$ +146° (*c* 2.05, water) (anhydrous),[3] $[\alpha]_D^{23}$+133° (*c* 4.5, water) (tetrahydrate).[21]

Found: C, 41.99; H, 6.70%. Calcd for $C_{24}H_{42}O_{21}\cdot H_2O$: C, 42.11; H, 6.48%.

O-(2,3,4,6-Tetra-O-acetyl-β-D-galactopyranosyl)-(1→6)-O-(2,3,4-tri-O-acetyl-α-D-galactopyranosyl)-(1→6)-O-(2,3,4-tri-O-acetyl-α-D-glucoyranosyl) 1,3,4,6-tetra-O-acetyl-β-D-fructofuranoside (7). Mercury(II) cyanide (2.0 g) and drierite (2.0 g) were added to a solution of **1** (0.81 g) and 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide[15] (1.03 g) in dry nitromethane (20 ml). After being left to stand for 4.5 h in the dark, the mixturr was filtered and the filtrate was concentrated. The residue was purified on a silica gel column using 2: 5 (v/v) 2-butanone–toluene. Fractions homogeneous on TLC (R_f 0.37) in 3: 5 (v/v) 2-butanone–toluene were combined and coccentrated. The residue was recrystallized from 2-propanol to give 588 mg (54%) of **7**, mp 89—91 °C, $[\alpha]_D^{21}$+69.4° (*c* 1.34, chloroform). ^1H NMR: δ 1.95 (s, 3, OAC), 1.97 (s, 3, OAc), 2.03 (s, 3, (OAc, 2.05 (s, 3, OAc), 2.06 (s, 3, OAc), 2.10 (s, 9, 3×OAc), 2.11 (s, 3, OAc), 2.12 (s, 3, OAc), 2.13 (s, 3, OAc), 2.15 (s, 3, OAc), 2.17 (s, 3, OAc), 2.20 (s, 3, OAc), 4.49 (d, 1, $J_{1''',2'''}$= 8.0 Hz, H-1‴), 4.85 (dd, 1, $J_{1,2}$=4.0 Hz, $J_{2,3}$=10.5 Hz, H-2), 5.73 (d, 1, H-1).

Found: C, 49.60; H. 5.58%. Calcd for $C_{52}H_{70}O_{35}$: C, 49.76; H, 5.62%.

We wish to express our thanks to Mr. Toshihide Ikeda for his technical assistance and to Mr. Saburo Nakada for the elemental analyses.

Studies of Peptide Antibiotics. XXXVIII.[1] Synthesis of *S,S'*-Bi([1-L-hemicystine]-gramicidin S), a Dimerized Analog of Gramicidin S

Kazuki SATO, Kazuo UEDA,* Michio KONDO,** Haruhiko AOYAGI, and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science 33, Kyushu University, Higashi-ku, Fukuoka 812

(Received November 12, 1977)

To investigate the importance of the orientation of side chains of amino acid residues in gramicidin S (GS) for the antibacterial activity, a dimerized analog of GS, namely *S,S'*-bi([1-L-hemicystine]-GS) (**13**) was synthesized *via* removal of *p*-methoxybenzyl group of [1-*S*-*p*-methoxybenzyl-L-cysteine]-GS (**12**) and subsequent oxidation. Compound **12** showed the same antibacterial activity as GS, whereas **13** was inactive. The resemblance of ORD curves of the two analogs to that of GS suggested the similarity of peptide-backbone structure of these three compounds. Strong activity of **12** was explained by similar conformation of **12** to that of GS. To explain the inactivity of **13**, a molecular model was proposed; four hydrophilic side chains are located on surface of the molecule, whereas six hydrophobic are burried.

Gramicidin S (GS) is a cyclic decapeptide antibiotic possessing the amino acid sequence shown in Fig. 1. Several models have been proposed[2] for the conformation of GS in solid state and solution. The most favorable model is the intramolecular antiparallel β-form with four hydrogen bondings between the valyl and the leucyl residues.[3] A characteristic feature of this conformation is the orientation of side chains in which the charged Orn side chains were on one side and the hydrophobic Val and Leu side chains on the other side of the molecule.[4] Recently, Kato and Izumiya introduced the sidedness hypothesis which means that the sidedness in GS molecule is important for the antibacterial activity of GS.[5,6] The sidedness hypothesis are supported by the results from many investigations of synthetic amino acid-substituted analogs.[2]

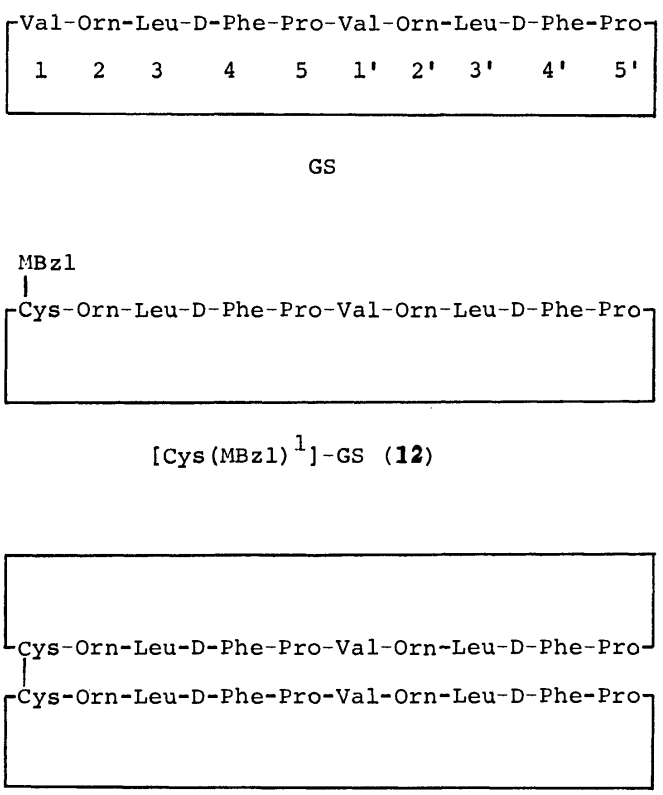

Fig. 1. Structure of GS and its analogs.

[3,3'-Di-*N*-methyl-L-leucine]-gramicidin S synthesized by Sugano *et al.*[7] showed the same antibacterial activity as GS. For the conformation of this analog, Kumar *et al.*[8] proposed a model, in which the side chains of Orn and Val were on the same side of the molecule, on the basis of NMR studies. On the other hand, Kato and Izumiya[5] showed the possibility of other two models which satisfy the sidedness hypothesis; the models were derived from the calculation of dihedral angles and other considerations. Therefore, it seemed interesting to synthesize an analog of GS which possesses a deviated conformation from the sidedness hypothesis. For this purpose, we selected a dimerized analog of GS containing a disulfide bridge. In this connection, it would be noteworthy that a synthetic digramicidin S, *cyclo*(–Val–Orn–Leu–D-Phe–Pro–)$_4$, possessed an appreciable antibacterial activity, and showed similar ORD curves as GS in ethanol, but quite different in aqueous urea.[9] These results suggested that digramicidin S also possesses somewhat GS-like orientation of side chains in spite of its soft and fairly different structures from that of GS.

The present paper deals with the synthesis, antibacterial properties, and ORD measurements of a dimerized analog of GS, *S,S'*-bi([1-L-hemicystine]-gramicidin S) (**13**), and a precursor of **13**, [1-*S*-*p*-methoxybenzyl-L-cysteine]-gramicidin S (**12**), the structure of them being shown in Fig. 1. The former compound, **13**, was a model in which the hydrophobic sides of two GS molecules were combined together by a disulfide bridge.

The synthesis of **12** was outlined in Fig. 2.[10] Cyclization reaction was achieved with leucyl residue at *C*-terminal.[11] Mercapto group of cysteine was protected with *p*-methoxybenzyl group which was removable smoothly with liquid hydrogen fluoride,[12] but stable for the treatment with hydrogen bromide in acetic acid. Mixed anhydride method was used for couplings between an amino acid and a peptide derivative, and azide method for fragment coupling and cyclization.

** Present address: Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840.

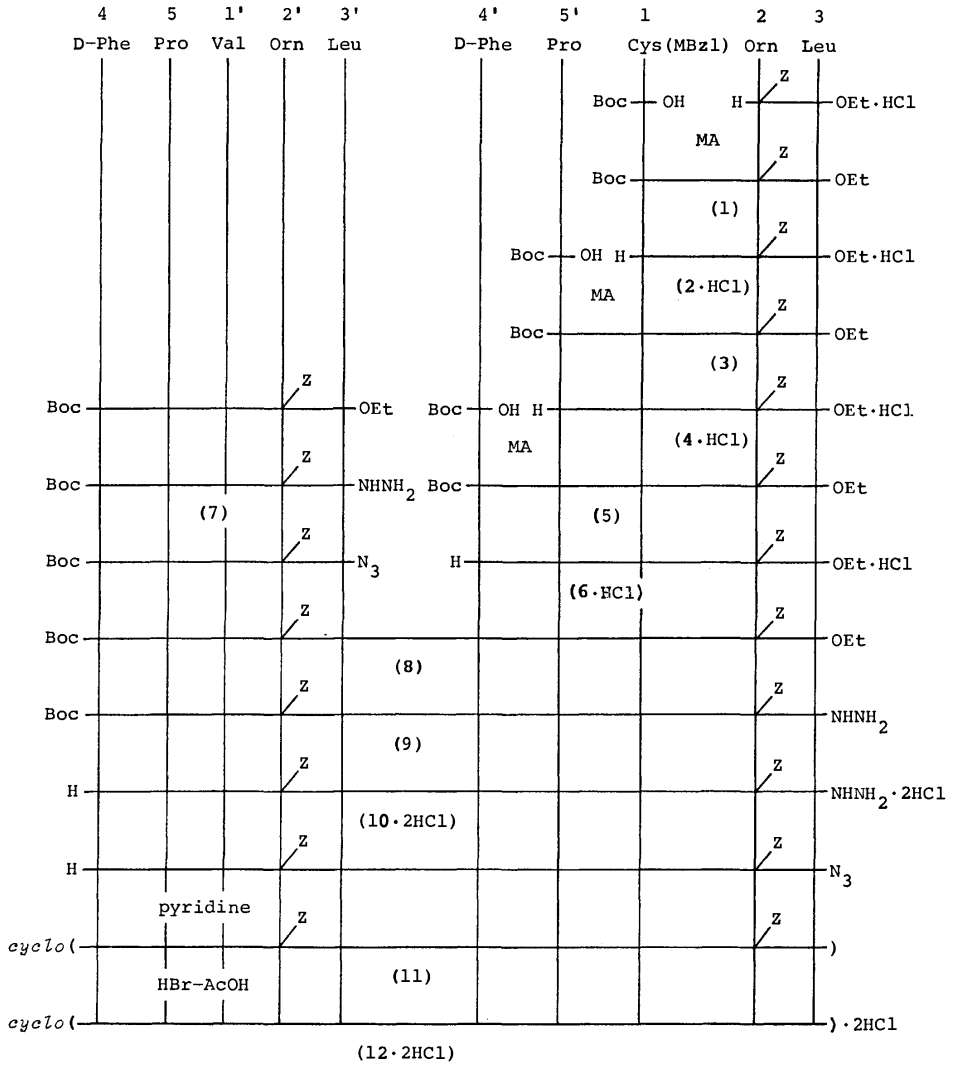

Fig. 2. Synthesis of [Cys(MBzl)[1]]-GS (**12**).

The pentapeptide ester (**6**) containing *S*-*p*-methoxybenzylcysteine residue was prepared by stepwise elongation from H–Orn(Z)–Leu–OEt·HCl[13] toward the amino end. Azide coupling of **6** and Boc-pentapeptide hydrazide (**7**) derived from Boc–D-Phe–Pro–Val–Orn(Z)–Leu–OEt[13] afforded a Boc-decapeptide ester (**8**), which was purified with silica gel column chromatography. Conversion of **8** to its hydrazide (**9**) and deblocking of Boc-group of **9** were performed without any difficulty. A key interemediate (**11**) was derived by the cyclization of **10** in a satisfactory yield of 64%. Z-groups of **11** were removed with hydrogen bromide in acetic acid and the dihydrobromide (**12**·2HBr) obtained was treated with Dowex 1 (OH^- form) to afford an acid-free **12**, which was converted to a dihydrochloride in a crystalline fine needle like GS dihydrochloride by the addition of ethanol and 1 M hydrochloric acid. The desired compound, **13**, was derived from **12** by the treatment with liquid hydrogen fluoride followed by oxidation with potassium hexacyanoferrate(III).[14] The molecular size of **13** shown in Fig. 1 was estimated by the fact that the elution volume of **13**·4HCl in the column chromatography of Sephadex G-25 coincided well with that of digramicidin S tetrahydrochloride.[9] The homogeneity of **12** and **13** was confirmed by paper and thin-layer chromatography, paper electrophoresis and elemental analysis.

Table 1. Antibacterial activity of GS and its analogs (Minimum inhibitory concentration, μg/ml)

Strain	GS	[Cys(MBzl)[1]]-GS (**12**)	*S,S'*-Bi([hemicystine[1]]-GS) (**13**)
Staphylococcus aureus	5	10	>100
Bacillus subtilis	2	5	>100
Escherichia coli	>100	>100	>100
Mycobacterium avium	100	>100	>100
Proteus vulgaris	>100	>100	>100

Antibacterial activities of **12** and **13** measured in nutrient agar are listed in Table 1. Compound **12** exhibited the same activity as GS against some organisms tested, whereas **13** was inactive. These data indicated that the Val[1] residue in GS was exchangeable to Cys(MBzl) residue without any significant effect on the antibacterial activity, and that the activity of **12**

was lost when the hydrophobic sides in position 1 were combined with a disulfide bridge.

The ORD curves of the two analogs as well as of GS are shown in Fig. 3. The fact that **12** exhibited closely similar curves to GS in EtOH (Fig. 3-a) and even in the strong denaturing agent such as 8 M urea (Fig. 3-b) suggested the rigid and stable conformation of **12** as well as natural GS. The dimerized analog, **13**, also exhibited the same pattern as GS though the negative trough was shallower than that of GS, the result suggesting that the structure of peptide-backbone was not changed significantly by the formation of a disulfide bridge.

The results of biological assay and ORD measurement

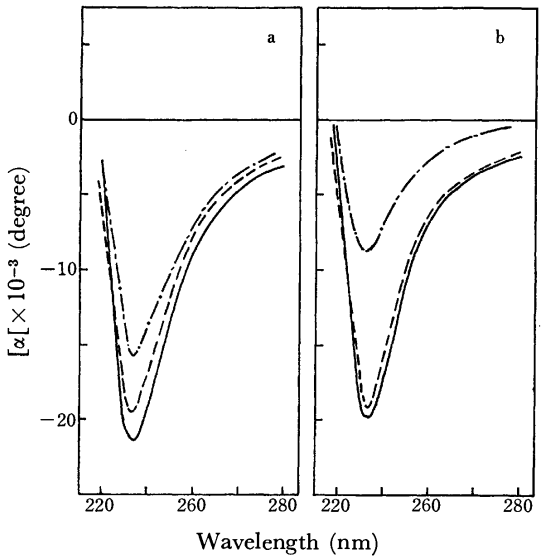

Fig. 3. ORD curves of GS and its analogs. Solvent: a, EtOH; b, 8 M urea. Curve: ——, GS; ----, **12**; -·-·-, **13**.

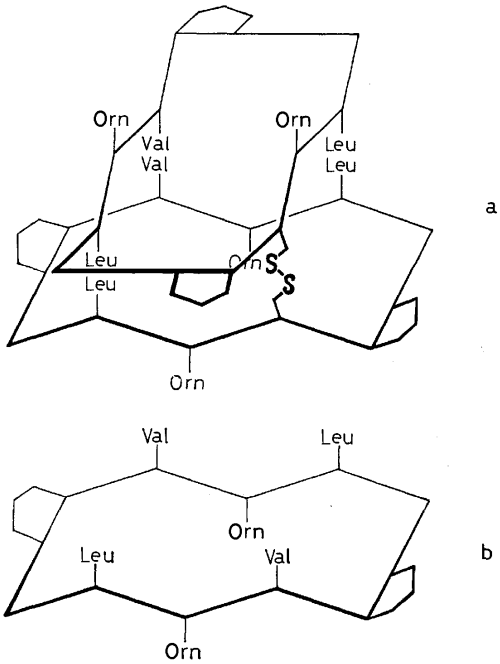

Fig. 4. A possible conformation (a) of a dimerized analog (**13**) and a conformation (b) of GS.

of **12** indicated the importance of definite orientation of side chains such that the hydrophilic side chains were on one side of a molecule and the hydrophobic were on the other side for the molecule such as GS and its active analogs. On the other hand, we propose a possible conformation (Fig. 4-a) of **13** suitable for the results of its biological assay and ORD measurement. In this model, (1) the H^{α}–C^{α} and C^{β}–S bonds are in antiperiplanar conformation regards to the C^{α}–C^{β} bond,[15] (2) the dihedral angle of C^{β}–S–S′–C^{β} is +90° (P-helical), and (3) charged side chains of four Orn residues are located on surface of the molecule, and bulky side chains of six Val and Leu residues make three pair of hydrophobic interactions in inside. In this connection, it would be noteworthy that NMR and CD studies on a bicyclic GS analog (cyclic decapeptide), [2,2′-cystine]-GS (**14**), revealed that its structure was identical with that of GS;[16] the fact indicated no distorting of the conformation of **14** by disulfide bridge which links the two β-antiparallel strands. The biological activity of **14**, however, has not been reported.

Experimental

All the melting points are uncorrected. The ratio in parentheses after a solvent system was indicated by vol. TLC was carried out on silica gel G (Merck) with the following solvent systems: R_f^1, CHCl–MeOH (5: 1); R_f^2, *n*-BuOH–AcOH–pyridine–H_2O (4: 1: 1: 2). Paper chromatography was carried out on Toyo Roshi No. 52 paper; R_f^3, same solvent as that used for R_f^2. Optical rotations were measured on a Union high sensitivity polarimeter PM-71. Amino acid analyses were performed with a Hitachi amino acid analyzer KLA-5. Molecular weight was determined with a Hitachi Osmometer, Model 115, MeOH being used as a solvent.

Boc-Cys(MBzl)-Orn(Z)-Leu-OEt (1). To a chilled solution of Boc-Cys(MBzl)-OH (5.12 g, 15 mmol) and TEA (2.1 ml, 15 mmol) in THF (30 ml) was added isobutyl chloroformate (1.97 ml, 15 mmol) at −10°C. After 10 min, a chilled solution of H-Orn(Z)-Leu-OEt·HCl[13] (6.65 g, 15 mmol) and TEA (2.1 ml, 15 mmol) in $CHCl_3$ (30 ml) was added. The mixture was left to stand at room temperature overnight, evaporated *in vacuo*, and the oily residue was dissolved in EtOAc. The solution was washed successively with 4% $NaHCO_3$, 10% citric acid and water, dried (Na_2SO_4), and evaporated under reduced pressure. The residual oil was solidified by the addition of ether and petroleum ether, and the product was recrystallized from EtOH–ether–petroleum ether; yield, 7.68 g (70%); mp 78—80 °C; $[\alpha]_D^{20}$—25.6 ° (*c* 1, EtOH); R_f^1 0.88.

Found: C, 60.90; H, 7.50; N, 7.77%. Calcd for $C_{37}H_{54}O^9N_4S$: C, 60.80; H, 7.45; N, 7.67%.

H-Cys(MBzl)-Orn(Z)-Leu-OEt·HCl (2·HCl). Compound **1** (6.58 g, 9 mmol) was dissolved in 2.8 M hydrogen chloride in EtOAc (64 ml). The solution was allowed to stand at room temperature for 1 h and then evaporated. Addition of ether to the oily residue gave hygroscopic crystals; yield, 5.47 g (91%); mp 170—171 °C; $[\alpha]_D^{20}$—10.6° (*c* 1, EtOH); R_f^1 0.80, R_f^2 0.84, R_f^3 0.93.

Found: C, 56.42; H, 7.08; N, 8.44%. Calcd for $C_{32}H_{46}O_7N_4S\cdot HCl\cdot H_2O$: C, 56.08; H, 7.21; N, 8.18%.

Boc-Pro-Cys(MBzl)-Orn(Z)-Leu-OEt(3). This was prepared from Boc-Pro-OH (1.64 g, 7.6 mmol) and **2**·HCl (5.09 g, 7.6 mmol) as described for the preparation of **1**.

The product was recrystallized from EtOH–ether; yield, 5.16 g (82%); mp 134—136 °C; $[\alpha]_D^{20}$—48.8° (*c* 1, EtOH); R_f^1 0.87.

Found: C, 60.44; H, 7.52; N, 8.39%. Calcd for $C_{42}H_{61}O_{10}N_5S$: C, 60.92; H, 7.43; N, 8.46%.

H–Pro–Cys(MBzl)–Orn(Z)–Leu–OEt·HCl (**4**·*HCl*). This was prepared from **3** (2.85 g, 3.5 mmol) as described for **2**·HCl; yield, 2.52 g (95%); mp 112—114 °C; $[\alpha]_D^{20}$—39.0° (*c* 1, EtOH); R_f^1 0.66, R_f^2 0.78.

Found: C, 57.37; H, 7.13; N, 8.87%. Calcd for $C_{37}H_{53}O_8N_4S$·HCl: C, 57.46; H, 7.17; N, 9.06%.

Boc–D-Phe–Pro–Cys(MBzl)–Orn(Z)–Leu–OEt (**5**). This was prepared from Boc–D-Phe–OH (0.85 g, 3.2 mmol) and **4**·HCl (2.47 g, 3.2 mmol) as described for **1**. The product was obtained as a foam; yield, 3.01 g (97%); $[\alpha]_D^{20}$—85.9° (*c* 2, EtOH); R_f^1 0.71.

Found: C, 62.66; H, 7.44; N, 8.50%. Calcd for $C_{51}H_{70}O_{11}N_6S$: C, 62.81; H, 7.24; N, 8.62%.

H–D-Phe–Pro–Cys(MBzl)–Orn(Z)–Leu–OEt·HCl (**6**·*HCl*). Compound **5** (1.95 g, 2 mmol) was treated with 2.8 M hydrogen chloride in EtOAc (14 ml) as described for **2**·HCl. The oily product was purified with a column (4.6×40 cm) of silica gel as follows. The crude **6**·HCl was applied on the column. The column was washed successively with EtOAc (1000 ml) and a mixture (300 ml) of EtOAc–EtOH (2:1), and eluted with EtOH (700 ml). Each fraction was assayed by TLC, and the fractions containing the desired product were evapotared to leave a foam; yfield, 1.29 g (70%); $[\alpha]_D^{20}$—119° (*c* 1, EtOH); R_f^1 0.62.

Found: C, 59.83; H, 7.00; N, 9.11%. Calcd for $C_{46}H_{62}O_9N_6S$·HCl·1/2H_2O: C, 60.01; H, 7.01; N, 9.13%.

Boc–D-Phe–Pro–Val–Orn(Z)–Leu–N_2H_3 (**7**). A solution of Boc–D-Phe–Pro–Val–Orn(Z)–Leu–OEt (0.86 g, 1 mmol)[13] and hydrazine hydrate (1.94 ml, 40 mmol) in DMF (6 ml) was allowed to stand at room temperature for 48 h. The solution was evaporated and the addition of water afforded a solid, which was recrystallized from MeOH–ether; yield, 0.77 g (92%); mp 178—182 °C; $[\alpha]_D^{20}$—62.8° (*c* 1, EtOH); R_f^1 0.72.

Found: C, 61.43; H, 7.95; N, 13.23%. Calcd for $C_{43}H_{64}O_9N_8$: C, 61.70; H, 7.71; N, 13.39%.

Boc–D-Phe–Pro–Val–Orn(Z)–Leu–D-Phe–Pro–Cys(MBzl)–Orn(Z)–Leu–OEt (**8**). To a solurion of **7** (313 mg, 0.37 mmol) in DMF (2 ml) were added 2.8 M hydrogen chloride in EtOAc (0.52 ml) and isopentyl nitrite (0.057 ml, 0.41 mmol) in DMF (0.57 ml) at −60 °C. After being left to stand at −20 °C for 10 min, the solution was cooled again to −60 °C and neurtalized with TEA (0.21 ml, 1.5 mmol). To this solution was added a chilled solution of **6**·HCl (337 mg, 0.37 mmol) and TEA (0.05 ml, 0.37 mmol) in DMF (1 ml). The reaction mixture was allowed to stir at 0 °C for 48 h and then evaporated. After the addition of 0.02 M citric acid (100 ml), the solid was collected and washed with water. The crude product was purified with a column (4.6×45 cm) of silica gel using $CHCl_3$–MeOH–AcOH (95:5:1) as a developing agent as described for **6**·HCl; yield, 370 mg (60%); mp 104—109 °C; $[\alpha]_D^{20}$—116° (*c* 0.5, EtOH); R_f^1 0.79.

Found: C, 63.32; H, 7.31; N, 9.96%. Calcd for $C_{89}H_{122}O_{18}N_{12}S·H_2O$: C, 63.32; H, 7.40; N, 9.95%.

Boc–D-Phe–Pro–Val–Orn(Z)–Leu–D-Phe–Pro–Cys(MBzl)–Orn(Z)–Leu–N_2H_3 (**9**). Compound **8** (336 mg, 0.2 mmol) was treated with hydrazine hydrate (0.39 ml, 8 mmol) as described for **7**; yield, 232 mg (70%); mp 208—209 °C $[\alpha]_D^{20}$—126° (*c* 0.5, EtOH); R_f^1 0.61.

Found: C, 61.12; H, 7.19; N, 11.55%. Calcd for $C_{87}H_{120}O_{17}N_{14}S·2H_2O$: C, 61.39; H, 7.34; N, 11.52%.

H–D-Phe–Pro–Val–Orn(Z)–Leu–D-Phe–Pro–Cys(MBzl)–Orn(Z)–Leu–N_2H_3·2HCl (**10**·2*HCl*). Compound **9** (216 mg, 0.13 mmol) was treated with 0.1 M hydrogen chloride in formic acid (3.3 ml) as described for **2**·HCl and the product was used for the next reaction without further treatment; yield, 196 mg (92%); R_f^1 0.58.

cyclo(*–D-Phe–Pro–Val–Orn(Z)–Leu–D-Phe–Pro–Cys(MBzl)–Orn(Z)–Leu–*) (**11**). To a solution of **10**·2HCl (178 mg, 0.11 mmol) in DMF (2 ml) were added 2.8 M hydrogen chloride in EtOAc (0.15 ml) and isopentyl nitrite (0.017 ml, 0.12 mmol) in DMF (0.17 ml) at −30 °C. After 30 min, the reaction mixture was added into pyridine (108 ml) at 0 °C. After being stirred at 5 °C for 4 days, the solution was evaporated and the residue was dissolved in a mixture (11 ml) of MeOH–H_2O (10:1). The solution was applied on columns (1.9×20 cm each) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (200 ml); the combined effluent was evaporated to leave an oil which was solidified by the addition of water. The crude product dissolved in MeOH (2 ml) was applied on a column (1.8×110 cm)of Sephadex LH-20 which was developed with MeOH. The fractions with the desired product were evaporated and the oily residue was crystallized by the addition of ether and petroleum ether; yield, 106 mg (64%); mp 187—189 °C; $[\alpha]_D^{20}$—290° (*c* 0.5, MeOH); R_f^1 0.78.

Found: C, 63.54; H, 7.05; N, 10.71%; mol wt, 1541. Calcd for $C_{82}H_{103}O_{15}N_{12}S·H_2O$: C, 63.46; H, 7.15; N, 10.83%; mol wt, 1552.

cyclo(*–D-Phe–Pro–Val–Orn–Leu–D-Phe–Pro–Cys(MBzl)–Orn Leu–*)·2HCl ([*Cys(MBzl)*^{1}]–*GS*·2HCl) (**12**·2*HCl*). To a solution of **11** (96 mg, 0.06 mmol) in AcOH (1 ml) was added 25% hydrogen bromide in AcOH (0.2 ml). The rereaction mixture was allowed to stand at room temperature for 4 h, evaporated, and the yellowish residue was crystallized by the addition of ether. The crude dihydrobromide was dissolved in a mixture of MeOH–H_2O (4:1) and the solution was applied on a column (1.9×20 cm) of Dowex 1 (OH^- form). The peptide in the column was eluted with the same solvent and the combined effluent (200 ml) was evaporated to leave a solid. The product was recrystallized from EtOH–1 M HCl; yield, 62 mg (75%); mp 270—271 °C (dec); $[\alpha]_D^{20}$—297° (*c* 0.3, EtOH); R_f^2 0.84, R_f^3 0.80.

Found: C, 55.64; H, 7.59; N, 11.45%. Calcd for $C_{66}H_{96}O_{11}N_{12}S$·2HCl·5$H_2O$: C, 55.49; H, 7.61: N, 11.75%.

S,S'-Bicyclo(*–D-Phe–Pro–Val–Orn–Leu–D-Phe–Pro–hemicystyl–Orn–Leu–*)·4HCl (S,S'–*Bi*([*hemicystine*^{1}]–*GS*)·4HCl) (**13**·4*HCl*). To a mixture of **12**·2HCl (40 mg, 0.03 mmol) and anisole (0.16 ml) was added liquid hydrogen fluoride (5 ml) at 0 °C. The reaction mixture was stirred at 0 °C for 1 h and then evaporated *in vacuo*. The residue was dissolved in 1 M AcOH (50 ml) and the solution was washed with ether (20 ml×2) and then lyophilized. To a solution of the lyophilizate (30 mg) in 0.05 M ammonium acetate containing 30% MeOH (50 ml, pH 6.8) was added 0.01 M potassium hexacyanoferrate(III) (5.6 ml).[14] After being stirred for 10 min, Amberlite IR-45 (Cl^- form) resin was added into the solution, and the resin was filtered off and washed with 30% MeOH. The filtrate and washings were evaporated, the residue was dissolved in a mixture (3 ml) of AcOH–MeOH–H_2O (1:1:1), and the solution was applied on a column of Sephadex G-25 (2×80 cm) which was eluted with the same solvent. The fractions of the desired product were evaporated to leave a solid, which was recrystallized from EtOH–1 M HCl; yield, 15 mg (41%); mp 258—259 °C (dec); $[\alpha]_D^{20}$—287° (*c* 0.4, EtOH); R_f^2 0.75; R_f^3 0.80. Amino acid ratios in acid hydrolyzate; Phe

4.20, Pro 3.76, Val 1.92, cystine 0.90, Orn 4.12, Leu 4.00. Found: C, 53.43; H, 7.37; N, 12.07%. Calcd for $C_{116}H_{174}O_{20}N_{24}S_2 \cdot 4HCl \cdot 10H_2O$: C, 53.28; H, 7.63; N, 12.36%.

Paper Electrophoresis. This was carried out with Toyo Roshi No. 52 paper and a solvent system of HCOOH–AcOH–MeOH–H_2O (1: 3: 6: 10, pH 1.8) for 2.5 h at 500 V/30 cm. Figure 5 showed that each of the peptides (**12** and **13**) revealed a single spot.

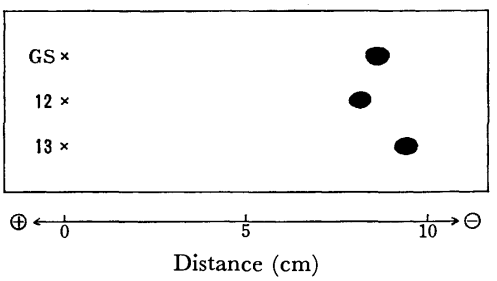

Fig. 5. Paper electrophoresis of GS and its analogs.

Microbiological Assays[17] *and ORD Measurements.* These were carried out as described in a previous paper,[13] the results being shown in Table I and Fig. 3.

The authors wish to express their thanks to Dr. T. Kato and Dr. M. Waki of this laboratory for their helpful discussions.

Preparation of Organic Copper(I) Complexes by the Reactions of Methylbis(triphenylphosphine)copper(I) with Nitroalkanes, β-Diketones, and Cyanoalkanes[1)]

Takakazu YAMAMOTO, Minoru KUBOTA, Akira MIYASHITA, and Akio YAMAMOTO

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta-cho, Midori-ku, Yokohama 227

(Received November 16, 1977)

Reactions of a methylcopper complex $CH_3Cu(PPh_3)_2$(diethyl ether)$_{0.5}$ (PPh_3=triphenylphosphine) with three types of active hydrogen compounds HA give the corresponding copper derivatives of active hydrogen compounds formulated as $ACu(PPh_3)_2$. Nitroalkanes (nitromethane, nitroethane and 2-nitropropane) form copper complexes bonded through aci-nitro groups. β-Diketone and its analogs such as acetylacetone, diethyl malonate and ethyl acetoacetate react in their enol form to give six-membered *O,O'*-bonded chelates, whereas cyanoalkanes including acetonitrile, propionitrile, and malononitrile afford organocopper complexes having a direct Cu–C bond.

The non-transition metal derivatives of active hydrogen compounds such as diethyl malonate and malononitrile serve as convenient and versatile starting materials for the syntheses of various organic compounds. Extensive studies have been made on the preparation and properties of the non-transition metal derivatives of the active hydrogen compounds. However, only limited information is available on the transition metal derivatives of the active hydrogen compounds except for some β-diketones which form chelate complexes with the transition metals. In the course of studies on the chemical properties of alkylcopper complexes having tertiary phosphine ligands[2)] it was found that reactions proceed smoothly between the alkylcopper complexes and various active hydrogen compounds having nitro, β-dicarbonyl, or cyano group to afford various copper derivatives of the active hydrogen compounds in high yields.

In this paper we report the preparation of the copper derivatives of the active hydrogen compounds and discuss their structures. Marsich and Camus and co-workers recently reported the preparation of copper derivatives of active hydrogen compounds having β-dicarbonyl or nitro group by the reaction of arylcopper(I) with the active hydrogen compounds in the presence of phosphine ligands.[3)] Tsuda *et al.* reported the formation of (cyanomethyl)copper complexes by the decarbonylation of Cu(I) and Cu(II) cyanoacetates as well as by the reaction of t-$C_4H_9OCu(P(n\text{-}C_4H_9)_3)$ with CH_3CN.[4)] Utilization of (cyanomethyl)copper prepared *in situ* by the reaction of CuI with $LiCH_2CN$ for organic syntheses[5)] was also reported.

Results and Discussion

Reactions of Alkylcopper Complexes with Active Hydrogen Compounds. Alkylcopper complexes smoothly react with active hydrogen compounds having nitro, β-dicarbonyl, or cyano group. The methylcopper complex $CH_3Cu(PPh_3)_2(Et_2O)_{0.5}$ gives three types of complex in high yields (63—92%) depending on the nature of the active hydrogen compound.

An active hydrogen compound with more acidic hydrogen reacts more easily with the methylcopper complex. As an example, **1** reacts with malononitrile immediately at −30 °C, but the reaction of **1** with

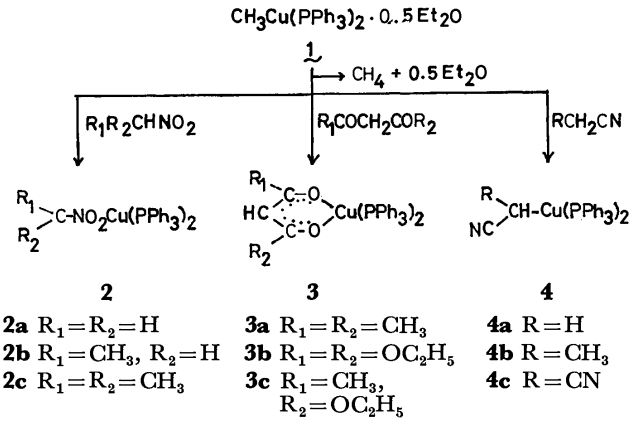

Fig. 1.

propionitrile at room temperature takes several hours to complete. All the complexes prepared are white indicating that the oxidation number of copper in the complexes is one. Type **2** and **3** complexes are soluble in organic solvents, but not the copper derivatives of cyanoalkanes, **4**. Most complexes are relatively insensitive to air, having very high thermal stability in the solid state. However, they are easily oxidized in solution, the thermal stability decreasing.

Of the products represented in Fig. 1, **2a**, **3a**, **3b**, **3c**, and **5** have been independently prepared by Marsich and Camus and co-workers through reactions of arylcopper(I) prepared *in situ* with the corresponding active hydrogen compounds in the presence of PPh_3.[3)] However, no NMR spectroscopic data have been given.[6)] Analytical and spectral data of the isolated complexes are summarized in Tables 1 and 2, respectively.

In addition to the nitromethanato complex **2a** they prepared a dinitrophenylmethane derivative of copper $(C_6H_5C(NO_2)_2)Cu(PPh_3)_2$, and confirmed by X-ray analysis that the copper atom in the complex is bonded to the dinitrophenylmethanato ligand through one of the two nitro groups in the solid state.[3d)] The IR and NMR spectroscopic data of complexes **2a**, **2b**, and **2c** support the view that the copper atom in these complexes is bonded to the nitroalkanato ligand through the same type of bonding (aci-nitro type bonding) as in the dinitrophenylmethane complex:

The ν(C=N) stretching frequencies of the nitroalkanes

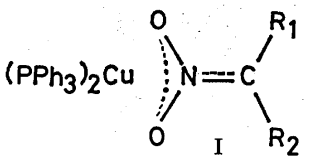
The triphenylphosphine signals are omitted from the table.



I

Fig. 2.

shift towards higher values on complex formation, the new bands appearing in the absorption regions characteristic of the aci-nitroalkanato anion.[7]

In the NMR spectra of the nitroalkanato complexes the α-proton signals of nitromethane and nitroethane are shifted to lower field by 1.44[6] and 1.86 ppm, respectively, and the α-methyl proton signals of nitroethane and 2-nitropropane to the same direction by 0.40 and 0.61 ppm, respectively. Since the protons attached to the carbon directly bonded to copper in alkylcopper complexes give rise to signals at relatively higher fields as compared with those in usual organic compounds,[2b] the low field shift of nitroalkane signals upon bonding to copper is not in line with the substitution of the nitroalkanes by copper at the α-position forming a nitroalkylcopper complexes.

The sp^2 character around the α-carbon in the aci-nitro type complex I accounts for the lowering of the

α-proton and α-methyl signals.

Since the nitroalkanato ligand $RCHNO_2$ is considered to be bonded to copper atom through the nitro group, the reaction of the complex with alkyl halide R'X is expected to give *O*-alkylated compound RCH=N(O)OR' as in the reactions of copper phenoxide with alkyl halides.[8] However, the reactions of complexes **2a**, **2b**, and **2c** with alkyl halides give α-*C* alkylated compounds $RCHR'NO_2$, *e.g.*,

$$\mathbf{2b} + CH_3I \xrightarrow[THF]{\text{r.t.}} \text{2-nitropropane (16\%)}$$

The α-alkylated compounds can be produced through a direct electrophilic attack of R'X at the α-carbon in the aci-nitromethanato ligand or through isomerization of the *O*-bonded species I to the *C*-bonded species.

On allowing complex **2a** to stand in chloroform at room temperature it is decomposed to release nitromethane.[6] Since employment of $CDCl_3$ does not cause the introduction of D into the nitromethane released, the possibility of the abstraction of hydrogen of chloroform by the nitromethanato ligand is excluded. The PPh_3 ligand coordinated with Cu may give its ortho hydrogen to the nitromethanato ligand with formation of ortho metalized PPh_3 ligand and nitromethane. This type of abstraction of ortho hydrogen of PPh_3 has been observed in the decomposition of $RhCH_3(PPh_3)_3$ in solutions.[9]

Cryoscopic determination of the molecular weight indicates that the nitroethanato complex has a monomeric structure in benzene with partial dissociation of the PPh_3 ligands.

The ν(C=O) bands assignable to free C=O groups of the β-dicarbonyl compounds (acetylacetone, diethyl malonate, ethyl acetoacetate) disappear on the complex formation with copper, new bands appearing in a lower frequency region which is shifted by *ca.* 100 cm^{-1} from the original ν(C=O). The IR data indicate the formation of an *O*,*O'*-bonded six-membered chelate β-dicarbonyl ligands, excluding the possible metalization of the β-dicarbonyl compounds through the α-carbon.[10] In the *C*-bonded complexes the ν(C=O) bonds are usually observed at much higher frequency, 1700—1800 cm^{-1}. The *O*,*O'*-bonded structure in $Cu(CF_3COCHCOCH_3)(PPh_3)_2$ has been established by X-ray crystallography.[11] The molecular weight determination of complexes **3b** and **3c** gave lower values than those calculated for each complex suggesting dissociation of one of PPh_3 ligands in benzene.

Some by-products such as the dimers of cyanoalkanes (*e.g.*, 2-aminocrotonitrile from acetonitrile) are formed in the metalization of cyanoalkanes by alkali metals, contamination of the alkali metal cyanoalkanate with the by-products being inevitable.[12] However, contamination of complexes **4a** and **4b** with the by-products is excluded since each IR spectrum of the complexes shows only a sharp ν(C≡N) band and acidolyses of the complexes with acetic acid give only the parent cyanoalkanes as confirmed by gas chromatography. Appearance of two ν(C≡N) bands in the IR spectrum of **4c** seems to be due to the separation of $\nu(CN)_{sym}$ and $\nu(CN)_{asym}$ vibrations in the dicyanomethanato ligand.

For the metal derivatives of cyanoalkanes the following forms (a)—(e) are conceivable ((c) is possible only when R=H):[12b]

MCHR–C≡N, MCR=C=NH, MC≡C–NHR,
(a) (b) (c)
RC≡C–NHM, HRC=C=NM
(d) (e)
M=metal

As for complexes **4a** and **4b**, however, the presence of the tautomeric species (b), (c), and (d) is not plausible since their IR spectra show no ν(N–H) band. Insolubility of complexes **4a**, **4b**, and **4c** prevents a detailed structural examination of the complexes by NMR spectroscopy, but form (a) is preferred to the other forms for the present copper derivatives of cyanoalkanes, since some sodium derivatives of cyanoalkanes are known to exist mainly in the *C*-bonded form and the ν(CN) bands of the present copper derivatives appear in the same range of the ν(CN) bands as in the sodium derivatives.[12a] The insolubility of the complexes in organic solvents (acetone, acetonitrile, tetrahydrofuran, benzene, chloroform *etc.*) suggests that the complexes are aggregated by intermolecular association between the CN group and copper.

In contrast to complexes **4a**, **4b**, and **4c** the copper derivative of the β-carbonyl cyanoalkane, ethyl cyanoacetate, is soluble in common organic solvents. The shift of the α-proton signal of ethyl cyanoacetate to lower magnetic field (NMR) by 0.27 ppm and a relatively large shift of ν(CO) band to lower frequency on the formation of the copper derivative suggest the formation of an *O*- and *NC*-bonded chelate:

The molecular weight determination of complex **5** also excludes the association of the complex through the CN group.

Experimental

General. Preparation and recrystallization of copper complexes were carried out under deoxygenated nitrogen or argon. IR spectra were recorded on a Hitachi Model 295 spectrometer in KBr discs, and ^{1}H-NMR spectra on a Japan Electron Optics Lab. JNM-PS-100 spectrometer (TMS as an internal standard). The amount of gas evolved was measured by volumetry and the composition of the gas was analyzed with a Hitachi RMU-5B mass-spectrometer and a Shimadzu GC-5B gas chromatograph. The microanalysis of carbon, hydrogen and nitrogen was performed by Mr. T. Saito with Yanagimoto CHN Autocorder Type MT-2. For analytical and spectral data see Tables 1 and 2.

Material. $CH_3Cu(PPh_3)_2$ $(Et_2O)_{0.5}$ **1** was prepared as reported previously.[2] Solvents were dried by the usual procedure, distilled, and stored under argon or nitrogen. Active hydrogen compounds were purified by distillation brfore use.

Preparations of Copper Derivatives of Nitroalkanes. *Complex 2a*: Nitromethane (3.00 g, 50 mmol) was introduced by a trap-to-trap distillation in a vacuum to complex **1** (100 g, 1.56 mmol) dissolved in tetrahydrofuran (THF, 10 ml). After the mixture had been stirred for 2 h at room temperature a colorless solution was obtained with evolution of methane (35.0 ml, S.T.P., 1.00 mol/Cu). Addition of diethyl ether (20 ml) to the solution and cooling gave white crystlas. They were washed with diethyl ether repeatedly

and dried in a vacuum to yield 899 mg of **2a** (1.39 mmol, 89%).

Complex 2b: Nitroethane (3.75 g, 50 mmol) was introduced to a THF (10 ml) solution of complex **1** (1.00 g, 1.56 mmol) in a vacuum. Stirring of the mixture for 2 h at 0 °C gave a colorless solution, releasing a quantitative amount of methane. Addition of diethyl ether (20 ml) to the solution and cooling afforded white crystals. They were recrystallized from THF and dried in a vacuum to give white crystals of **2b** (877 mg, 1.325 mmol. 85%).

Complex 2c: 2-Nitropropane (4.45 g, 50 mmol) was introduced by a trap-to-trap distillation in a vacuum to a THF (10 ml) solution of complex **1** (1.00 g, 1.56 mmol). Stirring the mixture at −20 °C for 2 h gave a light yellow solution with evolution of a quantitative amount of methane. A white solid was precipitated on condensation of the solution and was recrystallized from toluene-diethyl ether. The white crystals were dried in a vacuum to yield 644 mg (63%) of **2c**.

Preparation of Copper Derivatives of β-Dicarbonyl Compounds.

Complex 3a: Acetylacetone (90 mg, 1.00 mmol) was added to a THF (10 ml) solution of complex **1** (640 mg, 1.00 mmol) with a syringe at −78 °C. Stirring of the mixture at −30—0 °C for 2 h gave a colorless solution and methane. The solution was dried up and the residue was recrystallized from THF to give white crystals, which were dried in a vacuum to give 622 mg (92%) of **3a**.

Complex 3b and 3c: Complexes **3b** and **3c** were prepared in a similar way by the reactions of complex **1** 640 mg, 1.00 mmol) with diethyl malonate (160 mg, 1.00 mol) and ethyl acetoacetate (130 mg, 1.00 mmol), respectively (reaction conditions: −30—0 °C, 2 h).

Prepararions of Cyanoalkylcopper Complexes. *Complex 4a*: The reaction of complex **1** (640 mg, 1.00 mmol) with acetonitrils (2.0 g, 49 mmol) in THF (15 ml) at −10°C gradually produced a light yellow precipitate from a dark yellow solution with evolution of methane. After 5 h the precipitate was separated by filtration, washed with THF repeatedly, and dried in a vacuum to yield a pale yellow complex of **4a** (426 mg, 68%).

Complex 4b: Complex **4b** was prepared in the reaction of complex **1** (640 mg, 1.00 mmol) with propionitrile (2.9 g, 36 mmol) in 5 ml of THF solution at room temp. for 5 h. Work-up was carried out in the same way as in the preparation of **4a**. White yellow complex of **4b** (462 mg, yield 72%) was obtained.

Complex 4c: The reaction of complex **1** (1.10 g, 1.72 mmol) with malononitrile (113 mg, 1.72 mmol) in 10 ml of THF solution at −30 °C produced a white precipitate immediately with evolution of a quantitative amount of methane. The precipitate was washed with diethyl ether and THF and dried in a vacuum to yields a white complex of **4c** (870 mg, 78%).

Complex 5: The reaction of complex **1** (640 mg, 1 mmol) with ethyl cyanoacete (113 mg, 1 mmol) in THF solution at −30—0 °C for 2 h produced a colorless solution. The solution was dried up and the residue was recrystallized from diethyl ether and toluene and the crystals were dried in a vacuum to yield white crystals of **5** (582 mg, 78%).

1,3-Dipolar Cycloadditions of *N*-(*p*-Substituted benzylidene) *p*-Substituted Benzylamine *N*-Oxides with *trans*-Bis(*p*-substituted benzoyl)ethylenes and the Substituent Effects on the Reaction Rates

Keishi TADA, Tomoharu YAMADA, and Fujio TODA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 28, 1977)

1,3-Dipolar cycloadditions of *N*-(*p*-substituted benzylidene) *p*-substituted benzylamine *N*-oxides with *trans*-bis(*p*-substituted benzoyl)ethylenes gave the *trans*- and the *cis*-2,3-bis(*p*-substituted phenyl)-4,5-bis(*p*-substituted benzoyl)isoxazolidines. The configurations of the resulting isoxazolidines were determined by NMR spectra. The formation ratios of the *trans*- to *cis*-adducts were determined by liquid chromatography. The second-order rate constants in xylene at 60 °C were obtained by high speed liquid chromatographic analysis. The rates varied with the σ values of the substituents R_1 on the *N*-benzylidene benzylamine *N*-oxides and R_3 on the dibenzoylethylenes, and linear relationships between log *k* and σ have been established. These results indicate that the HOMO(*N*-oxide)–LUMO(dibenzoylethylene) interaction predominates. The ρ-values for R_1 and R_3 were respectively; $\rho=-0.41\pm0.01$, $\rho=+0.60\pm0.02$.

Several 1,3-dipolar cycloadditions of nitrones have been studied.[1-4] The reactions of *N*-benzylidene benzylamine-*N*-oxide with *trans*- or *cis*-dibenzoylethylene has been reported to give 2,3-diphenyl-4,5-dibenzoylisoxazolidine, quantitatively.[5] However the configurations of the resulting isoxazolidines have not been established.

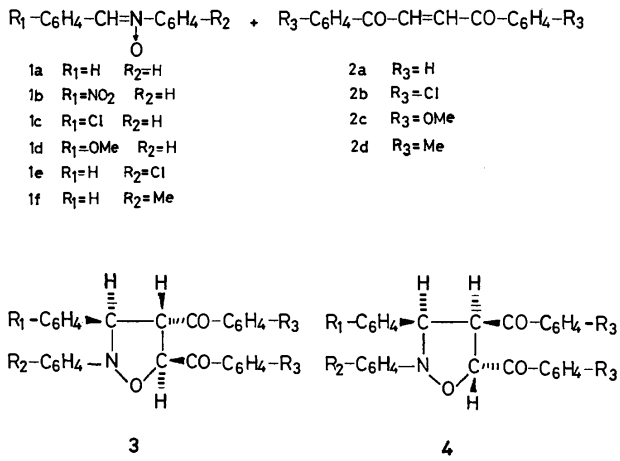
In the reaction of a 1,3-dipole and a dipolarophile, the eight stereoisomers are affected by the following three factors: the orientation of the addition, the direction of the cycloaddition, that is, either *exo* or *endo* and the reaction mechanism, either one or two-step. However, there have been few reported cases in which stereoisomers were obtained by the two-step mechanism. In the system here, the C_{2h}-symmetry of the *trans*-dibenzoylethylene prevented the formation of the stereoisomers caused by the two orientations. If these reactions proceed by a concerted mechanism, only two stereoisomers caused by *exo*- and *endo*-additions, the *trans*- and *cis*-isoxazolidines are expected.

This paper will report the configurations of the resulting isoxazolidines and some reactions of *N*-(*p*-substituted benzylidene) *p*-substituted benzylamine *N*-oxides with *trans*-bis(*p*-substituted benzoyl)ethylenes. The formation ratios of *trans*- to *cis*-forms were investigated to determine the substituent effect or the steric effect.

There have been some quantitative reports in the literatures[6-8] on the effect of substituents on the reaction rates. This paper describes the substituent effects on the reaction rate, and a semiquantitative treatment of the correlation between log *k* and σ using the second-order perturbation theory.

Results and Discussion

1,3-Dipolar cycloadditions of *N*-(*p*-substituted benzylidene) *p*-substituted benzylamine *N*-oxides (**1a**—**f**) (DPN) with *trans*-bis(*p*-substituted benzoyl)ethylenes (**2a**—**c**) (DBE) were conducted in anhydrous benzene to give a mixture of two stereoisomeric isoxazolidines, quantitatively. The configurations of these were determined to be as expected the *trans*- and *cis*-2,3-bis-



Scheme 1.

(*p*-substituted phenyl)-4,5-bis(*p*-substituted benzoyl)isoxazolidines, that is, **3** and **4** in Scheme 1. Thin-layer and high speed liquid chromatography have shown that the reaction mixture had no components other than the two stereoisomers. Column chromatography successfully isolated them from the reaction mixture.

The structures of **3** and **4** were determined by NMR spectra. For example, the NMR spectra of the *trans*- and *cis*-2,3-diphenyl-4,5-dibenzoylisoxazolidines which were produced by the reaction of *N*-benzylidene benzylamine *N*-oxide (**1a**) and dibenzoylethylene (**2a**) are shown in Fig. 1. In the spectrum of the *trans*-adduct (a), the peaks at $\delta=5.05$(d), 5.38(d-d) and 6.01(d) are C_3–H, C_4–H, and C_5–H, respectively. The decoupling signal of C_5–H turned the double-doublet peak of C_4–H to a doublet one. This result confirms these assignments. Coupling constants, C_3–H—C_4–H ($J_{3,4}$) and C_4–H—C_5–H($J_{4,5}$) were as follows; $J_{3,4}=6.0$ Hz, $J_{4,5}=3.4$ Hz. In the spectrum of the *cis*-adduct(b), the peaks C_3–H, C_4–H and C_5–H are situated at $\delta=5.44$(d), 5.82(d-d) and 6.32(d), respectively. The coupling constants are $J_{3,4}=7.5$ and $J_{4,5}=5.6$. In saturated or unsaturated rings, the *cis*-forms coupling constant is generally larger than that of the *trans*-form,[9,10] thus these stereoisomers were concluded to have the above configurations since

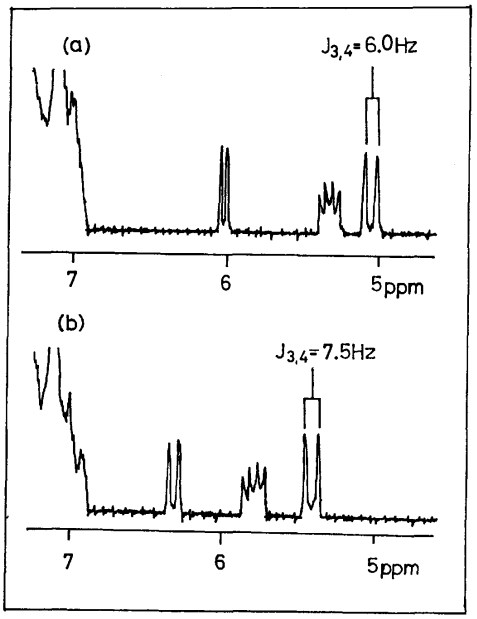


Fig. 1. NMR spectra of *trans*-(**3**) and *cis*-(**4**) isoxazolidine. (a); *trans* (b); *cis* (in DMSO-d_6, 60 MHz).

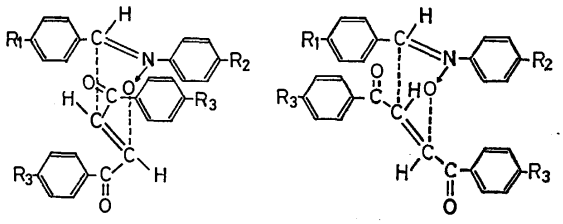
$7.5(J_{cis})>6.0(J_{trans})$. The observation that the *trans*-adduct, which is favored sterically, was the major product also supported these identifications. The NMR spectra of the other reaction products showed similar signal patterns.

DBE has C_{2h}-symmetry at the center of C=C double bond, so that two orientations of the addition give the same product. But there are two directions of the interaction between two components. *trans*-Isoxazolidine was formed through the *exo*-form transition state, and *cis*-isoxazolidine through the *endo*-form (Scheme 2).



Scheme 2.

Melting points and the analytical data of the resulting isoxazolidines are summarized in Table 1. The formation ratios of the *trans*-forms to the *cis*-forms are also shown. They were determined by high speed liquid chromatography.

The reactions of nitrones with *N*-phenylmaleimides have been reported.[11,12] In this system the formation ratios varied in the range 1.5—3.9, depending on the electronic characters of the substituents on the nitrones and maleimides. This result suggests that the two reactant species orient in such a way that the interaction of the two dipole moments is favored (Scheme 3). Between log (I_t/I_c) and the Hammett σ values of the substituents on the nitrones and maleimides a linear

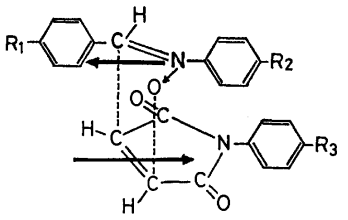
a) The upper line is for the *cis*-form, and the lower line is for the *trans*-form.



Scheme 3.

relationship has been established.

DBE has three planar configurations. Two of these have C_{2h}-symmetry, and the unsymmetric one is hindered sterically between a vinyl hydrogen and an *o*-hydrogen in the benzene ring. By this reasoning the dipole moment will have an insignificant influence on the formation ratios, and consequently the steric effect will be the predominant factor when the two components

are approaching and the π-orbitals begin to interact. The steric effect in the reaction of DPN with DBE would be expected to be greater than that in the reaction of DPN with *N*-phenylmaleimide. In this system the formation ratios are in the range 3.0—6.3, which are a little greater than the formation ratios of the maleimides. This result suggests that the *endo*-type addition is more hindered by the steric effect. In the reactions of DPNs with three DBEs, the values of the formation ratios are not so dissimilar, for example, the ratios of the reactions of **1a** with **2a**, **2b**, and **2c** are 4.2, 4.0, and 4.4, respectively, and the ratios of the reactions of **1c** with **2a**, **2b**, and **2c** are 5.0, 4.7, and 4.5, respectively.

The generation of C-T complexes between two benzene rings could be regarded as a factor governing the formation ratios. In *exo*- and *endo*-additions, the benzene ring of DPN makes about 90° with that of DBE when the two approach and interact in the most stable planar configurations, and about 30° in a less stable configuration. The generation of C-T complexes produces a fluorescence spectrum, but since this was not observed, this factor does not seem to have a predominating effect on the formation ratios.

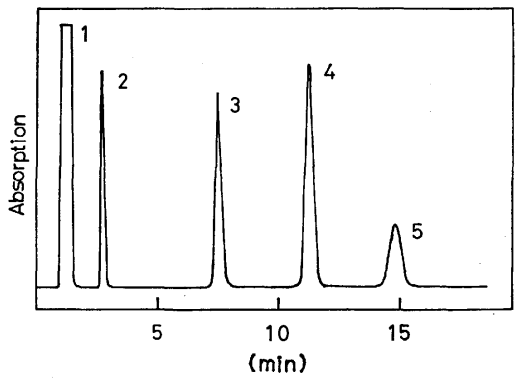


Fig. 2. The HLC chart of the reaction mixture of **1a** and **2a**.

In order to study the effects of substituents on the reaction rates, the rate constants of the reactions of **1a—d** with **2a—d** were determined by high speed liquid chromatography (HLC). Figure 2 shows an HLC chart of the reaction mixture of *N*-benzylidene benzylamine *N*-oxide (**1a**) and dibenzoylethylene (**2a**) at the middle stage of the reaction. The peaks 1, 2, and 4 are of xylene (solvent), nitrobenzene (standard) and DBE, respectively. Before reaction, there were only these three peaks, and as the reaction proceeded, peaks, 3 and 5 appeared and became larger. They are considered to be the *trans*- and *cis*-isoxazolidines. The R_f-values of *trans*-isoxazolidine is usually larger than that of *cis*-one, and the ratio of *trans*- to *cis*-isoxazolidine is greater than 1 due to the steric effect. From these facts, peak 3 is assigned as the *trans*-isomer, and peak 5 as the *cis*-isoxazolidine. The NMR spectra of the products further supported the assignments. In all cases, the peak of DPN was not found in the HLC chart because of a strong attachment to the packing material. In some cases the relative positions of the peaks of DBE and *cis*-isoxazolidine were reversed. In the plots of $1/C$ ("C" is the concentration of DPN or DBE, and the mol-concentrations of DPN and DBE were equal to each other throughout the reaction) *vs.* the reaction time, a linear relationship was established. Therefore, the cycloaddition proved to have a second-order rate constant, first-order with respect to each reactant species.

Table 2. The second-order rate constant k and $\log k$ of the reaction of **1** with **2** (in xylene, at 60 °C)

R_3		R_1: NO_2	Cl	H	MeO
Cl	$k\times10^3$	1.8	2.9	4.6	4.8
	$\log k$	−2.74	−2.54	−2.34	−2.32

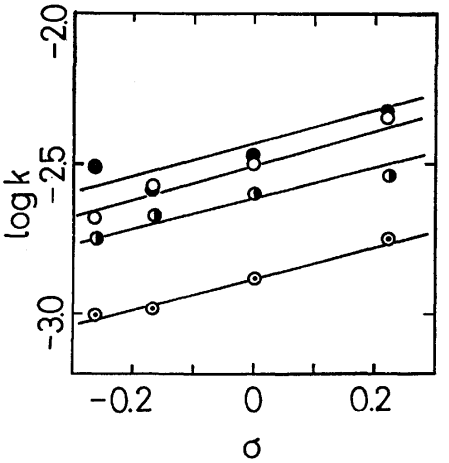

Fig. 4. The relation between the Hammett σ value of R_3 and $\log k$.
● MeO–DPN, ○ H–DPN, ◑ Cl–DPN, ⊙ NO_2–DPN.

The second-order rate constants k and log k are shown in Table 2. Figure 3 demonstrates the dependence of the σ value of R_1 on log k, and that the increasing negativity of R_1 brings about a decrease in rate. Plots of log k *vs.* the σ values of R_3 are shown in Fig. 4, which indicates the linear increase in rate when the negativity of R_3 is increased in every DPN. Thus the reaction rates are influenced by the energy difference, E_I(HOMO(1,3-dipole)–LUMO(dipolarophile)) more than E_{II}(HOMO(dipolarophile)–LUMO(1,3-dipole)). Therefore, these reactions belong to the Sustmann Type I.[8]

According to the perturbation theory, the interaction energy (ΔE) of the HOMO–LUMO combination is approximated as follows when a reaction belongs to the Sustmann Type I.[2,13,14]

$$\Delta E = \frac{(C_a C_d' \beta_{ad} + C_c C_e' \beta_{ce})^2}{E_I}, \quad (1)$$

where C and C' are the coefficients of the atomic orbitals of HOMO and LUMO, respectively, and β is the resonance integral. Assuming that the two resonance integrals are equal, $\beta_{ad}=\beta_{ce}=\beta$, and setting $(C_a C_d' + C_c C_e')^2=A$, Eq. 1 is turned into the following simple equation:

$$\Delta E = \frac{A\beta^2}{E_I}. \quad (2)$$

Since log k is proportional to ΔE, thus

$$\log k = m\frac{A\beta^2}{E_I} + q \quad (\text{"}m\text{" and "}q\text{" are constants}). \quad (3)$$

Here, E_I, the energy difference, is supposed to be a function of the electronic character of the substituents, R_1 and R_3. Assuming that E_I is the first-order function of σ, and setting E_0 the standard value of E_I when the σ value of the substituent is zero, we have, $E_I=E_0+n\sigma$. Thus, substituting we have

$$\log k = \frac{mA\beta^2}{E_0 + n\sigma} + q(\text{"}n\text{" is a constant}). \quad (4)$$

This equation shows that log k is the hyperbolic function of σ. When $n>0$, increasing σ decreases the value of log k since log $k<0$ and $mA\beta^2>0$. This relation is shown in Fig. 5-1. When $n<0$, the relation is as shown in Fig. 5-2. In each case, a linear relationship between log k and σ was observed. σ varied in the narrow range, $-0.3<\sigma<0.8$, and log k in the range $-3.00<\log k<-2.32$. These results are very sililar to the solid lines in Figs. 5-1 and 5-2, respectively.

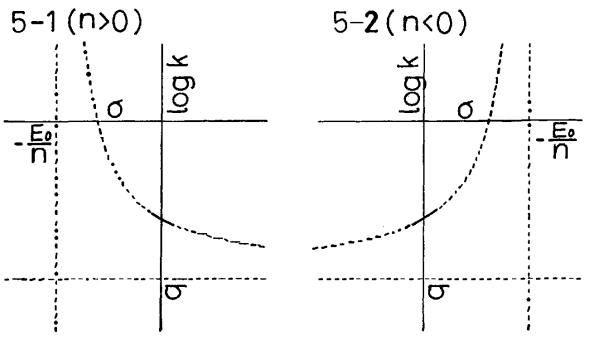

Fig. 5. The relation between log k and σ according to Eq. 4.

"n" is positive for the σ value of the substituent on a 1,3-dipole, and negative for that on a dipolarophile in Sustmann Type I reactions. In this way, log k is approximated to be the first-order function of σ in a very narrow range. Thus

$$\log k - q = \rho\sigma \quad (\text{"}\rho\text{" is a constant}). \quad (5)$$

From the experimental results, $\rho=-0.41\pm0.01$ for the σ value of the substituent R_1 and $\rho=+0.60\pm0.02$ for that of R_3 were obtained. Huisgen and coworkers have reported the linear correlation of log k ($\rho=0.77$) in the reaction of α-phenyl-*N*-methylnitrone with *p*-substituted styrene.[15] In the reaction of symmetrical bis(*p*-substituted benzoyl)-ethylenes with *N*-(*p*-substituted benzylidene) *p*-substituted benzylamine *N*-oxide, similar correlations of log k were observed.

Experimental

N-(p-Substituted benzylidene) p-Substituted Benzylamine N-Oxides(DPN). All DPNs were prepared in the usual manner.[16] Melting points and yields were as follows;

1a; mp; 111.0—112.0 °C yield; 40%
1b; mp; 182.0—183.0 °C yield; 34%
1c; mp; 149.0—150.0 °C yield; 45%
1d; mp; 134.5—136.0 °C yield; 27%
1e; mp; 169.0—171.0 °C yield; 63%
1f; mp; 122.0—123.5 °C yield; 24%

trans-Bis(p-substituted benzoyl)ethylenes (DBE). DBEs were prepared by the procedure of Conant and Lutz.[17–19] It has been established that the products by this method are only of the *trans*-form. Melting points and yields were as follows;

2a; mp; 106.5—108.0 °C (lit, 111 °C) yield; 30%
2b; mp; 170.5—171.5 °C (lit, 172 °C) yield; 13%
2c; mp; 166.0—166.5 °C (lit, 167.5—168.0 °C) yield; 16%
2d; mp; 147.0—148.0 °C (lit, 148 °C) yield; 18%

Reactions of DPNs with DBEs and Formation Ratios. All the reactions were carried out by the same method. For example, the reaction of *N*-benzylidene benzylamine *N*-oxide (**1a**) with *trans*-dibenzoylethylene (**2a**) was carried out as follows; **1a** (0.985 g(0.005 mol)) and **2a** (1.180 g(0.005 mol)) were dissolved in benzene (80 ml) and refluxed for about 3 h. The reaction was carried out in the dark, since **1a** is easily decomposed by sun-light. The reaction products, *trans*- and *cis*-isoxazolidines were isolated, respectively by column chromatography (200 mesh silica gel).

The formation ratios were determined by high speed liquid chromatography. The ε_{max} value of the *trans*-form was assumed to be equal to that of the *cis*-form. For example, the ε_{max} value of the *trans*-2,3-diphenyl-4,5-dibenzoylisoxazolidine and the *cis*-form were 32400 (247 nm) and 35300 (248 nm), respectively, consequently they can be assumed equal within an 8% difference. The HLC was performed using a stainless column (4 mmϕ × 50 cm) containing TSK-Gel LS310-P10 or Wakogel LC-ODS-10K. Chloroform and hexane were used as the eluent in various mixed ratios, depending on the samples and the gels. The flow rate was 2—4 ml/min. The eluate was analyzed by a UV detector in the range 254—270 nm region.

Kinetic Procedures. The rate constants were determined by HLC under the same conditions. A small amount of nitrobenzene (0.05 ml) was added to the reaction solvent

as a standard for analysis before reaction. Nitrobenzene has an ε_{max} at 252 nm, and the ε_{max} is 10000, so that only a small amount is sufficient for the standard. Moreovre, since the R_f-value was found to be near to 1 under the experimental conditions, there was no possibility for peak overlap.

The area ratio(r) of DBE peak relative to that of nitrobenzene at zero time (r_0) was obtained first. At time t, the residual concentration of DBE (C) was calculated by comparison of the area ratio (r_t) with r_0. Plots of $1/C$ *vs.* the reaction time (second) gave good linear relations, from which the second-order rate constants were obtained. The UV spectra of DBEs were as follows:

2a; $\lambda_{max}=262$ nm $\varepsilon_{max}=20000$
2b; $\lambda_{max}=272$ nm $\varepsilon_{max}=20800$
2c; $\lambda_{max}=241$ nm $\varepsilon_{max}=18300$
2d; $\lambda_{max}=275$ nm $\varepsilon_{max}=18000$

The spectra of all DBEs were satuarated at a concentration of about 10^{-4} mol/l. The concentration of samples in the detector were considered far below it, since the concentration of DBE in the reaction mixture was 1/30 mol/l in each case, a sample size was under 1 μl, and the flow rate of the eluent was about 4 ml/min. In point of fact none of the peaks of DBEs was saturated. For all DBEs, good linearity was found between the areas of the peak and the concentration under 10^{-4} mol/l.

For example, the reaction of *N*-benzylidene benzylamine *N*-oxide (**1a**) with dibenzoylethylene (**2a**) was carried out as the following; **2a** (0.236 g(0.001 mol)) was dissolved in anhydrous xylene (30 ml) containing nitrobenzene (0.05 ml). After the reaction temperature was controlled at 60 °C (±0.1), **1a** (0.197 g(0.001 mol)) was added and stirred well. At intervals of about twenty minutes, the reaction mixture was analyzed by HLC.

The authors are grateful to Dr. Yoshio Iwakura and the late Dr. Keikichi Uno for advice and helpful discussions.

The authors would like to thank Toyo Soda Manufacturing Co., Ltd. for a generous supply of TSK-Gel.

The Reaction of *N*-Alkylisoxazolium Salts with Hydroxylamine

Choji KASHIMA, Kimio ARAI, Satoshi IMADA, and Yoshihiko TSUDA

Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31

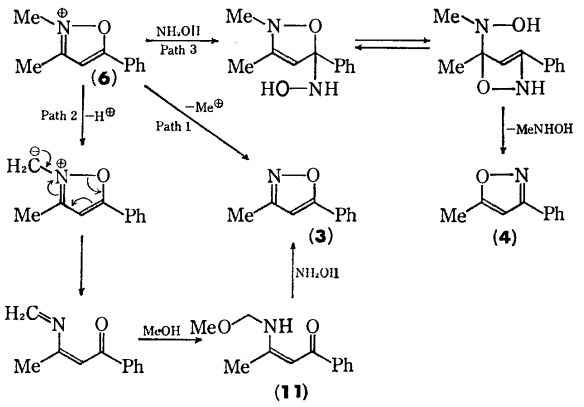
(Received November 30, 1977)

The alternating transposition of C-3 and C-5 substituents on 3,5-disubstituted isoxazoles was found by refluxing a mixture of hydroxylamine hydrochloride, potassium carbonate, and 3,5-disubstituted 2-methylisoxazolium salts, derived from the corresponding isoxazoles. Under the same conditions, 3,5-disubstituted 2-*t*-butyl- or 2-benzhydrylisoxazolium salts gave the corresponding isoxazoles without alternation of the substituents.

The reactions of 3,5-dimethylisoxazole (**1**) with various electrophiles in the presence of sodium amide have been investigated.[1] The 5-methylisoxazoles have been prepared from β-amino enones on treatment with hydroxylamine.[2] However the sterically hindered 5-trichloroacetamido-2,2-dimethyl-4-hexen-3-one will not give the 5-methyl-3-*t*-butylisoxazole (**2**), so it was necessary to devise a general preparative method for the 5-methylisoxazoles.

On the basis of the reported reactions of *N*-alkylisoxazolium salts[3] with various nucleophiles such as potassium alkoxide,[4] Grignard reagents,[5] and sodium borohydride,[6] the 3,5-disubstituted 2-methylisoxazolium salts would be expected to react with hydroxylamine. Thus, treatment of a mixture of 2,3,5-trimethylisoxazolium iodide (**5**) and hydroxylamine hydrochloride with potassium methoxide in methanol gave **1** in good yield. In the same manner, treatment of a mixture of 2,3-dimethyl-5-phenylisoxazolium iodide (**6**) and hydroxylamine hydrochloride with potassium methoxide gave an isomeric mixture of 3-methyl-5-phenylisoxazole (**3**, 46%) and 5-methyl-3-phenylisoxazole (**4**, 54%). Treatment of the mixture with potassium carbonate as a base yielded the isomer **4** as the major product. Similarly the isoxazolium iodides **7** and **8**, and also the isoxazolium perchlorates **9** and **10** may be converted into the corresponding isoxazoles as shown in Table 1. These results reveal the alternating transposition of the substituent groups on isoxazoles proceeds smoothly on treatment of *N*-methylisoxazolium salts with hydroxylamine hydrochloride in the presence of potassium carbonate.

For the formation of the isoxazoles from *N*-methylisoxazolium salts, three possible reaction paths are shown in Fig. 1. The β-amino enone **11** may be prepared as the sole product by the reaction of **6** with potassium methoxide. The interconversion of **3** and **4** did not occur in the presence of hydroxylamine, so that path 1 may be omitted from the consideration of the formation of the alternating transposition product. A weak base, such as potassium carbonate is not able to abstract the proton on *N*-methyl group of **6**. Furthermore, the treatment of **11** with hydroxylamine hydrochloride in the presence of potassium methoxide or carbonate gave the isoxazole **3** as listed in Table 2. Thus the *N*-methylisoxazolium salts undergo the transposition reaction to give **4** in the manner shown in path 3, whereas the formation of **3** is considered to proceed *via* path 2.



A mixture of 2-*t*-butyl-3-methyl-5-phenylisoxazolium perchlorate (**12**), hydroxylamine hydrochloride, and potassium carbonate was heated and gave **3** and **4** in 60 and 13% yields, respectively. Similarly, 2-benz-

Table 1. The reaction of *N*-alkylisoxazolium salts with hydroxylamine

Table 2. The reaction of 1-substituted 3-(methoxymethylamino)-2-buten-1-ones with hydroxylamine

5-Subst.	Base	Isoxazole yield	Retention	Transposition
Me	MeOK	29	—	—
Ph	MeOK	36	100	0
t-Bu	MeOK	32	100	0
CH_2CH_2Ph	MeOK	36	100	0

hydryl-3-methyl-5-phenylisoxazolium perchlorate (**13**) gave **3** and methyl benzhydryl ether but no isomer **4**. The formation of compound **3** from **12** and **13** is assumed to proceed *via* path 1.

In conclusion, the treatment of *N*-methylisoxazolium salts with hydroxylamine hydrochloride in the presence of potassium carbonate gave alternation transposition compounds of oxygen and nitrogen atoms attached to the isoxazoles. In contrast, the same treatment of *N*-*t*-butyl- or *N*-benzhydrylisoxazolium salts afforded isoxazoles without alternating the hetero atoms.

Experimental

Materials. 2,3,5-Trimethyl- (**5**), 2,3-dimethyl-5-phenyl- (**6**), 2,3-dimethyl-5-*t*-butyl- (**7**), and 2,3-dimethyl-5-phenethylisoxazolium iodide (**8**) were prepared from the corresponding isoxazoles.[3] According to the method of Adachi,[5] 2,3-dimethyl-5-phenyl- (**9**) and 2,5-dimethyl-3-phenylisoxazolium perchlorate (**10**) were prepared. *N*-*t*-Butyl- and *N*-benzhydrylisoxazlium perchlorates were prepared by the method of Woodman.[7] The physical data of these isoxazolium salts are listed in Table 3.

General Procedure. To a mixture of MeOK (or K_2CO_3, 4.8 mmol) in methanol (30 ml) was added an isoxazolium salt (2.0 mmol) and hydroxylamine hydrochloride (2.4 mmol). The mixture was refluxed for 18 h, poured into ice-water, extracted with CH_2Cl_2, and dried over $MgSO_4$. The isoxazole yield was estimated by the peak area of gas chromatography and the product ratio calculated by the intensity of methyl proton signals in the NMR spectra.

3-t-Butyl-5-methylisoxazole (2).[8] The title compound was isolated by fractional distillation. Bp 110—114 °C/73 mmHg. NMR (δ): 1.32 (s, 9H), 2.37 (s, 3H) and 5.98 ppm (s, 1H). Found: C, 68.73; H, 9.42; N, 10.09%. Calcd for $C_8H_{13}NO$: C, 69.03; H, 9.41; N, 10.06%.

3-Phenethyl-5-methylisoxazole (16). The title compound was isolated by fractional distillation. Bp 121—127 °C/2 mmHg. NMR (δ): 2.35 (s, 3H), 2.94 (s, 4H), 5.74 (s, 1H) and 7.23 ppm (s, 5H). Found: C, 76.83; H, 6.78; N, 7.17%. Calcd for $C_{12}H_{13}NO$: C, 76.97; H, 7.00; N, 7.48%.

Isomerization of Isoxazole. The mixture of isoxazole (**3** or **4**, 2.0 mmol), hydroxylamine hydrochloride (2.6 mmol) and MeOK (or K_2CO_3, 2.8 mmol) in methanol (20 ml) was refluxed and the resulting mixture poured into water, and extracted with CH_2Cl_2. The product was analyzed by gas chromatography and NMR spectroscopy.

The Reaction of 3-(Methoxymethylamino)-2-buten-1-ones with Hydroxylamine. The mixture of 3-(methoxymethylamino)-2-buten-1-ones (2.0 mmol) and hydroxylamine hydrochloride (2.4 mmol) was treated with MeOK (or K_2CO_3, 2.4 mmol) by the procedure described in reference 2. The results are listed in Table 2.

Cyclization of Isothiosemicarbazones. I. A New Route to 2-Mercaptoimidazole Derivatives and 4-Substituted Imidazoles[1)]

Chiji YAMAZAKI

Department of Chemistry, School of Hygienic Sciences, Kitasato University, Asamizodai, Sagamihara-shi 228

(Received November 30, 1977)

Some 1-arylmethyleneamino-2-mercapto-4-aryl-1*H*-imidazole derivatives were prepared by the condensation of isothiosemicarbazones of aromatic carbonyl compounds with phenacyl bromides. The 1,2,5-trisubstituted isomers were obtained by substitution of *dl*-α-bromophenylacetaldehyde for phenacyl bromide in this condensation. The reaction of isothiosemicarbazones of aliphatic carbonyl compounds with phenacyl bromides produced a dark, complex mixture from which the corresponding 1-alkylideneamino-2-mercapto-4-aryl-1*H*-imidazoles and 3,5-disubstituted 1,2,4-triazines were isolated in poor yields, with the latter being a main product or a sole heterocyclic product depending on the reaction conditions. Reductive cleavage of the cyclized products with zinc dust in acetic acid-acetic anhydride solution gave 1-acetyl-4-aryl-1*H*-imidazoles, which were readily hydrolyzed to 4-aryl-1*H*-imidazoles. The susceptibility to acid hydrolysis of the arylmethyleneamino group was dependent on the extent of conjugation between the azomethine double bond and the adjacent aromatic rings. Hydrazinolysis of the azomethine double bond yielded 1-amino-2-mercapto-4-aryl-1*H*-imidazoles in high yields. Their structures were established on the basis of NMR, IR, UV, and mass spectra as well as elemental analyses. Differentiation between 1,2,4- and 1,2,5-trisubstituted imidazoles was discussed.

Condensation of certain thiosemicarbazones of aromatic aldehyde with α-halo ketones leads to the formation of thiazole derivatives owing to the preferential attack of the most nucleophilic mercapto group on the halogen-bearing carbon of the halo ketone.[2)] If the potential mercapto group, however, is first blocked by alkylation, the reaction of *S*-alkylisothiosemicarbazone with an α-halo ketone should lead to the formation of an alkylthioimidazole. Very few examples have been known for cyclization of isothiosemicarbazone to a heterocyclic compound with retention of the alkylthio group.[3)] The present paper is concerned with an attempt to prepare imidazole derivatives by blocking the mercapto group of thiosemicarbazone with an alkyl, alkenyl, or arylalkyl group and condensing the isothiosemicarbazones with α-halo carbonyl compounds. The use of isothiosemicarbazone, especially of aromatic carbonyl compounds, allows to avoid extensive sulfide formation as encountered with the reaction between phenacyl bromide and *S*-benzylisothiourea[4)] which has a pronounced tendency to lose the thiol. This paper further describes reductive and hydrolytic cleavage of as well as hydrazinolysis of the cyclized products, as represented in Schemes 1 and 2.

In view of the fact that the condensation of isothiosemicarbazones (**1**) with *dl*-α-bromophenylacetaldehyde (**3**) gave sterically hindered 5-phenyl compounds (**5**), steric factor, as suggested in our preliminary report,[1)] should not be the directive force in the orientation of this ring closure. Differentiation between 4- and 5-phenyl-1*H*-imidazoles was made by observing the ortho deshielding phenomenon[5)] of the 4-phenyl protons and the C–H stretching absorption band at 5-position of the 1,2,4-trisubstituted imidazole series. Mass spectra showed no definitive difference between both isomers in

determining the substitution pattern with the exception of compounds carrying an ortho-substituent on the arylmethyleneamino group.

Results and Discussion

The condensation of isothiosemicarbazones (**1**) with phenacyl bromides (**2**) was carried out by heating a mixture of **1** and **2** in acetonitrile in the presence of an excess of sodium hydrogencarbonate at 75 °C for 3 h under stirring. With a few exceptions, the imidazoles usually crystallized out of the reaction mixture upon cooling or even at still hot and could easily be isolated by filtration. Most of the products, after being washed with water to remove any inorganic salts, were sufficiently pure to use for further reactions indicated in Scheme 1. Isolation of **4h**, **4m**, and **4p** was accomplished by means of column chromatography. 2-Allylthio compound **4t** was isolated by crystallization from ethanol of an amorphous gum obtained after evaporation of the reaction mixture under reduced pressure. Alternative process in which a mixture of **1** and **2** (2: 1) in ethanol is heated at 75 °C (Method A) could be applied to the cyclization of **1e** to **4h** with rather better yields than in the standard procedure described above. In some cases, the use of excess **2** up to 50% was found to somewhat improve the yield of imidazoles. For example, the yield of **4j** increased to 66% when the ratio of **2a** to **1g** was raised to 1.5: 1 compared with the yield 40% in the ratio 1: 1. This modification, however, was not generally applicable because the excess **2** may prevent crystallization of a cyclized product from the reaction mixture. The use of a tertiary amine such as pyridine or triethylamine in place of sodium hydrogencarbonate resulted in the predominant formation of the corresponding quaternary ammonium bromide of these acid binders with **2** and gave no cyclized product. Attempts to cyclize **1s** and *p*-methoxyacetophenone *S*-benzylisothiosemicarbazone with **2a** were unsuccessful presumably due to their sterically unfavorable structure. Cyclization of *m*- and *p*-nitrobenzaldehyde *S*-methylisothiosemicarbazones was also failed because of the extremely poor solubility.

In sharp contrast to the behavior of the isothiosemicarbazones of aromatic carbonyl compounds, the reaction of those of aliphatic ones with **2** produced a dark resinous mass even at room temperature with a poor yield of imidazoles and therefore might be less valuable for preparative purpose. Isolation of the 1-alkylideneamino-1*H*-imidazoles (**4w**—**4z**) was accomplished by means of column chromatography on silica gel using a benzene–ethanol mixture as an eluent. Unfortunately, **4z** tends to lose the acetone during the working up to form **7a** and therefore the conversion of **1r** to imidazole was estimated on the basis of the yield of a relatively insoluble derivative such as **4o** which was obtained by reacting both **4z** and **7a** with anisaldehyde in an acidic medium. 4-Aryl-1*H*-imidazoles thus obtained were listed in Table 1.

The reaction of aliphatic isothiosemicarbazones with **2** was further complicated by the formation of 3,5-disubstituted 1,2,4-triazines (**15**) and sulfides (R^3SCH_2-COR^4) in addition to **4**, with the ratio of these products being dependent upon the particular isothiosemicarbazone and the reaction conditions. The standard procedure described in the beginning of this section generally gives **4** as a main product along with a minor product **15**, while the latter predominates under the conditions of Method A. For example, the reaction of **1p** with **2a** by that method produced 3-methylthio-5-phenyl-1,2,4-triazine (**15a**) in 8% yield with no imidazole formation, whereas the reaction of **1q** with **2a** in dimethyl sulfoxide (DMSO) in the presence of sodium hydrogencarbonate gave **4y** in 11% yield but no **15c** at all. Under the conditions of Method A, **15b** was obtained in less than 30% yields from the reaction of **1p** or **1r** with **2c**. Similarly, **1s** gave **15c** in 38% yield. The structure of **15a** was confirmed by the unambiguous synthesis reported by Paudler *et al.*[6] and **15b** was well consistent in the melting point with that of the literature.[7]

The triazine formation was attributed to the tendency of an aliphatic isothiosemicarbazone to split off the carbonyl component and can be explained as the result of oxidation at the α-carbon of **2** by isothiosemicarbazide (**13**) thus liberated by analogy with osazone or dioxime formation of α-halo carbonyl compounds.[8] Since the reaction mixture becomes acidic under the conditions of Method A, the rate of hydrolysis of isothiosemicarbazone should increase and the triazine formation will be accelerated. On the other hand, acidic media are generally unfavorable to the imidazole formation because protonation of **1** evidently inhibits the first step of this cyclization (Fig. 2). Furthermore, aldehyde isothiosemicarbazones, particularly those of aliphatic aldehyde, are likely susceptible to intramolecular cyclization under such conditions through the addition of the terminal amino group to the aldimine double bond to form a dihydro-1,2,4-triazole structure which is believed to be an intermediate in the formation of *N*-isopropenyl-1,2,4-triazoles in acetic acid.[9] Thus **1p** or **1q** cannot produce the corresponding 1-propylideneamino-1*H*-imidazole by the reaction with **2** or **3** unless a stronger base than the isothiosemicarbazone itself is present as acid binder. The fact that **1q** does not give **15c** in DMSO in the presence of sodium hydrogencarbonate can be rationalized in terms of the strong proton-accepting nature of this solvent. The reaction of **13** ($R^3=CH_3$) with **2** produced a highly darkened, complex mixture from which the corresponding **15** was isolated only in 4—8% yields. The alkylidene group of aliphatic isothiosemicarbazone may therefore serve as a protective group for controlled liberation of relatively unstable **13**, thereby leading to better yields of **15**. Taking into account of the facts that ammonium bromide and **14** ($R^3=CH_3$) were isolated in significant amounts from the reaction mixture of **1r** with **2a** and that the triazine formation occurred in the absence of oxygen, a mechanism for this reaction was suggested in Fig. 1.

The reaction conditions employed for the preparation of **4** were not very suitable for the reaction of **1** ($R^1=$ aryl) with **3** because of unstability of the halo aldehyde to sodium hydrogencarbonate. With the exception of **1p**, the condensation of **1** with **3** was thus carried out by

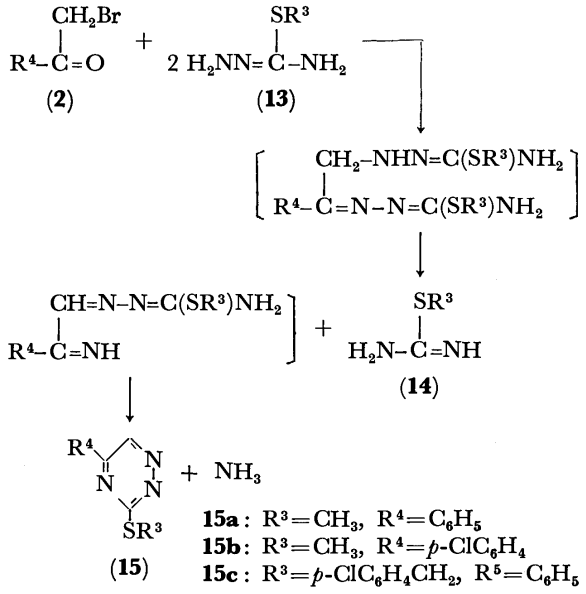

Fig. 1. A reaction mechanism for 1,2,4-triazine formation.

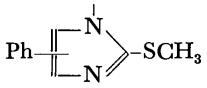
refluxing a mixture of **1** and **3** in a molar ratio of 2: 1 in acetonitrile without added sodium hydrogencarbonate and 5-phenyl-1*H*-imidazoles were isolated by means of column chromatography. As described above, **1p** did not produce the corresponding **5** under these reaction conditions but a complex mixture composed of many unidentifiable components. The standard procedure using sodium hydrogencarbonate was inevitably applied to the preparation of **5g** from **1p** in spite of the poor yield of this imidazole. 5-Phenyl-1*H*-imidazoles (**5**) thus obtained were listed in Table 2.

The structures of **4** and **5** were confirmed on the basis of analytical and spectral data (Tables 1—4) as well as their chemical transformation.

Table 3. Chemical shifts of phenyl protons on the imidazole ring (δ, in $CDCl_3$).



R^1	4-Phenyl H^o	$H^{m,p}$	Δ[a]	5-Phenyl $H^{o,m,p}$

Et	7.82	7.37	0.45	7.28

a) Differences (in ppm) between the chemical shifts of *ortho* (H^o) and *meta-para* ($H^{m,p}$) protons.

As has been observed by a number of investigators, the anisotropic deshielding of phenyl protons ortho to the heteroaromatic ring in phenylazoles disappeares or greatly diminishes when coplanarity between the two aromatic rings and the resulting resonance interaction is inhibited by the adjacent alkyl group on the azole ring.[5] The NMR spectral data (Table 3) showed that the ortho protons (H^o) in the compounds **4** obtained from the condensation with **2a** were deshielded by 0.45—0.53 ppm relative to the *meta*- and *para*-protons ($H^{m,p}$), whereas the phenyl protons in the compounds **5** gave a single signal only. Thus the phenyl group of **4** should lie at the position 4 and that of **5** is in the 5-position adjacent to the $R^1R^2C{=}N$ grouping.

Compounds which were derived from substituted phenacyl bromides (**2b**—**2f**) might also be expected to have the 4-aryl-1*H*-structure. The UV spectra of these compounds normally showed two maxima at near

TABLE 4. UV SPECTRA OF 1-ARYLMETHYLENEAMINO-2-METHYLTHIO-4-ARYL-1*H*-IMIDAZOLES

4p	*o*-HOC_6H_4	258 (1.55),	300 (2.70),	352 (2.18)
4q	*p*-$MeOC_6H_4$	290 (2.77)		348 (1.92)

280—290 and 340—350 nm with one or two inflections between these bands, with the former absorptions being more intense than the latter (Table 4). These characteristics in UV spectra are quite similar to those exhibited by 4-(unsubstituted phenyl) compounds (**4a**, **4f**—**g**, **4i**—**k**) and are essentially different from those of **5**, which had a main band within the limits λ_{max} 263—281 nm and $\varepsilon \times 10^{-4}$=2.01—2.82. The compound **4p**, which had an additional shorter band at 258 nm and a longer main band at 300 nm than the normal region, exhibited an intramolecularly hydrogen bonded O–H band (centered at 3050 cm^{-1}) at a concentration of 2.5×10^{-3} M in carbon tetrachloride. Such hydrogen bonding would be possible only in the 4-*o*-hydroxyphenyl structure because of lack of proton-accepting nature in N-1. Consequently the reaction between isothiosemicarbazones and phenacyl bromides should produce 4-aryl-1*H*-imidazoles independently of the nature of R's and the steric repulsion between R^4 and R^1R^2C=N groups in the transition state will have no effect upon the orientation of ring closure.

The 1,2,4- and 1,2,5-trisubstituted imidazoles could also be differentiated by their IR spectra. The differentiation of both series was based upon the appearance of a weak, but distinct absorption band at 3160—3140 cm^{-1} in the spectra of 1,2,4-trisubstituted isomers (Table 1). Such a difference consistently occurred between isomers both in crystalline materials in KBr disks and in carbon tetrachloride or chloroform solution and therefore does not reflect the difference between their crystal structures. This absorption band was absent in 5-deuterio compounds (**4g**-d_1 and **4k**-d_1) and thus assigned to a C–H stretching vibration at the 5-position of imidazole ring shifted to higher frequencies than usual aromatic region[10] presumably by steric compression.

o-Hydroxybenzylideneamino compounds **4i** and **5d** exhibited internally bonded O–H stretching bands (centered at 3220 and 3170 cm^{-1}) at 4×10^{-3} M in carbon tetrachloride. This observation suggests that the *o*-hydroxyphenyl group and the imidazole ring must be in *E* configuration about the azomethine double bond to which they attached. Other **4** and **5** may also be *E* form in view of the similarities of UV spectra observed between the members of each series. If they were in *Z* configuration, R^1 should be twisted out of the plane of the rest of molecule as evidenced by examination of a scale model. Thus the UV spectra of 4-aryl series would resemble that of **4m** which lacks the longer-wavelength band (Table 4) due to the steric inhibition of conjugation between R^1 and the heteroaromatic ring caused by the α-methyl group (R^2=CH_3); on the other hand, the UV spectra of 5-aryl series would become comparable with those of **5g**.

In mass spectrometry, molecular ions were obtained for all 1-arylmethyleneamino compounds studied (Tables 1 and 2) and always represented the base peak. Primary fragmentation occurred at the N–N bond, leading to an intermediate, M^+–R^1R^2C=N (≃100%), common to the 1,2,4- and 1,2,5-isomers. Another ionization occurred to produce R^1R^2C=N^+=CS (≈60%) which is also common to both isomers. Thus practically identical spectra resulted between the members of each pair of isomers except for **4f** and **4j** in which fragmentation M^+–Cl· and M^+–MeO· occurred only in 4-aryl compounds as shown by the appropriate metastable ions. The R^4CN^+ ion, one of the criteria on which the structural assignment had been made in Ref. 1, was invariably found in the spectra of both isomers in comparable abundance (9—38%) and therefore of no diagnostic value for differentiation.

Although no reaction intermediates have been isolated in this study, a probable reaction mechanism that accounts for the results obtained here was represented in Fig. 2.

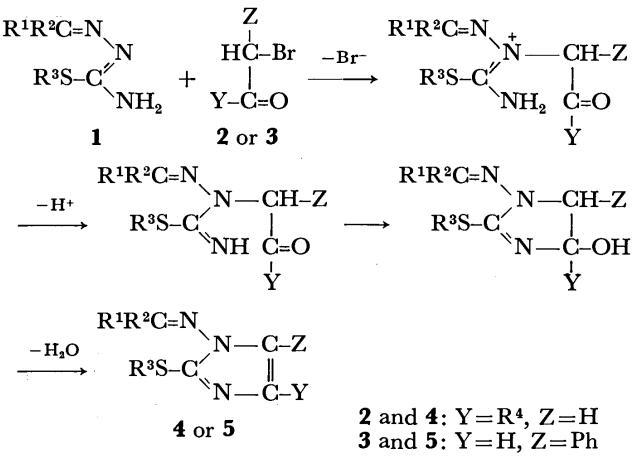

Fig. 2. A reaction mechanism for imidazole-ring formation.

The reaction should occur by the initial attack of N-2 which was believed to be the most nucleophilic center in **1**[11] on the α-carbon of **2** or **3**. An alternative path, in which the condensation of the terminal amino group of **1** with the carbonyl group of **2** or **3** is the first step, is unlikely to operate because the substitution of phenacyl chloride for **2a** resulted in substantial recovery of the starting materials under the same conditions. If the reaction proceeds through the latter path, there would accumulate an initial product, R^1R^2C=N–N=C(SR^3)–N=C(CH_2Cl)Ph, in the reaction mixture because of low reactivity of the halogen in phenacyl chloride.

Both 4- and 5-aryl-1*H*-imidazoles (**4** and **5**) were found to undergo reductive cleavage to 1-acetyl-4-aryl-1*H*-imidazoles (**6**), *N*-benzylacetamides (**10**), and thiols (**11**) upon stirring with acetic acid and zinc dust in the presence of acetic anhydride at room temperature. A possible product 1-acetyl-5-phenyl-1*H*-imidazole from **5a**, if any, may rapidly rearrange to a thermodynamically favorable 4-phenyl isomer through a reversible process of acetylation.[12] The benzylthio derivative (**4u**) was more resistant to the reduction than alkylthio compounds and prolonged reaction periods caused considerable formation of unidentifiable amorphous materials leading to a poor yield of **6**. The nitro group of **4d** was simultaneously reduced to give **6c**. The reduction of nitro group readily took place under the reaction conditions as evidenced by rapid disappearance of the red color due to this group prior to evolution of methanethiol and therefore a compound 1-acetyl-4-*p*-nitrophenyl-1*H*-imidazole could not be obtained by this process. The acetyl group at N-1 was susceptible to hydrolysis and partially splitted off in working up.

Two protons H-2 and H-5 on the imidazole ring of **6** appeared as two doublets with a coupling constant of 1.3 Hz at about δ 8.1 and 8.4 ppm in DMSO-d_6 due to cross-ring coupling. Peak assignment of these protons can unambiguously be made on the basis of the spectrum of 1-acetyl-4-phenyl-5-deuterio-1*H*-imidazole (**6a**-d_1) which lacks the upfield resonance. This is in accordance with the common practice of assigning H-2 to the most downfield resonance of 1-substituted imidazoles,[13] although H-2 is not always the most deshielded proton.[14]

Hydrolysis of the arylmethyleneamino to an amino group of **4g** or **4k** was unsuccessful either in aqueous ethanolic hydrogen chloride or sodium hydroxide solution at the reflux temperature over a period of 10 h with total recovery of the starting imidazoles (Table 5). The corresponding 5-phenyl isomers, however, underwent hydrolysis to an extent of 24 and 22%, respectively. Ortho substituents on the benzylideneamino group of **4** accelerated the rate of hydrolysis independently of whether it is electron-releasing or electron-withdrawing. No specific intramolecular catalysis[15] was observed. On the other hand, **4m** was hydrolyzed to 97% under the same conditions and the reaction was substantially completed within 30 minutes when the hydrolysis was carried out in concentrated hydrochloric acid at 130 °C. In view of these observations, the susceptibility to hydrolysis of arylmethyleneamino group directly reflects the diminished or inhibited conjugation between the azomethine double bond and the adjacent aromatic rings resulting from crowding around the double bond.

Hydrolytic products **7** and **9** could be obtained quantitatively by hydrazinolysis of **4** and **5**. When **4k** was heated with a large excess of hydrazine hydrate in

2-methoxyethanol at 170 °C for 1.5 h, **7a** was obtained in 98% yield after isolation by means of column chromatography on silica gel. It was also possible to isolate and purify **7a** by extraction with methanol followed by recrystallization from benzene. In most cases, however, repeated recrystallizations were required to accomplish complete removal of azine **12** causing a considerable loss of the aminoimidazoles. The yields reported in Table 6 were those for a homogeneous fraction obtained by means of column chromatography except for **7b** and **7d**. 4-*p*-Nitrophenylimidazole **4d** gave **7b** in addition to the expected product **7d** as a result of simultaneous reduction of the nitro group. The treatment of **4t** with hydrazine hydrate was also complicated by concomitant reduction of the allyl to a propyl group, if the reaction mixture contained an acid or accidentally absorbed an acid vapor. The formation of **7e** reached the maximum 28.5% when 4 molar equivalents of acetic acid was present, while no reduction occurred in the absence of acid.[16] In contrast to certain methylthiotriazine derivatives,[6,17] nucleophilic attack by a hydrazine molecule on C-2 was not observed even after heating over a period of 10 h.

The aminoimidazoles **7** underwent deamination upon treatment with sodium nitrite in a hydrochloric acid–methanol mixture to give the corresponding 2,4-disubstituted imidazoles **8** in moderate yields. They were characterized by their IR spectra which exhibited a broad absorption band at 3060—2600 cm^{-1} due to the bonded N–H.

Pyl *et al.*[18] had reported a melting point of 118 °C for 1-amino-2-methylthio-4-phenyl-1*H*-imidazole. This value corresponds to that of **7a** but obviously not to 5-phenyl isomer **9**. The strength in support of the structure for **7a** may thus be obtained. However, there is no reason to believe it is the ring nitrogen which attacks the α-carbon of **2a** and not the amino nitrogen in the formation of the precursor 2-substituted 6-phenylimidazo[2,1-*b*][1,3,4]thiadiazole by the reaction between 2-amino-1,3,4-thiadiazole and **2a**.[18] Consequently the practical agreement in the melting point of **7a** with that of the literature may be insufficient as the basis for determination of the substitution pattern of all the present 1,2,4- and 1,2,5-trisubstituted imidazoles.

Experimental

Melting points were determined in an open glass capillary and are uncorrected. IR spectra were recorded on a Hitachi EPI-G2 grating spectrophotometer. Spectra of solutions were obtained in 0.1-mm KBr or 5-mm KRS-5 cells and those of solid samples taken in KBr disks. UV spectra were recorded on a Hitachi EPS-2 spectrophotometer and mass spectra (75 eV) on a Japan Electron Optics JMS-OlS or JMS-D100 mass spectrometer using a direct inlet procedure. ^1H NMR spectra were obtained on a Nichiden-Varian T-60 or a Hitachi R-24 spectrometer, both operating at 60 MHz. Chemical shifts were reported in δ ppm downfield from internal tetramethylsilane. Following abbreviations were used: s=singlet, d=doublet, t=triplet, m=multiplet, br=broad singlet, dt=double triplet, and vs=very strong.

α-Halo Carbonyl Compounds. Phenacyl bromides (**2a**—**2f**) were prepared from the corresponding acetophenones by the known methods[19] and **3** was obtained from phenylacetaldehyde according to the method described by Riehl.[20] NMR (CCl_4) 5.11 (d, 1, J=3.6 Hz, BrCH), 7.34 (s, 5, C_6H_5), 9.48 (d, 1, J=3.6 Hz, CHO). α-Ethoxyphenylacetaldehyde 2,4-dinitrophenylhydrazone,[21] mp 139 °C (lit,[22] mp 140 °C).

Isothiosemicarbazones. The compounds (**1a**—**1s**) were prepared by the procedure reported previously[11] with some appropriate modifications. New ones are: **1c**: white prisms (from hexane), mp 60—62 °C, yield 46%; NMR ($CDCl_3$) 2.51 (s, 3, SCH_3), 5.50 (br, 2, NH_2), 7.15—8.15 (m, 4, ring protons), 8.80 (s, 1, CH=N). *Preparation of **4k** (a typical example).* A mixture of **1h** (0.56 g, 2.5 mmol), **2a** (0.60 g, 3.0 mmol), sodium hydrogencarbonate (0.63 g, 7.5 mmol), and MeCN (3 ml) was heated under stirring at 75 °C for 3 h. After cooling, the solids were filtered off, washed with cold MeCN, and then suspended in sufficient water to dissolve any inorganic salts. The insoluble crystals were collected on a filter, washed with water, and then dried to give **4k** (0.60 g, 75%), mp 169—169.5 °C. Recrystallization from benzene–EtOH did not raise the melting point, but resulted in improvement in the appearance of the crystal. When 0.75 g (3.75 mmol) of **2a** was used, the yield of **4k** increased to 0.65 g (80.3%). The 5-deuterio derivative (**4k**-d_1) was similarly prepared by substituting phenacyl-*methylene*-d_2 bromide ($C_6H_5COCD_2Br$), which in turn was obtained by brominating acetophenone-α,α,α-d_3 ($C_6H_5COCD_3$), for **2a** in 65% yield. Pale yellow needles (benzene–EtOH), mp 168—169 °C not depressed by **4k**. IR ($CHCl_3$) 2340 (C–D) cm^{-1}; NMR ($CDCl_3$) 2.70 (s, 3, SCH_3), 3.78 (s, 3, OCH_3), 6.87 (d,

2, J=8.7 Hz, *p*-methoxyphenyl protons), 7.21 (m, 3, $H^{m,p}$ of 4-phenyl), 7.63 (d, 2, J=8.7 Hz, *p*-methoxyphenyl protons), 7.69 (m, 2, H^{o} of 4-phenyl), 8.10 (s, 1, CH=N); M^+ 324 (M 324). Similarly, **4g**-d_1 was obtained in 64% yield as yellow needles, mp 173.5—174 °C. IR ($CHCl_3$) 2340 (C–D) cm^{-1}; NMR ($CDCl_3$) 2.67 (s, 3, SCH_3), 7.26 (m, 3, $H^{m,p}$ of 4-phenyl), 7.31 (d, 2, J=8.5 Hz, *p*-chlorophenyl protons), 7.65 (d, 2, J=8.5 Hz, *p*-chlorophenyl protons), 7.70 (m, 2, H^{o} of 4-phenyl), 8.08 (s, 1, CH=N); M^+ 328 (M 328).

Preparation of **5c** *(a typical example).* To a warm soln of **3** (0.5 g, 2.5 mmol) in MeCN (5 ml) was added **1d** (1.14 g, 5.0 mmol) and quickly dissolved with agitation. The reaction mixture solidified within a few min. After heating for 1 h at 83 °C, the solids were filtered off, washed with MeCN and then Et_2O. The filtrate and the washings were combined and evaporated. The residual liquid was dissolved in benzene (30 ml) and the soln was washed with 0.1 M hydrochloric acid and then with water. The organic layer was dried over anhyd. sodium sulfate and evaporated. The residue (0.73 g) was charged onto a silica gel column (40 g) and eluted by benzene–EtOH (98: 2 by volume). A homogeneous fraction (0.43 g, 52.4%) was crystallized from *i*-PrOH (0.5 ml) to give **5c** as bright yellow needles, mp 96—97 °C. Recrystallization from *i*-PrOH (1.0 ml) yielded yellow needles, mp 96.5—97 °C. NMR ($CDCl_3$) 7.45 (d, 2, J=8.0 Hz, *p*-chlorophenyl), 7.70 (d, 2, J=8.0 Hz, *p*-chlorophenyl), 8.22 (s, 1, CH=N).

Preparation of **5g**. A mixture of **1p** (0.73 g, 5.0 mmol), **3** (1.00 g, 5.0 mmol), sodium hydrogencarbonate (1.70 g, 20 mmol), and MeCN (10 ml) was stirred at 74 °C for 3 h and then filtered. After the inorganic salts were washed with MeCN, the filtrate and the washings were evaporated and the residue taken up in benzene (30 ml). When the soln was worked up in a similar manner to the preparation of **5c**, there was obtained **5g** as pale yellow prisms (0.19 g, 15%), mp 38—39.5 °C. NMR ($CDCl_3$) 1.11 (t, 3, J=7.0 Hz, CCH_3), 2.40 (m, 2, CH_2), 7.60 (t, 1, J=4.8 Hz, CH=N).

Reaction of **1p** *with* **2a**. A mixture of **1p** (0.73 g, 5 mmol), **2a** (1.0 g, 5 mmol), sodium hydrogencarbonate (1.7 g, 20 mmol), and MeCN (10 ml) was stirred at 75 °C for 3 h. The inorganic salts were filtered off and washed with benzene. The filtrate and the washings were combined and evaporated. The residue (1.41 g) was charged onto silica gel column (100 g) and eluted with benzene–EtOH (98: 2 by volume). Two fractions, an imidazole-rich fraction (0.53 g) containing a small amount of methyl phenyl sulfide and a triazine-rich fraction (0.17 g) were separated. The former was again subjected to column chromatography under the same conditions to give pure **4w** as a yellow oil (0.33 g, 27%). UV_{max} (MeOH) 254 (ε 20 100), 271 (ε 15 900), 311 (ε 8 300) nm; NMR ($CDCl_3$) 1.19 (t, 3, J=7.0 Hz, CCH_3), 2.52 (m, 2, CH_2), 2.70 (s, 3, SCH_3), 7.56 (s, 1, H-5), 7.79 (t, 1, J=4.8 Hz, CH=N). The perchlorate was prepared in a conventional manner; IR (KBr) 3170 (NH^+), 1100 *vs.* (ClO_4^-) cm^{-1}. The mixed melting point with a product prepared by reacting **7a** with propionaldehyde and salt-forming with perchloric acid did not show any depression (179.5 °C). The triazine-rich fraction was crystallized from *i*-PrOH (0.5 ml) to afford **15a** as pale yellow prisms (0.06 g), mp 99—99.5 °C (lit,[6] mp 99—100.5 °C); NMR ($CDCl_3$) 2.71 (s, 3, SCH_3), 7.52 (m, 3, $H^{m,p}$ of 5-phenyl), 8.10 (m, 2, H^{o} of 5-phenyl), 9.33 (s, 1, H-6). (Found: N, 20.97%). Methyl phenacyl sulfide separated from the imidazole-rich fraction exhibited the identical IR and NMR spectra with those of an authentic sample which was prepared by introducing methanethiol generated from a mixture of **14** (R^3=Me, as a sulfate) and aq sodium hydroxide into a soln of **2a** in Et_2O. 2,4-Dinitrophenylhydrazone: mp 164—165 °C (lit,[25] mp 164—165.5 °C).

Reaction of **1r** *with* **2a**. A solution of **1r** (10.0 g, 69 mmol) and **2a** (6.86 g, 34.5 mmol) in EtOH (100 ml) was heated at 70—75 °C for 3 h and then evaporated. The residue was taken up in chloroform and the soln was repeatedly washed with water acidified to pH 5 with hydrobromic acid. The organic layer was dried over anhyd. sodium sulfate and evaporated. The residue (6.69 g) was triturated with six 75 ml-portions of a hexane–diisopropyl ether mixture (2: 1 by volume) and the combined extracts were evaporated to give an oil (4.96 g). From a one-gram portion of this oil, there were separated **15a** (0.28 g, 20%), mp 95—98 °C; **4z** (0.13 g, 7.5%), NMR ($CDCl_3$) 1.90 (s, 3, CCH_3), 2.20 (s, 3, CCH_3), 2.61 (s, 3, SCH_3), 7.17 (s, 1, H-5), 7.35 (m, 3, $H^{m,p}$ of 4-phenyl), 7.80 (m, 2, H^{o} of 4-phenyl), perchlorate mp 180—180.5 °C, IR (KBr) 3180 (NH^+), 1120 (ClO_4^-) cm^{-1}; and impure **7a** (0.22 g). Ammonium bromise (0.38 g) and **14** (R^3=CH_3) as a picrate (1.0 g), mp 220 °C dec, not depressed on mixing with an authentic sample, were isolated from the aq washings. When **1s** was react d with **2a** by this method, **15c** was obtained in 38% yield and no imidazole was detected. Deep yellow powder (from EtOH), mp 115—116 °C; IR (KBr) 1540, 1500, 1250, 760 cm^{-1}; NMR ($CDCl_3$) 4.50 (s, 2, CH_2), 7.35 (m, 4, *p*-chlorophenyl protons), 7.55 (m, 3, $H^{m,p}$ of 5-phenyl), 8.10 (m, 2, H^{o} of 5-phenyl), 9.35 (s, 1, H-6). Found: C, 61.07; H, 3.92; N, 13.36%. Calcd for $C_{16}H_{12}ClN_3S$: C, 61,24; H, H, 3.80; N, 13.40%.

Reaction of **1r** *with* **2c**. A mixture of **1r** (1.45 g, 10 mmol), **2c** (3.50 g, 15 mmol), sodium hydrogencabronate (5.0 g, 60 mmol), and MeCN (20 ml) was heated at 80 °C under stirring for 5 h and the inorganic salts were filtered off. After the filtrate was evaporated, the residue was worked up by the same manner as that in the reaction with **2a** giving a hexane–diisopropyl ether extract (1.35 g) from which **15b** (0.18 g, 7.6%) was isolated by crystallization from *i*-PrOH. It was passed a silica gel column using chloroform as an eluent and the homogeneous fraction recrystallized from aq EtOH to afford yellow needles, mp 164—164.5 °C (lit,[7] mp 163 °C); NMR ($CDCl_3$) 2.71 (s, 3, SCH_3), 7.51 (d, 2, J=9.0 Hz, *p*-chlorophenyl protons), 8.12 (d, 2. J=9.0 Hz, *p*-chlorophenyl protons), 9.34 (s, 1, H-6). (Found: C, 50.46; H, 3.48; N, 17.80%). The mother liquor obtained after removal of **15b** was heated under reflux in EtOH (7 ml) containing concentrated hydrochloric acid (0.5 ml) and anisaldehyde (0.5 ml) for 30 min. When the reaction mixture was made basic (pH 9) with aq ammonia **4o** (0.57 g, 16%) precipitated. When **1r** (1.45 g, 10 mmol) was reacted with **2c** (1.17 g, 5 mmol) by heating in ethanolic soln at 65 °C for 4 h, there were obtained **15b** (0.33 g, 28%) and **4o** (0.30 g, 17%).

Reductive Cleavage of **4b** *(a typical example).* A mixture of **4b** (0.66 g), zinc dust (13.0 g), glacial acetic acid (42 ml), and acetic anhydride (21 ml) was stirred at room temperature for 3 h, filtered, and the filtrate was evaporated to give a residue which was then triturated with water (10 ml). The insoluble solid was collected by filtration, washed with water and then dried in vacuo giving **6b** (R^4=*p*-ClC_6H_4) (0.36 g, 82%), mp 180—183 °C. Recrystallization from EtOH yielded lustrous flat prisms. mp 186.5 °C. IR(KBr) 3140 (νC–H), 1720 *vs.* (C=O), 835 (δC–H) cm^{-1}. NMR (DMSO-d_6) 2.64 (s, 3, $COCH_3$), 7.39 (d, 2, J=8.2 Hz, *p*-chlorophenyl protons), 7.84 (d, 2, J=8.2 Hz, *p*-chlorophenyl protons), 8.17 (d, 1, J=1.3 Hz, H-5), 8.41 (d, 1, J=1.3 Hz, H-2). Found: C, 59.68; H, 4.00; N, 12.70%. Calcd for $C_{11}H_9ClN_2O$: C, 59.88; H, 4.11; N, 12.69%. The product (0.1 g) was hydrolyzed by refluxing in an EtOH–hydrochloric acid mixture to 4-*p*-chlorophenylimidazole hydro-

chloride which was then treated with aq sodium hydroxide soln and the free base (0.07 g, 87%) recrystallized from water affording 4-*p*-chlorophenylimidazole, mp 146—147 °C (lit,[26] mp 145—147 °C). IR(KBr) 3130—2600 *vs.* (N–H) cm^{-1}.

The following compounds were similarly obtained: **6a** ($R^4=C_6H_5$) from **4k** in 38% yield, mp 148—149 °C (lit,[27] mp 153 °C). IR (KBr) 1725 *vs.* (C=O) cm^{-1}; NMR (DMSO-d_6) 2.65 (s, 3, $COCH_3$), 7.32 (m, 3, $H^{m,p}$ of 4-phenyl), 7.81 (m, 2, H^o of 4-phenyl), 8.10 (d, 1, J=1.3 Hz, H-5), 8.38 (d, 1, J=1.3 Hz, H-2). (Found: N, 14.99%). 4-Phenylimidazole which was contained in the aq washings of **6a** was separated as picrate in 19% yield, mp 214—215 °C lit,[27] mp 215 °C). (Found: C, 48.17; H, 2.96; N, 18.77%). 1-Acetyl-4-phenyl-1*H*-imidazole was also obtained from **5a** in 55% yield, mp 149 °C not depressed by **6a** from **4k**. The 5-deuterio compound **4k**-d_1 gave **6a**-d_1 in 62% yield, mp 146—147 °C. IR(KBr) 1725 *vs.* (C=O) cm^{-1}; NMR (DMSO-d_6) 2.66 (s, 3, $COCH_3$), 7.30 (m, 3, $H^{m,p}$ of 4-phenyl), 7.82 (m, 2, H^o of 4-phenyl), 8.38 (s, 1, H-2). **6c** (R^4=*p*-AcNH-C_6H_4) from **4d** in 74% yield as colorless prisms, mp 258 °C (from AcOH–Ac_2O); IR(KBr) 1735 *vs.* (C=O), 1680 (C=O) cm^{-1}; NMR (CF_3CO_2D) 2.50 (s, 3, $COCH_3$), 2.91 (s, 3, $COCH_3$), 7.72 (s, 4, C_6H_4), 8.12 (d, 1, J=1.6 Hz, H-5), 9.29 (d, 1, J=1.6 Hz, H-2). Found: C, 64.30; H, 5.35; N, 17.13%. Calcd for $C_{13}H_{13}N_3O_2$: C, 64,18; H, 5.39; N, 17.27%. Selective hydrolysis at N-1 of **6c** was accomplished by agitating in water adjusted to pH 11 at room temperature and afforded 4-*p*-acetamidophenylimidazole, mp 250—250.5 °C (lit,[28] mp 250—251 °C); IR (KBr) 1685 cm^{-1} (C=O). (Found: C, 65.49; H, 5.50; N, 20.98%). **6d** (R^4=*p*-$MeOC_6H_4$) from **4c** in 78% yield as colorless needles, mp 184.5—185 °C (from EtOH); IR (KBr) 3140 (νC–H), 1730 *vs.* (C=O), 840 (δC–H) cm^{-1}; NMR (DMSO-d_6) 2.65 (s, 3, $COCH_3$). 3.78 (s, 3, OCH_3), 6.93 (d, 2, J=8.7 Hz, *p*-methoxyphenyl protons), 7.77 (d, 2, J=8.7 Hz, *p*-methoxyphenyl protons), 8.02 (d, 1, J=1.3 Hz, H-5), 8.37 (d, 1, J=1.3 Hz, H-2). Found: C, 66.45; H, 5.54; N, 12.98%. Calcd for $C_{12}H_{12}N_2O_2$: C, 66.65; H, 5.59; N, 12.96%. It was hydrolyzed to 4-*p*-methoxyphenylimidazole (75%), mp 137.5—138 °C (lit,[28] mp 136—137 °C); IR (KBr) 3100—2600 *vs.* (N–H) cm^{-1}. (Found: C, 68.92; H, 5.81; N, 16.25%).

*Reductive Cleavage of **4k** (another example for isolation of the cleaved products).* A mixture of **4k** (0.7 g), zinc dust (18 g), glacial acetic acid (70 ml), and acetic anhydride (28 ml) was stirred at room temperature for 2 h, filtered, and the filtrate was evaporated. The residue was heated with a mixture of water (10 ml) and MeOH (5 ml) and the aq extract was treated with a soln of picric acid (0.5 g) in water (30 ml) giving 4-phenylimidazole picrate (0.55 g, 69%). The mother liquor of picrate was evaporated and the residue was extracted with chloroform (50 ml). The extract was washed successsively with aq ammonia and water and then evaporated to afford **10** (R^1=*p*-$MeOC_6H_4$, R^2=H), mp 95—96 °C (0.35 g, 90%) (lit,[29] mp 95.5—97 °C). IR (KBr) 3250 (N–H), 1630 (C=O), 1255 (C–O–C) cm^{-1}; NMR ($CDCl_3$) 1.95 (s, 3, $COCH_3$), 3.74 (s, 3, OCH_3), 4.25 (d, 2, J=6.0 Hz, NCH_2), 6.30 (br, 1, NH), 6.77 (d, 2, J=8.3 Hz, ring protons), 7.12 (d, 2, J=8.3 Hz, ring protons). In the same manner, **4s**, **4t**, and **4u** gave 4-phenylimidazole picrate in 87, 73, and 17% yields, respectively.

*Hydrazinolysis of **4k** (a typical example).* A mixture of **4k** (0.24 g), 80% hydrazine hydrate (0.5 ml), and 2-methoxyethanol (2 ml) was heated to 165°C for 70 min and then evaporated. The residue was charged onto a silica gel column (30 g), eluted with chloroform, and the homogeneous fraction was evaporate giving practically pure **7a** (0.15 g, 98%), mp 119—120 °C. Recrystallization from benzene gave colorless needles, mp 122.5—123 °C. UV_{max} (MeOH) 271 nm (ε 16 900); NMR ($CDCl_3$) 4.70 (br, 2, NH_2), 7.30 (m, 3, $H^{m,p}$ of 4-phenyl), 7.71 (m, 2, H^o of 4-phenyl). From a fraction which preceded **7a**, there was obtained **12** (R^1=*p*-$MeOC_6H_4$, R^2=H), mp 167—169 °C (from benzene) (turned to a clear melt at 179—180 °C) (lit,[30] mp 167—163 °C). (Found: C, 71.78; H, 6.02; N, 10.31%). Alternatively, the residue obtained after evaporation of the reaction mixture was triturated with water and the insoluble solids were heated with MeOH at the reflux temperature for 30 min. Insoluble **12** was filtered off and the filtrate evaporated to give a residue which was then recrystallized from benzene affording **7a** (54%), mp 122—123 °C. According to the latter procedure, **5a** yielded **9** (74%) as colorless needles, mp 141—142 °C. UV_{max} (MeOH) 278 nm (ε 16 800); IR (KBr) 3340 and 3100 (NH) cm^{-1}; NMR ($CDCl_3$) 2.59 (s, 3, SCH_3), 4.55 (br, 2, NH_2), 7.00 (s, 1, H-4), 7.35 (s, 5, C_6H_5). Found: C, 58.75; H, 5.40; N, 20.66%; M^+, 205. Calcd for $C_{10}H_{11}N_3S$: C, 58.53; H, 5.40; N, 20.48%; M, 205.

*Hydrazinolysis of **4d**.* A mixture of **4d** (0.86 g), 80% hydrazine hydrate (7.5 ml), and 2-methoxyethanol (7.5 ml) was heated to 175 °C for 13 h[31] and then evaporated. The residual liquid was triturated with EtOH (6 ml) to crystallize **7d** (0.13 g, 20%), mp 177.5—178 °C (from EtOH). NMR (DMSO-d_6) 6.06 (br, 2, NH_2), 8.00 (d, 2, J=9.1 Hz, *p*-nitrophenyl protons), 8.23 (d, 2, J=9.1 Hz, *p*-nitrophenyl protons). The mother liquor after crystallization of **7d** was allowed to stand overnight and deposited **7b** (0.16 g, 29%) was collected by filtration, mp 175—176 °C (from EtOH). NMR (DMSO-d_6) 3.67 (br, NH_2), 5.88 (br, 2, NH_2), 6.54 (d, 2, J=8.6 Hz, *p*-aminophenyl protons), 7.38 (d, 2, J=8.6 Hz, *p*-aminophenyl protons). When the reaction was carried out by heating a mixture of **4d** (0.68 g), 80% hydrazine hydrate (6 ml), and 2-methoxyethanol (24 ml) for 2 h (**4d** had dissolved within 10 min) and concentrating the mixture to one half of the original volume, **7d** gradually crystallized (0.16 g, 32%), mp 177—178 °C.

*Hydrolysis of **4m**.* A soln of **4m** (0.92 g) in concentrated hydrochloric acid (20 ml) was heated to 130 °C for 30 min and the separated *p*-methoxyacetophenone (0.4 g, 98%) was removed by extraction with Et_2O. The aq layer was diluted with water (7 ml), made basic with aq ammonia, and extracted with chloroform (30 ml) giving **7a** (0.44 g, 79%), mp 120—122 °C.

*Deamination of **7**.* To a stirred mixture of **7a** (0.41 g), concentrated hydrochloric acid (4 ml), and MeOH (4 ml) was added a soln of sodium nitrite in water (0.1 g/ml) until an excess of nitrous acid remained after the last addition. Stirring was continued for 4 h at room temperature and the mixture was made alkaline (pH 10) with aq soln of sodium hydroxide. The solid was filtrered and washed with water giving **8a** (R^3=Me, $R^4=C_6H_5$) (0.26 g, 68%), mp 137—138 °C (lit,[32] mp 135.5—136.5 °C). IR (KBr) 3060—2600 (N–H) cm^{-1}. The following compounds were similarly obtained: **8b** (R^3=Me, R^4=*p*-ClC_6H_4): colorless plates (from *i*-PrOH), 84%, mp 181—182 °C; IR (KBr) 3050—2580 (N–H) cm^{-1}; NMR ($CDCl_3$) 2.64 (s, 3, SCH_3), 5.64 (br, 1, NH), 7.28 (d, 2, J=8.9 Hz, *p*-chlorophenyl protons), 7.36 (s, 1, H-4 or 5), 7.70 (d, 2, J=8.9 Hz, *p*-chlorophenyl protons). Found: C, 53.34; H, 4.08; N, 12.27%. Calcd for $C_{10}H_9ClN_2S$: C, 53.45; H, 4.04; N, 12.47%. **8c** (R^3=Me, R^4=*p*-$O_2NC_6H_4$): bright yellow needles (from benzene–MeOH), 47%, mp 211—212 °C; IR (KBr) 3140—2590 (N–H) cm^{-1}; NMR (CF_3CO_2D) 2.91 (s, 3, SCH_3), 7.88 (s,

1, H-4 or 5), 7.95 (d, 2, J=9.2 Hz, *p*-nitrophenyl protons), 8.48 (d, 2, J=9.2 Hz, *p*-nitrophenyl protons). Found: C, 51.24; H, 3.87; N, 18.03%. Calcd for $C_{10}H_9N_3O_2S$: C, 51.06; H, 3.86; N, 17.87%. **8d** (R^3=*n*-C_3H_7, R^4=C_6H_5): 48%, mp 79.5—80 °C (lit,[32] mp 78—79 °C), IR (KBr) 3050—2600 (N–H) cm^{-1}. (Found: C, 66.07; H, 6.53; N, 12.57%). **8e** (R^3=H_2C=$CHCH_2$, R^4=C_6H_5): colorless needles (from *i*-Pr_2O–hexane), 62%, mp 93—94 °C; IR (KBr) 3060—2550 (N–H) cm^{-1}; NMR ($CDCl_3$) 3.55 (dt, 2, J= 6.8 and 0.9 Hz, SCH_2), 5.00 (m, 2, =CH_2), 5.80 (m, 1, –CH=), 7.23 (m, 3, $H^{m,p}$ of phenyl), 7.32 (s, 1, H-4 or 5), 7.64 (m, 2, H^o of phenyl), 10.43 (s, 1, NH). Found: C, 66.56; H, 5.68; N, 12.73%. Calcd for $C_{12}H_{12}N_2S$: C, 66.65; H, 5.59; N, 12.96%. **8f** (R^3=$C_6H_5CH_2$, R^4=C_6H_5): 19%, mp 175—176 °C (lit,[4] mp 176.5—177.5 °C); IR (KBr) 3050—2580 (N–H) cm^{-1}. (Found: C, 72.00; H, 5.46; N, 10.30%).

The author wishes to thank Mr. Seizo Taira and Miss Tomoko Okawa for their assistance in the preparation of some compounds.

New β-Carbonylvinylpalladium(II) Complexes Derived from 2-Chlorovinyl Ketones and Tetrakis(triphenylphosphine)palladium(0)

Masayoshi ONISHI, Hideharu YAMAMOTO, and Katsuma HIRAKI

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received December 3, 1977)

Chloro(*trans*-3-oxo-3-phenyl-1-propenyl)bis(triphenylphosphine)palladium(II), chloro(*trans*-3-oxo-3-*p*-tolyl-1-propenyl)bis(triphenylphosphine)palladium(II), chloro(3-oxo-1-cyclohexenyl)bis(triphenylphosphine)palladium(II), and chloro(5,5-dimethyl-3-oxo-1-cyclohexenyl)bis(triphenylphosphine)palladium(II) were prepared by reactions between $Pd(PPh_3)_4$ and linear or cyclic 2-chlorovinyl ketones. The halogen metathesis reactions with LiBr yielded the corresponding bromo complexes. Each of the β-carbonylvinyl groups in these eight complexes was found to be situated at the *trans* position to a palladium-halogen bond, on the basis of IR and ^{1}H-NMR studies. The complexes with the cyclic β-carbonylvinyl groups were rather stable. The oxidative addition of linear 2-chlorovinyl ketones proceeded with retention of configuration about the double bond.

Several investigations have been reported on the oxidative addition of vinyl halides, for example, polyhalogenated olefins,[1] fluorovinyl halides,[2] and some styryl halide derivatives[3] with a tris- or tetrakis(tertiary phosphine)platinum(0) complex. A few halogeno-substituted vinylpalladium(II) complexes have been obtained by the reactions of $[Pd(PPh_3)_4]$ with polyhalogenated olefins[4] or fluorovinyl halides.[5] Moreover, Murahashi *et al.*[6] reported cross-coupling reactions of vinyl halides with alkyl magnesium bromide catalysed by $[Pd(PPh_3)_4]$, *via* the oxidative addition.

Although 2-chlorovinyl ketones are very reactive and useful intermediates for the syntheses of some organic compounds,[7] only a few investigations have been reported concerning the reactions between linear 2-chlorovinyl ketones and iron,[8] tungsten,[9] or rhenium[10] carbonyl derivatives.

We have been interested in the ease of carbon-chlorine bond cleavage in the linear and cyclic chloro olefins activated by electron-withdrawing acyl groups. In the present research, 2-chlorovinyl ketones were found to react with $[Pd(PPh_3)_4]$ to yield several new β-carbonylvinylpalladium(II) complexes, and some properties of these complexes were studied.

Experimental

General Procedures. IR spectra were obtained using a Hitachi 285 grating spectrometer and a Shimadzu IR 450 spectrometer. ^{1}H-NMR spectra were run on a Japan Electron Optics Laboratory JNM-MH-100 spectrometer. Melting points were determined on a Yanagimoto MP-S3 microstage apparatus in capillary tubes in dinitrogen and are uncorrected.

Phenyl 2-chlorovinyl ketone,[7,11] *p*-tolyl 2-chlorovinyl ketone,[7,12] 3-chloro-2-cyclohexen-1-one,[13] and 3-chloro-5,5-dimethyl-2-cyclohexen-1-one[14] were prepared according to the methods described in the literature. Solvents were dried and distilled by the usual methods, and all operations were performed in an atmosphere of dry dinitrogen.

Reactions of the Linear 2-Chlorovinyl Ketones with $Pd(PPh_3)_4$.

Phenyl 2-chlorovinyl ketone (0.60 g) in 8 ml of benzene was added dropwise to a suspension of $Pd(PPh_3)_4$ (3.40 g) in 25 ml of benzene, and the mixture was stirred at room temperature for two days. Benzene was removed *in vacuo* from the suspension, and the residue was extracted with dichloromethane. The extract was evaporated to dryness and the resulting solid was washed with acetone, ethanol, and diethyl ether to yield chloro(*trans*-3-oxo-3-phenyl-1-propenyl)bis(triphenylphosphine)palladium(II) (**1**), 0.56 g.

Chloro(*trans*-3-oxo-3-*p*-tolyl-1-propenyl)bis(triphenylphosphine)palladium(II) (**2**) was obtained similarly.

Reactions of the Cyclic 2-Chlorovinyl Ketones with $Pd(PPh_3)_4$.

A mixture of $Pd(PPh_3)_4$ (3.10 g) and 3-chloro-2-cyclohexen-1-one (0.71 g) in 25 ml of benzene was warmed at *ca.* 60 °C for 3 h. The solvent was removed *in vacuo* and the resulting residue was recrystallized from benzene to give a pale yellow powder of chloro(3-oxo-1-cyclohexenyl)bis(triphenylphosphine)palladium(II) (**3**), 1.71 g.

Chloro(5,5-dimethyl-3-oxo-1-cyclohexenyl)bis(triphenylphosphine)palladium(II) (**4**) was prepared by a similar method.

*Halogen Metathesis Reactions of **1**, **2**, **3**, and **4**.* The complex **1** (0.25 g) and LiBr (0.05 g) were mixed in 12 ml of acetone and the suspension was stirred at room temperature for four days. The resulting precipitate was collected and washed with acetone, ethanol, and diethyl ether to yield a pale yellow powder of bromo(*trans*-3-oxo-3-phenyl-1-propenyl)bis(triphenylphosphine)palladium(II) (**5**), 0.07 g.

Bromo(*trans*-3-oxo-3-*p*-tolyl-1-propenyl)bis(triphenylphosphine)palladium(II) (**6**), bromo(3-oxo-1-cyclohexenyl)bis(triphenylphosphine)palladium(II) (**7**), and bromo(5,5-dimethyl-3-oxo-1-cyclohexenyl)bis(triphenylphosphine)palladium(II) (**8**) were prepared by a method similar to **5**.

Results and Discussion

Four new β-carbonylvinylpalladium(II) complexes: **1**, **2**, **3**, and **4**, were obtained from the oxidative addition reaction between $Pd(PPh_3)_4$ and 2-chlorovinyl ketones. The halogen metathesis reaction with lithium bromide yielded the corresponding bromo complexes: **5**, **6**, **7**, and **8**. The cyclic 2-chlorovinyl ketones, such as 3-chloro-2-cyclohexen-1-one, were more thermally unstable and sensitive to moisture than the linear ketones. However, the reaction of the cyclic ketones

with $Pd(PPh_3)_4$ took place only at temperatures above 50 °C, while that of the linear ketones proceeded smoothly at room temperature. When the solvents were not sufficiently dried, the complexes with the linear β-carbonylvinyl groups decomposed partially and turned brown. Yields, analytical data, and the properties of the eight complexes prepared are summarized in Tables 1, 2, and 3. These complexes were readily soluble in dichloromethane and hot benzene, and the complexes with the linear β-carbonylvinyl groups were also moderately soluble in benzene at room temperature.

The complexes obtained in this study possess a palladium-vinyl σ bond, judging from the halogen metathesis reaction and the existence of ν(Pd–Cl) bands shown in Table 2.

The ν(C=C) stretching frequencies of all the complexes were lowered about 45—80 cm^{-1} relative to those of the starting 2-chlorovinyl ketones. These lowering shifts of the ν(C=C) frequencies were probably associated with some double-bonding character between the d orbitals of palladium and the sp^2 carbon atom. The ν(C=O) stretching frequencies of the complexes with the cyclic β-carbonylvinyl groups were shifted by 25—60 cm^{-1} towards lower wavenumbers, relative to those of the starting ketones. The lowering shifts of the ν(C=O) frequencies were possibly due to an extension of the π-conjugation through the β-carbonylvinylpalladium moiety. On the other hand, the complexes with the linear β-carbonylvinyl groups showed small lowering shifts (*ca.* 10 cm^{-1}) of the ν(C=O) frequencies, in comparison with the starting 2-chlorovinyl ketones. This fact might correspond to a small degree of additional

extension of the π-conjugation, owing to the complex formation.

It has been well known that the aryl 2-chlorovinyl ketones used in this study have a *trans* configuration about the double bond.[7] The ^{1}H-NMR couplings J_{ab} of the vinyl protons, H_a and H_b in **1**, **2**, **5**, and **6**, were about 14.0—18.0 Hz, which were of the order expected for *trans*-AB coupling across a double bond, and indicated that the *trans* arrangement of these protons was retained in these four complexes. No signal for H_a protons could be distinguished owing to the overlapping with many aromatic protons.

H_b resonances of the complexes with the linear and cyclic β-carbonylvinyl groups showed a double triplet and a triplet, respectively. These triplet splittings for both kinds of complexes were ascribed to the coupling with two equivalent phosphorus-31 atoms and indicated a *trans* geometry of the two triphenylphosphine ligands. (In the complex **5**, the coupling with phosphorus-31 could not be detected, because of its fairly fast decomposition.) Table 2 also shows reasonable ν(Pd–Cl) frequencies for the *trans* position to the palladium-carbon σ bond.

In addition, the resonances of the methyl groups in **4** and **8** showed large high-field shifts. The reason for these shifts was probably explained by the ring current of phenyl groups of triphenylphosphine.

The palladium-carbon σ bonds in the eight complexes studied here were stabilized by β-carbonylvinyl groups to some degree, and these complexes were stable in the solid state under dinitrogen at room temperature for several weeks. In a deoxygenated dichloromethane solution, the complexes with the cyclic β-carbonylvinyl groups were stable for more than a week at room temperature, whereas the complexes with the linear ones began to decompose in 1 h. This high stability of the former complexes can be accounted for probably by the steric hindrance of the cyclic β-carbonylvinyl groups against the species which attack the palladium-carbon σ bond.

We are grateful to Professor Keinosuke Hamada and Mr. Hirofumi Morishita, Nagasaki University, for their help with the Far IR measurements.

1,3-Dipolar Cycloadditions to Bicyclic Olefins. V. The Stereo- and Regiochemistry of 1,3-Dipolar Cycloadditions to Several Unsymmetrical Bicyclic Olefins[1,2]

Hisaji TANIGUCHI, Toshikazu IKEDA, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received December 12, 1977)

Each of the 1,3-dipolar cycloadditions of phenylglyoxylonitrile oxide (**1**), methylglyoxylonitrile oxide (**2**), benzonitrile oxide (**3**), and phenyl azide to 2-phenylsulfonyl-2-azabicyclo[3.2.1]octa-3,6-diene (**6**) occurs only to the C_6–C_7 double bond, affording two exo regioisomers. Each of the cycloadditions of **1**, **2**, and **3** to 2-phenylsulfonyl-2-azabicyclo[3.2.1]oct-3-ene (**7**) gives only one exo adduct. The cycloaddition of *C,N*-diphenylnitrone to 2-methylenenorbornane (**8**) gives a mixture of two exo adducts. These results show that the "exo rule" can be extended to the 1,3-dipolar cycloadditions to the bicyclic olefins, **6**, **7**, and **8**. Tentative explanations are offered to account for the exo stereoselectivity and the regio-selectivity in these cycloadditions.

1,3-Dipolar cycloadditions to norbornenes follow the "exo rule."[3] However, a previous paper reported that those to norbornadienes do not follow this rule.[4] This reactivity difference has been ascribed to the presence of homoconjugation in norbornadiene.[4] These results and the assumption prompted us to ascertain to what cases the "exo rule" could be extended. We undertook to study it through 1,3-dipolar cycloadditions to the following three kinds of bicyclic olefins: (i) 2-phenylsulfonyl-2-azabicyclo[3.2.1]octa-3,6-diene (**6**), which has a formally different homoconjugation from norbornadiene;[5] (ii) 2-phenylsulfonyl-2-azabicyclo[3.2.1]oct-3-ene (**7**), which has an unsaturated bridge larger by one nitrogen atom than that of norbornene, and (iii) 2-methylenenorbornane (**8**), whose double bond is of the exo type. The 1,3-dipolar cycloadditions of phenylglyoxylonitrile oxide (**1**), methylglyoxylonitrile oxide (**2**), benzonitrile oxide (**3**), and phenyl azide (**4**) to **6** or **7** and the 1,3-dipolar cycloaddition of α,*N*-diphenylmethanimine *N*-oxide (**5**) to **8** were carried out. Since all the bicyclic olefins used here were unsymmetrical, the regiochemistry of these cycloadditions was also studied.

Results

1,3-Dipolar Cycloadditions. The slow addition of a dilute THF solution of triethylamine (TEA) to a stirred solution of **6** and α-chloro-α-hydroxyiminoacetophenone (**9**), which is a precursor of **1**, in THF cooled in an ice bath gave two exo adducts, 8-phenylsulfonyl-5-benzoyl-2,6-*exo*-3-oxa-4,8-diazatricyclo[5.3.1.$0^{2,6}$]-undeca-4,9-diene (**10**) and 10-phenylsulfonyl-5-benzoyl-2,6-*exo*-3-oxa-4,10-diazatricyclo[5.3.1.$0^{2,6}$]undeca-4,8-diene (**11**). The cycloadditions of **2** to **6** and **3** to **6** were carried out by a method like that described above. The reaction of **2** to **6** afforded two exo adducts, 5-acetyl-8-phenylsulfonyl-2,6-*exo*-3-oxa-4,8-diazatricyclo-[5.3.1.$0^{2,6}$]undeca-4,9-diene (**12**) and 5-acetyl-10-phenylsulfonyl-2,6-*exo*-3-oxa-4,10-diazatricyclo[5.3.1.$0^{2,6}$]-undeca-4,8-diene (**13**). Moreover, the reaction of **3** with **6** also produced two exo adducts, 8-phenylsulfonyl-5-phenyl-2,6-*exo*-4,8-diazatricyclo[5.3.1.$0^{2,6}$]undeca-4,9-diene (**14**) and 10-phenylsulfonyl-5-phenyl-2,6-*exo*-4,10-diazatricyclo[5.3.1.$0^{2,6}$]undeca-4,8-diene (**15**). All the adducts obtained in the above reactions are produced by the addition of the nitrile oxides, **1**—**3**, to the C_6=C_7 double bond of **6**. The adducts which were to be produced by the addition of the nitrile oxides to the other carbon-carbon double bond (C_3=C_4 double bond) of **6**, the endo adducts, and the bisadducts were not detected at all.

The reaction of the azide, **4**, with an equiv of **6** in dry benzene at room temperature led to the formation of two exo monoadducts, 10-phenylsulfonyl-5-phenyl-2,6-*exo*-3,4,5,10-tetraazatricyclo[5.3.1.$0^{2,6}$]undeca-3,8-diene (**16**) and 8-phenylsulfonyl-5-phenyl-2,6-*exo*-3,4,5,8-tetraazatricyclo[5.3.1.$0^{2,6}$]undeca-3,9-diene (**17**). Similary, the adducts which were to be produced by the attack of **4** on the C_3=C_4 double bond of **6**, the endo adducts, and the bisadducts were not detected at all.

The yields of the adducts obtained in the reactions of **1**—**4** with **6** and the product compositions are summarized in Table 1.

The cycloadditions of the nitrile oxides, **1**—**3**, to **7** was carried out in a manner similar to that described above. Each of the three reactions gave only one exo adduct, 2-phenylsulfonyl-6-benzoyl-3,7-*exo*-4-oxa-2,5-diazatricyclo[6.2.1.$0^{3,7}$]undec-5-ene (**18**), 6-acetyl-2-phenylsulfonyl-3,7-*exo*-4-oxa-2,5-diazatricyclo[6.2.1.$0^{3,7}$]-undec-5-ene (**19**), or 2-phenylsulfonyl-6-phenyl-3,7-*exo*-4-oxa-2,5-diazatricyclo[6.2.1.$0^{3,7}$]undec-5-ene (**20**). When these reactions were carried out at 0 °C, the yields of the adducts were low. When the reaction temperature was raised to 66 °C, the yields of the adducts (**18**, **19**) increased, but no other product was

TABLE 1. THE YIELDS OF ADDUCTS AND PRODUCT COMPOSITIONS IN THE REACTIONS OF **1**—**4** WITH **6**

	66	**19**	45	39
3	0	**20**	33	50
	66	**20**	33	52

obtained (Table 2).

A solution of **4** and **7** in dry benzene was allowed to stand in the dark for one week at room temperature; however, this treatment gave no adduct.

When a solution of the nitrone, **5**, in toluene containing two equiv. of **8** was refluxed, a 1 : 1 mixture of two exo adducts, 1′-*exo*,3′-*endo*-2′,3′-diphenylspiro[norbornane-2,5′[1′]oxa[2′]azacyclopentane] (**21**) and 1′-*exo*,3′-*exo*-2′,3′-diphenylspiro[norbornane-2,5′[1′]oxa[2′]azacyclopentane] (**22**), was obtained in an 83% yield.

The above results show that the "exo rule" can be extended to the 1,3-dipolar cycloadditions to the bicyclic olefins, **6**, **7**, and **8**.

The separation or the isolation of the adducts from the reaction mixture was carried out using column chromatography on silica gel or alumina.

*Determination of Configurations of Adducts. a) Adducts (**10**—**17**) obtained in Cycloadditions to **6***: The structural assignments of the adducts were made on the basis of the NMR chemical shifts (Table 3), the coupling constants (Table 4), the spin-spin decouplings, and the nuclear Overhauser effects (NOE).[6]

In each adduct, the signal which appeared as a double doublet in the region of δ 6.50—6.66 was assigned to the vinyl proton, 9-H. This was confirmed by the spin-decoupling technique; the vinyl proton was coupled to the adjacent vinyl proton (J=8.0 or 7.5 Hz) and to the bridgehead proton which neighbors on the nitrogen atom (J=1.0 or 1.5 Hz). This finding indicates that all the adducts (**10**—**17**) are produced by the addition of 1,3-dipoles to the C_6=C_7 double bond of **6**.

The signals of the 2-H and the 6-H in each adduct appeared as simple doublets. The coupling constant between the 2-H (or 6-H) and the adjacent bridgehead proton was 0 Hz, as is shown in Table 4. This finding shows that all the adducts are produced by the attack of 1,3-dipoles on **6** from the exo side.

Each adduct pair, **10** and **11**, **12** and **13**, **14** and **15**, or **16** and **17**, consists of regioisomers to each other. The distinction between the **12** and **13** regioisomers was achieved by NOE experiments. Irradiation at the frequency of the 1-H of the adduct, **12**, caused a 24% increase in the integral of the multiplet (δ=5.00—5.12, 2-H and 6-H), but brought about no increase in the integral of the doublet (6-H). The saturation of the 7-H of the adduct, **13**, gave rise to a 20% enhancement of the integral of the 8-H and a 5% enhancement of that of the 6-H. These findings show that the oxygen atom of the isoxazoline moiety in the **12** adduct is on the opposite side of the molecule from the *N*-phenylsulfonyl group, while the corresponding oxygen atom of the adduct, **13**, is on the same side of the molecule as the *N*-phenylsulfonyl group. The difference in the chemical

16	*ca.* 4.7	4.82	4.25	2.60	5.28	6.64	—	0.57
17	2.88	5.12	4.28	*ca.* 4.4	—	6.66	5.49	0.84

a) The spectra were recorded at 60 MHz. b) Expressed in δ ppm units, with TMS as the internal standard, in $CDCl_3$ soln. c) The shift difference between the 2-H and the 6-H.

shift between the 2-H and the 6-H of the **12** adduct is greater by 0.54 ppm than the corresponding difference between the 2-H and the 6-H of the **13** adduct. Such a chemical-shift difference was applied to the distinction between the **10** and **11**, or **14** and **15** regioisomers (Table 3).

The distinction between the **16** and **17** regioisomers was also achieved by observing the NOE. Irradiation at the frequency of the bridgehead proton, 7-H, of the **16** adduct brought about an increase of 9% in the integral of the doublet (6-H) and an increase of 9% in the integral of the vinyl proton, 8-H, but caused no increase in the integral of the doublet (2-H). Also, the empirical data[7] suggest that the high-field doublet of the two doublet is due to the 6-H which is adjacent to the phenyl group. These findings show that the phenyl group is on the opposite side of the molecule from the *N*-phenylsulfonyl group, as is shown in the structure (**16**). In the case of the **17** adduct, it was confirmed by irradiation at the frequency of the bridgehead proton, 1-H, of this adduct that the phenyl group is on the same side of the molecule as the *N*-phenylsulfonyl group. An increment of 25% was observed in the integral of the multiplet, which consisted of a low-field doublet (2-H) and a triplet (10-H).

Table 5. The NMR data of adducts (**18**—**20**)[a,b]

Adduct	1-H	3-H	7-H	8-H	$J_{3,7}$	$J_{7,8}$
18	4.01	6.65	3.72	2.58	10	0
19	4.00	6.58	3.52	—	9.5	0
20	4.00	6.60	3.65	2.32	9.5	0

a) The spectra were recorded at 60 MHz. b) The chemical shifts are expressed in δ ppm units, with TMS as the internal standard, in $CDCl_3$ soln. J values in Hz.

b) Adducts (18—20) Obtained in Cycloadditions to 7: The structural assignments of the **18**—**20** adducts were carried out by means of their NMR data (Table 5). Each spectrum of these adducts showed two simple doublets at δ *ca.* 3.6 and *ca.* 6.6 (Table 5). The high-field doublet in each spectrum was assigned to the 7-endo H by making a comparison between its spectrum and the spectrum of the exo adduct (**25**)[4] formed in the cycloaddition of **1** to norbornadiene; in the spectrum of Compound **25**, the 6-endo H appears at δ 3.78 ppm as a simple doublet.[4] From the fact that the coupling constant between the 7-H and the adjacent bridgehead proton, 8-H, in each adduct is 0 Hz, it can be said that each adduct is an exo adduct; the dihedral angle between the 7-H and the 8-H is close to 90°.

c) The 21 and 22 Adducts: Since no hydrogen atom is attached to the 2-carbon atom of the **8** olefin, it is impossible to determine the structure of the 1 : 1 adducts obtained in the cycloaddition of **5** to **8** on the basis of the NMR spectrum alone. A solid obtained in this cycloaddition consisted of the two exo adducts **21** and **22**, not of the endo adducts, **23** and **24**. This was confirmed by the following observations. (i) The NMR spectrum of a mixture of **21** and **22** showed the signal of their 5′-methylene protons at δ 2.2—2.9 as a multiplet. This chemical-shift value indicated that these adducts are produced by the attack of the oxygen atom in the nitrone, **5**, on the 2-carbon atom in the olefin, **8**. (ii) It was revealed by the double-resonance technique that the solid obtained in this cycloaddition consisted of two adducts. Each 4′-H of the two adducts (**21** and **22**) has the same chemical shift (δ=4.61). When their 4′-H's were irradiated with an additional radio frequency at the resonance position, the multiplet which appeared at δ 2.2—2.9 was transformed into eight sharp peaks, which consisted of two sets of AB quartets (J_{AB}=11.0 and 14.0 Hz) assigned to 5′-methylene protons in **21** and to those in **22**. (iii) The hydrogenolysis of the solid which consisted of **21** and **22** gave only 2-phenethyl-2-*exo*-norbornanol (**26**) in a 79% yield. The structure of this alcohol was established by comparison with the corresponding endo alcohol (**27**), which had been prepared by a method like that described in the literature.[8]

These findings (i—iii) indicate that the solid obtained in this cycloaddition consists of the two exo adducts, **21** and **22**.

Discussion

This kind of 1,3-dipolar cycloaddition has been shown to be a kinetically controlled reaction.[4,9]

A Tentative Explanation of the exo Stereoselectivity. In view of the results obtained in previous work,[2,4] it may be suggested that the dipoles used here, **1**—**5**, act as electron-accepting 1,3-dipoles toward the olefins, **6**—**8**. This indicates that the present 1,3-dipolar cycloadditions may be classified as LU-controlled reactions.[10] On the other hand, it has been suggested by the orbital mixing rule that the highest occupied molecular orbital (HOMO) of norbornene extends more to the exo side than to the endo side because of the interaction beteen the HOMO of the carbon-carbon double bond and the strained methano-bridge orbital.[11] Each olefin used here has a strained methano-bridge such as norbornene. Similarly, it can be predicted by the orbital mixing rule that the HOMO of the carbon-carbon double bond in each olefin extends more to the exo side than to the endo side.[12] Consequently, the dipoles, **1**—**5**, attack the olefins, **6**—**8** from their exo sides.

Attacking Site of 1,3-Dipoles on 6. Although the **6** olefin has two double bonds which are to be attacked by 1,3-dipoles, cycloaddition occurs only to the C_6=C_7 double bond, not to the enamine-type double bond (C_3=C_4 double bond). This phenomenon may be ascribed to the following factors (i—iii): (i) In the 2-azabicyclo[3.2.1]octa-3,6-diene system (**28**,[5] **29**,[13] and **30**[5]), the signals of the 4-H and the 7-H shift to lower fields with an increase in the value of Hammett's σ_p[14] of the *N*-substituent, *R* (Fig. 1). Also, both the 4-H and the 7-H appear at higher fields than the 6-H. These findings indicate that not only the 4-carbon atom, but also the 7-carbon atom, is under the influence of the electron-donating character of the nitrogen atom. (ii) From the structural consideration of **6**, the interaction of the HOMO of the C_6=C_7 double bond with the methano-bridge orbital is assumed to be greater than that of the HOMO of the C_3=C_4 double bond with the methano-bridge orbital, so that the extension of the HOMO of the C_6=C_7 double bond into the exo side may be greater than that of the HOMO of the C_3=C_4 double bond.[15] (iii) The bulky *N*-substituent (phenylsulfonyl group) may hinder the approach of 1,3-dipoles to the C_3=C_4 double bond. From the fact that phenyl azide addition to bicyclo[3.2.1]octa-2,6-diene (**31**) occurs only to the C_6=C_7 double bond from the exo side,[16] however, this factor seems less probable.

TABLE 6. CHEMICAL SHIFTS OF VINYL PROTONS IN **6** AND **7**[a]

Olefin	3-H	4-H	6-H	7-H
6	6.30	5.1—5.5	6.14	5.1—5.5
7	6.37	5.19		

a) The spectra were recorded at 60 MHz. Expressed in δ ppm units, with TMS as the internal standard, in $CDCl_3$ soln.

Regioselectivity. In the **6** diene, the δ values of its vinyl protons (Table 6)[17] suggest the π electron-cloud on the C_6–C_7 double bond is polarized. This may be caused by the electron-donating character of the nitrogen atom, as has been described above, and by the structural characteristics of the bicyclic dienes with a bicyclo[3.2.1]octane skeleton.[19] In the **7** olefin, the π electron-cloud on the C_3=C_4 double bond may be polarized because of the electron-donating character of the nitrogen atom (see Table 6). In the **8** ofefin, the calculations of Houk *et al.* for the HOMO of ethylenes substituted by alkyl groups[21] suggest that the π electron-cloud of the double bond is polarized. As far as the present cycloadditions are concerned, it may be concluded from the product compositions (Table 1) and the structures of the adducts that the orientation in which the plus poles of 1,3-dipoles attack the minus poles of dipolarophiles is preferred.[22]

Conclusion

The "exo rule" can be applied to 1,3-dipolar cycloadditions to bicyclic olefins with a moiety of the bicyclo-[*n*.2.1]alkane(*n*=2 and 3) skeleton, except for norbornadienes, and can also be applied to such a cycloaddition to 2-methylenenorbornane.

Experimental

Materials. The precursors of the nitrile oxides (**9**),[23] α-chloro-α-hydroxyiminoacetone (**32**),[24] and *N*-hydroxybenzenecarboximidoyl chloride (**33**)[25] and the 1,3-dipoles

(**4**[26] and **5**[27]) were prepared by methods described in the literature. The olefines, **6**,[18] **7**,[18] and **8**,[28] were also prepared by methods described in the literature.

*Cycloaddition of **1** to **6**.* Into a stirred solution of 6 (494 mg, 2.0 mmol) and **9** (367 mg, 2.0 mmol) in dry THF (10 cm^3) cooled in an ice bath, a solution of triethylamine (TEA) (250 mg, 2.5 mmol) in dry THF (5 cm^3) was added, drop by drop, over a period of 1 h. After an additional 1 h's stirring at the same temperature, the resulting triethylammonium chloride was removed by filtration. The filtrate showed, on TLC with benzene–ether (97: 3), two spots at R_f 0.40 (**11**) and at R_f 0.33 (**10**). The evaporation of the solvent left a residue. The residue was chromatographed on silica gel (200—300 mesh). Elution with benzene–ether (97: 3) gave **11** (252 mg, 32%) and **10** (513 mg, 65%), in that order.

Adduct **10**: mp 119—121 °C (colorless cubic crystals from EtOH); IR(KBr) 1650 (C=O), 1642, 1570, 1453, 1362, 1340, 1255, and 1175 cm^{-1} (SO_2).

Found: C, 64.12; H, 4.64; N, 7.20%. Calcd for $C_{21}H_{18}N_2O_4S_1$: C, 63.94; H, 4.61; N, 7.10%.

Adduct **11**: mp 124—125 °C (colorless needles from 95% EtOH); IR (KBr) 1660 (C=O), 1640, 1575, 1450, 1360, 1340, and 1173 cm^{-1} (SO_2).

Found: C, 64.07; H, 4.57; N, 7.20%. Calcd for $C_{21}H_{18}O_4S_1$: C, 63.94; H, 4.61; N, 7.10%.

*Cycloaddition of **2** to **6**.* A solution of **6** (494 mg, 2.0 mmol) and **32** (250 mg, 2.0 mmol) in dry THF (10 cm^3) was treated with TEA (250 mg, 2.5 mmol) in dry THF (5 cm^3) as has been described above. A similar work-up of the reaction mixture and evaporation of the solvent produced a viscous oil, which was solidified by the addition of a few drops of CCl_4. The solid was separated by filtration and dried under a vacuum to give 621 mg (94%) of a mixture of **12** and **13**. The NMR spectrum of the mixture showed that the **12**/**13** product ratio was 76/24. The mixture was chromatographed on silica gel. Elution with benzene–ether (97: 3) gave **13** and **12**, in that order.

Adduct **12**: mp 148—149 °C (coloeless leaves from EtOH); IR (KBr) 1693 (C=O), 1639, 1575, 1457, 1362, 1340, and 1172 cm^{-1} (SO_2); MS (80 eV), *m/e* 332, 289, 221, and 80.

Found: C, 57.63; H, 4.65; N, 8.51%. Calcd for $C_{16}H_{14}N_2O_4S_1$: C, 57.81; H, 4.86; N, 8.43%.

Adduct **13**: mp 129—130 °C (colorless needles from EtOH): IR (KBr) 1700 (C=O), 1639, 1580, 1458, 1360, 1345, and 1180 cm^{-1} (SO_2); MS (80 eV), *m/e* 332, 289, 221, and 80.

Found: C, 58.02; H, 4.81; N, 8.63%. Calcd fro $C_{16}H_{16}N_2O_4S_1$: C, 57.81; H, 4.96; N, 8.43%.

*Cycloaddition of **3** to **6**.* A solution of **6** (494 mg, 2.0 mmol) and **33** (311 mg, 2.0 mmol) in dry THF (10 cm^3) was treated with TEA (250 mg, 2.5 mmol) in dry THF (10 cm^3) by a procedure like that described above. A similar work-up of the reaction mixture and evaporation of the solvent gave 703 mg (96%) of a mixture of **14** and **15**. The NMR spectrum of the mixture showed that the **14**/**15** product ratio was 71/29. The solid was recrystallized from benzene to give colorless, pure **14**. The evaporation of benzene from the mother liquor afforded a residue, which was chromatographed on silica gel with benzene–ether(95: 5) to give **15** and **14**, in that order.

Adduct **14**: mp 214—215 °C (colorless leaves from benzene); IR(KBr) 1635, 1450, 1360, 1335, and 1172 cm^{-1}.

Found: C, 65.68; H, 4.95; N, 7.88%. Calcd for $C_{20}H_{18}N_2O_3S_1$: C, 65.55; H, 4.96; N, 7.65%.

Adduct **15**: mp 151—153 °C (colorless cubic crystals from EtOH–$CHCl_3$); IR (KBr) 1640, 1452, 1360, 1340, and 1172 cm^{-1}.

Found: C, 65.34; H, 4.76; N, 7.64% Calcd for $C_{20}H_{18}N_2O_3S_1$: C, 65.55; H, 4.96; N, 7.65%.

*Cycloaddition of **4** to **6**.* A mixture of **6** (494 mg, 2.0 mmol) and **4** (238 mg, 2.0 mmol) was dissolved in dry benzene (5 cm^3). The solution was then allowed to stand in the dark for one week at room temperature. The resulting white solid was separated from the solution by filtration, washed with a small amount of cold benzene, and dried under a vacuum to give pure **16** (343 mg, 47%). The filtrate was evaporated to afford a residue, which was subsequently chromatographed on alumina. Elution with $CHCl_3$ gave **6** (38 mg, recovery 8%), **17** (76 mg, 10%), and an additional amount of **16** (156 mg, 21%), in that order.

Adduct **16**: mp 179—181 °C (from MeOH); IR (KBr) 1632, 1600, 1505, 1488, 1350, and 1177 cm^{-1}.

Found: C, 62.38; H, 4.88; N, 15.25%. Calcd for $C_{19}H_{18}N_4O_2S_1$: C, 62.28; H, 4.95; N, 15.29%.

Adduct **17**: mp 165—167 °C (from MeOH); IR (KBr) 1639, 1603, 1500, 1363, and 1180 cm^{-1}.

Found: C, 62.20; H, 5.01: N, 15.27%. Calcd for $C_{19}H_{18}N_4O_2S_1$: C, 62.28; H, 4.95; N, 15.29%.

*The Nuclear Overhauser Effects Experiments in the **12**, **13**, **16**, and **17** Adducts.* The NOE in the NMR of these adducts were measured in well-deoxygenated $CDCl_3$ solutions. Table 7 shows the results.

Table 7. NOE experiments in four adducts (**12**, **13**, **16**, and **17**)

Adduct	Signal-irradiated	Proton-affected	Enhancement (%)

*Cycloaddition of **1** to **7**.* *a) At 66 °C*: Into a refluxing solution of **7** (375 mg, 1.5 mmol) and **9** (275 mg, 1.5 mmol) in dry THF (5 cm^3) warmed in a water bath, we stirred, drop by drop over a 2-h period, a solution of TEA (200 mg, 2.0 mmol) in dry THF (5 cm^3). After an additional 1 h's stirring at the same temperature, the resulting ammonium chloride was removed by filtration. The filtrate showed, on TLC with benzene, their spots. After the removal of the solvent, the residue was chromatographed on silica gel. Elution with benzene gave a small amount of 3,4-dibenzoyl-1,2,5-oxadiazole 2-oxide (**34**) (mp 76—78 °C, (lit,[23] 78—80 °C)), **7** (103 mg, recovery 27%), and **18** (335 mg, 57%), in that order.

Adduct **18**: mp 188—190 °C (colorless cubic crystals from $CHCl_3$–EtOH); IR(KBr) 1648 (C=O), 1562, 1448, 1337, and 1167 cm^{-1}.

Found: C, 63.68; H, 4.98; N, 7.16%. Calcd for $C_{21}H_{20}N_2O_4S_1$: C, 63.61; H, 5.09; N, 7.07%.

b) At 0 °C: The same reaction was carried out under similar conditions, but the reaction temperature was maintained at 0 °C instead of at 66 °C. A similar work-up of

the reaction mixture gave **34**, **7** (272 mg, recovery 72%), and **18** (72 mg, 12%).

Cycloaddition of 2 to 7. *a) At 66* °C: A solution of **7** (375 mg, 1.5 mmol) and **32** (182 mg, 1.5 mmol) in dry THF (5 cm^3) was treated with TEA (200 mg, 2.0 mmol) in dry THF (5 cm^3) as described above. A similar work-up of the reaction mixture produced an oil after the evaporation of THF. The oil showed, on TLC with benzene, three spots—at R_f 0.34 (**7**), R_f 0.25 (3,4-diacetyl-1,2,5-oxadiazole 2-oxide (**35**)), and R_f 0.12 (**19**). The oil was chromatographed on silica gel with benzene to give **7** (145 mg, recovery 39%), an oil of **35** (20 mg), and **19** (218 mg, 45%). The structure of **35** was confirmed by the elemental analysis ($C_6H_6N_2O_4$) and by comparing its IR spectrum with that of the analogous furoxan, **34**.

Adduct **19**: mp 156—158 °C (colorless plates from EtOH); IR (KBr) 1692 (C=O), 1580, 1447, 1347, and 1173 cm^{-1}.

Found: C, 57.35; H, 5.48; N, 8.40%. Calcd for $C_{16}H_{18}N_2O_4S_1$: C, 57.46; H, 5.44; N, 8.38%.

b) At 0 °C: The same recation was carried out under similar conditions, but the reaction temperature was kept at 0 °C. A similar work-up of the reaction mixture gave **7** (295 mg, recoverry 79%), a small amount of **35**, and **19** (51 mg, 10%).

Cycloaddition of 3 to 7. *a) At 66* °C; A solution of **7** (375 mg, 1.5 mmol) and **33** (233 mg, 1.5 mmol) in dry THF (5 cm^3) was treated with TEA (200 mg, 2.0 mmol) in dry THF (5 cm^3) as has been described above. A similar work-up of the reaction mixture gave 3,4-diphenyl-1,2,5-oxadiazole 2-oxide (**36**) (mp 115—116 °C (lit,[29] mp 112 °C)), **7** (194 mg, recovery 52%), and **20** (184 mg, 33%).

Adduct **20**: mp 227—229 °C (colorless cubic crystals from EtOH–$CHCl_3$); IR(KBr) 1453, 1400, 1342, and 1178 cm^{-1}.

Found: C, 64.94; H, 5.41; N, 7.57%. Calcd for $C_{20}H_{20}N_2O_3S_1$: C, 65.19: H, 5.48; N, 7.60%.

b) At 0 °C: The same reaction was carried out under similar conditions, but the reaction temperature was kept at 0 °C. A similar work-up of the reaction mixture gave **36**, **7** (187 mg, recovery 50%), and **20** (185 mg, 33%).

Treatment of 4 with 7. A solution of **7** (375 mg, 1.5 mmol) and **4** (180 mg, 1.5 mmol) in dry benzene was allowed to stand in the dark for one week at room temperature. Then, the solution showed, on TLC with benzene, only two spots—at R_f 0.80 (**4**) and R_f 0.47 (**7**).

Cycloadditon of 5 to 8. A solution of **8** (2.22 g, 16.3 mmol) and **5** (1.60 g, 8.2 mmol) in dry toluene (4 cm^3) was heated under reflux for 24 h. The solvent was then removed under reduced pressure to give a solid which consisted of **5** and a mixture of **21** and **22**. It was column chromatographed on silica gel. Elition with benzene gave 2.25 g (83%) of a mixture of **21** and **22**. The NMR spectrum of the mixture showed that the **21**/**22** product ratio was *ca.* 1/1. The 1:1 mixture of **21** and **22**: mp 108—116 °C (from hexane); IR (KBr) 1600, 1500, and 1285 cm^{-1}; NMR ($CDCl_3$ δ=6.8—7.5 (20H, m), 4.61 (2H, t, J=8.0 Hz, 4′-H of **21** and 4′-H of **22**), 2.24 and 2.88 (2H, ABq of d, J=14.0 and 8.0 Hz, 5′-CH_2 of **21** or **22**), 2.20 and 2.86 (2H, ABq of d J=11.0 and 8.0 Hz, 5′-CH_2 of **21** and **22**), and 1.0—2.6 (20H, m).

Found: C, 82.69; H, 7.52; N, 4.81%. Calcd for $C_{21}H_{23}N_1O_1$: C, 82.58; H, 7.59; N, 4.59%.

Hydrogenolysis of a Mixture of 21 and 22. To a solution of a mixture of **21** and **22** (305 mg, 1.0 mmol) in ethyl acetate (10 cm^3), 5% paradium-on-carbon catalyst (300 mg) was added. The solution was then shaken with hydrogen for 3 days at room temperature in a low-pressure apparatus. After the removal of the catalyst by filtration, the solvent was evaporated under reduced pressure to afford an oil. The oil showed, on TLC with hexane–ether (6:4), two spots—at R_f 0.36 (**26**) and R_f 0.23 (aniline). The oil was chromatographed on silica gel. Elution with hexane–ether (6:4) gave pure **26** (171 mg, 79%).

Product **26**: oil; IR (naet) 3380 (OH), 1605, 1500, and 1475 cm^{-1}; NMR ($CDCl_3$) δ=7.21 (5H, m) and 1.1—2.9 (15H, m); 2-phenethyl-2-*exo*-norbornyl phenylcarbamate: mp 116—117 °C (from hexane).

Found: C, 78.99; H, 7.50; N, 4.23%. Calcd for $C_{22}H_{25}N_1O_2$: C, 78.77; H, 7.51; N, 4.18%.

*Preparation of 2-Phenethyl-2-*endo*-norbornanol (27).* This compound was prepared by a procedure similar to that described in the literature.[8] Phenethyl bromide (14.8 g, 0.08 mol) dissolved in dry ethyl ether (25 cm^3) was stirred, drop by drop, into a suspension of magnesium turnings (1.82 g, 0.075 mol) in dry ether (50 cm^3) containing a small amount of I_2. The resulting solution was treated dropwise with 2-norbornanone (5.50 g, 0.05 mol) in dry ether (25 cm^3). After this addition was complete (45 min), the reaction mixture was stirred for 1 h, after which it was hydrolyzed with a saturated aq solution of ammonium chloride and extracted with ether (3×50 cm^3). The ether layer was separated, dried over $MgSO_4$, and evaporated to yield a colorless oil (**27**): bp 132—134 °C/1.2 Torr; IR(neat) 3360 (OH), 1605, 1500, and 1455 cm^{-1}; NMR ($CDCl_3$) δ=7.21 (5H, s) and 1.0—2.9 (15H, m); 2-phenethyl-2-*endo*-norbornyl phenylcarbamate: mp 160—162 °C (from benzene–hexane).

Found: C, 78.92; H, 7.32; N, 4.23%. Calcd for $C_{22}H_{25}N_1O_2$: C, 78.77; H, 7.51; N, 4.18%.

The Reactions of 2-Fluoro-1,3,5-trinitrobenzene (FTNB) as a New Condensing Reagent

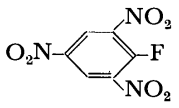
Katsuhiko INOMATA, Hideki KINOSHITA, Hirohiko FUKUDA, Kumiko TANABE, and Hiroshi KOTAKE

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received December 13, 1977)

2-Fluoro-1,3,5-trinitrobenzene (FTNB) was found to be a useful new condensing reagent. Various amides, esters and thiocarboxylic *S*-esters were prepared in good yields from carboxylic acids with the reagent.

As has been reported in a preliminary communication,[1] we have examined the reaction of various polynitrohalobenzenes with carboxylic acids in the presence of a base and have found that the readily available 2-fluoro-1,3,5-trinitrobenzene (FTNB) is most reactive for the amide formation. In this paper we wish to report that FTNB is a useful new condensing reagent for the preparation of amides, esters, and thiocarboxylic *S*-esters from carboxylic acids.



FTNB

Preparation of Amides. When triethylamine was added to a mixed solution of an equimolar amount of FTNB and carboxylic acid (**1a**—**h**) in acetonitrile at room temperature under a nitrogen atmosphere, a facile reaction began immediately; we checked the reaction by means of TLC. The spots of the starting materials, FTNB and carboxylic acid, disappeared, and a new spot of the intermediate appeared. After 1 h twice a molar quantity of aniline was added to the solution at room temperature, the reaction mixture was stirred for 1 h and then worked up to give the corresponding anilide (**2a**—**h**) in an excellent yield, as is listed in Table 1.

From these results, it will be noted that 2,2-dimethylpropanoic acid (**1e**) produces the initial active intermediate as fast as other carboxylic acids, but that the subsequent nucleophilic reaction of aniline with the intermediate is relatively slow. These differences in reactivity appear to be based on the differences in steric hindrance.

This versatile compound, FTNB, also proved to be an excellent condensing reagent for peptide synthesis, which will be described elsewhere.

Preparation of Esters and Thiocarboxylic S-*Esters.* In order to compare the results with those described above for amides, the same carboxylic acids (**1a**—**f**) except **1i** were used first and the corresponding benzyl ester derivatives (**3a**—**f, i**) were prepared. The benzyl group is a useful carboxyl-protecting group because it is easily cleaved by reductions.

The initial step in the formation of the active intermediate from carboxylic acid and FTNB was carried out in a similar manner; however, it was found that the subsequent nucleophilic reaction of benzyl alcohol to the intermediate in the presence of a base was very slow at room temperature. Consequently, the reaction with benzyl alcohol was run by refluxing to give the desired benzyl esters in good yields, as is shown in Table 2.

The low yields or the relatively slow reaction rates in the cases of 2,2-dimethylpropanoic acid (**1e**) and 2-methylpropanoic acid (**1f**) probably reflect the steric

Table 1. Preparation of anilides from carboxylic acids and aniline with FTNB

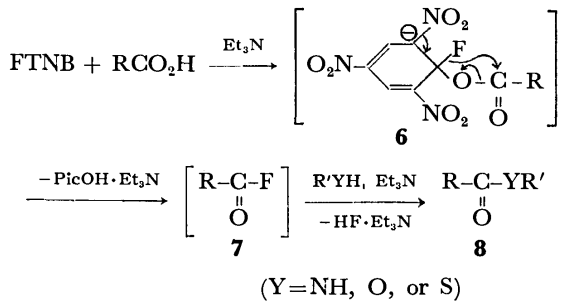
hindrance as well as the formation of 2,2-dimethylpropananilide (**2e**). The use of excess benzyl alcohol or 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) as a base was effective in such a case.

Various esters of benzoic acid (**5a—e**) and of thiobenzoic *S*-acid (**5f—h**) were prepared by this reaction; the results are shown in Table 3.

The failure to prepare *t*-butyl benzoate (**5b**) suggests that this reaction is also affected by the steric hindrance of alcohol; the fact that all the reactions (except that of *t*-butyl alcohol (**4b**)) proceeded at room temperature, unlike the case of benzyl alcohol, can be explained on the basis of the high nucleophilicity of the anions produced by the reaction of **4a**, **c—h** with triethylamine.

The extension of this reaction to macrolide synthesis is in progress.

Mechanism. The probable course of this reaction is illustrated in the following scheme. First, an anionic sigma complex (**6**) is formed *via* the aromatic nucleophilic addition of a carboxylate anion to FTNB, followed by the elimination of the picrate anion to produce an acyl fluoride (**7**), which then reacts with a nucleophile, R'YH, to give the corresponding product (**8**). Support for this scheme was found in the reaction of FTNB with cinnamic acid (**1a**) and triethylamine to isolate cinnamoyl fluoride by sublimation.



(Y=NH, O, or S)

Experimental

All the melting points are uncorrected. The proton NMR spectra were recorded on a JEOL JNM-MH 60 spectrometer. The chemical shifts are reported on the δ scale relative to TMS as the internal standard. The IR spectra were taken with a JASCO IRA-1 diffraction grating infrared spectrometer.

Materials. The acetonitrile used here was distilled according to the usual method and was stored over molecular sieves as a drying agent. 2-Fluoro-1,3,5-trinitrobenzene (FTNB, recrystallized from benzene; mp 127—128 °C [lit,[4] mp 122—123 °C or 130—131.5 °C]) was readily prepared using a modification of the procedure for the nitration of 1-fluoro-2,4-dinitrobenzene by 25% fuming sulfuric acid and fuming nitric acid (sp gr about 1.50). 2-Mercapto-4,6-dimethylpyrimidine hydrochloride was prepared by the reported procedure.[5] Thin-layer chromatography (TLC) and column chromatography were performed on Merck's Kieselgel 60 PF_{254} (Art. 7749) and on Alumina Woelm B (Akt. 1), respectively.

Cinnamanilide (2a). To a mixed solution of FTNB (116 mg, 0.5 mmol) and cinnamic acid (74 mg, 0.5 mmol) in acetonitrile (3 ml) was added an acetonitrile solution (1 ml) of triethylamine (55 mg, 0.55 mmol) at room temperature under a nitrogen atmosphere. After 1 h, a solution of aniline (93 mg, 1 mmol) in acetonitrile (1 ml) was added to the solution, after which the reaction mixture was stirred for an additional hour at room temperature. The solution was then evaporated under reduced pressure, and the residue was partitioned between ethyl acetate and a saturated solution of $NaHCO_3$. The organic layer was further washed with 1M HCl and a saturated solution of NaCl, dried over anhydrous Na_2SO_4, filtered, and evaporated to dryness under reduced pressure. The desired product, cinnamanilide, was separated from the residue by preparative TLC (development with 5:3 benzene: ethyl acetate) in a nearly quantitative yield (112 mg, mp 151—152 °C [lit,[2] mp 153 °C]).

In a similar manner, other anilides (**2b—h**) were prepared in excellent yields from the corresponding carboxylic acids and aniline with FTNB. The results are listed in Table 1.

Benzyl Cinnamate (3a). To an acetonitrile solution (3 ml) of FTNB (231 mg, 1 mmol) was added a mixed solution of cinnamic acid (148 mg, 1 mmol) and triethylamine (101 mg, 1 mmol) in acetonitrile (5 ml) at room temperature under a nitrogen atmosphere. After this mixture had been stirred for 2 h, a solution of benzyl alcohol (108 mg, 1 mmol) and triethylamine (101 mg, 1 mmol) in acetonitrile (4 ml) was added, and the reaction mixture was refluxed for 3 h. The solvent was removed under reduced pressure, and the residue was then dissolved in benzene, followed by injection into one end of a short column of basic alumina. The triethylammonium picrate was removed efficiently by elution with benzene. The eluate from the column was condensed, and pure benzyl cinnamate was separated from the residue by prepatative TLC (development with 5:1 benzene: hexane) in an 89% yield (212 mg).

The other examples reported in Tables 2 and 3 were carried out in a similar manner. The spectral data, physical proper-

ties, and analytical data of the products are listed below.

3a: oil, NMR (CCl_4) δ 5.09 (s, 2H), 6.29 (d, 1H, J=17 Hz), 7.22 (m, 10H), 7.56 (d, 1H. J=17 Hz). **3b**: oil, NMR (CCl_4) δ 5.20 (s, 2H), 7.0—7.5 (m, 8H), 7.8—8.1 (m, 2H). **3c**: oil, NMR (CCl_4) δ 3.48 (s, 2H), 4.94 (s, 2H), 7.11 (s, 5H), 7.13 (s, 5H). **3d**: mp 68—70 °C, NMR ($CDCl_3$) δ 3.86 (d, 2H, J=6 Hz), 4.98 (s, 2H), 5.03 (s, 2H), 5.1—5.6 (broad, 1H), 7.21 (s, 10H). **3e**: oil, NMR (CCl_4) δ 1.19 (s, 9H), 4.99 (s, 2H), 7.22 (s, 5H). **3f**: oil, NMR (CCl_4) δ 1.13 (d, 6H, J=7 Hz), 2.46 (h, 1H, J=7 Hz), 4.93 (s, 2H), 7.15 (s, 5H). **3i**: oil, NMR (CCl_4) δ 0.6—1.9 (m, 13H), 2.26 (t, 2H, J=7 Hz), 5.01 (s, 2H), 7.27 (s, 5H).

*S-(4,6-Dimethyl-2-pyrimidyl) Thiobenzoate (**5h**).* To a mixed solution of FTNB (231 mg, 1 mmol) and benzoic acid (122 mg, 1 mmol) in acetonitrile (6 ml) was added an acetonitrile solution (2 ml) of triethylamine (101 mg, 1 mmol) at room temperature under a nitrogen atmosphere. After 2 h, a mixed solution of 2-mercapto-4,6-dimethylpyrimidine hydrochloride (265 mg, 1.5 mmol) and triethylamine (253 mg, 2.5 mmol) in acetonitrile (10 ml) was added to the solution, after which the reaction mixture was stirred for an additional 6 h at room temperature. The solvent was removed under reduced pressure; the residue was then dissolved in benzene, followed by injection into one end of a short column of basic alumina. After elution with benzene, the eluate was condensed, and pure **5h** was separated from the residue by preparative TLC (development with 5:1 benzene: ethyl acetate) in a 76% yield (278 mg): mp 74—77 °C (recrystallized from cyclohexane), NMR (CCl_4) δ 2.41 (s, 6H), 6.78 (s, 1H), 7.2—7.5 (m, 3H), 7.7—8.0 (m, 2H). Found: C, 63.90; H, 4.94; N, 11.94%. Calcd for $C_{13}H_{12}N_2OS$: C, 63.92; H, 4.95; N, 11.47%.

The other thiocarboxylic *S*-esters, **5f** and **5g**, were prepared in a similar manner. Their spectral data and physical properties are listed below.

5f: oil, NMR (CCl_4) δ 0.7—1.9 (m, 7H), 2.97 (t, 2H, J=7 Hz), 7.1—7.5 (m, 3H), 7.6—8.1 (m, 2H). **5g**: mp 74—75 °C (lit,[6] mp 75°C).

Cinnamoyl Fluoride. To an acetonitrile solution (3 ml) of FTNB (231 mg, 1 mmol) was added a mixed solution of cinnamic acid (148 mg, 1 mmol) and triethylamine (101 mg, 1 mmol) in acetonitrile (5 ml) at room temperature under a nitrogen atmosphere. After the mixture had been stirred for 2 h, the solvent was removed under reduced pressure; then we sublimed cinnamoyl fluoride (102 mg) from the residue *in vacuo* in a 68% yield: mp 30 °C (lit,[7] mp 31—31.5 °C), IR 1782, 1615, 1182, 1092 cm^{-1}; NMR ($CDCl_3$) δ 6.32 (d·d, 1H, J_{HH}=16.2 Hz, J_{HF}=7.2 Hz), 7.44 (m, 5H), 7.82 (d, 1H, J_{HH}=16.2 Hz).

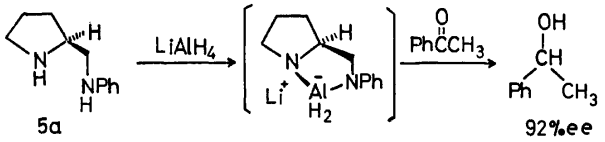
(Received December 20, 1977)

Asymmetric reduction of prochiral ketones with various hydride reagents prepared from lithium aluminium hydride and (*S*)-2-(*N*-substituted aminomethyl)pyrrolidines, derived easily by four steps from commercially available (*S*)-proline, yields optically active alcohols with 13—92% optical purity having the *S*-configuration.

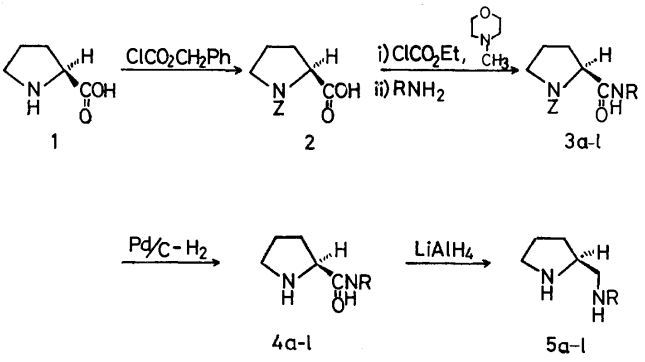
Asymmetric reduction of prochiral carbonyl compounds by chiral hydride reagents has been the object of extensive work and a number of methods have been reported.[1] Most of such works have been developed based on the use of chiral hydride reagents obtained by reaction of $LiAlH_4$ and chiral ligands such as alkaloids,[2] sugar derivatives,[3] amino alcohols,[4,5] chiral oxazolines,[6] tartaric acid derivatives,[7] chiral diols,[8] or chiral amines.[9] Relatively high optical yield (<83%) was achieved in the case of the reduction of acetophenone by using these ligands.

On the other hand, during the course of our synthetic investigation utilizing the onium salts of azaaromatics, we have reported the convenient and efficient methods for the optical interconversion of chiral secondary alcohols,[10a] and transformation of the alcohols to chiral halides,[10b] thiols,[10c] and primary amines.[10d] This prompted us to study on the exploration of a new and efficient chiral ligand, and (*S*)-2-(anilinomethyl)pyrrolidine (**5a**) is found to be efficient for the reduction of acetophenone to yield (*S*)-1-phenylethanol with 92% optical purity as briefly reported in the previous communication.[11] (Scheme 1).

(*S*)-2-(*N*-substituted aminomethyl)pyrrolidines (**5a**—**1**) were easily prepared from readily available (*S*)-proline as shown in the following scheme (Scheme 2): (*S*)-Proline (**1**) was converted to (*S*)-*N*-(benzyloxycarbonyl)-proline (**2**) by treatment with benzyloxycarbonyl chloride and sodium hydrogencarbonate. Then it was transformed into the corresponding amides (**3a**—**1**) by treatment with *N*-methylmorpholine, ethyl chloroformate and amines. *N*-Substituted (*S*)-prolinamides (**4a**—**1**) were obtained by the hydrogenolysis of the amides **3a**—**1** in the presence of 5% Pd–C catalyst under hydrogen atmosphere at ordinary pressure. The amides **4a**—**1** were further reduced to the required chiral diamines, (*S*)-2-(*N*-substituted aminomethyl)pyrrolidines **5a**—**1**, tabulated in Table 1.



Scheme 1.



Scheme 2.

In the first place, we examined suitable reaction conditions using chiral diamine **5a** as ligand and acetophenone as model substrate. The reactions were carried out as follows: The diamine **5a** in ether, THF, or toluene was added to the standardized $LiAlH_4$

a) $LiAlH_4$: **5a**: Acetophenon A 1.3: 1.5: 1, B 1.75: 2.00: 1, C 2.36: 2.73: 1. b) Based on $[\alpha]_D^{21}$ −43.1° (*c* 7.19, C_5H_{10}) reported by S. Yamaguchi and H.S. Mosher, *J. Org. Chem.*, **38**, 1970 (1973). c) Only trace of alcohol was detected by TLC.

solution. On addition of the diamine **5a**, *ca.* 2 mol of hydrogen gas evolved and white precipitates, presumably, the diamine **5a**–$LiAlH_4$ complex appeared in ether or toluene. But, in the case of THF, almost homogeneous solution resulted. After the evolution of gas had been completed, the mixture was stirred at room temperature for 1 h. Then it was cooled and was add d acetophenone. Stirring was continued for additional 3 h at the temperature and it was hydrolyzed to yield 1-phenylethanol. In the cases when additives (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA), 1,2-dimethoxyethane (DME), or $MgBr_2$) were used, they were added before lowering the temperature and the mixture was stirred at room temperature for about 1 h. Then it was cooled to −78 °C and added acetophenone and treated similarly. The results are summarized in Table 2.

These results indicate that ether is preferred as solvent and the optical purity increased by lowering the reaction temperature [Exp. 1, 3, 5, and 4, 6]. The molar ratio of each substances also affect both synthetic and optical yields. The presence of additives such as TMEDA, DME or $MgBr_2$ caused the decrease of optical purity, which indicates that lithium ion plays an important role in the present asymmetric reductions.

The effect of the *N*-substituents in the ligand diamines **5a**—**l** on the enantioselectivity in the present asymmetric reduction were examined with various *N*-substituted diamines **5a**—**l**–$LiAlH_4$ complexes under the same reaction conditions as Exp. 3 by employing the asymmetric reduction of acetophenone as a model. The results are summarized in Table 3. Relatively high optical purities were attained when *N*-aryl substituted diamines–$LiAlH_4$ complexes were employed as chiral hydride reagent. Electron-withdrawing group (3,4-dichloro) or electron-donating group (4-methoxyl) in *N*-aryl substituent did not cause the remarkable effect both on the synthetic and optical yields, but methoxyl group on the *o*-position (2-methoxyl) in *N*-aryl substituent which can coordinate to the metal atom, either lithium or aluminium of the bicyclic hydride reagents, deactivated the reagent.

a) Small amount of THF was used.

Further, the diamine–$LiAlH_4$ complex was applied to the asymmetric reduction of various ketones by choosing diamine **5a**–$LiAlH_4$ complex and diamine **5d**–$LiAlH_4$ complex as the chiral hydride reagents. In every case, the reactions were carried out according to a similar procedure as mentioned above and corresponding alcohols were obtained as summarized in Table 4.

As the result, in the case of the ketones having aromatic ring attached to the carbonyl group gave fairly good optical purities (50—85% with diamine **5a**–$LiAlH_4$ complex), but satisfactory results could not be obtained in the case of normal aliphatic ketones. We assume that enantioselectivities were induced by both electronic

Table 4. Asymmetric reduction of various ketones with $LiAlH_4$–chiral diamine **5a** complex and $LiAlH_4$–chiral diamine **5d** complex

and steric effects of the aromatic ring in the ketones attached to the carbonyl group. That is, the conjugation effect puts the aromatic ring and carbonyl group on the same plane. This makes possible to distinguish a sharp steric difference of the two substituents and enantioface of unsymmetrical ketones during hydride transfer to attain relatively high optical yield.

Although the precise mechanism of this asymmetric reduction is not clear, we assume that high enantioselectivity, namely, all of the produced alcohols have *S*-configuration (except the case THF was used as solvent) with high optical purity, in the present asymmetric reduction of prochiral ketones is due to the following factors: 1) The diamines, a simple structure having only one asymmetric carbon, produce the effective chiral environment by the treatment with $LiAlH_4$. This may be due to the formation of sterically restricted *cis*-fused bicyclic hydride reagents, creating the additional chiral center on the nitrogen atom in the pyrrolidine ring. 2) The reactivity of the two hydrogen atoms contained in this chiral reagent is remarkably different. Actually only one hydrogen atom was consumed by the reaction with ketones, but the other remained unreacted because of large steric hinderance. 3) Lithium ion, presumably coordinating to the nitrogen atoms on the pyrrolidine ring and/or on the side chain in the diamine–$LiAlH_4$ complex, restrict the direction of approach of the ketones.

Table 5. Comparison of various chiral reducing reagents prepared from $LiAlH_4$ and chiral ligands (optical purity)

Ketone	Ligand: Sugar[3a] derivative	Ligand: Darbon[a] [4]	Ligand: Chiral oxazoline[6]	Ligand: Chiral amine[9]	**5a**
PhCOMe	71	75	65	43	84 (92)[b]
PhCOEt	46	—	62	52	85
$PhCOCHMe_2$	—	48	43	—	57
α-Tetralone	—	—	4	—	50
$PhCH_2COMe$	—	—	1	—	31
n-$C_6H_{13}COMe$	25	—	4 (6)	—	13

a) (+)-(2*S*,3*R*)-4-Dimethylamino-3-methyl-1,2-diphenyl-2-butanol. b) at −100 °C.

In conclusion, it is noteworthy that the diamine **5a** produces effective chiral hydride reagent with $LiAlH_4$ and reduces prochiral ketones, including acetophenone, propiophenone, phenyl isopropyl ketone, α-tetralone, benzyl methyl ketone and 2-octanone, to afford corresponding chiral alcohols with 13—92% optical purity having *S*-configuration.

Experimental

Spectra. NMR were obtained on a Hitachi R-24 spectrometer. Infrared spectra were taken using a Hitachi EPI-G2 spectrometer. Mass spectra were taken using a Hitachi RMU-6 spectrometer. Optical rotations were taken on a JASCO DIP-SL automatic polarimeter using 1-dm or 1-cm thermostated microcell. Products were identified by NMR and IR with authentic samples.

Materials. All solvents used were distilled according to the general methods and stored over sodium metal as a drying agent. Further ether and THF were distilled from $LiAlH_4$ prior to use. A supernatant of etheral $LiAlH_4$ solution was stored in a flask closed with a rubber septum.

(S)-N-(Benzyloxycarbonyl)prolinanilide ***3a.*** Commercial *(S)*-proline **1** (11.5 g, 0.1 mol), sodium hydrogencarbonate (20.16 g) and benzyloxycarbonyl chloride (32 g, 30—35% toluene solution) in 150 ml of water were stirred for 2 h at room temperature. Then sodium hydrogencarbonate (10.08 g) and benzyloxycarbonyl chloride (32 g, 30—35% toluene solution) were added and stirred for 3 h at room temperature. The reaction mixture was washed two times with 50 ml of ether and the aqueous layer was acidified (pH 3—4) by 6M HCl. The mixture was extracted four times with ethyl acetate (250 ml) and the extracts were dried over Na_2SO_4. The solvent was evaporated and *(S)-N-*(benzyl-

oxycarbonyl)proline **2** (24.1 g, 96.8%, $[\alpha]_D^{22}-40.4°$ (*c* 1.027, EtOH) was obtained. Under an argon atmosphere (*S*)-*N*-(benzyloxycarbonyl)proline **2** (18.7 g) in 250 ml of ethyl acetate was added *N*-methylmorpholine (7.6 g) in 10 ml of ethyl acetate at −15 °C. And ethyl chloroformate (8.1 g) in 10 ml of ethyl acetate was added slowly to the solution at −15 °C during 5 minutes then aniline (7.0 g) in 20 ml of ethyl acetate was added to the reaction mixture at −15 °C. The mixture was kept at −15 °C for 1 h and at 0 °C for 1 h then gradually up to room temperature and it was stirred overnight. To the mixture was added 150 ml of ethyl acetate, and 100 ml of water. Then organic layer was washed with aqueous 4% sodium hydrogencarbonate solution, saturated sodium chloride solution, 2% hydrochloric acid, and saturated sodium chloride solution (50 ml each) successively. Then organic layer was dried over Na_2SO_4 and concentrated to give crude (*S*)-*N*-(benzyloxycarbonyl)prolinanilide **3a** (22.8 g). Recrystallyzation from acetone afforded 18.7 g (77%, mp 141—141.5 °C, $[\alpha]_D^{23}-63.2°$ (*c* 0.997, EtOH). Found: C, 70.07; H, 6.18; N, 8.65%. Calcd for $C_{19}H_{20}O_3N_2$: C, 70.35; H, 6.22; N, 8.64%. By similar prodecure amides **3b**—**1** were obtained.

(S)-2-(Anilinomethyl)pyrrolidine **5a**. *(S)-N*-(Benzyloxycarbonyl)prolinanilide **3a** (21 g) and 5% Pd—C catalyst (1g) were stirred vigorously in methanol (120 ml) under hydrogen atmosphere for 3 h. Then reaction mixture was filtered through celite and the filtrate was concentrated to give crude (*S*)-prolinanilide **4a**, which was recrystallized from cyclohexane to afford pure **4a** (11.5 g, 94%, mp 76—77 °C, $[\alpha]_D^{27}-71.0°$ (c 1.025, EtOH)). Found: C, 69.53; H, 7.58; N, 14.84%. Calcd for $C_{11}H_{14}ON_2$: C, 69.44; H, 7.42; N, 14.73%. **4a** (10.5 g) in 35 ml of THF was added to the $LiAlH_4$ (4.2 g) in 40 ml of THF at 0 °C under an argon atmosphere. The reaction mixture was stirred overnight at 0 °C and hydrolyzed with saturated sodium sulfate solution. After removal of the inorganic material and concentration of organic layer, fractional distillation under reduced pressure afforded a colorless oil **5a** (7.2 g, 81%, bp 111—112 °C/0.55 mmHg, $[\alpha]_D^{24}+19.7°$ (*c* 1.087, EtOH); IR 3280 cm^{-1} (N-H); NMR ($CDCl_3$) δ=0.93−2.13 (m, 5H), 2.35—3.46 (m, 5H), 4.10 (br, 1H), 6.33—6.86 (m, 3H), 6.86—7.38 (m, 2H). MS (70 eV), *m/e*, 176 (M^+), 107, 77, 70, and 43. By similar procedure diamines **5b**—**1** were also prepared. **5b**; IR 3280 cm^{-1} (N-H); NMR ($CDCl_3$) δ=1.00 (d, 6H), 1.32 (s, 2H), 1.20—2.03 (m, 4H), 2.30—3.34 (m, 6H). Found: C, 67.84; H, 13.00; N, 19.64%. Calcd for $C_8H_{18}N_2$: C, 67.55; H, 12.75; N, 19.64%. **5c**; IR 3280 cm^{-1} (N-H); NMR ($CDCl_3$) δ=0.62—1.95 (m, 15H), 1.21 (s, 2H), 1.91—3.32 (m, 7H); MS (70 eV), *m/e*, 185 (M^++1), 114, 70, 43. Asymmetric Reduction of Ketone with $LiAlH_4$–Diamine **5a** *Complex in Ether (Representative example).* The diamine **5a** (359.3 mg, 2.04 mmol) in 2 ml of ether was added to a standardized ethereal solution of $LiAlH_4$ (2.86 ml, 1.77 mmol) over ten minutes at room temperature under an argon atmosphere. On addition of **5a**, hydrogen gas evolved and white precipitates appeared. After stirring for 1 h at room temperature, propiophenone (134 mg, 1.00 mmol) in 2 ml of ether was added at −78 °C, and the reaction mixture was stirred for 3 h. The mixture was hydrolyzed with 0.4 ml of water and washed successively with 8 ml of 0.5 N hydrochloric acid and saturated sodium chloride solution. The ethereal layer was dried over Na_2SO_4 and the solvent was removed. The crude product was purified by preparative TLC to give 1-phenyl-1-propanol (120.0 mg, 90%). Further it was purified for the measurement of specific rotation by bulb to bulb distillation [175 °C (bath temperature/21 mmHg], and 104.3 mg of the alcohol was obtained, $[\alpha]_D^{25}$—23.65° (neat). Most of the chiral diamine was recovered from the aqueous layer by usual work up.

Asymmetric Reduction Acetophenone with $LiAlH_4$–Diamine **5a** *Complex in THF (or toluene).* Under an argon atmosphere, $LiAlH_4$ in ether (2.79 ml, 2.66 mmol) was transfered into the flask. The ether was removed under reduced pressure at room temperature for about 1 h, then 5.5 ml of THF was added. The diamine **5a** (540.2 mg, 3.07 mmol) in 4 ml of THF was added to the solution over ten minutes at room temperature. After stirring for 1 h at toom temperature, acetophenone (180.3 mg, 1.5 mmol) was added at —78 °C and the mixture was stirred for 3 h. The reaction mixture was treated similarly as mentioned above and 1-phenylethanol (97.3 mg, 54%) was obtained, which was further purified for the measurement of specific rotation by bulb to bulb distillation [150—160 °C (bath temperature)/21 mmHg], and 86 mg of alcohol was obtained, $[\alpha]_D^{24}+8.25°$ (*c* 4.00, cyclopentane).

Asymmetric Reduction of Acetophenone with $LiAlH_4$–Diamine **5a** *in the Presence of Additives.* The diamine **5a** (539 mg, 3.07 mmol)–$LiAlH_4$ complex (2.66 mmol) in 8 ml of ether was added TMEDA (307 mg, 2.66 mmol) in 2 ml of ether at room temperature. After stirring for 1 h, acetophenone (180.5 mg, 1.5 mmol) was added to the reaction mixture at −78 °C, which was stirred for 3 h. After the reaction mixture was treated similarly, 1-phenylethanol (122.5 mg, 67%) was obtained, which was further purified by bulb to bulb distillation [150—160 °C (bath temperature)/21 mmHg] and 115.9 mg of alcohol was obtained, $[\alpha]_D^{25}-7.6°$ (*c* 6.88, cyclopentane).

Formaldehyde Polymers. 22.[1] Reaction Products of 6,8-Dimethyl-4-chromanone with Formaldehyde—On the Dimeric Products—

Akira NINAGAWA and Haruo MATSUDA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received December 21, 1977)

The reaction of 6,8-dimethyl-4-chromanone with formaldehyde has been carried out in 96% sulfuric acid. From the mother liquors after obtaining 5-hydroxymethyl-6,8-dimethyl-4-chromanone, the methylene and oxydimethylene dimers of 6,8-dimethyl-4-chromanone, 6,6′,8,8′-tetramethyl-5,7′-methylenedichroman-4,4′-dione and bis(6,8-dimethyl-4-oxochroman-5-ylmethyl) ether, respectively, were isolated by recrystallization. ^{1}H- and ^{13}C-NMR spectra of 5-hydroxymethyl-6,8-dimethyl-4-chromanone in 96% sulfuric acid show the existence of 6,8-dimethyl-4-oxochroman-5-ylmethyl cation. The intermediate ion is stable, not reacting in sulfuric acid.

In a previous paper,[1] a report was given on the reactions of 4-chromanones with formaldehyde carried out in the presence of sulfuric acid or polyphosphoric acid. The reaction products of 4-chromanone, 6- as well as 8-methyl- and 5,7-dimethyl-4-chromanone with formaldehyde were the polymers linked by methylene bridges, while 6,8-dimethyl-4-chromanone gave only 5-hydroxymethyl-6,8-dimethyl-4-chromanone.

In this paper, the isolation of dimeric products from the reaction products of 6,8-dimethyl-4-chromanone with formaldehyde in the presence of sulfuric acid and the spectral characteristic of 5-hydroxymethyl-6,8-dimethyl-4-chromanone in sulfuric acid are reported.

Results and Discussion

Isolation of the Dimeric Compounds. The reaction of 6,8-dimethyl-4-chromanone (**1**) with formaldehyde was carried out in different mol ratios of the reactants in the presence of 96% sulfuric acid. The products are given in Table 1.

Table 1. Reaction of 6,8-dimethyl-4-chromanone with formaldehyde at 60 °C

Exp. No.	Reactant (mol)		CH_2O/**1** (mol ratio)	H_2SO_4 (g)	Time (hr)	Products and Yield (%)		
	1	CH_2O				**2**	**3**	**4**
1	0.10	0.05	0.5	38	4	—	3.1	—
2	0.20	0.10	0.5	80	4	0.5	—	—
3	0.20	0.10	0.5	80	8	0.15	0.9	—
4	0.28	0.28	1.0	230	6	36.	1.2	—
5	0.50	0.60	1.2	1000	4	55.	—	—
6	0.80	1.17	1.5	3000	4	60.	—	0.3

The reaction products of **1** with formaldehyde in a 2: 1 molar ratio in sulfuric acid were 5-hydroxymethyl-6,8-dimethyl-4-chromanone (**2**) and 6,6′,8,8′-tetramethyl-5,7′-methylenedichroman-4,4′-dione (**3**). The low yield of **2** is due to a lower fractionation of **2** from a mixture of unreacted **1** and **2**, and the solubility of **2** in aqueous sulfuric acid solution. With increase of the mol ratio the yield of **2** increased, another dimeric compound, bis(6,8-dimethyl-4-oxochroman-5-ylmethyl) ether (**4**) being obtained with **2** from the reaction product (6, Table 1).

Structures of the Dimeric Compounds. The ^{1}H-NMR spectra of the methylene dimer **3** and the oxydimethylene dimer **4** are given in Table 2.

Table 2. ^{1}H-NMR spectra of methylene dimer **3** and oxydimethylene dimer **4**

	Methylene dimer **3** (CCl_4; 1.0%)	Oxydimethylene dimer **4** (CCl_4; 5.0%)
Aromatic	7.08(1H, s) 6.17(1H, s)	6.98(2H, s)
Methylene between two aromatic rings	4.20(2H, s)	4.85(4H, s)
Pyrone ring	4.45(2H, t[a]) 4.40(2H, t[a]) 2.69(2H, t[a]) 2.65(2H, t[a])	4.41(4H, t[b]) 2.67(4H, t[b])
Methyl	2.65(3H, s) 2.20(3H, s) 2.04(3H, s) 1.96(3H, s)	2.30(6H, s) 2.11(6H, s)

a) J=6.7 Hz. b) J=6.7 Hz.

The ^{1}H-NMR spectrum of **3** shows two sharp singlet of aromatic protons, four sharp singlet of methyl protons and four sets of triplet of pyrone ring protons, while that of **4** shows a sharp singlet of aromatic protons, two sharp singlet of methyl protons and two sets of triplet of pyrone ring protons. The ^{1}H-NMR spectrum of the oxydimethylene dimer **4** is very similar to that of the symmetrical methylene dimers of 6- and 8-methyl-4-chromanone.[2] It is thought that an oxydimethylene bridge of **4** is formed between 5- and 5′-positions of 6,8-dimethyl-4-chromanones and a methylene bridge of **3** between 5- and 7′-positions of 6,8-dimethyl-4-chromanones.

Reactivity of 5-Hydroxymethyl-6,8-dimethyl-4-chromanone. Reactions of **2** with **1** or *p*-cresol which is more active than **1**[3] were carried out in the presence of sulfuric acid.

Table 3. Reaction conditions for the reaction of 5-hydroxymethyl-6,8-dimethyl-4-chromanone with 6,8-dimethyl-4-chromanone or *p*-cresol

Reactant (mmol)			H_2SO_4 (g)	Temp (°C)	Time (h)
2	**1**	*p*-Cresol			
25.0	50.0	—	40.0	60	4
1.0	2.0	—	16.6	80	6
1.0	—	2.0	16.6	80	6

Table 4. ^{1}H-NMR spectra of 5-hydroxymethyl-6,8-dimethyl-4-chromanone in 96% sulfuric acid and carbon tetrachloride

Solvent	Conc. (wt %)	2-H	3-H	5-CH_2	6-CH_3	8-CH_3	7-H	OH

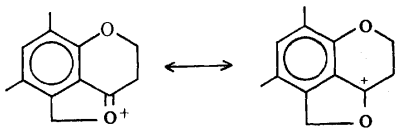
a) Chemical shifts are reported in ppm relative to Me_4Si. Δ=(H_2SO_4−$CDCl_3$) is the chemical shift difference.

The reaction conditions are given in Table 3. **2** was recovered from the reaction mixtures under these reaction conditions.

NMR Spectra of 5-Hydroxymethyl-6,8-dimethyl-4-chromanone in Sulfuric Acid. ^{1}H-NMR spectra of **2** in carbon tetrachloride and 96% sulfuric acid as solvents are given in Table 4. The chemical shift of the methylene protons of 5-hydroxymethyl group in 96% sulfuric acid moves towards lower magnetic fields relative to carbon tetrachloride. The remarkable ^{1}H-NMR down field shift of the absorption of the methylene protons on the 5-position of **2** together with the data in carbon tetrachloride suggest that **5a** is a more suitable representation for the ion **5b**. This chemical shift difference resembles that reported for 2-methyl-1-oxonia-1-cyclopentene hexachloroantimonate[5] and for 5-hexen-2-one in sulfuric acid.[6]

The spectrum of **2** in sulfuric acid remained unchanged even after being heated at 80 °C for 3 h. This indicates that five-menbered oxonium ion **5a** is very stable in sulfuric acid.



5a **5b**

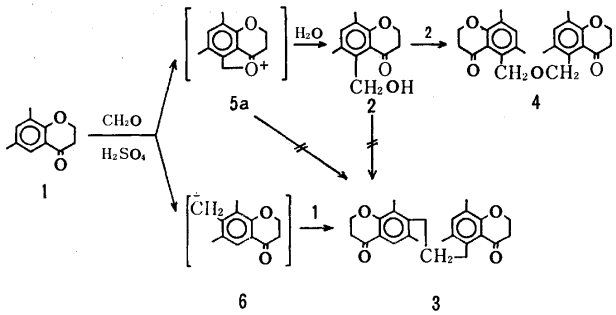
The ^{13}C-chemical shifts for **1** and **2** obtained in 96% sufuric acid and deuteriochloroform, as well as the chemical shift difference, Δ, between these two solvents are given in Table 5. Chemical shifts were assigned by comparison with the spectra of 4-chromanone,[7] and by consideration of the known substituent effects of methyl,[8] and hydroxymethyl groups.[9] All the assignments are supported by off-resonance decoupling experiments. A positive Δ indicates that the resonance is deshielded in sulfuric acid relative to deuteriochloroform.

Larger deshielding patterns (+Δ) of **2** except the aromatic carbons are observed for C-4 and CH_2OH with the shift of CH_2OH larger than that of C-4. The observed chemical shift trends for **2** are interpreted to result predominantly from 5-methylene cation. Larger contribution from resonance form **5a**, which places positive charge on oxygen of ketone, can be used to rationalize the deshielding noted for this carbon.

The chemical shift change of C-4 for **2** is smaller than that observed for **1** which is protonated in 96% sulfuric acid.[10] Chemical shift changes associated with the aromatic ring seem to result from further inductive and positive charge delocalization effects on these carbons.

Reaction of 1 with Formaldehyde in Sulfuric Acid. The orientation of **1** of the cationic substants appears to be 5- and 7-positions on account of the inductive effects of two methyl groups.[1] In an acid catalyzed reaction of aromatic compounds with formaldehyde, it is probable that the hydroxymethyl cation (CH_2OH^+) is generated at first to react with **1**. Accordingly, 5- and 7-hydroxymethyl derivatives of **1** should be generated. 5-Hydroxymethyl derivative **2** was isolated from the reaction products. 5,7'-Methylene dimer **3** was obtained, but not 7-hydroxymethyl derivative.

The oxonium ion **5a** formed from 5-hydroxymethyl derivative is very stable, not reacting with **1** in 96% sulfuric acid. After being poured into water, **2** was regenerated.



Scheme 1.

It seems that 5,7′-methylene dimer **3** arises from 7-hydroxymethyl derivative by a benzyl cation process. It is proposed that a hydroxide ion is first abstracted yielding the 7-methylene cation **6**, which then attacks on 5-position of **1** to give **3**.

4 might be formed from **2** during post-treatment of the reaction mixture.

A reasonable reaction mechanism might be as shown in Scheme 1.

Experimental

General. Melting points are uncorrected. IR spectra were obtained as KBr pellets on a Hitachi EPI-G2 spectrophotometer. Mass spectra were obtained on a Hitachi RMU-6 mass spcetrometer at 70 eV, and ^{1}H-NMR spectra on a JEOL Model PS-100 spectrometer with tetramethylsilane (Me_4Si) as an internal standard. Chemical shift values are given in terms of δ (ppm). ^{13}C-NMR spectra were obtained on a JNM-FX60 spectrometer. Chemical shifts in deuteriochloroform were measured using Me_4Si as an internal standard. Chemical shifts in 96% sulfuric acid were obtained relative to external deuteriochloroform and converted to the Me_4Si scale by the relationship $\delta Me_4Si = \delta CDCl_3 + 77.1$.

Materials. 6,8-Dimethyl-4-chromanone (**1**) was prepared by the previous method,[2] bp 108—110 °C/2 mmHg [lit,[2] bp 121.5—122 °C/7 mmHg]. Commercial 1,3,5-trioxane and 96% sulfuric acid were used.

*Reactions of **1** with Formaldehyde.* The general procedure is as follows. A mixture of **1** (0.10—0.80 mol) and 1,3,5-trioxane (0.05—1.17 mol) in 96% sulfuric acid (38—3000 g) was stirred at 60 °C.

After completion of the reaction, the reaction mixture was poured into ice water. Crystalline material was obtained by filtration. Benzene solution of the filtrate was washed successively with sodium hydroxide solution and water, dried over anhydrous sodium sulfate, and then condensed to a yellow paste. Both products were dissolved in hot ligroin and allowed to stand at room temperature. The first precipitate was **2**. Concentration and cooling of the mother liquor gave **3** or **4**. These products were purified as follows.

*5-Hydroxymethyl-6,8-dimethyl-4-chromanone (**2**)*: The first product separated from the hot ligroin solution of the reaction products was recrystallized from ligroin. Colorless needle crystals were obtained; mp 95—97 °C (lit,[2] mp 94—95 °C). The structure of this product was confirmed by IR, ^{1}H-NMR and MS spectra.

*6,6′,8,8′-Tetramethyl-5,7′-methylenedichroman-4,4′-dione (**3**)*: The compound soluble in the mother liquor after obtaining **2**, was fractionally recrystallized from hexane to give colorless needle crystals; mp 195—197 °C. IR; 1675 (ν C=O) and 885 (δ CH, aromatic, isolated H) cm^{-1}. MS; *m/e* 364 (M^+, 70.3%), 349 ($M^+ - CH_3$, 55.0%), 346 ($M^+ - H_2O$, 100%), and 189 ($M^+ - C_{11}H_{11}O_2$, 72.0%). Found: C, 75.64; H, 6.48%. Calcd for $C_{23}H_{24}O_4$: C. 75.80, H, 6.64%. ^{1}H-NMR spectrum of **3** is shown in Table 2.

Reduction of **3**; Reduction of **3** was carried out by the Clemmensen method.[11] To a mixture of 5.0 g of amalgamated zinc, 6.0 ml of water, 0.31 ml of concentrated hydrochloric acid and 20 ml of toluene was added 0.5 g of **3**. The mixture was refluxed briskly for 24 h, during which time a 3.0 ml portion of concentrated hydrochloric acid was added every 8 h. The solution was cooled to room temperature and the aqueous layer was separated and extracted with benzene. The combined benzene and toluene solutions were washed with water and dried over calcium chloride. After removal of the solvents, the residue was chromatographed on silica gel (Merk, silica gel 60 pre-paked column for LC size B) with benzene as an eluent to give 0.2 g of 6,6,′8,8′-tetramethyl-5,7′-methylenedichroman. Colorless oil. IR(neat); 1100 (ν C–O–C) and 875 (δ CH, aromatic, isolated H) cm^{-1}, the absorption at 1675 cm^{-1} disappearing. MS; *m/e* 336 (M^+, 19.5%) and 174 ($M^+ - C_{11}H_{13}O$, 100%). Found: C, 81.85; H, 8.08%. Calcd for $C_{23}H_{28}O_2$: C, 82.10; H, 8.39%. ^{1}H-NMR (CCl_4; 6.0%); 6.68 (1H, s, Ph), 5.95 (1H, s, Ph), 3.61 (2H, s, PhC$\underline{H}_2$Ph), 4.03 (4H, t, J=5.8 Hz, 2- and 2′-CH_2), 2.63 (2H, t, J=6.9 Hz, 4- or 4′-CH_2), 1.87 (2H, m, 3- or 3′-CH_2), 2.45 (2H, t, J=6.9 Hz, 4′- or 4-CH_2), 1.79 (2H, m, 3′- or 3-CH_2), 2.14 (3H, s, CH_3), 2.10 (3H, s, CH_3), 2.01 (3H, s, CH_3), and 1.91 (3H, s, CH_3).

*Bis(6,8-dimethyl-4-oxochroman-5-ylmethyl) Ether (**4**)*: The product separated from the ligroin solution (6, Table 1) was recrystallized repeatedly from ligroin to give **4**. mp 177—179 °C. IR; 1680 (ν C=O) and 1075 (ν C–O–C) cm^{-1}. MS; *m/e* 349 (M^+, trace), 205 ($M^+ - C_{12}H_{13}O_2$, 100%), and 190 (54.7%). Found: C, 73.08; H, 6.64%. Calcd for $C_{24}H_{26}O_5$: C, 73.08; H, 6.64%. ^{1}H-NMR spectrum of **4** is shown in Table 2.

*Reactions of **2** with **1** or p-Cresol.* A typical procedure is as follows. A mixture of **2** (0.21 g) and *p*-cresol (0.21 g) in sulfuric acid (16.6 g) was stirred at 80 °C for 6 h. The reaction mixture was then poured into ice water and extracted with chloroform. The chloroform layer was washed with aqueous sodium hydroxide solution and water, successively. After removal of the solvent, the residue was confirmed by IR and ^{1}H-NMR spectra.

Synthetic Bilayer Membranes with Anionic Head Groups*

Toyoki KUNITAKE and Yoshio OKAHATA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

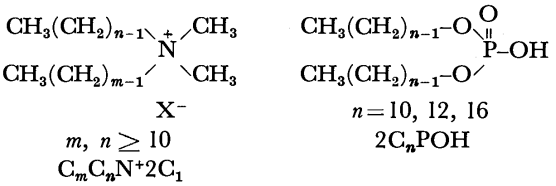
(Received January 6, 1978)

Anionic amphiphiles which possess two normal alkyl groups as the hydrophobic residue and sulfonate, phosphate or carboxylate groups as the hydrophilic residue were prepared. Most of these compounds aggregate extensively in water to form vesicles and lamellae which are probably formed by the molecular bilayer. These aggregates are quite similar to the lecithin liposome with respect to the restricted molecular motion and cholesterol binding.

The bilayer structure similar to that of biomembranes has been prepared mostly from biolipid molecules and related compounds (lecithins and modified lecithins). Although molecular bilayers can be prepared also from other simpler compounds, they are usually unstable and/or formed under rather exotic conditions.[1-3]

A series of dimethyldialkylammonium salts (C_nC_m-N^+2C_1) aggregate extensively in water to form stable structures similar to that of the biomembrane.[4,5] The aggregate structure (lamella or vesicle) depends on the length of the alkyl group, and no structure was found when one of the alkyl group was octyl or shorter. The results suggest that the formation of the stable molecular bilayer is a general physicochemical phenomenon and that particular molecular structure of biolipids is determined by biological necessity.

In order to establish the generality of bilayer formation, we prepared some amphiphilic compounds which possess anionic hydrophilic groups (phosphate, carboxylate and sulfonate) and two alkyl chains. The aggregation behavior of these compounds would be of interest since biolipid molecules contain phosphate, carboxylate and sulfonate groups in the hydrophilic head group. The chemical structures of the compounds used in this study are shown below.



$m, n \geq 10$
$C_mC_nN^+2C_1$

$n = 13$
$2C_n2COOH$

* Contribution No. 477 from this department.

Experimental

Preparation of $2C_nSO_3Na$. This type of compound is known as a lipophilic surfactant such as Aerosol OT. Maleic anhydride and twice molar alkyl bromides were heated in toluene in the presence of a few drops of concentrated sulfuric acid, and azeotropic water was removed for 3 h. The solvent was then removed and the residue was recrystallized twice: didecyl maleate, mp 40—42 °C (colorless flakes from hexane); didodecyl maleate, mp 53—55 °C (colorless flakes from hexane); dihexadecyl maleate, mp 64—65 °C (colorless flakes from toluene). These dialkyl maleates and equimolar amounts of $NaHSO_3$ were dissolved in a small amount of water, and allowed to react with stirring at 100 °C for 2—3 h[6] Water was removed *in vacuo* and the residue was dissolved in a large amount of hot methanol in order to separate inorganic materials. Colorless powder was recovered by removal of methanol and dried. NMR spectra are in line with the expected structures[7] The following characteristic bands were observed in the IR spectrum: 1725 cm^{-1} ($\nu_{c=o}$), 1250 cm^{-1} (ν_{so_3}, ν_{c-o-c}) and 1050 cm^{-1} (ν_{so_3}). The elemental analyses are summarized in Table 1.

Table 1. Elemental analysis

	Found	64.39	11.69
$2C_{13}COOH$	Calcd for $C_{32}H_{58}O_8$	73.03	12.19
	Found[a]	67.34	10.24

a) About 4 mol% of myristic acid is contained.

Preparation of $2C_nPOH$.[8] $POCl_3$ and three equivalents of the respective alcohols were refluxed in benzene for 18—20 h. The solvent was removed and the residue recrystallized twice or more: didecyl phosphate, mp 33—34 °C (colorless granules from hexane); didodecyl phosphate, mp 51—52 °C (colorless granules from hexane); dihexadecyl phosphate, mp 66—68 °C (colorless granules from benzene). The elemental analyses are given in Table 1. IR and NMR spectral data are in line with the expected structures: IR, $\nu_{p=o}$ 1230 cm^{-1}, ν_{p-o-c} 1060 cm^{-1}.

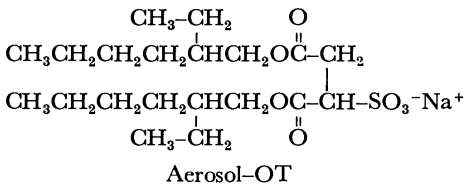
Preparation of $2C_{13}2COOH$.[9] Myristoyl chloride (24.7 g,

0.1 mol) in toluene was added to a pyridine solution of 7.5 g (0.05 mol) of *dl*-tartaric acid at 10 °C over a period of 30 min, the mixture being then stirred at room temperature for 1 h. Precipitates formed were separated and the solution was concentrated. The solid product was recrystallized twice from hexane, mp 49—50 °C. IR and NMR spectra are consistent with the expected structure but the elemental analysis shows some deviations from the calculated values. (Table 1, footnote).

Electron Microscopy. Weighed amounts of $2C_nSO_3Na$ were suspended in water (1—40 ml) and sonicated for 5—15 min using a Branson cell disruptor. $2C_nPOH$ and $2C_{13}$-2COOH were dissolved in water of pH 9 and sonicated. The final pH of the solutions was 8—9. All of these stock solutions were 10 mM. The stock solution (1 ml) was mixed with 1 ml of appropriate staining reagents (2% aqueous uranyl acetate, 2% aqueous phosphotungstic acid (pH 7), or 2% aqueous ammonium molybdate), sonicated for 15 s, kept for 30—60 min in an ice-water bath, and applied to carbon grids. A Hitachi electron microscope, model H-500 was used.

Results and Discussion

Electron Micrograph. All the dialkyl compounds were soluble under the conditions employed, giving clear to slightly turbid aqueous solutions. Multi-walled vesicles are observed in the electron micrograph of aqueous $2C_{12}SO_3Na$ (Fig. 1a). In contrast, no structure was detected for a 10 mM solution of Aerosol OT which posesses 2-ethylhexyl groups in place of dodecyl group.



Aerosol-OT

Lamellar structures are observed in the electron micrograph of aqueous $2C_{16}SO_3Na$ (Fig. 1b). However, vesicle structure is observed for $2C_{12}POH$ and $2C_{10}POH$ (Fig. 1c).

The layer width of these aggregates is 3—5 nm. This suggests that the molecular bilayer as in biomembranes is formed as the basic structural unit. The electron microscopic observation is summarized in Table 2. The aggregate weight determined by means of the light scattering method is also given. They are in the range of 2—20 million daltons, and much larger than those observed for the conventional anionic micelles: 10^5 daltons for sodium dodecyl sulfate.[10]

Table 2. Electron microscopy

Compound[a]	Stock solution 10 mM	Electron micrograph	Aggregate weight[b] 10^{-6}·dalton
$2C_{16}SO_3Na$	slightly turbid	lamella	—
$2C_{12}SO_3Na$	clear to slightly turbid	large vesicle	22
$2C_{10}SO_3Na$	clear	large vesicle	1.9
$2C_{16}POH$	slightly turbid	lamella	12

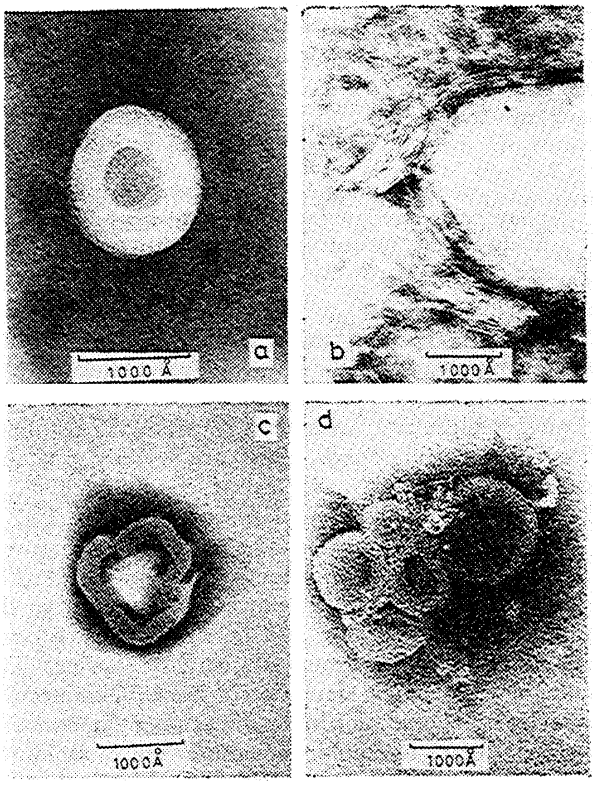

Fig. 1. Electron micrograph. a: $2C_{12}SO_3Na$, stained by phosphotungstic acid, ×300000. b: $2C_{16}SO_3Na$, stained by phosphotungstic acid, ×200000. c: $2C_{10}PONa$, stained by phosphotungstic acid, ×230000. d: $C_{18}C_{12}N^+2C_1$, stained by uranyl acetate, ×186000.

The present results obtained for the anionic dialkyl compound are similar to those obtained for dialkylammonium salts. Figure 1d shows an example of the aggregate structure of the latter salts. Both types of the amphiphile form molecular bilayers when dispersed in water. The aggregate structure (vesicle or lamella) commonly depends on the length of the alkyl chain. In the series of dialkyldimethylammonium bromides,[5] the didodecyl compound tends to form vesicles, whereas lamellar structures are produced readily with higher dialkyl compounds. A similar situation holds in the present study between $2C_{12}SO_3Na$ (Fig. 1a) and $2C_{16}$-SO_3Na (Fig. 1b). The difference in the nature of the hydrophilic head group may not change the aggregate structure drastically.

Cholesterol Binding. Cholesterol can be readily solubilized by these aggregates. Slightly turbid solutions were obtained when $2C_{12}SO_3Na$ or $2C_{12}POH$ and about one third molar cholesterol were suspended in deionized water (pH 8—9) and sonicated. Electron microscopic examination of these solutions indicates no definite structure formation. Bound cholesterol may destroy the regular aggregate structure. Only a turbid dispersion was obtained from $2C_{13}COOH$ and one third molar cholesterol.

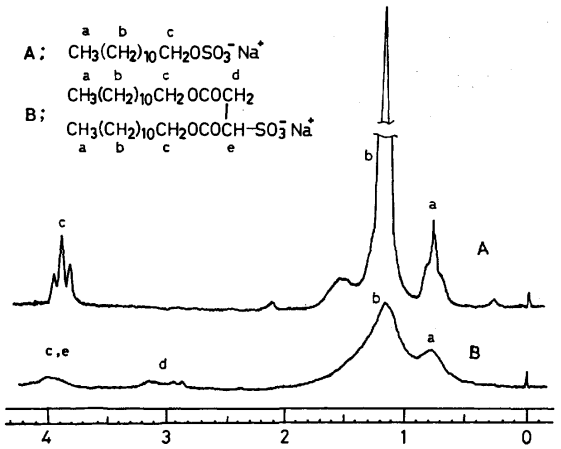

Fig. 2. ^{1}H-NMR spectra. 10 mM in D_2O. Internal reference, DSS.

NMR Spectroscopy. Figure 2 shows an ^{1}H-NMR spectrum of $2C_{12}SO_3Na$ (D_2O solution) obtained at an ambient temperature, in comparison with that of sodium dodecyl sulfate, the assignments being given. The methyl and methylene protons of the alkyl chain of the former compound are much broader than those of the latter. A similar broadening is seen for other protons. The extent of broadening is similar to that of the alkyl proton in the dipalmitoyllecithin vesicle at around the phase transition temperature (≈40 °C).[11] It is suggested that the molecular motion of the aggregated $2C_{12}SO_3Na$ is as restricted as that of the lecithin bilayer.

Comparisons of Lipid and Synthetic Bilayers. The major lipid constituent of biomembranes belongs to phospholipids. The hydrophilic head group of the phospholipid may bear a net negative charge or may be zwitterionic at neutral pH. In a very rare case, the head group is positively charged, since two positive groups (lysyl) and one negative group (phosphate) are present.[12]

The thermodynamic justification for the presence of two alkyl groups in the bilayer formation has been discussed.[13] However, how the head group structure is related to the bilayer formation was not explicitly stated, apart from the importance of its hydrophilic property.

Previous studies[4,5,14] have suggested that simple and modified ammonium groups can be the hydrophilic head group. The present study indicates that simple anionic groups such as phosphate, sulfonate and carboxylate can also be used as the head group. Thus, we conclude that the stable molecular bilayer can be produced from amphiphilic molecules if they contain two normal alkyl groups of appropriate chain length (C_{10}–C_{20}). The hydrophilic head group need not be as complex as those of biolipid molecules.

These synthetic bilayers possess characteristics very similar to that of biomembrane. In the first, they solubilize cholesterol of up to 40 mol% readily. Similar solubilization was observed for the dialkylammonium aggregate.[14] Secondly, considerable broadening of the proton NMR peak of the aggregate is observed, the extent of broadening being similar to that of the lecithin bilayer. This is also the case for the dialkylammonium bilayer.[4] The molecular motion of the synthetic bilayer might thus be as restricted as that of lipid bilayers.

In conclusion, some simple, synthetic amphiphiles, both cationic and anionic, can produce molecular bilayers in aqueous solutions. The structure and some properties of these bilayer aggregates are intrinsically the same as those of the biomembrane.

The authors are grateful to Prof. M. Takayanagi for use of the electron microscope, and to Union Giken Co. for use of the light scattering instrument.

Study on Solubilization by Electrophoresis and Diffusion

Keizo OGINO, MASAHIKO ABE, and Nobuo TAKESHITA

Faculty of Science and Technology, Science University of Tokyo, Yamazaki, Noda, Chiba 278

(Received August 1, 1977)

The difference in solubilization phenomena exhibited when polar and nonpolar oily materials are solubilized by Sodium dodecyl sulfate (SDS) has been investigated by measuring the electrophoresis, the diffusion, and the viscosity. Based on the assumption that the micelle is spherical the effective specific volume, the effective radius, the ζ-potential and the number of effective charges have been calculated. At the limit of solubilization all four quantities were larger for octanoic acid than for octane. The electrophoretic mobility of the micelle, $|U_M|$, increased when octanoic acid was solubilized, in contrast to a decrease observed in the solubilization of octane.

In the literature, we find a number of reports dealing with the electrophoresis, diffusion and light scattering of micelles composed of pure surfactant including SDS,[1] mixed ionic-nonionic surfactants[2] and polyether sulfate.[3] However, only a few are concerned with solubilizate-containing micelles. Among the ways of incorporating the solubilizate into the micelles are (a) adsorption on the surface of the micelles; (b) deep penetration in the palisade layer and (c) dissolution in the hydrocarbon core.

In this study, the mechanism of solubilization has been investigated. SDS micelles containing octanoic acid, a polar oily material, or octane, a nonpolar oily material, have been examined in terms of electrophoretic properties. The results indicate that octanoic acid is solubilized by deep penetration into the palisade layer whereas octane is solubilized by dissolution in the hydrocarbon core.

Experimental

Materials. Sodium dodecyl sulfate (SDS) of reagent grade was extracted with ether and recrystallized from ethanol. The octanoic acid and octane were supplied by Wako Pure Chemical Industries, LTD and were more then 99% pure.

Apparatus and Conditions. 0.3 and 1.5% SDS solutions, of above critical micelle concentration (CMC), were prepared with 0.2 mol dm^{-3} NaCl solutions. The procedure for the determination of the limits of solubilization was as follows. Into several 100-cm^3 glass-stoppered Erlenmeyer flasks, 50-cm^3 portions of 0.3 or 1.5% SDS solutoin were placed; varying amounts of oily materials were added to them, and the mixtures were stirred for 12 h in a thermostat at 25 °C, followed by settling for 36 h until equilibrium was established. After equilibrium had been established, the turbidity of the solution was measured with an Electro photocolorimeter of Hirama 2B type at wave length 655 nm, using a cell of 10.0 mm light path. The limit of solubilization was determined from the break point of the turbidity *vs.* solubilizate concentration curve. An amount of solubilizate, corresponding to 10, 30, 50, 80, 90, or 100% of the above-determined limit of solubilization in 0.3 and 1.5% SDS solutions. Two series of solutions with different degrees (10—100%) of solubilization were prepared by dissolving. The electrophoresis and diffusion measurements were carried out with a Hitachi, model HTB-2A Tiselius apparatus and a Tchukasa, Neurath cell immersed in a thermostat at 25 °C. A pair of 0.3 and 1.5% solutions with the same degree of solubilization were used as upper and lower layers, thus minimizing the boundary disturbance often encountered in electrophoresis and diffusion.

The relative viscosities of the solutions including solubilized oily substances were measured at 25 °C with an Ubbelohde viscometer with appropriate auxiliary equipment. The flow time was measured with a stopwatch of 0.1-s precision; the over-all fluctuations were within $\pm$0.1-s. The specific gravity gravity was determined using a pycnometer of 25-cm^3 capacity.

Results and Discussion

Relative Viscosity and Effective Specific Volume of the Micelle. Figure 1 shows the relative viscosity, η_r, of the solutions which were prepared by solubilizing octanoic acid using given concentrations of SDS.

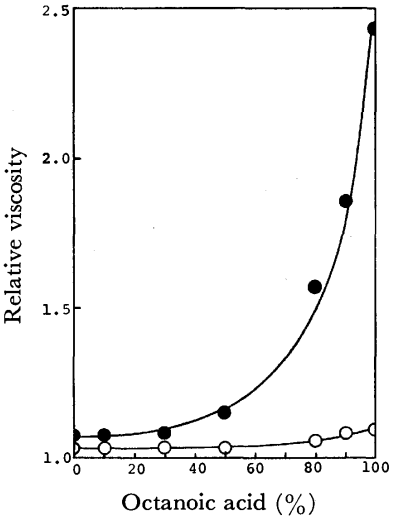

Fig. 1. Relative viscosity, η_r, of the solutions which were prepared by solubilizing octanoic acid using SDS of given concentrations.
○: 0.3% SDS, ●: 1.5% SDS.

From Guth and Simha's equation,[4-7] which is a form of Einstein's equation extended to more concentrated solutions,

$$\eta_r = 1 + 2.5\phi + 14.1\phi^2, \quad (1)$$

the volume fraction occupied by the spherical particles, ϕ, may be calculated from the relative viscosity, η_r. The effective specific volume of 1 g of SDS containing oily materials, V, is given by[5,8]

$$V = \phi/C, \quad (2)$$

where C is the concentration of the solution in g/cm^3.

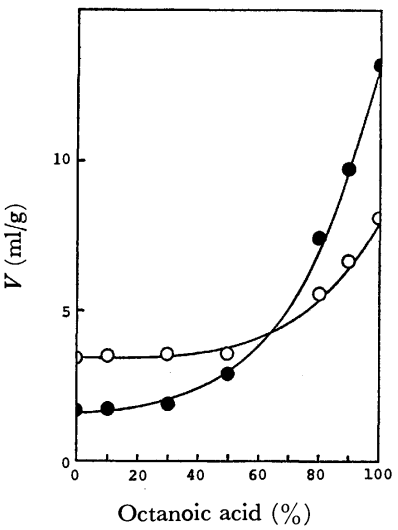

Fig. 2. Effective specific volume, V, plotted against the amount of octanoic acid.
○: 0.3% SDS, ●: 1.5% SDS.

Figure 2 shows the effective specific volume, V, plotted against the amount of octanoic acid. Nakagawa[9] suggested that the effective specific volume in various concentrations of the surfactant (0.3—3.0%) was approximately constant and did not tend to decrease or increase with increasing concentration of surfactant. For a solution of surfactant alone, it can be said that above the CMC the number of micelles increases with an increase in the amount of surfactant whilst the size of the micelle remains almost unchanged (aggregates of 50—100).[10] From Fig. 2, it is evident that the effective specific volume of 0.3 and 1.5% SDS solutions containing octanoic acid increases with an increase in the amount of octanoic acid.

Table 1. Micellar parameters for octanoic acid and octane

Octanoic acid (%)	$D\times10^7$ cm²/s	$a\times10^8$ cm	$-U_M\times10^4$ cm²/V s	$-\zeta$ mV	Q
0	9.33	25.2	2.56	45.3	23
30	8.76	26.9	3.01	52.9	30
50	6.22	37.9	3.06	52.0	54
80	3.88	60.7	3.15	51.0	126
90	2.78	84.7	3.22	50.3	233
100	2.15	109.5	3.26	49.7	376
Octane 100 %	5.59	42.1	1.49	25.1	32

Diffusion Coefficient and Effective Radius of the Solubilizate-containing Micelle. The diffusion coefficient of the SDS micelle containing solubilized octanoic acid was measured in 0.2 mol dm^{-3} NaCl. The diffusion of hydrophilic colloidal electrolyte usually becomes rapid, since the charged colloid is influenced by ionic atmosphere. This effect may be suppressed by keeping the concentration of the salt above 0.2 mol dm^{-3}.[10] Table 1 demonstrates the change in the diffusion coefficient and the effective radius of the micelle with an increase in the amounts of octanoic acid. This indicates that the diffusion coefficient of the micelle decreases with an increase in the amount of solubilized octanoic acid. Consequently, the effective radius of the micelle, a, increases as shown by the Stokes equation[11]

$$a = kT/6\pi\eta D, \tag{3}$$

where k is Boltzmann constant and η is the viscosity of the medium. The increase in the effective radius of the micelle is considered to be due to the deep penetration of octanoic acid into the micelle. This view is concordant with the results obtained for the relative viscosity and the effective specific volume measurements of the micelle. At the limit of solubilization of oily material, the diffusion coefficient of the micelle containing octanoic acid is smaller than that of octane-containing one. The effective radius of the micelle containing octanoic acid is larger than that of the micelle containing octane.

Electrophoresis. In the electrophoresis of the above mentioned surfactant solution, there exist Na^+, Cl^- and micelle, M^-, in both the upper and lower layers. Thus two boundaries appear when the current is applied.[12] (Since the concentrations of surfactant monomer and solubilizate are negligibly small compared with the concentration of the other ions, they may be neglected). One of the boundaries is an unmoving one named ζ and ε peak, which if the concentrations of NaCl and surfactant are correct do not appear.[13] With 0.2 mol dm^{-3} NaCl, the peak of the electrophoretic diagram was only one in both upper and lower sides. From the measurements at 25 °C of the velocities of the upper and lower boundaries, V_a and V_d, the electrophoretic mobility of the micelle, U_M, was calculated by the following equation:[2,12]

$$U_M = V_d\tau^\beta - (V_a\tau^\alpha - V_d\tau^\beta)/(T_M^\beta/T_M^\alpha) - 1, \tag{4}$$

where T_M is the transference number of the micelle, τ is the specific conductance of the solution, and the superscripts α and β refer to the upper and lower layers respectively. T_M^β/T_M^α in Eq. 4 is expressed as

$$T_M^\beta/T_M^\alpha = (C_M^\beta/\tau^\beta)/(C_M^\alpha/\tau^\alpha), \tag{5}$$

where C_M^α and C_M^β, which are the concentrations of M^- ions in α and β phases respectively, are given by

$$\begin{aligned} C_M^\alpha &= (C-\mathrm{CMC})_\alpha, \\ C_M^\beta &= (C-\mathrm{CMC})_\beta, \end{aligned} \tag{6}$$

where C is the concentration of the surfactant. Table 1 gives the data of the electrophoretic mobility of the micelle with corresponding amount of solubilized octanoic acid. The absolute value of the electrophoretic mobility of the micelle containing solubilized octanoic acid, $|U_M|$, increased a little with an increase in the amount of solubilized octanoic acid. The ζ-potential was calculated from U_M by the Henry equation[14]

$$\zeta = [6\pi\eta/\varepsilon f(\kappa a)] \times U_M, \tag{7}$$

where $f(\kappa a)$ is the Henry function; κ, the Debye-Hückel parameter; a, the radius of the micelle, and η and ε, the viscosity and dielectric constant of the medium respectively. Table 1 demonstrates that the ζ-potential of the micelle containing octanoic acid remained constant at about −50 mV, regardless of the amount of octanoic acid added. This may be responsible for the small

changes in U_M. At the limit of solubilization of oily material, the ζ-potential for octanoic acid is larger than that for octane. The value of U_M for octanoic acid, 3.26, is larger than that of the solubilizate-free micelle, 2.56, as compared to octane, 1.49, which is smaller. The effective micelle charge, Q, may be estimated by the following equation:[14]

$$Q = (1/e) \times [(1+\kappa a+\kappa r_i)/(1+\kappa r_i)] \times \varepsilon a\varphi, \quad (8)$$

where e is the elementary charge and r_i is the radius of the counter ion. (In the present study we have assumed 0.22 nm as its radius).[15] At the limit of solubilization of oily material, the effective charge of the octane-containing micelle is somewhat larger, and the octanoic acid-containing micelle much larger than that of the solubilizate-free micelle.

TABLE 2. DEGREE OF SOLUBILIZATION AND RELATIVE VISCOSITY FOR OCTANOIC ACID AND OCTANE

Concentration of SDS	Degree of solubilization (mol/l)		Relative viscosity	
	Octanoic acid	Octane	Octanoic acid	Octane
0.3%	0.53×10^{-2}	0.70×10^{-2}	1.09	1.03
1.5%	2.31×10^{-2}	2.80×10^{-2}	2.42	1.08

Table 2 demonstrates the degree of solubilization and relative viscosity of the solutions, prepared by solubilizing octanoic acid and octane up to the limit of solubilization. As is evident from Table 2, although the degree of solubilization of octanoic acid is smaller than that of octane, the relative viscosity of the solution containing octanoic acid is larger than that of the solution containing octane. This may be explained in terms that the effective specific volume is larger when the micelle is saturated with octanoic acid than when saturated with octane since octanoic acid carries a considerable amount of water of hydration, V (10.4), compared with octane, V (1.01). It is the carboxylic group that undergoes hydration. Since it is difficult energetically for this hydrated carboxylic acid to dissolve into the hydrocarbon core of the micelle, the carboxylic group of octanoic acid remains on the surface of the micelle, allowing the alkyl group of octanoic acid to penetrate into the palisade layer. Since octane does not undergo hydration, the whole molecule can dissolve into the hydrocarbon core of the micelle.

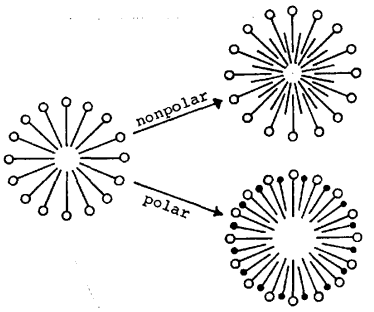

Fig. 3. Solubilization models of polar and nonpolar compounds.
○—— =Surfactant molecule, ●—— =polar molecule, —— =nonpolar molecule.

Thus, the solubilization model[16] shown in Fig. 3, which has been generally accepted, is consistent with the above results.

Calorimetric Phenomena of Methanol Adsorption on Active Carbon

Ryoichi TSUNODA and Yoshiyuki FUKAZAWA

Industrial Research Institute of Kanagawa Prefecture, Showa-machi, Kanazawa-ku, Yokohama 236

(Received October 5, 1977)

Synopsis. The heats of immersion in methanol of active carbon which preadsorbed methanol from the vapor phase at a given equilibrium pressure were measured. The calorimetric phenomena of methanol adsorption on active carbon were interpreted by comparing them with the distribution of the adsorption potential of methanol on active carbon.

The adsorption of gas on active carbon is accompanied by exothermic and/or endothermic phenomena. However, the direct measurement of the calorimetric phenomena on the gas adsorption is difficult without employing a specific calorimeter for solid-gas measurements. In this study, the calorimetric phenomena of methanol adsorption on active carbon have been measured by means of a conventional calorimeter (for solid-liquid) and the observed heats of immersion have been interpreted by comparing them with the distribution of the adsorption potential of methanol on active carbon.

In a spherical Pyrex glass tube, about 12 mm in diameter, *ca.* 200 mg of commercially available Pittsburgh SGL-type active carbon, dried overnight at 110 °C, was outgassed at a pressure of 10^{-6} Torr at 30 °C for 14 h by means of a conventional adsorption apparatus, while the adsorption of methanol at a given pressure was carried out at 30 °C. After 45 min of methanol adsorption, the Pyrex glass tube was sealed. The sample was then subjected to the measurement of the heat of immersion in methanol at 30 °C by means of a twin-type calorimeter manufactured by Oyo Denki.

The adsorption isotherm,[1] the characteristic and distribution curves of the adsorption potential,[1] and the heats of immersion in methanol of active carbon which preadsorbed methanol from the vapor phase are shown in Figs. 1—3 respectively.

The net-heat of adsorption corresponding to the coverage of the monolayer was calculated from the adsorption isotherm using the BET equation:[2]

$$\frac{P/P_0}{V(1-P/P_0)} = \frac{1}{V_mC} + \frac{(C-1)P/P_0}{V_mC}, \quad (1)$$

where $C=\exp[(E_1-E_L)/RT]$ is the BET constant; E_1, the mean heat of adsorption in the first adsorption layer; E_L, the heat of condensation; E_1-E_L, the so-called net heat of adsorption corresponding to the coverage of the monolayer; V, the amount adsorbed at the relative pressure of P/P_0, and V_m, the monolayer capacity. The calculated parameters in the BET equation are shown

TABLE 1. PARAMETERS IN THE BET EQUATION

Active carbon	C[a]	E_1-E_L[b] (cal/mol)	V_m[c] (cm^3/g)
SGL	12.6	1527	0.320

a) The BET constant. b) The net-heat of adsorption corresponding to the coverage of the monolayer. c) The monolayer capacity.

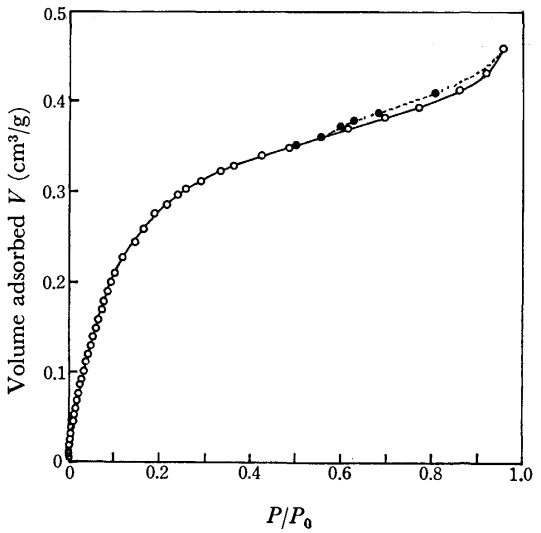

Fig. 1. Adsorption isotherm of methanol on SGL-type active carbon at 30 °C.[a]

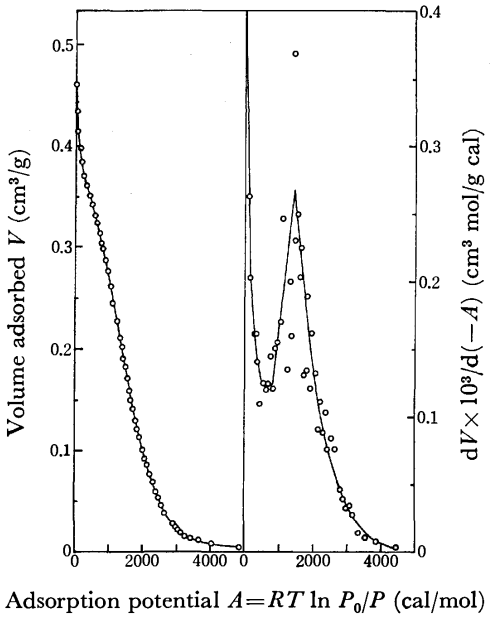

Fig. 2. Characteristic and distribution curves of adsorption potential of methanol on SGL-type active carbon at 30 °C.[a] a) Ref. 1.

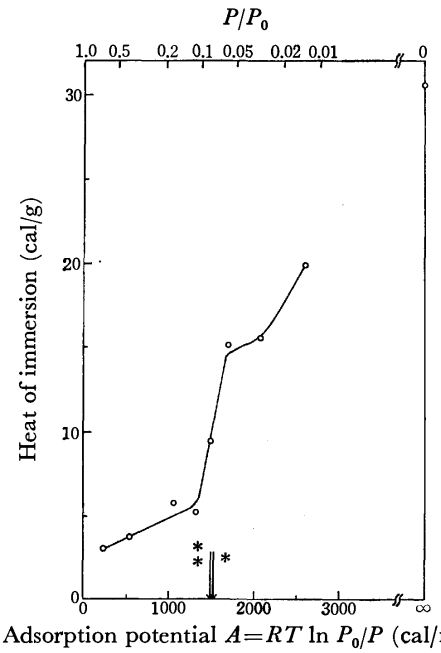

Fig. 3. Heat of immersion in methanol of SGL-type active carbon which preadsorbed methanol from the vapor phase at 30 °C.
The adsorption potential ($A=RT \ln P_0/P$) corresponds to the equilibrium partial pressure (P/P_0) at which the adsorption of methanol on active carbon was carried out at 30 °C. The heat of immersion in methanol of active carbon which preadsorbed methanol from the vapor phase was measured at 30 °C.
*: The adsorption potential corresponding to the net-heat of adsorption for the monolayer coverage.
‡: The adsorption potential corresponding to that at $dV/d(-A)$=maximum.

in Table 1.

The observed heats of immersion showed a drastic decrease at the adsorption potential ($A=RT \ln P_0/P$) corresponding to the net-heat of adsorption (1527 cal/mol) for the monolayer coverage (see Fig. 3). However, the BET constant, C, obtained form a simple fitting of the BET equation to the adsorption isotherm reflects only the average energy parameter of adsorption sites being filled in the region of the fitting, *i.e.*, usually in $0.05<P/P_0<0.3$.[3] Therefore, the so-called net-heat of adsorption, E_1-E_L, 1527 cal/mol, calculated from the value of C may also reflect the average energy of the net-heat of adsorption.

Meanwhile, the adsorption potential at the point of the drastic decrease in the heats of immersion corresponds also to the adsorption potential (*ca.* 1470 cal/mol) at $dV/d(-A)$=maximum on the distribution curve of the adsorption potential, as is shown in Fig. 2. The adsorption potential at 1470 cal/mol is equivalent to $P/P_0=0.0872$, indicating the adsorption volume of 0.195 cm^3/g, on the adsorption isotherm in Fig. 1. The adsorption volumes corresponding to the adsorption potentials at the * and ‡ marks in Fig. 3 are 0.181 and 0.195 cm^3/g respectively; therefore, the volume of methanol preadsorbed on active carbon, the drastic decrease of which in the heats of immersion is shown in Fig. 3, corresponds to a little more than half of the monolayer capacity of active carbon.

The observed heat of immersion in Fig. 3 corresponds to the heat of immersion of the uncovered part of the surface of the active carbon with methanol, although, strictly speaking, the observed calorimetric phenomena are accompanied by the heat of condensation of methanol adsorbed on the surface of carbon, and the decrease in the heat of immersion is proportional to the surface free-energy lowering. Moreover, taking into consideration the fact that the adsorption mechanism expressed in the relationship between $dV/d(-A)$ and A is changed at about 61% of the monolayer capacity of methanol adsorption, the observed lowering of the surface free energy seems to be due to the change in the adsorption state, *e.g.*, the change in the geometrical structure of the adsorbed methanol molecules.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (6), 1885—1886 (1978)

Location of the ν_1, ν_2, ν_3, and ν_5 Fundamental Vibrations of Ethylene-d_4

Nobukimi OHASHI, Tetsuo KYOGOKU, and Shin-ichi MATSUOKA

Institute for Spectroscopic Study of Matter, Faculty of Science, Kanazawa University, Maruno-uchi, Kanazawa 920

(Received November 15, 1977)

Synopsis. The ^{Q}Q branch peaks of the ν_1, ν_2, and ν_3 Raman active bands of ethylene-d_4 were located at ν_1= 2260.8±0.1 cm^{-1}, ν_2=1518.3±0.1 cm^{-1}, and ν_3=984.4±0.1 cm^{-1}, respectively. The band center of the ν_5 band which does not have a ^{Q}Q branch was determined to be ν_5=2315.6 ±0.3 cm^{-1} from the analysis in the symmetric top approximation.

While many Raman data have been presented for ethylene-d_0,[1-6] few Raman data have been published for ethylene-d_4. Though its pure rotational Raman spectrum was studied by Dowling *et al.*,[2] its vib-rotational Raman spectra have not been studied. Only the liquid state vibrational frequencies of the Raman active bands have been measured, by Hemptinne *et al.*[7] As a preliminary to the vib-rotational Raman study of ethylene-d_4, we report the ν_1, ν_2, ν_3, and ν_5 fundamental frequencies, since these data are considered to be important in the force constant calculation of this molecule.

Experimental

The experimental setup consisted of a He-Cd laser operated at 441.570 nm, a gas cell, and an Echelle grating monochromator. The scattered Raman radiation from a multi-reflection cell[8] placed inside the laser cavity was analyzed by the Echelle grating monochromator and detected by a cooled photomultiplier operated in conjunction with photon counting equipment. Ethylene-d_4 gas obtained from Merck, Sharp, and Dohme was used at a pressure of about 400 Torr. Wavelength calibration was made by using as standards the lines from an iron-neon hollow cathode lamp. A slit width of 0.4 cm^{-1} was used in the measurements of the ν_1 ^{Q}Q and the ν_2 ^{Q}Q branch peaks, and a slit width of 0.8 cm^{-1} was used in the measurements of the ν_3 ^{Q}Q branch peak and the ν_5 band.

Results

The ^{Q}Q branch peaks of the totally symmetric bands of ethylene-d_4 gas were determined to be ν_1=2260.8±0.1 cm^{-1}, ν_2=1518.3±0.1 cm^{-1}, and ν_3=984.4±0.1 cm^{-1}. The ν_1 value is larger than that in liquid state by 10 cm^{-1}, but the ν_2 and ν_3 fundamental frequencies are nearly equal to those in liquid state, as obtained by Hemptinne *et al.*[7] These circumstances are similar to those in ethylene-d_0.[9]

As the rotational structure of the ν_5 band was observed under low resolution (about 1.0 cm^{-1}), as shown in Fig. 1, this band was analyzed in the symmetric top approximation. In order to enable the K-assignment to be done exactly we made use of the simulated spectrum which was caculated using the calculation program for the asymmetric rotor. As the rotational constants in the v_5=1 state can not be obtained at the present stage, we calculated the spectrum with A_0=A_5=2.425 cm^{-1}, B_0=B_5=0.73630 cm^{-1}, and C_0=C_5=0.56355 cm^{-1}, where the ground state constants for ethylene-d_4 were taken from the paper of Duncan *et al.*[10] In the symmetric top approximation the $^{P,R}Q_k$ branches form a series of lines at the origins of subbands, if $\bar{B}_0$—$\bar{B}_5$ is negligibly small. From the least squares fit of the observed data we obtained the following quadratic equation for the subband origins:

$$\nu^{sub} = 2317.4 + 3.601K - 0.006K^2.$$

This equation gives ν_5=2315.6±0.3 cm^{-1} for the band

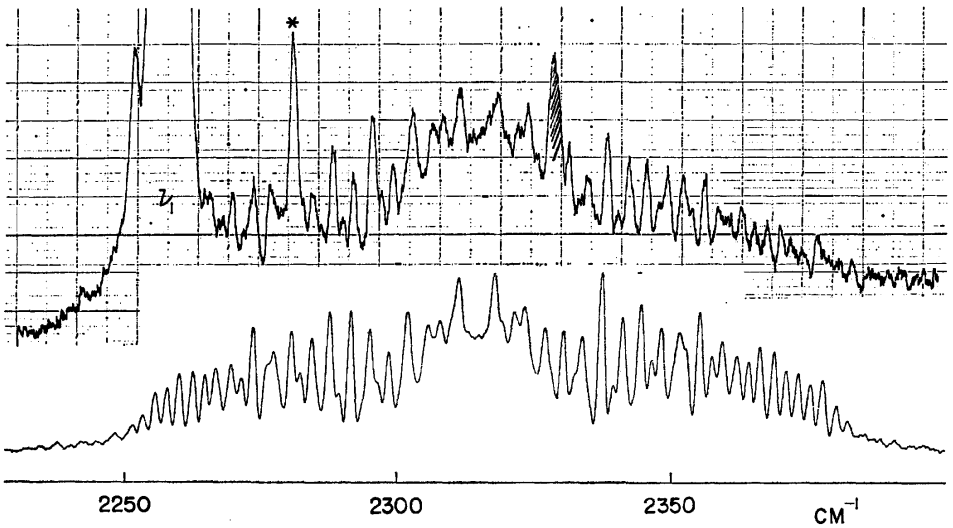

Fig. 1. Observed (top) and calculated (bottom) spectra of the ν_5 band of ethylene-d_4. The peak marked by * was attributed to ν_1 (C_2HD_3) and the peak with shadow was overlapped by N_2 line.

center, which is also about 11 cm^{-1} larger than that in liquid state. The negative value of the coefficient in K^2 is contradictory to $A_5-\bar{B}_5=1.801>A_0-\bar{B}_0=1.775$. It was perhaps caused by the circumstance that the correction for the term $(\bar{B}_5-\bar{B}_0)J(J+1)$ was not applied to the observed data and that the symmetric top approximation was used for an asymmetric top molecule.

Carbon Deposition on Nickel from a Mixture of Ethylene and Hydrogen

Shozo KISHIMOTO, Noriyuki SOTANI,* Kazuyo NIIMI, and Toshiko URATA

Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe 657

**College of Liberal Arts, Kobe University, Nada, Kobe 657*

(Received December 20, 1977)

Synopsis. Two periods (acceleration and steady state period) were defined in the process of carbon deposition on cold-worked nickel from ethylene. From the dependence of the former period on annealing temperature, it was found that lattice defects in the crystal play a role in the creation of carbon nuclei and the separation of nickel atoms from the surface.

Carbon deposition on catalysts has been an important topic in connection with catalytic processes involving hydrocarbons. Recently Lobo *et al.*,[1,2] studying the kinetics of these reactions on nickel foils, have reported that, in general, there are three periods in the course of the reaction: an induction period, an acceleration period, and a steady state period. Furthermore, they suggested that the length of the induction period is strongly dependent on both the mode of pretreatment of the catalyst and the reaction temperature, but the rate of reaction in the steady state is independent of the catalyst history. Many studies[3] have shown that the catalytic activities of metals for various reactions are greatly influenced by pretreatments, such as cold-working, irradiation, and annealing, and that these changes in the activity are mainly ascribed to the generation or the annihilation of active sites during the treatments. It seems probable that a similar situation exists in the case of the reaction of carbon deposition on metals. Shirasaki *et al.*[4] observed the deposit of carbon from C_2H_4 on Ni crystals by an electron microscope and claimed that the boundaries of crystallites were much more active than their plane surfaces. Walker and Thomas[5] have suggested that the deposition of carbon from CO is favored at dislocations in metal catalysts, in agreement with the hypothesis previously presented by Gwathmey *et al.*[6] Emphasis in the present work is placed on the effect of the pretreatments of Ni catalysts on the initial stages of the carbon deposition by the decomposition of C_2H_4.

The reactions were carried out in a static system and a Cahn electrobalance (Venton Instr. Corp.) was used to record the weight change due to the carbon deposition. Well annealed Ni wire (Japan Lamp Industrial Co., Ltd.) with a diameter of 0.5 mm was rolled to a thickness of 0.1 mm at room temperature. Specimens used for the experiment were in the form of ribbons (surface area approximately 10 cm^2). After being carefully washed with solvents, they were suspended from the balance arm and then were annealed at different temperatures between 350 and 800 °C in H_2 for 1 h. After this, the H_2 was pumped out.

C_2H_4 obtained from Takachiho Co., Ltd. was purified by repeated freezing and vacuum distillation. H_2 made by electrolysis was used after passage through hot Cu powder and a molecular sieve column cooled by liquid N_2. A mixture of C_2H_4 and H_2, 1 : 1 molar ratio, was used for all experiments at a total pressure of 13.3 kPa. Under these experimental conditions the reaction occurred at conveniently measureable rates in the temperature range of 360—600 °C. Carbon deposited surfaces were examined by a scanning electron microscope (Japan Electronics LAB-JSM U3 Type).

Figure 1 shows the typical time course of the reaction at 400 °C for the specimens annealed at four different temperatures. The rates increase gradually with the progress of the reaction and attain a steady limiting value (about 4.5 $\mu g/cm^2$ min). Thus, two periods are evident: (a) acceleration and (b) steady state period. It is seen that the former is very dependent on the annealing temperature but the latter is not much effected by the treatment. Figure 2(A) shows the effect of the annealing temperature on the catalytic activities in the range of the acceleration period at a reaction temperature of 400 °C. (The activities are expressed as the time to effect equal increment in the amounts of deposition). Although the experimental values are very scattered, the decrease in the activity is apparent in a range of 400—550 °C. It is also shown in Fig. 2(B) that the change in hardness of cold-worked Ni was paralleled

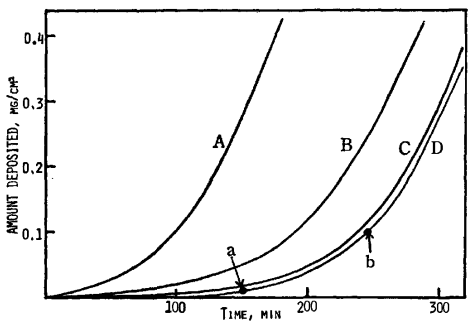

Fig. 1. Carbon deposition on Ni annealed at 400 (A), 450 (B), 550 (C), and 800 °C(D).

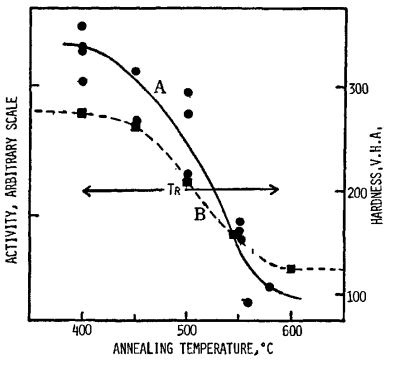

Fig. 2. Dependence of the catalytic activity in the acceleration period (A) and of hardness (B) on the annealing temperature.

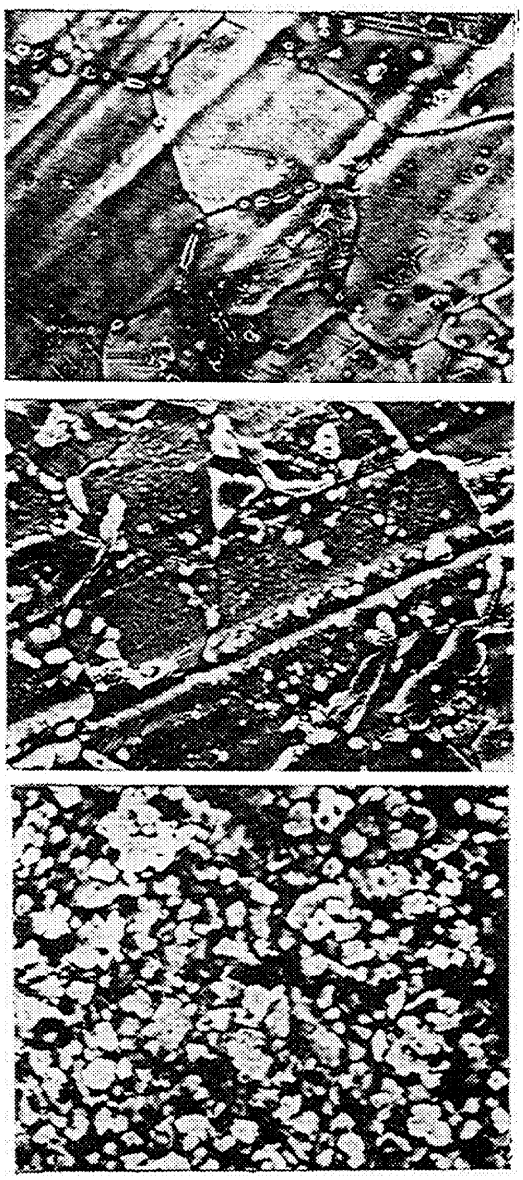

Fig. 3. Scanning electron micrographs (× 1000) of deposited carbon on Ni surfaces annealed at 800 °C.
(A) and (B) showing patterns at point a (10 μg/cm²) and b (100 μg/cm²) in Figure 1(D); (C), at a point in the steady state period.

by the change in the activity by annealing. According to our previous results,[7] this temperature range approximately corresponds to the recovery range (T_R) involving the migration and the annihilation of lattice defects (mainly dislocations) produced by cold-working. It has been already established that the acceleration period involves the creation of carbon nuclei and a subsequent growth process on the surface, and that the latter process is accompanied by the separation of Ni atoms from the surface.[1,8] From the facts presented above, it seems to be right to consider that the defects produced by cold-working in the crystals play a role in these processes in the acceleration period.

On the other hand, as the reaction temperature was raised, the reactions were always accompanied by the reduction in the acceleration period and the rates increased rapidly. At the temperatures above 450 °C, the acceleration periods were hardly discernible and the influence of the pretreatments on the catalytic activity was no longer detectable. These facts indicate that the contributions of normal surfaces to the catalytic activity overwhelm the effects which result from the special active sites responsible for the reactions at low temperatures.

In the case of the catalysts annealed at higher temperatures above 600 °C, the initial processes of deposit were examined with a scanning electron microscope. Figure 3 shows some typical examples observed at a reaction temperature of 400 °C. It is clear that the deposit occurs preferentially at special sites in a crystal face and at grain boundaries. These patterns are approximately similar to those of Shirasaki *et al.*[4] In conclusion, the present results suggest that on cold-worked catalysts the reaction is initiated at a large number of evenly distributed active sites formed by the pretreatment, while on the catalysts annealed at higher temperatures it proceeds on a localized region (*e.g.* grain boundaries) and on a small number of special sites which remain after annealing.

Gas-chromatographic Studies of the Thermal Decompositions of Carbonato-pentaammine-, Carbonatotetraammine-, and Dicarbonato-diamminecobalt(III) Complexes in the Solid State

Sukeo ONODERA*

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurasaka, Shinjuku-ku, Tokyo 162

(Received November 8, 1977)

Synopsis. This paper will describe gas-chromatographic studies of the thermal decompositions of $[CoOCO_2(NH_3)_5]X\cdot H_2O$ (I), $(CoCO_3(NH_3)_4]X\cdot nH_2O$ (II), and $K[Co(CO_3)_2(NH_3)_2(NH_3)_2]\cdot H_2O$ (III) (where, X=Cl, NO_3, SO_4, and n=0, 0.5, 3). The GEA curves for these compounds show that the complexes lose water between 80 and 160 °C, and that the decomposition of the anhydrous compounds begins with an evolution of ammonia at about 140 °C (for I) and 180 °C (for II and III).

The thermal decompositions of the cobalt(III) carbonatoammine complexes are usually studied by means of thermogravimetric analysis (TG)[1-3] and differential thermal analysis (DTA).[4,5] These techniques give information concerning the weight-loss and thermal changes in the compounds during the thermal reactions, but they do not give information on the species and the composition of the gases produced. Thus, gas-evolution analysis (GEA) is required for the above reactions in order to obtain more exact information on the decomposition processes of the compounds.

Although gas-chromatographic (GC) analysis may be expected to be useful to ascertain the composition of the gaseous decomposition products of the metal ammine complexes, few papers have been published on GC studies of thermal dissociation, even in simple metal complexes.[6-8] The present work illustrates the applicability of pyrolysis-gas chromatography in elucidating the mechanism of the decomposition of the cobalt(III) carbonatoammine complexes.

Experimental

The complexes, $[CoOCO_2(NH_3)_5]X\cdot H_2O$, $[CoCO_3(NH_3)_4]X\cdot nH_2O$, and $K[Co(CO_3)_2(NH_3)_2]\cdot H_2O$ (where, X=Cl, NO_3, SO_4, and n=0, 0.5, 3), were prepared according to the methods given in the Literature.[1,9] They were identified by measurements of the infrared absorption spectra. Samples ranging in particle size between 100 and 200 mesh was used in the present work.

The GEA apparatus employed has been described previously.[8] The procedure used for the pyrolysis of the sample and the analysis of the gaseous products are essentially the same as those reported in our previous paper.[8] The GC patterns for various pure substances are shown in Fig. 1.

Results and Discussion

In a preliminary examination of the thermal decompositions of the cobalt(III) carbonatoammine complexes, the differential scanning calorimetric (DSC) curves for these complexes were measured using a Rigaku Thermoflex 8001 with a standard differential scanning calorimeter in a dynamic nitrogen atmosphere at a heating rate of 5 °C/min. The ΔT_{max} values observed

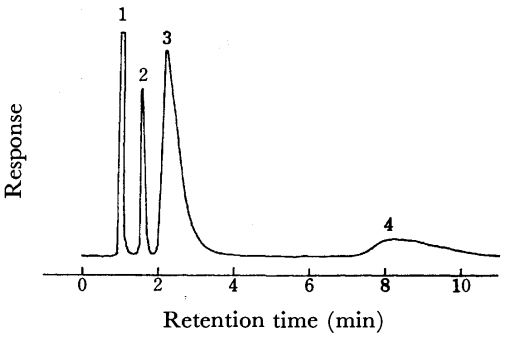

Fig. 1. Gas chromatogram of nitrogen (1), carbon dioxide (2), ammonia (3), and water (4) using 20% Silicon SF-96 on Fluoro Pack-80.

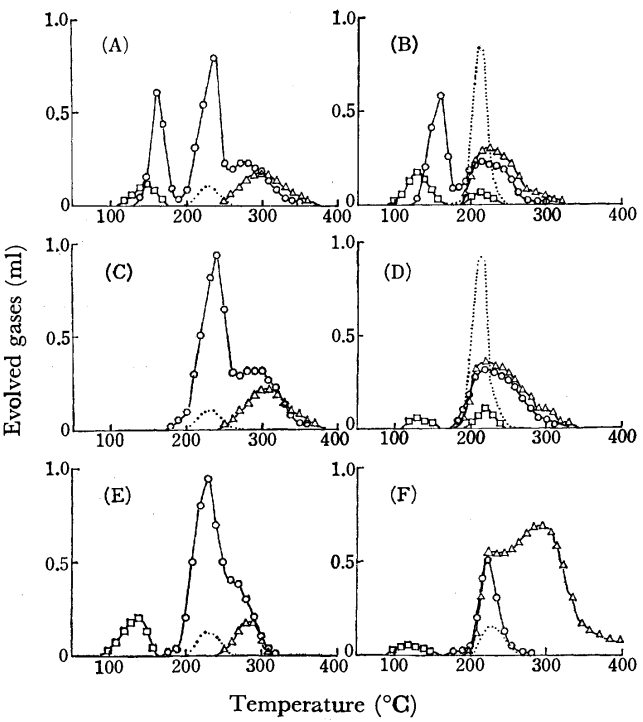

Fig. 2. GEA curves for $[CoOCO_2(NH_3)_5]Cl\cdot H_2O$ (A), $[CoOCO_2(NH_3)_5]NO_3\cdot H_2O$ (B), $[CoCO_3(NH_3)_4]Cl$ (C), $[CoCO_3(NH_3)_4]NO_3\cdot 0.5H_2O$ (D), $[CoCO_3(NH_3)_4]_2SO_4\cdot 3H_2O$ (E), and $K[Co(CO_3)_2(NH_3)_2]\cdot H_2O$ (F) in a helium atmosphere.

* Present address: Faculty of Pharmaceutical Science, Science University of Tokyo, Ichigaya-funagawara, Shinjuku-ku, Tokyo 162.

on the DSC curves for these compounds were (endo= endothermic peak, exo=exothermic peak): $[CoOCO_2(NH_3)_5]NO_3 \cdot H_2O$, endo 160, 210, exo 220 °C; $[CoOCO_2(NH_3)_5]Cl \cdot H_2O$, endo 165, 230, 280, and 350 °C; $[CoCO_3(NH_3)_4]NO_3 \cdot 0.5H_2O$, endo 140, 210, exo 220 °C; $[CoCO_3(NH_3)_4]Cl$, endo 230, 280, and 350 °C; $[CoCO_3(NH_3)_4]_2SO_4 \cdot 3H_2O$, endo 140 and 250 °C. The numbers of these endo- and exothermic peaks observed on the DSC curves are in agreement with those appearing on the DTA curves reported by earlier workers,[4,5] but the dissociation temperatures are somewhat different from those appearing on the DTA curves.

The GEA curves for the cobalt(III) carbonatoammine complexes in the 25—400 °C temperature range in a helium atmosphere are given in Fig. 2. The water in the gaseous products could not be exactly determined by means of the gas chromatography employed in the present work, because part of the water remained in the separation column even after a long time. Therefore, the amount of the evolved water given in the GEA curves is smaller than that estimated from the composition of these compounds.

The GEA curves for the cobalt(III) carbonatoammine complexes given in Fig. 2 show that the complexes lose water between 80 and 160 °C, and that the decomposition of the anhydrous compounds begins with an evolution of ammonia. The evolution of ammonia from the pentaammine complexes began at about 140 °C, while from the tetraammine and diammine complexes, it began at about 180 °C. Above 180 °C, both the pentaammine and tetrammine complexes decomposed in the same fashion. These temperature ranges and the number of peaks observed in the GEA curves are in agreement with those appearing on the DSC curves for the compounds obtained in the preliminary examination.

The thermally stable compounds as intermediate species, which may be formed by the evolution of 0.4—0.5 molar ammonia, were detectable in these GEA curves for the pentaammine complexes. However, no intermediate species were detectable in these GEA curves for the tetraammine and diammine complexes. In the GEA curves re-examined for the pentaammine complexes heated up to 170 °C, the first peak, which is due to the evolution of ammonia between 140 and 170 °C, disappeared. In addition, the IR spectra of the compounds heated up to 170 °C were characterized by the disappearance of the band at about 1490 cm^{-1} which was assigned to the CO_3^{2-} as an unidentate ligand, and by the appearance of new bands at about 840 and 770 cm^{-1} which were assigned to the CO_3^{2-} as bidentates.[10] As Yamada and Tada[5] concluded, this phenomenon indicates that most of the CO_3^{2-} as an unidentate ligand changed to a bidentate ligand when the pentaammine complexes were heated to 170 °C.

Based on the GEA curves for the cobalt(III) carbonatoammine complexes given in Fig. 2, it is confirmed that the endothermic peaks appearing on the DSC curves for the compounds obtained in the preliminary examination were caused by the evolution of water and ammonia, while, the exothermic peaks were caused by the oxidation of ammonia, with the nitrate anion as outer-ligand.

From the results described above and those obtained by earlier workers,[3,5] it may be seen that the processes of the thermal decomposition reactions of the cobalt(III) carbonatoammine complexes in a helium atmosphere take place by means of the following competition reactions:

$$[CoOCO_2(NH_3)_5]X \cdot H_2O \xrightarrow{140\text{—}170\,^\circ C} [CoCO_3(NH_3)_{4.5}]X + H_2O + 0.5NH_3$$

$$[CoCO_3(NH_3)_4]X \xrightarrow{180\text{—}200\,^\circ C} [CoXCO_3(NH_3)_3] + NH_3$$

$$[CoCO_3(NH_3)_4]X \xrightarrow{180\text{—}200\,^\circ C} \text{low ammine cobalt(II) complexes}$$

$$[CoCO_3(NH_3)_4]X \xrightarrow{200\text{—}300\,^\circ C} Co_2OX_2 + N_2 + NH_3 + CO_2$$

Since the evolution of ammonia and nitrogen during the decomposition of these compounds in the 180—250 °C temperature range was observed in these GEA curves, it may be concluded that the Co(III) in the compounds was reduced to Co(II) by ammonia, and that NH_4X was an intermediate dissociation product.

Although the peak maximum temperature is dependent upon the heating rate of the furnace, the flow rate of the carrier gas, the sample size, the furnace atmosphere, and so on, the combination of the above GEA curves with the results of TG and DTA (and DSC) studies allows a more complete interpretation of the thermal decomposition reactions of the cobalt(III) carbonatoammine complexes.

The author wishes to thank Professor Masaakira Iguchi, Tokyo University of Science, for his interest in this work, and also Dr. Hiroshi Ogino for his DSC analysis.

Electrochemical Fluorination of Thiols

Hajime BABA, Kazuo KODAIRA, Shunji NAGASE, and Takashi ABE

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received December 20, 1977)

Synopsis. Electrochemical fluorination of C_3 and C_4 thiols has been investigated. Perfluoroalkylsulfur pentafluoride derivatives including new compounds, together with fragmented fluorocarbons and sulfur hexafluoride, have been formed.

Our previous paper[1] showed that electrochemical fluorination of ethanethiol afforded a variety of fluoroalkyl sulfur compounds. As a continuation of this study, the electrochemical fluorination of C_3 and C_4 thiols including branched-chain compounds has been examined in the hope that the effects of branching on the products could be determined.

2-Propane- (I), 1-butane- (II), 2-methyl-1-propane- (III), 2-butane- (IV), and 2-methyl-2-propanethiols (V) have been subjected to the electrochemical fluorination. These were expected to yield perfluoroalkyl derivatives of sulfur hexafluoride, which have received considerable attention because of their unique inertness[2] and their usefulness as intermediates.[3]

The extensive breakdown of the thiols occurred, particularly in the carbon-sulfur bond during fluorination, and resulted in the formation of fluorocarbons and sulfur hexafluoride. Even so, a part of the starting materials was converted into the corresponding fully fluorinated analogs, perfluoroalkylsulfur pentafluorides. For example, II produced $CF_3(CF_2)_3SF_5$ (VI) in 12% yield. IV afforded a perfluoro compound which retained a sulfur pentafluoride group on the secondary carbon, $C_2F_5CF(CF_3)SF_5$[4] (VII), but the yield was poor (2%).

The physical constants and the ^{19}F and ^1H NMR spectral data of the isolated new compounds are shown in Table 1. These sulfur pentafluorides could be confirmed by their ^{19}F NMR spectra, which indicated the presence of two differently shielded types of fluorine nucleus bonded to the sulfur in the correct intensity ratio of 1 : 4 in the regions expected.[5] The molecular ion peaks for these compounds were undetectable, but such characteristic ions as $[M-SF_5]$ and $[SF_3]$ were always found.

In the electrochemical fluorination of a tertiary thiol, V, the formation of the fully fluorinated analog of the starting material could not be confirmed. It yielded the entirely rearranged products, VI and $(CF_3)_2CFCF_2SF_5$ (VIII) in low yields ($\approx$2%), together with perfluorobutane (42%) and perfluoro (2-methylpropane) (4%).

The secondary thiols also gave isomerized derivatives as well as perfluorinated analogs of the starting materials; $CF_3CF_2CF_2SF_5$ (IX), $(CF_3)_2CFSF_5$ (X), and $C_2F_5CH_2SF_5$ (XI) were isolated in the fluorination of I, and VI and VII in the fluorination of IV. The other branched-chain thiol, III, produced VIII and the straight-chain compound VI. In these cases the amounts of the straight-chain perfluoro derivatives were higher than those of the branched-chain isomers, the yields of the former being up to 12%. The isomerization by the migration of a methyl or an ethyl group located at a branching site of the chain has been observed in the electrochemical fluorination of branched organic compounds, *e.g.* amines.[6]

The low yields of the fluorinated products from the thiols may be attributable partly to the instability of the thiols in anhydrous hydrogen fluoride.[7] Considerable amounts of polymeric tarry materials and elemental sulfur were always found as deposits on the electrodes and at the bottom of the electrolytic cell.

Experimental

Materials and Apparatus. The thiols used were commercial chemicals. II (97%) contained a small amount of III. The others were more than 98% pure. The electrolytic fluorination apparatus[8] and operating procedures[1] were similar to the ones described previously. The mass spectra were recorded on a Hitachi RMU-7 instrument at 70 eV, the ^{19}F NMR spectra on a Hitachi R-20B instrument at 56.4 MHz, and the ^1H NMR spectra on a Hitachi R-22 instrument at 90 MHz.

Fluorination of 2-Propanethiol (I). I (25.0 g, 0.328 mol) was added to electrochemically purified anhydrous hydrogen fluoride (400 ml) in the cell. The resulting solution was electrolyzed under the following conditions: anodic current density, 2.6 A/dm^2 (effective surface area of anodes, 770 dm^2); cell voltage, 4.7—6.1 V; cell temperature, 8—10 °C; electricity supplied, 227 A h (670 min); helium flow rate, 60 ml/min.

The products collected in a series of cold traps immersed in ice and in liquid nitrogen were combined (71.3 g) and distilled into four fractions, and each fraction was then subjected to gas-chromatographic analysis (column: 2 m $\times$ 3 mm, silica gel; 4 m $\times$ 3 mm, Daifl oil 3 (20%) on Chromosorb P-AW). The following compounds were obtained (the compositions were calculated on the basis of the chromatographic peak areas): C_1 and C_2 fluorocarbons (0.9 g), SF_6 (18.8 g), C_3F_8 (30.1 g, 48.8%), *n*-C_4F_{10} (0.1 g), $CHF_2C_2F_5$ (1.1 g), $(CF_3)_2CHF$ (1.2 g), $CH_2FC_2F_5$ (6.4 g), $C_2H_5CF_3$ (0.9 g), $C_2F_5SF_5$ (0.2 g), IX (3.3 g, 3.4%), X (1.7 g, 1.8%), XI (0.8 g, 0.9%), others (unidentified complex mixtures, 5.6 g).

X, MS: *m/e* 169 $[M-SF_5]$, 131 $[C_3F_5]$, 127 $[SF_5]$, 119 $[C_2F_5]$, 100 $[C_2F_4]$, 89 $[SF_3]$, 70 $[SF_2]$, 69 $[CF_3]$. Found: C, 12.19; F, 76.5%. Calcd for $C_3F_{12}S$: C, 12.17; F, 77.0%. XI, MS: *m/e* 241 $[M-F]$, 191 $[M-CF_3]$, 133 $[M-SF_5]$, 131 $[C_3F_5]$, 127 $[SF_5]$, 119 $[C_2F_5]$, 113 $[C_3HF_4]$, 100 $[C_2F_4]$, 89 $[SF_3]$, 83 $[C_2H_2F_3]$, SF_2 [70], 69 $[CF_3]$. The Preparation of a Seven-Coordinate Dimethyllead(IV) Complex, $(CH_3)_2Pb(gbha)(H_2O)$, and Ionic Dissociation of the Coordinated Water

Tetsuro MAJIMA and Yoshikane KAWASAKI

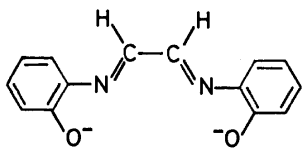
Department of Petroleum Chemistry, Osaka University, Yamadakami, Suita, Osaka 565

(Received December 22, 1977)

Synopsis. A seven-coordinate dimethyllead(IV) complex, $(CH_3)_2Pb(gbha)(H_2O)$, was prepared. From spectroscopic studies the water molecule in the complex was found to coordinate rather strongly to the lead atom as the seventh ligand. An interesting feature of the complex is that the dissociation of a proton from the coordinated water occurs in such coordinating solvents as DMSO and HMPA.

Although there are a great number of four- and six-coordinate dimethyllead(IV) complexes, seven-coordinate ones have not been reported. In a previous paper,[1] we reported on the interaction between a six-coordinate dimethyllead(IV) complex of *N,N'*-ethylenebis(salicylideneaminato); (saln), $(CH_3)_2Pb(saln)\cdot CH_3OH$, and donor-solvent molecules in solution. The formation of a seven-coordinate complex was assumed in the above experiments on the basis of the following data: 1) the $\delta(Pb-CH_3)$ value shifts to a higher magnetic field and 2) both the $^2J(^{207}Pb-CH_3)$ and $^3J(^{207}Pb-N=CH)$ values increase with an increase in the donor strength of the solvents. Similar observations have been reported for dimethyllead(IV) complexes of 8-qunolinolato,[2] β-diketonato,[3] and benzoato.[4]

We wish to report here on the first successful isolation of a seven-coordinate dimethyllead(IV) complex of bis(2-metidineaminophenolato); (gbha), $(CH_3)_2Pb(gbha)(H_2O)$; (**A**), and on the dissociation of a proton from the water molecule coordinated to the lead atom in such solvents as DMSO and HMPA.



gbha

Experimental

Preparation of $(CH_3)_2Pb(gbha)(H_2O)$. Dimethyllead dichloride was prepared by the chlorination of tetramethyllead in ethyl acetate at about −10 °C.[5] The *N,N'*-di(2'-hydroxyphenyl)-1,2-ethanediimine, H_2gbha, was prepared by a method reported previously.[6] $(CH_3)_2Pb(gbha)(H_2O)$[7] was prepared by the reaction of dimethyllead dichloride (2.5 g, 10 mmol) and Na_2gbha (Na; 0.5 g, 20 mmol and H_2gbha; 2.4 g, 10 mmol in 20 dm of methanol) in about 20 dm of methanol. The precipitates were recrystallized from a CH_2Cl_2/hexane (large excess) mixture. The complex was obtained as a black crystalline solid in a 78% yield and did not melt below 300 °C. Found: C, 38.68; H, 3.38; N, 5.77; Pb, 41.89%. Calcd for $C_{16}H_{18}N_2O_3Pb$: C, 38.94; H, 3.68; N, 5.68; Pb, 41.98%.

Measurements. The molar weight of the complex in $CHCl_3$ (0.72 wt%), established using a Mechrolab vapor-pressure osmometer at 25 °C, was found to be 514 (calcd 493). The molar conductances were measured by means of a Yokogawa F-255A Universal Bridge and a cell (cell constant; 0.377 cm^{-1}). The specific conductances of the solvents used, CH_2Cl_2, $(CH_3O)_3PO$, pyridine, DMSO, and HMPA, are $<10^{-7}$, 9.5×10^{-7}, 8.9×10^{-7}, 4.2×10^{-7}, and 4.8×10^{-7} Ω^{-1} cm^{-1} respectively.

The IR and ^1H NMR spectra of about a 4 wt% solution were recorded with a Hitachi EPI-2G Spectrophotometer and a JEOL-PS-100 Spectrometer operating at 100 MHz respectively. The chemical shifts were measured relative to TMS as an internal standard.

Results and Discussion

The ^1H NMR and IR spectral data and the molar conductance of the (**A**) complex in several solvents are summarized in Table 1. The $^3J(^{207}Pb-N=CH)$ value of the complex was observed in all the solvents. The stretching frequencies of the C–N double bond of the complex in CH_2Cl_2 (1712 cm^{-1}) and HMPA (1695 cm^{-1}) are almost the same and are different from that of free gbha (1640 cm^{-1} in Na_2gbha[8]). Therefore, gbha in the complex may be supposed to coordinate to the lead atom as an ONNO quadridentate ligand in all the solvents, according to the similar discussion of $(CH_3)_2Pb(saln)\cdot CH_3OH$.[1] The $^2J(^{207}Pb-CH_3)$ and

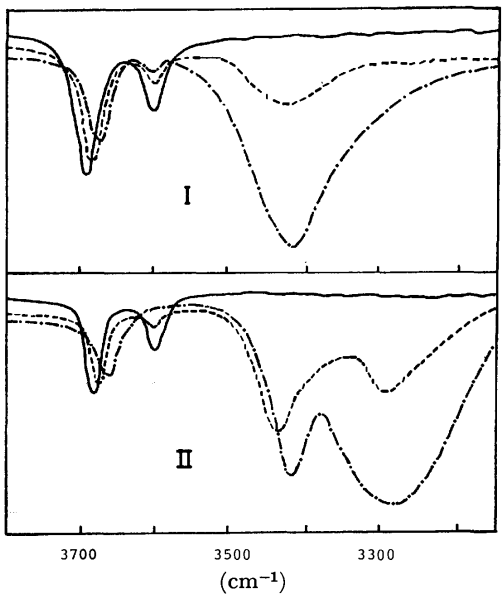


Fig. 1. IR spectra of free water molecule (I) and the gbha complex (II) in CH_2Cl_2–DMSO solutions (4 wt%). The concentration of DMSO added is 0(——), 0.8(——), and 7.8 wt%(-·-·-).

Table 1. The ^1H NMR and IR data and the molar conductance of $(CH_3)_2Pb(gbha)(H_2O)$ in several solvents

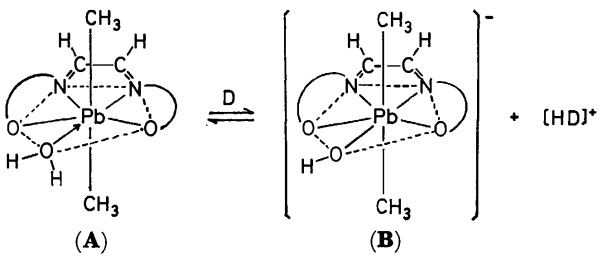
Solvent	δ(Pb–CH_3) (ppm)	δ(Pb–N=CH) (ppm)	$^2J(^{207}Pb–CH_3)$ (Hz)	$^3J(^{207}Pb–N=CH)$ (Hz)	ν(OH) (cm^{-1})	Λ_m[a] (Ω^{-1} cm^2 mol^{-1})
$CDCl_3$	1.96	8.65	176.4	37.8	—[b]	—[b]
CH_2Cl_2	1.94	8.67	178.9	37.9	3680 3600	0.1
$(CH_3O)_3PO$	1.75	8.68	177.6	36.8	3407 3270	10.0
Pyridine	1.85	8.66	180.5	38.4	3400[c] 3275	11.0
DMSO	1.68	8.84	179.0	38.0	3418 3280	15.2
HMPA	1.69	8.64	179.5	36.6	3425 3240	2.5

a) At 10^{-3} mol dm^{-3} (25±0.1 °C). b) Not measured. c) This peak may come from  .

$^3J(^{207}Pb–N=CH)$ values in $CDCl_3$ are much larger than those of $(CH_3)_2Pb(saln)\cdot CH_3OH$ with the six-coordinate structure ($^2J(^{207}Pb–CH_3)=157.8$ Hz and $^3J(^{207}Pb–N=CH)=23.4$ Hz in $CDCl_3$) and do not change even in such highly coordinating solvents as DMSO and HMPA. The $^2J(^{207}Pb–CH_3)$ value of $(CH_3)_2$-(gbha)Pb(H_2O) is similar to that of $(CH_3)_2Pb(saln)\cdot CH_3OH$ in DMSO. The above results suggest that the water molecule coordinates, as the seventh ligand, to the lead atom rather strongly in the (**A**) complex.

The IR spectrum of the (**A**) complex in CH_2Cl_2 showed two peaks, at 3680 and 3600 cm^{-1}, assigned to the O–H antisymmetric and symmetric stretching vibrations respectively. Figure 1 shows the IR spectra for free water (I) and the gbha complex (II) in CH_2Cl_2–DMSO solutions of the O–H stretching vibrational region. The frequencies and shapes of the O–H bands change continuously with the concentration of DMSO added. The changing features of the spectra for (I) and (II) are quite different and suggest that the water molecule in the complex is not free.

The molar conductance shows that the complex is an electrolyte in the coordinating solvents, but not in CH_2Cl_2 (Table 1). On the other hand, the free water does not show any electric conductivity even in DMSO and HMPA. Therefore, the appearance of the conductances in the complex suggests the presence of an ionic species, $[(CH_3)_2Pb(gbha)(OH)]^-$; (**B**), in the coordinating solvents. The values of the conductances are smaller than those for usual 1:1 electrolytes (for example, 25—40 Ω^{-1} cm^2 mol^{-1} for 1:1 electrolytes in DMSO at a concentration of *ca.* 10^{-3} mol dm^{-3} [9]). Consequently, the following equilibrium may occur in coordinating solvents, in which the dissociation of a proton takes place instead of the replacement of the coordinated water molecule by a solvent molecule. The existence of the anionic hydroxo complex (**B**) and the protonated solvent molecule ($[HD]^+$) is substantiated by the appearance of two peaks (at *ca.* 3270 and *ca.* 3400 cm^{-1}) in the IR spectra of the complex in coordinating solvents.



(**A**) (**B**)

D=HMPA, DMSO, pyridine, $(CH_3O)_3PO$.

In the conclusion, $(CH_3)_2Pb(gbha)(H_2O)$ may be supposed to take the seven-coordinate structure (**A**), with the water molecule coordinating to the lead atom rather strongly in non-coordinating solvents. On the other hand, in coordinating solvents, a partial dissociation of a proton from the coordinated water occurs, resulting in an equilibrium between **A** and the ionic species **B** and $[HD]^+$.

Magnetic Circular Dichroism Spectra of Amino Acid Complexes of the $[Co^{III}(N)_5(O)]^{n+}$ Type

Etsuyo UEDA, Nobuko MATSUOKA,* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received February 7, 1978)

Synopsis. MCD spectra of amino acid complexes of $[Co(NH_3)_5(OCOCHRNH_3)]^{3+}$, $[Co(NH_2CHRCO_2)(NH_3)_4]^{2+}$, and $[Co(NH_2CHRCO_2)(en)_2]^{2+}$ types have been measured. The complexes belonging to a given type show nearly identical MCD curves irrespective of variation in their natural CD patterns. The complexes of D-, L-, and DL-alanine show identical MCD spectra.

In connection with our previous study[1] on magnetic circular dichroism (MCD) spectra of a series of racemic tris(chelate)cobalt(III) complexes, it seems worthwhile to investigate MCD spectra of optically active cobalt(III) complexes. Larcher and Gabriel compared MCD spectra of mono- and bis(L-valinato)nickel(II) complexes with their natural CD spectra.[2] We have made a comparison of the MCD and natural CD spectra of α-amino acid complexes of the $[Co^{III}(N)_5(O)]^{n+}$ type, the result of which are reported here. The complexes studied are classified into three types, namely, a pentaammine type $[Co(NH_3)_5(OCOCHRNH_3)]^{3+}$, in which the carboxylate end of amino acid ligand is attached to the central cobalt ion,[3] and a tetraammine and a bis(ethylenediamine) type, $[Co(NH_2CHRCO_2)(NH_3)_4]^{2+}$ and $[Co(NH_2CHRCO_2)(en)_2]^{2+}$, which contain the amino carboxylato ligand as chelate one. The natural CD spectra of a large part of these complexes were investigated previously in our laboratory.[4] The following abbreviations are used for the amino acid ligands: Hgly for glycine, Hala alanine, Hser serine, and Hphe phenylalanine.

Experimental

Preparations. The pentaammine (chloride or perchlorate) and tetraammine (sulfate) complexes were prepared by the methods described in previous papers.[3-5] The bis(ethylenediamine) complexes were prepared as follows.

$[Co(gly)(en)_2]Br_2 \cdot H_2O$ and $[Co(DL\text{-}ala)(en)_2]Br_2 \cdot H_2O$: A solution containing glycine (0.4 g) (or DL-alanine, 0.5 g) and $[Co(NH_3)(en)_2(OH_2)]Br_3$ (2.5 g) in 20 cm³ of water was evaporated together with powdered activated charcoal (0.1 g) to about 5 cm³ at 80 °C on a water-bath. The solution was cooled to room temperature, filtered, and 1 cm³ of methanol was added. After mixture was kept in a refrigerator overnight, the orange red deposit was filtered, washed with methanol and ether, and dried in air. The crude complex was dissolved in 5 cm³ of water (*ca.* 50 °C). The solution was filtered, and kept in a refrigerator overnight after 3 cm³ of methanol had been added. The crystalline powder deposited was filtered, washed with methanol and ether, and dried in air. The pure complex was obtained by repeated crystallizations. Found: C, 16.93; H, 5.28; N, 16.50%. Calcd for $C_6H_{20}N_5O_2Br_2Co$ H_2O: C, 16.72; H, 5.14; N, 16.25%. Found: C, 18.60; H, 5.44; N, 15.53%. Calcd for $C_7H_{22}N_5O_2Br_2Co \cdot H_2O$: C, 18.89; H, 5.44; N, 15.74%.

Measurements. The CD and MCD spectra were recorded with a JASCO MOE-1 spectropolarimeter. The MCD measurements were made in a magnetic field of 1.5 T(= 15000 G). The MCD intensity is expressed in terms of the molar circular dichroism per unit magnetic field in the direction of the light beam, $\Delta\varepsilon_M$, which has the units of $cm^{-1} \cdot mol^{-1}\ dm^3\ T^{-1}$. The visible and near-ultraviolet absorption spectra were measured using a Shimadzu UV-200 spectrophotometer. All measurements were made at room temperature in aqueous solutions.

Results and Discussion

Figure 1 shows the observed curves of absorption, natural CD and MCD spectra of $[Co(NH_3)_5(L\text{-}Hala)]^{3+}$ and the related complexes. The MCD spectrum of the optically active complex is observed in overlap with the natural CD. Therefore the true MCD spectrum ($\Delta\varepsilon_M$ curve) was obtained by calculating the difference between the observed MCD and the natural CD curves, assuming that the natural CD and MCD are additive. The MCD spectra which are obtained in this manner are shown in Fig. 2. The MCD extremum data of the complexes studied are shown in Table 1. It is most

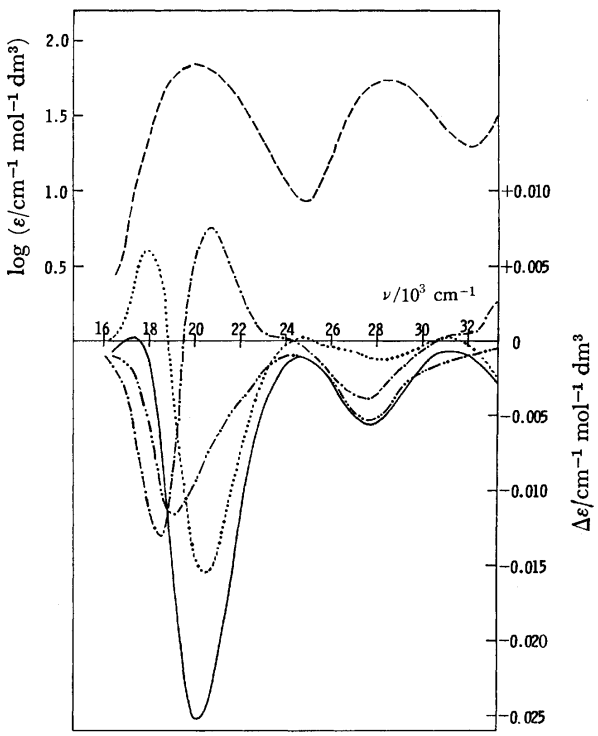

Fig. 1. The absorption (——) and CD (·····) spectra of $[Co(NH_3)_5(L\text{-}Hala)]^{3+}$, and overlapped curves of CD and MCD in a magnetic field of 1.5 T of $[Co(NH_3)_5(L\text{-}Hala)]^{3+}$ (——), $[Co(NH_3)_5(D\text{-}Hala)]^{3+}$ (—·—), and $[Co(NH_3)_5(DL\text{-}Hala)]^{3+}$ (-··-).

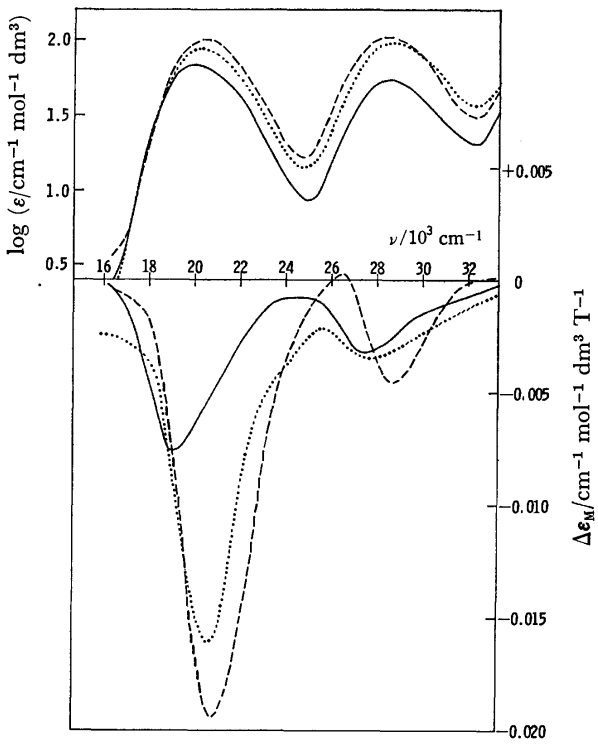

Fig. 2. The absorption and MCD spectra of $[Co(NH_3)_5$-(L-Hala)]$^{3+}$ (——), $[Co(L\text{-ala})(NH_3)_4]^{2+}$ (·····), and $[Co(DL\text{-ala})\ (en)_2]^{2+}$ (----).

remarkable that the D-, L- and DL-alanine complexes show strictly identical MCD spectra.

The MCD spectra of all the pentaammine type complexes are very similar, *viz.*, a negative band which may be mainly due to Faraday B term appears each in the first and the second absorption band region. Such a behavior in MCD is quite different from that in natural CD, which show a variety of patterns.[4] The natural CD curve of $[Co(NH_3)_5(L\text{-Hala})]^{3+}$ has two extrema, 18000 (+0.005) and 20600 cm^{-1} (−0.015), in the first d-d band region. In the same region the tetraammine complex $[Co(L\text{-ala})(NH_3)_4]^{2+}$ has three extrema, 18200 (−0.036), 19700 (+0.11), and 21900 cm^{-1} (−0.32). The $\Delta\varepsilon_M$ intensity in the first d-d band region is greater than that in the second band region as was also observed for tris(chelate) complexes.[1] The intensity increases in the order of pentaammine< tetraammine<bis(ethylenediamine) in both first and second band regions; this order is parallel to the increase of absorption intensity.

The pentaammine complex ion belongs approximately to the C_{4v} symmetry, and in the first absorption band region two components, $^1E \leftarrow {}^1A_1$ and $^1A_2 \leftarrow {}^1A_1$, are expected in 19600 and 21000 cm^{-1}, respectively, as is seen in Table 2. The observed MCD peak is located at 19100 cm^{-1}. Therefore the MCD peak is primarily due to the Faraday B term of the E transition. The fact that the peak is in longer wavelength than the expected position of the E transition may be rationalized in terms of the swamping of the Faraday A term having a negative wing in the longer wavelength region. In the tetraammine and bis(ethylenediamine) complexes the longer wavelength component (^1E in C_{4v} symmetry)

a) The complex of D or DL ligand also shows the identical spectra. b) The L-leucine and L-threonine complexes show the MCD spectra nearly identical to that of the L-serine complex. c) The L-valine and L-proline complexes show the MCD spectra nearly identical to that of the L-phenylalanine complex.

Table 2. Splitting of the first d-d band

Complex	Calcd position of component a)			MCD peak observed
	$E(C_{4v})$	$A_2(C_{4v})$	Weighted mean	
$[Co(NH_3)_5(OCOCHRNH_3)]^{3+}$	19.6	21.0	20.1	19.1
$[Co(NH_2CHRCO_2)(NH_3)_4]^{2+}$	19.8, 19.9	21.1	20.3	20.4
$[Co(NH_2CHRCO_2)(en)_2]^{2+}$	20.1, 20.1	21.4	20.5	20.8

a) The following values of Yamatera's parameters[6] are used: $\delta(NH_3)=0$ (the first band of hexaammine complex is in 21000 cm^{-1}), $\delta(en)=\delta$(N, amino carboxylate) = +400 cm^{-1}, δ(O, chelated amino carboxylate) = −4660 cm^{-1}, and δ(O, unidentate amino acid) = −5500 cm^{-1}, the latter two values of which were calculated from the data of the $E_g(D_{4h})$ bands of *trans*(*O*)-$[Co(gly)_2(en)]^+$ (18870 cm^{-1}) and *trans*(*O*)-$[Co(en)_2(L\text{-Hala})_2]^{3+}$ (18450 cm^{-1}).

splits into two components by the lowering of symmetry, and the Faraday A term is not expected. The MCD peaks of complexes of these types appeared near the mean position of the split components as is seen in Table 2. Thus it is concluded that the negative MCD peaks of these complexes are mainly due to the composed B terms of split components.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (6), 1897—1898 (1978)

Esterification of *N*-(Benzyloxycarbonyl)amino Acids and Amino Acids Using BF_3-Etherate as Catalyst

Takashi YAMADA, Nobuyuki ISONO,* Akemi INUI, Toshifumi MIYAZAWA, Shigeru KUWATA, and Hiroshi WATANABE

Laboratory of Chemistry, Faculty of Science, Kōnan University, Okamoto, Higashinada-ku, Kobe 658

(Received August 16, 1977)

Synopsis. Methyl and ethyl esters of *N*-(benzyloxycarbonyl)amino acids were prepared conveniently in good yields using BF_3-etherate as catalyst. Esterification of free amino acids was also examined.

Methyl or ethyl esters of *N*-(benzyloxycarbonyl)amino acids are useful intermediates not only for the peptide syntheses,[1] but also for the preparation of amino aldehydes[2,3] *etc.* While these compounds are usually prepared by benzyloxycarbonylation of amino acid esters, esterification of *N*-(benzyloxycarbonyl)amino acids is also useful and often affords better results than the former.[2] In the latter category, methylation with diazomethane is most widely used. The reagent is, however, highly toxic and known to react with phenol as well as carboxylic acid. Therefore, it is still unsuitable for the large scale preparation. Recently, Meienhofer and his co-workers[4] reported the facile syntheses of

a) Diester.

protected amino acid esters by alkylating their cesium salts.

In another attempt at finding a mild esterification method, we thus utilized the reaction of carboxylic acid with alcohol, using boron trifluoride–etherate as catalyst, which was reported by Kadaba and his coworkers.[5] This method has previously been applied to the preparation of ε-*N*-benzyloxycarbonyl-L-lysine ester by Coggins *et al.*[6] We could successfully extend this method to the esterification of a series of *N*-(benzyloxycarbonyl)amino acids. The results thus obtained are summarized in Tables 1 and 2. The method was very convenient and required neither special apparatus nor complicated manipulation: the alcoholic solution of *N*-(benzyloxycarbonyl)amino acid was refluxed for a short time in the presence of boron trifluoride–etherate. But the reactions of histidine and arginine were exceptionally slow (6 h-reflux was required) and the latter ester was isolated as boron trifluoride salt after the usual work-up.

Moreover, we tried to apply this method to free amino acids. The results are summarized in Table 3. While the results were not as good as in the cases of the *N*-protected amino acids, some lipophilic amino acids gave good results. It should be noted here that washing with water or a saturated aqueous sodium chloride solution, after neutralization of the reaction product, should be avoided, because any washing process markedly decreased the yield and the omission of this process had no influence upon the purity of the ester.

Experimental

The melting points are uncorrected. Optical rotations were measured on a Yanagimoto Polarimeter OR-10 for 1% solutions in methanol at 20 °C unless otherwise stated. The amino acids used in this experiment, except glycine, are all of L-configuration.

Esterification of N-*(Benzyloxycarbonyl)amino Acid.* A solution of *N*-(benzyloxycarbonyl)amino acid (4.76 mmol) in absolute methanol or ethanol (20 ml) was refluxed for 1 h in the presence of BF_3–etherate (10 mmol, 2.1 equivalent). After the solvent was evaporated, the residue was treated with ice–water (40 ml), and extracted with ethyl acetate. The extract was successively washed with water, 1M aqueous sodium hydrogencarbonate solution, and water, and dried over anhydrous sodium sulfate. After removal of the solvent under reduced pressure, almost analytically pure ester was obtained.

Esterification of Amino Acid. A mixture of a finely ground amino acid (2 mmol) and BF_3–etherate (10 mmol) in absolute methanol was refluxed for 24 h. After removal of the solvent, the residue was dissolved in ethyl acetate or ether, neutralized with a saturated aqueous solution of potassium carbonate, and dried over anhydrous sodium sulfate for 1 h. Into this solution was added *p*-toluenesulfonic acid (2 mmol) in ethyl acetate. After 1 h the separated crystals were collected.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (6), 1899—1900 (1978)

Resolution of α-Formyl-ε-acyl-DL-lysines by Acylase

Yoshihiro MINEMATSU, Yasuyuki SHIMOHIGASHI, Michinori WAKI, and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science 33, Kyushu University, Higashi-ku, Fukuoka 812

(Received August 16, 1977)

Synopsis. Taka-acylase hydrolyzed an α-formyl derivative of ε-acyl-L-lysine faster than the corresponding α-acetyl derivative. Preparative resolution by crude Taka-acylase afforded ε-formyl or ε-benzyloxycarbonyl-L-lysine from the corresponding α-formyl-ε-acyl-DL-lysine. The action of *p*-toluenesulfonic acid on α-formyl-ε-benzyloxycarbonyl-D-lysine under mild conditions afforded pure ε-benzyloxycarbonyl-D-lysine.

Many ε-acyl-L-lysines have been prepared by enzymatic resolution. For example, Chibata *et al.* prepared ε-benzoyl-L-lysine by the resolution of α-Ac-ε-benzoyl-DL-lysine[1] with Taka-diastase,[2] and Izumiya *et al.* ε-benzoyl-L-lysine from ε-benzoyl-DL-lysinamide by hog kidney amidase.[3] From recent findings that For-L-phenylalanine is hydrolyzed most rapidly among series of acyl-L-phenylalanines by Taka-acylase, we have undertaken the resolution of α-For-ε-acyl-DL-lysines by crude Taka-acylase. α,ε-Diformyl-DL-lysine was prepared by the action of formic anhydride[4] on free DL-lysine, and α-For-ε-Z-DL-lysine by that on ε-Z-DL-lysine.

Prior to the preparative resolution of α-For-ε-acyl-DL-lysines, their optimum pH values were determined by using reference compounds such as α-Ac-ε-Z-DL-lysine and Ac-DL-phenylalanine (Table 1). The hydrolytic rates of α-formyl derivatives and reference compounds at various concentrations were determined at each optimum pH, the relative hydrolytic rates at 0.005 M concentration being given in Table 1. The results indicate that α-For-ε-Z-L-lysine is more susceptible than the corresponding α-acetyl derivative. Although α,ε-diformyl-L-lysine is less susceptible than α-For-ε-Z-L-lysine, the resolution of α,ε-diformyl-DL-lysine might be achieved with a slightly increased amount of crude Taka-acylase. Actually, ε-For(or Z)-L-lysine and α-For-ε-For(or Z)-D-lysine were isolated in good yields from the incubation mixture of α-For-ε-For(or Z)-DL-lysine (see Experimental).

We have attempted selective removal of formyl group by a solution-phase procedure. α-For-ε-Z-D-lysine dissolved in aqueous dioxane was treated with one equivalent of *p*-toluenesulfonic acid at 50 °C, the reaction mixture being examined by TLC at selected intervals. After *ca.* 6 h an α-formyl group in the compound was removed, the ε-benzyloxycarbonyl group remaining intact. Wünsch and Fürst reported that by heating a suspension of α-For-*O*-benzyl-D-serine in 1 M hydrobromic acid until dissolution, *O*-benzyl-D-serine was isolated.[5]

Table 1. Optimum pH and relative hydrolytic rate of α-acylamino acids by crude Taka-acylase

Substrate[a]	Optimum pH	Relative hydrolytic rate
Ac-DL-Phe-OH	7.5	1.0
For-DL-Lys(For)-OH	7.1	1.25
For-DL-Lys(Z)-OH	7.4	2.9
Ac-DL-Lys(Z)-OH	7.6	0.72

a) Substrate concentration in respect to L-form, 0.005 M.

Experimental

The amino acid derivative was determined with a Hitachi amino acid analyzer KLA-5 with spherical resin under the following conditions: flow rate, 30 ml/h; jacket temperature, 55 °C.

For-DL-Lys(For)-OH. DL-Lysine monohydrochloride (3.65 g, 0.02 mol) dissolved in water (15 ml) was put on a column (2×10 cm) of Dowex 50X8 (H^+ form). The column was washed with water and eluted with 2 M NH_4OH (80 ml). The eluate was evaporated *in vacuo*. Evaporation was repeated several times by addition of water, and the residue was dissolved in 99% formic acid (84 ml). Acetic anhydride (28 ml, 0.28 mol) was added to the solution at 0 °C under stirring . After being stirred at 0 °C for 2 h and at room temperature overnight, the solution was evaporated, and the residual solid was recrystallized from EtOH–acetone; yield, 2.71 g (67%); mp 143—144 °C.

Found: C, 47.27; H, 6.96; N, 13.54%. Calcd for $C_8H_{14}O_4N_2$: C, 47.52; H, 6.98; N, 13.86%.

For-DL-Lys(Z)-OH. H-DL-Lys(Z)-OH[6] (0.02 mol) in 99% formic acid (42 ml) was treated with acetic anhydride (0.14 mol) as described above. The residual solid was recrystallized from EtOH–water; yield, 88%; mp 116—117 °C.

Found: C, 58.33; H, 6.56; N, 9.00%. Calcd for $C_{15}H_{20}O_5N_2$: C, 58.43; H, 6.54; N, 9.09%.

Ac-DL-Lys(Z)-OH. This was prepared by the following procedure in a better yield than in the previous synthesis, in which H-DL-Lys(Z)-OH was treated with acetic anhydride and sodium hydroxide.[6] A suspension of H-DL-Lys(Z)-OH (0.01 mol) in AcOH (10 ml) and acetic anhydride (0.014 mol) was refluxed for 10 min. The resulting solution was evaporated, evaporation being repeated several times by addition of water. The residual solid was recrystallized from EtOH–water; yield, 89%; mp 115—116 °C. Reported values; yield, 66%; mp 114 °C.[6]

Crude Taka-acylase. This was prepared by a procedure almost the same as that of Shimohigashi *et al.*[7] Takadiastase powder (200 g) was suspended in water (1100 ml), the insoluble material being filtered off at 0 °C. The filtrate was treated with $(NH_4)_2SO_4$ (165 g, 0.26 saturation) and centrifuged at 0 °C. The supernatant phase was brought to 0.85 saturation with $(NH_4)_2SO_4$ (375 g) and centrifuged. The sediment was suspended in 30% acetone (400 ml) at −5 °C and the suspension was centrifuged. The sediment was dissolved in a small amount of water, dialyzed, and lyophilized; yield of crude Taka-acylase, 1.21 g.

Determination of Optimum pH. To a solution of acyl-DL-amino acid (0.02 mmol) and 0.1 M NaOH (0.2 ml) in a 2-ml flask were added 1/7 M sodium barbital buffer (1 ml) with a specified pH, 1/80 M $CoCl_2$ (0.2 ml), and an aqueous enzyme

solution (0.2 ml) containing a specified weight. The solution was made up to 2.0 ml with water. The reaction mixture was incubated at 38 °C, an aliquot being withdrawn after 1 h. Appearance of L-amino acid was determined with an amino acid analyzer: column, 0.6×10 cm; buffer, standard 0.2 M sodium citrate at pH 3.25 for H-L-Lys(For)-OH, pH 4.25 for H-L-Phe-OH, and pH 5.28 for H-L-Lys(Z)-OH. Calculation of each L-amino acid produced was made on the basis of the color value determined for the corresponding authentic amino acid with the analyzer.

Determination of Relative Hydrolytic Rate of α-Acylamino Acids by Taka-acylase. A mixture of an acyl-DL-amino acid (0.02 mmol), 0.1 M NaOH (0.2 ml), 1/7 M sodium barbital buffer (1 ml) at optimum pH, 1/80 M $CoCl_2$ (0.2 ml) and an aqueous enzyme solution (0.2 ml) was made up to 2.0 ml with water. The rate of hydrolysis at 38 °C was followed by the analyzer under the conditions described above. The hydrolysis of substrates followed zero-order kinetics within experimental error. The relative hydrolytic rate was calculated by taking the hydrolytic rate of Ac-L-phenylalanine as 1.0.

Resolution of For-DL-Lys(For)-OH. H-L-Lys(For)-OH: For-DL-Lys(For)-OH (2.02 g, 10 mmol) was dissolved in aqueous triethylamine, the pH being adjusted to 7.1. To the solution were added crude Taka-acylase (80 mg), 1/80 M $CoCl_2$ (100 ml), and water. The solution (1000 ml) was left to stand at 38 °C, the pH of the solution being adjusted occasionally to 7.1. After 3 days, pH of the solution was adjusted to 5 with formic acid. A small amount of Norit was added, and the mixture was maintained at 50—60 °C for 10 min. To the filtrate was added Dowex 50X8 (H^+ form) (20 ml) at 0 °C. After a few minutes, the resin was collected and washed with cold water (the combined filtrates were used for the preparation of For-D-Lys(For)-OH). The resin was suspended in 2 M NH_4OH (60 ml) and stirred at room temperature for a few minutes. The filtrate was evaporated, and the residual solid was recrystallized from water–EtOH; yield, 0.79 g (91%); $[\alpha]_D^{20}$ +13.9° (*c* 2, saturated $NaHCO_3$). Reported value; $[\alpha]_D^{26}$ +15.5° (saturated $NaHCO_3$).[8]

For-D-Lys(For)-OH: The combined filtrates obtained above were evaporated, and the residual solid was recrystallized from water–acetone; yield, 0.80 g (75%); mp 119—121 °C; $[\alpha]_D^{20}$ +3.3° (*c* 2, H_2O).

Found: C, 45.64; H, 6.85; N, 13.14%. Calcd for $C_8H_{14}O_4N_2 \cdot 1/2H_2O$: C, 45.49; H, 7.16; N, 13.27%.

H-L-Lys-OH·HCl: To a solution of H-L-Lys(For)-OH (1 mmol) in a mixture (5 ml) of dioxane–water (1: 1, v/v) was added TosOH·H_2O (1.1 mmol). After being left to stand at 50 °C for 10 h, the solution was treated with 2 ml of Dowex 50X8 (H^+ form). The resin was eluted with 2 M NH_4OH. The eluate was evaporated, and the residue was dissolved in water, the pH being adjusted to 7 with 1 M HCl. The solution was evaporated, and the residual solid was recrystallized from water–EtOH; yield, 94%; $[\alpha]_D^{20}$ +20.8° (*c* 2, 5 M HCl). Reported value, $[\alpha]_D^{15}$ +20.5° (5 M HCl).[3]

H-D-Lys-OH·HCl: This was prepared from For-D-Lys-(For)-OH (0.5 mmol) with TosOH·H_2O (1.1 mmol) as described above; yield, 77%; $[\alpha]_D^{20}$ −20.1° (*c* 2, 5 M HCl).

Resolution of For-DL-Lys(Z)-OH. H-L-Lys(Z)-OH: For-DL-Lys(Z)-OH (0.77 g, 2.5 mmol) was dissolved in aqueous triethylamine, the pH being adjusted to 7.4. To the solution were added crude Taka-acylase (16 mg), 1/80 M $CoCl_2$ (25 ml), and water. After the solution (250 ml) had been left to stand at 38 °C for 3 days, the precipitate formed was collected and washed with water, and the combined filtrates were evaporated to a small volume. 6 M HCl was added to the solution until it reached a pH of 3. An oily product was extracted with EtOAc. The extract was used for the preparation of For-D-Lys(Z)-OH. The aqueous layer and the above precipitate dissolved in a small volume of 1 M HCl were put on a column (2.2×5 cm) of Dowex 50X8 (H^+ form). The column was eluted with 2 M NH_4OH (30 ml). The eluate was evaporated, and the residue was recrystallized from water–EtOH; yield; 0.28 g (80%); mp 233—235 °C (dec); $[\alpha]_D^{20}$ +16.7° (*c* 1, 5 M HCl). Reported value; $[\alpha]_D$ +17.3° (2 M HCl).[9]

For-D-Lys(Z)-OH: The extract obtained above was dried (Na_2SO_4) and evaporated. The residual solid was recrystallized from EtOH–water; yield, 0.31 g (79%); mp 93—95 °C; $[\alpha]_D^{20}$ −10.7° (*c* 2, EtOH). Reported values for the L-isomer; mp 74—78 °C; $[\alpha]_D^{24}$ +9.6° (EtOH).[8]

H-D-Lys(Z)-OH: To a solution of For-D-Lys(Z)-OH (0.3 mmol) in a mixture (10 ml) of dioxane–water (9: 1, v/v) was added TosOH·H_2O (0.33 mmol). After being left to stand at 50 °C for 6 h, aqueous triethylamine was added to the solution until its pH became 7, and the solution was evaporated. The residual solid was recrystallized from water–EtOH; yield, 75%; $[\alpha]_D^{20}$ −16.4° (*c* 1, 5 M HCl). Reported value for the L-isomer; $[\alpha]_D$ +17.3° (2 M HCl).[9]

Studies of Quinazoline Pigments. II. Synthesis of Dimethyl Substituted Pyrido[2,1-*b*]pyrido[1′, 2′: 1, 2]pyrimido-[4,5-*g*]quinazoline-7,15-diones

Yasukazu YOKOYAMA

Central Research Laboratory, Toyo Soda Manufacturing Co., Ltd., Tonda, Shin-nanyo-shi, Yamaguchi 746

(Received October 17, 1977)

Synopsis. In the presence of alkali, 4,12-, 3,11-, 2,10-, and 1,9-dimethyl derivatives of 6, 14-dihydropyrido-[2,1-*b*]pyrido[1′,2′:1,2]pyrimido[4,5-*g*]quinazoline-7,15-dione reacted with nitrobenzene to give 2,5-bis(3-, 4-, 5-, and 6-methyl-2-pyridylamino) terephtharic acids. The intramolecular cyclization of 3-, 4-, and 5-methyl derivatives, gave 4,12-, 3,11-, and 2,10-dimethylpyrido[2, 1-*b*]pyrido[1′,2′: 1,2] pyrimido[4, 5-*g*]quinazoline-7,15-dione respectively, but the 6-methyl derivative did not give any cyclization product. The synthesis of the 1,9-dimethyl derivative was accomplished by the dehydrogenation of 1, 9-dimethyl-6, 14-dihydropyrido-[2,1-*b*]pyrido[1′,2′: 1,2]pyrimido[4,5-*g*]quinazoline-7, 15-dione with *p*-chloranil.

Recently, pyrido[2,1-*b*]pyrido[1′,2′: 1,2]pyrimido-[4,5-*g*]quinazoline-7,15-diones (**1**) have been reported to be valuable red pigments with excellent light-fastness and good tinctorial strength, but their published chemistry is still very limited. Although Wiedemann mentioned the synthesis of **1** by the dehydrogenation of 6, 14-dihydropyrido [2, 1-*b*] pyrido [1′, 2′: 1, 2] pyrimido-[4, 5-*g*] quinazoline-7, 15-diones (**2**), he reported no details.[1]

In our previous paper, we described that the dehydrogenation of **2a** with a nitro compound in the presence of alkali is accompanied by ring opening to give 2,5-bis(2-pyridylamino)terephthalic acid (**3a**), which is then cyclized by treatment with acid to form **1a**.[2] This paper will describe the dehydrogenation of **2b**—**e** under alkali conditions to give **1b**—**e**.

Results and Discussion

Diethyl 2,5-dioxocyclohexane-1,4-dicarboxylate reacts with 2-aminopyridine or substituted 2-aminopyridines under acid catalysis to give **2**.[1,3] In glacial acetic acid, **2a** was obtained in an 80% yield, but the yields of **2b**—**d** were 50—65%. In the case of **2e**, under the same reaction conditions, only a 16% conversion was observed (Table 1). The low yield of **2e** is attributable to the steric hindrance of the methyl group.

The reactions of **2b**—**d** with nitrobenzene in the

a) Measured in CF_3COOH, with TMS as the internal standard. b) **3a**—**d**: in CD_3OD–NaOD; internal standard: TMS, **3e**: in D_2O–NaOD; internal standard: TSP. c) In overall yield from **2**.

presence of alkali gave **3b—d**, which cyclized easily to **1b—d** under acidic conditions. Since **3e** was not cyclized to **1e** under the same conditions, the synthesis of **1e** was achieved by heating **2e** with chloranil in glacial acetic acid. Some pertinent data on **1**, **2**, and **3** are compared in Table 1.

The hydrolytic ring opening of **1e** took place both in aqueous sulfuric acid and in alkali. On the other hand, **1a—d** were hydrolyzed in aqueous alkali, but not in acid. The ring opening of the same ring system has been studied. That is, it has been reported that the ring opening of 3-ethoxycarbonyl-6-methylpyrido[1,2-*a*]-pyrimidin-4-one is accelerated by the methyl group at the 6-position.[4]

Compounds **1b—e** are red to orange crystals, soluble in aqueous sulfuric acid but only sparingly soluble in organic solvents.

Experimental

The IR spectra were taken with a Shimadzu IR-27G spectrophotometer, while the NMR spectra were determined with a Varian HA-100 high-resolution NMR spectrometer.

*6,14-Dihydropyrido[2,1-*b*]pyrido[1',2': 1,2]pyrimido[4,5-*g*]quinazoline-7,15-diones (**2**).* The reactions of diethyl 2,5-dioxocyclohexane-1,4-dicarboxylate and 2-aminopyridines were carried out according to the methods reported by Wiedemann[1] and the products, **2a—e**, were characterized in the way described in the literature.[2] The yields of **2a—e** are listed in Table 1.

*Dimethylpyrido[2,1-*b*]pyrido[1',2': 1,2]pyrimido[4,5-*g*]quinazoline-7,15-diones (**1b—e**).* *a*): A mixture of 5.0 g of **2b**, 5.0 g of sodium *m*-nitrobenzenesulfonate, 10 g of a 50 wt% aqueous sodium hydroxide solution, and 100 ml of ethylene glycol was placed in a 500-ml round-bottomed flask equipped with a reflux condenser and a mechanical stirrer. The mixture was boiled and stirred under reflux for 2 h. The reaction mixture was allowed to cool to about 60 °C, diluted with 300 ml of cold water, and then neutralized with aqueous sulfuric acid. Pale yellow solids were collected on a filter, washed with water, and dried at 60 °C. IR, NMR, and analytical data are summarized in Table 1. These results proved that this compound was 2,5-bis(3-methyl-2-pyridylamino)terephthalic acid (**3b**).

Into 100 ml of 0.5 M-sulfuric acid, 5 g of **3b** was added after which the mixture was heated at 70—80 °C for 1 h. After cooling, the precipitate was collected by filtration, washed with water, and dried. The red product thus obtained was identified as **1b** on the basis of its IR, NMR, and analytical data. The total yield of **1b** was 3.8 g (76%).

Compounds **3c—e** were also obtained under the same reaction conditions. Compounds **3c—d** cyclized to give **1c—d**, except for **3e**. The yields, products, and analytical data for all the runs are listed in Table 1.

b): A mixture of **2e** (15 g) and chloranil (12 g) was refluxed in glacial acetic acid (300 ml) for 2 h. After the reaction mixture had been cooled, the resulting crystals were collected by filtration and dispersed in 300 g of a 2 wt% aqueous sodium hydroxide solution. The dispersion was filtered, and the resulting reddish orange crystals were thoroughly washed with water and dried to obtain 10.3 g of **1e**. Its IR, NMR, and analytical data are shown in Table 1.

*Ring Opening of **1a—e** (General Method).* Compound **1a** (5.0 g) was heated in a 1 M aqueous sodium hydroxide solution (100 ml) for 3 h. Then the solution was neutralized with aqueous sulfuric acid. The precipitated **3a** (5.3 g) was filtered off as pale yellow crystals.

Studies on Nucleosides and Nucleotides. VI.[1] A Facile Cleavage of the Anhydro Bond of 2′,3′-*O*-Isopropylidene-O^2,5′-cyclouridine with the Use of Proton Acid or Lewis Acid

Junji KIMURA and Oyo MITSUNOBU

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received November 9, 1977)

Synopsis. When 2′,3′-*O*-isopropylidene-O^2,5′-cyclouridine (**1**) was allowed to react with methanol in the presence of *p*-toluenesulfonic acid at room temperature, 5′-*O*-methyl-2′,3′-*O*-isopropylideneuridine was obtained in good yield. Similarly, with the use of boron trifluoride etherate, **1** reacted smoothly with diphenyl phosphate to give the corresponding 5′-phosphorylated product.

Cyclonucleosides are versatile reagents for the synthesis of nucleoside derivatives.[2] Except for a few cases, however, the reactions of cyclonucleosides with nucleophiles were carried out under rather drastic conditions.[3] It is, therefore, of interest to find out the conditions under which the anhydro bond of cyclonucleosides easily cleaves.[4]

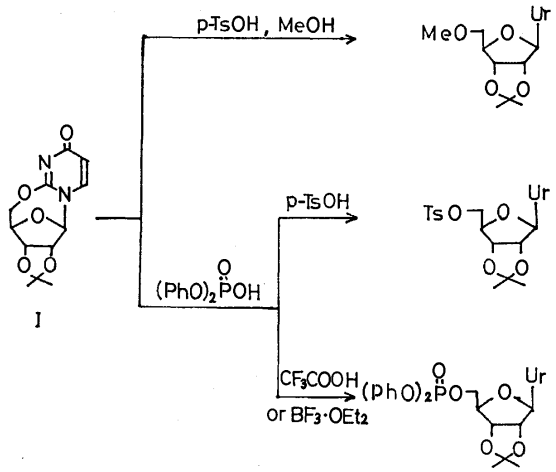
We wish to report herewith a facile cleavage of 2′,3′-*O*-isopropylidene-O^2,5′-cyclouridine by nucleophiles in the presence of a proton acid or Lewis acid.

It is known that the cleavage of O^2,5′-cyclouridine occurs in two directions. As an example, 2′,3′-*O*-isopropylidene-O^2,5′-cyclouridine (**1**) reacts with methanol to form O^2-methyl-2′,3′-*O*-isopropylideneuridine.[5] On the other hand, it reacts with phosphate ester to give 5′-phosphorylated uridine.[3a,b]

These results suggest that, when N^3-position of uracil moiety is first protonated, 5′-substituted uridines are predominantly formed. For the sake of clarification, we examined the reaction of **1** with methanol in the presence of a proton acid.

When a solution of **1** in dry methanol was stirred with an equimolar amount of *p*-toluenesulfonic acid at room temperature for 1 day, 5′-*O*-methyl-2′,3′-*O*-isopropylideneuridine[6] was obtained as expected in 80% yield. The 5′-*O*-tosyl-2′,3′-*O*-isopropylideneuridine was treated with methanol at room temperature for 1 day. The starting material was recovered quantitatively. The possibility of intermediary formation of the tosylate in the above reaction was thus ruled out. The reaction seems to proceed through initial protonation of uracil moiety followed by the attack of methanol on the 5′-carbon atom.

The reaction was further applied to phosphorylation of uridine. When **1** was reacted with diphenyl phosphate in the presence of *p*-toluenesulfonic acid in tetrahydrofuran (THF) at room temperature, 5′-*O*-tosyl-2′,3′-*O*-isopropylideneuridine[7] was unexpectedly obtained in 81% yield. On the other hand, when the reaction was carried out in the presence of trifluoroacetic acid, 2′,3′-*O*-isopropylideneuridine 5′-(diphenyl)phosphate (**2**) was isolated in 58% yield. The yield of **2** increased to 77%, when a solution of **1** and diphenyl phsophate in THF was stirred with boron trifluoride etherate at room temperature for 2 h. This shows that boron trifluoride activates the O^2,5′-anhydro bond by interaction with N^3(or O^4)-position of uracil moiety.



In order to obtain a carbon-carbon bond at the 5′-position of uridine, we studied the reaction of **1** with silyl enol ether in the presence of Lewis acid. A solution of 2′,3′-*O*-isopropylidene-O^2,5′-cyclouridine and cyclohexanone trimethylsilyl enol ether in THF was stirred with boron trifluoride at room temperature for 2 h. Examination by TLC revealed the formation of several products. No attempt was made to identify the products. Next, **1** was allowed to react with two molar equivalents of the silyl enol ether and titanium(IV) chloride[8] at 0 °C for 30 min. 5′-Chloro-5′-deoxy-2′,3′-*O*-isopropylideneuridine[9] was unexpectedly obtained in 84% yield.

2′,3′-*O*-Isopropylidene-O^2,5′-cyclouridine was allowed to react with benzylmagnesium bromide in THF at room temperature for 3 h to form 5′-bromo-5′-deoxy-2′,3′-*O*-isopropylideneuridine (79%).[9] So far no report seems to have appeared on halogenation with the use of Grignard reagents. The reason why no benzylation takes place is not obvious.

Experimental

5′-O-Methyl-2′,3′-O-isopropylideneuridine. A solution of **1** (266 mg, 1 mmol) in dry methanol (25 ml) was stirred with *p*-toluenesulfonic acid (190 mg, 1 mmol) in the presence of molecular sieve at room temperature for 1 day and the resulting mixture was evaporated *in vacuo*. The product was separated by preparative TLC (Merck silica gel PF_{254}, 20× 30 cm plate, developing solvent; ethyl acetate) to give 238 mg (80%) of 5′-*O*-methyl-2′,3′-*O*-isopropylideneuridine (foamy glass, λ_{max}^{MeOH} 262 nm λ_{min} 231 nm, NMR ($CDCl_3$–TMS) δ 10.22

(1H, br s, N^3H) 3.41 (3H, s, OCH_3).[6]

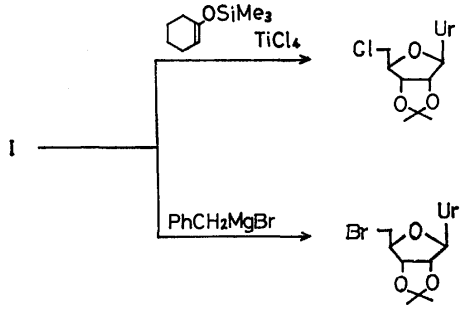
Reactions of **1** *with Diphenyl Phosphate. In the Presence of* p-*Toluenesulfonic Acid*: 2′,3′-*O*-Isopropylidene-O^2,5′-cyclouridine (1 mmol) was stirred with diphenyl phosphate (500 mg, 2 mmol) in the presence of *p*-toluenesulfonic acid (1 mmol) in THF (5 ml) at room temperature for 1 day. The reaction mixture was separated by preparative TLC (developing solvent; ethyl acetate). 5′-*O*-Tosyl-2′,3′-*O*-isopropylideneuridine was obtained in 81% yield (mp 152—154 °C, recrystallization from methanol, λ_{max}^{MeOH} 226 nm (ε 12500), 260 nm (ε 8500), λ_{min} 241 nm).[7] No phosphorylated product was obtained.

In the Presence of Trifluoroacetic Acid: When trifluoroacetic acid (*ca.* 2 mmol), instead of *p*-toluenesulfonic acid, was used in the above reaction, 2′,3′-*O*-isopropylidene 5′-(diphenyl)-phosphate (**2**) was isolated in 58% yield by preparative TLC (developing solvent; chloroform: methanol=10: 1). Rechromatography was carried out with ethyl acetate (colourless glass, λ_{max}^{MeOH} 261 nm, λ_{min} 230 nm, NMR($CDCl_3$–TMS) δ 10.10 (1H, s, N^3H) 7.19 (11H, PhO–, C^6H)).

In the Presence of Boron Trifluoride Etherate: The yield of **2** increased to 77% when a solution of **1** and diphenyl phosphate in THF was stirred with boron trifluoride etherate at room temperature for 2 h.

Attempts to form Carbon-Carbon Bond. Use of Titanium-(IV) Chloride: Titanium(IV) chloride (1 mmol) was added to a solution of 1 (1 mmol) and cyclohexanone silyl enol ether (170 mg, 2 mmol) in THF (5 ml) at 0 °C. After 30 min, satd. aqueous sodium hydrogen carbonate solution (2 ml) was added. The product was extracted with chloroform (5 ml×2) and separated by preparative TLC (developing solvent; ethyl acetate). 5′-Chloro-5′-deoxy-2′,3′-*O*-isopropylideneuridine was obtained in 84% yield (mp 178—179 °C, lit,[9] 175.5—176.5 °C) and 10% of 2′,3′-*O*-isopropylideneuridine was recovered.

Use of Grignard Reagent: A suspension of **1** (1 mmol) in THF (1 ml) was added to a freshly prepared solution of benzylmagnesium bromide (3 mmol) in THF (3 ml) at 0 °C. The reaction mixture was kept stirring at room temperature for 2 h and to it was added satd. aqueous ammonium chloride solution (20 ml). The solution was extracted with chloroform (20 ml×3) and the organic layer was evaporated *in vacuo*. 5′-Bromo-5′-deoxy-2′,3′-*O*-isopropylideneuridine was obtained in 79% yield (mp 187—189 °C, lit,[9] 184—186 °C) by preparative TLC (developing solvent; chloroform: ethyl acetate=1:1).



This work was carried out with financial support from the Ministry of Education.

A Proton Magnetic Resonance Study of the Amide Configurations of 2-Acetoacetamido Derivatives of 4-Methylpyridine and Pyrimidine

Michio KONDO

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi 1-2-58, Shinagawa-ku, Tokyo 140

(Received November 9, 1977)

Synopsis. It has been found by ^{1}H NMR spectroscopy that 2-acetoacetamido-4-methylpyridine (**1**) and 2-acetoacetamidopyrimidine (**2**) exist predominantly in keto forms in $CDCl_3$ and DMSO. The amide group of **1** seems to be in a *s-trans* configuration in both solvents, whereas that of **2** is in a *s-cis* form in $CDCl_3$, but predominantly in a *s-trans* isomer in DMSO at room temperature. Configurations of the enol forms are discussed.

It is well known that β-diketones and a number of derivatives of acetoacetic acid undergo keto-enol tautomerism in solution and that ^{1}H NMR spectroscopy has been used as a powerful tool to study such kinds of equilibrium.[1] However, only a few papers have been concerned with acetoacetamide derivatives, which have been proved to exist predominantly as keto forms.[2,3]

It is also familiar that *N*-monosubstituted amides undergo *cis-trans* rotational isomerism and that the isomers are almost all *s-trans* in the cases of acetylamino and higher acylamino derivatives.[4] For a few acetanilides with bulky ortho substituents, it has been reported that the *s-cis* isomers are appreciable.[5] The terms *s-cis* and *s-trans* refer to the relative location of the NH and CO group about the amide bond.

This paper will be concerned with 2-acetoacetamido-4-methylpyridine and 2-acetoacetamidopyrimidine, which undergo keto-enol tautomerism and *cis-trans* isomerism concurrently.

Experimental

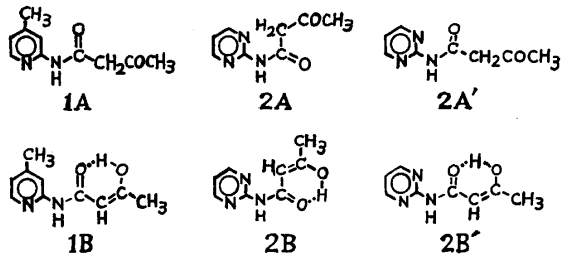
2-Acetoacetamido-4-methylpyridine (**1**) was prepared according to the literature method.[6] Commercial 2-acetoacetamidopyrimidine (**2**) was purified by recrystallization from water.

The ^{1}H NMR spectra were recorded on A Varian XL-100A-15 spectrometer, using TMS as the internal standard. In all spectra, the pulsed Fourier transform (FT) operation was utilized. The concentrations were 0.3—0.5% w/v.

Results and Discussion

Signal Assignment. The ^{1}H NMR spectra of **1** and **2** in $CDCl_3$ and DMSO seem to be explainable in terms of two molecular species, a keto and an enol tautomer, with preponderance of the keto tautomer (85—92%). The olefinic and the methylene proton signals almost completely disappeared when **1** and **2** were dissolved in CD_3OD, as did the amide and the enolic proton, on account of the replacement of H by D at the methylene and olefinic sites. The ^{1}H NMR spectra of the aromatic protons were of the first order. Therefore, signal assignment could be done straightforwardly. The chemical shifts thus determined are collected in Table 1. The large magnitude of "acylation shift" observed for the ring proton 3 of **1** suggests a *s-trans* configuration of the amide group of this compound in these solvents, on the basis of extensive studies[4b] concerning the acylation shifts of a number of anilides. Unfortunately, this kind of information was not obtained for **2**, because of the absence of a proton ortho to the acetoacetamide substituent.

Keto Tautomers. The methylene protons of **1** resonate at about the same field in both $CDCl_3$ and DMSO solution (δ 3.59 and 3.63), whereas those of **2** resonate at a very low field in $CDCl_3$ (δ 4.00) and at δ 3.81 in DMSO. These results suggest that the amide configuration of **1** is the same (*s-trans*) in both solvents, but that of **2** is solvent dependent. Lower field resonances of the methylene protons of **2** suggest that these protons are close to an electronegative atom, *e.g.*, the ring nitrogen atom; this can be realized in the *s-cis* configuration (**2A**).



Enol Tautomers. The methyl signals for the enol tautomers are located at fields higher by about 0.25—0.35 ppm than those for the keto tautomers. This value of about 0.3 ppm is very close to that for ethyl acetoacetate, but it is clearly larger than that for acetylacetone.[7] The enolic OH proton resonates at δ 13.5—14.2, intermediate between those for acetylacetone and ethyl acetoacetate (δ 15.6 and 12.2 in pure liquid, respectively[7]). From these results, it is reasonable to explain the enol-spectrum of **1** in terms of structure **1B** or the alternate enol form (**1C**: Ar–HNC(OH)=CHC(=O)CH_3), rather than in terms of a rapidly interconverting state between **1B**⇄**1C**. The olefinic proton signal of **1** in DMSO was observed as a broad quartet (J=0.7 Hz). This favors the structure **1B**. The structures **2B** and **2B′** are preferable to **2C** and **2C′** ((2-pyrimidyl)HNC(OH)=CHC(=O)CH_3) for the same reason (J=0.7 Hz for the DMSO solution).

Other enol forms, Ar–HNCOCHC=(OH)CH_3; Ar: pyridyl or pyrimidyl, which have no intramolecular hydrogen bond between the amide carbonyl oxygen and the enolic OH, could be neglected because of the

a) Population was estimated from the methyl peak heights of the two isomers. These values are in good agreement with the values obtained from the integration value measured under the CW mode for much concentrated solutions. b) Not identified. c) Averaged signal of the methylene, olefinic, amide, and enolic protons.

results of the ^1H NMR spectroscopic study of ethyl 3-(methylamino)crotonate, where the corresponding species have been found to be minor components.[8]

The olefinic proton of **1** in $CDCl_3$ resonates at δ 5.00, this value being almost the same as those for ethyl acetoacetate and 2′,5′-dichloroacetoacetanilide.[3] This signal shifts downfield a little with the solvent change from $CDCl_3$ to DMSO, as in the case of *N*-(2,5-dichlorophenyl)-3-aminocrotonamides.[9] In contrast to this, the olefinic proton of **2** in $CDCl_3$ resonates at δ 6.20, a field lower by as much as 1.20 ppm than that for **1**; furthermore, this signal even demonstrates an upfield shift of 0.41 ppm upon changing solvents from $CDCl_3$ to DMSO. These facts strongly suggest a solvent dependence of the amide configuration of **2**.

^1H NMR Spectra at Low Temperatures. Because of the low solubility of **2** in $CDCl_3$, recording the ^1H NMR spectra at low temperatures was not attempted. In a mixed solvent of $CDCl_3$ and DMSO (6: 1 v/v), the methylene protons of **2** were observed at δ 3.89 as a singlet at room temperature. Lowering the temperature of this solution below −10 °C caused an appreciable broadening in the methylene-signal and at −40 °C the methylene signal split into a clear doublet (δ 4.11 and 3.74) with about equal intensity. The olefinic proton showed an upfield shift as well as signal-broadening with temperature decrease and at −40 °C it was observed around δ 5.55 as a very broad signal. Further decrease of the temperature caused significant reduction of spectral resolution, probably due to solidification of DMSO. The amide proton shifted downfield a little with temperature decrease and gave an asymmetric signal, due to the occasional overlapping of two signals corresponding to the two rotational isomers. The ring proton signals also showed the expected complexity.

In the case of an acetone solution of **2**, lowering the temperature did not cause any sign of splitting in the methylene signal, which was located at δ 4.01 at room temperature. These results indicate that the chemical shift of the methylene protons well reflects the amide configuration of **2** in the solvents tested. A similar solvent dependence of the amide configuration has been reported for 2-acetamidopyrimidine (**3**).[10]

Conclusion. Compound **2** exists almost exclusively in the *s-cis*-keto and *s-cis*-enol forms in $CDCl_3$, but predominantly in the *s-trans*-keto and *s-trans*-enol in DMSO, though some appreciable contribution of the *s-cis* form cannot be discounted on the basis of a rather large difference of about 0.5 ppm between the olefinic proton resonances of **1** and **2**. A DMSO molecule intermolecularly hydrogen bonded with the amide proton may induce electrostatic repulsion with the amide carbonyl group in the *s-cis* form. This may be one reason why **2** in DMSO favors the *s-trans* form. On the other hand, **1** exists in the *s-trans*-keto and *s-trans*-enol in both solvents, $CDCl_3$ and DMSO.

The electrostatic repulsion between two lone pair electrons on the ring nitrogen and on the carbonyl oxygen, which is unavoidable in the *s-trans* form of **2** but avoidable in **1**, may be responsible for the considerable *s-cis* contribution in **2**.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (6), 1907—1908 (1978)

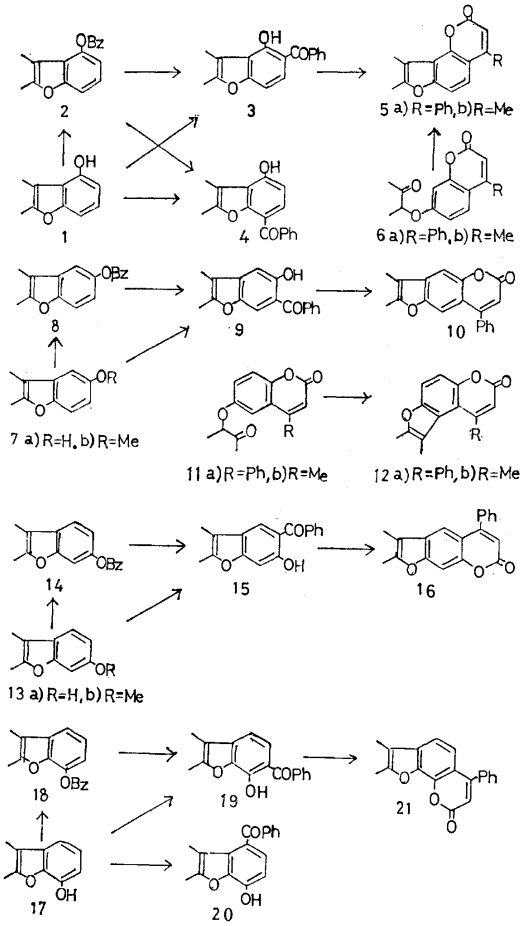
The Fries Rearrangement of *bz*-Benzoyloxybenzofuran Derivatives and the Synthesis of the Furo Derivatives of 4-Phenyl-2*H*-chromen-2-one

Yoshiyuki KAWASE, Seiji YAMAGUCHI, Kumiko AOYAMA, and Michiyo MATSUDA
Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930
(Received December 2, 1977)

Synopsis. The Fries rearrangement of 4-, 5-, 6-, and 7-benzoyloxy-2,3-dimethylbenzofurans gave exclusively or mainly the corresponding *o*-hydroxy ketones, which were converted to the dimethylfuro derivatives of 4-phenyl-2*H*-chromen-2-one.

In a previous paper, the Fries rearrangement of *bz*-acetoxy-2,3-dimethylbenzofurans to the corresponding *o*-hydroxy ketones accompanied by small amounts of para isomers in some cases was reported.[1] In the present experiments, the reaction of *bz*-benzoyloxy-2,3-dimethylbenzofurans was studied. In order to investigate their spectra and biological activity, the products were converted into the dimethylfuro derivatives of 4-phenyl-2*H*-chromen-2-one.

In the Fries rearrangement of benzoyloxybenzofuran derivatives, Shah and Shah[2] reported that 6-benzoyloxy-3-methylbenzofuran-2-carboxylic acid gave the corresponding 7-benzoyl-6-hydroxy compound. Royer *et al.*[3] reported the synthesis of the furo derivatives of 4-phenyl-2*H*-chromen-2-one, some of which were prepared by the Pechmann reaction of 2,3-dimethyl-*bz*-hydroxybenzofurans and ethyl benzoylacetate.



The Fries rearrangement of 4- (**2**), 5- (**8**), 6- (**14**), and 7-benzoyloxy-2,3-dimethylbenzofuran (**18**) was carried out at 120—130 °C. The reaction of **2** with aluminium chloride gave 5-benzoyl-4-hydroxy-2,3-dimethylbenzofuran (**3**) and some amounts of the 7-benzoyl isomer (**4**). The direct benzoylation of 4-hydroxy-2,3-dimethylbenzofuran (**1**) by benzoic acid and polyphosphoric acid (PPA) gave **2**, **3**, and a small amount of **4**. The Fries reaction of **8** and **14** gave 6-benzoyl-5-hydroxy- (**9**) and 5-benzoyl-6-hydroxy-2,3-dimethylbenzofuran (**15**), which were also prepared by the Friedel-Crafts benzoylation of 5- (**7b**) and 6-methoxy-2,3-dimethylbenzofuran (**13b**). The benzoylation of 5- (**7a**) and 6-hydroxy-2,3-dimethylbenzofuran (**13a**) with benzoic acid and PPA gave only **8** and **14**; in the case of acetylation or phenylacetylation, the hydroxy ketone was obtained.[4,5] The Fries reaction of **18** gave 6-benzoyl-7-hydroxy-2,3-dimethylbenzofuran (**19**) as compared to the benzoylation of 7-hydroxy-2,3-dimethylbenzofuran (**17**) with benzoic acid and PPA which gave **19** and some amounts of the para isomer (**20**).

The *o*-hydroxy ketones (**3**, **9**, **15**, and **19**) thus obtained were converted to the corresponding furo derivatives of 4-phenyl-2*H*-chromen-2-one (**5a**, **10**, **16**, and **21**) by the action of acetic anhydride and 1,8-diazabicyclo-[5.4.0]undecene-7 (DBU); in this reaction, anhydrous sodium acetate instead of DBU only gives the acetates. The cyclization of 7-(1-methyl-2-oxopropoxy)-4-phenyl-2*H*-chromen-2-one (**6a**) gave also **5a**. It is interesting to note that the furan ring formation of 6-(1-methyl-2-oxopropoxy)-4-phenyl-2*H*-chromen-2-one (**11a**) gave **12a** instead of the isomeric **10**, the furan ring having closed at the hindered position. The furo derivatives of 4-methyl-2*H*-chromen-2-one (**5b**[3] and **12b**) were also prepared through the analogous route in order to compare the spectra. Royer *et al.*[3] have reported the Pechmann reaction of the hydroxybenzofurans (**1** and **17**) gave the furochromenones (**5a**, **5b**, and **21**) compared to the reaction of **7a** which gave a mixture of **10** and **12a**. These were not however, separated into the pure components.

The structures of all the compounds were determined by means of IR, NMR spectroscopy and elemental analysis. In the NMR spectra, it was observed that the chemical shift of the 1-methyl protons of **12a** appeared at δ 1.01, a much higher magnetic field than that (δ 2.20) of the 3-methyl protons of **10**. This characteristic shift is analogous to the 4-phenyl-2*H*-chromen-2-one derivatives,[6,7] and appears due to the anisotropic shielding effect of the phenyl ring at the 9-position.[7] The chemical shift of the 1-methyl protons of **12b** appeared at δ 2.64, a lower field than those of

the corresponding methyl protons of other compounds; this appears due to the effect of the 9-methyl group.

Experimental[8]

The bz-*Benzoyloxy-2,3-dimethylbenzofurans (**2**, **8**, **14**, and **18**).* These compounds were prepared from *bz*-hydroxy-2,3-dimethylbenzofurans[9] (**1**, **7a**, **13a**, and **17**) by the benzoyl chloride-pyridine method (about 60% yields).

The Fries Rearrangement. A mixture of benzoyloxy-2,3-dimethylbenzofuran (1.3 g) and powdered anhydrous aluminium chloride (0.8 g) was heated for 1 h at 120—130 °C. The cooled mixture was decomposed with dilute hydrochloric acid, and extracted with ether. The ethereal solution was washed with 5% aqueous sodium hydroxide solution. The *o*-hydroxy ketones were obtained from the ethereal solution and the *p*-hydroxy ketone was obtained from the alkaline solution. Products(yields %): **3**(26.0) and **4**(8.3) from **2**, **9**(16.7)from **8**, **15**(15.4) from **14**, and **19**(15.0) from **18**.

The Benzoylation of bz-*Hydroxy-2,3-dimethylbenzofurans.* A mixture of the hydroxybenzofuran (4 g), benzoic acid (3.4 g), and PPA (n=1.5, 60 g) was heated for 1 h at 90—100 °C. The cooled mixture was decomposed with water, and extracted with chloroform. The chloroform solution was washed with 5% aqueous sodium hydroxide solution and the benzoyloxy compounds or/and the *o*-hydroxy ketones were obtained from the chloroform solution. In the case of **1**, **2**, and **3** were separated by chromatography on silica gel with benzene–hexane (1:9) as a solvent. The *p*-hydroxy ketones were obtained from the alkaline solution. Products(yields %): **2**(20.2), **3**(31.2), and **4**(1.1) from **1**, **8**(36.5) from **7a**, **14**(36.5) from **13a**, and **19**(15.5) and **20**(6.2) from **17**.

The Benzoylation of bz-*Methoxy-2,3-dimethylbenzofurans.* Anhydrous aluminium chloride (4.5 g) was added to a solution of methoxy-2,3-dimethylbenzofuran[9] (3.8 g) and benzoyl chloride (3.6 g) in benzene (30 ml) with cooling and stirring. The mixture stirred for 2 h at room temperature and then refluxed for 10 min. The usual treatment gave the *o*-hydroxy ketones. Products(yields %): **9**(44.6) from **7b**, and **15**(40.6) from **13b**.

The Preparation of the Furo Derivatives of Chromenone. A mixture of the hydroxy ketone (1 g), acetic anhydride (0.8 g), and DBU (0.4 g) was heated for 8 h at 180 °C. The cooled mixture was treated with water, allowed to stand overnight, and then extracted with chloroform. The chloroform solution was washed with 5% aqueous sodium hydroxide solution, and the product from the chloroform solution recrystallized. 8,9-Dimethyl-4-phenyl-2*H*-furo[2,3-*h*]chromen-2-one (**5a**); mp 124.5—125.5 °C (from ethanol), (lit,[3] mp 123 °C), ν_{CO}^{KBr} 1715 cm^{-1}, Anal. C, 78.45; H, 4.86%. Products(yields %): **5** (26.6) from **3**, **10**(40.4) from **9**, **16**(40.1) from **15**, and **21**(21.8) from **19**. 2,3-Dimethyl-6-phenyl-8*H*-furo[3,2-*h*]chromen-8-one (**21**); mp 151.5—152.5 °C (from methanol), (lit,[3] mp 146 °C), ν_{CO}^{KBr} 1725 cm^{-1}, Anal. C, 78.31; H, 4.64%.

The Preparation of the Furo Derivatives of Chromenones from Hydroxychromenones. *a*) Anhydrous potassium carbonate (3.5 g) was added to a mixture of hydroxy-2*H*-chromen-2-one[10] (2 g), 3-chloro-2-butanone (0.9 g), and acetone (10 ml), and the mixture was refluxed for 8 h. The cooled mixture was treated with water, extracted with chloroform, and the chloroform solution was washed with 5% aqueous sodium hydroxide solution. The product from the chloroform solution recrystallized to give 6- and 7-(1-methyl-2-oxopropoxy) derivatives of chromenones (**6a**, **6b**, **11a**, and **11b**), respectively (about 50% yields). *b*) A mixture of the alkoxychromenone (1 g) and PPA (n=2.5, 20 g) was heated for 4 h at 130 °C. The cooled mixture was treated with water, and the precipitates recrystallized to give the product. Products(yields %): **5a**(55.9) from **6a**, **5b**(67.3) from **6b**, **12a**(56.9) from **11a**, and **12b**(56.9) from **11b**. 4,8,9-Trimethyl-2*H*-furo[2,3-*h*]chromen-2-one (**5b**); mp 155—156 °C (from ethanol), (lit,[3] mp 155—156 °C), ν_{CO}^{KBr} 1710 cm^{-1}, Anal. C, 73.89; H, 5.43%.

(Received December 5, 1977)

Synopsis. The amino acid composition for each oligopeptide fragment in the hydrolysis mixture of polypeptides was determined using mass spectrometer with a CI source. The amino acid sequence was elucidated by structure construction logic in CHEMICS.

There have been several investigations[1-4] using mass spectrometry to determine the sequence of amino acids in polypeptide. Biemann *et al.*[4] developed a method in which di- or tripeptide fragments generated by the partial hydrolysis of the original peptide were determined by gas chromatography-mass spectrometry and reconstructed with the aid of a computer. This paper describes a new technique for the determination of the amino acid sequence in polypeptides using CI mass spectrometry and structure construction logic. The latter technique, established by two of the authors (S.S. and Y.K.) enumerates the isomers based on the molecular formula (*composition*) and probable partial structures (*components*) of an organic compound in the study of system CHEMICS.[5] The enumeration logic was thought applicable to the determination of the amino acid sequence of polypeptides, where the *composition* was the number and the kind of amino acids, and the *components* the nature of oligopeptides originated by the partial hydrolysis of the sample of an unknown polypeptide. In practice the *composition* may be determined by ordinary amino acid analysis and the *components* elucidated by CI mass spectrometry of the oligopeptide fragments generated by the partial acid hydrolysis of polypeptides.

The new determination method consists of six steps. Step 1: The composition of the unknown polypeptide was elucidated by amino acid analysis. Step 2: The sample was partially hydrolyzed with acid into oligopeptide fragments (mostly di- and tripeptides). The carboxylic and amino groups of all the fragments except the ε-amino group of lysine were converted into methoxycarbonyl and acetoamido groups, respectively, by the successive treatment of the mixture with CH_3OH–HCl and an equivalent mixture of acetic anhydride and acetic anhydride-d_6. Step 3: The CI mass spectrum for the esterified and acetylated mixture at step 2 was measured. This mixture was introduced into the spectrometer, *without any previous separation.* Each oligopeptide fragment may be detected as a doublet due to the acetylated molecule (M) and deuterioacetylated molecule (M+3). The execution of steps 4 through to 6 were performed by computer. Step 4: The constitution of amino acids in each oligopeptide was determined by comparing the mass with the composition of the sample determined at step 1. Step 5: The number of possible oligopeptides present in the sample were computed. The probable polypeptide structures (candidates) were constructed from the set of oligopeptides as executed in CHEMICS. Step 6: This routine involves the elimination of candidates which did not fulfil the necessary conditions. Compared with other methods, this method has the advantages of simplicity and high sensitivity brought about by the effective use of CI mass spectrometry and the computer logic of structure construction. Furthermore the logic can treat any type of peptide, either cyclic and branched.

PGL–LEU–TYR–GLU–ASP–LYS–PRO–ARG–ARG–PRO–TYR–ILE–LEU

Fig. 1. Neurotensin.

The present method was implemented for commercially available neurotensin[6] (Fig. 1). Ordinary amino acid analysis demonstrated that the polypeptide consisted of thirteen amino acids of nine types. One of two glutamic acids in the sample molecule was shown to be a pyroglutamic acid (PGL),** (there was no reaction of the sample with ninhydrin reagent) and this data was fed to the computer.

After hydrolyzing neurotensin with 6M-HCl (80 °C, 4 h), the hydrolysis mixture was treated with CH_3OH–HCl followed by a mixture of acetic anhydride and acetic anhydride-d_6. This was conducted at room temperature and overnight. The reaction mixture was introduced into a mass spectrometer with a CI source *without previous separative treatment.* The CI spectrum of the mixture suggested the presence of 14 oligopeptides (Nos. 1 through 10′) and the amino acid composition was computed by comparing the mass with the amino acid composition of the original polypeptide neurotensin, as shown in Table 1. In addition to these oligopeptides, FD mass spectrum demonstrated the presence of a dipeptide, ARG–ARG.

In order to construct the structure of neurotensin it is not necessary to use all the kinds of oligopeptides shown in Table 1. The reasons for this are as follows: No. 11 seems to be a fragment of No. 7, therefore No. 7 appears to be present in the form of either LYS–ASP–PRO or ASP–LYS–PRO. Paying attention to ASP, No. 7 may be connected to No. 4 to yield GLU–ASP–

** PGL was used for pyro-glutamic acid instead of P-GLU for the convenience of computer input and output.

Table 1. Peptide fragments of neurotensin analyzed by CI mass spectra

No.	*m/e*		Components
1	299	QM^+	LEU, PGL
2	301	QM^+	LEU, LEU
2′		QM^+	PRO, ASP
3	335	QM^+	PRO, TYR
4	347	QM^+	ASP, GLU
5	351	QM^+	LEU, TYR
6	381	QM^+	GLU, TYR

12	416	F	LEU, PRO, TYR
13	387	QM^+	ARG, ARG

QM^+: quasi-molecular ion of oligopeptide $(M+1)^+$
F: fragment ion ARG-ARG (No. 13): detected by FD mass spectrometry

LYS–PRO (No. 14). Nos. 2′, 7′, 8′, and 10′, which are not in agreement with No. 14, may be eliminated. Furthermore, two possible structures, ASP–GLU–TYR and TYR–GLU–ASP, are derived from Nos. 4 and 6. This structure is successively connected to No. 14 and 9 to give LEU–TYR–GLU–ASP–LYS–PRO (No. 15) as a longer partial structure of neurotensin.

Thus all the possible structures for neurotensin may be constructed from Nos. 1, 2, 3, 5, 8, 10, 12, 13, and 15. The number of structures (candidates) amounts to eight as shown in Fig. 2. In the present method, LEU cannot be distinguished from ILE, since both possess the same molecular weight. Consequently all the possible candidates amount to 24.

Fig. 2. Candidate polypeptides afforded by computer-aided CI mass spectrometry for neurotensin.

Experimental

Isobutane CI mass spectra were determined on a HITACHI RMU-6MG mass spectrometer with a combined EI-CI source under conditions of 100 eV ionizing potential and 80 μA ionizing current. FD mass spectra were obtained with a JEOL JMS-D100 mass spectrometer equipped with a combined FD-FI-EI source using an emitter current of 10—15 mA and a cathode potential of −5kV.

Partial hydrolysis of neurotensin: About 0.1 μmol of neurotensin was heated with 6M hydrochloric acid at 80 °C for 4 h in a sealed tube. Subsequently the hydrochloric acid was removed *in vacuo* and the residue used without purification.

Esterification: A solution of the partial hydrolysis product of neurotensin in 0.5 ml of methanol was allowed to stand overnight at room temperature.

Acetylation: To a solution of the methyl esters of the oligopeptides, 0.25 ml of acetic acid (d_0: d_3=1: 1) and 0.25 ml of acetic anhydride (d_0: d_6=1: 1) were added, then the mixture was allowed to stand overnight. Excess reagent was removed *in vacuo* and the residue used directly for the determination of CI spectrum.

Under these conditions, the ε-amino group of lysine appears resistant to acetylation. No mass peaks corresponding to oligopeptides including diacetamidolysine methyl ester were detected.

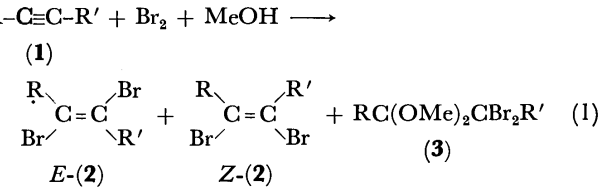
(Received December 16, 1977)

Synopsis. The reactions of acetylenes with bromine in alcohols at 20—25 °C afford dibromodialkoxyalkanes in good yields together with variable amounts of dibromoalkenes. Similar treatment of phenylacetylene with copper(II) bromide gives only bromophenylacetylene and 2-phenyl-1,1,2-tribromoethylene, the latter being formed by dibromination of the former with copper(II) bromide.

Contrary to fluorination[1] and chlorination[2] of acetylenes in alcohols where solvent incorporation occurs, it has been reported that bromination of 1-hexyne in methanol gave only 1,2-dibromo-1-hexene and none of solvent incorporated products.[2] This seems to be strange since bromination of olefin in alcohols usually gives both dibromoalkanes and alkoxybromoalkanes.[3] During studies on halogenation of acetylenes by molecular halogen and metal halides,[4,5,6] we found that bromination of acetylenes in methanol actually gives dibromodimethoxyalkanes as well as dibromoalkenes. It should be noted that the reactions of acetylenes with *N*-bromosuccinimide in alcoholic solvents have been known to produce dibromo acetals.[7]

Results and Discussion

When the reactions of various acetylenes with equimolar amount of bromine were carried out by adding methanolic solution of bromine to that of acetylene (**1**) at 20—25 °C and by stirring the resulting solution for 0.5—3 h, dibromodimethoxyalkanes (**3**) were obtained in good yields together with minor amounts of isomeric dibromoalkenes (**2**) [Scheme (1)], leaving excess **1** unreacted. In the reactions of phenylacetylene the following facts were revealed: (i) The product ratio is not much changed by lowering the reaction temperature or increasing the amount of methanol. (ii) The use of excess of bromine to **1** results in a slight decrease of the amount of **3**. (iii) The reaction proceeds also in ethanol or ethylene glycol to give **2** and **3**-analogue, while almost only **2** is obtained in 2-propanol or *t*-butyl alcohol. In ethylene glycol the attack of second alkoxyl group occurred intramolecularly to give 2-(dibromomethyl)-2-phenyl-1,3-dioxolane. The reaction with 1-hexyne gave (**3**; R=*n*-Bu, R′=H) in 40—60% yield in contrast to the report by Hennion *et al.*,[2] though the reason for the discrepancy is not yet clear. Typical results are shown in Table 1. The formation of only **3** as the solvent-incorporated product without any appreciable amounts of bromomethoxyalkenes may suggest that enol ethers are more reactive to electrophilic addition than acetylenes in these cases.



When phenylacetylene was treated with copper(II) bromide instead of bromine in methanol, bromophenylacetylene (**4**) and 2-phenyl-1,1,2-tribromoethylene (**5**) were obtained, none of (**3**; R=Ph, R′=H) being formed. Tribromination of terminal acetylenes with copper(II) bromide in refluxing methanol has been reported by Castro *et al.*[8] The mechanism which involves dibromination followed by tetrabromination and subsequent dehydrobromination has been proposed for this reaction. We would like to suggest another possible pathway for tribromination which consists of the initial formation of **4** followed by its dibromina-

tion, since we confirmed separately that **4** reacted with copper(II) bromide in methanol to give **5** [Scheme (2)]. As to the formation of **4**, the direct exchange of hydrogen by bromine may be conceivable as one of the possible pathways, since *E*- and/or *Z*-**2** did not give any **4** by dehydrobromination under these reaction conditions.

Experimental

Phenylacetylene, 1-phenyl-1-propyne, and 1-phenyl-1-butyne were prepared by the literature method.[4] 1-Hexyne, 1-octyne, alcohols, bromine, and copper(II) bromide were commercial products and used without further purification. The purification of these reagents by distillation or drying *et al.* did not give any effects on the results. The GLC analyses were carried out on Shimadzu 4BMPF and 4CMPF apparatus using EGSS-X (1 and 3 m) columns (N_2 as the carrier gas). The NMR spectra were recorded with a Varian EM-360 and a JEOL JNM-MH-100 apparatus using CCl_4 solvent (TMS as an internal standard). Authentic samples of **2**,[6] **4**,[9] and **5**[8] were prepared by the reported methods.

Formation of (3; R=Ph, R'=H). To a stirred methanol (25 ml) solution of phenylacetylene (0.51 g, 5 mmol) was added a methanol (25 ml) solution of bromine (0.80 g, 5 mmol) drop by drop (*ca.* 3—5 min) at 20—25 °C and the resulting mixture was stirred for 0.5 h during which period the red color of bromine gradually disappeared. The mixture was then added with aqueous sodium thiosulfate (*ca.* 1%, 150 ml) and extracted with benzene (70 ml×3). The benzene extract was washed with water and dried over $MgSO_4$. This extract was revealed to contain phenylacetylene, *E*- and *Z*-(**2**; R=Ph, R'=H), (**3**; R=Ph, R'=H), and trace amounts of **4**, **5**, and an unidentified compound by GLC analysis. Evaporation of benzene left 0.6 g of a white solid which contained *E*-**2**, *Z*-**2**, and **3** of the ratio of 9:1:90 (by NMR). Recrystallization from ethanol afforded 0.4 g of pure (**3**; R=Ph, R'=H): mp 65—67 °C, NMR δ 3.27 (s, 6H), 5.91 (s, 1H), 7.15—7.75 (m, 5H). Found: C, 36.62; H, 3.53%. Calcd for $C_{10}H_{12}O_2Br_2$: C, 37.07; H, 3.73%.

Identification of other **3** which was isolated similarly as above or by column chromatography on alumina (hexane as an eluent) was as follows: (**3**: R=Ph, R=Me), mp 49—51 °C, NMR δ 2.27 (s, 3H), 3.48 (s, 6H), 7.0—7.7 (m, 5H). Found: C, 39.04; H, 4.11%. Calcd for $C_{11}H_{14}O_2Br_2$: C, 39.08; H, 4.17%. $PhC(OEt)_2CHBr_2$, mp 35—36 °C, NMR δ 1.22 (t, 6H), 3.54 (q, 4H), 5.84 (s, 1H), 7.1—7.6 (m, 5H). Found: C, 41.20; H, 4.66%. Calcd for $C_{12}H_{16}O_2Br_2$: C, 40.94; H, 4.58%. $PhC(OCH_2CH_2O)CHBr_2$, mp 69—72 °C, NMR δ 3.73—4.0 (m, 2H), 4.0—4.38 (m, 2H), 5.66 (s, 1H), 6.9—7.7 (m, 5H). Found: C, 37.25; H, 3.06%. Calcd for $C_{10}H_{10}O_2Br_2$: C, 37.30; H, 3.13%. The following two products were identified by NMR without isolation: (**3**; R=*n*-Bu, R'=H), δ 0.8—2.2 (m, 7H), 2.57 (t, 2H), 3.27 (s, 6H), 5.70 (s, 1H); (**3**; R=*n*-Hexyl, R'=H), δ 0.85—2.4 (m, 11H), 2.60 (t, 2H), 3.29 (s, 6H), 5.67 (s, 1H).

Formation of 4 and 5. A heterogeneous mixture of phenylacetylene (0.26 g, 2.5 mmol), copper(II) bromide (2.70 g, 12.5 mmol) and methanol (25 ml) was kept at 25 °C for 24 h with stirring. Water (100 ml) was added to the mixture and the resulting solution was extracted with benzene (70 ml×3). The benzene extract was treated as described above. The GLC analysis of the residue revealed the presence of **4** (0.31 g, 1.7 mmol, 68% yield on the basis of the acetylene charged), a trace amount of *E*-**2**, and **5** (0.12 g, 0.35 mmol, 14% yield).

Treatment of **4** (1 mmol) with $CuBr_2$ (3 mmol) in methanol (10 ml) at reflux temperature for 5 h afforded 69% yield of **5**. Similar reaction at 25 °C gave 11% yield of **5**, leaving 84% of **4** unreacted.

Conversion of Disilanes to Functional Monosilanes. IV.[1] Synthesis of Methyldichlorosilane and Dimethylchlorosilane by the Reaction of Methylchlorodisilanes with Hydrogen Chloride in the Presence of Tetrakis(triphenylphosphine)palladium(0)

Hideyuki MATSUMOTO, Tsuneo MOTEGI, Minoru HASEGAWA, and Yoichiro NAGAI

Department of Chemistry, Gunma University, Kiryu, Gunma 376

(Received December 19, 1977)

Synopsis. Methylchlorodisilanes such as 1,2-dimethyl-1,1,2,2-tetrachlorodisilane, 1,1,2-trimethyl-1,2,2-trichlorodisilane and 1,1,2,2-tetramethyl-1,2-dichlorodisilane were effectively cleaved by hydrogen chloride in the presence of tetrakis(triphenylphosphine)palladium(0) to give methylchlorohydrosilanes in good yields.

The cleavage of methylchlorodisilanes by hydrogen chloride constitutes one of the important routes to methyldichlorosilane and dimethylchlorosilane and considerable effort has been devoted to this reaction.[2] The transition metal-catalyzed cleavage, however, had been overlooked until 1973, when Atwell and Bokerman reported in a patent literature that the cleavage of a disilane mixture containing 1,2-dimethyl-1,1,2,2-tetrachlorodisilane, 1,1,2-trimethyl-1,2,2-trichlorodisilane and 1,1,2,2-tetramethyl-1,2-dichlorodisilane was effected by dichlorobis(phenyldimethylphosphine)palladium-(II).[3] In their experiment a low boiling mixture was obtained which consisted of methyldichlorosilane, dimethylchlorosilane, methyltrichlorosilane and dimethyldichlorosilane (yield was not given), indicating that all the disilanes had been cleaved to some extent.

During the course of our recent investigation on various cleavage reactions of methylchlorodisilanes,[1] we have found that disilanes such as 1,2-dimethyl-1,1,2,2-tetrachlorodisilane, 1,1,2-trimethyl-1,2,2-trichlorodisilane and 1,1,2,2-tetramethyl-1,2-dichlorodisilane were effectively cleaved by hydrogen chloride in the presence of tetrakis(triphenylphosphine)palladium-(0). The results are summarized in Table 1.

In the presence of this particular palladium catalyst, *sym*-dimethyltetrachlorodisilane was readily cleaved at 140 °C by hydrogen chloride to give a 1 : 1 mixture of methyldichlorosilane and methyltrichlorosilane in a 90% combined yield. It is apparent, therefore, that reaction 1

$$Cl_2MeSiSiMeCl_2 + HCl \xrightarrow{Pd(0)} MeSiHCl_2 + MeSiCl_3 \quad (50 : 50) \qquad (1)$$

provides a convenient method for preparation of methyldichlorosilane. The reaction of *sym*-tetramethyldichlorodisilane with hydrogen chloride was rather slow at 140 °C, but at 170 °C, the reaction with 0.4 mol% of the palladium(0) catalyst proceeded with a 32% conversion to afford a 1 : 1 mixture of dimethylchlorosilane and dimethyldichlorosilane in a 97% combined yield based on the disilane consumption. Thus, Reaction 2 is of some validity for the production of dimethylchlorosilane by a single route.

$$ClMe_2SiSiMe_2Cl + HCl \xrightarrow{Pd(0)} Me_2SiHCl + Me_2SiCl_2 \quad (50 : 50) \qquad (2)$$

1,1,2-Trimethyl-1,2,2-trichlorodisilane was found to be cleaved at 150 °C in two ways as shown below. The slightly preponderant occurrence of path A and path B suggests that attack of chlorine on the Me_2SiCl group in the disilane is somewhat favored over that on the $MeSiCl_2$ group.

$$Cl_2MeSiSiMe_2Cl + HCl \longrightarrow \begin{cases} MeSiHCl_2 + Me_2SiCl_2 \quad (28 : 40) & \text{[path A]} \\ Me_2SiHCl + MeSiCl_3 \quad (8 : 24) & \text{[path B]} \end{cases} \qquad (3)$$

Comparison of the reaction conditions for the cleavages 1, 2 and 3 finds the reactivity order of the disilanes to be $Me_2Si_2Cl_4 > Me_3Si_2Cl_3 > Me_4Si_2Cl_2$. This was further found to be the case by the competitive

TABLE 1. REACTION OF METHYLCHLORODISILANES WITH HYDROGEN CHLORIDE IN THE PRESENCE OF TETRAKIS(TRIPHENYLPHOSPHINE)PALLADIUM(0)[a]

Disilane	Conversion of disilane %[b]	Yield of monosilanes %[c]	Product distribution, %[d]			
			$MeSiHCl_2$	Me_2SiHCl	$MeSiCl_3$	Me_2SiCl_2
$Cl_2MeSiSiMeCl_2$[e]	100	90	50		50	
$ClMe_2SiSiMe_2Cl$[f]	32	97		50		50
$Cl_2MeSiSiMe_2Cl$[g]	100	80	28	8	24	40

a) The reactions were carried out by passing hydrogen chloride (50 ml/min) through a solution of a disilane (200 mmol), mesitylene (10 ml) and the Pd(0) complex. b) Conversion is meant by 100 × (mol of the disilane consumed)/(mol of the disilane charged). c) Isolated yield based on the disilane consumption. d) Determined by GLC and NMR analyses. e) Carried out at 140 °C for 4 h. The catalyst concentration is 0.2 mol% based on the disilane charged. f) Carried out at 150 °C for 5 h. The catalyst concentration is 0.2 mol%. g) Carried out at 170 °C for 8 h. The catalyst concentration is 0.4 mol%.

cleavage of pairs of three disilanes at 150 °C in the presence of the palladium(0) catalyst which gave the relative rates $Me_2Si_2Cl_4$ 16, $Me_3Si_2Cl_3$ 10, and $Me_4Si_2Cl_2$ 1. The reactivity order thus found is in keeping with that for ammonium chloride-catalyzed cleavage reaction previously reported[4] and suggests that the present reaction is likely to involve the nucleophilic attack of chlorine atom in hydrogen chloride on the Si–Si bond for which the direct interaction with the Pd(0) complex is expected.[1c,5]

Finally, catalyst efficiency was tested briefly with other common Group VIII metal-phosphine complexes using the reaction of *sym*-dimethyltetrachlorodisilane with hydrogen chloride as standard (140 °C, 5 h, 0.2 mol% of the catalyst). For example, dichlorobis(triphenylphosphine)palladium(II) also was found to initiate the cleavage of the disilane, but the reaction gave a 34: 66 mixture of methyldichlorosilane and methyltrichlorosilane only in a 21% combined yield. Further, the reaction in the presence of dichlorobis(triphenylphosphine)nickel(II) gave only a 21% combined yield of methylchlorosilanes consisting of 3% methyldichlorosilane and 97% methyltrichlorosilane.

Experimental

1,2-Dimethyl-1,1,2,2-tetrachlorodisilane,[6] 1,1,2-trimethyl-1,2,3-trichlorodisilane,[7] and 1,1,2,2-tetramethyl-1,2-dichlorodisilane[7] were prepared by literature procedures. Commercial anhydrous hydrogen chloride was uesd without further purification. Authentic methylchlorosilanes (*e.g.*, $MeSiHCl_2$, Me_2SiHCl, Me_2SiCl_2, and $MeSiCl_3$) were obtained commercially. Reagent grade mesitylene was freshly distilled prior to use. The complexes $NiCl_2(PPh_3)_2$,[8] $Pd(PPh_3)_4$,[9] and $PdCl_2(PPh_3)_2$[10] were prepared according to literature directions. Structural assignment for the methylchlorosilanes obtained was performed by comparing their physical properties (*e.g.*, NMR and IR spectra and GLC retention times, *etc.*) with those of authentic samples.

General Procedure for the Cleavage Reactions. All cleavage reaction were carried out in an apparatus consisting of a 30 ml three-necked round-bottomed flask equipped with a magnetic stirrer, a thermometer and an inlet tube for hydrogen chloride and topped by a distillation column filled with glass helices. The upper part of this column was connecteed with an even pressure reflux regulator to which a 100 ml flask was attached for collection of methylchlorosilanes. Effluent gaseous materials were trapped in a tube immersed in a Dry Ice–acetone bath.

A typical procedure is exemplified by the cleavage of 1,2-dimethyl-1,1,2,2-tetrachlorodisilane in the presence of tetrakis(triphenylphosphine)palladium(0). To a mixture of 45.5 g (200 mmol) of the disilane and 10 ml of mesitylene was added 0.452 g (0.4 mmol) of the Pd(0) complex. The stirred mixture was kept at 140 °C, and hydrogen chloride was bubbled through the solution at a rate of 50 ml/min. The reaction was complete in 4 h and 47.6 g (90% yield based on the disilane charged) of methylchlorosilanes were collected. GLC and NMR analyses showed the product to be a 50: 50 mixture of methyldichlorosilane and methyltrichlorosilane.

Procedure for Competitive Experiments. Hydrogen chloride was bubbled through a mixture of two different disilanes, mesitylene and the palladium(0) complex (0.2 mol%) at 150 °C. After 30—70% completion, unconverted disilanes were analyzed by GLC. Relative rates were calculated using the Ingold-Shaw equation,[11] where A_t and B_t are the initial concentrations of two disilanes,

$$\frac{k_1}{k_2} = \frac{\log [A]_t/[A]_f}{\log [B]_t/[B]_f}$$

A_f and B_f final concentrations, and k_1/k_2 the ratio of rate constants for the attack of hydrogen chloride on the two species. Relative rates are expressed by taking that for 1,1,2,2-tetramethyl-1,2-dichlorodisilane as standard.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (6), 1915—1916 (1978)

A Simple Synthetic Method for 2,15-Hexadecanedione from a Butadiene Telomer

Jiro TSUJI,* Mitsumasa KAITO, Toshiro YAMADA, and Tadakatsu MANDAI

Tokyo Institute of Technology, Meguro, Tokyo 152

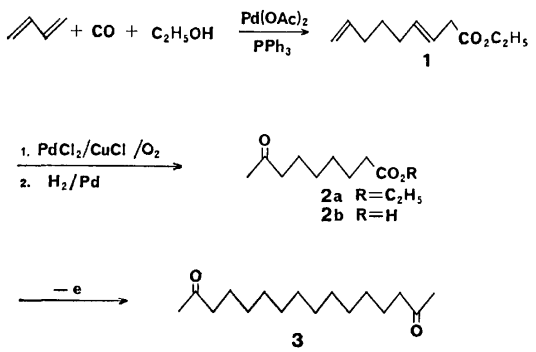
(Received January 20, 1978)

Synopsis. The terminal double bond of 3,8-nonadienoate was oxidized to methyl ketone with a catalyst system of $PdCl_2/CuCl/O_2$ and the internal double bond was reduced to give 8-oxononanoate, which was hydrolyzed to 8-oxononanoic acid. The Kolbe electrolysis of the acid produced 2,15-hexadecanedione in a high yield.

Palladium compounds are useful reagents for organic synthesis. Particularly there are two useful synthetic reactions catalyzed by palladium compounds. They are oxidation of olefins catalyzed by $Pd(II)/Cu(II)/O_2$ system to carbonyl compounds,[1-3] and telomerization of butadiene with nucleophiles catalyzed by palladium-phosphine complexes.[4]

We now wish to report the application of these two palladium catalyzed reactions to the synthesis of 2,15-hexadecanedione (**3**). The conversion of this diketone to muscone by aldol condensation had been reported by Stoll.[5] One drawback of the Stoll method is a low yield of the intramolecular aldol condensation, which competes with the intermolecular reaction. In order to make this method more useful and make up for the low yield of the aldol condensation, it is essential to synthesize the diketone **3** as the precursor easily in high yield. We have already reported the synthesis of the diketone **3** by coupling a C_8 chain, which is easily available by the palladium catalyzed telomerization of butadiene with acetic acid.[6,7]

The present method shown below utilizes a C_9 acid **2b** which was coupled by the Kolbe reaction. The method is simpler and gave a higher overall yield.



We have reported the dimerization-carbonylation of butadiene catalyzed by a system of palladium acetate and triphenylphosphine to give 3,8-nonadienoate (**1**) in a high yield.[8,9] In the present studies, this C_9 ester was converted into the C_{16} diketone as shown in the above scheme. The Kolbe coupling of 8-oxononanoic acid (**2b**) has been claimed by Tsuzuki and Motoki in a patent.[10] However, in their method, the acid **2b** was synthesized by the cross Kolbe reaction of adipic acid and levulinic acid, which gave inevitably a mixture of coupled products.[10,11] In the present method the easily available C_9 ester **1** is the starting material.

At first the terminal double bond of **1** was oxidized to a methyl ketone using $PdCl_2/CuCl/O_2$ as a catalyst system at room temperature in *N,N*-dimethylformamide.[12] Ethyl 8-oxo-3-nonenoate was isolated by distillation in 86.7% yield. The internal double bond which remained intact during the oxidation was hydrogenated by using palladium on carbon as a catalyst to give ethyl 8-oxononanoate in 98% yield. The ester was then hydrolyzed with methanolic KOH to give 8-oxononanoic acid as crystals in 92% yield. The final step of the synthesis is the Kolbe electrolysis. The sodium salt of the keto acid **2b** in methanol was subjected to Kolbe electrolysis using Pt electrode at 0° C. After the reaction, a neutral fraction was isolated by the usual work-up as a solid material which was recrystallized from methanol to afford the diketone **3** as colorless crystals in 63% yield. The diketone was identified by its mp and NMR spectral data.

Experimental

Melting points were measured on a Shibata (No. 297) melting point apparatus. The IR spectra were taken on a JASCO (IRA-2) spectrophotometer. The NMR spectra were taken on a HITACHI (R-24A) spectrometer (60 MHz) with tetramethylsilane as an internal reference.

Materials. Ethyl 3,8-nonadienoate (**1**) was prepared by the reaction of butadiene with carbon monoxide and ethanol using palladium acetate and triphenylphosphine as a catalyst under pressure of carbon monoxide,[8] bp 60—63 °C/4 Torr: IR (neat) 2980, 2920, 1740, 1640, 1160, 970, 910 cm^{-1}; NMR (CCl_4) δ 5.3—6.1 (m, 3H), 4.7—5.1 (m, 2H), 4.0 (q, J=7 Hz, 2H), 2.8—3.1 (m, 2H), 1.8—2.3 (m, 4H), 1.55 (t, J=6 Hz, 2H), 1.2 (t, J=7 Hz, 3H).

Oxidation of Ethyl 3,8-Nonadienoate. A mixture of $PdCl_2$ (877 mg, 4.95 mmol) and CuCl (4.90 g, 49.6 mmol) in aqueous *N,N*-dimethylformamide (25 ml, H_2O, 3 ml) was shaken in a 100 ml glass vessel under oxygen atmosphere for 1 h. Then the ester **1** (8.96 g, 49.2 mmol) was added and the mixture was shaken under oxygen atmosphere at room temperature for 5 h. The solution was poured into dilute hydrochloric acid and the resulting mixture was extracted with dichloromethane. Ethyl 8-oxo-3-nonenoate was isolated by distillation (8.44 g, 86.7%): bp 86—87 °C/5 Torr; NMR (CCl_4) δ 5.3—5.5 (m, 2H), 4.0 (q, J=7 Hz, 2H), 2.8—3.0 (m, 2H), 2.35 (t, J=6.5 Hz), 2.0 (s 3H), 1.4—2.1 (m, 4H), 1.2 (t, J=7 Hz, 3H); IR (neat) 2980, 2940, 1735, 1715, 1370, 1250, 1165, 1030, 970 cm^{-1}.

Hydrogenation of Ethyl 8-Oxo-3-nonenoate. Ethyl 8-oxo-3-nonenoate (2.88 g, 14.5 mmol) was dissolved in ethanol (20 ml) in a 50 ml flask and palladium on carbon (5%, 80 mg) was added. The resulting mixture was shaken under atmospheric pressure of hydrogen at room temperature for

3 h. The mixture was filtered and the solvent was removed to give crude ethyl 8-oxonoanoate (**2a**) (2.85 g, 98%): NMR (CCl_4) δ 4.0 (q, J=7 Hz, 2H), 2.2 (t, J=8 Hz, 4H), 2.05 (s, 3H), 1.0—1.7 (broad, 11H).

Hydrolysis of Ethyl 8-Oxononanoate. Ethyl 8-oxononanoate (17.7 g, 88.5 mmol) was dissolved in methanol (30 ml) in a 200 ml flask and an aqueous KOH solution (5.0 g, 89.3 mmol in 100 ml of H_2O) was added and the solution was stirred for 3 h. After the usual work-up, crude 8-oxononanoic acid (**2b**) (14.1 g, 82.0 mmol, 92%) was obtained. The acid **2b** was purified by recrystallization from hexane and benzene to give colorless needles, mp 42.5—44 °C (reported 40°C[13]): NMR (CCl_4) δ 11.3 (s, $-CO_2H$, 1H), 2.35 (t. J= 6 Hz, 2H), 2.30 (t, J=6 Hz, 2H), 2.1 (s, 3H), 1.0—1.9 (broad, 8H).

Kolbe Electrolysis. 8-Oxononanoic acid (6.28 g, 36.6 mmol) in sodium methoxide solution (50 mg of Na in 70 ml of MeOH) was placed in a 100 ml glass vessel equipped with a Pt electrode and a magnetic bar. The electrolysis was carried out with stirring at 0 °C under nitrogen atmosphere (65 volt, 0.2—0.6 ampere) for 2 h. After the reaction, precipitated white solid was filtered and the filtrate was concentrated. The residue was poured into an aqueous $NaHCO_3$ solution and the solution was extracted with dichloromethane. The dichloromethane solution was washed with brine and dried over $MgSO_4$. After removal of the solvent, white solid was obtained which was recrystallized from methanol to afford 2,15-hexadecanedione (**3**) as colorless crystals, 2.93 g, 63%, mp 83.5—85.0 °C, (reported 83—84 °C)[11]: NMR (CCl_4) δ 2.1—2.4 (t, J=7 Hz, 4H), 1.95 (s, 6H), 1.0—1.7 (broad, 20H); IR (KBr disk) 2900, 2830, 1710, 1460, 1160, 800, 720, 600 cm^{-1}.

A Molecular Orbital Study of the Electrophilicity of Hydroxyl Radical in Hydrogen Abstraction Reaction

Hiroyuki SHINOHARA*, Akira IMAMURA,** Takahiro MASUDA, and Masaharu KONDO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158

***Shiga University of Medical Science, Seta, Otsu, Shiga 520-21*

(Received June 11, 1977)

The electrophilicity of the hydroxyl radical in hydrogen abstraction from methane was studied by the CNDO/2 method. The stabilization energy due to the delocalization of the electrons (SEDE) between methane and the radical at a close distance was calculated. The electrophilicity defined by the SEDE from methane to the hydroxyl radical was larger than the nucleophilicity defined by that from the hydroxyl radical to methane. This result is consistent with the electrophilicity observed in hydrogen abstraction by the hydroxyl radical from a series of substituted methanes. For sulfhydryl radical, the electrophilicity was also suggested by the calculation for hydrogen abstraction from methane. The calculations were also carried out for various radicals which have low electron affinity (hydrogen atom and methyl radical), and the SEDE from methane to the radical was found to be large compared with that from the converse case.

Various kinds of radicals have been shown to react as electrophiles in reactions such as addition, substitution, or abstraction. A typical instance was given by Anbar *et al.*,[1,2] who determined the rate constants for reactions of hydroxyl radical with one series of aromatic and two series of aliphatic compounds (substituted methanes and acetate ions) in gamma-irradiated aqueous solutions. They concluded from the ρ values in the Hammett equation that the hydroxyl radical reacts as an electrophile in these reactions.

Recently, in order to explain the electrophilicity observed in radical reactions, theoretical attempts have been made by some workers. Nagase *et al.*[3] suggested the electrophilicity of a radical in hydrogen abstraction by an intermolecular perturbation approach and proposed a three-stage model which gives an insight into the mechanism of radical reactions.[4,5] Imamura has developed the molecular orbital (MO) method, which defines the polarity of the radical (nucleophilicity or electrophilicity) from the comparison of the stabilization energy due to delocalization of electrons (SEDE) between a substrate and the radical at a close distance.[6] According to this procedure, the nucleophilicity of the radical is evaluated by the SEDE from the occupied MO's of the radical to the vacant MO's of the substrate and the electrophilicity by that from the occupied MO's of the substrate to the vacant MO's of the radical. The electrophilicity of the hydroxyl radical in addition reactions with a series of mono-substituted benzenes was well understood by the differences in the SEDE.[6]

In the present work, as a first step in the investigation of the Hammett equation, we applied the MO method to hydrogen abstractions by the hydroxyl radical, sulfhydryl radical, hydrogen atom, and methyl radical from methane. The SEDE which corresponds to the electrophilicity is larger than that related to the nucleophilicity, and it can be concluded that these radicls react with methane as electrophiles.

Method of Calculation

The total energies for the reacting systems were calculated by the UHF method[7] in the CNDO/2 approximation.[8,9] The values of the parameters included in the CNDO-UHF calculation are the same as those used in the original papers.[8,9]

Procedure of Analysis. For the analysis of the polarity of a radical, a calculation should be carried out to obtain the MO's of substrate RH and radical X in the supposed model, in which they interact electrostatically with each other but are prohibited from any overlapping of MO's between them. Therefore the delocalization of electrons is prohibited in the model. These MO's can be obtained by the SCF calculation after dropping the resonance integrals I_{rs} between the atomic orbitals (AO's) of RH, χ_r, and AO's of X, χ_s, as given by

$$I_{rs} = \frac{1}{2}(\beta_r + \beta_s)S_{rs}. \tag{1}$$

Then the MO's for the reacting system [R···H···X] are classified into the MO's localized on RH and those localized on X:

$$\psi_{RHi} = \sum_r C_{RHi,r}\chi_r, \tag{2}$$

$$\psi_{Xj} = \sum_s C_{Xj,s}\chi_s. \tag{3}$$

ψ_{RHi} is the i-th MO localized on RH and $C_{RHi,r}$ is the coefficient of AO's in the i-th MO, and ψ_{Xj} and $C_{Xj,s}$ are for X. From Eq. 2, one obtains

$$\sum_i C_{RHi,r_1}\psi_{RHi} = \sum_r\sum_i C_{RHi,r_1}C_{RHi,r}\chi_r = \sum_r \chi_r \sum_i C_{RHi,r_1}C_{RHi,r}. \tag{4}$$

Since a set of ψ_{RHi},s is orthonormal,

$$\sum_i C_{RHi,r_1}C_{RHi,r} = \delta_{rr_1}, \tag{5}$$

and thus

$$\chi_r = \sum_i C_{RHi,r}\psi_{RHi}, \tag{6}$$

$$\chi_s = \sum_j C_{Xj,s}\psi_{Xj}. \tag{7}$$

From Eqs. 6 and 7, one obtains the relation between the I_{rs} represented by the AO basis of χ_r, χ_s, and the I_{ij} by the MO basis of ψ_{RHi}, ψ_{Xj}:

$$I_{rs} = \int \chi_r h^\circ \chi_s d\tau = \sum_i\sum_j C_{RHi,r}C_{Xj,s}\int \psi_{RHi}h^\circ\psi_{Xj}d\tau = \sum_i\sum_j C_{RHi,r}C_{Xj,s}I_{ij}. \tag{8}$$

Instead of Eq. 8, the I_{rs} in Eq. 9 is used in the SCF calculation in order to include the delocalization of electrons between particular orbital sets (i_1,j_1):

$$I_{rs} = \sum_{(i_1-j_1)} C_{RHi_1,r} C_{Xj_1,s} I_{i_1j_1}, \quad (9)$$

where $\sum_{(i_1-j_1)}$ denotes the summation over the sets (i_1,j_1). From Eq. 9, it is easily proved that the I_{ij} reduces to zero except for the $I_{i_1j_1}$ term, which has the same value as that obtained by using Eq. 8.

The procedure of the calculations is written as follows.
(i) The total energy of the reacting system without the delocalization of electrons is calculated by the SCF calculation after dropping the I_{rs} in Eq. 1. Thus we obtain the MO's in Eqs. 2 and 3.
(ii) By using the MO's obtained in the step (i), the modified resonance integrals between AO's are calculated according to Eq. 9 in order to take the delocalization of electrons between particular MO's into account.
(iii) The I_{rs} in Eq. 9 is employed to calculate the total energy of the reacting system with the delocalization of electrons, which corresponds to the nucleophilic or the electrophilic nature of the radical in question.
(iv) A measure of the nucleophilicity of the radical defined by the SEDE from the radical to the substrate, N, or the electrophilicity defined by the SEDE from the substrate to the radical, E, is evaluated by the difference between the two energies obtained in the steps (i) and (iii).

Results

Figure 1 shows a model for hydrogen abstraction by the hydroxyl radical from methane. The hydrogen atom of the hydroxyl radical lies at the opposite direction to the C^1–H^2 bond with regard to the C^1–H^5 bond. We examined the energy dependence of the CH_4–OH system upon the angle H^5OH in the intermolecular distance of 1.46 Å ;the result is given in Table 1. The minimum energy was situated at the angle between 100.45 and 104.45°. Therefore we assumed that the hydroxyl radical approaches to the H^5 atom of methane along the extension of the C^1–H^5 bond, maintaining the angle H^5OH at 104.45° (bond angle of water), and abstracts the H^5 atom.

Figure 2 shows the potential curves of the CH_4–OH system calculated by assuming that the HCH angle of the CH_3 group is not varied throughout the

reaction. In this figure, we specify the reaction path with a notation (r_1,r_2), where r_1 is the distance (in Å) between C^1 and H^5 atoms and r_2 is that between H^5 and hydroxyl oxygen atoms in Fig. 1. As the energy of the system increases monotonously, the geometry of the transition state is not obvious. However, it can be assumed that a more favorable reaction path for H^5 atom abstraction goes through the following points: A, B, C, and D, which are specified respectively by the sets of r_1 and r_2 indicated in the parenthesis: A(1.09, 1.46), B(1.20, 1.35), C(1.30, 1.25), D(1.40, 1.15).

Table 2 shows the schematic representation of the intermolecular interaction between the MO's of RH and X obtained by dropping the I_{rs} in Eq. 1. Here, Occ and Vac represent occupied and vacant MO's respectively; N or E denotes the nucleophilicity or the electrophilicity of the radical defined previously. Among them, N_1, N_2, E_1, and E_2 include the effect of the delocalization of electrons only, while N_3, N_4, E_3, and E_4 include the interaction between occupied MO's in addition to the effect of the delocalization. It can be noticed from the electron distribution shown

in Fig. 3 that the delocalization of electrons occurs from the hydroxyl radical to methane by the interaction N_1, while that from methane to the hydroxyl radical occurs by the interaction E_1. These results are summarized in Table 3. The ratios of E_1/N_1 are 2.7, 2.1, 1.8, and 1.5 at the points A, B, C, and D, respectively. As is shown in N_3 and E_3, the SEDE including the interaction of occupied MO's is larger than that including the delocalization of electrons only. This energy can be considered to include the redistribution energy as well as the delocalization energy. It should be noticed that the stabilization energy by delocalization is much larger than that by the redistribution effect, although the absolute magnitude of the latter is not negligibly small. Consequently, if we can determine the polarity of a radical from the viewpoint of the SEDE, it will be possible to conclude that the hydroxyl radical reacts as an electrophile in hydrogen abstraction from methane. The HOMO-LUMO interaction plays an important role in E_1 and the electrophilicity of the hydroxyl radical is closely related with this interaction.

As organic sulfur compounds are recognized to have high levels of HOMO and low levels of LUMO, it is interesting to determine the polarity of the sulfhydryl radical. Figure 4 shows a model for hydrogen abstraction by the sulfhydryl radical from methane.

method including overlap integrals; it is also confirmed by our analysis (Table 6), which was carried out in the strong interaction region, as is shown in Fig. 4.

Discussion

As the present analysis is based on the zero differential overlap approximation, the quantitative evaluation of the polarity of a radical is hardly possible because of the crudeness of the calculation. The aim of this work is to discuss qualitatively the polarity of a radical from the viewpoint of the SEDE between a substrate and a radical. Despite these inaccuracies, we believe that the results obtained here may still be useful as a working tool for understanding radical reactions. It is concluded that not only the hydroxyl radical but also the hydrogen atom or the methyl radical reacts as an electrophile in hydrogen abstraction from methane, in spite of its low electron affinity. The polarity of a radical is derived properly from the rate constants for reactions with a series of substrates. However, it is essentially dependent on the substrate, and thus a relative property given to individual reactions. The direction of the delocalization of electrons in an individual reaction may not necessarily accord with the electrophilicity defined by the ρ value.

Sakurai *et al.*[12] reported the linear relationship of the electron affinities of the radicals and the negative ρ values for hydrogen abstractions by various radicals from substituted toluenes. The electrophilicity defined in the present work is related to the electron affinity of the radical; therefore, the negative ρ values may be expected to correlate with the SEDE from a substrate to the radical calculated for individual reactions. Isopropyl and *t*-butyl radicals have recently been found to react as nucleophiles in hydrogen abstractions from substituted toluenes by Pryor *et al.*[13] The positive ρ value increases with a decrease in the ionization potential (*IP*) of the radical (i-C_3H_7: $\rho=0.8$, $IP=7.90$ eV, t-C_4H_9: $\rho=1.0$, $IP=7.07$ eV[14]). As the nucleophilicity defined in the present work is related with the ionization potential of the radical, SEDE from the radical to a substrate will provide a way to explain the reactions of positive ρ values. Further calculations of the SEDE are in progress for hydrogen abstractions by various kinds of radicals.

The authors are grateful to the Quantum Chemical Research Group in Kyoto University for helpful discussions.

The calculations were carried out on the FACOM 230-75 computer of the Computer Center of Kyoto University. The research was supported, in part, by Scientific Grants (139012 and 038012) from the Ministry of Education, Culture, and Sciences.

The Effect of the Vibrational and Translational Energies of Ionic Reactant on the Reaction $C_3H_4^+ + NH_3 \rightarrow C_3H_3 + NH_4^+$

Kenji HONMA,* Inosuke KOYANO,† and Ikuzo TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received August 12, 1977)

The effect of the internal and translational energies of ionic reactant on the rates of the reactions $C_3H_4^+ + NH_3 \rightarrow C_3H_3 + NH_4^+$ has been examined by producing the reactant ions from propyne, allene, and cyclopropene by photoionization at various wavelengths. The translational energy was varied by changing the repeller voltage in the ionization chamber. The cross sections for all the reactions decreased with an increase in the internal energy at all the translational energies studied. The results have been explained in terms of the complex mechanism.

The roles played by various forms of reactant energy in bimolecular reactions in the gas phase have been the subject of intensive study in recent years, both experimentally and theoretically.[1] In ion-molecule reactions, the effect of the vibrational energies of ionic reactants can be studied rather easily since the primary ions can be prepared in various vibrational states with known distributions. Photoionization is particularly suited for this purpose,[2] showing well-defined vibrational structure in the ionization efficiency curves. The distribution of ions among vibrational states can be determined precisely by photoelectron spectroscopy. In a favorable case, ions can be prepared in only one particular vibrational state (and even in a rotational state) selectively by making use of autionization[3,4]

Although many investigations have been performed from both experimental and theoretical viewpoints[5] on the proton transfer reactions:

$$\begin{aligned} XH^+ + Y &\rightarrow X + HY^+ \\ YH + X^- &\rightarrow Y^- + XH, \end{aligned} \qquad (2)$$

the main interest has centered on the comparison of the measured cross section with those predicted from the classical dipole theory; only a few works have been concerned with the effects of reactant vibration and translation. Chupka and Russell[6] studied this exothermic reaction:

$$NH_3^+ + NH_3 \rightarrow NH_2 + NH_4^+, \qquad (3)$$

by the use of a high-resolution photoionization technique and found that the cross section decreases as the vibrational energy increases at all the translational energies studied. On the other hand, by the use of a flow-drift tube technique, Lindinger *et al.*[7] measured the rate constants of the proton transfer reactions of several ions with NH_3 as a function of the relative kinetic energy. They found that the rate constants are generally in good agreement with those predicted by the ADO (average-dipole-orientation) theory in the thermal energy range.

In the present study, the photoionization technique has been applied to the study of the effects of the translational and internal energies on the probabilities of the proton transfer reactions:

$$C_3H_4^+ + NH_3 \rightarrow C_3H_3 + NH_4^+. \qquad (1)$$

As the sources of $C_3H_4^+$, three structural isomers of C_3H_4 (propyne, allene, and cyclopropene) were used. These systems constitute a favorable case for investigating the factors which govern the reaction probability, since, in these systems, the reduced masses and the polarizability and permanent dipole moment of the neutral reactant are identical.

Experimental

The experiments were carried out using a photoionization apparatus which has been described previously in considerable detail.[8] Briefly, it consists of a continuum light source, a Seya-Namioka-type vacuum monochromator, an ionization chamber, and a quadrupole mass spectrometer, these being combined together *via* a five-stage differential pumping system. Radiation from a Hinteregger-type hydrogen discharge lamp passed through the monochromator and irradiated the sample gas in the ionization chamber to produce reactant ions. Since the ionization potentials of allene and cyclopropene are 9.61 eV (corresponding to 129.0 nm) and 9.63 eV (corresponding to 128.3 nm) respectively, the radiation of wavelengths shorter than the respective IP, but longer than 121.7 nm (corresponding to the ionization potential of ammonia), produced only $C_3H_4^+$ ions as reactants in the mixture of C_3H_4 and NH_3, thus enabling one to study Reaction 1 by the single-source method. In the case of the propyne–ammonia system, however, the photons which can ionize propyne (IP=10.35 eV) always ionize ammonia in the mixture; thus there is a possibility that the secondary NH_4^+ ions were produced also by Reaction 3. This problem will be discussed in a later section.

Five or more wavelengths were used for each system to produce $C_3H_4^+$ ions in various vibrational states. Pressure studies were carried out at each wavelength, λ then to determine the phenomenological cross section, Q_λ. The results were this analyzed in terms of the "maximum excess internal energy," E, which is given by equation: E=(photon energy)−(ionization potential). The actual internal energy E_i, of the reactant ions produced by irradiation at λ ranges from 0 to E. The effect of the translational energy was studied by changing the ion-exit energy E_t, between 0.5 and 5.6 eV. The ions were detected by means of a pulse-counting technique using a 20-stage electron multiplier. The pressures of the 1 : 1 mixtures of C_3H_4 and NH_3 in the ionization chamber were typically less than 1×10^{-3} Torr, and the resolution width (FWHM) of the ionizing radiation was 0.23 nm.

Commercial pure propyne, allene, and ammonia were used without further purification. The cyclopropene was synthesized from allyl chloride and sodium amide by the method of Closs and Klantz;[9] it was then purified by bulb-to-bulb distillation.

† Present address: Institute for Molecular Science, Myodaiji, Okazaki 444.

Results and Discussion

General. In all the C_3H_4+NH_3 systems, the $C_3H_4^+$ ions react with C_3H_4 in addition to undergoing Reaction 1. These reactions have been studied by Myher and Harrison[10] in both pure propyne and pure allene. They found that Reactions 4 and 5 are dominant for propyne, while only Reaction 5 is dominant for allene:

$$C_3H_4^+ + C_3H_4 \rightarrow C_3H_5^+ + C_3H_3 \quad (4)$$

$$\rightarrow C_6H_7^+ + H. \quad (5)$$

In the present study, these results have been confirmed in runs with pure propyne and allene; in addition, similar reactions in pure cyclopropene have been examined. In the latter systems, it was found that the reaction

$$C_3H_4^+ + C_3H_4 \rightarrow C_3H_3^+ + C_3H_5, \quad (6)$$

is the dominant one, with the reaction

$$C_3H_4^+ + C_3H_4 \rightarrow C_6H_5^+ + H_2 + H, \quad (7)$$

occuring to a moderate extent and Reactions 4 and 5, to only a minor extent.[11] All these reactions were taken into account in all systems as the loss processes of the reactant $C_3H_4^+$ ion, in obtaining the relative cross sections for Reaction 1. That is, they were calculated by means of the equation

$$Q_J \cdot p_s \cdot d = I_{sJ}/(I_p + \sum_i I_{si}),$$

where I_p, I_{si}, p_s, and d are the intensity of the primary ion, the intensity of the secondary ion, the sample pressure, and the distance between the origin of the primary ion and the exit slit respectively.

Internal Energy Dependence. The experimental results for the cyclopropene–ammonia and allene–ammonia systems are shown in Figs. 1 and 2. In these figures, the relative cross sections (Q) at three ion-exit energies are plotted *vs.* the maximum excess internal energy. It may be seen from these figures that the reaction cross section decreases with an increase in the excess energy at all translational energies. This can be explained qualitatively in terms of the complex formation mechanism, as has been done in other reactions.[1,3,6] In the complex mechanism, the decrease in the reaction cross section with an increase in the internal energy can be predicted from the phase space theory of Light[12] if the cross section for complex formation is independent of the internal energy. According to this theory, the collision complex decomposes along all energetically available channels, including the backward reaction, the relative probabilities for the different decomposition channels depending on the energy content of the collision complex. When the vibrational energy of a reactant is low (*e.g.*, when all vibrational modes are in the ground state), only one backward decay channel (forming reactants with all modes in the ground state) would be energetically available for the collision complex. This channel is thermoneutral and would correspond to a very small volume of the phase space, resulting in a negligibly small probability for this channel compared with that

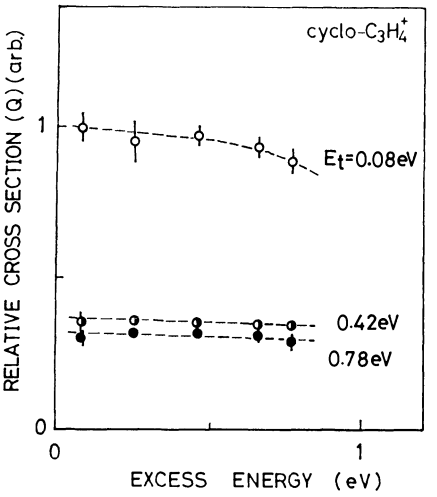

Fig. 1. Dependence of the cross section for the reaction $C_3H_4^+$(cyclopropene)+$NH_3 \rightarrow NH_4^+ + C_3H_3$ on the excess internal energy of $C_3H_4^+$. E_t indicates relative kinetic energies.

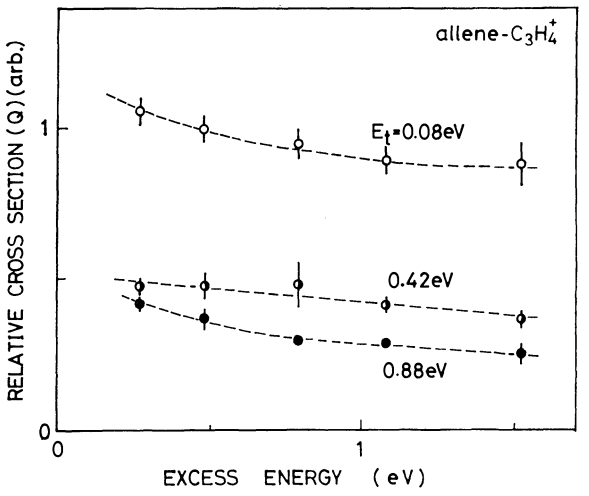

Fig. 2. Dependence of the cross section for the reaction $C_3H_4^+$(allene)+$NH_3 \rightarrow NH_4^+ + C_3H_3$ on the excess internal energy of $C_3H_4^+$. E_t indicates relative kinetic energies.

for the exothermic forward channels. As the excess energy of the reactant (and, accordingly, the energy content of the complex) increases, the exothermic backward decay channels, *i.e.*, the channels going back to the reactants which have lower vibrational quantum numbers than they had initially, become increasingly available. With complex molecular ions such as those used in the present study, the channels going back to the reactants which are excited in a different mode from the original one also become available at high excess energies. All these channels cause substantial increases in the relative volume of the phase space for the back reaction; thus, the reaction cross section decreases with an increase in the excess energy of the reactant ion.

Recently we have studied the translational and vibrational energy dependence of the cross section for the reaction:[1]

$$NO^+ + i\text{-}C_4H_{10} \rightarrow HNO + C_4H_9^+, \quad (8)$$

and have concluded that this reaction proceeds *via* complex formation at low translational energies, but the mechanism changes to a stripping type as the ionic translational energy increases. A similar mechanistic change has also been proposed by Chupka *et al.*[3] for the reaction

$$H_2^+ + H_2 \rightarrow H_3^+ + H. \quad (9)$$

These conclusions are based on the different vibrational energy dependence of the cross section at low and high translational energies. In contrast, all the present reactions show the same vibrational energy dependence at all the translational energies studied. The highest relative kinetic energy used here is much higher than the energy at which the mechanism change was observed in the previous system ($NO^+ + C_4H_{10}$). Thus, the above results indicate that the complex formation in the present system persists up to much higher energies than in Reactions 8 and 9. One of the origins of this difference might be the presence of a permanent dipole moment in the neutral reactant, NH_3. Because of the long-range interaction between the charge on the ion and the permanent dipole moment, the collisons in the present system are expected to be more "sticky" than those in Reactions 8 and 9. In this connection, it is to be noted that Reaction 3, which involves NH_3 as a neutral reactant, also shows a single-complex-type behavior at all the energies studied.[6]

Translational Energy Dependences. The translational energy dependences of Reaction 1 for the two $C_3H_4^+$ isomers with NH_3 are shown in Fig. 3. The solid and broken lines indicate the $E^{-1/2}$ and E^{-1} dependences respectively. In the ADO theory, the cross section for reaction between an ion and a polar molecule is given by

$$\sigma = \pi e[(2\alpha)^{1/2}E^{-1/2} + c\mu_D E^{-1}],$$

where E is the collision energy, α and μ_D, the polarizability and permanent dipole moment of the neutral molecule respectively, and c, a parameter characteristic of the neutral reactant. Thus, the cross-sections might be expected to show energy-dependence curves which lie between the solid and broken lines in Fig. 3. However the results were that the cross sections almost obey the $E^{-1/2}$ dependence.

The rate constants for several exothermic proton transfer reactions have recently been studied by Lindinger *et al.*[7] using a flow-drift tube. Their results show that the thermal-energy rate constants were given reasonably well by the Langevin (nonpolar) or the ADO(polar) collision rate constants in most cases. However, the translational-energy dependence of the reaction-rate constants was not that predicted by these theories; *i.e.*, the rate constants of all proton transfer reactions to NH_3, except that for the reaction $NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2$, decline with the relative kinetic energy less steeply than would be predicted from the ADO theory. These rate constants even show a Langevin-like behavior in a certain kinetic energy region above the thermal region. Thus, although no generalized conclusion can be drawn from this limited number of studies, the $E^{-1/2}$ dependence of the cross section observed in the present study is in line with the general trend observed by Lindinger *et al.* for the proton transfer reactions with NH_3.

Propyne–Ammonia System. In the propyne–ammonia system, the determination of the relative

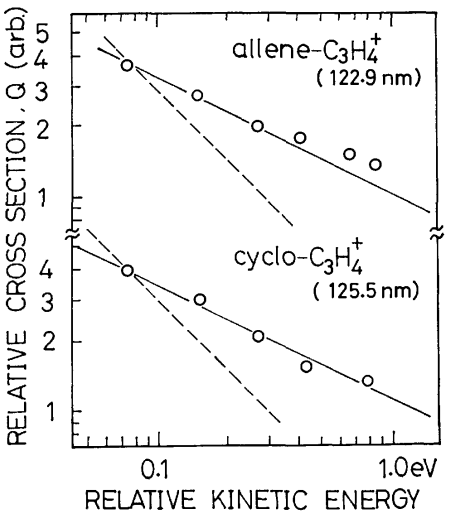

Fig. 3. Kinetic energy dependence of the cross sections for the reactions $C_3H_4^+ + NH_3 \rightarrow NH_4^+ + C_3H_3$. Allene and cyclopropene were ionized to produce $C_3H_4^+$ at 122.9 and 125.5 nm radiation, respectively. Solid and broken lines indicate the $E^{-1/2}$ and E^{-1} dependence, respectively.

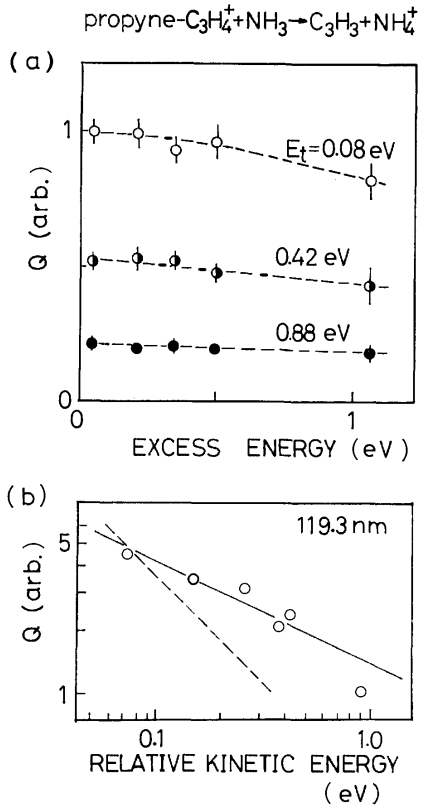

Fig. 4. Dependence of the cross section for the reaction $C_3H_4^+$(propyne) $+ NH_3 \rightarrow NH_4^+ + C_3H_3$ on the excess internal energy of $C_3H_4^+$ at 119.3 nm radiation. Solid and broken lines indicate the $E^{-1/2}$ and E^{-1} dependence, respectively.

cross section of Reaction 1 is not as straightforward as in the above two systems, since, as was mentioned earlier, ammonia is always ionized by the radiation which ionizes propyne. That is, the following reactions must also be taken into consideration:

$$NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2, \quad (10)$$

$$C_3H_4^+ + NH_3 \rightarrow NH_3^+ + C_3H_4, \quad (11)$$

$$NH_3^+ + C_3H_4 \rightarrow NH_4^+ + C_3H_3. \quad (12)$$

The extent to which Reaction 10 contributes to the formation of NH_4^+ could easily be estimated from the study with pure ammonia, thus, the NH_4^+ intensities obtained in the mixtures have been corrected for this contribution. However, it is difficult to assess the importance of Reactions 11 and 12 by the use of the present technique. We have examined the variation in the NH_3^+ intensity as a function of the pressure of the added C_3H_4, keeping the NH_3 pressure constant; no significant change was observed within the experimental error at any wavelength. The implication of this result may be either that both Reactions, 11 and 12, are negligible compared, respectively, with Reactions 1 and 10, or that both reactions are fast but proceed, fortuitously, at almost the same rate, leading to no net change in the NH_3^+ intensity. Although the latter possibility can not be ruled out completely, we dared to assume that both Reactions, 11 and 12, are negligible under the present experimental conditions and analyzed the data in the same way as in the allene–ammonia and cyclopropane–ammonia systems. The resulting relative cross sections for Reaction 1 are presented in Fig. 4 as a function of both the excess internal energy (Fig. 4a) and the relative kinetic energy (for the 119.3 nm irradiation). It is interesting to see that the cross sections obtained for the propyne-ammonia system with the above assumption show the same excess energy and translational energy dependence as those in the other two systems.

The Mechanism of Oxygen Reduction at a $LaNiO_3$ Electrode

Yasumichi MATSUMOTO, Hiroshi YONEYAMA, and Hideo TAMURA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka, 565

(Received September 7, 1977)

The reaction mechanism of the O_2 reduction at $LaNiO_3$ was studied by using a rotating ring-disc electrode, which consists of a $LaNiO_3$ disc and Pt ring electrodes. It was found that the O_2 was completely reduced to OH^- on the Hoare path. Oxygen vacancies seem to be required in the oxide surface for reduction of adsorbed O_2H^- to OH^-.

It was shown in previous studies[1,2] of the catalytic activity of transition metal oxides for the O_2 reduction that the band structure of oxides is a major factor in determining their catalytic activities. In order for the oxides to have a high catalytic activity, they must have a filled or partially filled σ^* band. $LaNiO_3$ satisfies this requisite, and hence shows high electrocatalytic activity for the O_2 reduction. It was also found that the O_2 reduction at $LaNiO_3$ and related oxides proceeded with the Hoare path and that the rate-determining electron transfer step, $O_2H+e\rightarrow O_2H^-$, was greately affected by the d-electron configuration in the σ^* band.

It is important to clarify the over-all reaction mechanism in order to elucidate the electrocatalysis of O_2 reduction. Especially important is the role which O_2H^- plays in the sequence of the reaction. The use of the rotating ring-disc electrode has been shown to be successful for this purpose.[3-7]

In the present study, therefore, the reaction mechanism of the O_2 reduction at $LaNiO_3$ is determined by using the rotating ring-disc electrode assembly, and the major factor which leads to O_2H^- formation is discussed.

Experimental

A rotating $LaNiO_3$ disc electrode with a Pt ring was prepared by the following method. A $LaNiO_3$ disc electrode of 6 mm diameter was prepared in the same manner as described in a previous paper,[8] and then assembled in a Teflon rod together with a Pt ring (6.7 mm in inner diameter and 9 mm in outer diameter). The area of the disc electrode was then 0.28 cm^2, and the geometric factor N was 0.39, as calculated from the dimension of the disc and ring electrodes.

The ring-disc electrode was set in a rotating ring-disc measurement system (Nikko Keisoku, model RRDE-1). The electrolytes were 1 M** NaOH and NaOH–Na_2SO_4 mixtures. The latter was prepared so as to give the same ionic strength as 2 M NaOH, but various pH values. A hydrogen electrode, H.E., in the test electrolytes was used as a reference electrode. The electrode potentials cited in this paper are referred to this electrode, unless otherwise stated.

As the pretreatment of the disc electrode, it was washed with acetone, followed by immersion in 0.5 M H_2SO_4 for 10 s, and then washed with distilled water.[9] The pretreatment of the Pt ring electrode was made electrochemically; it was polarized at 1.8 V for 30 s in the same solution as the test electrolyte in order to eliminate the adsorbed impurities on the surface, then at −0.1 V for 30 s to reduce an oxidized surface, and finally for about 3 h at 1.4 V, which was the same potential as that selected for detection of O_2H^-. The background current decreased to less than 0.2 μA by the final treatment, and thereby reproducible results could be obtained. Potential-current curves of the disc electrode were measured under a potentiostatic condition, and the oxidation current of O_2H^- at the ring electrode was measured at 1.4 V.[3]

** M=mol·dm^{-3}.

Results

Figure 1 shows the ring current, I_r, and the disc current, I_d, as a function of disc electrode potentials, E_d. The rotation rate, ω, was set at 2000 min^{-1}. A very small ring current was observed in the potential region less positive than 0.825 V.

$1/J$ *vs.* $\omega^{-1/2}$ plots are shown in Fig. 2 for the limiting current region, where $J=|I_d|+I_r/N$. As shown in Fig. 1, I_r was very small compared with I_d, and hence I_r negligibly contributed to J. The conclusion can be drawn, therefore, from the good linearities between J and $\omega^{-1/2}$ that the reaction order of O_2 is 1[10] in the potentials giving a saturated $|I_d|$ at which the rate detremining step is O_2 adsorption to the electrode surface[1].

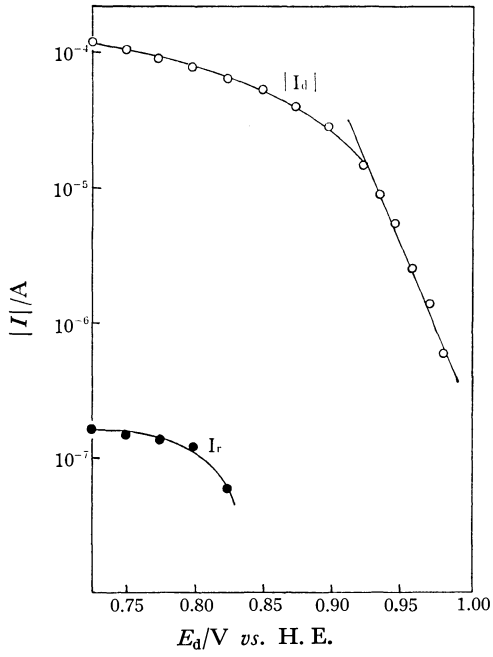

Fig. 1. Ring and disc currents in 1 M NaOH as a function of the disc potentials.

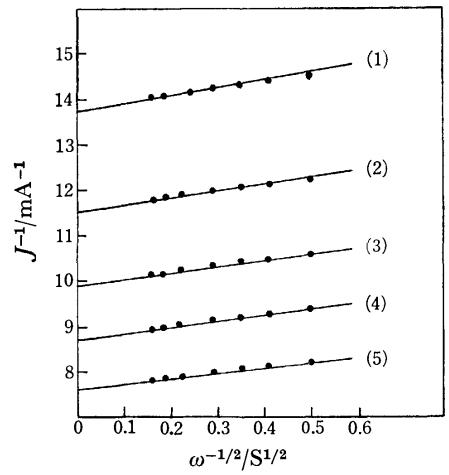

Fig. 2. $1/J$ *vs.* $\omega^{-1/2}$ plots in 1 M NaOH. E_d/V: (1) 0.825; (2) 0.8; (3) 0.775; (4) 0.75; (5) 0.725 (*vs.* H. E.).

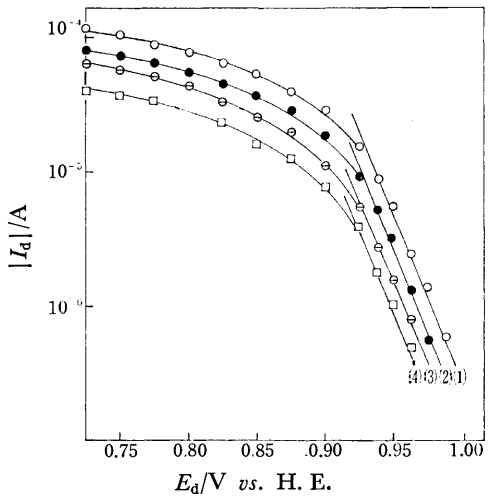

Fig. 3. Dependence of current-potential curve of O_2 reduction in 1 M NaOH on P_{O_2} at $\omega=2000\,\text{min}^{-1}$. P_{O_2}/atm: (1) 1; (2) 0.5; (3) 0.2; (4) 0.1.

Figure 3 shows an effect of introduced oxygen pressure, P_{O_2}, on the current-potential curves at the disc electrode. The relations between log P_{O_2} and log $|I_d|$ in the potentials giving the Tafel slope are shown in Fig. 4. The slope of the line in this figure is about 0.8, from which it is suggested that the reaction order of O_2 in the Tafel region is also 1.

Figure 5 shows $|I_d|$ in the Tafel region as a function of pH of the electrolytes. In this case, the disc potential values are converted into the normal hydrogen electrode scales so that the reaction order of OH^- can be directly obtained form the slope of log $|I_d|$ *vs.* pH plots.[11] It is noticed that good linearities were established between log $|I_d|$ and pH, and that the slope was about -0.8, although the points are a little scattered. This result implies that the reaction order of OH^- in this potential region is -1. Then the rate equation in the Tafel region can be written as follows with the rate constant k:

$$I_d = k[O_2][OH^-]^{-1}\exp(-\Delta G^*/RT), \qquad (1)$$

where ΔG^* is the electrochemical activation energy,

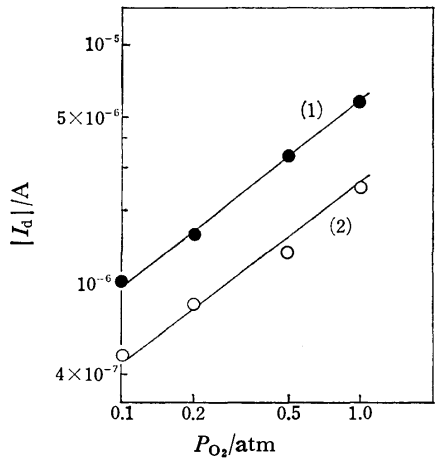

Fig. 4. log $|I_d|$ *vs.* log P_{O_2} plots in 1 M NaOH. E_d/V: (1) 0.95; (2) 0.9625 (*vs.* H. E.).

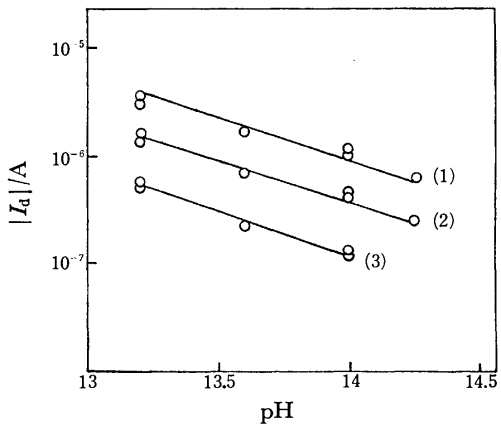

Fig. 5. log $|I_d|$ *vs.* pH plots in the Tafel region at $\omega=2000\,\text{min}^{-1}$. E_d/V: (1) 1.2; (2) 1.45; (3) 1.7 (*vs.* NHE).

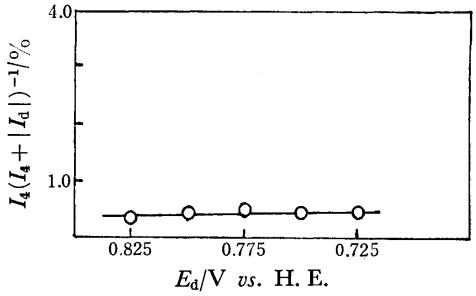

Fig. 6. $I_4/(I_4+|I_d|)$ at $\omega=2000\,\text{min}^{-1}$ in 1 M NaOH as a function of the disc potentials.

which was discussed in detail in Ref. 12. Equation 1 contains all the reaction steps preceeding to the rate determining step.

Figure 6 shows $I_4/(I_4+|I_d|)$ as a function of the disc potentials, where I_4 denotes the total current of OH^- diffusing away from the disc electrode to the solution (Fig. 7), and is given by I_r/N.[13] The I_1 path in Fig.7 means that O_2 is directly reduced to OH^- through a side-on type adsorption of O_2. The value of $I_4/(I_4+|I_d|)$ was 0.4% and almost equal to those observed at cobalt mixed oxides ($CoO+Co_2O_3$), Co_3O_4, and Co_2NiO_4 electrodes,[6,7] suggesting that

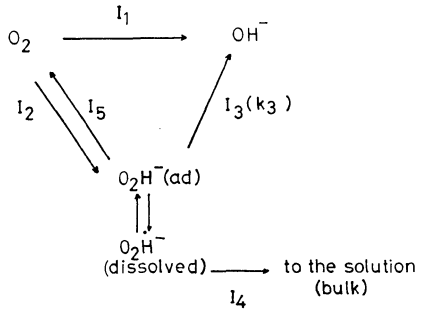

Fig. 7. A general scheme of O_2 reduction in alkaline solutions.

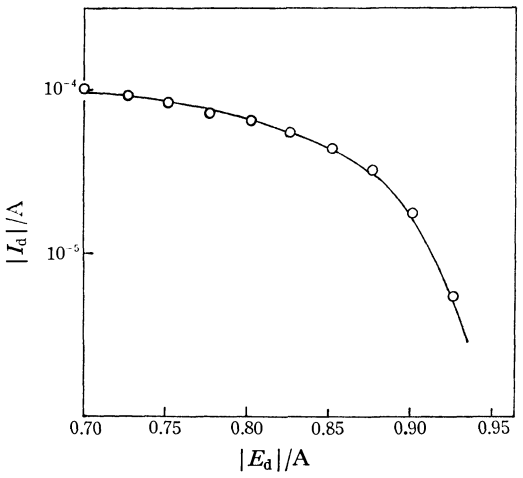

Fig. 8. Current-potential curves for reduction of O_2H^- at $\omega = 2000\ min^{-1}$.

O_2 is predominatnly reduced to OH^- at a $LaNiO_3$ electrode. The $|I_d|/I_r$ *vs.* $\omega^{-1/2}$ plots were so scattered that k_3 could not be determined. The small ring current seems to be responsible for the large scatter of the plots. In order to elucidate the role of OH^- in the reaction scheme of the Hoare path, the feasibility of the O_2H^- reduction was investigated in 1 M NaOH saturated with N_2. The O_2H^- concentration was 10^{-2} M. It was found that the reduction of O_2H^- proceeded easily at the disc electrode, as shown in Fig. 8.

As reported in a previous paper,[14] the NiO used as a starting material to synthesize $LaNiO_3$ remained as an isolated phase in $LaNiO_3$ if the preparation was made in a very short time or at a low temperature. Therefore, there is a possibility that the $LaNiO_3$ used in the present study contained a very small amount of isolated NiO, even though $LaNiO_3$ was prepared at 850 °C for 2 days. Bagotzky *et al.*[7] reported that O_2H^- ions were produced in the O_2 reduction on NiO at a potential region less positive than about 0.8 V and that the O_2H^- produced was not further reduced. This potential was in accord with that found in the present study for commencement of the very small ring current (see Fig. 1). Therefore, it seems reasonable to consider that NiO as an impurity in $LaNiO_3$ is responsible for the production of O_2H^- at the disc electrode. If this view is valid, then it can be concluded that O_2 is completely reduced to OH^- and that O_2H^- in solution is easily reduced to OH^- at $LaNiO_3$ with no isolated phase.

Discussion

The rate Eq. 1 holds for the Hoare path of the O_2 reduction at $LaNiO_3$, as described in previous papers.[1,2,14] Then the following reaction scheme will be valid:

$$O_2 \rightarrow O_2(ad), \quad (2)$$

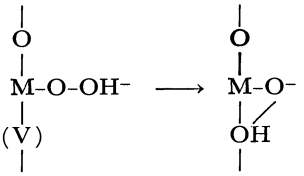
$$O_2(ad) + e \rightarrow O_2^-(ad), \quad (3)$$

$$O_2^-(ad) + H_2O \rightarrow O_2H(ad) + OH^-, \quad (4)$$

$$O_2H(ad) + e \rightarrow O_2H^-(ad). \quad (5)$$

The rate determining step was found to be step (5) when the Tafel relation holds, and (2) for the limiting current case.[1] Presnov *et al.*[15] proposed the feasibility of a reaction scheme similar to that proposed here from a general treatment of oxide catalysts on the basis of a knowledge of coordination chemistry.

Any step subsequent to (5) has to conform to the experimental result of non-detection of O_2H^- in the electrolyte. The rearrangement of adsorbed O_2H^- on the electrode surface in a manner such as that shown in Eq. 6 seems to be feasible for the formation of OH^-:



(6)

Here (V) denotes an O^{2-} ion vacancy on the oxide surface. If step (6) does rapidly occur, the desorption of O_2H^- (ad) will not take place, and hence no detection of dissolved O_2H^- is possible at the ring electrode. In this case the electron transfer from the electrode to the σ^* orbital of the adsorbed O_2H^-, which follows step (6), must destroy its σ bond and then OH^- will be produced. Such a mechanism seems to fit well for preferential reduction of O_2 to OH^- at $LaNiO_3$.

In the process of the rearrangement of the adsorbed O_2H^- (Eq. 6), an O_2^- ion vacancy is required at the oxide surface. In the case of $LaNiO_3$, the surface composition may be represented as $LaNiO_{3-\delta}$, where δ is the deficiency of O^{2-} from the stoichiometric composition and was about 0.2 to 0.3 in the O_2 reduction potential region[9] Therefore, step (6) is likely to take place. The results that O_2 was completely reduced to OH^- and that the reduction of O_2H^- proceeded quite easily at this oxide seem to be reasonable in the light of the mechanism proposed.

Co_2O_3, Co_3O_4, and Ni_3O_4 seem to have a fairly large number of O_2^- vacancies; but not so with NiO and CoO when these oxides are polarized in alkaline solutions in potentials less positive than about 0.9 V, in which the O_2 reduction proceeeds,[6,7] because thermodynamically NiO and CoO are very stable in this potential region. It was reported that the O_2 reduction at cobalt mixed oxides ($CoO+Co_2O_3$), Co_2O_3, and Co_2NiO_4 gave no appreciable amount of O_2H^- and that O_2H^-, when added to an electrolyte, was easily

reduced at these oxides.[6,7] On the contrary, the O_2 reduction at NiO gave O_2H^-, and O_2H^- was not reduced to OH^-.[6,7] These results, therefore, support the necessity of O^{2-} vacancies for the O_2 reduction. In the case of the mixed cobalt oxides, O_2H^- might be produced on the CoO phase but it must immediately be reduced further to OH^- on the co-existing Co_2O_3 phase. Because of this, the ring current is believed to have been detected only very faintly.[6,7]

It is predicted from the above discussion that O_2 is completely reduced to OH^- at $La_{1-x}Sr_xMnO_3$ and $La_{1-x}Sr_xCoO_3$ catalysts[16,17] in alkaline solutions, because these oxides have some O^{2-} vacancies in the potential region where the O_2 reduction proceeds.

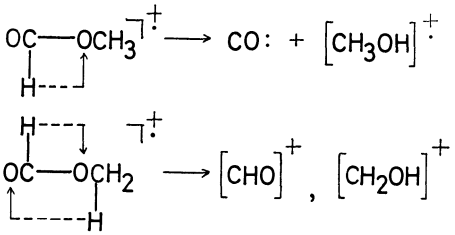
A Theoretical Approach to the Rearranged Ion in the Mass Spectrum of Methyl Formate

Tsutomu TAKAGI* and Masayoshi OIWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita, Osaka 564

(Received October 19, 1977)

The hydrogen-migration mechanism of the fragmentation of the methyl formate under electron impact has been discussed from the standpoint of the all-valence electron semi-empirical SCF-MO theory (CNDO/2-Unrestricted Hartree Fock), assuming the following models:

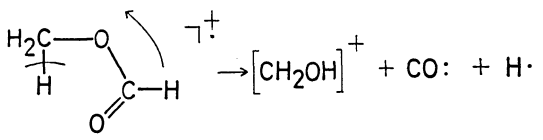


The model for the hydrogen migration and the possible driving force are presented based on the partition method. The localized MO calculation has been carried out, by the "energy localization" method of the MINDO MO's, for the origin and the terminus of the migration as an aid to the understanding of the migration. Although the possibility of the hydrogen migration in other models can not always be neglected, the hydrogen migration via Model 1 may be estimated to be energetically favorable, judging from the variation in the total energy and the conformation influence.

It is interesting to disclose the migration processes[1] involved in the fragmentation from the standpoint of the molecular orbital theory (MO theory), although the empirical speculations of the migration mechanisms based on a variety of mass spectral data have been presented by many investigators. The analyses of the mass spectral data of organic compounds has not been completely established because of the complexity of the driving factors governing the cleavage of the molecular ion $M^{\dagger}$ on electron-impact collision. In order to establish the rules governing fragmentation, it is important to clarify the mechanism of the intramolecular migration of hydrogen.

In a previous paper,[2] models for the hydrogen migration in butyl alcohol were reported. The results have been related to the ease of the cleavage of the $M^{\dagger}$ ion to the $[M-H_2O]^{\dagger}$ ion in the rearrangement process. This simple model employed was able to explain the mechanism.

In the mass spectrum of methyl formate, the peak thought to be the ion formed by the rearrangement was observed. Production of the ion with a *m/e* 32 involves hydrogen rearrangement from the formyl carbon to the oxygen atom. The base peak corresponds to the CH_2OH ion with a *m/e* 31 due to the loss of hydrogen[3] on the methyl group. The $[CH_2OH]^+$ ion is probably formed by the following mechanism:[4]



This migration mechanism has however not been fully elucidated, but only speculated from the mass spectral data.[5]

The present paper is concerned with the hydrogen-migration mechanism in methyl formate and the variation of energy in terms of the MO theory. In the model-process simulated, the migration points, the driving force in the hydrogen migration and the energy profiles obtained from the CNDO and MINDO calculations are reported. The bonding interaction along the migration path has also been examined.

Computation and Geometry

Computation. All computations were carried out on a NEAC 2200 Model 700 computer at Osaka University. The semi-empirical SCF-MO wave functions were computed with the CNDO-UHF method developed by Pople and coworkers.[6] The AO parameters used for CNDO were those originals[7] reported by the authors. The energy partitioning was obtained from the method reported by Fischer[8] and Gordon.[9] The LMO calculation was carried out using the "energy localization" method of Edmiston-Reudenberg.[10]

Geometry. The starting geometry for the migration requires a minimization of the total energy of the system with respect to all its independent internal coordinates, and the generation of a complete potential energy surface for the chemical reaction requires a path in the energy minimum. The problem is that the conformation and the electronic state of the $M^{\dagger}$ ion absorbing energy in the ionizing chamber have stable geometries and the migrating hydrogen has a path in the energy minimum.

For the rearrangement model, it is, therefore, important to clearly decide the geometry. However, under electron impact, it is difficult to absolutely determine the reaction coordinate passing through the equilibrium geometry. The instantaneous conformation of the $M^{\dagger}$ ion which had absorbed the energy could not be established. According to Franck-Condon,[11] it may

be assumed that the geometry of the M^+ ion is in the ground state. Consequently, the assumed models in the migration process are as shown in Fig. 1.

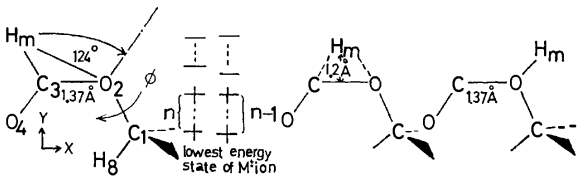


Fig. 1. Schematic representation of hydrogen-migration from carbon to oxygen.
n represents a number of the occupied MO and the numbering system of the atoms is that used in this paper.

Five points were chosen to form a path representing the hydrogen migration from the formyl carbon(C_3) to Oxygen(O_2). The terminus structure employed here was decided from the stability of the conformation of the CH_3OH. Point 3 in which angle $\angle C_3H_mO_2$ is 60° was also available for the intermediate structure and then the other points were situated in the middle of these points. The distance between the center of the C–O bond and the migrating hydrogen at Point 3 was assumed to be 1.2 Å; 1.2 Å was defined judging from the energy minimum state in which the conformation is energetically stable with 1.1 and 1.3 Å. The length of the O_2–C_3 bond with 1.37 Å was chosen as the terminus of the migration. As shown in Fig. 2, the total energy changed with the length of the O_2–C_3 bond at Points 4 and 5; thus the total energy was a minimum at 1.37 Å.

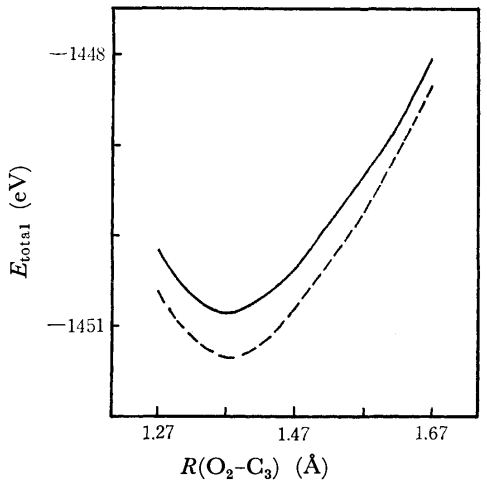

Fig. 2. Variation of the total energy with O-C bond length for Points 4 and 5.
——: Point 4, ----: Point 5.

The bond lengths and bond angles for the origin of the migration, with the exception of the C_2–O_3, were taken from the standard tables.[12]

The migrating hydrogen in the terminus is then situated in the XY plane as shown in Fig. 1 and the hydrogen atom migrates in this plane. The conformations in Models 1 and 2 were chosen to be planar with $\phi=0°$ and $\phi=180°$, respectively. The form of the CH_3OH in the terminus of the migration is an eclipsed one in Model 1, while in Model 2 it is a staggered one.

TABLE 1. MOLECULAR GEOMETRIES[a] FOR THE MIGRATING POINTS

Parameter[b]	1 Origin	2	3	4	5 Terminus
$\angle O_2C_3H_m$(°)	118.5	86.5	60.0	38.8	27.7
$R(O_2\text{-}H_m)$(Å)	2.119	1.736	1.382	1.052	0.960

a) The other parameters were described in Fig. 1.
b) Application of the law of cosines for a triangle.

In Model 3, the path synchronously representing the two hydrogenes (H_m and H_8) in the following figure was selected, in which the movement of H_8 was chosen with respect to the least-motion path from C_1 to the lone pair of O_4. The lengths between O_4 and H_8 in each point are 2.920, 1.753, 1.457, 1.184, and 0.960 Å, and then the others are the same as Model 1.

Finally, the electronic states of the M^+ ion are not the only states that loses an electron in the highest occupied orbital; the states in any part of the lower orbitals also lose electrons. However, the demotion step of an electron from the higher energy levels to the lower vacant level may occur before fragmentation.[13] Therefore, the electronic state of the M^+ ion employed has been the lowest energy state, as found in butyl alcohol.[2]

Results and Discussion

Energy Profile. The results of the CNDO calculation in methyl formate are summarized in Table 2. This treatment was found to give a good description of the cleavage of the C–H bond during the migration.

It is apparent from the shape of the curve in Fig. 3 that the transition state lies in the latter half of the reaction. Both the total energy profiles which were obtained from Models 1 and 2 show a maxima at Point 3 along the coordinate representing migration of the hydrogen from C_3 to O_2. The total energy tends to decrease after the transition state. These results suggest that the small potential energy easily

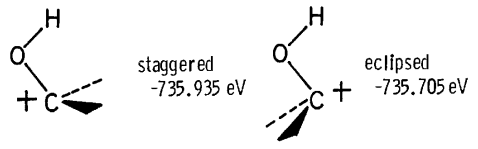
a) Energy in eV. b) The total energy, E, in the CNDO scheme, can be partitioned into chemically useful terms, $E=\sum_A^A E_A+\sum_{A<B} E_{AB}$; in which $E^U=\sum_r^A P_{rr}U_{rr}$ and $E^R=2\sum_r\sum_s P_{rs}S_{rs}\beta^\circ_{AB}$. There is a qualitative correspondence between E_{AB} and the bond length; thus the values of E_{AB} for the strong bonding interaction are very large and negative one.[14] c) Values in parentheses correspond to E^R.

initiated the migration. The potential energy, 3.3 eV in Model 1, is small in comparision with the ionization potential. Moreover, the variation of the total energy of the system is small in comparison with the appearance potentials of the fragment ions. The difference between the total energy of the ground state of the molecule and that of the M^+ ion is also smaller than the appearance potentials in the simple fragmentation. The potential energy, 3.3 eV, is thus small in comparision with the minimum energy required to bring about scission of the bonds. Then, the variation of the total energy in the origin of the migration in both Models, which is 2.4 kcal/mol, is the small difference. The difference in the terminus energies of both Models is smaller than that in the origin and this indicates that the migration by both Models is energetically favorable and that Model 1 is more favorable.



In the fragment ion, *i.e.*, CH_3OH ion, the calculation of methyl alcohol[15] in the cation radical state predicts the staggered form to be more stable energetically. In the calculation on the fragment ion, it is predicted that the CH_2OH ion in the cation state has the lower energy in the staggered form. The difference in the total energy is 5.3 kcal/mol. It seems that the terminus of the migration is favorable in the staggered form.

Here, the driving force in the hydrogen migration was interpreted using the partitioned energy. The variation of the one-center term $\Delta\sum E_A$, is 1.67 eV and that the two-center term $\Delta\sum E_{AB}$, 0.426 eV. The driving force from the origin to the terminus form is, therefore, found principally in the two-center term. As is shown in Table 2, it was found that the partitioned energy contributing to this migration was the resonance energy in which there was proportionality between the total energy and the E^R value. The resonance energy term (E^U+E^R) decreases with the hydrogen migration in both Models. It has been suggested that the decrease in energy is due to the resonance effect and that the decrease in total energy results from the steric effect.

The sum of the E_{AB} values of the two bonds ($C_3\text{-}H_m+O_2\text{-}H_m$) decreases along the latter half of the reaction. This decrease implies that the bonding interaction between oxygen and the approaching hydrogen becomes

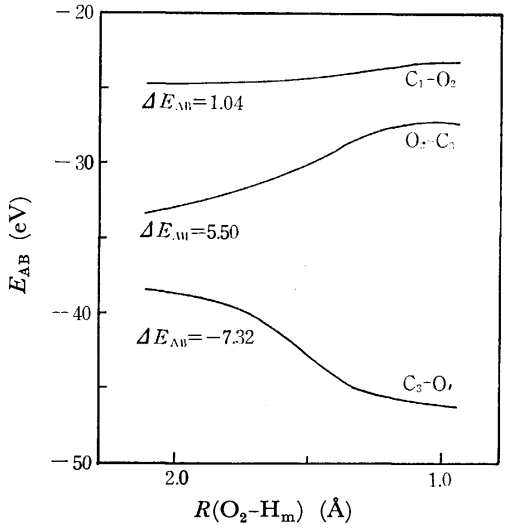


Fig. 4. Variation of E_{AB} of each bond to migration in Model 1.

stronger in this process. As shown in Fig. 4 the bonding interaction energy of the O_2–C_3 bond increases remarkably with the approach of hydrogen to O_2; this shows that the interaction between O_2 and C_3 is weakened by the hydrogen migration in Model 1. The variation of the E_{AB} value of the C_1–O_2 bond is smaller than that of the O_2–C_3 bond, whereas the E_{AB} value for the C_3–O_4 bond decreases remarkably. These results may be related to the ease of the cleavage from the M^+ ion to the CH_3OH ion.

Table 3 shows the energy profile calculated by the MINDO calculation in the hydrogen migration in Model 1; both predict the decrease of the E_{AB} value of the sum of the two bonds and the resonance energy, although there are some differences between the CNDO and MINDO. The total energy and the E_{AB} of the

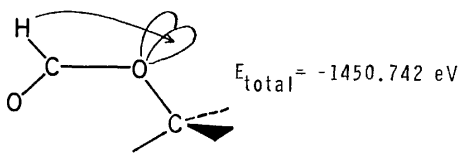
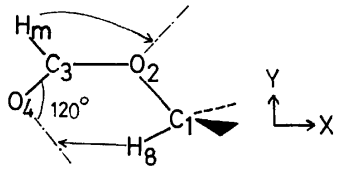
a) Geometries are same as CNDO and energy in eV.

O_2–C_3 bond are more stable at the terminus of the migration. It is also shown that investigation for hydrogen should be esitmated from MINDO.[16)]

The energy barrier by rotation of the O_2–C_3 bond is 1.2 kcal/mol, which is small in comparison with that of the CH_3 group. So, the hydrogen migration in Model in such a conformation was considered. Consequently, the total energy changes from −1453.279 to −1443.630 eV in the CNDO and this variation is larger than in the models discussed previously. There are then, as many conformations existing as migration processes, but the most likely conformation is the planar form. In the terminus form in the model the migration hydrogen is out of the molecular plane in the figure. The angle between the two lone pairs and the O_2–H_m bond is 61.8°[17)] in this model. As a results, the variation of the total energy is 61.7 kcal/mol which compared with Model 1 decreases



by more than 10 kcal/mol. It has been concluded this model that for the migration toward the lone pair of O_2 is energetically less favorable than Model 1. The formation of the CH_2OH ion has been discussed in terms of the synchronized migration model, *i.e.*, Model 3 in which the migration of hydrogen on the



CH_3 group in the molecular plane was employed. The movement of H_m is the same as in Model 1 and H_8 synchronously migrated to O_4. Table 4 shows the variation of the energies with the migration. The total energy increases remakably with the migration, though there is a slight decrease at the end of the migration. The change of the bonding interaction of the O_2–C_3 bond shows the remarkably increasing trend. The sum of the E_{AB} values of the two bonds for H_m changes randomly, implying that the migration of H_m is prevented by H_8. Convertly, the length between O_4 and H_8 at the origin and the terminus of the migration, 2.920 Å, is larger than that for H_m. However, the E_{AB} value decreases during the migration from Point 3 to Point 4. Consequently, the migration of H_8 may be possible, judging from the variation of the E_{AB} value. These results are energetically in agreement with regard to the mass spectral data; the peaks of the CH_2OH ion and the CHO ion are in abundance, which shows that this process is possible.

It may be possible that H_8 migrates from C_1 to O_4 just like protonated formaldehyde.[18)] Thus, the process which H_8 migrates to the lone pair of O_4 was calculated, in which H_m was fixed at the origin of the migration. The variation of the sum of the two bonds was similar to that in Model 3. The total energy increases with the migration, but in the latter half tends to decrease. The E_{AB} values of the O_2–C_3 bonds in the origin and the terminus were −33.145 and −33.572 eV, respectively, implying that the bonding interaction of the O_2–C_3 bond does not weaken by the migration of H_8 alone. These results show that the peaks of HCO(H)[19)] ion and CH_2O ion with a *m/e* 30 is in less abundance. These peaks are, in fact, in less abundance in the mass spectrum of methyl formate.

Considering the variation of the total energy, the profile is as follows, (the values are the total energies of the systems). The variation of the toatl energy in each system predicts that the fragmentation

TABLE 4. VARIATION OF THE TOTAL ENERGY AND E_{AB}[a)]

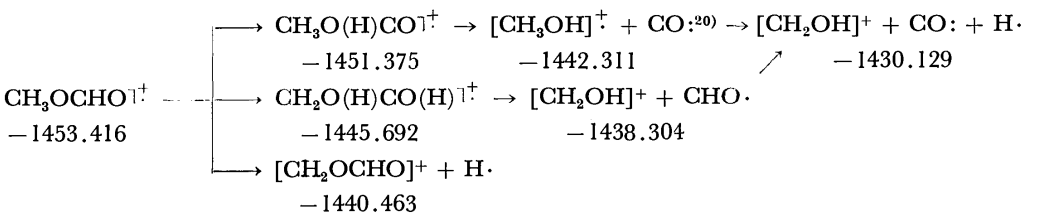
a) Energy in eV.



reaction in methyl formate would be *via* the $CH_3O(H)CO^+$; the fragment ion, $[CH_3OH]^+$, is produced by the elimination of CO from the terminus of the migration. Judging from the variation of the total energy the CH_2OH ion results from the elimination of hydrogen from the CH_3OH ion in methyl alcohol. In the case of methyl formate, the CH_3OH ion decomposes further, and one of the energetically most favorable paths appears to be α-cleavage[21] to give the stable CH_2OH ion. The bonding character of the particular bond, *i.e.*, the O_2–C_3 bond varies from bonding to antibonding with the migration. Moreover, the bonding character of the O_2–C_3 bond changed from bonding(0.232) to antibonding(−0.143), as the electron was excited from the single occupied MO to the lowest unoccupied MO; thus the O_2–C_3 bond was weakened by the migration and then by the excitation in the origin of the migration. There is then the possibility that hydrogen migrates to O_2 before scission of the O_2–C_3 bond.

Charge Distribution. The changes of the electron densities of the atoms along the reaction coordinates have been examined and the results of the calculation for Model 1 are summarized in Table 5. It is immediately apparent from the densities that the most significant electron density changes observed are on the atoms: *viz.* C_3 and O_4. There is an increase in the atomic population on C_3. This electron flow to C_3 and O_4 implies that the CO has a stabilizing radical in the migration process. There is the charge on the CHO side in the origin of the migration. However, when H_m migrates to O_2, the charge moves to the CH_3OH side;

$$[OHC]^+\text{-}OCH_3 \rightarrow CO\text{-}[HOCH_3]^+.$$

Thus, the elctron density of H_m decreases with the migration as is shown in Table 5. It seems the migrating hydrogen moves like a proton, judging from the variation of the density of H_m. From the results of the hydrogen migration, it appears that the charge of the system remains on the CO, suggesting the formation of the $[M-CO]^+$ ion with a *m/e* 32. A decrease of electron on H_8 and an increase on O_4, was seen, *i.e.*, H_8 in the methyl group is a movable hydrogen and in the same way as the rearrangement of hydrogen to oxygen in aldehydes, there is a good chance of migration from C_1 to O_4. The increase of the electron on O_4 interacts with H_8 and may be considered as a driving force. Therefore, the influence of the synchronized migration of H_8 on the migration of H_m should be discussed.

Table 5. Atomic populations

Atoms	1	2	3	4	5

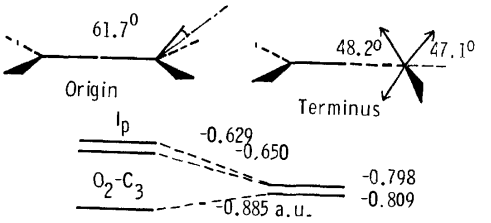
Localized MO. The simplest relation between the origin and the terminus of the migration by the LMO representation is as follows. In the terminus of the migration the O_2–C_3 bond becomes the lone pair of oxygen and the radical orbital of carbon.The increase of LMO energy of the O_2–C_3 bond due to the migration results from the change to the weak C–O bond due to the conversion of the O_2–C_3 bond to the lone pair. However, the increase of this MO energy is considerably offset by the lone pairs.

Table 6. % s nature[a] in Model 1

	Origin	Terminus
C_3–O_2	34.12	7.98
O_2–C_3	16.25	25.37
O_2–C_1	23.09	21.21
C_3–O_4	18.47	20.05

a) Percent s nature determined by summing the squares of the coefficients of the AO contribution to the LMO and dividing this by the 2s AO coefficient.



In Table 6, the values of the % s nature of the hybrid orbitals contributing to the localized orbitals are given. From this data, it seems that there is a remarkable decrease in % s in the C_3–O_2 bond. The % s of the C_3–O_2 bond decreases by 7.98 with the migration. This indicates that the electrons are highly localized in the C_3–O_4 bond and in the shape as the C_3 radical orbitals; since the s AO energy is lower than the p AO, the lower value of s nature leads to the more unstable state. This picture is more directly attainable than from the set of LMO.

Conclusion

There are many configurations in the M^+ ion produced by electron impact. The fragment ions and

the rearranged ions result from the fission of the M^+ ion produced. Therefore, it is difficult to absolutely determine the geometry and the electronic state of the M^+ ion which has absorbed the energy and the path of the hydrogen migration. As a model, the lowest energy state of the M^+ ion in the planar form and the terminus form of the migration which has the lower energy in the staggered form were employed . This indicates that the hydrogen on the formyl carbon migrates to O_2. This simple model gives a fairly good feature with respect to the CH_3OH ion and the CH_2OH ion in the mass spectrum. The treatment of the M^+ ion using the partitioning energy yielded results in the rearrangement reaction.

The authors wish to thank Professor Teijiro Yonezawa of Kyoto University for providing the program of LMO calculations.

The Structure of Water in the Vicinity of Complex Ions of Transition Elements in Their Aqueous Solutions as Revealed by the Shift of the Temperature of Maximum Density of Water

Goro WADA*, Emiko NAGAO, Nagako KAWAMURA, and Kyoko KINUMOTO

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received October 20, 1977)

The temperature of the maximum density (TMD) of aqueous solutions was measured for twenty complex ions of transition metals. From the degrees of depression of TMD, Despretz's constant k_D^{ion} and the constant of excess depression of mixing Δk^{ion} were determined. These constants along with B^{ion} coefficient of viscosity give us information on the structure of water in the vicinity of ions. $[Co(H_2O)_6]^{2+}$, $[Ni(H_2O)_6]^{2+}$, $[Cu(H_2O)_6]^{2+}$, and $[Zn(H_2O)_6]^{2+}$ are electrostrictive structure-breakers in the natural order of Irving-Williams, Co(II)<Ni(II)<Cu(II)>Zn(II). Of the complexes $[Co(NH_3)_6]^{3+}$, $[Co(en)_3]^{3+}$, and $[Co(pn)_3]^{3+}$, the pn-complex is the strongest hydrophobic structure-maker due to the hydrophobic nature of its aliphatic constituent. Both $[Fe(CN)_6]^{3-}$ and $[Co(CN)_6]^{3-}$ are fairly strong electrostrictive structure-breakers, while $[Fe(phen)_3]^{2+}$, $[Co(phen)_3]^{2+}$, and $[Co(phen)_3]^{3+}$ are clathrate-like structure-makers. The EDTA and CyDTA complex ions of Co(II), Ni(II), Cu(II), and Zn(II) show no significant difference in k_D^{ion}, the situation being complicated by the hydrophobicity of the ligands and the radius effect of the complex ion. The actions of ions as structure-makers should be classified into three categories; electrostrictive, hydrophobic (iceberg formation), and hydrophobic (clathrate-like structure formation). The characteristic influence of the structure-making nature on k_D^{ion}, Δk^{ion}, and B^{ion} is discussed.

The phenomenon of the maximum density of water occurring at 3.98 °C is interpreted as evidence that water exists as an equilibriating mixture of an ice-like structure (a so-called "iceberg") and a denser one without hydrogen bondings; the iceberg, whose fraction in water diminishes with increasing temperature, gives a smaller coefficient of thermal expansion than that of the denser structure, and the apparent coefficient of thermal expansion of water results in negative values below 3.98 °C.[1] Addition of a solute to water generally influences the equilibrium between the two different forms of water causing the shift of the temperature of maximum density (TMD) of water from 3.98 °C. Many simple electrolytes are known to depress the TMD of water, θ, as expressed by the Despretz rule,[2]

$$-\Delta\theta = k_D x \tag{1}$$

by which it is shown that the degree of depression of TMD, $-\Delta\theta$, is proportional to the mole fraction of a solute, x, at least in low concentration range with the Despretz constant, k_D. The observed data for many simple electrolytes have been published.[3]

Since Wada and Umeda[4,5] treated the TMD of aqueous solutions of various nonelectrolytes quantitatively in view of water structure, many investigations dealing with this phenomenon as a clue for clarifying the solute-water interactions have been carried out.[6–20] Cause of the depression of TMD of an aqueous solution from 3.98 °C ($-\Delta\theta>0$) might be explained as follows. The state of water in the solution at 3.98 °C corresponds to a state of pure water at a temperature higher than 3.98 °C, at which water is composed of the iceberg with a smaller fraction and the denser structure with a larger fraction than at 3.98 °C, the latter being promoted in the close vicinity around the solute added.

The molar volumes of pure water V_1, pure solute V_2, and their mixture V at a given temperature t in centigrade, in a small temperature range close enough to 3.98 °C, can be given by the following equations.

$$V_1 = V_1^*[1+\beta(t-3.98)^2] \tag{2}$$

$$V_2 = V_2^\circ(1+\alpha t), \tag{3}$$

$$V = (1-x)V_1 + xV_2 + \Delta V_x^E, \tag{4}$$

where V_1^* and V_2° are the molar volumes of water at 3.98 °C and of the solute at 0 °C, α and β are the coefficients of thermal expansion of the solute and water ($\beta=7.81\times10^{-6}\,K^{-2}$), and ΔV_x^E is the molar excess volume of mixing at the mole fraction of the solute x. By differentiating V with respect to t and equating the result to zero, the degree of the elevation of TMD, $\Delta\theta$, is given by the following relation.[4–6]

$$\Delta\theta = \theta - 3.98 = -\frac{1}{2(1-x)\beta V_1^*}\left[x\alpha V_2^\circ + \frac{\partial \Delta V_x^E}{\partial t}\right] \tag{5}$$

If ΔV_x^E were either zero in the case of an ideal mixing or constant by chance in the small temperature range around 3.98 °C in a special case, the second term in the bracket on the right-hand side of Eq. 5 would disappear and the Despretz constant k_D would be reduced to k at the limiting dilute concentration.

$$k = \frac{\alpha V_2^\circ}{2\beta V_1^*} \tag{6}$$

It is clear from Eq. 6 that k is always positive (namely, $-\Delta\theta>0$), since normal substances have positive values for α. Accordingly, the excess depression of TMD of real aqueous solutions at infinitely low concentration is dependent upon the temperature variation of the excess volume of mixing as follows.

$$\Delta k = k_D - k = \frac{1}{2\beta V_1^*}\left[\frac{1}{x}\cdot\frac{\partial \Delta V_x^E}{\partial t}\right]_{x\to 0} \tag{7}$$

For most simple electrolytes, ΔV_x^E is negative and $\partial\Delta V_x^E/\partial t$ positive due to the electrostriction in the hydration sphere of ions. On the other hand, some alcohols with hydrophobic alkyl radicals such as *t*-butanol exhibit large negative Δk, so large that k_D ($=k+\Delta k$) becomes negative and consequently $\Delta\theta$ positive.[4]

In the present investigation, twenty coordinate com-

plexes of some transition elements are adopted as solutes, with ligands of either hydrophilic or hydrophobic nature towards the surrounding water in contact. The observed $\Delta\theta$ might give some clue to the structure of water around the complex ions.

Experimental

Materials. Pure water was made up by treating tap water with ion-exchange resin, followed by double distillation of its alkaline permanganate solution.

For the preparation of aqueous solutions of $[Co(H_2O)_6]Cl_2$, $[Ni(H_2O)_6]Cl_2$, $[Cu(H_2O)_6]Cl_2$, and $[Zn(H_2O)_6]Cl_2$, hydrous salts of $CoCl_2$, $NiCl_2$, $CuCl_2$, and $ZnCl_2$ of special grade reagents were used without further purification. The concentrations of salts in each solutions were determined by titration with $AgNO_3$ for Co, Ni, and Cu salts and with EDTA for Zn salt. In order to avoid the partial hydrolysis of $ZnCl_2$, HCl was added to the solution of $ZnCl_2$. The TMD values for the solution were obtained by subtracting the value for HCl solution from that for the mixed solute, by virtue of the nature of additivity rule of TMD.[4]

The crystals of $[Co(NH_3)_6]Cl_3$ and $[Co(en)_3]Cl_3$ were prepared by the usual method. The crystalline $[Co(pn)_3]Cl_3$ (pn: propylenediamine) was obtained by modifying the method for the preparation of $[Co(en)_3]Cl_3$; an aqueous HCl solution of pn containing $CoCl_2$ was oxidized by aeration and the complex was crystallized by addition of hydrochloric ethanol.

The crystals of $K_3[Fe(CN)_6]$ and $K_3[Co(CN)_6]$ were obtained from commercial reagents of special grade.

The crystal of $[Fe(phen)_3]Cl_2\cdot 7H_2O$ was prepared as follows. An HCl solution saturated with nitrogen gas was mixed with $FeCl_2$ in the presence of iron wire at 60 °C for 20 min in order to reduce Fe(III) which might be present in $FeCl_2$. Stoichiometric amount of 1,10-phenanthroline was added to the mixture for the formation of the Fe(II) complex to which was added NaCl. Then the complex was crystallized by cooling. The crystal of $[Co(phen)_3]Cl_2\cdot 8H_2O$ was prepared in a similar manner to the case of Fe-complex. $[Co(phen)_3]Cl_3\cdot 7H_2O$ was made up by passing Cl_2 gas through $[Co(phen)_3]Cl_2$ solution for the purpose of oxidation, the excess amount of Cl_2 being eliminated by vacuum pumping. The concentrations of $[Fe(phen)_3]Cl_2$[21] and $[Co(phen)_3]Cl_2$[22] in solution were determined spectrophotometrically.

For the preparation of solutions of EDTA and CyDTA complexes (CyDTA: 1,2-cyclohexanediamine-*N*,*N*,*N'*,*N'*-tetraacetic acid), solutions of sodium salts of EDTA and CyDTA were mixed with those of chloride salts of respective metals in equivalent molar quantity. Thus each solution contained $Na_2[M(edta)]+2NaCl$ or $Na_2[M(cydta)]+2NaCl$. The TMD values for pure complex salt solutions were obtained by subtraction of the values for NaCl according to the additivity rule. In the case of Zn complexes, in addition to NaCl, HCl was necessary in their aqueous solutions for the purpose of suppressing the partial hydrolysis of Zn^{2+} ion. The TMD values were determined by also applying the additivity rule to the three kinds of solutes.

Determination of TMD. For the determination of TMD, a specially designed dilatometer was used.[4]

Determination of Coefficients of Thermal Expansion of Solutes. For the determination of α for various solutes, a specific gravity bottle of ordinary shape was used. Details of procedure have been reported.[4] Determination of α was not necessarily performed for all the complexes adopted in the present investigation, because of the difficulty in obtaining some complexes in pure form and not in the form of aqueous solution. It was found that the contribution of k to k_D was not large enough for the order of Δk in the respective series of homologues of complexes to be altered when k_D itself was adopted instead. Thus, theoretical considerations will be made by a comparison of either k or Δk_D.

Determination of B-Coefficients of Aqueous Solutions. The viscosity of the aqueous solutions of $K_3[Fe(CN)_6]$ and $K_3[Co(CN)_6]$ at 25 °C was determined with an Ostwald-type viscometer. It took 164.5 s for water to flow down at 25 °C. Accoding to the Jones-Dole equation,[23]

$$\frac{\eta}{\eta_0} = 1 + A\sqrt{C} + BC, \tag{8}$$

B-coefficient can be obtained from the slope of the linear plot of $[(\eta/\eta_0)-1]/\sqrt{C}$ against $\sqrt{C}$, in which η and η_0 denote viscosity of solution and of pure water, respectively, and C concentration of the solute.

Results and Discussion

The linear relationships of the shift of TMD, $\Delta\theta$, against the mole fraction of solutes, x, following Eq. 1, can be seen from the straight lines for some examples given in Fig. 1. The case for the solution of mixed

solute, $Na_2[Co(edta)]+2NaCl$, is shown in Fig. 2. Subtraction of the slope of the straight line independently observed for NaCl from that observed for the mixed solute gives the slope for $Na_2[Co(edta)]$ only.

Thus, the values of $\Delta\theta$ obtained for various solutes at various x give values of k_D for each solute. They are given in Table 1, along with the observed data of α and V_2° and the calculated values of k and Δk. On the simple assumption that the individual contributions of K^+ and Cl^- ions to the total KCl value of k_D, k, and Δk are equal to each other, these constants for all salts can be divided into each component ion, k_D^{ion}, k^{ion}, and Δk^{ion}, using values of $k_D^{ion}(K^+)=k_D^{ion}(Cl^-)=0.322\times10^3$ K, $k^{ion}(K^+)=k^{ion}(Cl^-)=0.007\times10^3$ K, and $\Delta k^{ion}(K^+)=\Delta k^{ion}(Cl^-)=0.315\times10^3$ K. The values of the ionic constants for complex ions thus obtained are given in Table 2, ionic values of B-coefficient also being given, on the basis of $B^{ion}(Cl^-)=-0.00_7$ at 25 °C.[28] The constants assigned for individual ions can be compared with each other only among ions of the same electric charges. However, it is meaningless to compare them between ions of opposite signs or different charges.

(i) $[Co(H_2O)_6]^{2+}$, $[Ni(H_2O)_6]^{2+}$, $[Cu(H_2O)_6]^{2+}$, *and* $[Zn(H_2O)_6]^{2+}$. As regards alkaline earth metal ions, the value of k_D^{ion} increases in the order Mg^{2+} $(0.10\times10^3) < Sr^{2+}(0.56\times10^3) < Ba^{2+}(0.66\times10^3)$.[3] It seems that the stronger electrostrictive structure-breaker the ion, the greater its k_D^{ion} value. The aqua complexes of transition metal ions are comparatively weak electrostrictive structure-breakers in the order Co(II)< Ni(II)<Cu(II)>Zn(II) as is seen in Table 2. Such an order is frequently recognized in the chemical properties of complexes of high spins, the so-called Irving-Williams' natural order[29] based on the crystal field stabilization energies and ionic radii. This indicates that the aqua complex of copper(II) displays the largest electrostrictive structure-breaking, probably due to Jahn-Teller's distortion, and that the structure of water in contact with the coordinated shell might be destroyed to the greatest extent in the case of copper(II).

(ii) $[Co(NH_3)_6]^{3+}$, $[Co(en)_3]^{3+}$, *and* $[Co(pn)_3]^{3+}$. The value of both k_D^{ion} and Δk^{ion} of these cobalt(III) complexes decreases in the order NH_3-complex>en-complex>pn-complex (Table 2). The outer layers of these complex ions are covered with many hydrogen atoms; $[Co(NH_3)_6]^{3+}$ has 18 H-atoms, which are all bonded with 6 N-atoms; $[Co(en)_3]^{3+}$ has 24 H-atoms, 12 of which are bonded with 6 N-atoms and the other 12 with 6 C-atoms; $[Co(pn)_3]^{3+}$ has 30 H-atoms, 12 of which are bonded with 6 N-atoms and 18 with 9 C-atoms. Due to the difference in the electronegativity of N and C atoms, an H-atom bonded with a C-atom is more hydrophobic than one bonded with an N-atom. Part of the positive charges on cobalt(III) is rather scattered on H-atoms bonded with N-atoms, in the manner $Co{\overset{\curvearrowright}{\underset{\curvearrowright}{N}}}H^{\delta+}$, making the ammine complex to

	H^+	0.032			
	Na^+	0.418			
	Cl^-	0.322	0.007	0.315	0.007[28]

be very hydrophilic. Thus, the outer layer of the coordinate sphere of the complex ions is more hydrophobic in the reverse order of k_D^{ion} and Δk^{ion}, namely NH_3-complex < en-complex < pn-complex. Probably, the icelike structure with hydrogen bondings might be promoted in the vicinity of $[Co(pn)_3]^{3+}$ in spite of its electrostrictive structure-breaking effect caused by the electric charge on the central metal ion. It seems that the stronger hydrophobic structure-maker a complex ion, the smaller both Δk_D^{ion} and k^{ion} values. A similar trend has been noticed in the series of hydrophobic alcohols.[4]

The values of *B*-coefficients from viscosity of their aqueous solutions are in the order NH_3-complex<en-complex<pn-complex,[24] in line with the expectation from the physical interpretation of *B*-coefficient.

(iii) $[Fe(phen)_3]^{2+}$, $[Co(phen)_3]^{2+}$, *and* $[Fe(phen)_3]^{3+}$. These 1,10-phenanthroline-complexes have very large values of k_D^{ion}, Δk^{ion}, and B^{ion} as compared with other cations with the same electric charges, but it is clear that they are of hydrophobic nature on account of phen molecules surrounding the central metal ions. The hydrophobicity of phen-complex ions of iron and cobalt is well accounted for by the fact that R_f-value of thin layer chromatography with aqueous solutions is 1.0 for $[Co(NH_3)_6]^{3+}$, while it is zero for phen-complexes.[30] The abnormally large values of k_D^{ion} and Δk^{ion} might arise not from iceberg promotion but from the occurrence of a clathrate-like structure of water formed around the phen-complex ions. This is deduced by the fact that a similar phenomenon has been found in the case of tetrabutylammonium ion where k_D^{ion} value is outstandingly large as compared with other homologous tetraalkylammonium ions, since only $(n\text{-}C_4H_9)_4N^+$ is of suitable shape and size to fit in a clathrate-like cage structure of water.[9] Of the three complexes, $[Co(phen)_3]^{2+}$ may have the most favored conditions[31] for the clathrate-like cage to wrap the complex ion in, although only the dimension of $[Fe(phen)_3]^{2+}$ is known.[32]

On the other hand, the large value of B^{ion} [24] indicates that the formation of clathrate-like structure would interfere with smooth flow of the aqueous solution; this may be easily understood by taking the steric framework of hydrogen bondings in clathrate structure into consideration.

The extent of development of clathrate-like structure is thus supposed to be in the order $[Fe(phen)_3]^{2+}$< $[Co(phen)_3]^{2+}$>$[Co(phen)_3]^{3+}$.

(iv) $[Fe(CN)_6]^{3-}$ *and* $[Co(CN)_6]^{3-}$. The value of both k_D^{ion} and Δk^{ion} of cyano complexes which are of hydrophilic nature lies in the order Fe(III)-complex>Co(III)-complex but that of *B*-coefficient lies in the reverse order. This is consistent, indicating that $[Fe(CN)_6]^{3-}$ ion is a stronger electrostrictive structure-breaker than $[Co(CN)_6]^{3-}$ ion. Since both are of low spin complexes, Fe(III)-complex has a smaller crystal field stabilization energy with a ionic radius longer than that of Co(III)-complex, thus being a weaker electrostrictive structure-maker or a stronger electrostrictive structure-breaker.

(v) EDTA and CyDTA Complexes of Co(II), Ni(II), Cu(II), and Zn(II). The values of k_D^{ion} and B^{ion} [26,27] do not significantly differ from each other among these complex ions, with the exception of k_D^{ion} of $[Co(cydta)]^{2-}$ ion. CyDTA has a cyclohexane ring in its molecule, which is very hydrophobic and is large in dimension. Consequently, the stronger hydrophobicity of CyDTA, which would make the value of k_D^{ion} smaller as a hydrophobic structure-maker, might cancel the effect of the larger ionic radius of cydta-complex ion, making the value of k_D^{ion} larger as an electrostrictive structure-breaker, as compared with the cases of edta-complex ions. This might be due to the fact that almost no difference is seen between the edta- and cydta-complexes. According to Yasuda,[24,27] divalent metal chelates of EDTA and CyDTA are supposed to be partly present in penta-coordinated structure in aqueous solution. The various forms of these complexes make the systematic differences caused by the crystal field theory ambiguous. A similar result is also noticed in the values of B^{ion}.

Up to the present time, ions in aqueous solution have often been simply classified into two types, the structure-maker and the structure-breaker on the basis of the interactions between ions and water molecules as solvent. In view of the present considerations, however, the simple classification seems to be no longer sufficient for understanding the behavior of complex ions. The structure-making or -breaking nature can be divided into more detailed categories as shown in Table 3.

There are two causes for structure formation of water around ions; "electrostrictive" and "hydrophobic", the

Table 3. General trends of variation of Δk^{ion} (or k_D^{ion}) and B^{ion} caused by a structure-maker
In case of a structure-breaker, the trends should be reversed.

	Δk^{ion} or k_D^{ion}	B^{ion}	Examples
Electrostrictive	Decrease	Increase	Simple ion (alkali and alkaline earth metals) Aqua ion
Hydrophobic			
Iceberg	Decrease	Increase	$[Co(pn)_3]^{3+}$
Clathrate-like	Increase	Increase	$[Co(phen)_3]^{2+}$ $(n\text{-}C_4H_9)_4N^+$

latter being further divided into "iceberg" formation and "clathrate-like" formation. They give rise not necessarily to similar behavior but in quite opposite direction on the variation of Δk^{ion} or k_D^{ion}, according to their kind and type of hydrophobicity, while B^{ion} shows always the same tendency of variation, irrespective of the sort of structure formation. Hydrophobic structure formation is usually promoted by the presence of alkyl radicals, giving rise to icelike structure or so-called icebergs in the vicinity of the ions. If the shape, size, and certain other unknown conditions are satisfied for any hydrophobic ions by chance, water molecules would come together, wrapping ions in clathrate-like polyhedral cages connected with each other by hydrogen bondings. This structure makes the solution more viscous.

The partial molar entropy of the solution for an ion of a structure-maker also always shows a nagative value, being useless, as well as B^{ion}, for identifying the cause of structure formation. The measurement of TMD thus affords one convenient and effective method for finding the water structure in the close range outside the complex ions.

Molecular Motions in Sodium Tetrachloroaurate Dihydrate as Studied by the Proton and Chlorine Nuclear Relaxation Times

Kenshô Sagisawa, Hideko Kiriyama,* and Ryôiti Kiriyama

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita 565

(Received November 25, 1977)

The ^{1}H and ^{35}Cl relaxation times in $NaAuCl_4 \cdot 2H_2O$ have been measured at temperatures between 79 and 350 K. The ^{1}H T_1 data revealed that the water molecule of crystallization reorients about its C_2 axis with an activation energy of 26 kJ mol^{-1}. The ^{35}Cl T_1 values of the four NQR absorptions indicated that the reorientation of the water molecule makes no important contribution to the chlorine T_1, in spite of the hydrogen bonds between them. A brief analysis of the ^{35}Cl T_1 led to a frequency of 58 cm^{-1} for the torsional vibration of the $AuCl_4^-$ ion.

It has been reported that vibrational and reorientational motions of a molecule containing resonant quadrupolar nuclei produce their nuclear relaxation. However, the relaxation resulting from random motions of atoms near the relaxing nucleus has received less attention. Woessner and Gutowsky suggested that the CH_3 reorientation in $(CH_3)_2CCl_2$ is responsible for not only the proton T_1 but also the chlorine T_1.[1] They estimated the chlorine T_1 by assuming that the electric field gradient at the chlorine nucleus fluctuates while the CH_3 reorientation is actually taking place, but their calculated value did not agree with the observed one even in order of magnitude.

Recently we measured T_1 of both the proton and chlorine nuclei in α-NH_4HgCl_3, and showed that the motion of the ammonium ion affects the chlorine T_1 as well as the proton T_1.[2] In α-NH_4HgCl_3 the ammonium ion reorients about its C_2 and C_3 axes, and flips by 90° about its S_4 axis. Obviously the former, C_2 and C_3 reorientations, do not change the orientation of the ammonium ion, whereas the latter, S_4 flip, does change it. In the preceding paper, we therefore proposed that only the flip mode should affect the chlorine T_1. In order to substantiate this proposal, our study was extended to $NaAuCl_4 \cdot 2H_2O$, in which one of the chlorine atoms is probably hydrogen-bonded to water molecules, whereas the other three do not participate in any hydrogen bonds. The comparison of these chlorine T_1 values will enable us to examine the influence of the reorientation of the water molecules on the chlorine T_1.

Experimental

A variable frequency pulsed spectrometer (Bruker, B-KR-322s) was employed to measure the ^{1}H and ^{35}Cl relaxation times. The spin-lattice relaxation time, T_1, was obtained by use of a 180°-τ-90° pulse sequence for ^{1}H, and a 90°-τ-90° sequence for ^{35}Cl. The ^{35}Cl spin phase-memory time, T_2, was measured by a 90°-τ-180° method, and the inverse line width parameter, T_2^*, was determined from the free induction decay following a 90° pulse. The ^{35}Cl signal after the r.f. pulses was often time-averaged because of its small signal to noise ratio. The temperature of the specimen was varied from 79 to 350 K by using liquid nitrogen or Dry Ice, and measured by means of a copper-constantan thermocouple with an accuracy of ±0.3 K. Polycrystalline $NaAuCl_4 \cdot 2H_2O$ was prepared from an equimolar solution of NaCl and $HAuCl_4 \cdot 4H_2O$, and identified by use of an X-ray diffractometer.

Results and Discussion

The orthorhombic crystal of $NaAuCl_4 \cdot 2H_2O$ contains one kind of planar complex ion, $AuCl_4^-$, the four chlorine atoms of which are crystallographically nonequivalent to one another.[3] The crystal structure shown in Fig. 1 suggests that only one of these four, Cl(1) atom, is hydrogen-bonded to four oxygen atoms; the distances between Cl(1) and the oxygen atoms (3.36 and 3.42 Å) are shorter than the van der Waals contact (4.0 Å). The lone-pair orbitals of the oxygen atom are probably directed to sodium atoms. The ^{35}Cl nuclear quadrupole resonance (NQR) gave four absorption lines corresponding to the four nonequivalent chlorine atoms, as listed in Table 1. Fryer and Smith and Sasane *et al.* have studied the temperature dependence of the resonance frequency, and suggested that the positive temperature coefficient of the lowest frequency line arises from the hydrogen bonds of the Cl(1) atom.[4,5]

In order to elucidate the orientation and motion of the water molecules of crystallization, the ^{1}H T_1 was measured at the resonance frequencies of 20 and 35 MHz. A plot of log T_1 *vs.* inverse temperature exhibited a minimum (0.44 s at 308 K for 20 MHz) as

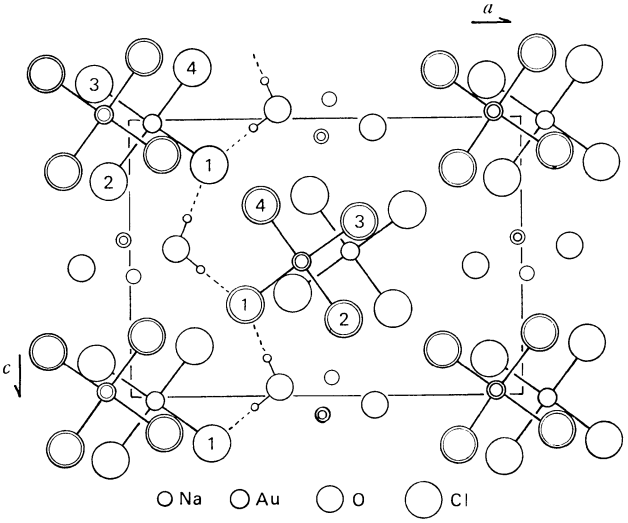

Fig. 1. The crystal structure of $NaAuCl_4 \cdot 2H_2O$ projected along the b axis. The tetrachloroaurate and sodium ions locate on the mirror plane at $y=1/4$ (single circle) or $y=3/4$ (double circle), while the oxygen atoms locate at $y \approx 0$ and $y \approx 0.5$.

●: 20 MHz, ○: 35 MHz.

shown in Fig. 2, and gave the activation energy of 26 kJ mol^{-1}. These results, together with the fact that the ^1H T_2 is almost unchanged in the temperature range studied, indicate clearly that the water molecule reorients about its C_2 axis.

The theoretical value of the ^1H T_1 for the reorienting water molecules was calculated as follows:[6]

$$\frac{1}{T_1} = \gamma^4\hbar^2 \frac{3I(I+1)}{16N} \sum_{i \neq j} \left[B_{ij}^{(1)} \frac{\tau_c}{1+(1/4)\omega_o^2\tau_c^2} + (2A_{ij}^{(1)} + B_{ij}^{(2)}) \frac{\tau_c}{1+\omega_o^2\tau_c^2} + 2A_{ij}^{(2)} \frac{\tau_c}{1+4\omega_o^2\tau_c^2} \right], \quad (1)$$

$$A_{ij}^{(q)} \equiv [F_{ij}^{(q)}(\beta,\beta) - F_{ij}^{(q)}(\delta,\delta)]^2 + [F_{ij}^{(q)}(\beta,\delta) - F_{ij}^{(q)}(\delta,\beta)]^2,$$

$$B_{ij}^{(q)} \equiv \frac{1}{2}[F_{ij}^{(q)}(\beta,\beta) + F_{ij}^{(q)}(\delta,\delta) - F_{ij}^{(q)}(\beta,\delta) - F_{ij}^{(q)}(\delta,\beta)]^2, \quad (2)$$

$$F_{ij}^{(o)}(\beta,\beta) \equiv r_{ij}^{-3}(\beta,\beta)[1-3\cos^2\theta_{ij}(\beta,\beta)],$$

$$F_{ij}^{(1)}(\beta,\beta) \equiv r_{ij}^{-3}(\beta,\beta)\sin\theta_{ij}(\beta,\beta) \times \cos\theta_{ij}(\beta,\beta)\exp[-i\phi_{ij}(\beta,\beta)],$$

$$F_{ij}^{(2)}(\beta,\beta) \equiv r_{ij}^{-3}(\beta,\beta)\sin^2\theta_{ij}(\beta,\beta)\exp[-2i\phi_{ij}(\beta,\beta)], \quad (3)$$

Table 2. Positional parameters of hydrogen atoms in $NaAuCl_4 \cdot 2H_2O$

		x/a	y/b	z/c
Model A	H (1)	0.1534	0.4327	0.3829
	H (2)	0.1776	0.5697	0.5199
Model B	H (1)	0.1553	0.4646	0.3728
	H (2)	0.1770	0.5378	0.5380

where N is the number of spins, $\omega_o = \gamma H_o$, and τ_c is the correlation time. The β and δ in parentheses refer to the two equilibrium lattice sites of a given proton. For polycrystalline specimens, one must take the spatial averages of the θ_{ij} and ϕ_{ij} terms.
Thus,

$$F_{ij}^{(o)}(\beta,\beta)^2 = \frac{4}{5} r_{ij}^{-6}(\beta,\beta),$$

$$F_{ij}^{(o)}(\beta,\beta) \cdot F_{ij}^{(o)}(\delta,\delta) = \frac{2}{5}[3\cos^2\alpha(\beta\beta,\delta\delta) - 1] \times r_{ij}^{-3}(\beta,\beta) r_{ij}^{-3}(\delta,\delta),$$

$$F_{ij}^{(1)}(\beta,\beta)^2 = \frac{2}{15} r_{ij}^{-6}(\beta,\beta),$$

$$F_{ij}^{(1)}(\beta,\beta) \cdot F_{ij}^{(1)}(\delta,\delta) = \frac{1}{15}[3\cos^2\alpha(\beta\beta,\delta\delta) - 1] \times r_{ij}^{-3}(\beta,\beta) r_{ij}^{-3}(\delta,\delta),$$

$$F_{ij}^{(2)}(\beta,\beta)^2 = \frac{8}{15} r_{ij}^{-6}(\beta,\beta),$$

$$F_{ij}^{(2)}(\beta,\beta) \cdot F_{ij}^{(2)}(\delta,\delta) = \frac{4}{15}[3\cos^2\alpha(\beta\beta,\delta\delta) - 1] \times r_{ij}^{-3}(\beta,\beta) r_{ij}^{-3}(\delta,\delta), \quad (4)$$

where $\alpha(\beta\beta,\delta\delta)$ is the angle between vector $\beta\beta$ and vector $\delta\delta$.

Prior to the T_1 calculation, the hydrogen atoms were located by assuming that: A) the H–H vector is parallel to the Cl(1)–Cl(1) vector or B) the H–H vector is normal to the Na–Na vector. In both cases the typical values ($\angle$H–O–H=106° and O–H=1.00 Å) were used for the geometry of a water molecule. The positional parameters of protons thus obtained (Table 2) yielded the T_1 minima of 0.28 s for model A, and 0.65 s for model B at the Larmor frequency of 20 MHz; both of these values are close to the experimental one. In both models the water molecule is hydrogen-bonded to the Cl(1) atoms, although the positions of the hydrogen atoms are slightly different from each other. Therefore, the agreement between the observed and calculated values of the T_1 minima supports the formation of the hydrogen bonds. Moreover, the hydrogen bonding is suggested from the fact that the spin phase-memory time, T_2, of the Cl(1) atom is shorter than those of the other chlorine atoms (Table 1). Presumably, the shorter T_2 of the Cl(1) atom is due to the magnetic dipole interaction with protons.

Figure 3 shows the temperature dependence of ^{35}Cl T_1 for the four absorptions. All ^{35}Cl T_1 decrease monotonously with an increase in temperature with the coefficients, $\Delta\log T_1/\Delta\log T$, ranging from −2.1 to −2.5. It should be noticed that the ^{35}Cl T_1 for the lowest frequency line is comparable to those for the other lines,

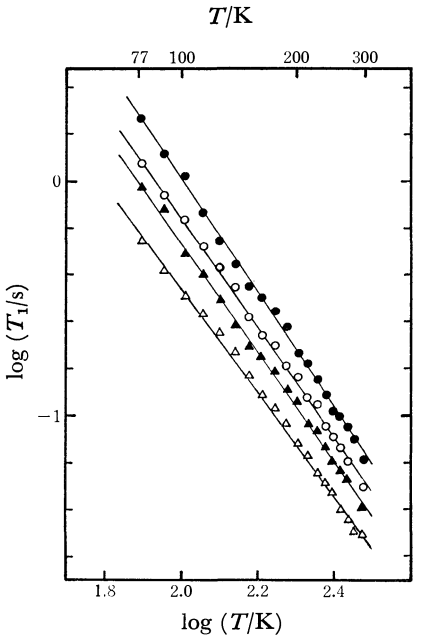

Fig. 3. The temperature dependence of ^{35}Cl T_1 in $NaAuCl_4 \cdot 2H_2O$.
●: ν_1, ▲: ν_2, ○: ν_3, △: ν_4.

and shows no anomalous temperature dependence. This finding, contrary to the suggestion of Woessner and Gutowsky,[1] permits us to conclude that the reorientation of the water molecule affects the chlorine T_1 very little, although the hydrogen bonds are formed between them. The very short T_1 observed in $(CH_3)_2CCl_2$ is probably caused not by the CH_3 reorientation but by molecular reorientations.

Then the chlorine T_1 in $NaAuCl_4 \cdot 2H_2O$ was interpreted on the basis of the torsional vibrations of the $AuCl_4^-$ ion. The quadrupole transition probabilities, $W_1(|\Delta m|=1)$ and $W_2(|\Delta m|=2)$, can be expressed by

$$W_1 = \frac{3}{2}\frac{\hbar\omega_Q^2}{I\omega_t^3}\frac{1}{\tau_a}\coth\left(\frac{x}{2}\right), \tag{5}$$

$$W_2 = \frac{3}{64}\left(\frac{\hbar\omega_Q}{I\omega_t}\right)^2\frac{\tau_a}{\sinh^4(x/2)}, \tag{6}$$

where ω_Q is the angular NQR frequency, ω_t is the angular torsional frequency, I is the moment of inertia, τ_a is the average life time of torsional levels, and $x=\hbar\omega_t/kT$. The T_1 for quadrupolar nuclei of spin 3/2 is given in terms of W_1 and W_2 by

$$\frac{1}{T_1} = 2(W_1+W_2). \tag{7}$$

Equations 5, 6, and 7 yield the following quadratic equation:

$$A_2\tau_a^2 - \frac{1}{2T_1}\tau_a + A_1 = 0, \tag{8}$$

where A_1 and A_2 are parameters determined by ω_Q, ω_t, I, and T.

In order to obtain ω_t, the Bayer approximation was used:[7]

$$\frac{(\Delta\nu_Q/\Delta T)}{\nu_Q} = -\frac{3}{2}\sum_i\frac{k}{(I\omega_t^2)_i}, \tag{9}$$

where the summation is taken over all effective modes.

Table 3. Calculated values of ν_t, τ_a, and $W_1=W_2$ at different temperatures

T/K	ν_t/cm^{-1}	τ_a/ps	$W_1=W_2$/s^{-1}
79	56.62	4.880	0.278
102	57.16	3.358	0.500
150	57.62	1.898	1.250
201	59.16	1.257	2.252
297	58.67	0.694	6.098

In the crystal lattice, the planar $AuCl_4^-$ ion may vibrate about the two Cl–Au–Cl axes and about the axis perpendicular to the plane. Supposing that these three rotary modes are degenerate, and taking account of the two effective modes, we estimated the value of $\nu_t(=\omega_t/2\pi)$ to be 38.1 cm^{-1} from the average temperature coefficient (-0.99×10^{-4} K^{-1}) of all the resonance frequencies except the lowest one. Substituting the value of ω_t and the average value of the experimental T_1 into Eq. 8, however, yielded imaginary values of τ_a at all temperatures of measurement. This means that the T_1 value predicted by the theory is shorter than the observed one. Such a discrepancy has also been pointed out in the chlorine relaxation study for *p*-dichlorobenzene.[1]

It is noteworthy that the ω_t dependence of the temperature coefficient of the resonance frequency is quite different from those of the transition probabilities of W_1 and W_2. If the approximation $e^x \approx 1+x+x^2/2$ is used, we obtain

$$W_1 = 3\sum_i\frac{\omega_Q^2 kT}{(I\omega_t^4\tau_a)_i}, \tag{10}$$

$$W_2 = \frac{3}{4}\sum_i\frac{\omega_Q^2 k^4T^4}{(\hbar^2I^2\omega_t^6)_i}(\tau_a)_i. \tag{11}$$

The powers of ω_t in Eqs. 10 and 11 are much smaller than that in Eq. 9. This means that high frequency modes contribute to the temperature coefficient of resonance frequency more strongly than to W_1 and W_2. Hence, a new attempt to evaluate the ω_t from the T_1 data was made by assuming

$$\left(\frac{1}{2T_1}\right)^2 = 4A_1A_2. \tag{12}$$

This predicts the minimum value of ω_t which will give a real τ_a. The quadratic equation then yields

$$\tau_a = \frac{1}{4T_1A_2} \tag{13}$$

and

$$W_1 = W_2 = \frac{1}{4T_1} \tag{14}$$

with the simplifying assumption of only one torsional mode, one finds

$$\omega_t = \sqrt[10]{36\frac{\omega_Q^4k^5T^5T_1^2}{\hbar^2I^3}}. \tag{15}$$

The calculated values of $\nu_t(=\omega_t/2\pi)$, τ_a, and W_1 $(=W_2)$ are summarized in Table 3. Though one has no justification for the use of Eq. 12, the resulting ratio of W_2/W_1 $(=1)$ is comparable to those obtained in *p*-dichlorobenzene (2—12 at 300K and 0.5—2 at 77K),[8] and the values of ν_t are approximately constant in the

temperature range studied. These results support the present model for the chlorine relaxation time. The ν_t value of about 58 cm^{-1} predicts a temperature coefficient of -0.28×10^{-4} K^{-1}, which is somewhat smaller than the average experimental one on the absolute scale. The residual part of the coefficient may be interpreted in terms of high frequency modes, as described above.

Vibrational Fine Structure of the Ligand Field Absorption Band of Halogenoammine Cobalt(III) Complexes

Kunimasa FUKUDA and Akio URUSHIYAMA*

Department of Chemistry, Faculty of Science, Rikkyo University, Nishiikebukuro, Toshima-ku, Tokyo 171

(Received December 13, 1977)

The crystal absorption spectra of some halogenoammine complexes of Co(III) were measured at liquid helium temperature. The vibrational fine structures observed for the spin-allowed ligand field bands were interpreted in terms of a vibronic intensity mechanism in comparision with the vibrational frequencies of the skeletons. It was found that all the vibrational fine structures consist of the uniquantal progression of totally symmetric Co–N stretching vibration. This suggests that the equilibrium Co–N distances of these complexes are elongated in the ligand field electronic excited state as compared with those in the ground state.

The vibrational fine structure of the ligand field absorption band of $[Co(NH_3)_6]^{3+}$ was studied by Wentworth.[1] He found in his low temperature optical study that the vibrational fine structure of the $^1T_{1g}\leftarrow{}^1A_{1g}$ band of the complex consists of the uniquantal progression correlated to the totally symmetric Co–N stretching vibration of the CoN_6 skeleton. Since then some reports concerning $[Co(en)_3]^{3+}$ have appeared.[2,3] A study was carried out for the mixed ligand complexes.[4] In the present study, the crystal absorption spectra of some halogenoammine complexes of Co(III) have been measured at liquid helium temperature, the vibrational fine structure of the ligand field bands of the complexes in reduced symmetries being of much interest. Complex fine structure could be observed for almost all the bands in the visible region. The observed fine structures were interpreted on the basis of the infrared and Raman data of the complexes assuming a vibronic intensity scheme.

Experimental

All the complex salts were prepared according to the procedures reported previously[5] except for *trans*-$[CoCl_2(NH_3)_4]_3[Co(CN)_6]$ and *trans*-$[CoBr_2(NH_3)_4]_3[Co(CN)_6]$. Excellent single-crystals of $[CoF(NH_3)_5]Cl_2\cdot 2H_2O$ for the transmission spectroscopy could be obtained by evaporation of the aqueous solution in a vacuum dessicator. In the cases of $[Co(NH_3)_6][Co(CN)_6]$, $[CoCl(NH_3)_5]Cl_2$, and $[CoBr(NH_3)_5]Br_2$, excellent crystals could be obtained when the aqueous solutions of $K_3[Co(CN)_6]$, 1M HCl, and 1M HBr, respectively, were dispersed extremely slowly into each of the solutions containing the corresponding complex cation. The fine crystalline powders of *trans*-$[CoCl_2(NH_3)_4]_3[Co(CN)_6]$ and *trans*-$[CoBr_2(NH_3)_4]_3[Co(CN)_6]$ were precipitated immediately from the freshly prepared aqueous solutions of *trans*-$[CoCl_2(NH_3)_4]Cl$ and *trans*-$[CoBr_2(NH_3)_4]ClO_4$, respectively, by adding an aqueous solution of $K_3[Co(CN)_6]$ at 0 °C. The diffuse reflectance spectra in the visible region and the infrared absorption spectra of the crystals suggest that the skeletons of the complexes are retained throughout these procedures. Found: Co, 29.1%. Calcd for *trans*-$[CoCl_2(NH_3)_4]_3[Co(CN)_6]$: Co, 29.1%. Found: Co, 22.0%. Calcd for *trans*-$[CoBr_2(NH_3)_4]_3[Co(CN)_6]$: Co, 21.9%.

The visible absorption spectra of the crystalline samples were measured with an apparatus (Fig. 1) consisting of a JASCO model CT-50 monochromater, a specially designed liquid helium optical cryostat, and a HTV model C767 photon counting system. The liquid helium flowed from the container of the cryostat to a specially designed cooling stage made of a copper block through a tunnel bored inside it. Single-crystals of appropriate size ($\sim 0.2\times\sim 0.2\times\sim 0.02$ mm) were mounted over a pinhole ($\phi=0.15$ mm) in an indium plate, which was then placed on the cooling stage of the cryostat. The sample crystals were made large enough to cover the pinhole completely for the measurements. Silicone grease ensured good thermal contact between the crystal, indium plate, and cooling stage. Silicone grease mulls of the powdered sample were mounted on a small glass plate, and placed on the cooling stage in a similar way to that for the single-crystal measurements. A thermocouple (gold-iron: chromel) indicated the cooling of samples to liquid helium temperature throughout the measurements. The values of transmission light recorded were corrected by those of the blank measurement adjusting the transmittance to unity in the lower wavenumber region where the samples could not absorb.

Results and Discussion

$[Co(NH_3)_6]^{3+}$. The single crystal absortpion spectrum of $[Co(NH_3)_6][Co(CN)_6]$ is shown in Fig. 2. Clear vibrational structure is superimposed on the $^1T_{1g}\leftarrow{}^1A_{1g}$ band of $[Co(NH_3)_6]^{3+}$ as reported by Wentworth.[1] However, no structure could be detected on the $^1T_{2g}\leftarrow{}^1A_{1g}$ band in the near-ultraviolet region. The crystal is hexagonal with the space group $R\bar{3}$ and the precise symmetry of $[Co(NH_3)_6]^{3+}$ is S_6.[7] However, the polarized absorption spectra with the light parallel and perpendicular to the crystal c axis appear to be almost identical.

Most of the lines can be explained in terms of the uniquantal progression of the $\nu_1(a_{1g})$ Co–N stretching vibration of the combination, $\nu_i+(N+n)\nu_1(a_{1g})$,

a) Normal modes are denoted according to Ref. 6a. b) Frequencies reported in Ref. 6a. c) Frequencies reported in Ref. 6b. d) Present work for the perchlorates.

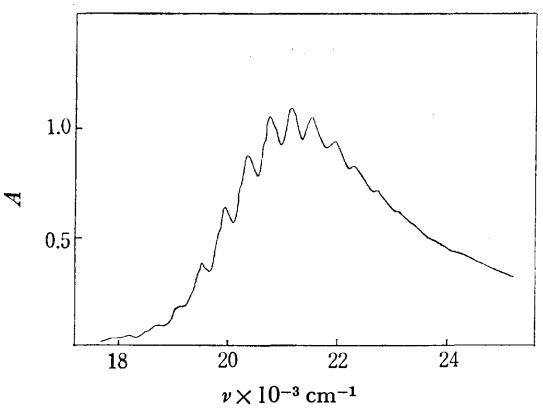

Fig. 2. Crystal absorption spectrum of $[Co(NH_3)_6]$-$[Co(CN)_6]$ at 4.2 K (with polarized light parallel to the crystal c axis).

where ν_i=ungerade vibration, N=integer, and n= 0, 1, 2, . . . , assuming a vibronic intensity scheme. The vibrational frequencies of the ammine complexes of Co(III) have been studied by several workers.[6)] The frequencies referred to in the present study are given in Table 1. The average spacing of 402 cm^{-1} seems to be reasonable for the $\nu_1(a_{1g})$ vibrational frequency at the $^1T_{1g}$ electronic excited state. It represents an 18% reduction in the $\nu_1(a_{1g})$ vibrational frequency as compared with the ground state value of 490 cm^{-1}. The electronic excitation into the antibonding e_g orbital may elongate the Co–N bond distances to some extent, giving rise to this frequency reduction. Each line could be resolved into two or more components. However, measurement with higher resolution is necessary for further discussion of the structure.

trans-$[CoCl_2(NH_3)_4]^+$ *and* trans-$[CoBr_2(NH_3)_4]^+$. The low temperature mull spectra of *trans*-$[CoCl_2(NH_3)_4]_3[Co(CN)_6]$ and *trans*-$[CoBr_2(NH_3)_4]_3[Co(CN)_6]$ are shown in Figs. 3 and 4, respectively. The bands in the 16000—18500 cm^{-1} region are assigned to the $^1E_g[^1T_{1g}(O_h)]\leftarrow{}^1A_{1g}$ transition and those in the 18500—22000 cm^{-1} region to the $^1A_{2g}[^1T_{1g}(O_h)]\leftarrow{}^1A_{1g}$ transition in D_{4h} symmetry. Some indistinct structure was found on the $^1E_g\leftarrow{}^1A_{1g}$ band of *trans*-$[CoCl_2(NH_3)_4]^+$, whereas no structure could be detected for the band of *trans*-$[CoBr_2(NH_3)_4]^+$. Due to its low resolution, no assignment of the structure is possible in the present study.

In the $^1A_{2g}\leftarrow{}^1A_{1g}$ band region, predominant progressions were found with average spacings of 422 and 411 cm^{-1}, for *trans*-$[CoCl_2(NH_3)_4]^+$ and *trans*-$[CoBr_2(NH_3)_4]^+$, respectively. These frequencies can naturally be correlated to the $\nu_2(a_{1g})$ Co–N stretch-

ing vibration of the *trans*-CoX_2N_4 groups in the electronic excited state. The frequency reduction of the ν_2 vibration were estimated to be 14 and 15% for *trans*-$[CoCl_2(NH_3)_4]^+$ and *trans*-$[CoBr_2(NH_3)_4]^+$, respectively, as compared with the values in the ground state. These findings suggest that the complexes are displaced along the Q_2 normal coordinate in the $^1A_{2g}$ electronic excited state. The coordinate has been analysed to consist mainly of the symmetric Co–N bond length changes in these complexes.[6] The $^1A_{2g} \leftarrow {}^1A_{1g}$ transition corresponds to an electronic excitation from the d_{xy} orbital to the antibonding $d_{x^2-y^2}$ orbital. It can be surmised that the Co–N equilibrium distances are elongated to some extent in the $^1A_{2g}$ electronic excited state as compared with those in the ground state. This is in line with the present results.

The selection rules of the ligand field absorption bands are given in Table 2. For the $^1A_{2g} \leftarrow {}^1A_{1g}$ transition, only the e_u vibrational mode can couple with the electronic state to give a vibronically allowed transition. Thus, the vibronic patterns observed should be characterized by the $\nu_9(e_u)$: Co–N str., $\nu_{10}(e_u)$: Co–X bend., and $\nu_{11}(e_u)$: N–Co–N def. vibrations combined with the totally symmetric vibration. If we compare the energy differences between adjacent peaks with the infrared absorption energies, the assignments (Table 3) seem reasonable, although the excited state vibrational frequencies may somewhat differ from those in the ground state. The vibronic pattern of the $^1A_{2g} \leftarrow {}^1A_{1g}$ band of *trans*-$[CoBr_2(NH_3)_4]^+$ can be interpreted similarly, although the components of $\nu_{11}(e_u)$ were indistinct.

$[CoF(NH_3)_5]^{2+}$, $[CoCl(NH_3)_5]^{2+}$, and $[CoBr(NH_3)_5]^{2+}$. The polarized absorption spectra of $[CoF(NH_3)_5]Cl_2 \cdot 2H_2O$, $[CoCl(NH_3)_5]Cl_2$, and $[CoBr(NH_3)_5]Br_2$ are shown in Figs. 5, 6, and 7, respectively. They were measured by polarized light along the extinction directions perpendicular to the crystal face which exhibited the most distinct dichroism under a polarizing microscope. A distinct splitting of the $^1T_{1g}(O_h) \leftarrow {}^1A_{1g}(O_h)$ band was observed in each case. The bands at lower energy are assigned to the $^1E[^1T_{1g}(O_h)] \leftarrow {}^1A_1$ transition and the higher energy ones to the $^1A_2[^1T_{1g}(O_h)] \leftarrow {}^1A_1$ transition in C_{4v} symmetry. A good deal of vibrational structure was observed for almost all the bands.

In the $^1E \leftarrow {}^1A_1$ band region of $[CoCl(NH_3)_5]^{2+}$, distinct lines appeared apparently with progressional spacing of 200 cm^{-1}, weak components being found in the alternate gaps between these lines. However, by careful inspection of the relative intensities of the peaks,

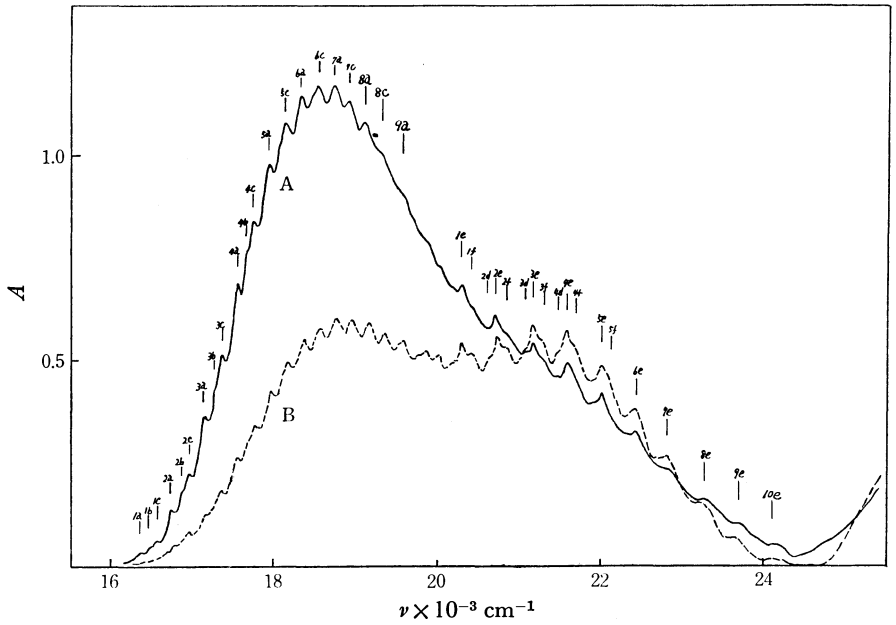

Fig. 6. Polarized absorption spectra of $[CoCl(NH_3)_5]Cl_2$ at 4.2 K.

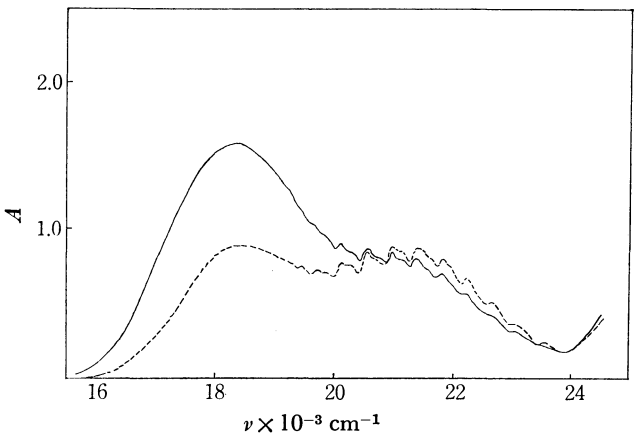

Fig. 7. Polarized absorption spectra of $[CoBr(NH_3)_5]Br_2$ at 4.2 K.

the vibronic pattern could be characterized to consist of the progression with average spacing of 397 cm^{-1} in three components. This frequency can be correlated to the $\nu_3(a_1)$: Co–N str. vibration in the ^1E electronic excited state, representing a 20% frequency reduction in comparision with the ground state value of 495 cm^{-1}. Stanko[4] studied the polarized absorption spectra of $[CoX(NH_3)_5]SiF_6$, where X=Cl, Br, CN, and concluded that the main features of the ligand field absorption bands of these complexes can be accounted for by a vibronic intensity mechanism. He also showed on the basis of intensity calculation that the $\nu_8(e)$: Co–N str., $\nu_{10}(e)$: Co–X bend., and $\nu_{11}(e)$: N–Co–N def. vibrational modes play an important role in the vibronic mechanism of the ^1E band of $[CoCl(NH_3)_5]^{2+}$. It was found in the present study that the A polarized spectrum (Fig. 6), which is thought to be rich with the xy-polarized spectrum of the complex because of the dominant emergence of the $^1A_2$ band, shows no vibrational component more than those observed in the B spectrum, which must be rich with the z-polarized spectrum of the complex (Table 2). The best fit to experimantal data when the energy differences between adjacent peaks are compared with the infrared frequencies of the e vibrational modes is shown in Table 4.

In the spectra of $[CoF(NH_3)_5]^{2+}$, the vibrational structure of the ^1E band appears in a different pattern for each polarization direction. This suggests that the a_2 and/or b_2 vibrational species responsible for the vibronic intensity along the xy axis of the complex are important for this band. However, the spacings of the progression were estimated to be 420 cm^{-1}. The frequency corresponds to the $\nu_3(a_1)$ vibration.

All the complexes in the present study show a complex fine structure in their $^1A_2 \leftarrow {}^1A_1$ band region.[4] Several components were found to form a progression for each complex. The intervals of the progression found in the spectra of $[CoF(NH_3)_5]Cl_2 \cdot 2H_2O$, $[CoCl(NH_3)_5]Cl_2$, and $[CoBr(NH_3)_5]Br_2$ were estimated to be 420, 419, and 429 cm^{-1}, respectively. These frequencies correspond to the $\nu_3(a_1)$ vibration in the $^1A_2$ excited state, representing frequency reductions of 15, 14, and 12%, respectively, as compared with the ground state values. The $^1A_2 \leftarrow {}^1A_1$ band of these complexes can be interpreted in terms of the vibronic intensity mechanism through the vibrations of e species (Table 2). The observed components can be assigned by considering the energy differences between adjacent peaks (Table 4). The vibronic patterns of the $^1A_2 \leftarrow {}^1A_1$ $[CoF(NH_3)_5]^{2+}$ and band of $[CoBr(NH_3)_5]^{2+}$ can be interpreted in a similar way to that for the chloro complex. The $\nu_{10}(e)$ components of $[CoBr(NH_3)_5]^{2+}$ are thought to be obscured due to the shift toward a position close to the $\nu_8(e)$ components because of the reduction in the $\nu_{10}(e)$ vibrational frequency of the complex.

The authors wish to express their thanks to Prof. Yukio Kondo, Rikkyo University, for his encouragement.

Phase-shift Studies of Cadmium-photosensitized Luminescence of Ammonia and Some Aliphatic Amines

Hironobu UMEMOTO,* Shigeru TSUNASHIMA, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 13, 1977)

A phase-shift method was used to study the cadmium-photosensitized luminescence of ammonia and some aliphatic amines. The phase angles between the resonance fluorescence at 326.1 nm and the luminescence from the excited complexes have been measured at various modulation frequencies (10—99 kHz). The results could not be explained by means of the reaction mechanism proposed by analogy with the mercury-photosensitized luminescence of ammonia. In order to obtain a consistency, the equilibrium between the unstabilized and stabilized complexes: $CdNH_3^{\dagger}+NH_3 \rightleftarrows CdNH_3^*+NH_3$, had to be taken into account. The reverse reaction was not necessary to explain the results of the mercury-photosensitized luminescence of ammonia. This discrepancy may be ascribed to the difference in the energy gap between the $^3P_1$ and $^3P_0$ states of mercury and cadmium.

In the cadmium(5^3P_1)-photosensitized reactions of ammonia and some other electron-donor molecules, such as water and amines, broad, diffuse emission bands can be observed in the visible light region, while in the cases of mercury(6^3P_1)-photosensitization, similar emission bands are observed in the ultraviolet region.

To the studies of mercury-photosensitized luminescence, flash methods and modulation techniques have been applied by several groups.[1-6] The mercury–ammonia system has been especially well studied because of the high quantum yield of the luminescence. It is now well established that the sensitized luminescence arises from a charge-transfer complex formed between an ammonia molecule and an excited mercury atom, and that an $Hg(^3P_0)$ atom plays a significant role in the formation of this complex. The lifetime of the $HgNH_3^*$ complex has been measured by several groups.[1-6]

As for cadmium-photosensitized luminescence, however, there is only one example of such a measurement.[7] In the last several years, we have studied this cadmium-photosensitized luminescence by using a method of stationary excitation at 326.1 nm.[8-10] We have measured the steady-state intensities of the resonance fluorescence at 326.1 nm and of the sensitized luminescence as a function of the pressure of foreign gases. The quantum yield of the luminescence for ammonia was larger than those for other substrates.[9-10] In the photosensitization of ammonia, the ratio of the resonance fluorescence at 326.1 nm in the absence of ammonia to that in the presence of ammonia increased nonlinearly with an increase in the ammonia pressure in the low-pressure region, although it increased linearly in the high-pressure region.[8] In order to explain this nonlinearity, we considered the formation of an unstabilized complex which is in equilibrium with the excited cadmium atom and ammonia and which is stabilized by collisions with third bodies.

In the present study, in order to investigate the mechanism of the luminescence, we applied a phase-shift method to the cadmium–ammonia and cadmium–aliphatic amine systems.

Experimental

The experimental system was similar to that described previously for the study of the mercury-photosensitized luminescence,[6] except that the reaction vessel was kept in an electric furnace at 525±1 K. The vapor pressure of the cadmium in the cell was kept constant, 4.0×10^{-3} Torr (1 Torr≃133.3 Pa),[11] by maintaining the temperature of the cadmium reservoir at 519±1 K. The exciting resonance lamp was a home-made microwave-powered one containing about 10 Torr of helium as a carrier gas. This cadmium lamp was made of Pyrex glass, which cut off another resonance line at 228.8 nm. The emitting part of the lamp was covered with another Pyrex glass tube, and the intervening space was evacuated to prevent cadmium metal from depositing on the wall of the lamp. The reaction vessel was made of quartz.

The emission from the reaction system was focused by means of a quartz lens and detected with a 1P28 photomultiplier (Hamamatsu TV) in conjunction with a Shimadzu QV-50 monochromator. The phase angles of the photomultiplier signals relative to the internal reference signal of a lock-in amplifier (NF Circuit Design Block Co., LI-573) were measured. The pressures of the gases were measured with a Wallace & Tiernan model 61-050 pressure gauge.

The cadmium used was a high-purity sample (99.9999%) manufactured by the Osaka Asahi Metal Co. Pure-grade ammonia (Takachiho Shoji Co.) was used after being degassed at the temperature of liquid nitrogen. Pure-grade methylamine and dimethylamine (Takachiho Shoji Co.) were used after repeated trap-to-trap distillation. An aqueous solution of trimethylamine (Tokyo Kasei Co.) was used after repeated trap-to-trap distillation and drying with calcium hydride and with an alloy of sodium and potassium.

Results

In the cadmium–ammonia system, the phase difference between the resonance fluorescence at 326.1 nm and the sensitized emission from the excited complex at 432 nm decreased with the increase in the pressure of ammonia, as is shown in Fig. 1. It is well known that, in the case of a pseudo-first order reaction, the phase shift, ϕ, is related to the lifetime of the excited species, τ, by means of the following equation:

$$\frac{\tan\phi}{\omega}=\tau,$$

where ω is the angular frequency of modulation.[12] In the present case, although this value of $\tan\phi/\omega$ was independent of the frequency, it depended on the ammonia pressure and had a linear relation with the reciprocal of the pressure in the range of 15—200 Torr, as is shown in Fig. 2. The phase angle of the

sensitized emission was independent of the wavelength of the emission band of the complex. Similar results could also be obtained in the cases of methylamine, dimethylamine, and trimethylamine, which are illustrated in Figs. 3—5 and 6. The phase angle did not change when a UVD-25 filter, which removes visible light, was inserted between the exciting lamp and the cell. The intensity of the background scattered light at 326.1 nm was measured on the assumption that 100 Torr of hydrogen can quench the triplet cadmium completely;[13] it was estimated to be 0.2% of the emission intensity at 326.1 nm in the absence of quenching gases.

Discussion

In a recent phase-shift study of the reaction of ammonia with triplet mercury, we found that the phase angle between the resonance fluorescence at 253.7 nm and the luminescence from the excited complex varies with the wavelength of the emission band of the complex.[6] This finding suggests that there are at

least two kinds of emitting species in this system. On the other hand, in the cadmium–ammonia system, the phase angle of the sensitized luminescence was found to be independent of the wavelength. In other words, the presence of an unstabilized complex could not be confirmed by the present measurements. However, as has been mentioned above, we have found nonlinearity in the Stern-Volmer plots for the quenching of the 326.1 nm resonance line.[8] This nonlinearity cannot be explained without assuming the presence of an unstabilized complex as a precursor of an emitting complex. Accordingly, at first, the following reaction mechanism, which is similar to the one proposed for the mercury–ammonia system, was considered:

$$Cd + h\nu \rightarrow Cd_1^*, \quad (1)$$

$$Cd_1^* \rightarrow Cd + h\nu, \quad (2)$$

$$Cd_1^* + NH_3 \rightarrow \text{Products}, \quad (3)$$

$$Cd_1^* + NH_3 \rightleftarrows CdNH_3^\dagger, \quad (4)$$

$$CdNH_3^\dagger \rightleftarrows Cd_0^* + NH_3, \quad (5)$$

$$CdNH_3^\dagger + NH_3 \rightarrow CdNH_3^* + NH_3, \quad (6)$$

$$CdNH_3^* \rightarrow Cd + NH_3 + h\nu'. \quad (7)$$

Here, Cd, Cd_1^*, and Cd_0^* stand for Cd atoms in the 5^1S_0, 5^3P_1, and 5^3P_0 states respectively, and $CdNH_3^\dagger$ and $CdNH_3^*$ stand for unstabilized and stabilized complexes. Since the energy difference between the $^3P_1$ and $^3P_0$ states is only 6.5 kJ/mol, the reverse reaction of Reaction 4, which was not considered in the mercury–ammonia system, was added. However, in consequence, we failed to explain the present experimental results in terms of this reaction mechanism. According to the above reaction scheme, the measured phase shift, ϕ, can be separated into two parts, the one associated with the finite rate of the removal of $Cd(^3P_0)$ and $CdNH_3^\dagger$ by Reactions 4—6, and the other, with the finite rate of Reaction 7. At limiting high pressures of ammonia, the former part of the phase delay can be ignored compared with the latter one, and the limiting value of $\tan\phi/\omega$ at high pressures, $\tan\phi_\infty/\omega$, becomes equal to the reciprocal of the emitting rate, which is identical to the lifetime of the complex. It should be noted that the rates for Reactions 1—3 make no contribution to the phase difference between the resonance fluorescence (Reaction 2) and the sensitized luminescence (Reaction 7). Once the value of ϕ_∞ has been estimated from the intercept of the linear relationship in Fig. 2, we can obtain the phase delay due to Reactions 4—6 in the low-pressure region by subtracting ϕ_∞ from ϕ. It can easily be verified that this value of $(\phi_\infty - \phi)$ corresponds to the phase difference between the a.c. component of the concentration of the unstabilized complex and that of Cd $(^3P_1)$. Figure 7 shows the the value of $\omega/\tan(\phi - \phi_\infty)$ increases linearly with the ammonia pressure. The fault of the above mechanism, Reactions 1—7, is that

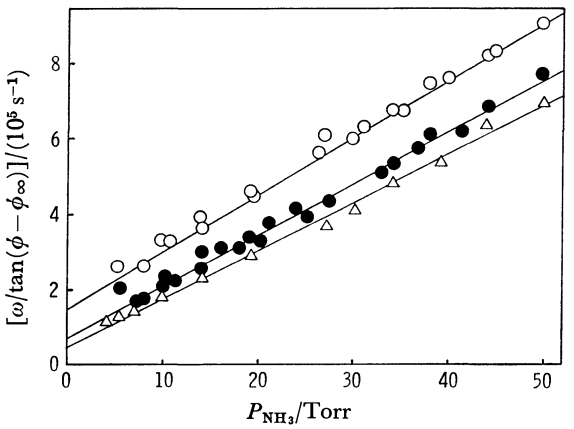

Fig. 7. Values of $\omega/\tan(\phi - \phi_\infty)$ as a function of NH_3 pressure.
△: 20 kHz, ●: 40 kHz, ○: 78 kHz.
Values for other modulation frequencies also showed similar pressure dependence.

the linear relation cannot be derived

Morten *et al.* also have presented a reaction mechanism for this system by analogy with the mercury–ammonia system; in this reaction mechanism a termolecular reaction is assumed in the formation of the complex.[7] However, the linear relationship shown in Fig. 7 cannot be interpreted in terms of their mechanism, either.

On the other hand, the following rather simple mechanism, in which only one intermediate complex is assumed, can explain the linear relations shown in Figs. 2 and 7:

$$Cd + h\nu \rightarrow Cd_1^*, \quad (1)$$

$$Cd_1^* \rightarrow Cd + h\nu, \quad (2)$$

$$Cd_1^* + NH_3 \rightarrow \text{Products}, \quad (3)$$

$$Cd_1^* + NH_3 \rightleftarrows CdNH_3^*, \quad (8)$$

$$CdNH_3^* \rightleftarrows Cd_0^* + NH_3, \quad (9)$$

$$CdNH_3^* \rightarrow Cd + NH_3 + h\nu'. \quad (7)$$

As will be shown in the Appendix, the phase difference between Reactions 2 and 7 is given by

$$\frac{\tan\phi}{\omega} = \frac{\omega^2 + k_{-9}^2[A]^2 + k_9k_{-9}[A]}{(k_9+k_7+k_{-8})\omega^2 + (k_7+k_{-8})k_{-9}^2[A]^2}, \quad (10)$$

where the rate coefficient for Reaction j is denoted by k_j, and the reverse reaction, by k_{-j}. The ammonia pressure is represented by [A]. If the following inequality is valid under the conditions that $\omega/2\pi<99$ kHz and [A]>15 Torr:

$$(k_7+k_{-8})k_{-9}^2[A]^2 \gg (k_9+k_7+k_{-8})\omega^2,$$

then Eq. 10 can be simplified as follows:

$$\frac{\tan\phi}{\omega} \simeq \frac{1}{k_7+k_{-8}} + \frac{k_9}{(k_7+k_{-8})k_{-9}}\frac{1}{[A]}. \quad (11)$$

Equation 11 corresponds to the linear plots in Fig. 2. The linear relation between $\omega/\tan(\phi-\phi_\infty)$ and [A] shown in Fig. 7 can also be derived under appropriate conditions such as

$$\omega^4 + \omega^2\{k_{-9}^2[A]^2 + (k_7+k_{-8})(k_7+k_{-8}+k_9)\} \ll \omega^2k_9k_{-9}[A] + (k_7+k_{-8})^2k_{-9}^2[A]^2$$

and

$$\omega^2 \ll k_{-9}[A](k_7+k_{-8}).$$

However, the value of $(\phi-\phi_\infty)$ as well as the value of $\tan\phi_\infty/\omega$ in this mechanism loses its simple physical meaning because of the presence of decay processes of the complex back into its initial components. Even though this scheme is consistent with the linear relations shown in Figs. 2 and 7, the nonlinearity in the Stern-Volmer plots for the quenching of the resonance line cannot be derived.

In order to overcome this discrepancy, we tried to combine these two reaction mechanisms. This was done by including the reverse reaction of Reaction 6 in the first mechanism, Reactions 1—7. Provided that the decay rate of the stabilized complex, $CdNH_3^*$, is much larger than the angular frequency of the modulation, ω, the phase difference between the concentrations of $CdNH_3^*$ and $CdNH_3^\dagger$ can be neglected and an equation similar to Eq. 11 can be obtained for the representation of $\tan\phi/\omega$. The exact expression of $\tan\phi/\omega$, according to the modified mechanism, is given by

$$\frac{\tan\phi}{\omega} = \frac{(k_{-4}+k_5+k_6[A]+k_{-6}[A]+k_7)\omega^2 + (k_{-4}+k_6[A]+k_{-6}[A]+k_7)k_{-5}^2[A]^2 + (k_{-6}[A]+k_7)k_5k_{-5}[A]}{-\omega^4 + \omega^2\{k_{-4}k_7+k_5k_7+(k_{-4}k_{-6}+k_5k_{-6}+k_6k_7-k_5k_{-5})[A]-k_{-5}^2[A]^2\} + \{k_{-4}k_7+(k_{-4}k_{-6}+k_6k_7)[A]\}k_{-5}^2[A]^2}. \quad (12)$$

If the following inequalities can be assumed

$$k_{-6}[A] \gg k_7, \ \frac{\omega^2}{k_{-4}}, \ \frac{k_5\omega^2}{k_{-4}k_{-5}[A]}, \quad (13)$$

$$k_{-5}^2[A]^2 \gg \frac{k_5\omega^2}{k_{-4}}, \ \left\{1+\frac{k_5}{k_{-4}+(k_6+k_{-6})[A]}\right\}\omega^2, \quad (14)$$

Eq. 12 can be approximated by the following equation:

$$\frac{\tan\phi}{\omega} \simeq \frac{k_6+k_{-6}}{k_{-4}k_{-6}+k_6k_7} + \frac{k_{-4}k_{-5}+k_5k_{-6}}{(k_{-4}k_{-6}+k_6k_7)k_{-5}}\frac{1}{[A]}. \quad (15)$$

The validity of Eqs. 13 and 14 will be checked in the Appendix. The intercept and the slope of the relationship shown in Fig. 2 correspond to the first and the second terms of the right-hand side of Eq. 15 respectively. The intercepts and the slopes in Fig. 6 also give the relations among the rate constants in the cases of the cadmium–aliphatic amine systems, which are summarized in Table 1.

TABLE 1. RELATIONS AMONG THE RATE CONSTANTS DEDUCED FROM Eq. 15

	$\frac{k_{-4}k_{-5}+k_5k_{-6}}{k_{-5}(k_{-4}k_{-6}+k_6k_7)}$/$10^{-5}$ s Torr	$\frac{k_6+k_{-6}}{k_{-4}k_{-6}+k_6k_7}$/$10^{-7}$ s
NH_3	7.1±0.1	6.0±0.3
CH_3NH_2	4.2±0.1	9.6±0.2
$(CH_3)_2NH$	1.8±0.2	2.9±0.8
$(CH_3)_3N$	1.4±0.1	5.7±0.2

It should be noted that, although the reaction mechanism proposed in this paper is a little different from that we presented in previous papers, where the reverse reaction of Reaction 6 is not considered,[8-9] this difference has no essential influence on the steady-state treatment. Tiny change in the meaning of the parameters has to be taken into account.

Because of the presence of the reverse reaction of Reaction 6, we could not determine the radiative lifetime of the complex, $CdNH_3^*$. The determination of the lifetime would be very difficult, even if the phase angle of the $Cd(^3P_0)$ absorption could be measured. In the mercury-photosensitized luminescence of ammonia, the radiative lifetime of $HgNH_3^*$ could be precisely determined to be (1.4±0.1) μs.[6] The difficulty in determining the radiative lifetime of $CdNH_3^*$ obviously results from the small energy difference between the $Cd(^3P_1)$ and $Cd(^3P_0)$ states.

Appendix

Derivation of Eq. 10. When the initial intensity of the resonance radiation from the lamp is modulated with the angular frequency, ω, the concentration of the excited species

oscillates with the same frequency. In the cases of Reactions 1—3 and 7—9, the concentration may be written as follows:

$$[Cd_1^*] = \bar{a} + \tilde{a}e^{i\omega t},$$
$$[Cd_0^* = \bar{b} + \tilde{b}e^{i(\omega t-\theta)},$$
$$[CdNH_3^*] = \bar{c} + \tilde{c}e^{i(\omega t-\phi)}.$$

Here, the d.c. and a.c. components of the concentration are respectively expressed by the first and the second terms of the right-hand sides. The phase angles of $[Cd_0^*]$ and $[CdNH_3^*]$ are denoted by θ and ϕ. On the basis of Reactions 1—3 and 7—9, the following differential equations can be obtained:

$$\frac{d[Cd_0^*]}{dt} = i\omega\tilde{b}e^{i(\omega t-\theta)}$$
$$= k_9(\bar{c}+\tilde{c}e^{i(\omega t-\phi)}) - k_{-9}[A](\bar{b}+\tilde{b}e^{i(\omega t-\theta)}),$$
$$\frac{d[CdNH_3^*]}{dt} = i\omega\tilde{c}e^{i(\omega t-\phi)}$$
$$= k_8[A](\bar{a}+\tilde{a}e^{i\omega t}) + k_{-9}[A](\bar{b}+\tilde{b}e^{i(\omega t-\theta)}) - (k_9+k_7+k_{-8})(\bar{c}+\tilde{c}e^{i(\omega t-\phi)}).$$

Separating the time-dependent parts, we obtain

$$(i\omega+k_{-9}[A])\tilde{b}e^{-i\theta} - k_9\tilde{c}e^{-i\phi} = 0,$$
$$-k_{-9}[A]\tilde{b}e^{-i\theta} + (i\omega+k_9+k_7+k_{-8})\tilde{c}e^{-i\phi} = k_8[A]\tilde{a}.$$

Equation 10 can easily be derived from these simultaneous equations. Equation 12 can also be obtained in a similar manner.

Validity of Eqs. 13 and 14. In order to explain theoretically the observed pressure dependence of the phase angle, ϕ, in Fig. 1, we tried to find a set of parameters according to the reaction mechanism proposed. The following values are some examples: $k_{-4}=5.5\times10^6$ s^{-1}, $k_5=3.8\times10^8$ s^{-1}, $k_{-5}=9.1\times10^5$ s^{-1} Torr^{-1}, $k_6=2.2\times10^7$ s^{-1} Torr^{-1}, $k_{-6}=8.6\times10^6$ s^{-1} Torr^{-1}, and $k_7=1.7\times10^5$ s^{-1}. The solid lines in Fig. 1 were drawn according to Eq. 12 by using these values. From these values, the validity of Eqs. 13 and 14 can easily be derived. Since the observable value is only the phase difference between the two kinds of emission, the resonance fluorescence at 326.1 nm and the luminescence from the excited complex, we cannot verify that the above set of parameters is unique.

The Mechanism of the CO Oxidation over Polycrystalline Platinum

Tatsuo MATSUSHIMA

The Research Institute for Catalysis, Hokkaido University, Sapporo 060

(Received December 15, 1977)

The kinetics of the CO oxidation has been studied on polycrystalline platinum at various partial pressures, total pressures, and temperatures; $0.1<P_{CO}/P_{O_2}<5$, $10^{-6}<P<10^{-3}$ Pa, and $300<T<900$ K. The reaction was first-order in CO and zero-order in O_2 for low pressures of CO, while it was inhibited by CO above a certain critical CO pressure, which increased with an increase in the O_2 pressure and temperature. Above that CO pressure, the reaction was first-order in O_2 and negative-order in CO. The amount of CO adsorbed was determined during the reaction with a flash-desorption technique. Above the critical CO pressure it was almost equal to that determined in the CO/Pt equilibrium system. It decreased sharply around the CO pressure and was very small at lower pressures. The kinetic behavior can be explained in terms of a Langmuir-Hinshelwood process and a change in the rate-limiting step.

Numerous investigations have been reported on CO oxidation over single-crystal and polycrystalline-platinum surfaces.[1–14] Different kinetic behavior at the steady state was observed below and above about 550 K, and the reaction orders with respect to O_2 and CO depend strongly on the partial pressure ratio.[1] Several transient techniques[5–14] have provided ample evidence that CO_2 is formed through two elementary processes: an Eley-Rideal process (E-R), CO(phys. ads.)+O(a)→CO_2, and a Langmuir-Hinshelwood process (L-H), CO(chem. ads.)+O(a)→CO_2. According to measurements with AES[10,11] and secondary-ion mass-spectroscopy,[15] CO(a) is much less than O(a) when $P_{CO}<P_{O_2}$, while the reverse is true for $P_{CO}>P_{O_2}$. Generally, the kinetics at the steady state has been explained in terms of the E-R process.[3–5] On the contrary, though, this work will report that the inhibitory region is narrowed with an increase in the temperature and will ascribe this to a contribution from the L-H process.

Experimental

The experimental apparatus and procedures were essentially the same as those reported previously.[16] A polycrystalline platinum foil ($30\times4\times0.05$ mm) was used as a catalyst. Prior to the experiments it was exposed to 1×10^{-4} Pa of oxygen at 1400 K for several hours, and then flashed to 1600 K for a few tens of minutes. Several repetitions of this treatment were sufficient to establish stable catalyst behavior. A Bayard-Alpert gauge was used for only the calibration of the sensitivity of the mass spectrometer. The observed $m/e=44$ signal was proportional to the CO_2 production rate, since the system was continuously pumped. All of these experiments utilize a hot-filament electron supply in the mass spectrometer. There is some background reaction on the filament, which was measured separately with the substrate at room temperature and subtracted from the results of measurements made at the operating temperatures.

Results

Since CO_2 is not adsorbed under the conditions used here[17] it is assumed that CO_2 interacts so weakly with the surface that the partial pressure exerts no influence on the rate of the reaction.

Temperature Dependence. The oxidation rate depended strongly on the substrate temperature. The profile was characterized by an optimum around the CO desorption temperature. Some typical results are shown in Fig. 1. For $P_{CO}<P_{O_2}$, the rate showed an increase similar to the other case below a certain critical temperature, where it increased discontinuously up to the maximum level, which was constant over a wide range of temperatures. The activation energies were estimated to be 55—84 kJ mol^{-1}, zero, and negative below, around, and above the optimum respectively.

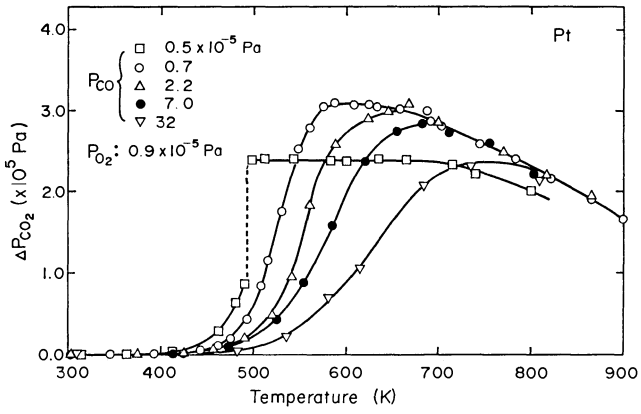

Fig. 1. Variation of the rate of CO_2 production at the steady state with temperature at various fixed pressures of CO and O_2. The vertical dotted line at 0.5×10^{-5} Pa of CO shows a discontinuous change of CO_2 production.

CO Pressure Dependence. The results are summarized in Figs. 2 and 3. These figures are both characterized by sharp transitions at a certain critical CO pressure. Below that pressure the reaction was first-order in CO and independent of the temperature, while above that pressure it was negative-order in CO and very sensitive to the temperature. The rate dropped discontinuously at the critical CO pressure, as is shown by the vertical dotted lines. The CO pressure shifted toward low values with a decrease in the temperature, and toward high values with an increase in the oxygen pressure.

O_2 Pressure Dependence. The results are displayed in Fig. 4. Like carbon monoxide, the oxygen-pressure dependence showed sharp transitions at some oxygen pressure. The rate showed first-order and zero-order behavior below and above the transition pressure respectively. Such sharp breaks in the CO and O_2 pres-

sure dependences were in general agreement with those reported by Bonzel and Ku for Pt (110), although they reported only turning points at a fixed high temperature.

CO Adsorption during the Catalyzed Reaction. The amount of CO adsorbed was determined in the course of the catalyzed reaction by means of flash desorption.[16] A steady-state $CO/O_2/Pt$ system was established at a fixed temperature, and then the substrate was heated while the CO peak was monitored. Afterward, the system was returned to the same steady state and the CO_2 peak was recorded during a second flash-desorption experiment. Figure 5 shows some typical transients of CO and CO_2 generated by flash desorption. The desorption of CO was complete around the final temperature, 900 K. The dashed lines in Fig. 5 are arbitrarily drawn as point-by-point reference lines for constructing a mirror image of the CO_2 production curve. Assuming that the only sink for CO, aside from the pump, is its conversion to CO_2, and that the only source of CO_2 is CO, it is clear as a result of the stoichiometry that the cross-hatched area gives the amount of CO adsorbed initially.[16,19] Figure 6 shows the CO adsorption at 468 and 526 K with 1.7×10^{-5} Pa of oxygen and without oxygen. Above the critical CO pressure, the coverage during the reaction equalled the value measured in the CO/Pt non-working system; *i.e.*, the adsorption-desorption process of CO was in equilibrium. It decreased sharply around the CO pressure and became very small under lower pressures. Note the marked difference between the CO/Pt non-working system and the $CO/O_2/Pt$ working system below the critical CO pressure. At a low temperature, the sharp drop occurred at lower CO pressures.

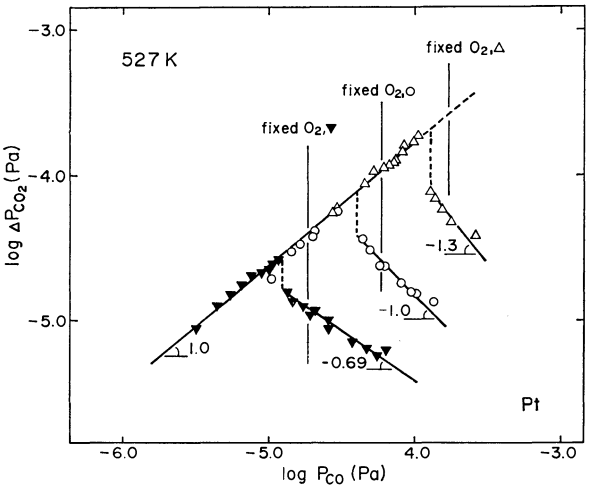

Fig. 2. Variation of the rate of CO_2 production with CO pressure at 527 K and various fixed oxygen pressures. The vertical bars indicate the fixed oxygen pressures. ▼: 1.9×10^{-5} Pa, ○: 6.0×10^{-5} Pa, △: 1.7×10^{-4} Pa. The reaction orders with respect to CO are indicated along the linear portion of each curve. The vertical dotted lines show sharp drops in the CO_2 production.

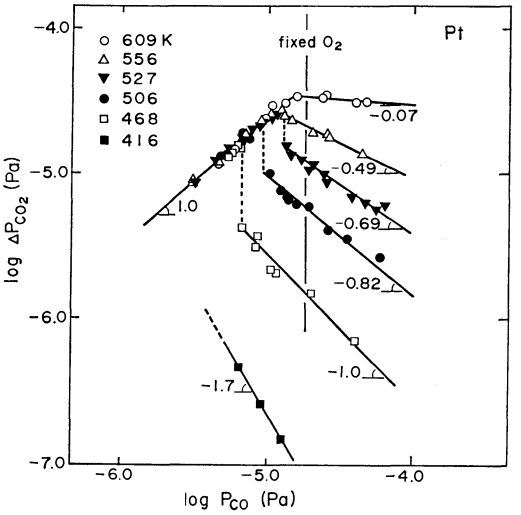

Fig. 3. Variation of the rate of CO_2 production with CO pressure at various temperatures, under a fixed O_2 pressure of 1.9×10^{-5} Pa. There are sharp transitions of the rate law at some critical CO pressure drawn by vertical dotted lines.

Discussion

The Activation Energy. The temperature dependence in Fig. 1 is qualitatively similar to the results reported on single-crystal ((100)[1] and (111)[12]) and on polycrystalline[2,13] platinum. Similar results have also been reported for other metal surfaces: Pd,[18,19] Ni,[26] Ir,[27–30] and Ru.[31,32] Below the optimum, Bonzel and Ku[1] concluded that the rate-limiting step was the desorption of CO(a) from the surface; they reached this conclusion by comparing the apparent activation energy with the enthalpy for the CO desorption. Recent studies of the L-H process[5] have shown that the rate at 415 K in the presence of 1×10^{-6} Pa of oxygen is comparable to that of CO thermal desorption. Under higher pressures of O_2, the former contributes more to the removal of CO(a). In general, under the experimental conditions employed here CO(a) can be removed mainly *via* the L-H process. The adsorption-desorption process of CO is in equilibrium below the optimum, and the surface area available for O_2 adsorption increases with the temperature. The apparent activation energy decreases with an increase in the CO pressure and becomes much less than the enthalpy of CO desorption, 120 kJ mol^{-1},[20–23,25] in contrast with the model, in which the CO desorption is rate-limiting. Around the optimum, the amount of CO(a) is much less than that in equilibrium with the CO partial pressure. The rate is limited by the CO collision frequency, and the reaction probability of CO is close to unity.[11] Thus, the activation energy is zero. Above the optimum, the surface is covered by O(a) and CO(a)≪O(a). When $P_{CO}>P_{O_2}$ the rate is limited by the O_2 adsorption; the decrease is attributed to the decrease in oxygen coverage through the thermal desorption.[11] When $P_{CO}<P_{O_2}$, the rate begins to decrease at temperatures as high as 730 K, since the CO collision is rate-limiting and the decrease in the surface oxygen near full coverage does not cause any decrease in the CO_2 production.[8]

Kinetic Behavior in Terms of Adsorbed Species. The

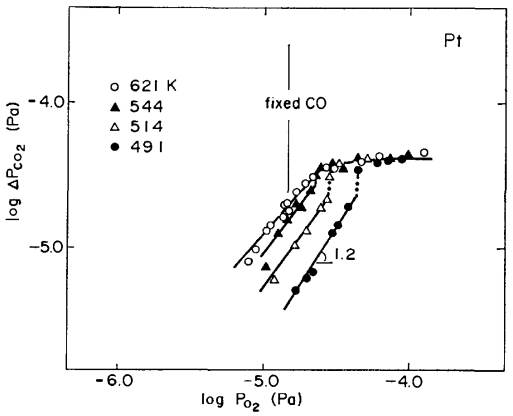

Fig. 4. Variation of the rate of CO_2 production with O_2 pressure at various temperatures under a fixed CO pressure of 1.3×10^{-5} Pa. The vertical dotted lines show sharp jumps in the CO_2 production.

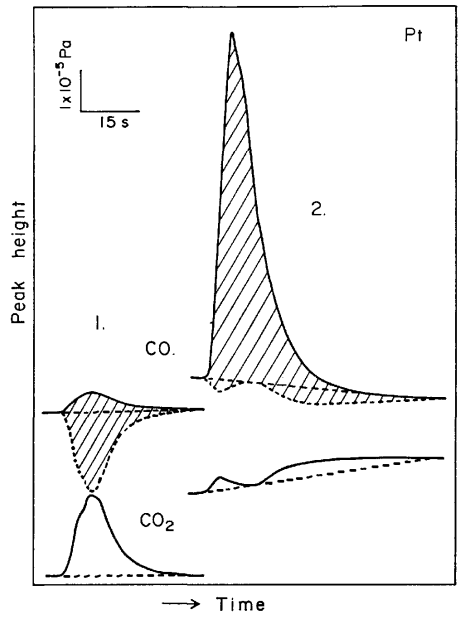

Fig. 5. Flash desorption peaks of CO and CO_2 induced by heating the substrate from a kinetic steady state at 468 K to a final temperature of 900 K. The steady state pressures (in pascals) of CO, O_2, and CO_2 for each pair of peaks are as follows in the form (P_{CO}, P_{O_2}, P_{CO_2}), (1) (4.8×10^{-6}, 1.7×10^{-5}, 1.3×10^{-5}): (2) (3.7×10^{-5}, 1.7×10^{-5}, 3.7×10^{-6}). Peaks are shifted with each other for easier viewing.

results shown in Figs. 2, 3, and 4 strongly suggest that a change in the rate-limiting step occurs around the critical CO pressure. At CO pressures below the critical value, CO(a) was not accumulated up to the equilibrium level. This fact shows that the L-H process plays a main role in eliminating CO(a) from the surface under working conditions and contributes to the CO_2 production. The rate-limiting step is the CO collision with the oxygen-covered surface. Thus, the reaction is first-order in CO and zero-order in O_2. On the other hand, above the critical CO pressure the amount of CO(a) was almost equal to that observed in the CO/Pt non-working system and O(a)≪CO(a).[11]

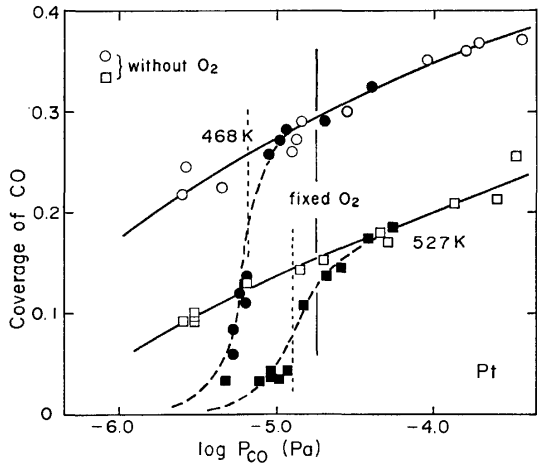

Fig. 6. CO adsorption isotherm determined by flash desorption in the presence and absence of oxygen. (○, □): without oxygen, (●, ■): with 1.7×10^{-5} Pa of oxygen. The coverage was defined as the CO peak area relative to the maximum area which was obtained by flashing from room temperature. The vertical dotted lines show CO transition pressures.

The rate is limited by the O_2 adsorption, which is severely retarded by CO(a). Thus, the reaction should be first-order in oxygen and negative-order in CO. The magnitude of the negative order should increase with an increase in the CO pressure and also with a decrease in the temperature, as was actually observed.

CO Inhibition Region. The inhibition becomes large as the temperature decreases, but not because the heat of adsorption of CO is larger than that of oxygen, since just the reverse is true.[20–22,25,34,36–39] Rather, it arises because the L-H process, which plays a role in eliminating CO(a) from the surface, is slower than the CO adsorption. The latter needs little activation energy, while at low temperatures the former requires a significant activation energy.[5] At temperatures as high as 550 K, where the L-H process is very fast, the boundary of the CO inhibition region is determined by the balance between the supply rates of oxygen and carbon monoxide onto the surface. At lower temperatures it can be ascertained by a comparison of the rate of the L-H process with the adsorption rate of CO. Below, a simple model will be used in the estimation of the boundary pressure. The four experimental situations involve different conditions with regard to the temperature, the relative collision frequency, and the rate of the L-H process. In the A(1) region the CO collision rate is greater than the maximum oxygen adsorption rate, while in the B(1) region the reverse is true. At relatively low temperatures the B(1) region is divided further into the A(2) and B(2) regions. In the A(2) region the CO collision rate is greater than the maximum rate of the L-H process, while in the B(2) region the reverse is true. We assume first of all that the reaction probability per CO collision is unity provided a steady-state oxygen coverage exists.[11] Second, we take the sticking probability of O_2 at zero coverage to be 0.36.[11] Finally, we assume that the variation in the sticking probability with the coverage

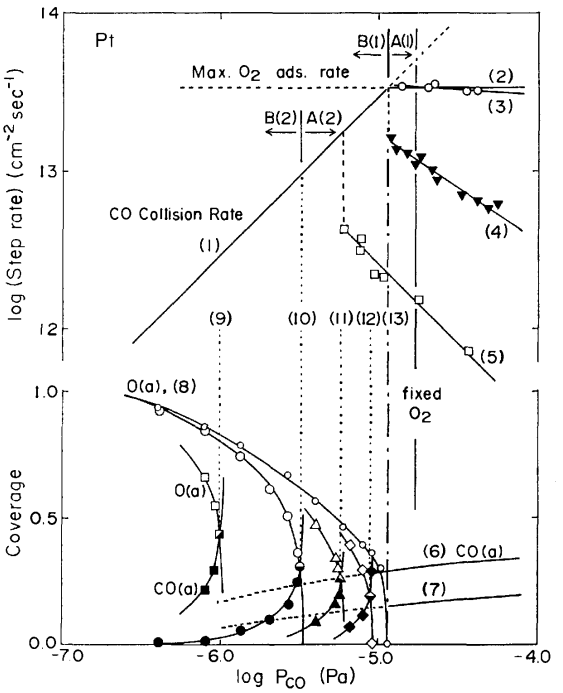

Fig. 7. A model of the reaction structure of the CO oxidation. At higher temperatures, the CO_2 production rate should follow line(1) and then line(2), as a function of CO pressure. At lower temperatures, the rate is retarded by CO(a) above critical CO pressure as shown by vertical dashed-dotted line(13) at relatively high temperatures and vertical dotted lines (9—12) at various lower temperatures. (1) CO collision rate, (2): maximum O_2 adsorption rate, (3)—(5): CO_2 production rates observed at 609, 527 and 468 K, (6), (7): CO adsorption isotherm observed at 468 and 526 K, (8): oxygen coverage when $CO(a) \ll O(a)$, (9)—(13): calculated boundary CO pressures at 313, 362, 400, 468, and above 500 K, respectively. Open and closed symbols in the lower panel show calculated coverages of O(a) and CO(a) at temperatures shown above.

is given by the data in Fig. 1 previously reported in Ref. 11. The results analyzed are presented in Fig. 7. For comparison with the experimental data, the rates observed in the inhibition region at 609, 527, and 468 K are also shown in the figure. The vertical position of the latter was shifted in such a way that the maximum CO_2 production observed was at the maximum O_2 adsorption rate calculated.

High Temperatures: The L-H process is very fast. The boundary between A(1) and B(1) occurs when $P_{CO}/P_{O_2}=0.6$. In the A(1) region the lifetime of O(a) is very short and no steady-state concentration of O(a) can accumulate. Kinetically, the adsorption of oxygen is rate-limiting. The reaction is zero-order in CO at temperatures where CO can not be adsorbed. At lower temperatures, where CO can be adsorbed, the CO_2 production drops when $P_{CO}/P_{O_2}=0.6$ and is negative-order in CO. In the B(1) region the rate at which oxygen atoms appear on the surface exceeds the CO collision rate. The reaction rate will be determined by the CO collision frequency. Since the O_2 pressure is known, the O_2 sticking probability can be determined,[11] and then the steady-state oxygen coverage can be predicted. The coverage calculated is shown as a function of the CO pressure in Fig. 7.

Low Temperatures: The rate of the L-H process is not fast enough to eliminate enough CO(a) for it to become negligible. The critical CO pressure should appear at the boundary between A(2) and B(2). Most of the CO(a) will be removed as CO_2 through the L-H process whenever the O_2 pressure is significant.[5] An upper boundary on the amount of CO(a) can be set by assuming that all the CO_2 arises from the L-H process and that the upper boundary is to be set by the CO collision frequency. As the rate constant of the L-H process has been deduced by Bonzel and Burton,[5] an upper boundary for the product, $\theta_{O(a)} \times \theta_{CO(a)}$, can be calculated ($\theta_1$ is defined as the coverage). The $\theta_{O(a)}+\theta_{CO(a)}$ sum can be estimated by using the procedures outlined in the former section, assuming that CO(a) influences the O_2 sticking probability in the same way as does O(a). The calculated coverages are shown in Fig. 7. After the two curves cross, the amounts change sharply to zero for O(a) and infinite for CO(a). Above that point the CO coverage must be equal to that at equilibrium with gaseous CO. Thus, the boundary CO pressure can be determined; it is shown by vertical dotted lines at various temperatures. In the A(2) region the adsorption of oxygen is still rate-limiting. Two adjacent empty sites are necessary for the dissociative adsorption of oxygen, and its rate is severely retarded as CO(a) increases. Therefore, the CO_2 production undergoes a very sharp drop in passing from the B(2) region to the A(2) region.

The sharp drop in the CO_2 production at 527 K occurred at the CO pressure predicted in the high-temperature region. The rate observed at 468 K, however, dropped at a CO pressure 30% less than that predicted. Generally, the criticalCO pressure predicted at low temperatures is 30—40% higher than that observed, as may be seen in Fig. 7. This discrepancy may be due to inadequacies in representing the coverage dependence of the sticking probability of oxygen as the same for O(a) and CO(a).

Electron Trapping in Irradiated NaOH Ices. Electrons Stabilized at 4 K in Shallow Traps Associated with Na^+ Cations

Jerzy KROH,** Shoji NODA, Kiyomi YOSHIDA, and Hiroshi YOSHIDA*

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received December 19, 1977)

Studies on electron trapping in 8 and 18 mol·dm^{-3} NaOH glassy ices were performed by means of 4 K γ-irradiation technique. The optical absorption spectra of e^-_t were found to be considerably red-shifted and broader compared with the spectra in the ices irradiated and examined at 77 K. This trend was more pronounced for the concentrated sample. The red part of the broad spectra was removed either by photobleaching with light of $\lambda > 800$ nm at 4 K or by thermally annealing at 77 K. These results, combined with electron spin resonance data, lead to the conclusion that the shallow electron traps responsible for the red part of the spectra are formed with the participation of Na^+ cations in the alkaline ices.

Electron stabilization in irradiated glassy alkaline ices has been commonly interpreted in terms of solvation of excess electrons by dipoles of H_2O molecules ("dipolar trap"), and the role of alkali metal cations has been ignored in most models.[1] However, taking into account the relatively high concentration of the cations in most experiments (usually *ca.* 20 mol%), such picture is hardly acceptable and does not appeal to chemical intuition. In 1964, Kevan, who examined the electron spin resonance (ESR) spectra of γ-irradiated 2—5 mol·dm^{-3} LiOH, NaOH, and KOH ices, indicated a contribution of the alkali metal cation interaction to the ESR line width and suggested that "the charge density of trapped electrons in alkaline ices encompasses several water molecules and one or more cations".[2]

Recently, Polewoj and one of the present authors (J. K.) reported optical absorption spectra of electrons trapped at 77 K in highly concentrated (up to 20 mol·dm^{-3}) NaOH ice.[3,4] The properties of the spectra were tentatively explained by the existence of relatively shallow and unstable traps due to the formation of a cation-electron pair ("cationic trap"), $(Na^+\cdots e^-)_t$, whose absorption maximum lay at *ca.* 750 nm, as compared with the maximum at 585 nm in 10 mol·dm^{-3} NaOH ice. Here we provide further data, based mainly on optical absorption measurements at 4 K, which demonstrate the increasing variety of trap depths at high NaOH concentrations.

Experimental

Glassy NaOH ice samples of two concentrations, 8 and 18 mol·dm^{-3}, of NaOH were prepared in the form of windowless discs, 0.2 cm thick, by rapid cooling in liquid nitrogen. A modified version of the liquid helium cryostat described previously[5] was used for measurements at 4 K. The irradiations were carried out in dark with ^{60}Co γ-rays at a dose rate of *ca.* 0.9 Mrad/h at 77 K or at *ca.* 0.25 Mrad/h at 4 K. The total dose applied was *ca.* 0.2 Mrad.

The optical absorption spectra were recorded using a double-beam recording spectrophotometer with a twin photodetection system (Shimadzu, Model MPS-5000). ESR experiments were carried out with a conventional X-band spectrometer (JEOL, Model JES-3M) for the ice sample sealed in thin quartz tubes.

The irradiated samples were photobleached with light from a 500 W Xe lamp through a 420±50 nm band-pass filter or an 800 nm cut-off filter. Typically the samples were photobleached for 3 min for optical absorption measurements and for 15 min for ESR measurements.

Results and Discussion

Effect of Temperature on Optical Absorption Spectra. The optical absorption spectra due to trapped electrons are presented in Figs. 1 and 2 for 18 M and 8 M ice samples (containing 18 mol·dm^{-3} and 8 mol·dm^{-3} NaOH) irradiated and also examined at 4 and 77 K. In each case, the spectrum at 4 K is wider and red-shifted compared with the spectrum at 77 K. At 4 K the 8 M sample displays the absorption maximum at 650 nm and the spectral halfwidth is 1.4 eV. The former value is in complete agreement with that reported by Hase *et al.*,[6] whereas the latter value is somewhat lower. The 18 M sample at 4 K has a maximum at 690 nm and a halfwidth of 1.65 eV. The halfwidths at 4 K are *ca.* 1.3 times larger than those at 77 K for both samples. On the other hand, however, no dependence on the temperature of measurement, when examined at 77 and 4 K, is seen in the spectra of the samples irradiated at 77 K. This con-

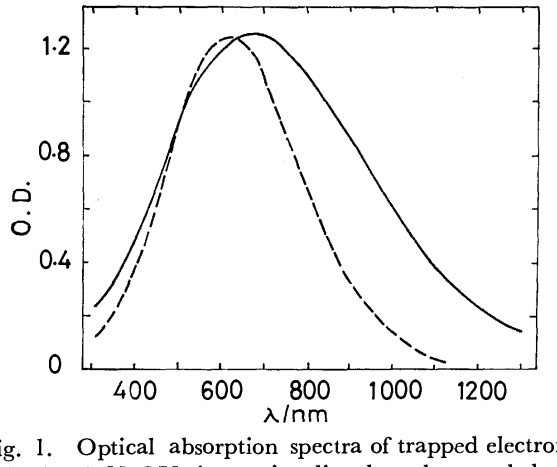

Fig. 1. Optical absorption spectra of trapped electrons in 18 M NaOH ices γ-irradiated and recorded at 4 K, —— and at 77 K, ----. The 77 K spectrum is normalized with the 4 K spectrum at peak height.

trast with blue-shift of the spectrum of trapped electrons in an ethanol glass observed upon cooling form 77 to 4 K after the irradiation at 77 K.[7]

Thermal bleaching, accomplished by transfer of the samples irradiated at 4 K into liquid nitrogen for 2 min and recording the spectra again at liquid helium temperature, led to the blue-shift and narrowing of the spectra. Thus, for the 18 M sample the absorption maximum shifts from 690 to 630 nm and the half-width decreases 1.1 times, whereas the 8 M sample shows the shift from 650 to 580 nm and the decrease in halfwidth of nearly 1.3 times. The effect of the thermal bleaching is more pronounced for the dilute sample than for the concentrated one.

Photobleaching of the Optical Absorption Spectra. The longer wavelength regions of the 4 K spectra are readily bleached by red light of $\lambda > 800$ nm, so that the absorption maxima effectively shift to the blue. The subsequent photo-bleaching with blue light of $\lambda \sim 420$ nm partially restores the longer wavelength regions and results in the red-shift of the maxima. The observed wavelength (transition energy) changes of the absorption maxima during the selective photo-bleaching for the 8 and 18 M samples are

$$\underset{(1.91\ \text{eV})}{650\ \text{nm}} \xrightarrow{\text{red light}} \underset{(2.16\ \text{eV})}{575\ \text{nm}} \xrightarrow{\text{blue light}} \underset{(1.98\ \text{eV})}{625\ \text{nm}}$$

and

$$\underset{(1.81\ \text{eV})}{685\ \text{nm}} \xrightarrow{\text{red light}} \underset{(2.10\ \text{eV})}{590\ \text{nm}} \xrightarrow{\text{blue light}} \underset{(1.77\ \text{eV})}{700\ \text{nm}}$$

respectively, and the shifts are more pronounced for the concentrated sample, whose recorded spectra are given in Fig. 3.

The changes of the spectral shape caused by photobleaching were first reported by Ershov *et al.*,[8] but they are not very distinct at 77 K. For 10 M NaOH ice, the shifts of the absortion maxima reported by Hase and Kevan do not exceed 35 nm.[9] For the 8 M sample at 77 K, photobleaching under the present experimental conditions did not change the spectral shape, though the total intensity decreased.

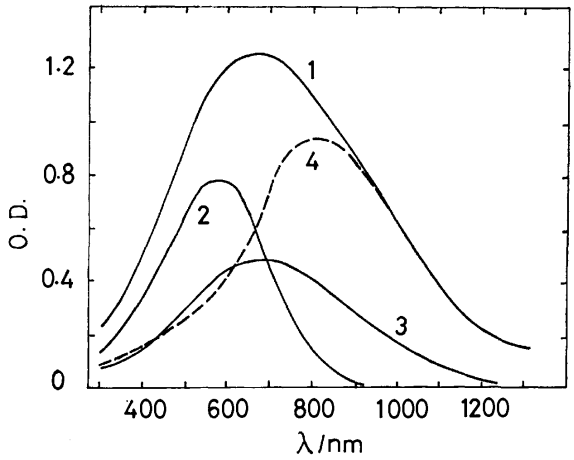

Fig. 3. The effects of selective photobleaching on the optical absorption spectrum of trapped electrons in 18 M NaOH ice irradiated and recorded at 4 K: 1, after γ-irradiation; 2, after photobleaching with 800 nm light; 3, after consecutive photobleaching with 400 nm light; 4, the spectrum bleached with the red light (1—2).

It is also interesting to note that the original 4 K spectrum can be generally reconstructed with respect to both absorption maximum and width by photobleaching at 4 K with the blue light the smaple which had been thermally bleached at 77 K.

The Nature of Shallow Electron Traps. All the above results of optical absortpion experiments seem to be consistent with the following picture: the trap depth distribution in NaOH ice shifts in favor of the shallow traps, responsible for the longer wavelength regions of the spectra, (a) with increasing NaOH concentration and (b) with decreasing temperature of irradiation. Point (a) suggests that the shallow traps may be of a cationic nature.

Electrons in the shallow traps are comparatively unstable and, in 18 M ice, were previously found to decay at 77 K.[3] It was suggested that about 15% of the trapped electrons generated in 18 M NaOH ice irradiated at 77 K are in "cationic" traps and are easily bleached.[4] At 4 K, the contribution of shallow traps significantly increases both for the 8 and 18 M samples. In contrast, the stable dipolar traps are responsible, in the 8 M sample irradiated at 77 K, for most trapped electrons, whose absorption spectra show very small shifts upon photobleaching.

Taking into account the fact that, at 77 K, the shallow trapped electrons still remain in the 18 M sample but not in the 8 M sample, it seems reasonable to expect that the thermal bleaching (4→77 K) effect may be larger for the dilute than for the concentrated sample. This has been found for both the shift of the absorption maxima and the narrowing of the spectral widths. It is suggested that no significant molecular rearrangements are required to allocate electrons in cationic traps and, therefore, they are more primary in nature. In the very early stage of electron trapping, probably in both the 8 and 18 M ices, a large number of electrons is stabilized by cations. The stabilization is

effective at 4 K, whereas it is short-lived at 77 K particularly in the 8 M ice.

Assuming that the spectral component bleached with red light at 4 K (curve 4 in Fig. 3) represents the electrons in the shallow, cationic traps, these electrons also have a very wide energy distribution. This may result from a variety of ion pairs more or less solvent separated, or more or less loose or tight, using the terminology of Seddon *et al.*[10] Their pulse radiolysis study indicated that the optical absorption bands of solvated electrons in amines and tetrahydrofuran are blue-shifted in the presence of alkali metal cations compared with those in neat solvents. Although the above results concerning liquid solutions bear a rather distant relation to the present work, they suggest that the cation-electon pairs form traps of intermediate depths between solvation wells in strongly (*e. g.* water) and weakly (*e. g.* tetrahydrofuran) polar media. It is also interesting to note that the solvated electron band in liquid ammonia shows a red-shift in the presence of metal ions, though this shift is not ascribed to the formation of a (M^+, e^-_s) pair.

The existence of two kinds of electron traps, the dipolar traps and the cationic ones, in the NaOH ice is also supported by more careful examination of the shape of the absorption spectra. None of the red parts of the spectra at 4 K fits a Gaussian distribution and all of them appear to be a superposition of two Gaussian components, as shown in Fig. 4. However, the spectral component in the longer wavelength region photobleached with red light at 4 K (curve 4 in Fig. 3) fits a single Gaussian shape (see curve 2 in Fig. 4) in agreement with the data reported for 77 K. The Gaussian form of the spectrum representing the ion-pairs should be also expected, judging from the results of Shubin *et al.*[11]

Electrons both in the shallow traps and in the deep ones are readily removable from their traps by photobleaching with light of a suitable wavelength (see Fig. 3). It is however worth noting that bleaching of the electrons in the shallow traps is not accompanied by any significant increase in the intensity of the shorter wavelength region of the spectra, corresponding to the electrons in the deep dipolar traps. The photobleached electrons probably disappear by reactions with O^- ions and impurities. On the other hand, the deep electrons are partially transformed into the shallow electrons by blue light. These results imply that an abundance of the shallow traps is available in the NaOH ice at 4 K.

ESR Evidence for the Shallow Traps Associated with Na^+ Cations. Additional evidence as to the wider variety of electron traps in the 18 M sample is provided by ESR measurements at 77 K. These results are shown in Fig. 5. The width of the initial trapped electron signal is 2.1 mT, in fairly good agreement with the data reported by Blandamer *et al.* for 20 M NaOH ice.[12] It decreases to 1.9 mT upon photobleaching with red light. The bleached component of the signal has the width of 2.4 mT, which is much broader than the width, 1.4 mT, of the ordinary trapped electrons in the dipolar traps in the alkaline ice

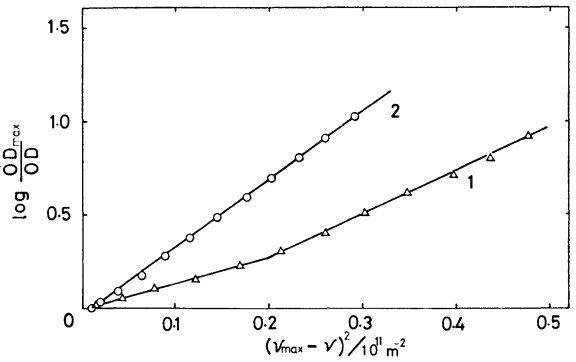

Fig. 4. The gaussian plots. The curve 1 for red parts of the spectrum of γ-irradiated 18 M NaOH ice at 4 K (Fig. 3, curve 1) and the curve 2 for the spectrum due to trapped electrons bleached with 800 nm light (Fig. 3, curve 4).

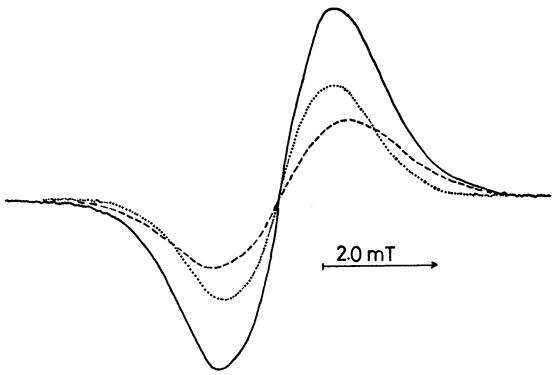

Fig. 5. ESR spectra of trapped electrons in γ-irradiated 18 M NaOH ice at 77 K: ——, after γ-irradiation; ·····, after photobleaching with 800 nm light; and ----, the spectrum bleached with the red light.

matrices of NaOH concentrations less than 10 M at 77 K.

It has been found that the ESR width of the trapped electrons in ethylene glycol–water mixed matrix is broadened from 0.3 to 1.4 mT when thermally annealed at 77 K after the irradiation at 4 K.[5] This change is accompanied by a tremendous blue-shift of the optical absorption spectrum of the trapped electrons.[5,6] This is interpreted in terms of the deepening of traps by the oriented matrix molecules with a polar hydroxyl group, which results in a closer distance between trapped electrons and neighboring protons and, therefore, a larger hyperfine broadening. However, the correlation between the ESR width and the optical absorption observed here is the reverse: when the absorption spectra effectively shift to the blue upon the photobleaching with red light, the ESR width becomes narrower. The present results strongly suggest that the deepening of traps (the blue-shift) in the 18 M sample is not due to the change in the orientational configuration of water molecular dipoles around the traps, but is due to the photorelease of electrons from the traps associated with Na^+ cations, leaving electrons in the dipolar traps.

The ESR width of 2.4 mT of the photobleached component of the signal can reasonably be under-

stood to be due to the hyperfine splitting of the Na nucleus, because it gives a non-negligible conctribution to the ESR width of electrons even in the ordinary dipolar traps in the NaOH ice of lower concentrations.[2] ESR spectra of 8 M and 18 M KOH glassy ice samples irradiated at 77 K have the same width of 1.2 mT. This is in good agreement with the reported data,[12] as reasonably expected from the small nuclear magnetic moment of the K nucleus.

Conclusion

The present data substantiate the results reported previously[3,4] and indicate the nature of shallow, cationic traps for excess electrons in irradiated NaOH ice. This kind of trap is abundant and contributes to the primary step in stabilizing and localizing the electrons.

In fact, the situation may be very complex. Dipolar traps themselves have a wide energy distribution and the contribution of shallow, unrelaxed dipolar traps probably increases at an early stage of the electron trapping process. Moreover, electrons in dipolar traps follow to some extent their own rearrangement pattern, when photo- or thermally bleached. The main purpose of the present work is to point out the possible importance of another type of electron stabilization, *i.e.*, by valence traps or in the form of ion pairs.

This work was performed by using the cryogenic facilities of the electron LINAC laboratory, Hokkaido University.

Direct Measurement of Interaction Energy between Solids and Gases. II. Microcalorimetric Studies on the Surface Acidity and Acid Strength Distribution of Solid Acid Catalysts

Tatsuo MASUDA,* Hitofumi TANIGUCHI, Kazuo TSUTSUMI, and Hiroshi TAKAHASHI

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received January 10, 1978)

The differential heats of adsorption of ammonia on several solid acids were measured by means of a twin conduction type microcalorimeter, and surface acid strength distribution and acidity were evaluated. Silica-alumina showed very high initial heats which were not observed in decationated zeolite and silica-magnesia. The acidity of zeolite was about 6 times as high as that of silica-alumina, showing very charactristic acid site distribution at 100 kJ/mol of adsorption energy, and suggesting the existence of homogeneous acid sites. The surface water modified surface acidic nature transforming strong acid sites into weaker ones. The poisoning of acid sites of silica-alumina with alkali occurred preferentially at sites on which adsorption energy of ammonia was 96—105 kJ/mol.

The measurement of the acidity and acid strength distribution of solid acid surfaces has been the subject of many researches, different methods being employed. The most common method is titration with amine in nonaqueous systems using various indicators. A number of reports have appeared on the adsorption of basic gases on solid acids.[1] Attempts were made to use a calorimeter for measurements of a surface acidic nature. Kevorkian and Steiner[2] measured heats of ammonia gas adsorption on alumina specimens from bayerite as a function of coverage. Hsieh[3] obtained the adsorption isotherms and heats of adsorption of ammonia at 0 °C on a series of commercial silica–alumina cracking catalysts and concluded that about one-tenth of the surface is heterogeneous with respect to ammonia adsorption. Similar measurements for alumina, silica–alumina, and X-type zeolite were carried out by Stone and Whalley.[4] None of these were satisfactory to account for the surface acidity and acid strength distribution of solid acids quantitatively. Tsutsumi *et al.*[5] have measured the differential heats of ammonia adsorption on several cation exchanged zeolites, obtaining a good correlation between the differential heats of adosrption and cumene-cracking activities.

In this work, the surface acidity and acid strength distribution were studied in detail with a twin conduction type microcalorimeter for several solid acids. The effects of surface water contents and sodium poisoning of silica–alumina were examined.

Experimental

Materials. Two types of silica-alumina catalyst(Al_2O_3 contents, 13 and 28%, SA-13 and SA-28, respectively) supplied by Shokubai Kasei Co., Ltd. were calcined at 500 °C for 3 h in the air. Sodium poisoned silica-alumina was obtained by impregnation with 0.1 M aqueous sodium acetate solution at 50 °C for 24 h, followed by washing with distilled water, drying at 110 °C and heating at 550 °C in the air (Na-1). Na-2 was obtained by repeated impregnation and washing 3 times under the same conditions as those of Na-1, followed by drying at 110 °C and heating at 550 °C in the air. Sodium contents were 0.38, 0.64 mmol/g in Na-1 and Na-2, respectively.

Y-type zeolite was supplied by Linde Co. in the sodium form. NH_4-Y zeolite was prepared by the conventional cation exchange procedure with NH_4NO_3 solution. The degree of ion-exchange determined by flame photometry was 69.78%.

Silica-magnesia and silica were supplied by Fuji Chem. Co. and Degussa Co., respectively. The magnesia content of silica-magnesia was 20.5 wt% on dry base.

All the substance were used as granules of 28—60 mesh in the calorimeter. The surface areas of these samples determined by N_2 adsorption at 77 K are given in Table 1. Ammonia was obtained from Matheson Co., and purified by the freezing and thawing method.

TABLE 1. SURFACE AREA OF SOLID ACIDS

a) Silica-magnesia.

Apparatus and Procedure. The calorimeter and the procedure of measurement have been described.[6] In order to measure differential heats of adsorption, ca. 0.5 g of adsorbent was weighed into the sample cell and outgassed at several temperatures, mainly at 400 °C, under a pressure of 10^{-5} Torr for 5 h and set in the calorimeter. The calorimeter was maintained at 25±0.01 °C. The amount adsorbed was calculated from the pressure change before and after adsorption measured by a MKS capacitance manometer (below ≈10 Torr) and a mercury manometer (above ≈10 Torr). The amount of gas admitted was *ca.* 5×10^{-6} mol at low surface coverages, while at higher coverages some larger doses were admitted. The fraction of surface coverage was calculated by taking the cross-sectinal area of the ammonia molecules as 16 A^2 at 25 °C.

Results and Discussion

Differential Heats of Silica–Alumina and Silica. Differential heats of adsorption of ammonia on SA-13, SA-28, and silica are given in Fig. 1 as a function of surface coverage. The samples were pretreated at 400 °C *in vacuo*. Curve (c) shows the results of re-adsorption of ammonia on SA-13 which was NH_3-pre-adsorbed and evacuated at 25 °C for 6 h. In silica–alumina, the differential heats fall abruptly from

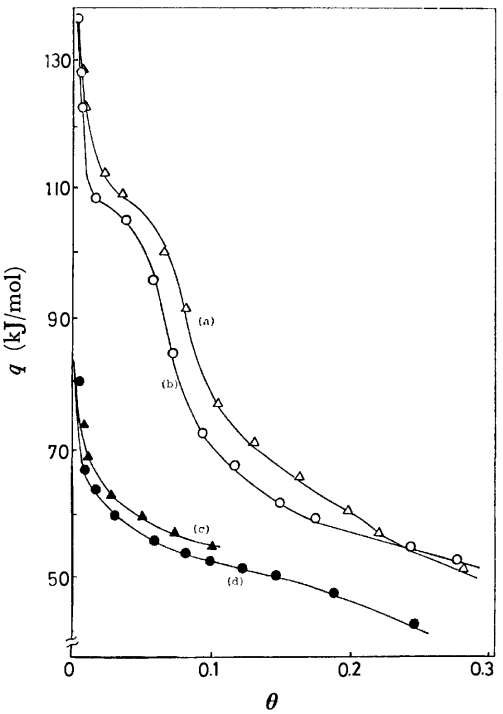

Fig. 1. Heats of adsorption of ammonia on silica-alumina and silica at 25 °C.
(a); SA-28, (b): SA-13, (c): NH_3-preadsorbed SA-13, (d): silica.

initial heat value of *ca.* 140 to 109 kJ/mol. The abrupt decrease in the differential heats indicates that the adsorption of ammonia molecules occurs on the strongest acid sites successively. Details of the q-θ curve in these regions were given previously.[6] After the abrupt decrease, the q-θ curve shows a stepped curve, differential heats decreasing gradually to 54.4 kJ/mol at 0.3 of θ. The stepped region in q-θ curve indicates that considerably homogeneous acid sites exist. The behavior of the q-θ curve is very similar in the two silica-alumina, but SA-28 has larger number of strong adsorption sites as compared with SA-13, especially over 105 kJ/mol. Clark and co-workers[7] studied the differential molar entropy for ammonia adsorbed on silica-alumina of various composition and reported that their values in the region of adsorbed amount smaller than 0.4 molecules/100 Å^2 are smaller than that of perfect two dimensional gas. This corresponds to the region of adsorption energy larger than about 96 kJ/mol, where no residual gas above 10^{-3} Torr was observed. This suggests that the mobilities of adsorbed ammonia are fairly restricted in this region.

Silica does not exhibit high intital heats of adsorption. the differential heats falling very slightly to *ca.* 41.8 kJ/mol at 0.25 of θ. From the fact that ammonia adsorbed on silica is easily desorbed by evacuation at 25 °C, the heat evolved during the course of adsorption is considered to be due to mainly hydrogen bonding and van der Waals interaction. The ammonia preadsorbed SA-13 shows a q-θ curve very similar to that of silica. However the former exhibits somewhat higher differential heat probably due to the interaction of ammonia molecules with the NH_4^+ ions. The

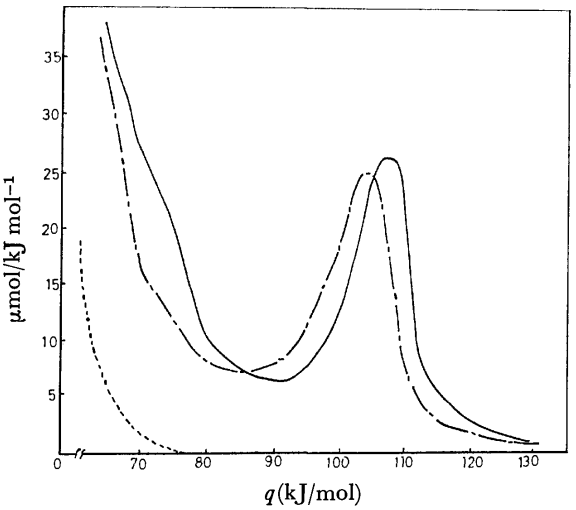

Fig. 2. Acid site distributions of silica-alumina and silica.
——: SA-28, ——: SA-13, ----: silica.

remaining amount of ammonia after evacuation at 25 °C on SA-13 measured by gravimetric methods is 0.6 mmol/g, corresponding to 0.1 of surface coverage. In comparison with the q-θ curve of SA-13 it can be concluded that the adsorbed ammonia with heat of adsorption lower than 70.0 kJ/mol can be desorbed by evacuation at 25 °C. The value nearly coincides with the initial heat of ammonia on preadsorbed SA-13.

The surface acid site distributions of silica-alumina and silica are given in Fig. 2. The maximum distributions are observed at 105 and 109 kJ/mol in SA-13 and SA-28, respectively. The region with a heat of adsorption between 75 and 92 kJ/mol shows relatively low distribution values, indicating that only a small amount of acid sites exists in these regions. Rouxhet and Sempls[8] observed two hydroxyl groups in silica-alumina; type 1, Si-OH groups identical with those present on the surface of silica; type 2, the sites responsible for the protonation of adsorbed ammonia whose acidity corresponds to the pK_a range from −4 to −8. The latter OH groups seem to be responsible for the maximum site energy distribution.

The distribution curve of silica has neither maximum nor minimum.

Effects of Outgassing Temperature on q-θ Curve of SA-13. The q-θ curves of SA-13 outgassed at various temperatures between 25 and 400 °C for 5 h are shown in Fig. 3. The initial heat obtained on the sample outgassed at 150 °C (curve b) is 159 kJ/mol, almost the same as that obtained on the sample outgassed at 400 °C (curve a). The sample outgassed at 25 °C exhibits no stronger adsorption energy than 110 kJ/mol. No apparent difference could be observed among all samples in the region below 70 kJ/mol. Similar results were also obtained in SA-28.

Figure 4 shows the acid strength distribution of the samples. The maximum at 105 kJ/mol in curve(a) shifted towards lower strength along with the lowering of outgassing temperature. The results indicate that the surface water modified the acidic nature and the strong acid sites were transformed into weak ones.

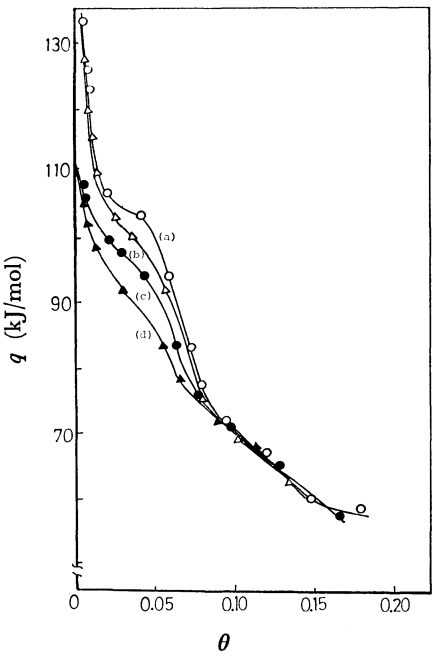

Fig. 3. Effects of outgassing temperature on q-θ curve of SA-13.
(a): 400 °C under 10^{-5} Torr, (b): 150 °C under 10^{-5} Torr, (c): 25 °C under 10^{-5} Torr, (d): 25 °C under 10^{-3} Torr.

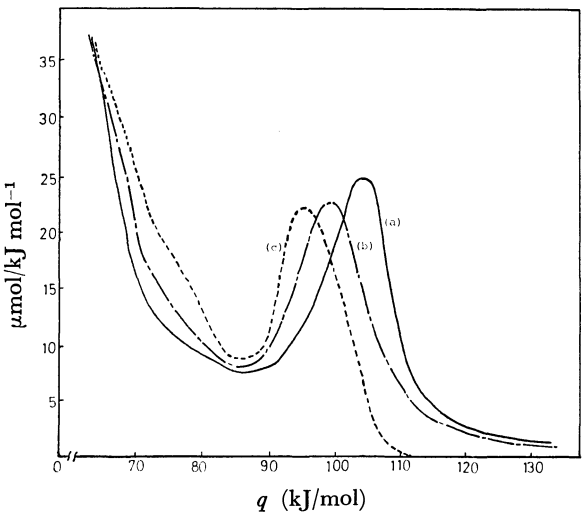

Fig. 4. Effects of outgassing temperature on acid site distributions of SA-13.
(a): 400 °C, (b): 150 °C, (c): 25°C under 10^{-5} Torr.

Gravimetric experiments showed that water released from SA-13 with an increase of evacuation temperature from 25 to 400 °C is *ca.* 3.1 mmol/g. The value is greater than the number of acid sites which were calculated to be *ca.* 0.6 mmol/g. This suggests that the surface water does not interact in a 1 : 1 molar ratio with acid sites. It should be pointed out that the infrared spectrum of pyridine adsorbed on SA-13 outgassed at 25 °C showed only pyridinium ion absorption band, suggesting the absence of Lewis acid sites. If protonic acid sites are formed by the interaction of water with Lewis acid sites, the adsorption energies

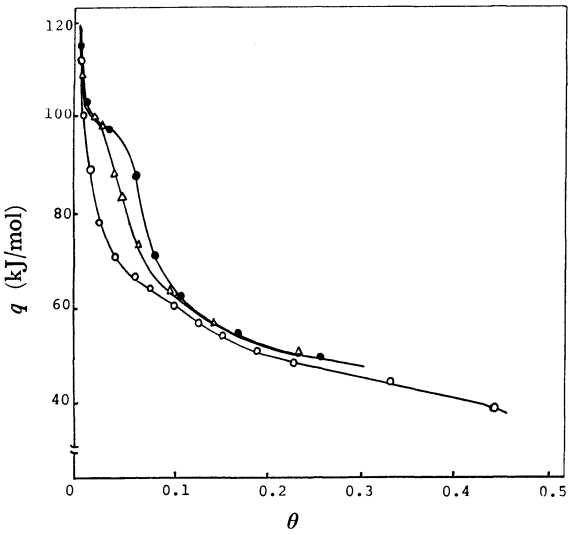

Fig. 5. Heats of adsorption of ammonia on sodium ion-exchanged silica-alumina at 25 °C.

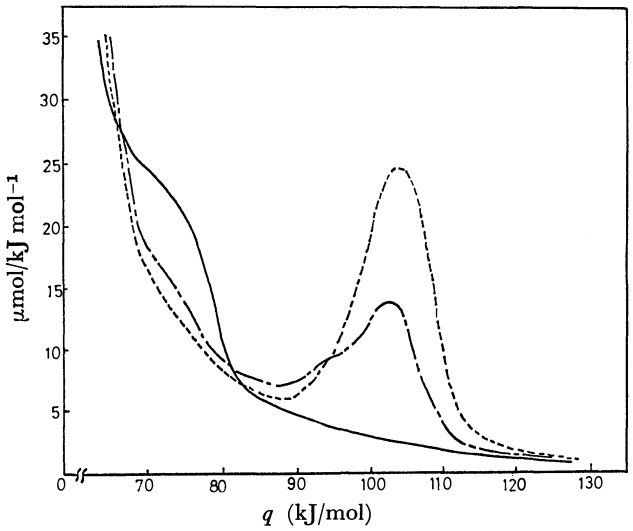

Fig. 6. Acid site distributions of sodium ion-exchanged silica-alumina.
——: Na-2, ———: Na-1, ----: SA-13.

of the resulting sites are probably lower than those of the original Lewis acid sites. The acid strength of the hydrated surface proton becomes less. The results given in Figs. 3 and 4 probably imply the circumstances of silica–alumina surface. It is noteworthy that the differential heats of the sample outgassed at 25 °C is greater than the heat of solution of ammonia in water, 35.6 kJ/mol.

The Effects of Alkali Metal Poisoning. The q-θ curves of sodium ion-exchanged SA-13 are shown in Fig. 5. These samples were pretreated at 400 °C *in vacuo*. The initial heat is almost the same as that of original SA-13. A remarkable difference from original SA-13 is a decrease of the number of the acid sites between 95 and 110 kJ/mol of adsorption heats. This is evident from the disappearance of a maximum in acid strength distribution of Na-2 shown in Fig. 6. In the region of adsorption heat lower than

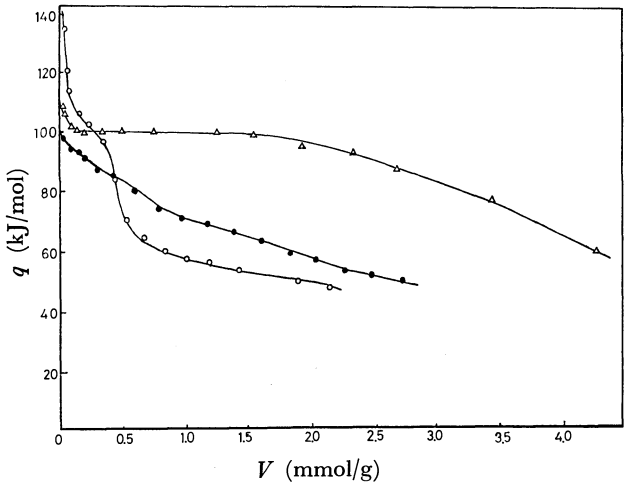

Fig. 7. Heats of adsorption of ammonia on H-$Y_{5.0}$ and silica-magnesia at 25 °C.
-△-: H-$Y_{5.0}$, -●-: silica-magnesia, -○-: SA-13.

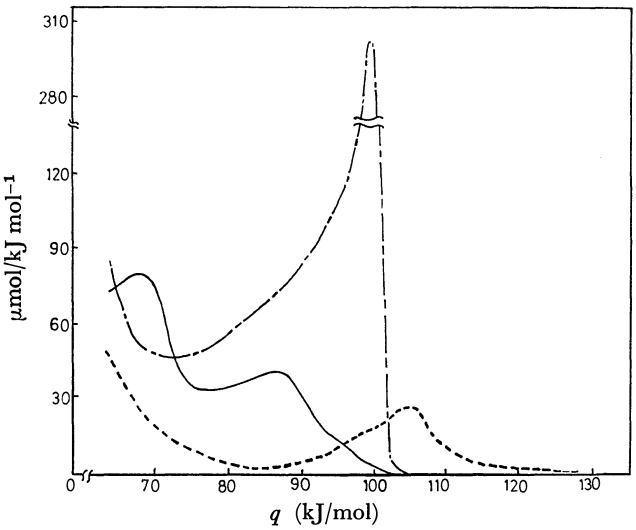

Fig. 8. Acid site distributions of H-$Y_{5.0}$ and silica-magnesia.
——: Silica-magnesia, ——: H-$Y_{5.0}$, ----: SA-13.

68 kJ/mol, however, the q-θ curve and acid strength distribution curve are little affected by sodium ion-exchange. This suggests that ammonia molecules probably interact physically with adsorption sites in this region An increase in the number of the acid sites between 68 and 80 kJ/mol implies that an exchanged Na^+ ion transforms a part of strong acid sites to weaker ones in line with the results of Hirshler.[9]

Flockhart and Pink[10] have reported that single base exchange-dehydration cycle can not poison all of the acid sites, especially Lewis acid sites. The infrared spectrum of ammonia adsorbed on Na-2 showed the presence of a very small amount of ammonium ions. This suggests that at low surface coverage, *i.e.*, in the region of high adsorption energy, ammonia molecules interact with Lewis acid sites on Na-2.

Differential Heats of H-$Y_{5.0}$ and Silica-Magnesia. The differential heats of H-$Y_{5.0}$ and silica-magnesia are shown in Fig. 7 together with the results of SA-13. Both samples were pretreated at 400 °C *in vacuo*. In H-$Y_{5.0}$, there are no acid sites with a value greater than 111 kJ/mol which can be seen in silica-alumina surface. The differential heats remain *ca.* 100 kJ/mol up to 1.5 mmol/g of the amount adsorbed and then smoothly decrease to 65 kJ/mol at 4.0 mmol/g. Those homogeneous acid sites giving about 100 kJ/mol of adsorption heats are probably protonic acid sites. The same results have been obtained in a series of H-Y zeolite with a different silica-alumina ratio.[5] The calculated number of protons which generated during the course of heat treatment of ammonium form zeolite at 400 °C is 2.27 mmol/g. This corresponds to the number of acid sites over 94 kJ/mol of adsorption heats.

The heat of adsorption on silica-magnesia is about 109 kJ/mol at an initial stage and then decreases gradually to 54 kJ/mol at 2.5 mmol/g of the amount adsorbed.

The acid strength distribution of these solid acids is shown in Fig. 8. Richardson[11] studied the effects of faujasite cations on acid sites by means of infrared spectroscopic measurements of several types of OH groups existing in the supercage and observed two kinds of centers with acid strength corresponding to pK_a=4.95 and −4.9, respectively. Although his model was not well defined, the shape of the distribution curve is very similar to ours. In comparison with the case of silica-alumina, maximum and minimum positions of site energy distribution of silica-magnesia differ greatly. At around 80—92 kJ/mol of the adsorption energy, silica-alumina has minimum distribution, and silica-magnesia a maximum one. Such a tendency is in line with the results of amine titration, *viz*, silica-magnesia has no stronger acid sites found in silica-alumina, its acid sites being more widely distributed from strong acid sites to weak acid sites as compared with the case of silica-alumina. More heterogeneous distributions observed for acid sites of amorphous silica-alumina and silica-magnesia in comparison with that of H-$Y_{5.0}$ might be probably due to a localization of their acid sites originated from surface Al and Mg, respectively.

Acid Distribution of Solid Acids. No estimation of the number of surface acid sites of solid from the measurements of differential heats of adsorption of basic molecules seems to have been made. The number and density of acid sites are shown as a function of adsorption energies (Table 2), calculated on the assumption that the effective acid sites are $q \geq 70$ kJ/mol and ammonia molecules interact in a 1:1 molar ratio with acid sites. The definition of the effective acid sites is somewhat arbitrary in this case. The results of acid distribution of silica-alumina measured with a Hammett indicator[12] show the existence of only very weak acids and very strong acids. However, our results show the existence of a considerable amount of medium strength acid sites between 75 and 95 kJ/mol, which is consistent with the results of H_R indicator[13] and ammonia desorption method.[14] The discrepancy might have resulted from the adsorption of Hammett

a) ($mmol/m^2 \times 10^3$)

indicators on the acidic surfaces.[15] The surface acid density of SA-28 is larger than that of SA-13, its difference becoming greater in the region over 110 kJ/mol of adsorption energy. In comparison with silica–alumina, $H\text{-}Y_{5.0}$ possesses about 6 times the number of acid sites with q higher than 70 kJ/mol, which are rather homogeneous. The acidic properties of $H\text{-}Y_{5.0}$ probably support its high catalytic activity and selectivity in cracking reaction.

In Na-2, the reduction of the number of acid sites by base exchange is 0.3 mmol/g, which is smaller than the number of Na^+ ions on Na-2, suggesting that exchanged Na^+ ions do not correspond in a 1:1 molar ratio to acid sites or that they only decrease the strength of some acids.

The use of adsorption calorimetry and particularly the measurement of differential heats of basic gas molecules on solid acids seems to be useful for the determination of surface acidity and acid strength distribution. The method could be utilized in the measurements of very strong acid sites which can not be measured exactly by the conventional amine titration.

Direct Measurement of the Interaction Energy between Solids and Gases. III. Comparison of the Calorimetric Titration Method with the Amine Titration Method for the Determination of Acid Strength Distribution of Silica–Alumina Surface

Hitofumi TANIGUCHI,* Tatsuo MASUDA, Kazuo TSUTSUMI, and Hiroshi TAKAHASHI

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received January 11, 1978)

The acid strength distribution of silica–alumina catalyst (alumina content 13 wt%) evacuated at 400 °C for 5 h was determined by the measurement of heat of adsorption of ammonia, and compared with that determined by amine titration by use of a series of Hammett indicators. The heats of adsorption of ammonia on silica–alumina poisoned with Hammett indicators were also measured in order to obtain the relation between the dissociation constant of the acid (pK_a) and the heat of adsorption. When the dissociation constants of acid were equal to -5.6 and $+3.3$, the differential heats of adsorption of ammonia were observed to be 76.1 and 55.1 kJ/mol, respectively. The number of acid sites calculated from the heat *vs.* adsorbed amount curve was found to be about twice as large as that determined by amine titration. The discrepancy is discussed.

In previous papers, calorimetric titration with ammonia gas was reported for various solids (silica–alumina:alumina content 13 and 28 wt%, decationated zeolites and silica gel).[1,2] The adsorption energy distribution curve was derived for each sample from calorimetric data. The curve obtained shows a new aspect of the acid strength distribution of solid acid catalysts: the differential heat of adsorption of ammonia corresponds to the acid strength and the adsorbed amount of ammonia to the number of acid sites.

The acid strength is generally expressed by the Hammett acidity function, H_0, which is related to the dissociation constant of acid, pK_a, as

$$H_0 = pK_a + \log([B]/[BH^+]) \quad \text{(Brønsted acid)}$$

$$H_0 = pK_a + \log([B]/[BA]) \quad \text{(Lewis acid)}$$

where [B] and [BH^+] are the concentrations of the base and its conjugated acid, respectively, and [BA] is the concentration of the coordination compound of Lewis acid A and Lewis base B. The number and the strength of acid sites can be determined by butylamine titration by use of indicators with known pK_a values.[3] However, the method is unsuitable for colored samples. Moreover, indicator molecules are so large that they can scarcely migrate into micro pores of porous materials such as silica–alumina. Though silica–alumina has been known to have stronger acid sites than $pK_a = -8.2$, the color change of indicator corresponding to these regions can hardly be recognized with the naked eye.

Calorimetric method can overcome these disadvantages. However, the relationship between a differential heat of adsorption of basic gas and an acid strength or pK_a value has not been clarified as yet. The purpose of this study is to correlate the heat of adsorption of ammonia with the acid strength and to compare calorimetric titration with amine titriation.

Experimental

The solid acid catalyst used in this study was commercial FCC silica–alumina (alumina content 13 wt%, Catalysts & Chemicals Ind. Co., Ltd.). Each sample was pretreated at 400 °C under 10^{-5} Torr for 5 h before measurement. Butylamine titration was carried out before and after ammonia adsorption at different coverages in cyclohexane with use of a series of Hammett indicators: anthraquinone ($pK_a = -8.2$), benzylideneacetophenone ($pK_a = -5.6$), dicinnamylideneacetone ($pK_a = -3.0$), *p*-anilinoazobenzene ($pK_a = +1.5$), *p*-dimethylaminoazobenzene ($pK_a = +3.3$).

The heat of adsorption of ammonia was measured with a twin conduction type calorimeter.[1,2,4] In most cases, calorimetric measurement and ammonia titration in solid-gas phase with use of the indicators were carried out simultaneously. Specific surface area was determined by the BET nitrogen method. Surface coverage of ammonia gas was calculated by assuming a cross sectional area of ammonia molecule to be 16 Å^2.

Results and Discussion

Figure 1 shows the relation between the preadsorbed amount of ammonia and the subsequently titrated amount with butylamine for each indicator. The end point of butylamine titration changed with the preadsorbed amount of ammonia for every indicator; as an example, when the indicator was benzylidene-

pK_a	−5.6	−3.0	+1.5	+3.3
n	2.0	2.8	2.0	2.6
		2.4	3.0	1.3
		(5.0)	1.8	1.6
Average		$n=2.2$		

Table 2. Acid amount determined by adsorbed amount of butylamine (1) and ammonia (2) (mmol/g)

pK_a	≦−5.6	≦−3.0	≦+1.5	≦+3.3
(1)	0.24	0.31	0.38	0.56
	0.24	0.33	0.39	0.57
			0.39	0.59
Average	0.24	0.32	0.38	0.57
(2)	0.52	0.68	0.83	1.21
	0.51	0.73	0.82	1.24
			0.84	1.27
Average	0.51	0.70	0.83	1.24

acetophenone($pK_a=-5.6$) and the preadsorbed amount of ammonia 0.45 mmol/g, the titrated amount of butylamine was 0.03 mmol/g, while the end point was 0.43 mmol/g at 0.35 mmol/g of preadsorbed ammonia. If butylamine molecules were adsorbed on acid sites in the same manner as ammonia, the end point would be independent of the preadsorbed amount of ammonia. However, this is not the case. The number of acid sites can be considered constant after pretreatment at the same temperature under the same pressure for the same period. Hence, the following simple equation should hold for every indicator:

$$x + ny = k, \quad (1)$$

where x is the preadsorbed amount of ammonia, y the titrated amount of butylamine, k the constant corresponding to the number of acid sites, and n the constant correlating the number of ammonia molecules with that of butylamine molecules adsorbed on silica–alumina surface. The values of n, calculated by means of Eq. 1 and on the basis of Fig. 1, are given in Table 1. Some scattering of values can be ascribed to the error of the titrated amount of butylamine. The average value, $n=2.2$, is considered to be reasonable as clarified in the following.

The numbers of acid sites calculated by use of conversion factor, $n=2.2$, are given in Table 2. They are constant within errors for a given pK_a value. Thus, if one ammonia molecule is adsorbed on one acid site, one butylamine molecule seems to occupy about two sites. The cross sectional area of ammonia molecule is 16 Å^2, and that of butylamine molecule 32 Å^2. Moreover, acid sites on silica–alumina surface seem to be localized due to localization of aluminum atom or ion.[5] The value of conversion factor, $n=2.2$, seems to depend mainly on the ratio of cross sectional areas, 32 Å^2/16 Å^2. Other factors such as the difference of basicity of amines may hardly affect the conversion factor.

In amine titration using Hammett indicators, butylamine in benzene or cyclohexane is generally used. In this study ammonia gas titration with a series of Hammett indicators was carried out, along with simultaneous calorimetric measurements for silica–alumina catalyst. Change from the basic to the acidic color was clearly observed as in amine titration in cyclohexane solution. The end points of gas titrations are shown in Table 3. These values are in good agreement with those in Table 2. The period required for adsorption equilibrium of ammonia was expected to be much shorter than that of butylamine in cyclohexane solution, since the diffusion rate of molecule in the gas phase is about ten thousand times as large as that in the liquid phase. The adsorption equilibrium seems to be attained within one or two hours, as estimated by simultaneous calorimetric measurement. Figure 2 shows the results of calorimetric measurement carried out simultaneously with gas titration. Each q-V (or q-θ) curve for the sample poisoned with indicator is similar in shape to that of the original sample. They are lower than the curve of the original sample by several kJ/mol in the low coverage range, coinciding with it in the higher coverage. The V values (adsorbed amount of am-

monia) at points where two curves coincide are in good agreement with those given in Tables 2 and 3 for all indicators. Smaller q values of the sample poisoned with the indicator, in the low coverage, can be ascribed to the desorption of the indicator. If we assume that the mechanism of ammonia titration consists of the desorption of indicator and the subsequent adsorption of ammonia, the observed heat of adsorption can be expressed by the following equation:

$$Q = nq_{(ads)} + mq_{(des)}, \quad (2)$$

where Q(kJ) is the observed heat, $q_{(ads)}$(kJ/mol) the heat of adsorption of ammonia, $q_{(des)}$(kJ/mol) the heat of desorption of indicator (negative value), n(mol) the adsorbed amount of ammonia, and m(mol) the desorbed amount of indicator. The q value in Fig. 2 derived from Eq. 2 is given by

$$q = Q/n = q_{(ads)} + (m/n)q_{(des)}. \quad (3)$$

The factor m/n represents the number of indicator molecules replaced by one ammonia molecule. Decrease in the q value, accompanied by poisoning with indicator, reflects the term $(m/n) \times q_{(des)}$ in Eq. 3.

In order to determine $q_{(des)}$, the heat of adsorption of indicator from indicator–cyclohexane solution was measured by a twin conduction type calorimeter. The adsorbed amount of indicator was determined spectroscopically before and after measurement. The adsorbed amounts of indicators, the heats of adsorption of indicators and the corresponding adsorbed amount of ammonia are given in Table 4. For *p*-dimethylaminoazobenzene, the ratio of the ammonia molecules adsorbed to the desorbed molecules of indicator, m/n in Eq. 3, is 0.21 on the assumption that the adsorbed amount of indicator is equal to its desorbed amount. Since the integral heat of adsorption of indicator is presumably equal to the integral heat of desorption, $(m/n) \times q_{(des)}$ in Eq. 3 can be equated to -19.0 kJ/mol for *p*-dimethylaminoazobenzene and -15.7 kJ/mol for *p*-anilinoazobenzene. A decrease in the q value induced by poisoning with indicator is sufficiently explained in terms of these values.

Gel Filtration Study of the Effect of Urea on the Dissolution State of Sodium Dodecyl Sulfate

Tsunetaka SASAKI,*† Hiroshi AMANO,†† and Hitoshi SUZUKI†††

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received January 27, 1978)

Using gel columns of Sephadex G 50 Fine and CPG gel, gel filtration studies were made of the sodium dodecyl sulfate (SDS)–urea system. The results demonstrated that both the CMC and the elution volume of SDS were increased by the addition of urea. The increase of the elution volume indicates the decrease in micellar size, and this coupled with the increase of CMC indicates the increased difficulty of micelle formation by the addition of urea. The direct interaction between SDS and urea was also examined by the gel filtration method and such interaction was confirmed to be absent both below and above the CMC of SDS. Furthermore, the micellar weight of SDS was estimated by the gel filtration method and values of 23000 and 11000 were obtained for SDS solutions containing 0 and 3 mol dm^{-1} urea, respectively.

A number of studies have been reported of the effect of urea on the micelle formation of surfactants.[1–6] The addition of urea increases the critical micelle concentration (CMC) of surfactants. This effect has been explained in terms of the decrease of entropy of micellization due to the breakdown of the structure of water or the weakening of the hydrophobic bonding between the hydrophobic chains of surfactant molecules by the addition of urea.[4] Other explanations have also been presented.[1,2,5]

A similar effect has been discussed for the urea–protein system.[1,7,8] Here, the interaction between the protein and urea is suggested in addition to the interaction between water and urea.[8] Furthermore, urea–polyethlene glycol[9] and urea–fatty acid interactions[10] have been reported. In these studies, conductometric,[1,5] spectroscopic,[2] surface tension,[3] and membrane-potential[5] measurements have been employed.

In the present paper. the gel filtration method which enables a simple and direct measurement[11] has been adopted to study the effect of urea upon the aqueous solution of the ionic surfactant, sodium dodecyl sulfate (SDS). The discussion has been made upon both the water–urea and the SDS–urea interactions.

Experimental

Materials. SDS was prepared according to the Dreger method.[12]. It was purified by recrystalliztion from ethanol and washed with ethyl ether. Purity was confirmed by the absence of a minimum in the surface tension-concentration curve. The commercial SDS product from Nippon Surfactant Chemicals Co. was similarly purified and used. Commercial urea of a guaranteed grade was recrystallized from 95% ethanol. Substances used as a molecular weight standards were reagent grade sodium chloride, blue dextran (Pharmacia product), Pluronics F 68 and F 108 (Asahi Denka products), poly(vinyl alcohol) (PVA) (Nippon Gōsei Kōgyō product), and poly(sodium ethylenesulfonate) (PES) (commercial product). Gel used for packing columns were Sephadex G 50 Fine (Uppsala Pharmacia product) and CPG-10 (Electro-Nucleonic Inc. product). Distilled water was used after degassing by boiling.

Apparatus and Measurement. The apparatus used for the gel filtration was the same as reported in a previous paper.[11] Gel columns used were of 1.2 cm inner diameter and 32 and 80 cm in height for Sephadex G 50 Fine and CPG-10, respectively.

Measurement was made by charging 20 to 35 cm^3 of the sample solution onto the top of the gel column and the solution eluted at constant flow rates of 20 and 30 cm^3/h for Sephadex gel and CPG-10 gel, respectively. In the case of the SDS gel filtration, elution was made using water. For the SDS–urea gel filtration, the gel column was previously filled with urea solution of the same concentration as that of the sample solution. The sample solution was then charged and the solution eluted with urea solution of the same concentration. The eluted solutions were detected either by a conductometer or a differential refractometer (Mitsumi LDC Refractomonitor) and the elution curves obtained on a recorder.

All experiments were conducted at 30±1 °C.

Results and Discussion

Sephadex–Urea System. CMC vs. Urea Concentration: The elution curves of conductance *vs.* flow volume are shown in Fig. 1a and 1b which are similar to those of SDS below and above the CMC in the absence of urea, respectively.[11] Here, κ_T and κ_S represent conductances of the total solution and single ions, respectively and V_f, V_m, and V_s denote elution volumes of the elution front, SDS micelles and single ions, respectively. From these data, the CMC's of the SDS–urea system were obtained for 0, 1.5, and 3 mol dm^{-3} urea concentrations by plotting κ_T and κ_S against the concentration of SDS, as shown for instance in Fig. 2 for the SDS–urea system (3 mol dm^{-3} urea). Figure 3 shows the CMC *vs.* urea concentration curve. The CMC's are seen to increase with increasing concentration of urea. Figure 3 also gives the values calculated from the conductometric data of Emerson and Holtzer.[13]

Urea–SDS Interaction: The urea–SDS interaction has been explained indirectly as the breakdown of the structure of water by urea. However, urea has been reported to interact directly with protein,[8] surfactant,[9] and fatty acid monolayers,[10] and since there is no confirmation of the absence of such a direct interaction between urea and SDS, it was necessary to establish this point. For this purpose, the gel filtration measurement offers a simple and direct method.[14]

Table 1 shows elution volumes V_f, V_m, and V_s of the urea–SDS system containing 0 and 3 mol dm^{-3} urea. Assuming that the urea–SDS complex is formed in the solution in equilibrium with single dodecyl sufate ions (DS^-) and urea, the complex will be eluted faster than DS^- or urea and thus V becomes smaller than V_s below the CMC as in the case of poly(vinyl acetate)–SDS complex formation.[14] However as seen in Table 1, V_f and V_s are equal to each other in the urea–SDS for a 3 mol dm^{-3} urea concentration below the CMC. Therefore the possibility of complex formation is excluded below the CMC. We also confirmed that the interaction of urea with SDS above the CMC or the solubilization was negligible, since the elution curve of the urea–SDS mixture above the CMC was obtained as a simple addition of the elution curves for the separate components as shown in Fig. 4. This differs from the complicated elution curve exhibited in the case of the solubilization of 1-dodecanol by SDS.[15] In Fig. 4, the broken lines show the elution curves of urea and

NaCl	32.1	32.9

SDS above the CMC and the solid line denotes the elution curve of the urea–SDS system which is obtained by the addition of the ordinates of the former two curves. A similar absence of interaction has also been reported between urea and nonionic surfactant.[16]

V_m of SDS in Urea Solution: As seen from Table 1, the values of V_m show a complicated change with concentration of SDS and urea. Also the V_s values are not equal to each other for the systems of 0 and 3 mol dm^{-3} urea solutions. These facts may be attributed to the change of Sephadex gel matric produced by the addition ures and SDS. This has been confirmed by the change in the elution volumes of the substances of known molecular weight such as NaCl, Pluronics, and dextran by the addition of urea as shown in Table 2. Therefore, to estimate the micellar weight of SDS, it becomes necessary to measure the elution volume of the urea–SDS, system using a gel which is free from such a change. For this purpose CPG-10 gel was chosen.

CPG–Urea–SDS System. Preparation of CPG Gel Column: The CPG gel was superior to the Sephadex gel since the gel matrix was not affected by various solvents, but it showed less difference between V_m and V_s of SDS. A gel column more than twice as long as the Sephadex gel column was necessary to obtain a comparable separation efficiency.

The CPG gel was purified first by washing with distilled water and decantation. Then it was left free in concentrated nitric acid overnight, washed with distilled water, with a water ethanol mixture and finally with pure ethanol. The purified CPG was packed in a glass column mentioned already and care was taken to pack the column uniformly. The packed column was further washed with concentrated aqeous solutions of SDS and ethanol. The completeness of the washing was confirmed by absence of a peak in the elution curve of water obtained by refractometry.

Micellar Weight of SDS: Elution volumes of SDS, NaCl and blue dextran were measured in the absence and presence (3 mol dm^{-3}) of urea. In the latter case, the gel column was previously filled with 3 mol dm^{-3} urea and the same solution used for the elution of the sample solution. Table 3 and 4 show the results. It may be seen in the tables that the elutions volume of SDS single ions (V_s), NaCl and blue dextran are not affected by the addition of 3 mol dm^{-3} urea. Comparison of these results with Table 2 confirms that the CPG gel matrix is unaffected by the urea addition. Further, as seen in Table 3, the values of V_m of SDS are independent of SDS concentration

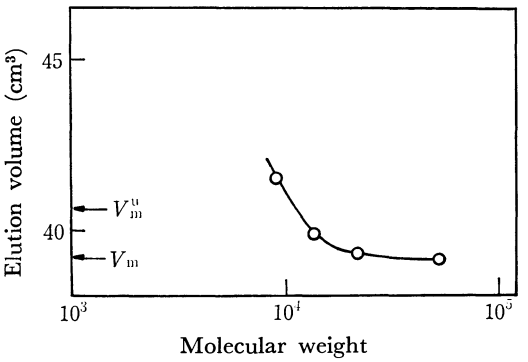

Fig. 5. Elution volume *vs.* molecular weight plot. Gel; CPG gel, V_m, V_m^u; Elution volumes of SDS micelles in water and in aq urea solution, respectively

both for the 0 and 3 mol dm^{-3} urea systems and the value of the 3 mol dm^{-3} urea solution is larger than that of the solution without urea. This evidently shows that the addition of urea decreases the size of the micelle independent of the SDS concentration.

To estimate the micellar weight or SDS, it was necessary to secure a series of substances of known molecular weight, which were used to construct a calibration curve of elution volume *vs.* molecular weight. A series of PVA of mean degrees of polymerization, 200, 300, 500, and 1200 were used as standard substances. The elution volume of PVA without urea is uncertain because of a marked tailing, whereas the tailing is reduced in the presence of 3 mol dm^{-3} urea and a distinct and identical elution volume is obtained for the front and the tail of PVA solution. This may indicate the absence of both CPG– and urea–PVA interactions and the elution volume was considered to be directly related to the molecular weight of PVA. Figure 5 shows the molecular weight *vs.* elution volume plot for 3 mol dm^{-3} urea solution, which was used as a calibration curve for the estimation of the micellar weight. It should be noted that the

range covered by this calibration curve is not satisfactory for the molecular weight determination, however it may be sufficient for the estimation of molecular weight as a whole. Thus, from this curve and the elution volumes of SDS micelles listed in Table 3, the micellar weights of 23000 and 11000 were obtained for SDS in 0 and 3 mol dm^{-3} urea solutions. The former value is comparable to the value of 25000 formerly reported.[17] Further, the micellar weight was confirmed to decrease by the addition of urea, which together with the increase of the CMC mentioned already may indicate the difficulty of micelle formation produced by the additon of urea. Contraty to this result, a slight increase of micellar aggregation number by the addition of urea has been reported for a nonionic surfactant.[18]

The above estimation of the micellar weight assumes a nearly equal weight ratio of hydration between PVA and SDS in the state of solution and the amount of hydration of SDS being independent of the addition of urea. The first point may be confirmed from the coincidence of unhydrated molecular weight *vs.* elution volume plots between PVA and SDS as estimated from the diagram of a previous paper.[17] The second point may be confirmed by comparison of the elution volumes of PES of nearly the same size (elution volume) as those of SDS micelles in 0 and 3 mol dm^{-3} urea solutions. This has been discussed in a previous paper.[19] From the data shown in Table 4, it may be seen that the elution volumes of PES measured in 0 and 3 mol dm^{-3} urea solution are equal to each other. From this we assumed that the amount of yhdration of PES and thereore SDS was not affected by the addition of urea.

Computation of the Correlation Functions for Fluids Composed of Diatomic Molecules by Means of the Method of Integral Equations

Kazumitsu KOJIMA and Kiyoshi ARAKAWA

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received February 6, 1978)

Pair correlation functions and structure factors of molecular fluids were computed, based on the reference interaction site model (RISM) integral equation coupled with the Percus-Yevick (PY) and the hyper-netted chain (HNC) approximations. The system considered is a fluid of diatomic molecules consisting of two identical spheres of diameter σ with each center located at a distance L ($L<\sigma$). The total potential energy for the molecular fluid is assumed to be the sum of pair potentials of the Lennard-Jones type. It is shown that the pair correlation functions calculated are in agreement with results of molecular dynamics studies. The structure factors calculated by using two kinds of approximations (PY and HNC) are found to deviate from each other for small values of k (wave vector). Discussions are given on the behavior of the structure factors, $S(k)$. The rise of $S(k)$ at small k is ascribed to the effect of attractive forces between molecules.

It has become evident from studies on the properties of simple atomic fluids with use of the Percus-Yevick (PY) and the hyper-netted chain(HNC) equations that these equations are useful for fluids composed of spherical particles.[1] In the case of fluids composed of nonspherical molecules, however, solving the equations is difficult since the interactions between molecules depend on the mutual orientation of molecules as well as on their positions. Chen and Steel[2] applied the generalized PY equation to a system of diatomic molecules. In order to solve the equation, they transformed it into a set of coupled integral equations by expanding the correlation functions in a series of spherical harmonics. However, this treatment was laborious and not successful.

Chandler and Andersen[3] proposed the embedded site and the reference interaction site models for fluids consisting of polyatomic molecules. In these models, the total interaction between molecules is expressed as a sum of site-site interactions depending only on the separation between sites. In the embedded site model, each molecule is regarded as a hard sphere with embedded sites. This model was applied to a system of water-like particles.[4] In the reference interaction site model a molecule is composed of rigidly-connected hard spheres (the spheres within a molecule may overlap), where the centers of interaction sites are located at the centers of the spheres.

Lowden and Chandler[5,6] solved the reference interaction site model (RISM) integral equation for molecular fluids in which each molecule interacts through the hard sphere site-site repulsive potentials only. Ladanyi and Chandler[7,8] applied a topological reduction procedure to the new cluster expansion formula on the basis of the RISM theory, giving a relationship between the RISM equation for molecular fluids and the PY equation for simple atomic fluids. Hsu *et al.*[9] calculated the correlation functions for systems of homonuclear diatomic molecules using the method of the associated RISM model and intermolecular site-site cluster functions. They treated the attractive potential as a perturbation.

Recently, Johnson[10] has given a set of equations which are analogous to the RISM equation from the Ornstein-Zernike equation using Fourier-Wigner series. The equations using the PY approximation were applied to a system of molecules interacting through the Lennard-Jones site-site potential.

We have attempted to solve the RISM integral equation coupled with the PY and HNC approximations for the purpose of dealing with systems interacting through intermolecular site-site potentials without use of the perturbation technique. The results of our calculation are compared with those of molecular dynamics studies[11,12] and other calculations.[9,10]

Theory

Model. In the theory proposed by Chandler and Andersen,[3] a molecule is assumed to have m interaction sites. The location of the αth site on jth molecule is denoted by $\boldsymbol{r}_j^\alpha=\boldsymbol{R}_j+\boldsymbol{l}_j^\alpha$. Here, $\boldsymbol{R}_j$ denotes the location of the center of the jth molecule. The vector $\boldsymbol{l}_j^\alpha$ depends on the orientation of the molecule as described by the Eulerian angles. We assume that the molecule as shown in Fig. 1 is rigid so that the magnitude of $\boldsymbol{l}_j^\alpha$ and of the angles between different $\boldsymbol{l}_j^\alpha$ vectors within the same molecule become constant. The total potential energy for the molecular fluid is assumed to be the sum of pair potentials, where the pair interaction between molecule 1 and 2 is given by

$$w(1,2)=\sum_{\alpha=1}^{m}\sum_{\gamma=1}^{m}w_{\alpha\gamma}(\boldsymbol{r}_1^\alpha-\boldsymbol{r}_2^\gamma). \tag{1}$$

The pair interaction between α site of a molecule and γ site of another molecule is expressed as

$$w_{\alpha\gamma}(r)=4\varepsilon\left\{\left(\frac{\sigma}{r}\right)^{12}-\left(\frac{\sigma}{r}\right)^{6}\right\}. \tag{2}$$

Reference Interaction Site Model Equation.[3] The pair correlation function considered is the intermolecular site-site radial distribution function defined as

$$g_{\alpha\gamma}(r)=\rho^{-2}\left\langle\sum_{\substack{i=1\\(i\neq j)}}^{N}\sum_{j=1}^{N}\delta(\boldsymbol{r}_i^\alpha)\delta(\boldsymbol{r}_j^\gamma-\boldsymbol{r})\right\rangle, \tag{3}$$

where the bracket $\langle\cdots\rangle$ denotes an ensemble average, $\rho=\langle N/V\rangle$ the average density, and $\delta(\boldsymbol{r})$ the Dirac delta function. The structure of molecular fluid is given by the $g_{\alpha\gamma}(r)$ function where $4\pi r^2\rho g_{\alpha\gamma}(r)$ is a probability distribution for finding a site γ associated with one molecule at a distance r from an origin when a site α (in another molecule) is located at the origin.

The total correlation function is

$$h_{\alpha\gamma}(r) = g_{\alpha\gamma}(r) - 1, \tag{4}$$

which is a functional of site-site cluster functions, $f_{\alpha\gamma}(r)$ and intramolecular pair distribution functions, $s_{\alpha\gamma}(r)$. These quantities are defined as

$$f_{\alpha\gamma}(r) = \exp\{-\beta w_{\alpha\gamma}(r)\} - 1, \tag{5}$$

where β^{-1} is Boltzmann's constant times temperature and

$$\begin{aligned} s_{\alpha\gamma}(r) &= (1-\delta_{\alpha\gamma})\rho^{-1}\langle\sum_{i=1}^{N}\delta(\boldsymbol{r}_i^{\alpha})\delta(\boldsymbol{r}_i^{\gamma}-\boldsymbol{r})\rangle, \\ &= (1-\delta_{\alpha\gamma})(4\pi L_{\alpha\gamma})^{-1}\delta(r-L_{\alpha\gamma}). \end{aligned} \tag{6}$$

The second equality in Eq. 6 holds for rigid molecules only, where the distance between site α and γ within the same molecule is a constant $L_{\alpha\gamma}$.

The site-site total correlation function $h_{\alpha\gamma}(r)$ and the site-site direct correlation function $c_{\alpha\gamma}(r)$ are related by an Ornstein-Zernike type equation:

$$\hat{\boldsymbol{h}}(\boldsymbol{k}) = \hat{\boldsymbol{\omega}}(\boldsymbol{k})\hat{\boldsymbol{c}}(\boldsymbol{k})[\boldsymbol{1}-\rho\hat{\boldsymbol{\omega}}(\boldsymbol{k})\hat{\boldsymbol{c}}(\boldsymbol{k})]^{-1}\hat{\boldsymbol{\omega}}(\boldsymbol{k}), \tag{7}$$

where $\hat{\boldsymbol{h}}(\boldsymbol{k})$, $\hat{\boldsymbol{c}}(\boldsymbol{k})$, and $\hat{\boldsymbol{\omega}}(\boldsymbol{k})$ denote matrices with elements $\hat{h}_{\alpha\gamma}(k)$, $\hat{c}_{\alpha\gamma}(k)$, and $\hat{\omega}_{\alpha\gamma}(k)$,

$$\begin{aligned} \hat{h}_{\alpha\gamma}(k) &= \int d\boldsymbol{r}\, h_{\alpha\gamma}(r)e^{-i\boldsymbol{k}\boldsymbol{r}}, \\ \hat{c}_{\alpha\gamma}(k) &= \int d\boldsymbol{r}\, c_{\alpha\gamma}(r)e^{-i\boldsymbol{k}\boldsymbol{r}}, \\ \hat{\omega}_{\alpha\gamma}(k) &= \int d\boldsymbol{r}\, \omega_{\alpha\gamma}(r)e^{-i\boldsymbol{k}\boldsymbol{r}}, \end{aligned} \tag{8}$$

respectively. The $\omega_{\alpha\gamma}(r)$ is defined as

$$\omega_{\alpha\gamma}(r) = \delta_{\alpha\gamma}\delta(r) + s_{\alpha\gamma}(r). \tag{9}$$

PY and HNC Approximations. The RISM integral equation can be solved when the site-site direct correlation function $c_{\alpha\gamma}(r)$ is expressed in terms of the site-site total correlation function $h_{\alpha\gamma}(r)$.[3] According to Chandler[8] the $c_{\alpha\gamma}(r)$ on the RISM integral equation is expressed as

$$c_{\alpha\gamma}(r) = y_{\alpha\gamma}(r)f_{\alpha\gamma}(r), \tag{10}$$

where $y_{\alpha\gamma}(r)$ is

$$y_{\alpha\gamma}(r) = \exp\{\beta\omega_{\alpha\gamma}(r)\}g_{\alpha\gamma}(r). \tag{11}$$

He refers to Eq. 10 as a "PY like approximation." We propose here the application of a "HNC like approximation" defined as

$$c_{\alpha\gamma}(r) = h_{\alpha\gamma}(r) - \ln y_{\alpha\gamma}(r), \tag{12}$$

which is similar to the HNC approximation for simple atomic fluids.[13] A set of coupled non-linear integral equations is formed by combining Eq. 7 with the closure Eq. 10 or Eq. 12.

Computational Procedure

Computational Method. For a fluid composed of homonuclear diatomic molecules such as shown in Fig. 1, we have $h_{\alpha\gamma}(r)=h_{11}(r)$ and $c_{\alpha\gamma}(r)=c_{11}(r)$ for all (α,γ). The RISM integral equation (Ref. 5, Eq. 2.7) is

$$\hat{h}_{11}(k) = \{1+\hat{\omega}_{12}(k)\}^2\hat{c}_{11}(k)/[1-2\rho\{1+\hat{\omega}_{12}(k)\}\hat{c}_{11}(k)], \tag{13a}$$

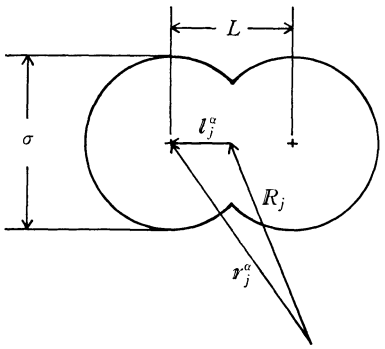

Fig. 1. The shape of RISM molecule.

$$\hat{\omega}_{12}(k) = (kL_{12})^{-1}\sin(kL_{12}), \tag{13b}$$

$$c_{11}(r) = y_{11}(r)f_{11}(r), \quad \text{(PY)} \tag{13c}$$

$$= h_{11}(r) - \ln y_{11}(r). \quad \text{(HNC)} \tag{13d}$$

An iteration procedure is carried out for solving Eqs. 13 numerically, the method of fast Fourier transformation (FFT) being used for the calculation.[14] The function $h_{11}(r)$ is discontinuous at $r=\sigma$ but the function $\gamma(r)=h_{11}(r)-c_{11}(r)$ is a continuous function of r.[5] With use of $\gamma(r)$, Eqs. 13a—d are written as

$$\rho\gamma(r) = \rho(2\pi)^{-3}\int d\boldsymbol{k}\left[\frac{\{1+\hat{\omega}_{12}(k)\}^2}{1-2\rho\{1+\hat{\omega}_{12}(k)\}\hat{c}_{11}(k)}-1\right]\hat{c}_{11}(k)e^{i\boldsymbol{k}\boldsymbol{r}} \tag{14}$$

and

$$\gamma(r) = y_{11}(r) - 1, \quad \text{(PY)} \tag{15a}$$

$$= \ln y_{11}(r), \quad \text{(HNC)} \tag{15b}$$

respectively. The iteraction procedure is carried out by means of Eqs. 14 and 15. The values of $\hat{c}_{11}(k)$ given by Lowden and Chandler[5] for the hard sphere intermolecular site-site interactions are taken as initial ones. The iteration has been continued until the self-consistency of

$$\left|\frac{y_{11}^{\text{out}}(r)-y_{11}^{\text{in}}(r)}{y_{11}^{\text{in}}(r)}\right| < 10^{-7} \tag{16}$$

is satisfied.

Structure Factor. Neutron scattering experiments determine the molecular structure factor, $S(k)$, which is defined as

$$S(k) = (\sum_{\alpha=1}^{m} b_{\alpha})^{-2}\sum_{\alpha,\gamma}^{m} b_{\alpha}b_{\gamma}\langle N^{-1}\sum_{i,j}^{N}\exp\{i\boldsymbol{k}\cdot(\boldsymbol{r}_i^{\alpha}-\boldsymbol{r}_j^{\gamma})\}\rangle. \tag{17}$$

In the calculation of $S(k)$ it is assumed that the interaction sites are located on the nuclei so that $\boldsymbol{r}_j^{\alpha}$ is the location of αth nucleus in the jth molecule. The coherent neutron scattering amplitude for a nucleus of type α is denoted by b_{α}. By performing the ensemble average in Eq. 17, the structure factor can be expressed in terms of site-site pair correlation functions:[6]

$$S(k) = (\sum_{\alpha=1}^{m} b_{\alpha})^{-2}\sum_{\alpha,\gamma}^{m} b_{\alpha}b_{\gamma}\{\hat{\omega}_{\alpha\gamma}(k)+\rho\hat{h}_{\alpha\gamma}(k)\}, \tag{18}$$

$$= \frac{1}{2}\{1+\hat{\omega}_{12}(k)\} + \rho\hat{h}_{11}(k). \tag{19}$$

The equality in Eq. 19 holds for fluids composed of homonuclear diatomic molecules. If the intermolecular

structure of a fluid is completely random (the ideal gas limit), the structure factor becomes

$$S_{\text{ideal}}(k) = \left(\sum_{\alpha=1}^{m} b_\alpha\right)^{-2} \sum_{\alpha,\gamma}^{m} b_\alpha b_\gamma \hat{\omega}_{\alpha\gamma}(k). \quad (20)$$

Molecular Parameters. We have carried out the calculation according to the procedure described above for liquid nitrogen. Barojas *et al.*[12] and Cheung and Powles[15] made a computer simulation for the homonuclear diatomic molecular liquid by means of a molecular dynamics method using the same potential as in the present paper. The parameters corresponding to liquid nitrogen are

$$L_{12} = |\boldsymbol{l}^1 - \boldsymbol{l}^2| = 1.100\,\text{A},$$
$$\sigma = 3.341\,\text{A},$$
$$\varepsilon/k = 44\,\text{K},$$

and

$$L^* = L_{12}/\sigma = 0.3,$$

where k is Boltzmann's constant. When these parameters are used, the values $\rho^*=\rho\sigma^3$ and $T^*=kT/\varepsilon$ at the triple point are 0.6964 and 1.437, respectively, and those at the critical point are $\rho^*=0.246$ and $T^*=2.86$. For the sake of comparison we have made a calculation of $S(k)$ for the same values of parameters. The values $\rho^*=0.6964$, $T^*=1.61$ used correspond to $T=71$ K, $\rho=0.868$ g/cm^3 for liquid nitrogen.[11]

Results and Discussions

Correlation Functions. Figures 2—5 show the site-site radial distribution functions calculated according to the procedure described in the preceding section. The $g_{11}(r)$ calculated are compared with the results of other theories[9,10] as well as those of molecular dynamics[11,12] in Figs. 2—4. The agreement between these results is satisfactory on the whole. The site-site pair correlation curve obtained from the RISM equation for the system with hard sphere site-site interactions is known to have two cusps appearing at $r^*=(r/\sigma)=1$ and $r^*=1+L^*$.[5] For the system with the Lennard-ones site-site potential, these cusps are supposed to be rounded off with a shoulder appearing instead at $r^*=1+L^*$. If one site is σ away from a site at the origin, then another site of the same molecule is located between σ and $\sigma+L_{12}$ from the site at the origin resulting in appearance of a shoulder at $r^*=1+L^*$. This feature distinguishes the structure of molecular fluids from

that of simple atomic fluids. The $g_{11}(r)$ obtained by Johnson[10] (Fig. 2) has no shoulder which is in sharp contrast to the result of our calculation as well as that of molecular dynamics.[11] The curve of Johnson deviates on the whole from the result of molecular dynamics[12] at higher temperatures (Fig. 4), while our curve is in a fairly good agreement. The shoulder disappears at higher temperatures, the $g_{11}(r)$ becoming similar to the radial distribution function for the fluid composed of spherical particles with the Lennard-Jones potential, as shown in Fig. 5.

Structure Factors. The structure factor calculated is compared with the results of molecular dynamics[11] in Fig. 6. Agreement is satisfactory except for small values of k. Figure 7 shows the structure factors calculated using the PY and HNC approximations, some difference appearing at small values of k. The difference appears also in structure factors calculated by use of the PY and HNC approximations for simple atomic fluids.[16] The structure factors we obtained for different temperatures at a fixed density are given in Fig. 8. The values of $S(k)$ increase in the small range of $k\sigma$ ($k\sigma<\pi$).[17] This has never been found in the results calculated by the method of a perturbation technique using blip function.[9] The behavior of the structure factors at small values of k seems to be due to the contribution of attractive potentials. In fact, at higher temperatures, the behavior of $S(k)$ becomes similar to that of $S(k)$ for the case of the hard sphere potential.

Weeks *et al.*[18] pointed out that the behavior of $\rho\hat{h}(k)$ is dominated by repulsive forces, and effect of the attractive forces is primarily manifested in the small wave vector portion as shown in Fig. 9. At lower densities, the contribution of the attractive forces becomes dominant at small values of k. On the other hand, at higher densities this contribution disappears and becomes similar to the behavior of $\rho\hat{h}(k)$ for the fluids consisting of hard sphere particles.

Concluding Remarks

The RISM integral equation coupled with the PY and HNC approximations has been applied to fluids consisting of homonuclear diatomic molecules interacting through the Lennard-Jones site-site potentials. Computation procedure and results are summarized as follows: (1) the RISM integral equation coupled with the PY and HNC approximations can be solved numer-

ically by means of a method of an iteration procedure with a fast Fourier transformation (FFT), (2) the site-site pair correlation function, $g_{11}(r)$, and structure factor, $S(k)$, are in agreement with the results of molecular dynamics, (3) the shoulder in $g_{11}(r)$ appears at $r^*=1+L^*$, which is considered to be characteristic of $g_{11}(r)$ for molecular fluids, not being present in $g(r)$ for simple atomic fluids, and (4) the behavior of $S(k)$ at small values of k is ascribed to the attractive part of potentials, the effect becoming more evident as compared with the results of the perturbation method.

The authers are much indebted to Dr. Yoshio Tago, Fujitsu Inc. Ltd., for preparation of the computer program used in the present paper.

Pressure-Induced Metal-to-Ligand Electron Transfer and the Electrical Conductivity of Some Pt(II)-Glyoximes†

Yoji HARA* and Malcolm F. NICOL††

Department of Chemistry,††† University of California, Los Angeles, CA 90024, USA

(Received January 28, 1978)

Mid-infrared (900—1600 cm^{-1}), visible absorption spectra and electrical resistance of bis(benzil dioximato)-platinum(II) [abbreviated as $Pt(bz)_2$], bis(dimethylglyoximato)platinum(II) [$Pt(dmg)_2$], bis(1,2-cyclohexanedione dioximato)platinum(II) [$Pt(cd)_2$], and bis(pyruvaldehyde dioximato)platinum(II) [$Pt(pa)_2$] have been measured at high pressures. A decrease of the C=N frequency by -40.0 cm^{-1}, with reduction of the $d\pi\rightarrow\pi^*$ optical transition intensity by $\simeq 14\%$, show that $[Pt(bz)_2]$ enhances thermally its $d\pi\rightarrow\pi^*$ electron transfer at high pressures up to 35 kbar. No such changes are observed for $[Pt(dmg)_2]$, $[Pt(cd)_2]$, and $[Pt(pa)_2]$. This backbonding causes $[Pt(bz)_2]$ to release the instability, due to increasing overlapping of the electron clouds around Pt(II) at high pressures, that is the cause of the resistance minimum.

Many one-dimensional Pt(II) complexes exhibit minima of electrical resistance at high pressures.[1-4] These minima can be explained by calculations that identify two opposing effects on the $5d_{z^2}$—$6p_z$ energy gap. Compression of Pt–Pt separations to as little as 2.80 Å increases the $5d_{z^2}$—$6p_z$ overlap, decreasing the band gap,[5,6] while compression of the Pt-ligand separation usually increases the band gap as a result of ligand π-Pt p_z and ligand σ-Pt $\sigma(d_{x^2-y^2})$ interactions.[6] Exceptions to these generalizations are known. $MgPt(CN)_4\cdot 7H_2O$ has no detectable resistance minimum.[1] The behavior of $MgPt(CN)_4\cdot 7H_2O$ has been interpreted as the result of an additional electronic effect, strong enhancement of Pt $d\pi$-ligand π^* backbonding with compression, which reduces Coulombic repulsions between electrons in Pt orbitals, including orbitals on adjacent Pt atoms.

In a previous paper, Hara et al reported the electrical behavior under high pressure of several Pt(II) one-dimensional solids, including bis(benzil dioximato)platinum(II) [as $Pt(bz)_2$], bis(dimethylglyoximato)platinum(II) [as $Pt(dmg)_2$], bis(1,2-cyclohexanedione dioxomato)platinum(II) [as $Pt(cd)_2$], and bis(pyruvaldehyde dioximato)platinum(II) [as $Pt(pa)_2$].[2] When polycrystalline $[Pt(dmg)_2]$ is compressed, its resistance decreases continuously, by as much as 16 orders of magnitude, to 40 kbar; further compression causes the resistance to increase. $[Pt(bz)_2]$, however, has no resistance minimum; compression to 150 kbar continuously decreases its resistance, by as much as 13 orders of magnitude. In this respect, the high pressure electrical characteristics of $[Pt(bz)_2]$ resemble those of $MgPt(CN)_4\cdot 7H_2O$.

Since the pressure dependence of the C=N stretching vibration and $d\pi\rightarrow\pi^*$ optical transition of $[Pt(bz)_2]$ could be measured with our optical apparatus, we sought to establish whether the pressure dependence of the relevant spectra provided direct evidence that enhancement of the $d\pi\rightarrow\pi^*$ thermal electron transfer was responsible for the atypical resistance characteristics of $[Pt(bz)_2]$. For comparative purposes, infrared and visible absorption spectra of $[Pt(dmg)_2]$, $[Pt(cd)_2]$, and $[Pt(pa)_2]$, which have distinct resistance minima, also were studied. Compression of $[Pt(bz)_2]$ to 35 kbar had two effects on its spectra, the wavenumber of one C=N stretching band of the infrared spectrum decreased by an unusually large amount, and the intensity of the visible $d\pi\rightarrow\pi^*$ absorption band diminished. No such changes were observed for $[Pt(dmg)_2]$ or the other comparison compounds. The former effect indicates that metal-to-ligand $d\pi\rightarrow\pi^*$ thermal electron transfer in the ground state, which reduces the $d\pi\rightarrow\pi^*$ optical transition intensity, is greatly enhanced by compression of $[Pt(bz)_2]$, and demonstrate that enhancement of $d\pi\rightarrow\pi^*$ backbonding by electron acceptors such as the four phenyl groups of $[Pt(bz)_2]$ can be an important factor for reducing the electron repulsion terms on the Pt chain and increasing the conductivity of one-dimensional Pt complexes.

Experimental

For the infrared and visible spectral measurements, pressures to 35 kbar were generated by means of a high presuure optical bomb using a NaCl pressure medium.[7] The infrared technique has been described elsewhere,[8] except that these measurements were performed with a Perkin-Elmer 421 infrared double-beam spectrometer and were carried out in the range 900—1600 cm^{-1}. The visible spectral measurement was performed with a Bausch-Lomb grating spectrometer. The polycrystalline materials studied were prepared by the method used in the previous work.[2] The molecular structures of these samples are illustrated in Fig. 1.

Results and Discussion

Figure 2 shows the effect of pressure on the electrical resistance of $[Pt(bz)_2]$, $[Pt(pa)_2]$, $[Pt(cd)_2]$, and $[Pt(dmg)_2]$. These effects are reversible and reproducible. The electrical resistance of $[Pt(dmg)_2]$, $[Pt(cd)_2]$ and $[Pt(pa)_2]$ show sharp resistance minima at 40, 90, and 120 kbar, respectively.

Infrared spectra of $[Pt(dmg)_2]$ at 0, 17, and 35 kbar are shown in Fig. 3. The C=N stretching modes are located at 1534 and 1482 cm^{-1}, and the N–O stretches at 1249 and 1078 cm^{-1}. The splitting of the C=N modes in $[Pt(dmg)_2]$ derives from the unequal C=N distance, 1.27 and 1.38 Å, respectively.[9] By way of comparison, $[Ni(dmg)_2]$ has single C=N stretching mode (1562 cm^{-1}) since its two distances are essentially identical, 1.30 and 1.29 Å.[10] Although the pressure effects are small, two are noteworthy. The C=N mode at 1482 cm^{-1}, corresponding to the 1.38 Å bond, disappears over 17 kbar, leaving single mode at 1533 cm^{-1}; this trend also is observed for $[Pt(cd)_2]$ and $[Pt(pa)_2]$. Also the degenerate and symmetric deformation modes of $C–CH_3$ between 1447—1330 cm^{-1} do not change much; thus, hyperconjugation must be less important than has been suggested.[2]

Comparable parts of the infrared spectra of $[Pt(bz)_2]$ at several pressures are reproduced in Fig. 4. Since two stretching bands are observed (at 1382 and 1430 cm^{-1}), the two C=N distances must be different. That these

----: The peak intensities at higher pressures are normalized to the corresponding ones at 1 atm.

bands, and similar bands of $[Pt(dmg)_2]$, $[Pt(cd)_2]$, and $[Pt(pa)_2]$, have different pressure dependence is easily understood if one considers that the lower frequency band corresponds to the longer, more compressible C=N bond. However, this interpretation does not explain the anomalous shift of the 1382 cm^{-1} band to lower wavenumbers, by -40 cm^{-1} in 35 kbar. It is known that the frequencies of C=N stretching modes of metal-glyoximes decrease with increasing metal-to-ligand ($d\pi \rightarrow \pi^*$) backbonding.[11] The large frequency reduction of the C=N modes of $[Pt(bz)_2]$ suggests that $d\pi \rightarrow \pi^*$ backbonding is greatly enhanced at high pressures. As can be seen in Fig. 5, only small pressure-induced shifts of the N–O stretching bands (as well as C=N bands) are observed for $[Pt(dmg)_2]$, $[Pt(cd)_2]$, and $[Pt(pa)_2]$, indicating that backbonding is very minor in these complexes.

The pressure dependence of the visible absorption spectra of $[Pt(bz)_2]$, shown in Fig. 6, also indicates the importance of $d\pi \rightarrow \pi^*$ backbonding in this compound. Both the 25.4 kK band ($d\pi \rightarrow \pi^*$ charge transfer[12]) and the 18.0 kK band ($5d_{z^2} \rightarrow 6p_z$) shift to lower wavenumbers with compression, by -67 and -208 $cm^{-1} \cdot kbar^{-1}$ respectively. However, the $\simeq 14\%$ decrease of the intensity of the 25.4 kK band appears more significant; no similar fadeout of the $d\pi \rightarrow \pi^*$ transition is observed for $[Ni(dmg)_2]$ or $[Pt(dmg)_2]$.[13,14] This diminishing intensity is caused, in the ground state at high pressures, by occupation of ligand π^* orbitals by $d\pi$ electrons from the Pt atom. Thus, the four phenyl groups in $[Pt(bz)_2]$, which withdraw π-electrons from the C=N bonds, also induce significant electron transfer from the Pt $d\pi$ orbital to the ligand π system. In $[Pt(bz)_2]$, the central Pt(II) can compensate for the increasing overlap of the electron clouds at high pressures; which is the cause of the resistance minimum, by removing electrons outwards to the edge of the plane of the complex. These observations suggest that, by selecting even better electron acceptors than phenyl, one could make Pt-complexes that are significantly more conductive than $[Pt(bz)_2]$.

Fluorescence Spectra of 1,1′-Binaphthyl and Related Compounds at High Pressures

Yoji HARA* and Malcolm F. NICOL*

Department of Chemistry, University of California, Los Angeles, CA 90024, USA

(Received February 7, 1978)

Relative to the related compounds 2,2′-binaphthyl (I) and 2,2′-dimethoxy-1,1′-binaphthyl (II), the pressure dependence of the fluorescence of crystals of 1,1′-binaphthyl (III) is complex. Compression to 30 kbar at room temperature shifts the ^{1}La fluorescence spectra of all three compounds to longer wavelength but, for I and II does not change the intensity profile, except for some 0-0 reabsorption. For III, this red shift characteristic of ^{1}La fluorescence spectra is dominated by growth of new bands about 3.5 to 5.0×10^3 cm^{-1} to lower energy. Similar new bands are observed when 1,1′-binaphthyl crystals are compressed at 90 K or resolved crystals are compressed at room temperature, but are not found to 30 kbar for dilute solutions of 1,1′-binaphthyl in polyacrylonitrile. The planes of adjacent naphthyl residues along $\vec{b}$ in the crystal are parallel but offset, the normal distance between planes being 3.55 Å; Raman spectra provide no evidence for a structural phase transformation upon compression. These new bands are assigned as the binaphthyl excimer.

The molecular spectroscopy of 1,1′-binaphthyl is unusual in many respects due to the strong dependence of the energies of its excited electronic states on the angle, θ, between the planes of the two naphthyl residues. In the crystal or rigid matrices (methyltetrahydrofuran or methanol glass) at low temperatures, the fluorescence and first absorption band are mirror images and closely resemble comparable spectra of naphthalene.[1-4] These observations are interpreted to imply that the equilibrium value of θ for both the ground and lowest excited state is approximately $\pi/2$; the X-ray structure of the crystal suggests $\theta=68°$ at room temperature.[5] In fluid solutions, the structure of the fluorescence spectrum resembles more closely the ^{1}La absorption of naphthalene and the fluorescence decay rate ($\approx10^9$ s^{-1}) is more typical of the ^{1}La fluorescence of anthracence and larger linear polyacenes. This transformation of the fluorescence has been interpreted in terms of a thermally-activated crossing from the ^{1}Lb to a ^{1}La excited state which can be stabilized relative to ^{1}Lb by rotation of the naphthyl residues toward $\theta=0$ or $\theta=\pi$.[1,4]

This report describes yet another fluorescence transformation observed for crystalline 1,1′-binaphthyl, but not for dilute solutions of 1,1′-binaphthyl in polyacrylonitrile, for crystalline 2,2′-binaphthyl or for derivative such as 2,2′-dimethoxy-1,1′-binaphthyl. Upon compression of crystals of 1,1′-binaphthyl to pressures above 5 kbar, new bands appear in the fluorescence spectra about 3.5 to 5.0×10^3 cm^{-1} to lower wave numbers from the origin of the ^{1}La fluorescence. These bands increase in intensity with compression such that, at 30 kbar, they dominate the emission spectrum. This spectral transformation is completely reversible to compression at room temperature (nominally 295 K) and at 90 K. The new spectrum is assigned as an excimer fluorescence originating from pairs of binaphthyl molecules favorably disposed along the $\vec{b}$ axis of the crystal. Both dilute solution in polyacrylonitrile and substitution at the 2 and 2′ positions prevent similar intermolecular naphthyl residue interactions between 1,1′-binaphthyl molecules.

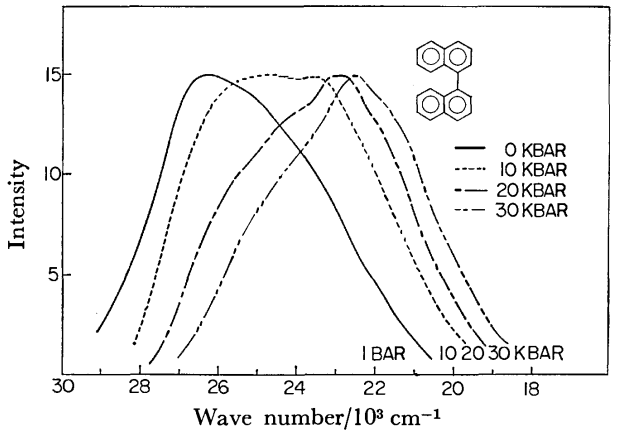

Fig. 1. Fluorescence spectra of 1,1′-binaphthyl at 295 K as a function of pressure.

Experimental

Commertially available reagent grade of 1,1′-binaphthyl from Eastman Kodak Co. was recrystallized from acetic acid and identified by infrared spectra.[6] 2,2′-dimethoxy-1,1′-binaphthyl were kindly provided by Dr. R. Helgesson of this department. The high pressure techniques for room[7,8] and low[9] temperatures are described elsewhere. The fluorescence from the samples which were excited at 3130 Å emission from 120W PEK Labs. Inc. high pressure mercury arc lamp was measured by means of front surface illumination in order to minimize reabsorption. The fluorescent intensities obtained at high pressures are normalized to that at 0 kbar. For Raman spectral measurement, a Spectra-Physics Model 165 argon laser was used for excitation. A Spex double monochrometer and photon-counting techniques were used to analyze the spectrum.

Results and Discussion

Fluorescence spectra of polycrystalline samples of 1,1′-binaphthyl at room temperature and 90 K at 1 bar, 10, 20, and 30 kbar are shown in Figs. 1 and 2. A typical pattern of other aromatics emerges from the spectra. The high wave number edge of the spectra appear to shift by -50 cm^{-1} kbar^{-1}, although reabsorption and the changing spectral profile make this value difficult to determine. For more important is the growth of intensity of new bands at low wave num-

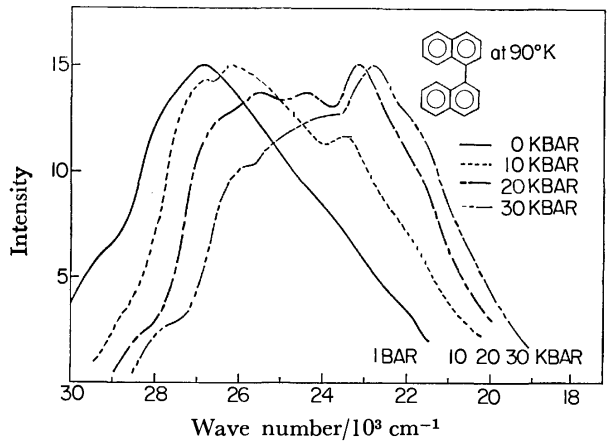

Fig. 2. Fluorescence spectra of 1,1′-binaphthyl at 90 K as a function of pressure.

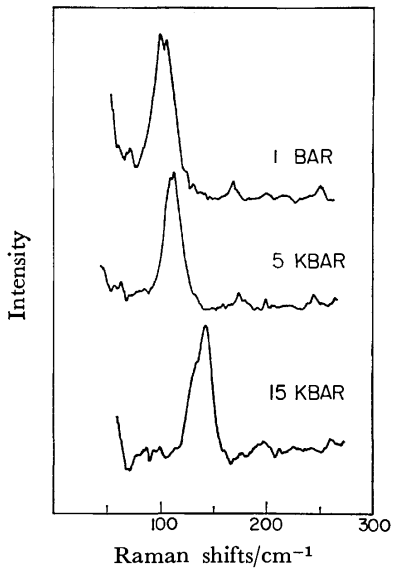

Fig. 3. Raman spectra of 1,1′-binaphthyl at 1 bar, 5 and 15 kbar.

bers, 3.5—5.0 × 10³ cm⁻¹ below the shifted 0-0. These transformation are completely reversible upon decompression. Similar new bands are observed when crystals of partially resolved 1,1′-binaphthyl are compressed.

Figure 3 shows the Raman spectra of polycrystalline 1,1′-binaphthyl at several pressures. These indicate that possibility of phase transition is very minor up to 15 kbar.

The new bands at low wave numbers in the fluorescence spectra of 1,1′-binaphthyl resemble in many respects new bands observed in the spectra of other crystalline aromatics at high pressures.[10–12] These spectra have been assigned to excimers formed by suitably oriented pairs of molecules at defect sites.

Figures 4 and 5 display the fluorescence spectra of 2,2′-binaphthyl and 2,2′-dimethoxy-1,1′-binaphthyl as a function of pressure. The primary effect of compression is to shift the fluorescence to lower wave numbers, by −30 cm⁻¹ kbar⁻¹ for 2,2′-binaphthyl and by about −40 cm⁻¹ kbar⁻¹ for 2,2′-dimethoxy-1,1′-binaphthyl. Except for some increased reabsorption of the 0-0

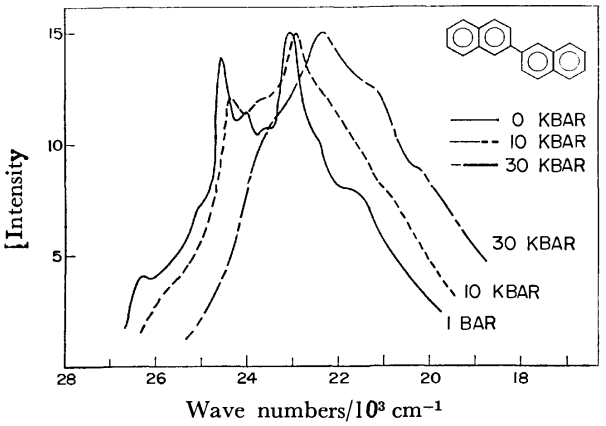

Fig. 4. Fluorescence spectra of 2,2′-binaphthyl at 1 bar, 10 and 30 kbar.

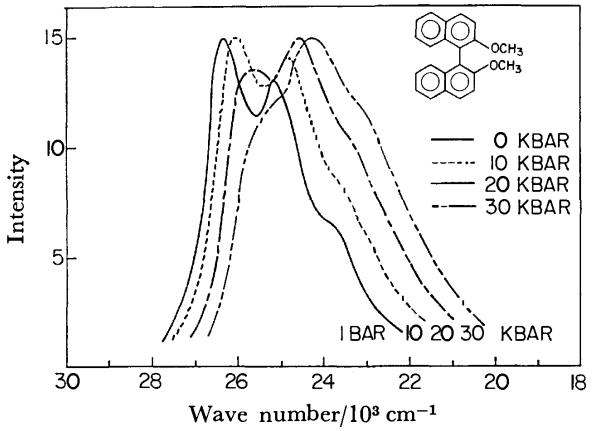

Fig. 5. Fluorescence spectra of 2,2′-dimethoxy-1,1′-binaphthyl at several pressures.

band at high pressures, the intensity profiles of these spectra change only slightly with compression which is the exception for aromatic hydrocarbons.[10–12] The interesting observation here is that the new bands are observed for 1,1′-binaphthyl but not for 2,2′-binaphthyl or 2,2′-dimethoxy-1,1′-binaphthyl. If the excimer fluorescence originated at defects, some excimer-like fluorescence would be anticipated from these compounds.

As steric hindrance between two naphthalene residues is at minimum in 2,2′-binaphthyl among various binaphthyls,[13] charge or excitonic resonance between two naphthyl residues should be maximized in 2,2′-binaphthyl. But no similar excimer fluorescence to 1,1′-binaphthyl was observed for 2,2′-binaphthyl. This indicates that the excimer fluorescence in 1,1′-binaphthyl is not originated from intramolecular interaction.

Figure 6 depicts the fluorescence spectra of dilute (≈ 10⁻³ M) solutions of 1,1′-binaphthyl in polyacrylonitrile at 1 bar and 30 kbar. No intensity redistribution is noted, which evidences the intermolecular nature of the excimer fluorescence.

An interesting explanation for the difference between 1,1′-binaphthyl and the other binaphthyls is suggested by examination of the structure of 1,1′-binaphthyl crystal.[5] Binaphthyl molecules with the same configuration are oriented with the planes of their naphthyl

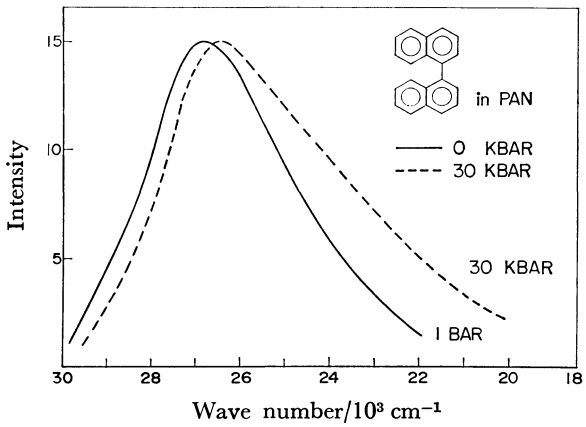

Fig. 6. Fluorescence spectra of dilute ($\approx 10^{-3}$ M) solutions of 1,1′-binaphthyl in polyacrylonitrile at 1 bar and 30 kbar.

residues parallel to each other and are separated by 6.35 Å along $\vec{b}$. For this geometry the normal distance between naphthyl planes of adjacent molecules is 3.55 Å, almost identical to the 3.53 Å separation between pyrene molecules in the dimeric structure of crystalline pyrene, the prototype excimer system.[14] Although the overlap of naphthyl residues is slightly less favorable for excimer emission, compression along $\vec{b}$ can compensate for this factor. However, substitution at the 2 position of the naphthyl residues necessarily increases the separation between binaphthyl molecules along this direction to a degree that should preclude excimer formation by this mechanism.

We are extremely grateful for the support provided by National Science Foundation and the binaphhtyl derivatives prepared by Dr. R. Helgesson.

Hydrogen-Deuterium Exchange Rate between a Peptide Group and an Aqueous Solvent as Determined by a Stopped-Flow Ultraviolet Spectrophotometry

Tetsuo TAKAHASHI, Mamoru NAKANISHI, and Masamichi TSUBOI*

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 22, 1978)

When an ^1H_2O solution of *N*-methylacetamide was rapidly mixed with ^2H_2O, a time-dependent decrease of the ultraviolet absorbance at 227 nm was observed. This was not the case with *N,N*-dimethylacetamide. Hence, the time-dependent decrease in absorbance was attributed to be caused by the deuteration (NH→ND) reaction of *N*-methylacetamide. This provides an appropriate method for determining deuteration rate of the peptide group in a polypeptide or in a protein. By this method the deuteration rate of poly-D,L-alanine has been examined in the pH=5—8 and temperature=10—40 °C range. In this range, the deuteration was found to proceed always as a single first-order reaction, and the rate constant k_e is expressed within an experimental error as $k_e = 6.4 \times 10^{(6+pH-3850/T)}$. This is to be used as a standard rate-constant value in estimating the attenuation factor $\gamma_j = k_j/k_e$ of a given peptide group (j) in a protein molecule whose rate constant value is k_j.

When a protein or a polypeptide is placed in an aqueous medium, a proton exchange reaction takes place between the peptide NH group and the solvent H_2O. The rate of this exchange reaction depends upon the intramolecular environment of the peptide group in question, and a kinetic study of such an exchange reaction provides a useful piece of information of the protein or the polypeptide structure.[1-5] The kinetics has so far been examined mostly by an infrared spectrophotometric tracing of the deuteration process of the peptide groups of a protein molecule thrown into ^2H_2O.[6] The kinetics was also examined by tracing hydrogen-tritium exchange reaction by means of a radioactivity measurement in combination with the Sephadex column chromatography.[7] By these methods, however, the reactions faster than 0.1 s^{-1} are not easily traced.[7,8]

The scope of this paper is two-fold. First we report that the hydrogen-deuterium exchange reaction of the peptide NH group can be followed by a stopped-flow ultraviolet spectrophotometry.[9-11] It will be shown that, by this method, the exchange reaction as fast as 30 s^{-1} can readily be traced. Secondly, rate constant values (k_e) for a peptide group fully exposed to the solvent are given in the pH=5—8 and temperature=10—40 °C range. Each of these values is serviceable as a standard in estimating an attenuation factor γ_j for a given peptide group (j) in a given protein molecule. Thus,

$$\gamma_j = k_j/k_e, \quad (1)$$

where k_j is the hydrogen exchange rate constant of the j-th peptide group now in question at a given pH and temperature. The attenuation factor γ_j is a measure of how deeply the j-th peptide group is buried in the protein molecule, and $\ln \gamma_j$ is often considered to be proportional to the free energy required for bringing this j-th peptide group into a state fully exposed to the solvent. In the most useful range of pH (5—8) and temperature (10—40 °C), however, the k_e values are so high (or the exchange reaction of the peptide NH is so fast) that only the new method is applicable. By the former methods, the measurements were so far made only in the lower pH region and/or lower temperature region, and the k_e value in the range now in question was estimated only by an extrapolation.

Experimental

N-Methylacetamide was obtained from Aldrich Chemical Company, and *N,N*-dimethylacetamide from Wako Pure Chemical Industries, Ltd. Poly-D,L-alanine with an average molecular weight 3800 (average degree of polymerization=53) was purchased from Miles Chemical Company and purified by a Sphadex G25 column chromatography. ^2H_2O (deuterium atom content 99.8%) was purchased from CEA-CEN-SACLAY.

The fast deuterations were examined by the use of a Union Giken Stopped-Flow Spectrophotometer RA-401. This is equipped with a rapid mixing device of a dead time 0.5 ms, with two syringes operated with nitrogen gas pressure. A fast flow of the mixture goes through a cell of optical path-length 10 mm. At about 17 millisecond after the pressure is applied, the flow is stopped, and a time-dependent absorbance change starts in the cell. This is detected by an ultraviolet spectrophotometer of focal length 25 cm, and of sensitivity 0.0001 OD. The temperature of the solution was controlled by circulating ethylene glycol through a mantle from a Haake model KT41 circulator. The actual temperature of the solution was monitored by a thermocouple.

Slower exchange reactions were traced with another stopped-flow equipment and a Hitachi EPS-3T Recording Spectrophotometer.

The hydrogen ion concentration of the solution was determined with a Hitachi-Horiba F7SS pH meter. The pH values given in this paper were always those of the solutions after the mixing (*i.e.*, in 50% ^1H_2O+50% ^2H_2O). Here, the pH-metric readings are given without any correction.

Hydrogen-Deuterium Exchange in *N*-Methylacetamide

When *N*-methylacetamide is suddenly brought into a ^2H_2O medium, a time-dependent decrease in absorbance at 227 nm is observed as illustrated in Fig. 1(a). Such an absorbance change is not observed at all when this molecule is brought by the same equipment into pure ^1H_2O (see Fig. 1(b)). This is not observed also when *N,N*-dimethylacetamide, where no NH group remains, is brought into the same ^2H_2O medium (Fig. 1(c)). Therefore, the time-dependent absorbance decrease is attributable to the NH→ND

reaction in *N*-methylacetamide. As is shown in Fig. 2(a), *N*-methylacetamide has a strong absorption band at about 190 nm. It is probable that this band is shifted very slightly towards shorter wavelength on deuteration, such a shift is considered to cause a slight but appreciable absorbance drop at 227 nm.

A replot of the kinetic data such as that given in Fig. 1(a) shows that the absorbance decrease takes place as a single first-order process. By extrapolating this first-order process to zero time, we are able to determine the total absorbance change associated with this process (NH→ND). The absorbance changes

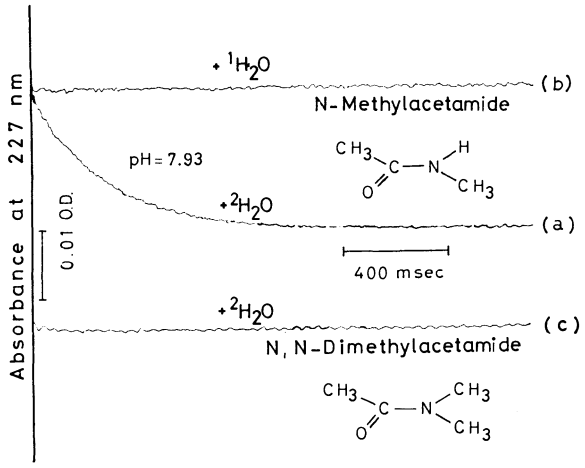

Fig. 1. (a) The time dependence of the decrease in absorbance at 227 nm observed when *N*-methylacetamide dissolved in ^1H_2O is mixed with ^2H_2O, so that final concentration of *N*-methylacetamide is 0.14 M and the solvent is 50% ^1H_2O+50% ^2H_2O of pH 7.93 at 22 °C. This is a photographic reproduction of the curve record on the plotter connected with a Union Giken stopped-flow spectrophotometer RA-401 and a data processor RA-450. This is a one scan datum; no accumulation was made. (b) The curve recorded in a control experiment, in which the same *N*-methylacetamide solution was mixed with pure ^1H_2O instead of ^2H_2O. (c) The curve recorded in another control experiment, in which a ^1H_2O solution of *N*,*N*-dimethylacetamide (instead of *N*-methylacetamide) was mixed with ^2H_2O.

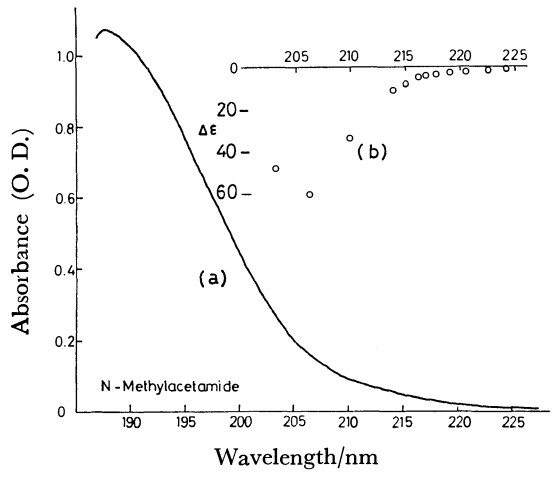

Fig. 2. (a) Ultraviolet absorption spectrum of 1.22×10^{-4} M *N*-methylacetamide in ^1H_2O at pH 5 and 25.2 °C. (b) A difference spectrum of *N*-methylacetamide *versus* *N*-methylacetamide-*d*, obtained from the kinetic measurement. Each point indicates the total absorbance change obtained for the first-order process observed on dilution with ^2H_2O to zero time. Ordinate scale $\Delta\varepsilon$ is the difference in the molar extinction coefficient ε.

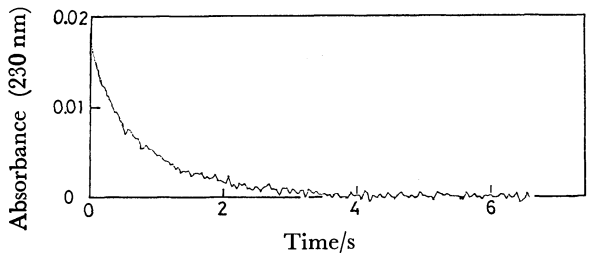

Fig. 3. The time dependence of the decrease in absorbance at 230 nm observed when poly-D,L-alanine dissolved in ^1H_2O is mixed with ^2H_2O, at pH 6.67 and at 13.5 °C. Final concentration of poly-D,L-alanine is 5.5 mM (for alanine residue).

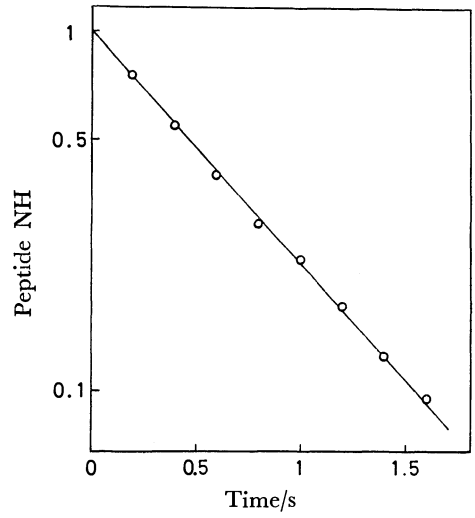

Fig. 4. Semilogarithmic plot of the data shown in Fig. 3.

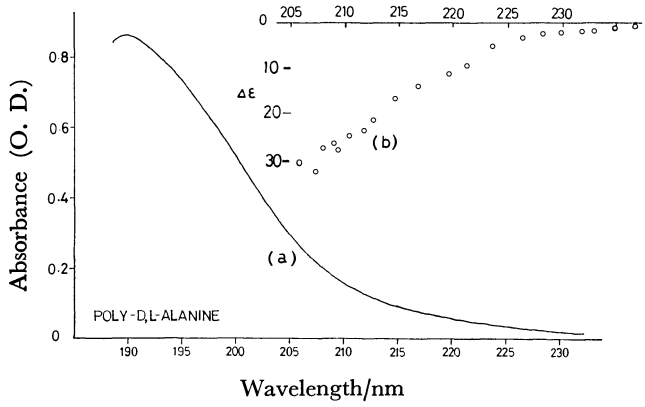

Fig. 5. (a) Ultraviolet absorption spectrum of poly-D,L-alanine in H_2O at pH 4 and 25.2 °C. (b) A difference spectrum of poly-D,L-alanine *versus* poly-D,L-alanine-*d*, obtained from the kinetic measurement, similar to what was described for Fig. 2(b).

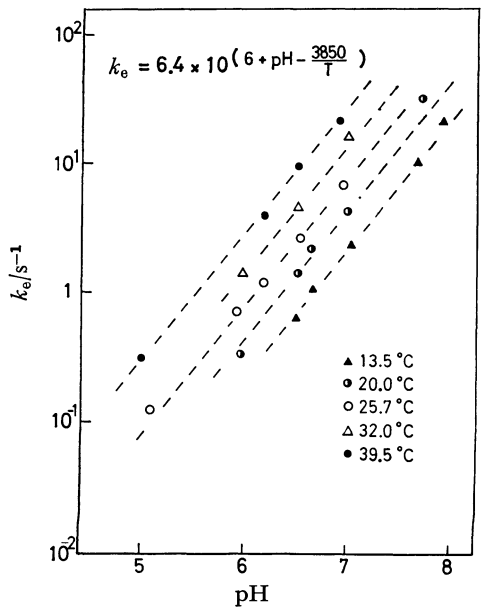

Fig. 6. The first-order rate constants k_e of the hydrogen-deuterium exchange reaction of poly-D,L-alanine, determined at various pHs and temperatures.

masured in this way at several different wavelengths generate a difference spectrum shown in Fig. 2(b). The rate constant of the NH→ND reaction is found to be 4.17 s^{-1} at pH 7.93 and at 22 °C and 0.31 s^{-1} at pH 6.83 and at 21 °C.

Hydrogen-Deuterium Exchange in Poly-D,L-alanine

Poly-D,L-alanine is an unfolded, non-helical polypeptide, and is soluble in H_2O. Every peptide group in this polypeptide is supposed to be "fully" exposed to the solvent at every pH and temperature in a proper range. This has been selected as a material, whose deuteration (NH→ND) rate (k_e) is used as a standard in estimating an attenuation factor γ_j with Eq. 1.

In Fig. 3, an example of the observed curve is given, which shows a time course of the absorbance change at 230 nm caused by the deuteration of poly-D,L-alanine. A replot of such a kinetic data on a logarithmic ordinate scale, as illustrated in Fig. 4, shows that the absorbance change takes place as a single first order process. The total absorbance change in such a process has been examined at various wavelengths. A difference spectrum of poly-D,L-alanine *versus* poly-D,L-alanine-*d*, thus obtained, is shown in Fig. 5.

The first-order rate constant k_e of the hydrogen-deuterium exchange reaction of poly-D,L-alanine has been determined in the pH range of 5—8 and temperature range of 10—40 °C. The results are graphically shown in Fig. 6. As may be seen in the figure, $\log_{10} k$ values fall on a single straight line at every pH, when they are plotted against reciprocal absolute temperature T. From the slope of this straight line the activation energy is estimated to be $\Delta H^* = 17.6 \pm 0.3$ kcal/mol, at every pH in the 5—8 range. When $\log_{10} k_e$ is plotted against pH, on the other hand, the points fall on a straight line of solpe=1, at every temperature. This fact indicates that in this pH range the reaction is catalyzed by OH^-. The empirical formula for the k_e value of poly-D,L-alanine is now given as

$$k_e = 6.4 \times 10^{(6+pH-3850/T)}. \quad (2)$$

It should be pointed out that what were previously given by an extrapolation[12–14] are slightly but appreciably different from the k_e values directly determined in our present work.

The Crystal Structure of L-Asparaginato-D-aspartatocobalt(III) Monohydrate

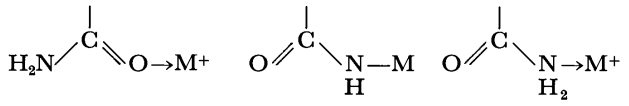
Masao SEKIZAKI

College of Liberal Arts, Kanazawa University, Marunouchi, Kanazawa 920

(Received August 8, 1977)

The crystal structure of L-asparaginato-D-aspartatocobalt(III) monohydrate, $[Co(H_2NCOCH_2CHNH_2COO)(OCOCH_2CHNH_2COO)]\cdot H_2O$, has been determined by an X-ray diffraction method and refined by a block-diagonal least-squares method to give $R=0.033$ for 1517 non-zero reflections. The crystals are orthorhombic with the space group $P2_12_12_1$, $a=11.790(2)$, $b=17.059(2)$, $c=5.830(2)$ Å, and $Z=4$. The complex molecule has a slightly distorted octahedral coordination with *fac*(*N*) geometry. The amide group of L-asparaginate ion is coordinated through the nitrogen atom, and an enolic system of Co←NH=C(OH)–CH_2– is formed. The complex molecules are held together through hydrogen bonds which form two-dimensional networks parallel to the (010) plane. The networks are piled up through hydrogen bonds by water molecules to complete three-dimensional networks.

There are generally two coordination modes for an acid amide group: O-coordination(I)[1-5] and N-coordination (II),[6] the latter being accompanied by deprotonation of the amide group. Recently



I II III

Takenaka and Shibata has suggested on the basis of infrared and visible spectra that the cobalt complex containing both L-asparaginate (L-2-aminosuccinamate, abbreviated as L-$aspNH_2^-$) ion and D-aspartate (D-2-aminosuccinate, D-asp^{2-}) ion, $[Co(L\text{-}aspNH_2)(D\text{-}asp)]\cdot H_2O$, has a *fac*(*N*) structure.[7] This means that the primary amide group of L-$aspNH_2^-$ is coordinated through the nitrogen atom without deprotonation, and the coordinating mode is neither I nor II. A third mode, like III, seems probable, although no example of this mode has been found to date. In order to investigate the coordination mode of this cobalt(III) complex, an X-ray single-crystal analysis has been undertaken.

Experimental

The crystals prepared and supplied by Professor Muraji Shibata of Kanazawa University are reddish-violet prisms. A crystal with dimensions of $0.2\times0.15\times0.15$ mm was selected, and the diffracted intensities were measured on a Philips PW 1100 four-circle diffractometer with Mo $K\alpha$ radiation monochromated by a graphite plate. The θ-2θ scan technique was used at a scan rate of 0.0668°/s in θ with a scan width of $(1.0+0.3\tan\theta)°$. The intensities of three reference reflections monitored every 2 h remained constant during data collection. A total of 2012 independent reflections was measured up to $2\theta=60°$, and 1517 of them with $|F|>3\sigma$ were used for the structure analysis. No corrections were made for absorption and extinction effects. Cell dimensions were obtained from the least-squares method based on 19 2θ values.

Crystal data:
$Co(H_2NCOCH_2CHNH_2COO)(OCOCH_2CHNH_2COO)\cdot H_2O$. *F. W.*=339.15. Orthorhombic, $a=11.790(2)$, $b=17.059(2)$, and $c=5.830(2)$ Å. $U=1173(1)$ Å^3. $\rho_x=1.921$ g·cm^{-3}, $Z=4$. Space group $P2_12_12_1$. $\mu=3.9$ cm^{-1} (Mo $K\alpha$, $\lambda=0.7107$ Å).

Determination and Refinement of the Structure

The coordinates of the cobalt atom were determined from the Patterson map; the successive Fourier synthesis phased by the cobalt atom gave an approximate skeletal structure shown in Fig. 1. In this figure, the four positions marked with * should be occupied by one nitrogen and three oxygen atoms, but, at this stage, it was impossible to distinguish these two kinds of atoms. Accordingly, the distinction between L-$aspNH_2^-$ and D-asp^{2-} was impossible. The block-diagonal least-squares refinement was carried out in expectation of getting a clue for the discrimination between oxygen and nitrogen. When all the four atoms marked with * (Fig. 1) were assumed to be oxygen, the *R*-value was 0.062. On the other hand when they were assumed to be nitrogen, *R* was 0.066. In both assumptions the isotropic temperature factors did not allow the two kinds of atoms to be distinguished. Anisotropic temperature factors were, then, introduced for all the atoms on the assumption that these four atoms were all oxygen. The *R*-value decreased to 0.050. The difference Fourier synthesis was calculated and gave the positions of all the 14 hydrogen atoms. The amide group could be distinguished at this stage from the carboxyl group. The obtained structure revealed the existence of both N–H and O–H bonds at the amide group, namely, the structure of the amide group is not I, II, nor III, but could be IV or V.

IV V

Several cycles of the refinements were carried out for these two modes IV and V, including the hydrogen atoms, the isotropic temperature factors of which were assumed to be 4.0 Å^2. Both modes, IV and V, gave the equivalent isotropic temperature factors (B_{eq})[8] 1.8—2.2 Å^2 for the coordinating atoms of the three carboxyl groups. The corresponding values for the non-coordinating oxygen atoms of these carboxyl groups were 2.8—3.2 Å^2. Similarly, those for the coordinating

TABLE 1. FINAL ATOMIC PARAMETERS AND THEIR ESTIMATED STANDARD DEVIATIONS IN PARENTHESES

and non-coordinating atoms of the amide group were 1.9 and 2.9 Å^2, respectively, for mode IV. But mode V gave reversed results: 3.1 and 1.9 Å^2, respectively. Usually, the thermal motions of binding atoms are smaller than those of terminal ones. Hence the structure of the amide group might be IV rather than V. Furthermore the R-value was 0.037 for IV while it was 0.042 for V. From a significance test,[9] the former might be prefered; this is in accordance with the suggestion of the spectroscopic investigation.[7]

The absolute configuration of the complex was obtained by comparing the absolute configurations of the two coordinating ligand ions with those of the respective free ligand molecules.

The anomalous scattering factor of the cobalt atom for Mo $K\alpha$ radiation was introduced into the refinement. The final R-value was 0.033 for the 1517 observed reflections. The final atomic parametes in a right-handed system of xyz-axes are listed in Table 1. The observed and calculated structure amplitudes are deposited with the Chemical Society of Japan (Document No. 7816).

To confirm the absolute configuration, equi-inclination Weissenberg photographs of the first and the second layers around the c axis were taken with Cu $K\alpha$ radiation. Differences between the intensities of 33 reflections and those of their counter-reflections were compared with the calculated intensity relations, as listed in Table 2.

The refinement of the structure and the drawing of thermal ellipsoids were carried out with the HBLS-IV[10] and ORTEP[11] programs, respectively. Other calculations were carried out with programs written by the author. The atomic scattering factors were taken from International Tables for X-Ray Crystallography.[12] The weights of reflections used in the refinements were 1.0 for $|F_o| \geqq 11.8$ and 0.5 for the others. A FACOM 230-75 computer at the Computation Center of Nagoya University and a FACOM 230-35 computer at the Data Processing Center of Kanazawa University were used.

Description of the Structure and Discussion

A projection of the structure along the c axis is shown in Fig. 2. The molecular structure and the

amino nitrogen, and amide nitrogen atoms. The amide group forms an enolic system on coordination. The aspartate ion, D-asp^{2-}, acts also as a terdentate ligand coordinating through two carboxyl oxygen atoms and one amino nitrogen atom. The cobalt atom is surrounded by these coordinating atoms in the *facial* $[Co(N)_3(O)_3]$ geometry. This structural feature agrees with the suggestion by Takenaka and Shibata.[7]

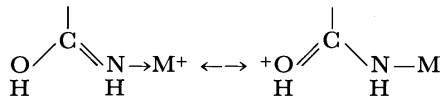
The coordination bond lengths are 1.902—1.926 Å, which agree with those of $[Co(L\text{-}asp)_2]^-$ within the estimated standard deviations.[17] The coordination bond angles around the cobalt atom are about 84° in the five-membered chelate rings, whereas they are 90—92° in the six- and seven-membered chelate rings. Hence the octahedron around the cobalt atom is slightly distorted.

The C–O and C–N bond lengths of L-aspNH$_2^-$ are listed in Table 5 along with those of other amide complexes. The C–N bond is longer than the C–O bond in the other complexes. But the present complex gives a reversed result, *i.e.* the C–N bond is slightly shorter (0.03 Å) than the C–O bond. This must be due to the difference between the enolic (the present complex) and keto (others) forms

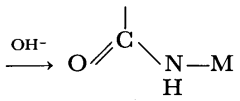
Some other facts which support the N-coordination of the amide group are as follows:

1. Spectroscopic evidence supports the N-coordination.[7]

2. The complex is easily deprotonated in an alkaline solution.[7] This is explained by the following reaction:



IV VI



II

3. Several examples which have structure IV have been reported for the secondary amide groups based on the spectroscopic evidence.[13–15] Furthermore, one example of structure IV has been reported for a primary amide on the basis of NMR.[16]

4. No example of structure V has so far been found.

The complex molecules are connected with one another through hydrogen bonds $N^i(2)\cdots O^{ii}(5c)$, $N^i(6)\cdots O^{ii}(5)$, and $N^i(2)\cdots O^{ii}(H_2O)$, forming infinite chains along the c axis. These chains are connected with the adjacent ones through hydrogen bonds $N^i(8)\cdots O^{iii}(1)$, $O^i(1c)\cdots O^{iv}(H_2O)$, and $O^i(4)\cdots N^{iii}(6)$. Thus, two-dimensional networks are formed parallel to the (010) plane. Among these networks no contact shorter than 3.3 Å is observed, except for a hydrogen bond $O^i(8)\cdots O^v(H_2O)$. The networks are piled up through this hydrogen bond to complete three-dimensional networks.

The author is grateful to Professor Muraji Shibata of Kanazawa University for valuable advice, and to Professor Fumiyuki Marumo of Tokyo Institute of Technology for his helpful discussion. The author is also indebted to Professor Seiji Sugiura and Dr. Kuniaki Kihara, Department of Mineralogy, Kanazawa University, for the use of a Philips PW1100 automatic four-circle diffractometer.

Chemical Shifts of Sulfur KLL Auger Electron Energies in Its Compounds

Shunichi NISHIKIDA and Shigero IKEDA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 13, 1977)

The sulfur 1s and 2p photoelectron spectra and $KL_{23}L_{23}$ Auger electron spectra in various sulfur compounds involving solid sulfur were measured by means of irradiation by Al $K\alpha$ and Cr $K\alpha$ X-rays. The chemical shifts of the S1s and S2p photoelectron spectra for compounds referred to the data for solid sulfur differ from each other in magnitude, but all are larger than that for the Auger electron spectra in the corresponding compound. The shift of the Auger electron spectra is different in fashion from those of the photoelectron spectra; the difference is largely attributable to the differences in relaxation energies. The extra-atomic relaxation energies due to core-electron emission were estimated by combining the atomic spectral data and the XPS and AES data of compounds; they were found not necessarily to depend upon the atomic charges. From the calculated sulfur $K\alpha$ X-ray spectra corresponding to the difference in the binding energy between 1s and 2p, the number of electrons on each sulfur atom was obtained by using the method derived from Coulson *et al.*, while the isolation was attempted on the basis of the contribution of polarization energies due to surrounding atoms to the extra-atomic relaxation energies.

Various arguments have been advanced during the last decade concerning the chemical shift of the kinetic energy of the Auger electron accompanied by the photoemission of the inner electrons of atoms in compounds.[1-7] Wagner[4] defined the difference in kinetic energy between an Auger line and a photoelectron line as the Auger parameter for an element. He attributed the difference in the Auger parameter to changes in the polarizabilities of the ligand ions. The first work concerning the chemical shift of the sulfur KLL Auger electron energy has been reported by Fahlman *et al.*[8,9] for two sulfur atoms with different oxidation numbers (+VI and −II respectively) in sodium thiosulfate. Recently Asplund *et al.*[10] and Keski-Rahkonen *et al.*[11] measured the sulfur $KL_{23}L_{23}(^1D)$ Auger energy in the free molecule.

With regard to the theoretical treatment for the Auger electron energy, Shirley[12,13] *et al.* introduced a static relaxation energy into the intermediate-coupling formulas given by Asaad and Burhop[14] in order to calculate the KLL Auger energies. This relaxation energy was derived by extending the concept of the polarization potential introduced by Hedin and Johansson[15] for photoemission to the case of the two-hole final state in the Auger electron emission process.

The present paper will report on the chemical shifts of the 1s and 2p photoelectron spectra and the $KL_{23}L_{23}$ ^1D Auger electron spectra for sulfur with various oxidation states in its compounds. The absolute values of the sums of the extra-atomic and outer relaxation energies are estimated from the total relaxation energies observed experimentally and the inner atomic relaxation energies obtained from the optical data for S^{6+} and S^{7+} ions.

Experimental

The measurements were performed by using an AEI ES-200-type electron spectrometer. Specimens were irradiated either with Cr $K\alpha_{1,2}$ radiation ($K\alpha_1$=5414.7 eV and $K\alpha_2$=5405.5 eV)[16] in order to obtain the S1s photoelectron line and the SKLL Auger line, or with Al $K\alpha_{1,2}$ radiation for the other photoelectrons. Because of the spin orbit interaction, two paired lines with an energy separation of 9.2 eV between Cr $K\alpha_1$ and Cr $K\alpha_2$ were always observed in the spectra.

For the purpose of the energy calibration of the spectrometer, in the case of alminium irradiation, the photoelectron peaks of four kinds of metals, Cu, Au, Pd, and Ag, which had been evaporated onto a stainless steel sample holder *in vacuo*, were used with the following binding energies,[17] and the spectrometer constant was determined.

$$Cu2p_{3/2} = 932.8,\ Au4f_{7/2} = 83.8,\ Pd4d = 0.0,$$
$$Pd3d_{3/2} = 335.2,\ Ag3d_{5/2} = 368.2.$$

In the case of Cr $K\alpha$ irradiation, however, the inner-shell photoelectron lines of the metals measured are not so strong in intensity because of the low ionization efficiency of such orbital electrons. Therefore, as is shown in Fig. 1, the calibration procedures were adjusted: the sodium 1s photoelectron and the $NaKL_{23}L_{23}$ ^1D Auger electron for freshly evaporated sodium chloride were measured by the irradiation of alminium $K\alpha_{1,2}$ and also by a chromium $K\alpha_1$ X-ray source. As the kinetic energy of the Auger line is independent of the excitation energies, the energy difference in the 1s photoelectron kinetic energies obtained by both methods must be equal to the energy difference between Al and Cr $K\alpha$

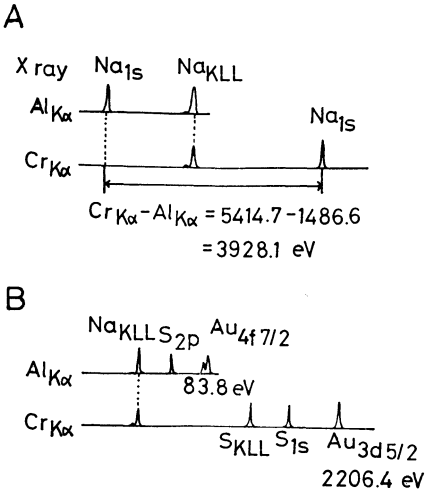

Fig. 1. Energy scale calibration for the case of Cr $K\alpha$ X-ray excitation.
A) i) Charging effect is calibrated by NaKLL Auger electron. ii) The energy difference of NaIs peaks obtained by Al $K\alpha$ and Cr $K\alpha$ excitation is calibrated with the energy difference of two X-ray sources.
B) The extent of charging is calibrated by the energy of $Au3d_{5/2}$ photoelectron peak of gold evaporated on the sample.

X-rays. Therefore, the spectrometer constant, the energy calibration for a scale reading, was calculated with the observed photoelectron energies and the energy difference between the two characteristic X-ray lines, 3928.1 eV.

The charging of the sample during each measurement was calibrated by the energy of the $Au4f_{7/2}$ photoelectron peak of the thin gold layer(83.8 eV) evaporated onto the sample from a tungsten filament. On the other hand, for Cr $K\alpha$ X-ray irradiation, not the $Au4f_{7/2}$ peak but the $Au3d_{5/2}$ photoelectron peak(2206.7 eV of the binding energy) was used to determine the extent of charging effects, except for sodium salts. For sodium salts, the Na_{KLL} Auger electron peak, whose energy was calibrated by the Al $K\alpha$-$Au4f_{7/2}$ method, was used for this purpose.

All the samples were powdered and placed onto a backing of double-backed cellophane tape at room temperature. All the chemicals were used without additional purification. Samples of the sodium salts were dried at 100 °C *in vacuo* for a few hours in order to remove any water of crystallization or any water adsorbed on the samples.

Results and Discussion

In Figs. 2a, b, and c, the spectra of the Sls and 2p photoelectrons and the $KL_{23}L_{23}$ ^1D Auger electron for sodium thiosulfate are shown. Sodium thiosulfate is a historic compound for which the chemical shift in the sulfur KLL Auger electron spectrum was first observed by the Uppsala group in 1966.[8,9] This compound has the structural formula of $2Na^+[S\text{-}SO_3]^{2-}$, containing two sulfur atoms in different chemical states, with oxidation numbers of +VI and −II. Three photoelectron peaks were observed for sulfur 1s in Fig. 2a; the central peak is an overlap of the other two peaks. The two kinds of sulfur in thiosulfate exhibit two peaks corresponding to the central and the ligand sulfur, each of which has two peaks due to the two strong energy sources of Cr $K\alpha$ X-rays used for the excitation, with a splitting energy of 9.2 eV. Therefore, there should be a total of four components, and the central one must be an overlapped peak for each of two different sulfur atoms. For the sulfur 2p photoelectron obtained by Al $K\alpha_{1,2}$ excitation and the $KL_{23}L_{23}$ ^1D Auger electron spectra, two peaks were observed corresponding to two kinds of different-oxidation-state sulfur. The magnitude of the chemical shift of the photoelectron line for two kinds of sulfur is different from those of the Auger electrons. That is, the chemical shift in the binding energy is 7.2 eV for the 1s orbital and 6.0 eV for the 2p orbital, while it is only 4.4 eV for the $KL_{23}L_{23}$ ^1D Auger electron.

Calculation of Extra-atomic Relaxation Energy. The $KL_{23}L_{23}$ Auger energy, $E_{KL_{23}L_{23}}$, can be expressed by the following relation;

$$E_{KL_{23}L_{23}} = E_K - E_L - E_L^*, \quad (1)$$

where E_K and E_L are the observed values of the binding energy for the K and L shells respectively. The E_L^* value is more complicated and does not correspond to the binding energy of the L shell. At the moment of the Auger electron ejection, one hole must have been in the L shell. Shirley *et al.*[12,13,18,19] presented the following formula for E_{KLL} by using the binding energy of E_L instead of E_L^*;

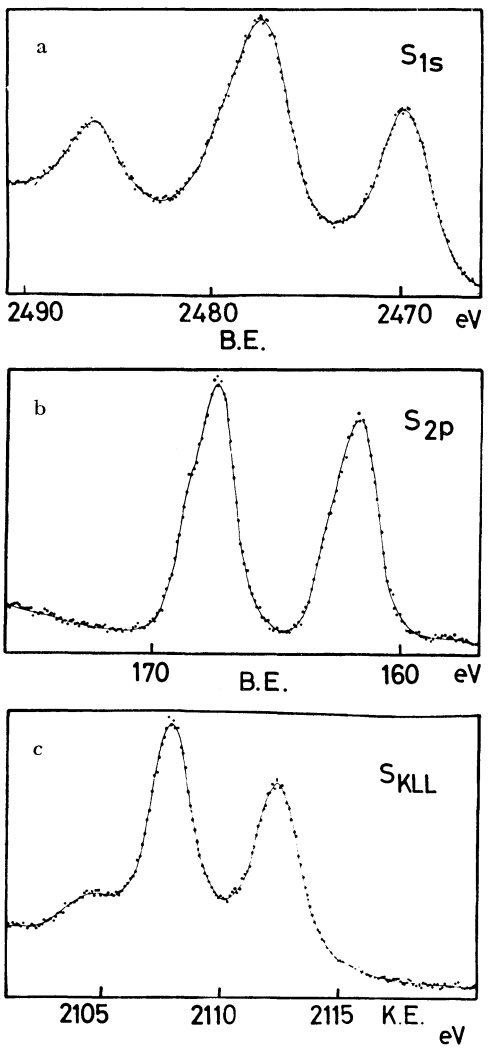

Fig. 2. Sulfur 1s and 2p photoelectron and $KL_{23}L_{23}$ Auger electron spectra in sodium thiosulfate.
a) 1s photoelectron (Cr $K\alpha$ excitation), b) 2p photoelectron (Al $K\alpha$ excitation), c) KLL Auger electron (Cr $K\alpha$ excitation).

$$E_{KL_{23}L_{23}} = E_K - 2E_L - \mathfrak{F} + E_R. \quad (2)$$

Here, the last two terms are the correction ones which result from substitution of E_L for E_L^*. $\mathfrak{F}$ is a final-state two-electron interaction term provided by the spin-orbit coupling.[14] Each final state interaction term can be evaluated from the values of Slater's integrals, F's and G's. E_R is a static relaxation energy. This term was derived from the work of Hedin and Johansson[15] on polarization energies for electron holes, by extending it to the two-hole final state resulting from the Auger process. The term is approximately twice the dynamic relaxation energy for a photoelectron ejection. Generally, the relaxation energy may be separated into two parts, atomic and extra-atomic relaxation energies.

It is difficult, however, to distinguish between the outer atomic relaxation energy and the extra-atomic relaxation energy, because the outer electrons participate in the bonding orbitals in the compound; that is, these electrons belong to both the central and the surrounding atoms. Here, for the analysis of the sulfur

$KL_{23}L_{23}$ Auger transition, we classified the 3s and 3p orbital electrons as contributing to the extra-atomic relaxation energy, together with the surrounding atoms. The 1s, 2s, and 2p orbital electrons are considered to contribute to the atomic relaxation energy.

Then, Eq. 2 is rewritten as follows;

$$E_{KLL} = E_K - 2E_L - \mathfrak{F} + E_R^A + E_R^{ex}, \quad (3)$$

where E_R^A and E_R^{ex} are the atomic and extra-atomic relaxation energies respectively. Here, it is a reasonable assumption* that the $-\mathfrak{F}+E_R^A$ term is independent of the oxidation numbers of the element to be investigated. The magnitude of the extra-atomic relaxation energy, E_R^{ex}, is a useful parameter for characterizing the bonding of ligand atoms in compounds.

The numerical value of $-\mathfrak{F}+E_R^A$ in Eq. 3 can be derived from the data for the atomic spectroscopy.[21] In the case of the sulfur ion with the oxidation number of +VI, there are no electrons in the 3s and 3p orbitals, so the contribution of the outer-orbital electrons to the relaxation energy for the ionization of the 2p electron is zero. Therefore, E(L) in Eq. 1 is equivalent to the ionization potential of S^{+6}, and E(L*), to that of S^{+7}. $-\mathfrak{F}+E_R^A$ can be obtained as the difference between these ionization potentials. The relative energy diagram for the total energies of the S^{6+}, S^{7+}, and S^{8+} ions, and also for the 1s hole state of the S^{6+} ion, is given in Fig. 3. In the Auger electron spectrum,

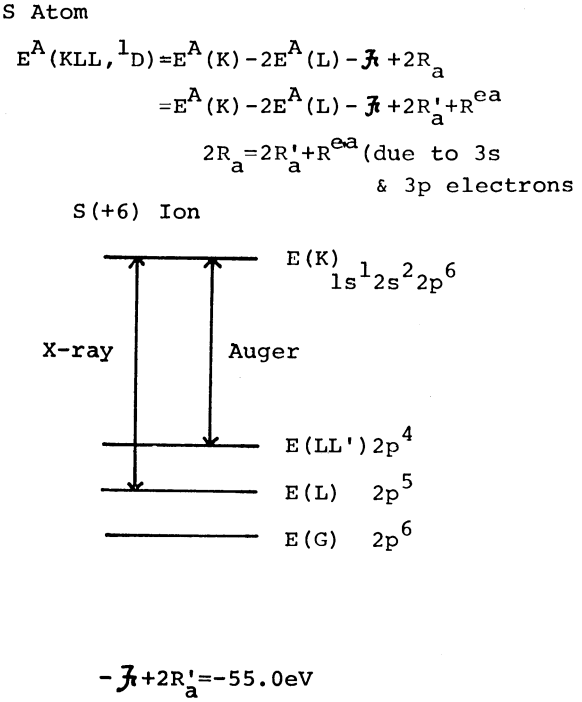

Fig. 3. Total energy level diagram of sulfur ions in various ionized states.
E(G): S^{6+} ground state, E(L): one 2p electron ionized state (S^{7+}), E(LL'): two 2p electrons ionized state (S^{8+}), E(k): one 1s electron ionized state.

* This assumption is supported by an atomic orbital calculation of the $-\mathfrak{F}$ term and of the relaxation energies of free atoms.[20]

TABLE 1. TOTAL ENERGY DIFFERENCES BETWEEN IONIZED STATES

	Change in electron configuration	Energy difference (eV)
S^{6+}	$1s^2 2s^2 2p^6$ —— $S^{7+} 1s^2 2s^2 2p^5$	280.99
S^{7+}	$1s^2 2s^2 2p^5$ —— $S^{8+} 1s^2 2s^2 2p^4({}^3P)$	328.80
S^{8+}	$1s^2 2s^2 2p^4({}^3P)$ —— $S^{8+} 1s^2 2s^2 2p^4({}^1D)$	7.19

the most intensive peak is assigned to the ^{1}D term, and it is necessary to add the energy difference between the ^{3}P and ^{1}D terms in the $2p^4$ configuration because the ^{3}P state in $2p^4$ is a ground state and the ionization energy of S^{7+} corresponds to the ^{3}P states in S^{8+}. The values for each state are obtained from the optical data[10] and are listed in Table 1. Consequently, from these data the value of −55.0 eV for $-\mathfrak{F}+2E_R^A$ is estimated. In Eq. 3, E_R^{ex} can be calculated by introducing the value for $-\mathfrak{F}+E_R^A$ and the measured values for the binding energy of 1s and 2p electrons and the Auger electron energy. In the gaseous state, the energy of the Auger electron is equal to the kinetic energy itself, and the binding energy of photoelectrons referred to the vacuum level can be obtained directly. In solid compounds, however, the energy reference used for photoelectrons is usually the Fermi level of the specimen. In order to evaluate E_{KLL} in Eq. 3, the Auger electron must be normalized with the same reference level as the photoelectron binding energies. When the Fermi level is used for the binding energy reference, the Auger electron kinetic energy should be estimated by referring to it. In this case, the kinetic energy of the electron ejected from the Fermi level is coincident with the X-ray source energy, 5414.7 eV for Cr $K\alpha_1$. This situation is shown schematically in Fig. 4.

In Table 2, the sulfur $KL_{23}L_{23}$ ^{1}D Auger electron

energies and binding energies for the sulfur 1s and 2p photoelectrons for various compounds are listed, together with their shifts from those of solid sulfur. A slight deviation in the magnitude of the chemical shifts between 1s and 2p photoelectron peaks is observed for each compound. Wagner's Auger parameter, which describes the energy difference between the kinetic energies of the photoelectron and the Auger electron, corresponds to the change in the extra-atomic relaxation energy, provided that the chemical shifts of two subshells associated with the Auger process are the same. This is not the case for the sulfur KLL Auger transition, however, and so the definition of the Auger parameter becomes ambiguous for these compounds. Ignoring the magnitude of the shifts, a similar tendency is observed in the energy gradation of the 1s and 2p photoelectrons for different samples. On the contrary, the Auger electron energy changes in a different fashion. It is necessary to note that, as photoelectron peaks are expressed with the binding energy scale, while Auger peaks are expressed in the kinetic energy scale, the signs of the chemical shifts are opposite to each other. The chemical shifts in the photoelectron binding energies increase with the increase in the formal charge of the corresponding sulfur atom in a compound. In the case of the S_{KLL} Auger electrons, though, the shift is not necessarily in the same direction as the photoelectron. That is, the chemical shift in photoelectron is largely the function of a charge distribution in the initial state, whereas the final state of electron ejection is largely responsible for the chemical shift of the Auger electron energy. Especially for a sulfur atom with a formal charge such as 0 or −2, the chemical shift is the reverse of that for photoelectrons. In thiourea, the S_{KLL} Auger electron shift is 4.6 eV in the opposite direction of the photoelectron shifts obtained by referring to the value for solid sulfur.

In the last column in Table 2, the extra-atomic relaxation energy, E_R^{ex}, derived from the method mentioned above is shown. The extra-atomic relaxation energy does not alter as much as the chemical shift in photoelectrons. These results predict that the chemical shift in the photoelectron for sulfur compound will follow a straight line against the calculated charge performed by ignoring the relaxation energy. The difference in the extra-atomic relaxation energy between two kinds of sulfur in thiosulfate is only 0.4 eV, while the chemical shift in the 1s photoelectron is 7.2 eV. It is apparent that less correlation was found between the extra-atomic relaxation energy and the charge density on the atom in these compounds. The fact that the extra-atomic relaxation energy of sulfur in thiourea is the least for the compounds investigated, while that in the sulfur molecule is the most, agrees with the results mentioned above, though the binding energies in the two compounds are not so different (only 1.4 eV).

Charge Density on the Sulfur Atom. As the difference in binding energies between the 1s and 2p orbitals corresponds to the energy of the $K\alpha$ X-ray, a difference in chemical shifts between the 1s and 2p binding energies would bring about a chemical shift in the $K\alpha$ X-ray. Sato *et al.*[22] have measured the $K\alpha$ X-ray energy shift for sulfur in various compounds in solid and liquid states, thus revealing the relationship between the formal oxidation number and the chemical shift from the sulfur molecule. The mean number of the valence electrons associated with the sulfur atom in compounds was calculated from the photoelectron energy shifts according to a theoretical correlation presented by Coulson *et al.*[23,24] According to Gianturco and Coulson,[24] the valence-electron density is calculated by using the self-consistent-field technique and by taking into account both parent and daughter systems for sulfur on the basis of Koopman's theorem model and the adiabatic model. In Fig. 5, the findings on the shifts of 1s and 2p photoelectrons for various oxidation numbers are shown. The two curves in Fig. 3 are adequately represented by

$$\Delta E = v(v+3)/11 \text{ for Koopman's theorem model, and} \quad (4)$$

$$\Delta E = v(v+4)/8 \text{ for adiabatic model,} \quad (5)$$

where ΔE is the chemical shift of the S$K\alpha$ X-ray fluorescence line at various oxidation numbers or degrees of ionization, v, from that for neutral sulfur. The energy shift in the $K\alpha$ fluorescence line of sulfur is attributed only to the electronic charge on the sulfur atom; therefore, the number of electrons, n, in the 3s and 3p orbitals of sulfur in a compound can be calculated by using Eq. 5, as $n=6-v$. This assumption seems reasonable, because the term which contributes

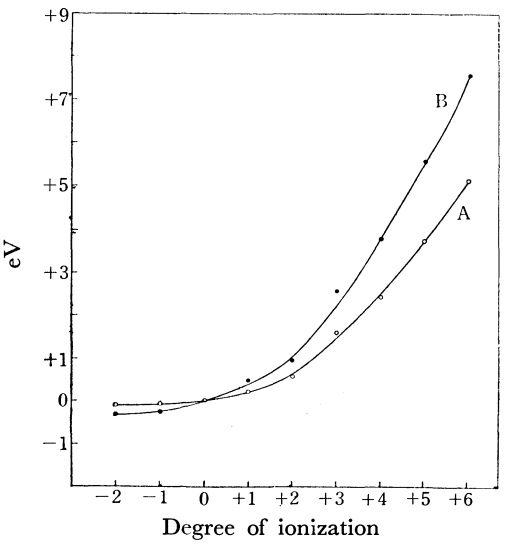

Fig. 5. Shifts in sulfur $K\alpha$ energy due to various degress of ionization.[24]
A) Koopmans' theorem model, B) Adiabatic model.

to the chemical shift in the binding energy is the same for each subshell except for the charge density on an atom. That is, the chemical shift in the $K\alpha$ X-ray energy is equal to the difference in the chemical shift between the binding energies of the two subshells. The chemical shifts for the binding energies of core electrons can be considered generally by dividing them into two parts——the inner atomic and the outer atomic parts. The inner atomic part is attributed to the charge density of the host atom and the relaxation energy due to the outer orbital electrons, while the outer atomic part is attributed to the potential energy and polarization energy due to the surrounding atoms which are bonding with the host atoms. The outer atomic part will contribute to the energy shift of orbital electrons homogeneously. Therefore, in the case of the chemical shift of the characteristic X-ray energy of inner orbitals, only the inner atomic part must be taken into account. In Table 3, the energy difference between the 1s and $2p_{3/2}$ photoelectron binding energies, which correspond to the calculated $K\alpha$ X-ray energy, are listed for various compounds. The shifts of these values from that for solid sulfur and the effective numbers of the electrons, n, in the 3s and 3p orbitals of the sulfur atom obtained from Eq. 5 for each compound are also listed in Table 3. Considering the core hole formation in the process of $K\alpha$ X-ray emission, Eq. 5 was adopted for the estimation of the relative atomic charge for sulfur in various compounds by referring to that in solid sulfur. It can easily be predicted that the relaxation energy due to outer-orbital electrons of sulfur atom is a function of the charge density on the outer orbital.

Extra-atomic Relaxation Energy Due to Ligand Atoms. Snyder[25] has recently shown that the relaxation from each shell is proportional to the population of each shell in the isolated atom. According to his investigation, the contribution of 3s and 3p electrons to the relaxation of the 2p core hole state in the sulfur atom is 1.09 eV per electron. For the Auger process, the

TABLE 3. ATOMIC CHARGE AND POLARIZATION ENERGY FOR SULFUR ATOMS

a) Energy shift in sulfur $K\alpha$ X-ray (calcd) from the sulfur molecule. The energy of $K\alpha$ X-ray (calcd) is equal to the difference between the 1s binding energy and 2p. b) Number of electrons on the sulfur 3s and 3p orbitals. c) Relaxation energy due to electrons on the 3s and 3p orbitals proportional to number of electrons(n). d) Polarization energy corresponding to the relaxation energy due to surrounding atoms.

static relaxation energy is approximately equivalent to twice that in the photoelectron process. Therefore, the static relaxation energy for the 2p hole state in the sulfur atom can be estimated as 2.2 eV per electron in the 3s and 3p orbitals. The static outer atomic relaxation energies for the S_{KLL} Auger electron calculated for various compounds are listed in the fourth column in Table 3. The static relaxation energy for a host atom due to only the surrounding atoms in a compound can be obtained by subtracting the static outer atomic relaxation energy from the static extra-atomic relaxation energy. The values for sulfur in various compounds are also listed in the fifth column in Table 3. The extra-atomic relaxation energy obtained above could be regarded as the polarization energy of surrounding atoms. The data in Table 3 indicate that these extra-atomic relaxation energies do not correlate with the chemical shift in the binding energy of the 1s and 2p photoelectrons. In sulfate, sulfite, and thiosulfate, the energy differences of the 2p photoelectron for the central sulfur atom from that in solid sulfur are appreciably large on the positive side, despite the large polarization energies for a core-hole formation, which generally decrease the binding energies. In these compounds, the largest polarization energy is found in the central sulfur of thiosulfate; the energies decrease from sulfate to sulfite. The central atom in thiosulfate bonds to three oxygen atoms and a sulfur atom, while the sulfur in the sulfate ion is surrounded by four oxygen atoms. Therefore, a sulfur atom bonded to a host atom may give a larger polarization energy than an oxygen atom. A slight difference in the polarization energies for the sulfur atom between sulfate and sulfite may be attributed to the decrease in the coordination number of the host atom. Therefore, the polarization energy is strongly correlated to the nature of the atoms

surrounding the sulfur, *e.g.*, the polarizability, the ionic radius, and the number of atoms. The terminal sulfur in thiosulfate, for which the photoelectron chemical shift of S2p is very small on the negative side, gets a little polarization energy. In this compound, the terminal sulfur atom adjoins only a sulfur atom and the distance from the nearest oxygen atom is twice that from a sulfur atom. It may be predicted that the polarization energy is mainly correlated to the nature of the nearest-neighboring atoms. Sulfur in zinc sulfide and sodium thiocyanate has small polarization energies, though the chemical shifts referred to the S2p energy for solid sulfur are negative. The polarizability of the bonding atoms also affect the polarization energy shifts of the host atom. For sodium thiocyanate, the sulfur atom is attached to the carbon atom, making only a little contribution to the polarization energy. This observation is further supported by the facts that the polarization energy of sulfur for 4,4′-dithio-bis(morpholine) is also very small and that no chemical shifts from the sulfur molecule are observable. In this case, considering the molecular structure of the morpholine group, the largest polarization energy can be expected for the core-hole formation of the sulfur atom. However, the results disagree with this prediction, presumably because of the small polarizability of the bonding carbon atoms.

Financial support for this research by the Toray Science Foundation is gratefully acknowledged.

The Temperature Dependence of the Solubilities of 1-Phenyl-1,3-butanedione and 4,4,4-Trifluoro-1-phenyl-1,3-butanedione in Water and Aqueous Electrolyte Solutions[1)]

Yasuki YOSHIMURA and Nobuo SUZUKI*

Department of Chemistry, Faculty of Science, Tohoku University, Aoba Sendai 980

(Received August 29, 1977)

The temperature dependence of the solubilities of 1-phenyl-1,3-butanedione (benzoylacetone) and 4,4,4-trifluoro-1-phenyl-1,3-butanedione (benzoyltrifluoroacetone) in water and in 1.0 mol l^{-1} aqueous solutions of $HClO_4$, HCl, $NaClO_4$, KCl, NaBr, NaCl, $BaCl_2$, and Na_2SO_4 was determined over the temperature ranges of 20 to 45 °C for benzoylacetone and of 15 to 30 °C for benzoyltrifluoroacetone. From these data, the thermodynamic quantities associated with the dissolution in water and with the transfer from water to the aqueous electrolyt solutions were estimated. Both the enthalpy and the entropy of solution of benzoyltrifluoroacetone in water were much smaller than those for benzoylacetone. This was interpreted by assuming a higher hydrophobic hydration for the less polar benzoyltrifluoroacetone. The thermodynamic quantities of the transfer of benzoyltrifluoroacetone from water to the aqueous perchloric acid solution showed characteristic features compared with those of the other electrolyte solutions. The overall salt effect on the dissolution of benzoylacetone and benzoyltrifluoroacetone is discussed in terms of the change in the thermodynamic quantities.

As the first step in clarifying the salt effect in the solvent extraction of metal chelates, we have investigated the salt effect on the liquid-liquid distribution of 1-phenyl-1,3-butanedione (benzoylacetone, abbreviated as BA) and 4,4,4-trifluoro-1-phenyl-1,3-butanedione (benzoyltrifluoroacetone, abbreviated as BFA).[2,3)] They are frequently used as extraction agents for various metal ions.[4)]

In the systems of the metal-chelate extraction, a system consists of an organic phase and an aqueous phase. Accordingly, in a thermodynamic study of the solvent extraction of metal chelates, it seems that the thermodynamic quantities of the dissolution of metal chelates in water give fundamental and important information. Because the solubilities of metal chelates in water are generally very low and metal chelates dissociate in water, few papers on the thermodynamic quantities of the dissolution of metal chelates in water have been published.

In view of the above points, in the present study the temperature dependence of the solubilities of BA and BFA in water and in several aqueous electrolyte solutions was measured. From the consequent data, the thermodynamic quantities of the dissolution of these β-diketones in water and of the transfer of these β-diketones from water to the aqueous electrolyte solutions were estimated. Such thermodynamic quantities of the transfer seem to give useful information relating to the salt effect.[5)]

Experimental

Materials. The benzoylacetone and BFA were purified as previously described.[2,3)] The stock solutions of the eight electrolytes used in this study were also prepared as previously described.[2,3)] The electrolytes used were as follows: perchloric acid, hydrochloric acid, sodium perchlorate, sodium chloride, sodium bromide, potassium chloride, barium chloride, and sodium sulfate. Redistilled water was used.

The Temperature Dependence of the Solubilities of Benzoylacetone and Benzoyltrifluoroacetone in Water and in 1.0 mol l^{-1} Aqueous Electrolyte Solutions. The solubility determination was made as follows: about 1—2 ml of a saturated solution of BA or BFA equilibrated with each solid phase at a desired temperature was transferred into a 25-ml volumetric flask which had been exactly weighed preliminarily (w_1 g). The saturated solution in the flask was allowed to stand for about 30 min at the constant room temperature of 25 °C, and then the total weight of the saturate solution and the flask was exactly weighed (w_2 g).

In an experiment at a temperature higher than room temperature, a modified procedure was applied to avoid any error due to recrystallization on standing in order to measure the weight. In this case, recrystallized BA or BFA was completely dissolved by adding 5 or 2.5 ml of 99.5% ethanol. Water was added to the mark, and then the absorbance was measured, if necessary, after appropriate dilution. To avoid any error due to the dissociation of BA and BFA, which are weak acids, the final solution was acidified to pH 3 with hydrochloric acid.

The addition of ethanol brought about a change in the content of the enol tautomer of BA in the solution; this was ascertained from the apparent extinction coefficient at 312 nm assigned to the enol tautomer of BA.[6)] Accordingly, in the case of the experiment for BA, the ethanol content in the final solution was adjusted to 20% (vol) by the further addition of ethanol. The concentration of BA in the equilibrated solution was then calculated from the absorbance at 312 nm. The apparent extinction coefficient of BA at 312 nm in the solution with the ethanol content of 20% (vol) was thus found to be 6860±27 l mol^{-1} cm^{-1} at 25 °C. This value was not affected by the electrolytes below 0.1 mol l^{-1}.

On the other hand, the extinction coefficient of BFA at the maximum absorption wave length of 249.5 nm was not affected by ethanol at contents below 10% (vol). In the case of BFA, the ethanol content in the final solutions was below 1% (vol), and so the concentration of BFA was simply determined as has previously been described.[3)] In the experiments at temperatures lower than room temperature for both BA and BFA, the addition of ethanol was not needed. Therefore, in these cases, too, the concentration of BA or BFA in the final sample solutions was measured as previously described.[2,3)]

The solubilities of BA and BFA in terms of the mole number in the saturate solution (1000 g), S, were calculated from

$$S = \frac{C \times (1/V_{dil}) \times 25}{w_2 - w_1}, \quad (1)$$

where C, V_{dil}, and $w_2 - w_1$ denote the measured concentration

of BA or BFA in the final sample solution (mol l^{-1}), the degree of dilution, and the weight of the saturated solution taken (g) respectively. The solubility measurements were made over the temperature ranges of 20 to 45 °C for BA and of 15 to 30 °C for BFA, and were made 4—8 times for the saturated solutions taken independently. The temperatures were kept at the desired temperatures within 0.2 °C.

The Temperature Dependence of the Keto-Enol Tautomerism Constants of Benzoylacetone in Water and in 1.0 mol l^{-1} Aqueous Electrolyte Solutions. The keto-enol tautomerism constants of BA at all the temperatures where its solubility was measured were estimated from the temperature dpendence of the apparent extinction coefficients at 310 nm of BA in water and in 1.0 mol l^{-1} aqueous electrolyte solutions.

The apparent extinction coefficients of BA in terms of the molarity at 310 nm in the respective solutions at 25 °C, which were measured in a previous work,[2] were converted into values in terms of molarity, $\varepsilon_{(m)}$, from the densities of the water and the 1.0 mol l^{-1} aqueous electrolyte solutions at 25 °C. The extinction coefficients for the enol tautomer, $\varepsilon_{(m)}$, were obtained from the above $\varepsilon_{(m)}$ and the enol contents estimated in the previous work.[2] The values for $\varepsilon_{(m)}$ estimated were as follows: 15058±69 (kg mol^{-1} cm^{-1}) in water (acidified to 0.001 mol l^{-1} HCl solution); 14787±87 in 1.0 mol l^{-1} HCl; 14276±140 in 1.0 mol l^{-1} $HClO_4$; 14775±10 in 1.0 mol l^{-1} NaCl, and 14458±91 in 1.0 mol l^{-1} $NaClO_4$.

The apparent extinction coefficients, $\varepsilon_{(m)}$, of BA at each temperature except 25 °C were determined as has been described above. In these measurements, the standard solutions of BA were immersed for about 30 min in a water bath kept at the desired temperature within 0.1 °C before the absorbance measurements at 310 nm. It was confirmed from a pre-experiment that the keto-enol tautomeric equilibrium of BA in an aqueous solution was attained within 10 min at a given temperature.

The keto-enol tautomerism constants of BA, K_{aq}, which were defined as the concentration ratios of the keto to the enol tautomers, were calculated by means of

$$K_{aq} = \frac{1-(\varepsilon_{(m)}/\varepsilon_{e(m)})}{\varepsilon_{(m)}/\varepsilon_{e(m)}}, \qquad (2)$$

where it was postulated that the values for $\varepsilon_{(m)}$ in the respective solutions were independent of the temperature.

The Densities of 1.0 mol l^{-1} Aqueous Electrolyte Solutions at 25 °C. The densities of 1.0 mol l^{-1} HCl, $HClO_4$, NaCl, KCl, NaBr, $BaCl_2$, and Na_2SO_4 solutions at 25 °C were obtained as follows. The densities of these aqueous electrolyte solutions at 25 °C have been listed in an earlier article as functions of the weight percent concentrations of these electrolytes.[7] For the respective electrolyte solutions, the plots of $W \times d$ against d, where W and d denote the weight-percentage concentrations of the electrolytes and the densities of the electrolyte solutions with the concentrations of W at 25 °C respectively, gave straight lines. Therefore the best-fit equations for these straight lines were obtained by the method of least squares. The densities of the above electrolyte solutions at 25 °C were calculated from the best-fit equations as has been described in the literature.[7]

The densities of aqueous $NaClO_4$ solutions at 25 °C have not yet been reported. Therefore, the density of the 1.0 mol l^{-1} $NaClO_4$ solution was measured with a pycnometer.

The densities of the 1.0 mol l^{-1} aqueous electrolyte solutions at 25 °C thus obatined were as follows: HCl, 1.0145 (g ml^{-1}); NaCl, 1.0368; KCl, 1.0426; $HClO_4$, 1.0455; NaBr, 1.0746; $NaClO_4$, 1.0754; Na_2SO_4, 1.1149; $BaCl_2$, 1.1741.

In the solubility experiments for the neutral electrolytes, the aqueous electrolyte solutions were acidified with HCl (0.001 M) to prevent the dissociation of BA and BFA. Therefore, contribution of added HCl to the densities of these solutions may be small enough to be neglected because of its low concentration.

Results and Discussion

The Thermodynamic Quantities of the Dissolution of Benzoylacetone and Benzoyltrifluoroacetone in Water.

(i) The Calculation of the Thermodynamic Quantities of the Dissolution in Water: The solubilities obtained by Eq. 1 were convereted to the value in terms of molality by using the densities of the respective electrolyte solutions at 25 °C.

The solubilities in terms of molality at different temperatures, $S_{(m)}$, are listed in Table 1 for BA and in Table 2 for BFA. In these tables, the addition of such small amounts of acids as 0.001 M to prevent the dissociation of BA and BFA does not introduce any error into the solubility determination.[2,3] The values quoted are the means of 4—8 independent experiments, and the deviations of the listed values denote mean errors,** in most cases, the relative mean errors did not exceed 0.6%.

In the case of BA, the solubilities tabulated in Table 1 are the apparent values for the mixtures of the enol and keto tautomers. The solubilities of the enol tau-

** The mean error, a, is given by

$$a = \frac{\sum_{i=1}^{n} |d_i|}{\sqrt{n(n-1)}},$$

where n and d indicate the times of measurement and the residue respectively.

Table 1. Temperature dependence of the solubility of benzoylacetone in water and 1.0 mol l^{-1} aqueous electrolyte solutions ($S_{(m)} \times 10^3$/mol kg^{-1})

Electrolyte	Temperature (°C)					
	20	25	30	35	40	45
Water[a]	$1.89_6 \pm 0.01_2$	$2.43_2 \pm 0.00_8$	$3.13_7 \pm 0.00_9$	$4.02_1 \pm 0.01_0$	$5.13_8 \pm 0.00_3$	$6.58_8 \pm 0.02_3$

tomer, $S_{e(m)}$, and those of the keto tautomer. $S_{k(m)}$, were estimated by using the keto-enol tautomerism constants of BA listed in Table 3.[2]

On the other hand, the solubilities of BFA tabulated in Table 2 can be regarded as those for the hydrate form of BFA previously reported.[3] Accordingly, in the following discussion of BFA, only the hydrate form will be considered.

Generally, the temperature dependence of the solubility of a solid nonelectrolyte can be written by

$$\ln S_{(m)} = -\frac{\Delta H_{soln}}{RT} + \text{const}, \quad (3)$$

where ΔH_{soln} indicates the heat of solution. The plots of $\ln S_{(m)}$ against $1/T$ grounded on Eq. 3 gave straight lines, as is shown in Fig. 1(a) for the enol tautomer of BA, in Fig. 1(b) for the keto tautomer of BA, and in Fig. 2 for BFA. The heats of solution in water, ΔH°_{soln}, were obtained from the slopes of the straight lines for the solubilities in water by the least-squares method. The free energies of solution in water, ΔG°_{soln}, were calculated by means of

$$\Delta G^\circ_{soln} = -RT \ln X^\circ_{sat}, \quad (4)$$

where X°_{sat} represents the solubilities in water in terms of the mole fraction. The values for $\ln X^\circ_{sat}$ were calculated from $\ln S^\circ_{(s)}$ at 25 °C obtained from the above straight lines. The entropies of solution in water, ΔS°_{soln}, were calculated from ΔH°_{soln} and ΔG°_{soln}. The activity coefficients of the enol and keto tautomers of BA, and of BFA in the saturated solutions are regarded as unity because of their quite low solubilities in water.[2,3] These results are tabulated in Table 4.

Table 4. Thermodynamic quantities of the dissolution of benzoylacetone and benzoyltrifluoroacetone at 25 °C in water

	ΔG°_{soln}[a] / cal mol^{-1}	ΔH°_{soln}[b] / cal mol^{-1}	ΔS°_{soln}[c] / cal mol^{-1} K^{-1}
Benzoylacetone (enol from)	6566±6	7913±5	4.5
Benzoylacetone (keto form)	6182±5	9840±4	12.2
Benzoyltrifluoroacetone (hydrate form)	4908±7	991±5	−13.1

a) Calculated by $\Delta G^\circ_{soln} = -RT \ln X^\circ_{sat}$. b) Obtained from the slopes of the plots of $\ln S^\circ_{(m)}$ *vs.* $1/T$. c) $\Delta S^\circ_{soln} = (\Delta H^\circ_{soln} - \Delta G^\circ_{soln})/T$.

(ii) A Comparison between the Thermodynamic Quantities of the Dissolution of Benzoylacetone and Those of Benzoyltrifluoroacetone: It has been confirmed by X-ray crystallography that BA exists in the enol form in the crystal.[8] Accordingly, it may be concluded that the thermodynamic quantities of the dissolution for the keto tautomer of BA are summations of those for the enol tautomer and the thermodynamic quantities of the ketonization in the saturated solution of BA.

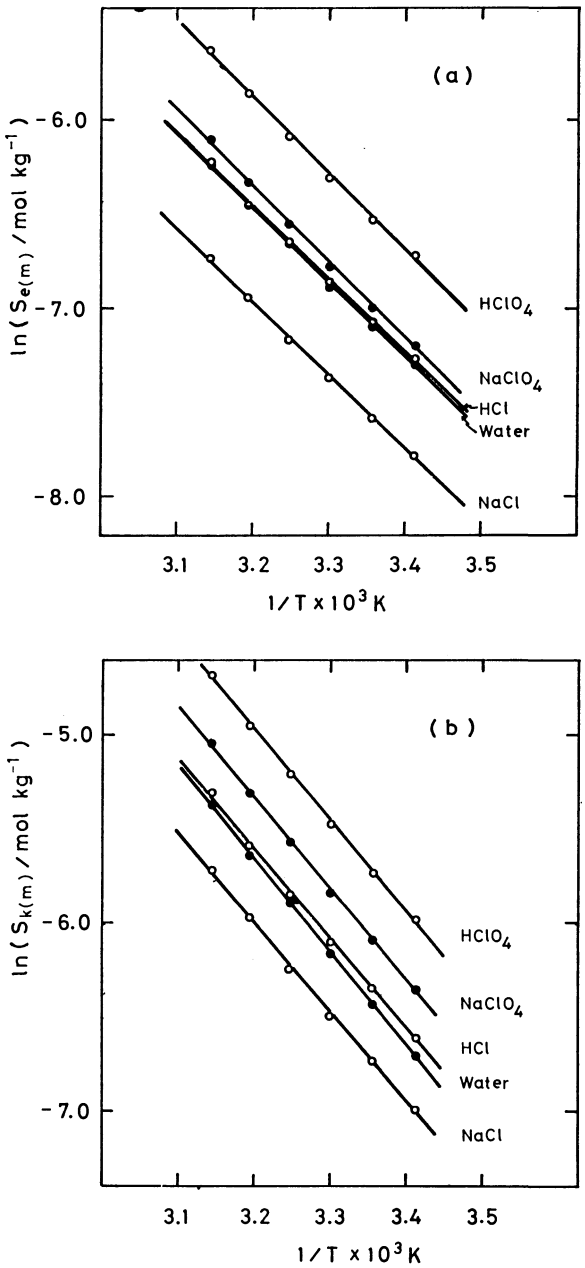

Fig. 1. Plot of $\ln S_{(m)}$ *vs.* $1/T$ for the solubilities of the respective tautomers of benzoylacetone in water and 1.0 mol l^{-1} aqueous electrolyte solutions.
Straight lines are drawn by method of least squares.
(a) For the enol tautomer,
(b) for the keto tautomer.

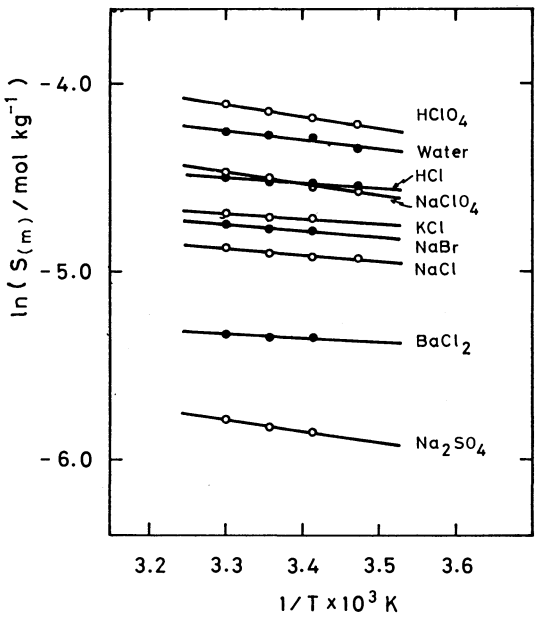

Fig. 2. Plot of $\ln S_{(m)}$ *vs.* $1/T$ for the solubilities of the hydrate form of benzoyltrifluoroacetone in water and 1.0 mol l^{-1} aqueous electrolyte solutions.
Straight lines are drawn by method of least squares.

Therefore, in the case of BA, the values for the enol tautomer ought to be discussed.

On the other hand, the reaction of 2-thenoyltrifluoroacetone (TTA) with water yields the crystal of its hydrate form.[9] Similarly, the solid phase of BFA equilibrated with its saturated solution seems to take the hydrate form. Thus, the solution equilibrium of BFA in the saturated solution may be established between the hydrate form in the aqueous phase and that in the solid phase. Therefore, the thermodynamic quantities of the dissolution of BFA do not involve the thermodynamic quantities of the hydrate formation.

The thermodynamic quantities of the dissolution of BFA in water are much smaller than those of BA. The smaller enthalpy of solution for BFA contributes to its smaller free energy of solution, and this results in its larger solubility in water. These results may be explained as follows, by assuming nearly identical volatilities for BA and BFA.[10] In water, the hydrophilic groups, such as the carbonyl and hydroxyl groups, can interact with water molecules through the electrostatic force and the hydrogen bond. On the other hand, the hydrophobic groups such as the alkyl group cause the formation of an "iceberg" structure of the water around them (hydrophobic hydration).[11] Our previous study suggests that the two hydroxyl groups and trifluoromethyl group in the hydrate form of BFA may behave as the hydrophobic groups rather than as the hydrophilic groups in its aqueous solution.[3] Thus, the higher hydrophobic hydration for BFA may cause a greater decrease in both the enthalpy and the entropy.

The above results give a useful suggestion regarding the dissolution behavior of metal chelates of BA and BFA in water. In these chelates, the hydrophilic parts in BA and BFA—that is, both the carbonyl group and the hydroxyl group—combine with the central metal ions, while the hydrophobic parts in BA and BFA mainly came in contact with water molecules in their aqueous solutions. This suggests that the hydrophobic hydration for their metal chelates may be higher than that for BA and BFA. This hydrophobic hydration of their chelates may contribute considerably to their thermodynamic quantities upon dissolution in water and a non-polar organic solvent.

a) Calculated by $\Delta G_T^\circ = -RT \ln K_{aq}^\circ$. b) Obtained from the slope of the plot of $\ln K_{aq}^\circ$ *vs.* $1/T$. c) $\Delta S_T^\circ = (\Delta H_T^\circ - \Delta G_T^\circ)/T$. d) Literature values (Ref. 12).

zation of BA in water, ΔH_T°, was obtained from the plot of $\ln K_{aq}^\circ$ against $1/T$. K_{aq}° is the keto-enol tautomerism constant of BA in water. This plot gave a good straight line. The free energy, ΔG_T°, and the entropy of ketonization, ΔS_T°, were obtained in the ordinary manners. These results are listed in Table 5, along with the literature values[12] for those of acetylacetone (AA).

The entropies of ketonization for BA and AA are nearly identical, but the heat of ketonization of BA is larger than that of AA. It is this that mainly contributes to the smaller negative free energy of the ketonization of the former, that is to the higher enol content of the former in water. The difference in the heats of ketonization of BA and AA may be attributed mainly to a difference in the enthalpies of the enol tautomer of BA and AA; that is, the enthalpy of the enol tautomer of BA is lowered due to the resonance energy between the phenyl group and the enol ring.

The Thermodynamic Quantities of the Transfer of Benzoylacetone and Benzoyltrifluoroacetone from Water to 1.0 mol l^{-1} Aqueous Electrolyte Solutions. The free energies, ΔG_{tr}, and the enthalpies, ΔH_{tr}, of the transfer of one mole of BA or BFA from water to 1.0 mol l^{-1} aqueous electrolyte solutions at hypothetically identical solute concentrations were obtained by means of the following equations:[5]

$$\Delta G_{tr} = RT \ln (X_{sat}^\circ / X_{sat}), \quad (5)$$

$$\Delta H_{tr} = \Delta H_{soln} - \Delta H_{soln}^\circ. \quad (6)$$

In Eq. 5, X_{sat} indicates the solubilities in a mole fraction of BA or BFA in the 1.0 mol l^{-1} aqueous electrolyte solutions at 25 °C. The values for $\ln X_{sat}$ were calculated from $\ln S_{(m)}$ at 25 °C obtained from the best-fit equations for the plots shown in Figs. 1 and 2. The values for ΔH_{soln} in Eq. 6, which indicates the heats of solution in the aqueous electrolyte solutions, were also calculated from the slopes of the above best-fit equations. The entropies of transfer, ΔS_{tr}, were calculated from ΔH_{tr} and ΔG_{tr}. These results are listed in Table 6 for the hydrate form of BFA and in Table 7 for the enol and keto tautomers of BA.

Very few inorganic electrolytes are known to exhibit a so-called "salting-in" effect on non-polar nonelectrolytes. Table 6 shows that the thermodynamic quantities of the transfer of BFA to the aqueous perchloric acid solution show a characteristic feature in comparison with those to the other electrolyte solutions studied. That is, though the enthalpy of transfer to the perchloric acid solution is positive, the positive entropy contributes to the negative free energy, which results in the salting-in effect.

The salt effect of tetraalkylammonium salts has been quite well studied,[13-17] and both the enthalpies and the entropies of transfer of various nonelectrolytes from water to the aqueous solutions of these ammonium salts have been found to be positive.[17,18] These results have been interpreted in terms of a so-called "hydrophobic interaction" between the nonelectrolyte solutes and the tetraalkylammonium cations.[17,19]

The positive enthalpy and entropy of transfer of BFA to the aqueous perchloric acid solution may also be interpreted in a similar way as follows. The perchlorate anion destroys the iceberg structure of water,[20] which may bring about the hydrophobic interaction with BFA, and this interaction in turn weakens the hydrophobic hydration for BFA. Thus, the decrease in the enthalpy and entropy of BFA through the hydrophobic hydration in the perchloric acid solution becomes smaller than that in water. This argument on the role of the perchlorate anion may offer a possible explanation of the well-known phenomenon that the perchlorate anion is markedly extracted into organic

solvents as ion pairs with large hydrophobic cations.[21]

For the transfer of BFA to the sodium sulfate solution, a negative entropy and a positive enthalpy are observed. This results in the largest positive free energy among the electrolytes studied. Both the enthalpies and the entropies of transfer to all the other electrolyte solutions, except for $HClO_4$, $NaClO_4$, and Na_2SO_4, are negative. Moreover, the larger negative entropies bring about positive free energies of transfer. However, it is very difficult at present to interpret the above results thoroughly.

The thermodynamic quantities of the transfer for the enol tautomer of BA in Table 7 show the same tendency as those for BFA. For all the electrolytes studied, the thermodynamic quantities of the transfer for the keto tautomer of BA are smaller than those for its enol tautomer. Probably these results may be ascribed to the stronger interaction between the more polar keto tautomer and its surroundings, such as water molecules and the electrolytes.

Very few papers on the salt effect in the solvent extraction of metal chelates have referred to the thermodynamic quantities. To clarify the very complicated salt in the solvent extraction of metal chelates, we consider the overall salt effect by dividing it into two stages, that is, the salt effect in chelate formation in the aqueous phase and that in the distribution of the metal chelates between aqueous and organic phases. In the former stage, the chemical reactions of metal ions with salt components must be taken into account; for example, the coordination of such anions as chloride and bromide ions to metal ions[22,24] and ion-pair formation between charged metal chelates and counter ions such as perchlorate anions[23,24] *etc.* Thus, the salt effect in this stage is very particular, and so it seems to be difficult to generalize about it. On the other hand, in the latter stage, the metal chelates distributed may be regarded as nonelectrolytes. Accordingly, the salt effect in this stage may described by analogy from the present results for the chelating agents. Thus, the present study gives useful suggestions for the generalized interpretation of the salt effect in the distribution of metal chelate compounds in the solvent extraction.

Carbon-13 NMR Spectra of Benzene Mono- and Di-Carboxylic Acids and Their Analytical Applications

Yoshio KOSUGI* and Tsugio TAKEUCHI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Nagoya 464

(Received September 28, 1977)

Carbon-13 NMR spectra of benzoic, and phthalic acids were compared both in D_2O with an excess of sodium hydroxide and in a mixture of DMSO-d_6 and H_2O (4:1). Tight ion pair forms of benzoate anion were considered. A simple additive rule for isomeric phthalic acids was employed to assign the spectral peaks. These carboxylic acids gave characteristic peaks and so can be distinguished from others in mixtures. Quantitative analyses of these carboxylic acids with calibration curves are also possible by a simple preparation of basic D_2O solutions. An example of the use of these data is the Henkel process (*cf.* Fig. 1) for the synthesis of terephthalic acid.

Better analyses of a mixture of benzoic acid (**1**) and isomeric phthalic acids (**6**—**8**) are highly desired not only in organic laboratories but also in polyester manufacturing industries. The most well-known method for the analyses of the benzenepolycarboxylic acids may be esterification, followed by gas-chromatographic separation. Ultraviolet spectroscopy is also of potential usefulness, but it is often interfered with by contamination.

Nuclear magnetic resonance (NMR) spectroscopic analysis is inferior to the gas-chromatographic method in accuracy and sensitivity, but it is still useful and of convenience in most cases when one needs to analyze a reaction mixture quickly or to follow its conversions as the reaction proceeds.

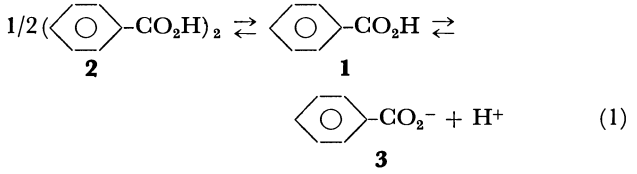
Unfortunately, the much more versatile ^1H NMR is often unsuitable for identifying structurally similar derivatives. On the other hand, the widely-ranging chemical shifts of ^{13}C NMR reflect a small difference in the structures.

Besides analytical purposes, the ^{13}C NMR data of aromatic carboxylic acids will be added to the data collections from which unambiguous empirical rules for the ^{13}C chemical shifts of substituted benzenes may be derived. The chemical shifts of carboxylic acids, however, often vary with the changes in solvent basicities, polarities, *etc.*, because the degrees of association and dissociation of carboxylic acids are solvent-dependent.[1] More generalized values of the chemical shifts of aromatic carboxylic acids are desirable.

Herein we will report some attempts to use ^{13}C NMR for comparing the differences among benzoic and benzenedicarboxylic acids.

Results and Discussion

Benzoic Acid. A few data on the ^{13}C NMR chemical shifts (δ^C) of benzoic acid have appeared in the literature.[2-4] The poor solubility of the acid in D_2O made it impossible to get a reasonable spectrum with an accumulation of 10000 transients at 26 °C. While no solubility problem is met with in aprotic polar solvents, such as DMSO-d_6, a small amount of water in the solvent often affects chemical shifts, especially when hydrogen bonding participates. Adding water in a 25 volume percentage to a DMSO-d_6 solution seems to be a successful way to eliminate the ill-defined effects of concentration changes and other factors which may vary the degrees of hydrogen bonding or dissociation of benzoic acid.[1] Species **1** seemed to be dominant in the possible equilibrations.



(1)

The peaks of the spectra are assigned with reference to the literature values, the off-resonance decoupled spectra, the gradual shift in peaks with different ratios of a mixed solvent, and the virtual peak intensities. The data are summarized in Table 1.

A large solvent dependency of the chemical shifts is evident in Table 1. The resonance-field change in δ_{CO} (the chemical shift of the carboxyl carbon atom) reaches *ca.* 5 ppm, this shift is attributable to the change in the association degree of benzoic acid.[1]

Benzoate Anion. Benzoic acid in a strong, basic heavy water shows a clean spectrum of the benzoate anion, the δ_{CO} of which shifts downfield by 11.4 ppm relative to δ_{CO} in DMSO-d_6, while the δ_{ipso} shifts by 8.8—10.1 ppm, compared to the values in DMSO-d_6 or $CDCl_3$ respectively. Essentially the same spectrum was obtained when sodium benzoate was dissolved in D_2O. This suggests that all the chemical shifts observed in a basic D_2O solution are attributable to the anion species, **3**. On the other hand, benzoic acid dissociated incompletely in the mixed solvent. The resulting chemical shifts were values between those of **1** and **3**. Similar chemical shifts were recorded when sodium benzoate was dissolved in the mixed solvent without adding sodium hydroxide (see

a) In DMSO-d_6–H_2O (4 : 1). b) In D_2O with an excess of sodium hydroxide.

the last column in Table 2).

Although an effort to record the spectrum of sodium benzoate in $CDCl_3$ was in vain, the benzoate anion in organic solvents was also generated by adding excess triethylamine. As may be seen in Table 2, the chemical shifts in $CDCl_3$ or DMSO-d_6 are independent of the solvent nature, but are different from those of the benzoate anion obtained in the D_2O solution. The downfield shifts of δ_{CO} and δ_{ipso} relative to those of benzoic acid in DMSO-d_6 were 2.9 ppm and 4.9 ppm respectively, smaller than those observed for the benzoate anion in D_2O (*vide ante*). That is, the chemical shifts of the benzoate anion in organic solvents are between these values of the free acid form, **1**, and of the completely ionized form, **3**. This may suggest that the negative charge on the carboxyl group is neutralized to some extent in a tight ion pair form, **4** or **5**.

4 **5**

Benzenedicarboxylic Acids. The ^{13}C NMR spectra of phthalic acid (**6**), isophthalic acid (**7**), and terephthalic acid (**8**) were obtained in a mixed solvent (with the same ratio as above) and in D_2O with an excess of sodium hydroxide. The results are given in Table 3.

The assignment of the peaks was aided by the additive rule for disubstituted benzene derivatives. The usefulness of the calculation for several compounds had also been tested previously in this laboratory.[4–5)] Used for the additive calculation[6)] were the chemical shifts of benzoic acid in the mixed solvent (Table 1) and of the benzoate anion in D_2O saturated with sodium hydroxide (Table 2). In the calculation, the increments of the shifts can not be estimated by using the benzene standard for its chemical shifts in a D_2O solution are not available. Therefore, the δ^C of meta carbon was set for the standard both in the mixed solvent and in basic D_2O (Table 4).

The agreement between the observed and the calculated chemical shifts of phthalic acid and its anion was not perfect (the largest discrepancy was 0.8 ppm). Similar disagreements are common for ortho-substituted benzenes,[7)] where usually two bulky groups interact with one another. On the other hand, a fairly good agreement was established for isophthalic acid and terephthalic acid in two different solvents.

Analytical Applications. Terephthalic acid is in high demand as a material of polyester fibers and plastics. Numberless studies on synthesizing or manufacturing the material have been reported. One of the most successful findings is Henkel reaction[8)] by which terephthalic acid is produced from benzoic, phthalic, and isophthalic acids.

The pathways of the Henkel reaction are given below, although the acid forms represent the corresponding alkali salts in actual reactions where carbon dioxide and catalysts such as cadmium iodide are also present.

The most routine process of analysis may be the acidification of the reaction mixture, followed by the extraction of the acids, esterification and finally gas-chromatographic separation. However, NMR spectroscopy would be more convenient for the analysis if rigorous accuracy were not crucial, as it is not for usual organic reactions. Unfortunately, the more accessible ^1H NMR method does not seem appropriate for the present case because spectral overlaps are inevitable.

The proton signal of carboxyl groups of terephthalic acid (δ^H=10.5—11.7) is too broad and weak to be

used for the present analysis. One exception is the case when a reaction mixture composed of benzoic acid and terephthalic acid is made up in a DMSO solution. This happens in some related studies of benzenepolycarboxylic acids. When the method is applied to the crude reaction mixture of the Henkel process, acidification and extraction (and perhaps replacing the solvent with DMSO) are necessary because it contains exclusively water soluble alkali salts of the carboxylic acids.

Contrary to the ^1H NMR method, ^{13}C Fourier-transform NMR spectra with ^1H noise-decoupling give narrow, single peaks whose resonance frequencies are printed out from an attached computer memory.

Surveying Tables 1—3, it seems that one can distinguish the peaks of terephthalic aicd from the others. In fact, the spectra of mixtures of terephthalic acid with either benzoic acid (Fig. 2a) or phthalic acid and isophthalic acid (Fig. 2b) in basic D_2O demonstrate

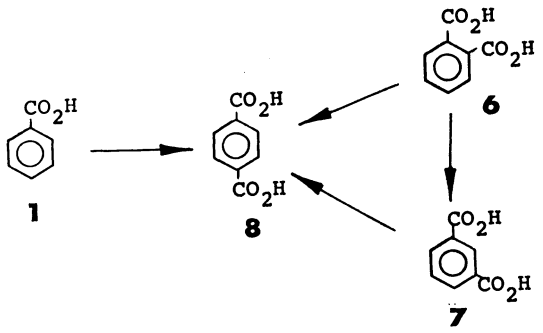

Fig. 1. Reaction paths of Henkel process.

applicable analyses of the Henkel process (Fig. 1)

When all these carboxylic acids are mixed, the only ambiguous distinction is the peak difference between benzoic acid and isophthalic acid. However, the mixed solvent instead of basic D_2O may be used for such a purpose.

Problems in Quantitative Determination. The application of ^{13}C NMR spectroscopy to quantitative analysis has recently been reported frequently.[9] Unlike the ^1H NMR, the ^{13}C peak intensity is affected by any nuclear Overhauser effects (NOE). Therefore, a simple integration of the peak intensity does not give quantitative amounts of carbon atoms. However, the amount of NOE on a particular carbon is usually independent of the sample concentrations, because the dipole-dipole (of proton) interaction dominates the ^{13}C relaxation. To confirm this accepted idea, benzoic acid was chosen to test the possibility of quantitative analysis.

A certain amount of benzoic acid was dissolved in basic D_2O with propionic acid (0.58 M). At lower concentrations, the peaks of carboxyl and ipso carbons were hidden in the noise levels. The relative peak intensities of the other ring carbons against methylene carbon of propionic acid (internal standard) were on fairly good straight lines in the range of 0.33—2.67M of benzoic acid (dotted lines in Fig. 3). These calibration lines, which had been expected to be straight are sufficient proof for the quantitative determination of other carboxylic acids, including therephthalic acid.

In connection with the NOE problem in the present analysis, pure oxygen, a paramagnetic substance, was saturated in the sample solutions. No improve-

ment for the determination was found, in spite of extra pretreatment before measurements.

Experimental

NMR Measurements. All the ^{13}C NMR spectra were recorded on a Varian XL-100-15 NMR spectrometer operating at 25.16 MHz in the pulsed Fourier transform mode with ^{1}H noise-decoupling with the 2 kHz band width at 8 mW. The pulse width of 60 μs (*ca.* 45° flip angle), with a pulse delay of 3 s, was applied. Spectral widths of 5000 Hz were swept with 4096 data points using a Varian DATA 620i computer with 8 K memory produced spectra with accuracies of better than 0.1 ppm. Normally 1000 transients were accummulated. Unless specified, a compound of *ca.* 500 mg and sodium hydroxide, when necessary, was dissolved in a solvent (3—5 ml) in a 12 φmm sample tube at a spinning rate of 10—16 rps at 26°. Tetramethylsilane (TMS) or sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS, δ_C 0.015) was the internal standard. Carbonyl carbon of methyl acetate (82% benzene-d_6 solution) showed a peak at 171.4 ppm, which was the exact mean value of those obtained on 65 different C-13 NMR machines throughout the country.[10]

Chemicals. All the aromatic carboxylic acids and sodium benzoate were of a guaranteed grade, while the triethylamine and sodium hydroxide were of a reagent grade. Dimethyl sulfoxide (DMSO) of a reagent grade was distilled from calcium hydride and stored over molecular sieves of Type 4 A. The deuterated solvents (D_2O, $CDCl_3$, and DMSO-d_6) for NMR spectroscopy were purchased from Merck Japan, Ltd. TMS and DSS were also of a NMR spectroscopic grade. Except for DMSO, none of them, including oxygen gas, was purified before use. A mixture of DMSO-d_6 and H_2O in a volume ratio of 4 to 1 was used in the present study (mixed solvent).

The authors wish to thank Mr. K. Okada for his technical assistance. Partial financial support from the Ministry of Education is acknowledged.

Preparation and Reactivities of Phenylethynyl[1,1,1-tris(diphenylphosphinomethyl)ethane]copper(I) Complex

Katsuma HIRAKI,* Yoshio FUCHITA,* and Yasushi MORITA

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received December 5, 1977)

Phenylethynyl[1,1,1-tris(diphenylphosphinomethyl)ethane]copper(I), [Cu(C≡CPh)(tdpme)]{tdpme=1,1,1-tris(diphenylphosphinomethyl)ethane}, has been prepared in good yield by a reaction between phenylethynylcopper(I), [{Cu(C≡CPh)}$_n$], and tdpme. From physicochemical and spectroscopic studies the complex is considered to have a monomeric tetrahedral structure. It reacts with *p*-cresol to give [Cu(O-C_6H_4-CH_3-*p*)(tdpme)] and also with highly active hydrogen compounds, methyl cyanoacetate and methyl nitroacetate, to give [Cu{CH(CN)-CO_2CH_3}(tdpme)] and [Cu{CH(NO_2)CO_2CH_3}(tdpme)], respectively. However, moderately active hydrogen compounds, such as acetonitrile, dimethyl malonate, and nitromethane, do not react with [Cu(C≡CPh)(tdpme)]. The reactivities of the complex with active hydrogen compounds are discussed in correlation with the pK_a values of the latter compounds.

Recently, the syntheses of organocopper compounds have been widely investigated in view of the fact that copper compounds play important roles in various copper-assisted organic reactions.

Alkyl-[1] and arylcopper(I)[2,3] complexes containing uni- or bidentate phosphorus ligand have been prepared and converted into substituted alkylcopper(I) complexes by reactions with active hydrogen compounds.[4,5] Coates and Parkin,[6] and Camus and Marsich[3] prepared tertiary phosphine-bonded phenylethynylcopper(I) complexes, which have complicated compositions depending on the phosphine or molar ratio of phosphine/copper, such as [Cu(C≡CPh)$(PR_3)_n$] (R=Me, n=1,2,3; R=Et and Ph, n=1) and [(CuC≡CPh)$_m${$Ph_2P(CH_2)_kPPh_2$}$_n$] (k=1, m/n=4/3; k=2, m/n=1/1,2/3,4/3).

A triphosphine ligand, 1,1,1-tris(diphenylphosphinomethyl)ethane, (tdpme), has a three-fold axis of symmetry (Fig. 1) and serves as a bidentate or a tridentate ligand in tetrahedral,[7-9] square pyramidal,[7] and octahedral[10] complexes. As for copper(I) complexes, the ligand afforded the tetrahedral complexes, [CuX(tdpme)] (X=halogen,[8] ONO_2, and $OClO_3$[9]) and a complex, [Cu(BH_4)(tdpme)], which seems to have a very distorted square pyramidal structure.[11]

In this paper, we report the preparation and characterization of [Cu(C≡CPh)(tdpme)] **1**, and its reactivities towards active hydrogen compounds.

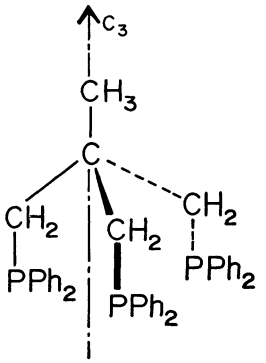

Fig. 1. Configuration of tdpme.

Experimental

Materials and Procedures. All the experiments were carried out in an atmosphere of dry nitrogen. Solvents were dried by the usual procedure and distilled.

1,1,1-Tris(diphenylphosphinomethyl)ethane (tdpme)[12] and phenylethynylcopper(I) [{Cu(C≡CPh)}$_n$][13] were prepared according to published procedures. Methyl nitroacetate was also prepared and purified by distillation under reduced pressure.[14]

General Procedures. IR spectra were measured on a Hitachi 285 spectrophotometer and ^{1}H-NMR spectra on a JEOL JNM-MH-100 spectrometer. Conductivity measurements were carried out for 1.0×10^{-3} M acetone solution at 25 °C on a Toa Electronics CM-6A conduct meter. Melting points were determined with a Yanaco micro melting point apparatus and are uncorrected. Molecular weight was determined in benzene by means of a cryoscopic method.

*Preparation of [Cu(C≡CPh)(tdpme)] **1**.* To a suspension of phenylethynylcopper(I) (158 mg, 0.96 mmol) in 20 ml of benzene was added tdpme (600 mg, 0.96 mmol) in 20 ml of benzene at room temperature. After the resulting pale yellow solution had been stirred for 24 h, the solvent was removed under reduced pressure. Recrystallization from toluene–hexane gave 637 mg of pale yellow crystals of **1** (yield 84%).

*Reaction of **1** with* p-*Cresol.* *p*-Cresol (30.2 mg, 0.28 mmol) in 5 ml of THF was added to a solution of **1** (200 mg, 0.25 mmol) in 30 ml of THF at room temperature. After being stirred for 5 h, the solvent was removed under reduced pressure. Recrystallization from benzene–hexane gave 80 mg of pale yellow crystals, [Cu(O-C_6H_4-CH_3-*p*)(tdpme)] **2** (yield 40%).

*Reaction of **1** with Methyl Cyanoacetate.* Methyl cyanoacetate (57.1 mg, 0.58 mmol) in 5 ml of THF was added to a solution of **1** (455 mg, 0.58 mmol) in 20 ml of THF at 0 °C. After being stirred for 5 h at 0 °C, the solvent was removed under reduced pressure and the resulting solid was washed with benzene. Recrystallization from dichloromethane–hexane gave 210 mg of white crystals, [Cu{CH(CN)CO_2CH_3}-(tdpme)] **3** (yield 46%).

*Reaction of **1** with Methyl Nitroacetate.* This reaction was carried out at 0 °C in the same way as described for **3**, and pale yellow crystals, [Cu{CH(NO_2)CO_2CH_3}(tdpme)] **4** were produced (yield 33%).

*Reaction of **1** with Other Active Hydrogen Compounds.* Complex **1** did not react with other moderately active hydrogen

compounds, *i.e.*, acetonitrile, dimethyl malonate, and nitromethane in THF either at 0 °C, room temperature, or 65 °C (refluxing conditions), only the starting complex **1** being recovered.

Results and Discussion

*Preparation and Properties of [Cu(C≡CPh)(tdpme)] **1**.* Complex **1** was prepared by the reaction of phenylethynylcopper(I) with tdpme in benzene at room temperature. The complex is considerably stable in air and soluble in common organic solvents.

$$[\{Cu(C{\equiv}CPh)\}_n] + n\,\text{tdpme} \xrightarrow[\text{r. t.}]{\text{benzene}} n[Cu(C{\equiv}CPh)(\text{tdpme})]\ \mathbf{1}$$

The IR spectrum of **1** shows a ν(C≡C) band at 2030 cm^{-1}, higher (*ca.* 100 cm^{-1}) than that of phenylethynylcopper(I), and is assigned to the ethynyl group bonded to copper. Such shift of the ν(C≡C) band was observed in other phenylethynylcopper(I) complexes containing phosphine ligands.[3] Molecular weight determination revealed that **1** is monomeric in benzene: Found: 828 (2.25 wt%). Calcd for $C_{49}H_{44}CuP_3$: 789.4. Conductivity of **1** (Λ=5.75 Ω^{-1} cm^2 mol^{-1}) in acetone solution did not change significantly on addition of excess methyl iodide. This indicates that tdpme serves as a tridentate ligand, leaving no uncoordinated phosphine group expected to yield a phosphonium salt on addition of methyl iodide,[7] and that **1** has a tetrahedral structure as shown in Fig. 2.

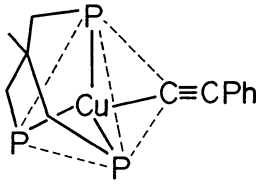

Fig. 2. Configuration of [Cu(C≡CPh)(tdpme)] **1**.

*Reactivities of [Cu(C≡CPh)(tdpme)] **1**.* Complex **1** reacted with *p*-cresol, methyl cyanoacetate, and methyl nitroacetate in THF to give new tdpme-copper complexes, [Cu(O–C_6H_4–CH_3-*p*)(tdpme)] **2**, [Cu{CH(CN)CO_2CH_3}(tdpme)] **3**, and [Cu{CH(NO_2)-CO_2CH_3}(tdpme)] **4**, respectively, which were characterized by elemental analyses, IR and ^{1}H-NMR spectroscopy. Some properties of the complexes are summarized together with those of **1** in Table 1.

$$[Cu(C{\equiv}CPh)(\text{tdpme})] + BH \xrightarrow[\text{THF}]{} [CuB(\text{tdpme})] + HC{\equiv}CPh$$

B: Conjugated base

Complexes **2**, **3**, and **4** show considerable thermal stability, and are moderately stable in air; they can be stored for a long time in dry nitrogen atmosphere. Their IR spectra show no ν(C≡C) band, which is found in the starting complex **1**.

A tetrahedral structure can be ascribed also to complex **2** in view of its ^{1}H-NMR showing only one methylene resonance for tdpme moiety.

The IR spectrum of **3** shows a ν(C≡N) band at 2155 cm^{-1} and a ν(C=O) band at 1610 cm^{-1}. The ^{1}H-NMR spectrum of **3** shows methine signal at a considerably high field (δ=0.64) and one methylene resonance at δ 2.42, indicating that the three methylene groups of tdpme moiety are equivalent. This indicates that **3** assumes a tetrahedral complex containing a copper-carbon σ-bond.

The conjugated base of methyl nitroacetate in **4** should be coordinated to copper either with methine carbon (structure A) or with an *aci*-nitro group (structure B), as shown in Fig. 3. In fact, [Cu(O_2NCH_2)-

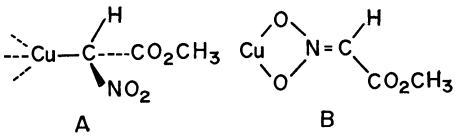

Fig. 3. Possible configurations of **4**.

(PPh_3)$_2$][15] and [Cu{O_2NCPh(NO_2)}(PPh_3)$_2$][16] were confirmed by X-ray analysis to be tetrahedral complexes, in which the nitro group is coordinated to copper with the *aci*-nitro form. Methylene protons in the *aci*-nitro group of [Cu(O_2NCH_2)(PPh_3)$_2$] show resonance at a very low field (δ=4.35).[15] On the other hand, the ^{1}H-NMR spectrum of **4** exhibits methine resonance at a considerably high field (δ=0.90), and only one methylene resonance at δ 2.38, similar to the respective one of **3**. This indicates that **4** has structure A, in which copper is coordinated with tdpme at three sites of phosphine groups. In order to confirm whether

TABLE 2. COMPARISON BETWEEN pK_a VALUE AND REACTIVITY

Compound	Reactivity of **1**	pK_a value	Ref.[a]
$C_6H_5C{\equiv}CH$	—	21	17
CH_3CN	No	25	17
$CH_2(CO_2CH_3)_2$	No	13.5	18
$CH_2(CN)_2$	Yes	11.2	17, 18
CH_3NO_2	No	10.2	17, 18
$NCCH_2CO_2CH_3$	Yes		
$O_2NCH_2CO_2CH_3$	Yes	5.8	18
$HO\text{-}C_6H_4\text{-}CH_3\text{-}p$	Yes	10.2	19

a) See references presented in the last part of this paper.

4 contains an uncoordinated phosphine group, conductivity of an acetone solution of **4** containing excess methyl iodide was measured. The experiment was unsuccessful owing to the immediate precipitation of a white solid , which was ascribed to [CuI(tdpme)][8] on the basis of elemental analysis and IR spectrum. Complex **4** seems to prefer structure A to B, owing to the chelating effect of the tridentate phosphine group which prevents the bidentate *aci*-nitro group from coordinating to copper. As for the IR spectrum of **4**, bands at 1440, 1620, and 1680 cm^{-1} were ascribed to $\nu_a(NO_2)$, $\nu_{as}(NO_2)$, and $\nu(C{=}O)$, respectively.

No reaction took place between **1** and other moderately active hydrogen compounds, *i.e.*, acetonitrile, dimethyl malonate, and nitromethane, even under refluxing conditions of THF. Malononitrile reacted with **1** to give yellow powder, which could not be isolated in a pure state.

As a whole, it appears that the reaction between **1** and active hydrogen compounds depends on the pK_a values of the latter[17-19] (Table 2). Complex **1** reacts with highly active hydrogen compounds having a pK_a value below 10, but not with less active hydrogen compounds with pK_a above 13. **1** shows fairly complicated reactivity towards the active hydrogen compounds with pK_a values in the range 10—13, while **1** reacts smoothly with *p*-cresol, a week Brönsted acid having a pK_a of 10.2. Such hydrogen activity is important for a similar exchange reaction with the phenylcopper(I)–triphenylphosphine system.[4]

Ligand Isotopic Exchange of Tris(acetylacetonato)germanium(IV) Perchlorate in Organic Solvents

Akira NAGASAWA and Kazuo SAITO*

Chemistry Department, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received December 8, 1977)

The ligand isotopic exchange between tris(acetylacetonato)germanium(IV) perchlorate and acetylacetone[^{14}C] has been studied in 1,1,2,2-tetrachloroethane (TCE), nitromethane (NM), and acetonitrile (AN), at 100—120 °C. In these solvents, the rate formula was $R=k[H_2O][complex]$; the concentrations of the complex, free ligand, and water in solution were in the ranges from 0.01 to 0.1 mol dm^{-3}. The activation enthalpies and entropies for the k's are 105, 98, and 90 kJ mol^{-1}; and −25, −53, and −69 J K^{-1} mol^{-1}, in TCE, NM, and AN, respectively. Influence of acid and base concentrations, and deuterium isotope effect on the rate in AN suggest that the rate controlling step of the exchange is governed by the ease of the proton transfer between the leaving and the incoming acac$^-$ in an intermediate.

Little information is collected concerning dynamic behavior of octahedral germanium(IV) compounds. We resolved tris(acetylacetonato)germanium(IV) [Ge(acac)$_3$]$^+$ and postulated an intramolecular mechanism for its racemization involving an intermediate with a unidentate acetylacetonate. The ligand isotopic exchange with free acetylacetone[^{14}C] (Hacac[^{14}C]) was much slower than the racemization, but the kinetics was left unknown.[1] This paper deals with kinetic studies of ligand isotopic exchange between [Ge(acac)$_3$]ClO$_4$ and Hacac[^{14}C] in dehydrated organic solvents at 100 to 120 °C. The mechanism is discussed with reference to the solvent effect, and compared with those of related reactions including the racemization.

Experimental

Materials. Tris(acetylacetonato)germanium(IV) Perchlorate: The complex was prepared by the reported procedure,[1] and recrystallized from acetonitrile (AN) by adding diethyl ether. Found: C, 38.58; H, 4.53%. Calcd for $C_{15}H_{21}O_{10}ClGe$: C, 38.38; H, 4.51%. The pattern of the absorption spectrum and the peak ($\tilde{\nu}$, 34700 cm^{-1}; ε, 35500 dm^2 mol^{-1}) in UV region coincided with those in the reference.

Acetylacetone: Commercially available Hacac was distilled under reduced pressure, dried with anhydrous calcium sulfate, and distilled at *ca.* 15 mmHg at 60 °C. The Hacac[^{14}C] was prepared by the Claisen condensation between acetone[^{14}C] (15 cm^3, 0.25 mCi) and ethyl acetate,[2] and distilled three times to yield ≈5 g of Hacac[^{14}C] with a specific activity ≈10 μCi g^{-1}. Acetylacetone[*methylene*-$^2H_2$] (Hacac[D]) was prepared by refluxing Hacac with deuterium oxide (D_2O) in dichloromethane, and fractionally distilled twice. The proton NMR spectrum indicated *ca.* 90% deuteration of methylene hydrogens. The purities of these reagents were checked by gas chromatography to be >99.99%.

Solvent for Kinetic Runs: Acetonitrile (AN) was dried by refluxing with diphosphorus pentaoxide (*ca.* 5 g for 1 dm^3) for *ca.* 3 h, and fractionally distilled at 81.6 °C. These procedures were repeated until ≲0.003 M (M=mol dm^{-3}) water remained on Karl Fischer titration. Nitromethane (NM) was distilled, frozen under a reduced pressure three times, dried with Molecular Sieve 4A Zeolite, and distilled at ≈15 mmHg. The product contained <10^{-2} M water, and ≈10^{-5} M nitroethane and nitropropanes. 1,1,2,2-Tetrachloroethane (TCE) was washed with concentrated sulfuric acid until the water layer remained colorless, and then with water, fractionally distilled at ≈15 mmHg at 60 °C in the dark, and aerated with dry air. 1,2-Dichloroethane (DCE) was washed successively with sodium hydroxide in water, dilute sulfuric acid, and water, and then fractionally distilled in the dark.

Other Reagents: Trichloroacetic acid was sublimed *in vacuo* at 60—70 °C. Trichloroacetic acid[^2H] (CCl_3COOD) was prepared by evaporating D_2O solution of trichloroacetic acid to dryness, and sublimed *in vacuo*. Pyridine was purified by recrystallizing pyridinium perchlorate, treating with solid potassium hydroxide, and distilling at 114—115 °C. Extra pure reagents of 2,6-lutidine and sodium perchlorate were used without further purification. Diethyl ether was dried over calcium chloride overnight, and distilled.

Kinetic Procedure. Ligand Isotopic Exchange: The solution of Hacac[^{14}C] (0.08 to 1 M) in a given solvent was prepared at least 48 h in advance to attain the keto-enol equilibrium. The complex solution (≈0.05 M) in the same solvent was mixed with the ligand solution at room temperature. Whenever required, given amounts of water and/or any other reagents were introduced and the final volume was adjusted to 10 cm^3. Several 1 to 2 cm^3 portions were sealed in Pyrex-glass tubes (10 cm in height and 0.8 cm in diameter) and placed in a thermostatted (±0.2 °C) silicone oil bath at 100—120 °C to let the exchange reaction start.

The ampoules were picked up one by one at proper time intervals and cooled in cold water for 1 min. The content of each ampoule was poured into diethyl ether (30—50 cm^3) and set aside for 30 min at *ca.* 10 °C. The crystallized complex was filtered off, washed with diethyl ether, and dried. It was dissolved in AN (3 to 10 mg in 3 cm^3). A one cm^3 portion was mixed with toluene containing *p*-terphenyl and *p*-bis(5-phenyl-2-oxazolyl)benzene to produce 15 cm^3 solution containing their 0.4 and 0.01%, respectively, and submitted to liquid scintillation counting. Another one cm^3 portion was diluted 100 to 500 fold with AN and the extinction was measured at 288 nm to find the concentration of the original solution in AN. The specific β-activity of the recovered complex, x, was known from these data.

The water content of the reaction mixture was determined by Karl Fischer titration. The UV absorption spectrum of the reaction mixture was recorded to find any change in composition during the kinetic runs.

Calculation of the Exchange Rate: The rate of isotopic exchange was calculated by the McKay formula,

$$R = -[3ab/(3a+b)][\ln(1-F)]/t, \quad (1)$$

where a and b are the concentrations of the complex and the free ligand, respectively, and t and F are the lapse of time and the extent of the reaction at time t, respectively. The F values were given by $(x_0-x_t)/(x_0-x_\infty)$, where the suffix denotes the time lapse from the initiation until the quenching of the exchange reaction.

Acetylacetone is present in tautomeric keto-enol equilibrium in TCE, NM, and AN. The percentages of the enolic form were estimated from the intensities of NMR signals for the enol and keto forms in deuterated solvents ([Hacac] = 10^{-2} M) to be 69, 50, and 58%, respectively at 110 °C. The rate of the keto-enol tautomerization was much greater (*ca.* 10^{-4} s^{-1}) than that of the exchange at >100 °C, and the *b* was taken as the gross concentration of free Hacac.[13]

Apparatuses. Hitachi 323 Spectrophotometer was used for recording the UV absorption spectra. The β-activity of ^{14}C was recorded with Nuclear Chicago Unilux II-A Liquid Scintillation Counter. Varian A-60 Spectrometer was employed for NMR spectroscopy.

Results

Ligand isotopic exchange was studied in acetonitrile, nitromethane, and TCE. The complex decomposed at >120 °C in TCE, whereas even at 100 °C in DCE.

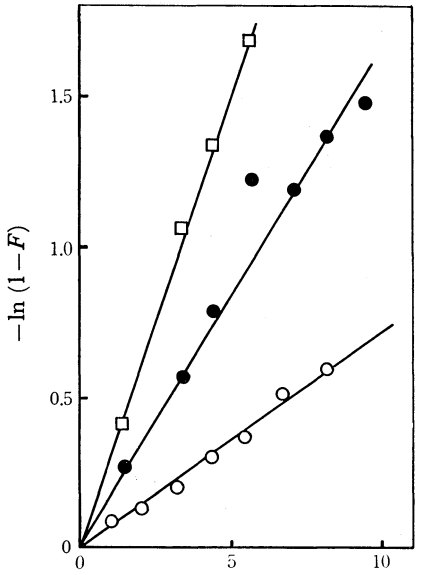

Fig. 1. McKay plot, $\ln(1-F)$ *vs.* *t*. The extent of reaction (*F*) was calculated from the specific activity of $[Ge(acac)_3]ClO_4$ in acetonitrile at 110.2 °C. Complex, 0.010 M; Hacac[^{14}C], 0.062 M; water, 0.013 M (○), 0.033 M (●), 0.047 M (□).

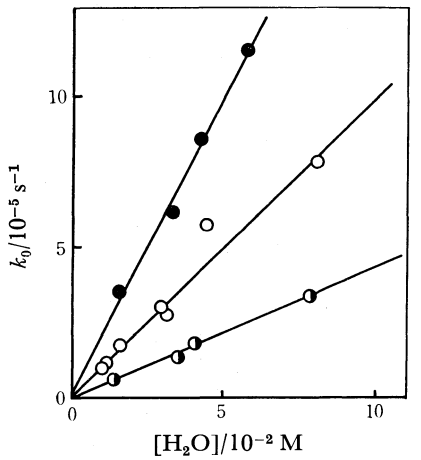

Fig. 2. Exchange rate constant k_0 *vs.* water content in acetonitrile, at 100.3 °C (◑), 110.2 °C (○), and 119.3 °C (●); [Hacac] ≈ 0.06 M, [complex] = 0.01 M.

General Aspect. McKay's *R* remained constant until *F* reached 0.7 (see Fig. 1) at 100—120 °C, and the UV absorption of the reaction mixture remained unchanged during these periods. Hence the following ligand exchange between the complex and the free ligand should take place exclusively.

$$[Ge(acac)_3]^+ + Hacac^* \rightleftharpoons [Ge(acac)_3{}^*]^+ + Hacac \quad (2)$$

The rate *R* was proportional to the complex concentration from 0.005 to 0.015 M, and the observed rate constant k_0 was calculated by the following equation:

$$R = k_0\,[complex], \quad (3)$$

while the free ligand concentration (0.03 to 0.09 M) gave very little influence, the plot of k_0 against water concentration (0.01 to 0.1 M) is linear as exemplified in Fig. 2 in AN, and the k_0 is expressed by

$$k_0 = k_x[H_2O]. \quad (4)$$

The k_x values in various solvents are given in Table 1. Ionic strength in acetonitrile solution (≤0.109 M, $NaClO_4$) gave very little influence on the rate at 110 °C.

Acid and Base Catalysis. Trichloroacetic acid enhanced the exchange in acetonitrile; also the separation-induced exchange became appreciable. The effect approached saturation when the acid concentration reached that of water (0.015 M) in the reaction mixture.

Pyridine and 2,6-lutidine caused change in UV absorption spectra of the reaction mixture in acetonitrile and gave precipitate after *ca.* 100 min at 110 °C even at a concentration lower than 0.01 M. A side reaction may have taken place. However, the original complex was partly recovered without decomposition to enable approximate measurement of its specific activity. The rate of exchange appeared to be smaller than in the absence of pyridine base.

Deuterium Isotope Effect. The rate of proton exchange between Hacac[^{14}C] and water is much greater than the ligand isotopic exchange rate of the complex. Hence the deuterium isotope effect should be reckoned as the gross influence of these protic species. Three kinetic runs were performed in solutions containing 0.010 M complex, 0.060 M Hacac, and 0.0060, 0.024, and 0.058 M water, the gross [H]/[D] ratios being 0.48, 0.60, and 0.71, respectively. The observed k_x's were smaller than those in the absence of excessive deuterium. Since the influence of proton and deuteron should be additive, the result was extrapolated to the purely deuterated system to find $k_{x(D)}$ 0.73 $M^{-1}\,s^{-1}$ at 110 °C. The gross $k_{x(H)}/k_{x(D)}$ ratio is therefore 1.4. Deuterated trichloroacetic acid also gave smaller rate than the ordinary trichloroacetic acid did.

Discussion

A plausible mechanism of the ligand exchange of $[Ge(acac)_3]^+$ is visualized in Fig. 3.

Catalytic Action of Water and Acid. If the solvent had contained no water, no ligand isotopic exchange

TABLE 1. RATE CONSTANTS OF LIGAND ISOTOPIC EXCHANGE OF $[Ge(acac)_3]ClO_4$[a)]

would have occured below 120 °C. Water in organic solvents can act as either a nucleophile or a proton donor of a moderate strength. It can also bring about indirect influence including change of permittivity of the bulk environment, and that of the degree of intermolecular association of the complex (*e.g.*, ion-pair formation with perchlorate). Since the ionic strength in acetonitrile gave very little effect on the exchange rate under the experimental conditions, intermolecular association should not give a dominant effect. Permittivity of the solvent can change with increase in water content, but neither this effect is important, because no exchange takes place in the absence of water in the given temperature range. Proton transfer from free Hacac to coordinated $acac^-$ is essential for the ligand exchange to take place, and proton donors such as protic acid and water can directly assist such a transfer. Acid as well as water accelerated the exchange, but bases did not. Catalytic activity of a protic acid seemed to saturate when the acid concentration reached a certain level. These observations as well as the deuterium isotope effect suggest that the water molecule serves as proton carrier, and that the proton transfer participates in the rate limiting step.[5)]

Reaction Mechanism. We postulated a plausible mechanism of racemization of $[Ge(acac)_3]^+$[1)]; *i.e.*, one of the Ge–O bonds of the original *Δ*-complex is broken with the aid of nucleophilic action of the solvent molecule to give an intermediate (II in Fig. 3, with a unidentate $acac^-$), which successively undergoes inversion to give *Λ*-isomer. The solvent-assisted break of Ge–O bond was reckoned as the rate limiting step.

The rate laws and the activation parameters of the present exchange differ considerably from those of the racemization(see Table 2). The racemization rate is insensitive to the water concentration, largely affected by the donor number[6)] of the solvent, and not

TABLE 2. RATE CONSTANTS AND ACTIVATION PARAMETERS OF RACEMIZATION AND LIGAND ISOTOPIC EXCHANGE OF $[Ge(acac)_3]ClO_4$ IN ORGANIC SOLVENTS

a) Relative permittivity at *ca.* 20 °C. b) Donor number in ref. 6. c) Rate$=k_r$[complex], where [complex]$\approx 10^{-3}$ M at 50 °C. d) Rate$=k_x[H_2O]$[complex], at 100 °C. e) k_2 in *rate*$=(k_1+k_2$[pyridine])[complex], in acetonitrile at 50 °C.

changed in the presence and the absence of excessive Hacac, while the exchange rate is sensitive to the water content, and the solvent effect is small as compared with that in the racemization. All these facts support that the ligand isotopic exchange has a different feature from that of the racemization.

The racemization equilibrium must have been readily reached at >100 °C where the isotopic exchange was observed. The solvent molecule in the sixth coordination site of intermediate II may be replaced by the free ligand, Hacac[^{14}C], to give intermediate III. Since the concentration of free Hacac overwhelms that of II, change in Hacac concentration would not affect the concentration of III. The solvent molecules, especially nitromethane and acetonitrile, can give stable second sphere coordination towards III, to make III more stable than II. Whenever originally coordinated acac$^-$ in III undergoes ring-closure to give I, no ligand exchange takes place. On the other hand, when proton is transferred from the incoming Hacac [^{14}C] to the originally coordinated acac$^-$, this is protonated and leaves the coordination site to result in ligand exchange; the deprotonated (acac[^{14}C])$^-$ undergoes ring-closure to restore $[Ge(acac[^{14}C])_3]^+$. The observed proton catalysis should operate in the proton transfer stage. The aprotic solvents used in this work can hardly assist the proton transfer, and the exchange is very slow in the absence of water or trichloroacetic acid, which assists the transfer. [Autoprotolysis constants (pK_i at 25 °C) of nitromethane and acetonitrile are 19.5 and 28.5, respectively.]

The activation enthalpies decrease and the activation entropies become more negative in the sequence 1,1,2,2-tetrachloroethane < nitromethane < acetonitrile, although the experimental errors remain rather large. The nucleophilicity of the solvent molecules (*e.g.*, Donor number) is well correlated with this sequence, which seems to reflect the ease with which the intermediate II is formed.

The large minus ΔS^* values (which are responsible for making the isotopic exchange slow) seem to reflect the steric difficulty with which the two unidentate moieties in III have their mutual orientations favorable for proton transfer. Especially in nitromethane and acetonitrile, these molecules in the second coordination sphere would prevent the tenure of favorable orientations to make ΔS^* values more negative.

The differences in ΔH^*, $\approx$10 kJ mol^{-1} regardless of the solvents, between the racemization and the isotopic exchange are significant beyond the experimental errors, and ΔH^*'s of the isotopic exchange are smaller than those of the racemization. This observation suggests that the activation enthalpies in a given solvent consist mostly of those for the formation of the intermediates II and III, *i.e.*, that for the break of one Ge–O bond. The smaller ΔH^*'s for isotopic exchange than those for racemization are explained by the larger stability of III than II, because Hacac is more nucleophilic than acetonitrile, nitromethane, and 1,1,2,2-tetrachloroethane,[7] to give stronger interaction at the sixth coordination site of the intermediate. The extent of the stabilization of III brought about by the substitution of Hacac for the solvent molecules in II's is smaller to one another for the three kinds of solvent. The differences in nucleophilicities between Hacac and the solvent molecules may be partly compensated by the stabilization coming from the second sphere coordination of the solvent molecules.

The donor number of water (18) is larger than those of the solvents (<14), and comparable with that of Hacac. The concentration of water is much lower than those of the sovents by a factor $\approx 10^2$, and water may be unable to assist the formation of intermediate II. However, the activity of water should be large enough in the vicinity of III, to assist the proton transfer. β-Diketones have large affinity with water; even crystalline hydrates are known with hexafluoroacetylacetone. Water can have loose association with free Hacac in these solvents. Hence, water molecules can be present in the neighborhood of III when free Hacac interacts with II to give III, and facilitate the proton transfer between two unidentate acac$^-$ ligands.

Comparison with Related Compounds. Silicon(IV), tin(IV), and titanium(IV), the other members of Family IV of the periodic table also give octahedral complexes of the type $[M(\beta\text{-dik})_3]^+$ and *cis*-[M(β-

$dik)_2X_2]$ with various β-diketones in enolate form. Since no ligand field effect can be expected for these d^0 and d^{10} ions, the contribution of the ionic radius should be important in interpreting the different kinetic behavior of these complexes. Silicon(IV)[8] and germanium(IV)[1] complexes of the type $[M(\beta\text{-dik})_3]^+$ are inert towards ligand exchange and hydrolysis. Their racemization was measured in the temperature range 30 to 70 °C, and the mechanism was claimed to be intramolecular involving a unidentate β-diketonate. Their ligand isotopic exchange is measurable at ≥ 100 °C, and the unidentate ligand must resist against break of the remaining bond. The central metal ion possesses a high charge, +4, and the partial charge separation caused by break of one M–O bond on unidentate formation will increase the effective charge of M(IV) furt er to make the remaining bond stronger.

Corresponding tin V)[9] and titanium(IV)[10] complexes are much more labile and their ligand isotopic exchange was measured only below −10 °C. In both cases water seems to play an important part in the rate determining step, presumably as a nucleophile. Particularly the tin(IV) complex gave a partially hydrated product $[Sn(OH)(H_2O)(acac)_2]ClO_4$, which was reckoned as a common intermediate for the hydrolysis and the isotopic exchange. Tin(IV) with a large ionic radius must be more readily subject to the nucleophilic attack of water even at a low temperature to result in rapid substitutions. Water acts as a proton carrier for germanium(IV) with a smaller ionic radius, (*loc. cit.*); overwhelming amount of donor solvent molecules can assist the break of one Ge–O bond only at a high temperature. Similar consideration was applied to octahedral complexes of aluminium, gallium, and indium, $[M(\beta\text{-dik})_3]^0$.[11]

Intramolecular site exchange process was observed by dynamic NMR technique in *cis*-$[M(\beta\text{-dik})_2X_2]^0$ complexes of Family IV metal ions.[12] There seems to be remarkable difference in the rate and in the activation parameters among these complexes. In the complexes of titanium(IV),[13] these values are centered around in the following ranges: rate constant k at 25 °C, 10^1—10^3 s^{-1}; Arrhenius activation energy E_A, 25—60 kJ mol^{-1}; activation entropy ΔS^*, −10—−150 J K^{-1} mol^{-1}. The tin(IV) complexes have the values: k, 10^{-1}—10^1 s^{-1}; E_A, 50—70 kJ mol^{-1}; ΔS^*, −40—−60 J K^{-1} mol^{-1}.[14] On the other hand the germanium(IV) complex $[Ge(dpm)_2X_2]$ (dpm=2,2,6,6-tetramethyl-3,5-heptanedionate, X=Cl, Br, and I) rearranges intramolecularly with $k \approx 10^{-6}$ s^{-1}, $E_A \approx 105$ kJ mol^{-1} and $\Delta S^* \approx 0$ J K^{-1} mol^{-1}.[15] These observations are very similar to those in the intermolecular ligand exchange and hydrolysis of $[M(\beta\text{-dik})_3]^+$ (although the total charges of the complexes are different) suggesting significant influence of the radius of the central ion.

The present octahedral germanium(IV) complex is as inert as cobalt(III) and chromium(III) complexes, and should be included in the group of "inert complex." The source of such an inertness seems to consist in, at least partly, the stability of the Ge–O bond between germanium(IV) and unidentate $acac^-$.

Flameless Atomic Fluorescence Spectrometry of Mercury by Dispersive and Nondispersive Systems in Combination with Cold-vapor Technique

Taketoshi NAKAHARA,* Toshiaki TANAKA, and Sôichirô MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-umemachi, Sakai 591

(Received December 14, 1977)

An atomic fluorescence spectrometer with dispersive and nondispersive systems has been designed and constructed. A flameless atomic fluorescence spectrometric method with the newly constructed spectrometer is described for the determination of mercury at the nanogram level. Mercury is reduced by tin(II) chloride and released from solution by a stream of argon into a quartz fluorescence cell. The fluorescence signal is measured by dispersive and nondispersive systems. Linear analytical working curves covering the mass range of mercury from the detection limits to approximately 10 and 1 μg have been established with dispersive and nondispersive systems, respectively. With the nondispersive system a detection limit of 0.003 ppb or 0.05 ng of mercury could readily be obtained. The present method was satisfactorily applied to the determination of mercury in wastewater samples.

As with atomic absorption spectrometry, atomic fluorescence spectrometry of mercury has been carried out both with flame and flameless vaporization(atomization) techniques. Atomic fluorescence spectrometric determination has some advantages over atomic absorption spectrometry, for example, a wider dynamic range not limited by the Lambert-Beer law, less susceptibility to interferences from spurious vapors, and a much greater possibility for simultaneous multi-element determination.

Mercury determination using atomic fluorescence spectrometry have been described by Winefordner and co-workers,[1-6] West and co-workers,[7-10] Vickers and co-workers,[11-13] Larkins,[14] and Vitkun *et al.*[15] using a flame as an atom reservoir. Muscat and co-workers,[16,17] Thompson and co-workers,[18,19] Shimomura and Hiroto,[20] Hawley and Ingle,[21] Cavalli and Rossi,[22] and Caupeil *et al.*[23] used a flameless cold-vapor technique. In the latter instances, the mercury reduced from solution has been excited in a fluorescence cell(quartz or quartz-windowed);[16,17,21] some workers[18-20,22,23] have eliminated the cell completely and vented the mercury vapor into the atmosphere where fluorescence excitation occured. Some authors[24,25] have used a flameless method of pulsed thermal atomization. For fluorescence measurements, a nondispersive system for atomic fluorescence spectrometry has certain advantages over a dispersive system such as greater energy throughput, simpler instrumentation, and simultaneous measurement of multiple lines of the analyte. In the case of flameless methods for mercury a nondispersive system might be preferable to a dispersive system, since mercury is mostly separated from the interfering matrix in the solution prior to fluorescence measurements. However a satisfactory detection limit for a nondispersive system has not always been substantiated in the literature concerning mercury.[1-25] Some authors[19,22,23] have reported the detection limits of 0.02—0.05 ng of mercury by using a cold-vapor technique. Until recently, the best reported detection limits[21] were 0.005 ppb or 0.005 ng of mercury, obtained with a dispersive system and a cold-vapor technique.

The present authors have designed and constructed an atomic fluorescence spectrophotometer which can be used with both dispersive and nondispersive systems. This paper describes the performance of the newly constructed atomic fluorescence spectrometer with which the atomic fluorescence of mercury has been measured using a cold-vapor technique. The present method has been successfully applied to the determination of mercury at the ppb level in wastewater samples.

Experimental

Chemicals. The mercury stock solution of Hg(II), 1000 ppm, was prepared from analytical-reagent grade $HgCl_2$, nitric acid and distilled water. Each mercury solution was prepared just before use from a 10-ppm solution of mercury which was prepared daily from the stock solution. The tin(II) chloride solution was prepared by dissolving tin(II) chloride (10 g) in hydrochloric acid(50 ml) and then by diluting to 100 ml with distilled water. The tin(II) chloride solution was bubbled with mercury-free argon, nitrogen or air to remove any mercury contamination. Magnesium perchlorate was used for drying the mercury vapor produced and granular activated charcoal for removing any trace amounts of mercury from argon, nitrogen or air. All the chemicals used in this study were obtained from Wakô

Recorder	QPD_{54}, Hitachi
Flow regulator	LAS-S301, Nippon Tokushu Keiki
Reduction vessel	Volume 30 ml, Kinoshita

Pure Chemicals Co.

Apparatus. The block diagram of the newly constructed atomic fluorescence apparatus for a nondispersive system is shown in Fig. 1. The specific components employed are summarized in Table 1. The right half of Fig. 1 shows an atomic fluorescence spectrometer with a fluorescence cell. For a dispersive system the photomultiplier and its housing in Fig. 1 are replaced by the monochromator equipped with another type of photomultiplier.

Fluorescence Cell. Two fluorescence cells, being similar to that previously reported,[16] were made from transparent quartz. The square cells have 1.2×3- and 2.5×3-cm^2 quartz windows on two adjacent sides. The other two-adjacent sides of the cells were blackened by lusterless paint. The fluorescence cell was heated to approximately 120 °C by a ribbon heater to prevent the deposition of water onto the inner surface of the cell. For inlet and outlet ports, the glass tubing of 6 mm inside diameter was connected to the top and bottom of the cell. The connections between the fluorescence cell, magnesium perchlorate drying tube, reduction vessel, and activated charcoal bottles(Fig. 1) were made from silicon rubber tubing of 5 mm inside diameter.

Preparation of Mercury Electrodeless Discharge Lamps. A microwave-excited electrodeless discharge lamp(EDL) is known to be one of the most useful spectral line sources for atomic fluorescence spectrometry.[26-29] The authors prepared a number of Hg-EDLs using a vacuum line as illustrated in Fig. 2. The EDL-blank was made from transparent quartz ("suprasil") tubing of 8-mm internal diameter and 1-mm wall thickness. A 15-cm length of quartz tubing was sealed at one end and a constriction made between 1 and 7 cm from the end to give a tube from 1 to 7 cm in length. The tubing, the other end of which had a 12/20 mm ground glass socket, was attached to one of the outlets on the vacuum line and pumped down to a pressure of approximately 9.3×10^{-2} Pa. Argon was then introduced into the system and it was again pumped down to a similar pressure. The quartz tube(EDL-blank) was then heated to just below its melting point for about 5 min, during which time argon was again introduced into the system and pumped out. This procedure was repeated three times. The tube was allowed to cool under vacuum and then removed from the line. Between 5 and 20 mg of mercury metal was introduced into the tube, which was then reconnected to the vacuum line. The tube was evacuated as before, flushed out with argon, and re-evacuated to a pressure of about 9.3×10^{-2} Pa. Very gentle heating was then applied to the tubing to drive off any moisture or occluded gases in the mercury. The system was flushed twice more with argon and finally a given pressure was introduced into the vacuum system and the constriction sealed by an

Table 2. Optimum experimental conditions

Light source	Hg electrodeless discharge lamp
Microwave power	19 W (incident power, 25 W; reflected power, 6 W)
RC time constant	1.0 s
High voltage for photomultiplier	800 V
Load resistor	470 kΩ
Modulation frequency	90 Hz (for nondispersive system), 240 Hz (for dispersive system)
Fluorescence cell	$25 \times 25 \times 30$ mm^3
Diaphragms	
For cell	20×20 mm^2
For detection system	8×15 mm^2 (for dispersive system), 2×5 mm^2 (nondispersive system)
Carrier gas	Argon
Flow rate	1.0 l min^{-1}
Drying tube	9 cm long × 3 cm diameter
Volume of sample	20 ml
Volume of reductant	1.0 ml (10% $SnCl_2$-6 M HCl)

oxygen-propane hand torch.

Initiation of the discharge in the resonant cavity was achieved with a simple Tesla coil vacuum tester. The most useful Hg-EDL employed throughout this study is shown in Table 1.

General Procedure. A fixed volume(20 ml) of a mercury solution was introduced into the reduction vessel where the ionic mercury was reduced to mercury vapor by tin(II) chloride. The mercury vapor was then quickly carried by a stream of mercury-free argon, nitrogen or air through a glass tube with a spherically sintered glass end, which was connected to the fluorescence cell *via* a magnesium perchlorate drying tube (Fig. 1). There, a fluorescence signal was instantaneously generated. The height of the recorded peak was a measure of the mercury concentration.

Table 2 shows the optimum oprating conditions for the flameless atomic fluorescence spectrometry of mercury with both the dispersive and nondispersive systems.

Results and Discussion

Effect of Diaphragms in the Optics. The constant background level was mainly attributed to direct specular reflection and scattering of light from the mercury lamp into the fluorescence measuring entry aperture. This background was carefully minimized by placing diaphragms in front of two adjacent windows of the fluorescence cell and the entrance slit of the monochromator for the dispersive system and the photomultiplier housing for the nondispersive system. For maximum sensitivity it was essential to minimize the background level. In this study a number of rectangular or square diaphragms were used; at the same time the fluorescence signal and the background level were measured with each diaphragm to maximize the signal-to-noise ratio for the mercury determination. The optimum sizes of the diaphragms employed are shown in Table 2.

Effect of Modulation Frequencies of Source Radiation. In this study two types of light choppers were used for modulation of the source radiation; one was for 14.4 and 28.8 Hz and the other for 90, 150, 240, 480, and 960 Hz. The former had a synchronous motor (Japan Servo Co., Type HM6P2D1) of 30 Hz with a 1/12.5 reduction gear (Japan Servo Co., Type 6G12.5 H). The latter had a synchoronous motor (Yokogawa Sertec Co., Type SM-D3N) of 30 Hz. The relationships between relative fluorescence intensities and modulation frequencies were obtained for both the dispersive and the nondispersive systems and are shown in Table 3. The differences in relative fluorescence intensities may be attributed to the frequency characteristics of the photomultipliers and to the precision of the sectors, especially at the higher frequencies. The sectors used in the light choppers were all handmade. The optimum frequencies were 90 and 240 Hz for the dispersive and the nondispersive systems, respectively.

Table 3. Effect of modulation frequencies on fluorescence signals

Frequency (Hz)	Relative fluorescence signal[a]	
	Nondispersive system	Dispersive system
14.4	0.91	0.75
28.8	0.77	0.55
90	1.00	0.79
150	0.84	0.69
240	0.84	1.00
480	0.70	0.69
960	0.11	0.05

Carrier gas[a]	Relative fluorescence signal[b]	
	Dispersive system	Nondispersive system
Air	1.00	1.00
Nitrogen	5.67	5.57
Argon	20.3	19.5

a) Flow rate of 1.0 l min^{-1}. b) Mercury of 10 ng.

Effect of Carrier Gas. Fluorescence measurements were made using argon, nitrogen, and air as the carrier gas. The enhancement of the fluorescence signals obtained by use of argon, compared with air, was approximately greater by a factor of 20, as shown in Table 4. Argon was the most useful carrier gas for fluorescence measurements taking advantage of its small cross section for the quenching of fluorescence, consequently argon was used throughout this study unless otherwise stated. The effect of carrier gas flow rates was also investigated. The flow rates between 0.4 and 1.4 l min^{-1} did not adversely affect the fluorescence measurements. However a decrease in flow rates caused an increase in half-widths of the fluorescence peaks. An optimum flow rate of 1.0 l min^{-1} was chosen in the following study.

Effect of Microwave Power on Source Radiation and Fluorescence Intensities. In atomic fluorescence spectrometry it is theoretically known that the fluo-

10000	0.77	0.80	0.80

a) With the nondispersive system for mercury of 20 ng.

rescence intensity is directly proportional to the source radiation intensity.[30-32] The characteristics of the Hg-EDLs prepared were studied in terms of emission intensities and fluorescence signals at various microwave powers. The results obtained are shown in Fig. 3. The microwave power is a net power for discharge, that is, the reflected power is subtracted from the incident power. The optimum power for the Hg-EDL was 19 W; *i.e.*, an incident power of 25 W and a reflected power of 6 W. The Hg-EDL described in Table 1 gave a stable intensity after a warming-up time of *ca.* 30 min during this work and could be used for further experiments.

Quenching of Organic Solvents. The excited atoms are subject to radiationless deactivation due to bimolecular collision with the other species present in the atom reservoir, resulting in a decrease of fluorescence signal.[33] In this study the effect of some organic solvents, *e.g.*, acetone, benzene, and ethanol, was examined in their range of 500 to 10000 μg at a constant mercury level of 20 ng. The results obtained are shown in Table 5. The decrease in fluorescence signals may be attributed mainly to the quenching of fluorescence. The organic solvents(compounds) of more than 1000 μg are thus able to decrease the fluorescence signals, and so the effect of such quenching by organic solvents of higher vapor pressures should be corrected for in the determination of mercury in practical samples.

a) $S/N=2$.

Analytical Working Curves, Sensitivity, and Presicion. Analytical working curves were obtained by using mercury standard solutions freshly prepared from a 1000-ppm mercury stock solution with both dispersive (at 253.7 nm) and nondispersive systems. A mercury pen lamp was used instead of Hg-EDL because of the much easier operation of the pen lamp. Two typical working curves obtained under the optimum conditions are shown in Fig. 4. The detection limits, expressed as the mass or concentration which produces a fluorescence signal equal to twice the noise level ($S/N=2$), are showed in Table 6. The analytical working curves were linear from the detection limits to approximately 10 and 1 μg of mercury with dispersive and nondispersive systems, respectively. The relative standard deviations for 10 measurements are shown in parentheses for the individual plots in Fig. 4. A blank value was negligible compared with instrumental limitations. The difference in sensitivities between with the Hg-EDL and with the mercury pen

a) Sample taken: 20 ml.

lamp may be explained by the fact that the Hg 253.7-nm line of the former was more intensive by a factor of 1.5 than that of the latter and that in atomic absorption measurements at 253.7 nm the sensitivity for 1% absorption with the former was higher by a factor of 1.4 than that with the latter.

Application of the Present Method to the Determination of Mercury in Wastewaters. The present method was applied to the determination of traces of mercury in wastewaters which were taken at the inlet of the Wastewater Treatment Facility of the University of Osaka Prefecture. The more sensitive nondispersive atomic fluorescence measurements were made using a mercury electrodeless discharge lamp and argon as an excitation source and carrier gas, respectively, under the optimum conditions as is shown in Table 2. The samples were acidified with a few drops of high-purity nitric acid. For atomic absorption spectrometry a quartz absorption cell of 1.8 cm internal diameter and 20 cm length was used as an atom reservoir instead of a fluorescence cell. The procedures for both methods were the same as already mentioned. The results are shown in Table 7. All the analytical results were obtained by referring to each calibration graph and 7 determinations taken and averaged for individual samples. The organic solvents(substances), being soluble in hexane, in the samples were not so much that they produced quenching of fluorescence in the measurements. The results by the present method are in good agreement with those by flameless atomic absorption spectrometry.

Conclusion

The present nondispersive and dispersive atomic fluorescence spectrometer which has been constructed has proved to be sensitive and reliable for the determination of trace amounts of mercury. The detection limits obtained with the nondispersive system were comparable with those obtained by recent authors.[19,21-23] The present detection limits would be improved by decreasing the scattering and reflection of light from the excitation souce into the measuring aperture and by developing the efficiency in light-gathering of the mercury lamp and the fluoresence of mercury vapor. It was impossible to measure the 184.9-nm mercury line of resonance fluoresence with the dispersive system due to appreciable atmospheric absorption at this wavelength. The present system is useful for the determination of traces of mercury in water samples.

Reactions of Bis(acetylacetonato)oxovanadium(IV) with Phenol and Its *para*-Substituted Derivatives

Hiroshi TAGUCHI, Kiyoshi ISOBE, Yukio NAKAMURA,* and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received December 16, 1977)

Bis(acetylacetonato)oxovanadium(IV) reacts with phenol or its *para*-substituted derivatives in methanol, affording stable adducts with the composition of $VO(acac)_2(p\text{-}XC_6H_4OH)$, where X=H, NO_2, CHO, COOH, Cl, or CH_3. The magnetic and spectral data reveal that these are vanadium(IV) complexes containing the phenol as a neutral ligand. They show an unusually low $\nu(V{=}O)$ frequency of ≈ 900 cm^{-1} as compared with the value of 1000 cm^{-1} for the parent complex, and are presumed to have a polymeric structure with an infinite chain of V=O···V=O···. The phenol is connected by a hydrogen bond to one oxygen atom of an acetylacetonate ligand. The behavior of the complex in solution is also discussed. The addition of 1,10-phenanthroline or 2,2′-bipyridine to a reaction mixture of $VO(acac)_2$ and nitrophenols results in phenolato complexes $VO(OC_6H_{5-n}X_n)(acac)$(phen or bpy), where $X=NO_2$ and $n=1$, 2, or 3. Two isomers of $VO(OC_6H_2(NO_2)_3)(acac)(bpy)$ are isolated and characterized.

Acetylacetone usually acts as a monoionic bidentate ligand in complexes with a variety of metal ions.[1] In recent years there have been reported several metal complexes which contain the acetylacetone molecule as a neutral ligand.[2] As one of the preparative methods, the reaction of the enolate chelates with dry hydrogen bromide was effective in obtaining $CrBr_2(acac)(acacH)$, $MnBr_2(acacH)_2$, $CoBr_2(acacH)$, and $NiBr_2(acacH)_2$.[2a] With the aim of extending the method to the preparation of similar oxovanadium(IV) complexes, the reactions of bis(acetylacetonato)oxovanadium(IV), $VO(acac)_2$, with phenol and its derivatives have now been examined. Although their acidities are appreciably different, neither phenol nor *p*-nitrophenol, afforded the desired complexes such as VO(acac)(acacH)(phenolate), but produced molecular adducts instead.

It is well known that the square pyramidal $VO(acac)_2$ forms 1:1 adducts in solution with a variety of bases, filling the sixth coordination site,[3] but little is known as to the interaction with acids. This paper will report on the phenol adducts and the phenolato complexes produced by these reactions.

Experimental

Bis(acetylacetonato)oxovanadium(IV) was prepared according to the method reported by Rowe and Jones.[4] Acetylacetone and methanol were distilled before use. Dichloromethane and diethyl ether were also distilled over phosphorus pentoxide and metallic sodium respectively. Commercially available phenols, 1,10-phenanthroline, and 2,2′-bipyridine were used without further purification.

Reactions of $VO(acac)_2$ with the Phenols in Methanol: Preparation of the $VO(acac)_2$(p-X-C_6H_4OH) Adducts (X=H, NO_2, CHO, COOH, Cl, or CH_3). To a solution of $VO(acac)_2$(1 g, 3.8 mmol) in methanol (30 ml) was added a methanol solution (10 ml) containing an equimolar amount of phenol or its *para*-substituted derivatives, and the mixture was kept at 70 °C for about 1 h in order to vaporize the solvent slowly. The concentrated dark brown mixture (*ca.* 5 ml) was then cooled to room temperature to deposit reddish brown needles. The yields and analytical data are summarized in Table 1.

Preparation of the Phenolato Complexes $VO(OC_6H_{5-n}X_n)(acac)$(phen or bpy) (X=NO_2; n=1, 2, or 3). To a solution of $VO(acac)_2$(1 g, 3.8 mmol) in methanol (30 ml) was added a methanol solution (10 ml) containing an equimolar amount of 4-nitro-, 2,4-dinitro- or 2,4,6-trinitrophenol, after which the mixture was kept at 70 °C in order to vaporize the solvent slowly. The resulting dark brown mixture (*ca.* 5 ml) was cooled to 0 °C. The addition of a methanol solution ($\approx$5 ml) containing an equimolar amount of a bidentate nitrogen base, phen or bpy, gave a crystalline product. The picrato complexes were also deposited from the dichloromethane solution of the 4-nitrophenolato complex containing an excess of picric acid when the solution stood at room temperature for a few hours. Two kinds of products, yellow and yellow-green, with the same composition of $VO(OC_6H_2(NO_2)_3)(acac)(bpy)$ were obtained by these alternative routes. The phenolato complexes were all stable in air. The analytical data and some physical properties are listed in Table 2.

Measurements. The absorption spectra in solution and the reflectance spectra were obtained using a Hitachi EPS-3T recording spectrophotometer. The IR spectra of solid specimens were measured by means of JASCO IR-E (4000—700 cm^{-1}) and Hitachi EPI-L (700—200 cm^{-1}) infrared spectrophotometers.

The electric conductance of 10^{-3} M solutions of the phenolato complexes in methanol was measured at 25 °C by using a Yanagimoto-type MY conductivity apparatus. Tetraethylammonium iodide was used as the standard of the uni-univalent electrolytes. The molecular weight was determined by means of vapor-pressure osmometry in a dichloromethane solution [(1—2)$\times 10^{-2}$M] with an apparatus manufactured by Knauer, Berlin, Germany.

The magnetic susceptibility was measured at room temperature on a Shimadzu automatically recording magnetic balance by the Faraday method. Mercury(II) tetraisothiocyanatocobaltate(II) was used as the reference.

Results and Discussion

Recently Aly[5] examined the reactions of neutral acetylacetonato complexes of Zn(II), Ni(II), Co(II), Al(III), and Fe(III) with nitrophenols in a refluxing mixture (1:1 by volume) of benzene and ethanol. In most of the reactions with 2,4,6-trinitro- and 2,4-dinitrophenols, cationic complexes of the $[M(acac)_n(H_2O)_m]$(nitrophenolate)type were obtained, although 4-nitrophenol did not react. On the contrary, the neutral adducts $VO(acac)_2(p\text{-}X\text{-}C_6H_4OH)$ are the only products in the reactions of $VO(acac)_2$ with phenol and its *para*-substituted derivatives in methanol, in spite of the

widely different acidities of the phenols. Moreover, 2,4-dinitro- and 2,4,6-trinitrophenols do not react with $VO(acac)_2$ under the same reaction conditions. 2,2′-Bipyridine and 1,10-phenanthroline, however, induce reactions with the nitrophenols, resulting in the phenolato complexes $VO(X_nC_6H_{5-n}O)(acac)$(phen or bpy) ($X=NO_2$; $n=1$, 2 or 3).

The Phenol Adducts $VO(acac)_2$(p-X-C_6H_4OH). The magnetic, spectral, and molecular-weight data of the $VO(acac)_2(p\text{-}X\text{-}C_6H_4OH)$ complexes are shown in Table 3. The observed magnetic moments correspond to those of the vanadium(IV) state.

A crystal of $VO(acac)_2$ consists of discrete molecules of a square-pyramidal structure, with the vanadium atom near its center of gravity.[6] On the contrary, the present 4-nitrophenol adduct was disclosed by preliminary X-ray analysis[7] to have a polymeric structure of an infinite chain of square-pyramidal molecules connected by V=O···V=O··· bonds, as is depicted in Fig. 1. The phenol molecule is connected to one oxygen atom of an acetylacetonate ligand *via* the hydrogen bond with the OH···O distance of 2.68 Å. Our attempts to isolate the 1:1 adducts of $VO(acac)_2$ with anisole and sodium phenolate were unsuccessful. Thus, the presence of the phenolic hydrogen atom might be essential for making such a 1:1 adduct bearing a polymeric chain.

The ν(V=O) band of $VO(acac)_2$ appears at 1000 cm^{-1}, but the frequency decreases on adduct formation.[3] Caira *et al.*[8] reported that the ligation of a substituted pyridine to vanadium at the position cis to the oxo ligand lowers the ν(V=O) frequency by 42±4 cm^{-1}, while the trans ligation by 29±4 cm^{-1}. As may be seen in Table 3, the observed ν(V=O) frequencies for the present compounds are too low to be taken as those for simple phenol adducts. Such a low ν(V=O) frequency is characteristic of the oxovanadium(IV) complex bearing V=O···V=O··· bonds. For example, bis(trifluoroacetylacetonato)- and bis(thenoyltrifluoroacetonato)oxovanadium(IV) complexes display the ν(V=O) band at 1015 and 1012 cm^{-1} in dichloromethane, but at 932 and 900 cm^{-1} in Nujol, respectively, and so may be presumed to have the polymeric structure[9] in a solid. A similar polymeric structure has been

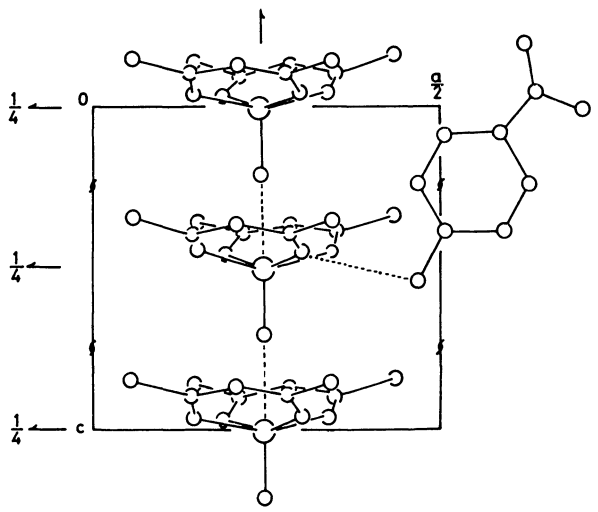

Fig. 1. The structure of $VO(acac)_2(p\text{-}NO_2C_6H_4OH)$ (from Ref. 7).

established by the X-ray analysis for (*N,N'*-disalicylidene-1,3-propanediaminato)oxovanadium(IV), VO(sal)$_2$tn,[10] the ν(V=O) vibration of which appears at 854 cm^{-1} in a solid.

We may now assign the new band at 280 cm^{-1}, which is not involved in the spectra of the parent complex and the free phenol, to the stretch of the bridging V···O linkage in the polymeric structure, according to the literature.[9] On the basis of the similarity of the IR spectra, the other adducts seem also to have an analogous chain structure. The anomalous orange-brown color of these complexes also supports the chain structure.[10–12]

It is worth noting that the order of each V=O bond length in $VO(acac)_2$ (1.56 Å, Ref. 6), $VO(acac)_2(p\text{-}NO_2C_6H_4OH)$ (1.60 Å, Ref. 7), and VO(sal)$_2$tn (1.633 Å, Ref. 10) is reflected in the ν(V=O) frequencies: 1000, 910, and 854 cm^{-1} in series. The reverse order of the V···O distance in $VO(acac)_2(p\text{-}NO_2C_6H_4OH)$ (2.32 Å) and VO(sal)$_2$tn (2.213 Å) is also reasonable.

The parent complex, $VO(acac)_2$, exhibits two d-d absorption maxima in non-coordinating media at 15000 and 16800 cm^{-1}, with a shoulder at 11500 cm^{-1}; those maxima are shifted to around 13000 and 17000 cm^{-1} in coordinating media.[13] As may be seen in Table 3, the reflectance spectra of the present phenol adducts have distinct maxima at around 13000 and 18000 cm^{-1}, indicating the formation of hexa-coordinate complexes. This is compatible with the polymeric structure discussed above. In dichloromethane, however, these two maxima for, *e.g.*, the 4-nitrophenol adduct are observed at 14700 and 16800 cm^{-1}. These shifts imply the V···O bond cleavage and the release of the phenol molecule, resulting in monomeric penta-coordinate species, even in such a non-coordinating medium. In methanol, these maxima revert again to 12700 and 17200 cm^{-1} due to the formation of the hexa-coordinate species by the ligation of a solvent molecule.

Such a dissociation of the adduct in solution is also indicated by the molecular-weight and IR data. The molecular weight determined in dichloromethane at 25 °C (Table 3) is close to half the value calculated for

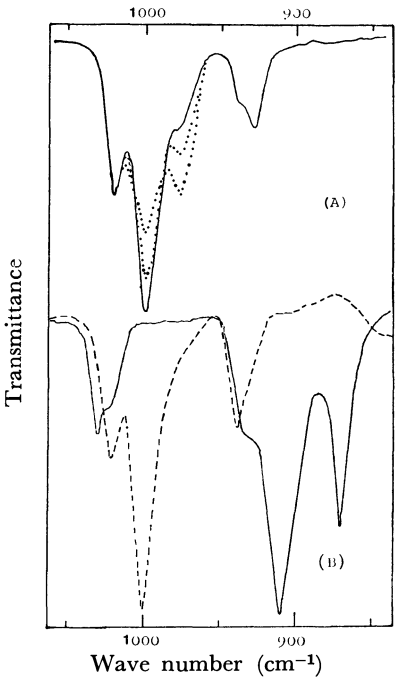

Fig. 2. IR spectra in CH_2Cl_2 (A) and in Nujol (B): $VO(acac)_2(p\text{-}NO_2C_6H_4OH)$ (——), $VO(acac)_2(p\text{-}NO_2C_6H_4OH)$ + $p\text{-}NO_2C_6H_4OH$ (·····), and $VO(acac)_2$ (----).

the monomeric adduct, revealing the extensive liberation of the phenol in solution in addition to the V···O bond cleavage. The IR spectrum of the 4-nitrophenol adduct in dichloromethane is quite different from that in Nujol and nearly coincides with that of $VO(acac)_2$ (Fig. 2), in accordance with the dissociation scheme noted before. If successive portions of 4-nitrophenol are added to the solution, the shoulder at 980 cm^{-1} grows gradually to a new absorption band at the expense of the 1000 cm^{-1} band. According to the assignment by Selbin *et al.*,[14] the new band can be assigned to the ν(V=O) vibration of the phenol adduct, in which the site trans to the exo ligand of $VO(acac)_2$ is occupied by the phenol molecule.

In the case of β-diketonato complexes, the driving force for the V=O···V=O stacking has been attributed mainly to the inductive effect of electron-withdrawing groups introduced in the parent acetylacetonate ligand.[9] The present case, however, involves only $VO(acac)_2$, in which the β-diketonate ligand does not bear any substituent exerting an electron-withdrawing effect on the metal acidity. It is not clear how the hydrogen bonding between the phenol and an acetylacetonate oxygen can exert an electronic and/or steric effect to make possible the V=O···V=O stacking in crystals.

The Phenolato Complexes $VO(OC_6H_{5-n}X_n)(acac)(phen$ or bpy) ($X=NO_2$; $n=1$, 2, or 3). The magnetic, spectral, molecular-weight, and conductance data of the phenolato complexes are shown in Table 4. The observed magnetic moments correspond to the d^1 spin state of the vanadium ion, indicating that no redox process of vanadium occurs during these reactions.

Caira *et al.*[8] examined the IR spectra of the substituted pyridine adducts $VO(acac)_2L$, as has been de-

Table 4. The magnetic, spectral, mol wt,[a] and conductance data of the $VO(OC_6H_{5-n}X_n)(acac)L$ complexes

$X_nC_6H_{5-n}O^-$	L	Magnetic moment / B. M.	ν(V=O) / cm^{-1} (in Nujol)	Visible spectra in CH_2Cl_2, ν_{max} / 10^3 cm^{-1}		Mol wt in CH_2Cl_2	Molar conductance in CH_3OH / ohm^{-1} cm^2 mol^{-1}

scribed previously. For the *cis* configuration, the ν(V=O) frequency showed no appreciable dependence upon the electronic nature of the pyridine substituent, whereas for the *trans* one the electron release by the substituent caused a reduction in the frequency. All of the present nitrophenolates except the yellow isomer of picrate (*vide infra*) display ν(V=O) bands in the 962—973 cm^{-1} region which are higher than those for the phenol adducts and which are almost constant, irrespective of the great difference in the pK_a's of the nitrophenols (pK_a=7.149, 4.110, and 0.708 at 25 °C for 4-nitro-, 2,4-dinitro-, and 2,4,6-trinitrophenols respectively). If the above IR criterion for the geometrical structure of $VO(acac)_2L$ is also applicable to the present complexes, the *cis* arrangement of the phenolate to the oxo ligand would be more probable. However, at the present stage it is not clear which atom, oxygen (acac) or nitrogen (bpy), occupies the position *trans* to the oxo ligand.

As may be seen in Table 4, the present phenolato complexes exhibit two d-d absorption maxima in dichloromethane at around 12500 and 17000 cm^{-1}, with a shoulder at around 21000 cm^{-1}. These spectra are similar to those of the phenol adducts in a solid and are typical ones for octahedral oxovanadium(IV) complexes. The two band positions are almost constant for these complexes and do not relate to the change in the pK_a's of the nitrophenols, again indicating no electronic effect of the substituted phenol on vanadium.

The observed molecular weight in dichloromethane at 25 °C is close to the calculated value, indicating that these complexes exist intact in solution without liberating the phenolate ligand. This contrasts with the cationic complex derived by Aly.[5] The conductance measured in methanol, on the contrary, depends on the nature of the nitrophenol contained in these complexes. The 4-nitrophenolato complex exists as a non-electrolyte even in methanol, while the picrato complex behaves practically as a uni-univalent electrolyte in this solution, presumably with the release of the picrate ion. The conductance of the 2,4-dinitrophenolato complex is intermediate between those of the 4-nitro- and the 2,4,6-trinitrophenolato complexes, suggesting partial ionization to a complex cation and a 2,4-dinitrophenolate ion in solution. The enhanced ionization with the increase in the number of the nitro substituent on the phenol ring appears to reflect the increase V–O(phenolate)-bond instability in these complexes resulting from the electronic and/or steric effect of the substituent.

Two kinds of $VO(OC_6H_2(NO_2)_3)(acac)(bpy)$ complexes were produced by different synthetic routes. The yellow-green isomer was prepared by the picrate substitution of the 4-nitrophenolato complex in dichloromethane, while the yellow isomer was obtained by the direct reaction of $VO(acac)_2$, 2,4,6-trinitrophenol, and bpy in methanol. However, it is likely that the difference in kind was caused by the difference in the donor abilities of the solvents used rather than by that in the synthetic routes, since the yellow-green isomer could also be prepared by means of a direct reaction in dichloromethane.

The ν(V=O) frequency of the yellow isomer lies at 901 cm^{-1} abnormally lower than those of other phenolato complexes, and is close to those of the phenol adducts. Thus, it is suggested that the isomer also has a V=O···V=O chain structure in a solid and is formulated by [VO(acac)(bpy)](picrate). The low solubility of the complex in nonpolar solvents may be due to its polymeric and ionic character. On the other hand, the complex dissolves in methanol and behaves as a uni-univalent electrolyte, as does the yellow-green isomer.

The existence of two isomers for the picrato complex containing bpy appears to be caused by a delicate balance among the coordinating abilities of a picrate ion, an adjacent vanadyl oxygen atom, and a methanol molecule, toward the sixth coordination site of a particular vanadium cation $[VO(acac)(bpy)]^+$. The yellow-green isomer is stable in dichloromethane, but releases the picrate ion in methanol, depositing the yellow isomer on evaporation. Why a pair of isomers of the phen derivative can not be derived is a question left to be solved.

The authors are grateful to Mr. Junichi Gohda for the elemental analysis. Financial aid by the Ministry of Education is also acknowledged.

cis-Dioxovanadium(V) and Mixed-Valence Divanadium(IV, V) Complexes Containing β-Diketonate and Heterocyclic Nitrogen-base Ligands

Hiroshi TAGUCHI, Kiyoshi ISOBE, Yukio NAKAMURA,* and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received December 16, 1977)

Diamagnetic dioxovanadium(V) complexes, VO_2(β-dik)(phen or bpy),† were prepared by the direct reactions of VO(β-dik)$_2$ with 1,10-phenanthroline and 2,2′-bipyridine in dichloromethane under aerobic conditions as well as by two other methods. These compounds were concluded to have a *cis* configuration on the basis of the IR and Raman data. These complexes are solvolyzed to afford the di-μ-methoxo- or di-μ-hydroxo-divanadium(V) species, and are reduced by hydrogen bromide to the oxovanadium(IV) species in dichloromethane. In methanol instead of dichloromethane, $VO(acac)_2$ reacted with 2,2′-bipyridine to produce a novel mixed-valence divanadium-(IV, V) complex, $V_2O_3(acac)_3$(bpy), which was revealed by the magnetic, spectral, and polarographic data to be a trans adduct of $VO(acac)_2$ with VO_2(acac)(bpy) *via* an oxide ligand.

Bis(acetylacetonato)oxovanadium(IV), $VO(acac)_2$, acts as an effective and highly selective catalyst for the epoxidation of olefins[1] and olefinic alcohols[2] by *t*-butyl hydroperoxide. Gould *et al.*[1] provided some evidence showing that a vanadium(V) hydroperoxide complex produced by the reaction of $VO(acac)_2$ with a hydroperoxide served as an effective catalyst for the epoxidation. The intermediary vanadium(V) complex, however, was neither isolated nor characterized.

Solid $VO(acac)_2$ is stable in air for a long period, but in solution it is slowly oxidized by atmospheric oxygen to some as yet unknown quinquevalent species.[3] In general, VO^{2+} ions are stable for 6 months or more in concentrated strong acids, but they are rapidly oxidized above pH 2.45, especially in alkaline solutions.[4]

The reaction of $VO(acac)_2$ with a slight excess of 1,10-phenanthroline in methanol yielded a mixed ligand V(IV) complex with the composition of VO(acac)$_2$(phen)·2MeOH,[5] but the same reaction in dichloromethane under aerobic conditions resulted in a V(V) complex, VO_2(acac)(phen).[6] We wish now to report more detailed results on the reactions of several bis(β-diketonato)oxovanadium(IV) complexes with 1,10-phenanthroline and 2,2′-bipyridine under the latter reaction conditions to afford diamagnetic VO_2(β-dik)(phen or bpy).

Experimental

Materials. The oxovanadium(IV) complexes, $VO(acac)_2$,[7] $VO(tfac)_2$,[8] and $VO(bzac)_2$,[9] were prepared by the methods described in the literature and gave satisfactory elemental analyses and IR spectra. Commercially available β-diketones, 1,10-phenanthroline, and 2,2′-bipyridine were used without further purification. The organic liquids were dried and distilled before use. A stock solution of hydrogen bromide was prepared by dissolving in dichloromethane the gas which had been generated by the reaction of tetralin with bromine and by then drying through a tube containing calcium bromide.

Preparation of the Diamagnetic cis-*Dioxovanadium(V) Complexes.* These complexes were prepared by the following methods.

† β-dikH (β-diketone)=acacH(acetylacetone), bzacH (benzoylacetone), tfacH (trifluoroacetylacetone), dbmH (dibenzoylmethane), and hfacH (hexafluoroacetylacetone); phen and bpy stand for 1,10-phenanthroline and 2,2′-bipyridine respectively.

Method A: Direct Reaction of Bis(β-diketonato)oxovanadium-(IV) with 1,10-Phenanthroline and 2,2′-Bipyridine under Aerobic Conditions. cis-*Dioxo(acetylacetonato)(1,10-phenanthroline)-vanadium(V),* cis-VO_2(acac)(phen) (**1**): To a dichloromethane solution (40 ml) of $VO(acac)_2$ (1.0 g, 3.8 mmol) we added a solution of an excess of 1,10-phenanthroline monohydrate in dichloromethane (40 ml); oxygen was bubbled through the mixture for about 5 h to deposit reddish brown crystals. They were then filtered off, washed with diethyl ether, and dried *in vacuo*, but they still contained dichloromethane as the solvent of crystallization. Recrystallization from a mixture (1:1 by volume) of methanol and acetylacetone freed the complex from the solvent of crystallization.

Compounds **2**, **3**, **4**, and **6** in Table 1 were prepared by similar methods, but the oxidation was continued for 7—9 h. In the preparation of 2,2′-bipyridine derivatives the solution after oxidation was concentrated to 10 ml to deposit crystals.

Method B: Replacement Reactions of VO_2(acac)(phen or bpy) by Other β-Diketonate Ligands. The VO_2(acac)(phen or bpy) complex (1 mmol) was added to a methanol solution (20 ml) containing twice the molar amounts of a β-diketone other than acetylacetone, and the mixture was heated to dissolve the complex. The solution was then filtered and cooled to room temperature to separate out crystals of the corresponding β-diketonate complex, VO_2(β-dik)(phen or bpy).

This method was useful for the preparation of *cis*-dioxo complexes **3**—**10**. The low yield of *cis*-dioxo(2,2′-bipyridine)-(dibenzoylmethanido)vanadium(V) monohydrate *cis*-VO_2(dbm)(bpy)·H_2O is caused by partial methanolysis. Thus, a reddish brown methanolysis product was first precipitated and analyzed to fit $VO(OCH_3)_2$(dbm) (Found: C, 57.84; H, 4.85. Calcd for $C_{17}H_{17}O_5V$: C, 57.96; H, 4.86%). The desired red compound separated out from the filtrate.

Method C: Replacement of the 2,2′-Bipyridine in VO_2(β-dik)-(bpy) by 1,10-Phenanthroline. A methanol solution (10 ml) of 1,10-phenanthroline (3 mmol) was added to a methanol solution (25 ml) containing VO_2(β-dik)(bpy) (1 mmol) and the same kind of β-diketone ligand (3 mmol). The mixture was heated to 60 °C for 1 h, and then kept at room temperature to precipitate the phen complex.

Compounds **1**, **3**, and **5** were prepared according to this method. The analytical data, decomposition temperatures, and yields (by each synthetic method, A, B, or C) of these dioxovanadium(V) complexes are listed in Table 1.

Solvolysis Reactions of cis-VO_2(β-dik)(phen or bpy). When the *cis*-VO_2(β-dik)(phen or bpy) complex (1 mmol) was heated to dissolve it in methanol (20 ml), a solvolytic reaction occurred and a product with the composition of $V_2O_4(OCH_3)_2$(phen or bpy) was separated out on cooling

a) Calculated values in parentheses. b) Yield by each synthetic method (A, B or C) described in Exptl Section. c) Yield by an equimolar reaction between $VO(acac)_2$ and VO_2(acac)(bpy).

to room temperature. The yields were 54% for $V_2O_4(OCH_3)_2$(phen) (Found: C, 40.67; H, 3.37; N, 6.83. Calcd for $C_{14}H_{14}N_2O_6V_2$: C, 41.20; H, 3.46; N, 6.86%. Dec 179—180 °C), and 63% for $V_2O_4(OCH_3)_2$(bpy) (Found: 37.17; H, 3.70; N, 7.12. Calcd for $C_{12}H_{14}N_2O_6V_2$: C, 37.52; H, 3.67; N, 7.29%. Dec 169—170 °C). The latter compound was also prepared by stirring for a few days a suspension of vanadium(V) pentoxide in methanol containing 2,2′-bipyridine. The subsequent heating of the complex in other organic solvents, such as chloroform, dichloromethane, acetone, and nitromethane, resulted in $V_2O_4(OH)_2$(phen)·3/2H_2O or $V_2O_4(OH)_2$(bpy)·2H_2O. The yield was 67% for $V_2O_4(OH)_2$(phen)·3/2H_2O (Found: C, 35.38; H, 2.49; N, 6.55. Calcd for $C_{12}H_{13}N_2O_{7.5}V_2$: C, 35.37; H, 3.22; N, 6.88%. Dec 194—196 °C). The yield was 48% for $V_2O_4(OH)_2$(bpy)·2H_2O (Found: C, 30.97; H, 2.74; N, 6.60. Calcd for $C_{10}H_{14}N_2O_8V_2$: C, 30.89; H, 3.60; N, 7.14%. Dec 156—158 °C). The products of methanolysis and hydrolysis were all unstable in air and were insoluble in most solvents, thus precluding physical measurements.

Reduction of cis-*VO_2(acac)(phen or bpy) with Hydrogen Bromide.* The *cis*-VO_2(acac)(phen or bpy) complex (2 mmol) was dissolved in dichloromethane (60 ml) containing acetylacetone (9 mmol), and to the mixture we then added, drop by drop, a solution (0.16 M, 25 ml) of hydrogen bromide in dichloromethane. The resultant white-green precipitate was found to be dibromooxo(1,10-phenanthroline)vanadium(IV) $VOBr_2$(phen) or dibromo(2,2′-bipyridine)oxovanadium(IV) $VOBr_2$(bpy) on the basis of elemental analysis. The filtrate was concentrated to 20 ml to deposit yellow-green crystals with the composition of VOBr(acac)(phen)·2H_2O (**11**) or VOBr(acac)(bpy)·2H_2O (**12**). The corresponding VOBr(bzac)(phen)·1/2H_2O (**13**) and VOBr(bzac)(bpy)·H_2O (**14**) complexes were produced in a similar manner and gave satisfactory analyses (Table 1).

*Preparation of the Mixed-Valence Divanadium(IV, V) Complex. Tris(acetylacetonato)(2,2′-bipyridine)trioxo-divanadium(IV, V), V_2O_3(acac)$_3$(bpy) (**15**):* A methanol solution (30 ml) containing $VO(acac)_2$ (1.6 g, 6.2 mmol) and 2,2′-bipyridine (1.0 g, 6.4 mmol) was concentrated to about 10 ml at 60 °C on a water bath and then cooled to room temperature to deposit green crystallites of $V_2O_3(acac)_3$(bpy). The complex was also prepared by simple adduct formation between $VO(acac)_2$ and **2**: equimolar amounts of $VO(acac)_2$ (0.58 g, 2.2 mmol) and VO_2(acac)(bpy) (0.74 g, 2.2 mmol) were dissolved in methanol (50 ml) containing acetylacetone (2 ml), and then the mixture was concentrated to 20 ml to separate $V_2O_3(acac)_3$(bpy).

The analytical data, decomposition temperature, and yield of the complex are listed in the last row of Table 1.

Measurements. Each specimen of the complexes was dried *in vacuo* at room temperature before being subjected to elemental analysis. The absorption spectra of the solutions and the reflectance spectra of the solid specimen were measured by means of a Hitachi EPS-3T autorecording spectrophotometer equipped with an RIO reflectance attachment. The infrared spectra were taken in Nujol on JASCO IR-E (4000—700 cm^{-1}) and Hitachi EPI-L (700—200 cm^{-1}) infrared spectrophotometers. The Raman spectra were recorded with the aid of a JRS-S1 Laser Raman spectrophotometer by exciting a solid specimen in a rotating cell with a 5145 Å Argon laser.

The magnetic susceptibility was measured by means of a Shimadzu MB-2 automatically recording magnetic balance, employing mercury tetraisothiocyanatocobaltate(II) as a reference. The electric conductivities of compounds **11** and **12** were measured in methanol by means of an MY-7 apparatus of the Yanagimoto Seisakusho, Ltd.

Results and Discussion

As has been described in the Experimental Section, each VO_2(β-dik)(phen or bpy) complex could be prepared by one or more of three synthetic methods. The complexes are all yellow to red crystals. The magnetic susceptibilities of the representative compounds, **1** and **2**, were measured at room temperature. They are both diamagnetic, χ_M being -1.52×10^{-4} and -4.72×10^{-5} c.g.s. unit respectively. This implies that the vanadium atom is in a quinquevalent state with the d^0 configuration in these complexes,

Table 2. The characteristic IR bands of the $VO_2(\beta\text{-dik})$(phen or bpy) complexes (cm^{-1})

No.	Compound	ν_s(C=O)	ν_{as}(C=C=C)	$\nu_s(VO_2)$	$\nu_{as}(VO_2)$	$\delta(VO_2)$
1	VO_2(acac)(phen)	1613	1515	916	891	340
2	VO_2(acac)(bpy)	1613	1513	911	886	344
3	VO_2(bzac)(phen)	1612	1515	915	891	337
4	VO_2(bzac)(bpy)·1/2H_2O	1615	1516	914	881	336
5	VO_2(tfac)(phen)	1653	1545	923	900	326
6	VO_2(tfac)(bpy)	1651	1537	922	901	328
7	VO_2(dbm)(phen)	1600	1515	918	892	327
8	VO_2(dbm)(bpy)·H_2O	1610	1518	915	887	337
9	VO_2(hfac)(phen)	1662	1554	932	907	322
10	VO_2(hfac)(bpy)	1663	1555	939	912	327

The diamagnetism of the other dioxo complexes can also be inferred by analogy with **1** and **2**.

Geometrical Structure. To our knowledge, only the *cis* arrangement of two oxide ligands has been elucidated by X-ray analysis for octahedral dioxovanadium(V) complexes, such as ammonium salts of dioxobis(oxalato)vanadate(V)[10] and (dihydrogenethylenediaminetetraacetato)dioxovanadate(V),[11] and trisodium (ethylenediaminetetraacetato)dioxovanadate-(V) tetrahydrate.[12] Hence, it is of interest to explore whether or not the two oxo groups in the present complexes are in a *cis* configuration. As has been described in a preliminary communication,[6] the *cis* structure was also established by a single crystal X-ray analysis of compound **1**.

Griffith and Wickins[13,14] proposed that the strong π-donor effect of the oxo ligand in octahedral complexes will make the d^0 species of the $[MO_2X_4]^{n-}$ type take the *cis* configuration. From the theoretical treatment of the vibrational modes they[14] showed that, for the *cis* form, the three vibrational modes of $\nu_s(MO_2)$, $\nu_{as}(MO_2)$, and $\delta(MO_2)$ are active in both IR and Raman spectra, while for the trans form only the symmetric stretching mode is Raman-active, with the other modes being IR-active only. They examined the IR and Raman spectra of a number of d^0 species of the $[MO_2X_4]^{n-}$ type (Mo^{VI}, W^{VI}, or V^V; X=F, Cl, or ½ox). All of them exhibited three bands due to the vibrational modes described above at around 950, 900, and 370 cm^{-1} respectively in either the IR or Raman spectra. Thus, these d^0 complexes were concluded to have a *cis* rather than a *trans* arrangement of the oxo ligands.

The IR spectrum of compound **1** in Nujol shows two strong bands assignable to the V–O (oxide) stretching vibration at 916 and 891 cm^{-1}, together with a band due to the O–V–O bending mode at 340 cm^{-1} (Table 2). The Raman spectrum also exhibits two stretching bands, although the O–V–O bending mode is indiscernible because of the intense background. These results are compatible with the conclusion drawn from the theoretical treatment. As may be seen in Fig. 1, the higher-frequency $\nu(VO_2)$ band is weaker in IR, but is much stronger in Raman than the lower-frequency one, revealing that the former band is attributable to the symmetric vibration, and the latter, to the anti-symmetric vibration. In many bent triatomic molecules the ν_{as} band is observed in a higher-

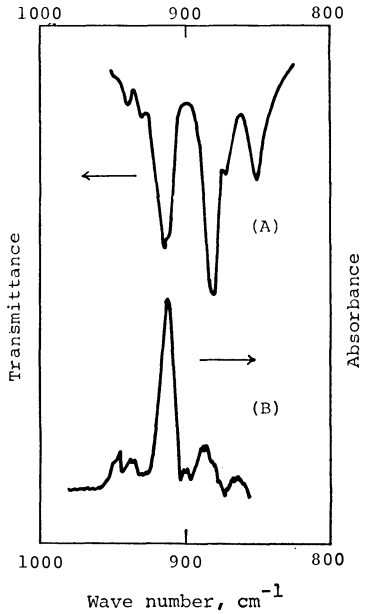

Fig. 1. The IR (in Nujol) (A) and Raman (in solid state) (B) spectra of VO_2(acac)(phen) in the V–O (oxide) stretching region.

frequency region than the ν_s band, but compound **1** shows an opposite pattern. A similar situation is also observed in $(NH_4)_3[VO_2(ox)_2]\cdot 2H_2O$,[14] while VO_2Cl, VO_2F and VO_2SbF_6[15] show the $\nu_{as}(VO_2)$ band in a higher-frequency region than the $\nu_s(VO_2)$ band. The presence of the ν_s band at a higher frequency in the oxalato complex and the present compound **1** might be attributable to the enhanced repulsion between the oxide ligands as compared with the other three compounds. Such a reversion of ν_{as} and ν_s frequencies is also observed for triatomic molecules with an isosceles-triangular structure such as O_3 and OF_2 because of the large repulsion between the two atoms on the base.[16] As may be seen in Table 2, all the dioxo complexes other than compound **1** also exhibit three IR bands assignable to the $\nu_s(VO_2)$, $\nu_{as}(VO_2)$, and $\delta(VO_2)$ vibrations, although Raman spectra of these complexes were not examined. By analogy with compound **1**, the *cis* configuration of the two oxide ligands in these complexes can also be inferred with confidence.

Other Characteristics. It has been well established that the β-diketonate chelates exhibit their ν_s(C=O) and

ν_{as}(C=C=C) bands in the 1500—1600 cm^{-1} region.[17] On the contrary, the present dioxo complexes display the carbonyl band at frequencies higher than 1600 cm^{-1}, as may be seen in Table 2. A similar situation was noticed when a bidentate nitrogen base, such as ethylenediamine, 1,10-phenanthroline, or 2,2′-bipyridine, was added so as to coordinate it to a neutral metal β-diketonate.[18] The increase in frequency was attributed to the weakening of the metal-oxygen(β-dik) bond by donation of electron from the base to the metal center. In the present case, it is most likely that the strong π-donor ability of oxide ligands weakens the V–O(β-dik) bond. Such a *trans* influence of two oxide ligands essentially resulted in the elongation of one of the two V–O(acac) bonds and of one of the two V–N bonds which are *trans* to the two oxide ligands in VO_2(acac)(phen)[6] (V–O: 2.177(4) and 1.949(4) Å, V–N: 2.300(4) and 2.148(4) Å). An additional weakening of the V–O(β-dik) bond is effected when an electron-withdrawing substituent is introduced into the acetylacetonate ligand of compounds **1** and **2**. In the trifluoro- and hexafluoroacetylacetonato complexes (**5**, **6**, **9**, and **10**) the carbonyl band is, in fact, observed at still higher frequencies than those of **1** and **2**, with concomitant shifts of $\nu_s(VO_2)$ and $\nu_{as}(VO_2)$ to the higher-frequency region (Table 2). It is also of interest that compound **5** was not prepared by Method A. This is probably because the reaction of $VO(tfac)_2$ with 1,10-phenanthroline gave the stable *cis*-adduct $VO(tfac)_2$(phen),[5] which hindered oxidation to the *cis*-dioxo complex.

The reflectance spectra of all the dioxo complexes prepared in this paper exhibit no band assignable to the d-d transitions in the visible region, in conformity with d^0 configuration. A similar feature is also observed in the solution spectra in methanol containing a small quantity of β-diketone to prevent decomposition.

Solvolysis Products. The solvolysis products, $V_2O_4(OCH_3)_2$ (phen or bpy) and their dihydroxo counterparts, include a $V_2O_4^{2+}$-moiety in these complexes. Although many binuclear molybdenum(V) complexes containing a $Mo_2O_4^{2+}$-moiety are known,[13] scarcely no corresponding vanadium(V) complexes with $V_2O_4^{2+}$-moiety have been found. Very recently, (2,2′-bipyridine)fluorodioxovanadium(V), VO_2F(bpy) was prepared[19] and its structure was found by X-ray analysis to have one V=O(terminal) bond on each vanadium(V) atom and asymmetric oxygen bridges (V  V).[20] The IR spectrum of this compound shows three V–O stretching bands, at 954, 938, and 872 cm^{-1}, while the present dimethoxo complexes exhibit two bands in the 940—960 cm^{-1} region, together with a broad band in the 700—720 cm^{-1} region. The lower frequency of the last band might be indicative of the presence of more symmetric oxygen bridges (V V).[21] However, these solvolysis products are unstable in air and insoluble in any solvents, thus precluding further examination.

Reduction of VO_2(β-dik)(phen or bpy) Complexes. The VO_2(acac) (phen or bpy) complexes were easily reduced by hydrogen bromide in dichloromethane to produce the vanadium(IV) species, VOBr(acac)(phen or bpy)·$2H_2O$, which show the magnetic moments of 1.75 and 1.73 B.M. per vanadium atom. The complexes are very similar in composition to the corresponding nitrophenolato complexes, $VO(OC_6H_{5-n}X_n)$(acac)(phen or bpy) (X=NO_2; n=1—3), previously isolated by us.[22] One of the latter complexes, the 4-nitrophenolato derivative, reacted with sodium bromide to afford VOBr(acac)(phen or bpy)·$2H_2O$. The reactions of complexes **3** and **4** with hydrogen bromide also gave the corresponding benzoylacetonato vanadium(IV) complexes, **13** and **14**. The ν(V=O) bands of these bromo complexes appear in the 960—980 cm^{-1} region, just as do those of the nitrophenolato complexes which have the *cis* configuration,[22] indicating the cis arrangement of the bromide and oxo ligands.

The absorption spectra of VOBr(acac)(phen or bpy)·$2H_2O$ in dichloromethane showed two bands near 13000 and 16000 cm^{-1}, together with a shoulder around 21000 cm^{-1}. These frequencies are very close to those of the nitrophenolato complexes (12500, 17000, and 21000 cm^{-1}),[22] suggesting the octahedral monomeric structure of the bromo complexes in dichloromethane. On the contrary, the complexes behave as uni-univalent electrolytes in methanol, as evidenced by the Λ_M values of 99(phen) and 91(bpy) ohm^{-1} cm^2 mol^{-1}.

The Mixed-valence Divanadium(IV, V) Complex. Unlike the reaction with 1,10-phenanthroline in methanol leading to $VO(acac)_2$(phen)·$2CH_3OH$,[5] $VO(acac)_2$ reacts with 2,2′-bipyridine in the same solvent to afford green crystals with the composition of $V_2O_3(acac)_3$(bpy) (**15**). The magnetic moment of **15** was found at room temperature to be 1.70 B.M. per divanadium unit, nearly corresponding to the value for a single spin. Thus, complex **15** seems to consist of two vanadium atoms in different oxidation states, V(IV)

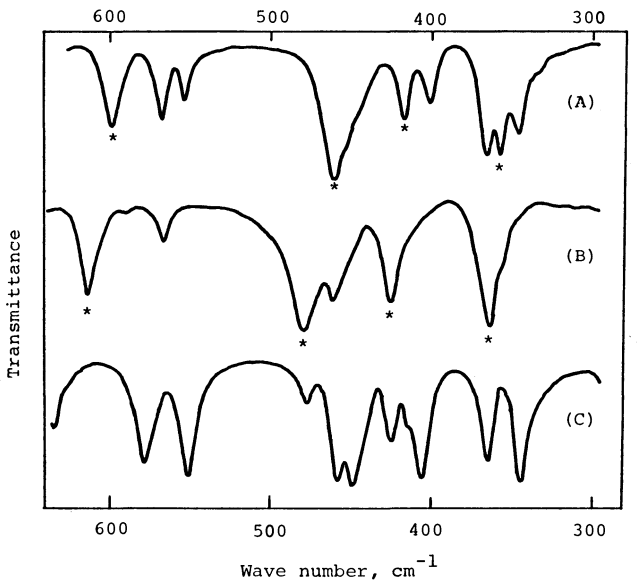

Fig. 2. The far IR spectra of $V_2O_3(acac)_3$(bpy) (A), $VO(acac)_2$ (B) and VO_2(acac)(bpy) (C) in Nujol. Asterisks denote V–O sensitive bands according to the assignment by Caira *et al.* [28].

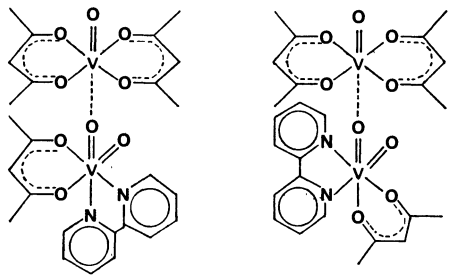
and V(V).

It has been well established that the ν(V=O) band of $VO(acac)_2$ at 1000 cm^{-1} is shifted to the lower-frequency region on adduct formation, and that the extent of the frequency reduction varies in the range of 20 to 60 cm^{-1} according to the variation in the bases.[23-29] The IR spectrum of the present mixed-valence complex **15** exhibits three intense bands in the ν(V=O) region of 850 to 1000 cm^{-1}. The first band, at 960 cm^{-1}, is just in the range of the ν(V=O) frequencies of the base adducts, and the other two, at 930 and 883 cm^{-1} are very close to the $\nu_s(VO_2)$ and $\nu_{as}(VO_2)$ frequencies of $VO_2(acac)(bpy)$ (**2**) derived earlier in this paper. Hence, a simple adduct of $VO(acac)_2$ and **2** with one of the oxo ligands in **2** intervening between two vanadium atoms may be presumed for complex **15** ((I) or (II)):



(I) (II)

In Fig. 2, the IR spectrum of **15** in the lower-frequency region is shown, together with those of $VO(acac)_2$ and **2** for comparison. The spectrum of **15** (Spectrum A) is very similar to a superposition of those for the latter two (Spectra B and C), supporting the proposed structure of **15**. Four bands, at 611, 488, 425, and 367 cm^{-1} of $VO(acac)_2$ previously assigned by Caira *et al.*[28] to the V–O sensitive modes, are lowered to 600, ≈460, 420, and 360 cm^{-1} respectively in complex **15**. Such a lowering without splitting of those bands has also been noted for the *trans* adducts of $VO(acac)_2$ with substituted pyridines[28] and substituted pyridine *N*-oxides.[29] Thus, these data again support the idea that complex **15** is a *trans* adduct of $VO(acac)_2$ with **2**. In fact, complex **15** could be synthesized by an equimolar reaction of $VO(acac)_2$ and $VO_2(acac)(bpy)$ in methanol containing excess acetylacetone. However, it is not possible at the present stage of investigation to discriminate the above two possible structures.

In Table 3 the reflectance and solution spectral data of **15** are shown, together with those of $VO(acac)_2$. As has been described earlier, $VO_2(acac)(bpy)$ exhibits no d-d band in the visible region. Hence, it is likely that the two bands in the reflectance spectrum of complex **15** at 13000 and 17200 cm^{-1}, along with a shoulder at around 22700 cm^{-1}, were brought about by the shift of the absorption bands of $VO(acac)_2$ at 14600 and 16800 cm^{-1} and a shoulder 25000 cm^{-1} respectively. Such shifts of the first and second bands of $VO(acac)_2$ to the lower and higher frequencies respectively are caused by the attainment of the octahedral environment around the vanadium(IV) ion on adduct formation.[30] If a dilute solution of **15** in methanol containing a small quantity of acetylacetone is left standing, $VO_2(acac)(bpy)$ is deposited from the mixture. These results may indicate that complex **15** dissociates in this solvent to $VO(acac)_2$ and $VO_2(acac)(bpy)$. The absorption spectrum of **15** in methanol containing acetylacetone in a large excess to prevent the decomposition of the complex exhibits two bands, at 22700 (ε=1670) and 12700 (ε=45) cm^{-1}, as is shown in Table 3. Because of the low solubility of **15** in this solution, a 10 cm-cell was used for the measurement of the low intensity band. The former band corresponds essentially to the absorption band at 22200 cm^{-1} (ε=1690) of $VO_2(acac)(bpy)$ in methanol containing acetylacetone in a large excess, while the latter corresponds to the first band of $VO(acac)_2$ in the same solvent. The other bands of $VO(acac)_2$ are masked by the tails of the strong ligand bands of $VO_2(acac)(bpy)$.

Table 3. The reflectance (in solid) and absorption (in methanol) spectra of $V_2O_3(acac)_3(bpy)$ and $VO(acac)_2$ (ν_{max}, 10^3 cm^{-1})

Compound	Reflectance spectra	Absorption spectra[a]
$V_2O_3(acac)_3(bpy)$	13.0	12.7 (45)[b]
	17.2	
	22.7	22.7 (1670)[b]
$VO(acac)_2$	14.6	13.0 (40)
	16.8	17.3 (16)
	25.0	25.0 (91)

a) ε values in parentheses.
b) In the presence of acetylacetone (0.503 M).

Another support for the presence of the $VO_2(acac)(bpy)$ species in methanol was obtained polarographically. The current-voltage curves of **15** and $VO_2(acac)(bpy)$ in methanol containing acetylacetone in 6.6×10^{-3} M were recorded using tetrabutylammonium perchlorate as a supporting electrolyte. In addition to the similarity of both the wave-shape and the wave-height, the half-wave potential of −0.02 V *vs.* SCE obtained for **15** is very close to that of −0.03 V *vs.* SCE for $VO_2(acac)(bpy)$, indicating the presence of $VO_2(acac)(bpy)$ in the solution.

The authors are grateful to Mr. Junichi Gohda and Mr. Akio Ichimura for the elemental analysis and polarographic measurements respectively. The measurements of the Raman spectrum at JOEL, Ltd., and a financial aid from the Ministry of Education are also acknowledged.

Synthesis and Oxygenation Reaction of Cobalt(II) Complexes with Jäger-Type Open-Chain Ligands[1)]

Koichi KUBOKURA, Hisashi OKAWA,* and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received December 22, 1977)

Cobalt(II) complexes with Jäger-type open-chain ligands, H_2(J-R) (R=en, pn, ph, and tn), were prepared. It was found that Co(J-en), Co(J-pn), and Co(J-ph) are in low-spin state, and Co(J-tn) in high-spin state with a pseudo-tetrahedral configuration. The formation constant of pyridine adduct of Co(J-en)was spectrophotometrically determined to be 2.70, 2.18, and 1.90 M^{-1} at 0, 20, and 30 °C, respectively. Co(J-en)py forms oxygen adducts, Co(J-en)pyO_2 and [Co(J-en)py]$_2O_2$, in a 1,2-dichloroethane solution at room temperature, exhibiting a characteristic band at 525 nm. The ease of oxygenation and the characteristic absorption in the visible region were interpreted in terms of the electron-withdrawing ability of acetyl group in the ligand.

The copper(II) and nickel(II) complexes of the quadridentate ligands (Fig. 1) were synthesized and characterized by Wolf and Jäger.[2)] These ligands are abbreviated as H_2(J-R) in this paper, where R is en(ethylene), pn(propylene), ph(*o*-phenylene), or tn(trimethylene), representing the bridging chain in Fig. 1. One of the characteristics of Jäger's complexes is the ability of forming a macrocyclic ring when it is reacted with diamines.[2,3)] The cyclization is facilitated by the electron-withdrawning ability of the acetyl group attached to the γ-position of the ligand. The acetyl group of the coordinated ligand is also expected to exert the electron-withdrawing effect on the coordination geometry, the reactivity, and the electronic configuration of the complex. In this study we have prepared cobalt(II) complexes of H_2(J-R) in order to examine their pyridine- and oxygen-adduct formation in relation to the electronic configuration of the cobalt ion, which may adopt either the $(d_{xy})^2(d_{z^2})^1$ or $(d_{xy})^2(d_{yz})^1$ configuration depending on its ligand.

Experimental

Syntheses. Syntheses of H_2(J-R) (R=en, pn, ph, and tn) were carried out following the method of Wolf and Jäger.[2)]

Co(J-en): A mixture of H_2(J-en) (10 g), cobalt(II) acetate tetrahydrate (9 g) and sodium hydroxide (2.9 g) in ethanol (150 ml) was stirred at 60 °C for 1 h in nitrogen atomosphere in order to avoid the reaction with oxygen. After being left to stand overnight, the product was collected and recrystallized from chloroform to give orange needles.

Found: C, 49.89; H, 5.38; N, 8.38%. Calcd for $C_{14}H_{18}N_2O_4Co$: C, 49.86; H, 5.38; N, 8.31%.

Co(J-en)py: Co(J-en) was recrystallized from pyridine in an atmosphere of nitrogen, the complex being obtained as brown crystals.

Found: C, 55.19; H, 5.63; N, 10.16%. Calcd for $C_{19}H_{23}N_3O_4Co$: C, 54.81; H, 5.57; N, 0.10%.

Co(J-en)py$O_2 \cdot 1/4C_6H_5CH_3$: Co(J-en) was dissolved in toluene containing pyridine (*ca.* 5%), and oxygen or air was bubbled through the solution until black-purple prisms separated.

Found: C, 52.53; H, 5.52; N, 8.86%. Calcd for $C_{19}H_{23}N_3O_6Co \cdot 1/4C_6H_5CH_3$: C, 52.88; H, 5.35; N, 8.92%.

Co(J-en): This complex was obtained as orange needles in the same way as that for Co(J-en) except for the use of H_2(J-pn) instead of H_2(J-en).

Found: C, 51.20; H, 5.71; N, 8.03%. Calcd for $C_{15}H_{20}N_2O_4Co$: C, 51.29; H, 5.74; N, 7.97%.

Co(J-pn)py: Co(J-pn) was recrystallized from pyridine to afford the complex as brown crystals.

Found: C, 55.41; H, 5.86; N, 9.67%. Calcd for $C_{20}H_{25}N_3O_4Co$: C, 55.83; H, 5.86; N, 9.77%.

Co(J-pn)py$O_2 \cdot 1/4C_6H_5CH_3$: This complex was obtained as dark purple prisms when oxygen or air was passed through a solution of Co(J-pn) in toluene–pyridine (95:5) mixture.

Found: C, 53.49; H, 5.76; N, 8.66%. Calcd for $C_{20}H_{25}N_3O_6Co \cdot 1/4C_6H_5CH_3$: C, 53.83; H, 5.60; N, 8.66%.

Co(J-ph): This complex was obtained as deep red needles by reacting H_2(J-ph) and cobalt(II) acetate tetrahydrate in ethanol. The product was recrystallized from ethanol.

Found: C, 55.79; H, 5.15; N, 6.85%. Calcd for $C_{18}H_{18}N_2O_4Co \cdot 1/2C_2H_5OH$: C, 55.89; H, 5.18; N, 6.86%.

Co(J-ph)py: This complex was obtained as deep red prisms by recrystallizing Co(J-ph) from pyridine.

Found: C, 59.29; H, 5.04; N, 8.96%. Calcd for $C_{23}H_{23}N_3O_4Co$: C, 59.49; H, 4.99; N, 9.05%.

Co(J-tn): H_2(J-tn), cobalt(II) acetate tetrahydrate, and sodium hydroxide were reacted in ethanol at 70—75 °C to afford the complex as reddish brown crystals. The product was throughly washed with warm ethanol in order to separate sodium acetate.

Found: C, 50.98; H, 5.72; N, 7.89%. Calcd for $C_{15}H_{20}N_2O_4Co$: C, 51.29; H, 5.74; N, 7.97%.

Determination of Pyridine Adduct Formation Constants. Absorption spectra of Co(J-en) in 1,2-dichloroethane containing pyridine were measured at 0, 20, and 30 °C by successively altering the pyridine content (0—1 M), where the concentration of the complex was kept constant (3×10^{-4} M). Equilibrium constants were determined from the absorbance at 375 nm by the method of Marzilli *et al.*[4)]

Determination of Oxygen Adduct Formation Equilibrium. A thermostatted three necked flask (200 ml, filled with dry nitrogen) was fitted with a dropping funnel containing a solution of Co(J-en) (4×10^{-4} M) in deoxygenated 1,2-dichloroethane–pyridine (99.7:0.3), a tube connected to the cell for spectral measurement and a tube connected to the apparatus for controlling the partial pressure of oxygen (Fig. 2). The temperature of the flask was maintained at 0 °C by means of ice–water. The pressure in the flask was then partially reduced and oxygen introduced until it reached 760 mmHg. The partial pressure of oxygen was manometrically determined. A solution of the complex was then dropped into the flask and vigorously stirred for about 15 min. After equilibrium had been reached, the solution was introduced into the cell. Spectrophotometric measurements were carried out at 0 °C.

Other Physical Measurements. Electronic spectra on solid

and in solution were measured with a Shimazu Multipurpose Spectrophotometer Model MSP-5000. Magnetic susceptibility was measured by the Faraday method, diamagnetic correction being carried out by means of Pascal's constants. ESR spectra (X-band) were measured on powder and in solutions with a JES-ME-3 spectrometer.

Results and Discussion

Effective magnetic moments of Co(J-en), Co(J-pn), Co(J-ph), and Co(J-tn) at room temperature are 2.24, 2.43, 2.56, and 4.36 BM, respectively. It is evident that the complexes except for Co(J-tn) are in low-spin state. ESR spectra of Co(J-R) (R=en, pn, and ph) diluted in the cooresponding Ni(J-R) were measured by X-band at 78 K. The spectra are similar to each other, showing a rhombic pattern. A typical example is shown in Fig. 3a. A band at $g=3.10$ shows an eight-lined hyperfine structure due to $^{59}Co(I=7/2)$ hyperfine coupling, from which A is determined to be 150 G. On the other hand two bands around $g=1.78$—1.85 are not well resolved because of their similar g and A values. The spectra of this type have been interpreted by Nishida and Kida[5] in terms of the $(d_{xy})^2(d_{yz})^1$ ground state for cobalt(II) ion. Electronic spectra of the present complexes exhibit one absorption around 1200 nm characteristic of low-spin cobalt(II) complexes.

The effective magnetic moment of Co(J-tn) is much larger as compared with other complexes, the electronic spectrum showing a complicated pattern with absorption bands at 1550, 695, 570, and 460 nm. Judging

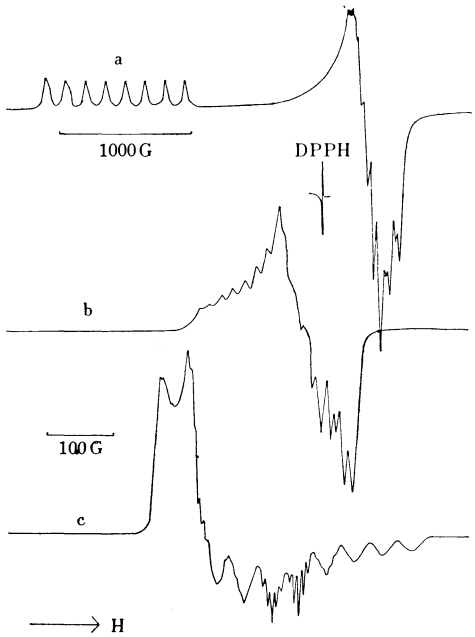

Fig. 3. Esr spectra at 78 K of a) Co(J-en) doped in Ni(J-en), b) oxygenated species of Co(J-en) in dichloroethane-pyridine, and c) pyridine adduct of Co(J-en) in dichloroethane-pyridine.

from the fact that the moment falls in the values of tetrahedral cobalt(II) ions and that the spectrum resembles that of *N,N'*-disalicylidenetrimethylenediaminatocobalt(II),[6] whose configuration was found to be pseudo-tetrahedral, we may conclude that the coordination geometry of Co(J-tn) is pseudo-tetrahedral.

The pyridine adducts Co(J-R)py (R=en, pn, and ph) were obtained when Co(J-R) was recrystallized from pyridine. They are also low-spin complexes (Co(J-en)-py, 1.94; Co(J-pn)py, 2.09; Co(J-ph)py, 2.04 BM). It is supposed that the pyridine adducts have a square-pyramidal structure with a pyridine molecule at the apex.

The orange colored solution of Co(J-en) in 1,2-dichloroethane or toluene containing a small amount of pyridine turned purple when air or oxygen was bubbled through the solution at room temperature. Orange color was recovered when nitrogen was passed through the solution or the solution was warmed at *ca.* 60 °C. It seems that this process is reversible. The purple colored solution exhibited a well defined ESR spectrum indicating two signals of $g_{//}=2.081$ and $g_{\perp}=2.005$ (Fig. 3b). Each signal consists of eight lines due to hyperfine splitting of ^{59}Co nucleus, $A_{//}$ and $A_{\perp}$ being estimated at 18 and 12 G, respectively. The eight-lined hyperfine structure with the very small hyperfine splitting indicates that the 1:1 oxygen adduct is formed in the purple solution.

The equilibrium between Co(J-en) and pyridine was studied in order to elucidate the oxygenation reaction of Co(J-en). A solution of Co(J-en) in 1,2-dichloroethane exhibits an absorption band at 377 nm. By addition of pyridine to this solution the band gradually disappeared and two isosbestic points were observed at 365 and 400 nm (Fig. 4). The spectrum converged when pyridine concentration exceeded 1M.

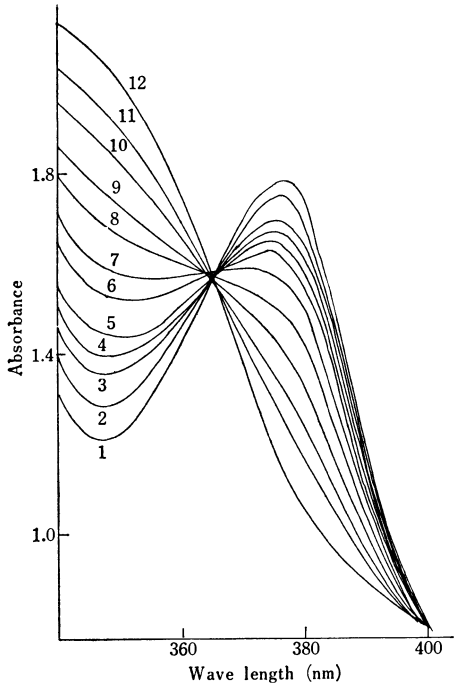

Fig. 4. Electronic spectra of Co(J-en) in dichloroethane with various contents of pyridine: 1), 0; 2), 5×10^{-4}; 3), 1.0×10^{-3}; 4), 1.5×10^{-3}; 5), 2.0×10^{-3}; 6), 3.0×10^{-3}; 7), $4.\times10^{-3}$; 8), 6.0×10^{-3}; 9), 9.0×10^{-3}; 10), 1.5×10^{-2}; 11), 2.4×10^{-1}; 12), 1.0 M. The concentration of Co(J-en) is maintained constant (3×10^{-4} M).

The equilibrium constant of the equation, Co(J-en)+ $n$py$\rightleftarrows$Co(J-en)$(py)_n$, is given by the relation,

$$K_{py} = [Co(J\text{-en})(py)_n]/[Co(J\text{-en})][py]^n. \quad (1)$$

If we denote the absorbances of Co(J-en) at 377 nm in the absence of pyridine, in the presence of large excess of pyridine, and in the presence of proper amount of pyridine by A_0, A_∞, and A, respectively, the equilibrium constant is given by

$$\log K_{py} = \log [(A_0-A)/(A-A_\infty)] - n \log[py]. \quad (2)$$

Absorption spectra of Co(J-en) were determined at 0, 20, and 30 °C at various concentrations of pyridine and $\log [A_0-A/(A-A_\infty)]$ was plotted against log [py] (Fig. 5). The plot gives a straight line with a slope nearly equal to 1. This indicates that the main species formed in the solution is Co(J-en)py and the formation of Co(J-en)$(py)_2$ is negligibly small even at the concentration of pyridine higher than 1M. This seems to contradict the fact that the ESR spectrum of the solution of Co(J-en) in 1,2-dichloroethane–pyridine (99 : 1) at 77.4 K displays the five-lined superhyperfine structure in addition to the eight-lined hyperfine structure, indicating that the unpaired electron interacts with two $^{14}N(I=1)$ nuclei in apical positions (Fig. 3c). This can be explained by assuming that Co(J-en)$(py)_2$ is preferred to Co(J-en)py at liquid nitrogen temperature, while Co(J-en)py is preferred at room temperature. The equilibrium constants ($\log K_{py}$) were evaluated to be 2.70, 2.18, and 1.90 M^{-1} at 0, 20, and 30 °C, respectively, by extraporating log[py] to zero. The equilibrium

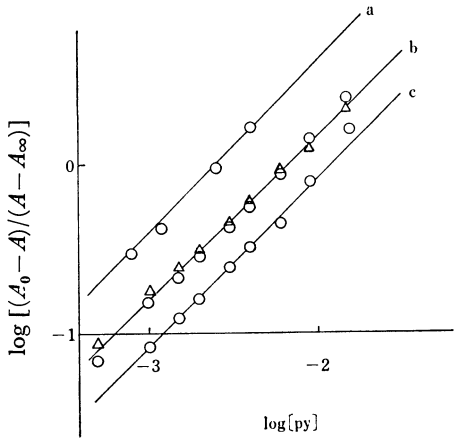

Fig. 5. Plots of $\log [(A_0-A)/(A-A_\infty)]$ *versus* log [py] at a) 0, b) 20, and c) 30 °C, based on the absorbance at 375 nm (○) and at 350 nm (△).

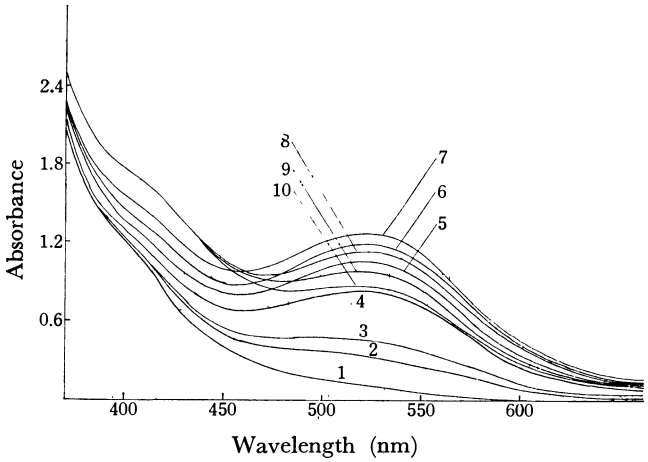

Fig. 6. Electronic spectra of Co(J-en) (4×10^{-4} M) in dichloroethane containing pyridine (0.3%) at 0 °C under various oxygen pressures: 1), 0; 2), 5; 3), 7; 4), 15; 5), 36; 6), 75; 7), 190; 8), 400; 9), 620; 10), 760 mmHg.

constant of Co(J-en)py is a little lower than that of *N,N'*-disalicylidene-*o*-phenylenediaminatocobalt(II).[4]

The electronic spectra of Co(J-en) in 1,2-dichloroethane containing 0.3% pyridine were measured under various oxygen partial pressures. As is shown in Fig. 6 a new absorption was observed when the complex was oxygenated. The intensity of this band reached maximum when the partial pressure of oxygen was *ca.* 200 mmHg and then gradually decreased with the increase in oxygen pressure. This implies that there are at least two oxygenated species in the solution. The species formed under high oxygen partial pressure may be the 1 : 1-type complex, Co(J-en)pyO_2, since this solution exhibits the absorption spectrum similar to the reflectance spectrum of Co(J-en)py$O_2\cdot1/4C_6H_5CH_3$ and ESR spectrum characteristic of the 1:1 oxygenated cobalt(II) complexes. Thus, it can be concluded that the species formed under low oxygen pressure is the 2 : 1-type "peroxo-bridged" complex. The oxygenation reaction of Co(J-en) is represented as follows:

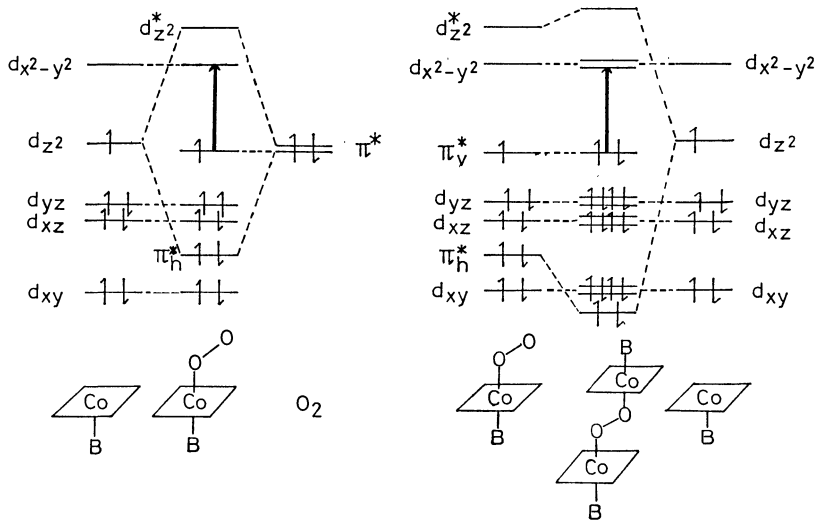

Fig. 7. Qualitative molecular orbital diagrams for Co(J-en)pyO_2 (left) and $[Co(J\text{-en})py]_2O_2$ (right).

$$Co(J\text{-en}) + py \rightleftharpoons Co(J\text{-en})py$$
$$2Co(J\text{-en})py + O_2 \rightleftharpoons [Co(J\text{-en})py]_2O_2$$
$$[Co(J\text{-en})py]_2O_2 + O_2 \rightleftharpoons 2Co(J\text{-en})pyO_2.$$

It is to be noted that Co(J-en)py forms "μ-peroxo-bridged" species even in dilute solution (4×10^{-4}M). In contrast, the formation of the 2:1 oxygen adduct for *N,N'*-disalicylidenealkanediaminatocobalt(II) complexes is negligibly small in dilute solution (less than 10^{-3} M).

Only a few cobalt(II) complexes showing absorption in the visible region upon oxygenation are known.[7,8] Oxygenation reactions of the cobalt(II) complexes with the quadridentate Schiff bases, in general, occur at low temperature.[9] Thus, Co(J-en) is characterized by 1) oxygenation at room temperature, 2) resistance against oxidation to cobalt(III), and 3) a new absorption in the visible region. These characteristics are closely connected with the electron-withdrawing effect of acetyl groups.

The metal-oxygen bond is interpreted in terms of the σ-type overlapping between the d_{z^2} orbital of cobalt(II) and the antibonding orbital (π^*_h) of molecular oxygen.[10] The d_{z^2} orbital in five-coordinated cobalt(II) complexes is generally higher in energy than the antibonding π^* orbital of oxygen. This often causes the irreversible oxidation of cobalt(II) to cobalt(III) during the course of oxygenation. The fact that the oxygen adducts of synthetic iron(II) complexes are obtainable only under a selected conditions, at low temperature and in aprotic solvents, and that the oxygen adduct of *meso*-tetraphenylporphyrinmanganese(II) is barely obtained at low temperature without sixth donor[11] can also be explained in terms of the correlation of the energies of the metal d_{z^2} orbital and the molecular oxygen π^* orbital (electronegativity increases in the order Mn(II)<Fe(II)<Co(II)).

Recently, Pillsbury and Busch[12] studied electrochemical properties of a series of nickel(II) complexes of the fifteen-membered N_4-macrocycles and found that the oxidation potential of Ni(II)→Ni(III) becomes higher when the γ-substituent is replaced by the more electron-attracting group. This suggests that in the present complexes the electron-attracting effect of the acetyl group lowers the energy of the cobalt d-orbitals. In this case the d_{z^2} orbital of Co(J-en)py might be low-lying as compared to the molecular oxygen π^*_h orbital, thereby forming a stable cobalt-oxygen bond even at room temperature without oxidation to cobalt(III) (Fig. 7).

Miskowski *et al.*[13] and McLendon *et al.*[14] studied the characteristic band around 500 nm for the μ-superoxo complex, $[Co(CN)_5\text{–}O_2\text{–}Co(CN)_5]^{5-}$, and the 1:1 oxygen adduct, $[Co(CN)_5O_2]^{3-}$, and assigned this band to the charge-transfer transition from the metal d_π orbital to the π^*_v orbital of oxygen. However, the assignment is invalid for the present complexes, since the π^*_v orbital of $[Co(J\text{-en})py]_2O_2$ is occupied. For the origin of the band at 525 nm of Co(J-en)pyO_2 and $[Co(J\text{-en})py]_2O_2$ it seems reasonable to assign it to the charge-transfer transition from the π^*_v orbital to the vacant $d_{x^2-y^2}$ orbital (Fig. 7). The $\pi^*_v(O_2)\rightarrow d_{x^2-y^2}(Co)$ charge-transfer transition is expected at a wavelength less than 400 nm for most cobalt oxygen carriers.[10] It can be concluded that in the present complexes the electron-attracting effect of the acetyl group lowers the energy of metal d orbital, so that the $\pi^*_v\rightarrow d_{x^2-y^2}$ charge-transfer band appears in the visible region.

(Received December 26, 1977)

The crystal structure of the title compound has been determined by single crystal X-ray diffraction techniques. The compound crystallizes in the space group C2/c with unit-cell dimensions $a=23.54(1)$, $b=9.672(3)$, $c=15.941(7)$ Å, $\beta=114.90(4)°$, and $Z=4$. The manganese atom is octahedrally coordinated by two triphenylphosphines in the trans positions, three equatorial carbonyl ligands, and a hydrido hydrogen. The Mn–H bond has a normal covalent length, 1.46(8) Å. The molecule has C_2 symmetry, and Mn, O(1), C(1), and H_h are on special positions of (0, y, 1/4).

The crystal structure of hydrido(tricarbonyl)-bis(triphenylphosphine)manganese(I), $HMn(CO)_3[P(C_6H_5)_3]_2$, has been studied in order to obtain quantitative data on the Mn–H bond and interactions of hydrido hydrogen with other ligands.

Experimental

The compound was prepared by the reaction of manganese carbonyl and triphenyl phosphine in the presence of metallic sodium in dioxane.[1] The samples used for the X-ray diffraction studies were obtained by recrystallization from a mixture of benzene-petroleum ether. A specimen, a transparent yellow rhombus, stable in the air, of dimensions *ca.* $0.2\times0.2\times0.25$ mm, was used for collection of diffraction intensity data and for measurement of the unit cell dimensions. A Rigaku automated four-circle diffractometer with Mo $K\alpha$ radiation, ($\lambda=0.71069$ Å) monochromated by a graphite crystal was used. Unit cell dimensions were calculated by a least-squares refinement of 14 reflection data obtained for $20°<2\theta<40°$.

Crystal data: $C_{39}H_{31}O_3MnP_2$, $M=664.56$, monoclinic, C2/c, $a=23.54(1)$, $b=9.672(3)$, $c=15.941(7)$ Å, $\beta=114.90(4)°$ $U=3292.1$ Å^3, $D_c=1.34$ g cm^{-3}, $D_m=1.32$ g cm^{-3}, $Z=4$, μ(Mo $K\alpha$)$=6.5$ cm^{-1}.

The diffraction intensities were measured with the 2θ-ω scan technique and 1945 independent reflections for which $|F_{abs}|\geq19$ and $|F_o|\geq3\sigma(|F_o|)$ up to $2\theta=60°$ were obtained at 23 ± 1 °C. The intensity data were corrected for the Lorenz and the polarization effects, but not for absorption. The structure was solved by the heavy atom method. The atomic parameters and the temperature factors were refined by the block-diagonal least-squares method, the function minimized being $\Sigma w(|F_o|-K|F_c|)^2$ where $w=1$ for all the reflections. The atomic scattering factors used were taken from "International Tables for X-Ray Crystallography" Vol. IV (1974).[2]

Two possible space groups, Cc and C2/c, deduced from the extinction rule (hkl: $h+k=2n+1$, $h0l$: $l=2n+1$) gave almost the same R-values (6.6 and 6.4%) for all the non-hydrogen atoms. However, Cc was ruled out since it gave unreasonable bond lengths and angles in the structure of phenyl groups. All the 16 independent hydrogen atoms were found as 0.35—0.52 eÅ^{-3} peaks in difference Fourier maps. The final R-value converged to 4.83%, all the hydrogen atoms being included in the calculation, and no peak higher than 0.26 e Å^{-3} was found in the last difference Fourier maps.

All the calculations were performed on a HITAC 8700/8800 computer at the Computer Centre of the University of Tokyo using a local version of UNICS[3] and the ORTEP[4] program.

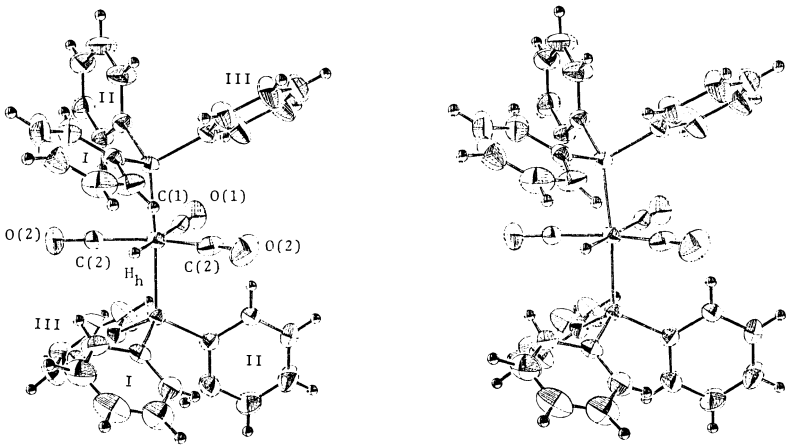

Fig. 1. Stereoscopic drawing of the molecule of $HMn(CO)_3[P(C_6H_5)_3]_2$. The non-hydrogen atoms are represented by their thermal ellipsoids with 50% probability, while the hydrogen atoms are represented by arbitrary spheres.

Table 1. Final atomic coordinates ($\times 10^4$) and thermal factors ($\times 10^3$ Å^2)

The anisotropic thermal factors are of the form:

$$\exp[-2\pi^2(U_{11}h^2a^{*2}+U_{22}k^2b^{*2}+U_{33}l^2c^{*2}+2U_{12}hka^*b^*+2U_{13}hla^*c^*+2U_{23}klb^*c^*)]$$

The isotropic temperature factor is of the form $\exp[-B(\sin\theta/\lambda)^2]$.

Results and Discussion

The atomic parameters and standard deviations are given in Table 1. The F_o-F_c Table is kept at the Office of the Chemical Society of Japan as Document No. 7825.

The molecular geometry $HMn(CO)_3[P(C_6H_5)_3]_2$ is shown in Figs. 1 and 2, the packing in the unit cell in Fig. 4. The molecule has C_2 symmetry, Mn, O(1), C(1), and H_h lying on special positions of (0, y, 1/4). The manganese atom is octahedrally coordinated by one hydrogen (H_h), three carbonyl ligands on the equator, and two phosphorus atoms of triphenylphosphine in trans positions. However, the octahedron is deformed. The eight atoms, Mn, H_h, two C(2), two O(2), C(1), and O(1), lie exactly on a plane, $0.99790x-0.06478z+1.90852=0$, and six atoms, Mn, H_h, C(1), O(1), and two P, form another plane, $-0.08441x-0.99643z+3.4603=0$; x, y, and z, are orthogonal coordinates in Å along a, b, and c^*, respectively. These two planes are almost perpendicular to each other. The two phosphorus atoms and two carbonyl ligands bend down toward H_h to deform the octahedron, the angle Mn–C(2)–O(2) not being linear. The bond distances and angles are given in Tables 2 and 3, respectively.

The Mn–H_h distance was determined to be 1.46(8) Å. The length is quite normal as a covalent bond length as compared to the value calculated from the covalent atomic radii of manganese (1.171 Å) and hydrogen (0.30 Å).[5] Concerning the Mn–H bond length, very few data are available. In the case of $HMn(CO)_5$, the distance 1.601(16) Å was found by neutron diffraction techniques.[6] The value 1.5 Å was reported in the crystal structure determination of $HMn(CO)_3[PCH_3(C_6H_5)_2]_2$.[7]

However, this value does not seem to be refined by the least-squares method. Interactions of the hydrido

C-6	0.0032	−0.0036	0.0089

hydrogen with the surrounding atoms are discussed below.

The atom C(1) which is in the position trans to H_h is nearer to the manganese atom than the two other carbon atoms C(2) in *cis* positions, the C(1)–O(1) bond being shorter than C(2)–O(2). As shown in Fig. 2, three carbon atoms, C(11), C(21), and C(31), attached to the phosphorus do not form an equilateral triangle. The conformation of the triphenylphosphine ligand looks like a propeller with three blades having different pitches. The angles between the $Mn(CO)_3H$ plane and the three phenyl rings, (I), (II), and (III), are 35.6, 92.5, and 148°, respectively.

The phenyl ring (I) is nearest to H_h, having hardly any van der Waals contact with any carbonyl or other ligand. The bond angle Mn–P–C(11) (Table 3) is the smallest among the corresponding angles of three phenyl groups, the phosphorus atom P being bent towards H_h. Moreover, (I) is also declined to the same direction by 5°, the angle between the plane of the phenyl ring (I) and the P–C(11) vector being 175°. The phenyl group (II) seems to be balanced between carbon atoms of two carbonyl ligands, the distances C(1)–C(23) and C(2)–C(23) being 3.43 and 3.23 Å, respectively. In the case of the phenyl ring (III), a fairly short distance of 3.15 Å is found between C(31) and C(2), and an oxygen atom of the neighbor molecule O(2) is close to H(32) with the distance of 2.61 Å. These interactions might have stabilized the phenyl group (III) at the present position.

Figure 3 shows the interatomic distances from the hydrido hydrogen to the surrounding atoms. The distance to H(13) agrees with the sum of the van der Waals radii of two hydrogen atoms. The H_h–C(11) and H_h–C(13) distances are understood as the sum of the half thickness of an aromatic ring and the van der Waals radius of hydrogen atom. The two C(2) atoms of carbonyl groups and the two phosphorus atoms of triphenylphosphine ligands are found close to H_h, the distances being 2.11 and 2.59 Å, respectively. Such short contacts have been reported also in $HMn(CO)_5$[6] and $HMn(CO)_3[PCH_3(C_6H_5)_2]_2$.[7] The short contacts shown in Fig. 3 might give rise to the stability of the present hydrido complex.

The equations of the best planes for the three aromatic rings and deviations of each carbon atoms from these planes are given in Table 4. The average of all the C–C bonds is 1.378(13) Å and that of the C–H bonds 0.90(5) Å. The C–C–C angles are 120° within 1.2°. It is worthwhile to note that C(33), C(35), and C(36) having the largest deviations from the best plane (III) for an unknown reason have also the largest temperature factors (Fig. 2). Van der Waals contacts were found between O(2)···H(32) [2.61(7) Å] and H(25)···H(12) [2.54(10) Å]; there is no other intermolecular distance smaller than 2.7 Å. The crystal volume per each triphenylphosphine molecule is 411.6 Å^3. This volume is near 418 Å^3 of $Os(CO)_3[P(C_6H_5)_3]_2$[8], 423 Å^3 of $Mn(NO)(CO)_2[P(C_6H_5)_3]_2$[9] and $Ir(CO)Cl(SO_2)[P(C_6H_5)_3]_2$,[10] and 404 Å^3 of $ReNCl_2[P(C_6H_5)_3]_2$.[11] Triphenylphosphine itself has a molecular volume of 364 Å^3 in its crystals, the ligand occupying about 90% of the space in the solid of the present complex.

Nondispersive and Dispersive Atomic Fluorescence Spectrometry of Arsenic by Utilizing the Arsine-generation Technique

Taketoshi NAKAHARA,* Toshiaki TANAKA, and Sôichirô MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-umemachi, Sakai 591

(Received January 5, 1978)

Atomic fluorescence spectrometry with nondispersive and dispersive systems by utilizing the arsine-generation technique is described for the determination of arsenic at the nanogram level, where the premixed argon (entrained air)– and nitrogen(entrained air)–hydrogen flames and a microwave-excited electrodeless discharge lamp were used. For the low-temperature flames, a newly designed burner has been constructed. The best detection limits obtained for arsenic are 2.3 ng in mass and 0.12 ppb in concentration with a nondispersive system in argon(entrained air)–hydrogen flame. Linear analytical working curves covering the mass range of arsenic from 30 ng to around 1000 ng have been obtained with nondispersive and dispersive systems at 193.7 and 197.2 nm in both the hydrogen flames. Several elements including other hydride-forming elements, such as antimony, bismuth, selenium, and tellurium, have caused a decrease in fluorescence signals. The present method, with the most sensitive nondispersive system and argon(entrained air)–hydrogen flame, can be applied to the determination of trace amounts of arsenic in wastewaters.

In atomic fluorescence spectrometry by the direct nebulization of solutions into flame, some authors[1–6] have reported detection limits of 0.2—25 ppm of arsenic with a dispersive system, mostly at 189.0, 193.7, 197.2, and 235.0 nm, while others[7–9] have obtained the detection limits of 0.3—6 ppm of arsenic with a nondispersive system. For both systems they have used an arsenic electrodeless discharge lamp as the radiation source and air–acetylene, oxygen–, argon(entrained air)–, and nitrogen(entrained air)–hydrogen flames as the atom reservoir. Dagnall *et al.*[10] have applied the atomic fluorescence method to the determination of arsenic in nickel-base alloys and obtained a detection limit of 1.4 ppm of arsenic at 193.7 nm with a nitrogen (entrained air)–hydrogen flame and an arsenic electrodeless discharge lamp.

On the other hand, in atomic absorption spectrometry the sensitivity for arsenic has been remarkably improved by using an arsine-generation technique based on the reduction of arsenic to arsine and the introduction of the generated arsine into an atom reservoir (flame, heated quartz tube, or heated graphite furnace). As the reductant, zinc,[11–17] sodium tetrahydroborate,[17–24] and titanium trichloride and magnesium rod[25] have been used. Especially for arsenic, zinc has been recommended as a reductant.[15,17]

Tsujii and Kuga[26] have reported a detection limit of 2 ng of arsenic by nondispersive atomic fluorescence spectrometry with an arsine-generation technique in which arsenic is reduced by zinc to arsine. Thompson[27] has described a dispersive atomic fluorescence method at 193.7 nm in conjunction with an arsine-generation technique using sodium tetrahydroborate as a reductant; by using this method he obtained a detection limit of 0.1 ng of arsenic for a sample volume of 1.0 ml.

Recently the present authors have designed and constructed an atomic fluorescence spectrometer which can be used with both dispersive and nondispersive systems. They have demonstrated the performance of the newly constructed spectrometer by measuring mercury atomic fluorescence signals with dispersive and nondispersive systems combined with the cold-vapor technique.[28] This paper will describe the nondispersive and dispersive atomic fluorescence spectrometric determination of arsenic by using the arsine-generation technique and the premixed argon(entrained air)– and nitrogen(entrained air)–hydrogen flames produced with a new burner constructed in this laboratory. The interference effects of acids and diverse elements on the fluorescence signals of arsenic were examined. The most sensitive nondispersive atomic fluorescence method was also applied to the determination of arsenic in wastewater samples with satisfactory results.

Experimental

Reagents. All the reagents used were of an analytical reagent grade. The stock solution of arsenic, 1000 ppm, was prepared by dissolving 1.320 g of diarsenic trioxide in 20 ml of 2.5 mol dm^{-3} sodium hydroxide and by diluting to 1000 ml with a 5% sulfuric acid–20% hydrochloric acid solution. The diluent for the stock solution was a 5% sulfuric acid–20% hydrochloric acid solution. Diluted arsenic standard solutions were prepared immediately before use by dilution of the stock solution with the diluent.

Also used were: tin(II) chloride (10% $SnCl_2 \cdot 2H_2O$ in 6 mol dm^{-3} hydrochloric acid), potassium iodide (20% in distilled water), and zinc tablets. Zinc tablets were prepared as has previously been described.[17] Each tablet was 10 mm in diameter, 3 mm thick, and approximately 0.6 g in weight.

Apparatus. All the measurements were made with a laboratory-constructed atomic fluorescence spectrometer,[28] equipped with a Nippon Jarrell-Ash Model ASD-1A arsenic measurement unit and a newly constructed burner (*vide infra*). The atomic fluorescence instrument used contained the specific components shown in Table 1.

Burner. The present authors have reported the performance of a "multi-flame" burner of the slot type for atomic absorption spectrometry.[29] Based on a similar concept for premixed hydrogen flames, we designed and constructed a nitrogen-sheathed, water-cooled burner which can produce premixed argon (entrained air)– and nitrogen(entrained air)–hydrogen flames for atomic fluorescence measurements; the burner is shown in Fig. 1. It consists of a burner top and its holder, both of which are made of brass. To ensure the adequate entrainment of secondary air, the outer surface of the nozzle is tapered. Inside the burner is placed a porous

ceramic plate which contains about 50 holes(0.5 mm in diameter) per cm^2 and is 1.25 cm thick, to maintain the stability of the hydrogen flames of a higher burning velocity. In this study the new burner was fitted to a Techtron nebulizer chamber. A schematic diagram of the apparatus used in this work is shown in Fig. 2. The right half of the figure represents a nondispersive atomic fluorescence spectrometer. For a dispersive measuring system, the photomultiplier and its housing (10 in Fig. 2) are replaced by a monochromator equipped with a photomultiplier. The fluorescence radiation is measured at right angles to the axis of the optical path from the light source to the flame.

Procedures. The optimum instrumental variable settings used for the atomic fluorescence measurements are shown in Table 2. The arsine generated by the procedure previously reported for the atomic absorption spectrometry of arsenic[17] was introduced into premixed argon(entrained air)- and nitrogen(entrained air)-hydrogen flames in which argon and nitrogen respectively were used as the carrier gas as well as the auxiliary gas. The fluorescence signal was recorded on the pen recorder for the peak-height measurement throughout this work.

Oscilloscope	CS-1351, Trio
Recorder	QPD_{54}, Hitachi
Arsine-generating unit	ASD-1A, Nippon Jarrell-Ash

Results and Discussion

Atomic Fluorescence Spectrum of Arsenic. The spectral characteristics of all 15 lines of arsenic have been found by the solution-nebulization technique to exhibit atomic fluorescence in air–acetylene and argon- and nitrogen–hydrogen flames.[1] With the dispersive system, the spectral characteristics of the emission and fluorescence of all 15 lines of arsenic were examined in this study. The results obtained are shown in Table 3. With the present instrument, the 193.7 nm line gave the highest sensitivity in both the hydrogen flames. The values shown in Table 3 were not corrected for the photomultiplier spectral response.

Effect of Microwave Power. The present authors have previously described the relationship between the emission intensity of the arsenic 193.7 nm line and the microwave power applied for an arsenic electrodeless discharge lamp used for atomic absorption spectrometry.[30] In atomic fluorescence spectrometry for arsenic with the same arsenic electrodeless discharge lamp, the effect of microwave power ranging 18 to 40 W on the fluorescence signals was examined with the dispersive system at 193.7 nm. The results obtained were analogous to those previously reported in atomic absorption spectrometry.[30] This phenomenon can be easily explained on the base of the theoretical concept that the atomic fluorescence energy is directly proportional to the spectral irradiance of the light source.[31–33] The optimum power used is shown in Table 2.

Effect of Flame Composition and Flame Height. Tsujii and Kuga[26] have reported that the flame composition was not a critical factor with regard to the fluorescence

Table 2. Optimum experimental conditions

Microwave power applied	24 W (Incident power, 35 W; Reflected power, 11 W)
RC time constant	1.0 s
High voltage for photomultiplier	700 V
Load resistance	470 kΩ
Modulation frequency	90 Hz (for nondispersive system) and 240 Hz (for dispersive system)
Volume of sample	20 ml
Zinc tablet	One piece (Zn 0.6 g)
Potassium iodide solution	1.0 ml
Tin(II) chloride solution	1.0 ml
Hydrogen flow rate	3.6 l min^{-1}
Argon or nitrogen flow rates	Carrier 4.0 l min^{-1} Auxiliary 2.0 l min^{-1}
Nitrogen flow rate for flame sheathing	1.0 l min^{-1}
Flame height	4 cm (for argon (entrained air)-hydrogen flame) and 5 cm (for nitrogen (entrained air)-hydrogen flame)

intensity, but that the noise level remarkably affected by the flame composition in the argon(entrained air)-hydrogen flame.

In argon(entrained air)- and nitrogen(entrained air)-hydrogen flames, the effects of the flame composition and the flame height on the fluorescence signals of arsenic were examined over the range of hydrogen flow rate of 1.8—4.5 l min^{-1}, with the flow rate of argon or nitrogen kept constant. The results obtained in

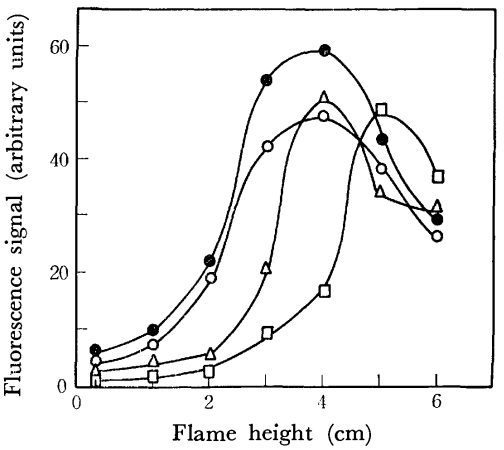

Fig. 3. Effect of flame composition and flame height on the fluorescence measurements.
Flame: argon (entrained air)-hydrogen flame, arsenic: 400 ng, argon flow rate for carrier gas: 4.0 l min^{-1}, argon flow rate for auxiliary gas: 2.0 l min^{-1}, hydrogen flow rates: ○ 1.8 l min^{-1}, ● 2.7 l min^{-1}, △ 3.6 l min^{-1}, □ 4.5 l min^{-1}.

the argon(entrained air)-hydrogen flame with the nondispersive system are shown in Fig. 3. Similar results were obtained in the nitrogen(entrained air)-hydrogen flame. As is shown in Fig. 3, the fluorescence signals varied remarkably with the variations in the flame composition and the flame height above the burner top. Taking account of noise levels, the optimum conditions for the flames were determined to be as is shown in Table 2. The flow rate of nitrogen as a sheath gas was fixed at 1.0 l min^{-1} throughout this work, because the flow rate did not affect the fluorescence signals in the range of 1.0 to 5.0 l min^{-1}.

Effect of Flow Rate of Carrier Gas. The fluorescence signals with the nondispersive system increased

a) The amount added, 400 μg. b) Relative to atomic fluorescence signal for 400-ng arsenic. c) Added as boric acid. d) Added as ammonium vanadate or molybdate respectively. e) Added as chloride. f) Added as sodium tungstate, silicate, or selenite respectively. g) Added as nitrate. h) Added as sulfate.

with an increase in the flow rates of the carrier gas up to 4.0 l min^{-1} when the total flow rate of argon or nitrogen as the carrier and auxiliary gases was kept constant, but the presence of carrier gas for over 5.0 l min^{-1} caused a gradual decrease in the reproducibilities of the fluorescence signals. Below 3.0 l min^{-1} of the carrier gas the fluorescence signal was broadened because of the slower introduction of arsine into the flame. The optimum flow rate is shown in Table 2.

Effect of Pressure in Collection Vessel. The pressure of the arsine and hydrogen generated in the reaction flask (21 in Fig. 2) was indicated with a pressure gauge (24 in Fig. 2). The effect of the pressure in the range from 10 to 40 kPa on the fluorescence signals for arsenic was examined with the nondispersive system in the argon(entrained air)–hydrogen flame. The optimum pressure was found to be 30 kPa. The pressure increased proportionally with an increase in the reaction time. In this work it was considered to be preferable to allow the reaction to continue until the pressure had attained to 30 kPa rather than to monitor the reaction time. At higher pressures, the precision in the fluorescence measurements became poor because the higher pressures resulted in unstability in the flame because of the disturbance of the carrier gas stream.

Effect of Acids. The effects of nitric, perchloric, phosphoric, and sulfuric acids in the range from 0.05 to 2.0 mol dm^{-3} on the fluorescence signal of arsenic were examined. As a consequence, it was found that perchloric, phosphoric, and sulfuric acids did not interfere, but nitric acid caused a large depressing interference. This interference may be attributed to the strong oxidizing action of nitric acid depressing the generation of arsine.

Effect of Various Other Elements. With the arsine-generation technique, most of the interference might be related to the process of reducing arsenic to arsine in both the atomic absorption and atomic fluorescence methods. The effects of 37 elements at the level of a 1000-fold excess were examined in a solution containing 400 ng of arsenic with the nondispersive system and the argon(entrained air)–hydrogen flame. The results are summarized in Table 4, in which the reaction time required to reach a pressure of 30 kPa is also shown for the elements investigated. A large number of elements including other hydride-formimg elements, such as antimony, bismuth, selenium, and tellurium, had great depressing interferences.

It has been reported that bismuth fluorescences at 206.170, 269.7, and 302.5 nm excited with the iodine line at 206.163 nm can be observed.[34,35] A strong emission of the iodine line was observed in the arsenic electrodeless discharge lamp used. However, no enhancement in the fluorescence signal with the nondispersive system was observed in the presence of bismuth. This means that hardly no bismuth hydride(bismuthine) is produced by the zinc reduction method under the conditions suitable for arsenic.

Analytical Working Curve, Sensitivity, and Precision. Analytical working curves were obtained by using arsenic standard solutions freshly prepared from a 1000 ppm stock solution with both the nondispersive and dispersive systems in both the hydrogen flames. Figure 4 shows the analytical working curves thus obtained. The lower limits of the linear range in the curves were severely restricted by the relatively high background due to the reagent blank, as is shown in Fig. 4. The reagent blank was approximately 20 ng of arsenic in 20 ml of a sample. As has previously been reported by Dagnall *et al.*,[1] the 193.7 nm line was more sensitive at lower concentrations of arsenic than the 197.2 nm line.

The detection limits, expressed by the mass or concentration which produces a fluorescence signal equal

to twice the noise level(signal-to-noise ratio=2), are shown in Table 5. The detection limits with the dispersive system were obtained at 193.7 nm.

Standard solutions containing 30, 100, 300, and 1000 ng of arsenic were prepared, and the fluorescence signals were repeatedly measured with the nondispersive system in the argon(entrained air)-hydrogen flame. The relative standard deviations, calculated from seven measurements, were 11.5, 8.9, 4.2, and 2.7% for 30, 100, 300, and 1000 ng of arsenic respectively.

Application to the Determination of Arsenic in Wastewaters. The present method was also applied to the determination of arsenic in wastewaters. The wastewater samples were taken at the inlet of the Wastewater Treatment Facility of the University of Osaka Prefecture. The most sensitive nondispersive atomic fluorescence measurements were made with the argon (entrained air)-hydrogen flame under the optimum conditions shown in Table 2. The samples were diluted by a factor of 2 to adjust the concentrations of sulfuric and hydrochloric acids to 5 and 20% respectively. The results

thus obtained are shown in Table 6. The atomic absorption measurements at 193.7 nm in the argon(entrained air)-hydrogen flame with a long-path "multiflame" burner[29,30,36-38] instead of the burner newly constructed for the atomic fluorescence measurements were made by means of the same procedures as in the atomic fluorescence method. The results obtained by the atomic fluorescence method were in good agreement with those obtained by the atomic absorption method.

Conclusion

The present nondispersive and dispersive atomic fluorescence spectrometers have been proved to be sensitive and reliable for the determination of arsenic at the nanogram order. The detection limits obtained with the nondispersive system and the argon(entrained air)-hydrogen flame produced by using a newly constructed burner were comparable with those reported by other authors.[26,27] In this study the sensitivity obtained by the nondispersive system was about one order of magnitude better than that obtained by the dispersive system at 193.7 nm. The former system requires a considerably simpler and less expensive instrumentation than the latter system. Moreover, there is little or no spectral interference except for the presence of the other hydride-forming elements examined in the present study, because of the separation of the analyte from the solution prior to atomization in the flame.

It was verified that the most sensitive nondispersive atomic fluorescence spectrometry can give a lower detection limit and a much larger linear dynamic range for arsenic than the corresponding atomic absorption spectrometry. With respect to interference, however, the present system was similar to the atomic absorption spectrometry.

An improvement in the sensitivity and linear dynamic range of arsenic might be made with a nonflame atomizer as an atom reservoir and/or the sodium tetrahydroborate($NaBH_4$) reduction method, which gives a much lower reagent blank than the zinc tablet reduc-

tion combined with tin(II) chloride and potassium iodide. Work is currently under way in this laboratory to investigate this possibility.

Photoaddition Reaction of 9,10-Phenanthrenequinone with Alicyclic Olefins.[1] Product Distribution

Kazuhiro MARUYAMA,* Tatsuaki IWAI,** Yoshinori NARUTA, Tetsuo OTSUKI, and Yo MIYAGI***

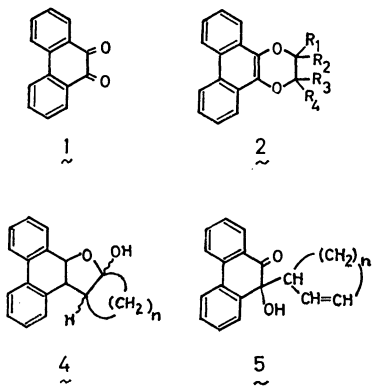
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received July 21, 1977)

The phtoaddition reaction of 9,10-phenanthrenequinone (**1**) with several alicyclic olefins (**6**) has been investigated. In addition to the expected products, dihydrodioxin(**2**) and keto oxetane (**3**), the hydroxydihydrofuran derivative (**4**, **5**) were found. Product distribution was shown to be deeply dependent on the structure of the olefins. Product **4** has been shown to be produced *via* the photorearrangement of **3**.

9,10-Phenanthrenequinone (PQ) **1** photochemically adds to olefins to give several products. Schönberg and Mustafa reported first the photochemical reaction of **1** with olefins gave dihydrodioxin **2**. The subsequent reaction has been investigated by many workers.[2-6] According to the literature[7] the product distribution is dependent on the olefins used in the reaction. For example, dihydrodioxin **2**, a common product in the reaction with acyclic olefins, is the exclusive product in the reaction of **1** with either *cis*- or *trans*-stilbens.[8] In contrast, the reactions with benzofuran,[9] isocumarin,[9] and vinylene carbonate[5,10] afforded keto oxetanes as the major products.

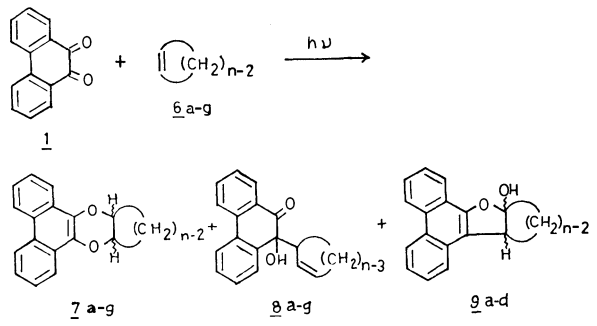
In this investigation the chemical reaction of **1** with alicyclic olefin **6** of various ring sizes from six to twelve membered has been examined. A novel type of product **4** has been isolated and the amounts of **4** were found to be dependent on the structure of the olefins.



Results

Photochemical Reactions of 9,10-Phenanthrenequinone ***1*** *with Alicyclic Olefins* ***6a—g.*** Irradiation of a benzene solution of **1** and **6a—g** in a Pyrex tube using a 300W high pressure Hg lamp gave three kinds of products **7**, **8**, and **9**. Under these conditions no keto oxetane was found. The keto oxethane was obtained (yield 18%), however, using light of wavelength longer than 400 nm in the reaction of **1** with **6c**.

The formation of dihydrodioxin **7** has been reported in many photochemical reactions of **1** with olefins.[2-6] However, the products of adduct **8** type have been found only in a few cases.[11] So far hydroxydihydrofuran **9** has never been described in the literature. The structure of these products has been determined on the basis of their spectral data and yields are given in Table 1. Although the dihydrodioxins **7a—g** consisted of a mixture of the *cis*- and *trans*-isomers, the two isomers were separated in some cases by fractional crystallization. The isomer ratios were determined, in general, by means of ^{1}H-NMR spectroscopy taking advantage of the bridge-head methine protons exhibiting two distinct signals. The ^{1}H-NMR signal at lower field has been assigned to the *cis*-isomer and that at higher field to the *trans*-isomer.[12] It has been found that, in the conformational equilibrium that the bridge-head proton of the *trans*-isomer is advantageous to take axial position (Fig. 1); The *cis*-isomer favors the equatorial position, where it is affected strongly by the anisotropic effect of the dihydrodioxin ring.



a; $n=6$, **b**; $n=7$, **c**; $n=8$, **d**; $n=9$, **e**; $n=10$, **f**; $n=11$ **g**; $n=12$.

As a result, the bridge-head proton of the *cis*-isomer appears at lower field. Table 2 shows the isomer ratios of the dihydrodioxins **7a—g**.

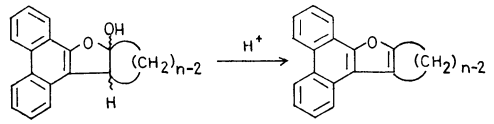
Adducts **8a—c**, which arose from the α-hydrogen abstraction from the olefinic double bond, are mixtures of two diastereomers. Therefore, **8a** and **8b** show two distinguishable ^{1}H-NMR absorption signals which can be assigned to each of the diastereomer's. In the case of **8c**, the two diastereomers could not be distinguished by ^{1}H-NMR spectroscopy. Such phenomena have been observed by other investigators in the photochemical reactions of 1,1,4,4-tetramethyltetralin-2,3-dione, 1,1,4,4-tetramethylcyclohexane-2,3-dione, and 1,1-dimethylindan-2,3-dione with cyclohexene.[13] Adducts **8d—g** were isolated respectively as a mixture of four geometrical isomers in cycloalkene moiety. Hydroxydihydrofurans **9c** and **9d** can be easily dehydrated in the presence of a trace amount of acid. Dehydration in acidified methanol gave **10c** and **10d** in nearly quantitative yield. The dehydration strongly supports the structure of **9**. Under neutral conditions **9c, d** are fairly stable, but **9a, b** are not, decomposing to yield unidentifiable products.



9 c,d 10 c,d

Photochemical Reaction of ***1*** *with Norbornene* ***11***.
The major products of the photoreaction of **1** with cycloalkenes **6a—g** as described above are the dihydrodioxines **7a—g**. In the photoreaction of **1** with norbornene **11** only the oxetane **12** was produced (yield: 75%), consequently the structure of the oxetane product has to be either **12A** or **B**. The configuration of the obtained oxetane **12** was determined by ^{1}H-NMR spectrocsopy: H_1' proton (δ 4.8, d, J=5 Hz) couples with H_2' proton (δ 2.42, d, J=5 Hz) and *vice versa*. However, the *endo* protons, H_1' and H_2', do not couple with the bridge-head protons, H_6' and H_3', respectively. It has been shown by Kumpler[14] that the coupling constants between the *endo* protons and the bridge-head protons in bicyclo[2.2.1]heptane system are very small (J=*ca.* 0). This phenomenon has been applied to determine the configuration of *exo*- and *endo*-oxetanes which were obtained from the photochemical reaction of norbornene with acetylcyanide.[15] From this evidence the configuration of the obtained oxetane **12** has been set as *exo*, *cis*. The orientation of the bicyclo[2.2.1]heptane ring to the C=O group in **12** has been determined from lantanide induced shift data. The shifts of the proton signals due to complex formation with tris(dipivalometanato)europium(III) [Eu(DPM)$_3$][16] are given in Table 3. The signals of the protons, H_1', H_6', and H_{7s}' underwent larger shifts than those of the protons, H_2', H_3', and H_{7a}', respectively. In addition, the same induced shift values were observed for each of the *endo* protons, H_{4N}' and H_{5N}'.

Phenanthrenequinone **1** + Nornene **11** ⟶ **12A** + **12B**

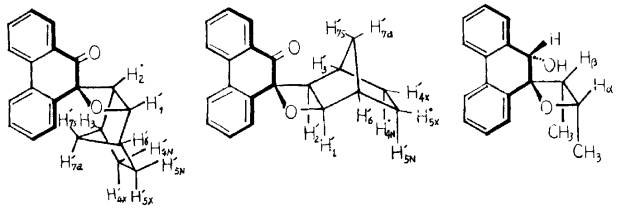
Similarly, the two *exo* protons, H_{4x}' and H_{5x}', showed the same induced shift. The induced shift values of the oxetane ring α- and β-protons are small compared with the corresponding oxetane ring protons of **15**. In the investigation of the structure of **15** it has been shown that the Eu^{3+} ion in the complex predominantly

TABLE 3. Eu(DPM)$_3$ INDUCED SHIFTS[a] IN THE ^{1}H-NMR SPECTRUM OF **12**[c]

Proton	H_1'	H_2'	H_3'	H_{4X}' and H_{5X}'	H_{4N}' and H_{5N}'	H_6'	H_{7s}'	H_{7a}'
Chemical shift[b] ppm	4.80	2.42	2.55	1.08	0.77	2.55	1.78	1.30
Induced shift ppm	18.4	15.0	2.1	1.2	3.9	7.2	7.0	3.7

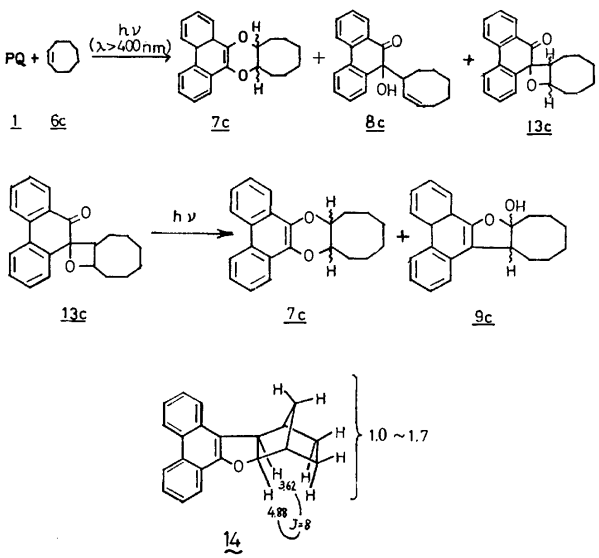
a) Determined from the slopes of the plots of shifts (in ppm) *vs.* molar ratio of Eu(DPM)$_3$: **12** by least-squares method; concentration of **12**, *ca.* 0.125 M in CCl_4. b) CCl_4 was used as the solvent. c) The Chemical shifts and the induced shifts of aromatic protons are omitted in this table.

associates with the ethereal oxygen rather than with the alcohlic oxygen.[5] Moreover, in **12** the C-8 proton undergoes a smaller shift than that of the C-8 proton of **15**. Consequently, it has been concluded that by complexing with **12** the Eu^{3+} is situated at an equilibrium position between the ethereal oxygen and the carbonyl oxygen and the bicyclo[2.2.1]heptane ring is located *trans* to the carbonyl group; the isolated one corresponds to **12A**. The same conclusion may be drawn on the basis of the down-field shift of the *syn* proton H_{7s}', compared with the *anti* proton, H_{7a}', interpreted in terms of the benzene ring current.



12A **12B** **15**

Photorearrangement of Oxetanes. Irradiation of a benzene solution of **1** with cyclooctene **6c** (300W high pressure Hg lamp) gave a mixture of **7c**, **8c**, and **9c** as described above. When the reaction was stopped at a relatively low conversion (irradiating light of a wavelength longer than 400nm), the corresponding oxetane **13** (18%) was isolated from the reaction mixture together with **7c** (39%, *cis*: *trans*=64: 36) and **8c** (5%). **9c** was not isolated. Further irradiation of **13c** dissolved in benzene using all the light of the high pressure lamp demostrated that **13c** easily photorearranged to **7c** and **9c** (relative ratio; 9 : 1). Since **7c** is photostable, the above results lead to the conclusion that **9a**—**d** and a part of **7a**—**d** are the photorearraged products of **13a**—**d**.

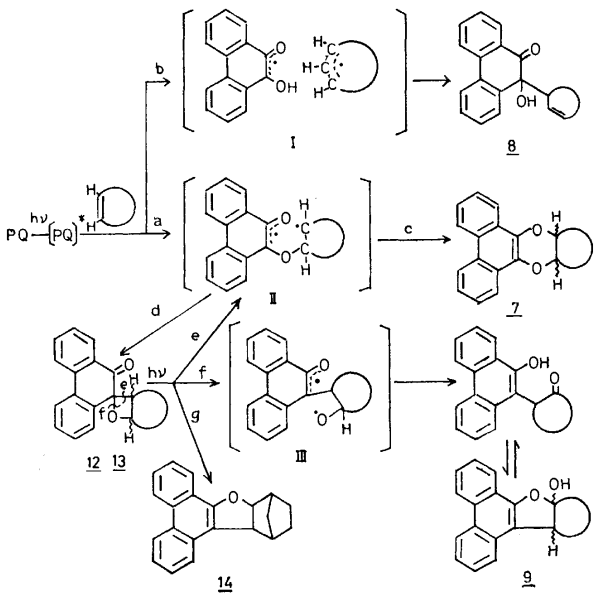


The oxetane **12** derived from norbornene, in comparison, was comparatively photostable, being ultimately decomposed under prolonged irradiation to give rather intractable products. After repeated column chromatography dihydrofuran **14** (*ca.* 12%) was isolated. On the basis of the ^{1}H-NMR spectrum the configuration of **14** was determined to be *exo*.[20]

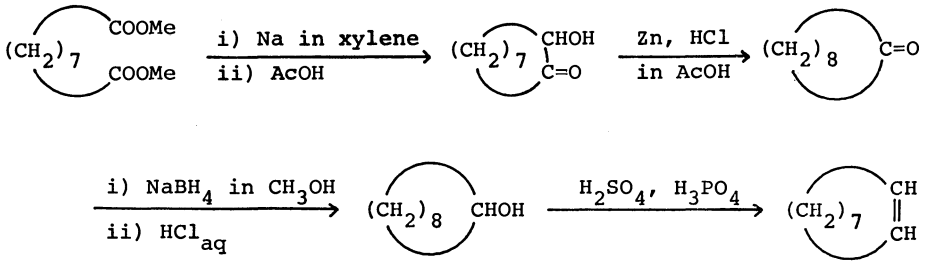
Discussion

Using cycloalkenes with a *cis*-configuration,[22] a mixture of the *cis*- and *trans*-dihydrodioxins were obtained in every reaction (Table 2). These results suggest that each of the dihydrodioxins was formed in a stepwise fashion, perhaps *via* a biradical intermediate. Similar experimental results have been reported in the reaction of **1** with *cis*-2-butane,[17] *trans*-2-butene,[17] and *trans*-stilbene.[18]

In the formation of oxetane the present investigation gives no unambiguous information. However, the results published strongly indicate the contribution of a biradical intermediate.[9,10] Possible reaction pathways compatible with the present results are shown in Scheme 1. Photoexcited phenanthrenequinone reacts with a olefin in two competitive manners; addition to the olefin to give II (path a) and hydrogen abstraction from the olefin resulting in the formation of a radical pair I (path b). As shown in Tables 1 and 2, cyclo-



Scheme 1.



Scheme 2.

octene is most reactive for path a and least for path b for the examined monocycloolefins, because the yield of **8** is least in this case. In addition, the resulting biradical II is likely to be of rather a longer lifetime compared with those derived from other monocycloolefins;[22] this has been deduced from the relatively high yield of the corresponding *trans*-dihydrodioxin, *i.e.*, *trans*-**7e**, since the *cis*- and *trans*-dihydrodioxins are photostable in general. Thus, the difference in energy barriers between path a and path b could be highest in the case of cyclooctene of the examined mono-cycloolefins. In the case of norbornene the difference is thought to be so large that path b can not contribute to the reaction, being coincident with the fact that the α-hydrogen atom to the double bond of norbornene corresponds to the bridge-head one. The difference in cycloolefin behavior may be attributed to the cumulative effect of the internal strain and the restricted freedom of the ring fluctuation (depending on the ring size).

The resulting biradical II is stablized to give **7** and **13** (or **12**). Further irradiation of **13** with the light from a high pressure Hg lamp gave two biradicals II and III, finally resulting in the formation of **7** and **9**. The relative preference of path c or path d was found to be strongly dependent on the structure of olefins. In the case of norbornene, path d was the exclusive course. In the case of cyclooctene there may be a comparatively high contribution of path d, since the highest yield of **9** was attained in the reaction. The high selectivity for path d in the cases of norbornene and cyclooctene is likely to be correlated with the lesser yield of **8** in the reactions. Although the mechanism still remains ambiguous, the relative preference for path d seems to be connected with the higher *s*-charactor of the relating orbitals in the ring closure, especially of the orbital in the olefin moiety. The special behavior of norbornene and other highly strained cycloolefins in photocycloadditions with 1,4-naphthoquinone have been reported by the present auther and co-workers.[21] The higher *s*-charactor of the relating orbitals will result in the stronger σ-bond and this may be the reason for the stable isolation of oxetanes **12** and **13** derived from norbornene and cyclooctene respectively. In the other cases, isolation of the corresponding oxetanes was unsuccessful, perhaps due to the lack of stability.

As described in the previous section, the oxetane **12** photochemically rearranges to hydroxydihydrofuran **9** and dihydrodioxin **7**. The photorearrangement of **12** to **9** is of novel type. Farid has isolated an oxetane in the reaction of phenanthrenequinone with 1,2-di-*t*-butylethylene. Investigation of the photorearrangement yielded a mixture of dihydrodioxin, furan, and dioxole. However, the hydroxydihydrofuran derivative has not been isolated.[19]

Experimental

Instrumentation. ^{1}H-NMR spectra were recorded with JEOL PS-100 spectrometer and chemical shifts have been recorded in δ units using tetramethylsilane as an internal standard. Infrared spectra were taken with a JASCO IR-G spectrometer. Ultraviolet and visible spectra were obtained with a Shimadzu UV-200 spectrometer. Mass spectra were recorded with a Hitachi M-52 mass spectrometer. Elemental analyses were performed at the Microanalysis Center of Kyoto University. VPC was carried out using a JEOL JGC-20K equipped with a flame ionization detector using a column of 5% Ucon oil LB 550X on 80—100 mesh Diasolid L. Melting points and boiling points of materials or products have not been corrected.

Materials. 9,10-Phenanthrenequinone (**1**) was prepared by the oxidation of phenanthrene[23]; mp 209—210 °C (lit, mp 208.5—210 °C). Cyclohexene (**6a**), cycloheptene (**6b**), *cis*-cyclooctene (**6c**), cyclododecene (**6g**), and bicyclo-[2.2.1]hept-2-ene (norbornene) (**11**) were commercially available (reagent grade) and used without further purification. Analyzed by VPC, cyclododecene (**6g**) proved to be a mixture of 30% *cis*- and 70% *trans*-isomer. Cyclononene (**6d**) was synthesized from diethyl azelate according to the route described above (Scheme 2); bp 160—172 °C (lit,[26] bp 167—169 °C/740 mmHg for the *cis*-isomer, 73—74 °C/30 mmHg for the *trans*-isomer); ^{1}H-NMR (CCl_4) δ 1.0—2.4 (14H, m), 5.56 (2H, m); IR (NaCl) 2910, 2840, 717, 728 cm^{-1}. Analysis by VPC and IR indicated that the synthesized cyclononene (**6d**) contained mainly the *cis*-isomer.

Cyclododecene (**6e**) and cycloundecene (**6f**) were synthesized from cyclodecanone and cycloundecanone, respectively. Cyclodecanone and cycloundecanone were synthesized from cyclododecanone in good yield by the method of Garbish and Wohlleke.[25] Cyclodecene (**6e**); bp 87—92 °C/42 mmHg (lit,[24] bp 194—195 °C/740 mmHg for the *cis*-isomer, 68—70 °C/10 mmHg for the *trans*-isomer); ^{1}H-NMR (CCl_4) δ 1.2—2.4 (16H, m), 5.48 (2H, m); IR (NaCl) 2900, 2840, 980 cm^{-1}. Analysis by VPC and IR indicated that the synthesized cyclodecene (**6e**) contained approximately 45% of the *cis*- and 55% of the *trans*-isomer. Cycloundecene (**6f**); bp 110—111 °C/40 mmHg; ^{1}H-NMR (CCl_4) δ 1.0—2.4 (18H, m), 5.30 (2H, m); IR (NaCl) 2905, 2840, 970 cm^{-1}. Analysis by VPC and IR indicated that the synthesized cycloundecene (**6f**) contained about 28% of the *cis*- and 72% of the *trans*-isomer.

Irradiation of PQ (1) with Cycloalkene(6a—g) and Norbornene (11). Pyrex test tubes were charged with PQ (**1**)

a) Compound **9d** showed the complicated ^{1}H-NMR spectrum because hemiacetal ring was somewhat dissociated. Phenolic OH proton was observed at δ 10.28 ppm.

(1 mmol), cycloalkene (**6a—g**) (2 mmol) or norbornene (**11**) and reagent grade benzene (30 ml) (dried over sodium). The solutions were irradiated with a 300 W high-pressure mercury lamp and during irradiation, the test tubes were often shaken. The course of the reactions was followed by TLC. When the PQ had mostly disappeared the solvent was evaporated, and products separated by preparative silica gel TLC eluted with hexane–benzene or by florisil column chromatography eluted with hexane–benzene. The yield of products were determined from the weight of the corresponding fractions. The structures of each fraction were confirmed by means of ^{1}H-NMR technique. The crystalline products were recrystallized from hexane, benzene, or cyclohexane. The spectral data and the results of elementa analyses are summarized in Tables 4—6.

furane **9c,d** (20 mg) in methanol (20 ml), one drop of concd HCl was added. After standing for 1 h at room temperature, TLC analysis indicated that hydroxydihydrofurane (**9c**) had disappeared and furan (**10c**) exclusively formed. After evaporation of the solvent, product **10c** was recrystallized from pentane; mp 141—142 °C, which showed the following spectral data; ^{1}H-NMR (CCl_4) δ 1.2—2.1 (8H, m), 2.96, 3.10 (4H, two overlapped t), 7.50 (4H, m), 8.22 (2H, m), 8.61 (2H, m); IR (KBr) 1620, 1605, 1575 cm^{-1}; mass spcetrum *m/e* 300 (M^+). Found: C, 87.86; H, 6.51%. Calcd for $C_{22}H_{20}O$: C, 87.96; H, 6.71%.

Similarly, **10d** was obtained from **9d**. **10d**, mp 151.5—153 °C, gave the following spectral data; ^{1}H-NMR (CCl_4) δ 1.2—2.0 (14H, m), 2.92 (2H, t), 3.10 (2H, t), 7.42 (4H, m), 8.16 (2H, m), 8.52 (2H, m); IR (KBr) 1620, 1605, 1575 cm^{-1}; mass spectrum *m/e* 314 (M^+).

Irradiation through a Filter. A solution containing PQ (**1**) (216 mg, 1.04 mmol) and cyclooctene (**6c**) (219 mg, 1.99 mmol) in reagent grade benzene (30 ml) was irradiated with a 300W high-pressure mercury lamp through a filter (Toshiba color glass filter V-Y 42) to exclude light below 400 nm. After the usual work-up the products were separated by preparative TLC eluted with benzene. Products; dihydrodioxin (**7c**) (128 mg) (*cis*: *trans*=64:36), detectable amounts of α-hydrogen abstracted adduct **8c**, and oxetane **13c** (61 mg) were isolated. **13c**, mp 190—191 °C, slightly yellowish leaflets gave the following spectral data; ^{1}H-NMR ($CDCl_3$) δ 1.0—2.4 (12H, m), 2.88 (1H, ddd, J=2,8,8 Hz), 5.00 (1H, dd, J=8,14 Hz), 7.2—8.2 (8H, m); IR (KBr) 1680, 1600 cm^{-1}; UV λ_{max} ($CHCl_3$) 245 nm (ε 25000), 281 (2700), 327 (2900); mass spectrum *m/e* 318 (M^+). Found: C, 82.98; H, 6.96%. Calcd for $C_{22}H_{22}O_2$: C, 82.70; H, 6.72%. Under similar conditions, a benzene solution of PQ (**1**) with cyclododecene (**6g**) was irradiated, but no oxetane could be isolated.

*Photorearrangement of Oxetane **13c**.* A solution of oxetane **13c** (62 mg) in reagent grade benzene (10 ml) (dried over sodium) was irradiated with a 300W high-pressure mercury lamp for 25 h. The TLC analysis indicated that dihydrodioxin (**7c**) and hydroxydihydrofurane (**9c**) were formed. After evaporation of solvent, the residue was dissolved in methanol (10 ml) and one drop of concd HCl added. After standing for 1 h at room temperature, dihydrodioxin (**7c**) and furane (**9c**) were isolated after the usual work-up. The ratio of **6c** to **9c** was determined as 10:1 by means of ^{1}H-NMR spectroscopy utilizing the bridge-head methine protons of **6c** and methine protons adjecent to furane ring of **9c** as their indices.

*Photorearrangement of Oxetane **12**.* A solution of oxetane (**12**) (215 mg) in benzene (30 ml) was irradiated with a 300W high pressure Hg lamp for about 10 days. The TLC analysis indicated that oxetane (**12**) almost disappeared. After evaporation of the solvent, dihydrofurane (**14**) (24 mg) was isolated from the residue. The other products were an intractable matter. **14** was recrystallized from hexane, mp 136—138 °C, which gave the following spectral data; ^{1}H-NMR (CCl_4) δ 1.0—1.7 (6H, m), 2.66 (2H, bs), 3.62 (1H, d, J=8 Hz), 4.88 (1H, d, J=8 Hz), 7.40 (5H, m), 7.92 (1H, m), 8.48 (2H, m); IR (KBr) 1640, 1615 cm^{-1}; mass spectrum *m/e* 286(M^+). Found: C, 87.99; H, 6.22%. Calcd for $C_{21}H_{18}O$: C, 88.08; H, 6.34%.

Reduction of Acetals with $TiCl_4$–$LiAlH_4$

Hiroshi ISHIKAWA* and Teruaki MUKAIYAMA†

Laboratories of Medicinal Chemistry, Otsuka Pharmaceutical Co., Ltd., Kagasuno, Kawauchi-cho, Tokushima 771-01

† *Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received October, 12, 1977)

The reduction of dialkyl acetals derived from aromatic aldehydes and ketones with $TiCl_4$–$LiAlH_4$ in THF or diethyl ether at room temperature afforded the coupling products, pinacol ethers or olefins, in high yields. On the other hand, when acetals derived from aliphatic aldehydes and ketones were treated with $TiCl_4$–$LiAlH_4$ in diethyl ether, the reductive dealkoxylation took place and the corresponding ethers were isolated in good yields. As to the reaction mechanism we propose that Ti(II) is the reactive species in reductive coupling reaction of acetals derived from aromatic aldehydes and ketones, and that Ti(0)–H_2AlCl complex may be the reactive species in reductive dealkoxylation of acetals derived from aliphatic aldehydes and ketones.

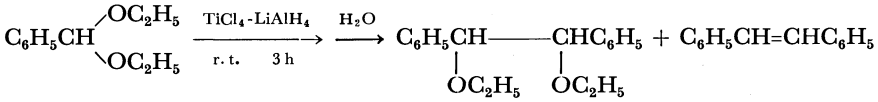
The reactivity of $LiAlH_4$ can be greatly modified by addition of metal salts. $LiAlH_4$–$AlCl_3$ has been found to have an unusual applicability in epoxide reductrion[1] and in reduction of acetals to the corresponding ethers.[2–7] Further, $LiAl(OCH_3)_3H$–CuI can effect reductive removal of halo and mesyloxy groups,[8] and $LiAlH_4$–$TiCl_3$ has been found to be a coupling reagent.[9] Recently Ashby *et al.* have reported that 1,4-reduction of α,β-unsaturated ketones by using $LiAlH_4$–CuI proceeds with almost complete functional selectivity.

During the course of our investigation on the exploration of various synthetic reaction by the use of $TiCl_4$, we reported in the previous paper[11] that various olefins were prepared in good ylieds by the treatment of allyl methyl ethers with $TiCl_4$–$LiAlH_4$ in THF or diethyl ether.

Recently, it has been shown[12] that a low valent titanium compound, prepared from $TiCl_4$ and Zn, reduces aldehydes or ketones to afford the corresponding pinacols or olefins in high yields and that the selectivity of the reaction depends on the reaction conditions.

In the present work the reduction of various acetals using $TiCl_4$ and $LiAlH_4$ was studied, and it was found that reductive coupling or dealkoxylation took place depending on the types of starting acetals and on the solvents employed.

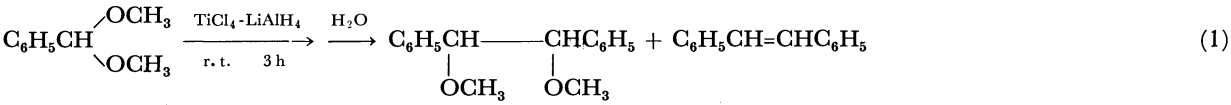
At first the reaction of benzaldehyde diethyl acetal (**1**) with the low valent titanium compound was examined under various conditions. For example, benzaldehyde diethyl acetal (**1**) was added to a mixture of equimolar amounts of $TiCl_4$ and $LiAlH_4$ in THF at room temperature, and after stirring at room temperature for 3 h, the mixture was quenched with aqueous potassium carbonate. Purification by column chromatography (silica gel) gave 1,2-diethoxy-1,2-diphenylethane (**2**) and stilbene (**3**) [trans: 86%, cis: 14%] in 85 and 10% yields, respectively.



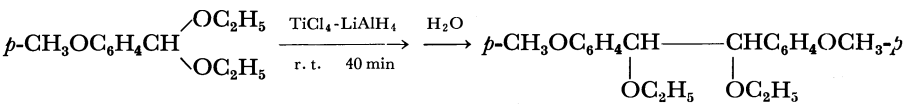
(**1**) (**2**) 85 (**3**) 10%

As shown in Table 1, when the ratio $LiAlH_4$ to $TiCl_4$ was decreased, the yield of products decreased. On the other hand, no difference in yields was observed when molar ratio of $LiAlH_4$ was increased.

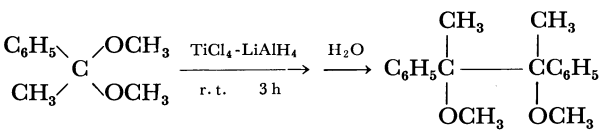
The reaction of various acetals derived from aromatic aldehydes or ketones with equimolar amounts of $TiCl_4$–$LiAlH_4$ was tried in THF at room temperature, and the corresponding pinacol ethers and olefins were obtained in high yields as shown in the following equations; (1)-(4).



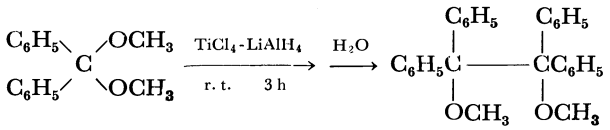
(**4**) (**5**) 77% (**3**) 15% (1)



(**6**) (**7**) 98% (2)



(**9**) (**10**) 97% (3)



(4)

(11) (12) quant.

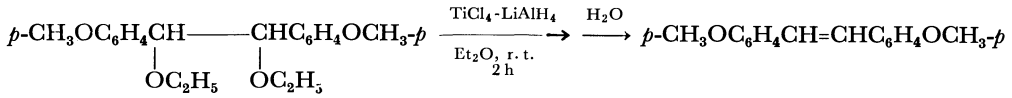
Table 1. Reductive coupling of benzaldehyde diethyl acetal with different ratio of the reagents in THF

Acetal	Molar ratio		Yield (%)	
	$LiAlH_4$	$TiCl_4$	Pinacol ether	Stilbene
1	0.5	1	41	5
1	1	1	85	10
1	2	1	83	9

As shown in the above equations, pinacol ethers were obtained in high yields by the reaction of acetals derived from aromatic aldehydes and ketones with $TiCl_4$–$LiAlH_4$. The yields of the two kinds of products, pinacol ether and olefins, markedly depended on the solvents used. For example, when *p*-methoxybenzaldehyde diethyl acetal (**6**) was treated with $TiCl_4$–$LiAlH_4$ in THF at room temperature, 4,4′-dimethoxystilbene (**8**) could not be detected and pinacol ether was obtained exclusively. In sharp contrast with this, when diethyl ether was used as solvent, olefins, (**8**) were isolated in 36% yield together with pinacol ether (**7**). However the reductive coupling did not proceed in benzene.

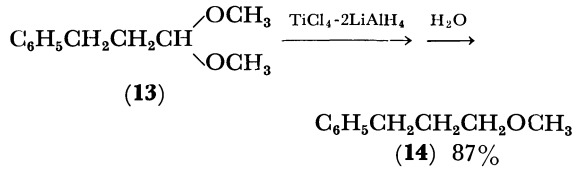
The results are show in Table 2.

Further, it was found that pinacol ether (**7**) reacted with two molar amounts of $TiCl_4$–$LiAlH_4$ in diethyl ether at room temperature to afford the corresponding olefins (**8**) in 57% yield.



(7) (8) 57%

On the other hand, the reduction of acetals derived from aliphatic aldehydes and ketones such as 3-phenylpropanal dimethyl acetal (**13**) with $TiCl_4$–$LiAlH_4$ did not take place in THF. But when, the acetal (**13**) was treated with $TiCl_4$ and two molar amounts of $LiAlH_4$ in diethyl ether, the acetal was reduced to the corresponding ether, 1-methoxy-3-phenylpropane (**14**), in 87% yield.



(13) (14) 87%

The generality of the reaction was examined by the use of various acetals such as 3-phenylpropanal diethyl acetal, benzylacetone dimethyl acetal, benzylacetone diethyl acetal, cyclohexanone dimethyl acetal, cyclohexanone ethylene acetal, and in all cases the corresponding ethers were obtained in good yield (see Table 3).

Although a detailed understanding of the reaction mechanism must wait knowledge of the nature of the reagent, Eq. 5, shows a possible explanation for the observation of a black precipitate and gas evolution in the first step of this reaction.

$$TiCl_4 + LiAlH_4 \longrightarrow TiCl_2 + LiCl + H_2AlCl + H_2 \quad (5)$$

McMurry[9] has suggested that Ti(II) is the reactive species in reductive coupling reactions. Recently, Corey[15] has proposed that Ti(II) is the reactive species in the intermolecular and intramolecular pinacolic coupling reaction of aldehydes and ketones. Based on these assumptions a possible mechanism of the reductive coupling reaction is proposed (Scheme 1).

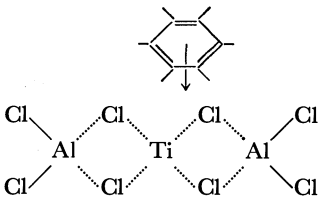
(8)

Reductin of acetals derived from aromatic aldehydes and ketones by the Ti(II) reagent may give a radical intermediate (Eq. 6), which dimerizes into pinacol ethers. Further reaction of the pinacol ether with Ti(II) reagent may give olefins.

In order to certify the hypothesis embodied in Scheme 1, we examined the reductive coupling using well-defined Ti(II) species. We have found Ti(II) complexes of known structure which are capable of

effecting the reduvtive coupling of acetal derived from aromatic aldehyde. The complex [**A**],[16] prepared by the reaction of Al–$AlCl_3$, $TiCl_4$, and hexamethylbenzene is especially effective: 1,2-diethoxy-1,2-bis (*p*-methoxyphenyl)ethane (**7**) was obtained in 52% yield by the reaction of [**A**] with *p*-methoxybenzaldehyde diethyl acetal (6).[17]



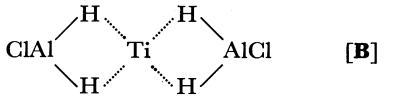
[**A**]

The observed solvent effects may reflect the different coordination ability of Ti(II) species with THF from that with diethyl ether.

On the other hand, the mechanism of the reduction of acetals derived from aliphatic aldehydes and ketones by $TiCl_4$–$2LiAlH_4$ could not be made clear. However, when $TiCl_4$ is treated with two molar amounts of $LiAlH_4$, titanium metal is supposed to be formed (Eq. 9). In fact, the formation of titanium metal was observed in this reaction.

$$TiCl_4 + 2LiAlH_4 \rightarrow Ti(0) + 2LiCl + H_2AlCl + H_2 \quad (9)$$

It is well known that the low valent titanium compound form complexes with organic or inorganic aluminum compounds[16,18] and with alkyl halides.[19]



[**B**]

Accordingly, we assume that the reactive intermediate is complex [**B**] in the reduction of acetals derived from aliphatic aldehydes and ketones by using $TiCl_4$–$2LiAlH_4$.

We are continuing the mechanistic study on the intermediates of the titanium complex [**B**] in this reductive dealkoxylation.

In conclusion, it has been made clear that the combination of $TiCl_4$ and $LiAlH_4$ is effectively applied to the reduction of acetal like $AlCl_3$–$LiAlH_4$. It is characteristic that when the acetals derived from aromatic aldehydes and ketones are treated with $TiCl_4$–$LiAlH_4$ in THF, pinacol ethers are obtained in high yields.

Experimental

Materials. Commercially available $TiCl_4$ was distilled under argon atmosphere before use. Various acetals were prepared according to the procedures described in the literature[20] and purified by distillation. All boiling points and melting points were uncorrected. The IR spectra were recorded with a Hitachi 215 grating infrared spectrophotometer. The proton NMR spectra were recorded using Varian EM360 spectrometer and Hitachi R-20B high resolution spectrometer with TMS as an internal standard. The physical properties and analytical data of the products are shown in Table 4.

*Reductive Coupling of Benzaldehyde Diethyl Acetal (**1**).* To a stirred suspension of $TiCl_4$ (0.95 g, 5 mmol) in 15 ml of THF was added a suspension of $LiAlH_4$ (0.19 g, 5 mmol) in 10 ml of THF at room temperature under argon atmosphere. During the addition of $LiAlH_4$ hydrogen evolved vigorously and the reaction mixture turned to black, which indicated the formation of a low valent titanium compound. After stirring the mixture for 30 min at room temperature, benzaldehyde diethyl acetal (0.90 g, 5 mmol) in 10 ml of THF was added dropwise to the reaction mixture during 10 min at room temperature, and the reaction mixture was stirred for 3 h. The reaction was quenched by the addition of 10 ml of 10% aqueous potassium carbonate, and a dark brown precipitate appeared was filtered off. The filtrate was extracted with ether. The ether extract was washed with saturated sodium chloride solution and dried over sodium sulfate. After removal of the solvent under reduced pressure, 1,2-diethoxy-1,2-diphenylethane (**2**) and stilbene (**3**) were isolated by column chromatography (silica gel) using hexane–dichloromethane (1:1) as an eluent in 85% (0.75 g) and 10% (0.045 g) yields, respectively.

*Reduction of 1,2-Diethoxy-1,2-bis(p-methoxyphenyl)ethane (**7**) with $TiCl_4$–$LiAlH_4$.* To a sirred suspension of $TiCl_4$ (0.38 g, 2 mmol) in 5 ml of diethyl ether was added a suspension of $LiAlH_4$ (0.08 g, 2 mmol) in 8 ml of diethyl ether at room temperature under argon atmosphere. After stirring the mixture for 20 min at room temperature, pinacol ether (**7**) (0.33 g, 1 mmol) in 5 ml of diethyl ether was added at room temperature during the period of 5 min. The mixture was stirred at room temperature for 2 h. The reaction mixture was worked up as mentioned in the previous case. After removal of the solvent and purification by preparative TLC (silica gel) using dichloromethane to give 0.13 g (57%) of 4,4′-dimethoxystilbene (**8**).

*Reduction of 3-Phenylpropanal Dimethyl Acetal (**13**).* To a stirred suspension of $TiCl_4$ (0.95 g, 5 mmol) in 15 ml of diethyl ether was added a suspension of $LiAlH_4$ (0.38 g, 10 mmol) in 10 ml of diethyl ether at room temperature under argon atmosphere. After stirring the mixture for 30 min at room temperature, 3-phenylpropanal dimethyl acetal (0.90 g, 5 mmol) in 15 ml of diethyl ether was added at room temperature. The mixture was stirred at room temperature for 2 h, then refluxed for an additional 1 h, and worked up as mentioned in the previous procedure. After removal of the solvent and purification by column chromatography (silica gel), 1-methoxy-3-phenylpropane (**14**) was isolated in 87% (0.65 g) yield. The NMR and IR spectra of the product (**14**) are shown in Table 4.

*Reduction of Cyclohexanone Ethylene Acetal (**23**).* To a stirred suspension of $TiCl_4$ (9.5 g, 50 mmol) in 150 ml of diethyl ether was added a suspension of $LiAlH_4$ (3.8 g, 100 mmol) in 100 ml of diethyl ether at room temperature under argon atmosphere. After stirring the mixture for 1 h at room temperature, cyclohexanone ethylene acetal (7.1 g, 50 mmol) in 100 ml of diethyl ether was added during the period of 40 min. The mixture was stirred at room temperature for 2 h. After the usual work-up, 2-(cyclohexyloxy)ethanol (**24**) (5.4 g, 75%) was collected by distillation.

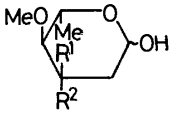
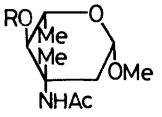
Branched-chain Sugars. XI. Synthesis of 2,3,6-Trideoxy-3-*C*,4-*O*-dimethyl-3-nitro-D-*arabino*-hexopyranose (D-Evernitrose)[1]

Juji YOSHIMURA,* Masafumi MATSUZAWA, and Masuo FUNABASHI
Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Techgnology, Nagatsuta, Midori-ku, Yokohama 227
(Received October 31, 1977)

2,3,6-Trideoxy-3-*C*, 4-*O*-dimethyl-3-nitro-D-*arabino*-hexopyranose was synthesized by the oxidation of methyl α-glycoside of the corresponding 3-amino derivative with *m*-chloroperbenzoic acid followed by hydrolysis. The 3-amino derivative was synthesized from methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose by introduction of the amino-branching function according to the method of Bourgeois, followed by 6-deoxygenation and 4-*O*-methylation.

Evernitrose (**1**) is a natural nitro-sugar first found by Ganguly *et al.* in oligosaccharide antibiotics, everninomicin B, C, and D.[2] The structure of **1** was deduced from spectroscopic evidence and chemical degradation[3] to be 2,3,6-trideoxy-3-*C*,4-*O*-dimethyl-3-nitro-L-*ribo*-hexophyranose (**2**). However, this was revised to L-*arabino* configuration by X-ray analysis of methyl β-glycoside of the corresponding 3-acetamido derivative (**3**).[4] Brimacombe and Doner attempted the sysnthesis of **1** by the nitroethane cyclization of dialdehyde obtained from methyl α-L-rhamnopyranoside, the product with the revised configuration at nitro-branching position being converted into 4-*epi*-vancosaminide (**4**).[5] However, this process is unsuitable for the synthesis of **1**, because of the poor yield (12%) and the difficulty of selective 4-*O*-methylation of the cyclization product, and the inevitable reduction of the nitro group in the subsequent 2-deoxygenation. Bourgeois reported a new method for the introduction of methyl and amino groups into C-3 position of 1,2 : 5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose by subsequent reactions of cyano-mesylation, reduction into spiro-aziridine and hydrogenolysis of the aziridine ring.[6] The steric course of the aziridine ring formation was proved by Brimacombe *et al.* to proceed by the intramolecular S_N2 mechanism[7] from the fact that identical amino-branched derivative was obtained by addition of azide to the corresponding 3-methylene derivative followed by hydrogenation.





(**1**) R^1=Me, R^2=NO_2 (**3**) R=Me
(**2**) R^1=NO_2, R^2=Me (**4**) R=Ac

We have synthesized the enantiomer (**27**) of **1** from methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranoside-3-ulose (**5**)[9] *via* the oxidation of the amino group of the corresponding amino-branched derivative into a nitro group. Since the method of Brimacombe *et al.*[7] was unsuccessful for the pyranoside ring, the amino-branched sugar was synthesized by that of Bourgeois.

Results and Discussion

Reaction of **5** with hydrogen cyanide in pyridine gave cyanohydrin (**6**) in *ca.* 50% yield. However, subsequent addition of trimethylsilyl chloride to the reaction mixture gave the corresponding ether (**7**) quantitatively. The configuration of **7** was determined to be D-*ribo* from the fact that the hydrogenation of **7** with lithium aluminium hydride(LAH) gave the corresponding 3-aminomethyl derivative (**8**) which was identical with the product obtained from known methyl 4,6-*O*-benzylidene-2-deoxy-3-*C*-nitromethyl-α-D-*ribo*-hexopyranoside[9] by hydrogenation. This indicates that cyanide anion attacks the carbonyl function of **5** from the upper side of the pyranoside ring selectively.

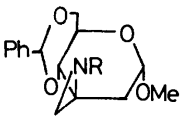
(**25**) R^1=NO_2, R^2=Me



(**11**) R=H (**12**) R=Ac

Cyano-mesylation of **5** in a similar manner afforded the corresponding 3-*C*-cyano-3-*O*-mesyl derivative of D-*ribo* (**9**) and D-*arabino* (**10**) configuration in 64% and 3% yields, respectively. Compound **9** was converted into the corresponding spiro-aziridine (**11**) in 81% yield by reduction with LAH, which was then characterized as the *N*-acetyl derivative (**12**). Catalytic hydrogenation of **11** in the presence of Raney nickel gave the amino-branched derivative (**13**) in 93% yield, which was also characterized as the *N*-acetyl derivative (**14**). The two characteristic singlets (δ 2.24 and 2.70) of the methylene protons of aziridine ring in the NMR spectrum of **12** turned into a singlet of methyl protons (δ 1.59) in that of **14**. Treatment of **14** with *N*-bromosuccinimide and barium carbonate gave methyl 3-acetamido-4-*O*-benzoyl-6-bromo-2,3,6-trideoxy-3-*C*-methyl-α-D-*arabino*-hexopyranoside (**15**) in 60% yield, 6-bromine atom of which was hydrogenolyzed with Raney nickel to give the corresponding 6-deoxy derivative (**16**) as a sirup.

On the other hand, attempted dehydrobromination of **15** with silver fluoride[10] in pyridine or with 1,8-diazabicyclo[5.4.0]undec-7-ene in boiling benzene

unexpectedly gave a bicyclo pyrrolidine (**17**) quantitatively. The structure of **17** was distinguished from the possible seven-membered oxazolidine derivative by de-*O*-benzoylation with methanolic ammonia, followed by successful de-*N*-acetylation with aqueous potassium hydroxide. The 1C conformation of the pyranoside ring was confirmed by the NMR spectrum of de-*O*-benzoylated prodect (**18**: $J_{1,2a}=9.0$, $J_{1,2e}=4.0$ Hz). The conversion confirmed the configuration of the branching point of **15**—**16**, and also the steric course of the aziridine formation.

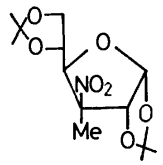
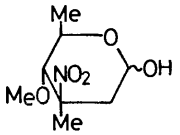
(**22**)

Compound **16** was de-*O*-benzoylated and then methylated with equimolar sodium hydride and methyl iodide to give 4-*O*-methyl derivative (**21**) in 93% yield. It is interesting that **21** anomerized to the β-anomer (**22**) by treatment with cation exchanger (IR-120) in boiling methanol for 17 h, due to the 1,3-diaxial interaction between 3-*C*-Me and 1-OMe groups. Treatment of **21** with potassium hydroxide in hot aqueous ethanol gave a sirupy de-*N*-acetyl derivative (**23**) in 52% yield. In order to examine the oxidation of an amino group at the branching point, potassium permanganate and magnesium sulfate[11] were used for 3-amino-3-deoxy-1,2:5,6-di-*O*-isopropylidene-3-*C*-methyl-α-D-*gluco*-hexofuranose[5] and **13** in aqueous acetone, but the yields of the corresponding 3-nitro derivatives (**24** and **25**) were very poor (18% and 7.6%, respectively). However, *m*-chloroperbenzoic acid oxidation[12] of **13** in chloroform improved the yield (41%) of **25**. Thus, **23** in dichloromethane was successfully oxidized into the corresponding 3-nitro derivative (**26**) in 77% yield. The final hydrolysis of **26** with 0.05M sulfuric acid in aqueous dioxane at 90—95 °C gave D-evernitrose (**27**) in 72% yield.





(**24**) (**27**)

Experimental

All the melting points are uncorrected. The solutions were evaporated under reduced pressure at a bath temperature not exceeding 45 °C. Specific rotations were measured in a 0.5-dm tube with a Carl Zeiss LEP-Al polarimeter with use of chloroform as the solvent unless otherwise stated. The IR spectra were recorded with a Hitachi Model EPI-G2 spectrometer. The NMR spectra were taken with a JEOL PS-100 spectrometer using tetramethylsilane as an internal standard in deuteriochloroform unless otherwise stated. Chemical shifts and coupling constants were recorded in δ and Hz units and IR frequencies in cm^{-1}.

*Methyl 4,6-O-Benzylidene-3-C-cyano-2-deoxy-α-D-ribo-hexopyranoside (**6**).* Hydrogen cyanide (1 ml, 25 mmol) was added to an ice-cooled solution of methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose (**5**: 5 g, 18.9 mmol) in anhydrous pyridine (40 ml), and the resulting solution was kept at room temperature for one day. Appearance of a new spot was detected on TLC. Evaporation of the reaction mixture gave crystals which were fractionally recrystallized to give **6** in 50% (2.7 g) yield. Mp 156—159 °C, $[\alpha]_D^{22}$ +55.2° (*c* 1.0), IR: 3450 (OH), 2240 (CN), NMR: 7.64—7.24 (Ph; m, 5.65 (PhCH, s), 4.78 (H_1: q, $J_{1,2e}=1.6$, $J_{1,2a}=4.0$), 4.40—3.60 (H_4, H_5, H_6, H_6': m), 3.40 (OMe), 2.53 (H_{2e}: q, $J_{gem}=15.0$), 2.26 (H_{2a}: q).

Found: C, 61.73; H, 5.88; N, 4.86%. Calcd for $C_{15}H_{17}NO_5$: C, 61.85; H, 5.88; N, 4.81%.

*Methyl 4,6-O-Benzylidene-3-C-cyano-2-deoxy-3-O-trimethylsilyl-α-D-ribo-hexopyranoside (**7**).* Trimethylsilyl chloride (0.37 g, 3.4 mmol) was added to a reaction mixture of **5** (0.5 g, 1.9 mmol) and hydrogen cyanide (1 ml, 25 mmol) in pyridine (5 ml) as described above, and the resulting solution was kept at room temperature for one day. After evaporation of the mixture, the residue was extracted with toluene. Evaporation of the extracts gave pure crystals (0.65 g, 95%). Mp 88—91 °C, $[\alpha]_D^{22}$ +67.6° (*c* 1.0), IR: 2250 (CN), NMR: 0.24 (Me_3Si: s).

Found: C, 59.46; H, 6.86; N, 3.71%. Calcd for $C_{18}H_{25}NO_5Si$; C, 59.48; H, 6.93; N, 3.85%.

*Methyl 3-Aminomethyl-4,6-O-benzylidene-2-deoxy-α-D-ribo-hexopyranoside (**8**).* A suspension of **7** (0.5 g, 1.4 mmol) and excess LAH (75 mg) in ether was stirred at room temperature for 2 h, then poured gradually into ice-water containing acetic acid. The resulting mixture was extracted with chloroform and then worked up in the usual way to give **8** as crystals in 60% (0.24 g) yield. Mp 138—139 °C (ethanol-hexane), $[\alpha]_D^{22}$ +94.0° (*c* 1.0), IR: 3500—3000 (NH and OH), NMR: 7.6—7.1 (Ph: m), 5.57 (PhCH), 4.82 (H_1; q, $J_{1,2e}=1.0$, $J_{1,2a}=4.3$), 4.62—3.5 (H_4, H_5, H_6, and H_6': m), 3.36 (OMe), 2.96 and 2.62 (CH_2: each d, $J_{gem}=13.5$), 2.35 (OH), 2.12 (NH_2), 2.03 (H_{2e}: q, $J_{gem}=14.0$), 1.84 (H_{2a}: q).

Found: C, 60.81; H, 7.17; N, 4.54%. Calcd for $C_{15}H_{21}NO_5$: C, 61.00; H, 7.17; N, 4.74%.

The same compound was also obtained from methyl 4,6-*O*-benzylidene-2-deoxy-3-nitromethyl-α-D-*ribo*-hexopyranoside by catalytic reduction with Raney nickel.

*Methyl 4,6-O-benzylidene-3-C-cyano-2-deoxy-3-O-methylsulfonyl-α-D-ribo- (**9**) and D-arabino-Hexopyranoside (**10**).* Methylsulfonyl chloride (70 ml, 0.9 mol) was added dropwise at 0 °C to a reaction mixture of **5** (40 g, 0.15 mol) and hydrogen cyanide (10 ml, 0.25 mol) in pyridine, and the resulting solution was kept at 0 °C for 2 days. The mixture was poured into ice–water and extracted with chloroform. The usual work-up of the extract gave a half-crystalline mass which was triturated with ethanol to give crystals (34 g, 62%). **9**: Mp

161—162 °C (from dichloromethane-hexane), $[\alpha]_D^{22}$ +38.1° (*c* 1.0), IR: 2230 (CN), 1370 and 1190 (OMs), NMR: 7.56—7.24 (Ph: m), 5.66 (PhCH), 4.81 (H_1: q, $J_{1,2e}=1.0$, $J_{1,2a}=4.0$), 4.42—3.60 (H_4, H_5, H_6, and $H_{6'}$: m), 3.46 (OMs), 3.41 (OMe), 3.20 (H_{2e}: q, $J_{gem}=15.0$), 2.28 (H_{2a}: q).

Found: C, 51.92; H, 5.19; N, 3.65; S, 8.52%. Calcd for $C_{16}H_{19}NO_7S$: C, 52.03; H, 5.19; N, 3.79; S, 8.66%.

Chromatographic separation of the sirup obtained from the mother liquor of the above experiment gave **9** (0.2 g, 0.5%) and the 3-epimer, **10** (1.13 g, 3%). **10**: Mp 151—151.5 °C, $[\alpha]_D^{22}$ +102.1° (*c* 1.0), IR: 1360 and 1180 (OMs).

Found: C, 52.03; H, 5.18; N, 3.76; S, 8.50%. Calcd for $C_{16}H_{19}NO_7S$: C, 52.03; H, 5.19; N, 3.79; S, 8.60%.

*Spiro[aziridine-2,3'-(methyl 4,6-*O*-benzylidene-2,3-dideoxy-α-*D*-arabino-hexopyranoside)] (**11**) and Its* N*-Acetyl Derivative (**12**).* A suspension of **9** (30 g, 82 mmol) and LAH (4.6 g, 121 mmol) in ether (500 ml) was stirred at room temperature for 4 h, and then poured into water containing ethyl acetate to decompose excess LAH. The usual work-up of the resulting mixture gave unstable **11** in 81% (18.42 g) yield. Base-catalyzed acetylation of a part of this sirup gave **12** quantitatively. Mp 112—113 °C, $[\alpha]_D^{22}$ +34.6° (*c* 1.0), IR: 1680 (amido), NMR: 7.32 (Ph: s), 5.54 (PhCH), 4.82 (H_1: q, $J_{1,2e}=1.0$, $J_{1,2a}=4.0$), 4.36—3.64 (H_4, H_5, H_6, and $H_{6'}$: m), 3.35 (OMe), 2.70 and 2.24 (CH_2: each s), 2.56 (H_{2a}: q), 2.03 (NAc), 1.62 (H_{2e}: q, $J_{gem}=14.0$).

Found: C, 63.48; H, 6.65; N, 4.15%. Calcd for $C_{17}H_{21}NO_5$: C, 63.93; H, 6.63; N, 4.39%.

*Methyl 3-Amino-4,6-*O*-benzylidene-2,3-dideoxy-3-*C*-methyl-α-*D*-arabino-hexopyranoside (**13**) and Its* N*-Acetyl Derivative (**14**).* Hydrogenation of a suspension of **11** (18 g, 65 mmol) and Raney nickel (30 g) in methanol (400 ml) in an autoclave at 40 °C under 100 kg/cm² hydrogen atmosphere, and then the usual work-up gave a sirupy **13** in 93% (16.8 g) yield. Base-catalyzed acetylation of **13** and purification of the sirupy product on a silica gel column (benzene–acetone) gave pure **14** as an amorphous solid. The yield from **9** was 49%. $[\alpha]_D^{22}$ +38.6° (*c* 1.0), IR: 3300 (NH), 1650 and 1540 (amide), NMR: 7.60—7.28 (Ph: m), 5.56 (PhCH), 5.50 (NH: broad s), 4.72 (H_1: q, $J_{1,2a}=4.0$), 4.40—3.60 (H_4, H_5, H_6, and $H_{6'}$: m), 2.69 (H_{2a}: q), 2.35 (H_{2e}: q, $J_{gem}=14.0$), 1.93 (NAc), 1.59 (Me).

Found: C, 63.25; H, 7.22; N, 4.14%. Calcd for $C_{17}H_{23}NO_5$: C, 63.52; H, 7.21; N, 4.36%.

*Methyl 3-Acetamido-4-*O*-benzoyl-6-bromo-3-*C*-methyl-2,3,6-trideoxy-α-*D*-arabino-hexopyranoside (**15**).* A suspension of **14** (10 g, 31 mmol), *N*-bromosuccinimide (6.6 g, 37 mmol) and barium carbonate (7.3 g, 37 mmol) in dried carbon tetrachloride (400 ml) was refluxed for 4—5 h under normal room light until the colour changed from red to yellow, and then filtered. The filtered mass was washed with dichloromethane. The filtrate and washings were combined and washed in turn with aqueous sodium hydrogensulfite (5%), sodium hydrogencarbonate and water, and then dried. Evaporation of the solution gave a sirup (9.86 g) which was purified on a silica gel column (benzene–acetone) to give pure **15** in 60% (7.4 g) yield. The sirup gradually crystallized in a desiccator. Mp 71—72 °C, $[\alpha]_D^{22}$ +81.0° (*c* 1.0), IR: 3400 (NH), 1720 (ester), 1650 and 1530 (amide), NMR: 8.2—7.3 (Ph: m), 6.26 (NH: broad s), 5.48 (H_4: d, $J_{4,5}=10.0$), 4.85 (H_1: t, $J_{1,2e}=J_{1,2a}=3.0$), 4.18 (H_5: dt, $J_{5,6}=3.0$), 3.64—3.44 (H_6 and $H_{6'}$: m), 3.42 (OMe), 2.56 (H_{2e} and H_{2a}: d), 1.85 (NAc), 1.64 (Me).

Found: C, 50.55; H, 5.99; N, 3.08%. Calcd for $C_{17}H_{22}NO_5Br$: C, 51.01; H, 5.54; N, 3.50%.

*Methyl 3-Acetamido-4-*O*-benzoyl-3-*C*-methyl-2,3,6-tridoxy-α-*D*-arabino-hexopyranoside (**16**).* Catalytic hydrogenation of a suspension of **15** (0.36 g, 0.9 mmol) and triethylamine (0.11 g, 1.1 mmol) and Raney nickel (0.83 g) in methanol (100 ml) in an autoclave under 95 kg/cm² hydrogen atmosphere for 2 days and the usual work-up for the separation of the product from the amine salt gave sirupy **16** in 95% (0.28 g) yield. IR: 3400 (NH), 1720 (ester), 1650 and 1540 (amide), NMR: 8.18—7.30 (Ph: m), 6.20 (NH: s), 5.14 (H_4: d, $J_{4,5}=10.0$), 4.71 (H_1: q, $J_{1,2e}=1.6$, $J_{1,2a}=4.0$), 4.05 (H_5: dq, $J_{5,6}=7.2$), 3.37 (OMe), 2.68 (H_{2e}: q, $J_{gem}=15.0$), 2.36 (H_{2a}: q), 1.86 (NAc), 1.66 (Me), 1.24 (H_6: d).

Found: C, 62.94; H, 7.02; N, 4.41%. Calcd for $C_{17}H_{23}NO_5$: C, 63.53; H, 7.21; N, 4.36%.

Methyl N*-Acetyl-3,6-epimino-4-*O*-benzoyl-2,3,6-trideoxy-3-*C*-methyl-α-*D*-arabino-hexopyranoside (**17**) and Its De-*O*-benzoyl Derivative (**18**).* A solution of **15** (4.4 g, 11.0 mmol) and 1,8-diazabicyclo[5.4.0]undec-7-ene (1.84 g, 12.1 mmol) in dried benzene (70 ml) was refluxed for 3 h, and the crystals deposited were filtered off. A sirup obtained by evaporation of the filtrate was purified on a silica gel column to give **17** in 82% (2.9 g) yield. Mp 169—174 °C, $[\alpha]_D^{22}$ −111.3° (*c* 1.0), IR: 1720 (ester), 1622 (amide).

Found: C, 63.49; H, 6.49; N, 4.16%. Calcd for $C_{17}H_{21}NO_5$: C, 63.93; H, 6.63; 4.39%.

Treatment of **17** with methanolic ammonia in the usual manner gave **18** in 66% yield. Mp 109—111 °C, $[\alpha]_D^{22}$ −74° (*c* 1.0), IR: 3300 (OH), 1640 (amide), NMR (in CD_3OD): 4.62 (H_1: q, $J_{1,2e}=4.0$, $J_{1,2a}=9.0$), 4.23 (H_5: dt, $J_{5,6}=J_{5,6'}=2.0$), 3.50 (H_4: d, $J_{4,5}=3.0$), 3.46 (OMe), 3.67 (H_6 and $H_{6'}$: d, $J_{gem}=0$), 3.50 (H_4: d, $J_{4,5}=3.0$), 3.46 (OMe), 2.08 (H_{2a}: q), 2.05 (NAc), 1.74 (H_{2e}: q, $J_{gem}=13.0$), 1.52 (Me).

Found: C, 55.56; H, 7.93; N, 6.53%. Calcd for $C_{10}H_{17}NO_4$: C, 55.80; H, 7.96; N, 6.51%.

*Methyl 3,6-Epimino-3-*C*-methyl-2,3,6-trideoxy-α-*D*-arabino-hexopyranoside (**19**).* A solution of **18** (60 mg, 0.28 mmol) in 2 M potassium hydroxide (4 ml) was refluxed for 4 days. The starting material was still detected on TLC, but the solution was neutralized with acetic acid and evaporated. The residue was extracted with chloroform and the product obtained was separated on TLC to give sirupy **19** (15 mg, 31%). NMR: 4.24 (H_5: q, $J_{5,6}=2.7$), 4.88 (H_1: q, $J_{1,2e}=5.0$, $J_{1,2a}=8.1$), 3.51 (OMe), 3.45 (H_4: d, $J_{4,5}=3.8$), 3.19 (H_6 and $H_{6'}$: d, $J_{gem}=0$), 2.51 (NH and OH: s), 1.99 (Me), 1.80 (H_{2a}: q), 1.61 (H_{2e}: q, $J_{gem}=14.0$).

Found: C, 55.02; H, 8.16; N, 8.00%. Calcd for $C_8H_{15}NO_3$: C, 55.47; H, 8.73; N, 8.09%.

*Methyl 3-Acetamido-3-*C*-methyl-2,3,6-trideoxy-α-*D*-arabino-hexopyranoside (**20**).* A solution of **16** (120 mg, 0.37 mmol) in saturated methanolic ammonia (5 ml) was kept at room temperature overnight, evaporated, and the residual sirup was purified on TLC to give pure **20** (60 mg, 72%). $[\alpha]_D^{22}$ +73.8° (*c* 1.0, 50% MeOH–H_2O), IR: 3700—3150 (OH and NH), 1650 and 1540 (amide), NMR: 6.05 (OH), 5.84 (NH: broad s), 4.66 (H_1: q, $J_{1,2e}=1.6$, $J_{1,2a}=4.0$), 3.61 (H_5: dq, $J_{5,6}=6.0$), 3.38 (H_4: d, $J_{5,4}=9.4$), 3.32 (OMe), 2.01 (H_{2e}: q, $J_{gem}=15.8$), 2.00 (NAc), 1.85 (H_{2a}: q), 1.52 (Me), 1.31 (H_6: d).

Found: C, 56.08; H, 8.87; N, 6.16%. Calcd for $C_{10}H_{19}NO_4$: C, 55.28; H, 8.82; N, 6.45%.

The positive rotational change of this compound in cuprammonium solution ($[M]_{436}^{22}$ +254° → $[M]_{436}^{cuprA}$ +296°) also supports the configuration.

*Methyl 3-Acetamido-2,3,6-trideoxy-3-*C*,4-*O*-dimethyl-α-*D*-arabino-hexopyranoside (**21**).* To a solution of **20** (1.2 g, 5.4 mmol) in *N*,*N*-dimethylformamide (20 ml) was subsequently added equimolar sodium hydride (0.27 g) and methyl iodide (0.8 g) with stirring at room temperature. After

30 min, the reaction mixture was poured into ice-water and extracted with ether. The usual work-up of the extracts gave crystals (1.18 g, 93%), a part of which was recrystallized from hexane. Mp 136—138 °C, $[\alpha]_D^{22}$ +73° (*c* 1.0), NMR: 5.36 (NH: broad s), 4.68 (H_1: d, $J_{1,2a}$=4.5), 3.90 (H_4: d, $J_{4,5}$=10.0), 3.64 (H_5: dq, $J_{5,6}$=6.0), 3.49 and 3.28 (2×OMe), 2.97 (H_{2a}: q, J_{gem}=13.6), 1.94 (NAc), 1.77 (H_{2e}: d), 1.35 (Me), 1.28 (H_6: d).

Found: C, 56.50; H, 8.98; N, 5.90%. Calcd for $C_{11}H_{21}NO_4$: C, 57.12; H, 9.15; N, 6.06%.

Anomerization of ***21***. A suspension of **21** (0.1 g) and IR-120 (0.3 g) in absolute methanol (10 ml) was refluxed for 17 h and filtered, the filtrate then being evaporated to give a sirup (65 mg). Separation of the sirup on TLC (benzene: acetone=4:1) gave the β-anomer (**22**, 35 mg). Mp 159—160 °C, $[\alpha]_D^{22}$ −57° (*c* 1.0), NMR: 5.54 (NH: s), 4.50 (H_1: q, $J_{1,2e}$=2.5, $J_{1,2a}$=8.9), 3.75 (H_4: d, $J_{4,5}$=8.8), 3.54 (H_5: dq, $J_{5,6}$=6.0), 3.49 and 3.44 (2×OMe), 2.55 (H_{2a}: q, J_{gem}=13.5), 1.95 (H_{2e}: q), 1.93 (NAc), 1.34 (H_6: d), 1.30 (Me).

Found: C, 56.76; H, 9.00; N, 5.95%. Calcd for $C_{11}H_{21}NO_4$: C, 57.12; H, 9.15; N, 6.06%.

*Methyl 3-Amino-2,3,6-trideoxy-3-*C*,4-*O*-dimethyl-α-*D*-arabino-hexopyranoside (**23**).* A solution of **21** (630 mg, 2.73 mmol) and potassium hydroxide (612 mg) in 70% aqueous ethanol (3 ml) was refluxed under nitrogen atmosphere at 100—105 °C (bath temperature) for 4 days, neutralized with acetic acid, and then extracted with chloroform. The usual work-up of the extracts gave a sirup which was separated on a silica gel column to give sirupy **23** (113 mg) and the starting material (360 mg). NMR: 4.65 (H_1: q, $J_{1,2e}$=1.5, $J_{1,2a}$=4.0), 3.64 (H_5: dq, $J_{5,6}$=6.4), 3.57 and 3.29 (2×OMe), 2.67 (H_4: d, $J_{4,5}$=9.6), 1.82 (H_{2e}: q, J_{gem}=13.5), 1.70 (H_{2a}: q), 1.69 (NH_2: s), 1.28 (H_6: d), 1.24 (Me).

Found: C, 56.85; H, 10.22; N, 7.15%. Calcd for $C_9H_{19}NO_3$: C, 57.11; H, 10.12; N, 7.40%.

*3-Deoxy-1,2:5,6-di-*O*-isopropylidene-3-*C*-methyl-3-nitro-α-*D*-glucofuranose (**24**) and Methyl 2,3-Dideoxy-4,6-*O*-benzylidene-3-*C*-methyl-3-nitro-α-*D*-arabino-hexopyranoside (**25**). By Permanganate Oxidation*: A suspension of 3-amino-3-deoxy-1,2 : 5,6-di-*O*-isopropylidene-3-*C*-methyl-α-D-glucofuranose[5] (150 mg, 0.55 mmol), potassium permanganate (0.6 g, 3.8 mmol), and magnesium sulfate 7 hydrate (0.18 g) in acetone (4 ml) and water (1 ml) was stirred at room temperature for 29 h. Inorganic substances were precipitated by addition of acetone, and then filtered. The filtrate was evaporated and the residual sirup was extracted with chloroform. The usual work-up of the extract gave a sirup which was purified on a silica gel column to give **24** (30 mg, 18%). Mp 58—60 °C, $[\alpha]_D^{22}$ +52.6° (*c* 1.0), IR: 1550 (NO_2).

Found: C, 50.90; H, 6.86; N, 4.42%. Calcd for $C_{13}H_{21}NO_7$: C, 51.48; H, 6.98; N, 4.62%.

In a similar manner, **13** was oxidized to give **25** in 7.6% yield. Mp 131—132 °C (from ethanol), $[\alpha]_D^{22}$ +57.9° (*c* 1.0), IR: 1540 (NO_2).

Found: C, 57.95; H, 6.02; N, 4.23%. Calcd for $C_{15}H_{19}NO_6$: C, 58.24; H, 6.19; N, 4.53%.

By Peroxide Oxidation: A solution of **13** (0.2 g, 0.72 mmol) in chloroform (10 ml) was added dropwise over a period of 20 min to a refluxing solution of *m*-chloroperbenzoic acid (0.98 g, 5.7 mmol) in chloroform (10 ml). Heating was continued for 30 min. The resulting solution was then washed thoroughly with aqueous sodium sulfite (10%), saturated potasium hydrogencarbonate and water. Evaporation of the organic layer gave crystals which were fractionated on a silica gel column to give **25** in 41% (91 mg) yield.

*Methyl 2,3,6-Trideoxy-3-*C*,4-*O*-dimethyl-3-nitro-α-*D*-arabino-hexopyranoside (**26**).* Oxidation of **23** (112 mg) in dichloromethane with *m*-chloroperbenzoic acid in a similar way gave sirupy **26** in 77% (99 mg) yield. $[\alpha]_D^{22}$ +95.4° (*c* 1.9), IR: 1540 (NO_2), NMR: 4.74 (H_1: q, $J_{1,2e}$=1.5, $J_{1,2a}$=4.5), 3.78 (H_4: d, $J_{4,5}$=9.5), 3.64 (H_5: dq, $J_{5,6}$=5.4), 3.40 and 3.31 (2×OMe), 2.46 (H_{2a}: q, J_{gem}=13.5), 2.14 (H_{2e}: q), 1.75 (Me), 1.34 (H_6: d).

Found: C, 49.05; H, 7.78; N, 6.02%. Calcd for $C_9H_{17}NO_5$ C, 49.30; H, 7.82; N, 6.39%.

*2,3,6-Trideoxy-3-*C*,4-*O*-dimethyl-3-nitro-α-*D*-arabino-hexopyranose (*D*-Evernitrose) (**27**).* A solution of **26** (97 mg, 0.44 mmol) in 0.05 M sulfuric acid of dioxane-water (50%, 3 ml) was heated at 90—95 °C for 8 h, neutralized with excess barium carbonate and then filtered. The filtrate was evaporated to give a sirup which was purified on TLC. The sirup thus obtained (65 mg, 72%) was crystallized from benzene-hexane. Mp 84—88 °C, $[\alpha]_D^{22}$ +23.6° (*c* 0.9, ethanol) [lit,[3] the enantiomer: mp 88—93 °C, $[\alpha]_D$ −19.4°], IR: 3400 (OH), 1550 (NO_2). NMR spectrum showed the presence of α-(H_1: δ 5.33, q, $J_{1,2e}$=1.5, $J_{1,2a}$=4.0) and β-anomers (H_1: δ 4.88, q, $J_{1,2e}$=4.4, $J_{1,2a}$=7.2) in the ratio 1:1.

Found: C, 46.68; H, 7.33; N, 6.65%. Calcd for $C_8H_{15}NO_5$: C, 46.82; H, 7.37; N, 6.83%.

The authors are indebted to Mr. H. Matsumoto for NMR measurements and to the members of the Laboratory of Organic Analysis for microanalysis.

(Received November 4, 1977)

4,5-Dihydro-3*H*-naphtho[1,8-*bc*]furans (**1a—d**) reacted with a variety of electrophilic reagents to give the corresponding 2-substituted 4,5-dihydro-3*H*-naphtho[1,8-*bc*]furans. Hydrogenation of **1a—d** gave the corresponding 2*a*,3,4,5-tetrahydro-2*H*-naphtho[1,8-*bc*]furans. 2*H*-Naphtho[1,8-*bc*]furans (**7a—c**) which were prepared from **1a—c** were gradually converted to the 8-hydroxynaphthalene-1-carbaldehydes in air. The facile cleavage of the ether bond of **7a—c** is thought due to ring strain in the 2*H*-naphtho[1,8-*bc*]furan ring system.

In a previous paper,[1] the synthetic methods for 4,5-dihydro-3*H*-naphtho[1,8-*bc*]furans (**1a—d**) were reported. Since the novel ring system of **1a—d** possesses a furan ring at the *peri*-position of a partially saturated naphthalene ring, there may be some ring strain[1b] and so a difference in reactivity between **1a—d** and benzofurans is expected. In the present study, several reactions of **1a—d** have been examined and compared with those of the benzofurans.

Electrophilic substitution reactions and dimerization of **1a—d** are summarized in Table 1. Bromination of **1a—d** was carried out with bromine in carbon tetrachloride. Although **1b** and **1d** gave the corresponding 2-bromo compounds (**2b** and **2d**) in 89 and 74% yields, respectively, **1c** gave the corresponding 2-bromo compound (**2c**) in low yield (21%). The low yield was attributed to the formation of a resinous product. **1a** gave a complex mixture and the expected bromide was not isolated. Formylation of **1a,c,d** with *N,N*-dimethylformamide and phosphoryl chloride gave the corresponding 2-formyl compounds (**3a,c,d**). The yields of **3a** and **3c** were good (74 and 65% respectively), but **3d** gave only a 27% yield and the starting material (**1d**) was recovered; the low reactivity of **1d** is thought due to the strong inductive effect of the chlorine atom. Friedel-Crafts reaction of **1a** and **1c** was carried out with benzoyl chloride and tin(IV) chloride in carbon disulfide. The expected 2-benzoyl compounds (**4a** and **4c**) were obtained in low yields (27 and 25%, respectively) due to the formation of a resinous product. It appears that the 4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan ring is appreciably unstable under the reaction conditions. When **1a—d** were treated with sulfuric acid in ethanol, **1a—c** gave the corresponding dimers (**5a—c**) in good yields (56—90%), but the dimerization of **1d** did not occur. Again, the strong inductive effect of the chlorine atom of **1d** reduces the electron deisity at the 2-position in the furan ring.

These results suggest that the position of electrophilic substitution reactions of **1a—d** are similar to those of the benzofurans. Thus, bromination, formylation, and acylation of the 3-alkylbenzofurans occur at the 2-position of the furan ring[3] and the dimerization of the

3-alkylbenzofurans is achieved readily by acid catalysis.[2] However, **1a—d** are significantly less stable compared with the benzofurans under vigorous conditions such as acylation.

Hydrogenation and dehydrogenation reactions of **1a—d** are summarized in Table 2. Palladium on charcoal catalyzed hydrogenation of **1a—c** in ethanol at ambient temperature and pressure gave the corresponding tetrahydro compounds (**6a—c**) in good yields (92—98%). In the case of **1d**, the chlorine atom was subjected to hydrogenolysis along with hydrogenation of the furan ring to give **6b** (90% yield). The benzofurans subjected to hydrogenation gave the corresponding 1,2-dihydrobenzofurans under the same conditions[1a,4] and the rate of hydrogen consumption of **1a—d** was comparable with that of the benzofurans. If **1a—d** contains a larger strain compared to that of the benzofurans, the former should be more readily hydrogenated than the latter. The above results suggest that **1a—d** contain little strain compared with the benzofurans.

When **1a—c** were heated with palladium on charcoal in *p*-cymene, the corresponding 2*H*-naphtho[1,8-*bc*]-furans (**7a—c**) were obtained in fairly good yields (41—58%). However **1d** could not be dehydrogenated to the corresponding 2*H*-naphtho[1,8-*bc*]furan and the starting material was recovered. Thus, the reactivity of **1d** is affected by the strong inductive effect of the chlorine atom. Reduction of **7a—c** with sodium and ethanol gave the corresponding tetrahydro compounds (**6a—c**) in good yields (73—88%). Colorless compounds of **7a—c** are appreciably unstable and turned yellow or red upon storage; the liqiud compound **7b** gave a particullarly prominent coloration. Berry *et al.*[5] have suggested that the coloration of **7a** is due to the formation of 8-hydroxynaphthalene-1-carbaldehyde (**8a**). The cause of the coloration of both **7b** and **7c** was examined; **7b** was chromatographed over silica gel and **8b** isolated as the main colored product. Similarly, the colored material of **7c** was confirmed to be **8c**. Thus the compounds of the general type **7a—c** are easily subjected to cleavage of the ether bond. It has been pointed out that acenaphthene (**9**) which possesses a similar ring skeleton with **7a—c** contains a strain in the fused ring system.[6] Therefore, the facile cleavage of the ether bond of **7a—c** is thought due to ring strain in the 2*H*-naphtho[1,8-*bc*]furan ring system.

Experimental

All the melting points are uncorrected. The column chromatography was performed on silica gel (Wakogel C-200). Unless otherwise stated, anhydrous sodium sulfate was employed as the drying agent. The infrared absorption spectra were determined with a JASCO Model DS 402 G infrared spectrophotometer. The ultraviolet absorption spectra were determined with a Shimadzu Model UV-200 spectrophotometer. The nuclear magnetic resonance spectra were determined at 100 MHz with a JEOL Model 4H-100 NMR spectrometer, using tetramethyl silane as the internal standard.

*Bromination of 4,5-Dihydro-3H-naphtho[1,8-bc]furans (**1a—d**).* Bromine (0.85 g) in carbon tetrachloride (10 ml) was added dropwise to **1b** (1.0 g) in carbon tetrachloride (10 ml) with stirring at ambient temperature and the mixture further stirred for 30 min. After the removal of the solvent, the resulting oil was chromatographed and eluted with benzene to give **2b** (1.2 g, 89%). Colorless oil; bp 135 °C/1.5 Torr (partially decomposed). NMR(CCl_4): δ 1.85—2.09 (2H, m), 2.55—2.80 (4H, m), 3.96 (3H, s), 6.51 (1H, d, J=8 Hz), 6.71 (1H, d, J=8 Hz). Found: C, 53.88; H, 4.26%. Calcd for $C_{12}H_{11}O_2Br$: C, 53.96; H, 4.15%.

Similarly, **1c** and **1d** were brominated to give **2c** and **2d** (21 and 74%), respectively; **1a** was brominated to give a complex mixture and the simple bromide was not isolated.

2c: Colorless needles; mp 52—53 °C (from hexane). NMR(CCl_4): δ 1.85—2.08 (2H, m), 2.61 (2H, t, J=6 Hz), 2.73 (2H, t, J=6 Hz), 3.79 (3H, s), 6.61 (1H, d, J=8 Hz), 7.01 (1H d, J=8 Hz).
Found: C, 53.85; H, 4.20%. Calcd for $C_{12}H_{11}O_2Br$: C, 53.96; H, 4.15%.

2d: Colorless needles; mp 109—110 °C (from hexane). NMR (CCl_4): δ 1.87—2.11 (2H, m), 2.61 (2H, t, J=6 Hz), 2.75 (2H, t, J=6 Hz), 3.97 (3H, s), 6.55 (1H, s). Found: C, 47.68; H, 3.46%. Calcd for $C_{12}H_{10}O_2BrCl$: C, 47.79; H, 3.34%.

*Formylation of 4,5-Dihydro-3H-naphtho[1,8-bc]furans (**1a,c,d**).* Phosphoryl chloride (2.7 g) in *N,N*-dimethylformamide (4.5 g) was added to **1a** (1.5 g) in *N,N*-dimethylformamide (6.0 g) and the mixture heated at 90 °C for 3 h. The reaction mixture was then poured into ice water and allowed to stand overnight. The resulting precipitates were collected by filtration to give **3a** (1.3 g, 74%), which was purified by recrys-

tallization. Yellow needles; mp 88—89 °C (from methanol). IR(KBr): ν_{max} 1680 (CHO) cm^{-1}. NMR($CDCl_3$): δ 1.97—2.22 (2H, m), 2.93 (2H, t, J=6 Hz), 3.10 (2H, t, J=6 Hz), 6.98—7.48 (3H, m), 9.87 (1H, s). UV(EtOH): λ_{max} (ε) 203 (14300), 233^{sh} (9100), 238 (10000), 304 nm (22300). Found: C, 77.13; H, 5.41%. Calcd for $C_{12}H_{10}O_2$: C, 77.40; H, 5.41%.

Similarly, **1c** and **1d** were formylated to give **3c** and **3d** (65 and 27%), respectively.

3c: Yellow needles; mp 154—155 °C (from ethanol). IR(KBr): ν_{max} 1680 (CHO) cm^{-1}. NMR($CDCl_3$): δ 1.93—2.18 (2H, m), 2.86 (2H, t, J=6 Hz), 3.06 (2H, t, J=6 Hz), 3.86 (3H, s), 7.03 (1H, d, J=9 Hz), 7.22 (1H, d, J=9 Hz), 9.85 (1H, s). UV(EtOH): λ_{max} (ε) 206 (19500), 224^{sh} (10300) 306 nm (24000). Found: C, 72.02; H, 5.68%. Calcd for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59%.

3d: Yellow needles; mp 171—172 °C (from methanol). IR(KBr): ν_{max} 1675 (CHO) cm^{-1}. NMR($CDCl_3$): δ 1.95—2.20 (2H, m), 2.85 (2H, t, J=6 Hz), 3.07 (2H, t, J=6 Hz), 4.00 (3H, s), 6.87 (1H, s), 9.92 (1H, s). UV(EtOH): λ_{max} (ε) 206 (28900), 247 (17000), 301 nm (19700). Found: C, 62.07; H, 4.52%. Calcd for $C_{13}H_{11}O_3Cl$: C, 62.29; H, 4.42%.

*Benzoylation of 4,5-Dihydro-3*H*-naphtho[1,8-*bc*]furans (**1a** and **1c**).* Tin(IV) chloride (2.0 g) was added to a solution of **1a** (1.0 g) and benzoyl chloride (1.1 g) in carbon disulfide (10 ml) under cooling with ice water and stirring, and the mixtures was further stirred at ambient temperature for 3 h. After the addition of diluted hydrochloric acid, the mixture was extracted with ether, ethereal layer washed successively with aqueous sodium hydrogencarbonate and water, and dried. After removal of the solvent, the resulting oil was chromatographed and eluted with benzene to give **4a** (0.44 g, 27%), which was identical with the sample previously prepared[1b] from the melting points and infrared spectra. Similarly, **1c** was benzoylated to give **4c** (25%).

4c: Colorless prisms; mp 90—91 °C (from ethanol). IR(KBr): ν_{max} 1625 (C=O) cm^{-1}. NMR($CDCl_3$): δ 1.89—2.13 (2H, m), 2.85 (2H, t, J=6 Hz), 3.00 (2H, t, J=6 Hz), 3.85 (3H, s), 7.02 (1H, d, J=9 Hz), 7.25 (1H, d, J=9 Hz), 7.38—7.58 (4H, m), 8.01—8.11 (2H, m). UV(EtOH): λ_{max} (ε) 207 (25500), 257 (7900), 322 nm (21700). Found: C, 78.01; H, 5.64%. Calcd for $C_{18}H_{16}O_3$: C, 78.06; H, 5.52%.

*Dimerization of 4,5-Dihydro-3*H*-naphtho[1,8-*bc*]furans (**1a—d**).* Sulfuric acid (6.0 g) was added dropwise to **1a** (1.0 g) in ethanol (4 ml) under cooling with ice water and stirring, and the mixture further stirred at ambient temperature for 3 h. The reaction mixture was then poured into ice water and the mixture extracted with ether. The ethereal layer was treated, in the usual manner, to give **5a** (0.84 g, 84%) which was purified by recrystallization. Colorless plates; mp 158—159 °C (from benzene-hexane). NMR(CCl_4): δ 1.60—1.90 (7H, m), 2.58—2.78 (5H, m), 4.18 (1H, d, J=8 Hz), 4.85 (1H, d, J=8 Hz), 6.52—7.13 (6H, m). UV(EtOH): λ_{max} (ε) 208 (40300), 215^{sh} (34100), 256 (16500), 286 nm (3500). Found: C, 83.40; H, 6.38%. Calcd for $C_{22}H_{20}O_2$: C, 83.51; H, 6.37%. Similarly, **1b** and **1c** were dimerized to give **5b** and **5c** (56 and 90%), respectively; **1d** was not dimerized and the starting material was recovered.

5b: Colorless plastic solid. NMR(CCl_4): δ 1.57—1.90 (7H, m), 2.53—2.78 (5H, m), 3.85 (3H, s), 3.94 (3H, s), 4.20 (1H, d, J=8 Hz), 4.92 (1H, d, J=8 Hz), 6.49 (1H, d, J=8 Hz), 6.53 (1H, d, J=8 Hz), 6.66 (1H, d, J=8 Hz), 6.70 (1H, d, J=8 Hz). UV(EtOH): λ_{max} (ε) 216 (46400), 249 (16300), 357 (15500), 280 (3900), 290 nm (3000). Found C, 76.80; H, 6.60%. Calcd for $C_{24}H_{24}O_4$: C, 76.57; H, 6.43%.

5c: Colorless plates; mp 182—183 °C (from benzene-hexane). NMR($CDCl_3$): δ 1.55—2.00 (7H, m), 2.60—2.70 (5H, m), 3.81 (6H, s), 4.21 (1H, d, J=8 Hz), 4.90 (1H, d, J=8 Hz), 6.64 (2H, s), 6.74 (1H, d, J=8 Hz), 7.10 (1H, d, J=8 Hz). UV(EtOH): λ_{max} (ε) 215^{sh} (34400), 260 (15900), 291 nm (7900). Found: C, 76.75; H, 6.54%. Calcd for $C_{24}H_{24}O_4$: C, 76.57; H, 6.43%.

*Catalytic Hydrogenation of 4,5-Dihydro-3*H*-naphtho[1,8-*bc*]furans (**1a—d**).* **1a** (1.0 g) in ethanol (50 ml) was hydrogenated in the presence of 10% palladium on charcoal (0.8 g) at ambient temperature and pressure for 10 h. After the removal of the catalyst by filtration, the solvent was evaporated to give **6a** (1.0 g, 98%), which distilled off at 101 °C/1 Torr and the distilate solidified in a short time. Colorless solid; mp 33—34 °C. NMR(CCl_4): δ 1.10—1.86 (2H, m), 1.90—2.20 (2H, m), 2.53—2.90 (2H, m), 3.00—3.37 (1H, m) 3.85 (1H, dd, J=8 and 12 Hz), 4.63 (1H, t, J=8 Hz), 6.42 (1H, d, J=8 Hz), 6.46 (1H, d, J=8 Hz), 6.88 (1H, t, J=8 Hz). Found: C, 82.21; H, 7.56%. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%. Similarly, **1b** and **1c** were hydrogenated to give **6b** and **6c** (92 and 97%), respectively; **1d** was hydrogenated to give **6b** (92%) instead of **6d**.

6b: Colorless oil; bp 106 °C/1.5 Torr. NMR(CCl_4): δ 1.15—1.82 (2H, m), 1.92—2.20 (2H, m), 2.32—2.85 (2H, m), 3.00—3.40 (1H, m), 3.80 (3H, s), 3.86 (1H, dd, J=8 and 10 Hz), 4.67 (1H, t, J=8 Hz), 6.40 (1H, d, J=8 Hz), 6.53 (1H, d, J=8 Hz). Found: C, 75.54; H, 7.34%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

6c: Colorless oil; bp 112 °C/2 Torr. NMR(CCl_4): δ 1.00—1.85 (2H, m), 1.93—2.22 (2H, m), 2.35—2.81 (2H, m), 2.95—3.35 (1H, m), 3.68 (3H, s), 3.80 (1H, dd, J=2 and 8 Hz), 4.59 (1H, t, J=8 Hz), 6.35 (2H, s). Found: C, 75.60; H, 7.31%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

*Dehydrogenation of 4,5-Dihydro-3*H*-naphtho[1,8-*bc*]furans (**1a—d**).* A mixture of **1a** (1.8 g) and 10% palladium on charcoal (1.5 g) in *p*-cymene (20 ml) was heated at 180 °C for 4 h under a nitrogen atmosphere. The reaction mixture, after the usual treatment, was chromatographed and eluted with benzene-hexane (1:1) to give **7a** (0.73 g, 41%). Colorless plates; mp 53.5—54.5 °C (from methanol) (lit,[5] 53—54 °C). NMR(CCl_4): δ 5.60 (2H, s), 6.56 (1H, d, J=7 Hz), 6.97—7.50 (5H, m). UV(EtOH): λ_{max} (ε) 202 (14200), 251 (7700), 312 (8800), 340 nm (4200). Found: C, 84.44; H, 5.09%. Calcd for $C_{11}H_8O$: C, 84.59; H, 5.16%. Similarly, **1b** and **1c** were dehydrogenated to give **7b** and **7c** (58 and 47%), respectively; **1d** was not dehydrogenated and the starting material was recovered.

7b: Colorless oil; bp 96 °C/0.9 Torr. NMR(CCl_4): δ 4.00 (3H, s), 5.65 (2H, s), 7.01 (3H, s), 7.16 (1H, d, J=8 Hz), 7.41 (1H, d, J=8 Hz). UV(EtOH): λ_{max} (ε) 213 (21400), 238 (44000), 303 (3600), 334 nm (3200). Found: C, 77.38; H, 5.52%. Calcd for $C_{12}H_{10}O_2$: C, 77.40; H, 5.41%.

7c: Colorless needles; mp 46—47 °C (from benzene-hexane). NMR(CCl_4): δ 3.84 (3H, s), 5.61 (2H, s), 6.47 (1H, d, J=7 Hz), 6.50 (1H, d, J=7 Hz), 7.05 (1H, d, J=7 Hz), 7.33 (1H, t, J=7 Hz), 7.69 (1H, d, J=7 Hz). UV(EtOH): λ_{max} (ε) 207 (39300), 242 (24200), 246 (23600), 325 (7200), 339 nm (7500). Found: C, 77.13; H, 5.29%. Calcd for $C_{12}H_{10}O_2$: C, 77.40; H, 5.41%.

*Reduction of 2*H*-Naphtho[1,8-*bc*]furans (**7a—c**).* Sodium (2.0 g) was added, in limited amounts over 30 min, to **7a** (0.2 g) in ethanol (15 ml) with stirring at 80 °C and th mixture refluxed for an additional 1 h. The reaction mixture was poured into ice water, acidified with dilute hydrochloric acid and then extracted with ether. After evaporation of the ether, the resulting oil was chromatographed and eluted with benzene to give **6a** (0.16 g, 78%). Similarly, **7b** and **7c**

were reduced to give **6b** and **6c** (73 and 88%), respectively.

Examination of the Coloration of 2H-Naphtho[1,8-bc]furans (7b and 7c). The deeply reddish **7b** (1.0 g) was chromatographed and eluted with benzene–ether (9:1) to give **8b** (60 mg, 6%). Orange needles; mp 85—87 °C (from benzene–hexane). IR(KBr): ν_{max} 1660 (CHO), 3290 (Ar-OH) cm^{-1}. NMR($CDCl_3$): δ 4.00 (3H, s), 7.29—7.46 (3H, m), 7.95 (2H, d, J=8 Hz), 10.08 (1H, s), 10.75 (1H, s). Found: C, 71.39; H, 5.05%. Calcd for $C_{12}H_{10}O_3$: C, 71.28; H, 4.99%.

The colored material of **7c** was identical, by TLC analysis, with **8c** which was prepared from **7c** as below. A solution of **7c** (0.5 g) and lead tetraacetate (1.3 g) in acetic acid (60 ml) was stirred at ambient temperature for 4 h. The reaction mixture, after the usual treatment, was chromatographed to give **8c** (50 mg, 9%). Orange needles; mp 96—98 °C (from benzene–hexane). IR(KBr): ν_{max} 1665 (CHO) cm^{-1}. NMR ($CDCl_3$): δ 3.95 (3H, s), 6.93 (1H, d, J=8 Hz), 7.11 (1H, d, J=8 Hz), 7.55 (1H, t, J=7 Hz), 8.05 (1H, dd, J=1 and 6 Hz), 8.67 (1H, dd, J=1 and 6 Hz), 9.87 (1H, s), 10.97 (1H, s). Found: C, 71.38; H, 5.08%. Calcd for $C_{12}H_{10}O_3$: C, 71.28; H, 4.99%.

The authors wish to thank Mr. Yoshiaki Takahashi for the elemental analyses and Mr. Takao Oono for the nuclear magnetic resonance analyses.

Calculation of the Carbon-13 NMR Chemical Shifts of Some Organic Compounds Using the Improved Virtual Orbital Method

Masahiro KONDO and Isao ANDO*

Department of Polymer Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 28, 1977)

Using the wavefunction obtained from the improved virtual orbital (IVO) method proposed by Huzinaga, the ^{13}C NMR chemical shifts in some organic compounds (acetylene, ethylene, ethane, pentane, benzene, pyridine and acetone) have been calculated and compared with those obtained from the ordinary SCF-MO method. If the molecule considered is small, highly symmetric and non-polar, it can be expected that there is little difference in the calculated values between these two methods. If the molecule considered is rather large or polar, modification of the calculated values are apt to be induced by the IVO method. As far as qualitative tendencies of the chemical shifts of carbon in a molecule are concerned, both methods give similar results.

The carbon-13 NMR chemical shifts have been calculated by many methods[1,2] for organic compounds using various molecular orbital theories. The sum-over-state method[3,4] is one of such theories. In this method, not only the wavelfunctions for occupied orbitals but also those for virtual (or unoccupied) orbitals are needed in the calculation of the paramagnetic contribution. It is known[5] that in the system of 2N electrons the wavefunctions obtained by the ordinary Hartree-Fock operator are appropriate to the occupied orbitals but not to the virtual orbitals. These wavefunctions for the virtual orbitals are appropriate to the system of 2N+1 electrons rather than 2N electrons because an electron virtually involved in any virtual orbital suffers from the potentials of all the 2N electrons involved in the occupied orbitals. Thus, it is preferable to correct the wavefunctions for virtual orbitals so that they are appropriate for the system of 2N electrons as well as those for occupied orbitals. In an attempt to improve the situation, Huzinaga *et al.*[6,7] reported the improved virtual orbital (IVO) method in which a projection operator is introduced to modify the Hartree-Fock orperator for the virtual orbitals.

The carbon-13 chemical shifts and their tensors in some organic compounds have been calculated by the sum-over-state method without any improvement of the wavefunctions for virtual orbitals.[8,9] It appears that the calculated values systematically deviate from experimental values with relation to the size of the molecules;[9] in saturated hydrocarbons, as the number of carbons increase the paramagnetic contribution to the shielding constant tends to decrease. This trend makes it difficult to compare the relative shifts among the carbons in different molecules. Such a systematic deviation might come from an approximation adopted there, for example, the neglect of the overlap integral or the inexact wavefunction for virtual orbitals described above. This paper will focus on the latter case, *i.e.* the inexact wavefunction for virtual orbitals. The carbon-13 shielding constants will be calculated by the sum-over-state method using the wavefunctions obtained by the IVO method and these will be compared with the calculated results obtained by the ordinary SCF method.

Theoretical

In the sum-over-state method, one of the diagonal components of the paramagnetic shielding tensor of nucleus A, $\sigma^{p}_{\alpha\alpha}$ (α=x, y, or z), is expressed as follows:[3]

$$\sigma^{p}_{xx} = -\frac{2e^2\hbar^2}{m^2c^2}\langle r^{-3}\rangle_{2p}\sum_{i}^{occ}\sum_{k(\neq i)}^{unocc}(\Delta E_{i-k})^{-1}(C_{iy_A}C_{kz_A}-C_{iz_A}C_{ky_A}) \times\sum_{B}(C_{iy_B}C_{kz_B}-C_{iz_B}C_{ky_B}). \quad (1)$$

In these formulas, C_{ix_A} is the coefficient of the $2p_x$ atomic orbital on atom A of the i-th molecular orbital in the LCAO MO theory, ΔE_{i-k} the singlet-singlet excitation energy from the occupied orbital ϕ_i to the unoccupied orbital ϕ_k and $\langle r^{-3}\rangle_{2p}$ the mean inverse cubic radius of a 2p electron. The molecular orbitals are obtained from the IVO method[5-7] based on the MINDO/2 method.[10]

According to Huzinaga *et al.*[5-7] a new Fock operator $\mathbf{F}'_i$ in one-electron excitation from an occupied orbital ϕ_i is given by

$$\mathbf{F}'_i = \mathbf{F} + \mathbf{V}'_i \quad (2)$$

where

$$\mathbf{V}'_i = (\mathbf{1}-\mathbf{P})\Omega_i(\mathbf{1}-\mathbf{P}).$$

Here $\mathbf{F}$ is the ordinary Fock operator, $\mathbf{P}$ the projection operator, Ω_i the correction operator for the energy level of the virtual orbitals and these operators are given as follows:

$$\mathbf{F} = \mathbf{H}^{core} + \sum^{occ}(2\mathbf{J}_j-\mathbf{K}_j), \quad (3)$$

$$\mathbf{P} = \sum^{occ}|\phi_j\rangle\langle\phi_j|, \quad (4)$$

$$\Omega_i = -\mathbf{J}_i + 2\mathbf{K}_i, \quad (5)$$

where $\mathbf{J}_i$ and $\mathbf{K}_i$ are the Coulomb and Exchange operators, respectively. In the case of the new Fock operator $\mathbf{F}'_i$, for the occupied orbitals ϕ_j's

$$\mathbf{F}'_i|\phi_j\rangle = \mathbf{F}|\phi_j\rangle = \varepsilon_j|\phi_j\rangle \quad (6)$$

and for the virtual orbitals ϕ_k's

$$\mathbf{F}'_i|\phi_k\rangle = (\mathbf{F}+\Omega_i-\mathbf{P}\Omega_i)|\phi_k\rangle, \quad (7)$$

$$\varepsilon_k = \langle\phi_k|\mathbf{F}+\Omega_i|\phi_k\rangle. \quad (8)$$

That is, the operator $\mathbf{F}'_i$ gives an alteration of the eigenvalues and eigenfunctions for the virtual orbitals. A molecular orbital ϕ_j is given by a linear combination

of atomic orbitals χ_p's as follows:

$$\phi_j = \sum_p C_{jp}\chi_p. \quad (9)$$

Then a matrix representation of the operator $\mathbf{V}_i$ in Eq. 2 based on these atomic orbitals is given as

$$\mathbf{V}_i = (\mathbf{1}-\mathbf{D})\Omega_i'(\mathbf{1}-\mathbf{D}), \quad (10)$$

where $\mathbf{D}$ is the density matrix, Ω_i' the correction operator on the basis of atomic orbitals, which are given by

$$\mathbf{D} \equiv D_{pq}\sum_j^{occ} C_{ip}C_{jq} = \sum_j^{occ} D_{i,pq}, \quad (11)$$

$$\Omega_i' \equiv \Omega_{i,pq}' = \langle\chi_p|\Omega_i'|\chi_q\rangle = \sum_{v,w}\{-(pq|vw)+2(pw|vq)\}D_{i,vw}. \quad (12)$$

In these equations, (pq | vw) and (pw | vq) correspond to the Coulomb and Exchange integrals, respectively. Adopting the semi-empirical molecular orbital method, *i.e.* the MINDO/2 method,[10] the integrals may be estimated by the Slater-Condon parameters.[11] For the numerical values of bond lengths and bond angles the standard values determined by Pople and Gordon[12] were used. The numerical calculation was carried out by an HITAC-8800 computer at the Computer Center of the University of Tokyo.

Results and Discussion

The ^{13}C paramagnetic shielding constants of some organic compounds (acetylene, ethylene, ethane, pentane, benzene, pyridine, and acetone) were calculated using the wavelfunctions obtained from the ordinary Hartree-Fock method and the IVO method.[5-7] The calculated values by both methods are shown in Table 1. The characteristic feature in each compound is as follows:

A. Acetylene. The symmetry of the acetylene molecule belongs to the $D_{\infty h}$ point group and its electronic structure is composed of molecular orbitals with symmetry as shown in Table 2, in which the molecular orbitals were calculated by the MINDO/2 method.[10] According to the IVO method, the wavefunctions for the virtual orbitals are modified by the introduction of the correction operator $\mathbf{V}_i$ given in Eq. 2 while those for the occupied orbitals are not modified. This modification in virtual orbitals is responsible for the mixing among the virtual orbitals by the operator $\mathbf{V}_i$. From the viewpoint of the symmetry of the unoccupied orbitals, it is to be expected that the operator $\mathbf{V}_i$ causes the mixing between ϕ_6 and ϕ_{10} and between ϕ_7 and ϕ_8. ϕ_9 is not mixed because of orthogonality with the other unoccupied orbitals. From a considration of symmetry of the occupied and unoccupied orbitals it is possible to predict which transition can contribute to the paramagnetic shielding. As is seen from Eq.1, non-vanishing values of σ_{xx}^p, σ_{yy}^p and σ_{zz}^p are obtained if the transitions obey the selection rule that a direct product representation between the occupied and unoccupied orbitals contains representations of E_{1g}, E_{1g} and E_{2g}, respectively. Thus, two types of transitions can contribute to the σ_{xx}^p and σ_{yy}^p; one is the transition from the occupied orbital with a_{1g} symmetry to the unoccupied orbital with e_{1g} symmetry (σ-π^* transition), and the other is that from the e_{1u} occupied orbital to the a_{2u} unoccupied orbital (π-σ^* transition). Any transition does not contribute to σ_{zz}^p because any direct product representation between the occupied and unoccupied orbitals does not contain the representation of E_{2j}.

Focus will now be made on the molecular orbitals

Table 1. Calculated ^{13}C shielding constants in some organic compounds with and without IVO method

	Calculated without IVO					Calculated with IVO					Observed[a]

relating to the allowed transitions. New virtual orbitals ϕ_7' and ϕ_8' calculated by the IVO method are expressed as a linear combiantion of unoccupied orbitals ϕ_7 and ϕ_8 which are calculated by the ordinary Hartree-Fock method. When one electron is excited from the occupied orbital ϕ_1 to the unoccupied orbital ϕ_7 or ϕ_8, the wavefunctions of ϕ_7 and ϕ_8 are modified as follows:

$$\phi_7' = 0.7934\phi_7 - 0.6087\phi_8, \quad (13\text{-}1)$$

$$\phi_8' = 0.6087\phi_7 + 0.7934\phi_8, \quad (13\text{-}2)$$

and when one electron is excited from the occupied orbital ϕ_3 to the unoccupied orbital ϕ_7 or ϕ_8,

$$\phi_7'' = 0.7789\phi_7 - 0.6272\phi_8, \quad (14\text{-}1)$$

$$\phi_8'' = 0.6272\phi_7 + 0.7789\phi_8. \quad (14\text{-}2)$$

As the orbitals ϕ_7 and ϕ_8 degenerate with each other as shown in Table 2, the mixing between them by the operator $\mathbf{V}_i$ becomes large. However, if the excitation energy from the occupied orbital ϕ_1 or ϕ_3 to the unoccupied orbital ϕ_7 or ϕ_8 is not modified, induced modifications in the wavefunctions for orbitals ϕ_7 and ϕ_8 will not cause any change in the value of the paramagnetic shielding constant because of the degeneracy between these orbitals. The excitation energy, ΔE_{i-k}, can be simply calculated as a separation in energy levels between the virtual and occupied orbitals in the IVO method. If the excitation energy in the ordinary Hartree-Fock method is calculated from Eq. 15 taking into account Coulomb and Exchange integrals, little difference in the excitation energies with and without the IVO method is seen:

$$\Delta E_{i-k} = \varepsilon_k - \varepsilon_i - J_{ki} + 2K_{ki}. \quad (15)$$

For the other type of transition, when one electron is excited from the occupied orbital ϕ_4 or ϕ_5 to the unoccupied orbitals ϕ_6 and ϕ_{10}, modified wavefunctions for these virtual orbitals are expressed as follows:

$$\phi_6' = 0.9999\phi_6 - 0.0070\phi_{10}, \quad (16\text{-}1)$$

$$\phi_{10}' = 0.0070\phi_6 + 0.9999\phi_{10}. \quad (16\text{-}2)$$

The mixing between the orbitals ϕ_6 and ϕ_{10} by the operator $\mathbf{V}_i$ is very small. Thus, it is expected that there will be little difference in the contribution through these transitions whether the IVO method is used or not. For acetylene, it is seen that the improvement of the wavefunction for the virtual orbital by the IVO method induces little change in the magnetic shielding constant.

B. Ethylene. The ethylene molecule has the symmetry of the D_{2h} point group and has molecular orbitals with symmetry as shown in Table 3. Therefore, the wavefunctions for only two virtual orbitals ϕ_8 and ϕ_{12} are modified by the operator $\mathbf{V}_i$ because the other unoccupied orbitals are orthogonal to one another. The allowed transitions in the expression of σ_{xx}^p, σ_{yy}^p, and σ_{zz}^p are given by the selection rule that direct product representation between the occupied and unoccupied orbitals contains the representation of B_{3g}, B_{2g}, and B_{1g}, respectively; they are $\phi_1 \rightarrow \phi_7$, $\phi_4 \rightarrow \phi_7$, $\phi_6 \rightarrow \phi_8$, and $\phi_6 \rightarrow \phi_{12}$ for σ_{xx}^p, $\phi_5 \rightarrow \phi_7$ and $\phi_6 \rightarrow \phi_{10}$ for σ_{yy}^p, and $\phi_1 \rightarrow \phi_{11}$, $\phi_4 \rightarrow \phi_{11}$, $\phi_2 \rightarrow \phi_{10}$, $\phi_3 \rightarrow \phi_8$, $\phi_3 \rightarrow \phi_{12}$, and $\phi_5 \rightarrow \phi_9$ for σ_{zz}^p. The results on a part of the virtual orbitals ϕ_8 and ϕ_{12} are as follows: when one electron is excited from the occupied orbital ϕ_3 to the unoccupied orbital ϕ_8 or ϕ_{12}, modified wavefunctions ϕ_8' and ϕ_{12}' are expressed as

$$\phi_8' = 0.9854\phi_8 - 0.1705\phi_{12}, \quad (17\text{-}1)$$

$$\phi_{12}' = 0.1705\phi_8 + 0.9854\phi_{12}, \quad (17\text{-}2)$$

and when one electron is excited from the occupied orbital ϕ_6 to the unoccupied orbital ϕ_8 or ϕ_{12}, modified wavefunctions ϕ_8'' and ϕ_{12}'' are

$$\phi_8'' = 0.9997\phi_8 + 0.0255\phi_{12}, \quad (18\text{-}1)$$

$$\phi_{12}'' = -0.0255\phi_8 + 0.9997\phi_{12}. \quad (18\text{-}2)$$

The transition from ϕ_3 to ϕ_8 or ϕ_{12} corresponds to $\sigma \rightarrow \sigma^*$ and that from ϕ_6 to ϕ_8 or ϕ_{12} to $\pi \rightarrow \sigma^*$. It should be noted that the mixing by the operator $\mathbf{V}_i$ for the former type of transition is larger than that for the latter type. However, as the contributions to the paramagnetic shielding constant from the former transitions are vanishingly small, it is expected that the calculated value for σ_{zz}^p is hardly changed by modification of the virtual orbitals, ϕ_8 and ϕ_{12}. On the contrary, for the latter transitions, although a portion of these contributions to σ_{xx}^p is larger, the mixing between the orbitals ϕ_8 and ϕ_{12} due to the operator $\mathbf{V}_i$ is very small. For ethylene the result is similar to that of acetylene, namely the magnetic shielding constant is hardly changed by the IVO method.

C. Acetone. The acetone molecule has the symmetry of the C_{2v} point group and has molecular orbitals with the symmetry shown in Table 4. This compound is different from the above two compounds in that it contains an electronegative oxygen atom. The selection rules for the allowed transitions in the expressions of σ_{xx}^p, σ_{yy}^p, and σ_{zz}^p are, respectively, given by the terms of the direct product representations, B_2, B_1, and A_2, between the occupied and unoccupied orbitals. It is

well-known that the n-π* transition gives a larger contribution to the paramagnetic shielding because of its low excitation energy. So, attention will be focused on the n-π* transitions. Some of the n-π* transitions give the contribution to σ^p_{xx} and σ^p_{zz}, *i.e.* $\phi_{11}\rightarrow\phi_{14}$, $\phi_{11}\rightarrow\phi_{17}$, and $\phi_{12}\rightarrow\phi_{20}$ to σ^p_{xx} and transitions $\phi_{11}\rightarrow\phi_{20}$, $\phi_{12}\rightarrow\phi_{14}$, and $\phi_{12}\rightarrow\phi_{17}$ to σ^p_{zz}. The unoccupied orbitals ϕ_{14} and ϕ_{17} are mixed with each other by the operator $\mathbf{V}_i$ while the unoccupied orbital ϕ_{20} is not mixed. When one electron is excited from the occupied orbital ϕ_{11} to the unoccupied orbital ϕ_{14} or ϕ_{17}, the modified orbitals ϕ'_{14} and ϕ'_{17} are expressed as

$$\phi'_{14} = 0.9809\phi_{14} + 0.1947\phi_{17}, \quad (19\text{-}1)$$

$$\phi'_{17} = -0.1947\phi_{14} + 0.9809\phi_{17}, \quad (19\text{-}2)$$

and when one electron is excited from the occupied orbital ϕ_{12} to the unoccupied orbital ϕ_{14} or ϕ_{17},

$$\phi''_{14} = 0.9843\phi_{14} + 0.1777\phi_{17}, \quad (20\text{-}1)$$

$$\phi''_{17} = -0.1777\phi_{14} + 0.9843\phi_{17}. \quad (20\text{-}2)$$

The virtual orbitals ϕ_{14} and ϕ_{17} are mainly located in the region of the carbonyl and methyl groups in acetone, respectively. Modification of these virtual orbitals decreases their delocalization in this case; the coefficients of the wavefunctions ϕ'_{14} and ϕ''_{14} at the carbonyl carbon are larger than that of ϕ_{14}. Therefore for the paramagnetic shielding of the carbonyl carbon, the values of σ^p_{xx} and σ^p_{zz} calculated by the IVO method are larger than those calculated by the ordinary method. As n-π* transitions do not largely contribute to the shielding constant of the methyl carbon, the corresponding increase in this contribution by the modification of the virtual orbitals is not so large compared to the case of the carbonyl carbon. For σ^p_{yy}, differences between the values calculated with the two methods is hardly the recognized in both of the methyl and carbonyl carbons, since the n-π* transition does not contribute to σ^p_{yy} at all. Ultimately, as far as a difference in the chemical shifts between the methyl and carbonyl carbons is concerned, the value obtained from the IVO method is larger than that from the ordinary method and it is noted that the former becomes closer to the observed one.

D. Other Compounds(ethane, pentane, benzene and pyridine). One of the aims of this paper was to examine whether the systematic deviation from the observed data described above could be avoided by the IVO method. In consequence the paramagnetic shielding constants calculated by the two methods in ethane and pentane will be compared. As shown in Table 1, for the ordinary method, the calculated value for any carbon of pentane is considerably underestimated if ethane is considered as a reference. For ethane, a difference between the calculated values with and without the IVO method is hardly observed. For pentane the contribution to the paramagnetic shielding in the most de-shielded carbon(C-3) increases by the modification of the virtual orbitals while that of the most shielded carbon (C-1) decreases. However, it may be seen that even for the C-3 carbon the underestimation of σ^p is still large. Thus, it does not seem that the IVO method serves to avoid the systematic deviation described above.

A brief examination of the calculated values for aromatic compounds will now be discussed. For benzene, it is seen that a small difference in the value of σ^p_{xx} or σ^p_{zz} is induced by the modification of the virtual orbitals while a small change is induced in the value of σ^p_{yy}. For pyridine, the value of σ^p_{xx} for C-2 carbon bonded to the nitrogen atom is considerably increased by the modification of the virtual orbitals, while the values of σ^p_{yy} and σ^p_{zz} do not increase as much because the n-π* transitions can contribute to only σ^p_{xx}. As far as differences in the chemical shifts among the carbons in pyridine are concerned, the IVO method gives rather poor agreement between the calculated observed results.

Conclusion

Using the wavefunction obtained from the improved virtual orbital (IVO) method proposed by Huzinaga, the ^{13}C NMR chemical shifts in some organic compounds have been calculated and compared with those obtained from the ordinary SCF-MO method. The following points were noted: If the molecule considered is small, highly symmetric and non-polar, it can be expected that there is little difference in the calculated values between these two methods because the mixings among the virtual orbitals are unlikely to be induced except for degenerate orbitals. If the molecule considered is rather large or polar, modification of the calculated values are apt to be induced by the IVO method. As far as qualitative tendencies of the chemical shifts of carbon in a molecule are concerned, both methods give similar results.

The authors wish to thank Professor A. Nishioka and Associate Professor R. Chujo of this Department and Dr. E. Hiroike of The University of Tohoku for their many helpful suggestions and discussions.

Total Synthesis of (±)Variotin and Its Analogs

Akihiko ISHIDA* and Teruaki MUKAIYAMA†

Organic Chemistry Research Laboratory, Tanabe Seiyaku Co. Ltd., Kawagishi, Toda, Saitama 335

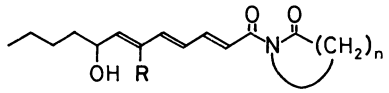
†*Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received December 1, 1977)

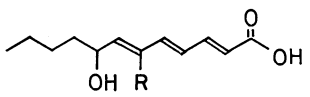
1-Sorboyl-2-pyrrolidone was prepared from sorbic acid and 2-ethoxy-1-pyrroline using 1-methyl-2-chloropyridinium iodide as a coupling reagent. Variotin and its analogs were similarly synthesized from lactim ethers and (2*E*, 4*E*, 6*E*)-8-hydroxy-2,4,6-dodecatrienoic acids without protecting the hydroxyl group at C-8. (2*E*,4*E*,6*E*)-8-Hydroxy-6-methyl-2,4,6-dodecatrienal, a precursor of trienoic acid, was synthesized by the elimination of methanol from (2*E*,6*E*)-8-acetoxy-5-methoxy-6-methyl-2,6-dodecadienal prepared from the reaction of 1-trimethylsiloxy-1,3-butadiene with (2*E*)-4-acetoxy-2-methyl-2-octenal dimethyl acetal.

The structure of variotin (**1b**), an antifungal antibiotic isolated from Pacecilomyces variotin Bainier var. antibioticus,[1] has been established by Yonehara and Takeuchi.[2]

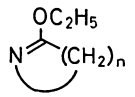
Recently, a method for the preparation of polyenals[3] has been reported and applied to the synthesis of the naturally occurring polyolefinic compounds, vitamin A[4] and β-carotene.[5] Also, the synthesis of variotin (**1b**) has been reported briefly in a previous communication.[6b] This paper describes the experimental details employed for the synthesis of (±) **1b** and its analogs (**1a** and **1c**).



1 a) R=H n=3
b) R=CH$_3$ n=3
c) R=CH$_3$ n=4



2 a) R=H
b) R=CH$_3$



3 a) n=3
b) n=4

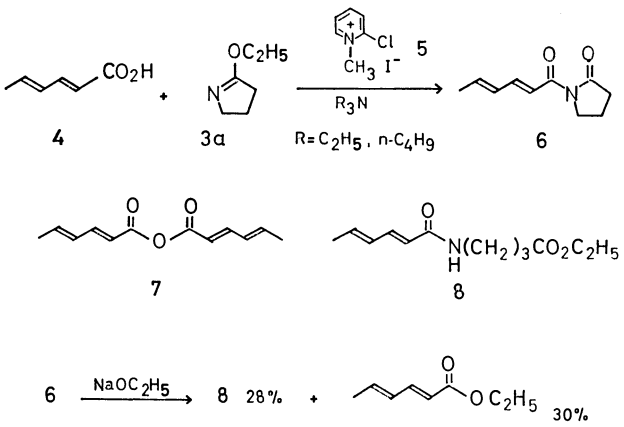
In the synthetic approach towards **1b**, the molecule was regarded as a condensation product of trienoic acid (**2b**) and lactim ether (**3a**). In the preliminary experiment, the reaction between sorbic acid (**4**) and 2-ethoxy-1-pyrroline (**3a**) was studied, employing 1-methyl-2-chloropyridinium iodide (**5**) as a coupling reagent (Scheme 1).

The hydroxytrienoic acids, **2a** and **2b**, may be derived from the corresponding polyenals (**20a** and **20b**).[3]

Results and Discussion

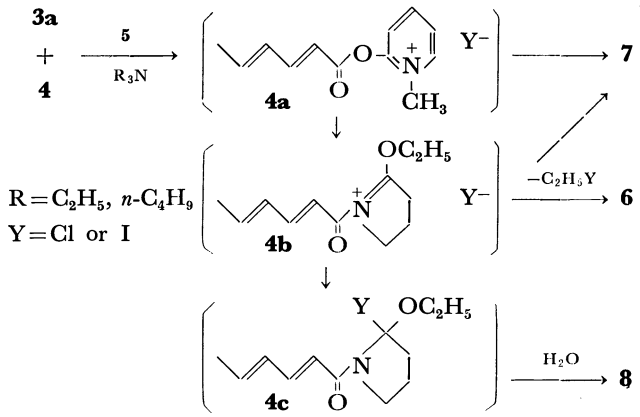
The Reaction of Sorbic Acid (4) and 2-Ethoxy-1-pyrroline (3a).[6a] The preparation of *N*-acyl lactam (**6**) in the presence of **5** and a tertiary amine was investigated under several conditions (Scheme 1).

The distribution of products depended on the method of addition (A, or B) as summarized in Table 1. An undesired acyl anhydride (**7**) was obtained as the major product when a solution of triethylamine in 1,2-dichloroethane was added immediately to a mixture of **3a**, **4**, and **5** at 0 or 50 °C (method A). In contrast, 1-sorboyl-2-pyrrolidone (**6**) was formed (63% yield) when a solution of **4** and tributylamine in toluene was added dropwise to a mixture of **3a** and **5** in toluene at 90 °C (method B). In addition to the small amount of **7**, ethyl 4-(sorboylamino)butanoate (**8**) was obtained (18% yield) as a side product identical to that prepared by the reaction of **6** and sodium ethoxide (Scheme 1).



Scheme 1.

The reactions may be explained by assuming the initial formation of an active intermediate **4a**, which in turn reacted with nucleophiles (**3a** or **4**) to afford an intermediate **4b** and acyl anhydride (**7**). Subsequent elimination of ethyl halide from **4b** gave the



Scheme 2.

Table 1. The reaction of sorbic acid (**4**) and 2-ethoxy-1-pyrroline (**3a**) in the presence of 1-methyl-2-chloropyridinium iodide (**5**) and a base

Base	Reaction conditions			Addition method	Yield (%)		
	Solvent	Temp	Time (h)		**6**	**7**	**8**
$(C_2H_5)_3N$	$ClCH_2CH_2Cl$	0 °C	1.0	A[a]	—	93	—
$(C_2H_5)_3N$	$ClCH_2CH_2Cl$	50 °C	1.0	A	11	70	—
$(C_2H_5)_3N$	$ClCH_2CH_2Cl$	50 °C	4.0	B[b]	59	8	17
$(C_2H_5)_3N$	CH_3CN	50 °C	4.0	B	61	8	14

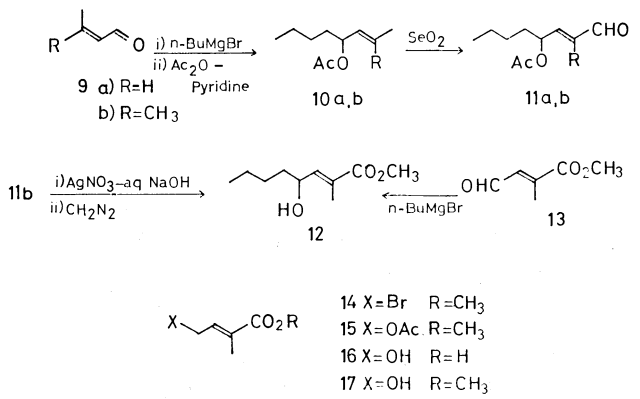
n-Bu_3N	toluene	90 °C	2.0	B	63	7	18

a) The base was added immediately to the mixture of **3a**, **4**, and **5**.
b) The base and **4** were added dropwise to the mixture of **3a** and **5**.

desired acyl lactam (**6**). The amide (**8**) may be formed though an intermediate **4c** produced by the attack of an anion Y^- at the N^+=C bond of **4b** (Scheme 2).

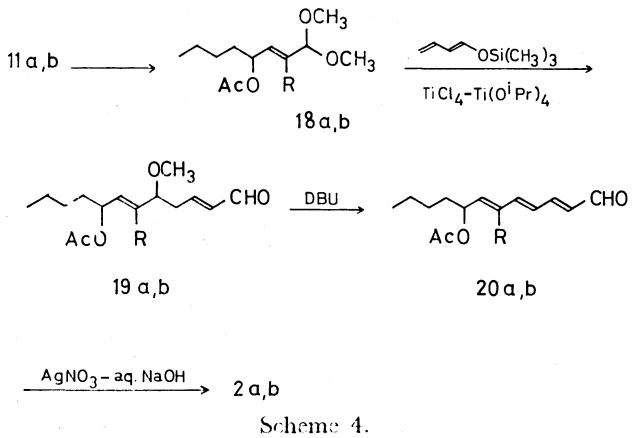
Synthesis of Hydroxytrienoic Acid (2a and 2b). (2*E*)-4-Acetoxy-2-methyl-2-octenal (**11b**) was a key intermediate for the synthesis of **2b**. 3-Methyl-2-butenal (**9b**) was chosen as the starting material for the preparation of **11b** (Scheme 3).



Scheme 3.

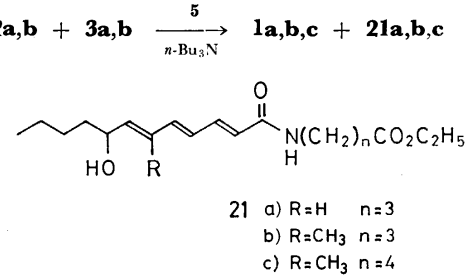
The reaction of **9b** with butylmagnesium bromide in ether, followed by acetylation with acetic anhydride–pyridine, gave 4-acetoxy-2-methyl-2-octene (**10b**). The yield was 81% after purification by distillation. The allylic oxidation of **10b** with 1.5 molar amounts of selenium dioxide[7] in refluxing xylene resulted in (2*E*)-4-acetoxy-2-methyl-2-octenal (**11b**) (43% yield). In order to determine the configuration of the C_2-double bond in **11b**, the aldehyde (**11b**) was converted into methyl 4-hydroxy-2-methyl-2-octenoate (**12**) by oxidation with silver oxide under basic conditions and subsequent treatment with ethereal diazomethane in 76% yield based on **11b**. Authentic methyl (2*E*)-4-hydroxy-2-methyl-2-octenoate (**12**) was derived from methyl (2*E*)-4-bromo-2-methyl-2-butenoate (**14**)[8] as follows. Treatment of **14** with potassium acetate in refluxing ethanol[9] afforded acetoxy ester (**15**). Hydrolysis of **15** with 20% KOH solution–methanol afforded (2*E*)-4-hydroxy-2-methyl-2-butenoic acid (**16**) (59% yield based on **14**). Treatment of **16** with diazomethane gave the hydroxy methyl ester (**17**) (85% yield), which on oxidation with pyridinium chlorochromate[10] in dichloromethane afforded methyl (2*E*)-2-methyl-4-oxo-2-butenoate (**13**) (75% yield). The reaction of **13** with butylmagnesium bromide in ether gave authentic (2*E*)-octenoate (**12**) (60% yield). The spectral data, the TLC and the GC behavior of the hydroxy ester (**12**) derived from **11b** were identical with those of the authentic sample obtained by the above route.

(2*E*,4*E*,6*E*)-8-Hydroxy-6-methyl-2,4,6-dodecatrienoic acid (**2b**) was derived from **11b** as depicted in Scheme 4. (2*E*)-Octenal (**11b**) was readily converted into its dimethyl acetal (**18b**) on treatment with trimethyl orthoformate–methanol in the presence of a catalytic amount of *p*-toluenesulfonic acid (89% yield). The reaction of 1-trimethylsiloxy-1,3-butadiene with the acetal (**18b**) in the presence of titanium tetrachloride and titanium tetraisopropoxide proceeded smoothly at −40 °C to (2*E*,6*E*)-8-acetoxy-5-methoxy-6-methyl-2,6-dodecadienal (**19b**). Preparative TLC gave a yield of 85%. The δ-methoxyl group of **19b** was readily eliminated with 4 molar amounts of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) at room temperature in the presence of 3A molecular sieves to give (2*E*,4*E*,6*E*)-8-acetoxy-6-methyl-2,4,6-dodecatrienal (**20b**) (75% yield). The acetoxy aldehyde (**20b**) was converted into **2b** on oxidation with silver oxide at room temperature for 24 h (93% yield). (2*E*,4*E*,6*E*)-8-Hydroxy-2,4,6-dodecatrienoic acid (**2a**) was also prepared from crotonaldehyde (**9a**) through a similar synthetic route as described for **2b**.



Scheme 4.

Condensation of Hydroxytrienoic Acid (2) and Lactim Ether (3). For the final step of the synthesis of **1b**, the condensation of **2b** and **3a** in the presence of tributylamine and **5** was conducted under similar conditions used for the preliminary reaction (Scheme 5). The reaction proceeded along a similar path without protecting the hydroxyl group of **2b**, and the yield of (±) variotin (**1b**) was improved (30—37%),[11b] together with ethyl 4-[(2*E*,4*E*,6*E*)-8-hydroxy-6-methyl-2,4,6-dodecatrienamido]butanoate (**21b**) (10—18% yield).



Scheme 5.

Similarly, **1a** and **1c** were prepared from **2** and **3** (36 and 27% yields, respectively). The spectral data of synthetic **1b** and **1c** were identical with those reported in the literature.[11,12] The potency of **1b**, thus obtained, against Trichophyton Asteroides was half that of the optically active natural variotin.

Experimental[13]

Reaction of Sorbic Acid (4) and 2-Ethoxy-1-pyrroline (3a). A solution of **4** (112 mg, 1.0 mmol) and tributylamine (195 mg, 1.05 mmol) in toluene (2 ml) was added dropwise to a mixture of 1-methyl-2-chloropyridinium iodide (614 mg, 2.4 mmol) and **3a** (208 mg, 2.4 mmol) in toluene (1 ml) over a period of 1 h at 85—90 °C under an argon atmosphere. After stirring for 1 h ethyl acetate (30 ml) was added. The resulting mixture was washed with dil HCl, 10% $NaHCO_3$ solution and water, dried and the organic layer concentrated under reduced pressure. The residue, subjected to preparative TLC on silica gel [hexane–ethyl acetate (1:1)] yielded four bands. The first band (highest R_f) consisted of ethyl sorbate (3 mg). IR(neat) 1710, 1640, 1620 cm^{-1}. NMR($CDCl_3$) δ 7.1—7.6 (1H, m), 6.1—6.25(2H, m), 5.82(1H, d, J=16Hz), 4.24 (2H, q), 1.86(3H, d, J=5Hz), 1.30(3H, t). The second band consisted of sorbic anhydride (**7**) (14 mg, 7%). IR(neat) 1780, 1710, 1640, 1610 cm^{-1}. NMR($CDCl_3$) δ 7.2—7.7 (2H, m), 6.25—6.45 (4H, m), 5.90(2H, d, J=16Hz), 1.90 (6H, d, J=5Hz). The third band consisted of 1-sorboyl-2-pyrrolidone (**6**) (113 mg, 63%), mp 122—123 °C (recrystallized from ethyl acetate) (lit,[14] mp 124—125 °C). IR (Nujol) 1730, 1660, 1630, 1590 cm^{-1}. NMR($CDCl_3$) δ 7.15—7.5 (2H, m), 6.1—6.4(2H, m), 3.87(2H, t), 2.60(2H, t), 2.00 (2H, quasi q), 1.87(3H, d, J=5Hz). The fourth band (lowest R_f) consisted of ethyl 4-(sorboylamido)butanoate (**8**) (41 mg, 18%), mp 63—64 °C (recrystallized from ether–petroleum ether). IR (Nujol) 3350, 1730, 1660, 1630, 1610 cm^{-1}. NMR($CDCl_3$) δ 6.95—7.45 (1H, m), 6.35—6.70(1H, br), 6.0—6.3(2H, m), 5.80(1H, d, J=16Hz), 4.10(2H, q), 3.40(2H, quasi q), 2.40(2H, quasi t), 1.8—2.2 (2H, m),1.90(3H, d, J=5Hz), 1.22(3H, t). Found: C, 64.26; H, 8.53; N, 6.02%. Calcd for $C_{12}H_{19}NO_3$: C, 63.97; H, 8.50; N, 6.22%.

Reaction of 1-Sorboyl-2-pyrrolidone (6) with Sodium Ethoxide. To a mixture of sodium ethoxide (1 mmol) and abs C_6H_6 (5 ml) was added a solution of **6** (180 mg, 1 mmol) in abs C_6H_6 (4 ml) at room temperature under an argon atmosphere. After stirring for 10 min ethyl acetate (10 ml) and acetic acid (66 mg, 1.1 mmol) were added. The resulting mixture was washed with water and dried over anhydrous Na_2SO_4. The solvent was removed and the residual oil chromatographed on silica gel. Elution with hexane–ethyl acetate (4:1) afforded 52 mg (30%) of ethyl sorbate. Further elution with hexane–ethyl acetate (1:1) gave 63 mg (28%) of ethyl 4-(sorboylamido) butanoate (**8**).

4-Acetoxy-2-methyl-2-octene (10b). The Grignard reagent was prepared from Mg (1.6 g, 66 mg-atom) and butyl bromide (9.32 g, 68 mmol) in dry ether (25 ml). To this was added a solution of **9b** (5.04 g, 60 mmol) in ether (30 ml) at −30 °C under an argon atmosphere. The mixture was stirred fro 30 min at −30 °C and brought to room temperature. After 2 h, the reaction was quenched by adding sat NH_4Cl solution, the mixture extracted with ether and the extract dried over anhydrous Na_2SO_4 and concentrated under reduced pressure. The residual oil was distilled to afford 7.70 g (90%) of 4-hydroxy-2-methyl-2-octene, bp 100—102 °C /27 mmHg. IR(neat) 3350, 1680 cm^{-1}. NMR($CDCl_3$) δ 5.20(1H, br d), 4.10—4.60 (1H, br), 1.72(6H, s), 1.1—1.7 (6H), 0.89(3H). A mixture of the above alcohol (7.70 g, 54.2 mmol) and acetic anhydride (10 g, 100 mmol) in pyridine (40 ml) was stirred for 15 h at room temperature. The reaction mixture was poured into ice-cold water, extracted with ether and the extract was washed with dil HCl, 10% $NaHCO_3$ solution, and water, dried over anhydrous $MgSO_4$, and evaporated to give an oil. The oil was distilled to yield 9.02 g (90%) of **10b**, bp 99—102 °C/20 mmHg. IR(neat) 1740, 1680 cm^{-1}. NMR($CDCl_3$) δ 5.30—5.70(1H, m), 5.10(1H, br d), 2.01(3H, s), 1.71, 1.73(6H, 2s), 1.1—1.7 (6H), 0.9(3H).

In the same manner, 4-acetoxy-2-octene (**10a**) was obtained from **9a** (81% yield), bp 105—107 °C/45 mmHg. IR(neat) 1740, 1670, 1235 cm^{-1}. NMR(CCl_4) δ 5.45—5.9(2H, m), 5.0—5.4 (1H, br), 2.04 (3H, s), 1.70(3H, d), 1.1—1.7(6H), 0.9(3H).

(2E)-4-Acetoxy-2-methyl-2-octenal (11b). The acetate (**10b**) (7.4 g, 40 mmol) in xylene (30 ml) was refluxed with SeO_2 (6.6 g, 60 mmol) for 40 min under an argon atomsphere. The black precipitates were removed by filtration, and the filtrate evaporated to give an oil. The oil was purified by column chromatography on silica gel [hexane–ethyl acetate (4:1) as an eluent] to yield 3.40 g (43%) of **11b**, bp 80 °C/0.05 mmHg. IR(neat) 1740, 1690, 1650, 1240 cm^{-1}. NMR ($CDCl_3$) δ 9.45(1H, s), 6.31 (1H, br d), 5.5—5.8(1H, br), 2.07(3H, s), 1.84(3H, s), 1.2—1.8(6H), 0.95(3H).

(2*E*)-4-Acetoxy-2-octenal (**11a**) was obtained in 45% yield by treating **10a** with SeO_2 under similar conditions. Bp 104—105 °C/1 mmHg. IR(neat) 1740, 1690, 1640, 1235 cm^{-1}. NMR(CCl_4) δ 9.55(1H, d, J=8Hz), 6.75 (1H, dd, J=6,16Hz), 6.10 (1H, dd, J=8,16Hz), 5.30—5.65(1H, br), 2.10(3H, s), 1.10—1.90(6H), 0.95(3H).

Methyl (2E)-4-Acetoxy-2-methyl-2-butenoate (15). A mixture of methyl (2*E*)-4-bromo-2-methyl-2-butenoate (1.93 g, 10 mmol) and potassium acetate (1.18 g, 12 mmol) in abs ethanol (13 ml) was refluxed for 3 h under a nitrogen atmosphere. The mixture was cooled to 0 °C, the precipitates filtered off and the filtrate evaporated to give an oil. The oil was distilled to yield 1.54 g (90%) of **15**, bp 140 °C/28 mmHg. IR(neat) 1740, 1720, 1660 cm^{-1}. NMR($CDCl_3$) δ 6.75 (1H, quasi t), 4.75(2H, quasi d),2.05(3H, s), 1.87(3H, s).

*(2E)-4-Hydroxy-2-methyl-2-butenoic Acid (**16**).* To a solution of **15** (372 mg, 2.16 mmol) in methanol (10 ml) was added 20% KOH solution (1.5 ml) at 0 °C. The mixture was stirred for 15 h at room temperature and methanol removed under reduced pressure. The aqueous solution was acidified with dil HCl, extracted with ethyl acetate and the extract dried over anhydrous Na_2SO_4 and evaporated to give an oil. The oil was purified by column chromatography on silica gel [hexane–ethyl acetate (1:2) as an eluent] to yield 163 mg (65%) of **16**, mp 78—80 °C. IR(KBr) 3200, 1670, 1630 cm^{-1}. NMR($CDCl_3$) δ 6.7—7.3(3H, br s), 4.33(2H, d, J=6Hz), 1.82(3H, s).

*Methyl (2E)-4-Hydroxy-2-methyl-2-butenoate (**17**).* To a solution of **16** (314 mg, 2.71 mmol) in abs ether (5 ml) was added a solution of diazomethane (excess) in ether at 0 °C. The mixture was kept at 0 °C for 1 h and the solvent removed under reduced pressure. The resulting oil was distilled to afford 298 mg (85%) of **17**, bp 124 °C/7 mmHg. IR(neat) 3400, 1720, 1660, 1260 cm^{-1}. NMR($CDCl_3$) δ 6.85(1H, quasi t), 4.35(2H, quasi d), 3.70(3H, s), 3.01(1H, s), 1.83 (3H, s).

*Methyl (2E)-4-Oxo-2-methyl-2-butenoate (**13**).* A solution of **17** (650 mg, 5 mmol) in dichloromethane (5 ml) was added in one portion to the stirred suspension of pyridinium chlorochromate (1.62 g, 7.5 mmol) and sodium acetate (125 mg, 1.52 mmol) in dichloromethane (5 ml). After 2 h, the reaction mixture was conducted according to Corey and Suggs.[10] Distillation of the crude oil gave 480 mg (75%) of **13**, bp 89 °C/15 mmHg (lit,[15] bp 76—78 °C/12 mmHg). IR(neat) 1720, 1680, 1630, 1260 cm^{-1}. NMR($CDCl_3$) δ 10.28(1H, d, J=8Hz), 6.85(1H, quasi d), 3.88(3H, s), 2.35 (3H, d, J=1.5Hz).

2,4-Dinitrophenylhydrazone, mp 206—207 °C (lit,[15] mp 204—205 °C).

*Methyl (2E)-4-Hydroxy-2-methyl-2-octenoate (**12**). From Methyl (2E)-4-Oxo-2-methyl-2-butenoate (**13**):* To a solution of the Grignard reagent prepared from Mg (59 mg, 2.4 mg atom) and butyl bromide (357 mg, 2.6 mmol) in ether (1 ml) was added a solution of **13** (256 mg, 2 mmol) in ether (1 ml) at −30 °C under an argon atmosphere. The mixture was stirred for 2 h at room temperature. After the usual work-up a crude oil was obtained. This oil was purified by preparative TLC on silica gel [hexane–ethyl acetate (4:1) as an eluent] to yield 227 mg (60%) of **12**, bp 95 °C/0.04 mmHg. IR(neat) 3400, 1720, 1650 cm^{-1}. NMR($CDCl_3$) δ 6.68(1H, br d), 4.3—4.8(1H, br). 3.74(3H, s), 2.64 (1H, br s), 1.87(3H, d, J=1.5Hz), 1.1—1.8(6H), 0.90(3H).

*From (2E)-4-Acetoxy-2-methyl-2-octenal (**11b**):* To a solution of silver nitrate (408 mg, 2.4 mmol) in water (4 ml) was added a solution of **11b** (396 mg, 2 mmol) in ethanol (8 ml) and aqueous NaOH (368 mg in 5 ml of H_2O). The mixture was stirred for 24 h at room temperature in the dark. The precipitates filtered off and ethanol removed under reduced pressure. The residual aqueous solution was acidified with dil HCl, extracted with ethyl acetate and the extract was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure to give a crude acid (324 mg). This was treated with a small excess of ethereal diazomethane at 0 °C for 1 h. After evaporation of ether, the residual oil was purified by column chromatography on silica gel [hexane–ethyl acetate (2:1) as an eluent] to afford 282 mg (76%) of **12**, bp 95 °C/0.04 mmHg. The ester (**12**) was identified by comparison of its GLC retention time,[16] IR and NMR spectrum with those of an authentic sample (**12**) prepared from **13**.

*(2E)-4-Acetoxy-2-methyl-2-octenal Dimethyl Acetal (**18b**).* To a solution of **11b** (2.80 g, 14 mmol) and trimethyl orthoformate (4.5 g, 42 mmol) in abs methanol (7 ml) was added a catalytic amount of *p*-toluenesulfonic acid at −10 °C under an argon atmosphere. The mixture was stirred for 10 min at the same temperature and brought to room temperature. After stirring for a further 3 h, the reaction was quenched by adding anhydrous K_2CO_3. The solvent was removed under reduced pressure at 20 °C, the residue dissolved in petroleum ether (bp 30—60 °C), filtered and the filtrate evaporated to give an oil which distilled to give 3.04 g (89%) of **18b**, bp 85 °C/0.04 mmHg. IR(neat) 1740, 1240 cm^{-1}. NMR($CDCl_3$) δ 5.55(1H, br s), 5.45—5.70(1H, br), 4.52(1H, s), 3.30(6H, s), 2.01(3H, s), 1.71(3H, s), 0.9—1.8(9H).

(2*E*)-4-Acetoxy-2-octenal dimethyl acetal (**18a**) was obtained by treating **11a** with trimethyl orthoformate–methanol as described above (85% yield). Bp 98—100 °C/0.5 mmHg. IR(neat) 1740, 1240 cm^{-1}. NMR(CCl_4) δ 5.5—5.8(2H, m), 5.0—5.4(1H, m), 4.70 (1H, br d), 3.20(6H, s), 2.00(3H, s), 1.1—1.7(6H), 0.95(3H).

*(2E,6E)-8-Acetoxy-5-methoxy-6-methyl-2,6-dodecadienal (**19b**).* To a mixture of $Ti(O^iPr)_4$ (8 mmol) and $TiCl_4$ (8 mmol) in dichloromethane (40 ml) was added a solution of **18b** (976 mg, 4 mmol) and 1-trimethylsiloxy-1,3-butadiene (680 mg, 4.8 mmol) in dichloromethane (10 ml) at −40 °C under an argon atmosphere. After stirring for 30 min at −40 °C, the reaction was quenched by adding K_2CO_3 (7 g in 10 ml of H_2O). The resulting precipitates were removed by filtration and the filtrate extracted with ether and the extract was washed with water, dried over anhydrous $MgSO_4$ and evaporated. The residual oil was purified by preparative TLC on silica gel [hexane–ethyl acetate (4:1) as an eluent] to yield 959 mg (85%) of **19b**. Bp 135 °C/0.04 mmHg. IR (neat) 1740, 1690, 1640, 1240 cm^{-1}. NMR ($CDCl_3$) δ 9.55 (1H, d, J=8Hz), 6.83(1H, ddd, J=16.8, 8Hz), 6.13(1H, dd, J=16,8Hz), 5.2—5.6(2H, br), 3.64(1H, t), 3.22(3H, s), 2.5—2.7(2H, m), 2.01 (3H, s), 1.70(3H, s), 1.1—1.8(6H), 0.9(3H).

(2*E*,6*E*)-8-Acetoxy-5-methoxy-2,6-dodecadienal (**19a**) was obtained by reacting **18a** with dienoxysilane in the presence of $TiCl_4$ and $Ti(O^iPr)_4$ (83% yield). Bp 125 °C/0.08 mmHg. IR(neat) 1735, 1690, 1640, 1240 cm^{-1}. NMR (CCl_4) δ 9.40(1H, d, J=8Hz), 6.70(1H, ddd, J=16,8,8Hz), 6.00(1H, dd, J=8,16Hz), 5.45—5.60 (2H, m), 4.9—5.3 (1H, br), 3.5—3.8(1H, br), 3,20(3H, s), 2.3—2.7 (2H), 1.05—1.70(6H), 0.9(3H).

*(2E,4E,6E)-8-Acetoxy-6-methyl-2,4,6-dodecatrienal (**20b**).* To a mixture of **19b** (282 mg, 1 mmol) and molecular sieves 3A (500 mg) in dichloromethane (8 ml) was added a solution of DBU (304 mg, 2 mmol) in dichloromethane (2 ml) at room temperature under an argon atmosphere. After stirring for 1 h, a solution of DBU (2 mmol) in acetonitrile (3 ml) and molecular sieves 3A (500 mg) were added. The mixture was stirred for 2 h and poured into ice-cold brine containing acetic acid, the organic layer separated, washed with brine and dried over anhydrous Na_2SO_4. After removal of the solvent, the residual oil was purified by preparative TLC on silica gel [hexane–ethyl acetate (4:1) as an eluent] to yield 193 mg (77%) of **20b**. IR(neat) 1735, 1680, 1610, 1240 cm^{-1}. NMR($CDCl_3$) δ 9.63(1H, d, J=8Hz), 7.00 —7.50(1H, m), 6.5—7.0(2H, m), 6.20(1H, dd, J=16, 8Hz), 5.5—5.8(2H, br), 2.04(3H, s), 1.93(3H, s). 1.1—1.9(6H), 0.9(3H).

(2*E*,4*E*,6*E*)-8-Acetoxy-2,4,6-dodecatrienal (**20a**) was obtained by treating **19a** with DBU under similar conditions (75% yield). IR(neat) 1740, 1680, 1615, 1240 cm^{-1}. NMR ($CDCl_3$) δ 9.50 (1H, d, J=8Hz), 5.7—7.3(6H, m), 5.05—5.40(1H, br), 2.05(3H, s), 1.10—1.75(6H), 0.9(3H).

*(2E,4E,6E)-8-Hydroxy-6-methyl-2,4,6,-dodecatrienoic Acid (**2b**).* To a solution of silver nitrate (646 mg, 3.80 mmol) in water (5 ml) were added a solution of **20b** (791 mg, 3.16 mmol) in ethanol (13 ml) and NaOH (581 mg in 8 ml of H_2O). The mixture was stirred for 24 h at room temperature in the dark. After the usual work-up, **2b** (661 mg) was obtained (93% yield). IR(neat) 3300, 1690, 1620 cm^{-1}. NMR ($CDCl_3$) δ 7.2—7.7(1H, m), 6.3—6.8 (3H, m), 5.90(1H, d, J=16Hz), 5.70(1H, br d), 4.3—4.7(1H, br d), 1.86(3H,), 1.1—1.8(6H), 0.85(3H). UV $\lambda_{max}^{C_2H_5OH}$ 296 nm (ε 2.6×10). MS *m/e* 225(M^++1), 206, 139, 121. Found: C, 69.88; H, 9.02%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%.

(2*E*,4*E*,6*E*)-8-Hydroxy-2,4,6,-dodecatrienoic acid (**2a**) was obtained by treating **20a** with silver oxide under similar conditions (90% yield). Mp 85—86 °C (recrystallized from ethyl acetate-hexane). IR(Nujol) 3400—3300, 1700, 1610 cm^{-1}. NMR(CCl_4) δ 7.1—7.4(3H, m), 5.7—5.6 (4H, m), 4.0—4.3(1H, br), 1.1—1,7(6H), 0.9(3H). UV $\lambda_{max}^{C_2H_5OH}$ 296 nm(ε 2.9×10⁴). MS *m/e* 210(M^+), 192, 125. Found C, 68.41; H, 8.51%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%.

*Reaction of (2E,4E,6E)-8-Hydroxy-6-methyl-2,4,6,-dodecatrienoic Acid (**2b**) with 2-Ethoxy-1-pyrroline (**3a**).* A solution of **2b** (112 mg, 0.5 mmol) and tributylamine (102 mg, 0.55 mmol) in toluene (1 ml) was added dropwise to a mixture of 1-methyl-2-chloropyridinium iodide (307 mg, 1.2 mmol) and **3a** (136 mg, 1.2 mmol) in toluene (1 ml) over a period of 30 min at 85 °C under argon atmosphere. The mixture was stirred for an additional 10 min and the solvent removed under reduced pressure and the residue chromatographed on silica gel. Elution with dichloromethane-ether (4:1) afforded 44 mg (30%) of **1b**. Further elution with dichloromethane-ether (1:1) gave 17 mg (10%) of **21b**. In another experiment under the same conditions, **1b** (54 mg) and **21b** (30 mg) were obtained in 37% and 18% yields, respectively. **1b**: IR(neat) 3400, 1740, 1670, 1600 cm^{-1}. NMR ($CDCl_3$) δ 7.3—7.7(2H, m), 6.4—6.7(2H, m), 5.70(1H, br d), 4.3—4.8 (1H, br), 3.90(2H, t), 2.65(2H, quasi t), 2.50(1H,s), 1.8—2.4 (2H, m), 1.75(3H, s), 1.1—1.8(6H), 0.9(3H). UV $\lambda_{max}^{C_2H_5OH}$ 320 nm (ε 2.61×10⁴). MS *m/e* 291(M^+), 273, 206. Found: C, 70.03; H, 8.41; N, 4.66%. Calcd for $C_{17}H_{25}NO_3$: C, 70.07; H, 8.65, N, 4.81%. **20b**: IR(neat) 3300, 1740, 1650, 1610 cm^{-1}. NMR($CDCl_3$) δ 7.1—7.6(1H, m), 6.10—6.10(3H, m), 5.95(1H, d, J=16Hz), 5.65(1H, br d), 4.15(2H, q), 4.2—4.7(1H, br), 3.15—3.89(3H, m). 2.2—2.6(2H, m), 1.85(3H, s), 1.25(3H, t), 1.1—2.2(8H), 0.9(3H). UV $\lambda_{max}^{C_2H_5OH}$ 294 nm (ε 4.0×10⁴). MS *m/e* 337(M^+). Found: C, 67.91; H, 9.45; N, 4.09%. Cacld for $C_{19}H_{31}NO_4$: C, 67.62; H, 9.26; N, 4.15%.

In a similar manner, **1a** was obtained from **2a** and **3a** (36% yield), together with **21a** (16%). Similarly, **1c** (27%) and **21c** (28%) were obtained from **2b** and **3b**. Compound **1a**: IR(neat) 3400, 1730, 1660, 1600 cm^{-1}. NMR($CDCl_3$) δ 7.3—7.6(2H, m), 5.9—6.7(4H, m), 3.9—4.5(1H, br), 3.90 (2H, t), 2.3—2.8(3H, m), 1.8—2.3(2H, br q), 1.1—1.8(6H), 0.9(3(H). UV $\lambda_{max}^{C_2H_5OH}$ 324 nm (ε 2.68×10⁴). MS *m/e* 278(M^+), 193. Found: C, 69.51; H, 8.38; N, 5.25%. Calcd for $C_{16}H_{23}NO_3$: C, 69.28; H, 8.36; N, 5.05%. Boron Trifluoride Hydrate-catalyzed Competitive Benzylation of Benzene and Toluene with Benzyl and Substituted Benzyl Chlorides

Akiko TAKEMATSU, Kyoko SUGITA, and Ryohei NAKANE*

The Institute of Physical and Chemical Research, Wako-Shi, Saitama 351

(Received December 8, 1977)

The competitive benzylation of benzene and toluene catalyzed by boron trifluoride hydrate was carried out with benzyl, chlorobenzyl, alkylbenzyl, and alkoxybenzyl chlorides in boron trifluoride hydrate and hexane solutions. The relative rates of toluene to benzene were smaller than 1 in the benzylation with benzyl and chlorobenzyl chlorides, while they were larger than 1 with alkylbenzyl and alkoxybenzyl chlorides. Competitive benzylation catalyzed by boron trifluoride was also carried out in a nitromethane solution. The relative rates were reduced by from several to ten times in the former solutions as compared to the latter solution; the k_T/k_B value became smaller than 1 when the electrophile was such a very strongly electron-deficient reagent as the benzyl or chlorobenzyl cation. On the other hand, the k_T/k_B value was still larger than 1 when the electrophilicity was lower, as in the alkylbenzyl or alkoxybenzyl cation. The isomer distribution was insensitive to the nature of the solvents. The formation of the meta isomer was always only a small percentage. These results substantiate our previous conclusions obtained in the ethylation and isopropylation catalyzed by boron trifluoride hydrate.

Boron trifluoride-catalyzed ethylation with ethyl-2-^{14}C fluoride carried out in nonpolar organic solvents has indicated that an electrophile is not a donor:acceptor complex, but an ethyl cation.[1] Stock and Brown[2] suggested that, in aromatic substitution involving an ultimate powerful electrophile, the rate of toluene relative to benzene is 5/6 and that the orientation in the alkylation of toluene is 40% ortho, 40% meta, and 20% para isomer (statistical value). However, we found that the formation of the meta isomer of ethyltoluene or cymene is much lower than the statistical value, though the rate of toluene relative to benzene is smaller than 5/6, when the electrophile is such a very strongly electron-deficient reagent as the ethyl[3] or isopropyl[4] cation. The results do not agree with Brown's Selectivity Relationship.

Recently, some criticisms have been posed about such anomalous substrate selectivity that toluene is less reactive than benzene in spite of the electrophilic aromatic substitution. Carter *et al.*[5] carried out an ethylation of benzene and toluene with ethyl bromide under the influence of aluminium bromide in a hexane solution and concluded that the disproportionation and isomerization of products which occurred in the layer separation cause the reverse in the k_T/k_B value. Olah[6] suggested that, because of the secondary intermolecular rearrangement, the k_T/k_B value may apparently become smaller than 1 in the ethylation and the isopropylation, in which the *m*-isomer of ethyltoluene or isopropyltoluene usually is formed in a quantity of more than 20%.

In this work the benzylation catalyzed by boron trifluoride hydrate has been carried out with benzyl and substituted benzyl chlorides in order to substantiate our previous suggestion concerning the reaction mechanism of aromatic substitution involving the ultimate powerful electrophile.

Results and Discussion

Water dissolves small amounts of benzene and methylbenzenes.[7] Liquid boron trifluoride hydrate, which is formed when boron trifluoride is placed in contact with water, can also dissolve small amounts of benzene and methylbenzenes. When a boron trifluoride hydrate solution in which *o*-xylene and benzene have been dissolved is allowed to stand for many hours, both isomerization and disproportionation are observed to progress very slowly. When benzyl chloride is added to the boron trifluoride hydrate solution, dissolving the aromatics, the benzylation, accompanied by a little polymerization, occurs. The reaction is very rapid. The competitive benzylation of benzene and toluene with benzyl, *o*-, *m*-, *p*-chlorobenzyl, *p*-methyl-, *p*-ethyl-, *p*-isopropyl-, and *p*-methoxybenzyl chlorides was carried out in the boron trifluoride hydrate solution. The reaction proceeded in a homogeneous system. The data obtained are shown in Table 1. The rates of toluene relative to benzene, k_T/k_B, were smaller than 1 in the reactions with benzyl and chlorobenzyl chlorides, while they were larger than 1 in the reactions with *p*-alkyl- and *p*-alkoxybenzyl chlorides. No dibenzyltoluene was found. The benzylation catalyzed by boron trifluoride was also carried out in hexane. The data obtained are shown in Table 2. The results obtained were almost the same as those obtained in the boron trifluoride hydrate solution. Therefore, it appears that the catalyst in the hexane solution is not boron trifluoride itself, but boron trifluoride hydrate, as was suggested in previous works.[3,4] For comparison, a boron trifluoride-catalyzed benzylation was

carried out in nitromethane. The results obtained were similar to those obtained by others,[8] as is shown in Table 3. The finding that the formation of the *m*-isomer is only a small percentage in most of the reactions indicates that few thermodynamical side reactions (*i.e.*, isomerization and transalkylation) occur. The isomer distribution was almost independent of the nature of the solvent, while the k_T/k_B value was very sensitive to the reaction conditions.

Electrophile in Boron Trifluoride Hydrate-catalyzed Benzylation. The hydrates of $SnCl_2$, $SnCl_3$, $SnCl_4$, $ZnCl_2$, $FeCl_3$, $SbCl_3$, $SbCl_5$, $BiCl_2$, and $TiCl_4$ catalyze the benzylation of aromatics with benzyl chloride in aqueous media.[9] Olah[10] suggested that the investigated hydrates of metallic halides possess certain proton-acid catalytic activity and that the hydrolysis of benzyl chloride itself must proceed through a cation-type intermediate, capable under suitable conditions of effecting concurrent benzylation. The boron trifluoride hydrate is also a strong proton acid of a trifluorohydroxoboric or difluorodihydroxoboric acid type. The molar ratio of boron trifluoride to water in the boron trifluoride hydrate used for the benzylation is 0.77. In the solution there exists no free boron trifluoride which forms with benzyl chloride a polar donor:acceptor complex, $C_6H_5\overset{\delta+}{C}H_2Cl\cdot\overset{\delta-}{B}F_3$. The reaction of benzyl chloride with the boron trifluoride hydrate cannot give a donor:acceptor complex, since benzyl chloride is a much weaker donor than water. Therefore, in the boron trifluoride hydrate solution a benzyl cation-type intermediate is formed. Benzyl cation polymerizes when aromatics are not dissolved in the solution, but it becomes the electrophile of the benzylation in the presence of aromatics.

$$H_2O + BF_3 \rightleftharpoons H^+BF_3OH^-$$

$$H^+BF_3OH^- + C_6H_5CH_2Cl \longrightarrow C_6H_5CH_2{}^+BF_3OH^- + HCl$$

$$C_6H_5CH_2{}^+BF_3OH^- + ArH \longrightarrow C_6H_5CH_2Ar + H^+BF_3OH^-$$

The above presumption is also supported by the observations that an ethyl cation is the electrophile in the ethylation carried out with ethyl-1-^{13}C fluoride and ethyl-1,1-d_2 fluoride in the boron trifluoride hydrate solution.[11]

Effect of Electrophilicity of Reagents on Selectivity. Olah, *et al.*[8] concluded that intermolecular selectivity (rate ratio) is inversely related to the amount of polarization of the polar complex, while intramolecular selectivity (isomer distribution) is insensitive to the nature of the alkylating agent in the benzylation of benzene and toluene with benzyl and substituted benzyl halides in the presence of various Lewis acid catalysts. The explanation was made that the transition state can vary from a late one resembling an intermediate (σ complex) to an early one resembling the starting material (π complex), whereas the isomer distribution is related to the stability of the σ complex. The results obtained in this work showed effects similar to those found by Olah. The electrophile is the cation in the boron trifluoride hydrate-catalyzed benzylation, while it is the polar complex in the boron trifluoride-catalyzed benzylation. Since the electron deficiency of the former is much higher than that of the latter, the k_T/k_B values are reduced by as much as ten times in the boron trifluoride hydrate and hexane solutions as compared to the nitromethane solution. When the boron trifluoride-catalyzed benzylation was carried out with benzyl and chlorobenzyl chlorides in the latter solution, the k_T/k_B value was about 3. Consequently, the k_T/k_B value became smaller than 1 in the boron trifluoride hydrate and hexane solutions. On the other hand, the isomer distribution is less sensitive to the nature of the catalyst.

Rate-determining Step in the Boron Trifluoride Hydrate-catalyzed Benzylation. In the benzylation catalyzed by the boron trifluoride hydrate, the rupture of the C–Cl bond in benzyl or substituted benzyl chloride is complete before the reaction with the aromatics. The question arises whether or not an S_N1-type mechanism is applicable. If the rupture of the C–Cl bond determines the rate of the benzylation, the relative rate should always become 1, whether a substituted group of benzyl chloride is electron-attractive or electron-donative. The fact that the k_T/k_B values in the benzylation with *p*-alkyl- and *p*-alkoxybenzyl chlorides are from 4 to 34 indicates that the formation of *p*-alkyl- and *p*-alkoxybenzyl cations is not involved in the rate-determining step. On the other hand, the k_T/k_B values in the benzylation with chlorobenzyl chlorides are much smaller than 1. These values also suggest that the

rate-determining step is not the rupture of the C–Cl bond in chlorobenzyl chlorides.

The benzylation proceeds in the homogeneous system, and few thermodynamical side reactions occur. However, since the reaction is very rapid, there are the possibilities that the reaction takes place at a point of entrance of benzyl or substituted benzyl chlorides into the boron trifluoride hydrate solution in which aromatics are dissolved and that the diffusion of aromatics in the solution determines the rate of the benzylation. If so, the k_T/k_B value should be nearly 1, but it may change from 0.5 to 34 depending on the electrophilicity of the substituted benzyl cations.

Consequently, the benzylation catalyzed by the boron trifluoride hydrate involves an electrophilic attack on aromatics by the benzyl or substituted benzyl cation. When the electron deficiency of the cation is very high, benzene is more reactive than toluene, but only a small percentage of the meta isomer of benzyltoluene is formed. This substantiates our previous suggestions[4] that the rate-determining transition state formed in the substitution of toluene closely resembles the oriented π complex, that the difference in rates between benzene and toluene is due primarily to the difference in the entropies of activation, which can be negative, since the difference in the activation energies between the two aromatics is very small, and that the isomerization of benzyltoluene is mainly determined by the stability of the intermediate (σ complex).

Experimental

Material. The benzene, toluene, *p*-methoxybenzyl chloride, and nitromethane were obtained from the Wako Pure Chemical Co. (Osaka, Japan). The benzyl chloride, chlorobenzyl chlorides, *p*-alkylbenzyl chlorides, and hexane were obtained from the Tokyo Kasei Co. (Tokyo, Japan). The boron trifluoride gas was obtained from the Hashimoto Kasei Co. (Osaka, Japan). They all were commercially available materials of the highest purity and were used without further purification.

Benzylation in Boron Trifluoride Hydrate Solution. Preparation of a Boron Trifluoride Hydrate Solution Saturated with Aromatics: Boron trifluoride gas was introduced into an ice-cooled and stirred mixture composed of 20 mol of distilled water, 1 mol of benzene, and 1 mol of toluene. The amount of boron trifluoride absorbed in the mixture was estimated by means of the flow speed of the boron trifluoride gas (6.2 l/min). The molar ratio of boron trifluoride to water in the mixture was 0.77. After the introduction of boron trifluoride gas had finished, the mixture was allowed to stand overnight and was then separated into two liquid-phase layers. The lower layer was the boron trifluoride hydrate solution saturated with benzene and toluene. It was a clear, colorless, viscous solution, and its specific gravity was 1.73 at 30 °C. Small amounts of aromatics dissolved in the boron trifluoride hydrate solution were extracted with hexane and analyzed by gas chromatography. About 5 mg of aromatics[11] were dissolved in 10 g of the boron trifluoride hydrate solution, the molar ratio of toluene to benzene was from 0.8 to 1.2, according to the preparative conditions.

Preparation of a Boron Trifluoride Hydrate Solution Saturated with Benzyl or Substituted Benzyl Chlorides: Boron trifluoride gas was absorbed into an ice-cooled and stirred mixture of 20 mol of water and 0.05 mol of benzyl chloride or substituted benzyl chloride. The reactivity of benzyl chloride varied greatly with the substituent group. Therefore, the molar ratio of boron trifluoride to water in a boron trifluoride hydrate solution in which benzyl chlorides were dissolved was changed in order to obtain such appropriate reaction conditions that less than 15% of the combined aromatics were alkylated and no side reactions proceeded. The amount of boron trifluoride gas blown into the mixture was estimated by means of the flow speed (6.2 l/min). The molar ratio of boron trifluoride to water was 0.20 for *o*- and *m*-chlorobenzyl chlorides, 0.10 for benzyl chloride, *p*-chloro-, *p*-ethyl-, *p*-isopropyl-, and *p*-methoxybenzyl chlorides, and 0.01 for *p*-methylbenzyl chloride. Benzyl or substituted benzyl chlorides do not polymerize in a boron trifluoride hydrate solution in which the ratio of boron trifluoride to water is small. Benzyl or substituted benzyl chlorides dissolved in a boron trifluoride hydrate solution were used for benzylation after filterings out the crystals of boric acid which were produced by the hydrolysis of boron trifluoride, and after separating out any excess benzyl or substituted benzyl chlorides. Gas-chromatographic analysis showed no isomerization of benzyl or substituted benzyl chlorides dissolved in the boron trifluoride hydrate solution.

Competitive Benzylation in Boron Trifluoride Hydrate Solution. From 10 to 80 g of boron trifluoride hydrate, in which benzyl chloride or substituted benzyl chlorides had been dissolved, were added to a glass beaker containing 20 g of a boron trifluoride hydrate solution saturated with benzene and toluene. The reaction mixture, which was a clear, colorless solution, was stirred at room temperature and then instantly quenched by adding 70 g of icewater. The organic layer was extracted with 1 ml of hexane, washed with water, and dried with calcium chloride. It was analyzed by gas chromatography. Benzylation proceeded for about 15% of the combined aromatics.

Competitive Benzylation in Hexane. Competitive benzylation was carried out by blowing boron trifluoride gas into a mixture of benzene, toluene, benzyl chloride, and hexane which had been saturated with water. The molar ratio of reactants was as follows; C_6H_6: $C_6H_5CH_3$: $C_6H_5CH_2Cl$: C_6H_{14}: BF_3=5 : 5 : 3 : 30 : 2. The flow speed of the boron trifluoride gas was 230 ml/min. The mixture was stirred at room temperature, it was quenched with water after 5 to 60 min, and then it was washed with water, dried with calcium chloride, and analyzed by gas chromatography.

Competitive Benzylation in Nitromethane. Competitive benzylation was carried out in a solution with the following molar ratio: C_6H_6 : $C_6H_5CH_3$: $C_6H_5CH_2Cl$: CH_3NO_2 : BF_3 =5 : 5 : 3 : 30 : 2. The flow speed of the boron trifluoride gas was 230 ml/min. After from 5 to 60 min, the reaction mixture was quenched with water, extracted with diethyl ether, and dried with calcium chloride. It was then analyzed by means of gas chromatography.

Gas-chromatographic Analysis. The reaction products were analyzed with a Hitachi 163-type gas chromatograph using a hydrogen flame-ionization detector and a 3380A Reporting Integrator of Hullet Packard. A glass capillary column(length, 30 m; i.d., 0.28 mm) coated with sillicon OV-101 was used at 180 °C for benzylated products, while one with Ucon 550X was used at 150 °C for the analysis of the isomer of *o*-chlorobenzyltoluene.

Carbon-13 NMR Spectra of Octahydro-1,4-naphthoquinones and of Their Derivatives

Hajime IRIKAWA* and Yasuaki OKUMURA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received December 15, 1977)

The ^{13}C NMR spectra are reported for hexahydro- and octahydro-1,4-naphthoquinones and their derivatives. The shielding trends of the methyl group are utilized for conformational analysis. A comparison of octahydro-1,4-naphthoquinones with the corresponding decalins reveals that the effects of the carbonyl group are the large downfield shift of the α-carbons and the upfield shifts of the β- and γ-carbons.

^{13}C NMR spectroscopy is a powerful method for clarifying stereochemical problems. Systematic studies of methyldecalins and decahydroquinolines have provided useful parameters for signal assignments.[1,2] This paper deals with a ^{13}C NMR study of *cis*-2,3,4a,5,8,8a-hexahydro- and *cis*-octahydro-1,4-naphthoquinones (**1a,b—5a,b**), *trans*-octahydro-1,4-naphthoquinones (**1c—3c**), and a number of derivatives (**6a,b, 7—13, 14a,b**).

Natural-abundance 15.04 MHz ^{13}C FT-NMR spectra were obtained by use of the ^{1}H noise-decoupling technique. The signals of methyl, methylene, and methine carbons were identified by a combination of off-resonance decoupling and partially relaxed FT spectra.[3]

Results and Discussion

Materials. Compounds **1a—5a** were prepared from the Diels-Alder adduct[4-8] of *p*-benzoquinone and the corresponding diene by zinc reduction, respectively. Catalytic hydrogenation of **1a—5a** provided **1b—5b**, respectively.[4,8,9] The configuration of the methyl group in **3b** was estimated to be *cis-syn* because of the hydrogenation from less hindered side. Compound **2b** was isomerized into *trans*-**2c** by acid treatment and **3b** into *trans*-**3c** by alumina column. Hydrogenation of **6a**, derived from **5a**, with platinum oxide in methanol provided the dihydro keto oxime (**6b**), whereas that in acetic acid afforded the δ-lactam (**15**). The ^{13}C NMR spectrum of **15** was similar to that of **13** except for C-1, supporting the position of the hydroxyimino group and the cis ring junctions in **6a** and **6b**. Compounds **10** and **14b** were obtained by acetylation of **8** and **13**, respectively.[8]

The chemical shifts of the $\Delta^{6,7}$-compounds (**1a—6a, 14a**) are summarized in Table 1, those of the octahydro-compounds (**1b—6b, 1c—3c**) in Table 2, and those of **7—13** and **14b** in Table 3.

Signal Assignments. Assignments for the signals in **2b, 3b,** and **4b** were made on their preferred conformations shown below. The methylene signal at 26.62 ppm in **4b** was assigned to C-8, since it was shifted upfield upon reduction of the C-1 carbonyl to the hydroxyl group (to **7**). Accordingly, the signal at 26.01 ppm in **2b** was assigned to C-8, which seems to be little affected by the substituent. Carbons α to the double bond in cyclohexenes are characteristically shielded ($\Delta\delta = \delta_C^{alkane} - \delta_C^{alkene} > 0$).[10] The shielding trends of the double bonds for C-5 in **2a** and **4a** ($\Delta\delta$ 2.23 ppm between **2a** and **2b**; $\Delta\delta$ 1.22 ppm between **4a** and **4b**) support the assignments for C-8 in **2b** and **4b** ($\Delta\delta$ 3.45 ppm between **2a** and **2b**; $\Delta\delta$ 2.80 ppm between **4a** and **4b**). Saturation of the double bonds in **1a—6a** causes the downfield shifts of C-4a and -8a. The trend is in agreement with the

downfield shifts of the carbons β to the double bond in cyclohexenes.[10] Assignment for C-5 in **3b** is based on the β_e parameter (9.03 ppm) of the methyl group[1a] and the chemical shift of C-8 in **2b**, since both carbons seem to be similarly affected by the 1,4-cyclohexanedione ring. The situation of C-6 in **2b** is similar to that of C-7 in **3b**, their signals being observed at 29—30 ppm.

Of the two signals for C-2 and -3 in **5a** and **5b**, the signals at lower fields were assigned to C-3, respectively, since they were slightly shifted upfield upon replacement of the C-1 carbonyl with the hydroxyimino group (to **6a** and **6b**). In the spectra of **7** and **8**, the signals shifted upfield upon acetylation were assigned to C-2 and -8a, and the C-8 signals appearing upfield were compared with those in **4b** and **5b** by the γ-gauche effects of the hydroxyl groups, respectively.[11]

Assignments for C-4a, -7, -8, and -8a in **11** and **12** are based on the Dalling-Grant parameters.[1] The effects of the equatorial methyl group on C-7 and -8a in **12** are in line with the predicted values (C-7: $\beta_e+\beta_e\alpha_a=8.2$ ppm; C-8a: $\beta_e+\alpha_a\beta_e=5.6$ ppm), although the effect on the α-carbon is larger than the predicted value (C-8: $\alpha_e+\alpha_e\beta_a=3.1$ ppm) (Table 4). The relatively large downfield shift of C-4a might come from the $\beta_g\gamma_t$ effect. In the spectrum of **13**, the signals shifted upfield upon acetylation (to **14b**) were assigned to C-3 and -4a, and the C-5 signal appearing upfield was compared with that in **12** by the γ-gauche effect of the hydroxyl group.

As shown in Fig. 1, the large downfield shift of the α-carbon of the hydroxyl group in **7** upon lactonization (to **11**) seems due to the characteristic deshielding effect of the lactone group, since the similar trend was observed between methyl *cis*-3-hydroxycyclohexanecarboxylate and 1,3-cyclohexanecarbolactone.[12]

Conformational Analysis. The shielding trends of the methyl substituent (Table 4) are useful for conformational analysis. The γ-effects on C-4a and -6 found in **8** and **10** suggest the axial orientation of the methyl group. The δ-effects observed for C-2 indicate the *syn*-diaxial Me–CH_2(C-2) interaction.[13] In contrast to the large upfield shift of C-1 in **12**, the characteristically small γ-gauche effects of the methyl group on C-1 in **8** and **10** are in line with the observation that the γ-gauche effects of the hydroxyl group are reduced whenever it is *syn*-diaxial to a δ-carbon.[14] Thus **8** and **10** are thought to exist in a form bearing

TABLE 4. METHYL SUBSTITUENT EFFECTS[a]

Compound	C-1	C-2	C-4a	C-5	C-6	C-7	C-8	C-8a

8 R_1=OH R_2=H
10 R_1=OAc R_2=H

the axial methyl group, as shown above. The estimation is in line with the ^1H NMR of **8**.[8]

Conformation of **5b** bearing two substituents in cis relation is of interest, since the conformational distribution of methyl *cis*-4-methylcyclohexanecarboxylate is estimated to be 67% of the equatorial methyl conformer by conformational free energy of a methyl and a methoxycarbonyl group.[12] In **5b**, the γ-effects of the methyl group are observed on C-4a and -6, the β-effect on C-8a being smaller than those on C-8a in **12** and C-4a in **2c**. Saturation of the $\Delta^{6,7}$-double bond causes upfield shift of the methyl signal in **5a**, in contrast to the downfield shifts of those in **2a** and **14a**. The chemical shift of C-5 in **5b** is similar to that in **4b** bearing equatorial methoxycarbonyl group. These data indicate that **5b** also exists in a form similar to that of **8** and **10**. Absence of the δ-effect on C-2 might be due to the nonchair conformation of the 1,4-cyclohexanedione ring.[15]

Comparison with Carbocyclic Analogues. It is of interest to compare **1c**—**3c**, **2b**, and **3b** with the corresponding decalins (X=CH_2).[1b] The chemical shift differences are summarized in Table 5. The ^{13}C NMR spectra of decalins were recorded as neat substance, whereas the spectra reported here were obtained in $CDCl_3$. A comparison of the shift values of *trans*-decalin in $CDCl_3$ (26.86, 34.37, and 43.70 ppm) with the literature values of the neat substance (27.17, 34.74, and 44.22 ppm) indicates that the solvent effect is not large.

2b X=CO

3b X=CO

The strong shieldings for C-5 and -8 in **1c**—**3c**, and for C-8 in **3b** are similar to that for the methyl group (−9.4 ppm) in 2-methylcyclohexanone,[16] and mainly ascribed to the β-effect of the carbonyl group. Although the effects of the axial carbonyl group on cyclohexane ring are not clear, the fact that C-7 in **2b** and C-6 in **3b** are shielded indicates the presence of the γ-effect of the carbonyl group similar to that of oxygen and nitrogen on *anti*-periplanar γ-carbons.[17] The upfield shifts of C-5 and -7 in **5b** compared with those in **8** might be rationalized by the shielding effect of the C-1 carbonyl group. Accordingly, the upfield shifts of C-6 and -7 in **1c**—**3c** seem to be mainly due to the effect of the carbonyl group at the γ-position.

On the other hand, C-6 and -8 in **2b**, and C-5 and -7 in **3b** are little affected. The feature might be explained by two opposing effects: shielding by the two carbonyl groups and deshielding due to the absence of the γ_{HH} interaction,[1b] the latter being in line with the small chemical shift differences between C-2 and -3 in **2b**—**5b**.

Experimental

Melting points are uncorrected . The IR spectra were recorded on a Hitachi Infrared Spectrometer EPI-G_3 in Nujol. The ^{13}C NMR spectra were obtained on a JEOL JNM-PFT-60 (15.04 MHz) at 27 °C. Samples were observed in 10 mm spinning tubes at *ca.* 20% solution in $CDCl_3$, unless otherwise stated. The solvent provided the internal lock signal. The measurement conditions are shown in Fig. 1. All the chemical shifts are expressed in terms of δ(ppm downfield from internal TMS). Each observed chemical shift is estimated to be accurate to $\delta \pm 0.08$.

Preparation of ***2a***. A crude adduct[5] formed by 1.00 g of *trans*-1,3-pentadiene and 0.80 g of *p*-benzoquinone was reduced with 5 g of zinc in 20 ml of AcOH at room temperature for 1 h. Work-up in the usual way afforded 1.16 g of **2a**: mp 84—85 °C (from diisopropyl ether); IR 1708 cm^{-1}. Found: C,74.08; H, 7.99%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H,7.92%.

Compound ***3a***. In a similar way to the preparation of **2a**, a crude adduct[6] formed by 6.81 g of isoprene and 7.00 g of *p*-benzoquinone was reduced with zinc to afford 6.52 g of **3a**: mp 86—87 °C (from hexane); IR 1714 cm^{-1}. Found: C, 74.09; H, 8.04%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%.

Compound ***4a***. In a similar way to the preparation of **2a**, 2.00 g of the adduct[7] of methyl 2,4-pentadienoate and *p*-benzoquinone was reduced with zinc to afford 0.92 g of **4a**: mp 130—131 °C (from benzene-hexane); IR 1733 and 1709 cm^{-1}. Found: C, 64.64; H, 6.32%. Calcd for $C_{12}H_{14}O_2$: C, 64.85; H, 6.35%.

a) Values obtained from $\delta_c^{X=CO} - \delta_c^{X=CH_2}$ for the corresponding carbons in each case.

Compound ***2b***. Hydrogenation of 1.10 g of **2a** with 117 mg of 5% Pd-C in 100 ml of AcOEt afforded 0.84 g of **2b**: mp 55—56 °C (from diisopropyl ether); IR 1718 and 1704 cm^{-1}. Found: C, 73.25; H, 9.07%. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%.

Compound ***2c***. Treatment of 149 mg of **2b** with 2 ml of 6% methanolic hydrogen chloride at room temperature overnight afforded 48 mg of **2c**: mp 62—63 °C (from petroleum ether); IR 1705 cm^{-1}. Found: C, 73.12; H, 9.05%. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%.

Compounds ***3b*** *and* ***3c***. Hydrogenation of 1.14 g of **3a** with 165 mg of 5% Pd-C in 80 ml of AcOEt afforded 0.78 g of **3b**: mp 66—67 °C (from diisopropyl ether); IR 1705 cm^{-1}. Found: C, 73.44; H, 9.08%. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%. The mother liquor was chromatographed on 5 g of Al_2O_3. Elution with benzene afforded 0.20 g of **3c**: mp 119—120 °C (from hexane); IR 1707 cm^{-1}. Found: C, 73.27; H, 9.16%. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%.

Preparation of ***6a***. A mixture of 17.56 g of **5a**,[8] 5.54 g of $NH_2OH \cdot HCl$, and 6.67 g of NaOAc in MeOH–H_2O (400 ml–100ml) was refluxed for 2 h. Concentration of the solution afforded 16.41 g of **6a**: mp 208—209 °C (from MeOH); IR 3480, 1731, and 1708 cm^{-1}. Found: C, 61.97; H, 6.84; N, 5.51%. Calcd for $C_{13}H_{17}O_4N$: C, 62.14; H, 6.82; N, 5.57%.

Compound ***6b***. Hydrogenation of 2.54 g of **6a** with 65 mg of PtO_2 in 300 ml of MeOH afforded 1.55 g of **6b**: mp 211—213 °C (from MeOH); IR 3490, 1736, and 1701 cm^{-1}. Found: C, 61.66; H, 7.65; N, 5.49%. Calcd for $C_{13}H_{19}O_4N$: C, 61.64; H, 7.56; N, 5.53%.

Compound ***15***. Hydrogenation of 2.89 g of **6a** with 195 mg of PtO_2 in 150 ml of AcOH afforded 1.46 g of **15**: mp 199—200 °C (from AcOEt); IR 3430, 3190, and 1668 cm^{-1}; ^{13}C NMR 19.47(Me), 26.17(C-3), 28.52(C-7), 30.80(C-2*), 32.09(C-6*), 35.26(C-8), 36.88(C-5), 40.17(C-8a), 45.16 (C-4a), 46.91(C-1), 71.54(C-4), and 176.69 ppm (C=O). Found: C, 68.84; H, 9.31; N, 6.95%. Calcd for $C_{12}H_{19}O_2N$: C, 68.86; H, 9.15; N, 6.69%.

The Acetate ***10***. Treatment of 310 mg of **8**[8] with 3 ml of Ac_2O and 4 ml of pyridine at room temperature overnight afforded 339 mg of **10**: mp 115—117 °C(from AcOEt-hexane); IR 1737, 1710, and 1249 cm^{-1}. Found: C, 63.72; H, 8.00%. Calcd for $C_{15}H_{22}O_5$: C, 63.81; H, 7.85%.

The Acetate ***14b***. In a similar way to the preparation of **10**, 216 mg of **13**[8] was acetylated to afford 229 mg of **14b**: mp 97.5—99 °C (from benzene-hexane); IR 1740, 1717, and 1241 cm^{-1}. Found: C, 66.59; H, 8.07%. Calcd for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99%.

A Novel Type of Polycondensation Utilizing Transition Metal-Catalyzed C–C Coupling. I. Preparation of Thermostable Polyphenylene Type Polymers

Takakazu YAMAMOTO,* Yasuhiro HAYASHI, and Akio YAMAMOTO

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received January 21, 1978)

Transition metal compounds including $NiCl_2$(bpy) (bpy=2,2′-bipyridine), $NiBr_2(PPh_3)_2$ (PPh_3=triphenylphosphine), $PdCl_2$(bpy), $NiCl_2$, $CoCl_2$, $FeCl_2$, and $FeCl_3$ catalyze polycondensation of di- and polyhalogenated organic aromatic compounds by dehalogenation with magnesium under mild conditions. Poly(*p*-phenylene), poly(*m*-phenylene), poly(oxybiphenylene), and poly(phenylenemethylene) were prepared from *p*-dihalobenzene, *m*-dichlorobenzene, bis(*p*-bromophenyl) ether, and α,*p*-dichlorotoluene. They have a high degree of polymerization and high thermal stability. Poly(*p*-phenylene), poly(oxybiphenylene), and poly(phenylenemethylene) have regularly repeated structures as proved by IR spectroscopy and X-ray powder diffraction. Polymerization of polyhalogenated aromatic compounds (1,3,5-trichlorobenzene and hexachlorobiphenyl) in tetrahydrofuran (THF) gave copolymers having aromatic nuclei and THF units. Polymerization of the haloaromatic compounds is considered to proceed through a mechanism in which consecutive cycles of oxidative addition of haloaromatic compounds (R–X) to the transition metal catalyst take place so as to cause alkylation (arylation) by the Grignard reagent formed in the system (R′MgX) and elimination of R–R′ from an active transition metal compound having R and R′ groups.

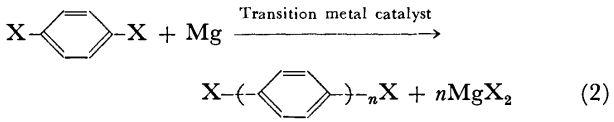
Polyphenylene type polymers consisting of coupled aromatic nuclei have high heat-resistance. Some of them have been utilized as material for rocket nozzles, electrical insulation, and fabrics which must withstand high temperatures.[1] Numerous reactions which produce the polyphenylene-type polymers have been developed over the past 15 years. The preparative methods include: (1) oxidative cationic polymerization of aromatic compounds by use of Friedel-Crafts type catalysts,[2] (2) dehalogenation of di- and poly-halogenated aromatic compounds with metals such as copper (Ullmann reaction)[3] and alkali metals (Wurtz-Fittig reaction),[4] (3) denitrogenation polymerization of diazonium compounds.[5] Of these methods the dehalogenation of di- and poly-halogenated aromatic compounds with metals such as copper[3] and alkali metals[4] serve as one of the most convenient and versatile routes for the preparation of the polyphenylene type polymers. However, the dehalogenation reaction by metals generally requires high temperatures, the polymers obtained having some structural irregularity and/or branching due to the radical nature of the conventional dehalogenation reactions by metals.

It was recently reported that transition metals or their compounds catalyze the coupling of Grignard reagents with aryl halides.[6]

$$RMgX + R'X \xrightarrow{\text{Transition metal}} R\text{-}R' + MgX_2 \qquad (1)$$

Since the transition metal-catalyzed coupling reaction proceeds selectively and quantitatively under mild conditions, it has been applied to the preparation of various organic aromatic compounds.[6]

Extension of the principle of the transition metal catalyzed coupling led us to its application to the preparation of polyphenylene-type polymers having regular recurring units by starting from dihalogenated aromatics. *p*-Dihalobenzene, for example, can be readily dehalogenated by coupling on reaction with magnesium which is promoted by transition metal catalysts, a linear polyphenylene being formed.



$$\qquad + nMgX_2 \qquad (2)$$

The net reaction resembles the conventional dehalogenation polymerization of haloaromatic compounds with Cu and Na. However, the reaction by the new method proceeds under much milder conditions, and can be applied more widely. A part of the results was reported previously.[7]

Results and Discussion

Polymerization of Halo Aromatic Compounds. The results of polymerization of di- and poly-halogenated aromatic compounds are given in Table 1. Although the halo aromatic compounds are not polymerized with magnesium alone in the absence of transition metal catalyst (Exp. No.1, Table 1), addition of a catalytic amount of a suitable transition metal compound to the reaction mixtures initiates very smooth polymerization to yield polyphenylene-type polymers in high yields.

Dihalo Aromatic Compounds: A variety of transition metal compounds catalyze the polymerization of *p*-dibromobenzene. Of the transition metal complexes, $NiCl_2$(bpy) (bpy=2,2′-bipyridine) acts as one of the most effective catalysts. Even a minor amount of the compound (*e.g.*, 5 mg of the complex with Ni/monomer of 3.4×10^{-4} in Exp. No. 3) gives a polymer in a high yield in 4 h at refluxing temperature of tetrahydrofuran (THF).

The polymerization proceeds most smoothly in THF under reflux conditions. However, since the catalytic activity of the complex is very high, it proceeds even at 0 °C (No. 4) though there is some induction period in this case. Employment of other ethereal solvents such as dibutyl ether (No. 5) and diglyme

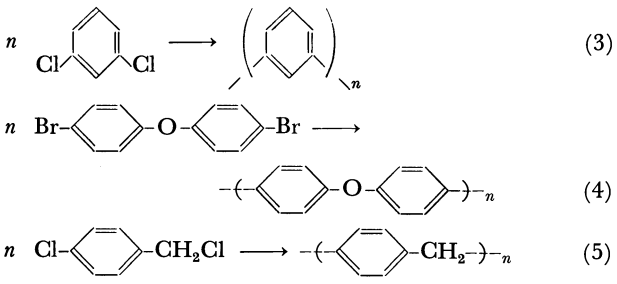
a) Under reflux except for No. 4. b) bpy=2,2′-bipyridine, PPh_3=triphenylphosphine, cod=1,5-cyclooctadiene, Me=methyl, Et=ethyl. c) THF=tetrahydrofuran, Bu_2O=dibutyl ether. d) Based on the amount of carbon taken into the polymer. e) At 0 °C. f) Copolymer with THF (see the text).

gives similar results.

Other nickel and palladium complexes such as $NiBr_2(PPh_3)_2$ (PPh_3=triphenylphosphine) and $PdCl_2$-(bpy) also show high catalytic activities, but the catalytic activities of iron and chromium complexes, $Fe(C_2H_5)_2(bpy)_2$ and $CrCl_2(CH_3)(THF)_3$, are relatively low. Simple transition metal compounds such as $NiCl_2$, $FeCl_2$, and $CoCl_2$ catalyse the polymerization as well. In contrast to these transtion metal compounds metallic Pd and Ni, $PdCl_2$, $CuBr_2$, Cu(acetylacetonato)$_2$, and $MnCl_2$ have negligible or no catalytic activity for the polymerization, although Pd metal and $PdCl_2$ are known to act as effective catalysts for the preparation of low molecular weight aromatic compounds by Reaction 1.[6d,6e] Cuprous halides do not catalyze the polymerization of halo aromatic compounds, either, but they catalyze the polymerization of halo aliphatic compounds to yield aliphatic polymers having high molecular weight. *p*-Dichlorobenzene and *p*-diiodobenzene are also polymerized by the transition metal catalysts, the yields being lower than in the polymerization with *p*-dibromobenzene.

Polymerization is not restricted to *p*-dihalobenzene. *m*-Dichlorobenzene (No. 17, Table 1) and other dihalo aromatic compounds such as bis(*p*-bromophenyl) ether and α,*p*-dichlorotoluene can be polymerized by using the transition metal catalysts.



(3)

(4)

(5)

Some transition metal compounds catalyze the coupling between organolithiums and organic halides:[8]

$$RLi + R'X \xrightarrow{[M]} R\text{-}R' + LiX \quad (6)$$

However, attempts to utilize lithium instead of magnesium as the dehalogenating reagent in the preparation of polyphenylene type polymers from aromatic halides were unsuccessful.

Polyhalo Aromatic Compounds: When the dehalogenation polymerization of aromatic compounds having three or more halogen atoms is carried out in THF (Nos. 25 and 27, Table 1), the polymers obtined

Table 2. Properties of the polyphenylene type polymers

26	$-(-C_6H_3-)-_n$	brown	290 dec	
27	$C_{12}H_4Cl_6$-THF copolymer[f]	brown	185—200	

a) Numbers correspond to those in Table 1. b) Extracted with hot toluene in a Soxhlet extractor for 50 h. c) For polymers soluble in hot toluene. d) For polymers insoluble in hot toluene. e) Soluble in acidic water. f) See the text.

contain both the aromatic nuclei and THF units. The IR spectra show bands characteristic of not only aromatic compounds but also of polytetrahydrofuran $-(-O\text{-}CH_2\text{-}CH_2\text{-}CH_2\text{-}CH_2-)-_n$. The NMR spectra show signals of aromatic protons at δ 7—8 ppm and those of THF-protons at δ 1.8 ppm $-(-CH_2\text{-}C\underline{H}_2\text{-}CH_2-)-$, δ 2.4 ppm $-(-C_6H_4\text{-}C\underline{H}_2-)-$, δ 3.7 ppm $-(-O\text{-}C\underline{H}_2-)-$, and δ 4.1 ppm $-(-C_6H_4\text{-}O\text{-}C\underline{H}_2-)-$. The polymers are not soluble in THF, which dissolves polytetrahydrofuran, but soluble in chloroform, which does not dissolve polyphenylene type polymers. The resutls suggest that the polymers are copolymer such as

$$-(-A-)_m-(-O\text{-}CH_2\text{-}CH_2\text{-}CH_2\text{-}CH_2-)-_n,$$

where A represents the aromatic units.

In the case of hexachlorobiphenyl polymerized with magnesium in THF, the NMR spectrum indicates that the copolymer contains the two monomer units in about 1:1 ratio in line with the analytical data. The peak areas of methylene protons at δ 2.4 ppm and δ 4.1 ppm contained in the THF units adjacent to the aromatic unit are considerably small, although the copolymer contains the two monomer units in about 1:1 ratio. This suggests that the copolymer has a block structure rather than a random structure.

The copolymers of polyhaloaromatic compounds and THF melt without decomposition at considerably high temperatures (Table 2). The polymerization of polyhalogenated aromatic compounds in other ethereal solvents such as dibutyl ether and diglyme gives normal dehalogenated homopolymers of the polyhalogenated aromatic compounds (No. 26).

Properties of Polymers. Physical Properties: The color, melting point, and solubility of the polymers obtained are given in Table 2. The polymers prepared by the present method are much less colored than those prepared by conventional methods such as oxidative cationic polymerization of benzene and dehalogenation polymerization of halo aromatic compounds. For example, poly(*p*-phenylene) prepared by the present method is light yellow, whereas the one prepared by conventional methods is brown or black.[1-5] Poly(*m*-phenylene) prepared by the Wurtz-Fittig reaction[4b] of $m\text{-}C_6H_4Br_2$ and poly(oxybiphenylene) prepared by the polycondensation of potassium *p*-(*p*-bromophenyl)phenoxide[9] were reported to be yellow and gray, respectively.

The polymers prepared here generally have high thermal stability. The thermal stability of poly(*p*-phenylene) prepared by the present method is comparable with that prepared by the oxidative cationic polymerization of benzene. It does not melt up to 550 °C, where it begins to decompose in the air. Differential thermoanalysis (DTA) of poly(*p*-phenylene) in the air showed an exothermic peak at 580 °C due to the oxidation of the polymer. Poly(*m*-phenylene), poly(oxybiphenylene), poly(phenylenemethylene), and poly(2,5-pyridinediyl) melt above 200 °C. Poly(1,3,5-benzene-triyl)(No. 26) which appears to have a three dimentional structure decomposes at 290 °C without melting. The copolymers with THF melt at relatively low temperatures, their melting points being much higher than the melting point of the THF homopolymer.

The solubility of the polyphenylene-type polymers is low. Poly(*p*-phenylene), poly(*m*-phenylene), poly(oxybiphenylene), and poly(phenylenemethylene) are partially extracted by hot toluene as shown in Table 2, but the extracted fractions do not dissolve in toluene at room temperature. Poly(pyridinediyl) (No. 21—23) is soluble in an aqueous solution containing HCl with the concentration higher than 3 M. Dilution or neutralization of the solution caused precipitation of the polymer. The copolymers with THF are soluble in chlorinated hydrocarbons such as $CHCl_3$ and CCl_4.

IR Spectra and Molecular Weight: Figute 1 shows IR spectra of typical polymers. The IR spectrum of poly(*p*-phenylene) prepared by the present method is essentially of poly(*p*-phenylene)s prepared by conventional methods such as oxidative cationic polymerization of benzene. The out-of-plane vibration of *p*-phenylene units, δ(para), in poly(*p*-phenylene)s prepared under various conditions appears in the region 805±

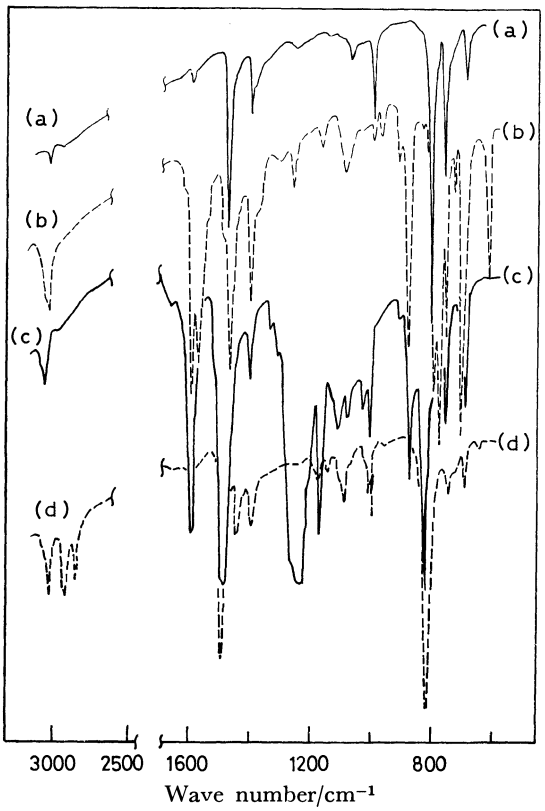

Fig. 1. IR spectra of (a) poly(*p*-phenylene) prepared from *p*-dibromobenzene, (b) poly(*m*-phenylene), (c) poly(oxybiphenylene), and (d) poly(phenylenemethylene).

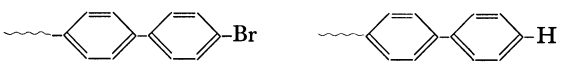
5 cm^{-1}. Weak ν(C–Cl), ν(C–Br), and ν(C–I) bands of terminal *p*-halophenyl groups are observed at 1085, 1065, and 1055 cm^{-1}, respectively, in the IR spectra of poly(*p*-phenylene)s prepared from the corresponding *p*-dihalobenzenes. In addition to the δ(para) band at 805±5 cm^{-1} assignable to the *p*-phenylene units the IR spectrum of poly(*p*-phenylene) shows two out-of-plane vibration bands due to terminal phenyl group at 760 cm^{-1} (δ(mono$_1$)) and 690 cm^{-1} (δ(mono$_2$)).[2b] These IR spectroscopic data suggest that the poly(*p*-phenylene) has both *p*-halophenyl and phenyl groups as the terminal groups:



The fact that the intensities of the bands due to the terminal phenyl group (δ(mono$_1$) and δ(mono$_2$)) are much greater than the ν(C–X) band suggests that the proportion of the terminal group bearing the halogen is not so high.

Kovacic and Oziomek took the relative intensity of δ(para) to that of δ(mono$_1$) and δ(mono$_2$), $A(\delta(\text{para}))/\{A(\delta(\text{mono}_1))+A(\delta(\text{mono}_2))\}$ (A=absorbance of the peak), as a measure for the degree of polymerization.[2b,2c] The value $A(\delta(\text{para}))/\{A(\delta(\text{mono}_1)+A(\delta(\text{mono}_2))\}$ for poly(*p*-phenylene) prepared from dibromobenzene with various catalysts lies between 1.92 (No. 2, Table 1) and 3.85 (No. 7, Table 1), indicating that poly(*p*-phenylene)s obtained have considerably high degrees of polymerization, comparable to that

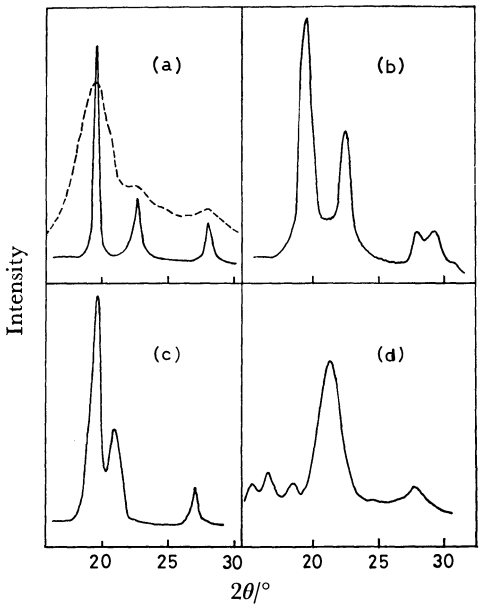


Fig. 2. X-Ray diffraction patterns of (a) poly(*p*-phenylene), (b) poly(oxybiphenylene), (c) poly(phenylenemethylene), and (d) poly(*m*-phenylene). See the text for the broken line in Fig. 2a.

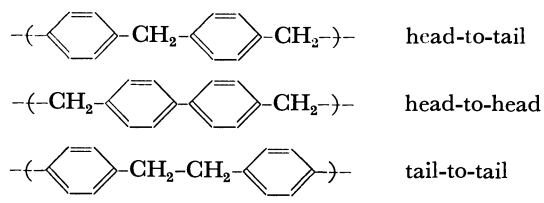
prepared by Kovacic and Oziomek through oxidative cationic polymerization of benzene.[2b]

The IR spectra of types of polymers other than poly(*p*-phenylene) are also in line with the expected structures as represented in Eqs. 3—5. The absorptions in the region of the out-of-plane vibration of poly(*m*-phenylene) are more complicated than those of poly(*p*-phenylene) since each *m*-phenylene unit has both isolated δ(C–H) and three adjacent δ(C–H)'s. Poly(oxybiphenylene) has strong ν(C–O) band at 1245 cm^{-1} and poly(phenylenemethylene) has aliphatic ν(C–H) bands at 2860 and 2960 cm^{-1}. Poly(oxybiphenylene) and poly(phenylenemethylene) have ν(C–X) (1050—1090 cm^{-1}) band of terminal halophenyl group and δ(C–H) (680—770 cm^{-1}) bands of terminal phenyl group. The fact that the relative intensities of these bands assignable to terminal phenyl and halophenyl groups are considerably weaker than those of δ(C–H) bands due to the inner repeating aromatic units (800—900 cm^{-1}) indicates that these polymers have high degree of polymerization.

X-Ray Diffraction: Figure 2 shows X-ray diffraction patterns of the powdery polymers prepared by polycondensation with magnesium. The X-ray diffraction spectrum of poly(*p*-phenylene) shows strong and sharp peaks even before annealing of the polymer, indicating that the polymer has high crystallinity due to the polymer structure having regularly repeated units in the polymer chain produced by highly selective condensation reaction between the Grignard reagents and aryl halides (Eq. 1). The poly(*p*-phenylene) prepared by the oxidative cationic polymerization of benzene shows only broad signals as represented by the broken line in Fig. 2a when it is not annealed; sharp peaks appear only after the annealing of the polymer.[2d]

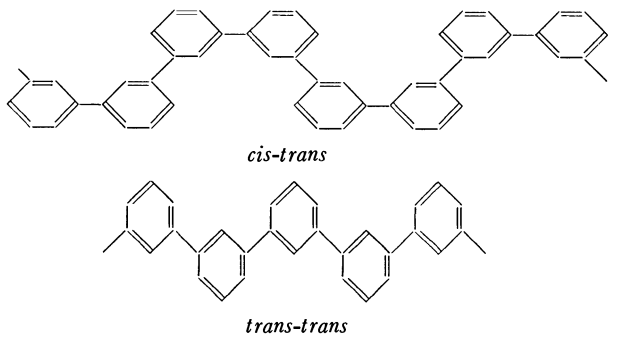
The X-ray diffraction patterns of poly(oxybiphenylene) and poly(phenylenemethylene) also show sharp

peaks before annealing. Formation of the following three units is possible in the polymerization of α,*p*-dichlorotoluene:



However, the sharp X-ray diffraction peaks of the polymer as well as the simple IR pattern in the region of the out-of-plane vibration suggest that the polymer contains mainly one of the three units, presumably the head-to-tail structure.

The X-ray diffraction pattern of poly(*m*-phenylene) shows broad peaks and that of poly(2,5-pyridinediyl) shows no clear peaks. The broadness of the peaks in the X-ray pattern of poly(*m*-phenylene) might be due to the irregularities caused by the presence of both *cis-trans* and *trans-trans* configurations:



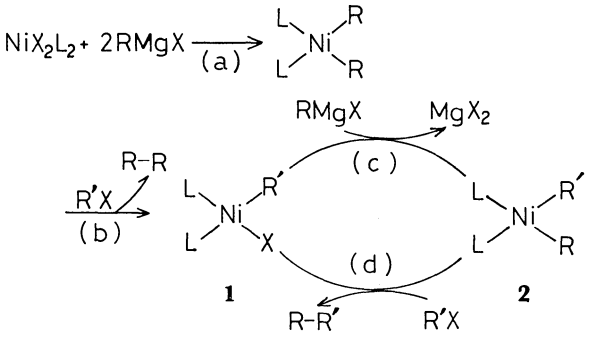
3. Polymerization Mechanism: The coupling between a Grignard reagent RMgX and an aryl halide R'X catalyzed by a dihalonickel complex NiX_2L_2 (L= ligand) (Eq. 1) seems to proceed through a mechanism comprised of

(a) formation of NiR_2L_2 by the reaction of NiX_2L_2 with RMgX,

(b) reaction of NiR_2L_2 with R'X to yield R–R and $NiR'(X)L_2$,

(c) alkylation of $NiR'(X)L_2$ with RMgX to yield $NiR(R')L_2$, and

(d) elimination of R–R' with formation of $NiR'(X)L_2$ in the reaction of $NiR(R')L_2$ with R'X:[6b]



In the mechanism the starting complex NiX_2L_2 is converted into the active species $NiR'(X)L_2$ by reactions (a) and (b). The catalytic formation of R–R' then proceeds through the key intermediates $NiR'(X)L_2$ and $NiR'(R)L_2$.

If the same mechanism can be applied to the present polymerization of *p*-$C_6H_4Br_2$, it seems to proceed as follows:

$$\mathrm{BrNiL_2\text{–}(\text{–}C_6H_4\text{–})_{n_1}MgBr} + \mathrm{Br\text{–}(\text{–}C_6H_4\text{–})_{n_2}MgBr}$$
$$\mathbf{1}(n_1) \qquad\qquad \mathbf{P}(n_2)$$
$$\xrightarrow{\text{(c) type reaction}} \mathrm{Br\text{–}(\text{–}C_6H_4\text{–})_{n_2}NiL_2\text{–}(\text{–}C_6H_4\text{–})_{n_1}MgBr} + \mathrm{MgBr_2}$$
$$\mathbf{2}(n_1, n_2)$$
$$\mathbf{2}(n_1, n_2) + \mathrm{Br\text{–}(\text{–}C_6H_4\text{–})_{n_3}MgBr}$$
$$\mathbf{P}(n_3)$$
$$\xrightarrow{\text{(d) type reaction}} \mathrm{BrNiL_2\text{–}(\text{–}C_6H_4\text{–})_{n_3}MgBr} + \mathrm{Br\text{–}(\text{–}C_6H_4\text{–})_{\overline{n1+n2}}MgBr}$$
$$\mathbf{1}(n_3) \qquad\qquad \mathbf{P}(n_1+n_2)$$
$$\mathbf{1}(n_3) + \mathbf{P}(n_4) \rightarrow \mathbf{2}(n_3, n_4)$$
$$\mathbf{2}(n_3, n_4) + \mathbf{P}(n_5) \rightarrow \mathbf{1}(n_5) + \mathbf{P}(n_3+n_4)\cdots etc.$$

Scheme 1.

where $\mathbf{P}(n)$ stands for the polymer having n phenylene units and $\mathbf{P}(1)$ represents the monomer *p*-BrC_6H_4MgBr which is the main product of the reaction between *p*-$C_6H_4Br_2$ and Mg. $\mathbf{1}(n_1)$, $\mathbf{2}(n_1,n_2)$... represent intermediate nickel complexes **1** and **2** having phenylene groups bonded to nickel. We have examined the time course of the polycondensation by following the disappearance of the mono-Grignard reagent Br–C_6H_4–MgBr, di-Grignard reagent BrMg–C_6H_4–MgBr and intact dibromobenzene formed by the reaction of dibromobenzene with Mg in a 1:1 ratio by means of gas chromatography. The amounts of the di- and mono-Grignard reagents were measured as benzene and bromobenzene after hydrolysis of the reaction mixture.

Figure 3 shows time-course of the decrease of species in the $NiCl_2$(bpy)-catalyzed dehalogenation polymerization of *p*-$C_6H_4Br_2$ with Mg at 3±1 °C where the rate of polymerization is not very high. As shown in Fig. 3 the reaction of *p*-$C_6H_4Br_2$ with Mg in a 1:1 molar ratio gives a mixture of *p*-$C_6H_4(MgBr)_2$, *p*-BrC_6H_4MgBr, and intact *p*-$C_6H_4Br_2$. The rate of consumption of these chemical species is low at the early stage, becoming higher after the induction period. The dihalonickel complex $NiCl_2$(bpy) seems to be converted into the active species (*e.g.*, Ni(C_6H_4MgBr)(Br)(bpy), **1**(1)) during the induction period.

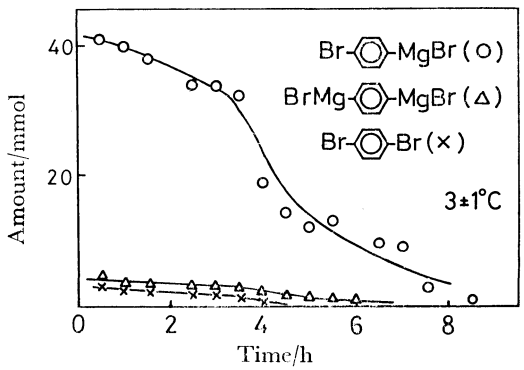


Fig. 3. Time course of mnomer consumption during the polymerization of p-$C_6H_4Br_2$ (11.8 g, 50 mmol) in THF (50 ml) at 3±1 °C; p-BrC_6H_4MgBr (○), p-$C_6H_4(MgBr)_2$ (△), and p-$C_6H_4Br_2$ (×), Catalyst = $NiCl_2$(bpy) (50 mg).

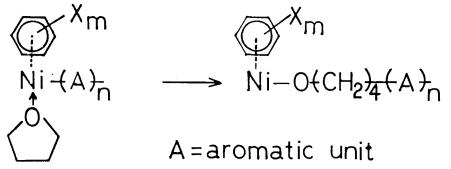
According to Scheme 1 the polymer should have both $-C_6H_4MgBr$ and $-C_6H_4Br$ terminals. The phenyl terminal of poly(p-phenylene) was thought to be formed from the $-C_6H_4MgBr$ terminal during the work-up of the polymer. However, reactions of the raw polymer with D_2O or CO_2 did not introduce D or carboxyl group into the polymer. This excludes the presence of the $-C_6H_4MgBr$ terminal in the polymer. The phenyl terminal can be formed through the incorporation of mono-functional species such as C_6H_5MgBr and C_6H_5Br formed by the reactions of p-$C_6H_4(MgBr)_2$ and p-BrC_6H_4MgBr with trace amounts of water in the solvent. If these nomo-functional species should participate, the polymerization would be terminated with formation of the phenyl terminal(s). Under certain conditions the polymerization might be terminated mainly through this process, and most of the polymer end would be the phenyl group. The infrared spectra of some polymers suggest the formation of polymers with phenyl end group(s). Addition of C_6H_5Br or C_6H_5MgBr into the polymerization system decreases the degree of polymerization as judged from the increase in the intensities of $\delta(\text{mono}_1)$ and $\delta(\text{mono}_2)$ in the IR spectrum of the polymer obtained.

When an aromatic compound having three or more halogen atoms is employed for the polymerization, it may act as an electron acceptor, coordinating with the transition metal complex. Coordination of the electron acceptor to the transition metal would enhance the Lewis acidity of the transition metal and initiate the ring-opening polymerization of THF, which is usually catalyzed by Lewis acid, producing the copolymer with THF units:



Experimental

Material. Commercial haloaromatic compounds except for hexachlorobiphenyl were used. Hexachlorobiphenyl was supplied by Prof. Emeritus S. Kambara. Solvents were dried over sodium wire and distilled under nitrogen. $NiCl_2$(bpy),[10] $NiBr_2(PhP_3)_2$,[11] $PdCl_2$(bpy),[12] $Fe(C_2H_5)_2$-(bpy)$_2$,[13] $Cr(CH_3)Cl_2(THF)_3$,[14] and (1,5-cyclooctadiene)bis-(triphenylphosphine)nickel[15] were prepared according to the literature. Commercial products were used for simple transition metal compounds.

Polymerization. When 51 mg of $NiCl_2$(bpy) was added to a mixture of the products obtained by the reaction of 11.8 g (50 mmol) of p-dibromobenzene with 1.22 g (50 mg-atom) of magnesium in dry tetrahydrofuran (50 ml), smooth polymerization started. Polymerization was almost completed after refluxing the mixture for 1 h. After further refluxing for 4 h the reaction mixture was poured into 500 ml of ethyl alcohol. The polymer precipitated was collected over a glass filter, washed with dilute hydrochloric acid and ethyl alcohol, and dried in a vacuum to yield 3.8 g (95%) of light yellow poly(p-phenylene) (No. 2, Table 1). Extraction of the polymer by hot toluene with Soxhlet extractor for 50 h gave 0.70 g of the extractable fraction. Polymerization of p-dibromobenzene catalyzed by other transition metal compounds and that of other haloaromatic compounds were carried out in a similar manner. Analytical data of the polymers agreed with the structures given in the text. Percent yields in Table 1 are calculated based on the amount of carbon taken into the polymer.

The polyphenylene type polymers were also prepared by stirring the mixture of halo aromatic compound, magnesium, and the catalyst added before formation of the Grignard reagent. The yields and spectral data of the polymers prepared by this method were almost the same as those prepared by the method described above.

Kinetics. The reaction of p-dibromobenzene (11.8 g, 50 mmol) and magnesium (1.22 g, 50 mg-atom) was carried out in 50 ml of THF at room temperature. After completion of the reaction the reaction vessel was immersed in thermostatted water. Toluene (2.00 g) was added to the reaction mixture as an internal standard of gas chromatography and then 50 mg of $NiCl_2$(bpy) was added with stirring. The reaction mixture was occasionally pipetted out and treated with dil HCl. The amounts of p-$C_6H_4(MgBr)_2$, p-BrC_6H_4MgBr, and p-$C_6H_4Br_2$ were determined by measuring the amounts of benzene, bromobenzene, and p-dibromobenzene with a Shimadzu GC-3BT Gas Chromatogram.

Spectral Measurement and Analyses. IR spectra were recorded on a Hitachi Model 295 spectrometer. NMR spectra were taken with a Japan Electron Optics Laboratory SP-100 NMR spectrometer. Differential thermoanalyses were performed with a Shimadzu DT-30 thermal analyzer. X-Ray diffraction spectra were obtained with a Phillips PW-1051 X-Ray Diffractometer. Microanalyses of the polymers were performed by Mr. T. Saito with a Yanagimoto CHN Type MT-2 autocorder.

Medium Effects on Stereochemistry of Acid-Catalyzed Ethanolysis of *trans*-2,3-Diphenyloxirane

Masashi INOUE,* Yoshio TAGUCHI, Toshio SUGITA, and Katsuhiko ICHIKAWA

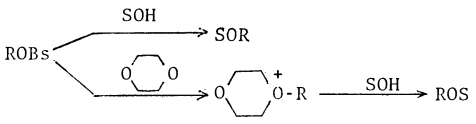
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received January 23, 1978)

The acid catalyzed ethanolysis of *trans*-2,3-diphenyloxirane was examined in a wide variety of binary ethanolic solvent systems. The reaction proceeded with 26% retention and 74% inversion of configuration in pure ethanol at 50 °C. The dilution of ethanol by hexane or benzene produced almost no change in stereochemistry of the ethanolysis. The addition of acetonitrile, nitromethane, or sulfolane to the ethanolic solution resulted in increased degrees of retention. In binary ethanolic mixtures containing DMSO, DMF, or HMPA, increased ratios of inverted product were obtained. The steric course of the ethanolysis could be controlled from 85% retention–15% inversion (CH_3NO_2:ethanol=20:2 by volume) to 10% retention–90% inversion (HMPA:ethanol=10:12) by the choice of co-solvent. The results are discussed in terms of the solvation-shell concept.

Reaction media have an enormous effect on organic reactions, and many papers have been published on the solvent effects of reaction kinetics. Since the physical properties can be varied continuously by changing the composition of the solvents, binary solvent systems are particularly interesting, and a number of papers have discussed the reaction kinetics in binary solvent mixtures. Arnett and his co-workers have reported that the rates of solvolysis of *t*-butyl chloride in aqueous mixture are determined by changes in the stability of the *ground state* and not of the transition state.[1]

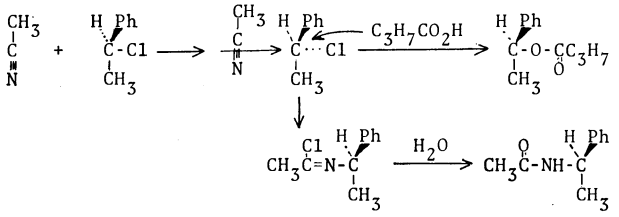
Although the effects of the composition of the binary solvent mixture on the steric course of reaction seem to be interesting, only a few papers have dealt with this problem. The results of the solvolysis of optically active 1-methylheptyl *p*-bromobenzenesulfonate by Weiner and Sneen[2] are the most famous and have been quoted in many texts. The reaction in 75% aqueous dioxane gave inverted 2-octanol in 77% optical purity, whereas the solvolysis in pure water resulted in 100% inversion of configuration. The results were explained by assuming an intermediate, an oxonium ion formed by the S_N2 attack by dioxane.



(1)

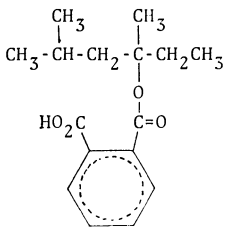
A similar mechanism was proposed by Streitwieser for the solvolysis of optically active 1-butyl-1-*d* *p*-nitrobenzenesulfonate in the mixtures of dibutyl ether and acetic acid.[3]

Okamoto and his co-workers found that the butyrolysis of optically active α-methylbenzyl chloride in pure butanoic acid gave α-methylbenzyl butanoate with 3.5% net inversion. The reaction proceeded faster in the binary solvent system of butanoic acid and acetonitrile than in pure butanoic acid to yield the product with 2.9% net retention. A small amount of *N*-(α-methylbenzyl)acetamide was also isolated with net (3.2%) inversion.[4] The results were explained by the following reaction scheme, which includes a nucleophilic solvation of the ion-pair intermediate from the side opposite to that of the leaving group, *i.e.* a shielding from the back mechanism.



(2)

The largest variation in the steric course of solvolytic reactions with the variation of the composition of binary solvent mixture was found in the acid-promoted methanolysis of 1,3-dimethyl-1-ethylbutyl hydrogen phthalate.[5]



In pure methanol, the steric course of the reaction was 60% net inversion, whereas the result was 100% racemization in a mixture of 20% methanol and 80% nitromethane. The complete discussion and experimental details have not yet been published.

In the steric course of epoxide ring-opening, Italian workers have proposed a shielding from the back mechanism for the trichloroacetolysis of aryl-substituted epoxycyclohexanes.[6] Ito reported that the dielectric constant of the medium is an important factor affecting the steric course of the hydrolysis of 2,3-diphenyloxirane.[7] However, these workers did not explore the effects of the composition of the binary solvent mixture.

Aryloxiranes are interesting compounds for the stereochemical investigations on the medium effects in binary solvent systems. This present paper reports the experimental results of the acid-catalyzed ethanolysis of *trans*-2,3-diphenyloxirane (**1**) in binary ethanolic mixtures containing various kinds of co-solvents (solvents added to ethanol), and discusses the relationship between the steric course of the reaction and the nature of solvation in binary solvent mixtures.

Table 1. Ethanolysis of **1** in pure ethanol at 50 °C

1	$[H^+]$ [a]	Total yield	Product distribution			Ret.[c]
			Rearr.[b]	*threo*-**2**	*erythro*-**2**	
mmol l^{-1}	mmol l^{-1}	%	%	%	%	%

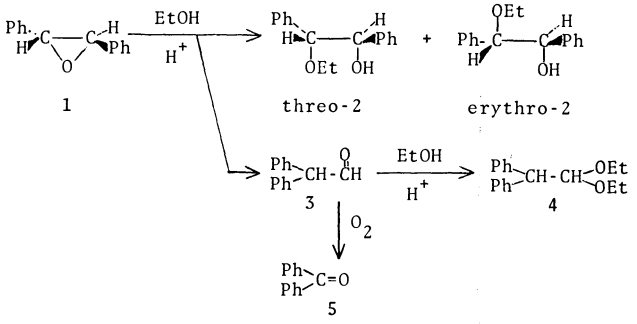
46.4	0.78	92	12	23	65	26

a) H_2SO_4 was used. b) **4**+**5**. c) (*threo*-**2**/**2**)×100.



Scheme 1.

Results

The acid-catalyzed ethanolysis of **1** in pure ethanol gave *threo*- and *erythro*-2-ethoxy-1,2-diphenylethanols (*threo*- and *erythro*-**2**), diphenylacetaldehyde (**3**), and the diethyl acetal of **3** (**4**) as shown in scheme 1. The total yields of the four compounds were more than 90 per cent by GLC analysis and more than 80 per cent after isolation.

The autoxidation catalyzed by potassium carbonate,[8] which was added to neutralize the catalyst acid, converted completely **3** into benzophenone (**5**) (see experimenatl section). Therefore, the yields of **5** were presumed to be those of **3**. To check the possibility of the formation of **5** during the ethanolysis, the reaction mixture was subjected to GLC analysis directly without potassium carbonate treatment. The yield of **5** was less than 0.5 per cent, which would be attributed to the oxidation of **3** under the ethanolysis conditions. As the authors were mainly concerned with the steric course of the ethanolysis of **1**, the detailed processes of the oxidation were not examined.

Table 1 shows the effects of concentrations both of acid and of **1** on the product distribution of the ethanolysis in pure ethanol at 50 °C. The ratio of the two ethanolysis products, *threo*- and *erythro*-**2**, was not affected within experimental error, whereas the reaction rate increased with the increase of acid concentration. This demonstrates that both of the stereoisomers **2** are formed through a common intermediate, *i.e.* the conjugate acid of **1** (**1**-H^+). At high acid-concentrations, 1-ethoxy-2,2-diphenylethylene (**6**) was observed in the latter stage of the reaction and seems to be formed by the elimination of ethanol from **4**.

a) See foot-note of Table 1. b) Several other products were detected, see text.

Table 2 shows the variation in yield of products with variation of the composition of the ethanol–acetonitrile system at 70 °C. With an increasing percentage of acetonitrile, the reaction rate decreased and the proportion of the retained product (*threo*-**2**) increased, though the yields of the rearranged products, **4** and **5**, also increased. The formation of products other than those listed in Table 2 was negligible except in the case of the solvent system composed of 91% acetonitrile by volume. The products were detected by GLC analysis in the experiment of 91% acetonitrile, and isolation of the products was carried out by column chromatography. The isolated products were as follows: *threo*-**2**, 28%; *erythro*-**2**, 8%; **5**, 21%; **3**, trace; **4**, 13%; **6**, 7%; benzyl phenyl ketone (**7**), 1%; 2-hydroxy-1,2-diphenylethanone (**8**), 4%; diphenylethanedione (**9**), trace; 1,2-diphenylethanol (**10**), 2%; 2,2-diphenylethanol (**11**), 3%. The compound **7** is another rearranged product of **1**, and a trace of **7** was always observed in GLC analyses in all experiments throughout this paper. The last four are the redox-reaction products.

Table 3 shows the results of ethanolysis at 50 °C in the ethanol–acetonitrile system. Similar results to those in Table 2 are observed, but the proportion of the retained product *threo*-**2** at 70 °C was always higher, as compared with the result of the same solvent composition at 50 °C.

Table 4 shows the variation of the product distribution with different times of reaction. As shown in Table 4, **4** seems to be formed by a successive reaction

of **3**, and therefore, the mechanism that **4** is a primary reaction product may be ruled out.

Figure 1 shows the effect of the composition of benzene or dioxane systems on the steric course of the ethanolysis at 70 °C. The proportion of retained product increased with an increase in the composition of co-solvents as is the case of acetonitrile, but the effect of benzene or dioxane was smaller than that of acetonitrile. The yields of the rearranged products were found to increase with an increasing proportion of co-solvent in the same manner as acetonitrile.

Figure 2 shows the effects of the composition of various solvent systems at 50 °C. With an increasing percentage of nitromethane, the proportion of the retained product increased as is the case of acetonitrile, while the stereochemical outcome of the ethanolysis was virtually unchanged when hexane was added to the solvent system. Aromatic hydrocarbons and dioxane had slightly retentive effects. In every solvent system, large amounts of the retained product were formed at higher reaction temperatures.

In Table 5 are presented the data of the ethanolysis of **1** in binary solvent systems, ethanol–co-solvent

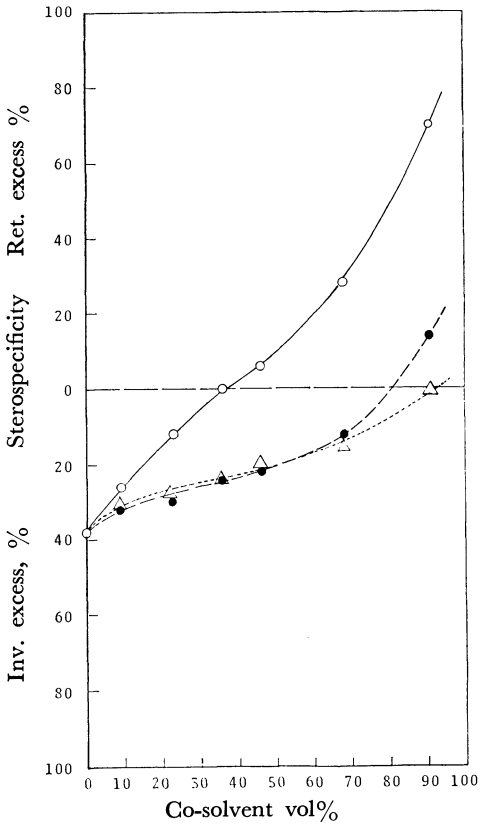

Fig. 1. Co-solvents on stereospecificity of the ethanolysis of **1** in binary solvent systems at 70 °C.

(12:10 by volume). Different stereochemical results were observed with change in co-solvent. As the reaction in DMSO, HMPA, and DMF proceeds quite slowly, higher concentrations of acid (10 times) than in the other experiments were used. The nature of these co-solvents was such that **1** gave larger amounts of inverted **2** in these systems than in pure ethanol. In all cases except those of these three co-solvents, the total yield of the four compounds in Scheme 1 was

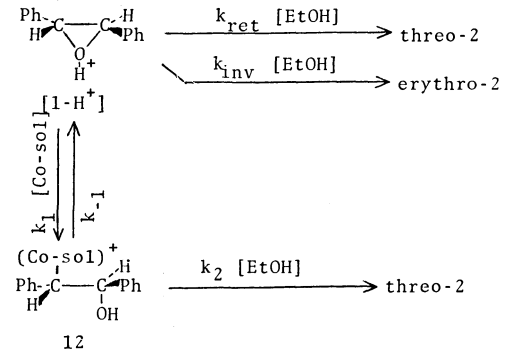
greater than 80 per cent. By-products, **6**–**11** were formed in some solvent systems. but the yield of these by-products was less than 2 per cent. When DMSO was used as the co-solvent, the total yield decreased unexpectedly, but no products other than described above could be isolated.

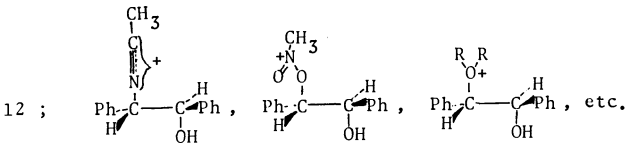
In Table 6 are presented the results of the ethanolysis of **1** in mixtures composed of ethanol and substituted nitrobenzenes. As many of nitrobenzenes are solid and it was difficult to determine the volume ratios, experiments were carried out with fixed mol fractions.

Discussion

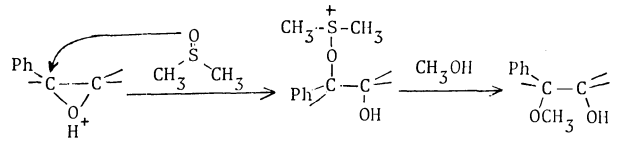
Several kinds of mechanisms have been proporsed to explain the solvent effects on the steric course of solvolysis and these will be examined here in the light of the results reported. From the application of Sneen's mechanism[2] to the reaction, it may be deduced that the co-solvent reacts from the back of the epoxide ring at an ionizing stage of the epoxide C–O bond, as shown in Scheme 2.

Upon closer examination of the experimental results (see Appendix), this scheme meets a difficulty in that the co-solvent should have a stronger nucleophilicity to the conjugate acid of **1** than ethanol. However, the scheme involves the assumption that the co-solvent has no nucleophilicity to co-solvent-participating intermediate (**12**).





Scheme 2.



Scheme 3.

The results reported involve several kinds of data which conflict with the shielding from the back mechanism. For example: 1. The proportion of the retained product decreased in the following orders of co-solvent; benzene>toluene>*m*-xylene>mesitylene; nitrobenzene>*p*-nitrotoluene, which is inverse to the order of nucleophilicity.

2. Swern and his co-workers reported that DMSO reacts with epoxide to yield the alkoxysulfonium salt which is the same type of ion as the assumed intermediate **12** and that this sulfonium ion reacts with alcohol to yield *β*-alkoxy alcohol (Scheme 3).[9] However, the reaction of DMSO with epoxide requires a much higher acid concentration than the ethanolysis experiments reported here. When DMSO was used as co-solvent in our experiment, larger amounts of inverted product were formed than in pure ethanol. These facts make it difficult to assume the alkoxysulfonium ion as an intermediate of the ethanolysis of **1** in DMSO.

3. Acetonitrile, nitromethane, and sulfolane, in which the ethanolysis of **1** yielded large amounts of the retained product, are known as relatively weak bases. Although no data are available to compare directly the nucleophilicity of the solvents toward a carbonium ion, their coordination abilities to metal cations may afford some insight. The coordinating abilities of acetonitrile and nitromethane are much weaker than those of DMSO and DMF. Since the nucleophilic participation of DMSO has been dis proved (see above), it is improbable that acetonitrile or nitromethane, which are poorer nucleophiles than DMSO, participate in the ionizing stage of **1**.

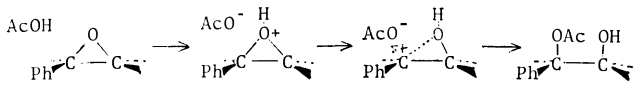
None of the mechanisms proposed for solvolytic

reaction can explain the experimental results reported here.

In the epoxide reactions, the mechanism of the ring-opening leading to the formation of stereoisomeric products has been reviewed by Parker and Isaacs. They discussed the reaction kinetics and stereochemistry and concluded that the reactions took place concurrently in these reactions, one of which gave the retained product and the other the inverted one.[10] This proporsal has been widely accepted, and the results of the reaction of aryl-substituted epoxycyclohexanes reported by Italian workers also supports this concurrent reaction mechanism.[11] The results presented in this paper, that the stereospecificity of the reaction varied widely from 80% inversion excess to 76% retention excess by changing the co-solvent, appear to support Parker and Isaacs' conclusion, in that the results can not be explained by a single mechanism.

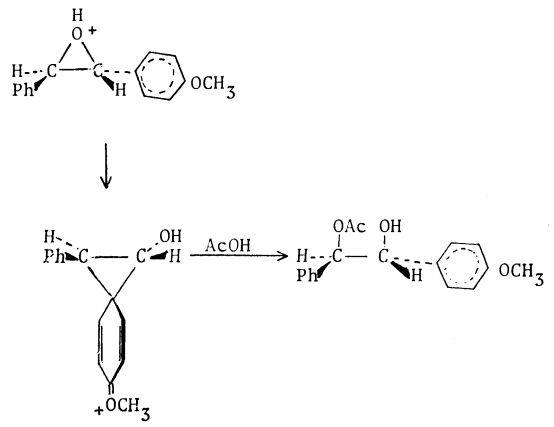
A short comment against the S_N1 mechanism for the epoxide reaction is necessary. By examining the entropies of activation in the acid-catalyzed methanolysis of aryloxiranes, Chapman and his co-workers suggested that the reaction does not proceed *via* an unimolecular mechanism except in the case of 2.2-diphenyloxirane which shows a deviation towards an S_N1 mechanism.[12]

Two mechanisms have been proporsed for the retention reaction, one of the concurrent reactions. Brewster explained the retentive acetolysis of *trans*-2-methyl-2,3-diphenyloxirane in terms of an ion pair in a "cage" of solvent molecules (S_Ni mechanism, Scheme 4).[13]



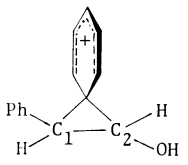
Scheme 4.

Another mechanism is a double inversion or a phenonium-ion mechanism (Scheme 5),[10] and was proporsed as a possible explanation for the results of the acetolysis of 2-(*p*-methoxyphenyl)-3-phenyloxirane.[14] Recently Ito found, however, that the position attacked by acetic acid is not benzyl carbon but *p*-anisyl one of that compound.[15] To explain this by a phenonium-ion mechanism, the participating group should not be a methoxyphenyl but a phenyl group, which is an unlikely process.



Scheme 5.

Although the phenonium-ion mechanism has been employed by many workers, there is no clear evidence to confirm the existence of the phenonium ion substituted by heteroatoms. If the double inversion mechanism were valid here, the phenonium ion (**13**) depicted below should exist as an intermediate and react with ethanol. The existence of this intermediate appears to be unlikely, when the following processes are taken into account. When the bridging phenyl group moves from the center of two carbon atoms (C_1, C_2) towards the C_1 atom, a developing p-orbital on the C_2 carbon atom can conjugate with a lone pair of oxygen atom adjacent to the C_2 carbon atom, and the cation gains additional stabilization energy. At the end of this drift, an oxonium ion or the conjugate acid of the aldehyde is formed which is well established as more stable than the phenonium ion by kinetic evidence.[16] Consequently, the phenonium ion, if it were to be formed, is not an intermediate of the retentive solvolysis but the transition state of the rearrangement to **3**.



(**13**)

As summarized in Table 7, the stereochemical results of the acid-catalyzed solvolysis of **1** are closely related to those of the optically active 2-phenyloxirane. Here, the phenonium ion cannot be an intermediate of the solvolysis of 2-phenyloxirane, since nucleophiles attack the benzyl carbon atom. Therefore, it is unreasonable to consider that the phenonium ion is the intermediate in the solvolysis of **1**, and thus the conclusion drawn is that an S_Ni (ion pair) mechanism opperates in the retentive ethanolysis which is one of the concurrent reactions of **1** (Scheme 6).

As indicated by Parker and Isaacs,[10] the transition state depicted by Brewster is similar to the borderline S_N2 mechanism with the added proviso that the reagent is held close to the epoxide oxygen by electrostatic forces. However, the authors consider that the transition state of retentive ethanolysis of **1** has a stronger

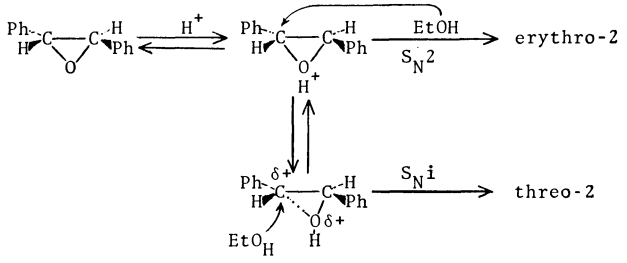


Scheme 6.

tendency toward an S_N1 mechanism than that of the borderline S_N2 reaction giving the inverted product, and this will be discussed in a separate paper.

In Table 8, the stereochemical results in binary solvent systems are given together with the dielectric constants, the pK_a of conjugate acids,[17] and the E_T values[18] of the co-solvents. No direct relationship has been established between the stereochemical results and the physical properties of the co-solvents. However, a detailed examination of Table 8 suggests that the co-solvents can be classified into three groups. The first group (group 1) contains acetonitrile, nitromethane, sulfolane,[19] *etc.*, which have poor basicities and high dielectric constants in which the ethanolysis of **1** yields large amounts of retained product. The second group (group 2) solvents have poor basicities and low dielectric constants, and these co-solvent have no effect or a slightly retentive effect on the ethanolysis of **1**. The third group (group 3) contains aprotic polar solvents such as DMSO, DMF, and HMPA. The difference between the aprotic polar solvents and those of the first group is that the former have a much more basic character, therefore, higher coordinating abilities than those of the first group.

To discuss the function of co-solvents in ethanolysis of **1**, the nature of the solvation has to be known. Solvation shells are most often discussed in terms outlined by Gurney[20] as regions A, B, and C. Region A is one of high order imposed by the influence of the solute on nearby solvent molecules. Region C is a region of unaltered bulk solvent. Region B is a "disordered" compromise region which is influenced comparably both by the forces exerted by the solute which produce region A near the solute and by the solvent-solvent forces which produce region C in the bulk far from the solute.[21]

A modification of Gurney's classification will be made,[22] extended to the solvation of protons in binary solvent mixtures, and used here. Region A is defined as a primary coordination sphere. In region A, the proportion of the solvent with strong basicity, *i.e.* high coordinating ability to a proton, should be larger than in the whole solvent system. For example, in the ethanol–acetonitrile system, the proportion of ethanol in region A should be larger than that in the bulk solution, since ethanol is a stronger base than acetonitrile. In the ethanol–DMSO system, the proportion of DMSO in region A is larger, since DMSO is a

stronger base than ethanol. Region C is a bulk region, in which the composition of solvents is the same as the compostition of the whole solvent system. Region B is defined as a transition region between region A and region C, and influenced by many kinds of forces. Among them, charge-dipole interaction which is a long range intermolecular force appears to be the most important in the present case. It is difficult to estimate the composition of solvents in region B of the binary solvent systems, since the nature of charge-dipole interactions in solution is not yet clear. However, it may be pointed out that the proportion of the solvent of high dielectric constant should be higher in region B than in the bulk solution, since the effects of the dielectric field of the proton can be relaxed by the dielectric polarizability of the solvent. The discussion is clearly oversimplified, but is able to explain the stereochemical results.

It is well established that initial protonation is a fast reversible step in the acid-catalyzed ring-opening reaction of epoxides. Around the proton of the protonated epoxide, solvent molecules build up region A,[23] and the back of the epoxide ring borders on region B.[24,25] Ethanol proportions in the two regions A and B differ by the influence of basicity and dielectric polarizability of co-solvent, and therefore, the effective concentrations of ethanol on both sides of epoxide differ in the *ground state* of ethanolysis. In other words, the effective concentrations[26] of ethanol for S_Ni and S_N2 reactions differ from each other and this difference results in the changes of the steric course of ethanolysis of **1**.

On the basis of the above discussion, the stereochemistry of the ethanolysis can be explained as follows. In binary ethanolic mixtures containing group 1 co-solvents, effective concentration of ethanol to the front of the epoxide is much higher than to the back of the epoxide, since the proportion of co-solvent in region B and that of ethanol in region A are higher than those in the whole solvent system. Consequently, the ethanolysis of **1** in these solvent system yields larger amounts of the retained product than in pure ethanol.[27] In binary ethanolic mixture containing group 3 co-solvents, the strong basicity of the co-solvent results in an increase of co-solvent proportion in region A, and in a decrease of effective concentration of ethanol to the front of the epoxide. Consequently, the ethanolysis of **1** in ethanol-group 3 co-solvent mixtures yields larger amounts of the inverted product. In binary ethanolic mixtures containing group 2 co-solvents, which have low dielectric constants, the probability of the existence of group 2 co-solvents in regions A and B is low, since the two regions are in a dielectric field of positive charge. As a results, the steric course of the ethanolysis of **1** in these solvent mixtures is similar to that in pure ethanol.

The discussion mentioned above may not be limited to the epoxide reaction, and Streitwieser and Doering's results quoted at the beginning of this paper may be explained using this theory.

The medium effects on the steric course of acid-catalyzed solvolitic reactions of **1** and optically active 2-phenyloxirane are now being investigated.

Experimental

Materials. *trans*-2,3-Diphenyloxirane (**1**) was prepared by the *m*-chloroperbenzoic acid oxidation of *trans*-stilbene and recrystallized from hexane and then from benzene, mp 68.5—69.5 °C (lit,[28] 69.0—69.5 °C). Ethanol was dried by Lund and Bjerrum's method.[29] All the co-solvents were dried by the most efficient ways reported in the literature[30] and distilled before use.

erythro-*2-Ethoxy-1,2-diphenylethanol* (erythro-**2**). A mixture of *meso*-1,2-diphenyl-1,2-ethanediol[31] (2.0 g) and triethyloxonium tetrafluoroborate (2.66 g) in dry ether (100 ml) was stirred for 24 h at room temperature, poured into water, and extracted with ether. The ether layer was dried over sodium carbonate and removal of the solvent gave 1.3 g of a white solid. GLC analysis indicated that it contained three products. After separation of the products by column chromatography, *erythro*-**2** (117 mg) was obtained from the middle fraction, mp 52.5—53.5 °C (lit,[32] 45—50 °C). NMR ($CDCl_3$) δ: 1.1[0] (3H, t, J=7 Hz), 2.4[7] (1H, d, J=4 Hz, OH), 3.3[7] (2H, AB part of ABX_3 coupling), 4.4[0] (1H, d, J=5 Hz), 4.8[3] (1H, d d, J=4 and 5 Hz), and 7.1[3] (10H, phenyl). Found: C, 79.47; H, 7.56%. Calcd for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

The other products were the starting material and *meso*-1,2-diethoxy-1,2-diphenylethane.

threo-*2-Ethoxy-1,2-diphenylethanol* (threo-**2**). 2-Ethoxy-1,2-diphenylethanone was reduced with sodium borohydride in the usual way. GLC analysis indicated that the crude product was composed of two components with a ratio of 87:13. The crude product was purified by column chromatography. The major product consisted of *erythro*-**2**, and *threo*-**2** was obtained as the minor one which did not crystallize even after several months. NMR ($CDCl_3$) δ: 1.2[1] (3H, t, J=7 Hz), 1.7 (1H, s, OH), 3.3[9] (2H, q, J=7 Hz), 4.1[8] (1H, d, J=8 Hz), 4.5[8] (1H, d, J=8 Hz), and 7.0[7] (10H, phenyl). Found: C, 79.32; H, 7.52%. Calcd for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

Ethylation of *dl*-1,2-diphenyl-1,2-ethandiol by the oxonium salt gave no reaction.

1,1-Diethoxy-2,2-diphenylethane (**4**). To a solution of **3**[33] (2.0 g) in abs ethanol (70 ml), a drop of concd sulfuric acid was added. The reaction mixture was stirred for 24 h at room temperature. GLC analysis of the reaction mixture indicated 97% conversion to **4**. Distillation of the neutralized reaction mixture gave 1.6 g of **4**: bp 117—119 °C/2.5 mmHg: IR: 1060 and 1120 cm^{-1}; NMR ($CDCl_3$) δ: 1.0[3] (6H, t, J=7 Hz), 3.5 (4H, AB part of ABX_3 coupling $\Delta\nu$=10 Hz, J_{AB}=9.3 Hz, J_{AX}=6.8 Hz, J_{BX}=7.2 Hz), 4.2[3] (1H, d, J=7.8 Hz), 5.0[5] (1H, d, J=7.8 Hz), and 7.3[0] (10H, phenyl).

When anhydrous copper(II) sulfate was used for the acetallization instead of sulfuric acid, initially formed **4** was converted into **6**[34] before acetallization was completed.

Ethanolysis of **1** *in Pure Ethanol.* To a 20 ml ethanolic solution of weighed quantities of **1** and dibenzyl ether (internal standard) held in a controlled-temperature block, acidified (H_2SO_4) ethanol (2 ml) was added with vigorous shaking. After a definite period, the reaction mixture (0.5 ml) was pipetted into a sampling tube containing a small amount of potassium carbonate and the tube shaken vigorously. The quenched sample was kept at room temperature for a day and analyzed by GLC.

Ethanolysis of **1** *in Binary Solvent Systems.* To a 10 ml ethanolic solution of **1** (200 mg) and dibenzyl ether (30—50 mg, weighed), co-solvent (10 ml) was added and the mixture held in a controlled temperature block. Ethanolic solu-

tion of sulfuric acid (2 ml, *ca* 0.01 N)[35] was added to the mixture and then treated as reported above.

GLC Analysis. The GLC analyses (Hitachi 163 gas chromatograph) were carried out successfully on a 4 m column of 5% PEG-20M on Shimalite W at a column temperature of 205 °C. For example, the retention times of dibenzyl ether, **4**, **5**, **6**, **3**, *threo*-**2**, **7**, *erythro*-**2**, **8**, and three compounds (**9**, **10**, and **11**) were 9.3, 11.4, 12.3, 14.6, 15.2, 18.2, 20.3, 23.8, 25.8, and 31.2 min respectively.

Autoxidation of **3**. To a solution of freshly prepared **3** (10 mg) in ethanol (10 ml), a catalyst was added. The reaction mixture was kept at room temperature for 24 h and subjected to GLC analysis. The conversions of **3** to **5** (catalyst; a small amount of potassium carbonate, a small amount of sodium carbonate, 0.1 ml of 0.1 N sulfuric acid solution in ethanol) were 100, 53, and 0.3%. Only a trace of **5** was found when the ethanolic solution of **3** was allowed to stand for a day without catalyst.

Appendix

From the reaction sequence described in Scheme 1, the following equations may be obtained:

$$\frac{d[\textit{threo}\text{-}\mathbf{2}]}{dt} = k_{ret}[EtOH][\mathbf{1}\text{-}H^+] + \frac{k_1k_2[\text{co-sol}][\mathbf{1}\text{-}H^+][EtOH]}{k_2[EtOH]+k_{-1}},$$

$$\frac{d[\textit{erythro}\text{-}\mathbf{2}]}{dt} = k_{inv}[EtOH][\mathbf{1}\text{-}H^+].$$

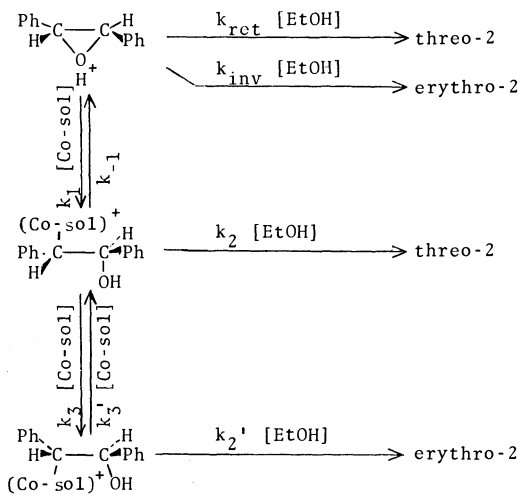
Therefore,

$$\frac{[\textit{threo}\text{-}\mathbf{2}]}{[\textit{erythro}\text{-}\mathbf{2}]} = \frac{k_{ret}}{k_{inv}} + \frac{\frac{k_1}{k_{inv}}[\text{co-sol}]}{[EtOH]+\frac{k_{-1}}{k_2}}.$$

If the effective concentrations in reaction kinetics are the same as the molar concentration of the medium, the values 0.48, 2.04, and 0.55 for k_{ret}/k_{inv}, k_1/k_{inv}, and k_{-1}/k_2 respectively can satisfy the experimental results presented in Table 2 except in the case of 91 vol % of acetonitrile concentration.

However, the value 2.04 for k_1/k_{inv} indicates that the nucleophilicity of acetonitrile to the conjugate acid of **1** (**1**-H^+) is stronger than that of ethanol, whereas the reaction scheme includes an assumption that the co-solvent, as compared with ethanol, has a negligibly small nucleophilicity to the intermediate **12**.

It is difficult to consider that the two orders of the nucleophilicities of ethanol and acetonitrile toward **1**-H^+ and **12** have been reversed. The nucleophilicity of co-solvent to **12** is assumed, which leads to the following reaction scheme (Scheme 7).



Scheme 7.

The implications of this reaction-scheme are similar to Streitwieser's. However, a solution of the reaction kinetics using the steady state method leads to the same difficulties as mentioned above since the experimental results are satisfied only when $k_1 > k_{inv}$ and $k_2 > k_3$.

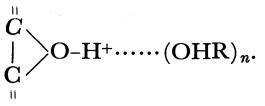
23) Major parts of solvation energies should come from hydrogen bonding from acidic hydrogen of the conjugate acid of epoxide to "bulk ethanol,"



For a detailed discussion of hydrogen bonding from the hydrogen of onium ion to "bulk water," see for example; E. M. Arnett, B. Chawla, L. Bell, M. Taagepera, W. J. Hehre, and R. W. Taft, *J. Am. Chem. Soc.*, **99**, 5729 (1977).

24) A variety of the values for the solvation number of proton have been reported; 1—2,[a] 2.5,[b] 3.9,[c] 5,[d] and 10.[e] The oxonium ion (**1**-H$^+$) in solution can be considered to be formed by substitution of one of the solvent molecules in solvation shell of proton (region A) for the epoxide.

As the first solvation shell of proton (region A) is small, the side opposite to that of the epoxide oxygen of **1** borders on region B.

Glueckauf, *Trans. Faraday Soc.*, **51**, 1235 (1955); d) H. Ulich, *Z. Phys. Chem.*, **168**, 141 (1934); e) J. B. Hasted, D. M. Riston, and C. H. Collie, *J. Chem. Phys.*, **16**, 1 (1948).

25) These structures of solution are easily fading, but have enough life time for epoxide to be attacked in these solution structures, because acidic hydrogen should exist at the epoxide oxygen during the reaction.

26) A similar concept has been discussed in terms of preferential solvation, see Ref 21.

27) If ethanol molecules in region A are completely oriented by the effect of charge of proton, nucleophilicity of the ethanol should be much lower than that of ethanol in region C. However, this problem can be solved by Backrins-Saluja's model for solvation, in which coordination number is always larger than solvation number.[a] In other words, they pointed out the existence of non-solvated coordinated molecules in region A. In the present case, the non-solvated coordinated ethanols in region A have ordinary nucleophilicity to **1** to yield the retained product (*threo*-**2**).

35) A definite concentration of sulfuric acid solution in ethanol (0.01 N) was prepared initially, but the correction factor decreased gradually on storage. However, the stereochemical results of ethanolysis of **1** in binary solvent systems were not affected by the acid concentration.

A New Synthesis of α-Phenylsulfonyl-γ-lactones and Their Use for Syntheses of Actinidiolide Derivatives[1)]

Kenji UNEYAMA, Manabu KUYAMA, and Sigeru TORII*

Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700

(Received January 25, 1978)

The acid-catalyzed cyclization of 2-phenylsulfonyl-4,8-dimethyl-3,7-nonadienoic acid (**5**) was performed by treatment with sulfuric acid-acetic acid and/or boron trifluoride in various aprotic solvents to afford 2,2,6-trimethyl-9-phenylsulfonyl-7-oxabicyclo[4.3.0]nonan-8-one (**4**) in 70—75% yield. Similarly, 2-phenylsulfonyl-2-(2,6,6-trimethyl-1,3-cyclohexadienyl)acetic acid provided 2,2,6-trimethyl-9-phenylsulfonyl-7-oxabicyclo[4.3.0]non-4-en-8-one (**7**) in 62% yield. The lactones **4a**, **4b**, and **7** were converted into dihydroactinidiolide, tetrahydroactinidiolide, and 4,5-dihydroactinidiolide. The reaction conditions and mechanism of the cyclization of **5** are discussed.

In connection with syntheses of terpenoids, the acid-catalyzed cyclization of functionalized polyisoprenoids has been reviewed.[2)] However, in spite of need for obtaining naturally occurring γ-lactones, very few satisfactory results have been obtained concerning one-step lactonization of acyclic polyolefinic carboxylic acids.[3)]

Reports have been given on a convenient preparation of 2-phenylsulfonyl-1,3,3-trimethylcyclohexene (**1a**) by the acid-catalyzed cyclization of 1-phenylsulfonyl-3,7-dimethylocta-2,6-diene (**2a**), as well as its use for the syntheses of terpenoids such as deoxytrisporone, vitamin A acid and ferruginol.[4)] On the cyclization of **2**, it was assumed that the reaction proceeds *via* the carbonium ion **3** which would undergo deprotonation or ring closure by intramolecular nucleophilic attack of another carbon-carbon double bond. This assumption prompted us to carry out one-step preparation of 2,2,6-trimethyl-9-phenylsulfonyl-7-oxabicyclo[4.3.0]nonan-8-one (**4**) from 2-phenylsulfonyl-4,8-dimethyl-3,7-nonadienoic acid (**5**). The presence of a phenylsulfonyl group at the terminal position of polyolefin chain allows the introduction of carboxyl group at the α-position, affording both α,β-unsaturated and saturated γ-lactones by either thermal elimination or reductive removal of the phenylsulfonyl group.

This paper gives details on cyclization[5)] of **5** and 2-phenylsulfonyl-2-(2,6,6-trimethyl-1,3-cyclohexadienyl)-acetic acid (**6b**) along with a novel transformation of lactones **4a**, **4b**, and 2,2,6-trimethyl-9-phenylsulfonyl-7-oxabicyclo[4.3.0]non-4-en-8-one (**7**) into dihydroactinidiolide (**8**), isolated from Actinidia polygama Mig. (Matatabi),[6,7)] tetrahydroactinidiolide (**9a** and **9b**),[8)] and 4,5-dihydroactinidiolide (**10**).[9)]

Results and Discussion

Acid-catalyzed Lactonization of the Carboxylic Acids 5 and 6b. The carboxylic acids **5** and **6b** were easily prepared from the corresponding sulfones **2a** and **6a** by carboxylation.[10)] Treatment of **2a** with 2 equiv. of butyllithium in tetrahydrofuran at −70 °C followed with dry carbon dioxide yielded **5** in 99% yield. Similarly, **6b** was obtained in 96% yield.

Table 1. Cyclization of 5 with sulfuric acid

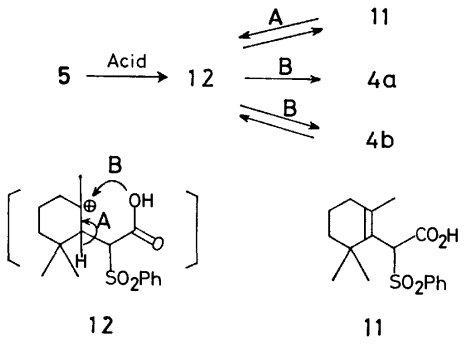
Entry	Ratio of acids[a)] H_2SO_4/AcOH	Temp[b)] °C	Product, %	
			4 (*cis*/*trans*)	**11**
1	1/1	12	64 (1.6)	26
2	4/1	5	66 (2.3)	3
3	4/1	20	66 (6.0)	0
4	1/0	5	75 (∞)[c)]	0

a) v/v. b) Reaction time 0.5 h. c) No *trans*-isomer obtained.

The acid-catalyzed lactonization of **5** was performed using protonic or Lewis acid (Table 1). Treatment of **5** with sulfuric and acetic acids (1:1) at 12 °C for 0.5 h provided **4** (64%) and **11** (26%). The product **4** consists of a mixture of *cis*- and *trans*-fused γ-lactones, which were separated by column chromatography and identified by a comparison with spectral data and also conversion of **4a** and **4b** into the corresponding tetrahydroactinidiolides **9a** and **9b** by reductive removal of the phenylsulfonyl group. The structure of **11** was confirmed by a comparison of the spectral data with those of the authentic sample prepared by the carboxylation of **1a**.

Increase of the concentration of sulfuric acid and/or the higher reaction temperature (Table 1, Runs 3—4) facilitates the formation of *cis*-lactone **4a**. In particular, the reaction of **5** in concd sulfuric acid at 5 °C gave **4a** in 75% yield as the sole product.

The carboxylic acid **11** was converted into **4** (**4a**/**4b**=4/1) in 45% yield on treatment with sulfuric and acetic acids (1:1) for 4 h. The *trans*-lactone **4b** undergoes complete isomerization to *cis*-lactone **4a** on treatment with sulfuric acid at 5 °C for 1 h. In strong acidic media the thermodynamically more stable *cis*-lactone **4a** would be produced preferentially to *trans*-isomer **4b**. Thus, it is assumed that the intermediate **12** would suffer either deprotonation to afford monocyclic carboxylic acid **11** (Path A in Scheme 1) or intramolecular nucleophilic attack by carboxyl group to produce a mixture of *cis*- and *trans*-lactones (Path B), although the mechanism of the concerted lactonization of **5** to *trans*-**4b** followed by isomerization of **4b** to **4a** *via* **12** could not be ruled out.



Scheme 1.

Among Lewis acids, boron trifluoride gave satisfactory results as shown in Table 2. Treatment of **5** with boron trifluoride in refluxing benzene for 1 h provided **4** (75%) and **11** (20%). Changes of solvents did not seriously affect the yield of **4**. Only carbon tetrachloride slightly improved the yield of *trans*-lactone **4b**.

Cyclization of the carboxylic acid **6b** with sulfuric and acetic acids (1:6) afforded *cis*-lactone **7** (62%). The stereochemistry of **7** was confirmed by the fact that hydrogenation of **7** with PtO_2 affords **4a** exclusively.

Preparation of Actinidiolide Derivatives. Many attempts have been made to synthesize **8** and related compounds **9a** and **9b**, because of its significant biological activity and importance as a strong fragrance for tea and tobacco. Photochemical oxidation of β-ionone derivatives,[11] β-carotenoids,[12] and retinal[13] gives **8** in poor yield. Another approach includes lactonization of homogeranic acid derived from 2,2,6-trimethylcyclohexanone resulting in unsatisfactory total yield.[14]

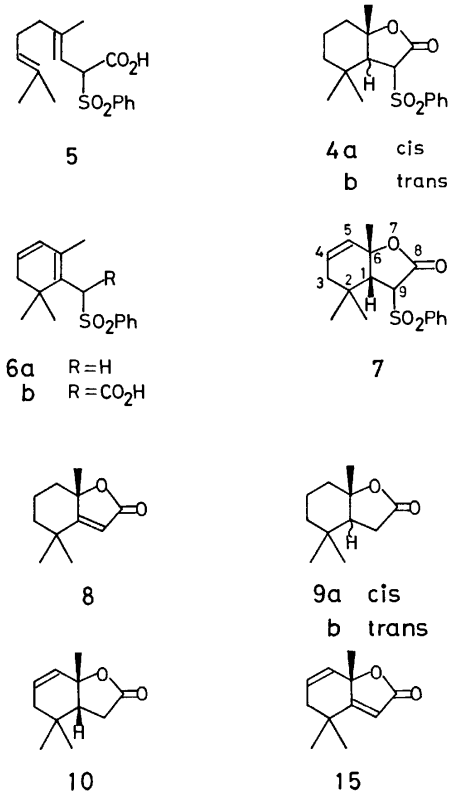


Table 2. Cyclization of **5** with boron trifluoride in various solvents

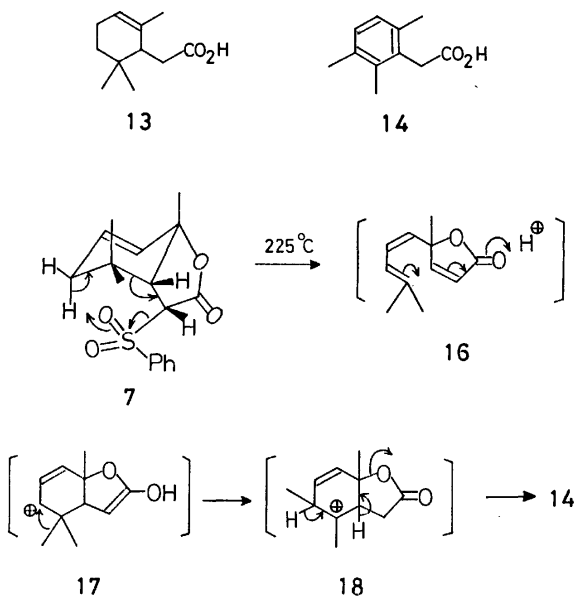
Entry	Solvent	Temp °C	Time h	Product, %	
				4 (*cis*/*trans*)	**11**
1	Toluene	reflux	1	73 (2.4)	3
2	Benzene	reflux	1	75 (2.4)	20
3	$CHCl_3$	reflux	1	71 (2.3)	26
4	CH_2Cl_2	reflux	1	70 (2.0)	21
5	CH_2Cl_2	0—4	168	71 (2.3)	21
6	CCl_4	reflux	1	55 (1.7)	12

The present attempt deals with a straightforward preparation of **8**, **9a**, **9b**, and **10** *via* the lactones **4** and **7**. Thermolysis of the lactone **4a** at *ca.* 300 °C afforded **8** (67%) and diphenyl disulfide (66%). The spectral data of **8** are in line with those reported.[6,9] Reduction of **4a** with Raney Ni W-2 in ethanol afforded *cis*-tetrahydroactinidiolide (**9a**) (84%). Similarly, **4b** yielded the *trans*-isomer **9b** (81%). The structure of both **9a** and **9b** were identified by a comparison of their spectral data.[15,16]

Reduction of **7** with potassium metal in liquid ammonia at −70 °C afforded **10** (91%)[9] and **13** (4%).[14e] Hydrogenation of the lactone **10** with Pd/C in methanol gave **9a** in 91% yield.

In contrast to the thermal elimination of phenylsulfonyl group of **4**, the lactone **7** gave **14** (75%) and diphenyl disulfide (65%) instead of actinidiolide (**15**), when **7** was heated to 225 °C. The thermal reaction of **7** can be initiated by the preferential 1,4-elimination of phenylsulfonyl group and allylic proton on C-3 as shown in Scheme 2. The incipient intermediate **16** might undergo recyclization producing **17**, which would be transformed into the stable aromatic compound **14** by subsequent Wagner-Meerwein rearrangement followed by deprotonation and aromatization.



Scheme 2.

Experimental

Melting points are uncorrected. IR spectra were determined with a JASCO IRA-1 infrared spectometer. NMR spectra were obtained at 60 MHz with a Hitachi R-24 spectrometer, chemical shift values being expressed in δ value (ppm) relative to Me_4Si in $CDCl_3$.

*2-Phenylsulfonyl-4,8-dimethyl-3,7-nonadienoic Acid (**5**).* To a stirred solution of 56 mg (0.2 mmol) of **2a** in 4 ml of dry THF was added dropwise 0.8 ml (0.4 mmol) of BuLi at −70 °C under N_2. After stirring at −70 °C for 5 min, dry CO_2 was introduced into the solution with vigorous stirring for 2.5 h. The mixture was concentrated to 1 ml under reduced pressure. The residue was dissolved in ether, the acidic products being extracted with saturated $NaHCO_3$. The combined $NaHCO_3$ extracts were acidified with 10% HCl. The organic material was extracted with AcOEt. The extracts were washed with brine, dried (Na_2SO_4) and concentrated *in vacuo*. The residue was chromatographed (SiO_2, hexane and then EtOH–CH_2Cl_2=4/1) to give 64 mg (99%) of **5** as a colorless liquid. Esterification of **5** with diazomethane gave 66 mg of the corresponding methyl ester. Methyl ester of **5**: IR (neat): 1745 (C=O), 1580, 1327, 1149 (SO_2) cm^{-1}; NMR : δ 7.32—7.99(m, 5, ArH), 5.26 (d, 1, J=11 Hz, CH=), 5.03(m, 1, CH=), 4.78 (d, 1, J=11Hz, $CHSO_2$), 3.75(s, 3, CH_3O), 1.90—2.19 (m, 4, CH_2), 1.70 (s, 3, CH_3), 1.60 (s, 3, CH_3), 1.51 (s, 3, CH_3). Found: C, 64.52; H, 7.30%. Calcd for $C_{18}H_{24}O_4S$: C, 64.26; H, 7.19%.

*2-Phenylsulfonyl-2-(2,6,6-trimethyl-1,3-cyclohexadienyl)acetic Acid (**6b**).* The carboxylic acid **6b** was obtained in 96% yield as a slight yellow oil by a procedure similar to that for **5**. Methyl ester of **6b**: IR(neat): 1741 (C=O), 1320, 1145 (SO_2) cm^{-1}; NMR: δ 7.37—8.12 (m, 5, ArH), 5.79 (br s, 2, CH=), 4.89 (s, 1, CH), 3.66 (s, 3, CH_3O), 1.96—2.28 (m, 2, CH_2), 1.81 (s, 3, CH_3), 1.16 (s, 3, CH_3), 1.01 (s, 3, CH_3). Found: C, 64.93; H, 6.55%. Calcd for $C_{18}H_{22}O_4S$: C, 64.65: H, 6.63%.

*2-Phenylsulfonyl-2-(2,6,6-trimethyl-1-cyclohexenyl)acetic Acid (**11**).* Mp 182—182.5 °C; IR (Nujol): 1706 (C=O), 1325, 1150 (SO_2) cm^{-1}; NMR of methyl ester of **11**: δ 7.35—8.08 (m, 5, ArH), 4.70 (s, 1, CH), 3.70 (s, 3, CH_3O), 1.98—2.30 (m, 2, CH_2C=), 1.88 (s, 3, CH_3), 1.47—1.78 (m, 4, CH_2), 1.08(s, 3, CH_3), 0.89 (s, 3, CH_3). Found: C, 63.51; H, 6.92%. Calcd for $C_{17}H_{22}O_4S$: C, 63.33; H, 6.88%.

*2,6,6-Trimethyl-9-phenylsulfonyl-7-oxabicyclo[4.3.0]nonan-8-one (**4**).* To a refluxing solution of 161 mg (0.5 mmol) of **5** in 6 ml of freshly distilled CH_2Cl_2 under N_2 was added BF_3 etherate (150 mg). After the mixture had been refluxed for 30 min, 100 mg of BF_3 etherate and after 30 min an additional 30 mg were added. The mixture was further refluxed for 1 h. After being cooled to room temperature and quenched with saturated $NaHCO_3$, the mixture was washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. The residual crystalline product was chromatographed (SiO_2, benzene–AcOEt=10:1) to give 121 mg (75%) of **4** (**4a**/**4b**=2.4/1) as colorless crystals. The $NaHCO_3$ solution was acidified with 5% HCl, the organic material being extracted with AcOEt. The extracts were washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield 32 mg (20%) of **11** as crystals.

(**4a**): Mp 173.5—174.5 °C; IR (Nujol): 1770 (C=O), 1317, 1150 (SO_2) cm^{-1}; NMR: δ 7.35—8.07 (m, 5, ArH), 4.01 (d, 1, J=6 Hz, CHCO), 2.76 (d, 1, J=6 Hz, CH), 1.31—2.00 (m, 6, CH_2), 1.60(s, 3, CH_3), 1.14 (s, 3, CH_3), 1.06 (s, 3, CH_3). Found: C, 63.50; H, 7.03%. Calcd for $C_{17}H_{22}O_4S$: C, 63.33; H, 6.88%.

(**4b**): Mp 131—132 °C; IR (Nujol): 1770 (C=O), 1305, 1145 (SO_2) cm^{-1}; NMR: δ 7.30—8.00 (m, 5, ArH), 4.17 (d, 1, J=13 Hz, CHCO), 2.78 (d, 1, J=13 Hz, CH), 1.25—2.05 (m, 6, CH_2), 1.41 (s, 3, CH_3), 1.34(s, 3, CH_3), 1.15 (s, 3, CH_3). Found: C, 63.16; H, 6.83%. Calcd for $C_{17}H_{22}O_4S$: C, 63.33; H, 6.88%.

*Cyclization of **4** with H_2SO_4.* 1 ml of ice-cooled concd H_2SO_4 was added dropwise to 75 mg (0.23 mmol) of **5**. After vigorous stirring at 0 °C for 1 h, the mixture was poured into 10 ml of ice water. The organic layer was extracted with AcOEt. The extracts were washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed (SiO_2, benzene) to give 56 mg (75%) of **4a**.

*2,2,6-Trimethyl-9-phenylsulfonyl-7-oxabicyclo[4.3.0]non-4-en-8-one (**7**).* To 50 mg (0.16 mmol) of **6b** was added dropwise 3.5 ml of an ice-cooled mixture of H_2SO_4 (0.5 ml) and AcOH (3 ml). After being stirred at room temperature for 18 h, the mixture was poured into 15 ml of ice water and the organic layer was extracted with AcOEt. The extracts were washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed (SiO_2, benzene–AcOEt=10/1) to give 31 mg (62%) of **7** as colorless crystals: mp 134—134.5 °C (benzene–hexane); IR (Nujol): 1769 (C=O), 1321, 1150 (SO_2) cm^{-1}; NMR: δ 7.35—8.10 (m, 5, ArH), 5.80 (br s. 2, CH=), 4.00 (d, 1, J=4 Hz, CHCO), 2.91 (d, 1, J=4 Hz, CH), 1.85—2.07 (m, 2, CH_2), 1.63 (s, 3, CH_3), 1.09 (s, 3, CH_3), 0.95 (s, 3, CH_3). Found: C, 63.58; H, 6.16%. Calcd for $C_{17}H_{20}O_4S$: C, 63.73; H, 6.29%.

*Isomerization of **4b** to **4a**.* 1 ml of ice-cooled concd H_2SO_4 was added dropwise to 35 mg (0.11 mmol) of **4** (**4a**/**4b**=1/2.3). After vigorous stirring at 0 °C for 1 h, the mixture was poured into ice water and the organic layer was extracted with AcOEt. The extracts were washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed (SiO_2, benzene) to give 31 mg (89%) of **4a** as colorless crystals.

*Hydrogenation of **7** to **4a**.* A suspension of 32 mg (0.1 mmol) of **7** and 10 mg of PtO_2 in 2 ml of dry MeOH was stirred vigorously at room temperature under H_2 for 12 h. The usual work-up and chromatography (SiO_2, benzene–AcOEt=10/1) yielded 31 mg (96%) of **4a** as colorless crystals.

*2,2,6-Trimethyl-7-oxabicyclo[4.3.0]non-9-en-8-one (Dihydroactinidiolide) (**8**).* Sulfone **4a** (40 mg, 0.12 mmol) in a glass tube (7ϕ, 25 cm) was refluxed in an air bath at 300—320 °C for 12 min, the volatile oil being collected. The oil was chromatographed (SiO_2, hexane–AcOEt=2/1) to give 15 mg (67%) of **8** as a colorless oil and 9 mg (66%) of diphenyl disulfide.

trans-*Tetrahydroactinidiolide (**9b**).* A suspension of 120 mg of Raney Ni W-2 and 37 mg (0.11 mmol) of **4b** in a mixture of 1.5 ml of EtOH and 1.5 ml of distilled water was refluxed at 110—120 °C for 10 h. After separation of Raney Ni through a short column, the organic phase was concentrated and chromatographed (SiO_2, benzene–AcOEt=10/1) to yield 17 mg (81%) of **9b** as a colorless oil.

cis-*Tetrahydroactinidiolide (**9a**).* Similarly, reduction of **4a** with Raney Ni W-2 provided **9a** in 84% yield.

*2,2,6-Trimethyl-7-oxabicyclo[4.3.0]non-4-en-8-one (**10**).* A few pieces of potassium metal (29 mg, 0.75 mmol) were added to a solution of **7** (80 mg, 0.25 mmol) in 1 ml of dry THF and 20 ml of liq ammonia at −70 °C. After 1 min, saturated NH_4Cl was added and then liq ammonia was evaporated at room temperature for 2 h. The residue was combined with 2 ml of 5% HCl and the organic substances were extracted with AcOEt. The extracts were washed with

brine, dried (Na_2SO_4), and concentrated under reduced pressure to yield 44 mg of colorless liquid which was chromatographed (SiO_2, benzene–AcOEt=30/1) to give 41 mg (91%) of **10** as a colorless liquid and 2 mg (4%) of **13**.

Hydrogenation of ***10***. A suspension of 7 mg of Pd/C and 37 mg (0.21 mmol) of **10** in 2 ml of dry MeOH was stirred under H_2 at room temperature for 12 h. After the usual work-up and chromatograph (SiO_2, benzene), 34 mg (91%) of **9a** was obtained as a colorless oil.

*2,3,6-Trimethylphenylacetic Acid (****14****)*. Lactone **7** (48 mg, 0.15 mmol) was heated to 225 °C in a glass tube settled in a Kugelrohr distillation apparatus for 3 h. During the course of heating, 45 mg of a dark colored oil was distilled out and chromatographed (SiO_2, benzene) to give 20 mg (75%) of **14**, 10 mg (61%) of diphenyl disulfide, and 8 mg (17%) of **7**. The carboxylic acid **14** was esterified with CH_2N_2 and subjected to preparative GLC (SE-30) to show a single peak: IR ($CHCl_3$) 3400—2400 (OH), 1697 (C=O) cm^{-1}; NMR: δ 9.59 (s, 1, CO_2H), 6.94 (s, 2, ArH), 3.72 (s, 2, CH_2), 2.28 (s, 3, CH_3), 2.24 (s, 3, CH_3), 2.20 (s, 3, CH_3). Methyl ester of **14**; Found: C, 74.90; H, 8.55%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%.

The Synthesis of Tetrakisdehydrotetraazaannulenes. Tetramethyl[32]-, [40]-, and Tetrabenzo[32]annulene

Jūro Ojima,* Yūji Shiroishi, and Masamitsu Fujiyoshi

Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930

(Received January 25, 1978)

The conjugate aldehydes, containing terminal acetylenes, were converted to the corresponding conjugated azines **6a**—**c** and **8a**—**c**, respectively. Oxidative couplings of these azines were attempted. The azines **6b**, **6c**, and **8b** afforded the corresponding cyclic dimers **9**, **10**, and **11**, respectively. Examination of ^{1}H NMR spectra indicates that the tetraazaannulenes are atropic.

In 1974, Yamamoto and Sondheimer attempted the oxidative couplings of the conjugated azines of type **1** to obtain the corresponding cyclic monomer and/or dimer, which are the macrocyclic analogues of pyridazine **2** and 1,2,4,5-tetrazine **3**, respectively.[1] In attempted oxidative couplings, they obtained the cyclic dimer **4** from the azine **1b** using copper(II) acetate monohydrate in ether and pyridine under relatively dilute concentrations. Also, quite recently, Darby *et al.* found that oxidative coupling of terminal diacetylenes to macrocyclic 1,3-diacetylenes usually proceeds in higher yield when anhydrous copper(II) acetate instead of the monohydrate is employed.[2]

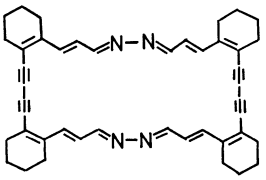
2

3



4

Bearing these results in mind and expecting to obtain the cyclic monomeric compounds using the conditions reported by Darby *et al.*, we undertook to examine oxidative couplings of the conjugated azines of types **6** and **8**. In practice, we obtained no cyclic monomeric compounds, but the respective cyclic dimers **9**, **10**, **11**, from the azines **6b**, **6c**, and **8b**.

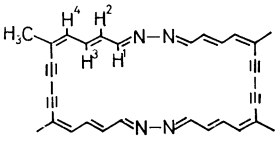
Table 1. Yields and melting points of the azines **6** and **8**

	Azines	
	Yield (%)	Mp (°C)
6a	82	110 (dec)
6b	76	160 (dec)
6c	87	110 (dec)
8a	85	140 (dec)
8b	64	169—170
8c	64	199—200

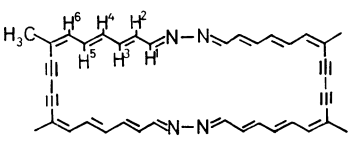
The trienyne aldehyde **5c** was prepared from its lower homologue, the dienyne aldehyde **5b** in 50% yield by condensation with ethyl vinyl ether according to the Isler's method[3,4] or by Wittig condensation with (1,3-dioxolan-2-ylmethyltriphenyl)phosphonium bromide.[5,6]

Treatment of the aldehydes **5a**—**c** and **7a**—**c** in ethanol with aqueous hydrazine, as described by Yamamoto and Sondheimer,[1] yielded the corresponding conjugated azines **6a**—**c** and **8a**—**c**, respectively. The yields and melting points of the azines are summarized in Table 1.

All of attempted oxidative couplings of these azines (**6a**—**c**, **8a**—**c**) were carried out with anhydrous copper(II) acetate in pyridine and ether at 50 °C as reported by Darby *et al.*[2] The azines **6b**, **6c**, and **8b** afforded the corresponding cyclic dimers **9** (14%), **10** (17%), **11** (20%), and they formed red needles (122 °C (dec)), purple needles (*ca.* 95 °C (dec)), yellow needles (170 °C (dec)), respectively; the compound **10** was a rather unstable material. Under the same conditions as above, the yellow crystals were isolated from the azine **8c**, but the structure of the material is not yet established. In the cases of **6a** and **8a**, the oxidative couplings were also investigated under several different conditions (see Experimental), but no desired cyclic product could be obtained.



9



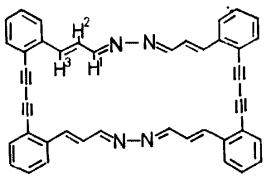
10

The dimeric structure of the product from **6b**, **6c**, and **8b** was established by the mass spectra. The mass spectral measurement of **10** using direct inlet system were not satisfactory owing to decomposition

Table 2. ^{1}H-NMR parameters of **9**, **10**, and **11** in $CDCl_3$ at 100 MHz
(τ-Values; internal standard, TMS; J values in Hz in parentheses)

Proton	**9**	**10**	**11**
H^1	2.30 (d, 9)	2.03 (d, 9)	1.86 (d, 9)
H^2	3.51 (dd, 15, 9)	2.6—3.6 (m)	2.92 (dd, 16, 9)
H^3	2.86 (dd, 15, 11)		2.51 (d, 16)
H^4	3.45 (d, 11)		
H^5, H^6			
CH_3	7.98 (s)	7.96 (s), 7.99 (s)	
benzenoid H			2.3—2.6 (m)

during measurement. However, the mass spectrum obtained by field desorption technique was satisfactory one, revealing a molecular ion peak (mol wt, 573) clearly. The UV spectra of **9**, **10**, and **11** are illustrated



11

in Fig. 1. These spectra are similar as those of **4**,[1] and shows characteristic feature of [4*n*]annulene.[7] The ^{1}H-NMR data of **9**, **10**, and **11** are given in Table 2. The chemical shifts of the olefinic and methyl protons of these compounds suggest that the compounds **9**, **10**, and **11** are atropic molecules.

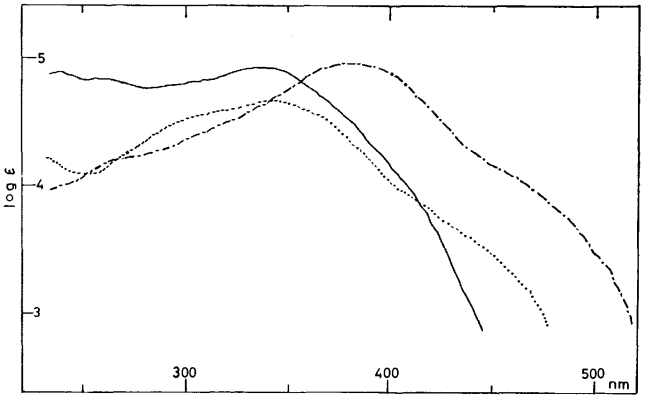


Fig. 1. Electronic spectra of tetrakisdehydrotetraazaannulenes **9** (----), **10** (——-), and **11** (——) in THF.

In conclusion, although we expected that the cyclic monomers, which are the macrocyclic analogues of pyridazine **2**, might also result from the azines by using the procedure reported by Darby *et al.*, the compounds obtained are dimeric ones.

Experimental

All melting points are uncorrected. The IR spectra were measured on Hitachi EPI-S2 or Unicam SP 200 spectrophotometer: only significant maxima are reported. The electronic spectra obtained on Hitachi 124 or Unicam SP-800 spectrophotometer were recorded in nm. The ε-values are given in parentheses, the shoulder being denoted by sh. The mass spectra were measured with JEOL JMS-OI-SG-2, AEI MS-12 or JEOL JMS-D equipped with field desorption system. The ^{1}H-NMR spectra were obtained on Varian EM-930, Varian T-60 or Varian XL-100 spectrometer, and refer to solutions in $CDCl_3$, in τ-values with TMS as an internal standard at 90 MHz unless otherwise stated. The coupling constants (J) are given in Hz. The individual assignments are made on the basis of the multiplicity and coupling constants. The number indicated in the by-line starts from the carbon adjacent to nitrogen atom of the azine group, as shown in the formulae of **9**, and in **5c** the number starts from the carbon of the aldehyde group. Alumina (Act. II—III) was used for column chromatography unless otherwise indicated. Progress of most reactions was followed by TLC using Merck precoated alumina. Evaporation of the solvents was carried out at water aspirator pressure.

7-Methyl-2,4,6-nonatrien-8-ynal **5c**.[4] A 1% soln of *p*-toluenesulfonic acid monohydrate in absolute ethanol (15 drops) was added to a soln of the aldehyde **5b**[3] (6.1 g, 0.05 mol) and ethyl orthoformate (9.2 g, 0.06 mol) in absolute ethanol (10 ml). After being stirred at room temperature overnight, the mixture was treated with pyridine (1 ml) and poured into 2% aqueous $NaHCO_3$ (100 ml). Extraction with ether, drying over $MgSO_4$, and evaporation of the solvents yielded the crude diethyl acetal of **5b** as a red liquid. The liquid was dissolved in ethyl acetate (10 ml) and warmed to 35 °C in a flask equipped with two dropping funnels, a condenser, and a magnetic stirrer. A 10% soln of zinc chloride in ethyl acetate (20 drops) was added, and then the same soln (10 ml) and ethyl vinyl ether (40 ml) were added simultaneously during 5 min under stirring at 35 °C. The mixture was stirred for 2 h at room temperature, stoppered, and allowed to stand overnight. A soln of sodium acetate (15 g) in water (10 ml) and acetic acid (150 ml) was then added, and the mixture was heated to 90 °C for 2 h. Dilution with water (700 ml), extraction with ether, drying over $MgSO_4$, and evaporation gave a residue, which was chromatographed on alumina (200 g, Woelm, Act. III). Elution with pentane-ether (96:4—90:10) and evaporation of the solvents gave the aldehyde **5c** (3.6 g, 50%) as solid. Recrystallization from ether-hexane gave pure **5c** as orange needles, mp 64—65 °C; MS: *m/e* 146 (M^+), 131 (M^+-15), 117 (M^+-29); mol wt, 146.2; IR ($CHCl_3$): 3290 (-C≡CH), 2100 (-C≡C-), 1670, 1600 (C=O, C=C), 995 cm^{-1} (*trans* C=C); UV (ether): λ_{max} 234 (14600), 305 sh (32900), 324 (47500), 337 nm (44900); NMR (60 MHz): 0.41 (d, 8, 1H, CH^1O), 2.80 (dd, 15, 11, 1H, H^5), 2.87 (dd, 15, 11, 1H, H^3), 3.41—3.67 (m, 2H, H^4 and H^6), 3.82 (dd, 15, 8, 1H, H^2), 6.54 (s, 1H, -C≡CH), 7.99 (s, 3H, $-CH_3$).

Found: C, 82.42; H, 6.71%. Calcd for $C_{10}H_{10}O$: C, 2.16; H, 6.90%.

The compound **5c** was also prepared in 42% yield by Wittig condensation with (1,3-dioxolan-2-ylmethyl) triphenyl-

phosphonium bromide as reported for the preparation of **7b**,[6] except the use of lithium ethoxide instead of lithium methoxide as a base.[5]

Azine ***6a***. A soln of **5a**[8] (2.0 g, 2.1 mmol) in ethanol (20 ml) was added to a soln prepared from hydrazine sulfate (1.5 g), Na_2CO_3 (2.0 g), and H_2O (15 ml), with stirring at ambient temperature. After the reaction was continued for 2 h at the same temperature, the reaction mixture was poured into aqueous $NaHCO_3$ soln (200 ml), and extracted with benzene, washed with aqueous $NaHCO_3$ and dried over K_2CO_3. The residual red liquid, after solvent removal, was chromatographed on alumina (120 g) with light petroleum–ether (80:20) to give **6a** (1.6 g, 82%). Recrystallization from chloroform–ethanol afforded yellow needles, mp *ca.* 110 °C (dec), MS: *m/e* 184 (M^+, 50), 183 (100); mol wt, 184.2; IR (KBr disk): 3200 (–C≡CH), 2100 (–C≡C–), 1610 (N=C); UV (EtOH): λ_{max} 302 sh (19900), 315 (26700), 328 (27100), 344 sh (18200); NMR: 1.38 (d, 10, 2H, H^1), 3.40 (broad d, 10, 2H, H^2), 6.55 (s, 2H, –C≡CH), 7.90 (s, 6H, $-CH_3$).

Found: C, 78.05; H, 6.30; N, 15.00%. Calcd for $C_{12}H_{12}N_2$: C, 78.23; H, 6.57; N, 15.21%.

Azine ***6b***. In a similar manner, **6b** was prepared from **5b**[3] (1.4 g, 12 mmol) in EtOH (15 ml) and hydrazine sulfate (0.79 g), Na_2CO_3 (0.98 g), and H_2O (8.1 ml). Elution with light petroleum–ether (20:80—5:95) from the column of alumina (130 g) gave **6b** (1.05 g, 76%), obtained as yellow needles from benzene–hexane, mp *ca.* 160 °C (dec), MS: *m/e* 236 (M^+, 44), 193 (100); mol wt, 236.3; IR (KBr disk): 3300 (–C≡CH), 2100 (–C≡C–), 1615 (N=C), 1600 (C=C), 980 cm^{-1} (*trans* C=C); UV (THF): λ_{max} 231 (11400), 239 sh (9710), 247 sh (6380), 280 sh (6420), 292 (7600), 322 sh (22400), 341 sh (42500), 357 (57200), 373(57700), 392(36800); NMR (100 MHz): 1.79 (d, 10, 2H, H^1), 2.84 (dd, 15, 11, 2H, H^3), 3.52 (dd, 15, 11, 2H, H^2), 3.53 (d, 11, 2H, H^4), 6.56 (s, 2H, –C≡CH), 7.99 (s, 6H, $-CH_3$).

Found: C, 81.42; H, 6.86; N, 11.65%. Calcd for $C_{16}H_{16}N_2$: C, 81.32; H, 6.83; N, 11.86%.

Azine ***6c***. This substance was similarly prepared from **5c** (430 mg, 2.94 mmol) in EtOH (3.8 ml) and hydrazine sulfate (199 mg), Na_2CO_3 (247 mg), and H_2O (2 ml). Elution with ether–chloroform (1:1) from the column of alumina (120 g) gave **6c** (370 mg, 87%), obtained as brownish yellow needles from chloroform, mp *ca.* 110 °C (dec), MS: *m/e* 288 (M^+, 100); mol wt, 288.3; IR (KBr disk): 3280 (–C≡CH), 2100 (–C≡C–), 1620 (N=C), 1590 (C=C), 995 cm^{-1} (*trans* C=C); UV (THF): λ_{max} 260 (6460), 271 sh (5590), 281 sh (4020), 312 sh (5460), 325 sh (7070), 396 (40000), 413 (40900), 434 (25200); NMR: 1.81 (d, 9. 2H, H^1), 3.0—3.7 (m, 10H, olefinic H), 6.63 (s, 2H, –C≡CH), 8.03 (s, 6H, $-CH_3$).

Found: C, 83.27; H, 6.72; N, 9.87%. Calcd for $C_{20}H_{20}N_2$: C, 83.29; H, 6.99; N, 9.71%.

Azine ***8a***. Similarly, **8a** was prepared from **7a**[9] (3.0 g, 2.3 mol) in EtOH (30 ml) and hydrazine sulfate (1.6 g), Na_2CO_3 (1.9 g), and H_2O (16 ml). Elution with light petroleum–ether (85:15—60:40) from the column of alumina (150 g) gave **8a** (2.5 g, 85%), obtained as yellow needles from benzene–hexane, mp *ca.* 140 °C (dec), MS: *m/e* 256 (M^+, 75), 255 (100); mol wt, 256.2; IR (KBr disk): 3200 (–C≡CH), 2100 (–C≡C–), 1625 cm^{-1} (N=C); UV (THF): λ_{max} 232 (31400), 248 sh (25700), 255 sh (19900), 302 sh (26200), 315 (29200). 332 sh (24500), 349 sh (11300); NMR: 0.83 (s, 2H, H^1), 1.66—1.85 (m, 2H, benzenoid H), 2.36—2.75 (m, 6H, benzenoid H), 6.60 (s, 2H, –C≡CH).

Found: C, 84.27; H, 4.92; N, 10.66%. Calcd for $C_{18}H_{12}N_2$: C, 84.35; H, 4.72; N, 10.93%.

Azine ***8b***. This material was similarly prepared from **7b**[6] (1.8 g, 0.12 mmol) in EtOH (20 ml) and hydrazine sulfate (0.97 g), Na_2CO_3 (0.98 g), and H_2O (1.1 ml). The resulting precipitates were collected and washed with EtOH, giving **8b** (1.14 g, 64%), obtained as yellow needles from benzene–ethanol, mp 169—170 °C, MS: *m/e* 308 (M^+, 30), 280 (100); mol wt, 308.3; IR (KBr disk): 3250 (–C≡CH), 2100 (–C≡C–), 1635 (N=C), 1590 (C=C), 980 cm^{-1} (*trans* C=C); UV (THF): λ_{max} 290 sh (8260), 339 sh (44600), 353 (52900), 370 sh (47400), 390 sh (24000); NMR: 1.67 (d, 9, 2H, H^1), 2.43 (d, 16, 2H, H^3), 2.97 (dd, 16, 9, 2H, H^2), 2.32—2.90 (m, 8H, benzenoid H), 6.68 (s, 2H, –C≡CH).

Found: C, 86.43; H, 5.33; N, 8.83%. Calcd for $C_{22}H_{16}N_2$: C, 86.69; H, 5.23; N, 9.09%.

Azine ***8c***. This substance was similarly prepared from **7c**[10] (1.0 g, 5.5 mmol) in EtOH (7.1 ml) and hydrazine sulfate (371 mg), Na_2CO_3 (460 mg), and H_2O (3.7 ml). Fractions eluted with light petroleum–ether (50:50) from the column of alumina (150 g) gave **8c** (623 mg, 64%), obtained as yellow plates from chloroform, mp 199—200 °C. Attempts to obtain a satisfactory elemental analysis were unsuccessful in our hands, but the Mass (*m/e* 360 (M^+, 45), 180 (100); mol wt, 360.4), the IR (KBr disk) (3300 (–C≡CH), 2100 (–C≡C–), 1615 (N=C), 995 cm^{-1} (*trans* C=C)), the UV (THF) λ_{max} 276 sh (14300), 368 sh (54000), 389 (67000), 405 sh (62000), 430 sh (15000)), and the NMR (1.75 (d, 9, 2H, H^1), 2.35—3.48 (m, 16H, benzenoid and olefinic H), 6.65 (s, 2H, –C≡CH)) were found to be consistent with the assigned structure.

Oxidative Coupling of ***6b*** *to the Tetrakisdehydrotetraaza[32]annulene* ***9***. A soln of **6b** (950 mg, 4.02 mmol) in pyridine (63 ml) and dry ether (21 ml) was added dropwise during 4 h to a stirred soln of anhydrous copper(II) acetate (5.1 g) in pyridine (140 ml) and dry ether (47 ml) kept at 50 °C; the mixture was stirred for further 2 h at the same temperature. Then the mixture was chilled, diluted with benzene (100 ml), and filtered through Hyflo Super-Cel. The precipitates formed were washed with benzene (100 ml × 4). The filtrate was washed with H_2O thirteen times to remove pyridine, and dried over K_2CO_3. After solvent removal, the residual red liquid was chromatographed on alumina (200 g). Fractions eluted with light petroleum–ether (65:35)—ether–benzene (30:70) contained **9**. The slightly crude **9** was dissolved in ether and chromatographed on alumina (140 g) with ether to give **9** (129 mg, 14%), obtained as orange needles from benzene–hexane, mp 122 °C (dec); MS: *m/e* 470 (M^+, 8), 324 (100); mol wt, 470.5; IR (KBr disk): 2150 (–C≡C–), 1610 (N=C), 1600 (C=C), 975 cm^{-1} (*trans* C=C); UV (THF): (see Fig. 1) λ_{max} 232 (14000), 269 sh (15700), 312 sh (33000), 339 nm (45000): NMR: see Table 2.

Oxidative Coupling of ***6c*** *to the Tetrakisdehydrotetraaza[40]annulene* ***10***. To a stirred soln of anhydrous copper(II) acetate (1.3 g) in pyridine (36 ml) and dry ether (12 ml) kept at 50 °C was added with stirring a soln of **6c** (300 mg, 1.04 mmol) in pyridine (40 ml) and dry ether (10 ml) during 2.5 h: the mixture was stirred for further 2.5 h at 45—50 °C (bath temp). Then the mixture was worked up as in the preparation of **9**. Elution with benzene from the column of alumina (200 g) gave **10** (50 mg, 17%), obtained as purple microcrystals from chloroform mp *ca.* 95 °C (dec); MS (field desorption method): *m/e* 573 (M^+), 574 ($M^+ + 1$); mol wt, 572.6; IR (KBr disk): 2200 (–C≡C–), 1620 (N=C), 1580 (C=C), 995 cm^{-1} (*trans* C=C), UV (THF): (see Fig. 1) λ_{max} 238 sh (10100), 258 sh (14900), 381 (87500), 468 sh (9630); NMR: see Table 2.

Oxidative Coupling of ***8b*** *to the Tetrakisdehydrotetraaza[32]annulene* ***11***. A soln of azine **8b** (710 mg, 2.30 mmol) in pyridine (42 ml) and dry ether (14 ml) was added during

2 h to a stirred soln of anhydrous copper(II) acetate (2.9 g) in pyridine (80 ml) and dry ether (27 ml) at 50 °C; the mixture was stirred for further 3 h. Then the product was worked up as in the preparation of **9**. The residual liquid, after solvent removal, was chromatographed on alumina (150 g) with ether–benzene (50:50—90:10) to give **11** (144 mg, 20%), obtained as yellow microcrystals from chloroform, mp 168—170 °C (dec): MS: *m/e* 613 (M^+, 27), 307 (100); mol wt, 612.7; IR (KBr disk): 2200, 2150 (–C≡C–), 1635 (N=C), 1595 (C=C), 980 cm^{-1} (*trans* C=C); UV (THF): (see Fig. 1) λ_{max} 287 sh (60200), 303 sh (65400), 333 (83400); NMR: see Table 2.

The yield of **11** was only 8% when the coupling of **8b** was carried out with copper(II) acetate monohydrate in pyridine and ether at 70 °C according to the procedure described for the preparation of **4**.[1)]

*Oxidative Coupling of **6a** and **8a**.* These oxidative couplings were carried out under the following conditions: a) with conditions as described for the preparation of **9**; b) with copper(II) acetate monohydrate in pyridine and ether as reported for the preparation of **4** (Ref. 1); c) with copper(II) acetate monohydrate in pyridine under concentrate conditions.[11)] In all attempted runs, only polymeric products were obtained.

*Oxidative Coupling of **8c**.* In a run performed under similar conditions as the preparation of **9**, the yellow crystals (260 mg) were obtained from the azine **8c** (690 mg, 1.91 mmol) in pyridine (50 ml) and dry ether (16 ml), and anhydrous copper(II) acetate (2.4 g) in pyridine (66 ml) and dry ether (22 ml). After chromatographic purification, they formed yellow microcrystals from chroloform, mp 180 °C (dec). However, the structure of the material is not established.

The authors wish to thank Prof. Franz Sondheimer, University College London, for permitting us to publish some experimental data. We also thank Dr. Fumio Ogura and Prof. Masazumi Nakagawa, Osaka University, for measurement of NMR spectra at 100 MHz, and Mr. Tetsuo Higuchi, Nippon Denshi Co., for the measurement of mass spectrum using field desorption technique. Financial aid by the Ministry of Education (Grant-in-Aid 054103, 1975) is acknowledged.

Branched-chain Sugars. XII. The Stereoselectivities in the Reaction of Methyl 4,6-*O*-Benzylidene-α- and -β-D-hexopyranosid-3-uloses with Diazomethane[1]

Ken-ichi SATO and Juji YOSHIMURA*

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midoriku, Yokohama 227

(Received February 7, 1978)

The stereoselectivities in the diazomethane reaction of methyl 4,6-*O*-benzylidene-2-*O*-methyl-α-D-*ribo*-hexopyranosid-3-ulose (**2**), its 2-epimer (**3**), β-anomer of **2** and the corresponding 2-*O*-Benzoyl derivative were examined, in comparison with those in the Grignard reaction and sodium borohydride reduction. The complemental stereoselectivity of diazomethane reaction in the case of **2** and **3** indicated that the electrostatic attractive effect in the transition state between diazomethyl cation and the axial methoxyl oxygen at the α-position to carbonyl function in **3** is much stronger than that at β-position which is predominat in the case of **2**. In cases of β-anomers having no axial oxygen, stereoselectivies were preferentially controlled by the usual steric factors.

In previous papers, we examined the stereoselectivities in nucleophilic reactions of methyl 2-*O*-Benzyl-4,6-*O*-benzylidene-α-D-*ribo*-hexopyranosid-3-ulose (**1**)[2] and other uloses,[3,4] and found the complemental stereoselectivity between the Grignard and diazomethane reactions. The abnormality of the latter reaction was deduced to be controlled predominantly by the electrostatic attractive interaction between vicinal or neighboring hydroxyl oxygens and diazomethyl cation in the zwitterionic intermediate.

In order to confirm the above hypothesis, the stereoselectivities in the Grignard and diazomethane reactions and in sodium borohydride reduction of 2-*O*-methyl derivative (**2**)[5] of **1**, its 2-epimer (**3**),[6] β-anomer (**4**)[7] of **1** and its 2-*O*-methyl derivative (**5**)[8] were examined in this paper. Compound **5** was obtained by the dimethyl sulfoxide–trifluoroacetic anhydride oxidation[6,9] of methyl 4,6-*O*-benzylidene-2-*O*-methyl-β-D-altropyranoside which was synthesized by the preferential ring-opening of the corresponding 2,3-epoxide[10] of D-allo configuration with methanol. Epimerization at C-2 position during the oxidation could not be suppressed in this case.

Results

In general, diazomethane reaction was carried out in less polar solvent than benzene–ether–ethanol (1:1:1) to suppress the accompanying ring-expansion, and the Grignard reaction in benzene–ether at room temperature.

Reaction of **2** with diazomethane gave the corresponding spiro epoxide (**6**) in 73% yield which was reduced with lithium aluminium hydride to give the corresponding 3-*C*-methyl derivative (**7**), quantitatively. Besides, the reaction of **2** with methylmagnesium iodide gave the epimeric 3-*C*-methyl derivative (**8**) of **7** in a good yield which was methylated with sodium hydride and methyl iodide to give 3-*O*-methyl derivative (**9**). The same compound was obtained by *O*-methylation of known methyl 4,6-*O*-benzylidene-3-*C*-methyl-α-D-allopyranoside[3,11] which is the Grignard reaction product of **1**. The 3-*O*-methyl derivative (**10**) of **7** was not identical with **9**. These results indicate that the stereoselectivities in the both reactions of **2** are complemental as was depicted in the case of **1**.[2]

Diazomethane reaction of **3** gave the corresponding spiro epoxide (**11**) and ring-expansion product (**12**) in 41 and 36.9% yields, respectively, by the separation on a TLC. Reduction of **11** gave a 3-*C*-methyl derivative (**13**) which was identical with that obtained by the Grignard reaction of **3**. The configuration of **13** was determined to be D-altro from the following conversions. De-*O*-benzylidenation of **13** with 70% acetic acid and subsequent acetonation gave the corresponding 3,4-*O*-isopropylidene derivative (**14**) which gave the 6-*O*-acetate (**15**) by base-catalyzed acetylation. These results indicate that the tertiary hydroxyl group in **13** was protected by the acetonation, and consequently in *cis*-interrelation to the 4-hydroxyl group.

Chemical shifts of tertiary acetoxyl groups of 3-*O*-acetate of **8** (**16**: δ 2.04) and **13** (**17**: δ 2.00) in the region of axial one (δ 2.07—1.96) supported also the above configurational assignment, but, that of 3-*O*-acetate of **7** (**18**: δ 2.04) was not in agreement with equatorial one (δ 1.93—1.88).[12] Such instances were also reported in the case of nitromethyl-branching derivatives.[13] The position of ring methylene in ring-expanded **12** was determined to be C-3 from the coupling constants ($J_{1,2}$=6.2, $J_{2,3}$=11.0, $J_{2,3'}$=1.8, and $J_{3,3'}$=14.0 Hz) of ring protons.[14]

(**23**)	Me	OMe	H	OMe
(**27**)	H	OH	H	OMe

The configuration of the spiro epoxide (**19**) predominantly obtained by the diazomethane reaction of **4** was determined to be D-allo by the rotational change of the corresponding reductively cleaved product (**20**) in cupraammonium solution ($[M]_{436}$ −329.2°→ $[M]_{436}^{\text{cupra A}}$ +77.4°). The Grignard reaction of **4** gave a mixture of epimeric pair of 2-*O*-benzoates (**21** and **22**) and their de-*O*-benzoylated products from which **21**, **22**, and **20** were separated in a pure state on a TLC. The configuration of **21** was determined from the fact that partial benzoylation of **20** gave **21**. The ratio of epimers was measured after de-*O*-benzoylation with a densitometer. Diazomethane reaction of **5** gave the corresponding epimeric spiro epoxides (**23** and **24**) by the separation on a TLC, and the predominant product (**23**) was reduced into the 3-*C*-methyl derivative (**25**). The configuration of **25** was determined to be D-allo from the identity of 2,3-di-*O*-methyl derivative of **20** and 3-*O*-methyl derivative (**26**) of **25**. The Grignard reaction of **5** gave preferentially **25**.

As a standard for the comparison of stereoselectivities, reduction of **2**, **3** and **5** with sodium borohydride in methanol was also carried out. The configuration and the ratio of products were determined with NMR and/or densitomer, after conversion of the products into the corresponding 3-*O*-acetate. In all cases, a product caused by the equatorial attack (from the less-hindered upper side of the pyranose-ring) of the reagent was preferentially obtained, as is known in the cases of cyclohexanone derivatives.[15]

Table 1. Yields of products and the attacking direction of nucleophiles to the pyranose-ring in the reaction with methyl 4,6-*O*-benzylidene-α- and -β-D-hexopyranosid-3-uloses

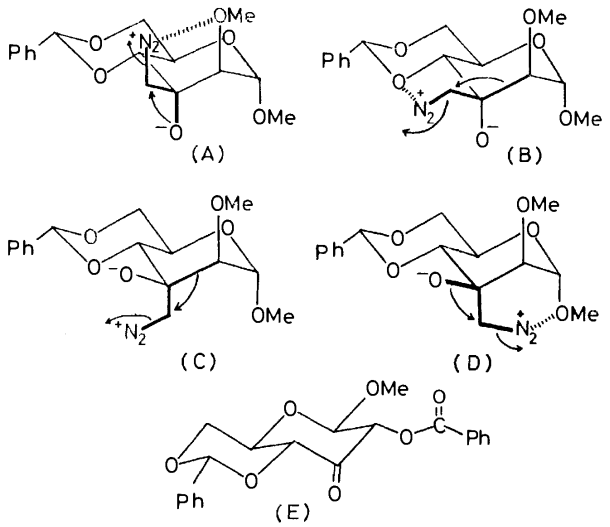
Discussion

Coupling constants ($J_{1,2}$ and $J_{4,5}$) of ring protons in starting materials used here [**2** (4.5 Hz and unclear), **3** (0 and 9.0 Hz), **4** (7.5 and 9.5 Hz), and **5** (7.5 and 9.5 Hz)] indicate that the pyranose ring of these compounds is in C_1 chair conformation flattened slightly by the introduction of the carbonyl group. Consequently, it is reasonable that nucleophiles preferentially attack the carbonyl group from the equatorial direction, unless any special factors control the stereoselectivity strongly. As shown in Table 1, compound **2** afforded similar results to that of **1** in which the Grignard reaction gave the normal product and diazomethane reaction showed an abnormal stereoselectivity by the electrostatic attractive effect of the oxygen atom in axial C_1-methoxyl group.



In the diazomethane reaction of **3**, three typical transition states (A, B, and C) will be considered for the formation of **11** and **12**. The state (A) in which

the conformation of diazomethylene cation is stabilized by the electrostatic attractive effect of axial C_2-methoxyl oxygen will give smoothly **11**. For the formation of **12** the state (B) in which the conformation of diazomethylene cation is stabilized by C_4-oxygen will be more probable than (C) in which no stabilizing effect can be expected. If diazomethane attacks the carbonyl group of **3** from axial direction as seen in (C), rather stable conformation (D) would afford the 3-epimer of **11**, and actually, a similar transition state should play the essential role in the formation of **6** from **2**. Thus, it will be concluded that **12** was formed *via* (B) and that the complemental stereoselectivity in diazomethane reaction of **2** and **3** is attributed to the more effective electrostatic attractive force of axial oxygen in α-position than β-position to the carbonyl group.

On the other hand, it is known that in reduction of alicyclic six-membered ketones, sodium borohydride produces more axial alcohol than lithium aluminum hydride, reflecting a greater effective size of the reagent.[16] Although there are no remarkable differences in the stereoselectivities of the Grignard reaction and sodium borohydride reduction, the differences in the results of **4** and **5** should be explained by C_2-substituents. However, results in the both reactions of **4** can not compare in the same sense with others, because 2-*O*-benzoyl group is hydrolzyed in reduction and reacts with the Grignard reagent. Nevertheless, it is common that the stereoselectivities in the both reactions of 2-*O*-benzoyl derivatives, **1** and **4**, are lower than those of 2-*O*-methyl derivatives. Higher stereoselectivity in diazomethane reaction of **4** than that of **5** may suggest an attractive effect of carbonyl oxygen of benzoyl group which is placed in the upper region of the pyroanosering as shown in (E).

From the results mentioned above, the followings will be concluded. 1) Diazomethane having zwitterionic structure attacks 3-uloses from the side of axial alkoxyl group nearer to the carbonyl group by the electrostatic attractive force of oxygen atom which is also stabilize the conformation of diazomethyl cation in the transition state. Thus, the stereoselectivity in diazomethane reaction of **1** and **2** is complemental to that in usual reactions, whereas, it is the same in the reactions of **3**. 2) When a 3-ulose has no axial substituent, the stereoselectivity in the diazomethane reaction is controlled by the same steric factors as in other reactions.

Experimental

All melting points were uncorrected. The solutions were evaporated under reduced pressure at a bath temperature not exceeding 50 °C. Optical rotations were measured in a 0.2-dm tube with Carl Zeiss LEP-Al polarimeter in chloroform unless otherwise stated. IR spectra were recorded with Hitachi Model EPI-G2 spectrometer. NMR spectra were taken with JEOL SP-100 spectrometer in deuteriochloroform containing TMS as an internal reference. Chemical shifts and coupling constants were recorded in δ and Hz units, and IR frequencies in cm^{-1}.

*Methyl 4,6-O-Benzylidene-2-O-methyl-β-D-*ribo*-hexopyranosid-3-ulose (5).* A solution of methyl 2,3-anhydro-4,6-*O*-benzylidene-β-D-allopyranoisde[8] (2 g, 7.6 mmol) and sodium (2 g) in methanol (50 ml) was refluxed for 24 h, poured into water, and then extracted with chloroform. An usual work up of the extract and fractional crystallization of the product from ethanol–hexane and ether–hexane gave the corresponding 2-*O*-methyl-β-D-altropyranoside [mp 122—124 °C; $[\alpha]_D^{22}$ −60.5° (*c* 1.0); Found: C, 59.96; H, 6.91%. Calcd for $C_{15}H_{20}O_6$: C, 60.80; H, 6.80%; coupling constants ($J_{1,2}=1.2$, $J_{2,3}=J_{3,4}=3.0$, $J_{4,5}=9.0$) in the NMR spectrum of the corresponding 3-*O*-acetate supported the structure] and 3-*O*-methyl-β-D-glucopyranoside [mp 168—170 °C; $[\alpha]_D^{22}$ −50.0° (*c* 1.4); lit,[17] mp 172—173 °C, $[\alpha]_D^{14}$ −40.0° (*c* 0.3). Found: C, 60.28; H, 6.77%. Calcd for $C_{15}H_{20}O_6$; C, 60.80; H, 6.80%; coupling constants ($J_{1,2}=J_{2,3}=8.0$, $J_{3,4}=J_{4,5}=7.5$) in the NMR spectrum of the corresponding 2-*O*-acetate supported the structure] in 45 and 8% yields, respectively.

Oxidation of the above β-D-altropyranoside with dimethyl sulfoxide–trifluoroacetic anhydride under a similar condition reported before[6] afforded **5**, accompanying with the epimerization of 2-*O*-methoxyl group, in 89% yield which was recrystallized from ethanol. Mp 217—219 °C; $[\alpha]_D^{22}$ −110.5° (*c* 0.9) (lit,[8] mp 178—180 °C, $[\alpha]_D^{22}$ −128.2°); IR: 1735 (C=O); NMR: 7.60—7.25 (Ph: m); 5.54 (PhCH); 4.51 (H_1: d, $J_{1,2}=7.5$), 4.49 (H_6: q, $J_{5,6}=4.5$), 4.28 (H_4: q, $J_{4,5}=9.6$, $J_{2,4}=1.5$), 3.89 ($H_{6'}$: t, $J_{5,6'}=J_{6,6'}=9.8$), 3.78 (H_2: q), 3.64 (H_5: sex), 3.60 (2×OMe).

Found: C, 61.21; H, 6.18%. Calcd for $C_{15}H_{18}O_6$: C, 61.21; H, 6.17%.

Reaction of 3-Uloses (2—5) and Diazomethane. To a suspension of **2** (294 mg, 1.0 mmol) in ethanol (30 ml) was added dropwise a solution of diazomethane (2.0 mmol) in ether (10 ml) at 0 °C. With proceeding of the reaction, the mixture turned to homogeneous. After keeping the mixture at room temperature for 12 h, the solution was evaporated to give a crystalline methyl 3,3′-anhydro-4,6-*O*-benzylidene-3-*C*-hydroxymethyl-2-*O*-methyl-α-D-glucopyranoside (**6**), which was recrystallized from benzene–hexane. The diazomethane reaction did not proceed in the benzene–ethanol (30 ml, 1:1) in this case. Yield, 167 mg (57%); mp 131—133 °C, $[\alpha]_D^{22}$ +76.5° (*c* 0.6), NMR: 7.44—7.20 (Ph: m), 5.45 (PhCH), 4.89 (H_1: d, $J_{1,2}=4.0$), 4.35—4.17 (H_5: m), 3.84 ($H_{6'}$:t, $J_{5,6'}=J_{6,6'}=9.0$), 3.84—3.67 (H_4, H_5 and H_6: m), 3.61 (H_2: d), 3.05 (epoxy CH_2: s), 3.49 and 3.44 (2×OMe).

Found: C, 62.10; H, 6.57%. Calcd for $C_{16}H_{20}O_6$: C, 62.32; H, 6.54%.

A similar reaction of **3** (294 mg. 1.0 mmol) in benzene–ethanol (30 ml, 1:1) with diazomethane, and sepatartion of two products on a preparative TLC (ether:hexane=1:1) gave methyl 3,3′-anhydro-4,6-*O*-benzylidene-3-*C*-hydroxymethyl-2-*O*-methyl-α-D-altropyranoside (**11**) and a ring-expanded product (**12**) in 41.0% and 36.9% yields, respectively.

11: Mp 141—143 °C (from ether–hexane), $[\alpha]_D^{22}$ +76.1° (*c* 2.1), NMR: 7.55—7.27 (Ph: m), 5.55 (PhCH), 4.76 (H_1: s), 4.44—4.12 (H_4, H_6, and $H_{6'}$: m), 3.86 (H_5: m), 3.18 and 2.75 (epoxy CH_2: ABq, $J=4.8$), 3.44 (2×OMe), 3.06 (H_2: s).

Found: C, 61.58; H, 7.05%. Calcd for $C_{16}H_{20}O_6$: C, 62.32; H, 6.54%.

12: Mp 157—160 °C (from ether–hexane), $[\alpha]_D^{22}$ +91.6 °C (*c* 0.5), NMR: 7.55—7.27 (Ph: m), 5.46 (PhCH), 4.48 (H_1: d, $J_{1,2}=6.2$), 4.72 (H_7: q, $J_{6,7}=4.4$), 4.04 (H_6: m), 3.85 (H_5: d, $J_{5,6}=9.0$), 3.67 (H_2: octet), 3.62 ($H_{7'}$: t, $J_{7,7'}=J_{6,7'}=8.8$), 3.23 and 2.73 (epoxy CH_2: ABq, $J=5.6$), 2.34 (H_3: q, $J_{2,3}=11.0$), 1.45 ($H_{3'}$: q, $J_{2,3'}=1.8$, $J_{3,3'}=14.0$), 3.44 and 3.37 (2×OMe).

Found: C, 63.31; H, 6.84%. Calcd for $C_{17}H_{22}O_6$: C, 63.34; H, 6.88%.

Reaction of **4** and diazomethane in a similar manner as above gave methyl 3,3′-anhydro-2-*O*-benzoyl-4,6-*O*-benzylidene-3-*C*-hydroxymethyl-β-D-allopyranoside (**19**) as a sirup in 90.2% yield. $[\alpha]_D^{27}$ −32.6° (*c* 1.9), NMR: 8.13—7.95 and 7.60—7.24 (Ph: m), 5.54 (PhCH), 5.42 (H_1: d, $J_{1,2}$=7.5), 4.83 (H_2: d), 4.43 (H_5: m), 3.58—4.03 (H_4, H_6, and $H_{6'}$: m), 3.10 and 2.72 (epoxy CH_2: ABq, J=4.5), 3.55 (OMe).

Found: C, 65.95; H, 5.46%. Calcd for $C_{22}H_{22}O_7$: C, 66.32; H, 5.57%.

A similar reaction of **5** (294 mg, 1.0 mmol) in benzene-ethanol (10 ml, 1:1) with diazomethane and the separation of two products in a similar way gave the epimeric pair of spiro epoxides, methyl 3,3′-anhydro-4,6-*O*-benzylidene-3-*C*-hydroxymethyl-2-*O*-methyl-β-D-allopyranoside (**23**) and the corresponding β-D-glucopyranoside (**24**) in 76.5 and 17.6% yields, respectively.

23: Mp 157—158 °C, $[\alpha]_D^{22}$ −63.8° (*c* 1.1), NMR: 7.56—7.23 (Ph: m), 5.51 (PhCH), 4.58 (H_1: d, $J_{1,2}$=7.5), 4.23—4.47 (H_6: m), 3.95—3.60 (H_4, H_5, and $H_{6'}$: m), 3.37 (H_2: d), 3.10 and 3.01 (epoxy CH_2: ABq, J=5.7), 3.59 and 3.55 (2×OMe).

Found: C, 62.53; H, 6.47%. Calcd for $C_{16}H_{20}O_6$: C, 62.32; H, 6.54%.

24: Mp 150—151 °C, $[\alpha]_D^{22}$ −74.9° (*c* 1.0), NMR: 7.55—7.20 (Ph: m), 5.46(PhCH), 4.35 (H_6: q, $J_{5,6}$=5.0), 4.34 (H_1: d, $J_{1,2}$=7.6), 3.83 (H_4: d, $J_{4,5}$=9.5), 3.77 ($H_{6'}$: t, $J_{5,6'}$=$J_{6,6'}$=10.4), 3.65—3.35 (H_5: m), 3.36 (H_2: d), 3.06 (epoxy CH_2: s), 3.47 and 3.55 (2×OMe).

Found: C, 62.22; H, 6.51%. Calcd for $C_{16}H_{20}O_6$: C, 62.32; H, 6.54%.

*Hydrogenation of Spiro Epoxides (**6**, **11**, **19**, and **23**) with Lithium Aluminium Hydride.* To a solution of **6** (150 mg, 0.52 mmol) in tetrahydrofuran (THF, 20 ml) was added lithium aluminium hydride (LAH, 50 mg), and then the mixture was stirred at room temperature for 1 h. The excess hydride was carefully decomposed with water, and then filtered. The water layer was extracted with chloroform. The combined extract was washed with water, dried with anhydrous magnesium sulfate, and evaporated to give a colorless sirup of methyl 4,6-*O*-benzylidene-3-*C*:2-*O*-dimethyl-α-D-glucopyranoside (**7**). The sirup was purified with preparative TLC (benzene:acetone=8:1, R_f=0.25). Yield 92%, $[\alpha]_D^{22}$+67.4° (*c* 1.2), NMR: 7.60—7.20 (Ph: m), 5.49 (PhCH), 4.84 (H_1: d, $J_{1,2}$=4.0), 4.28 (H_5: m), 3.80—3.30 (H_2, H_4, H_6, and $H_{6'}$: m), 3.42 and 3.30 (2×OMe), 2.43 (OH: s), 1.46 (Me).

Found: C, 61.87; H, 7.16%. Calcd for $C_{16}H_{22}O_6$: C, 61.92; H, 7.15%.

A similar reduction of **11** (150 mg, 0.52 mmol) in THF (10 ml) as above gave methyl 4,6-*O*-benzylidene-3-*C*:2-*O*-dimethyl-α-D-altropyranoside (**13**) in quantitative yield, which was crystallized from ether-hexane. Mp 88—91 °C, $[\alpha]_D^{22}$ +26.6° (*c* 2.1), IR: 3530 (OH), NMR: 7.60—7.20 (Ph: m), 5.58 (PhCH), 4.79 (H_1: broad s), 4.33 (H_6: q), 4.06 (H_5: sex), 3.80 ($H_{6'}$: t, $J_{5,6'}$=$J_{6,6'}$=8.6), 3.67 (H_4: d, $J_{4,5}$ =9.0), 3.15 (H_2: s), 3.49 and 3.46 (2×OMe), 1.38 (Me).

Found: C, 61.99; H, 7.19%. Calcd for $C_{16}H_{22}O_6$: C, 61.92; H, 7.15%.

A similar hydrogenation of **19** (150 mg) in THF (5 ml) as above gave methyl 4,6-*O*-benzylidene-3-*C*-methyl-β-D-allopyranodise (**20**) in 87% yield. Mp 123—125 °C (from benzene-hexane). $[\alpha]_D^{22}$ −53.2° (*c* 1.2), IR: 3480 (OH), NMR: 7.50—7.16 (Ph: m), 5.47 (PhCH), 4.47 (H_1: d, $J_{1,2}$=8.0), 4.33 (H_6: q, $J_{5,6}$=3.6), 3.67 ($H_{6'}$: t, $J_{5,6'}$=$J_{6,6'}$=10.0), 3.30 (H_4: d, $J_{4,5}$=9.6), 3.20 (H_2: d), 3.50 (OMe), 1.40 (Me).

Found: C, 60.52; H, 6.73%. Calcd for $C_{15}H_{20}O_6$; C, 60.80; H, 6.80%.

A similar hydrogenation of **23** (100 mg) in THF (5 ml) afforded methyl 4,6-*O*-benzylidene-3-*C*:2-*O*-dimethyl-β-D-allopyranoside (**25**) in 92% yield, which was crystallized from ethanol hexane. Mp 150—151 °C, $[\alpha]_D^{22}$ −79.8° (*c* 1.3), IR: 3525 and 3400 (OH), NMR: 7.50 —7.16(Ph: m), 5.47 (PhCH), 4.47 (H_1: d, $J_{1,2}$=8.0), 4.43 (H_6: q, $J_{5,6}$ =3.6), 3.67 ($H_{6'}$: t, $J_{5,6'}$=10.0), 3.30 (H_4: d, $J_{4,5}$=9.6), 3.20 (H_2: d), 3.50 (OMe), 1.40 (Me).

Found: C, 61.91; H, 7.05%. Calcd for $C_{16}H_{22}O_6$: C, 61.92; H, 7.15%.

*Reaction of 3-Uloses (**2**—**5**) with Methylmagnesium Iodide.* To a solution of methylmagnesium iodide in ether (5 ml)-benzene (5 ml) prepared from magnesium turnings (60 mg, 2.47 mmol) and methyl iodide (1 ml) was added **2** (294 mg, mmol) in benzene (5 ml), and the reaction mixture was kept at room temperature for 1.5 h, poured into cold ammonium chloride solution. The resulting solution was extracted with dichloromethane. The extract was washed with water and evaporated to give a white powder of methyl 4,6-*O*-benzylidene-3-*C*:2-*O*-dimethyl-α-D-allopyranoside (**8**) which was crystallized from ethanol-hexane. Yield, 93.2%, mp 140—142° C, $[\alpha]_D^{22}$ +85.0° (*c* 1.5), IR: 3530 (OH), NMR: 7.65—7.27 (Ph: m), 5.55 (PhCH), 4.94 (H_1: d, $J_{1,2}$=3.8), 4.37 (H_6: q, $J_{5,6}$=4.8), 4.10 (H_5: sex), 3.72 ($H_{6'}$:t, $J_{5,6'}$=$J_{6,6'}$=9.8), 3.37 (OH), 3.30 (H_4: d, $J_{4,5}$=9.0), 3.15 (H_2: d), 3.55 and 3.49 (2×OMe), 1.42 (Me).

Found: C, 61.60; H, 7.06%. Calced for $C_{16}H_{22}O_6$: C, 61.92, H, 7.15%.

A similar reaction of **3** and methylmagnesium iodide as above gave **13** in 95.4% yield, which was identical with the authentic sample obtained *via* the diazomethane reaction of **3**.

Reaction of **4** and methyl magnesium iodide in a similar manner as above and separation of three products on a preparative TLC (benzene: acetone=8:1) gave methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-3-*C*-methyl-β-D-allopyranodide (**21**), its 3-epimer (**22**) and de-benzoylated product, **20** in 33, 8, and 19% yields, respectiviely.

21: Mp 180—181 °C (from benzene-hexane), $[\alpha]_D^{22}$ −40.3° (*c* 1.7), IR: 3540 and 3475 (OH), 1724 and 1690 (ester), NMR: 8.15—8.00 and 7.60—7.20 (Ph: m), 5.65(PhCH), 5.02 and 4.86 (H_1 and H_2: each d, $J_{1,2}$=8.0), 4.35 (H_4: d, $J_{4,5}$=8.0), 4.00 (H_5: sex), 4.40 (H_6: q, $J_{5,6}$=4.0), 3.77 ($H_{6'}$: t, $J_{5,6}$=$J_{6,6'}$=10.0), 3.47 (OMe), 2.07 (OH), 1.35 (Me).

Found: C, 65.15; H, 5.93%. Calcd for $C_{22}H_{24}O_7$: C, 65.99; H, 6.04%.

22: $[\alpha]_D^{22}$ −37.2° (*c* 1.5), IR: 3500 (OH), 1735 (ester), NMR: 8.20—8.04 and 7.70—7.27 (Ph: m), 5.58 (PhCH), 5.18 (H_2: d, $J_{1,2}$=8.0), 4.57 (H_1: d), 4.39 (H_6: q, $J_{5,6}$=4.2), 3.82 ($H_{6'}$: t, $J_{5,6'}$=$J_{6,6'}$=10.0), 3.82—3.54 (H_4 and H_5: m), 3.49 (OMe), 2.60 (OH: broad s), 1.50 (Me).

20: all phisical constants were identical with the authentic sample which was derived from the reaction of **4** and diazomethane.

Grignard reaction of **5** in a similar way as above gave **25** in 94.2% yield, which was identical with the authentic sample obtained *via* the diazomethane reaction of **5**.

*O-Methylation of 3-C-Methyl Derivatives (**7**, **8**, **20**, and **25**) with Sodium Hydride and Methyl Iodide.* To a solution of **7** (50 mg. 0.16 mmol) and sodium hydride (10 mg, 0.42 mmol) in DMF (1 ml) was added methyl iodide (0.1 ml) at

0 °C. After keeping the mixture at room temperature for 30 min, the solution was poured into cold water, and the water layer was extracted with ether. The extract was evaporated to gave sirupy methyl 4,6-*O*-benzylidene-3-*C*-methyl-2,3-di-*O*-methyl-α-D-glucopyranoside (**10**) in a good yield. $[\alpha]_D^{22}$ +56.4° (*c* 1.7), NMR: 7.60—7.24 (Ph: m), 5.54 (PhCH), 4.82 (H_1: d, $J_{1,2}$=4.0), 4.28 (H_6: m), 3.87—3.60 (H_4, H_5, and $H_{6'}$: m), 3.34 (H_2: d), 3.52, 3.43, and 3.40 (3×OMe), 1.47 (Me).

Found: C, 62.31; H, 7.66%. Calcd for $C_{17}H_{24}O_6$: C, 62.95; H, 7.46%.

A similar methylation of **8** gave methyl 4,6-*O*-benzylidene-3-*C*-methyl-2,3-di-*O*-methyl-α-D-allopyranoside (**9**) in a quantitative yield which was recrystallized from hexane. Mp 91—92 °C, $[\alpha]_D^{22}$ +95.6° (*c* 2.1), NMR: 7.60—7.20 (Ph: m), 5.41 (PhCH), 4.85 (H_1: d, $J_{1,2}$=4.0), 4.45—4.10 (H_5 and H_6: m), 3.80—3.35 (H_4 and $H_{6'}$: m), 3.09 (H_2: d), 3.45, 3.44 and 3.43 (3×OMe), 1.46 (Me).

Found: C, 63.00; H, 7.43%. Calcd for $C_{17}H_{24}O_6$: C, 62.95; H, 7.46%.

A similar methylation of methyl 4,6-*O*-benzylidene-3-*C*-methyl-α-D-allopyranoside[2] gave also **9** in a good yield.

Methylation of **20** in a similar manner as above gave sirupy methyl 4,6-*O*-benzylidene-3-*C*-methyl-2,3-di-*O*-methyl-β-D-allopyranoside (**26**) in 89% yield which was crystallized from ether-hexane. Mp 94—95 °C, $[\alpha]_D^{22}$ −45.1° (*c* 1.7), NMR: 7.56—7.27 (Ph: m), 5.39 (PhCH), 4.72 (H_1: d, $J_{1,2}$=8.0), 4.36 (H_6: q, $J_{5,6}$=4.5), 3.90 (H_5: m), 3.68 ($H_{6'}$: t, $J_{5,6'}=J_{6,6'}$=9.8), 3.34 (H_4: d, $J_{4,5}$=9.0), 2.78 (H_2: d), 3.56, 3.52, and 3.47 (3×OMe), 1.49 (Me).

Found: C, 62.82; H, 7.88%. Calcd for $C_{17}H_{24}O_6$: C, 62.95; H, 7.46%.

Methylation of **25** gave also compound **26** in a good yield.

Determination of the Configuration of ***13***. To a solution of **13** (150 mg, 0.48 mmol) in 70% aqueous acetic acid was refluxed until the starting material disappeared on TLC (benzene:acetone=8:1). Then the solution was evaporated to give a sirup which was chromatographically homogeneous.

A solution of the sirup and anhydrous copper(II) sulfate (300 mg) in acetone (10 ml) containing one drop of sulfuric acid was stirred for 24 h at room temperature, neutralized with barium carbonate, filtered, and the filtrate was evaporated to give a sirupy methyl 3,4-*O*-isopropyliden-3-*C*-2-*O*-dimethyl-α-D-altropyranoside (**14**) in 73% yield, which was purified on TLC (ether:hexane=1:1). $[\alpha]_D^{22}$ +112.3° (*c* 1.4), IR: 3480 (OH), NMR: 4.37 (H_1: d, $J_{1,2}$=6.0), 4.00—4.30 (H_4, H_5, H_6 and $H_{6'}$: m), 3.30 (H_2: d), 3.60 and 3.46 (2×OMe), 2.15 (OH: broad s), 1.52 and 1.43 (isopropylidene-Me), 1.37 (Me).

Found: C, 54.98: H, 8.35%. Calcd for $C_{12}H_{22}O_6$: C, 54.95; H, 8.45%.

Base-catalyzed acetylation of **14** gave a sirupy methyl 6-*O*-acetyl-3,4-*O*-isopropylidene-3-*C*,2-*O*-dimethyl-α-D-altropyranoside (**15**) in a quantitative yield. $[\alpha]_D^{22}$ +101.9° (*c* 1.0). IR: 1740 (ester), NMR: 4.35 (H_1: d, $J_{1,2}$=6.0), 4.50—3.87 (H_5, H_6, and $H_{6'}$: m), 3.83 (H_4: d, $J_{4,5}$=9.0), 3.28 (H_2: d), 3.57 and 3.28 (2×OMe), 2.12 (OAc), 1.49 and 1.40 (isopropylidene-Me), 1.35 (Me).

Found: C, 55.33; H, 7.98%. Calcd for $C_{14}H_{24}O_7$: C, 55.25; H, 7.95%.

Acid-catalyzed Acetylation of Tertiary Hydroxyl Gruop in ***7***, ***8***, *and* ***13***. A solution of **7** (100 mg) and *p*-toluensulfonic acid (10 mg) in acetic anhydride (3 ml) was stirred at room temperature for 1.5 h, poured into ice-water, and the resulted solution was extracted with chloroform. The extracts were washed with sodium hydrogencarbonate and then water, dried and evaporated to give methyl 3-*O*-acetyl-4,6-*O*-benzylidene-3-*C*:2-*O*-dimethyl-α-D-glucopyranoside (**18**) which was recrystallized from ethanol-hexane. Yield, 92%; mp 111.5—112.5 °C; $[\alpha]_D^{22}$ +11.9° (*c* 1.4) IR: 1720 (ester), NMR: 7.60—7.25 (Ph: m), 5.53 (PhCH), 4.90 (H_1: d, $J_{1,2}$=4.2), 4.78 (H_4: d, $J_{4,5}$=9.0), 4.62 (H_2: d), 4.45—4.15 and 3.95—3.60 (H_5, H_6 and $H_{6'}$: m), 3.51 and 3.43 (2×OMe), 2.04 (OAc), 1.55 (Me).

Found: C, 59.86; H, 6.69%. Calcd for $C_{18}H_{24}O_7$: C, 61.35; H, 6.86%.

Acid-catalyzed acetylation of **8** in a similar way as above gave methyl 3-*O*-acetyl-4,6-*O*-benzylidene-3-*C*:2-*O*-dimethyl-α-D-allopyranoside (**16**) in 94% yield, which was crystallized from ethanol-hexane. Mp 192—194 °C, $[\alpha]_D^{22}$ +39.2° (*c* 0.6), IR: 1738 (ester), NMR: 7.60—7.27 (Ph: m), 5.53 (PhCH), 4.86 (H_1: d, $J_{1,2}$=4.0), 4.33 (H_6: q, $J_{5,6}$=5.0), 4.22 (H_5: m), 3.68 ($H_{6'}$: t, $J_{5,6'}=J_{6,6'}$=9.0), 3.32, (H_4: d, $J_{4,5}$=9.2), 3.14 (H_2: d), 3.56 and 3.46 (2×OMe), 2.04 (OAc), 1.94 (Me).

Found: C, 61.49; H, 6.32%. Calcd for $C_{18}H_{24}O_7$: C, 61.35; H, 6.86%.

A similar acetylation of **13** as above gave methyl 3-*O*-acetyl-4,6-*O*-benzylidene-3-*C*:2-*O*-dimethyl-α-D-altropyranoside (**17**) in 91% yield, which was crystallized from benzene-hexane. Mp 189—191 °C, $[\alpha]_D^{22}$ +34.9° (*c* 0.7), IR: 1730 (ester), NMR: 7.64—7.28 (Ph: m), 5.55 (PhCH), 4.68 (H_1: d, $J_{1,2}$=1.4) 4.34 (H_2: d), 4.45—4.10 and 3.90—3.60 (H_4, H_5, H_6 and $H_{6'}$: m), 3.52 and 3.38 (2×OMe), 2.00 (OAc), 1.70 (Me).

Found: C, 61.55; H, 6.85%. Calcd for $C_{18}H_{24}O_7$: C, 61.35; H, 6.86%.

Partial Benzoylation of ***20*** *with Benzoic Anhydride.* A solution of **20** (150 mg, 0.51 mmol) and benzoic anhydride (175 mg, 0.77 mmol) in pyridine (2 ml) was stirred at room temperature for 12 h, poured into ice-water, and the resulting solution was extracted with chloroform. The usual work up of the extracts gave **21** which was identical with that obtained by the reaction of **4** with methylmagnesium iodide.

*Hydrogenation of 3-Uloses (****2****, ****3****, and* ***5****) with Sodium Borohydride in Mathenol.* To a vigorously stirring solution of **2** (100 mg) in methanol (15 ml) was added dropwise a solution of sodium borohydride (400 mg) in methanol (8 ml). After the reduction was continued for 10 min at room temperature, acetic acid was added to the reaction mixture to decompose the excess hydride, and the resulting solution was evaporated. An aqueous solution of the crude product was extracted with chloroform in a usual manner to give sirupy product. The configuration and the ratio of products were examined with NMR spectrometer and/or densitomether after conversion into the corresponding *O*-acetate by a usual method. In this case, only methyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-*O*-methyl-α-D-allopyranoside was obtained in 82% yield. Mp 116—117 °C, (from ethanol-hexane), IR: 1738 (ester), $[\alpha]_D^{22}$ +78.8° (*c* 0.7), NMR: 7.60—7.25 (Ph: m), 5.90 (H_3: t, $J_{2,3}=J_{3,4}$=3.0), 4.83 (H_1: d, $J_{1,2}$=4.0), 4.30 (H_5: m, $J_{4,5}$=9.6), 4.16 (H_6: q, $J_{5,6}$=5.0), 3.70 ($H_{6'}$: t, $J_{5,6'}=J_{6,6'}$=9.6), 3.62 (H_4: q, $J_{4,5}$=9.6), 3.47 and 3.45 (2×OMe), 2.17 (OAc).

Found: C, 60.36; H, 6.61%. Calcd for $C_{17}H_{22}O_7$: C, 60.34; H, 6.55%.

A similar reduction of **3** and subsequent acetylation of the product gave sirupy methyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-*O*-methyl-α-D-altropyranoside in 77.9% yield. $[\alpha]_D^{22}$ +113.1° (*c* 1.9), NMR: 7.65—7.20 (Ph: m), 5.57 (PhCH), 5.27 (H_3: t, $J_{2,3}=J_{3,4}$=3.2), 4.66 (H_1: s), 3.49 and 3.88 (2×OMe), 2.09 (OAc).

Reduction and acetylation of **5** as above gave epimeric mixture of methyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-*O*-methyl-β-D-glucopyranoside and -allopyranoside in 75.1 and 16.6%

yields, respectively. NMR data of the mixture was the following: major product: 7.60—7.24 (Ph: m), 5.85 (H_3: t, $J_{2,3}=J_{3,4}=3.0$), 5.50 (PhCH), 4.62 (H_1: d, $J_{1,2}=9.0$), 4.37 (H_6: q, $J_{5,6}=3.4$, $J_{6,6'}=8.4$), 4.03—3.46 (H_4, H_5 and $H_{6'}$: m), 3.20 (H_2: q), 3.55 and 3.44 (2×OMe), 2.14 (OAc). Minor product: 5.45 (PhCH), 5.24 (H_3: t, $J_{2,3}=J_{3,4}=9.4$), other protons could not be assigned.

The authors are indebted to the members of the Laboratory of Organic Analysis for microanalysis and to Mr. H. Matsumoto for NMR measurements.

Synthesis of 6-*O*-Acyl Derivatives of Immunoadjuvant Active *N*-Acetylmuramyl-L-alanyl-D-isoglutamine[1]

Shoichi KUSUMOTO, Satoshi OKADA, Koji YAMAMOTO, and Tetsuo SHIBA*

(Received December 26, 1977)

Seven acyl derivatives of *N*-acetylmuramyl-L-alanyl-D-isoglutamine, which had previously been shown to be a minimum structure required for the immunoadjuvant activity, were synthesized in order to evaluate the significance of lipophilicity on the adjuvant activity and on the possible antitumor effect. Among them, are included 6-*O*-docosanoyl, stearoyl, lauroyl, octanoyl, butyryl, acetyl, and 4,6-di-*O*-acetyl derivatives. Some of these compounds were found to serve an improvement in the administration method to living body.

Synthetic studies by us[2] as well as Merser *et al.*[3] had established that a minimum structure required for the "immunoadjuvant activity" of bacterial cell walls is *N*-acetylmuramyl-L-alanyl-D-isoglutamine (**1**), which corresponds to a common building unit of the cell wall peptidoglycans. The synthetic muramyl dipeptide (**1**) enhanced distinctly both humoral and cellular immunities of living bodies towards various antigens. Since that time, it became possible to discuss the immunopotentiating activity in a sense of molecular level. Meanwhile, we have already reported a synthesis of the labelled compound of **1** for the purpose of an elucidation of the action mechanism of such unique molecule.[4] Relationships between structure and activity of the muramyl peptides were also investigated by syntheses of various analogs of **1**.[2,5]

Our synthetic effort was next brought in focus on the following two subjects, namely, i) an improvement in the administration method of the muramyl dipeptide (**1**) which exhibited the adjuvant activity in the injection only in an emulsified form of water in mineral oil; ii) a possible appearance of an antitumor activity in derivatives of the muramyl peptides on an extended line of the adjuvant activity. It has long been known that even bacterial cell walls must be injected in a form of water in mineral oil emulsion for test of the adjuvant activity.[6] Synthetic muramyl dipeptide (**1**) also requires such physical form. These facts may indicate that the physical state predominates over the chemical entity in this biological action. Furthermore, the mineral oil emulsion causes a severe tissue reaction like the skin swelling in tested animals and may not be applicable to human beings. Therefore, a derivative of the muramyl peptide which can be used in a form other than emulsion to the living bodies has been desired not only for a clarification of physical character of the adjuvant active material, but also for the therapeutic purpose.[7] It could be assumed that the immunoactive substance must be anyhow transported to a lipophilic region in lymph system. A role of the mineral oil in the emulsion may be related to an importance of the lipophilicity in this action, although it is not quite clear.[8] Therefore, we anticipated that the use of the mineral oil could be avoided if enough lipophilicity is given to the molecule of muramyl dipeptide (**1**).

On the other hand, an antitumor effect of BCG cell wall has been understood on the basis of the immunoadjuvant activity.[9] Although the distinct adjuvant activity was observed in *N*-acetylmuramyl-L-alanyl-D-isoglutamine (**1**) as mentioned before, it did not show any antitumor activity so far.[10] One of the big differences between BCG cell wall and **1** itself must be in a lack of the lipophilicity in the latter, since the BCG cell wall is covered with a long-chain fatty acid, *i.e.*, mycolic acid, on the surface. Now, an assumption is made that the lipophilicity in the molecule may be required for the antitumor effect, if the muramyl peptide moiety is also essential to this activity.

In these respects, we planned to prepare several acyl derivatives of the muramyl dipeptide (**1**) for investigation of the biological activities. For the synthesis, the primary hydroxyl group at C-6 of muramic acid moiety in **1** was chosen for introduction of various acyl groups.[11]

Two alternative pathways for the synthesis of 6-*O*-acyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamines (**2**) were tested in terms of 6-*O*-stearoyl derivative (**2e**) to elucidate whether the muramic acid moiety should be first condensed with the acyl group (route A) or with the peptide moiety (route B).

The synthesis *via* route A was carried out by an introduction of stearoyl group to benzyl *N*-acetyl-α-muramide (**3**) prior to coupling with the peptide moiety. Selective stearoylation of the primary hydroxyl group in **3** was performed by use of mixed anhydirde with trifluoroacetic acid[12] though in a rather low yield. Thus, two monostearoyl products were isolated from the reaction mixture after silica gel column chromatography. From elemental analyses and spectral data, the slower moving product was assumed to be the desired 1-α-*O*-benzyl-6-*O*-stearoyl-*N*-acetylmuramic acid (**4**) while the faster one, without free carboxyl group in it, was determined to be an intramolecular ester (**5**) of the former. The 6- rather than 4-*O*-acyl structure for the compound **4** was deduced by its conversion into **5** by treatment with dicyclohexylcarbodiimide. Use of stearoyl chloride in the above acylation did not improve the yield of **4**. Condensation of stearoyl muramic acid (**4**) with L-alanyl-D-isoglutamine benzyl ester[2b] with dicyclohexylcarbodiimide–*N*-hydroxysuccinimide gave the protected stearoyl muramyl dipeptide (**7e**), *i.e.*, 1-α-*O*-benzyl-6-*O*-stearoyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine benzyl ester, in a good yield. Hydrogenolytic deprotection of **7e** in acetic acid afforded 6-*O*-stearoyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine (**2e**).

Synthesis of the stearoyl derivative (**2e**) *via* route B

was then examined starting from the protected muramyl dipeptide,[2b] *i.e.*, 4,6-*O*-benzylidene-1-α-*O*-benzyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine benzyl ester. The benzylidene group of this compound was selectively removed in the usual manner with 60% acetic acid to afford 1-α-*O*-benzyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine benzyl ester (**6**), which was then treated with stearoyl chloride in a mixture of pyridine and tetrahydrofuran (THF). For the selective acylation of the primary hydroxyl group, a short reaction time and use of large excess of the chloride were preferable. When the reaction was stopped just after the disappearance of the starting material in the reaction mixture, **7e** was obtained as a practically sole product. The structure of **7e** was identified with the compound prepared above *via* route A by means of NMR and TLC. It was then converted into free stearoyl muramyl dipeptide (**2e**) similarly as described above.

Ample solubilities of 6-*O*-stearoyl derivative (**2e**) thus obtained both in chloroform and in water may indicate a detergent-like property of this compound, and actually its aqueous solution showed vigorous foaming in a procedure of evaporation *in vacuo*.[13] Since **2e** showed enough adjuvant activity in a preliminary test, we then synthesized various acyl derivatives of **1**, *i.e.*, acetyl, butyryl, octanoyl, lauroyl, and docosanoyl derivatives, in order to compare the effect of the acyl groups on the activity.

For the syntheses of these acyl derivatives, we adopted the route B rather than A, since the muramyl dipeptide derivative (**6**) can be used as a common synthetic intermediate in the former route and the intramolecular ester formation, which was observed in the route A, could be avoided by a prior introduction of the peptide moiety. On acetylation of **6** with acetic anhydride, 6-*O*-monoacetate (**7a**) was obtained at 0 °C and 4,6-di-*O*-acetate (**8**) at above room temperature. The protected 6-*O*-butyryl, octanoyl, lauroyl, and docosanoyl derivatives (**7b—d, f**) were prepared by use of the corresponding acid chlorides on the muramyl dipeptide (**6**) in a similar manner to that described for the stearoyl derivative (**7e**). Hydrogenolysis of **7a—d, f** and **8** afforded pure 6-*O*-acyl and 4,6-di-*O*-acetyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine (**2a—d, f** and **9**) in quantitative yields, respectively. The physical properties and results of elemental analyses of the protected and free acyl muramyl dipeptides are summarized in Tables 1 and 2.

As shown in Table 2, the R_f values of the compounds increase with the carbon number of the acyl groups, indicating the augmentation in lipophilicity in this order. However, the partition coefficients of the series

of the compounds between water and chloroform showed a peculiar phenomenon at the stearoyl derivative (**2e**). In Table 2, the values obtained by extraction from their aqueous solutions with chloroform are shown without parentheses, and those obtained reversely by extraction from chloroform solutions with water were indicated in parentheses. Whereas both values were practically equal in the case of lauroyl derivative (**2d**), the stearoyl derivative (**2e**) gave different values depending on the procedure used. This fact may suggest that **2e** could exist as micelles of different type of association either in chloroform or in water, thus resulting in the unusual behavior on extraction. The following observation also supports this assumption. In the NMR spectrum of **2e** in chloroform-*d*, no distinct signals were observed at all in the regions of protons due to the sugar peptide moiety around at δ 3—5, while those of fatty acid moiety were clearly recognized. However, when methanol-d_4 was added to the same solution, the former signals appeared instantaneously and a spectrum expected from the structure was finally obtained. This indicates that methanol could destroy the micellar structure of **2e** in chloroform, where the fatty acid moiety can interact with the solvent or can fluoctuate freely whereas the sugar peptide are rigidly fixed. The partition coefficient of docosanoyl derivative (**2f**) could not be determined by the above extraction procedure because of facile emulsion formation of the two phases. This might indicate the most effective detergent activity of this compound of all the acyl derivatives prepared.

The adjuvant activities of the 6-*O*-acyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine (**2a**—**f**, **9**) thus obtained were investigated by Kotani *et al.* of our collaborative group.[14] Thus, 6-*O*-acetyl and 6-*O*-stearoyl derivatives (**2a** and **2e**) have activities comparable to that of the original *N*-acetylmuramyl dipeptide (**1**) while the other derivatives showed somewhat less activities when administered in a form of water in oil emulsion. The relatively high activity of **2e** seems to reflect an adequate balance of lipophilicity and hydrophilicity in the molecule, although the details of this relation are not yet clear. Furthermore, Kotani *et al.* found that highly lipophilic congeners, **2e** and **2f**, can manifest their adjuvant activities even if they are applied in liposomes to animals.[14] This finding will give an ample hope for the therapeutic use of these substances in the future.

Unfortunately, no antitumor activity was found even in **2e**, which showed the maximum adjuvant activity among those prepared in this study. However, we further extended the study along this line and finally reached the synthesis of 6-*O*-mycoloyl derivative of the muramyl dipeptide (**1**)[15] which exhibited a distinct antitumor activity in the animal test. The results were already reported in a preliminary form.[16]

Experimental

Melting points are uncorrected. All fatty acids were of commercial sources and purified by fractional distillation of their methyl esters if necessary. The purities of the acids were guaranteed over 99.9% by means of gas chromatography.

Acid chlorides were prepared by refluxing the corresponding acids in thionyl chloride followed by distillation as usual. Silica gel 60 (0.063—0.2 mm) and G, Merck, were used for column chromatography and TLC, respectively.

Benzyl N-*Acetyl-α-muramide (3).* Benzyl 4,6-*O*-benzylidene-*N*-acetyl-α-muramide[17] (2.0 g, 4.2 mmol) was heated in 60% aqueous acetic acid (150 ml) at 100 °C for 35 min. After evaporation of the solvent *in vacuo*, benzene and ethanol were added to the residue and agin evaporated *in vacuo*. The residual colorless solid was recrystallized from ethyl acetate; yield, 1.35 g (84%); mp 156—157 °C; $[\alpha]_D^{22}$ +163° (*c* 0.5, methanol), (lit,[18] mp 160—161 °C; $[\alpha]_D^{20}$ +168° (*c* 1.25, methanol)).

Found: C, 56.22; H, 6.56; N, 3.66%. Calcd for $C_{18}H_{25}O_8N$: C, 56.39; H, 6.57; N, 3.65%.

1-α-O-Benzyl-6-O-stearoyl-N-acetylmuramic Acid (4). A mixture of stearic acid (0.90 g, 3.2 mmol) and trifluoroacetic anhydride (1.0 ml) was heated at 50 °C for 15 min and then dissolved in anhydrous THF (2 ml). This solution was added with pyridine (2 ml) to a stirred solution of **3** (1.0 g, 2.6 mmol) in anhydrous THF (8 ml) at −14 °C. After 35 min, the mixture was poured into 10% aqueous K_2CO_3 solution (25 ml) and set aside for 10 min. The solution was brought to pH 4 by addition of 6 M HCl and extracted with $CHCl_3$ (25 ml×2). The $CHCl_3$ layer was dried ($MgSO_4$), and evaporated *in vacuo*. The residue was subjected to silica gel column chromatography. Elution with benzene–ethyl acetate (1:1 v/v) gave a mixture of stearic acid and the intramolecular ester (**5**). Recrystallization from ether afforded pure **5**; yield, 0.45 g (27%); mp 122—123 °C.

Successive elution with $CHCl_3$–methanol–acetic acid (20:1:0.05 v/v) afforded a syrup, which was dissolved in 0.3 M aqueous NaOH (4 ml) and acidified with 1 M HCl to give **4** as a waxy solid; yield, 0.43 g (25%); mp 62—65 °C; $[\alpha]_D^{22}$ +61.6° (*c* 0.5, $CHCl_3$).

Found: C, 66.70; H, 9.39; N, 1.96%. Calcd for $C_{36}H_{59}O_9N$: C, 66.53; H, 9.15; N, 2.16%.

Conversion of 4 into 5. Dicyclohexylcarbodiimide (16 mg, 0.076 mmol) was added to a solution of **4** (48 mg,

0.074 mmol) in anhydrous THF (2 ml) and the mixture was stirred at room temperature overnight. *N,N'*-Dicyclohexylurea was filtered off, the solvent was evaporated *in vacuo* and the residue was recrystallized from ether; yield, 44 mg (94%); mp 121—123 °C. This product was identified with the intramolecular ester (**5**) obtained above by means of IR, NMR and TLC ($CHCl_3$–methanol–acetic acid 30:1:0.3 v/v).

*1-α-O-Benzyl-N-acetylmuramyl-L-alanyl-D-isoglutamine Benzyl Ester (**6**).* 1-α-*O*-Benzyl-4,6-*O*-benzylidene-*N*-acetylmuramyl-L-alanyl-D-isoglutamine benzyl ester[2b] (2.72 g, 3.6 mmol) was heated in 60 % aqueous acetic acid (270 ml) on a boiling water bath for 30 min. After the procedure as described for **3**, the product was recrystallized from methanol–ether; yield, 1.77 g (71%); mp 221.5—223 °C (dec); $[\alpha]_D^{22}$ +93.6° (*c* 0.5, methanol).

Found: C, 58.42; H, 6.55; N, 8.27%. Calcd for $C_{33}H_{44}O_{11}N_4 \cdot 1/2CH_3OH$: C, 58.42; H, 6.73; N, 8.14%.

*1-α-O-Benzyl-6-O-stearoyl-N-acetylmuramyl-L-alanyl-D-isoglutamine Benzyl Ester (**7e**).* *i) From **4** (*via *route A*)*: To an ice-cooled solution of **4** (125 mg, 0.19 mmol) in anhydrous THF (5 ml), *N*-hydroxysuccinimide (45 mg, 0.39 mmol) and dicyclohexylcarbodiimide (39 mg, 0.19 mmol) were added. After the mixture had been stirred in an ice bath for 2 h, *N,N'*-dicyclohexylurea formed was filtered off. The filtrate was again cooled, L-alanyl-D-isoglutamine benzyl ester hydrochloride[2b] (66 mg, 0.19 mmol) and triethylamine (0.027 ml, 0.22 mmol) were added, and the final mixture was stirred overnight. After the usual work-up the product was recrystallized from ethyl acetate; yield, 122 mg (68%); mp 167—169 °C; $[\alpha]_D^{15}$ +58.9° (*c* 1, $CHCl_3$).

Found: C, 64.97; H, 8.35; N, 5.96%. Calcd for $C_{51}H_{78}O_{12}N_4$: C, 65.21; H, 8.37; N, 5.97%.

*ii) From **6** (route B)*: Stearoyl chloride (3.0 g, 10 mmol) in anhydrous THF (30 ml) was added to a solution of **6** (1.34 g, 2.0 mmol) in pyridine (100 ml) and anhydrous THF (90 ml) with stirring, The reaction mixutre was kept at 12 °C and further amount of stearoyl chloride (4.2 g, 14 mmol) was added within 3 h. The remaining chloride was destroyed with addition of ice. After evaporation of the solvent *in vacuo*, the mixture was diluted with water and extracted with $CHCl_3$. The $CHCl_3$ layer was washed with 1 M HCl and aqueous NaCl solution. It was then dried ($MgSO_4$) and evaporated *in vacuo*. The residue was extracted with hot hexane to remove excess stearic acid. The insoluble material was subjected to silica gel column chromatography. Elution with $CHCl_3$–methanol (20:1 v/v) followed by recrystallization from methanol afforded **7e**, which was identical with the sample obtained above in (i) by means of NMR and TLC ($CHCl_3$–methanol 9:1 v/v); yield, 1.03 g (55%); mp 174.5—175.5 °C.

Found: C, 65.13; H, 8.40; N, 5.86%.

*6-O-Stearoyl-N-acetylmuramyl-L-alanyl-D-isoglutamine (**2e**).* A solution of **7e** (253 mg, 0.27 mmol) in acetic acid (20 ml) was hydrogenolyzed at room temperature in the presence of palladium black. After the catalyst had been filtered off and washed with water, the filtrate and the washing were combined and then subjected to lyophilization to afford colorless solid; yield, 204 mg (95%); mp 133—136 °C (dec); $[\alpha]_D^{16}$ +29.3° (*c* 1, H_2O, 2 days after dissolution).

Found: C, 55.99; H, 8.57; N, 7.09%. Calcd for $C_{37}H_{66}O_{12}N_4 \cdot 2H_2O$: C, 55.90; H, 8.88; N, 7.05%.

*6-O-Acetyl-1-α-O-benzyl-N-acetylmuramyl-L-alanyl-D-isoglutamine Benzyl Ester (**7a**).* Acetic anhydride (0.20 ml, 2.1 mlmo) was added to a stirred solution of **6** (200 mg, 0.30 mmol) in pyridine (4 ml) under ice-cooling. After 1 h, ice was added and the mixture was worked up as usual. Recrystallization was effected from methanol; yield, 130 mg (59%); mp 184—185 °C; $[\alpha]_D^{22}$ +72.3° (*c* 0.5, $CHCl_3$).

Found: C, 57.14; H, 6.58; N, 7.65%. Calcd for $C_{35}H_{46}O_{12}N_4 \cdot H_2O$: C, 57.36; H, 6.60; N, 7.65%.

*4,6-Di-O-acetyl-1-α-O-benzyl-N-acetylmuramyl-L-analyl-D-isoglutamine Benzyl Ester (**8**).* Acetic anhydride (0.20 ml, 2.1 mmol) was added to a stirred solution of **6** (160 mg, 0.24 mmol) in pyridine (3 ml) under ice-cooling. The mixture was then stirred at 45 °C for 3.5 h, worked up as usual and the product was recrystallized from ethanol; yield, 118 mg (65%); mp 219—220 °C; $[\alpha]_D^{22}$ +78.7° (*c* 0.5, $CHCl_3$).

Found: C, 58.87; H, 6.45; N, 7.45%. Calcd for $C_{37}H_{48}O_{13}N_4$: C, 58.72; H, 6.39; N, 7.40%.

*6-O-Acyl-1-α-O-benzyl-N-acetylmuramyl-L-alanyl-D-isoglutamine Benzyl Ester (**7b—d, f**).* These compounds were prepared from the corresponding acid chlorides and **6** in similar manners to that described for **7e** (route B). Selective monoacylation with excess of butyryl, octanoyl and lauroyl chlorides were better carried out under ice-cooling, whereas reaction with stearoyl and docosanoyl chlorides were performed at 12—15 °C. The latter two chlorides were not dissolved sufficiently in a mixture of THF and pyridine at low temperature. In all cases, the products were pure enough after single recrystallization from ethyl acetate, so that no chromatographic purification was needed. The yields, physical constants and results of elemental analyses of the products are summarized in Table 1.

*6-O-Acyl and 4,6-Di-O-acetyl-N-acetylmuramyl-L-alanyl-D-isoglutamine (**2a—d, f, and 9**).* These compounds were prepared by catalytic hydrogenolysis of **7a—d, f** and **8** in acetic acid followed by lyophilization as described above for **2e**. The yields, physical constants and results of elemental analyses are summarized in Table 2.

*Determination of Partition Coefficients of **2a—f** and **9**.* The compound **2a—f** and **9** (2 mg each) were dissolved in water (5.0 ml) in a test tube (1.2 × 15.5 cm), respectively. After $CHCl_3$ (5.0 ml) had been added, the tube was stoppered, gently rotated upside down 50 times, and then set aside overnight. The aqueous phase was withdrawn with a pipette. The $CHCl_3$ layer was once evaporated *in vacuo*, and the residue was dissolved in an exact amount of water. The relative amounts of the substances in aqueous and $CHCl_3$ layer were determined colorimetrically by modified Morgan-Elson method[19] described for *N*-acetylglucosamine. In some cases the substances were first dissolved in $CHCl_3$ and then extracted with water. The results are summarized in Table 2.

Studies of Peptide Antibiotics. XXXIX.[1] Syntheses of Gramicidin S Analogs Containing L-Histidine in Place of L-Ornithine

Kazuhiko NONAKA,† Kazuki SATO, Shigeyuki TERADA, Tetsuo KATO, and Nobuo IZUMIYA*

Laboratory of Biochemistry, Faculty of Science 33, Kyushu University, Higashi-ku, Fukuoka 812

(Received February 10, 1978)

Two analogs of gramicidin S, [2-L-histidine]-gramicidin S (**14**) and [2,2′-di-L-histidine]-gramicidin S (**19**), were synthesized to compare the biological role of δ-amino groups in L-ornithine residues in the antibiotic with that of weakly basic imidazolyl groups in L-histidine residues. Compound **14** exhibited identical activity to that of gramicidin S, but **19** was only 1/8 as active. The optical rotatory dispersions of these analogs and gramicidin S were nearly the same: molecular conformation of these peptides must be very similar. Compounds **14** and **19** showed esterolytic activity against *p*-nitrophenyl acetate. The activity of **14** was higher than that of imidazole, **14** being more active than **19**.

There is ample evidence that the presence of charged amino groups in ornithine residues is essential to the antibacterial activity of gramicidin S (GS). Change in the length of the methylene chain in basic amino acid residues does not alter the activity.[2,3] Conversion of the amino group into strongly basic guanidino group afforded similarly active [Arg$^{2,2'}$]-GS.[4] On the other hand, acylation of the amino groups caused drastic decrease in activity.[5] However, no attempt seems to have been made to substitute the ornithine residues with weakly basic histidine residues and to examine the role of amino and imidazolyl groups for antimicrobial activity. This paper deals with the syntheses, antibacterial properties, and ORD measurements of [His^2]-GS (namely, [His^2]-hybrid GS) and [His$^{2,2'}$]-GS, in which the L-ornithyl residues in 2 and 2′ positions are replaced, singly or together, by L-histidine residues (Fig. 1). Possible esterolytic activity of these analogs was tested, because histidine is known to constitute a part of the catalytic site in several esterolytic enzymes such as α-chymotrypsin and subtilisin.

The syntheses of [His^2]-GS and [His$^{2,2'}$]-GS are outlined in Figs. 2 and 3.[6] The principle of the syntheses is to locate the leucyl residue at the *C*-terminal.[7]

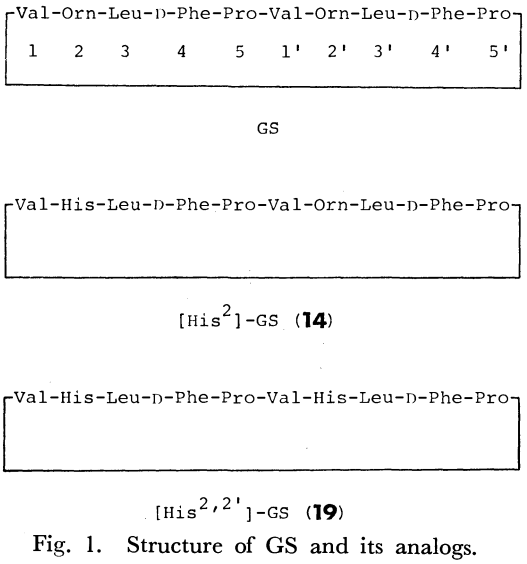

Fig. 1. Structure of GS and its analogs.

† Present address: Teikoku Hormone Mfg. Co., Ltd., Takatsu-ku, Kawasaki 213.

The imidazolyl function of histidine is protected by the benzyloxycarbonyl group only in the first coupling step, and unprotected in later steps, because azide coupling is known to proceed without affecting imidazolyl function, and because there is no suitable and conveniently cleavable protecting group for imidazolyl function.

For the synthesis of [His^2]-GS (**14**), Boc-pentapeptide ester (**7**) was perpared by the coupling of Boc-tripeptide hydrazide (**6**) with dipeptide ester (**2**) which was obtained by mixed anhydride coupling of Z–His(Z)–OH and H–Leu–OEt and subsequent hydrogenation. Boc–Pro–Val–OEt (**3**) and Boc–D-Phe–Pro–Val–OEt (**5**) were obtained similarly. A part of **7** was converted into Boc-pentapeptide hydrazide (**8**). Coupling of **8** and **9**, which was derived from Boc–D-Phe–Pro–Val–Orn(Z)–Leu–OEt,[8] afforded Boc-decapeptide ester (**10**). This was converted into the corresponding hydrazide (**11**) which was then subjected

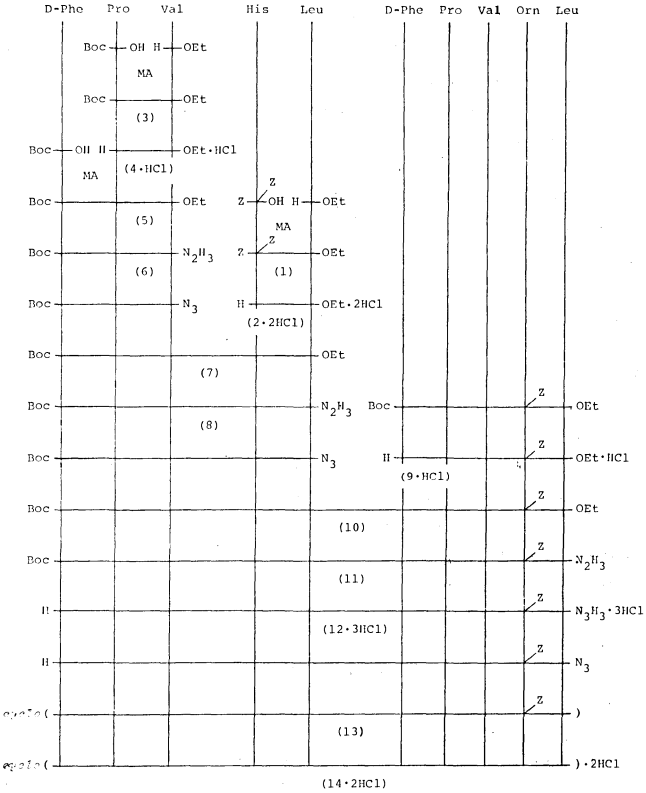

Fig. 2. Synthesis of [His^2]-GS.

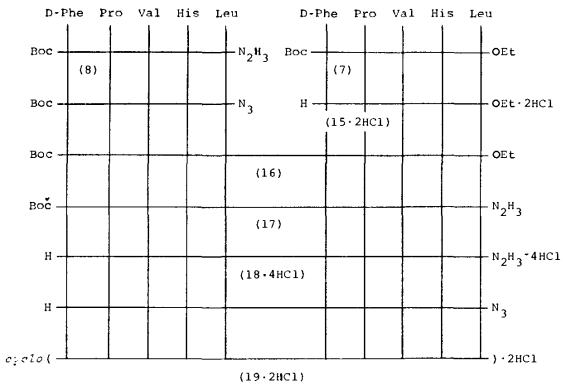

Fig. 3. Synthesis of [His$^{2,2'}$]-GS.

TABLE 1. ANTIBACTERIAL ACTIVITY OF GS AND ITS ANALOGS
(Minimum inhibitory concentration, μg/ml)

Strain	GS	[His^2]-GS (**14**)	[His$^{2,2'}$]-GS (**19**)
Staphylococcus aureus	3.12	3.12	50
Staphylococcus epidermidis	3.12	3.12	25
Bacillus subtilis	1.56	1.56	12.5
Escherichia coli	>100	>100	>100

to cyclization. The protected cyclodecapeptide (**13**) was obtained in 54% yield. A product **14** was obtained by hydrogenation of **13** in 75% yiled. Another product **19** was synthesized from cyclization of linear decapeptide precursor (**16**) instead of doubling cyclization with use of pentapeptide precursor (**7**). Synthesis of **19** was carried out thus because the results of previous experiments suggested that cyclization from **7** could give a mixture of cyclic penta- and decapeptides and, furthermore, the content of the cyclic pentapeptide might be considerably high.[9]

The homogeneity of **14** and **19** was confirmed by paper and thin-layer chromatography, paper electrophoresis and elemental analysis. Intermediates containing histidine such as **7** and **13** and the final product **19** were purified by silica gel column chromatography, and intermediates **10** and **16** by Sephadex LH-20, instead of the usual acid washing in order to avoid loss of the basic peptides. Satisfactory results were obtained for elemental analyses of all the crystalline compounds.

Table 1 shows antibacterial activities of **14**, **19**, and GS. Activity of **14** was exactly the same as that of GS, the presence of one amino and additional one imidazolyl groups apparently being enough to exhibit full activity. In contrast, **19** was only 1/8 or 1/16 times active as compared with GS. This result is interesting but somewhat unusual, because many amino acid-substituted analogs gradually change their activity from mono- to di-substitution. We tentatively explain the apparent discrepancy as follows: [His^2]-GS can gain access to bacterial membrane by ionic interaction between amino group and phospholipid.[5] A weakly basic imidazolyl group also can make a salt-like linkage

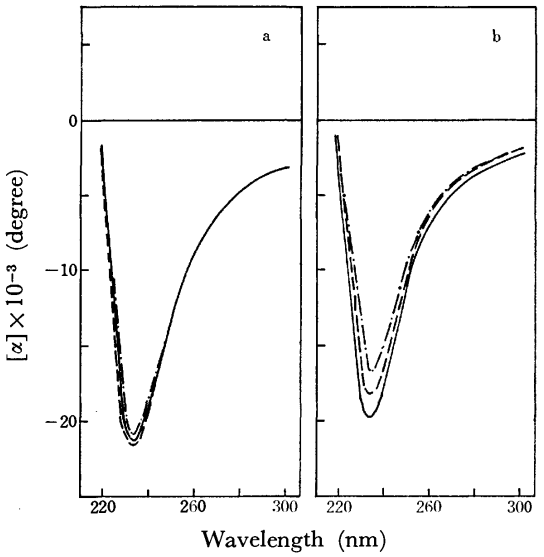

Fig. 4. ORD curves of GS and its analogs.
Solvent: a, EtOH; b, 8 M urea. Curve: ——, GS; – – –, [His^2]-GS; —•—, [His$^{2,2'}$]-GS.

TABLE 2. HYDROLYSIS OF *p*-NITROPHENYL ACETATE WITH CATALYSTS[a]

Catalyst	Second order rate constant ($M^{-1} \cdot min^{-1}$)	
	20% EtOH	50% EtOH
[His^2]-GS (**14**)	38	12
[His$^{2,2'}$]-GS (**19**)	22	7
Boc-pentapeptide-OEt (**7**)	10	10
GS	0	0
Imidazole	22	13

a) Buffer, 1/30 M phosphate at pH 7.86 containing EtOH. Temp, 25 °C. Concentrations, 1.4×10^{-5} M and 6×10^{-5} M for *p*-nitrophenyl acetate and each catalyst, respectively.

with the phospholipid, when the antibiotic sufficiently approaches the membrane. However, ionic interaction between [His$^{2,2'}$]-GS and the membrane may be so weak that it is difficult for the antibiotic to come near the lipid membrane, thus causing weakening of its antimicrobial activity.

Figure 4-a shows the ORD curves of **14**, **19**, and GS measured in ethanol, all the curves being superimposable. In 8 M urea, which causes denaturation of various polypeptides, a slight deviation was observed, the trough at 233 nm being slightly shallower in the case of **14** and **19** (Fig. 4-b). The results of ORD measurements indicate that the conformation of the analogs must be very similar to that of GS but the stability of the analogs decreases with the number of the substitution. Dygert *et al.* proposed the presence of intramolecular hydrogen bondings between δ-amino groups in ornithine and carbonyl groups in D-phenylalanine.[10] Loss of these hydrogen bondings might cause slight instabilization in the peptide backbone of the analogs.

Table 2 shows catalytic activities of **14** and **19** on

the hydrolysis of *p*-nitrophenyl acetate. Experimental conditions are similar to those described by Katchalski *et al.*[11] In 1/30 M phosphate buffer, pH 7.86, containing 20% ethanol, catalytic activity of **14** was enhanced, but the enhancement disappeared in a more hydrophobic solvent, 50% ethanol. This suggests that the enhancement was caused by the hydrophobic interaction between the peptides and the substrate. Nakajima and Okawa reported a similar enhanced catalytic activity of cyclo(–L-His–L-Glu–L-Cys–D-Phe–Gly–)$_2$ on the hydrolysis of *p*-nitrophenyl acetate.[12] Imanishi *et al.* observed strongly enhanced catalytic activity of cyclo(–L-His–D-Leu–) on *p*-nitrophenyl laurate.[13] Since **7** shows no enhancement on the catalysis, the mere presence of an imidazolyl group in a peptide does not give high catalytic activity. Rigid β-sheet backbone conformation of **14** and **19** and hydrophobic environment derived from this conformation should be responsible for the activity. The high activity of **14** is interesting because it contains only one histidine residue. The presence of a free amino group in ornithine might cause additional accelerating effect.

Experimental

All the melting points are uncorrected. TLC was carried out on silica gel G (Merck) with the following solvent systems, the ratio in parentheses after each solvent system being indicated by vol: R_f^1, $CHCl_3$–MeOH (5:1); R_f^2, $CHCl_3$–MeOH–AcOH (95:5:1); R_f^3, *n*-BuOH–AcOH–pyridine–H_2O (4:1:1:2). Optical rotations were measured on a Union high sensitivity polarimeter PM-71. Amino acid analyses were performed with a Hitachi amino acid analyzer KLA-5.

*Z-His(Z)-Leu-OEt (**1**).* To a chilled solution of Z-His(Z)-OH·EtOH (5.84 g, 12.4 mmol) and NMM (1.36 ml, 12.4 mmol) in THF (10 ml) was added isobutyl chloroformate (1.36 ml, 12.4 mmol) at −15 °C. After 10 min, a chilled solution of H–Leu–OEt·TsOH (4.10 g, 12.4 mmol) and NMM (1.62 ml, 12.4 mmol) in CH_2Cl_2 (10 ml) was added. The mixture was stirred at 0 °C for 1 h and at room temperature overnight, evaporated *in vacuo*, and the residue was dissolved in EtOAc. The solution was washed successively with 4% $NaHCO_3$, 10% citric acid and water, dried (Na_2SO_4), and evaporated. The resulting solid was recrystallized from EtOH–ether; yield, 5.60 g (80%); mp 116—118 °C; $[\alpha]_D^{20}$ −6.4° (*c* 0.5, EtOH); R_f^1 0.75, R_f^2 0.46.

Found: C, 63.78; H, 6.39; N, 9.96%. Calcd for $C_{30}H_{36}O_7N_4$: C, 63.81; H, 6.43; N, 9.92%.

*H–His–Leu-OEt·2HCl (**2**·2HCl).* Compound **1** (3.95 g, 7 mmol) dissolved in 0.2 M hydrogen chloride in EtOH (70 ml) was hydrogenated using palladium black as a catalyst. After 5 h, the filtrate from the catalyst was evaporated. Addition of ether to the oily residue gave hygroscopic crystals, which were recrystallized from EtOH–ether; yield, 2.09 g (81%); R_f^1 0.17.

*Boc–Pro–Val-OEt (**3**).* This was prepared from Boc–Pro–OH (6.46 g, 30 mmol) and H–Val–OEt·TsOH (9.52 g, 30 mmol) as described for **1**. The product was recrystallized from EtOH–ether–petroleum ether; yield, 7.50 g (73%); mp 72—75 °C; $[\alpha]_D^{20}$ −70.1° (*c* 0.5, EtOH); R_f^1 0.88, R_f^2 0.66.

Found: C, 59.35; H, 8.80; N, 8.06%. Calcd for $C_{17}H_{30}O_5N_2$: C, 59.62; H, 8.83; N, 8.18%.

*H–Pro–Val-OEt·HCl (**4**·HCl).* Compound **3** (3.60 g, 10.5 mmol) was dissolved in 2.8 M hydrogen chloride in EtOAc (75 ml). The solution was allowed to stand at room temperature for 30 min and then evaporated to leave an oil; yield, 2.93 g (100%); R_f^1 0.32.

*Boc–D-Phe–Pro–Val-OEt (**5**).* This was prepared from Boc–D-Phe–OH (2.79 g, 10.5 mmol) and **4**·HCl (2.93 g, 10.5 mmol) as described for **1**. The product was obtained as an oil; yield, 4.63 g (90%); R_f^1 0.82.

*Boc–D-Phe–Pro–Val–N_2H_3 (**6**).* A solution of **5** (4.63 g, 9.46 mmol) and hydrazine hydrate (9.18 ml, 189 mmol) in MeOH (40 ml) was allowed to stand at room temperature for 3 days. The solution was evaporated and the residue was dissolved in $CHCl_3$ (200 ml). The solution was washed with water, dried (Na_2SO_4), and evaporated. The residual oil was solidified by the addition of ether, and the product was recrystallized from EtOH–ether; yield 3.59 g (80%); mp 158—160 °C; $[\alpha]_D^{20}$ −86.8° (*c* 0.5, EtOH); R_f^1 0.65, R_f^2 0.31.

Found: C, 60.40; H, 7.82; N, 14.58%. Calcd for $C_{24}H_{37}O_5N_5$: C, 60.61; H, 7.84; N, 14.73%.

*Boc–D-Phe–Pro–Val–His–Leu-OEt (**7**).* To a solution of **6** (1.76 g, 3.7 mmol) in DMF (70 ml) were added 2.8 M hydrogen chloride in EtOAc (3.96 ml) and isopentyl nitrite (0.57 ml, 4.07 mmol) at −60 °C. After being left to stand at −20 °C for 10 min, the solution was cooled again to −60 °C and neutralized with TEA (1.55 ml, 11.1 mmol). To this solution was added a chilled solution of **2**·2HCl (2.05 g, 5.55 mmol) and TEA (1.55 ml, 11.1 mmol) in DMF (30 ml). The reaction mixture was stirred at 0 °C for 48 h and then evaporated. The residue was dissolved in EtOAc and the solution was washed successively with 4% $NaHCO_3$ and water, dried (Na_2SO_4), and evaporated. The oily product was applied to a column (5×50 cm) of silica gel (Merck) and the column was washed with $CHCl_3$–EtOH–AcOH (95:5:1) (3200 ml). The product was then eluted with a mixture (1500 ml) of $CHCl_3$–EtOH (5:1). Each fraction was assayed by TLC, and the fractions containing the desired product were evaporated to leave an oil which was crystallized by the addition of ether and petroleum ether; yield, 2.14 g (78%); mp 89—92 °C; $[\alpha]_D^{20}$ −74.5° (*c* 0.5, EtOH); R_f^1 0.66, R_f^2 0.07.

Found: C, 58.83; H, 7.61; N, 12.48%. Calcd for $C_{33}H_{57}O_8N_7\cdot 2H_2O$: C, 58.82; H, 7.92; N, 12.64%.

*Boc–D-Phe–Pro–Val–His–Leu–N_2H_3 (**8**).* Compound **7** (601 mg, 0.81 mmol) was treated with hydrazine hydrate (1.58 ml, 32.5 mmol) as described for **6**; yield, 498 mg (84%); mp 170—175 °C; $[\alpha]_D^{20}$ −69.4° (*c* 0.5, EtOH); R_f^1 0.53, R^2 0.04.

Found: C, 58.15; H, 7.58; N, 16.92%. Calcd for $C_{36}H_{55}O_7N_9\cdot H_2O$: C, 58.13; H, 7.72; N, 16.95%.

*H–D-Phe–Pro–Val–Orn(Z)–Leu-OEt·HCl (**9**·HCl).* This was prepared from Boc–D-Phe–Pro–Val–Orn(Z)–Leu–OEt[8] (2.21 g, 2.6 mmol) as described for **4**·HCl. The oily product was crystallized by the addition of ether and petroleum ether; yield, 1.85 g (91%); mp 111—120 °C; $[\alpha]_D^{20}$ −120° (*c* 0.5, EtOH); R_f^1 0.67, R_f^2 0.14.

Found: C, 60.80; H, 7.71; N, 10.45%. Calcd for $C_{40}H_{58}O_8N_6\cdot HCl$: C, 61.01; H, 7.55; N, 10.67%.

*Boc–D-Phe–Pro–Val–His–Leu–D-Phe–Pro–Val–Orn(Z)–Leu-OEt (**10**).* This was prepared from **8** (327 mg, 0.45 mmol) and **9**·HCl (425 mg, 0.54 mmol) as described for **7**. The crude product dissolved in MeOH (5 ml) was applied to a column (2.8×156 cm) of Sephadex LH-20. The column was developed with MeOH, the fractions with the desired product were evaporated, and the oily residue was crystallized by the addition of ether; yield, 408 mg (63%); mp 135—138 °C; $[\alpha]_D^{20}$ −106° (*c* 0.3, EtOH); R_f^1 0.69, R_f^2 0.13.

Found: C, 62.01; H, 7.63; N, 12.42%. Calcd for $C_{76}H_{109}O_{15}N_{13}\cdot 3/2H_2O$: C, 62.02; H, 7.67; N, 12.37%.

Boc–D-Phe–Pro–Val–His–Leu–D-Phe–Pro–Val–Orn(Z)–Leu–

*N_2H_3 (**11**).* Compound **10** (387 mg, 0.27 mmol) was treated with hydrazine hydrate (0.26 ml, 5.4 mmol) as described for **6**; yield, 359 mg (94%); mp 140—145 °C; $[\alpha]_D^{20}$ −82.1° (*c* 0.5, MeOH); R_f^1 0.49, R_f^2 0.05.

Found: C, 60.45; H, 7.55; N, 14.38%. Calcd for $C_{74}H_{107}O_{14}N_{15}\cdot 2H_2O$: C, 60.60; H, 7.63; N, 14.32%.

*H-D-Phe-Pro-Val-His-Leu-D-Phe-Pro-Val-Orn(Z)-Leu-N_2H_3·3HCl (**12**·3HCl).* Compound **11** (341 mg, 0.24 mmol) was treated with 0.1 M hydrogen chloride in formic acid (7.4 ml) as described for **4**·HCl and the oily product was crystallized by the addition of ether; yield, 330 mg (96%); mp 174—178 °C; $[\alpha]_D^{20}$ −154° (*c* 0.5, MeOH); R_f^1 0.22.

Found: C, 56.81; H, 7.17; N, 14.51%. Calcd for $C_{69}H_{99}O_{12}N_{15}\cdot 3HCl\cdot H_2O$: C, 56.84; H, 7.19; N, 14.41%.

*cyclo(-D-Phe-Pro-Val-His-Leu-D-Phe-Pro-Val-Orn(Z)-Leu-) (**13**).* To a solution of **12**·3HCl (310 mg, 0.22 mmol) in DMF (4 ml) were added 2.8 M hydrogen chloride in EtOAc (0.24 ml) and isopentyl nitrite (0.031 ml, 0.22 mmol) in DMF (0.3 ml) at −30 °C. After 15 min, the reaction mixture was added to pyridine (66 ml) at 0 °C. After being stirred at 5 °C for 4 days, the solution was evaporated and the addition of water afforded a white precipitate, which was filtered and washed with water. The crude product was purified with a column (3.3×42 cm) of silica gel using a mixture of $CHCl_3$–EtOH (5:1) as a developing agent as described for **6**; yield, 151 mg (54%); mp 238—240 °C; $[\alpha]_D^{20}$ −295° (*c* 0.5, MeOH); R_f^1 0.66, R_f^2 0.05.

Found: C, 61.07; H, 7.28; N, 13.25%. Calcd for $C_{65}H_{95}O_{12}N_{13}\cdot 3H_2O$: C, 61.26; H, 7.53; N, 13.46%.

*cyclo(-D-Phe-Pro-Val-His-Leu-D-Phe-Pro-Val-Orn-Leu-)·2HCl ([His^2]-GS·2HCl) (**14**·2HCl).* Compound **13** (78 mg, 0.06 mmol) dissolved in 0.05 M hydrogen chloride in MeOH (2.7 ml) was hydrogenated as described for **2**·2HCl. The product was recrystallized from EtOH–ether; yield, 56 mg (75%); mp 274—275 °C (dec); $[\alpha]_D^{20}$ −283° (*c* 0.5, EtOH); R_f^1 0.35, R_f^3 0.81. Amino acid ratios in acid hydrolyzate; Phe 2.10, Pro 2.05, Val 1.96, His 1.06, Orn 1.08, Leu 2.00.

Found: C, 56.37; H, 7.40; N, 13.55%. Calcd for $C_{61}H_{89}O_{10}N_{13}\cdot 2HCl\cdot 4H_2O$: C, 55.95; H, 7.62; N, 13.91%.

*H-D-Phe-Pro-Val-His-Leu-OEt·2HCl (**15**·2HCl).* This was prepared from **7** (592 mg, 0.8 mmol) as described for **4**·HCl. The oily product was crystallized by the addition of ether and petroleum ether; yield, 520 mg (91%); mp 190—200 °C; $[\alpha]_D^{20}$ −147° (*c* 0.5, EtOH); R_f^1 0.26.

Found: C, 54.64; H, 7.44; N, 13.16%. Calcd for $C_{33}H_{49}O_6N_7\cdot 2HCl\cdot H_2O$: C, 54.24; H, 7.31; N, 13.42%.

*Boc-(D-Phe-Pro-Val-His-Leu)$_2$-OEt (**16**).* This was prepared from **8** (363 mg, 0.5 mmol) and **15**·2HCl (428 mg, 0.6 mmol) as described for **7**. The crude product was purified by a column (2.8×156 cm) of Sephadex LH-20 as described for **10**; yield, 213 mg (32%); mp 150—156 °C; $[\alpha]_D^{20}$ −123° (*c* 0.3, EtOH); R_f^1 0.61.

Found: C, 59.45; H, 7.37; N, 13.97%. Calcd for $C_{69}H_{100}O_{13}N_{14}\cdot 3H_2O$: C, 59.72; H, 7.70; N, 14.13%.

*Boc-(D-Phe-Pro-Val-His-Leu)$_2$-N_2H_3 (**17**).* Compound **16** (200 mg, 0.15 mmol) was treated with hydrazine hydrate (0.15 ml, 3 mmol) as described for **6**; yield, 181 mg (91%); mp 190—192 °C (dec); $[\alpha]_D^{20}$ −111° (*c* 0.4, MeOH); R_f^1 0.30.

Found: C, 57.53; H, 7.05; N, 14.73%. Calcd for $C_{62}H_{86}O_{10}N_{14}\cdot 2HCl\cdot 2H_2O$: C, 57.44; H, 7.15; N, 15.12%.

Paper Electrophoresis. This was carried out with Toyo Roshi No. 52 paper and with a solvent system of HCOOH–AcOH–MeOH–H_2O (1:3:6:10, pH 1.8) for 2.5 h at 500 V/30 cm. Each of the peptides (**14** and **19**) revealed a single spot, the mobility being the same as that of GS.

Microbiological Assays and ORD Measurements. Measurements were carried out as described in a previous paper,[7] the results being shown in Table 1 and Fig. 4.

Kinetic Measurements. The esterolytic reaction was initiated by the addition of an ethanolic solution of *p*-nitrophenyl acetate (10 μl) to an aqueous ethanolic solution of catalyst (2.99 ml). Hydrolysis by the action of the catalyst was monitored by the increase in absorbance at 400 nm on a Hitachi 124 spectrophotometer; light path, 1 cm.

The Sensitized Photooxidation of Cycloheptatriene (Tropilidene). Isolation and Thermal Isomerization of $(4\pi+2\pi)$ Cycloadduct, 8,9-Dioxabicyclo-[3.2.2]-2,6-nonadiene, and Preparation of Tropone[1]

(Received February 20, 1978)

The sensitized photooxidation of cycloheptatriene (tropilidene) in methanol afforded $(4\pi+2\pi)$ cycloadduct; 8,9-dioxabicyclo[3.2.2]-2,6-nonadiene (**1**), 6-hydroxy-2,4-cycloheptadienone and 6-oxoheptadienal presumably derived from $(6\pi+2\pi)$ cycloadduct, and small amounts of tropone and benzaldehyde. Mechanism of their formation are discussed. It was found that the treatment of the photooxidation mixture with triethylamine afforded tropone in about 50% yield. Thermal isomerization of **1** in refluxing xylene afforded *cis*-3,9-dioxatricyclo-[6.1.0.0^{2,4}]-5-nonene, 8-oxabicyclo[5.1.0]-4-octen-3-one and 4-hydroxy-2,6-cycloheptadienone.

Kende and Chu have reported evidence that the oxidation of tropilidene by photochemically generated singlet oxygen gave $(4\pi+2\pi)$ and $(6\pi+2\pi)$ cycloadducts and hydroperoxide by isolating their hydrogenation products including cycloheptanol, 3-hydroxycycloheptanone and *cis*-1,4-cycloheptanediol.[3] However, they could not isolate any direct oxidation products. Meanwhile, the oxidation of tropilidene with peracetic acid gave monoepoxide, 8-oxabicyclo[5.1.0]-2,4-octadiene,[4] and its further oxidation with excess peracid afforded a mixture of diepoxides and triepoxides.[5]

We have studied the similar photooxidation reaction for the purpose of the isolation of the oxidation products and the preparation of tropone *via* photooxidation of tropilidene,[6] and we have isolated a $(4\pi+2\pi)$ cycloadduct; 8,9-dioxabicyclo[3.2.2]-2,6-nonadiene, 6-hydroxy-2,4-cycloheptadienone and 6-oxoheptadienals presumably derived from a $(6\pi+2\pi)$ cycloadduct, and have discussed the mechanisms of the formation of these products. We have also obtained tropone in considerable yield by the base treatment of the photooxidation mixture. Furthermore, it was found that the thermal reaction of $(4\pi+2\pi)$ cycloadduct in refluxing xylene afforded three isomeric rearranged products. The results are reported in this paper.

Results and Discussion

When a 1.5% solution of tropilidene in methanol was irradiated with visible light (6×20 W) in the presence of methylene blue for 2 days[7] while oxygen was slowly passed through the solution, $(4\pi+2\pi)$ cycloadduct (8,9-dioxabicyclo[3.2.2]-2,6-nonadiene) (**1**) (8.4%), 6-hydroxy-2,4-cycloheptadienone (**2**) (23.4%), tropone (**3**) (trace), benzaldehyde (**4**) (trace), *trans,trans*-6-oxoheptadienal (**5**) (0.4%), *trans,trans*-6-oxoheptadienal dimethylacetal (**6**) (0.63%) and a mixture of stereoisomer of 6-oxoheptadienal dimethylacetal (**7**) (0.55%) were isolated after repeated purification by column chromatography on silica gel.

When the photooxidation of tropilidene was performed in acetone in the presence of hematoporphyrin, benzaldehyde was obtained in 51% yield, and the reaction in a mixture of methanol and acetone (1:1) afforded the compound (**1**) in 15% yield.

The structures of the products were determined mainly by their spectroscopic data as well as some chemical transformations. ^{1}H-NMR spectrum of **1**, and ^{1}H-NMR parameter of the compounds (**1**, **2**, **5**, and **6**) were shown in Fig. 1, and Table 1, respectively.

Kende and Chu have reported[3] that catalytic hydrogenation of the total crude photooxidation mixture in ethyl acetate in the presence of 10% Pd–C afforded a mixture of cycloheptanone (**8**), cycloheptanol (**9**), 3-hydroxycycloheptanone (**10**), 4-hydroxycycloheptanone (**11**) and *cis*-1,4-cycloheptanediol (**12**). We have also isolated the same products[8] by the catalytic hydrogenation of the photooxidation mixture in the presence of 5% Pd–C, and furthermore we have obtained **11** and **12**, and **10** by the catalytic hydrogenation of **1**, and **2**, respectively.

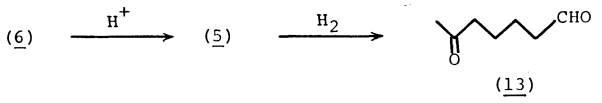
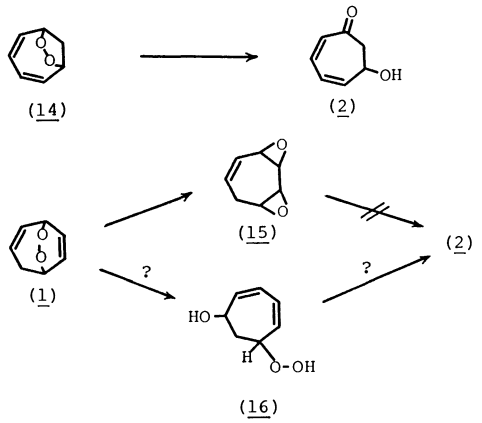
Hydrolysis of **6** with hydrochloric acid afforded the corresponding aldehyde (**5**), which can be converted to 6-oxoheptanal (**13**) upon catalytic reduction. Acid hydrolysis of **7** afforded **5** as one of the products.



The compound (**2**) must be resulted from the cleavage of dioxide ring of ($6\pi+2\pi$) adduct (**14**). But as less likely mechanism, Kende and Chu have pointed out that **2** could be arised by multiple rearrangement of ($4\pi+2\pi$) adduct (**1**) through an allylic diepoxide intermediate (**15**) or *via* S_N'-hydrolysis of **1** to 6-hydroperoxy-2,4-cycloheptadien-1-ol (**16**) in the reaction condition.

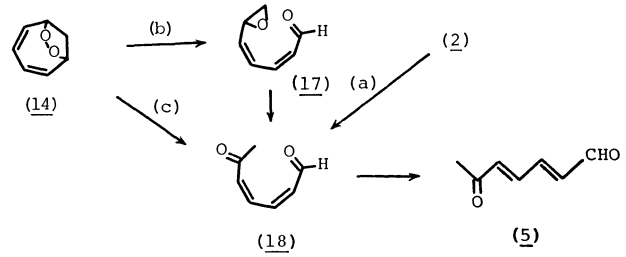
As will be described later, thermal isomerization of the adduct (**1**) did not give **2**, but gave diepoxide (**15**) as one of the products, and it was found that **15** does not change to **2**, but gradually changed to 4-hydroxy-2,6-cycloheptadienone on column of silica gel. Furthermore, the compound (**1**) did not change in aqueous methanol in the presence or absence of

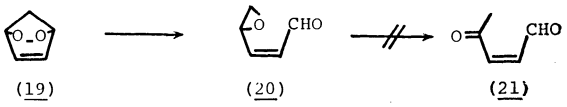


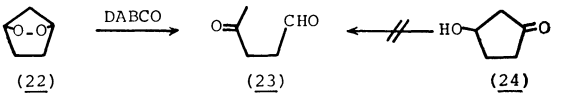
diluted perchloric acid by standing at room temperature for 5 days. Therefore, it is assumed that the compound (**2**) must not be resulted from ($4\pi+2\pi$) adduct (**1**), but must be resulted from the initially formed ($6\pi+2\pi$) adduct (**14**) as has been posturated by Kende.[3]

The formation of acyclic compounds (**5**—**7**) can be explained by the following three processes. Path (a) involves a retro-Aldol cleavage of the compound (**2**).

Path (b) involves a rearrangement of ($6\pi+2\pi$) adduct (**14**) to epoxyaldehyde (**17**) followed by isomerization to the aldehyde (**5**) *via cis,cis*-6-oxoheptadienal (**18**). Path (c) proceeds through the direct new peroxide rearrangement of **14** to **18** followed by *cis-trans* isomerization.

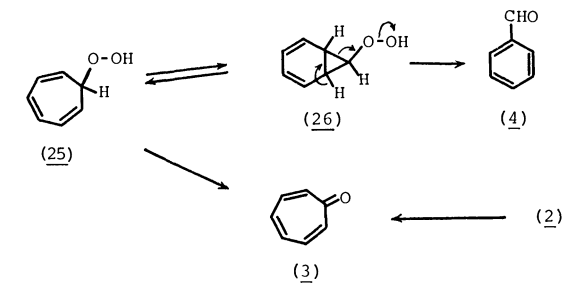




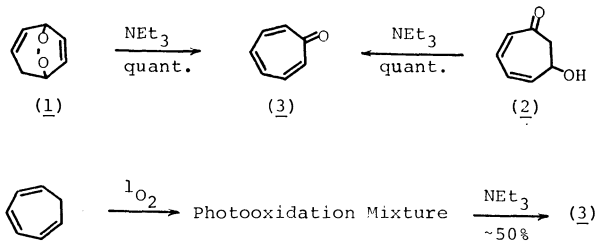


The possibility of path (a) may be ruled out since **2** does not change on standing in methanol. Ohloff *et al.*, and Adams *et al.* have isolated a epoxide (**20**) derived from 1,4-epidioxy-2-cyclopentene (**19**) during photooxidation of cyclopentadiene, however, they did not observe the formation of 4-oxopentenal (**21**).[9] Therefore, the path (c) is assumed to be more plausible for the formation of **5**—**7**, although further study is needed to establish a mechanism. Recently, it has been reported that 5,6-dioxabicyclo[2.2.1]heptane (**22**) underwent a rearrangement upon exposure to 1,4-diazabicyclo[2.2.2]octane to give levlinaldehyde (**23**) and that the possibility might arise *via* retro-aldol cleavage of 3-hydroxycyclopentanone (**24**) was ruled out.[10] The both rearrangements to ketoaldehydes (**5** and **23**) may proceed by the similar mechanism.

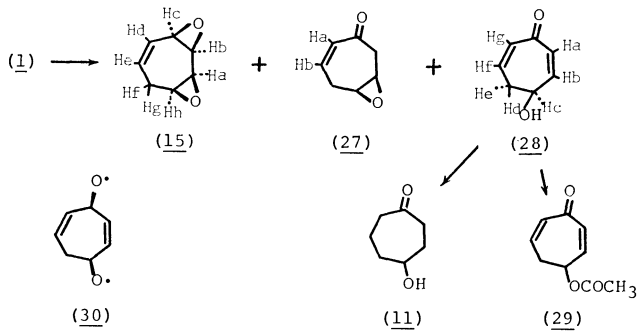
The mechanism of the formation of benzaldehyde can be explained by the rearrangement of the initially formed hydroperoxide (**25**) *via* norcaradiene intermediate (**26**). The formation of tropone can also be explained by the dehydration of **25**[3] and/or 6-hydroxy-2,4-cycloheptadienone (**2**).



When the compounds (**1** and **2**) were treated with triethylamine, tropone was formed in quantitative yields, respectively. Furthermore, it was found that when the crude photooxidation mixture was allowed to stand in the presence of triethylamine at room temperature for 12 h, tropone was obtained in about 50% yield from tropilidene. Therefore, the photooxidation of tropilidenes will become a useful synthetic method of tropone and its derivatives.



Since it has long been known that some epidioxy compounds are thermally and photochemically labile, and many interesting rearranged products have been derived from the epidioxy compounds, the thermal reaction of the compound (**1**), isolated for the first time, was studied. Heating of **1** in refluxing xylene afforded three isomeric products; *cis*-3,9-dioxatricyclo-[6.1.0.0^{2,4}]-5-nonene (**15**), 8-oxabicyclo[5.1.0]-4-octen-3-one (**27**) and 4-hydroxy-2,6-cycloheptadienone (**28**), in the yield of 25, 20, and 18%, respectively. The structure of the products including a stereochemistry of **15** was determined by the analyses of their NMR (Table 1) and the comparison of the NMR with those of their phenyl and methoxy derivatives obtained from phenyl- and methoxytropilidenes,[11] and general mechanistic consideration of the rearrangement of epidioxides.[12] Catalytic hydrogenation and acetylation of **28** afforded 4-hydroxycycloheptanone (**11**) and 4-acetoxy-2,6-cycloheptadienone (**29**).



Although Prinzbach and Rücker have already reported[5] the synthesis of *cis*-diepoxide (**15**) as a mixture with other epoxides the present work is the first time to isolate **15** in pure state.

During the purification of the compounds (**15** and **27**) using column chromatography on silica gel, they gradually changed to the hydroxyketone (**28**). Therefore, **28** may be formed as secondary product by the rearrangement of **15** and/or **27** which may be formed as primary rearranged products of **1** *via* biradical intermediate (**30**). It would also be considered that epoxyketone (**27**) also results from the rearrangement of the diepoxide (**15**),[13] however, **27** could not be detected during the purification of **15**. Upon treatment of these isomers with triethylamine, tropone was obtained in quantitative yields.

Experimental

The mp values are uncorrected. The IR spectra were recorded with Hitachi EPI 510 and Hitachi 215 grating spectrophotometer and for the UV spectra Hitachi EPS 035 and Hitachi 323 spectrophotometers. The mass spectra were obtained with a Hitachi RMU 60 mass spectrometer. The NMR spectra were recorded on Varian HA-100, A-60 and Hitachi R-22 spectrometers.

Sensitized Photooxidation of Cycloheptatriene. A solution of cycloheptatriene (3.5 g, 0.038 mol) and Methylene Blue (100 mg) in methanol (250 ml) was irradiated by visible light (6×20 watt) for 2 days at around 25 °C by cooling with water while oxygen was slowly passed through the solution. The solvent was removed under reduced pressure, the residue was extracted with ether and an oil (2.13 g) was obtained from the extract. The oil was submitted to column chromatography on silica gel (60 g) and eluted with chloroform. From the effluents, benzaldehyde (trace), adduct (**1**) (402.5 mg, 8.4%), a mixture of ring opening products, tropone (**3**) (trace), and 6-hydroxy-2,4-cycloheptadienone (**2**) (1.09 g, 23.4%) were obtained by the order of the effluents. A mixture of ring opening products were further purified by a column chromatography on silica gel using a mixture of benzene and ethyl acetate as solvent, and *trans,trans*-6-oxoheptadienal dimethylacetal (**6**) (40.6 mg, 0.63%), a mixture of stereoisomer of 6-oxoheptadienal dimethylacetal (**7**) (35.3 mg, 0.55%), and *trans,trans*-6-oxoheptadienal (**5**) (18.5 mg, 0.4%) were obtained. **1**; Colorless oil; IR (neat) 1640, 1058, 995, 975, 905, 880, 750 cm^{-1}; MS *m/e* 124 (M^+, 22), 106 (92), 105 (100), 96 (29), 95 (49), 81 (28), 78 (37), 77 (96). Catalytic Hydrogenation of 1, 2, and 5. a) A solution of **1** (200 mg, 1.61 mmol) in ethyl acetate (20 ml) was submitted for a catalytic hydrogenation in the presence of 5% Pd–C (10 mg) at room temperature and atmospheric pressure, and about 120 ml of hydrogen was absorbed. The catalyst was filtered off, the solvent was removed under reduced pressure, the residue was purified by column chromatography on silica gel using ethyl acetate as solvent. From the effluents, 4-hydroxycycloheptanone (**11**) (158 mg, 1.23 mmol, 76.4%) and 1,4-cycloheptanediol (**12**) (40 mg, 0.31 mmol, 19.3%) were obtained.[8]
b) A solution of **2** (100 mg, 0.8 mmol) in ethyl acetate (10 ml) was hydrogenated in the presence of 5% Pd–C (5 mg), and worked up the same as in the above procedure. 3-Hydroxycycloheptanone (**10**) was obtained in almost quantitative yield.[8]
c) A solution of 5 (30 mg) in ethyl acetate was hydrogenated in the presence of 5% Pd–C, and 6-oxoheptanal (**13**) was obtained as colorless oil in almost quantitative yield by purification using column chromatography on silica gel. The compound showed bp 100 °C/0.1 mmHg; IR (CCl_4) 2930, 1715, 1370 cm^{-1}; MS *m/e* 128 (M^+), and was identified by the comparison of its IR and NMR spectra with those of 6-oxoheptanal obtained by oxidation of 1-methylcyclohexene with ozone.

Formation of Tropone from the Photooxidation Products. a) A crude photooxidation mixture (2.62 g) obtained by oxidation of cycloheptatriene (3.5 g) in methanol (250 mg) in the presence of Methylene Blue (90 mg) was dissolved in methanol (50 ml) containing triethylamine (1 ml), and the solution was allowed to stand at room temperature for 12 h. The solvent was removed under reduced pressure, the residue was purified by column chromatography on silica gel using a mixture of chloroform and 3% methanol as solvent, and tropone (2.01 g, *ca.* 50%) was obtained. b) A solution of **1** (200 mg) and triethylamine (0.5 ml) in methanol (30 ml) was allowed to stand at room temperature for 12 h. The solvent was removed under reduced pressure, and tropone was obtained in almost quantitative yield.

Thermal Reaction of 1. A solution of **1** (602 mg, 4.86 mmol) in anhydrous xylene (30 ml) was refluxed under nitrogen atmosphere for 2 days. The solvent was removed under reduced pressure, the residue was submitted to column chromatography on silica gel (40 g) and eluted with a mixture of benzene and ethyl acetate (9:1), and in the order of the effluents, diepoxide (**15**) (150.5 mg, 1.21 mmol, 24.9%), ketoepoxide (**27**) (119.5 mg, 0.96 mmol, 19.8%), and ketoalcohol (**28**) (107 mg, 0.86 mmol, 17.8%) were obtained. The compounds (**15** and **27**) were gradually changed to **28** during further purification by chromatography on silica gel. **15**; Colorless crystals, mp 23—25 °C; IR (neat) 940, 915, 905, 840 cm^{-1}; MS *m/e* 124 (M^+, 4), 95 (35), 68 (87), 67 (47), 66 (100). Found: C, 67.50; H, 6.60%. Calcd for $C_7H_8O_2$: C, 67.73; H, 6.50%. **27**; Colorless oil; IR (neat) 1670, 820 cm^{-1}; UV λ_{max}^{MeOH} 228 nm (log ε, 3.89), 275 (2.63); MS *m/e* 124 (M^+, 5.5), 96 (42), 95 (29), 81 (28), 68 (100), 67 (26). Found: C, 68.02; H, 6.30%. **28**; Colorless oil; IR (CCl_4) 3430, 1650, 1615, 1430 cm^{-1}; UV λ_{max}^{MeOH} 232.5 nm (log ε, 4.06), 240 (3.97), 303 (3.11), 312 (3.08); MS *m/e* 124 (M^+, 28), 106 (47), 96 (54), 95 (91), 78 (77), 55 (54), 28 (100). Found: C, 67.94; H, 6.55%.
Acetate (**29**); Colorless oil; IR (neat) 1745, 1650, 1615 cm^{-1}.

Studies on Diazo Type Process. VI. Physico-chemical Studies on 1-(*p*-Dimethylaminophenylazo)-2-naphthol-3,6-disulfonic Acid in Aqueous Solutions

Shin SUZUKI,* Rebati C. DAS, and Kieko HARADA
Department of Image Science and Engineering, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba-shi, Chiba 280
(Received January 5, 1978)

1-(*p*-Dimethylaminophenylazo)-2-naphthol-3,6-disulfonic acid is formed in many important commercial "dry process" diazo-printing. Some physico-chemical properties of this dye in solutions have been investigated. Its absorption spectra in various solvents and in water at various acidities have been discussed on the basis of azo-quinone hydrazone tautomeric and acid-base equilibria respectively. The dissociation constants of the acid-base equilibria in the pH range of 1—14 in aqueous solutions have been determined at 25 °C and 1.0 M ionic strength. Conductivities of aqueous solutions at various concentrations and temperatures have been interpreted on the basis of the colloidal nature of the dye. The polarograms of the compound have been drawn at various pH's and discussed. Polarographic method indicates complex formation between Zn(II) salt and the dye in the mole ratio of 1:2.

The authors are presently engaged in the study of the physico-chemical properties of azo dyes formed in "diazo-printing" processes. *p*-Dimethylaminobenzenediazonium chloride and 2-naphthol-3,6-disulfonic acid (R-acid) are very commonly used in many commercial "two-component" diazo papers as the photosensitive "diazo" and "coupler" components respectively for "dry process" printing.[1] The present paper reports the behaviour in aqueous solutions of the important azo dye formed by reaction between the above two components.

Experimental

Materials. *p*-Dimethylaminobenzenediazonium salt was prepared from the corresponding amine (analytical grade), precipitated as fluoroborate and then coupled with R-acid. The dye so prepared was recrystallized from water and stored in the absence of light. The other materials used were of analytical grade.

Methods. A Shimadzu (Model UV-180) spectrophotometer was used for absorbancy measurements. Conductance measurements were taken with a Yokokawa Denki universal bridge in conjunction with a Kikusui Denshi-Kogyo (Model 537) oscilloscope. A TOA Electronics Ltd. pH-meter (digital type, Model HM 20B) was used for pH measurement. Polarographic measurements were taken with a recording polarograph (Yanagimoto, Model PG-5). The DC current-voltage curves were obtained by measuring against saturated calomel electrode. Nitrogen gas was bubbled through the solution for 20—25 min immediately before measurement to remove dissolved oxygen. 0.02% gelatin was used as "suppressor," without which good polarographic waves were not obtained. The capillary characteristics of the dropping mercury electrode were $m=1.116$ mg s^{-1} and $\tau=3.49$ s at a mercury head of 74 cm. 1M solution of potassium nitrate was used as the supporting electrolyte.

Results and Discussion

Tautomerism. Azo dyes with a hydroxyl group located ortho- or para- to azo link are well known to exhibit azophenol-quinone hydrazone tautomerism.[2] This has been the subject of study of many workers[3–18] by various physico-chemical means *e.g.* IR, UV-Vis and NMR spectroscopies. Most of the works have been done in nonaqueous solvents or in the solid state and the tautomerism of the present compound has not been studied. It was thought necessary to study in greater detail the extent of tautomerism of the compound in aqueous solution.

Azo form Quinone hydrazone form

(A)

The absorption spectrum of the dye has been drawn in different polar and nonpolar solvents and shown in Fig. 1. In nonaqueous solvents, the dye derived from β-naphthol in stead of R-acid was used because the presence of sulfonate groups in R-acid makes the dye insoluble in nonaqueous solvents. The presence of $-SO_3H$ group is irrelevant in spectral analysis. Two characteristic features of the spectrum are (a) a band, usually appearing as a shoulder, at ≈430 nm and (b) a strong band at ≈500 nm whose shape and position are markedly dependent upon the solvent. The two bands at ≈430 and ≈500 nm can be unequivo-

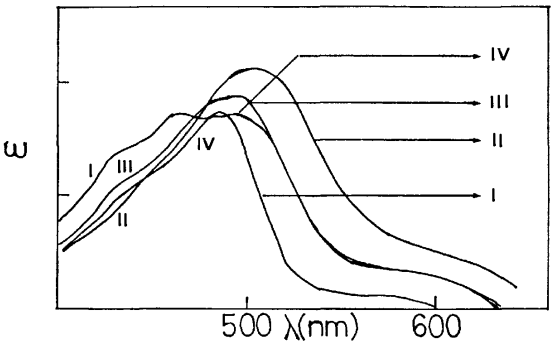

Fig. 1. Absorption spectrum of 1-(*p*-dimethylaminophenylazo)-2-naphthol in different solvents. I: Hexane, II: formamide, III: methanol, IV: chloroform. Molar absorptivity coefficents are arbitrary.

cally assigned to azo and quinone hydrazone forms respectively.[5,6,10,13,14] The band due to the hydrazone form is a split one which is clearly observed in non-polar solvents. The split bands coalesce and move to higher wavelength region in more polar solvents due to greater solute-solvent interaction. Similar splittting of bands have been observed at low temperatures.[7] It is clear that the polarity of the solvent has a greater influence on the shape and position of the spectrum of the quinone hydrazone tautomer which has a more polar structure of the two forms. As observed in the figure, the proportion of the quinone hydrazone form increases with the increase of the polarity of the solvent.[7,12] For the purpose of quantitative interpretation, the following ratio proposed by Ospenon[9] may be used,

$$\varepsilon_{quin}/\varepsilon_{azo} + \varepsilon_{quin},$$

where ε_{azo} and ε_{quin} are molar absorptivity of the azo and quinone hydrazone bands respectively, deduced from Gaussian analysis of the spectra. Table 1 gives the value of this ratio for different solvents. In water, this ratio is 0.80 which corresponds to 80% of the quinone hydrazone form in the tautomeric mixture, if the molar absorptivity of both the forms are nearly equal. This very high proportion of the quinone hydrazone form in aqueous solution of the dye may be ascribed to (i) strong polar nature of the solvent favoring more polar quinone hydrazone form[7,12] and (ii) intramolecular hydrogen bond between the hydroxyl oxygen** and the azo nitrogen atoms facilitating hydrogen transfer fom O- to N-atom,[12] which more than compensate the opposite influence of the highly electron donating $-N(CH_3)_2$ group.[15]

Table 1. Proportion of azo tautomer present in different solvents

Solvent	Hexane	Chloroform	Methanol	Water	Formamide
% Azo	33.3	24.5	23.8	20.5	17.9

The color of the dye in aqueous solutions is markedly dependent upon the pH of the solution as can be seen in Fig. 2. In highly acidic solutions (pH<1.5) the color is yellow-orange. At intermediate (7—9) and high (>12.0) pH's, the colors are violet and red respectively. The spectra of the dye at different pH's pass through clear isobestic points characteristic of equilibria (not shown in the figure). The following acid-base equilibria are obviously operative in aqueous solution.

$$RH_2^- \underset{H_2O}{\overset{K_1}{\rightleftharpoons}} RH^{2-} + H_3O^+$$

$$K_2 \uparrow\downarrow H_2O$$

$$R^{3-} + H_3O^+$$

Identification of the species, RH_2^-, RH^{2-} and R^{3-}, responsible for different colors, is clearly necessary.

** The term hydroxyl oxygen is used in keeping with the general practice, although in this compound it is actually a quinonic oxygen.

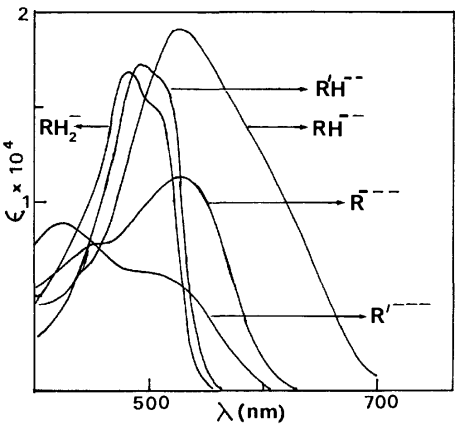

Fig. 2. Absorption spectra of different species of 1-phenylazo-2-naphthol-3,6-disulfonic acid and 1-(*p*-dimethylaminophenylazo) - 2 - naphthol - 3,6 - disulfonic acid in aqueous solutions. RH_2^-: Structure VI, RH^{2-}: structure II, R^{3-}: structure III, $R'H^{2-}$: structure VI without *p*-NR_2 group. R'^{3-}: structure III without *p*-NR_2 group.

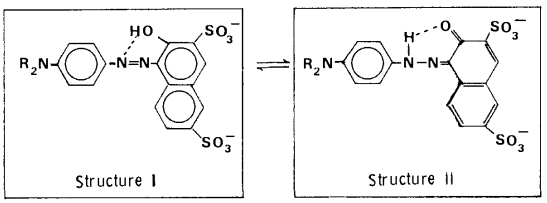
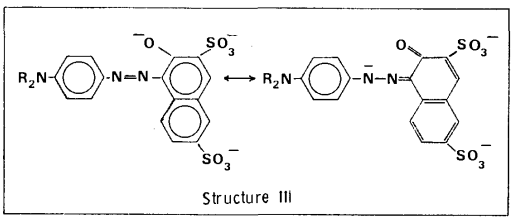
In neutral medium the dye (RH^{2-}) may have structures I and/or II.



(B)

The aforesaid discussion has clearly indicated that RH^{2-} predominantly exists in sturcture II.

In highly alkaline medium (pH>12) where the phenolic group is completely dissociated (R---),*** the compound exists as structure III. The azo and quinone hydrazone structures are the different canonical forms of structure III.



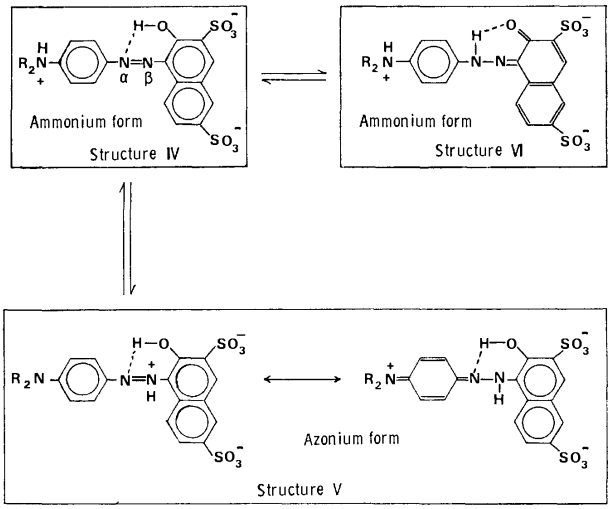
(C)

The spectrum of R^{3-} contains clear bands at ≈420 and ≈520 nm.

In acidic medium (pH<1.5), the species RH_2^-, may be formed by protonation of the N-atom of the tertiary amino group or the O-atom of the phenolic group.[19] Protonation of the amino group of the azo form causes the possibility of resonance between ammonium (structure IV) and azonium (structure V) forms, the azonium form being stabilized by reson-

*** Strictly speaking, the hydrogen belongs to the N-atom in the quinone hydrazone structure.

ance as shown.[20,21] Suggestion that proton could be bonded preferentially to the α-azo nitrogen in the protonated structure[22] is too untenable from theoretical argument and spectroscopic evidence[20,23] to warrant detailed discussion.

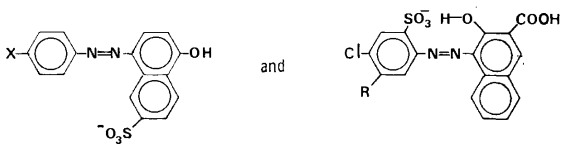


(D)

The possible azonium form of the quinone hydrazone structure (VI) lacks the resonance stabilization as in structure V and hence, may not be existing in solution, but the possibility cannot be completely ruled out. A suitable choice of structure for RH_2^- between structures IV, V, and VI can be made by comparison of the spectrum with that of the dye without the $-N(CH_3)_2$ group (1-phenylazo-2-naphthol-3,6-disulfonic acid). Figure 2 also shows the spectrum of 1-phenylazo-2-naphthol-3,6-disulfonic acid. At all pH's below 6.5 (spectrum measured upto pH 0.4) only one spectrum is observed which is similar with that of RH_2^- of the present dye. Similarly at pH's above 12, its spectrum remains unchanged. One may conclude that 1-phenylazo-2-naphthol-3,6-disulfonic acid only exists in two species containing undissociated and dissociated phenolic group (denoted as $R'H^{2-}$ and R'^{3-} respectively) at the pH range studied. The striking similarity of the spectra of RH_2^- and $R'H^{2-}$ is not surprising as it is well known that although aniline and *N*-substituted anilines in neutral solutions absorb at longer wavelengths and have higher intensities than benzene, the absorption characteristics of the anilinium ions are very similar to those of benzene.[24] From this it may be concluded that, in very acidic solutions, the protonation of the present dye takes place at the amino nitrogen atom and structure V is not present in any appreciable amount (this structure is not possible with $R'H^{2-}$) and consequently, RH_2^- probably exists predominantly in the quinone hydrazone from (structure VI). However, at very highly acidic media, there may be possibilities of protonation at other sities, particularly at the phenolic oxygen,[19] which has not been investigated in the present work.

Aggregation. Aggregation of some arylazonaphthols having formulae,† in aqueous solutions have

† Only the structure of the azo tautomers are presented.



(E)

been reported from the non-Beer's law behavior of the solution spectra by Zollinger[25] and Monahan[26,27] *et al.* respectively. This may be due to intermolecular H-bonding through the phenolic or carboxylic hydrogen atom. In the present compound the hydroxyl group, which is present at ortho position, is H-bonded with the azo nitrogen atom (intramolecular H-bonding) and there would be less possibility of intermolecular hydrogen bonding. It is found that Beer's law is followed in dilute aqueous solutions (0.5×10^{-5} to 3×10^{-4} M). But addition of some electrolytes to a concentrated solution of the dye causes precipitation. It was, therefore, thought necessary to check the aggregation by another physical method.

Whereas the plots of equivalent conductance, Λ (ohm^{-1} cm^2 g equiv^{-1}) *vs.* $C^{1/2}$ (C=g eqiv dm^{-3})of a pure strong electrolyte follows Debye-Hückel-Onsager theory, the same in the case of a colloidal electrolyte has two conspicuous features: (a) a sudden deviation at low concentrations from theoretical Debye-Hückel-Onsager theory and (b) almost a constant value of Λ, or sometimes a weak minimum, at high concentrations.[28] Similar plot as prescribed for colloidal electrolytes was obtained as can be seen in Fig. 3.

Mushran and Prakash[29] have studied the conductance of several colloidal systems and have found that, in general, the "temperature of zero conductance" of a true electrolyte lies at about −40 °C, whereas in colloidal systems, this temperature ranges between −15 and −35 °C. This has been further verified by Srivastava, Seth, and Dey.[30] Conductances of three solutions of the present dye were determined at different temperatures. The plots of specific conductance, k (ohm^{-1} cm^{-1}) *vs.* temperature (°C) were linear and are shown in Fig. 4. The extrapolated value of the "temperature of zero conductance" was found to be −23 °C lending further evidence about the colloidal nature.

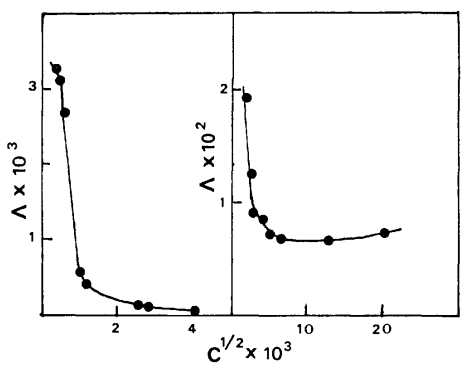


Fig. 3. Variation of equivalent conductance of 1-(*p*-dimethylaminophenylazo)-2-naphthol-3,6-disulfonic acid with square root of equivalent concentration.

From the foregoing observations one may be tempted to conclude that in the case of the aqueous solutions of the present dye, the dye-dye interaction through hydrogen bonding may not be responsible for the aggregation. More detailed study is necessary to throw light on the cause of aggregation of azo dyes in aqueous solutions.

In view of the colloidal nature of the dye, all equilibrium studies reported in the subsequent part of this paper have been carried out in as dilute solutions as possible.

Dissociation Constants. It was thought useful to determine the dissociation constants of the two dissociation processes existing in aqueous solutions. The following method was followed.

The pH's and absorbances at appropriate wavelengths of a series of solutions were measured. The pK_1 was calculated from the data of solutions at pH's where only RH_2^- and RH^{2-} exist in equilibrium. Similarly pK_2 was calculated from the data where RH^{2-} and R^{3-} co-exist. The molar absorptivity (ε) of RH_2^-, RH^{2-}, and R^{3-} species at appropriate wavelengths were determined separately by measuring absorbances of the dye solutions at suitable pH's where singular species exist. The method of calculation is shown below.

As a general case, where the following equilibrium is operative,

$$\underset{(1-\alpha)C}{HA} + H_2O \rightleftharpoons H_3O^+ + \underset{\alpha C}{A^-}$$

(for convenience the charge on the different species are omitted, α is the degree of dissociation and C is the molar concentration), absorbancy of the solution is given by the equation,

$$A = \varepsilon_{HA}(1-\alpha)Cl + \varepsilon_A Cl. \quad (1)$$

ε_{HA} and ε_H are molar absorptivity of HA and A respectively and l is the length of the light path. It follows from Eq. 1 that

$$\alpha C = \frac{A-\varepsilon_{HA}Cl}{(\varepsilon_A-\varepsilon_{HA})}. \quad (2)$$

Knowing α, K can be calculated from Eq. 3.

$$K = \frac{[H^+]\alpha}{1-\alpha}. \quad (3)$$

For the calculation of pK_1, absorbancies at wavelengths 580 and 620 nm were measured. Similarly data at 540 and 600 nm were used for calculation of pK_2. Table 2 gives pK_1 and pK_2 values at 25 °C and 1 M KNO_3 solution. The values are 3.69±0.03 and 10.56±0.03 respectively. The corresponding free energy changes (ΔG) of the first and second dissociation processes are 21.1 and 60.3 kJ mol^{-1} respectively. (1 J=0.2392 cal)

Reaction with Metal Salts. It has been reported that the presence of zinc salts during diazo-printing improves the image area and in some cases, the prints can be used as "intermediate prints on a transparent base."[31] Zinc chloride is also often used as "stabilizer" for diazonium salts.[32] It was, therefore, thought useful to study the complexation reaction of the dye with Zn(II). Spectrophotometric method was found unsuitable as it was observed that the absorption spectrum

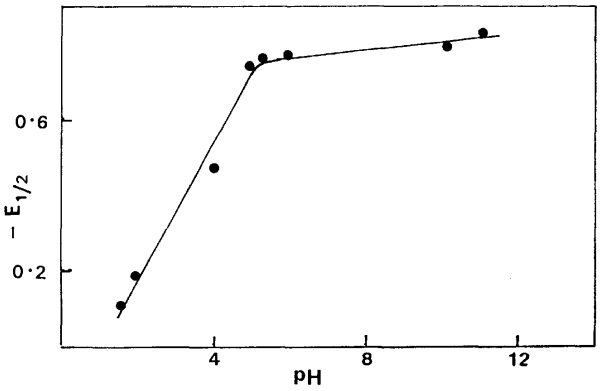

Fig. 5. Variation of half-wave potential of 1-(*p*-dimethylaminophenylazo)-2-naphthol-3,6-disulfonic acid with pH of solution. [azo]$=2.963\times10^{-4}$ M.

of the dye is not sufficiently altered in the presence of zinc(II) salts to make any quantitative study possible. Hence, polarographic method was tried.

In the preliminary runs in water, the polarograms of the dye indicated a two electron process reduction as calculated from the famous Heyrovsky-Ilkovic equation,[33]

$$E_{de} = E_{1/2} - \frac{RT}{zF}\log\frac{i}{i_d - i}, \qquad (4)$$

where E_{de} is the potential at the dropping mercury electrode, $E_{1/2}$ is the half-wave potential of the dye in solution, z is the number of electrons involved in the electrode reaction, i_d is the limiting diffusion current, i is the current corresponding to the potential E_{de}, and R, T, and F have their conventional meanings. A plot of the half-wave potential of the dye against pH, as shown in Fig. 5, indicate that $E_{1/2}$ is dependent on pH of the solution. The variation of $E_{1/2}$ with pH is not surprising in view of the fact that the nature of the species existing in solution is also dependent upon the hydrogen ion concentration.

The half-wave potential of zinc nitrate changed to more negative values in the presence of the azo dye, clearly indicating complex-formation between them. The shift of half-wave potential and the overall stability constant (β_n) of the complex, ML_n, formed is related by the following equation,

$$\Delta E_{1/2} = \frac{2.303RT}{zF}\log\beta_n + \frac{2.303RT}{zF}n\log[L]. \qquad (5)$$

([L]=concentration of the ligand in solution)

Figure 6 shows the plot of $\Delta E_{1/2}$ *vs.* log[L]. The slope of the plot gives $n\approx2$. Unfortunately, it was not possible to work at high concentrations of the ligand (azo dye) because, at high concentrations, it precipitates in the presence of the zinc salt. For this reason calculation of β_2 was not attempted. Essential condition for the calculation of β is that the concentration of the ligand should be much greater than that of the metal ion.[35] Qualitative conclusion regarding the metal: ligand ratio in the complex can, however, be made from our experimental plots.[36]

The authors are grateful to the Japan Society for the Promotion of Science for financial support. The

A Convenient Method for the Synthesis of Dihydropyranobenzopyrandiones and Their Sulfur Analogs

J. R. MERCHANT* and S. Y. DIKE

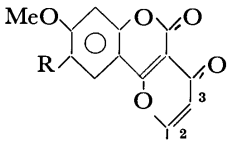
Organic Chemistry Department, Institute of Science, Madame Cama Road, Bombay 400032, India

(Received May 23, 1977)

A general and convenient synthesis is described of a number of 2,3-dihydro-4*H*,5*H*-pyrano[3,2-*c*][1]benzopyran-4,5-diones and 2,3-dihydro-4*H*,5*H*-pyrano[2,3-*b*][1]benzothiopyran-4,5-diones. It involves the condensation of 4-hydroxycoumarin derivatives and their thioanalogs with different α,β-unsaturated acids in the presence of PPA. Assignments of the structures in both the cases are based on analytical and spectroscopic evidence.

The well-known anticoagulant activity of dicoumarol has led to the synthesis of large number of 4-hydroxycoumarin derivatives. Recently, a number of 3-[3-(*p*-substituted phenyl)-1,2,3,4-tetrahydro-1-naphthyl]-4-hydroxycoumarins have been reported, many of which show outstanding activity against both warfarin sensitive and warfarin resistant rats.[1]

A major degradation product of the fungal metabolite citromycetin has also a 4-hydroxycoumarin skeleton.[2]



I R=OMe

II R=H; 2,3-dihydro

One of the common methods for the synthesis of such type of compounds is to treat the appropriate 4-hydroxycoumarin derivative with ethyl acetoacetate.[3] Also, in connection with the synthesis of radicinin and (±)-dihydroradicinin, Kato and coworkers[4] have reported the formation of similar types of compounds from the reaction of 4-hydroxy-2-pyranone and crotonoyl chloride in the presence of titanium tetrachloride in 1,1,2,2-tetrachloroethane. Using the same method, Whalley and coworkers[5] have synthesised di-*O*-methylcitromycinone (I).

The synthetic method described in the present work is a new route to a variety of 2,3-dihydro-4*H*,5*H*-pyrano-[3,2-*c*][1]benzopyran-4,5-diones which involves the reaction of 4-hydroxycoumarin derivatives with α,β-unsaturated acids in the presence of polyphosphoric acid. Besides acrylic acid other acids such as methcrylic, crotonic, β,β-dimethylacrylic and cinnamic acids could be used. Generally, the products were separated after quenching the reaction mixture with water, but in some cases, extraction with chloroform becomes necessary. Mechanistically the reaction follows a Friedel-Crafts acylation route. The reaction conditions used are compatible with a variety of substituents. The yields of the diones range from 35 to 40%. Hydroxycoumarins could be recoverred to the extent of 20 to 25%. In this context it is pertinent to mention that the cyanoethylation of 4-hydroxycoumarin derivative with acrylonitrile does not take place either in the presence of acidic or basic catalyst.

The structures of the compounds **1**—**17** were established on the basis of spectral and analytical data. In general dihydropyranobenzopyrandiones exhibit characteristic UV bands at λ_{max}^{MeOH} 215, 220, 280—290 (>C=O, lactonic), 315 nm (>C=O chromanone). The IR (Nujol or CH_2Cl_2) spectra of these compounds showed two bands: 1720—1740, 1660—1680. In the ^1H NMR spectra in $CDCl_3$ the aromatic protons appeared in the region δ 7.3—7.8 but in trifluoroacetic acid they were observed at δ 8.0.

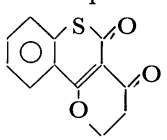
Further, all of them readily gave 2,4-dinitrophenylhydrazones, which rule out the possibility of the acryloyloxy derivatives. As a model compound for the synthesis of I, 4-hydroxy-7-methoxycoumarin was reacted with crotonic acid in the presence of PPA to yield a crystalline solid (II) which readily gave 2,4-dinitrophenylhydrazone (mp 264 °C) and was found to be identical (mmp) with the compound previously reported.[5]

The above reaction was extended to 4-hydroxythiocoumarin and its derivatives. The chemistry of the latter is of interest since they also show the same pharmacological properties as the oxygen analogs. The activity of the sulfur analog of dicoumarol is 1/10th that of parent compound but the sulfur analog of warfarin has the same activity as that of dicoumarol.[6]

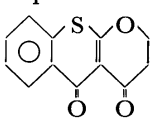
When 4-hydroxy(thiocoumarin) was allowed to reacted with α,β-unsaturated acids in the presence of polyphosphoric acid, the dihydropyranobenzothiopyrandiones were obtained in good yields (55—70%). However, the spectral data of these compounds revealed that they are not the expected 2,3-dihydro-4*H*,5*H*-pyrano[3,2-*c*][1]benzothiopyran-4,5-diones (III) but rather the isomeric chromanones (IV) as follows:

Firstly, their UV_{max}^{MeOH} showed only two principal bands namely at λ 225—230 nm and λ 305—315 nm indicating that absorption due to carbonyl group of the coumarin is absent.

The IR (CH_2Cl_2) of some typical compounds of this type showed bands at 1680 and 1610 cm^{-1} corresponding to CO frequencies at 4 and 5 positions.



III



IV

Additional and convincing proof of the above structures was deduced from their NMR spectra.

In the latter, the aromatic protons were shifted much downfield to δ 8.7—9.1 whereas in the expected dihydropyrano[3,2-*c*][1]benzothiopyrandiones the signals for aromatic protons would have come to δ 7.4—7.8.

It would be expected that the hydrogen nucleus proximate to the carbonyl group *i.e.* at the position 6,

would be the most pertubed of aromatic hydrogen atoms of the 2,3-dihydro-4*H*,5*H*-pyrano[2,3-*b*][1]-benzothiopyran-4,5-diones. These aromatic protons constitute a complex system wherein the proton at position '6' produces a quartet at unusually low field. In contrast the aromatic protons of the angular 2,3-dihydro-4*H*,5*H*-pyrano[3,2-*c*][1]benzothiopyran-4,5-diones would absorb around δ 7.4—7.8 as observed by us as well as by Berndt and Holzer[7] in their work on the Beckmann rearrangement of oximes of thiochromanones.

This difference helps in distinguishing angular and linear pyranobenzothiopyrandione structures.

The general applicability of this reaction was demonstrated by reacting 4-hydroxy-8-methyl, 7-methyl; 6-methylcoumarins as well as thiocoumarins with α,β-unsaturated acids in presence of PPA.

Experimental

^{1}H NMR spectra were recorded for solutions in deuteriochloroform and trifluoroacetic acid with a Varian A-60 instrument (tetramethylsilane as an internal reference). IR spectra were measured for Nujol mulls and for solutions in dichloromethane with a Perkin-Elmer spectrophotometer. UV spectra were measured for solutions in methanol with a Hilger instrument. Melting points were determined in a sulfuric acid bath. Purity of compounds was tested by TLC in all cases.

General procedure for the condensation of 4-hydroxycoumarin or thiocoumarin with α,β-unsaturated acids.

To a freshly prepared mixture of phosphorus pentaoxide (20 g) and phosphoric acid (10 ml) preheated to 100° for 30 min, 4-hydroxycoumarin or thiocoumarin (0.01 mol) and α,β-unsaturated acid (0.01 mol) were added. Temperature of the reaction mixture was maintained at 120 °C for 5 h. Reaction mixture was then cooled and cold water added and it was kept overnight. The product that separated was collected by filtration and washed well with sodium hydrogencarbonate solution to remove unreacted hydroxycoumarin and then with water, dried and crystallized from appropriate solvents. In cases of extraction with chloroform, the solvent layer was thoroughly washed with sodium hydrogen carbonate solution, water and dried. Evaporation of the solvent yielded a solid in most cases, crystallised from suitable solvent.

13 Mp 158—160 °C (ethyl acetate–petroleum ether), yellow needles. IR (KBr) cm^{-1}: 1725 (>C=O, coumarin); 1680 (>C=O, chromanone) 1600, 1550, and 1500 (ar.). NMR ($CDCl_3$) δ: 1.63 $\left(6H, s, C\langle^{CH_3}_{CH_3}\right)$; 2.8 (2H, s, CH_2); 7.1—7.8 (3H, m, ar.). Found: C, 69.6; H, 5.6%. Calcd for $C_{15}H_{14}O_4$: C, 69.8; H, 5.4%. 2,4-DNP, mp 274—275 °C. Found: N, 15.9%; Calcd for $C_{21}H_{18}N_4O_7$: N, 15.7%. Yield: 720 mg.

14 Mp 221—223 °C (ethanol–chloroform), pale yellow needles. Found: C, 68.1; H, 4.2%. Calcd for $C_{13}H_{10}O_4$: C, 67.8; H, 3.9%. Yield: 680 mg.

15 Mp 225—227 °C (ethanol–chloroform), pale orange needles. Found: C, 69.2; H, 4.7%. Calcd for $C_{14}H_{12}O_4$: C, 68.9; H, 4.9%. 2,4-DNP, mp >290 °C. Found: N, 14.4%. Calcd for $C_{20}H_{16}N_4O_7$: N, 14.2%. Yield: 790 mg.

16 Mp 170—172 °C (ethanol–chloroform), brown needles. Found: C, 69.1; H, 5.2%. Calcd for $C_{14}H_{12}O_4$: C, 68.9; H, 4.9%. Yield: 900 mg.

17 Mp 165—167 °C (ethyl acetate–petroleum ether), brown prisms. Found: C, 69.6; H, 5.5%. Calcd for $C_{15}H_{14}O_4$: C, 69.8; H, 5.4%. 2,4-DNP, mp 279—280 °C. Found: N, 12.9%. Calcd for $C_{21}H_{18}N_4O_7$: N, 12.8%. Yield: 750 mg.

b) From 4-Hydroxy(thiocoumarin):

18 Mp 178—180 °C (ethanol–chloroform), pale yellow needles. UV (MeOH) λ_{max}: 230 and 315 nm. IR (CH_2Cl_2) cm^{-1}: 1710 (>C=O, chromanone); 1615 (>C=O, chromone), 1600, 1500 (ar.). NMR (CF_3CO_2H) δ: 3.9 (2H, t, CH_2 next to >C=O); 5.15 (2H, t, CH_2– next to –O–), 8.1—8.5 (3H, m, ar.), 8.83—9.1 (1H, m, ar.); MS: *m/e* 232, 204 (M−CO). Found: C, 62.4; H, 3.8%. Calcd for $C_{12}H_8O_3S$: C, 62.1; H, 3.5%. 2,4-DNP, mp 254—256 °C. Found: N, 13.4%. Calcd for $C_{18}H_{12}O_4$: N, 13.6%. Yield: 900 mg.

19 Mp 199—201 °C (ethanol), brown prisms. UV (MeOH) λ_{max} 230, 305 nm. Found: C, 63.3; H, 4.3%. Calcd for $C_{13}H_{10}O_3S$: C, 63.4; H, 4.1%. 2,4-DNP, mp 275—277 °C. Found: N, 13.1%. Calcd for $C_{19}H_{14}O_6N_4S$: N, 13.1%. Yield: 1.1 g.

20 Mp 203—205 °C (methanol), yellow prisms. IR (Nujol) cm^{-1}; 1700 (>C=O, chromanone); 1610 (>C=O, chromone), 1600, 1500 (ar.). NMR (CF_3CO_2H) δ: 1.9 (3H, d, CH_3, J=5 Hz); 3.2 (2H, broad t, CH_2– next to >C=O); 5.4 (2H, broad t, CH_2– next to –O–); 8.0 (3H, broad s, ar.); 8.75 (1H, broad d, ar. J=10 Hz). Yield: 1.3 g.

21 Bp 180—190 °C/2.5 mmHg, yellow oil. Found: C, 64.9; H, 4.7%. Calcd for $C_{14}H_{12}O_3S$: C, 64.6; H, 4.6%. 2,4-DNP, mp 220—221 °C. Found: N, 12.9%. Calcd for $C_{20}H_{16}N_4O_6S$: N, 12.7%). Yield: 900 mg.

22 Mp 194—195 °C (aqueous ethanol), brown prisms. Found: C, 63.6; H, 4.4%. Calcd for $C_{13}H_{10}O_3S$: C, 63.4; H, 4.1%. 2,4-DNP, mp 264—265 °C. Found: N, 13.6%. Calcd for $C_{19}H_{14}N_4O_6S$: N, 13.8%. Yield: 1.32 g.

23 Yellow oil. Found: C, 64.5; H, 4.8%. Calcd for $C_{14}H_{12}O_3S$: C, 64.6; H, 4.6%. 2,4-DNP, mp 205—207 °C. Found: N, 12.8%. Calcd for $C_{20}H_{16}N_4O_6S$: N, 12.7%. Yield: 1.1 g.

24 Mp 159—161 °C (aqueous ethanol), yellow prisms. Found: C, 64.4; H, 4.7%. Calcd for $C_{14}H_{12}O_3S$: C, 64.6; H, 4.6%. 2,4-DNP, mp 268—270 °C. Found: N, 12.8%. Calcd for $C_{20}H_{16}N_4O_6S$: N, 12.7%. Yield: 1.45 g.

25 Yellow oil. Found: C, 65.9; H, 5.4%. Calcd for $C_{15}H_{14}O_3S$: C, 65.7; H, 5.1%. 2,4-DNP, mp 260—261 °C. Found: N, 12.2%. Calcd for $C_{21}H_{18}N_4O_5S$: N, 12.3%. Yield: 1.2 g.

26 Mp 164—165 °C (benzene–petroleum ether), pale yellow needles. Found: C, 64.9; H, 4.8%. Calcd for $C_{14}H_{12}O_3S$: C, 64.6; H, 4.6%. Yield: 1.43 g.

27 Yellow oil. Found: C, 65.5; H, 4.9%. Calcd for $C_{15}H_{14}O_3S$: C, 65.7; H, 5.1%. 2,4-DNP, mp 205—207 °C. Found: N, 12.5%. Calcd for $C_{21}H_{18}N_4O_6S$: N, 12.3%. Yield: 1.2 g.

28 Mp 214—215 °C (acetic acid), pale yellow prisms. Found: C, 63.6; H, 4.3%. Calcd for $C_{13}H_{10}O_3S$: C, 63.4; H, 4.1%. Yield: 1.38 g.

29 Mp 226—228 °C (acetic acid), pale black needles. Found: C, 64.7; H, 4.9%. Calcd for $C_{14}H_{12}O_3S$: C, 64.6; H, 4.6%. Yield: 1.25 g.

30 Mp 203—204 °C (ethanol), pale brown needles. Found: C, 64.3; H, 4.5%. Calcd for $C_{14}H_{12}O_3S$: C, 64.6; H, 4.6%. Yield: 1.47 g.

31 Yellow oil. Found: C, 65.5; H, 5.1%. Calcd for $C_{15}H_{14}O_3S$: C, 65.7; H, 5.1%. Yield: 1.3 g.

We thank Dr. K. Nagarajan, Ciba-Geigy Research Centre, for IR and NMR spectra. Senior Research Fellowship from Council of Scientific and Industrial Research to (S.Y.D.) is gratefully acknowledged.

Studies on the Cannabinoid Field: Synthesis of New Cannabinoids from 4-Hydroxycoumarin and 4-Hydroxythiocoumarin by Pyridine-catalysed Condensation of Citral and Citronellal

S. Y. Dike and J. R. Merchant*

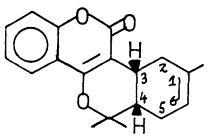
Department of Organic Chemistry, Institute of Science, Madame Cama Road, Bombay 400032, India

(Received June 27, 1977)

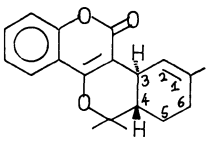
The reaction of 4-hydroxycoumarin and 4-hydroxythiocoumarin with citral in basic as well as acidic conditions led to the formation of tetrahydrocannabiol derivatives. With citronellal, the above hydroxycoumarins afforded the corresponding hexahydrocannabiol derivatives in moderate yields. The structures and the stereochemistry of the compounds obtained are established on the basis of spectral-analytical evidence.

In connection with studies[1] on the synthesis of cannabinoid analogs, we have investigated the reaction of 4-hydroxycoumarin (**1**) and 4-hydroxythiocoumarin (4-hydroxy-2*H*-1-benzothiopyran-2-one)(**2**) with citral and citronellal under different conditions. This work was prompted by the fact that both **1** and **2** can exist in tautomeric forms and that the hydroxyl group in them is highly acidic as indicated by their easy solubility in aqueous hydrogen carbonate solution. Another point of interest is the fact that the 4-hydroxycoumarin structure exists in a number of naturally occurring as well as physiological active compounds, such as the antibiotics novobiocin,[2] coumarmycin[3] and the well-known anticoagulants like dicoumarol[4] and warfarin.[5]

The reaction of **1** with citral in the presence of pyridine at 140 °C for 8 h or at 45—50 °C for 15 h gave a mixture of products, from which two compounds **3** and **4** could be isolated by careful chromatographic procedure. Their structural assignment is based on spectroscopic data, especially on NMR analysis.



3



4

These compounds exhibit similar spectral features. The mass spectrum of both shows the molecular ion peak at *m/e* 296. It also shows an M−43 peak which suggests that they are not the normal chromene derivatives in which this peak is invariably absent. The elemental analysis indicates their molecular formula as $C_{19}H_{20}O_3$. The UV spectra of **3** and **4** are also similar and show λ_{max} at 215, 280, and 300 nm, indicating that the reaction occurred with the retention of the coumarin ring and thus ruling out the alternate chromone structure. This assumption is supported by their IR spectra which show a carbonyl band at 1720 cm^{-1} corresponding to the coumarin ring.

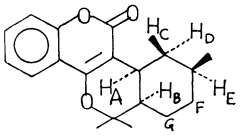
The analysis of NMR spectra of **3** and **4** is fully consistent with their assigned structures. The presence of a broad doublet for one olefinic proton at 5.19 and of a signal at 3.7 for one proton rules out other isomeric structures with a double bond in different positions in the cyclohexane ring. The four aromatic protons appeared as complex multiplet at 7.35—7.85. The assignment of *cis* configuration to **3** follows from the signal in the NMR at 3.7 due to the C_3 proton and the olefinic proton observed at 5.19 confirms that it is the Δ^6 isomer. A signal for the olefinic proton in **4** at 6.35 indicates that the compounds **3** and **4** should differ in the relative position of the double bond and the position of the C_3 proton at 3.25 supports a trans ring fusion. Hence **4** is a Δ^1-*trans* isomer. The NMR values we obtained are in perfect agreement with those obtained for Δ^1- and Δ^6-3,4-*cis*- and *trans*-tetrahydrocannabiol (abbreviated to THC) by Taylor[6] as well as by Archer and co-workers.[7]

It has been reported that the reaction of citral with *m*-benzenediols in the presence of pyridine generally leads to the synthesis of either chromene or cannabicyclol derivatives whereas, under acidic conditions, the formation of THC is observed.[8] The formation of THC in the presence of pyridine does not seem to have been reported so far.

In view of the above observations, the reaction of **1** which citral under mild acid conditions was studied. Compounds **3** and **4** were obtained after chromatography over silica gel (superimposable IR and NMR spectral).

Mechanistically, the formation of **3** and **4** in acid medium could be explained in the same way as that described by Crombie and Ponsford[8] for the acid-catalyzed reaction of citral and olivetol. In pyridine medium the formation of **3** and **4** is somewhat surprising. Our findings can be explained by the earlier observations of Berkoff and Crombie[9] who, in their work on citrylidenemalonic acid involving the reaction of citral with malonic acid in pyridine, reported that whenever "weak proton sources are available, the reaction seems to be so catalyzed." In our case strongly acidic 4-hydroxycoumarin is a good proton source and the reaction follows the acid-catalyzed pathway described above giving **3** and **4**.

Due to the ready reaction of citral with **1** leading to the formation of **3** and **4**, we investigated the reaction of **1** with citronellal in the presence of pyridine (molar proportions) at 140 °C. The reaction has not been studied so far and this is the first report of its use in the work connected with synthesis of cannabinoids. After purification by chromatography over silica gel only one compound **5** was isolated as a crystalline solid.



5

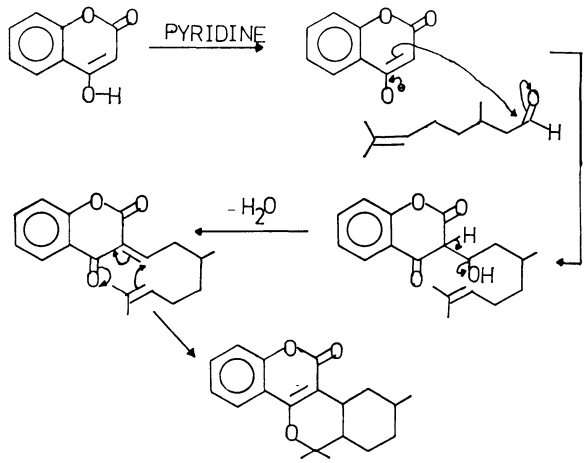
The mass spectrum of **5** showed a molecular ion peak at *m/e* 298. Comparison of the mass spectra of **3** and **5** revealed that the fragmentation pattern in both is very similar. The above observation and the analytical data show that **5** has the molecular composition $C_{19}H_{22}O_3$. Its UV showed λ_{max} at 215 and 300 nm whereas in the IR spectrum the carbonyl frequency was observed at 1725 cm^{-1}. The NMR spectrum of **5** revealed four aromatic protons at 7.1—7.7 in addition to other signals. The 100 MHz NMR ($CDCl_3$) spectrum provided additional proof for the structure as well as its stereochemistry.

The proton H_D unusually appears upfield at 0.66 as a quartet and is coupled to protons H_C (geminal), H_A, and H_E. The analysis of the system (three J_s of 11 Hz) requires the proton to be axial in order to have two ax-ax and one geminal couplings. This makes protons H_A, H_E, and H_D axial as H_D is diaxially coupled to H_A and H_E. Hence CH_3 at C_8 is equatorial. Arnone *et al.*[10] have also observed that the most stable conformation is the one where the Me group is disposed equatorially. The fact permits the assignment 1,3-*trans* configuration (Me-eq, H_B–A_X) to compound **5**. The chemical shifts of the methyl group on C_1 of **5** in the ^{13}C NMR spectrum (22.0 ppm, $CDCl_3$) confirms its equatorial orientation[11]. Similarly, the proton H_C appears unusually low field at 3.14 as a doublet of tripletes (J=11,3,3Hz). The samll values of coupling constants require the H_C proton to be equatorial. The abnormal downfield shift exhibited by the proton H_C as well as the upfield shift of the proton H_D are presumably due to the effect of a carbonyl functionality on the γ-methylene hydrogen and is well documented in the work of Williams *et al.*[12] on 11-keto steroids. Further, such methylene units are characterized by a marked upfieild shift of H axial and a very marked downfield shift of H equatorial. A triplet of doublet signals at 2.39 is attributed to the tertiary H_A proton as the protons oriented 1,3-diaxial to the methyl groups are deshielded. The H_A proton is coupled to H_B and H_D (J=11 Hz) diaxially. This defines the realtive stereochemistry of all the chiral centres in **5**.

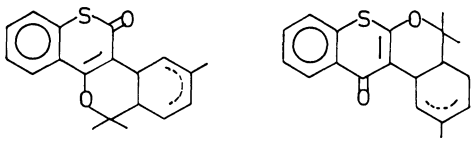
Mechanistically the formation of **5** can be explained as shown in the upper part of the next column.

The pyridine catalysed condensation of citral and citronellal was studied with 4-hydroxythiocoumarin **2**.

The chemistry of the latter is equally interesting in that it possesses the same physiological and chemical properties as **1**. Citral on condensation with **2** afforded a yellow oil which after chromatography over silica gel was found to contain a mixture of isomers in the ratio 1:1 as evident from the NMR spectrum. Its IR showed only a strong carbonyl band at 1610 cm^{-1} indicating that the coumarin ring was not present.

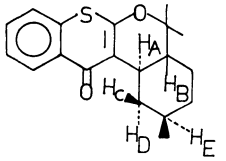


Further, in the NMR spectrum, the aromatic protons gave two different signals at 7.4 and 8.15 integrating for three and one proton, respectively, The latter downfield shift of the aromatic proton can be explained on the basis of structure **7** in which the C_5 proton is deshielded due to its proximity to the carbonyl group of the chromone ring whereas in **6** the aromatic protons would have shown signals at 7.3—7.8 as observed in **5**. The position of the olefinic protons at 6.2 and 5.4 of nearly equal intensity suggests that the compound is a mixture of stereoisomers, the difference being only in the position of double bond. The mass spectrum also favours the THC structure as, in addition to M^+ peak at 312, it shows M—43 peak due the loss of a C_3H_7 unit from the molecule.



6 7

The reaction of **2** with citronellal in the presence of pyridine yielded after purification by chromatography only a single crystalline compound which was assigned the structure **8** on the basis of spectral-analytical evidence. Its UV spectrum showed only two bands at λ_{max} 225 and 305 nm and the IR gave a NMR spectrum was also in line with the structure **8** and the various proton positions indicated its stereochemistry as shown. In the mass spectrum prominent peaks were obtained at *m/e* 314, 299 (M—15), and 271 (M—43).



8

Experimental

Melting points are uncorrected. UV spectra were measured in MeOH solutions. The IR spectra were measured

with a Perkin Elmer instrument, NMR (values in δ, J in Hz, TMS as internal standard, $CDCl_3$ as solvent unless otherwise stated) with a Varian A-60 spectrophotometer, and NMR 100 MHz with a Varian XL-15-100 spectrometer. Chromatography was performed with silica gel.

General procedure for the condensation of hydroxycoumarins with citral and citronellal.

4-Hydroxycoumarin or 4-hydroxythiocoumarin (0.01 mol) in dry pyridine (0.01 mol) was heated to 120 °C, and pure citral or citronellal (0.01 mol) was added slowly in 10 min. The resulting reaction mixture was refluxed at 140 °C for 7 h and then extracted with chloroform. The solvent layer was washed with dilute HCl and water to remove pyridine. Further washing of aqueous $NaHCO_3$ solution was carried out in order to remove unreacted 4-hydroxycoumarin or thiocoumarin. The organic phase was dried (Na_2SO_4) followed by removal of the solvent to yield a gummy mass which was subjected to chromatography over silica gel.

(a) Compound **3** (0.2 g), mp 113—114 °C. Found: C, 77.2; H, 7.1%. Calcd for $C_{19}H_{20}O_3$: C, 77.0; H, 6.8%. IR (Nujol) cm^{-1}: 1720(CO), 1600, 1560 (ar.). NMR ($CDCl_3$) δ: 1.2 (3H, s, CH_3), 1.35 (3H, s, CH_3), 1.65 (3H, s, CH_3), 0.9—2.2 (4H, m), 2.89 (1H, br, d, C_2H), 3.7 (1H, m, C_3H), 5.19 (1H, s, olefinic-H), 7.35—7.8 (4H, m, ar.), MS *m/e*: 296, 281, 253, 213.

(b) Compound **4** (180 mg), a viscous oil. Found: C, 76.8; H, 6.9%. Calcd for $C_{19}H_{20}O_3$: C, 77.0; H, 6.8%. IR (CH_2Cl_2) cm^{-1}: 1720 (CO), 1600, 1500 (ar.). NMR ($CDCl_3$)δ: 1.2 (3H, s, CH_3), 1.55 (1H, s, CH_3), 1.66 (1H, s, CH_3), 0.9—2.5 (4H, m), 3.2 (1H, br, m, C_3H), 6.35 (1H, br, d, olefinic-H), 7.3—7.85 (4H, m, ar.). MS *m/e*: 296, 281, 253, 213. Compound **5** from citronellal (600 mg), mp 113—114 °C (light petroleum ether (40—60 °C)). Found: C, 76.7; H, 7.4%. Calcd for $C_{19}H_{22}O_3$: C, 76.5; H, 7.4%. IR (CH_2Cl_2) cm^{-1}: 1725 (CO), 1600, 1500 (ar.). NMR ($CDCl_3$: 60 MHz) δ: 0.66 (1H, q, J=11 Hz, 11 Hz, and 11 Hz, H_D), 1.0 (3H, d, CH_3), 1.2 (3H, s, CH_3), 1.55 (3H, s, CH_3), 1.8—2.0 (6H, m), 2.4 (1H, 3d, H_A), 3.1 (1H, m, H_C), 7.35—7.8 (4H, m, ar.). NMR ($CDCl_3$, 100 MHz) δ: 0.66 (1H, q, $J_{DC}=J_{DE}$=11.5 Hz), 0.96 (3H, d, CH_3), 1.2 (1H, s, CH_3), 1.54 (1H, s, CH_3), 0.90—2.00 (6H, br, m, CH_{2F}, CH_{2G}, H_E, H_B), 2.39 (1H, 3d, $J_{AD}=J_{CE}$=3 Hz), 7.35—7.78 (4H, m, ar.). ^{13}C NMR: 19.47 (q, C_{12} or C_{13}), 22.00 (q, C_8), 35.07 (T, C_5), 37.2 (T, C_9), 26.91 (T, C_6), 27.35 (q, C_{12}, C_{13}), 32.13 (d, C_7), 34.15 (d, C_{10}), 48.2 (d, C_{11}), 81.05 (s, C_4) ppm.

(c) Compound **7**, from 4-hydroxythiocoumarin and citral viscous oil, 1 : 1 mixture. Found: C, 73.1; H, 6.5%; Calcd for $C_{19}H_{28}O_2S$: C, 73.4; H, 6.7%. IR (CH_2Cl_2) cm^{-1}: 1610 (>C=O), 1600, 1500 (ar.). NMR (CCl_4) δ: 1.25 (3H, s, CH_3), 1.4 (1H, s, CH_3), 1.65 (1H, d, CH_3), 1.8—2.5 (5H, m), 3.2 (1H, m, CH), 5.4 (1H, br, m, olefinic H), 6.2 (1H, d, olefinic H), 7.42 (3H, s, ar.), 8.15 (1H, broad, ar.).

(d) Compound **8**, from 4-hydroxythiocoumarin and citronellal (400 mg), mp 172—175 °C (ethyl acetate). Found C, 72,6; H, 7.0%; Calcd for $C_{19}H_{22}O_2S$: C, 72.8; H, 7.1%. IR (KBr) cm^{-1}: 1610 (>C=O), 1600, 1500 (ar.). NMR ($CDCl_3$) δ: 0.56 (1H, q, J=11.5, 11.5, 11.5 Hz, H_D), 1.0 (3H, d, CH_3), 1.2 (3H, s, CH_3), 1.5 (3H, s, CH_3), 1.8—2.2 (5H, m), 2.51 (1H, 3d, J=11.5 Hz, 3.5 Hz, 3.5 Hz, H_A), 3.0 (1H, 2t, J=11.5, 11.5, 11.5 Hz, H_C), 7.35 (3H, m, ar.), 8.15 (1H, m, ar.), MS *m/e*: 314, 299, 271.

We are grateful to Dr. V. V. Kane, Ortho Pharmaceutical Corporation, U.S.A., for providing ^1H NMR and ^{13}C NMR data as well as for valuable suggestions. We wish to thank the staff of Ciba-Geigy Research Centre and the Hoechst Research Centre, Bombay, for IR, NMR, and mass spectral data. One of us (S.Y.D.) wishes to thank the C.S.I.R., New Delhi for financial assistance.

Phthalimides. III.[1,2] Ammonolysis, Aminolysis, Hydrazinolysis, Pyrolysis, and Action of Grignard Reagents on Phthalimide Derivatives

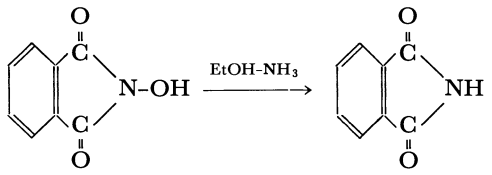
A. F. M. Fahmy,* N. F. Aly, and M. O. Orabi
Faculty of Science, Ain Shams University, Abbassia, Cairo, Egypt

(Received September, 14 1977)

N-Hydroxyphthalimide undergoes ammonolysis to give phthalimide. *N*-(Aroyloxy)phthalimides undergo alcoholysis followed by ammonolysis to give mixtures of phthalimide and ester. *N*-(Arylsulfonyloxy)phthalimides undergo ammonolysis, followed by Lossen rearrangement to give mixtures of 2,4-quinazolinedione and ammonium salts of arenesulfonic acids. *N*-Hydroxyphthalimide undergoes aminolysis to give the corresponding *N*-arylphthalimides. *N*-Hydroxyphthalimide reacts with hydrazine hydrate and/or phenylhydrazine in acetic acid or ethanol to give the corresponding 1,4-phthalazinedione, or by fusion to give phthalimide and *N*-phenylphthalimide, respectively. Pyrolysis of *N*-hydroxyphthalimide gives phthalimide, and *N*-(aroyloxy)phthalimides give mixtures of phthalimide and carboxylic acids. *N*-(Arylsulfonyloxy)phthalimides give mixture of phthalimide and arenesulfonic acids. However, pyrolysis of *N*-(arylcarbamoyloxy)phthalimides gave *N*-arylphthalimides. *N*-Hydroxyphthalimide reacts with phenylmagnesium bromide to give 1,1-diphenyl-3-(phenylimino)-1,3-dihydroisobenzofuran *via* ring opening followed Beckmann rearrangement, while *N*-(arylsulfonyloxy)phthalimides react with arylmagnesium bromide to give mixtures of [*O*-(arylamino)phenyl]diarylmethanols, and arenesulfonic acids *via* ring opening followed by Lossen rearrangement.

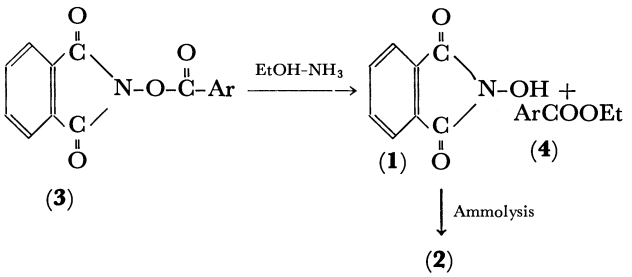
In a previous publication[1] *N*-(arylsulfonyloxy)phthalimides were reported to undergo base-catalyzed Lossen rearrangement with amines and acid-catalyzed Beckmann rearrangement with anhydrous aluminium chloride in the presence of aromatic substrates. We have reinvestigated the problem imide rearrangement and ring opening with different types of imides under different reaction conditions.

I. Ammonolysis. The hitherto unknown reaction of *N*-hydroxyphthalimide, and its *O*-arylsulfonyl and *O*-aroyl derivatives with ammonia was investigated. *N*-Hydroxyphthalimide (**1**) reacts with ethanolie ammonia to give phthalimide (**2**).



(**1**) (**2**)

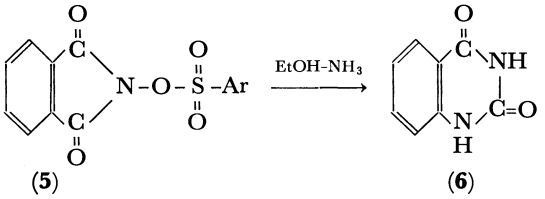
N-(Aroyloxy)phthalimides (**3**) undergo ammonolysis to give mixtures of phthalimide (**2**), esters (**4a**—**d**) *via* the intermediate *N*-hydroxyphthalimide (**1**).



(**3**) (**1**) (**4**) (**2**)

a: Ar=C_6H_5; **b**: Ar=$C_6H_4CH_3$(*p*-);
c: Ar=$C_6H_4OCH_3$(*p*-); **d**: Ar=C_6H_4Cl(*p*-).

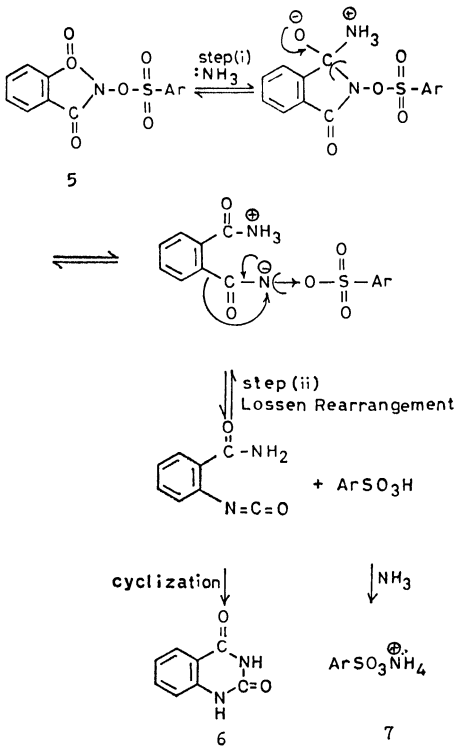
The reaction is actually alcoholysis, followed by ammonolysis. It was found that *N*-(arylsulfonyloxy)-phthalimides (**5a** and **b**) undergo ammonolysis *via* Lossen-rearrangement to give mixture of 2,4-quinazolinedione (**6**) and ammonium salts of arenesulfonic acids (**7a** and **b**).



(**5**) (**6**) + $ArSO_3^+NH_4$ (**7**)

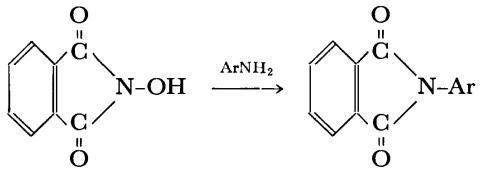
a: Ar=C_6H_5; **b**: Ar=$C_6H_4CH_3$(*p*-)

The reaction probably takes place according to Scheme 1.



Scheme 1.

II. Aminolysis. When **1** is allowed to react with aromatic amines, and/or amino acids, it undergoes aminolysis to give *N*-arylphthalimides (**8a**—**m**).

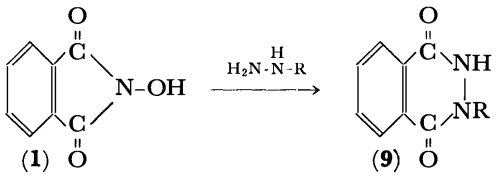


(1) (8)

a: Ar=C_6H_5, **b**: Ar=$C_6H_4CH_3(o)$, **c**: Ar=$C_6H_4CH_3(p)$, **d**: Ar=$C_6H_4OCH_3(o)$, **e**: Ar=$C_6H_4OCH_3(p)$, **f**: Ar=$C_6H_4Cl(o)$, **g**: Ar=$C_6H_4Cl(m)$, **h**: Ar=$C_6H_4Cl(p)$, **i**: Ar=$C_6H_4Br(p)$, **j**: Ar=$C_6H_5NO_2(p)$, **k**: $C_6H_4COOH(o)$, **l**: Ar=$C_6H_4COOH(m)$, **m**: Ar=$C_6H_4COOH(p)$

III. Hydrazinolysis. A novel reaction of **1** with hydrazines was found to occur under different conditions.

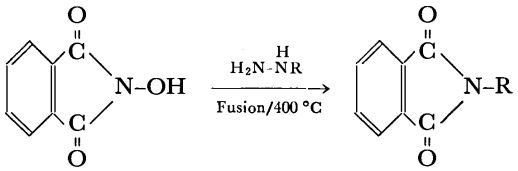
N-Hydroxyphthalimide (**1**) reacts with hydrzaines in acetic acid or ethanol to give the corresponding 1,4-phthalazinedione (**9a** and **b**)



(1) (9)

a: R=H **b**: R=C_6H_5

It was also found that **1** reacts with hydrazine hydrate, and/or phenylhydrazine by fusion at 400 °C to give phthalimide (**2**), and *N*-phenylphthalimide (**8a**), respectively



(1) **2**: R=H **8a**: R=C_6H_5

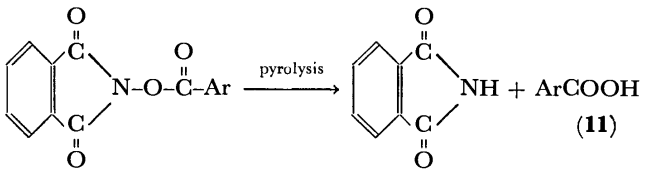
The reaction takes place according to Scheme 2.

This was confirmed by the fact that heating of *N*-anilinophthalimide (**10b**) at 200 °C for 2 h gives 2-phenyl-1,4-phthalazinedione (**9b**) in 67% yield, and the latter on pyrolysis at 400 °C giving *N*-phenylphthalimide (**8a**) in 65% yield.

The results shows that **9b** and **10b** are intermediates in Scheme 2.

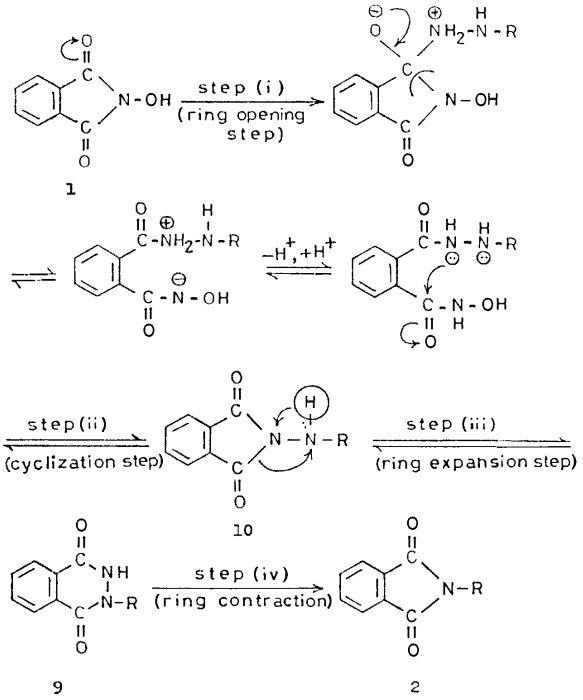
IV. Pyrolysis. It was found that **1** gives **2** on pyrolysis quantitatively. We studied the thermal decomposition of *N*-hydroxyphthalimide derivatives to see the effect of substituents on the mode of pyrolysis.

Pyrolysis of (**3a—d**) give mixtures of **2** and the corresponding acids (**11a—d**)



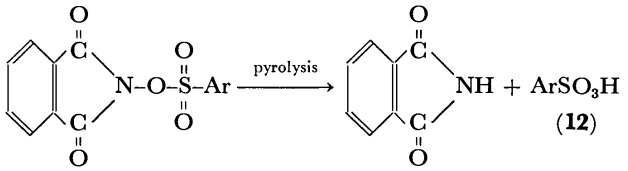
(3) (2) (11)

a: Ar=C_6H_5, **b**: Ar=$C_6H_4CH_3(p)$, **c**: Ar=$C_6H_4OCH_3(p)$, **d**: Ar=$C_6H_4Cl(p)$



Scheme 2.

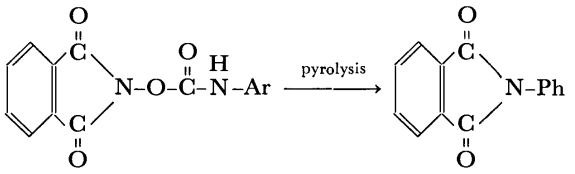
Similarly **5a** and **b** undergo pyrolysis to give mixtures of **2** and the corresponding arenesulfonic acids (**12**).



(5) (2) (12)

a: Ar=C_6H_5, **b**: Ar=$C_6H_4CH_3(p)$

However, *N*-(arylcarbamoyloxy)phthalimides (**13a—d**) give *N*-arylphthalimides (**8a, e, h, j**) by pyrolysis.

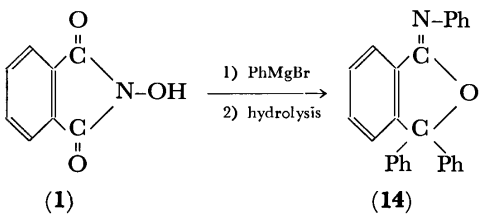


(13) (8)

a: Ar=C_6H_5, **e**: Ar=$C_6H_4OCH_3(p)$, **h**: Ar=$C_6H_4Cl(p)$, **j**: Ar=$C_6H_4NO_2(p)$

V. Addition of Grignard Reagents. A novel reaction of **1** and **5** with Grignard reagents was studied.

N-Hydroxyphthalimides reacts with phenylmagnesium bromide to give 1,1-diphenyl-3-(phenylimino)-1,3-dihydroisobenzofuran (**14**).



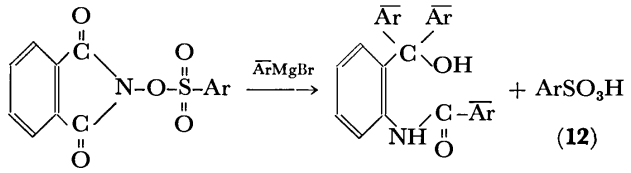
(1) (14)

The reaction might be the ring opening followed by

Beckmann rearrangement, and cyclization.

N-(Arylsulfonyloxy)phthalimides (**5**) were used instead of *N*-hydroxyphthalimide (**1**) in order to see the effect of the introduction of arylsulfonyl group on the imide reaction with Grignard reagent.

N-(Arylsulfonyloxy)phthalimide (**5a** and **b**) react with arylmagnesium bromide to give mixtures of [*O*-(arylamino)phenyl]diphenylmethanols (**15a—d**), and (**12a** and **b**).

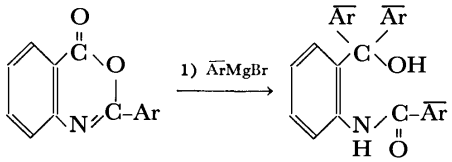


(**5**) (**15**) (**12**)

a: $\overline{Ar}=C_6H_5$, **b**: $\overline{Ar}=C_6H_4CH_3(p)$,

c: $\overline{Ar}=C_6H_4OCH_3(o)$, **d**: $\overline{Ar}=C_6H_4OCH_3(p)$

Structures of products (**15a—d**) were confirmed from their identity with products obtained by the reaction of arylmagnesium bromides with the corresponding 2-aryl-3,1-benzoxazin-4-ones (**16**).



(**16**) (**15**)

The reaction is actually the ring opening of the phthalimide ring with Grignard reagents followed by Lossen rearrangement.

Experimental

All the melting points are not corrected. IR spectra were measured on a Unicam Sp 1200 spectrophotometer using KBr wafer technique. Mass spectrum was measured with A.E.I.M.S. 12 single focusing mass spectrophotometer at a beam energy of 70 eV. and accelerating voltage of 8 kV. The sample was introduced to the sources *via* a direct inlet system the operating temperature being 270 °C.

I. Ammonolysis of N-*Hydroxyphthalimide and Its Derivatives.*

A. Action of Ethanolic Ammonia on N-*Hydroxyphthalimide (1); Formation of 2*: A mixture of *N*-hydroxyphthalimide (**1**) (prepared *via* phthalic anhydride and hydroxylamine)[3] (0.005 mol) and concd ethanolic ammonia (40 ml) was heated under reflux for about 3 h, then concentrated, and cooled. The solid obtained was filtered off, and recrystallised from methanol to give **2** as white crystals (mp 231—232 °C, yield 82%). It was confirmed to be phthalimide **2** by comparison of mp and mixture mp with those of an authentic sample[4] and its IR spectrum.[5,6]

B. Action of Ethanolic Ammonia on N-*(Aroyloxy)phthalimides (3a—d); Formation of 2*: A mixture of *N*-(aroyloxy)phthalimides (**3**) (prepared from *N*-hydroxyphthalimide and aroyl halides)[7] (0.005 mol), and concd ethanolic ammonia (50 ml) was heated under reflux for 3 h, then cooled to afford white crystals. It was filtered off, and recrystallized from ethanol to give white crystals (mp 230—231 °C, yield 71%). It was confirmed to be phthalimide by comparison of mp and mixture mp with authentic sample.[4]

The filtrate was heated under reflux with KOH for 30 min, cooled and acidified with hydrochloric acid to yield the corresponding acids (**11a—d**) which were proved by mp and mixture mp.[8]

C. Action of Ethanolic Ammonia on N-*(Arylsulfonyloxy)phthalimides (5a, b); Formation of 6 and 7*: A mixture of *N*-(arylsulfonyloxyl)phthalimides (**5a** and **b**) (0.01 mol) and ethanolic ammonia (60 ml) was heated under reflux for 2 h, then cooled. The solid obtained was filtered off, and recrystallised from acetic acid to give **6** as white needles (mp >350°, yield 74%).

It was found to be 2,4-quinazolinedione (**6**) by mp and mixture mp with authentic sample[9,10], and IR spectrum which showed ν_{NH} in the region 3280—3080 cm^{-1}, and coupling carbonyl bands in the regions 1740—1700 and 1680—1660 cm^{-1}.

The mother liquor was concentrated to low bulk to give the corresponding ammonium salts of arenesulfonic acids (**7**) which was confirmed by means of mp and mixture mp.

II. Aminolysis of N-*Hydroxyphthalimide. Action of Primary Amines and Amino Acids on* N-*Hydroxyphthalimide (1); Formation of* N-*Arylphthalimides (8a—m)*: A mixture of 1 (0.01 mol), and aromatic amines and/or aminoacids (0.04 mol) in ethanol (20 ml) was heated under reflux for 3 h, then concentrated, and cooled. The solid products were filtered off and recrystallized from suitable solvent to give (**8a—m**), *cf.* Table 1. It was found to be *N*-arylphthalimides by means of mp and mixed mp[11-17] and IR spectra.[5,6]

III. Hydrazinolysis of N-*Hydroxyphthalimide.*

A. Action of Hydrazines on N-*Hydroxyphthalimide in Acetic Acid or Ethanol: Formation of 9*: A mixture of **1** (0.01 mol) and hydrazine (0.03 mol), in acetic acid or ethanol (10 ml) was heated under reflux for about 12 h, then cooled. The solid obtained was filtered off, and recrystallized from acetic acid to give **9** (*cf.* Table 1).

It was found to be 1,4-phthalazinediones (**9a** and **b**) by means mp and mixture mp[18,19] and IR spectra which showed $\nu_{C=O}$ (1640—1630 cm^{-1}) and ν_{NH} (3180—3170 cm^{-1}).

B. Reaction of Hydrazine Hydrate with N-*Hydroxyphthalimide by Fusion (1); Formation of 2*: A mixture of **1** (0.01 mol), and hydrazine hydrate (0.05 mol) was heated at (400 °C) on a sand bath for 1.5 h. The solid product was extracted with hot ethanol, and recrystallized from ethanol to give **2** as white crystals (mp 230—231 °C, yield 65%).

It was proved to be phthalimide (**2**) by means of mp, mixture mp[4], and IR spectrum.[5,6]

C. Action of Phenylhydrazine on N-*Hydroxyphthalimide (1) and/or Phthalic Anhydride; Formation of 8a*: A mixture of **1** (0.01 mol) and/or phthalic anhydride (0.01 mol) and phenylhydrazine (0.03 mol) was heated at (400 °C) on a sand bath for 2 h, then cooled. The product was extracted with hot ethanol and recrystalized from the same solvent to yield a white crystals mp 204—205°; yield 65%. It was found to be *N*-phenylphthalimide (**8a**) by means of mp and mixture mp,[11] and IR spectrum.[5,6]

IV. Pyrolysis of N-*Hydroxyphthalimide and Its Derivatives.*

A. Pyrolysis of N-*Hydroxyphthalimide (1); Formation of Phthalimide (2)*: *N*-Hydroxyphthalimide (**1**) was heated above its mp on a sand bath for 1 h. The solid product was obtained in sublimed needles; collected in an air condenser, mp 231—232 °C, yield 60%. It was found to be phthalimide (**2**) by means of mp and mixture mp,[4] and IR spectrum.[5,6]

B. Pyrolysis of N-*(Aroyloxy)phthalimides (3a—d); Formation of Phthalimide (2) and Benzoic Acids (11a—d)*: *N*-(Aroyloxy)-phthalimides (**3a—d**) were heated at 300 °C in a sand bath for 3 h. After cooling the solid product obtained was recrystallized from ethanol and charcoalized to give solid (**2**) (mp 230—231 °C, yield 70%). It was found to be phthalimide (**2**) by means of mp and mixture mp,[4] and IR spectra.[5,6]

The mother liquors were concentrated by evaporation to give the corresponding benzoic acids,[11] identified by means of mp and mixture mp[8] (*cf.* Table 2).

C. Pyrolysis of N-*(Arylsufonyloxy)phthalimides (**5a** and **b**); Formation of **2** and Arenesulfonic Acids (**12a**, **b**)*: *N*-(Arylsulphonyloxy)phthalimides (**5**) were heated at (400 °C) on a sand bath for *ca.* 2 h, The solid products were recrystallized from ethanol with charcoalization to give white crystals mp 230—231 °C, yield 71%. It was found to be phthalimide (**2**) by means of mp and mixture mp[4] and IR spectrum.

The mother liquors were evaporated to dryness to give the corresponding arenesulfonic acids[20] (**12**).

D. Pyrolysis of N-*(Arylcarbamoyloxy)phthalimides (**13**); Formation of* N-*Arylphthalimides (**8a**, **e**, **h**, **j**)*: *N*-(Arylcarbamoyloxy)phthalimides (**13a—d**) were heated on a sand bath for 3 h. The products were extracted with hot ethanol and recrystalized from the same solvent. They were proved to be the corresponding *N*-arylphthalimides (**8**) by means of mp and mixture mp with authentic samples and IR spectra (*cf.* Table 3).

V. Action of Grignard Reagent on N-*Hydroxyphthalimide and Its Derivatives.*

A. Action of Phenylmagnesium Bromide on N-*Hydroxyphthalimide (**1**); Formation of 1,1-Diphenyl-3-phenylimino-1,3-dihydrobenzofuran (**14**)*: A solution of phenylmagnesium bromide (0.6 mol) in dry ether was added to a solution of *N*-hydroxyphthalimide (**1**) (0.1 mol) in dry ether. The reaction mixture was refluxed on a boiling water bath for 6 h and left to stand overnight. The reaction mixture was decomposed with ice-cold concentrated solution of ammonium chloride. The ethereal layer was separated, dried over anhydrous sodium sulfate, and the solvent was distilled off.

The solid product was filtered off and recrystallized from ethanol to give 1,1-diphenyl-3-(phenylimino)-1,3-dihydrobenzofuran (**14**) as colourless crystals (mp 188—190 °C, yield 68%). (Found: C, 86.4; H, 5.2%; Calcd for

$C_{26}H_{19}NO$: C, 86.4; H, 5.2%).

Structure **14** was confirmed by IR spectrum showing $\nu_{C=N}$ (1600 cm^{-1}), and MS showing [M^{+}; at (*m/e* 361); and $M^{+}-16$; at *m/e*=345].

B. Action of Grignard Reagents on N-*(Arylsulfonyloxy)phthalimides (**5a, b**); Formation of* [O-*(Arylamino)phenyl*] *Diarylmethanols (**15a—d**), and Arenesulfonic Acids (**13a, b**)*: The solution of arylmagnesium bromide (0.6 mol) in dry ether was added to a solution of *N*-(arylsulfonyloxy)phthalimides (**5**) (0.1 mol) in dry ether. The reaction mixture was heated under reflux on a boiling water bath for 6 h, and then allowed to stand overnight at room temperature. It was poured onto ice-cold concentrated solution of ammonium chloride. The ethereal layer was separated, dried over anhydrous sodium sulphate, and the solvent was distilled off. The solid product was filtered off and recrystalized from ethanol to give [*O*-(aroylamino)phenyl]diarylmethanols (**15a—d**) as white crystals (*cf.* Table 4). The mother liquor was concentrated by evaporation to give the corresponding arenesulfonic acids (**12**).[20]

Kinetics and Mechanism of the Oxidation of the Esters of Mandelic Acid by Lead Tetraacetate

Kalyan K. BANERJI,* Sudheer K. BANERJEE,** and Rama SHANKER**

Department of Chemistry, University of Jodhpur, Jodhpur 342001, India

(Received November 7, 1977)

The oxidation of eight esters of mandelic acid by lead tetraacetate in benzene solution has been studied. The product of the oxidation is the corresponding phenylglyoxylic ester. The oxidation is of first order with respect to the oxidant and second order to the ester. The reaction is catalysed by pyridine, the catalysed reaction being first order in pyridine. In the presence of pyridine, the reaction is first order with respect to each the oxidant and the ester. The oxidation of ethyl α-deuteriomandelate indicated a kinetic isotope effect. The activation parameters have been determined. The results have been interpreted in terms of a slow decomposition of lead tetraalkoxide derivative involving heterolysis of Pb–O bond.

Oxidation of organic compounds by lead tetraacetate (LTA) is known to involve both homolytic and heterolytic reactions.[1] The mechanism depends mainly on the nature of the compound and the reaction conditions. Baer and Kates[2] observed that the yield of pyruvic ester in the oxidation of methyl lactate varies with the solvent used. The oxidation of methyl mandelate in boiling benzene by LTA yields 70% methyl phenylglyoxylate.[2] Little kinetic data are available on the oxidation of mandelic esters by LTA. Oxidation of mandelic acid has earlier been reported from this laboratory.[3] However, hydroxy acids and their esters are known to react by different mechanisms.[4,5] The present communication reports the oxidation of some esters of mandelic acid by LTA, both uncatalysed and pyridine-catalysed.

Results

The rate laws and other experimental data were obtained for the oxidation of eight esters of mandelic acid. Since results are similar, only those of methyl mandelate (MM) are reproduced here.

The oxidation of mandelic esters by LTA, both uncatalysed and catalysed, yields carbonyl products as evidenced by the isolation of their 2,4-dinitrophenylhydrazones (2,4-DNP). However, no data were available on the 2,4-DNP of phenylglyoxylic esters. The esters of phenylglyoxylic acid were therefore, prepared by the reported mehtods.[6] Then the esters were converted into their 2,4-DNP. The 2,4-DNP of phenylglyoxylic esters and those of the oxidation products had identical mp. Mixed mp and mixed TLC confirmed that 2,4-DNP obtained by both the methods are identical. 2,4-DNP of the oxidation products of butyl and isopropyl mandelates showed correct analysis for C, H, and N. The mp of 2,4-DNP of the phenylglyoxylic esters are recorded in Table 1, along with the results of elemental analysis.

Stoichiometry. Excess of LTA was allowed to react with 0.0025 M of isopropyl mandelate in the presence of varying amounts of pyridine and the unreacted oxidant estimated. The ester and LTA react in 1 : 1 ratio. For some runs, the carbonyl product was estimated as its 2,4-DNP, using an excess of the ester. The carbonyl product is isolable in 80±3% yield. The overall reaction is as follows:

$$PhCH(OH)COOR + Pb(OAc)_4 \rightarrow PhCOCOOR + Pb(OAc)_2 + 2\,AcOH. \quad (1)$$

Rate Laws. When the ester is in excess, the rate of disappearence of LTA follows first order rate laws. The rate constant is independent of the initial concentration of LTA (Table 2) confirming that the order with respect to LTA is one. In uncatalysed reactions the order with respect to the ester is two (Table 3), In the presence of pyridine, the order with respect to LTA remains unchanged but the reaction becomes first order with respect to the substrate also (Table 4). The catalysed reaction is of first order in pyridine (Table 5).

An attempt was made to detect the formation of free radicals, during these oxidation in benzene, using acrylonitrile in an atmosphere of nitrogen. No free

radicals could be detected.

To ascertain the importance of α-C–H bond rupture in the rate-determining step, the oxidation of ethyl α-deuteriomandelate (PhCD(OH)COOEt) was investigated. The results are summarised in Table 6.

Tables 7 and 8 record the data on the effect of temperature on the uncatalysed and the catalysed oxidation respectively. The average error limits in the values of ΔH^*, ΔS^*, and ΔF^* are ±5 kJ mol^{-1}, ±10 J mol^{-1}·K^{-1}, and ±7 kJ mol^{-1}, respectively.

Discussion

The constancy of ΔF^* values indicates that the esters are oxidised by the same mechanism. Data in Tables 7 and 8 indicate the rate of oxidation of various esters do not differ markedly and a random variation becomes apparent when these rates are compared at different temperatures. This suggests that the structural changes in the alcohol moiety of the ester fail to affect the reaction rate. This is not surprising considering that at least four sigma bonds intervene between the reaction site and the substituent. Similar effects have been observed in many Ce(IV) oxidations.[7] Another possibility is that the reaction has been studied

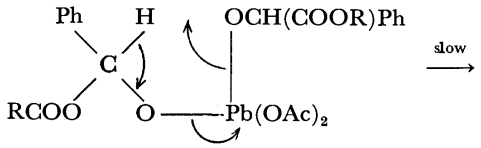
at or very near the isokinetic temperature. A plot of ΔH^* and ΔS^* ($r=0.986$) of the uncatalysed reaction gives an isokeintic temperature 312 K. Since the rates were determined close to the isokeintic temperature, consideration of rates alone could lead to erroneous conclusion about the nature of the reaction.

The formation of the keto ester in good yield and a second order dependence on substrate concentration indicate that the oxidation takes place through the decomposition of dialkoxylead(IV) derivative, the monoalkoxylead(IV) derivative being kinetically insignificant. The oxidation of alcohols is known to proceed through the disproportionation of such derivatives.[8,9]

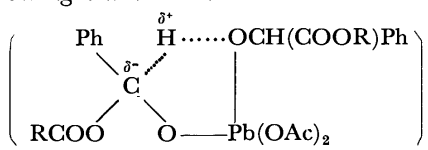
The disproportionation of the dialkoxy derivative may either involve a heterolysis of Pb–O bond (and a C–H bond rupture) or a rapid sequential two successive one electron processes. The presence of kinetic isotope effect and failure to induce polymerisation of acrylonitrile suggest that the disproportionation is a two-electron process. It may be mentioned here that homolytic oxidation of alcohols by LTA in nonpolar solvents results in cyclisation and fragmentation products—tetrahydrofurans and tetrahydropyrans.[1,10] Absence of such products also indicate a two-electron process.

$$Pb(OAc)_4 + 2\,PhCH(OH)COOR \rightleftharpoons 2\,AcOH + (PhCH(COOR)O)_2Pb(OAc)_2 \quad (2)$$



$$PhCOCOOR + PhCOCOOR + Pb(OAc)_2 + PhCHOH\cdot COOR \quad (3)$$

The observed negative entropies of activation also favour this mechanism over homolysis of Pb–O bond. The following transition state could be envisaged.



Due to partial positive charge created in the transition state in a nonpolar solvent like benzene, the solvent molecules will acquire induced dipoles and ion-dipole forces will restrict the movements of many benzene molecules. Further, since the dielectric constant is small, the lines of force will go far out into the solvent and a great many solvent molecules will be involved. The immobilisation of a large number of benzene molecules reduces the partition function of the transition state as compared to the reactant states. This would result in a large negative entropy of activation.

The reaction in the presence of pyridine is a neat one involving heterolysis of Pb–O bond.[8] The first order dependence on the ester concentration shows that pyridine coordinates with LTA to form a complex. Such a complex has been isolated from benzene by Partch and Monthony.[8] The increased polarisation interaction in Pb–N as compared to Pb–O bond renders the complex more labile and electrophilic. When [pyridine]$\gg$[Pb(IV)] the effective concentration of species like LTA-Py will be fairly constant and catalysis due to bases like pyridine seems to be quite profound. Further, a high kinetic isotope effect in pyridine-catalysed oxidation also requires a catalysis by pyridine. It therefore, appears that pyridine also acts as a base in facilitating the rupture of α-C–H bond. Lowering of ΔF^* in all cases in going from the uncatalysed to catalysed reaction is expected.

Experimental

Esters of mandelic acid, prepared by the reported methods,[11] were purified by distillation under reduced pressure and crystallization. Their mp and bp agreed with the literature values.[12] Solvents and other reagents were purified and dried in the usual manner. Ethyl mandelate (α-D, 90±5% deuterated) was prepared by the esterification of α-deuteriomandelic acid, which itself was prepared by the method of Kemp and Waters.[13] LTA was prepared by the reported method[14] (purity=98%).

Kinetic Measurements. The solvent used was benzene. AcOH (1% v/v) was added to each reaction mixture to avoid phase separation and to keep $Pb(OAc)_2$ in solution. Conductivity measurements showed that there was no appreciable interaction between pyridine and AcOH in this medium, hence no correction was applied to the initial concentration of pyridine. The reaction was studied under pseudo-first-order conditions by keeping a large excess the ester over LTA and were followed by the method of Cordner and Pausacker.[15] A parallel blank was always run to account for the decomposition of LTA, if any. The observed rates of pyridine-catalysed reactions were corrected for the rate of uncatalysed reaction. Similarly the rate of oxidation of the deuterated ester was corrected for the ordinary ester present. The first order rate constant, k_1, was evaluated from the plots of log[LTA] against time by a least square method and were reproducible within ±4%.

Preparation, Infrared and Mass Spectral Studies of 6-Substituted 6,7-Dihydro-5*H*-dibenzo[*d*,*f*][1,3,2]diazaphosphepine 6-Oxides

M. S. R. Naidu*,† and C. Devendranath Reddy

Department of Chemistry, Post-Graduate Centre, Sri Venkateswara University, Anantapur 515003, India

(Received November 1, 1976)

Several 6-substituted 6,7-dihydro-5*H*-dibenzo[*d*,*f*][1,3,2]diazaphosphepine 6-oxides have been synthesized and their structures were confirmed by IR and mass spectra. The existence of hydrogen bonding between the amidic hydrogens and the phosphoryl oxygen in theses compounds is indicated by the IR spectra. Under electron impact, the splitting pattern of these compounds takes about four major fragmentation pathways. The stability of dibenzodiazaphospheine cyclic system is indicated by the appearence of ions at *m/e* 229 and 211 corresponding to the species $C_{12}H_{10}N_2OP^+$ and $C_{12}H_8N_2P^+$, respectively, in all the spectra of the compounds except in the methyl and ethyl substituted compounds.

Considerable interest in organophosphorus compounds has been sustained by medical and commercial applications of their biological properties. The syntheses of these compounds containing benzodiazaphosphole ring have acquired much importance recently as these compounds have been investigated for their insecticidal, bactericidal, antiviral and anticarcinogenic properties.[1] The search for a satisfactory drug for cancer produced many new phosphorus heterocyclic compounds[2-5] and many of them possessed significant antitumour activity. These laboratories have reported[6] earlier the synthesis of several 2-(4-chloro-3-methylphenoxy)-2,3-dihydro-1*H*-1,3,2-benzodiazaphosphole 2-oxides, and the present paper describes the synthesis, infrared and mass spectral studies of 6-substituted 6,7-dihydro-5*H*-dibenzo[*d*,*f*][1,3,2]diazaphosphepine 6-oxides (**1**—**8**).

2	C_2H_5	**6**	O-$C_6H_4CH_3$(*p*-)
3	$(CH_2)_2CH_3$	**7**	O-$C_6H_4NO_2$(*p*-)
4	$CH(CH_3)_2$	**8**	O-$C_6H_3ClCH_3$(4,3-)

These cyclizations were accomplished by reacting equimolar quantities of various phosphonic dichlorides and phosphorodichloridates with 2,2'-diaminobiphenyl in refluxing benzene or toluene under nitrogen atmosphere. The yields of diazaphosphepines obtained (see Table 1) indicate that nucleophilic substitution of the amino groups proceeds more easily leading to the completion of cyclization with phosphorodichloridates than with phosphonic dichlorides. This may be explained by the fact that substituted phenoxyl groups attached to the phosphorus atom renders it more electrophilic. The lowest yield is obtained in the case of methylphosphonic dichloride. This may be due to the electron donating effect of methyl group by hyperconjugation which renders the phosphorus atom of the dichloride less electrophilic. All these compounds are crystalline solids with high melting points and are also easily soluble in organic solvents. They appear to be more stable than benzodiazaphosphole 2-oxides.[6]

The infrared frequencies associated with the major functional groups of the compounds in the present investigation are plotted in Table 2. All the compounds have exhibited P=O and P–NH vibrations in the regions 1210—1140 cm^{-1} and 3400—3080 cm^{-1}. The free P=O and NH stretching vibrations would give rise to bands around 1300—1250 cm^{-1} and 3350—3210 cm^{-1} [7,8] respectively. Bellamy[8] has also assigned 1250—1150 cm^{-1} for P=O stretching vibrations in the compounds which involve hydrogen bonding. The frequencies exhibited by P=O and P–NH groups indicate that they have involved in the hydrogen bond formation. All the compounds exhibited characteristic infrared frequencies for P–O–C_{aryl}[9-13], P–N_{phenyl}[14], P–N[14], aryl C–NO_2[15-17] and aryl C–Cl[18] groups.

To confirm the configuration of the cyclic system present in these molecules and also to study the splitting patterns and fragmentation pathways of this system, the mass spectra of these compounds (**1**—**8**) have been studied. As a general representation of this series, the splitting pattern and the fragmentation pathways of (*p*-methylphenoxy)dibenzodiazaphosphepine (**6**) under electron impact are shown in Scheme 1 (Fig. 1). The molecular ion, $C_{19}H_{17}N_2O_2P^+$, (*m/e* 336) itself appears as the most abundant ion for this compound. The initial fragmentation of the molecular ion occurs by ejecting the C_7H_7O radical attached to the phosphorus atom with the formation of the ion $C_{12}H_{10}N_2OP^+$ at *m/e* 229 (20%). This ion loses a water molecule to form the ion, $C_{12}H_8N_2P^+$ at *m/e* 211 (15%).

The ions at *m/e* 182 (16%) and 181 (24%) corresponding to the species $C_{12}H_{10}N_2^+$ and $C_{12}H_9N_2^+$ might

8	372(20), 371(14), 370(60), 229(33), 228(13), 211(19), 182(21), 181(26), 168(14), 167(100), 166(17), 154(11).

have been formed from the molecular ion by the cleavage of P–N bonds followed by the loss of hydrogen atom.

The ion at *m/e* 168 (16%) might have resulted by the loss of $C_7H_7NO_2P^{\cdot}$ from the molecular ion. In another mode of decomposition, the molecular ion might have lost $C_7H_8NO_2P$ resulting with the formation of a cation radical at *m/e* 167 (92%) corresponding to the species $C_{12}H_9N^{\ddagger}$. This ion on further loss of a hydrogen radical leads to the formation of the ion $C_{12}H_8N^{+}$ at *m/e* 166 (13%). The loss of $C_{12}H_{10}N_2OP^{\cdot}$ from the molecular ion by the rupture of the P–O bond results with the formation of the ion at *m/e* 107.

This general fragmentation pattern is observed for all other compounds in this series. The mass spectral data of the other compounds (**1**—**5**, **7**, and **8**) are presented in Table 3. An examination of all their spectra indicates that 6-aryl substituted compounds are more stable under electron impact than the 6-alkyl substituted compounds. The methyl and ethyl substituted dibenzodiazaphosphepines (**1** and **2**) do not show any peaks corresponding to their molecular ions. The mass spectra of **4**, **7**, and **8** show uniformly the ion at *m/e* 167 as their base peak. Even for **6** this ion appears with an intensity of 92 per cent.

The ions at *m/e* 229 and 211 corresponding to the species $C_{12}H_{10}N_2OP^{+}$ and $C_{12}H_8N_2P^{+}$ respectively (refer Scheme 1) are present as characteristic peaks in all the compounds except for methyl- and ethyl-substituted compounds (**1** and **2**). The ions at *m/e* 182 and 181 derived from the diamine fragment of the molecular ions are found to appear in the spectra of all the compounds.

Apart from these general peaks present in the spectra of all these molecules, the peaks can be explained as follows: the ion at *m/e* 337 in the spectrum of **7** might have been formed by the loss of NO from the NO_2 of the compound.[20] The ion at *m/e* 244 is observed in the spectra of both **3** and **4** and it might have been formed by the ejection of C_2H_4 from the alkyl substituents of their molecular ions.[21]

Experimental

All melting points were determined on a Mel-Temp apparatus and are uncorrected. The elemental analyses were performed by Dr. R. D. MacDonald, Australian Microanalytical Service. IR spectra were recorded on a Perkin-Elmer Model 700 in Nujol mulls. Mass spectra were determined using a Varian Mat CH7, electron energy 70 eV and trap current 100 μA at Indian Institute of Technology, Madras.

2,2′-Diaminobiphenyl. It was prepared by reduction of 2,2′-dinitrobiphenyl,[22] mp 78—79 °C (lit,[23] mp 77—78 °C).

Methyl-, ethyl-, propyl-, and isopropylphosphonic dichlorides were obtained from Speciality Organics, Inc., U. S. A. and phenylphosphonic dichloride was procured from Fluka. 4-Chloro-3-methylphenyl phosphorodichloridate[6], *p*-tolyl phosphorodichloridate,[6] *p*-nitrophenyl phosphorodichloridate[24] were prepared according to the procedures reported in the literature.

*6-Phenyl 6,7-Dihydro-5*H*-dibenzo*[d,f][*1,3,2*]*diazaphosphepine 6-Oxide (5).* A solution of phenylphosphonic dichloride (3.9g, 0.02 mol) in dry benzene (20 ml) was added drowise to a warm (40—50 °C) and stirred solution of 2,2′-diaminobiphenyl (3.7g 0.02 mol) in dry benzene (30 ml). A slow stream of nitrogen was bubbled through the reaction mixture and the progress of the condensation was followed by titrating the evolved HCl gas with standard alkali. The reaction mixture was brought to reflux temperature and the evolution of the calculated amount of HCl was complete in 95 min. The reaction mixture was refluxed with vigorous stirring for an additional 20 min and cooled. On working up, the reaction mixture yielded 5.4g (89%) of the product which on recrystallization from 95% ethanol four times afforded an analytical samples of 6-phenyl-6,7-dihydro-5*H*-dibenzo[*d,f*]-[1,3,2]diazaphosphepine 6-oxide (**5**), mp 330—333 °C (dec).

This typical procedure was used as a general method for the preparation of all other compounds (**1**—**4**, **6**—**8**) reported and their relevant details are summarized in Table 1.

The authors would like to express their sincere appreciation to Dr. K. L. Loening, Nomenclature Director, Chemical Abstract Service, for his advice in naming

the heterocyclic compounds in this article. The authors are also thankful to the University Grants Commission, for the award of a Junior Research Fellowship to one of them (CDR).
