Reaction of **7** *with Potassium* t-*Butoxide.* To a stirred solution of 0.778 g (2.89×10^{-3} mol) of **7** in 10 ml of DMSO was added at room temperature 2.37 ml (2.89×10^{-3} mol) of *t*-butyl alcoholic $KOC(CH_3)_3$ (1.22 M). After the mixture had been stirred for 1 h, 2.89 ml of 2.00 M HCl solution was added. The mixture was then treated according to procedure (a). **8** and **9** were obtained in 78% yield and in a small amount, respectively.

Reaction of **8** *with Sodium Methoxide.* To a stirred solution of 0.341 g (1.27×10^{-3} mol) of **8** in 10 ml of DMSO was added at room temperature 0.62 ml (1.27×10^{-3} mol) of methanolic $NaOCH_3$ (2.05 M). After the mixture had been stirred for 30 min and 2.53 ml of 1.00 M HCl solution added, the mixture was treated according to procedure (a). **9** was obtained in 89% yield.

Reaction of **8** *with Hydrochloric Acid.* To a stirred solution of 0.309 g (1.15×10^{-3} mol) of **8** in 10 ml of DMSO was added 2.30 ml (2.30×10^{-3} mol) of 1.00 M HCl aqueous solution at room temperature. After stirring for 30 min at room temperature, the mixture was poured into 100 ml of water, filtered, dried, and purified. **8** was quantitatively recovered.

NMR Measurement. About 35 mg of a sample was dissolved in *ca.* 0.25 ml of DMSO in NMR tube. After an equimolar amount of alkoxide had been added to the solution through a microsyringe and shaken vigorously, the mixture was subjected to measurement.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Syntheses of Cyano Derivatives of Triphenylphosphoniocyclopentadienide

Shigeo YONEDA, Masatake WATANABE, and Zen-ichi YOSHIDA*

Department of Synthetic Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received October 4, 1977)

Bromo derivatives of triphenylphosphoniocyclopentadienide were found to react with copper cyanide in *N,N*-dimethylformamide to give the corresponding nitriles without decomposition. The mono- and dicyano derivatives were prepared under relatively mild reaction conditions, but no tricyano derivatives were obtained from the cyclopentadienide having more than three bromine atoms in the cyclopentadienyl ring.

Preceding papers contain reports on the electronic structures[1-3] and the syntheses[4-7] of various derivatives of triphenylphosphoniocyclopentadienide (**1**)[8] by the reactions of **1** with electrophiles and electron-deficient unsaturated compounds such as dialkyl acetylenedicarboxylate, tetracyanoethylene and maleimide. In the present research, the syntheses of the cyano derivatives of **1** have been attempted. Introduction of cyano groups into the five-membered ring might result in the stabilization of **1**, since cyano-substituted cyclopentadienide anions are known to be remarkably stable. Webster[9] synthesized tetra- and pentacyanocyclopentadienide salts from diazotetracyanocyclopentadiene prepared with use of 1,1,-2,3,4,4-hexacyano-2-butene dianion and observed that these highly cyano-substituted cyclopentadienides are very stable. For example, the potassium salt of pentacyanocyclopentadienide is so stable that it can be heated at 400 °C in the air without decomposition. The pK_a values of polycyanocyclopentadienes are extremely small as compared with those of 14—15 for cyclopentadiene,[10] indicating that the cyano group effectively stabilizes the cyclopentadienide anion. We have succeeded in introducing cyano groups into the cyclopentadienyl ring of **1** by cyano-debromination at the cyclopentadienyl ring (a different method from that of Webster). The reactions of the bromo derivatives of **1** with cuprous cyanide have been attempted in *N,N*-dimethylformamide(DMF). The cyanation products were obtained in good yields, when the derivatives substituted by two or three bromine atoms together with other substituents such as nitro, phenylazo, formyl, methoxycarbonyl and cyano groups in the cyclopentadienyl ring were employed as the bromo derivatives. The substitution reaction of bormine atom(s) in cyclopentadienyl ring with cyano group is a convenient method to introduce cyano group into cyclopentadienyl ring.

Results and Discussion

The bromo derivatives of **1** employed in the reaction were synthesized by the reactions of **1** and its derivatives with *N*-bromosuccinimide. The yields, melting points and analytical data are given in Table 1. The starting materials **2**, **3**, **4**, and **5** were prepared by nitration, diazo coupling and Vilsmeier reaction of **1**.[4,7] The substitution at 2-position was indicated by the reaction indices calculated from HMO treatment[7] and confirmed experimentally in the diazo coupling[11] and nitrosation reactions.[7] Triphenylphosphonio-2,5-bis(methoxycarbonyl)cyclopentadienide (**6**) was prepared by the oxidation of **5** and subsequent treatment with diazomethane. Refluxing of the oxime of **5** in acetic anhydride afforded triphenylphosphonio-2,5-dicyanocyclopentadienide (**7**). The remaining hydrogens in the cyclopentadienyl ring of these derivatives (**2**, **3**, **4**, **5**, **6**, and **7**) were easily bromainted by *N*-bromosuccinimide.

Triphenylphosphonio-2,5-dibromocyclopentadienide (**8**) was prepared by treatment of **1** with cyanogen bromide. Cyanogen bromide is known as a reagent for direct cyanation of aromatic compounds in the presence of Lewis acid.[12] However, the reaction of **1** with cyanogen bromide in the presence of aluminum trichloride gave the 2,5-dibrominated one(**8'**) but no cyanation product. Compound **8'** is not as stable as the other bromo drivatives, but diazo coupling reaction of **8'** led to the formation of a stable compound, **9'**. All the bromo derivatives (**2'**, **3'**, **4'**, **5'**, **6'**, **7'**, **8'**, and **9'**) are new compounds.

The reactions of these bromo derivatives with cuprous cyanide (Rosenmund-von Braun type reaction) were examined. The preparative method of aryl cyanides from aryl halides and cuprous cyanide was established,[13] its improvement[14,15] and mechanism[16,17] also being reported. Reactions of the bromo derivatives, **2'**, **3'**, **4'**, **5'**, and **6'** with cuprous cyanide in DMF under reflux resulted in the formation of the cyanation products, which showed the characteristic absorption due to the cyano groups in the IR spectrum. Elemental analyses indicated the products to be dicyano-substituted one, **2''**, **3''**, **4''**, **5''**, and **6''**. No tricyanation compounds were obtained even under reflux for a week. This can be attributed to the steric hindrance in the formation of the intermediate complex [RBr–CuCN], through which the reaction might proceed.

The chlorinated derivatives of **1** did not undergo Rosenmund-von Braun type reaction. For example, triphenylphosphonio-2,5-diformyl-3,4-dichlorocyclopentadienide with cuprous cyanide in DMF did not take place under reflux for several days.

The bromine atoms of 2,5-dicyano-3,4-dibromocyclopentadienide (**7'**) were not replaced with cyano groups. The result can be accounted for by the poor interaction between the copper metal and the bromine atom, presumably because of the dominant interaction of copper with the cyano groups attached to the 2,5-positions.

In the reaction of triphenylphosphonio-2,5-dibromocyclopentadienide (**8'**) with cuprous cyanide, decomposition immediately occurs to afford a tarry substance. The inherently unstable derivative **8'** was

not recovered. More stable derivative **9′** reacts with cuprous cyanide to give the monocyano-substituted product, **9″**. The results are summarized in Table 2. Although the positions of the cyano-debromination in the five-membered ring were not experimentally determined for **2″**, **3″**, **4″**, and **9″**, most probable structures were deduced from examination of the intermediate complex in the reaction by the use of CPK atomic models.

Attempt to replace the bromine atoms in the five-membered ring of **2′**—**9′** with cyano groups using sodium cyanide was unsuccessful, but treatment of the bromo derivatives with sodium cyanide in the presence of cuprous bromide gave the cyano-substituted derivatives. The reaction of the bromo derivatives with cupric cyanide also afforded the cyanated products. Thus, it is obvious that copper is important as a catalyst in the substitution of the bromine by cyano group on the five-membered ring of triphenylphosphoniocyclopentadienide. The reaction is considered to proceed *via* a complex of copper with bromine atom and cyanide ion.

All the cyano-substituted products synthesized are stable in the air as well as in acidic and basic media.

Experimental

Spectra. Ultraviolet spectra were taken on a Hitachi EPS-3T recording photometer. Infrared spectra were recorded on a Hitachi grating infrared spectrophotometer, Model 215, and NMR spectra on a JNM C-60H NMR spectrometer with tetramethylsilane as an internal standard.

*Preparation of Triphenylphosphoniocyclopentadienide and Its Derivatives, **1**—**7** (Starting Materials in Table 1).* Triphenylphosphoniocyclopentadienide (**1**) and the derivatives (**2**, **3**, **4**, and **5**) were prepared according to the methods reported.[4-8] The derivative **6** was prepared by the oxidation of **5** and subsequent treatment with diazomethane. Mp 244 °C; IR(KBr) 1695 cm^{-1} (C=O); NMR ($CDCl_3$), δ=7.5—8.0 (15H, m, phenyl), 6.85 (2H, d, J_{P-H}=5.0 Hz, cyclopentadienyl), 3.80 (6H, s, methyl).

The 2,5-dicyano derivative **7** was prepared by the reaction of acetic anhydride with the dialdehyde oxime derived from **5** under reflux for 1 h. The IR spectrum showed and absorption band at 2250 cm^{-1} due to the cyano group; NMR ($CDCl_3$) δ=7.4—7.9 (15H, m, phenyl), 3.45 (2H, d, J_{P-H}=5.5 Hz, cyclopentadienyl).

Found: C, 72.83; H, 5.09; N, 6.79%. Calcd for $C_{25}H_{17}N_2P$: C, 72.54; H, 5.37; N, 6.86%.

Bromination of Triphenylphosphoniocyclopentadienide Derivatives. A solution of *N*-bromosuccinimide was added to a solution of triphenylphosphonio-2-nitro, 2-phenylazo, 2-formyl, 2,5-diformyl, 2,5-bis(methoxycarbonyl), and 2,5-dicyano-substituted cyclopentadienides (**2**—**7**). Stirring was continued for 30 min at room temperature and the precipitate was collected and recrystallized from dichloromethane–methanol.

Triphenylphosphonio-2,5-dibromocyclopentadienide (**8′**) was prepared by the following procedure. 0.750 g (0.70 mol) of cyanogen bromide in 20 ml of dichloromethane was added at 0—5 °C for 10 min to a solution of 1.141g (0.035 mol) of **1** in 100 ml of dichloromethane. After being stirred for 1 h at 110—115 °C the solvent was evaporated and the residue was chromatographed on alumina using dichloromethane as an eluent. A solid product precipitated when hexane was added to the dichloromethane solution. The precipitate was collected and purified by recrystallization from dichloromethane–methanol. The product **8′** is unstable, and accordingly the successive reaction should be carried out in mild conditions. However, triphenylphosphonio-2,5-dibromo-3-phenylazocyclopentadienide (**9′**) prepared by the diazo coupling reaction of **8′** is stable.

The yields, melting points and analytical data of **2′**—**9′** are summarized in Table 1.

Reaction of Bromo-substituted Phosphoniocyclopentadienide (2′—9′) with Cuprous Cyanide. The reactions of the bromo derivatives with cuprous cyanide in DMF were carried out under the reaction conditions given in Table 2. The reaction mixture was poured into water and the procut precipitated was collected, washed with water and purified by column chromatography on alumina using dichloromethane–methanol as eluents. The yields and the melting points are summarized

in Table 2. The spectral and analytical data of each product are as follows.

Triphenylphosphonio(2-nitro-3,4-dicyano-5-bromo)cyclopentadienide (**2''**): mp 295 °C (dec); IR (KBr) 2220 cm^{-1} (C≡N); NMR ($CDCl_3$) δ=7.4—8.0 (m, phenyl); UV_{max} (CH_3CN) 222 nm (log ε 4.54), 393 (4.08).

Thermolysis of Bis(diarylmethylenecarbamoyl) Peroxides

Tadashi SUEHIRO,* Yukio MATSUI, and Yoshio INOGUCHI

Department of Chemistry, Faculty of Sciences, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171

(Received October 24, 1977)

Diacyl peroxides of structure $(XC_6H_4)_2C{=}N{-}C(=O)OOC(=O){-}R$ ($R=(XC_6H_4)_2C{=}N$, X=H (**1**), X=2-CH_3 (**3**), X=4-CH_3; R=4-ClC_6H_4, X=H (**2**) have been prepared by the reaction between the corresponding carbamoyl chloride and hydrogen peroxide–urea complex in the presence of pyridine or between the carbamoyl chloride and 4-chloroperbenzoate in anhydrous ether at low temperature. Thermolysis of **1**—**3** follows first order kinetics. The large rates of thermolysis of **1** and **3** relative to those of bis(diphenylmethyleneacetyl) peroxide have been ascribed to steric compressions of **1** and **3** in the ground state and to the concerted cleavage of three bonds. Stable diphenylmethyleneamino radicals do not substitute in toluene by themselves but they do with the aid of aroyloxy radicals. The iminyl radicals abstract hydrogen from the methyl group of toluene, and the rate constant has been estimated to be 5×10^2—2×10^3 $M^{-1}s^{-1}$ at 50 °C.

The rates of the addition reactions of acyloxy radicals to benzene relative to those of their decomposition reactions to give carbon dioxide and aryl or alkyl radicals have been studied.[1] During the course of the studies it has been found that some of the ortho substituents in aroyloxy radicals such as methoxyl and bromo groups exhibited an increase in the activation energies for the decomposition of aroyloxy radicals.[2] The activation energy of the decomposition of cinnamoyloxy radicals was also higher than that of benzoyloxy radicals.[2] Studies on these phenomena could disclose the exact manner of the carbon dioxide cleavage of acyloxy radicals. Investigation of methylenecarbamoyloxy radicals would enable clarification of the nature of the $=N{-}CO_2$ bond in comparison with the $=CH{-}CO_2$ bond. Since the bond dissociation energies of C–N are 2—9 kcal/mol smaller than those of C–C bonds,[3] some amount of concerted multibond fission in the thermolysis of the peroxides having a $=N{-}CO_2$ structure is expected. This work also aimed to confirm the reactivity of N-centered radicals, of which increasing interest has been recently shown in reviews on aminyl radicals,[4] hydrazynyl radicals,[5] and aminium radicals.[6]

Results and Discussion

Preparation of Bis(diarylmethylenecarbamoyl) Peroxides. The preparations of bis(diarylmethylenecarbamoyl) peroxides were difficult due to the hydrolysis of carbamoyl chloride. Carbamoyl chlorides, when treated with a hydrogen peroxide–urea complex[7] and pyridine in anhydrous ether under cooling at −20 °C were however successful in the preparation of the peroxides.

Bis(di-2-methylphenylmethylenecarbamoyl) peroxide (**3**) is very labile and on standing at room temperatures turns yellow in a few minutes. The CH-analysis of the peroxide agrees fairly well with the calculated values, but the active oxygen determinations gave values below 100%: the di-2-methylphenyl compound **3** gave 67%, the di-4-methylphenyl peroxide **5** 85%, and the diphenyl peroxide **1** 86%, in comparison with bis(diphenylmethyleneacetyl) peroxide (**4**) 97%. The low values of active oxygen suggest a fast breakdown of the $=N{-}CO_2$ bond, yielding imniyl radicals, which are reduced slowly.

Product Studies. Products formed in the thermolysis of **1** and **2** in toluene at 50 and 100 °C, respectively, are given in Table 1.

During the thermolysis of **2** the absorption bands at 1740, 1700, and 1280 cm^{-1}, presumably the 4-chlorobenzoate of benzophenone oxime and 4-chlorobenzoic acid appear, and increase in intensities. The same appearance of absorption bands, however, was not found in the case of **1**.

Diphenylmethyleneamino radicals abstract hydrogen from the methyl group of toluene. Diphenylmethylenecarbamoyloxy radicals, if formed, loose carbon dioxide very rapidly, so that the carbamoyloxy radicals hardly add to the solvent toluene. The fast cleavage of carbon dioxide from diphenylmethylenecarbamoyloxy radicals was partly suggested by the iodometric determination of active oxygen, giving 67—86% of the theoretical value, and partly by the experiments, attempting to prepare methyltetraphenylmethanes by the reaction between **1** and triphenylmethyl radicals in toluene. This reaction is applicable to benzoyl peroxide,[1a] but it was not successful in the case of **1**.

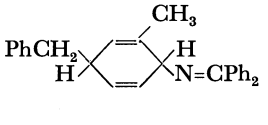
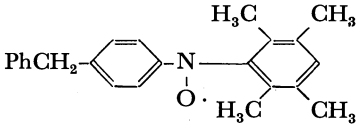
a) Yield in mol % per mole peroxide, determined by GLPC.



A



B

Although benzoyloxy radicals add to the solvent toluene under these reaction conditions, they do not appreciably abstract hydrogen from toluene. In the thermolysis of **1** therefore it is expected that the hydrogen abstraction by diphenylmethylenecarbamoyloxy radicals does not occur and diphenylmethyleneamine would be formed solely by the reaction of the iminyl radicals.

Hydrogen sources responsible for the high yield of diphenylmethyleneamine from **1** and **2** have not been explained well: some of the diphenylmethyleneamine could be formed in secondary reactions. In the thermolysis of **1** a small amount of *m*-tolylphenylmethane was found (1.2%). Its precurcer would be an adduct of the benzyl radical to toluene trapped by the diphenylmethyleneamino radicals, **A**, which on heating will give diphenylmethyleneamine and *m*-tolylphenylmethane. A similar addition of benzyl radicals to benzene has been observed in spin trapping experiments of the thermolysis of azobisphenylmethane in benzene in the presence of 2,3,5,6-tetramethylnitrosobenzene (nitrosodurene), yielding nitroxide **B**.[8]

Bis(diphenylmethylene)hydrazine has been reported to give diphenylmethyleneamine and other compounds on heating at 375—500 °C.[9] During the GLPC determination of bis(diphenylmethylene)hydrazine at 220 °C, however, no formation of the imine was observed. In the thermolysis of **2** the presense of the ester of benzophenone oxime was suggested by IR spectra, and the suggestion was that the ester might give diphenylmethyleneamine in the GLPC determination.

In the thermolysis of **1**, 3,3′-dimethylbiphenyl was not detected. If the iminyl radicals can add to toluene to give (diphenylmethyleneamino)methylcyclohexadienyl radicals, the cyclohexadienyl radicals could subsquently dimerize and decompose yielding dimethylbiphenyl and diphenylmethyleneamine. The formation of biphenyl and ammonia by the reaction mechanism between amino radicals and benzene has been suggested.[10]

Further marked differences between the products from **1** and **2** are that no bibenzyl and no (diphenylmethyleneamino)toluenes were formed from **1**, but were produced from **2**. The (dipheynylmethyleneamino)toluenes from **2** were composed of more meta isomer than ortho and para derivatives. The substitution at the meta position of toluene by diphenylmethyleneamino radicals agrees with the findings of Ishikawa *et al.*[11] in the photolysis of the benzoate and the 4-chlorobenzoate of benzophenone oxime in toluene. The subsititution of diphenylmethyleneamino radicals proceeds probably *via* the intermediate aroyloxycyclohexadienyl radicals as in the case of the homolytic triphenylmethylation of toluene in the reaction between triphenylmethyl radicals and benzoyl peroxide in toluene.[1a] Diphenylmethyleneamino radicals do not subsitute in toluene by themselves but they do with the aid of aroyloxy radicals.

During the thermolysis of **2** the concentration ratio $(PhCH_2\cdot)/(Ph_2C{=}N\cdot)$ will be larger than that in the case of **1**, sicne the half moiety of the peroxide molecule **2** is chlorobenzoyloxyl and 4-chlorophenyl radicals derived from the aroyloxy radicals are effective in abstracting hydrogen. Two benzyl radicals more frequently combine together in the thermolysis of **2** than in the case of **1**.

For the thermolysis of **1** and **2** the following scheme can be formulated.

For **1**

$$Ph_2C{=}N\underset{\underset{O}{\|}}{C}O\underset{\underset{O}{\|}}{C}N{=}CPh_2 \longrightarrow 2Ph_2C{=}N\cdot + 2CO_2 \quad (1)$$

$$Ph_2C{=}N\cdot + PhCH_3 \longrightarrow Ph_2C{=}NH + PhCH_2\cdot \quad (2)$$

$$Ph_2C{=}N\cdot + PhCH_2\cdot \longrightarrow Ph_2C{=}N{-}CH_2Ph \quad (3)$$

$$2Ph_2C{=}N\cdot \longrightarrow Ph_2C{=}N{-}N{=}CPh_2 \quad (4)$$

$$PhCH_2\cdot + PhCH_3 \longrightarrow PhCH_2\dot{C}_6H_5CH_3 \quad (I)$$

$$(I) + Ph_2C{=}N\cdot \longrightarrow Ph_2C{=}N(CH_3)C_6H_5CH_2Ph \quad (II)$$

$$(II) \longrightarrow Ph_2C{=}NH + PhCH_2C_6H_4CH_3 \quad (5)$$

For **2**

$$Ph_2C{=}N\underset{\underset{O}{\|}}{C}O\underset{\underset{O}{\|}}{C}C_6H_4Cl \longrightarrow Ph_2C{=}N\cdot + CO_2 + ClC_6H_4COO\cdot \quad (6)$$

$$ClC_6H_4COO\cdot \longrightarrow ClC_6H_4\cdot + CO_2 \quad (7)$$

$$Ph_2C{=}N\cdot \text{ or } ClC_6H_4\cdot + PhCH_3 \longrightarrow Ph_2C{=}NH \text{ or } ClC_6H_5 + PhCH_2\cdot \quad (8)$$

$$2PhCH_2\cdot \longrightarrow PhCH_2{-}CH_2Ph \quad (9)$$

$$ClC_6H_4COO\cdot + PhCH_3 \longrightarrow ClC_6H_4COO\dot{C}_6H_5CH_3 \quad (III)$$

$$(III) + Ph_2C{=}N\cdot \longrightarrow ClC_6H_4COOC_6H_5(CH_3)N{=}CPh_2 \quad (IV)$$

$$(IV) \longrightarrow CH_3C_6H_4N{=}CPh_2 + ClC_6H_4COOH \quad (10)$$

$$Ph_2C{=}N\cdot + ClC_6H_4COO\cdot \longrightarrow Ph_2C{=}N{-}OCOC_6H_4Cl \quad (11)$$

Reactions (3) and (4).

Kinetic Studies. Peroxides **1**—**4** were decomposed in benzene and in toluene under nitrogen. The rate of decompostion was followed by observing the decrease in absorption bands $\nu_{C=O}$ (1775 cm^{-1}), ν_{O-O}(1095 cm^{-1} for **1** and **3**, 1065 cm^{-1} for **4**), and ν_{C-O}(1195 and 1120 cm^{-1} for **2**). The change of toluene for benzene caused no effect in the rates. The decompositions followed first order kinetics and the activation parameters are given in Table 2. The extent of the free radical decomposition of **1** was 99% (DPPH) and 90% (Galvinoxyl) at 50 °C. The value for **2** was 81% (DPPH). These results indicate homolytic reactions for **1** and **2**, accompanied by a small degree of cage reaction for **2** (about 20%). Reaction 11 in the Scheme is a cage reaction.

The very fast and nearly complete homolyses of **1** and **2** are characterized by small activation parameters, ΔH^* and ΔS^*. *t*-Butyl peroxycarbamate were reported to decompose *via* a homolytic pathway to the extent of 73—95%,[12] although the ESR studies on the

Table 2. Rate constants and activation parameters for thermolysis of **1**, **2**, **3**, and **4** together with those of benzoyl peroxide and *t*-butyl diphenylmethyleneperoxycaramate

photochemical decomposition of *t*-butyl *N*-alkylperoxycarbamates showed the presence of the alkylbutyloxyamino radicals instead of the alkylamino radicals.[13] Examination of the decomposition of **1** in toluene at 50 °C by the ESR technique showed formation of diphenylmethyleneamino radicals in about 10^{-5} M from the peroxide in 3×10^{-2} molar concentration. The spectrum of the iminyl radical (triplet of septets, a_N 10.20 G and a_H 0.34 G) agrees exactly with those reported by Hudson *et al.*,[14] in the study of thiocarbamate of benzophenone oxime.

The activation enthalpies and enthropies of **1** and **3** are smaller than those of benzoyl peroxide, and the situation is the same for **2** but to a smaller extent. These results suggest a concerted cleavage of three bonds in a manner similar to those of peresters investigated by Bartlett and Hiatt.[15] The activation enthalpy for peroxide **4** is about 5 kcal/mol smaller than that of benzoyl peroxide, contrary to almost the same value of activation entropy for both peroxides. This indicates an appreciable assistance in thermolysis caused by the phenyl groups, resulting in an elevation of the energy of the ground state due to steric compression. Steric compression by phenyl groups is also expected in the peroxides **1**—**3**. In **1**—**3** some reorganization of bonds is operating in the transition state, leading to a decrease in the activation entropy: partial formation of stable free radicals $Ph_2C{=}N\cdot$ and carbon dioxide will be the cause of the reorganization of the bonds.

The methyl substituents in the peroxide **3** make the steric compression more serious and the conformations of tolyl groups in the ground state resembles those of ditolylmethyleneamino radicals as suggested by Symons.[16] A much smaller ΔH^* and a moderate decrease in ΔS^* arises from these situations.

The smaller rate constant for **2** than that for **1** implies a marked contribution of the diphenylmethyleneamino group to the thermolysis rate. In general the rates of decomposition of asymmetric diacyl peroxides are larger than the symmetric ones, owing to the polar effect of asymmetric structure in the transition state. Walling *et al.*[17] and Leffler and More[18] have discussed the effect of the polar nature in the transition state. The effect of the asymmetric structure of **2** on the rate of decomposition is probably a minor one in the presence of the diphenylmethyleneamino group.

Promotion of the decomposition by non-bonding electrons on nitrogen atoms through donation to the O–O bond will be of minor importance because the conformation **C** is more hindered than that of **D** owing to the bulkiness of the diphenylmethyleneamino groups. In the confornation **C** the phenyl groups P_1, P_2, P_1', and P_2' come near to each other more seriously than the phenyl groups P_2 and P_1' do in the conformation **D**. Consequently the former conformation will be destabilized more than the latter. The participation of the non-bonding electrons on nitrogen in electron donation to the O–O bond would be facilitated if the σ^* orbital of the O–O bond overlaps strongly with the non-bonding orbital of nitrogen. The favorite conditions for overlapping can be expected more in conformation **C** than in **D**. (Fig. 1).

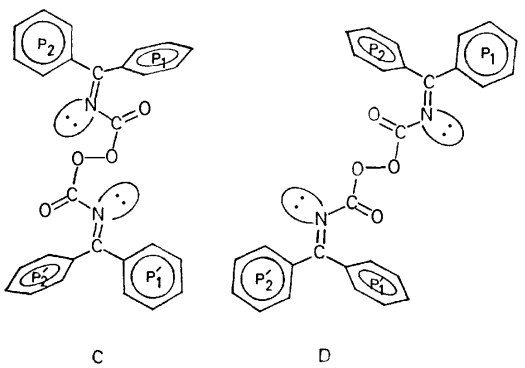

Fig. 1.

Estimation of Rate Constant of Hydrogen Abstraction Reaction of Diphenylmethyleneamino Radical from Methyl Group of Toluene. The main products of the thermolysis of **1** in toluene at 50 °C were diphenylmethyleneamine, 71.5%, *N*-(diphenylmethylene)benzylamine, 14.7%, and bis(diphenylmethylene)hydrazine, 35.2%. Although the yield of diphenylmethyleneamine was as high as 71.5%, the formation of the methyleneamine was not solely confined to Reaction 2. If all diphenylmethyleneamine were produced by the process, Reaction

2, then the termination reaction products of benzyl radicals, which were formed in the Raction 2, should be detected in an equal amount as diphenylmethyleneamine. *N*-(Diphenylmethylene)benzylamine and *m*-tolylphenylmethane have been determined together in 15.9% and a large amount of benzyl radicals (about 55%) could not be explained. For simplification it has been assumed that diphenylmethyleneamino radicals abstract hydrogen from toluene to an extent to yield benzyl radicals in *ca.* 15% per mole peroxide and that diphenylmethyleneamine was also produced *via* an unknown parallel process, 55%. Based on these assumptions the rate constant k_2 of the reaction sequences of Eqs. 2—4 can be estimated assuming a steady state in benzyl radicals, if k_4 and the stationary concentration of the diphenylmethyleneamino radicals (N) were known. Thus the Relation 12 is obtained:

$$\frac{\mathrm{d(ketazine)}/dt}{\mathrm{d(diphenylmethylenebenzylamine)}/dt} = \frac{k_4(\mathrm{N})^2}{k_3(\mathrm{N})(\mathrm{benzyl_radical})} = \frac{k_4(\mathrm{N})^2}{k_2(\mathrm{N})(\mathrm{toluene})}. \quad (12)$$

The value of k_4 was reported to be 2×10^8 M^{-1} s^{-1} at -35 °C.[19] At 50 °C k_4 will be 10^9 M^{-1} s^{-1}. The stationary concentration of the iminyl radicals was assumed by ESR technique to be 10^{-5} M at 50 °C in toluene when a solution of **1** in 3×10^{-2} M was used. Setting (toluene) = 10 M, gives

$$k_2 = 5\times10^2\ M^{-1}\ s^{-1}.$$

This is the lower limiting value of k_2. Another estimation will give maximum of k_2, if we assume that Reaction 2 is the sole process for the formation of diphenylmethyleneamine and that benzyl radicals in 55% per mole are ignored in the determination. From Relation 13,

$$\frac{\mathrm{d(ketazine)}/dt}{\mathrm{d(diphenylmethyleneamine)}/dt} = \frac{k_4(\mathrm{N})^2}{k_2(\mathrm{N})(\mathrm{toluene})}, \quad (13)$$

$$k_2 = 2\times10^3\ M^{-1}\ s^{-1}.$$

The rate constant 5×10^2 M^{-1} s^{-1} of diphenylmethyleneamino radicals for the hydrogen abstraction reaction from toluene at 50 °C is larger than the value 23 M^{-1} s^{-1} of trichloromethyl radicals from cyclohexane at 40 °C,[20] and 2.7×10^{-2} M^{-1} s^{-1} of *t*-butylperoxy radicals from toluene at 30 °C.[21] These can be explained in terms of heats of reaction using bond dissociation energies,[22] =N–H, $PhCH_2$–H, Cl_3C–H, C_6H_{11}–H, and *t*-BuOO–H of ⩾95, 85, 96, 94, and 90 kcal/mol, respectively.

Experimental

Peroxides. Diarylmethylenecarbamoyl chlorides were prepared by the reaction between diarylmethyleneamine and phosgen or oxalyl chloride by the method of Samaraj and others.[23] To a mixture of diarylmethlylenecarbamoyl chloride and a 20% excess of hydrogen peroxide–urea complex[7] in dry ether was added at -20 °C a 20% excess of pyridine in ether under stirring. Stirring was continued for 5 h and the mixture treated to the usual work up. Recrystallization of peroxide was effected from dichloromethane–methanol.

*$(Ph_2C{=}NCOO)_2$ (**1**).* Yield 18%. Mp 108—108.5 °C, dec. Active oxygen determined by iodometry was 86% of the theoretical value. Found: C, 74.71; H, 4.52; N, 6.21%. Calcd for $C_{28}H_{20}N_2O_4$: C, 74.99; H, 4.50; N, 6.25%.

*4-$ClC_6H_4COOOCON{=}CPh_2$ (**2**).* Sodium 4-chloroperbenzoate, prepared from peracid and sodium hydride, was set in dry ether at -15 °C and to this was added diphenylmethylenecarbamoyl chloride. Yield 66%. Mp 98.5—99 °C, dec. Found: C, 66.34; H, 3.54; N, 3.70%. Calcd for $C_{21}H_{14}NO_4Cl$: C, 66.41; H, 3.72; N, 3.68%.

*$((2\text{-}CH_3C_6H_4)_2C{=}NCOO)_2$ (**3**).* Yield 16%. Mp 78—80 °C, dec. Active oxygen by iodometry 67%. Found: C, 75.77; H, 5.50; N, 5.40%. Calcd for $C_{30}H_{24}N_2O_4$: C, 76.18; H, 5.59; N, 5.55%.

*$(Ph_2C{=}CHCOO)_2$ (**4**).* Diphenylmethyleneacetyl chloride, prepared from 1,1-diphenylethylene and oxalyl chloride,[24] was transformed to peroxide. Mp 98—99 °C, dec. Yield 23%. Active oxygen 97.1%. Found: C, 80.60; H, 4.85%. Calcd for $C_{30}H_{22}O_4$: C, 80.70; H, 4.97%.

*$((4\text{-}CH_3C_6H_4)_2C{=}NCOO)_2$ (**5**).* Yield 3%. Mp 103—105 °C, dec. Active oxygen 85%. Found: C, 75.75; H, 5.90; N, 5.42%. Calcd for $C_{30}H_{24}N_2O_4$: C, 76.18; H, 5.59; N, 5.55%.

Authentic Compounds for GLPC. Diphenylmethyleneamine: Prepared from diphenylmethyleneamine hydrochloride and sodium methylate. Bp 121—122 °C/0.5 Torr. Mp 59—63 °C.[25]

Diphenylmethylenebenzylamine: Obtained from benzophenone and benzylamine, Mp 60—61 °C.[26]

Bis(diphenylmethylnene)hydrazine: Prepared from benzophenone and hydrazine. Mp 164—165 °C.[27]

N-*(o-, m-, and p-Diphenylmethyleneamino)toluenes*: Toluidine and benzophenone were heated in the presence of fused zinc chloride for 2 h at 150 °C. Mp 48.5—50 °C (*o*-),[28] 77—78 °C (*m*-),[28] and 45—46 °C (*p*-).[28]

m-*Tolylphenylmethane*: Obtained by the method of Lamneck, Jr., and Wise.[29] Bp 86—86.5 °C/0.5 Torr.

GLPC Measurements. The products of thermolysis of peroxides were determined by GLPC using a JGC-1100 (JEOL) type apparatus, 3-m column of Apiezon L (5% on Chromosorb W(AW)) at 220 °C, and 3-m column of Apiezon L (1.5% on Cohrmosorb W(AW)) at 154 °C. Helium as carrier gas.

For the elemental analyses of the peroxides we are grateful to Dr. Shozo Masuda of the University of Tokyo.

α,β-Unsaturated Carboxylic Acid Derivatives. XV. The Reaction of Ethyl 3-Nitro-2-alkenoate with Bromine Azide or Bromine, and Transformations of the Products[1)]

Chung-gi SHIN,* Yasuchika YONEZAWA, Kaoru SUZUKI, and Juji YOSHIMURA**

Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221

***Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227*

(Received November 4, 1977)

The reaction of ethyl (*Z*)-3-nitro-2-alkenoate (**1**) with one or two equivalents of bromine azide gave a one-to-one mixture of ethyl (*E*)-2-azido-3-nitro-2-alkenoate (**3**) and 4-ethoxycarbonyl-1,2,5-oxadiazole 2-oxide (**5**), or ethyl 3-bromo-2,2-diazido-3-nitroalkanoate (**6**), respectively, and the subsequent thermal and photochemical reactions of (*E*)-**3** gave 2-ethoxycarbonyl-3-nitro-1-azirine, together with a small amount of **5**. The addition of bromine to **1**, and the subsequent elimination of hydrogen bromide from the product, gave exclusively, the (*Z*)-2-bromo derivative (**9**). The reduction of **6** and **9** with diethyl phosphonate was examined, and the reaction mechanisms were discussed.

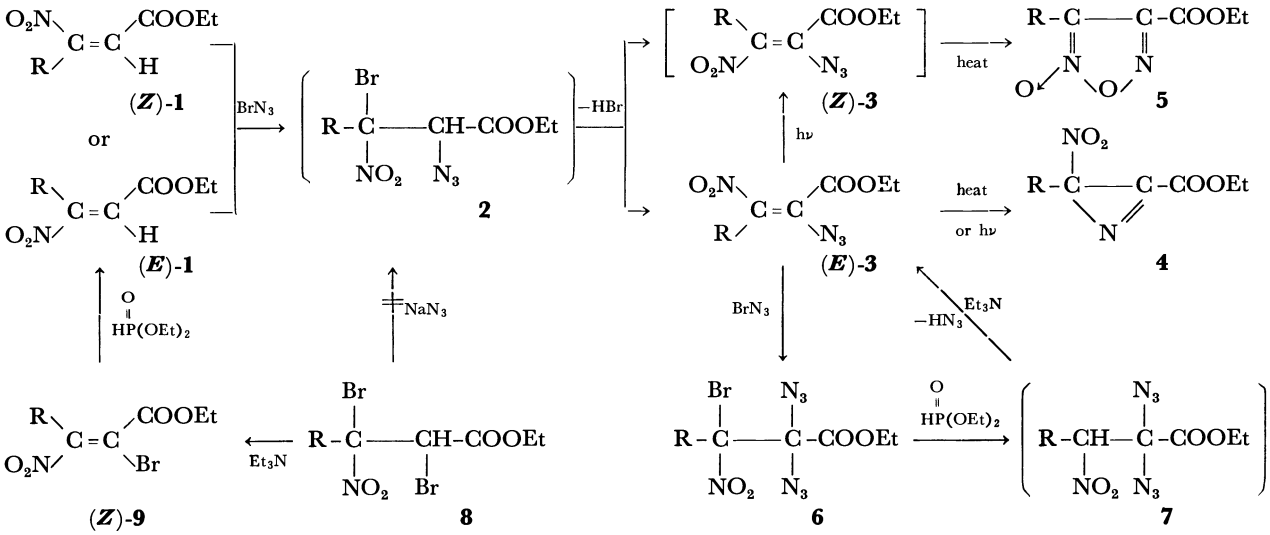
Although a few articles have been published on the properties of vicinal azido nitro olefins as intermediates, their isolation and their conversion into the corresponding nitroazirines have never been reported, except for the formation of 1,2,5-oxadiazole 2-oxides.[2–4)] Previously, however, we have ourselves reported the synthesis of stable α- and β-azido olefins[5,6)] and their conversion into the corresponding azirines[6)] and enamines.[7)]

In this paper, the reaction of bromine azide or bromine with ethyl 3-nitro-2-alkenoate[8)] and the subsequent elimination, substitution, and thermal and photochemical reactions of the products were examined, in order to isolate stably and convert the azido nitro olefins into the nitroazirine derivatives. Consequently, the expected several kinds of new vicinal azido nitro and bromo nitro compounds, nitroazirine, and 1,2,5-oxadiazole 2-oxide derivatives were obtained, as is shown in Scheme 1.

Results and Discussion

When an equimolar amount of ethyl (*E*)- or (*Z*)-3-nitro-2-alkenoate (**1**; **a**; R=CH_3, **b**; R=C_2H_5, **e**; R=C_6H_5) was treated with halo azide [formed from *N*-bromo- or *N*-chlorosuccinimide (NBS and NCS) and sodium azide in water][9)] in *N*,*N*-dimethylformamide (DMF), a syrup composed of two chemical species was obtained. In order to separate the mixture, it was carefully subjected to chromatography on a silica gel column, using benzene–petroleum ether (1:1 v/v), to give a pale yellow syrup (**3**) (1st fraction) and a colorless syrup (**5**) (2nd fraction) in a ratio of *ca.* 1:1. On the other hand, when the reaction was carried out in benzene under refluxing, **5** and a colorless syrup (**4**) were obtained in a ratio of *ca.* 1:1.

The structures of **3**, **4**, and **5** were assigned to ethyl 2-azido-3-nitro-2-alkenoate, 3-substituted 2-ethoxycarbonyl-3-nitro-1-azirine and 3-substituted 4-ethoxycarbonyl-1,2,5-oxadiazole 2-oxide respectively on the basis of their spectroscopic data as well as the results



a; R=CH_3, **b**; R=C_2H_5, **c**; R=*n*-C_3H_7, **d**; R=*i*-C_3H_7, **e**; R=C_6H_5

Scheme 1.

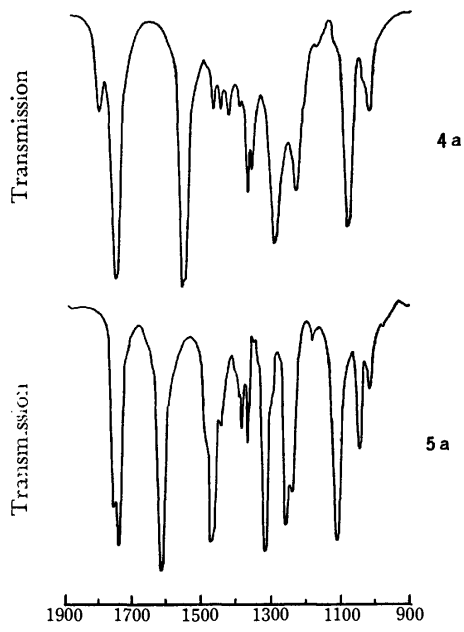


Fig. 1. IR spectrum of **4a** and **5a**.

of their elemental analyses. The difference between **4** and **5** can be characterized unambiguously by a comparison of their IR spectral data, shown in Fig. 1. The absorption bands at 1555—1560 and 1370 cm^{-1} assigned to the nitro group and the carbon-nitrogen double bond[6] of the azirine ring at 1790—1800 cm^{-1} indicate the formation of nitroazirine (**4**), whereas the disappearance of the nitro group in **5** supports the idea of ring formation between the oxygen in the nitro group and the nitrogen atom caused by the azido group.[2-4]

The configuration of a separated isomer of **3** could be determined as (*E*)-geometry by the formation of **4**, since the (*Z*)-isomer of vicinal azido nitro olefins is known to convert immediately at a higher temperature into the corresponding 1,2,5-oxadiazole 2-oxide.[2-4] It is noteworthy that (***E***)-**3** is the first example of an isolated azido nitro olefin.

Next, the thermal isomerization from (***E***)-**3** to (***Z***)-**3** was performed in benzene under reflux; however, only **4** was obtained in *ca.* a 60% yield. The irradiation of (***E***)-**3** in carbon tetrachloride externally with a high-pressure mercury lamp under a stream of nitrogen gas at room temperature also gave **4** in *ca.* a 35% yield, together with a small amount of **5**. This shows that (***E***)-**3** is slightly isomerized to (***Z***)-**3**, which is then immediately cyclized to **5**.

Moreover, the similar treatment of (***E***)-**1** or (***Z***)-**1** with two molar bromine azide gave the same compound as a colorless syrup in *ca.* a 70% yield. It was identified, by means of spectroscopic analyses, as ethyl 3-bromo-2,2-diazido-3-nitro-alkanoate (**6**). It is known that diethyl phosphonate does not react with both nitro[10] and azido[11] groups in the carboxylic acid ester and that it reduces the halogen atom.[12] Accordingly, when **6** was treated with diethyl phosphonate in benzene in the presence of triethylamine, (***E***)-**3** was obtained in a fairly good yield, along with **5** in a low ylied. This fact indicates that the bromide atom of **6** is reduced with phosphonate to form an unstable intermediate, ethyl 2,2-diazido-3-nitroalkanoate (**7**); the subsequent rapid elimination of hydrazoic acid[13] in the presence of the base from **7** gives (***E***)-**3** snd (***Z***)-**3**, the latter of which is further transformed into **5**.

From the above facts, the formation of **3** and **6** from **1** seems to be through successive the addition reaction of bromine azide to **1** and the elimination of hydrogen bromide to give (***E***)-**3** and (***Z***)-**3**, formed as a labile intermediate, which in turn reacts further with excess bromine azide to give **6**, as is shown in Scheme 1. The latter addition was substantiated unambiguously by the reaction of the isolated (***E***)-**3** with bromide azide.

The yields, physical constants, and spectral data of **3**—**6** are summarized in Tables 1 and 2.

On the other hand, the dehydrobromination of ethyl 2,3-dibromo-3-nitroalkanoate (**8**), prepared in a good yield from the reaction of (***E***)-**1** or (***Z***)-**1** with bromine in chloroform, with triethylamine gave 2-bromo-3-nitro-2-alkenoate (**9**) in *ca.* a 90% yield. Although the compound, **8**, derived from individual (***E***)-**1** and (***Z***)-**1** consisted of two stereoisomers in various ratios, listed in Table 3, according to the reaction, a single product, **9**, was formed stereospecifically. The configuration of **9** could be determined as the (*Z*)-geometry by conversion into (***E***)-**1** in *ca.* a 50% yield by reduction with diethyl phosphonate. From the above results, it was deduced that the base-catalyzed β-elimination of **8** composed of erythro- and threo-stereoisomers (see Table 3) proceeded by means of ElcB mechanism *via* the corresponding nitronate carbanion.[8] Attempts at the substitution of the bromo atom at the 2-position with the azido group in **8** and **9** by treatment with sodium azide was unsuccessful, forming an ambiguous mixture.

Experimental

All the boiling and melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrometer. The NMR spectra were measured with a JNM-PS-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.), using tetramethylsilane as the internal standard.

*Preparation of **3**, **4**, and **5**.* Into a solution of NBS or NCS (0.06 mol) in DMF (100 ml) we stirred, drop by drop, a solution of sodium azide (0.06 mol) in water (18 ml) at −20 °C for 15 min. The resulting solution was added, drop by drop, to a solution of (***E***)-**1** or (***Z***)-**1** (0.06 mol) in DMF (20 ml) at −40——45 °C. After stirring at −30 °C for 45 min, the mixture was poured into ice-water (350 ml). After continuous stirring for 1 h, the aqueous solution was extracted three times with dichloromethane (130 ml). The extracts were collected, washed twice with water, and then dried over anhydrous magnesium sulfate. The dichloromethane layer was evaporated to give a residual syrup, which was chromatographed on a silica gel column, using benzene–petroleum ether (1:1 v/v) as an eluent below 5 °C. Mainly two fractions were obtained. After concentrating each fraction, the (***E***)-**3** compound as a pale yellow syrup from the first eluted fraction and **5** as a colorless syrup from the second eluted one were obtained.

On the other hand, the syrup obtained from the above dichloromethane solution was directly dissolved in dry benzene (60 ml), and then the benzene solution was refluxed for 1 h. The resulting solution was evaporated to give a residual syrup, which was distilled under reduced pressure to give a colorless syrup composed of a mixture of **4** and **5**. A similar separation gave **4** and **5** in *ca.* a 1:1 ratio.

*Preparation of **6**.* *Procedure A*: Into a solution of (***E***)-**1** or (***Z***)-**1** (0.05 mol) and NBS (0.11 mol) in DMF (100 ml) we stirred drop by drop, a solution of sodium azide (0.11 mol) in DMF–water (1:1 v/v) (30 ml) below −10 °C. After continuous stirring for 40 min, the mixture was poured into ice water (400 ml). After stirring for 1 h, the aqueous solution was extracted three times with hexane (100 ml). The extracts were collected, washed twice with water, dried over sodium sulfate, and finally evaporated under reduced pressure to dryness. The residual syrup was placed in a silica gel column using benzene as the eluent. The fractions were collected and evaporated under reduced pressure to give **6** as a colorless syrup.

Procedure B: Into a solution of (***E***)-**3** (0.01 mol) in DMF (30 ml) we stirred drop by drop, a solution of NBS (0.01 mol) and sodium azide (0.01 mol) in water (10 ml) below −10 °C. After continuous stirring for 30 min, the mixture was worked up such as has been described in Procedure A.

*Thermal Reaction of (**E**)-**3**.* A solution of (***E***)-**3** (0.03 mol) in dry benzene (20 ml) was refluxed for 1 h. After the removal of the solvent under reduced pressure, the residual syrup was purified on a silica gel column, using benzene–ethyl acetate (20:1 v/v) as the eluent. The fraction was then collected and concentrated. The residue was distilled under reduced pressure to give **4**.

*Photochemical Reaction of (**E**)-**3**.* A solution of (***E***)-**3** (0.03 mol) in dry carbon tetrachloride (80 ml) was irradiated with a high-pressure mercury lamp (450 W) in a stream of nitrogen gas at 10 °C for *ca.* 7 h, at which time the azido group band at *ca.* 2100 cm^{-1} disappeared. The resultant solution was evaporated; the purification of the residual syrup thus obtained was worked up such as above to give **4** and **5** in *ca.* a 10:1 ratio.

*Reaction of **6** with Diethyl Phosphonate.* Into a mixture of **6** (0.01 mol) and diethyl phosphonate (0.01 mol) in dry benzene (30 ml) we stirred, drop by drop, triethylamine (0.01 mol) below 10 °C. After continuous stirring for 30 min, triethylammonium bromide was filtered off, and then the benzene layer was concentrated under reduced pressure. The residual syrup was chromatographed on a silica gel column, using benzene as the eluent; two fractions were thus obtained. After each fraction had been concentrated under reduced pressure, the first fraction gave (***E***)-**3** in *ca.* an 80% yield, while the second one gave **5** in *ca.* a 13% yield.

*Preparation of **8**.* To a solution of (***E***)-**1** or (***Z***)-**1** (0.1 mol) in chloroform (70 ml) we added, drop by drop, a solution of bromine (0.1 mol) in chloroform (30 ml) with occasional shaking. The mixture was allowed to stand at room temperature for 24 h and then concentrated to dryness. The residual oil was distilled under reduced pressure to give **8** as a colorless oil.

*Preparation of **9**.* Into a solution of **8** (0.1 mol) in dry benzene (80 ml) we stirred, drop by drop, triethylamine (0.12 mol) under cooling. After continuous stirring overnight at room temperature, triethylammonium bromide was precipitated. It was filtered off, and the filtrate was washed sucessively with 3 M-hydrochloric acid and water. The resulting benzene layer was dried over anhydrous magnesium sulfate and concentrated under reduced pressure to give a residual syrup. The residue was distilled under reduced pressure to give (***Z***)-**9** as a colorless oil.

*Reaction of (**Z**)-**9** with Diethyl Phosphonate.* Into a solution of (***Z***)-**9** (0.1 mol) and diethyl phosphonate (0.1 mol) in dry benzene (70 ml) we stirred, drop by drop, triethylamine (0.12 mol) under cooling. After continuous stirring for 1 h at room temperature, triethylammonium bromide was filtered off and the filtrate was washed successively with 3 M-hydrochloric acid and water. The benzene layer was dried over anhydrous magnesium sulfate and concentrated under reduced pressure to give (***E***)-**1** as a colorless oil.

(Received November 2, 1977)

The Diels-Alder reaction of individual (*E*)- and (*Z*)-isomers of ethyl 3-nitroacrylate and 3-nitrocrotonate with 1,3-butadiene, 1-acetoxy- or 1,4-diacetoxy-1,3-butadiene was conducted to give ethyl 6-nitro-3-cyclohexene-, 5-acetoxy-, and 2,5-diacetoxy-6-nitro-3-cyclohexene-carboxylates, respectively. The stereochemistry of the cycloaddition products has been elucidated by analysis of the NMR spectrum.

In previous papers, the Diels-Alder reaction of cyclopentadiene with ethyl (*E*)- and (*Z*)-3-nitrocrotonate (**6**) or ethyl (*Z*)-3-nitrocinnamate and subsequent reduction of the resulting (2+2)- and (2+4)-nitro adducts with aluminum–amalgam (Al–Hg) were carried out to give unique tricyclic isoxazolidione derivatives.[1,2]

In order to synthesize desirable starting materials for antibiotics oryzoxymycin[3] and related compounds[4,5] having a 6-amino-5-hydroxy-1,3-cyclohexadiene-1-carboxylate structure, here, the cycloaddition reaction of ethyl (*E*)-3-nitroacrylate (**1**) or **6** has been extended to 1,3-butadiene, 1-acetoxy- and 1,4-diacetoxy-1,3-butadienes. The conformational determination of all the new (2+4)-nitro adducts has been established on the basis of the spectral data.

Results and Discussion

*Reaction of **1** with 1,3-Butadiene.* According to the method of Shechter[6] and Shin,[7,8] compound **1** was prepared stereoselectively from the reaction of ethyl 2-chloro-3-nitropropanoate with sodium acetate. Thermal and photochemical isomerization of **1** to its (*Z*)-isomer failed. However, the structure of **1** was determined to be the (*E*)-isomer from the coupling constant between C-1 and C-6 protons and the spectral properties of the cycloaddition products.

Heating a solution of (***E***)**-1** and 1,3-butadiene in chloroform in an autoclave at 80—100 °C under 2—3 atmospheres for *ca.* 40 h gave a cycloaddition product of a colorless oil (**2**) in *ca.* 80% yield. The reaction of **1** with 1-acetoxy-1,3-butadiene in benzene at room temperature for 72 h afforded an analogous nitro adduct (**3**) as colorless crystals in a 57.4% yield. Similarly, the reaction of **1** with 1,4-diacetoxy-1,3-butadiene[9] under reflux for 5.5 h gave only the nitro adduct (**5**) quantitatively as colorless crystals. The reaction conditions and yields for **2** and **3** are listed in Tables 1 and 2.

Table 1. Cycloaddition of **1** with 1,3-butadiene

Reaction condition[a]

reflux	1	6	toluene	1.2	21.2

a) Room temperature. b) With stirring.

From the NMR spectral and TLC analyses, it was found that each reaction proceeded stereospecifically to give a homogeneous product. The structural assignment of **2**, **3**, and **5** was based on their NMR spectral data as well as the satisfactory elemental analysis. The chemical shifts and the coupling constants are given in Table 4. The structure of **3**, being either (A) or (B) as illustrated in Fig. 1, was confirmed chemically to be (A) as shown in Scheme 1. The reduction

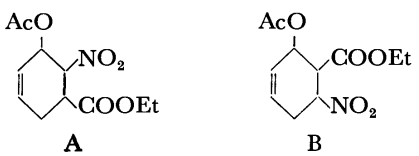

Fig. 1.

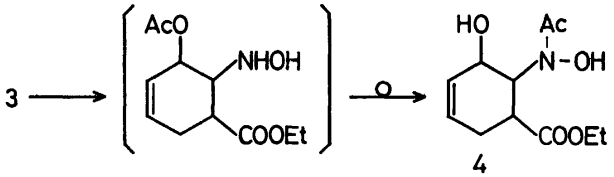

Scheme 1.

of **3** with Al–Hg gave the corresponding hydroxyamino derivative, in which *O*-acetyl 1,4-shift to nitrogen occurred to give ethyl 6-*N*-acetylhydroxyamino-5-hydroxy-3-cyclohexene-1-carboxylate (**4**). The migration product gave satisfactory elemental analysis and turned deep violet with ferric chloride in methanol, indicating the presence of a hydroxamic acid structure.

Furthermore, the conformational assignment of **2**, **3**, and **5** was studied. In the spectrum of **2**, the signals at δ 3.24 ($J_{1,6}=J_{1,2a}=11.0$ Hz, $J_{1,2e}=6.0$ Hz) and 4.88 ($J_{5a,6}=10.0$ Hz, $J_{5e,6}=6.0$ Hz) appearing as two sextets are attributable to the two protons at C-1 and C-6 positions, respectively. The similar signals at δ 3.43 and 4.90 in the spectrum of **3** exhibit a sextet ($J_{1,6}=J_{1,2a}=11.8$ Hz) and a quartet ($J_{5e,6}=3.9$ Hz), respectively, which have been assigned as axial hydrogens. From the relatively large J value (11.8 Hz), the dihedral angle between C-1 and C-6 or C-2a protons has been deduced to be near to 180°. The orientation of C-5 (δ 5.76, $J_{5e,6}=7.0$ Hz) and C-6 positions of **3** have been established by a spin-spin decoupling method, since the irradiation of C-6 proton collapsed C-5 proton at δ 5.76 to a doublet ($J_{4,5}=4.0$ Hz). The large J value of C-2 ($J_{2a,2e}=18.0$ Hz) is in agreement with the quasi-axial and quasi-equatorial protons at allyl positions on shikimic acid ($J_{2a,2e}=18.5$ Hz).[10] The signals of **5** at δ 3.49 and 5.04 and the coupling constant ($J_{1,6}=12.0$ Hz) between C-1 and C-6 protons are remarkably identical with those of **3**, but the J value between C-1 and C-2 protons exhibits 9.2 Hz as a broad doublet. Moreover, the chemical shift and coupling constant of the C-5 proton (δ 5.86, $J_{5e,6}=6.0$ Hz) of **5** was also remarkably similar to that of C-5 proton of **3**. Accordingly, the orientation of the C-2 proton has been assigned as quasi-axial and, therefore, that of the C-2 acetoxyl group as quasi-equatorial. The above results are further confirmed by the irradiation of the signal at δ 5.64 due to the C-2 proton collapsing to a quartet ($J_{1,2e}=9.2$ Hz) of methine proton to a doublet ($J_{1,6}=12.0$ Hz).

From the above facts, the structures of the three (2+4)-nitro adducts have been unambiguously assigned to be ethyl *t*-6-nitro-3-cyclohexene-*r*-1-carboxylate (**2**), ethyl *t*-5-acetoxy-*t*-6-nitro- (**3**) and *t*-2, *t*-5-diacetoxy-*t*-6-nitro-3-cyclohexene-*r*-1-carboxylates (**5**), respectively, all of which have half-chair conformations. The physical constants and IR spectral data of **2**, **3**, and **5** are summarized in Table 3.

*Reaction of **6** with 1,3-Butadienes.* The reaction of (***E***)-**6** with 1,3-butadiene in chloroform in a sealed tube at 100 °C for 35 h gave only a kind of syrup (**7**) in 66.6% yield. Similarly, the reaction of (***E***)-**6** with 1-acetoxy-1,3-butadiene for 25 h gave a syrup, containing two diastereomers (**8** and **9**) in poor yield. Similarly, the reaction of (***Z***)-**6**[8] with 1,3-butadiene gave a syrup (**10**) in 20.0% yield together with **7** in 22.9% yield, whereas the reaction of (***Z***)-**6** with 1-acetoxy-1,3-butadiene gave crystals (**11**) in poor yield along with a mixture of **8** and **9**. This indicates that (***Z***)-**6** is partially isomerized by heating[8] to (***E***)-**6**, which undergoes the cycloaddition to give **8** and **9**.

The structures and conformations of **7**—**10** and **11** have also been elucidated from their spectroscopic data and elemental analyses (see Tables 3 and 4).

The NMR spectra of **7** and **10** showed the C-1 proton signals at δ 3.49 ($J_{1,2a}=10.0$ Hz, $J_{1,2e}=7.0$ Hz) and 3.40 ($J_{1,2a}=5.5$ Hz, $J_{1,2e}=2.5$ Hz) as a quartet. Furthermore, from the comparison of the NMR spectral data of **7** and **10** with that of **2** and **3**, the conformations of **7** and **10** were inferred to be ethyl *c*-6-methyl-*t*-6-nitro- and *t*-6-methyl-*c*-6-nitro-3-cyclohexene-*r*-1-carboxylates. Although the mixture of **8** and **9** could not be separated, both signals at δ 3.57 ($J_{1,2a}=11.5$ Hz,) $J_{1,2e}=6.3$ Hz) and 3.26 ($J_{1,2a}=11.3$ Hz, $J_{1,2e}=6.3$ Hz) as a quartet have been clearly assigned to be an axial protons of C-1 position. However, the coupling constant ($J_{4,5}=10.0$ Hz) of **8** was remarkably different from that of **9** ($J_{4,5}=4.8$ Hz), suggesting that the orientation of the 3-acetoxyl group of **8** was quasi-axial whereas that of **9** was quasi-equatorial. The different NMR spectral pattern of **11** ($J_{1,2e}=6.3$ Hz, $J_{1,2a}=8.8$ Hz) contrasted to that of **8** and **9** and of the

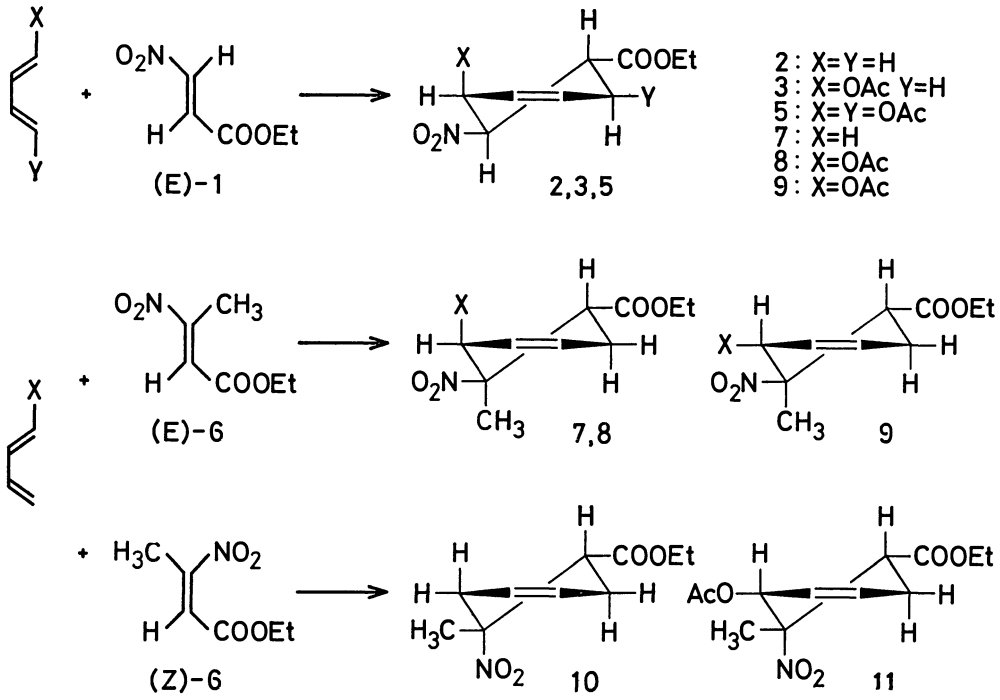
Measured in $CDCl_3$.



Scheme 2.

cis-addition principle, indicates the structure of **11** to be ethyl *t*-5-acetoxy-*t*-6-methyl-*c*-6-nitro-3-cyclohexene-*r*-1-carboxylate.

Experimental

All boiling and melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrometer. The NMR spectra were measured with a JNM-PS-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd), using tetramethylsilane as an internal standard.

Preparation of ***1*** *and* ***6***. A solution of ethyl acrylate (70 g, 0.7 mol) and nitrosyl chloride (90 g, 1.36 mol) in $CHCl_3$ (500 ml) was allowed to stand at room temperature for 2 weeks. After the usual work up, 63.4 g (50.1%) of ethyl 2-chloro-3-nitropropionate, bp 64—68 °C/1 mmHg was ob-

tained. Subsequently, to a mixture of AcONa (100 g, 1.2 mol) in ether (300 ml) was added the prepared propionate (100 g, 0.55 mol) at room temperature. After stirring for 24 h, the excess AcONa and the precipitated NaCl were filtered off and the ether filtrate concentrated. The residue was distilled under reduced pressure to give **1** as a pale yellow oil, bp 95—98 °C/21 mmHg, yield 71.3 g (89.5%). IR (KBr): 1740 (ester), 1650 (C=C), 1555 and 1360 (NO_2) cm^{-1}. NMR ($CDCl_3$): δ 7.09 and 7.73 (2H, d, $J_{2,3}$=13.5 Hz, 2, 3-H).

The (*E*)- and (*Z*)-isomer of **6** were prepared by the method previously reported.[7,8]

Preparation of ***2***. *Typical Procedure*: To a solution of 1,3-butadiene (22.7 g, 0.42 mol) in dry $CHCl_3$ (50 ml) was added **1** (40 g, 10.2 mol) at room temperature. The resulting solution was heated in an autoclave at 80 °C under 2—3 atmospheres for 40 h. After removal of $CHCl_3$, the residue was distilled under reduced pressure to give **2** as a colorless oil.

Preparation of ***3***. *Typical Procedure*: To a solution of 1-acetoxy-1,3-butadiene (34 g, 0.34 mol) in dry benzene (200 ml) was added **1** (40 g, 0.28 mol), with stirring, at room temperature. After stirring for 72 h, the mixture was evaporated under reduced pressure to give a syrup. The syrup was dissolved in a solution of EtOH (50 ml) and petroleum ether (20 ml). After standing in the refrigerator for 1—2 days, the crystals separated out, were collected and washed once with petroleum ether. Recrystallization from EtOH gave **3** as colorless needles.

Reduction of ***3***. A solution of **3** (7 g, 27.2 mmol) in ether (20 ml) was added dropwise to a suspension of Al-Hg (made from Al (5 g) and $HgCl_2$ (5 g)) in ether (200 ml) with vigorous stirring at room temperature. After a few minutes, the ether began to reflux, the state being maintained by addition of a few drops of water at 20-min intervals. After addition was complete, stirring was continued for 6 h. The mixture was extracted several times with ether and the combined extracts evaporated to a crude syrup (4.8 g) which gradually solidified to give crystals. Recrystallization from $CHCl_3$ gave colorless needles to be ethyl *t*-6-*N*-acetyl-hydroxyamino-*t*-5-hydroxy-3-cyclohexene-*r*-1-carboxylate (**4**), yield 2.1 g (32%) mp 148—150 °C. IR (KBr): 3220 (OH), 1740 (ester), 1655 (C=C), 1630 (amide) cm^{-1}. NMR (DMSO-d_6): δ 1.97 (3H, s, CH_3), 2.31 (1H, dd, $J_{2a,2e}$=15.5 Hz, 2a-H), 2.49 (1H, dq, 2e-H), 3.13 (1H, dt, $J_{1,6}$=12.0 Hz, $J_{1,2e}$=5.5 Hz, $J_{1,2a}$=12.0 Hz, 1-H), 4.09 (1H, m, 5-H), 4.44 (1H, dd, $J_{5,6}$=8.0 Hz, $J_{1,6}$=12.0 Hz, 6-H), 5.73 (2H, d, 3, 4-H), 4.93 and 8.96 (2H, s and bs, OH).

Found: C, 54.38; H, 7.03; N, 5.87%. Calcd for $C_{11}H_{17}NO_5$: C, 54.31; H, 7.04; N, 5.76%.

Preparation of ***5***. A solution of 1,4-diacetoxy-1,3-butadiene (1.0 g, 5.9 mmol) and **1** (1.0 g, 6.9 mmol) in dry benzene (30 ml) was refluxed for 5.5 h and then evaporated under reduced pressure to give **5** as colorless prisms after recrystallization from EtOH.

Preparation of ***7***. A solution of (***E***)-**6** (5.0 g, 31 mmol) and 1,3-butadiene (2.0 g, 37 mmol) in dry $CHCl_3$ (30 ml) was heated in a sealed tube at 100 °C for 35 h. After removal of $CHCl_3$, the syrup was distilled under reduced pressure to give **7** as a colorless oil.

Preparation of ***8*** *and* ***9***. In the same manner, the reaction of (***E***)-**6** (4.0 g, 25 mmol) with 1-acetoxy-1,3-butadiene (3.4 g, 30 mmol) in $CHCl_3$ (30 ml) for 25 h gave a mixture of **8** and **9** as a colorless oil.

Preparation of ***10***. Similarly, the reaction of (***Z***)-**6** (5.0 g, 25 mmol) with 1-acetoxy-1,3-butadiene (2.0 g, 37 mmol in $CHCl_3$ (80 ml) for 35 h gave a mixture of **7** and **10** (6:5), which on distillation afforded **10** (20.0%).

Preparation of ***11***. A solution of (***Z***)-**6** (4.0 g, 25 mmol) and 1-acetoxy-1,3-butadiene (3.4 g, 30 mmol) in dry $CHCl_3$ (50 ml) was stirred overnight at room temperature. After removal of $CHCl_3$, the residual syrup was chromatographed on a silica gel column (benzene) to give two fractions. After removal of benzene under reduced pressure, the first fraction gave **11** as colorless crystals and the second one gave a mixture of **8** and **9** as a colorless oil.

Reduced Copper Catalyzed Conversion of Primary Alcohols into Esters and Ketones

Kenji TAKESHITA,* Shigeaki NAKAMURA,** and Kazuaki KAWAMOTO
Institute of Commodities, Faculty of Economics, Kagawa University, Saiwaimachi, Takamatsu, Kagawa 760

(Received November 17, 1977)

Vapor phase reactions of a mixture of two types of primary alcohols to esters and ketones over a reduced copper catalyst have been investigated. The reactions between primary alcohols and propionaldehyde have also been investigated. The effects of the molar ratio of the reactants and the reaction temperature on the yields of esters, ketones, and aldehydes have been examined. A mixture of ethyl alcohol and propyl alcohol when passed over the catalyst, the main products have been found to be propyl acetate, ethyl acetate, propyl propionate, ethyl propionate, ethyl methyl ketone, diethyl ketone, acetone, acetaldehyde, and propionaldehyde. The formation of the ester and the ketone may be presented as follows:

$$RCHO + R'CH_2OH \rightarrow \left[\begin{array}{c} OH \\ | \\ R-C-O-CH_2R' \\ | \\ H \end{array}\right] \rightarrow RCOOCH_2R' + H_2,$$

$$RCHO + R'CH_2OH \rightarrow RCOR' + CO + 2H_2.$$

Many investigators[1] have shown that the esters and the ketones were obtained, upon passing primary alcohols, aldehydes, and mixtures of them over catalysts such as copper chromite, zinc oxide, copper, metallic palladium, magnesia, and alkalized zinc chromium oxide. These papers have shown that primary alcohols with n carbon atoms are readily converted to symmetrical ketones with $2n-1$ carbon atoms and esters with $2n$ carbon atoms. The mechanism has been described in these papers for ester formation as the Tischenko Reaction mechanism. Recently, another mechanism for ester formation has been proposed by Kunugi *et al.*[2] and one of the present authors.[3] The former investigators found that the ester was formed by the reaction between an aldehyde and an alcohol. In a study of the action of the reduced copper catalyst on alcohols, one of the present authors reported that the ester was formed by a hemiacetal mechanism.

In the formation of ketones, Komarewsky *et al.*[4] found that, in the presence of a chromium oxide catalyst, primary alcohols were converted to ketones by the following mechanism: (1) the dehydrogenation of the alcohol to the aldehyde, (2) the aldol condensation of the aldehyde, (3) the removal of carbon monoxide from the CHO group of the aldol, leaving a secondary alcohol, and (4) the dehydrogenation of this alcohol to the ketone. Kagan *et al.*[5] found that ethyl acetate was an important intermediate when ethyl alcohol was converted to acetone. Matsota *et al.*[6] reported that aliphatic ketones were prepared by heating esters in the presence of manganese oxide at 400—500 °C. Bolotov *et al.*,[7] however, reported that ethyl acetate was not an intermediate in the formation of acetone. Geisler *et al.*[8] examined the catalytic ketonization of ethyl alcohol in the presence of water vapor, and found that the formation of the ketone was presented by the reaction equation as follows:

$$2C_2H_5OH + H_2O \rightarrow CH_3COCH_3 + CO_2 + 4H_2.$$

The present investigation has been undertaken in order to clarify the mechanism of the formation of the ester and the ketone.

Experimental

Reactants. The aliphatic alcohols such as ethyl alcohol, propyl alcohol, butyl alcohol, and isobutyl alcohol were purified, after being dried with calcium oxide or potassium carbonate, by distillation through a fractionating column. Propionaldehyde, ethyl acetate, propyl propionate, ethyl propionate, propyl acetate, isobutyl acetate, and ethyl isobutyrate were purified by drying with anhydrous sodium sulfate, followed by fractional distillation under atmospheric pressure. The purity of the reactants was confirmed by gas chromatographic analysis. (PEG-6000, DEGS, and PEG-1000 F columns.)

Catalyst. The catalyst was prepared by the same method as described in a previous paper.[9]

Apparatus and Procedure. The apparatus and the procedure employed were similar to those used in a previous investigation.[9] Experiments were performed at 250 and 300 °C under atmospheric pressure.

Identification and Analysis of the Reaction Products. The reaction products were separated by gas chromatography (PEG-6000, DEGS, and Tween-80 columns. For the determination of water, a 3 m column packed with Shimalite F impregnated with PEG-1000 was used.), and each constituent was identified by NMR and IR spectra. The gaseous products were analyzed by gas chromatography. (activated charcoal and silica-gel columns.) The quantitative analysis of liquid and gaseous products was performed by gas chromatography.

Results

Table 1 shows the influences of the molar ratio of the reactants and the reaction temperature on the yields of the products. The results obtained by passing a mixture of butyl alcohol and propyl alcohol or propionaldehyde over the catalyst are summarized in Table 2. Further, the results obtained by the reaction of isobutyl alcohol and propyl alcohol or propional-

dehyde are summarized in Table 3. Tables 4 and 5 show the results of the catalytic decomposition of the esters. The yields of each compound shown in these tables are an average of two and three experiments under constant operating conditions.

Influence of the Molar Ratio of the Reactants on the Yields of Esters and Ketones. *a) Reaction between Ethyl Alcohol and Propyl Alcohol*: As may be seen from Table 1, the yields of esters and ketones depended on the molar ratio of the reactants as follows: 1) The yield of ethyl acetate increased with an increase in the molar ratio of ethyl alcohol to propyl alcohol. 2) The yield of propyl propionate decreased with an increase in the molar ratio of ethyl alcohol to propyl alcohol. 3) The maximum yields of propyl acetate and ethyl propionate were obtained when ethyl and propyl alcohols were mixed in the ratio of approximately 1:1. 4) Further, the yield of each ester was in the following order: propyl acetate>ethyl acetate, propyl propionate>ethyl propionate. 5) The yield of acetone increased with an increase in the molar ratio of ethyl alcohol to propyl alcohol, but the yield of diethyl ketone decreased. When the molar ratio of the reactants was about 1:1, the maximum yield of ethyl methyl ketone was obtained. As may be seen from Table 1, the yield of the unsymmetrical ketone was larger than that of the symmetrical ketone except in the case of a large excess of propyl alcohol.

From these results, it is considered that ethyl acetate and acetone may be formed from ethyl alcohol, that propyl propionate and diethyl ketone may be formed from propyl alcohol, and that propyl acetate, ethyl propionate, and ethyl methyl ketone may be formed by the reaction between ethyl alcohol and propyl alcohol.

When the mixture of two alcohols or an alcohol and propionaldehyde was passed over the catalyst, carbon monoxide, carbon dioxide, and hydrocarbon were detected as gaseous products, and it was found that the molar ratio of carbon monoxide to carbon dioxide was 3 : 1—2 in the cases of Experiment Nos. 2—6 in Table 1.

b) Reaction between Ethyl Alcohol and Propionaldehyde: As may be seen from Table 1, when propionaldehyde was used in place of propyl alcohol, the kinds of reaction products were the same as those obtained by passing the mixture of ethyl and propyl alcohols over the catalyst, but there were distinct differences in the yields of the ester and the ketone in the products. It was found that, when propionaldehyde was used in place of propyl alcohol, the yield of ethyl propionate increased remarkably, but the yield of propyl esters decreased, and little diethyl ketone was obtained. As is shown in Experiment No. 12 of Table 1, propionaldehyde did not condense to give the ester and ketone.

c) Reaction between Secondary Alcohol and Primary Alcohol or Propionaldehyde: When the mixture of a secondary alcohol and a primary alcohol or propionaldehyde was passed over the catalyst, the esters and the ketones were obtained. For example, when

propyl alcohol and isopropyl alcohol were used as the reactants, propyl propionate, isopropyl propionate, diethyl ketone, and acetone were obtained.

Influence of the Reaction Temperature on the Yields of Ester and Ketone. As may be seen in Experiment Nos. 4 and 13 of Table 1, the conversion of primary alcohols depended upon the reaction temperature, and the yields of aldehydes and ketones increased with a rise in the reaction temperature, but the yield of the ester was little affected.

Decomposition of Ester. When ethyl acetate was passed over the catalyst, acetone was obtained, and in the case of propyl propionate, diethyl ketone. Experiment Nos. 22 and 23 of Table 4 showed that the kinds of the reaction products obtained by using propyl acetate as the reactant were the same as those obtained by using ethyl propionate. Further, Table 5 showed that the kinds of the products obtained from isobutyl acetate were the same as those obtained from ethyl isobutyrate, when isobutyl acetate and ethyl isobutyrate were passed over the catalyst in the presence of hydrogen.

Experiment Nos. 20 and 21 of Table 4 showed that, when the ester type $C_nH_{2n+1}COOC_{n+1}H_{2n+3}$ such as $CH_3COOC_2H_5$, $C_2H_5COOC_3H_7$, and $C_3H_7COOC_4H_9$ was passed over the catalyst, a symmetrical ketone was produced. However, Experiment Nos. 22, 23, 25, and 26 of Tables 4 and 5 showed that, when the other esters were passed over the catalyst, the results were as follows: (1) most of the ketones formed were unsymmetrical ketones. (2) the yield of the ketone increased in the presence of hydrogen. (3) the yield of carbon monoxide was larger than that of carbon dioxide.

Discussion

The Formation Mechanism of Ester and Ketone Obtained by the Catalytic Reaction of Primary Alcohols. a) Formation Mechanism of Ester: Eto[10] reported that the copper catalyst strongly accelerated the ester formation by the Tischenko Reaction. Saito and Tanabe[11] also reported that the formation of the ester was similar to the Tischenko Reaction mechanism, when benzyl benzoate was formed from benzaldehyde in the presence of magnesium oxide or calcium oxide.

However, in the present research, propionaldehyde did not condense to give the ester. This indicates that the Tischenko Reaction type esterification does not take place under the present reaction conditions. Kunugi *et al.*[12] reported that the ester was not formed by the Tischenko Reaction mechanism, but by the reaction between an alcohol and an aldehyde. Dolgow[13] found that, when the mixture of alcohol or aldehyde and hydrogen was passed over the copper catalyst, an ester was obtained. He proposed a hemiacetal intermediate mechanism as the scheme of the

formation of the ester. It was reported by Tarama[14] that, when the hydrogenolysis of an ester was carried out, the ester was converted to two alcohols *via* a hemiacetal. Covert *et al.*[15] reported that a cyclic acetal was converted to ether, alcohol, and hydrocarbon *via* a hemiacetal.

As reported above, when propionaldehyde was used in place of propyl alcohol, the yield of propyl esters which appear to be produced by the participation of propyl alcohol was very small, suggesting that the ester is produced by the reaction between the aldehyde and the alcohol.

From these results, the formation mechanism of esters may be explained by the hemiacetal intermediate mechanism as follows:

$$CH_3CH_2CH_2OH \rightarrow CH_3CH_2CHO + H_2$$

$$CH_3CH_2CHO + CH_3CH_2CH_2OH \rightarrow \left[\begin{array}{c} OH \\ | \\ CH_3CH_2-C-O-CH_2CH_2CH_3 \\ | \\ H \end{array}\right]$$

$$\left[\begin{array}{c} OH \\ | \\ CH_3CH_2-C-O-CH_2CH_2CH_3 \\ | \\ H \end{array}\right] \rightarrow CH_3CH_2-\overset{O}{\overset{\|}{C}}-O-CH_2CH_2CH_3 + H_2$$

b) Formation Mechanism of Ketone: Komarewsky *et al.*[16] reported that aldehydes and aldols seemed to be logical intermediates when the ketone was formed from primary alcohols, and that the order of the conversion of the reactants to the ketones was aldol> aldehyde>alcohol. Bolotov *et al.*[7] reported that the acetone was formed by the aldol condensation of acetaldehyde. Geisler and Danneberg[8] reported that ethyl alcohol was converted to acetone *via* the aldehyde and acid. Further, Kagan *et al.*[5] reported that, when ethyl alcohol was converted to acetone, ethyl acetate was an important intermediate in the chain of reactions involved. Dolgow and Golodnikow[17] showed that the ketone was obtained by the catalytic reaction of primary alcohol, and that the reaction was proceeded by an ester intermediate mechanism.

In the present research, however, as may be seen in Experiment No. 12 of Table 1, no ketone and aldol were produced from propionaldehyde. Aldol condensation products were not obtained by the catalytic reactions of the alcohols except ethyl alcohol. Therefore, aldol appears not to be an intermediate of the ketone formation from primary alcohol with the reduced copper catalyst.

From the experimental results obtained in the reaction between ethyl alcohol and propyl alcohol or propionaldehyde and by the decomposition of esters, the formation of ketones with the reduced copper catalyst may proceed along two paths.

I) One appears to be formed by the following scheme.

$$\left.\begin{array}{l} CH_3CH_2CH_2OH + CH_3CHO \\ CH_3CH_2OH + CH_3CH_2CHO \end{array}\right\} \longrightarrow CH_3CH_2-\overset{O}{\overset{\|}{C}}-CH_3 + CO + 2H_2$$

II) Another may be accounted for by Kagan's Process[5] as follows:

$$2C_2H_5COOC_3H_7 \rightarrow C_2H_5COC_2H_5 + C_3H_7OH + C_3H_6 + CO_2 .$$

From the molar ratio of carbon monoxide to carbon dioxide, it is considered that, when the primary alcohol is converted to the ketone, the ketone may be produced by either Process I or II, but that Process I predominates. In the case of the decomposition of the esters, most of the ketone may be formed by Process I.

Photo-induced Oxidation of Diethylene Glycol Dimethyl Ether and Analogues with Aqueous Hydrogen Peroxide[1a)]

Yoshiro OGATA,* Kohtaro TOMIZAWA, and Kohzo FUJII

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 19, 1977)

Photo-oxidation of diethylene glycol dimethyl ether(DEDE), ethylene glycol dimethyl ether(EDE) and ethylene glycol monomethyl ether(EME) in the presence of aqueous H_2O_2 has been studied. DEDE and EDE give photo-oxidation products containing methanol, EME, methoxyacetaldehyde, methoxyacetic acid and methyl formate. EME gives products containing methanol, methoxyacetaldehyde and methyl formate. The oxidation is started by hydrogen atom abstraction by HO· radicals formed by the photolysis of H_2O_2. A reaction mechanism leading to the products(derived by initial C–O and C–C fissions) is postulated.

The photolysis of ethylene glycol monomethyl ether (EME) alone gives formaldehyde, methane, methanol, hydrogen *etc.*,[1b)] while that of EME and ethylene glycol dimethyl ether(EDE) under oxygen atmosphere gives formaldehyde, methanol, methyl formate.[2)]

However, no data are available on the photo-oxidation of glycols and their ethers in the presence of hydrogen peroxide. We are interested in this photo-oxidation as a model reaction for the photo-oxidative removal of nonionic surfactants in waste water which are difficult to remove biologically.

Here we wish to present data on the products and probable schemes for the photo-oxidation of diethylene glycol dimethyl ether(DEDE), EDE and EME in the presence of aqueous H_2O_2. Most of the experiments were carried out with DEDE, since it is the most suitable model compound for polyethylene glycols.

Results

A. Diethylene Glycol Dimethyl Ether(DEDE). Products: The photo-oxidation products of 0.25 M DEDE in the presence of 0.48 M H_2O_2 in water at pH 3.9 in a quartz tube with a high-pressure Hg lamp for 1 h gave the following products after vacuum distillation: CH_4, C_2H_6, CH_3OH, CH_3CHO, HCO_2CH_3, HCO_2H, $HOCH_2CH_2OH$, CH_3OCH_2CHO, $CH_3OCH_2CH_2OH$-(EME), $CH_3OCH_2CO_2H$, $HCO_2CH_2CH_2O_2CH$ and $CH_3OCH_2CH_2OCH_2CH_2OH$. The products were identified by GC-MS analysis and also by GLC analysis in comparison with GLC peaks of authentic samples using two kinds of columns.

Photolysis of H_2O_2. The rate of photo-oxidation of 0.184 M DEDE with 0.937 M H_2O_2 in water at pH 3.7 was measured at 20 °C by iodometry of H_2O_2 and GLC analysis of substrate (Table 1A). With the progress of reaction, the yields of the products changed (Table 1B).

$$\text{Yield (\%)} = \frac{\text{[produced product] (M)}}{\text{[decomposed substrate] (M)}} \times \frac{\text{carbon number of product}}{\text{carbon number of substrate}} \times 100$$

The decomposition of H_2O_2 is of zeroth-order within 60 min, and over two equivalents of H_2O_2 are necessary in order to decompose DEDE(Table 1A).

The yields changed only in a small range after 20 min irradiation(Table 1B). This suggests fast attainment of steady state in which the formation and consumption of the intermediates are fairly balanced.

a) Irradiated for 1 h in H_2O at 20 °C.

Effect of Initial Concentration of H_2O_2. In order to examine the contribution of H_2O_2 to the oxidation of DEDE, the effects of initial concentration of H_2O_2 ($[H_2O_2]_0$) on the oxidation rate of DEDE(Table 2A) and on product distribution(Table 2B) were studied with a nearly constant initial concentration of DEDE.

The decomposition of DEDE is proportional to that of H_2O_2, indicating the efficient oxidation of the substrate by H_2O_2. The decomposition rates of H_2O_2 in runs 1—3(Table 2A) are greater than those in runs 4 and 5. The number of absorbed photon per unit time is almost constant regardless of the initial concentration of H_2O_2 and substrate. Thus the observed variation of decomposition rates of H_2O_2 with change of $[H_2O_2]_0$ indicates the presence of a scheme for the decomposition of H_2O_2 induced by HO· radicals and/or other radicals generated by substrate decomposition.

The product distribution depends considerably on $[H_2O_2]_0$. The yields of methoxyacetic acid, methyl formate and formic acid increase with increasing $[H_2O_2]_0$. The effect of $[H_2O_2]_0$ on the yields of methoxyacetaldehyde and ethylene glycol monomethyl ether (EME) is reversed, these products being more susceptible to further oxidation as compared with other products.

Effect of Pyrex-filtered Light. Photo-oxidation with light through a Pyrex-filter was examined with an aqueous mixture of 0.060 M DEDE and 1.18 M H_2O_2 at pH 3.6 for 5 h. The conversion of substrate was 28% after 1 h; 39% after 2 h; 47% after 3 h; 63% after 5 h. Photo-oxidation in a Pyrex vessel is slower than that in a quartz vessel, since Pyrex absorbs 250 nm light which is much more effective for decomposition of H_2O_2 than above 300 nm light.

Formation of CO_2. To test the possibility of complete oxidation of DEDE, an aqueous mixture of

0.0711 M DEDE and 1.16 M H_2O_2 was irradiated for 29 h. The CO_2 gas evolved, which was absorbed in aqueous $Ba(OH)_2$, was 77.5% of calculated value from the substrate. Taking into account the probable loss of CO_2, polyglycols may be completely converted to CO_2 and water after long irradiation.

B. Ethylene Glycol Dimethyl Ether (EDE). Photo-oxidation of 0.233 M EDE with 0.909 M H_2O_2 in water at pH 3.7 afforded the same products as those from DEDE, but with different composition (Table 3).

C. Ethylene Glycol Monomethyl Ether (EME). Photo-oxidation of 0.167 M EME with 0.919 M H_2O_2 in water gave the same products as those from EDE along with acetic acid (Table 4).

Discussion

The absorption coefficients(ε) for H_2O_2 and DEDE in an aqueous solution were measured at 250 nm, which is the principal wavelength of the high-pressure Hg lamp employed. The values of ε were: 26.4(250 nm) for H_2O_2, 0.437(250 nm) for DEDE, 0.94(300 nm) for H_2O_2, 0.36(315 nm) for H_2O_2 and 0(over 300 nm) for DEDE. Thus the photolysis of DEDE itself should be negligible in comparison with that of H_2O_2. The same is true with other substrates(EDE and EME). The initial step for the photo-oxidation should be the excitation and photo-decomposition of H_2O_2 as[3,4]

$$H_2O_2 \xrightarrow{h\nu} [H_2O_2]^* \longrightarrow 2\cdot OH. \quad (1)$$

The hydroxyl radicals formed are known to react, abstracting H-atom from both substrate and another molecule of H_2O_2.[4,5]

$$HO\cdot + H_2O_2 \longrightarrow H_2O + HOO\cdot \quad (2)$$

The HOO· radicals may abstract H-atom from substrate and add to substrate radicals. Otherwise, HOO·radicals disappear by reacting with each other ($2\,HOO\cdot \rightarrow H_2O_2 + O_2$) or with H_2O_2 ($HOO\cdot + H_2O_2 \rightarrow H_2O + O_2 + \cdot OH$).[4,5]

The products observed from DEDE can be explained by the following:

$CH_3OCH_2CH_2OCH_2CH_2OCH_3$—
1 (DEDE)

$$\xrightarrow[-H_2O]{\cdot OH} \begin{cases} \rightarrow \dot{C}H_2OCH_2CH_2OCH_2CH_2OCH_3 \ (\mathbf{2}) & (3) \\ \rightarrow CH_3O\dot{C}HCH_2OCH_2CH_2OCH_3 \ (\mathbf{3}) & (4) \\ \rightarrow CH_3OCH_2\dot{C}HOCH_2CH_2OCH_3 \ (\mathbf{4}) & (5) \end{cases}$$

The H-atom may be abstracted from 3-positions of DEDE as shown by Eqs. 3, 4, and 5. Their rates of abstraction were calculated to be *ca.* $3.6\times10^8\ M^{-1}\,s^{-1}$ for Eq. 3 and $5.6\times10^8\ M^{-1}\,s^{-1}$ for Eqs. 4 and 5 on the basis of the reported abstraction rates for CH_3OH ($0.6\times10^8\ M^{-1}\,s^{-1}$) and RCH_2OR ($1.4\times10^8\ M^{-1}\,s^{-1}$).[6]

Three radicals (**2**, **3**, and **4**) formed from DEDE by H-atom abstraction may undergo β-fission and/or HOO·radical addition to give products and/or other radicals(Eqs. 6—15). The products and radicals produced by Eqs. 6—15 may undergo secondary reaction to give fairly stable products (Eqs. 16—38), all of which were identified.

a) No M^+ was detected.

Acid-catalyzed decomposition of radicals in Eqs. 11 and 15 were postulated for the oxidation of 1,2-diols with Ti(III) peroxide system in acidic media at lower pH (≤ 2).[7,8a] The acidity was in pH range 3.5—4.0. With the progress of oxidation the acidity increased gradually to pH$\approx$3. Therefore, the contribution of Eqs. 11 and 15 to the reaction of radicals would be less than that of the reaction with H_2O_2 in higher concentration. The observed increase of acidity may be due to the formation of acidic products.

The processes for the formation of alkyl radicals (Eqs. 6, 8, and 13) are less probable than those for the formation of alkoxyl radicals(Eqs. 9 and 12) because of the stability of alkoxyl radicals as compared with alkyl radicals.

The presence of peroxides such as **11** and **16** is suggested from the reported photochemical autoxidation of EDE and EME.[2] These peroxides afford C–C fission products, methyl formate and formadlehyde hemiacetal, respectively(Eqs. 24 and 32). Disproportionation of methoxyl radical to formaldehyde and methanol (Eq. 28) was reported.[11]

Equations 20 and 29 are those of well-known acid-catalyzed solvolysis of vinyl ethers.[9] The reactions between vinyl ethers and HO·radical (Eqs. 21 and 30) were studied by ESR spectroscopy.[10] Equations 36 and 37 are also those of well-known acid-catalyzed hydrolysis of hemiacetal.

The unexpectedly low yields of formic acid and formaldehyde are ascribed to their facile oxidation to CO_2 in the presence of H_2O_2. Only trace of products **8** and **22** was detected by GC-MS and GLC analyses.

In the photo-oxidation of EME, the yield of MeOH is larger than that of methoxyacetaldehyde, hence the C–O fission appears to occur preferentially at the ether linkage rather than at the hydroxyl linkage. As shown in Table 4, the conversion of EME and H_2O_2 is generally low. Thus further oxidation product (*e.g.*, methoxyacetic acid) from methoxyacetaldehyde is smaller than that shown in Tables 2B and 3.

The formation of acetic acid in photo-oxidation of EME may be due to the preferential C–O fission of **23** at the ether linkage (Eq. 39) and/or due to acid-catalyzed reaction of **18** (Eqs. 35 and 26) and **23** (Eq. 41). The acetaldehyde formed should undergo the further oxidation by H_2O_2 or O_2 (Eq. 42).

Experimental

Materials. Commercial diethylene glycol dimethyl ether(DEDE), bp 160—161 °C, ethylene glycol dimethyl ether(EDE), bp 82—83 °C and ethylene glycol monomethyl ether(EME), bp 123—124 °C of first grade materials were used after distillation. Their GLC analyses showed single peaks. Hydrogen peroxide (90%, Mitsubishi Gas Chem. Co.) was used.

Photo-oxidation. An ice-cooled aqueous solution of DEDE was mixed with ice-cooled 90% H_2O_2 with stirring. The mixture was introduced into a quartz cell and warmed to room temperature. The cell was irradiated at 20 °C with a 300 W high-pressure Hg lamp through a water filter or a Pyrex filter. After completion of reaction, the mixture was cooled with ice.

Analyses. The ice-cooled mixture was analyzed by iodometry in order to determine the content of H_2O_2. The organic products were analyzed by GLC. After being condensed by evaporation, the products were analyzed by GC-MS. GLC analysis was carried out with a Yanagimoto GCG 550F gas chromatograph with a hydrogen flame ionization detector employing two kinds of columns, Porapak QS and PEG 20M. The products were identified by comparison of GLC peaks with those of authentic samples in two columns. Estimation of yield was carried out by GLC with a Porapak QS using 2-propanol as an internal standard.

The GC-MS analysis of the products was carried out with a Shimadzu GCMS-7000 mass spectrometer with a column of Porapak QS. The main *m/e* values of products are given in Table 5.

The CO_2 evolved was absorbed in saturated aqueous $Ba(OH)_2$ and titrated with HCl. The organic gaseous products were collected in a gas burette and analyzed by GLC (TCD and FID) using columns of Porapak QS and Porapak T. The acidity was measured with a Hitachi-Horiba M-7 type pH meter.

Solvolysis in Carboxamides. IV.[9] Solvolytic Elimination of *exo*-2-Norbornyl Arenesulfonates in Carboxamides. Kinetic, Product, and Deuterium Tracer Studies

Seiki SAITO,* Toshio MORIWAKE, Ken'ichi TAKEUCHI,** and Kunio OKAMOTO**

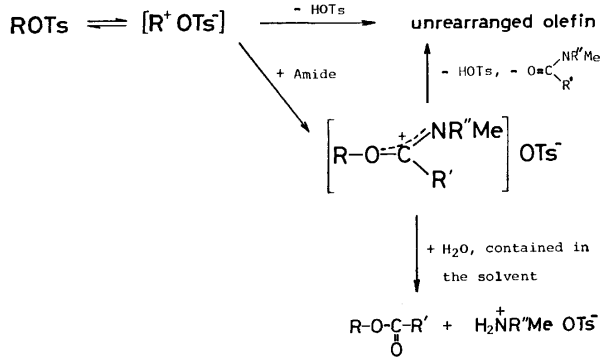
Department of Synthetics Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

** *Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606*

(Received January 17, 1978)

Solvolysis of *exo*-2-norbornyl arenesulfonates (RX: X=OTs (**1a**), $-OSO_2C_6H_4$-*p*-OCH_3, $-OSO_2C_6H_5$, and OBs) and the deuterium labeled tosylates (**1a**-3-*endo-d*, **1a**-3-*exo-d*, and **1a**-3,3-d_2) has been carried out in four carboxamides (*N*-methylformamide, *N*-methylacetamide, *N,N*-dimethylformamide, and *N,N*-dimethylacetamide (DMA) at 25—100 °C. The solvolysis has also been conducted in the solvents containing 0.01—0.2 mol/dm^3 water. On the basis of kinetic measurements, product analyses, and the examination of isotopic distribution in the reclaimed substrate and the products (nortricyclene, norbornene, and *exo*-norbornyl carboxylates) it has been suggested that the reaction proceeds by *syn*-*E*l and S_Nl mechanisms, and that the carboxylates which are produced in the presence of water are derived from an imidatonium ion [R-Amide]$^+$, which is formed by the attack of carboxamide on the intimate ion-pair [R$^+$X$^-$]. It has been observed that the isotopic scrambling occurs only between C(3) and C(7) positions of both norbornene and the reclaimed **1a**-3-*endo-d* in DMA solvolysis at 75 °C, and that the isotopic distribution to these positions in norbornene is 57:43 at 10% completion and reaches 50:50 at half-life, indicating that only Wagner-Meerwein rearrangement is predominant in the course of norbornene formation, and also that the intimate ion-pair, from which norbornene is formed, is unsymmetrical and most probably with "classical" norbornyl-cation structure.

In the previous paper,[1] it was demonstrated that 7β-methylbicyclo[3.3.1]non-3β-yl tosylate undergoes S_N1 and *E*1 type reactions in the carboxamide solvents such as *N*-methylformamide (NMF), *N*-methylacetamide (NMA), *N,N*-dimethylformamide (DMF), and *N,N*-dimethylacetamide (DMA), to give the unrearranged olefin as a major product. The 5,1-hydride shift, which is a major course in acetic acid[2] and in 80% ethanol,[3] was markedly suppressed in the carboxamide solvents. The following scheme has been presented to account for the main course of the solvolytic elimination.



Scheme 1.

The predominant formation of the unrearranged olefin in the carboxamide solvolysis, as compared with other solvolyses,[2,3] was reasonably ascribed to the acceleration of *syn*-*E*l process by the leaving tosylate anion, because the basicity of the tosylate anion is expected to increase in such non-hydroxylic solvents owing to very weak hydrogen-bonding ability of these carboxamides.[1]

Thus, one of the principal characteristics of the carboxamide solvolysis of secondary cycloalkyl tosylates is that the carboxamides suppress the formation of rearranged products even when the substrate has a structure prone to rearrangement. Therefore, it is of interest to explore the generality of this phenomenon by the use of the *exo*-2-norbornyl system, because the 2-norbornyl cation, generated both in solvolytic conditions[4] and in stable ion conditions,[5] easily undergoes three types of rearrangement, *i.e.*, Wagner-Meerwein, 6,2-hydride, and 3,2-hydride shifts.

These processes take place, however, to regenerate the identical structure with that of the starting ion (automerization[6] or degenerated rearrangement[7]). Consequently, we selected *exo*-2-norbornyl tosylate labeled at the 3-position (**1a**-3-*endo-d*, **1a**-3-*exo-d*, and **1a**-3,3-d_2) to follow automerization.

In this paper, we report on a) the rates and products of the solvolysis of several *exo*-2-norbornyl *p*-substituted arenesulfonates (**1a**—**d**) in NMF, NMA, DMF, and DMA, b) effects of added water on the product distributions, and c) deuterium distributions of the products in the solvolyses of the tosylate labeled at C(3). We also discuss the generality of the mechanism (Scheme 1) and the structural problem of the norbornyl ion intermediate, since it remains as a controversial problem

and still is a basic problem of organic chemistry toward which active effort continues both experimentally and theoretically.[8]

Results and Discussion

Solvolysis Rates of exo-*2-Norbornyl Arenesulfonates in Carboxamides.* The rates of solvolysis of **1a**—**d** in the carboxamides were determined titrimetrically by the use of the same method as described in the previous paper.[1] A good first-order behavior was observed for all the kinetic runs over two to three half-lives. The results, along with the thermodynamic parameters, are tabulated in Table 1 for **1a** and in Table 2 for **1b**—**d**.

The following findings present unambiguous evidence which demonstrates that the solvolysis proceeds *via* a typical S_N1 or *E*1 mechanism. First, pyridine, added to neutralize the liberated arenesulfonic acids, did not alter the rates. Secondly, a satisfactory linear free-energy relationship was observed when log k_1 values of **1a** were plotted against those for 2-adamantyl tosylate in carboxamides[9] and a number of other solvents (Fig. 1). Since 2-adamantyl tosylate has a mechanistic feature of S_N1 substrate,[10] it is a suitable model substrate for the examination of the S_N1 character of other secondary substrates. The slope (0.864) of the least-squares line is larger than those (0.55—0.78)[11] for other secondary systems. Furthermore, the magnitude (0.83)[12] of the Grunwald-Winstein *m* value is also larger than those (0.4—0.7) for the solvolysis of usual secondary substrates[13] and is comparable to that (0.87)[14] for 2-adamantyl tosylate. Thirdly, at 5% completion of the solvolysis of **1a**-3-*endo*-*d* in DMA the recovered tosylate was incorporated with *exo*-2-norbornyl-7-*anti*-*d* tosylate (25%), which must be formed *via* an ionization and a subsequent return step (*vide infra*).

Products of the Solvolysis of ***1a—d*** *in the Carboxamides.* As expected from the Scheme 1, the products in the solvolysis of **1a**—**d** in the carboxamides were elimination products, nortricyclene and norbornene. If water is contained in the amides, the substitution products, *exo*- and *endo*-norbornyl carboxylates were found as the additional products (Scheme 2).

a) [$ROSO_2C_6H_4$-*p*-X]=0.075 mol/dm³; [C_5H_5N]=0.077 mol/dm³; [H_2O]=0.003 (for DMA or DMF), 0.01 (for NMA), or 0.02—0.03 (for NMF) mol/dm³. b) The averages of two or three determinations, with reproducibility of ±3%, relatively. c) Acetate for DMA and NMA, and formate for DMF and NMF. d) Extrapolated from data at other temperatures. e) The amounts of the substrates were three times as much as those for other amides.

The compositions of the products were determined by the use of GLC and ^1H NMR spectroscopy. The yield of a mixture of *exo*- and *endo*-norbornyl esters was assayed by means of GLC. The epimeric ratio was determined also by means of GLC analysis after conversion of the ester mixture to corresponding norbornanol mixture by lithium aluminum hydride. The

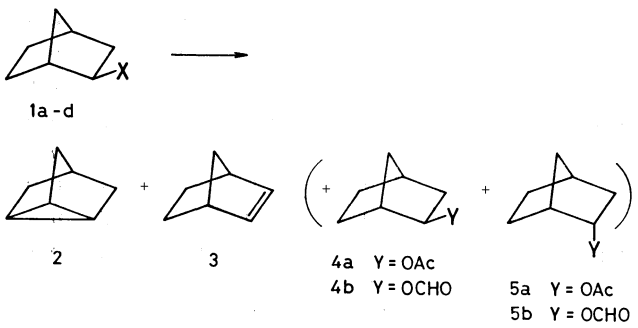

Scheme 2.

yield of norbornene was determined by measuring the integrated intensity of NMR signals of olefinic protons relative to that of the methyl protons of anisole (internal marker). The results of the product analysis are summarized in Table 2.

As illustrated in Scheme 1, the esters may be formed by the reaction of an imidatonium ion[15] with water, which is contained in the carboxamides. In this connection, the effect of water content on the product distribution was examined for the solvolysis of **1a** in DMA and in DMF in the presence of various amounts of water. The results are tabulated in Table 3 and illustrated in Figs. 2-1 and 2-2.

In completely dry DMA or DMF nortricyclene and norbornene were sole products, and there was no longer obtained any esters (Fig. 2), indicating that the esters are not a primary solvolysis product in DMA or in DMF.

	0.185	11.8	4.0	84.0	0.2

a) [**1a**] = 0.075 mol/dm³; [C_5H_5N] = 0.077 mol/dm³. b) Trace amounts of 2-norbornanol was detected on GLC (≤0.1%). c) Remaining water in the amides after purification. d) See footnote (c) in Table 2.

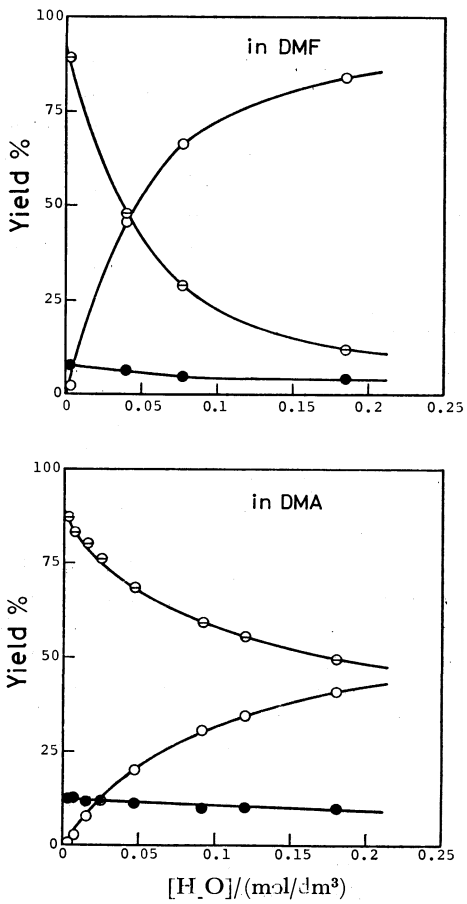

Fig. 2. Effect of water content of DMA(bottom) and of DMF(upper) on the formation of norbornene **3** (●), *exo*-ester **4** (○), and nortricyclene **2** (⊖).

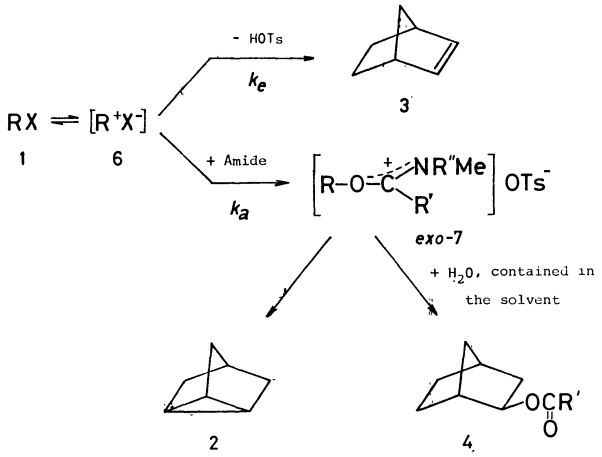
The yield of norbornene was not much affected by the water content of DMA or of DMF (*vide infra*). The yield of nortricyclene, however, decreased with an

increase in water content of DMA and of DMF, and the yield of *exo*-norbornyl acetate or formate increased complementing the decrease in the yield of nortricyclene (Figs. 2-1 and 2-2). Therefore, these results indicate that the direct products from the intimate ion-pair [R^+X^-] are norbornene and an imidatonium ion [R-Amide]$^+$. The latter is so unstable that it would be rapidly converted to nortricyclene, otherwise it would be hydrolyzed by the water in the amide solvent; this is illustrated in Scheme 3.



Scheme 3.

When log k_1 values were plotted against the logarithms of the ratio (%**2**+%**4**): %**3**, a reactivity-selectivity linear relation[16] was observed; this linear relation was established for each carboxamide solvent (Fig. 3). This also indicates that norbornene and the imidatonium ion stem from a single intermediate, *i.e.*, an intimate ion-pair [R^+X^-].

This mechanism is essentially the same as that depicted in Scheme 1 for the carboxamide solvolysis of bicyclo[3.3.1]nonyl system.

syn-*El Mechanism for the Formation of Norbornene.* The formation of norbornene depends on the nature of both the leaving group and the solvent. Thus, the norbornene yield increases in the order **1b** (MeO)> **1a** (Me)>**1c**(H)>**1d** (Br) in any carboxamide solvent (Table 2), the sequence fitting in with the order of the increase in the electron-releasing nature of the *para*-substituent in the respective leaving groups. Furthermore, the yield of norbornene also increased in the solvent sequence DMA>DMF>NMA>NMF for each substrate (Table 2), similarly to the order observed in the yield of unrearranged olefin in the case of bicyclo-[3.3.1]nonyl system.[1] This sequence may be explained in terms of the change in the basicity of the leaving group anion which is affected by the hydrogen-bonding ability (NMF>NMA>DMF>DMA)[1] of the respective carboxamides. These trends in the yield of norbornene suggest that a *syn-El* reaction occurs in the norbornene forming step, and that the leaving group anion acts as a base.

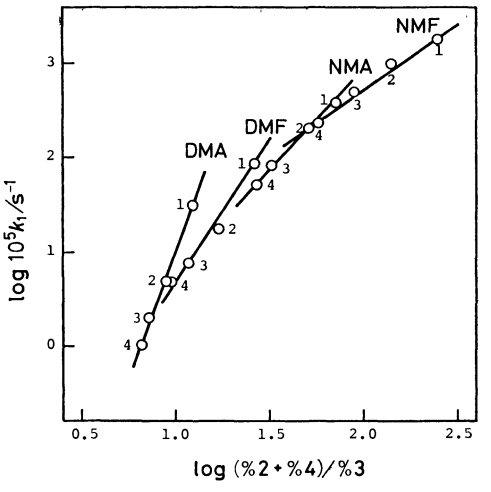


Fig. 3. Linear reactivity-selectivity relationships between log k_1 and log (%**2**+%**4**)/%**3** for the solvolysis of **1a—d** in the carboxamide solvents at 75 °C: 1= **1d** (Br); 2=**1c** (H); 3=**1a** (CH_3); 4=**1b** (OCH_3).

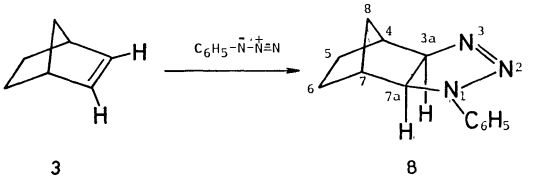
In order to confirm this, the stereochemistry of the *El* reaction was examined on the solvolysis of **1a**-3-*exo-d* and **1a**-3-*endo-d* in DMA at 75 °C. The norbornene was converted into norbornene–phenyl azide adduct (**8**) by 1,3-dipolar cycloaddition reaction of phenyl azide to norbornene,[17] because of the ease in separation and purification of small amounts of norbornene (Scheme 4).



Scheme 4.

The adduct **8** was analyzed by ^{13}C NMR spectroscopy in order to obtain the information on the rearrangements during solvolysis by determining the carbon bearing a deuterium atom which shows –CD– triplet (see Experimental). ^{13}C chemical shifts for the adduct **8** were assigned from the multiplicities of the individual nuclei in the off-resonance decoupled spectra and from comparison with the spectra of other substituted norbornanes.[18] Spectral assignments of the ^{13}C NMR are given in Table 4, together with those for the other norbornane derivatives.

In the case of **1a**-3-*exo-d*, the spectrum of **8** derived from norbornene exhibited –CD– triplet only at 31.9 ppm, indicating the presence of deuterium at C(8) of the adduct **8**. On the other hand, the spectrum of **8** obtained in the case of **1a**-3-*endo-d* showed three triplets (–CD–) at 0.3 ppm upfield from C(3a), C(7a), and C(8) signals. These results clearly indicate that the leaving anion abstracts exclusively *syn*-β-hydrogen atom (or deuterium atom) of the intimate ion-pair intermediate **6**; they also demonstrate that the formation of the ion-pair is attended by the Wagner-Meerwein rearrangement (Table 5, *vide infra*).

Cram and Sahyun,[19a] Cocivera and Winstein,[19b] Skell and Hall,[19c] and Kim and Brown[19d] have emphasized the importance of the nature of the counter ion and its possible assistance to the proton abstraction in the intimate ion-pair.

In order to know a quantitative relationship between the rate, k_e, of norbornene forming step and the leaving

Table 4. ^{13}C chemical shifts of nortricyclene, *exo*-2-substituted norbornyl derivatives, and adduct **8**

Compound	Chemical shift[a,b]								
	C-1	C-2	C-3	C-4	C-5	C-6	C-7	CH_3	C=O

	C-7	C-7a	C-3a	C-4	C-5	C-6	C-8		
Adduct **8**[e]	40.2*	60.3	86.4	41.5*	25.7†	25.0†	32.2		

a) Chemical shifts are expressed in ppm downfield from Me_4Si (in $CDCl_3$ except for the adduct **8** (CD_2Cl_2)). b) Signals marked *, †, may be interchangeable in the column where they appear. c) See Ref. 18a. d) See Ref. 18c. e) The numbering is shown in Scheme 4.

group structure, a linear relationship between log k_e and the Hammett σ value of the *para*-substituent in the leaving group was examined. The log k_e values were estimated from the product distribution (Table 2) using Eqs. 1 and 2, where the magnitude of k_a[Amide] is a constant in the respective carboxamide solvents. The plot of log %**3**/(%**2**+%**4**) against the σ value is illustrated in Fig. 4.

$$\%\mathbf{3}/\%\mathbf{7} = \%\mathbf{3}/(\%\mathbf{2}+\%\mathbf{4}) = k_e/k_a[\text{Amide}] \quad (1)$$

$$\log k_e = \log \%\mathbf{3}/(\%\mathbf{2}+\%\mathbf{4}) + \log k_a[\text{Amide}] \quad (2)$$

Good linear relations, with negative ρ values, -0.54——-1.2, were observed for the series of carboxamides. These linear relations also suggest that in the *E*1 process the leaving group anion intramolecularly abstracts the C(3) proton at the stage of the intimate ion-pair intermediate **6**.

Wagner-Meerwein Rearrangement in the Intimate Ion-Pair and 6,2-Hydride Shift in the Imidatonium Ion. The solvolyses of **1a**-3-*endo-d* in DMA, DMF, and NMF were carried out at 75 °C and the deuterium distribution of *exo*-norbornyl carboxylate, norbornene, and nortricyclene were determined by means of ^{13}C and, in some cases, ^1H NMR spectroscopies in the Fourier transform mode (see Experimental). The results of the deuterium analyses of the products are tabulated in Table 5 and also illustrated in Scheme 5.

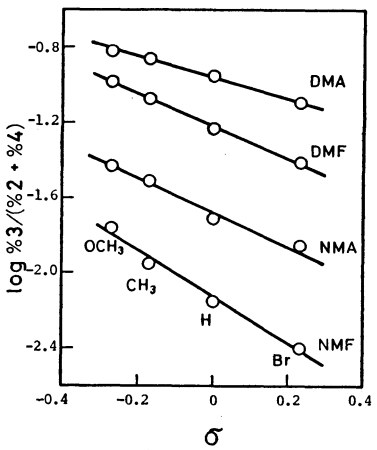

Fig. 4. Linear free-energy relationships between log %**3**/(%**2**+%**4**) and σ for the solvolysis of **1a**—**d** in the carboxamide solvents at 75 °C: $\rho = -0.54$, -0.86, -0.86, and -1.2, respectively for DMA, DMF, NMA, and NMF.

In norbornene the deuterium at *endo*-position of C(3) of **1a**-3-*endo-d* scrambled at the C(3) and C(7) positions, whereas in the *exo*-norbornyl ester (acetate or formate) the deuterium scrambled to C(5) position besides C(3) and C(7) positions.

In addition, when the deuterium distribution in the

5	75	0	25
10	66	0	34
25	50	0	50
50	51	0	49
90	53	0	47

a) [ROTs]=0.075 mol/dm³; [C_5H_5N]=0.077 mol/dm³; $[H_2O]$=0.003 mol/dm³. b) Calculated from the reaction time by the use of the rate constant $k_1=1.69\times10^{-5}$ s^{-1}. c) The percentages of deuterium at the carbons other than C(3), C(5), and C(7) are below the limit of the accuracy (< 1%); reproducibility=±3%.

unchanged tosylate was examined in the course of the solvolysis of **1a**-3-*endo*-*d* in DMA, the deuterium was detected at C(3) and C(7) positions, but no deuterium was found at C(5) position. This is summarized in Table 6.

Since the scrambling of the C(3) deuterium to C(7) position must be caused by the Wagner-Meerwein rearrangement and the appearance of deuterium at C(5) position must be caused by 6,2-hydride shift, it is concluded that only the Wagner-Meerwein rearrangement attends the formation of the intimate ion-pair intermediate (Scheme 5) and that 6,2-hydride shift takes place at the stage of the subsequent reaction of the imidatonium ion (Scheme 5). Furthermore, it is deduced that the imidatonium ion can not return to the intimate ion-pair. If such a return course is probable, the deuterium should be located at C(5) positions of norbornene and of the unchanged tosylate. This, however, is not the case (Tables 5 and 6). Similarly, since no deuterium was found at C(5) of norbornene, it is deduced that the imidatonium ion can not give rise to norbornene.

This absence of the 6,2-hydride shift at the stage of the intimate ion-pair may be ascribed to an increase in the solvent capture caused by the relatively high nucleophilicity of carboxamides, and also to acceleration in *syn*-*E*1 as mentioned above. Such accelerations of both of the subsequent reactions are expected to decrease the life-time of the intimate ion-pair, thereby suppressing the 6,2-hydride shift.

The 6,2-hydride shift, when it occurs in the imidatonium ion, is suppressed in the order of DMF>DMA (Table 5). In addition the increase in the water content of NMF and DMA also suppresses the 6,2-hydride shift in the ester product. Especially, in NMF no 6,2-hydride shift was found in **4b**[20] when the solvolysis was carried out in the presence of 0.15 mol/dm³ of water. These are summarized in Table 7. These trends clearly indicate that the 6,2-hydride shift competes with the hydrolysis of the imidatonium ion [R-Amide]$^+$, which is originally formed without any 6,2-hydride shift.

Table 7. Distribution % of deuterium for esters as a function of water content in the carboxamide solvolysis of **1a**-3-*endo*-*d* at 75 °C[a]

Amide	$[H_2O]$ mol/dm³	Product[b]	Deuterium, %[c] C-3	C-5	C-7

	0.20	**4a**	43	12	43
NMF	0.15	**4b**	49	0	49

a) See footnote (a) in Table 5. b) See footnote (d), (e), (g), and (h) in Table 5. c) The percentages of deuterium at the carbons other than C(3), C(5), and C(7) are below the limit of the accuracy (< 1%); reproducibility=±3%.

Examination of 3,2-Hydride Shift in the Intimate Ion-Pair and in the Imidatonium Ion Intermediate. Roberts and his collaborators[21] have demonstrated that the 6,2-hydride shift is highly competitive with solvent capture of the 2-norbornyl cation and that the intrusion of the 3,2-hydride shift is much more pronounced in the less nucleophilic solvent such as formic acid. Lee and Lam[22] have suggested that even in acetic acid the 3,2-hydride shift occurs to a significant extent prior to the attack by solvent on the cation. Under the stable ion conditions, it has also been demonstrated that both 3,2- and 6,2-hydride shifts attend the formation of the 2-norbornyl cation.[23]

Thus, we examined by the use of **1a**-3,3-d_2 whether the 3,2-hydride shift actually occurs in this solvolysis or not. When the solvolysis was carried out in DMA solvent at 75 °C, and then isolated nortricyclene was subjected to ^{13}C NMR analysis, the spectrum showed a single $-CD_2-$ signal (quintet) centered at 32.3 ppm, 0.6 ppm upfield from C(3), C(5), or C(7) signal of nortricyclene (Table 4), but no sign of another quintet or triplet. This result unequivocally indicates that neither 3-*exo*- nor 3-*endo*-deuterium has migrated from C(3) to C(2) position and that the 3,2-hydride shift never attends the formation of nortricyclene. This means that no 3,2-hydride shift occurs in the stage of the intimate ion-pair.

The absence of deuterium at the C(2) position in the *exo*-norbornyl ester (acetate or formate) (Table 5) also shows that the 3,2-hydride shift does not occur in the course of the formation of these esters in DMA or in DMF.

Structure of the Ion-Pair Intermediate and the Reaction Pathway for the Formation of Deuterium Labeled Norbornene. The deuterium distributions in the norbornene and in the unchanged tosylate were determined at intervals in the course of the solvolysis of **1a**-3-*endo*-*d* in DMA at 75 °C; the results are tabulated in Tables 8 and 6, respectively. Since no deuterium was detected at C(5) positions of norbornene and of the unchanged tosylate, it is obvious, as mentioned above, that merely the Wagner-Meerwein rearrangement competes with the *syn*-*E*1 elimination and with the solvent capture.

Table 8. Change in deuterium distributions of norbornene in the course of solvolysis of **1a**-3-*endo*-*d* in DMA at 75 °C[a]

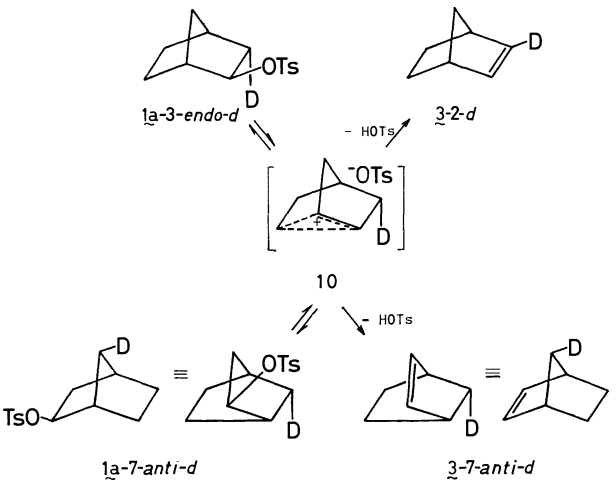
100	44	0	56

a) $[ROTs]=0.075$ mol/dm^3; $[C_5H_5N]=0.077$ mol/dm^3; $[H_2O]=0.003$ mol/dm^3. b) Calculated from the reaction time by use of the rate constant: $k_1=1.69\times10^{-5}$ s^{-1}. c) The percentages of deuterium at the carbons other than C(3), C(5), and C(7) are below the limit of the accuracy (< 1%); reproducibility = ±3%. d) Calculated from data of the adduct **8**.

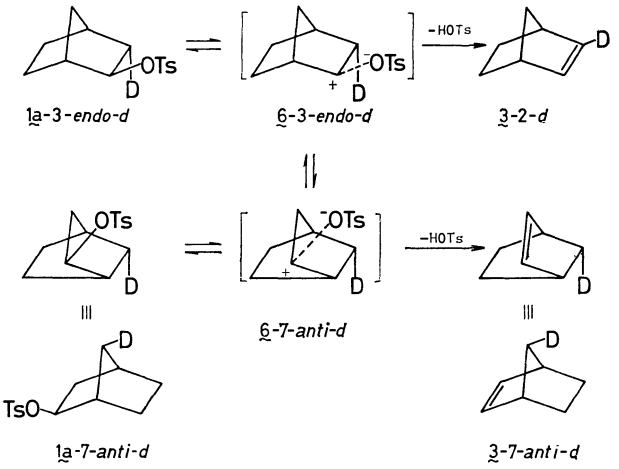
The structural problem of this intimate ion-pair has been long debated[8] and it is pertinent to discuss it in the light of the change of the deuterium distribution in norbornene in the progress of the solvolysis.

When the intimate ion-pair has a non-classical structure (**10**) depicted in Scheme 6, it would give rise to **1a**-7-*anti*-*d* and norbornene, **3**-2-*d* and **3**-7-*d*, by an internal return and by *syn*-*E*1 pathway, respectively. In addition, the tosylate **1a**-7-*anti*-*d* can also afford the intimate ion-pair which has the structure identical with that from the starting tosylate **1a**-3-*endo*-*d*. In other words, there is a single structure (non-classical) **10** in the course of the norbornene formation from both **1a**-3-*endo*-*d* and **1a**-7-*anti*-*d*. Consequently, the ratio of norbornene **3**-2-*d* and **3**-7-*anti*-*d* should be invariant regardless the degree of conversion of the tosylate, even if the ratio of the tosylate **1a**-3-*endo*-*d* and **1a**-7-*anti*-*d* varies as the solvolysis proceeds (see Scheme 6).



Scheme 6.

On the other hand, if the intermediate exists as an equilibrium mixture of the classical ions **6**-3-*endo*-*d* and **6**-7-*anti*-*d*, and in addition, if the *syn*-*E*1 elimination can compete with the Wagner-Meerwein rearrangement between these ions, the ratio of norbornene **3**-2-*d* and **3**-7-*anti*-*d* would vary as the elimination progresses (Scheme 7).



Scheme 7.

Since the deuterium distribution in the norbornene varies as the reaction proceeds in DMA, as is shown in Table 8, it is clear that the structure of the intimate ion-pair can not be expressed by the non-classical ion **10**, but by the classical ion **6**, in so far as the norbornene is produced strictly from the intimate ion-pair.

The deuterium content at C(3) of the tosylate decreases from 100 to 50% at 25% completion of the solvolysis, and then increases to 53% at 90% completion (Table 6). Meanwhile, the deuterium content at C(7) of norbornene increases from 50 to 56% as the reaction proceeds from 50 to 100% completion. The slight accumulation of deuterium at C(3) of **1a**-3-*endo-d* and that at C(7) of **3**-7-*anti-d* may be ascribed to the possible slight sluggishness in the rate of solvolysis of **1a**-3-*endo-d* as compared with **1a**-7-*anti-d*. In fact the secondary isotope effect of **1a**-3-*endo-d* amounts to 1.18± 0.02 in DMA at 75 °C.[24] However, the accumulation of deuterium at C(7) of norbornene at 100% reaction appears to be too high to be ascribed to the possible secondary isotope effect, even if the experimental error (±3%) is taken into account. This point will be subjected to a more detailed study with precision.

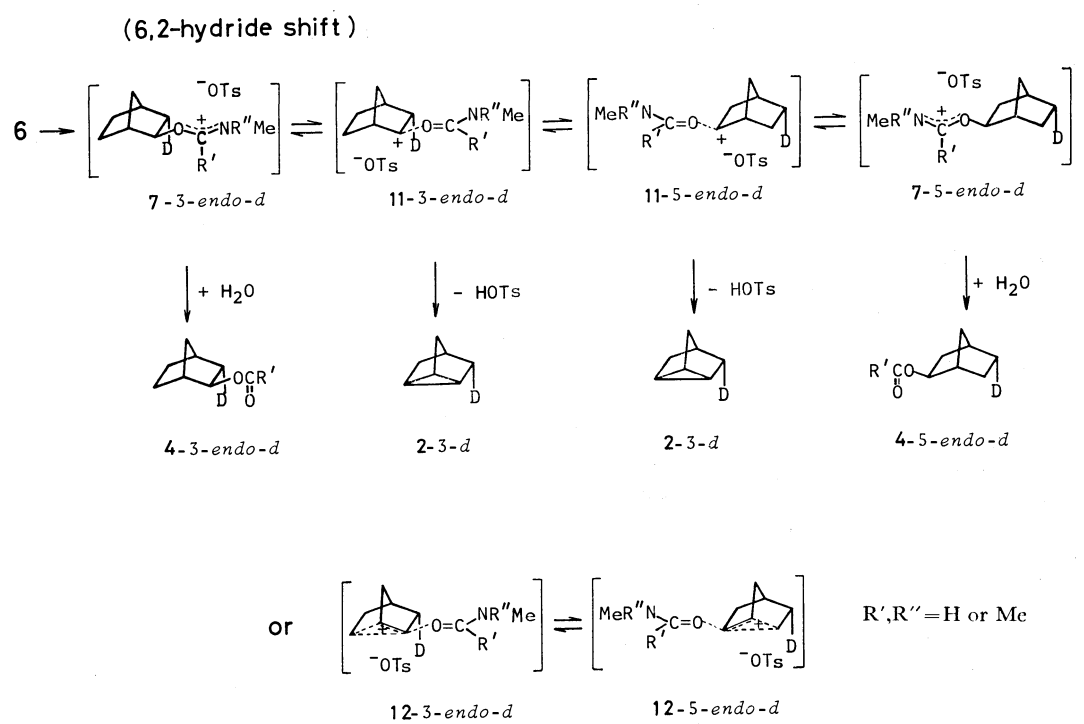
The Formation of exo-*2-Norbornyl-5-*d *Carboxylates and Nortricyclene.* The C(5) positions of *exo*-2-norbornyl esters contain appreciable amounts of deuterium, as it is shown in Table 5. This indicates that the *exo*-imidatonium ion **7**-3-*endo-d* easily rearranges to the **7**-5-*endo-d* ion by the 6,2-hydride shift. Since the classical intermediates **11**-3-*endo-d* and **11**-5-*endo-d* (Scheme 8) give rise to the identical nortricyclene, **2**-3-*d*, we can not obtain more detailed information about the mechanistic insights. Therefore, the possibility of 6,2-hydride shift *via* non-classical structure, **12**-3-*endo-d*,[25] can not be ruled out in the γ-elimination of the *exo*-imidatonium ion **7**.

It is not clear at the present stage of our knowledge why the *exo*-imidatonium ion can easily afford nortricyclene, and why the *exo*-imidatonium ion easily undergoes 6,2-hydride shift.

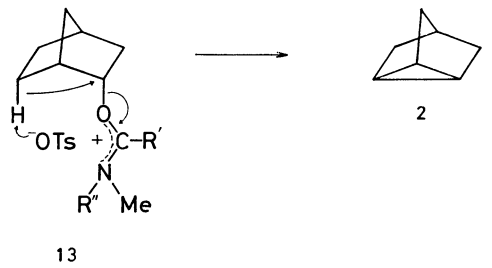
The Formation of endo-*2-Norbornyl Carboxylates.* Small amounts of *endo*-norbornyl acetate or formate, **5a** (≤0.9%) or **5b** (≤1.1%), were produced in the solvolysis of **1a**—**d** in the carboxamide solvents as it is shown in Tables 2 and 3. However, these are in substantial amounts as compared with the result of acetolysis of *exo*-norbornyl brosylate **1d** (0.02%),[26] and also in comparison with the amounts of *exo*-2-norbornyl carboxylates (Table 2). The formation of *endo*-norbornyl esters obviously indicates that the *endo*-imidatonium ion is actually formed in the course of solvolysis. This *endo*-imidatonium ion most probably is formed from the intimate ion-pair with a classical norbornyl ion structure, since it is rather difficult that the *endo* product is formed from a non-classical norbornyl ion.

The C(6) hydrogen of the *endo*-imidatonium ion **13** may be easily abstracted in a cyclic fashion, as depicted in Scheme 9, to give rise to nortricyclene. Peeters and Anteunis[27] have proposed similar cyclic mechanism for solvolytic dehydrobromination of 2-methyl-2-pentyl bromide in DMF at the imidatonium ion stage.

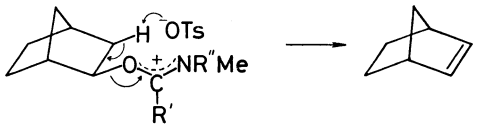
A Possible Norbornene Formation from exo-*Imidatonium Ion.* The possibility that norbornene is formed through the *exo*-imidatonium ion **7**, as depicted in Scheme 10, may not be ruled out. Thus the slight decrease in the yield of norbornene with an increase in water content (Fig. 2) might be attributable to the intrusion of this process. However, as mentioned above, it is clear that at the stage of the imidatonium ion the deuterium scrambles to C(5) position as the result of the 6,2-hydride shift. Therefore, if the elimination occurs by the pathway depicted in Scheme



Scheme 8.



Scheme 9.



Scheme 10.

10, norbornene labeled at C(5) position would be formed; however, this is not the case (Table 5 and Scheme 5). Thus, only the decrease in the basicity of the tosylate anion, due to the increase in the water content, can explain the decrease in the yield of norbornene (Fig. 2).

Experimental

All the melting points are uncorrected. NMR spectra were measured with a Hitachi R-24 (60 MHz) or JEOL JMN MH-100 (100 MHz) instruments. Tetramethylsilane was used as an internal standard in $CDCl_3$ unless otherwise noted. IR spectra were obtained with Hitachi EPI-S2 spectrometer, only the major absorptions being cited. GLC analysis was performed with a Hitachi K-53 gas chromatograph fitted with TCD and a 3 m column (i.d.=3 mm) packed with PEG 6000 on Chromosorb W.

Materials. The four carboxamides were purified by the same method described in the previous paper.[1] Norbornene oxide,[28] *exo*-2-norbornanol,[29] norcamphor,[29] phenyl azide,[30] $(n\text{-Bu})_4NOAc$,[31] trifluoroacetic acid-*d*,[32] *p*-methoxybenzenesulfonyl chloride,[33] and 1-adamantyl bromide[34] were prepared following the published methods. Reagent grade chemicals were used without further purification unless otherwise mentioned. Norbornene was commercial product purified by sublimation.

exo-*2-Norbornyl Arenesulfonates* ***1a—d.*** The *exo*-alcohol was converted into the corresponding sulfonates in the usual manner.[35] Tosylate **1a**: mp 54.5—55.5 °C (lit, mp 53—54 °C,[4] 53.7—54.6 °C[36]). Brosylate **1d**: mp 55.5—57 °C (lit,[4] mp 55.3—57 °C). Benzenesulfonate **1c** could not be crystallized and was purified by being settled as an oil repeatedly from pentane solution at −30 °C: IR (neat); 1360 (SO_2), 1190 (SO_2), 1100 (Ar–S), and 875—960 cm^{-1} (five max, S–O–C): NMR (60 MHz) δ=0.8—1.75 (m, 8H), 2.3 (broad s, 2H, bridge head CH), 4.36 (t, 1H, $CHOSO_2$), and 7.25—8.0 ppm (m, 5H, Ar–H).

Found: C, 61.93; H, 6.28%. Calcd for $C_{13}H_{16}O_3S$: C, 61.88; H, 6.39%.

p-Methoxybenzenesulfonate **1b**: mp 47.5—49 °C; IR (KBr); 1356 (SO_2), 1263 (Ar–O–C), 1190 (SO_2), 1170, 1100 (Ar–S), and 875—960 cm^{-1} (five max, S–O–C); NMR (60 MHz) δ=0.8—1.8 (m, 8H), 2.30 (broad s, 2H, bridge head CH), 3.88 (s, 3H, OCH_3), 4.41 (t, 1H, $CHOSO_2$), 6.98 (d, 2H, Ar–H), and 7.81 ppm (d, 2H, Ar–H).

Found: C, 59.65; H, 6.38%. Calcd for $C_{14}H_{18}O_4S$: C, 59.55; H, 6.43%.

exo-*2-Norbornanol-3*-endo-d *and Its Tosylate* ***1a****-3*-endo-d. *endo*-3-Deuterium was introduced by the $LiAlD_4$ reduction of norbornene oxide.[37,38] A solution of $LiAlD_4$ (99.5% D, 3.0 g) and norbornene oxide[28] (7.3 g) in DME (distilled from Na–benzophenone ketyl, 250 cm^3) was heated at 100—105 °C for 28 h. After the mixture had been cooled in an ice bath, a mixture of THF–H_2O (1:1, v/v, 200 cm^3) was added slowly, and then K_2CO_3 was added to separate water layer. An organic layer was dried ($MgSO_4$), concentrated (Vigreux column), and the residual oil was distilled to give *endo*-3-*d* alcohol (6.0 g, 80% yield): bp 178—179 °C. Sublimed sample of the alcohol was subjected to ^1H NMR (100 MHz) spectroscopic analysis to show an isotopic purity of 99%. The alcohol was converted into the tosylate in the usual manner.[35] **1a**-3-*endo-d*: mp 54—55 °C; NMR (60 MHz) δ=0.85—1.75 (m, 7H), 2.3 (broad s, 2H, bridge head CH), 2.43 (s, 3H, Ar–CH_3), 4.34 (s, 1H, CHOTs), 7.34 (d, 2H, Ar–H), and 7.78 ppm (d, 2H, Ar–H). ^{13}C NMR spectrum of the tosylate indicated the absence of deuterium scrambling during its preparation.

exo-*2-Norbornanol-3*-exo-d *and Its Tosylate* ***1a****-3*-exo-d. *exo*-3-Deuterium was introduced by deuterioboration of norbornene.[37,39] Deuterioboration–oxidation was carried out according to the standard procedure including external generation of diborane-d_6.[39] The 3-*exo-d* alcohol was obtained in 80% yield. ^1H NMR (100 MHz) analysis showed an isotopic purity of 97%. Tosylate **1a**-3-*exo-d* was synthesized from this alcohol in the usual manner.[35] **1a**-3-*exo-d*: mp 54—55 °C; NMR (60 MHz) δ=0.85—1.75 (m, 7H), 2.27 (broad s, 2H, bridge head CH), 2.43 (s, 3H, Ar–CH_3), 4.45 (d, 1H, J=6.2 Hz, CHOTs), 7.32 (d, 2H, Ar–H), and 7.79 ppm (d, 2H, Ar–H). ^{13}C NMR spectrum of the tosylate showed the absence of deuterium scrambling throughout its synthesis.

exo-*2-Norbornanol-3,3*-d_2 *and Its Tosylate* ***1a****-3,3*-d_2. Norcamphor-3,3-d_2 was prepared by the method of Schaefer *et al.*[40] in 70% yield: bp 168—169 °C. ^1H NMR (100 MHz) analysis showed an isotopic purity of 97.7%. Reduction of the ketone with $LiAl(OCH_3)_3H$ in THF afforded the *endo*-alcohol stereoselectively[41] (98%) in 94% yield. Then, the alcohol was converted into the brosylate in the usual manner,[35] which was then partially solvolyzed in AcOH–NaOAc for 2 h at 45 °C. The usual work-up and recrystallization from pentane at −30 °C gave *endo*-2-norbornyl-3,3-d_2 brosylate in 70% yield based on the *endo*-alcohol. The brosylate was subjected to S_N2 reaction with $(n\text{-Bu})_4NOAc$[31] in benzene (reflux, 3 h),[37] furnishing *exo*-2-acetate-3,3-d_2 in 98% yield after Kugelrohr distillation. Reduction of the acetate with $LiAlH_4$ gave *exo*-2-norbornanol-3,3-d_2 in 90% yield. ^{13}C NMR analysis showed the absence of deuterium scrambling during the procedures. Tosylate **1a**-3,3-d_2 was prepared in the usual manner:[35] mp 53.5—54.5 °C; NMR (60 MHz) δ=0.87—1.75 (m, 6H), 2.30 (broad s, 2H, bridge head CH), 2.43 (s, 3H, Ar–CH_3), 4.44 (s, 1H, CHOTs), 7.32 (d, 2H, Ar–H), and 7.78 ppm (d, 2H, Ar–H).

Product Analysis. Arenesulfonate (2—3 mmol) was weighed into an ampoule (dried in an oven), which was then repeatedly evacuated and filled with dry nitrogen. A desired amount of solvent was introduced to attain the concentration of the substrate to be 0.075 mol/dm^3 with a syringe through a septum and then pyridine (3% excess) was added in the same manner as above. The ampoule was then sealed under nitrogen and kept at 75 °C for ten half-lives. The ampoule was opened and weighed amounts of anisole was added to the mixture. The resulting solution was poured

into ice–water and extracted with pentane. The pentane solution was washed several times with water, dried ($MgSO_4$), and concentrated carefully by the use of 30-cm column packed with glass helices to *ca.* 1 cm^3. A part of the condensed pentane solution was transferred into an NMR tube with a syringe and the sample was repeatedly scanned over the respective regions for olefinic protons of norbornene **3** and O–CH_3 protons of anisole ten times at 30 s intervals. The ratio of the peak area of CH=CH to O–CH_3 was calculated as an average of these scans. The yield calculated from the ratio was reproducible relatively to $\pm 3\%$ or less on repeated runs.

Another part of the pentane solution was analyzed for nortricyclene **2**, norbornene **3**, and esters **4** and **5** by means of GLC.

The remaining pentane solution was combined with that used for NMR assay, concentrated, and the residue was chromatographed over SiO_2, being eluted successively with pentane, pentane–CH_2Cl_2 (8 : 2, v/v), and CH_2Cl_2. The CH_2Cl_2 fractions afforded the ester (**4**+**5**) which was reduced with $LiAlH_4$ in ether to give norbornanol, epimeric composition of which was analyzed by means of GLC (80 °C).

Preparation of Norbornene–Phenyl Azide Adduct. Norbornene **3** obtained from partial or complete solvolysis of **1a**-3-*endo-d* or **1a**-3-*exo-d* was converted into the adduct with phenyl azide[30] (1-phenyl-4,7-methano-3a,4,5,6,7,7a-hexahydrobenzotriazole, **8**) by the method described by Huisgen *et al.*[17] for the sake of easy separation and purification of small amounts (~mg) of norbornene **3** from the solvolysis products without loss and scrambling of deuterium.[42] A typical run is described in the followings.

Tosylate **1a**-3-*endo-d* (2 g) was solvolyzed in DMA for 0.5 half-lives in the same manner as described above. A mixture of nortricyclene **2**, norbornene **3**, the acetates **4** and **5**, and unchanged tosylates was obtained as a pentane solution after the usual work-up. The mixture was passed through an SiO_2 column and the column was eluted with additional pentane. To the combined pentane solution was added dry benzene (0.25 cm^3) and the mixture was concentrated carefully through a column packed with glass helices to *ca.* 1 cm^3. Then, phenyl azide[30] (0.02 cm^3) was added to the condensate and the resulting solution was allowed to stand at room temperature for three days. The volatile components were removed under reduced pressure to give yellow crystalline residue which was recrystallized from hexane to furnish the adduct as fine needles (0.02 g), mp 100—101 °C (lit,[17] mp 100—101 °C, unlabeled adduct **8**).

Separation of Nortricyclene. Tosylate **1a**-3,3-d_2 (0.5 g) was solvolyzed in DMA at 75 °C for ten half-lives. A condensed pentane solution was obtained in the same manner as described above. The solution was then treated with *m*-chloroperbenzoic acid in CH_2Cl_2 (slight excess to norbornene **3**) at 0 °C for 1 h. The mixture was washed with 10% Na_2CO_3, dried ($MgSO_4$), and concentrated by use of 30-cm column packed with glass helices. The residue was chromatographed over SiO_2 (5 g), being eluted with pentane (30 cm^3). The pentane solution was again concentrated through the column and the residue was allowed to stand open to the atmosphere at room temperature for 30 min to give crystalline nortricyclene **2**, which was then separated and purified by sublimation.

Separation of Unchanged Tosylate. The tosylate recovered from partial solvolysis was separated from pentane solution by repeated recrystallization at −30 °C. Colorless crystalline tosylate was obtained, which was kept under high vacuum at room temperature overnight.

^{13}C NMR Spectra. Chemical Shift Determinations. ^{13}C spectra were determined on a JEOL JMN FX-100 spectrometer operated at 25.05 MHz and equipped with JEOL JEC 980B computer (8K) in the Fourier transform mode. All ^{13}C chemical shifts are reported relative to tetramethylsilane in $CDCl_3$ or in CD_2Cl_2.

Spectral assignments were made easily from the multiplicities of the individual nuclei in the off-resonance decoupled spectra and from comparisons with the chemical shifts reported for other substituted norbornanes.[18] The chemical shifts of nortricyclene[18a] and the formate[18c] were available in the literature and our data were satisfactorily consistent with those reported.

Quantitative Intensity Measurements. For the deuterium distribution analysis, the proton-decoupled spectra of nortricyclene **2**, the esters **4a** and **4b**, the adduct **8**, and recovered tosylate were recorded at spectral widths of 2000, 2500, 3000, and 1000 Hz, respectively, by use of a 90° pulse and a pulse repetition of 30 s. A 180°-τ-90° pulse sequence[43] was used to demonstrate that 30 s delay was comparable to $5T_1$ for each of the observed nuclei. A pulse repetition of 60 s was also used to determine more definitely the nuclei labeled by deuterium atom. To circumvent the potential source of error on quantitative analysis,[44] the NOE suppressed gated decoupling technique[45] was used and each spectrum was compared with calibration spectra taken for unlabeled sample, employing unaffected carbon signals such as $\underline{C}H_3$-COO, –$\underline{C}(6)H_2$–, and Ar–$\underline{C}H_3$, respectively for **4a**, **4b** and **8**, and **1a**, as an internal calibration.

For the acetate **4a** deuterium distribution analysis was carried out as follows. The spectrum of an unlabeled sample in $CDCl_3$ was recorded by use of the operating parameters as indicated above. The ratio of the peak area of each observed nuclei to that of $\underline{C}H_3COO$ was directly computed on a JEOL 980B computer with SYSTEM Q/D PROGRAM FAFT08/11. The spectrum of a deuterated sample was then recorded in the identical manner as used in the case of the unlabeled sample. The ratio of the peak area of each observed nuclei so that of $\underline{C}H_3COO$ was measured in the same method as described above. A decrease in the intensity of –CH_2– signals was calculated from the each ratio obtained.

The deuterium distribution analysis of the adduct **8** obtained from the partial solyolysis of low %reaction ($\leq 50\%$) was carried out by means of ^1H NMR spectroscopy in the Fourier transform mode. Since the ^{13}C spectrum of the adduct **8**, obtained from the solvolysis of **1a**-3-*endo-d* in DMA (100% reaction), has indicated that the deuterium is located at C(3) and C(7) positions of norbornene skeleton, a decrease in the peak area of well-resolved C(3a)- and C(7a)-proton signals was measured. The ratio of the peak area of the concerned protons to that of the bridge head protons was directly obtained by the same method as described for the ^{13}C intensity measurement, which was compared with the corresponding ratio for the unlabeled sample. The operating parameters employed were a spectral width of 1000 Hz, a 45° pulse, pulse repetition of 10 s, and 10—200 pulses, to provide almost same S/N ratio for each sample.

Kinetic Measurements. Solvolysis rates for **1a—d** and specifically-labeled tosylates in the carboxmaides were determined in the same manner as described in the previous paper,[1] by the use of KOH (in EtOH) titrant and Thymol Blue–phenolphthalein indicator.

Except for the case of NMA, an experimental infinity titer was in excess of the theoretical one, in proportion to the amounts of the carboxylic acid which was produced by an acid-catalyzed hydrolysis of the amide solvent. The solvent hydrolysis is caused by contaminated water even after rigorous

purification of the amide. In all cases, however, $\log a/(a-x)$ $-t$ plots gave straight lines with intercept at an origin even when the excessive infinity titer was employed to calculate $a/(a-x)$ values. In fact, there have been obtained essentially the same rate constants for the solvolysis of **1a—d** in the amides containing various amounts of water, although the infinity titers were in the range of 1.1—1.65 times the theoretical titer.

Another control experiment was carried out; the rate constant obtained by the acid-base titration method, infinity titer being in excess, was the same as that obtained by the Volhard method within an experimental error for the solvolysis of 1-adamantyl bromide in the amides.

Rate constants listed in Tables 1 and 2 are the data calculated from experimental infinity titers without correction for the excess because the above-mentioned findings do not require the correction for the excess.

The rates of solvolysis of **1a** in aqueous ethanol and in aqueous acetone were determined titrimetrically in a usual manner.

Control Experiments. All the products were stable under the conditions employed in the present study. It was found that the presence of pyridinium tosylate, acetic acid, formic acid, or pyridine in equimolar amounts to the substrates did not alter the respective yields of the solvolysis products.

Preparation and Properties of Nickel–Phosphine Complexes Coordinated with α,β-Unsaturated Ester

Junichi Ishizu, Takakazu Yamamoto,* and Akio Yamamoto
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227
(Received January 24, 1978)

Reactions of bis(1,5-cyclooctadiene)nickel, $Ni(cod)_2$, with α,β-unsaturated esters in the presence of tertiary phosphine give a series of nickel–phosphine complexes formulated as Ni(tertiary phosphine)$_n$L (L=alkyl methacrylates, methyl acrylate, or methyl cinnamate; n=2 for $P(C_6H_5)_3$, $P(C_2H_5)(C_6H_5)_2$, $P(CH_3)_2(C_6H_5)$, $P(C_2H_5)_3$, n=1 for P(cyclo-$C_6H_{11})_3$). Elemental analyses, IR and NMR spectra, and chemical properties of the complexes confirm the molecular formula. The olefinic proton signals of methyl acrylate and alkyl methacrylates coordinated to nickel shift to upfield by 2.6—4.9 ppm from those of free olefins in the ^{1}H-NMR spectra, indicating that the α,β-unsaturated esters coordinate to nickel through the double bond. The IR spectra show only small low frequency shifts of the ν(C=O) bands of the α,β-unsaturated esters on complex formation. The reactions of Ni(P-$(C_6H_5)_3)_2$ (ethyl methacrylate) and Ni(P(cyclo-$C_6H_{11})_3$) (ethyl methacrylate) with vinyl acetate at room temperature cause the scission of the C–O bond in vinyl acetate to yield ethylene and nickel acetate.

Although a number of nickel–olefin complexes are known,[1] only a few reports have appeared on the isolation of nickel complexes coordinated with α,β-unsaturated esters.[2] No studies seem to have been carried out on the isolation of a series of α,β-unsaturated ester–nickel complexes with stabilizing ligands such as tertiary phosphines or on the effects of the stabilizing ligands on the properties of the isolated complexes. In the course of our study on the C–O bond activation of esters in contact with some zero-valent nickel complexes,[3] we found that the reactions of bis(1,5-cyclooctadiene)nickel $Ni(cod)_2$ with α,β-unsaturated esters in the presence of tertiary phosphine ligands serve as a convenient and versatile synthetic route to α,β-unsaturated ester–coordinated nickel complexes having various tertiary phosphine ligands, although the reactions of $Ni(cod)_2$ with other types of esters (alkenyl acetates, phenyl carboxylates, *etc.*) in the presence of tertiary phosphine ligands often lead to the scission of the C–O bonds in the esters.[3]

In this paper we report the isolation of α,β-unsaturated ester–nickel complexes having tertiary phosphine ligands from the reaction mixtures of $Ni(cod)_2$, α,β-unsaturated esters (methyl acrylate, alkyl methacrylate, and methyl cinnamate), and tertiary phosphine ligands and some chemical properties of the isolated complexes.

Results and Discussion

Reactions of $Ni(cod)_2$ with methyl acrylate (mac), methyl methacrylate (mma), ethyl methacrylate (ema), and methyl cinnamate (mci) in the presence of tertiary phosphines at room temperature give orange or red nickel–phosphine complexes formulated as Ni(tertiary phosphine)$_n$(α,β-unsaturated ester) in high yields (62—92%):

$$Ni(cod)_2 + \text{tertiary phosphine} + CH(R_1)=C(R_2)COOR_3 \longrightarrow (PR_3)_nNi\text{---}\underset{R_2}{\overset{R_1}{C=C}}\overset{H}{}\overset{}{}COOR_3 \quad (1)$$

where PR_3 represents the tertiary phosphine ligand,

	Tertiary phosphine	R_1	R_2	R_3	n
1a	PPh_3	H	CH_3	C_2H_5	2
1b	$PEtPh_2$	H	CH_3	C_2H_5	2
1c	PMe_2Ph	H	CH_3	C_2H_5	2
1d	PEt_3	H	CH_3	C_2H_5	2
1e	PCy_3	H	CH_3	C_2H_5	1
1f	PPh_3	H	CH_3	CH_3	2
1g	PPh_3	H	H	CH_3	2
1h	PPh_3	C_6H_5	H	CH_3	2

PCy_3: tricyclohexylphosphine.

Table 1 summarizes the analytical data of the isolated complexes. Complex **1a** was also obtained by the ligand exchange reaction of $Ni(cod)(PPh_3)_2$ with ema. When the cone angle θ[4] of the phosphine ligand is large as in the case of tricyclohexylphosphine PCy_3 (θ=179°) a complex with one phosphine ligand (**1e**) is obtained. Similar acrylonitrile–nickel[5] and acrylaldehyde–nickel[6] complexes with one PCy_3 ligand are known. On the contrary, in other cases when the cone angle of the phosphine ligand is smaller as given in Table 1, complexes with two phosphine ligands are obtained. Since triethylphosphine and tricyclohexylphosphine have similar basicities, the difference in the number of the coordinated ligands can be ascribed mainly to the steric rather than electronic effect. Attempts to prepare an ema–nickel complex by use of bidentate phosphine ligands, 1,2-bis(diphenylphosphino)ethane(dpe), gave only $Ni(dpe)_2$, no ema-coordinated dpe complex being isolated. Among the ema complexes with two phosphine ligands (**1a**—**1d**) the sensitivity of the complex to oxygen increases with the increase in the basicity of the phosphine ligand in the order **1a**<**1b**<**1c**<**1d**. Complex **1a** is moderately stable in air. However, complex **1d** is highly air-sensitive.

NMR and IR Spectra of the Complexes. Table 2 summarizes the IR and ^{1}H-NMR data of the complexes. Figure 1 shows the ^{1}H-NMR spectrum of complex **1a** in benzene at room temperature with and without ^{31}P-decoupling. The signals of olefinic protons of ema shift on complex formation to the upfield region where the signals of olefinic protons in the usual

Table 1. Analytical data of Ni(tertiary phosphine)$_n$(α,β-unsaturated ester)

a) In KBr disk except for **1d**. b) $\nu(C=O)_{free}-\nu(C=O)_{complex}$. c) In C_6D_6 at room temperature; s=singlet, d=doublet, t=triplet, q=quartet, m=multiplet; br=broad; *cis*- and *trans*-CH are referred to the ester groups. The tertiary phosphine signals are omitted from the table. d) This signal is partly overlapped with the tertiary phosphine signals. e) In benzene.

π-type transition metal–olefin complexes are observed.[1] Without ^{31}P-decoupling the two olefinic protons of ema in **1a** give rise to complex multiplet signals due to the geminal coupling and the coupling with one or two ^{31}P's (Fig. 1a). The ^{31}P-decoupled ^1H-NMR spectrum of **1a** gives an AB quartet pattern typical of the geminal olefinic protons coupled with each other (Fig. 1b). The α-CH_3 protons are coupled with one of the ^{31}P nuclei of the two PPh_3 ligands. The existence of the coupling between ^{31}P of PPh_3 ligand and ^1H's of ema indicates that these ligands are bonded to nickel on NMR time scale.

The appearance of PPh_3 signal as a sharp quartet in $^{31}P\{H\}$-NMR spectrum of **1a** (Fig. 2a) reveals that two PPh_3 ligands occupy magnetically non-equivalent positions to each other in the square planar complex, there being neither rapid dissociation of ligands nor rotation of the ema ligand around the Ni–ema bond axis.

The CH_2 protons of OC_2H_5 group of ema in **1a** give rise to a complex pattern (probably a double quartet) in the ^1H-NMR spectrum. The pattern is not simplified by the ^{31}P-decoupling, indicating that the two protons in the OCH_2 group are magnetically non-equivalent. The non-equivalence of the two protons most probably arises from the prevention of free rotation about the O–CH_2 bond axis due to steric hindrance.

The IR spectrum of **1a** shows a shift of ν(C=O) band

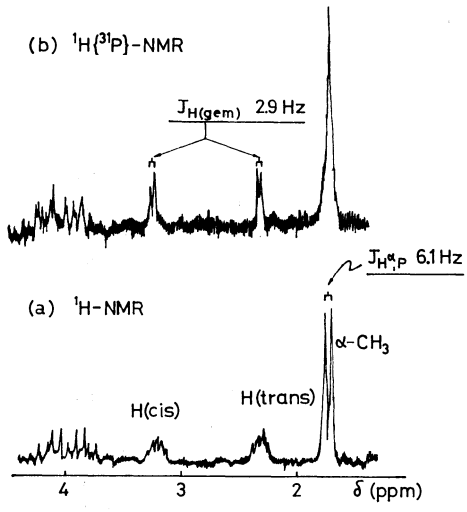

Fig. 1. (a) ^1H-NMR spectrum of complex **1a**, (b) ^{31}P-decoupled ^1H-NMR spectrum of **1a**; in benzene-d_6 at room temperature. *cis*-H and *trans*-H are referred to the ester group.

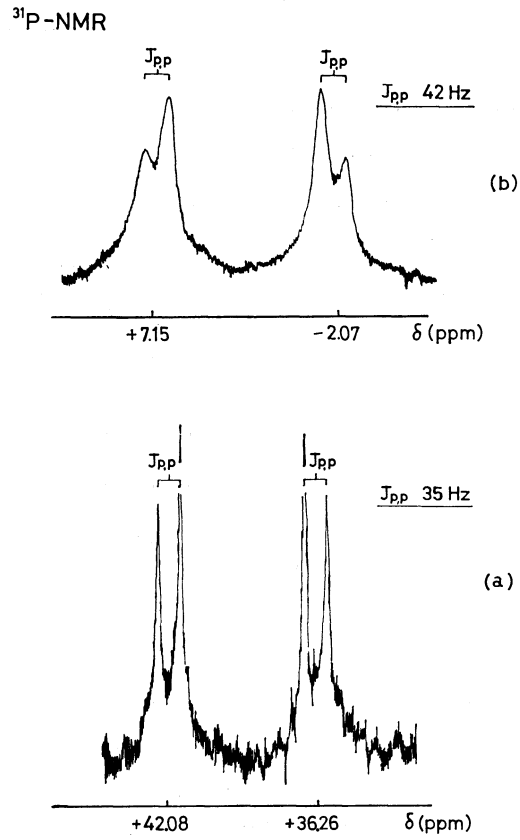

Fig. 2. ^{31}P-NMR spectra of (a) **1a** and (b) **1c** in toluene at room temperature. δ value is referred to external PPh_3 (downfield positive).

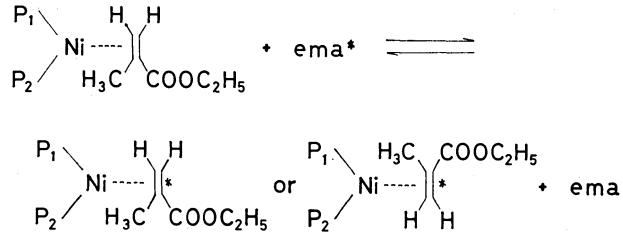
of ema to a lower frequency by 43 cm^{-1}, suggesting that there is no direct end-on type interaction between the C=O group and the nickel atom. When a carbonyl group of an ester has direct end-on type interaction with a metal, the ν(C=O) band usually shifts to lower frequency by more than 100 cm^{-1}.[7]

These NMR and IR data indicate that the ema ligand in **1a** is coordinated to nickel predominantly through the C=C double bond. It has recently been established by X-ray structural analysis that methyl acrylate (mac) in solid Ni(2,2′-bipyridine)$(mac)_2$ is coordinated to nickel through the C=C double bond the carbonyl group not participating in the direct bonding.[8] In this complex the ν(C=O) of mac shifts to lower frequency by 50 cm^{-1} on coordination.[2a]

The ^1H-NMR spectrum of **1d** is similar to that of **1a**, showing coupling of olefinic and α-CH_3 protons with ^{31}P of PEt_3 and non-equivalence of the two protons in the OCH_2 group. The ^1H-NMR spectrum of **1b** is also similar to that of **1a** showing the coupling of ^{31}P of $PEtPh_2$ with olefinic and α-CH_3 ^1H's of ema, but in this spectrum the OCH_2 signal appears as a simple quartet indicating that free rotation around the O–CH_2 bond occurs.

In contrast to **1a**, **1b**, and **1d**, the ^1H-NMR spectrum of **1c** shows that the α-CH_3 protons of ema are not coupled with ^{31}P of PMe_2Ph and the signals of the olefinic protons of ema are somewhat broadened at room temperature. The ^{31}P-NMR spectrum of **1c** also shows broadening of the AB quartet (Fig. 2b). On cooling a toluene solution of **1c** to −70 °C the coupling between α-CH_3 protons and ^{31}P of PMe_2Ph becomes observable in the ^1H-NMR spectrum and the AB quartet in the ^{31}P-NMR spectrum becomes sharp. These results indicate that coordinated ema in **1c** is rapidly exchanged at room temperature with a trace amount of free ema liberated from the complex:



Peaks assignable to free ema are not observable in the ^1H-NMR of **1c** both at room temperature and at −70 °C presumably because of minor dissociation of ema from the complex.

In the Ni–ema complexes having two phosphine ligands there is a tendency that the upfield shift of the olefinic protons of ema on coordination increases with increase in the basicity of the phosphine ligand. The trend is more obvious with *cis*-olefinic proton than with *trans*-olefinic proton. Figure 3 shows plots of the chemical shifts of the olefinic protons against the pK_a value of the conjugate acid of the phosphine ligand. The relation shown indicates that the coordination of a basic phosphine ligand enhances the migration of electrons from nickel to ema to increases the shielding of the olefinic protons. The shift of ν(C=O) to lower frequency also supports this view. When the IR spectrum is taken in a KBr disc the coordination of a more basic phosphine ($PEtPh_2$($pK_a^{9)}$=4.9) or PMe_2Ph($pK_a^{9)}$=6.2)) to nickel causes a larger shift of ν(C=O) than the coordination of the less basic phosphine (PPh_3-($pK_a^{9)}$=3.0)), suggesting that the coordination of a more basic phosphine causes a greater Ni→ema back-

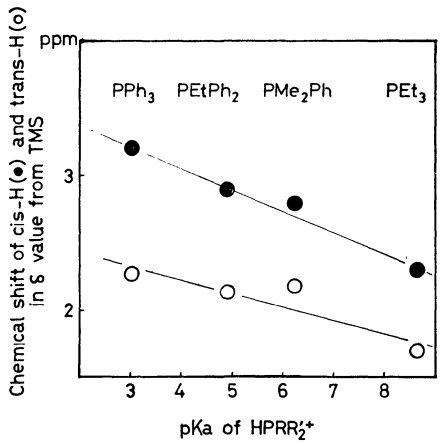


Fig. 3. Polts of the chemical shifts of *cis*-H(●) and *trans*-H(○) of Ni(ema)(tretiary phosphine)$_2$ against the pK_a[9] value of conjugate acids of the tertiary phosphines.

donation decreasing the bond order of the C=O group.

The olefinic protons of mma, mac, and mci are also shifted upfield in the ^{1}H-NMR spectra on complex formation, the coupling between ^{31}P of PPh_3 and α-CH_3 protons of mma being observable in the ^{1}H-NMR spectrum of **1f**.

Reactions of the Complexes. The α,β-unsaturated esters are readily liberated from the complex on addition of excess amounts of tertiary phosphines or pyridine:

$$\mathbf{1a} + PPh_3 \text{ (excess)} \xrightarrow{\text{r. t.}} \text{ema (100\%)} + Ni(PPh_3)_4. \quad (2)$$

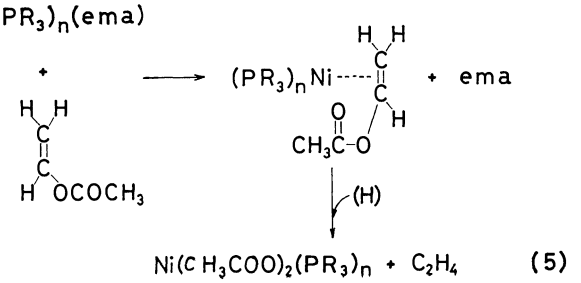
The α,β-unsaturated esters in the complexes are hydrogenated by dry HCl in diethyl ether to yield the corresponding saturated esters (*e.g.*, ethyl isobutyrate from ema).

Reactions of the α,β-unsaturated ester–nickel complexes with vinyl acetate give no nickel-vinyl acetate adduct expected as a product of a simple ligand exchange reaction. However, they lead to the scission of the C–O bond in vinyl acetate to yield ethylene and nickel acetate in high yields (Eq. 3), a result similar to our findings on the C–O bond activation of vinyl acetate by $RuH_2(PPh_3)_4$[10] and by bis(1,5-cyclooctadiene)nickel Ni(cod)$_2$ in the presence of phosphine ligands (Eq. 4):[3]

$$\mathbf{1} + CH_2{=}CHOCOCH_3 \longrightarrow Ni(CH_3COO)_2(PR_3)_n + CH_2{=}CH_2, \quad (3)$$

$$Ni(cod)_2 + CH_2{=}CHOCOCH_3 + PR_3 \longrightarrow Ni(CH_3COO)_2(PR_3)_n + CH_2{=}CH_2. \quad (4)$$

Reaction 3 presumably proceeds through the olefin exchange reaction and the activation of the C–O bond of vinyl acetate on the nickel atom:



Ease of the cleavage of the C–O bond in vinyl acetate promoted by **1** depends on the coordinated phosphine ligand. Thus, the PCy_3-coordinated complex **1e** promotes cleavage of the C–O bond even at 10 °C, whereas the PPh_3-coordinated complex **1a** causes it only at 50 °C or above. A similar effect of the coordinated phosphine ligand on the activation of the C–O bond in phenyl carboxylate by Ni has been found.[3] The sources of hydrogen to yield ethylene from the vinyl moiety (Eq. 5) have not been clarified yet.

The interaction of some transition metal complexes with olefic esters such as alkyl methacrylates and vinyl acetate causes the activation of the olefinic C–H bond to form σ-alkenyl-transition metal complexes.[11] However, no C–H bond activation of such a type has been observed for the nickel complexes we prepared.

Experimental

General Procedures and Materials. Preparation and recrystallization of complexes **1a**—**1h** were carried out under deoxygenated nitrogen or argon. Melting points were determined in sealed tubes in a vacuum. Bis(1,5-cyclooctadiene)nickel, Ni(cod)$_2$ was purchased from Merck Co., Ltd. and recrystallized. α,β-Unsaturated esters were purified by distillation. Tertiary phosphine ligands were used as purchased or synthesized by the methods given in literature.[12] Solvents were dried by the usual procedures, distilled, and stored under argon or nitrogen. Yields and melting points of the complexes are given in Table 1.

Preparation of α,β-Unsaturated Ester–Nickel Complexes.. *Ni(PPh$_3$)$_2$(ema)* ***1a***: ema (0.55 g, 4.8 mmol) was added to a mixture of Ni(cod)$_2$ (0.92 g, 3.4 mmol) and PPh_3 (1.76 g, 6.8 mmol) dispersed in 2 ml of hexane. Stirring of the mixture for 5 h at room temperature afforded an orange solution, which was condensed to give a light orange precipitate. The precipitate was collected by filtration and recrystallized from diethyl ether–hexane at −30 °C.

Ni(PEtPh$_2$)$_2$(ema) ***1b***: $PEtPh_2$ (0.95 g, 5.8 mmol) was added to a mixture of Ni(cod)$_2$ (0.80 g, 2.9 mmol) and ema (1.0 g, 8.0 mmol) dispersed in 3 ml of diethyl ether. Stirring of the solution for 6 h at 10 °C gave an orange solution which was condensed to give an orange oil. The oil was dissolved in a mixture of ether and hexane and standing of the solution at −30 °C for 2 days yielded orange crystals.

Ni(PMe$_2$Ph)$_2$(ema) ***1c***: PMe_2Ph (0.74 g, 5.4 mmol) was added to a mixture of Ni(cod)$_2$ (0.74 g, 2.7 mmol) and ema (0.46 g, 4.0 mmol) dispersed in 2 ml of diethyl ether. Stirring of the mixture at 10 °C for 6 h gave a homogeneous red solution. This was condensed to afford a black oil, which was crystallized from diethyl ether–hexane.

Ni(PEt$_3$)$_2$(ema) ***1d***: PEt_3 (0.46 g, 3.9 mmol) was added to a mixture of Ni(cod)$_2$ (0.54 g, 2.0 mmol) and ema (1 g, 0.88 mmol) dispersed in 3 ml of diethyl ether. After stirring the mixture at 10 °C overnight the orange solution obtained was condensed to give an orange oil. The oil was crystallized from hexane at −78 °C. The orange crystals obtained were washed several times with ether at −78 °C and dried in a vacuum.

Ni(PCy$_3$)(ema) ***1e***: ema (2.7 g, 24 mmol) was added to a mixture of Ni(cod)$_2$ (0.73 g, 2.7 mmol) and PCy_3 (1.9 g, 6.8 mmol) dispersed in a mixture of 2 ml of hexane. Stirring of the mixture for 1 h at −15—10 °C gave a homogeneous solution. After further stirring for 5 h at room temperature the yellow precipitate formed was collected by filtration and

recrystallized from tetrahydrofuran or toluene at −20 °C.

Ni(PPh$_3$)$_2$(mma) **1f**: mma (0.47 g, 4.7 mmol) was added to a mixture of Ni(cod)$_2$ (0.56 g, 2.0 mmol) and PPh$_3$ (1.1 g, 4.2 mmol) dispersed in a mixture of 2 ml of diethyl ether and 1 ml of hexane. The mixture was stirred at 0 °C for 6 h to give a homogeneous solution. This was cooled to −30 °C to yield a yellow precipitate, which was collected by filtration and recrystallized from toluene containing mma. When the solvent contained no excess mma, no analytically pure compound was obtained.

Ni(PPh$_3$)$_2$(mac) **1g**: mac (0.90 g, 10.6 mmol) was added to a mixture of Ni(cod)$_2$ (0.50 g, 1.8 mmol) and PPh$_3$ (0.96 g, 3.7 mmol) dispersed in 3 ml of diethyl ether. The solution was stirred at room temperature for 8 h to give a homogeneous orange solution, which was condensed to give an orange oil. The oil was dissolved in a mixture of tetrahydrofuran and hexane. Cooling of the solution to −20 °C gave red crystals.

Ni(PPh$_3$)$_2$(mci) **1h**: A toluene (2 ml) solution containing mci (0.68 g, 4.2 mmol), Ni(cod)$_2$ (1.13 g, 4.1 mmol), and PPh$_3$ (2.2 g, 8.4 mmol) was stirred at room temperature for 6 h to give a red precipitate, which was collected by filtration, washed with diethyl ether, and recrystallized from acetone.

Spectral Measurements and Analysis. IR spectra were recorded on a Hitachi Model 295 infrared spectrophotometer, ^{1}H-NMR spectra on a Japan Electron Optics Laboratory (JEOL) Mode JNM-PS-100 spectrometer, and ^{31}P-NMR spectra on a JEOL Model JNM-PFT-PS-100 Fourier transform spectrometer. PPh$_3$ was used as an external standard. Microanalyses of C and H were performed by Mr. T. Saito in our laboratory with a Yanagimoto CHN Autocorder Type MT-2. Macroanalyses of nickel were carried out by volumetric titration.[13] The analyses of gaseous and liquid products obtained by the reactions of complexes were carried out with a Shimadzu GC-3BT gas chromatograph.

Kinetic and Stereochemical Studies of the Reaction of Trialkyl-(alkylthio and arylthio)stannanes with Haloalkanes

Seizi KOZUKA* and Sadamu OHYA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received January 28, 1978)

A kinetic study has been conducted on the reaction of arylthio(trimethyl)stannane with haloalkanes giving halotrimethylstannane and alkyl aryl sulfide. The reaction has been found to obey second order kinetics. Substituent effects of the arylthio group, solvent effects, relative reactivities of the leaving halogens and steric effects of the haloalkanes have been investigated. Optically active (+)-1-methylheptyl bromide gives an inverted product *i.e.*, (−)-methyl 1-methylheptyl sulfide by the reaction with trimethyl(methylthio)stannane. A mechanism involving bimolecular nucleophilic attack of the sulfur atom on the haloalkane has been confirmed for the reaction.

The reactions of methylthiostannanes with iodomethane have been known to give iodostannane and

$$R_2Sn(SMe)_2 \xrightarrow{MeI} R_2SnI_2 + 2Me_3S^+I^-$$

$$R_3SnSMe \xrightarrow{MeI} R_3SnI + Me_3S^+I^-$$

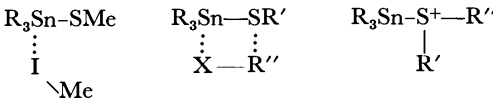
R=Me, Et, and *n*-Bu

trimethylsulfonium iodide.[1] Recently, the reactions of trialkyl(arylthio)stannanes with various haloalkanes have been examined and it has been found that the reactions proceed in a way similar to those of methylthiostannanes but give alkyl aryl sulfides, instead of sulfonium salts.[2]

$$R_3SnSAr \xrightarrow{R'X} R_3SnX + R'SAr$$

R=Me, *n*-Bu, R'=Me, Et, 2-Pr, and benzyl.

Several different mechanisms have been forwarded for the reaction: Five-coordination of the tin atom to iodine (I) has been suggested by Balcombe *et al.*[1] Four-centered reaction (II) is another plassible process in view of the analogous reaction of stannanes.[3] Contrary to these mechanisms, formation of a transient sulfonium salt (III) by a nucleophilic attack of the sulfur atom has been suggested based on the observations that the reaction of trimethyl(phenylthio)stannane with iodomethane proceeds much slower than that of trimethyl(methylthio)stannane.[2] The salt III



(I) (II) (III)

had been accepted as the final product of the reaction of trimethyl(methylthio)stannane with iodomethane[4] but recently it has been shown to be a non-isolable intermediate.[2] In this paper, the kinetic and stereochemical studies of the reaction are reported and the reaction mechanism discussed.

Results and Discussion

Kinetics. The rate of the reaction of trimethyl(*p*-tolylthio)stannane with a 10-fold excess of iodomethane in chloroform solution at 100 °C was measured by following the decrease and rise of the ^1H NMR of the starting trimethyl signal and product. A pseudo-first-order kinetic plot was obtained up to nearly completion of the reaction. First order dependency of the rate was observed on the concentration of iodomethane. Thus, the reaction was found to be second order, first order with respective to thiostannane and haloalkane.

Activation parameters were observed for the reactions of the tolylthiostannane and trimethyl(phenylthio)stannane with iodomethane. Remarkably large negative entropy values were obtained for the reactions in non-polar solvents. These results indicate tight transition states for the reactions but do not suggest a 4-centered reaction since the rate is markedly accelerated in better solvents for ionic reaction (PhCN). Also the entropy vales appeares to be reasonable in magnitude for a bimolecular reaction. The tight transition state may be rationalized in terms of an ionic reaction which is forced to proceed in non-polar solvents.

Clear evidence was obtained in the present study supporting nucleophilic attack as the mechanism. Hammett plots of the rates of reactions for *p*-substituted phenylthiostannanes gave a significant negative ρ values (−1.4) against σ parameters. This result does not support the mechanism involving 5-coordination of the tin atom to the halogen since the mechanism would result in a positive ρ value of moderate magnitude. The reactions of more efficient nucleophiles, such as trimethyl(methylthio)stannane and other alkylthiostannanes with haloalkanes would proceed by the same mechanism to that of arylthio(trimethyl)stannane, since the nucleophilic reaction has been confirmed for the reaction of a less efficient nucleophile *i.e.*, arylthiostannane.

The kinetics of the reactions with various haloalkanes were also performed to elucidate steric and electronic effects on the rate of reaction. The steric effect observed for the reactions with iodomethane, iodoethane and 2-iodopropane (k_{rel} : 1.00, 0.125, and 0.014, respectively) appears smaller than that for standard S_N2 reactions[5] but consistent with that observed with the benzenethiolate ion as the nucleophile.[6] The small steric retardation is undoubtedly due to the longer length of the forming carbon–sulfur bond. Relative reactivity of benzyl chloride, bromide and iodide (k_{rel}: 0.023, 1.2, and 5.9, respectively) was observed in the present study and is in good agreement with that of S_N2 reactions.[5,7] These results obtained by the kinetic studies are shown in the Table 1.

Table 1. Rate constants for the reactions of arylthio(trimethyl)stannanes with haloalkanes

Me_3SnS-C_6H_4Y-p[a] Y	RX	Mole ratio RX/SnS	Solvent	Temp °C	$k_{obsd} \times 10^4$	Remark

a) 6.0×10^{-2} mol/l as the initial concentration. b) Relative rate. c) Activation parameters, ΔH^*(kcal/mol) and ΔS^*(e. u.), respectively. d) Estimated value. e) ρ value against σ constants.

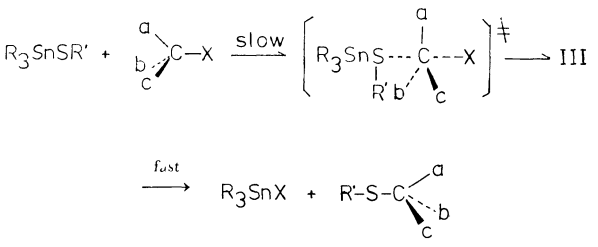
Stereochemistry. Inversion of configuration of the alkyl group of the haloalkane would be expected by the bimolecular nucleophilic attack of the sulfur atom on the haloalkane. Retention or partial racemization, on the other hand, may result if the reaction proceeded by 5-coordination of the tin atom or by a 4-centered process.

Optically active (+)-1-methylheptyl bromide was allowed to react with the thiostannane in order to confirm the mechanism. Trimethyl(methylthio)stannane, instead of arylthio(trimethyl)stannane, was employed for the reaction with the optically active bromide since the sterically hindered secondary bromide is less reactive. The reaction was stopped at about half completion. The product, methyl 1-methylheptyl sulfide did not undergo sulfonium salt formation with the remaining bromide probably due to steric hindrance of the bulky 1-methylheptyl groups. The stereochemical result is shown below. This result indicates inversion of configuration of the alkyl carbon atom during the reaction since S_N2 reaction of optically active 1-methylheptyl bromide with sodium methanethiolate in ethanol has been shown to give optically active methyl 1-methylheptyl sulfide of opposite sign.[8] The starting bromide underwent partial racemization during the reaction and consequently, the stereospecificity of the reaction could not be determined. However, high stereospecific inversion may be assumed for the present reaction in comparison with the optical activities of the bromide and sulfide with stereochemical results obtained by the S_N2 reaction.[8]

$$(CH_3)_3SnSCH_3 + (+)\text{-}n\text{-}C_6H_{13}CH(CH_3)Br \xrightarrow{120\,^\circ C,\ 115\,h} (CH_3)_3SnBr + (-)\text{-}n\text{-}C_6H_{13}CH(CH_3)\text{-}S\text{-}CH_3 + \text{recov. } (+)\text{-}n\text{-}C_6H_{13}CH(CH_3)Br$$

$[\alpha]_D^{30}$ $+36.4^\circ$ → $[\alpha]_D^{30}$ -9.7° + $[\alpha]_D^{30}$ $+24.3^\circ$

Mechanism. All the results are consistent with a mechanism involving bimolecular nucleophilic attack of the sulfur atom on the haloalkane to form the sulfonium salt III as a transient intermediate. No evidence was found to support the 5-coordination or 4-centered mechanism for the reaction.



Experimental

Materials. Preparation of the thiostannanes have previously been reported.[2,9] Solvents for the kinetic studies were dried and distilled before use. Commercial haloalkanes except for benzyl iodide were used for the kinetic studies

after distillation. Benzyl iodide was prepared from benzyl bromide by the halogen exchange reaction with sodium iodide.

Kinetic Procedure. The general procedure was as follows: arylthio(trimethyl)stannane (3×10^{-4} mol) and haloalkane (3×10^{-3} mol) were dissolved in the solvent using a 5 ml volumetric flask. The solution was divided into 10 portions and sealed in glass tubes of *ca.* 0.7 ml volume. The tubes were heated in a constant temperature bath (100 °C) and samples taken at appropriate intervals. Each sample of the solution was analyzed by ^1H NMR with 5-repeated integrations of the starting trimethyl signal (δ 0.38 ppm, Me_3SnSPh) and that of the product (δ 0.88 ppm, Me_3SnI). Pseudo-first-order rate constant was obtained by a least square calculation of the relative intensities of the signals at the time intervals.

Preparation of (+)-1-Methylheptyl Bromide. The bromide was prepared from L-(−)-2-octanol and phosphorus tribromide by the usual procedure,[10] bp 82 °C/16 mmHg, $[\alpha]_D^{30}$ +36.4° (c=2.00, acetone).

Reaction of (+)-1-Methylheptyl Bromide with Trimethyl(methylthio)stannane. The stannane (300 mg, 1.42 mmol) and the bromide (277 mg, 1.42 mmol) were mixed and heated at 120 °C for 115 h in a sealed tube. Bromotrimethylstannane, methyl 1-methylheptyl sulfide and the remaining 1-methylheptyl bromide were identified in the reaction mixture by GLC analysis (Silicon SE-30, 2 m, 70 °C). Among these, methyl 1-methylheptyl sulfide, $[\alpha]_D^{30}$ −9.7° (c=0.65, acetone), and 1-methylheptyl bromide, $[\alpha]_D^{30}$ +24.3° (c=0.07, acetone), were isolated by GLC and the rotations measured. No appreciable racemization of 1-methylheptyl bromide was found when the bromide was heated alone or with bromotrimethylstannane in chloroform under the reaction conditions (120 °C, 115 h).

Faculty of Pharmaceutical Sciences, Osaka University, Suita, Osaka 565

*** Institute for Protein Research, Osaka University, Suita, Osaka 565*

(Received February 8, 1978)

Proton magnetic resonance and Raman spectra indicate that the backbone of γ-aminobutyric acid is fairly flexible and rotational isomers are almost equally populated in aqueous solution. The population is not much affected by change of pH. On the other hand, in γ-amino-β-hydroxybutyric acid the *trans*†† -*trans* and *gauche-trans* conformations of the backbone are equally populated in neutral solution, *trans-trans* conformation being predominant in non-zwitterionic forms. The conformation in solution is discussed in relation to the structure of these molecules in crystal.

γ-Aminobutyric acid (GABA) has been found in mammalian brain,[1] where it is enzymatically produced from glutamic acid.[2] By virtue of its potent synaptic effect and other evidences, GABA seems to play the physiological role as "inhibitory transmitter" in mammalian central nervous system.[3–6] γ-Amino-β-hydroxybutyric acid (GABOB) is also a central inhibitory transmitter like GABA.[7] Their chemical structures are shown in Fig. 1. The crystal structures of GABA, GABOB, and their analogues have been reported.[8–13]

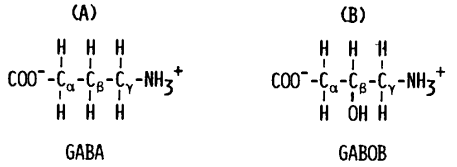

Fig. 1. Chemical structures of (A) γ-aminobutyric acid (GABA) and (B) γ-amino-β-hydroxybutyric acid (GABOB).

It is remarkable that a difference in the conformation of GABA molecule was found for crystal structures of GABA[9] and its hydrochloride:[10] the conformation of C_α–C_β–C_γ–N skeleton of GABA hydrochloride is all *trans*, but that of GABA in its free form is *gauche* (73.6°) about the C_α–C_β bond and *trans* about the C_β–C_γ bond, while GABOB takes the all *trans* conformation as GABA hydrochloride.[11]

The preferred conformation of GABA is theoretically predicted by molecular orbital calculations.[14–16] Pullman and Berthod[16] predicted that the intrinsically preferred conformation of the isolated GABA molecule is a highly holded one, but the hydrated zwitterionic GABA molecule might exist as a mixture of a number of conformers having different degrees of folding.

In the present study, we aimed to elucidate the molecular conformations of GABA and GABOB in aqueous solution by means of proton magnetic resonance (PMR), attempting to correlate the conformations in solution with those in crystal by measuring laser Raman spectra.

† This paper is Part VIII of "Crystal and Molecular Structure of ω-Amino Acids, ω-Amino Sulfonic Acids, and Their Derivatives."

†† The term *trans* used in the present paper denoted *s-trans* or *anti* in the nomenclature of stereochemistry.

Materials and Procedures

GABA and racemic GABOB (Nakarai Chemical Co., Kyoto) were used without further purification. GABA hydrochloride was prepared from GABA and crystallized.

Proton magnetic resonance spectra were recorded on a JEOL-PFT-100 pulse Fourier transform NMR spectrometer equipped with temperature control apparatus. The probe temperature was kept at 45 °C unless otherwise stated. The resolution due to digitalization by computer is 0.04 Hz. The sample solutions were prepared in D_2O with concentration of 100 mg/ml. The pD value was adjusted with DCl and NaOD. Sodium 3-(trimethylsilyl)propionate-2,2,3,3-d_4 (TMSP-d_4) was used as an internal reference. The assignments of resonance signal were made by comparison with those of GABA and GABOB analogues, 3-aminopropanesulfonic acid, 3-amino-2-hydroxypropanesulfonic acid and γ-guanidinobutyric acid. The spin analysis of the spectra was accomplished by computer with an iterative program based on the least-squares method. The spectra were analyzed as six spin system for GABA and five spin system for GABOB. Raman spectra were taken with a JEOL-JRS-02AS and JEOL-JRS-400D Raman spectrometer by excitation with argon ion laser (wavelength, 488.0 nm).

Results and Discussion

PMR Spectra of γ-Amino-β-hydroxybutyric Acid (GABOB). The 100-MHz proton magnetic resonance spectra of GABOB in solution at pD 1.7 and 7.2 are shown in

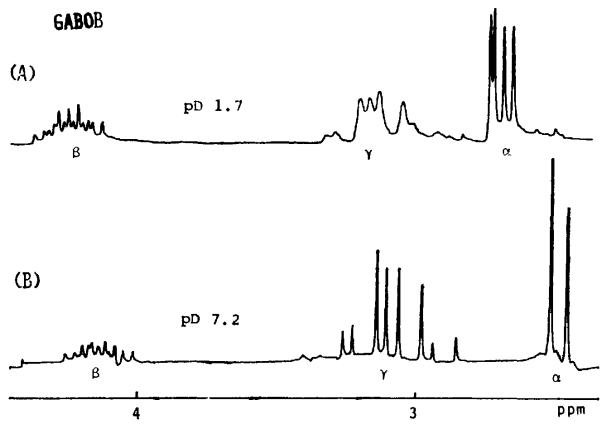

Fig. 2. The 100 MHz PMR spectra of γ-amino-β-hydroxybutyric acid in D_2O (A) at pD 1.7 and (B) at pD 7.2. Assignment are shown in the spectra.

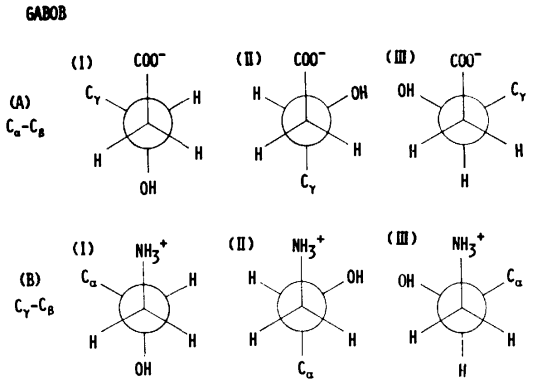

Fig. 3. The possible rotational isomers of γ-amino-β-hydroxybutyric acid (A) about the C_α–C_β bond and (B) about the C_β–C_γ bond.

Fig. 2. GABOB is considered to exist as a mixture of three possible rotational isomers both about the C_α–C_β bond and about the C_β–C_γ bond. The Newman projections of the possible rotamers of zwitterionic GABOB molecule which has the ABX spin system are shown in Fig. 3. The rotamers are thought to interconvert rapidly to each other. The observed coupling constants are weighted mean values of those for the distinct rotamers.

The vicinal coupling constants are assumed to satisfy the Karplus equation[17] and the coupling constants of either *gauche* or *trans* conformer are assumed to have the same value regardless of the particular conformation. The vicinal coupling constants, J_{ax} and J_{bx}, are then given by

$$J_{ax} = P_I J_t + P_{II} J_g + P_{III} J_g, \quad (1)$$

$$J_{bx} = P_I J_g + P_{II} J_t + P_{III} J_g, \quad (2)$$

where P_I, P_{II}, and P_{III} are the populations of the rotamers I, II, and III, respectively, and J_g and J_t are the coupling constants for the *gauche* and *trans* conformations with respect to the two C–H bonds.

In this case, J_g was determined by application of the Karplus type equation to hydroxyproline,[18] since the C_α–C_β part of GABOB corresponds to the C_3–C_4 part of hydroxyproline and the C_β–C_γ of GABOB to the C_4–C_5 of hydroxyproline. Thus J_g of GABOB was assumed to be 2.73 Hz with respect to the C_α–C_β and 2.53 Hz for the C_β–C_γ bond, respectively. J_t was determined as follows according to the method reported by Abraham and Pachler.[19] The average coupling constant is defined by

$$J_{av} = 1/3(J_t + 2J_g). \quad (3)$$

On the other hand, J_{av} was found to be proportional to the total electronegativities as follows.

$$J_{av} = 17.97 - 0.796 \sum_{n=1}^{6} E_n \quad (4)$$

With use of Huggins' electronegativities,[20] J_t was calculated to be 11.92 Hz for C_α–C_β part and 11.24 Hz for the C_β–C_γ part.

Figure 4 shows the populations of GABOB conformers calculated from the coupling constants obtained at various pD values. In the case of GABOB, it is impossible to assign J_{ax} and J_{bx}, namely, P_I and P_{II} only from the spin analyses. The rotamer populations mainly depend on steric and ionic interactions. It seems that rotamer II is more favorable and more stable than rotamers I and III for non-zwitterionic structure as considered from the attractive interactions between the hydroxyl and the polar groups. Thus we assigned the predominant conformer to rotamer II. The assumption is supported by the unambiguously determined population for some β-monodeuterated amino acid.[21] Thus about the C_α–C_β bond in the zwitterionic form, rotamers I and II equally exist with a population of about 40% as shown in Fig. 4 mainly due to the ionic interactions of the ionized amino and carboxyl groups. The effect of intermolecular interaction on population can be neglected since the vicinal coupling constants do not change in any of the concentrations 10, 1, and 0.1%.

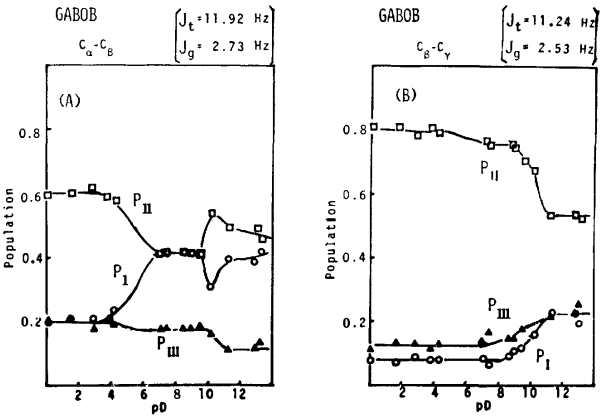

Fig. 4. The effect of pD on the populations of γ-amino-β-hydroxybutyric acid (A) about the C_α–C_β bond and (B) about the C_β–C_γ bond.

It appears anomalous with increase in pD from neutral to alkaline, that the vicinal coupling constants of rotamers I and II about the C_α–C_β bond once diverge and converge again to a common value; the vicinal coupling constants diverge at pD 10 by deprotonation of the amino group whose pK_a is about 9.5 obtained from the PMR chemical shift. However, it seems impossible to explain the convergence of the constants at about pD 10 only by the change in intramolecular interactions. Figure 5 shows the temperature dependence of the coupling constants of the GABOB molecule

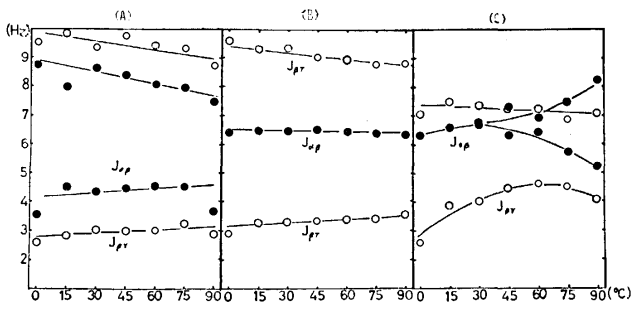

Fig. 5. The observed vicinal coupling constants at various temperatures for γ-amino-β-hydroxybutyric acid: (A) cationic form, (B) zwitterionic form and (C) anionic form.

at anionic, zwitterionic and cationic states, respectively. It is intuitively expected that when the temperature increases, the rotamer populations would tend to become equal according to the Boltzmann distribution; the coupling constants, therefore, would converge to a common value. At either zwitterionic or cationic state, the constants actually converged with increasing temperature, but they diverged at anionic state in alkaline solution. Another effect of intramolecular interaction accessible only in the anionic state should be considered. From the NMR studies of ^{23}Na ion in aqueous solution,[22] it was suggested that the sodium ion forms weak complex with several anions, notably with hydroxy and keto acids such as α- and β-hydroxybutyric acid.

As regards the C_β–C_γ bond, rotamer II is the most stable at any pD value. This is similar to the case of acetylcholine[23] and phosphatidyl choline and phosphatidyl ethanolamine[24] in which the O–C–C–N system is in the *gauche* conformation in aqueous solution. If there is no correlation between the population about the C_α–C_β bond and that about the C_β–C_γ bond in neutral solution, about 30% of GABOB molecules have the *trans*(about the C_α–C_β bond)-*trans*(about the C_β–C_γ bond) conformation as well as the *gauche-trans* conformation. Thus the *trans-trans* conformation of GABOB found in the crystal structure may correspond to one of the stable conformations in aqueous solution as anticipated from the PMR studies. In acidic solution, on the other hand, about 50% of GABOB molecules are in the *trans-trans* conformation and about 15% of GABOB in the *gauche-trans*.

PMR Spectra of γ-Aminobutyric Acid (GABA). Figure 6 shows the 100 MHz proton magnetic resonance spectra of GABA at pD 13.3, where the upper is the magnified spectrum of lower one. GABA is considered to exist as a mixture of three rotational isomers in regard to both the C_α–C_β bond and the C_β–C_γ bond. The Newman projections of the rotamers of the zwitterionic GABA molecule are shown in Fig. 7. In this case, it was considered that GABA has the A_2B_2 spin system both about the C_α–C_β and the C_β–C_γ bonds. The A_2B_2 type spectra are described in terms of four coupling constants, J, J', J_t, and J_g, defined by

$$J = P_t J_g + 1/2 P_g (J_t + J_g), \quad (5)$$

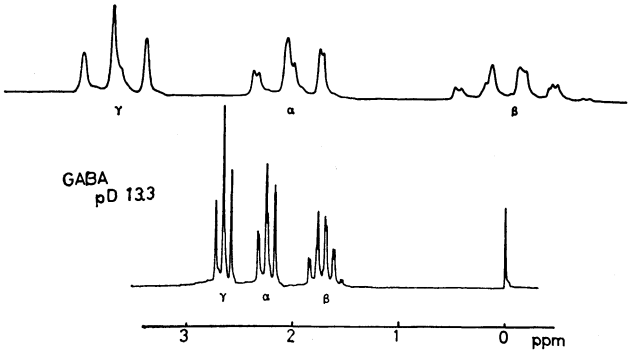

Fig. 6. The 100 MHz PMR spectra of γ-aminobutyric acid in D_2O at pD 13.3. The upper is the magnified spectrum of the lower one in the region between 1.4 and 2.8 ppm.

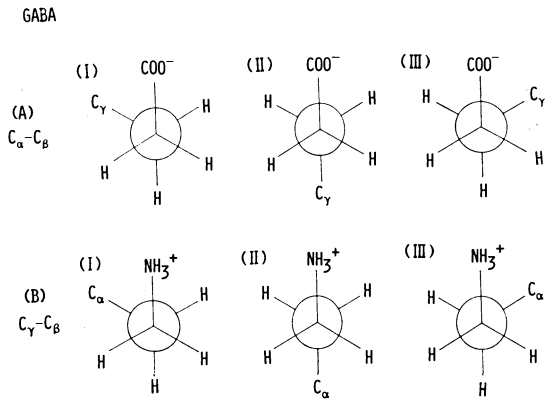

Fig. 7. The possible rotational isomers of γ-aminobutyric acid (A) about the C_α–C_β bond and (B) about the C_β–C_γ bond.

$$J' = P_t J_t + P_g J_g, \quad (6)$$

where P_t and P_g are the populations of the *trans* and *gauche* rotamers, respectively, and

$$L = J - J' = (1/2 - 3/2P_t)(J_t - J_g), \quad (7)$$

$$P_t = 1/3 - 2L/3(J_t - J_g). \quad (8)$$

Eq. 8 indicates that if L is positive, P_t is smaller than 1/3 and; if negative, P_t is larger than 1/3, since $(J_t - J_g)$ is positive in general. In this analysis, the sign of L, namely, J and J', could not be assigned to each of the coupling constants obtained from the spin analysis. The average coupling constant is defined by

$$J_{av} = 1/3(2J + J'). \quad (9)$$

As regards Eq. 4 Abraham and Pachler[19] found the relation between the average coupling constants J_{av} and the electronegativity of attached atoms. In the case of pD 13.3, the $3J_{av}$ value about the C_α–C_β bond is 22.9 Hz by virtue of Eq. 9, if L is assumed to be positive, and $3J_{av}$ becomes 21.8 Hz if L is negative, while Eq. 4 gives 20.49 Hz for $3J_{av}$. By comparison of the three values, it seems likely that the sign of L is negative. Likewise, if L is positive, $3J_{av}$ about the C_β–C_γ bond should be 22.3 Hz. If L is negative, it becomes 21.2 Hz, whereas it is calculated to be 19.41 Hz from Eq. 4. Thus the sign of L is also considered to be negative.

The value obtained for L and calculated populations of the rotamers from the spin analyses at pD 13.3 and 7.6 are given in Table 1. The coupling constant at pD 0.9 could not be obtained, because of the broadening of the C_γ-proton signals. Only the data at pD 7.6 about the C_α–C_β bond are given in the Table, since L for C_β–C_γ is too small (<0.2 Hz) to be determined

Table 1. Populations of *trans* and *gauche* forms in GABA

Torsional axis	pD	J(Hz)	J'(Hz)	L(Hz)	P_t	P_g
C_α–C_β	13.3	6.9	8.0	−1.1	0.40	0.60
	7.6	7.0	7.6	−0.6	0.37	0.63
C_β–C_γ	13.3	6.7	7.8	−1.1	0.40	0.60

by the least squares method.

It is of interest to compare the conformation of the GABA molecule in solution at various pD with the crystal structure and the predicted conformations from theoretical calculations. Five possible conformations of GABA molecule are *trans-trans gauche-trans*, *trans-gauche*, *gauche-gauche*(A) and *gauche-gauche*(B) as the rotational isomers about the C_α–C_β bond and the C_β–C_γ bond. If the population of trans isomer is 1/3 about both the C_α–C_β bond and the C_β–C_γ bond, the estimated populations of the five conformations are 1/9, 2/9, 2/9, 2/9, and 2/9, respectively. As the result of PMR studies of GABA, the population of each isomer in alkaline solution is 0.16(*trans-trans*), 0.24(*gauche-trans*), 0.24(*trans-gauche*), 0.18(*gauche-gauche*(A)), and 0.18 (*gauche-gauche*(B)). The *trans-trans* conformation is a little more predominant than the case of freely rotating molecule. Although the spectrum of GABA in acidic solution is too broad to be used for spin analysis, its pattern does not differ a great deal from that of alkaline solution. Thus the conformation of GABA in acidic solution might be similar to that in alkaline solution. The crystal structure of GABA hydrochloride shows the GABA molecule to be *trans-trans*, while the molecular conformation of neutral GABA in the crystal is *gauche-trans*. The present PMR data and the crystal data both imply that the energy difference between the two conformers is small. The GABA molecule in aqueous solution can take many conformations, and the change in population by pH is estimated within 10%. The extended Hückel MO calculation predicted that the *trans-trans* conformation is most stable for the zwitterionic GABA molecule,[14] not agreeing with our PMR result. The CNDO/2 calculations also predicted that for non-zwitterionic form six stable conformations involving all *trans* and for zwitterionic form some folded conformations are preferable.[15] The result is not in line with ours. The PCILO and SCF *ab initio* calculations by Pullman and Berthod[16] showing GABA to be a mixture of a number of conformers agree with our PMR result.

Raman Spectra of γ-Aminobutyric Acid and γ-Amino-β-hydroxybutyric Acid. The Raman spectra of GABOB in solid state, neutral solution and acidic solution are given in Fig. 8. Because of the complex spectra, it is hard to assign each band to the definite vibrational mode. From X-ray diffraction studies, the conformation of GABOB was found to be *trans-trans* in the solid state. From PMR studies the *trans-trans* conformation is thought to exist *ca.* 30% in neutral solution and *ca.* 50% in acidic solution. As a whole the Raman spectrum in solid and that in neutral solution is similar to each other. But no Raman line corresponding to the line at 830 cm^{-1} either in neutral or in acidic solution was observed in solid. Therefore, the Raman line at 830 cm^{-1} is thought to be due to the *gauche-trans* conformation, differing from the *trans-trans* conformation found in crystal.

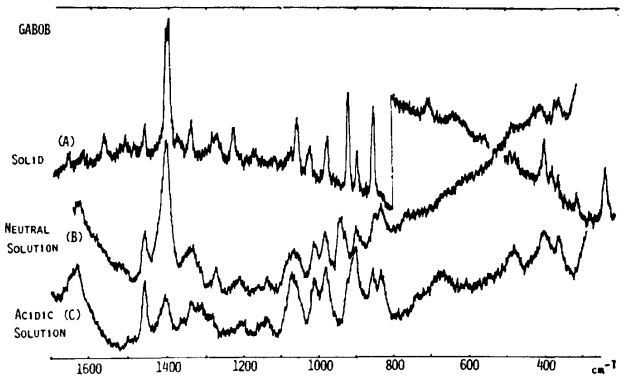

Fig. 8. The Raman spectra of γ-amino-β-hydroxybutyric acid (A) in solid, (B) in neutral solution and (C) in acidic solution.

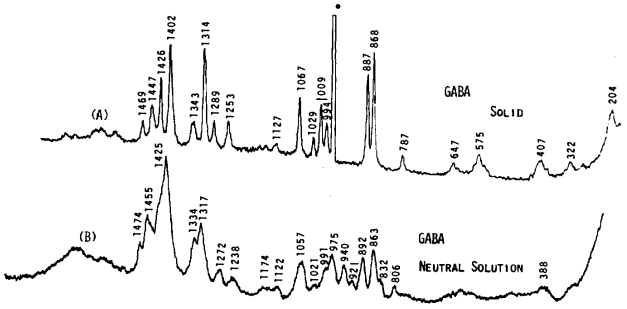

Fig. 9. The Raman spectra of γ-aminobutyric acid (A) in solid and (B) in neutral solution. The Raman line with asterisk is due to the ghost of spectrometer.

The Raman spectra of GABA in solid state and in neutral solution are given in Fig. 9. The spectral features differ from each other: the Raman lines are observed at 921 and 940 cm^{-1} in neutral solution, but there is no line in the range 887—994 cm^{-1} in solid state. These lines which are sensitive to the conformational change should be mainly due to the stretching modes of the C–C skeletal bonds or the rocking modes of the CH_2 group. The Raman spectra of GABA hydrochloride either in solid or solution are also not very similar to each other, especially in the region 800—1100 cm^{-1}. It is apparent that the molecular conformation of GABA found in crystal is not retained in solution.

Conclusion

Proton magnetic resonance and Raman spectra indicate that the backbone of the GABA molecules is fairly flexible and probable rotational isomers are almost equally populated in aqueous solution. The population is not much affected by changing pH. On the other hand, the GABOB molecule tends to take *trans* conformation about each backbone bond. The *trans-trans* and *gauche-trans* are equally populated in neutral solution, the *trans-trans* conformation being predominant in the non-zwitterionic forms. In the crystal, zwitterionic GABA molecule is in the *gauche-trans* form and its hydrochloride takes the *trans-trans* form, while the neutral GABOB is in the *trans-trans* form. It is interesting to note that the molecular structure of GABA in the crystal is restricted to the *trans-trans* and *gauche-trans* forms, and the GABOB molecules take mainly the *trans-*

trans and *gauche-trans* conformations in solution. It seems that GABA and GABOB are apt to take either of the two forms under certain circumstances, the forms being important for the exhibition of their biological activities.

The authors wish to express their thanks to Dr. M. Abe, Shoin Women's College, for her invaluable discussion on the vibrational spectra.

Chlorination of Phenylsulfinylcyclopropanes and Phenylthiocyclopropanes

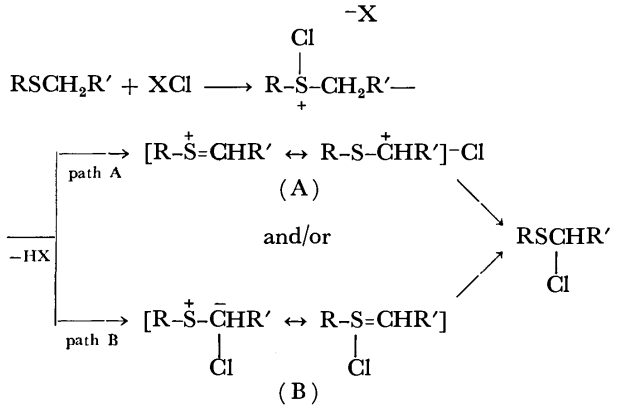
Toshiaki MASUDA, Naomichi FURUKAWA, and Shigeru OAE*

Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31

(Received February 17, 1978)

Chlorination of phenylsulfinylcyclopropanes or phenylthiocyclopropanes with various chlorinating agents provides the corresponding 1-chloro-1-(phenylthio)cyclopropanes but not any ring opening product. Kinetic isotope effects, (k_H/k_D), for the chlorination were measured with 1-deuterated cyclopropane derivatives and found to be small, *i.e.*, 1.6—2.8. The chlorination is considered to be a kind of the Pummerer reaction of the chlorosulfonium salt formed as the initial intermediate in the reaction of sulfides or sulfoxides with such chlorinating agents as *N*-chlorosuccinimide (NCS) or thionyl chloride and proceeds *via* the ylide-ylene intermediate.

Earlier, the formation of α-chloro sulfides from the reaction of sulfides with chlorinating agents was suggested to go through an ylide-ylene type intermediate (B) after the initial formation of the chlorosulfonium salt, as shown below,[2] as in the ordinary Pummerer reaction.



Scheme 1.

As to the subsequent S–Cl bond cleavage and the α-C–Cl bond formation, both an E2 like process forming an incipient carbonium ion (A)[3] and an ElcB type mechanism through an ylide-ylene (B)[4] have been proposed. The former involves a free carbonium ion (A) stabilized by the sulfur's lone pair electron while the latter implies a chloro-migration in the ylide-ylene intermediate (B). Thus the whole process is considered to be a kind of the Pummerer reaction. Meanwhile our recent work[5] revealed that the Pummerer reaction of phenylsulfinylcyclopropanes with acetic anhydride afforded the corresponding 1-acetoxy-1-(phenylthio)cyclopropanes nearly quantitatively without any ring opening, whereas the solvolysis of 1-chloro-1-(phenylthio)cyclopropanes gave a concomitant mixture of both the unrearranged solvolysis products and some ring opening allylic products. Accordingly, the Pummerer reaction of this system is considered to proceed *via* an ylide-ion pair but not a free carbonium ion.

As an extension of our studies on the Pummerer reaction, we have carried out the reaction of phenylsulfinylcyclopropanes (**1a**—**c**) and phenylthiocyclopropanes (**2a**—**c**) with various chlorinating agents, in order to examine the formation of any ring opening product, since the cyclopropyl cation once formed will definitely give the ring opening products. However, the chlorination afforded nothing but the corresponding 1-chloro-1-(phenylthio)cyclopropanes in good yields.

This paper describes the reaction of phenylsulfinylcyclopropanes (**1a**—**c**) and phenylthiocyclopropanes (**2a**—**c**) with various chlorinating agents and the hydrogen–deuterium kinetic isotope effects estimated by the competitive reaction between the 1-deuterated and undeuterated cyclopropane derivatives in the chlorinations.

Results

*Chlorination of Phenylsulfinylcyclopropanes (**1a**—**c**) and Phenylthiocyclopropanes (**2a**—**c**).* Chlorination of **1** with thionyl chloride or propionyl chloride under reflux for 1 h in methylene chloride afforded 1-chloro-1-(phenylthio)cyclopropanes (**3**) in good yields without any ring opening (Table 1). The products (**3a**—**c**) obtained were purified further by distillation *in vacuo* (by bulb to bulb distillation) and identified by their IR and NMR spectra (Table 2) and by conversion to the corresponding sulfoxides (**4a**—**c**) upon treatment with *m*-chloroperbenzoic acid in dichloromethane (Scheme 2 and Table 2).

Meanwhile, chlorination of **2** with NCS at room temperature for overnight in benzene also afforded **3** in high yields without any ring opening (Scheme 3 and Table 3).

The Hydrogen-Deuterium Kinetic Isotope Effects for the Chlorination. The hydrogen-deuterium kinetic isotope effects were estimated by the competitive reaction of both 1-deuterated phenylsulfinylcyclopropane (**5**) and undeuterated compound (**1a**) with thionyl

chloride and acetyl chloride by means of quantitative GLC and GLC-mass spectrometry (Table 4). The kinetic isotope effects of these competitive chlorinations were calculated by the following equation:

$$\frac{k_H}{k_D} = \frac{\ln([H]_f/[H]_0)}{\ln([D]_f/[D]_0)}. \quad (1)$$

The extent of conversion of the reaction was estimated by comparing the relative peak areas of phenylsulfinylcyclopropane for each reacting sample with that without thionyl chloride, respectively, in GLC. Ratios of [H]/[D] were determined from the relative intensities of the sulfoxides in the respective molecular peaks in GLC-mass spectrometry.

Meanwhile, the hydrogen-deuterium kinetic isotope effects in the competitive chlorination of 1-deuterated phenylthiocyclopropane (**6**) and undeuterated compound (**2a**) with NCS and sulfuryl chloride were also determined by quantitative GLC and GLC-mass spectrometry (Table 5).

Discussion

The Pummerer reaction of sulfoxides with thionyl chloride or acyl chloride has been shown by Bordwell *et al.*[2c,d] to yield α-chlorosulfides. However, the reaction of sulfoxides with such chlorinating agents as acetyl chloride afforded the reduced sulfide though the reaction also involves the initial formation of the chlorosulfonium salt intermediate.[6]

The Pummerer reaction of **1** with thionyl chloride or propionyl chloride in methylene chloride afforded readily the corresponding α-chlorosulfides (**2**) in a good yield without any ring opening, though, in the case of 2,2-dimethyl-1-(phenylsulfinyl)cyclopropane (**1c**), 2,2-dimethyl-1-(phenylthio)cyclopropane (**2c**) was obtained only in 14% yield (Table 1).

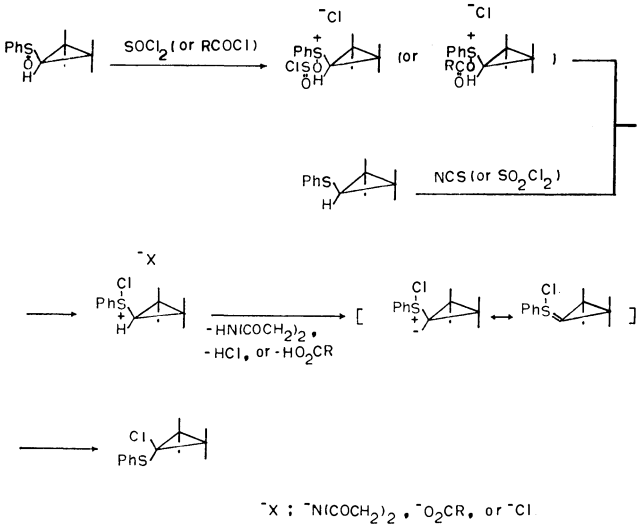
Meanwhile, the reaction of sulfides with such chlorinating agents as NCS is generally considered to proceed *via* the initial formation of the chlorosulfonium salt which then decomposes to afford the α-chlorosulfides. Mechanism of the chlorination of sulfides has previously been proposed by Wilson, Jr. *et al.*[3] to involve a free carbonium ion intermediate. Tuleen *et al.*,[4] however, suggested the reaction to proceed *via* an ylide-ylene intermediate. The chlorination of **2** with NCS was also carried out and was found to afford the corresponding (**3**) in a high yield without any ring opening (Table 3). The lack of any ring opening product both in the Pummerer reaction of **1** with thionyl chloride and acyl chlorides and in the chlorination of **2** with NCS suggests that these chlorinations do not proceed *via* the mechanistic route which involves a free carbonium ion intermediate, since the methanolysis[7] and acetolysis[5a] of 1-chloro-1-(phenylthio)cyclopropanes gave the ring opening products which undoutedly arise from the cyclopropyl carbonium ion as the intermediate.

In the reaction of **1a/5** with thionyl chloride to yield **2a**, the kinetic isotope effect, (k_H/k_D), determined by the competitive chlorinations, was found to be 2.1 (Table 4), while, in chlorination of **2a/6** with sulfuryl chloride the value was 1.8 (Table 5). Thus, the kinetic isotope effects obtained in these chlorinations are quite small in comparison with those of chlorinations of tetrahydrothiophene with chlorine[3b] and of benzyl phenyl sulfide with NCS;[4a] namely 5.1 and 5.7, respectively. These observed values of the kinetic isotope effects are smaller than even those of the general Pummerer reaction (2.9 for the reaction methyl *p*-tolyl sulfoxide with acetic anhydride).[8] The kinetic isotope effects of the chlorination of **1a/5** with thionyl chloride or **2a/6** with sulfuryl chloride are of nearly the same order of magnitude with that of the Pummerer reaction of methylphenylsulfonium methylide with acetic anhydride, *i.e.*, 1.57. Incidentally the Pummerer reaction of methylphenylsulfonium methylide is believed to proceed *via* an ElcB path.[9]

Tuleen[4a] proposed that both the acidity of α-proton of sulfides and the basicity of the counter anion ($^-$X) of the chlorosulfonium salt are two important factors in the chlorination of sulfides.

In Tables 4 and 5 are presented the kinetic isotope effects of chlorination of the sulfoxides (**1a/5**) and the sulfides (**2a/6**) with various chlorinating agents. The basicities of the counter anion ($^-$X) fall in the following order; $^-N(COCH_2)_2 > ^-O_2CMe > ^-Cl$. However, the results obtained cannot be correlated with the order of the basicities; these observed values of kinetic isotope effects are nearly identical. Thus, the results revealed that the basicity of the counter anion ($^-$X) does not significantly affect on the process.

The product distribution, *i.e.*, lack of any ring opening product, the small size of the kinetic isotope effect



Scheme 4.

and the insensitivity of the reaction toward basicity of the counter anion, all seems to suggest that both the Pummerer reaction of **1** and the chlorination of **2** with chlorinating agents such as thionyl chloride or NCS proceed *via* an ylide-ylene intermediate.

Experimental

Material. Spectroscopic grade dichloromethane and benzene and acetic acid-*d*, which were obtained from E. Merck, were used without further purification. All the chlorinating agents, *i.e.*, NCS, thionyl chloride, sulfuryl chloride, acetyl chloride and propionyl chloride were purified by recrystallization or distillation.

*Phenylthiocyclopropanes (**2a—c**).* Phenylthiocyclopropane (**2a**) was prepared by the reaction of 3-chloropropylphenyl sulfide with sodium amide in liquid ammonia.[10] Other phenylthiocyclopropanes (**2b, c**) were prepared by the reaction of chloromethyl phenyl sulfide and potassium *t*-butoxide in 2-methylpropene or *trans*-2-butene.[11]

*Phenylsulfinylcyclopropanes (**1a—c**).* Phenylsulfinylcyclopropanes (**1a—c**) were prepared by the usual oxidation (H_2O_2–AcOH) of the corresponding sulfides (**2a—c**) by the method described in our previous paper.[5c]

*The Reaction of Phenylsulfinylcyclopropanes (**1a—c**) with Chlorinating Agents.* The reaction was carried out as follows. To a solution of 3 mmol of phenylsulfinylcyclopropane (**1**) in 10 ml of dichloromethane was added a 1.2 mol excess of thionyl chloride (or propionyl chloride) in 10 ml of dichloromethane. The mixture was kept refluxing for 1 h and then at room temperature for 2 h. Then, the solution was poured into 50 ml of 5% aqueous sodium carbonate and washed with water. The dichloromethane layer was dried over magnesium sulfate. After removal of dichloromethane, the product (**3**) was purified by distillation *in vacuo* (by bulb to bulb distillation). The products obtained (**3a—c**) were identified by their IR and NMR spectra (see Table 2) and by conversion on treatment with *m*-chloroperbenzoic acid in dichloromethane to the corresponding sulfoxides **4a—c**) (see Table 2).

*Chlorination of Phenylthiocyclopropanes (**2a—c**) with NCS.* The reaction was carried out as follows. A 1.2 mol excess of NCS was added to a solution of 2 mmol of phenylthiocyclopropane (**2**) in 20 ml of benzene in the presence of a 1.5 mol excess of pyridine at room temperature. After keeping the mixture for overnight at room temperature, the solution was poured into cold water and washed with 5% aqueous sodium thiosulfate, water, 5% aqueous hydrochloric acid, and again water. The product (**3**) was purified further by distillation *in vacuo* (by bulb to bulb distillation).

*Preparation of 1-Chloro-1-(phenylsulfinyl)cyclopropanes (**4a—c**).* A 1.2 mol excess of (dichloroiodo)benzene was added to a solution of 3 mmol of phenylsulfinylcyclopropane (**1**) in 10 ml of dichloromethane in the presence of a 1.5 mol excess of pyridine at 0 °C. After keeping the mixture for 3 h at room temperature, the reaction mixture was poured into cold water and washed with 5% aqueous sodium thiosulfate and water. After removal of dichloromethane, the residue was subjected to the column chromatography packed with silica gel using dichloromethane as eluent. The product (**4**) was purified further by recrystallization from ether–hexane. The structures of these products (**4a—c**) were determined from their IR and NMR spectra (see Table 2). Yields of the products were 92, 87, and 86% for **4a**, **b**, and **c**, respectively.

1-Chloro-1-(phenylsulfinyl) cyclopropanes (**4a—c**) were also prepared in yields of 78, 72, and 73% for **4a**, **b**, and **c**, respectively, by the reaction of **3a—c** with an equimolar amount of *m*-chloroperbenzoic acid in dichloromethane at 0 °C for 5 h. These compounds obtained (**4a—c**) were identified by comparing their IR and NMR spectra with those of the samples obtained by the reaction of **1a—c** with (dichloroiodo)benzene.

*Preparation of 1-Deuterated Phenylsulfinylcyclopropane (**5**).* 1-Deuterated phenylsulfinylcyclopropane (**5**) was prepared by treating the corresponding sulfoxide (**1a**) in NaOD/D_2O-MeOD at reflux for 12 h.[5c]

*Preparation of 1-Deuterated Phenylthiocyclopropane (**6**).* 1-Deuterated phenylthiocyclopropane (**6**) was prepared by treating the corresponding sulfide (**2a**) with butyllithium it tetrahydrofuran at 0 °C for 2 h and then quenching with acetic acid-*d*.[12]

Determination of the Hydrogen-Deuterium Kinetic Isotope Effects in Competitive Chlorination. The kinetic isotope effect in the competitive reaction of phenylsulfinylcyclopropane (**1a**/**5**) was carried out as follows. Three samples, which were dissolved 0.5, 1.0, or 1.5 ml of the dichloromethane solution of thionyl chloride (about 172.8 mmol l^{-1}) in 5 ml of dichloromethane containing known amount of the mixture of **1a** and **5**, respectively, and one sample without thionyl chloride were prepared. These four samples were allowed to react for 24 h at 20±1 °C until the reaction was complete. Then from each sample an aliquot portion (5 μl) of the content was directly injected into the GLC column (1% OV-1; 1 m; 3 mm i.d.; glass column; temperature 100 °C; He flow 40 ml min^{-1}) and the extent of conversion for each sample was calculated from the relative peak areas of phenylsulfinylcyclopropane for each sample and one sample without thionyl chloride, respectively. Meanwhile, ratio of [H]/[D] for each compound was calculated from the intensities of the molecular peaks for undeuterated phenylsulfinylcyclopropane (**5**), respectively, by GLC-mass spectrometry. The hydrogen-deuterium kinetic isotope effects in this competitive reaction were calculated by the Eq. 1. The result was summarized in Table 4.

The kinetic isotope effects in other chlorinations were also estimated similarly in the competitive reactions as described above. These results were summarized in Tables 4 and 5.

A Highly Stereoselective Reduction of Substituted Cyclohexanones Using Triisobutylaluminum–Amine Complexes

Toshimitsu SUZUKI, Maki ITOH,* Shigeyuki OGAWA, and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received February 23, 1978)

The stereochemistry of the reduction of substituted cyclohexanones with a triisobutylaluminum(TIBA)–amine complex has been investigated, and the origin of the stereoselectivity has been discussed. Although a reduction of 4-*t*-butylcyclohexanone with free TIBA at 60 °C gave 83% *trans* alcohol, with a high stereoselectivity, 91—98% *trans* alcohol was obtained in this study. In order to discuss the reactivity of the reagent, the mode of the complexing of an amine to TIBA was investigated by infrared and NMR spectroscopy.

The stereochemistry of the reduction of substituted cyclohexanones has been investigated by many workers, and there have been a large number of discussions about factors controlling stereoselectivity.[1] Eliel *et al.*[2] reported the reduction of 4-*t*-butylcyclohexanone with $LiAlH_4$ to give 91—93% *trans*(OH equatorial) alcohol. Recently Ashby[3] reexamined the reduction of the same ketone with several metal hydrides and demonstrated it to give 86—92% *trans* alcohol in THF. Eliel *et al.*[2] reported the epimerization equilibrium of 4-*t*-butylcyclohexanol with aluminum isopropoxide in 2-propanol, resulting in 79% *trans* and 21% *cis* isomers.

The origin of stereochemical controls was first reported by Dauben *et al.*,[4] who suggested two concepts, *i.e.*, "product development control" and "steric approach control." On the other hand, Chérest and Felkin[5] considered "steric strain" and "torsional strain" as alternatives to these concepts. Richer[6] proposed that steric interactions take place between the entering group and 3,5-axial hydrogens.

The reduction of substituted cyclohexanones with triisobutylaluminum (TIBA) was studied by Haubenstock[7] and Ashby,[8] who reported interesting stereochemical results. In this experiment, the reduction of 4-*t*-butylcyclohexanone and other substituted cyclohexanones with a TIBA–amine complex was investigated, and the changes in the stereoselectivity were discussed. A remarkable change in the product distribution was observed. Recently Mukaiyama *et al.*[9] reported a selective reduction of carboxamides to aldehydes with aluminum diamide hydrides.

Experimental

Materials. The toluene was distilled over calcium hydride and stored under an argon atmosphere.

4-*t*-Butylcyclohexanone prepared by the oxidation of 4-*t*-butylcyclohexanol[10] was purified by vacuum distillation (93 °C/10 Torr).

The pyrrole, piperidine, and aniline were purified by vacuum distillation.

The triisobutylaluminum(TIBA) and triethylaluminum (TEA) were purified by vacuum distillation and prepared as about a 1 M toluene solution. The concentration of the solution was determined by titration using EDTA·2Na.

The 3,3,5-trimethylcyclohexanone, 2,2,6-trimethylcyclohexanone, camphor, norcamphor, diphenylamine, dicyclohexylamine, diethylamine, pyrrolidine, benzylamine, octylamine, triethylamine, triphenylamine, and *N*,*N*-dimethylaniline were commercially available reagents and were used without further purification.

Ketones and amines were used as 1 M toluene solutions, which were stored over "Drierite"(calcium sulfate) or calcium hydride.

Procedure. The following procedure for the reduction of a ketone is representative. A three-necked flask equipped with a magnetic stirrer, a gas inlet, a self-sealing rubber cap, and a gas outlet connected to a bubbler was flushed with argon. Eight ml of toluene and 1 ml (1 mmol) of an amine solution were then introduced into the flask at 0 °C, after which 1 ml(1 mmol) of a TIBA solution was stirred in. After a three-hours' reaction, 1 ml (1 mmol) of a ketone solution was added, and then the reaction was carried out at 60 °C. After a certain reaction time, the reaction mixture was hydrolyzed with a small piece of ice and the aluminum hydroxide was removed. Then the solution was extracted with ether, and the ether solution was dried over "Drierite". GLC(Hitachi model F6-D with a Golay R45 column) was employed for the qualitative and quantitative analyses.

Results and Discussion

Various amines were selected for use in the modification of TIBA, and the reductions of 4-*t*-butylcyclohexanone(4*t*BC) and several substituted cyclohexanones were investigated. The results of the reductions of ketones with amine-modified TIBA and free TIBA at 60 °C in toluene are shown in Table 1.

In the case of 4*t*BC, as the conformation of the cyclohexane ring is fixed by the bulky 4-*t*-butyl group, the stereochemistry of the reduction will be discussed only in terms of the steric requirement of the reducing agent. When 4*t*BC was reduced with free TIBA at 60 °C, 83% *trans* alcohol was obtained. This is almost an equilibrium composition of two isomeric alcohols. When diphenylamine, dicyclohexylamine, pyrrole, triethylamine, or *N*,*N*-dimethylaniline was used as an amine, the reduction of 4*t*BC proceeded quantitatively, and 91—98% *trans* alcohol was obtained. In contrast to this, the reaction hardly proceeded at all with TIBA–piperidine, pyrrolidine, benzylamine, or octylamine system.

3,3,5-Trimethylcyclohexanone(335TMC) introduces a methyl group in the 3-axial position which hinders axial attack strongly. An equatorial attack of $LiAlH_4$ predominates to give 75—80% OH axial alcohol.[3] However, in the reduction of 335TMC with TIBA, the diisobutylaluminum 3,3,5-trimethylcyclohexyl oxide undergoes epimerization to give 99.7% OH equato-

a) The reaction was carried out in a 1:1:1 ratio of an amine, TIBA, and a ketone at 60 °C in toluene. b) The isomeric alcohols produced are standardized at 100%. c) Reaction at 0 °C. d) Ref. 7. Reaction at 41 °C in benzene.

rial alcohol during the prolonged reaction time.[8] In this study, at an early stage of the reaction 30—70% OH axial alcohol was obtained, depending on the amine employed. Also, during the course of a prolonged reaction, isomeric aluminum alkoxide underwent epimerization to give OH equatorial alcohol almost entirely.

As 2,6-methyl groups(axial and equatorial) hinder the reaction at the carbonyl group in the reduction of 2,2,6-trimethylcyclohexanone (226TMC), the rate of reduction was very slow and the stereoselectivity was not seen; that is, a 1:1 mixture of isomeric alcohols was obtained after 48 h reaction. 61% OH axial alcohol was obtained in the reduction with TIBA itself at 0 °C.

An attack from the less hindered side was seen in the reduction of camphor and norcamphor, and the reaction proceeded almost 100% with the dicyclohexylamine–TIBA system. The stereoselectivity was the same as in the reduction with free TIBA.

As has been shown above, an improvement in the stereoselectivity using amine-modified TIBA compared with the case of the reduction with free TIBA was observed in the reduction of 4*t*BC, which has not so severe a steric hindrance as the other ketones used in this study.

The results of the reductions of 4*t*BC and 335TMC using an excess of TIBA–amine reagent are shown in Table 2. The reduction of 4*t*BC with a threefold quantity of TIBA–diphenylamine gave 55% *cis* alcohol. Reduction with excess TIBA did not change the products distribution compared with the 1:1 reaction of TIBA and 4*t*BC at 0 °C. The reduction of 335TMC with a threefold quantity of TIBA and diphenylamine gave 93% OH axial alcohol even after 24 h reaction.

Ashby reported 60% *trans* alcohol in 1:1, 2:1, and 5:1 ratios of TIBA and 4*t*BC, and 70% *trans* alcohol in a 1 : 2 ratio at 22 °C in benzene.

IR Spectroscopy of the TIBA–Amine–4tBC System. With respect to TIBA and diphenylamine, Neumann[11] reported that an aluminum amide was not produced at room temperature, but was produced slowly at 50 °C and rapidly at 80 °C. In this study, the reaction of TIBA with an amine was carried out at 0 °C; an aluminum amide was not formed, however.

The infrared spectral data of TIBA–amine–4*t*BC systems are given in Table 3. When diphenylamine was added to TIBA in toluene at room temperature, the ν_{NH} of the amine shifted to a lower frequency, *i.e.*, from 3430 to 3200 cm^{-1}. This indicates that a TIBA–amine complex is formed. When 4*t*BC was added to this complex, ν_{NH} appeared at 3430 cm^{-1} and $\nu_{C=O}$ was not observed. When the reaction of TIBA

Table 3. IR characteristic absorptions of TIBA-amine-ketone systems in toluene[a)]

Sample	ν_{NH} (cm^{-1})	$\nu_{C=O}$ (cm^{-1})
Free 4*t*BC	—	1720, sharp
Free diphenylamine	3430, sharp	—

Piperidine + TIBA + 4*t*BC	3230, broad	1640, broad

a) Reaction carried out at room temperature. $[TIBA]_0 = 1.0$ M.

and diphenylamine was carried out at 60 °C for 4 h, the ν_{NH} disappeared, thus indicating the formation of aluminum amide.

The reduction of 4*t*BC with the TIBA–piperidine system was completely interupted. The IR data of this system exhibits a red shift of ν_{NH} from 3310 cm^{-1} to 3230 cm^{-1}, indicating the formation of a complex. The addition of 4*t*BC to this complex, however, did not change the ν_{NH} frequency. In addition, a broad absorption at 1640 cm^{-1} due to $\nu_{C=O}$, which was at a frequency 80 cm^{-1} lower than that of free 4*t*BC in toluene was observed. These findings indicate that the amine and the ketone are complexed to TIBA at the same time; that is, the ketone added to the TIBA–amine complex coordinates to TIBA, but the amine was not liberated from the complex as in the case of the results described above.

^1H NMR Spectroscopy of TEA–Amine Systems. In order to discuss the difference in the reactivity of TIBA–amine complexes, ^1H NMR studies were carried out. Triethylaluminum(TEA)–amine systems were employed instead of TIBA–amine systems. The internal shifts of the CH_3–CH_2 group in various TEA–amine systems are given in Table 4. In general, the internal shift($\Delta\delta$) of the ethyl derivative, CH_3–CH_2–X, is proportional to the electronegativity of the substituent, X.[12)] A larger value of $|\Delta\delta|$ means a stronger coordination of an amine to TEA. The internal shift, τ_{CH_3}-τ_{CH_2}, of free TEA was −0.80 ppm, while

Table 4. Internal shifts of the ethyl group in various TEA-amine systems[a)]

Amine	τ_{CH_3}-τ_{CH_2}	Difference from free TEA	pK_b of Amine
——	−0.80	0	
Piperidine	−1.33	−0.53	2.80 (in water)
Pyrrolidine	−1.33	−0.53	2.7[b)]
Diphenylamine	−0.93	−0.13	13.2
Pyrrole	−0.83	−0.03	13.6
Aniline	−0.80	0	9.40 (in water)[c)]
Triphenylamine	−0.80	0	

a) 60 MHz ^1H NMR in C_6D_6; shifts in ppm. b) Ref. 13. c) Ref. 14.

those of the piperidine and pyrrolidine complexes were −1.33 ppm. Those of the diphenylamine and pyrrole complexes were −0.93 and −0.83 ppm respectively. In the case of the aniline complex, a sharp peak appeared at δ 0.97, indicating the formation of ethane and an aluminum amide. Triphenylamine seems to be difficult to coordinate to TEA because of its bulkiness, so the value of the internal shift was not changed. The reduction of 4*t*BC with the TIBA–triphenylamine system gave 82% *trans* alcohol, similar to the result of the reduction with free TIBA.

Meanwhile, the pK_b values of amines are correlated with the internal shrfts; *i.e.*, the basicity is not so strong in diphenylamine and pyrrole, but is very strong in piperidine and pyrrolidine.

The coordination between Al and N being strong for an amine such as piperidine, the amine cannot be liberated from the TIBA–amine complex upon the addition of a ketone. Thus, the ketone cannot coordinate to TIBA enough to undergo subsequent reduction. When the Al–N coordination is moderately strong, the amine is liberated from the TIBA–amine complex upon the addition of a ketone; then a high selectivity is obtained. Moreover, triphenylamine showed no effect in selectivity because of the difficulty of complexing; this result is the same as in the reduction with free TIBA.

In the reduction of 4*t*BC with TIBA–diphenylamine, in which the reaction of TIBA and the amine was carried out at 60 and 80 °C, about 50% 4*t*BC was reduced to give 74 and 83% *trans* alcohol respectively. Thus, the formation of an aluminum amide decreases the reactivity and the stereoselectivity. The addition of diphenylamine to the reaction mixture of 4*t*BC and TIBA did not change the composition of isomeric alcohols. The high selectivity to *trans* alcohol was caused by the complexation of an amine to TIBA and the liberation of the amine from the complex upon the addition of a ketone, and not by the formation of an aluminum amide.

As is shown in Table 2, when excess TIBA–amine was allowed to reduce 4*t*BC or 335TMC, a larger amount of OH axial alcohol was produced compared with the case of the equimolar reaction of TIBA–amine to a ketone. In these ketones, OH axial alcohol is produced by the attack from the less hindered side; *i.e.*, the equatorial attack that was seen in the reduction of camphor and norcamphor. Especially in the reduction of 335TMC, 93% OH axial alcohol was produced, irrespective of the reaction time, with a three-fold quantity of TIBA–diphenylamine. On the other hand, 100% OH equatorial alcohol was produced after 24 h with equimolar TIBA–diphenylamine. As is shown in the reduction of 335TMC with TIBA at 41 °C in benzene, 82.7% OH axial alcohol was obtained after 2 h, while 99.7% OH equatorial alcohol was obtained in 31 h(Table 1, Run 15). Thus, diisobutylaluminum 3,3,5-trimethylcyclohexyloxide undergoes epimerization to a more stable isomer remarkably well. This epimerization was scarcely observed in an excess of TIBA–amine to the 335TMC system. The results of the reduction of 335TMC with excess TIBA–

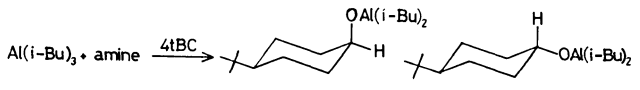
amine show the net steric course of the reducing agent to this ketone; the subsequent epimerization is almost suppressed. The result, 93% OH axial alcohol, is highly stereoselective compared with that in the reduction with $LiAlH_4$ in THF, which gives 75—80% OH axial alcohol.[2)]

Considering the suppression of epimerization using an excess of a TIBA–amine reagent, the 55% OH axial alcohol obtained in the reduction of 4*t*BC with a threefold quantity of TIBA–diphenylamine shows stereoselectivity at the point of the attacking of the reducing agent. When one-to-one TIBA–amine to 4*t*BC was used, however, a great amount of OH equatorial alcohol was obtained.

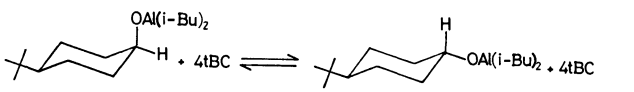
It is also noteworthy that the reaction was almost completed in 2 or 3 h when an equimolar amount of TIBA–amine to a ketone was used, while a large quantity of unreacted ketone existed in the presence of an excess of the TIBA–amine complex. Therefore, the completion of the reaction seems to be one of the factors in the epimerization to a more stable isomer.[15)] In the reduction of 4*t*BC with free TIBA, however, the reaction also proceeded almost quantitatively to give only 83% *trans* alcohol.

When the reaction time was 0.5 h in the reduction of 4*t*BC with an equivalent amount of TIBA–diphenylamine, unreacted 4*t*BC remained and the *trans* alcohol was 85%. Even if the remaining 14% of 4*t*BC is allowed to be reduced only by axial attack, the amount of *trans* alcohol cannot reach 95.5%, the result after a reaction time of 2 h. The high selectivity to *trans* alcohol may be interpreted not only by the steric requirement of the transition state, but also by the enhancement of the reaction rate and epimerization. This is more marked in the reduction of 335TMC.

As has been mentioned above, when a TIBA–amine reagent was used in an amount equimolar to a ketone, epimerization between diisobutylaluminum alkoxide of *cis*- and *trans*-4-*t*-butylcyclohexanol occurred; it was promoted further in the presence of an amine (Eqs. 1 and 2). Consequently, 95—98% *trans* alcohol was obtained after hydrolysis.



(1)



(2)

When a large excess of a TIBA–amine reagent was used, the amount of the least stable axial alcohol increased and a large amount of unreacted ketone was found. This means that the reduction of the ketone and the epimerization of the diisobutylaluminum alkoxide that produced are suppressed by an excess of a TIBA–amine complex. This unusual behavior of the reagent cannot be interpreted at present, indicating that the characteristics of the reagent are more complicated than those of a usual reducing agent such as $LiAlH_4$.

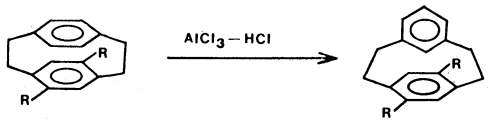
(Received March 10, 1978)

Skeletal rearrangements of multilayered [2.2]paracyclophanes to [2.2]metaparacyclophanes with several Friedel-Crafts acids have been studied. Two types of rearrangements depending on the catalyst were observed. Treatment of triple-layered paracyclophane(**8**) with $AlCl_3$–HCl gave mainly triple-layered metaparacyclophane(**9**), which was derived by migration of one of the ethylene bridges attached to the outer benzene rings. Treatment of **8** with mild protonic acids such as $SnCl_4$–HCl, $TiCl_4$–HCl, *etc.* afforded two kinds of metaparacyclophanes **10** and **11** in high yields, which arose from double migration of the two ethylene bridges attached to the inner benzene ring. Such a double migration of substitutents was also observed in the case of tertamethyl[2.2]paracyclophane and quadruple-layered one. The structures of products were determined by means of NMR spectra, alternative syntheses, and X-ray analyses. The mechanism of the rearrangements is discussed in view of protonation experiment.

[2.2]Paracyclophane(**1**), a typical layered compound, has been extensively investigated from the viewpoint of transannular π-electronic interaction. A number of anomalous physical and chemical behaviors have been reported.[2] Cram and his coworkers observed an interesting skeletal rearrangement of **1** to [2.2]metaparacyclophane(**2**) in the presence of aluminium chloride–hydrogen chloride.[3] This reaction is known to be the most practical and convenient method for the preparation of **2** since the starting material **1** is commercially available.



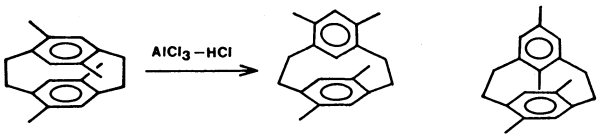
1: R=H 2: R=H

3: R=CH_3 4: R=CH_3

Multilayered [2.2]paracyclophane,[4] in which stronger electronic interaction[4a] and severer strain[5] than in **1** were observed, are expected to be highly reactive with Friedel-Crafts acid. In this paper, we report two types of skeletal rearrangement of double-, triple-, and quadruple-layered [2.2]paracyclophanes with several Friedel-Crafts acids to give unique multilayered metaparacyclophanes, and discuss their mechanisms.

Results and Discussion

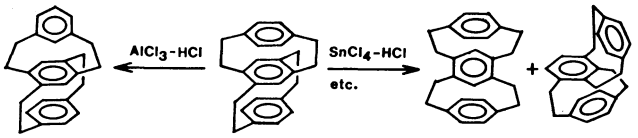
Rearrangement and Structure. Before starting with multilayered cyclophanes, methyl-substituted [2.2]paracyclophanes were examined according to Cram's procedure.[3] Treatment of 4,7-dimethyl[2.2]paracyclophane(**3**) with $AlCl_3$–HCl at 0 °C for 30 min gave a 38% yield of 12,15-dimethyl[2.2]metaparacyclophane (**4**), which was formed by 1,2-migration of an ethylene bridge attached to the non-substituted benzene ring. Product **4** was identified by comparison of its melting point and NMR data with those of an authentic sample.[6a,b] Under the same conditions, D_2-symmetric 4,7,12,15-tetramethyl[2.2]paracyclophane(**5**) afforded 4,6,12,15-tetramethyl[2.2]metaparacyclophane(**6**) in 15% yield, which was derived by positional exchange



5 6 7

of a methyl group and an ethylene bridge attached to a benzene ring. The structure of **6** was easily assigned by comparing its NMR data with those of 4,6- and 12,15-dimethyl[2.2]metaparacyclophanes.[6b] Another isomer **7** expected to be formed by single 1,2-migration of an ethylene bridge was not obtained, probably because of severe steric repulsion between the inner methyl group and the faced para-bridging benzene ring.

Treatment of more highly strained triple-layered [2.2]paracyclophane(**8**)[5b] under the same conditions as in the case of double-layered ones gave only polymeric material. However, when the reaction was



9 8 10 11

carried out at a lower temperature (−17 °C) in a shorter time, triple-layered metaparacyclophane **9** was obtained in 39% yield, together with a small amount of two isomeric cyclophanes **10** and **11**. Compound **9** was identified with the authentic sample synthesized by an alternative, stepwise method.[6a,b]

On the other hand, when **8** was treated with a large excess of weak Friedel-Crafts acid $SnCl_4$–HCl at room temperature, a mixture of **10** and **11** in a 56:46 ratio was obtained in 80% yield along with a very small amount of polymeric substance, no detectable amount of isomer **9** being observed. Use of $TiCl_4$–HCl, BF_3–HCl, or $ZnCl_2$–HCl as a catalyst gave results similar to the case of $SnCl_4$–HCl as shown in Table 1. It is of great interest that the formation of **10** and **11** is achieved by double migration of the two ethylene bridges attached to the inner benzene ring and that a molar ratio of 1.2:1 of the two isomers remains unaltered even by

Table 1. Rearrangement conditions of cyclophane **8** in dry dichloromethane

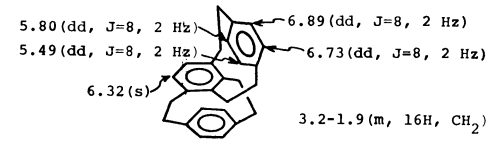
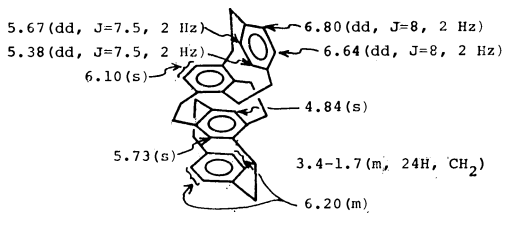
a) Determined by the intensities in NMR spectra (100 MHz).

elongation of the reaction time and by the use of different kinds of catalyst. Application of $GaCl_3$–HCl, $SbCl_5$–HCl, or $FeCl_3$–HCl as a catalyst gave rise to only the formation of polymeric material and/or the recovery of the starting cyclophane **8**. Hydrogen fluoride was found to catalyze the reaction to give a mixture of **10** and **11** in a low yield (Table 1), while no rearrangement takes place in the presence of hydrogen chloride or hydrogen bromide alone. Treatment of double-layered cyclophanes **3** and **5** with weak protonic acid $SnCl_4$–HCl caused no formation of migration products, indicating that triple-layered paracyclophane is much more reactive than a double-layered one.

Isomers **10** and **11** were separated by fractional crystallization from benzene. Gel permeation liquid chromatography was also useful for separating them. Cyclophane **10** is identical with an authentic sample.[6a,b] The structure of new cyclophane **11** having a prehnitene (1,2,3,4-tetramethylbenzene) framework as the inner benzene ring was assigned by its spectral data and elemental analysis. Its NMR signals are explained in terms of the anisotropic effect of benzene rings (Fig. 1). The molecular structure of **11** was confirmed by X-ray crystallographic analysis of its bromoderivative **12** which was derived by bromination of **11** almost quantitatively (Figs. 2 and 3).[7a] Analysis showed no appreciable nonbonding interaction between bromine and its neighboring atoms, *viz.*, a structural resemblance



11



14

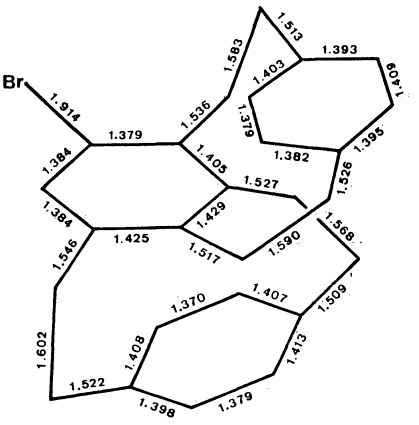
12



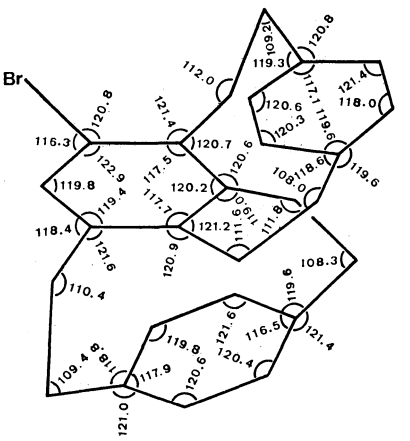


Fig. 2. Profile of the compound **12** together with bond lengths (Å) and angles (°).

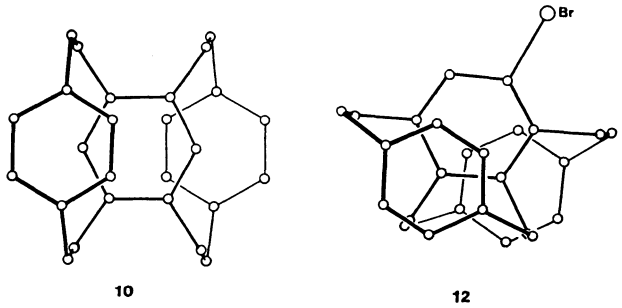

Fig. 3. Projection of the compounds **10** and **12** along the normal to the plane defined with the inner benzene ring.

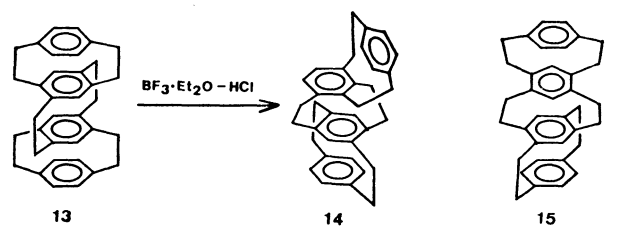
of **12** to the parent hydrocarbon **11** is seen.

A similar rearrangement was observed in the treatment of quadruple-layered [2.2]paracyclophane(**13**) with boron trifluoride etherate–hydrochloric acid at 0 °C for 30 min. Compound **14** was isolated by column chromatography on silica gel from the reaction mixture.



However, there was no detectable isomer **15**, corresponding to **10** in the case of triple-layered series.[6c] No rearranged product was obtained from **13** by treatment with mild reagent $ZnCl_2$–HCl. The results indicate relatively low stability of **13** as compared with **1** and **8**. The structure of **14**, determined on the basis of its elemental analysis and NMR data (Fig. 1), can be assigned by considering the data of **11** and the anisotropic effect of an additional benzene ring.

In previous papers,[6b,c] the electronic spectra of multilayered metaparacyclophanes except for cyclophanes **11** and **14** having a prehnitene framework were reported and a discussion on the relationship between structure and spectrum was given. The spectra of compounds **10**, **11**, and **14**, derived from skeletal rearrangement on the inner benzene ring, are shown in Fig. 4 together with the spectrum of compound **15**. The spectral resemblance between **10** and **11** can be attributed to the same extent of overlapping between the inner and the two outer benzene rings (Fig. 3), although their modes of overlapping differ to some extent. A similarity was observed in the spectra of quadruple-layered metaparacyclophanes **14** and **15**.

Mechanism. Cram *et al.* reported the NMR spectral measurement of protonated compound **16** formed by dissolving **1** in fluorosulfuric acid–sulfuryl chloride fluoride–dichloromethane at −98 °C, and proposed a mechanism of the rearrangement of **1** to **2**, the first step of which is the protonation at a bridgehead carbon, followed by 1,2-migration of the ethylene bridge attached to the protonated carbon and finally by deprotonation.[3b]

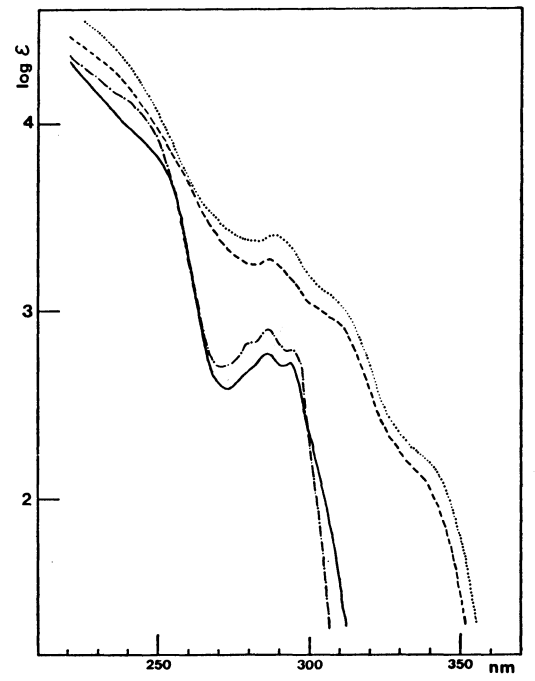


Fig. 4. Electronic spectra of cyclophanes **10** (—·—), **11** (——), **14** (----), and **15** (·····) in tetrahydrofuran.

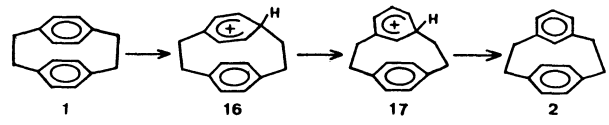

A similar treatment of cyclophane **8** in the same reagent at −78 °C gave a deep red solution, in which a single protonated species **18** was confirmed as the main product by NMR analysis. As seen in Fig. 5, the aromatic protons of the inner benzene ring appear at δ 7.21 and 6.11 ppm as singlets showing downfield shifts by 1.81 and 0.71 ppm, respectively, as compared to the corresponding protons of **8**. Such downfield shifts are comparable to the values (1.80 and 1.12 ppm)[3b] observed in protonation of [2.2]para-

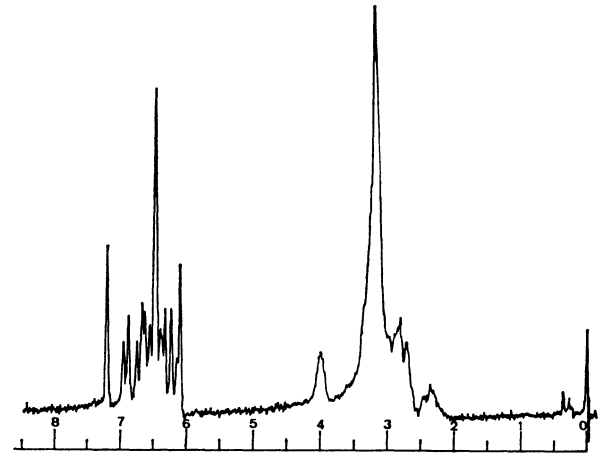

Fig. 5. NMR spectrum (100 MHz) of protonated triple-layered [2.2]paracyclophane **18** in FSO_3H-SO_2ClF-CD_2Cl_2 at −100 °C.

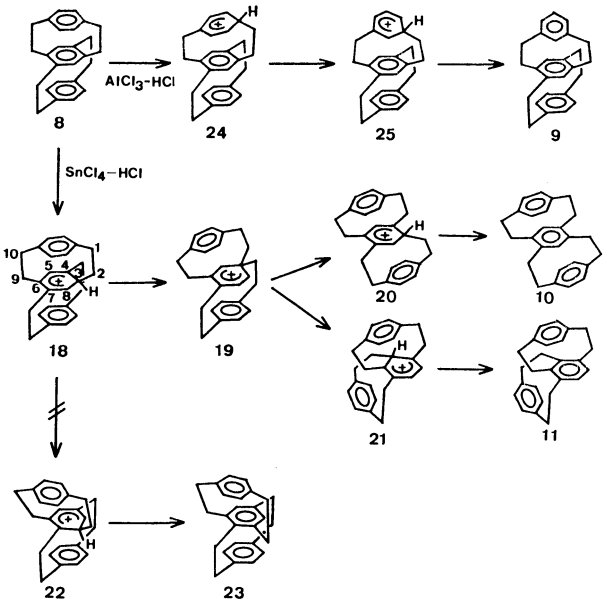
cyclophane. The fact that protonation occurred preferentially at a bridgehead carbon of the inner benzene is ascribed to a stronger basicity than that of the outer benzene ring due to the difference in the number of alkyl substituent and to considerable relief of bond angle strain, *viz.*, π-π repulsive strain between two benzene rings. On the other hand, the protonation of **10** occurred at bridgehead carbons of the two outer benzenes in preference to more basic inner one to give diprotonated species under marked strain release. The results of protonation demonstrate the strain relief to be a more important factor than π-basicity.

We propose a mechanism of the rearrangement of **8** to **10** and **11** as follows. At the initial stage, a proton would add to a bridgehead carbon (C_3) in the inner



benzene ring of **8** to form a cation (**18**), releasing bond angle strain of **8**. Although the same extent of strain relief is considered for another possible protonated species **24**, the difference in π-basicity of the inner and the outer benzene rings and the difference in relative stability of the two cations **18** and **24** due to transannular π-electronic delocalization are probably responsible for the predominance of **18**. The ethylene bridge attached to the protonated carbon would migrate intramolecularly to the adjacent bridgehead carbon C_4 to yield cation **19**, in which considerable strain reduction might result between the inner ring and both outer rings. Cation **19** is probably a common intermediate for the two rearranged products **10** and **11**, since a constant ratio was obtained for these products in the reaction mixtures regardless of the kind of weak protonic acid, reaction time, and temperature (Table 1), no interconversion between **10** and **11** being found under the same conditions. Finally, another ethylene bridge attached to the carbon C_4 would migrate in two ways, *viz.*, to C_3 and C_5 to give cations **20** and **21**, respectively, from which products **10** and **11** would be formed by deprotonation. No other possible migration of **18** to cation **22** was realized due to severe strain in the structure **23** as expected from the examination with molecular models.

In the rearrangement with aluminium chloride–hydrogen chloride, the initial protonation might take place at a bridgehead carbon of the outer benzene rings under strain relief, followed by bridge migration to cation **25** and deprotonation to **9**. Predominance of such a different type of initial protonation may be associated with the strong acidity and/or the bulkiness of this protonic acid.

The results suggested that the relief in molecular strain functions as a driving force in both the rearrangements **8**→**9** and **8**→**10**+**11**, and the relative π-basicity serves as an additional factor in the case of the latter rearrangement.

Experimental

Melting points are uncorrected. All the solvents are of reagent grade unless otherwise stated. Commercial Lewis acids were used. Chromatography was carried out on silica gel (Merck, activity II) or neutral alumina (Woelm, activity I). PMR spectra were taken with Hitachi-Perkin-Elmer R-20 (60 MHz) and Nihon Denshi JNM-TS-100 (100 MHz) spectrometers using TMS as an internal standard, MS with Hitachi RMU-7 spectrometer at 70 eV using a direct insertion technique, IR with Jasco DS-402 and UV with Hitachi EPS-3T spectrophotometers. Multilayered [2.2]paracyclophanes were synthesized according to the 1,6-Hofmann elimination method.[4a,c]

Rearrangemnet of 4,7-Dimethyl[2.2]paracyclophane ***3*** *to 12,15-Dimethyl[2.2]metaparacyclophane* ***4***. After dry hydrogen chloride gas had been bubbled into a stirred solution of anhyd aluminium chloride (1.694 g, 12.7 mmol) in dry dichloromethane (50 ml) for 30 min, 4,7-dimethyl[2.2]paracyclophane **3** (500 mg, 2.12 mmol) was added at once to the solution. The resulting blood red complex solution was vigorously stirred at 4—6 °C for 180 min, cooled to −15 °C, and decomposed with 6*N*-hydrochloric acid. The aqueous layer was extracted with dichloromethane and the combined organic layer was successively washed with water, saturated aq sodium hydrogencarbonate and water. After drying and evaporation of the solvent, the residual oil was filtered through neutral alumina (6 g) with hexane. The crystals obtained from the filtrate were recrystallized from pentane to give 192 mg (38%) of **4**, colorless plates, mp 66.5—67.5 °C (lit, 65—66 °C).[6a]

Rearrangement of D_2*-symmetric 4,7,12,15-Tetramethyl[2.2]paracyclophane* ***5*** *to 4,6,12,15-Tetramethyl[2.2]metaparacyclophane* ***6***. A suspension of anhyd aluminium chloride (2.28 g, 17.1 mmol) in dry dichloromethane (150 ml) was saturated with dry hydrogen chloride and cooled to −15 °C. Compound **5** (750 mg, 2.84 mmol) was added in one portion to the solution and the resulting deep red solution was stirred at −9—−10 °C for 100 min under slow bubbling of dry hydrogen chloride. The reaction mixture was worked up in the same way as in the case of **4**. Chromatography on silica gel (80 g) with hexane gave, after elution of unidentified oily products, 112 mg (15%) of 4,6,12,15,-tetra methyl[2.2]metaparacyclophane **6**, white columns from hexane, mp 78—81 °C. Further recrystallization from the same solvent gave pure **6**, mp 81—82 °C.

Found: C, 90.60; H, 9.18%. Calcd for $C_{20}H_{24}$: C, 90.85; H, 9.15%. NMR($CDCl_3$, δ ppm): 6.88(s, 1H, ArH), 6.62 (s, 1H, ArH), 5.69(s, 1H, ArH), 5.34(s, 1H, ArH), 3.4—1.9 (m, 8H, CH_2), 2.45(s, 3H, CH_3), 2.22(s, 6H, CH_3), 1.65 (s, 3H, CH_3): MS (rel intensity): 264(M^+, 52), 249(57),

133(63), 132(100), 117(30), 91(18); UV λ_{max} in THF, nm(ε): 279(520), 287.5(540).

When the above reaction was carried out at −20——21 °C for 15 min, the starting material was recovered, a tarry material only being produced at 0 °C for 1 h.

Rearrangement of Triple-layered [2.2]Paracyclophane ***8***.

a) With Aluminium Chloride–Hydrogen Chloride: A suspension of powdered anhyd $AlCl_3$ (472 mg, 3.54 mmol) in dry dichloromethane (40 ml) was saturated with dry HCl and cooled to −20 °C. Triple-layered [2.2]paracyclophane **8** (200 mg, 0.59 mmol) was added to the solution at once and the resulting deep red solution was stirred at −17 °C for 15 min. After cold 6M-HCl had been added, the separated aqueous layer was extracted with dichloromethane. The combined organic solution was washed with water, dried over anhyd magnesium sulfate, and evaporated to dryness. The residual oil was chromatographed on silica gel (30 g) with hexane. From the first eluate, triple-layered [2.2]metaparacyclophane **9** was obtained and recrystallized from benzene–ethanol to give 60 mg of colorless plates, mp 141—142 °C (lit, 144—145 °C).[6a]

The mother liquor and the following eluates gave a mixture of cyclophane (42 mg) consisting of **8**:**9**:**10**:**11**=3:76:11:10 on the basis of NMR analysis (100 MHz).

b) With Stannic Chloride–Hydrogen Chloride: To a stirred solution of anhyd $SnCl_4$ (460 mg, 1.75 mmol) in dry dichloromethane (20 ml) saturated with hydrogen chloride was added **8** (100 mg, 0.30 mmol). The resulting purple red solution was stirred at 29 °C for 30 min and quenched with cold dil hydrochloric acid. The reaction mixture was worked up as above and the product was purified by filtration through alumina (7 g) with 10% benzene–hexane to give a mixture of **10** and **11** (79.7 mg, 80% yield). Repeated recrystallization of the mixture from benzene gave two forms of crystal, colorless plates **10** and colorless prisms **11**, which were separated with tweezers and purified by recrystallization. The mixture was also separated into **10** and **11** by gel permeation chromatography (Nihon Bunsekikogyo LC-08). Cyclophane **10** gave spectral data and melting point (259—260 °C) identical with those of an authentific sample.[6a] Data of the new cyclophane **11** are as follows: mp 209—210 °C (partly sublime).

Found: C, 92.42; H, 7.63%. Calcd for $C_{26}H_{26}$: C, 92.26; H, 7.74%. The NMR datum is given in Fig. 1. MS (rel intensity): 338(M^+, 100), 233(38), 219(47), 104(92). UV λ_{max} in THF, nm(ε): 285(590), 293(530).

The rearrangement of **8** was carried out with the other protonic acids, $TiCl_4$–HCl, BF_3–HCl, and $ZnCl_2$–HCl in the same way as in the case of $SnCl_4$–HCl. The results are given in Table 1. A similar treatment with $GaCl_3$–HCl (at 28 °C, 30 min), $SbCl_5$–HCl (−5——2 °C, 60 min), and $FeCl_3$–HCl (29 °C, 10 min) gave only polymeric substances; with $SbCl_5$–HCl (−40——30 °C, 60 min) and HCl (reflux, 180 min) or HBr alone (22 °C, 60 min) the starting cyclophane **8** was recovered .

c) With Hydrogen Fluoride: Hydrogen fluoride (5 ml) was distilled in a solution of **8** (100 mg, 0.30 mmol) in dichloromethane (20 ml) which had been cooled in a Dry Ice–acetone bath. The resulting purplish red solution was gradually warmed up to 0 °C under stirring over a period of 20 min, stirring being continued at the temperature for 20 min. After HF had been removed, the reaction mixture was poured into a saturated aq. sodium hydrogencarbonate solution and worked up as described above. A mixture (20 mg, 20%) of **8**, **10**, and **11** was obtained in the ratio given in Table 1.

6-Bromo[2.2]paracyclo(4,8)[2.2]metaparacyclophane ***12***.

To a stirred solution of bromine (14.2 mg, 0.11 mmol) in carbon tetrachloride (0.3 ml) was added triple-layered metaparacyclophane **11** (37.2 mg, 0.11 mmol) in dry dichloromethane (1.5 ml) at 0 °C. The mixture was slowly warmed up to room temperature and then stirred for 15 min. After filtration through neutral alumina (1 g) and removal of the solvent, the residue was chromatographed on silica gel (10 g) with 10% benzene–hexane to give 45.1 mg (98%) of the desired bromoderivative **12**, colorless prisms from benzene –ethyl acetate, mp 242—243 °C with decompn. (in a sealed tube).

Found: C, 74.70; H, 5.96; Br, 18.82%. Calcd for $C_{26}H_{25}Br$: C, 74.82; H, 6.04; Br, 19.14%. NMR($CDCl_3$, δ ppm): 6.91 (dd, J=8, 2 Hz, 2H, ArH), 6.75(dd, J=8, 2 Hz, 1H, ArH), 6.62(s, 1H, ArH), 6.05(dd, J=8, 2 Hz, 1H, ArH), 5.92(dd, J=8, 2 Hz, 1H, ArH), 5.63 (dd, J=8, 2 Hz, 1H, ArH), 5.62(dd, J=8, 2Hz, 1H, ArH), 3.3—1.7 (m, 16H, CH_2). MS (rel intensity): 416(M^+, 32), 418(M^++2, 33), 337(37), 314(6), 312(6), 233(15), 104(100), 91(10). UV λ_{max} in THF, nm(ε): 285(620), 294(280), 305(210)(sh).

Rearrangement of Quadruple-layered [2.2]Paracyclophane ***13*** *with Boron Trifluoride Etherate–Hydrogen Chloride.* To a solution of boron trifluoride etherate (0.49 ml, 3.82 mmol) in dry dichloromethane (60 ml) saturated with dry HCl was added quadruple-layered [2.2]paracyclophane **13** (300 mg, 0.64 mmol) at once under stirring. The purplish blue solution was stirred at 0 °C for 30 min and then decomposed with dil hydrochloric acid. The mixture was worked up as usual. Chromatography of the product on silica gel (20 g) with 2% benzene–hexane gave quadruple-layered metaparacyclophane **14**, colorless prisms from benzene–hexane, mp 336.5—337.5 °C, yield 25 mg (8%).

Found: C, 92.53; H, 7.60%. Calcd for $C_{36}H_{36}$: C, 92.26; H, 7.74%. The NMR datum is given in Fig. 1. MS (rel intensity): 468(M^+, 100), 363(44), 349(34), 245(32), 104(44). UV λ_{max} in THF, nm(ε): 286(1790).

Protonation of Triple-layered [2.2]Para- and Metapara-cyclophanes ***8***, ***10***, *and* ***11***. Protonation was carried out according to the general procedure for **8** described below.

Sulfuryl chloride fluoride (0.6 ml) and fluorosulfuric acid (0.2 ml, freshly distilled) were carefully added successively at −78 °C to a solid of **8** (40 mg) placed in an NMR tube. When the tube was shaken, the solution turned clear deep red. After the NMR spectrum of protonated species **19** was measured, the solution was poured into water, compound **8** being recovered quantitatively. Cyclophane **10** was also protonated in a similar manner to yield diprotonated species, which was analyzed by NMR spectrum.

Diprotonated species of **10**, NMR(SO_2ClF–FSO_3H–CD_2Cl_2, δ ppm): 8.70(br d, J=8 Hz, 2H), 7.91(br d, J=8 Hz, 2H), 7.48(br d, J=8 Hz, 2H), 6.51(br d, J=8 Hz, 2H), 5.98(br s, 2H), 4.16(br s, 2H), 4.0—2.0(m, 16H).

The present work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Synthesis of 1,4-Dithiafulvenes and 1,4-Dithiafulvalenes by Carbonyl Olefination Using 2-Dimethoxyphosphinyl-1,3-benzodithiole

Kin-ya AKIBA,* Kiyofumi ISHIKAWA, and Naoki INAMOTO

Department of Chemistry, Faculty of Science,
The University of Tokyo, Hongo, Tokyo 113

(Received April 11, 1978)

The reactions of 1,3-dithiolylium salts with tertiary phosphines and trialkyl phosphites in dry acetonitrile gave the corresponding phosphonium salts and the phosphonates respectively in high yields. Both 2-triphenylphosphonio-1,3-benzodithiole tetrafluoroborate and 2-dimethoxyphosphinyl-1,3-benzodithiole were deprotonated with butyllithium in THF at −78 °C and the resulting phosphorane (*A*) and the phosphonate carbanion (*B*) reacted with a variety of carbonyl compounds to give 1,4-benzodithiafulvenes in 74—98% yields. Moreover, *B* reacted with conjugated cyclic ketones (**5**) such as dibenzo[a,d]cyclohepten-5-one, 10*H*-9-thiaanthracen-10-one, 9-alkyl-9,10-dihydro-9-azaanthracen-10-one, 9-fluorenone, and so on to give 1,4-benzodithiafulvalenes (**6**) in 73—96% yields. The UV spectral data of **6** were discussed in comparison with those of **5**.

Heteroaromatic cations such as pyrylium, thiopyrylium, pyridinium, thiazolium, and dithiolylium have been attractive target of research both for physical organic and synthetic chemists. Preparation and use of dithiolylium salts have acquired renewed interest in connection with the synthesis of tetrathiafulvalene derivatives, one component of organic metals. Our interest to develop new utility of heteroaromatic cations in organic synthesis has led us to general preparation of 1,4-dithiafulvenes and fulvalenes, starting from 1,3-dithiolylium salts.

On the other hand, fulvenes and fulvalenes have been investigated from the standpoint of both synthetic and theoretical aspects and dithia analogues have also been investigated as their iso-π-electronic systems.

However, there has been no general synthetic method of 1,4-dithiafulvenes (2-alkylidene-1,3-dithioles), although those with electron-withdrawing groups on the exo-methylene can be prepared by condensation of 2-methylthio-1,3-dithiolylium salts with acitve methylene compounds in 34—77% yields.[1] Some of them were obtained among photolysis products of 1,2,3-thiadiazoles in 45—50% yields.[2] It was also reported that 2-benzylidene-4-phenyl-1,3-dithole was prepared by the reaction of 2-methylthio-4-phenyl-1,3-dithiolylium iodide with benzylmagnesium chloride, but this method required long reaction time and the yield was low.[3]

On the other hand, there are a couple of recent reports on the preparation of 2-alkylidene-1,3-dithioles when electron-withdrawing groups are on the ring. 1,3-Dithiol-2-ylidene-tributylphosphoranes were prepared *in situ* by addition of activated acetylenes to a mixture of tributylphosphine and carbon disulfide and used for subsequent Wittig reaction.[4] Intermediate phosphorane can be trapped as a phosphonium salt when the active acetylene has at least one carboxylic acid group.[5] The intermediacy of the same kind of phosphorane during desulfurization of 4,5-dicyano-1,3-dithiole-2-thione with tertiary phosphines was recently reported,[6] however, Scherowsky and Weiland could not detect the same kind of phosphorane in desulfurization of 1,3-benzodithiole-2-thione with triethyl phosphite.[7] To our knowledge, only these three special cases have been reported to date on this type of phosphorane and their Wittig reaction.

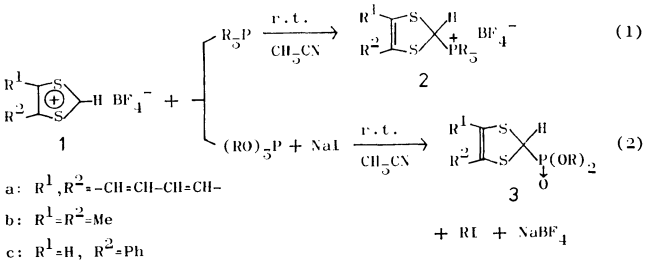
1,4-Dithiafulvalenes have been prepared by condensation of 1,3-dithiolylium salts with cyclopentadienide anions[8] and active methylenes contained in heterocycles,[9] and their properties were compared with sesquifulvalenes which are iso-π-electronic each other.

Now, it is expected that 1,4-dithiafulvenes can generally be prepared by a single method, *i.e.*, Wittig-Horner reaction with acyclic and cyclic carbonyl compounds, if phosphonium salts or phosphonates are prepared from 1,3-dithiolylium salts. This paper offers a new synthetic method for such type of compounds.

Results and Discussion

Synthesis of 2-Phosphonio- and 2-Dialkoxyphosphinyl-1,3-dithioles. Slightly exothermic reaction took place immediately on addition of tertiary phosphine to 1,3-dithiolylium tetrafluoroborate (**1**) in dry acetonitrile solution and stirring was continued for 2 h at room temperature. After evaporation of the solvent under reduced pressure, addition of dry ether to the residue gave the precipitates, 2-phosphonio-1,3-dithiole tetrafluoroborate (**2**) in high yields.

1,3-Dithiolylium salt (**1**) reacted also with trialkyl phosphite in the presence of an equimolar amount of sodium iodide in dry acetonitrile under nitrogen at room temperature. Michaelis-Arbuzov reaction took place very rapidly to give 2-dialkoxyphosphinyl-1,3-dithioles (**3**) in high yields while the reaction did not take place in the absence of sodium iodide under otherwise the same conditions. Yields and mp of **2** and **3** are shown in Table 1.



Scheme 1.

The structures of these products (**2** and **3**) were confirmed by means of elemental analyses, IR, and NMR spectra. The IR spectra of **2** showed very strong absorption bands at about 1100 and 520 cm^{-1}

Table 1. Yields and mp of phosphonium salts (**2**) and phosphonates (**3**)

Compound	R^1	R^2	R	Yield (%)	Mp (°C)
2a	-CH=CH-CH=CH-		Ph	87	211.5—212.5 (dec)
2b	-CH=CH-CH=CH-		*n*-Bu	90	166.5—167.0
2c	Me	Me	Ph	84	175.0—177.0 (dec)
3a	-CH=CH-CH=CH-		Me	93	122.0—123.0
3b	-CH=CH-CH=CH-		Et	90	115.5—116.5
3c	Me	Me	Me	83	—
3d	H	Ph	Me	90	87.0— 88.0

(BF_4^-). The NMR spectrum of each of **2** showed a broad singlet signal assignable to 2-CH (*i.e.*, $J_{PCH} \fallingdotseq 0$). The NMR spectrum of **2c** showed a singlet signal at an extraordinarily high field as a vinylic methyl ($\delta = 1.30$) assignable to two methyl groups at 4 and 5 positions. IR spectra of all the phosphonates (**3**) showed strong absorption bands characteristic of P=O (1250—1260) and P-O-C (1050—1065 and 1030—1040 cm^{-1}), respectively.

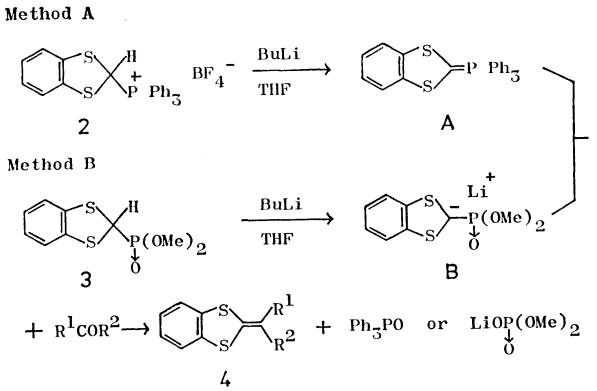
Each NMR spectrum of **3** showed a doublet signal at δ 4.75—5.06 ($J_{PCH} = 4.4$—5.8 Hz) assignable to 2-CH and also a doublet signal at δ 3.63—3.85 ($J_{POCH} =$ 10.4—10.8 Hz) assignable to POMe except for **3b**. The compounds (**3a**, **b**, and **d**) showed the parent peak (4—9%) and the base peak assignable to $M^+ - P(O)(OR)_2$ in MS.

The ^{31}P-NMR spectrum of **3a** exhibited a signal at δ −19 ppm.

Gross *et al.*[10] reported that the ^{31}P-NMR spectrum of 5,6-dichloro-2-diethoxyphosphinyl-1,3-benzodioxole exhibited a signal at δ −7.3 ppm, and that this value was compared with those of diethyl methylphosphonate and its monochloro-, dichloro-, and trichloromethyl compounds (δ_P −30, −18.1, −9.3, and −6.5 ppm, respectively)[11] in relation to the electronegativity of the substitutent. The effect of the substitution of a catechol ring for two hydrogen atoms of the methyl group nearly corresponded to that of three chlorine atoms for three hydrogen atoms of the methyl group. In the present case, the effect of the substitution of a thiocatechol ring for two hydrogen atoms of the methyl group is smaller than that of a catechol ring and corresponds approximately to that of one chlorine atom for the methyl group.

The compound (**3c**) has low melting point (−20 °C), and was purified by dry column chromatography over neutral alumina. However, this compound is so hygroscopic and sensitive to air as an oil or in solution that it could not be purified enough for elemental analysis.

*Wittig-Horner Reaction of 2-Triphenylphosphonio-1,3-benzodithiole Tetrafluoroborate (**2a**) and 2-Dimethoxyphosphinyl-1,3-benzodithiole (**3a**): Synthesis of 1,4-Benzodithiafulvenes (**4**).*[12] Both 2-triphenylphosphonio-1,3-benzodithiole tetrafluoroborate (**2a**) and 2-dimethoxyphosphinyl-1,3-benzodithiole (**3a**) were deprotonated with butyllithium in THF at −78 °C and the resulting phosphorane (*A*) and phosphonate carbanion (*B*) were allowed to react with a wide variety of carbonyl compounds to give the expected products, *i.e.*, 1,4-benzodithiafulvene (**4**) at low temperatures in very good yields. The reaction scheme is shown below.



Scheme 2.

Comparison of two methods recommends Method B for synthetic purpose by the following reasons: i) shorter reaction time of Method B than Method A, because the former can be carried out in homogeneous solution but the deprotonation of **2a** is a heterogeneous reaction, ii) no need of chromatographic separation of the product, the resulting phosphoric acid being soluble in water, iii) higher reactivity of *B* than *A*, hence the former can be carried out at lower temperatures than the latter, and *B* reacted smoothly with *p*-dimethylaminobenzaldehyde at low temperature to give **4a** in high yield, but *A* did not react with the same aldehyde even under reflux of THF, iv) higher yield in every case, and v) no by-production of dibenzotetrathiafulvalene, which is the case in method A when the reaction is carried out at higher temperatures (room temperature).

Yields and mp of **4** are shown in Table 2.

All the products (**4a**—**g**) showed correct elemental analysis and reasonable IR, ^1H-NMR, and MS spectra. All **4** showed the parent peak as the base peak in MS, with the exception of **4b** and **4f**. This fact shows large stability of the parent radical cations which are contained in 1,4-benzodithiafulvene ring. The parent peak of **4b** appeared at *m/e* 272 (88%) and the base peak at *m/e* 257 assignable to $M^+ - Me$. The parent peak of **4f** appeared at *m/e* 268 (94%) and the base peak at *m/e* 128 assignable to $M^+ - C_6H_4S_2$.

The phosphonate carbanion (*B*) reacted also with 3-buten-2-one (methyl vinyl ketone) to give crude 2-(1-methyl-2-propenylidene)-1,3-benzodithiole (**4r**) in 53% yield. But this compound could not be purified

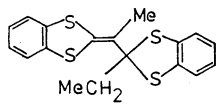
a) Numerical values in parentheses show yields of triphenylphosphine oxide.

enough for elemental analysis because of its instability.

The reaction of *B* with acetaldehyde was also carried out under the genreal procedure. Purification of the product by preparative thin-layer chromatography (SiO_2/CCl_4) afforded, however, only a trace amount of a product. The structure of the compound was proposed to be the dimer of the expected one from its ^{1}H-NMR spectral data; δ (CCl_4) 1.07 (t, 3H), 1.99 (s, 3H), 2.42 (q, 2H), and 6.7—7.6 (m, 8H).



The same type of dimerization accompanied by prototropy is known for active methylene contained in benzothiazoline.[13]

The reaction of *B* with 9(10*H*)-anthracenone resulted in proton abstraction to give an oxidized product, *i.e.*, 9,10-anthracenedione, whereas *B* did not react with 10,10-dibenzyl-10*H*-anthracen-9-one at all, probably because of steric hindrance.[14]

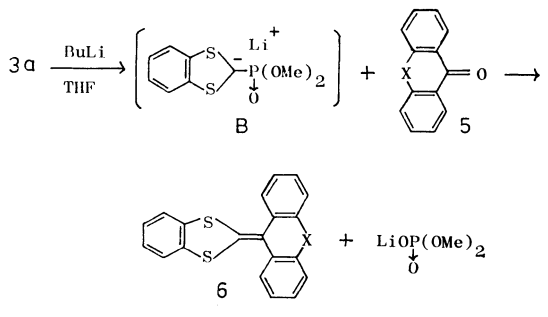
Moreover, the phosphonate carbanion derived from **3d** reacted with 4,4'-dichlorobenzophenone to give 2-[bis(*p*-chlorophenyl)methylene]-4-phenyl-1,3-dithiole in 83% yield.

It should be noted that extraordinarily rapid Wittig-type reaction was observed in both methods A and B as compared with usual reaction conditions.[15] Furthermore, *B* reacted with cycloalkanones, acetophenones, and even benzophenones at low temperatures in contrast to 1,3-dithiacyclohexylidenetrimethoxyphosphorane which did not react with those ketones mentioned above even by heating at 60 °C for 24 h.[16] It seems that the high reactivity of phosphorane (*A*) and phosphonate carbanion (*B*) can be attributed to the following reasons. These intermediates, especially *B*, can be classified as antiaromatic anions and hence high reactivity is expected toward carbonyl compounds, moreover, it is also probable in our case that some contribution of pseudoaromaticity (dithiolylium) to the product lowered the energy of the transition state, because that of Wittig reaction has been shown to lie at the decomposition of the betaine.[17]

In fact, Mikolajczyk *et al.*[18] and Kruse *et al.*[19] recently reported the preparation of di(thioalkyl)methylphosphonates and their use in Wittig-Horner reaction to give ketone dithioacetals in high yields at low temperatures. However, comparison of reactivity of carbanions of these phosphonates and *B* has not yet been done.

As described above, Wittig-Horner reaction of 2-dimethoxyphosphinyl-1,3-dithioles has been shown to be very useful for the synthesis of 1,4-dithiafulvenes which could not be synthesized by conventional methods or were obtained only in low yields. At the same time, some limitations (steric hindrance, *etc.*) of this new method were revealed.

*Wittig-Horner Reaction of 2-Dimethoxyphosphinyl-1,3-benzodithiole (**3a**) with Conjugated Cyclic Ketones: Synthesis of 1,4-Benzodithiafulvalenes (**6**).*[20] A new synthetic method for the preparation of **4** by Wittig-



Scheme 3.

Horner reaction of **3a** was extended successfully to the preparation of 1,4-benzodithiafulvalenes (**6**). The phosphonate carbanion (*B*) derived from **3a** reacted with conjugated cyclic ketones (**5**) such as dibenzo-[a,d]cyclohepten-5-one, 9-thiaanthracen-10-one, 9-alkyl-9*H*-9-azaanthracen-10-one, 9-oxaanthracen-10-one (xanthone), 9-fluorenone, tetraphenylcyclopentadienone (tetracyclone), and so on, to afford 1,4-dithia-analogs of heptafulvalene or sesquifulvalene (**6**) in good yields. Yields and mp of **6** and UV spectral data of **6** and **5** are shown in Table 3.

It is noteworthy that all **6** were obtained by the same procedure irrespective of the nature of the carbonyl compounds (**5**), *i.e.*, group I (**5a**, **b**, **c**, **d**, and **e**) which

Table 3. Yields and mp of 1,4-benzodithiafulvalenes (**6**) and fulvenes (**4o**, **4p**) and UV spectral data of them and the corresponding ketones (**5**)

a) Only the longest absorption maximum, whose log ε are greater than 3.5 (probably ascribed to π-π^* excitation with CT character), is shown. See experimental section for other data. b) The difference of λ_{max} of the product (**6**) and the ketone (**5**) is shown, *i. e.*, $\Delta\lambda=\lambda_{max}(\mathbf{6})-\lambda_{max}(\mathbf{5})$

can be classified as π-excessive carbonyl compounds, group II (**5h**, **i**, and **j**) which can be classified as π-deficient carbonyl compounds, group III (**5o** and **p**) which are benzophenones.

The structures of these 1,4-benzodithiafulvalenes (**6**) were confirmed by means of the elemental analyses, IR, ^{1}H-NMR, UV, and mass spectra. All **6** showed reasonable IR and ^{1}H-NMR spectra without any significant characteristic features. The molecular ion peak in MS was the base peak in all **6** except for **6d** and **6f**. This fact shows large stability of the parent radical cations which are conjugated through the ring system. The parent peak of **6d** appeared at *m/e* 359 (72%) and the M^+-Et peak as the base peak. The parent peak of **6f** appeared at *m/e* 364 (48%) and the $M^+-C_7H_4OS_2$ ($C_{13}H_8S$) peak as the base peak.

A comparison of absorption maxima of the longest wave length in the UV spectra of compounds **5** and **6** with log $\varepsilon>3.5$ (probably to be ascribed to π-π^* excitation with CT character) reveals the following facts:

—In group I, the longest absorption of **6** is observed at a shorter wavelength than that of **5**, except for the case of **6e**.

—In groups II and III, the longest absorption of **6** and **4** is observed at a longer wavelength than that of **5**.

—In comparison of the data of the sulfides (**5b**/**6b**), the sulfoxides (**5f**/**6f**), and the sulfones (**5g**/**6g**), the distinct change is observed from the blue shift (−19 nm) to the red shifts (+30 and +116 nm) according to the increase of electron-withdrawing ability of the sulfur group.

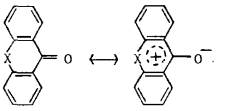
—In the case of xanthone (**5e**/**6e**), the red shift which is almost equal to that of the sulfoxide is observed in spite of the presence of a lone pair of electrons on the oxygen atom.

These facts may be explained as follows, although assignment of each absorption has not been made. The facts obtained in group I may be understood by assuming that the resonance contribution of a polar structure to π^* state in **5a**—**d** is significant and thus the excitation energy is reduced, whereas the contribution of a polar structure to π^* state in **6a**—**d** is less significant due to the competition between the electron-donating power of the 1,3-benzodithiol-2-ylidene moiety and that of the other part of the molecule, *i.e.*, the π-excessive cyclic system containing vinyl, sulfur, or nitrogen group, and hence the excitation energy is enhanced relatively. This enhancement of the excitation energy due to the electron-donating power of the 1,3-benzodithiol-2-ylidene moiety appears to be stronger than the lowering of the excitation energy by the extenstion of the conjugated system in **6** by the inclusion of the 1,3-benzodithiol-2-ylidene group instead of the carbonyl oxygen atom. The latter effect should be common to groups I, II, and III.

The stretching frequency of a carbonyl group in IR is affected by the contribution of a polar structure to the ground state in a carbonyl compound, *i.e.*, the lower the frequency, the larger the polar character. Indeed, the carbonyl frequencies of group I compounds are lower compared with those of group II compounds

Table 4. The IR spectral data of some of the carbonyl compounds

Compounds	IR (KBr), $\nu_{C=O}$ (cm^{-1})	Group
5a	1630	I
5b	1630	I
5c	1625	I
5d	1625	I
5e	1670	I
5f	1675	—
5g	1680	—
5h	1700	II
5p	1660	III



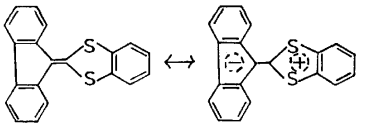
5a—e

due to the π-excessive character of the ring as shown in Table 4.

Carbonyl frequency of **5e** is very close to that of **5f**. This may be the reason for the exception of **5e**/**6e** (+28.5 nm shift) as a member of group I, that is, the contribution of the polar structure in **5e** is smaller than those in **5a**—**d** due to the large electronegativity of the ring oxygen and is almost the same as that by sulfoxide group of **5f** (+30 nm shift). The fact in the case of **5f,g**/**6f,g** can similarly be understood.

However, it has been shown that even tropone is a highly polyenic compound in the ground state with some contribution of a polar structure.[21] Hence, the degree of the contribution of the polar structure to the ground state in all these carbonyl compounds may not be so significant.

The findings obtained in groups II and III may be understood by assuming that the contribution of a polar structure to π^* state in **6h**—**j** is significant due to the electron-donating property of the 1,3-benzodithiolylidene moiety in concurrence with the electron-withdrawing property of the other part of the molecule, whereas the contribution of a polar structure to π^* in **5h**—**j** is less significant. The decrease in the excitation energy of **4o,p** as compared with **5o,p** may chiefly be ascribed to the extension of the conjugated system in **4o,p** by the inclusion of the 1,3-benzodithiolylidene group instead of the carbonyl oxygen atom.



The assumption that the contribution of a polar structure to the ground state in **6** is not so significant was supported by the observed ESCA spectral data of **6a**, **b**, **c**, **e**, and **h** ($S_{2P\ 3/2}=163.1\pm0.3$ eV, respectively), which showed almost equal binding energy for all the sulfur atoms contained in a number of molecules.[22]

Neuenschwander *et al.*[23] reported also that the resonance contribution of a dipolar form is not significant in sesquifulvalene, fulvene, and heptafulvene,

which were shown to have a largely olefinic character from their ^{13}C-NMR spectral data and relatively small dipole moments.

Experimental

All the melting points are not corrected. IR spectra were measured with a Hitachi EPI-G2 spectrometer, ^1H-NMR spectra with Hitachi R-20B and Hitachi R-24 spectrometers (60 MHz, TMS as an internal standard), MS with a Hitachi RMU-6L mass spectrometer at 70 eV, and UV spectra with a Hitachi EPS-3 spectrophotometer. ^{31}P-NMR spectra were measured with a Hitachi R-20B-R-204-PB (24.3 MHz) spectrometer using 85% phosphoric acid as an external standard. ESCA spectra were recorded on a McPherson ESCA 36 electron spectrometer. The Al $K_{\alpha 1,2}$ line (1486.6 eV) provided the activation energy. The instrument was adjusted so that the Au-$4f_{7/2}$ line fell at 84.0 eV. Accuracy: $\pm$0.15 eV.

Materials. 1,3-Benzodithiolylium tetrafluoroborate (**1a**) was prepared according to the literature, mp 149—150 °C (dec) (lit,[24] mp 149—150 °C). 4,5-Dimethyl-1,3-dithiolylium tetrafluoroborate (**1b**), mp 123—125 °C (lit,[25,26] mp is not described), was prepared from 4,5-dimethyl-1,3-dithiole-2-thione[27] and 4-phenyl-1,3-dithiolylium tetrafluoroborate (**1c**), mp 143.5—145.5 °C (dec) (lit,[28] mp 161 °C for ClO_4^- and 180 °C for HSO_4^- salts), was prepared from 4-phenyl-1,3-dithiole-2-thione.[3]

Dibenzo[a,d]cyclohepten-5-one (**5a**) was a commercial material from Sakai Rikagaku Kenkyujyo, mp 88.0—89.0 °C; IR (KBr): 1630 cm^{-1} (C=O); UV (CH_2Cl_2): λ_{max}= 257 (log ε=4.92), 309.5 (4.47), and 361 nm (3.89).

10*H*-9-thiaanthracen-10-one (thioxanthone) (**5b**) was prepared from *o*-mercaptobenzoic acid and benzene by treatment with concentrated sulfuric acid, mp 214—215 °C (from EtOH) (lit,[29] mp 209 °C); IR (KBr): 1630 cm^{-1} (C=O); UV (CH_2Cl_2): λ_{max}=257.5 (log ε=4.74), 289 sh (3.89), 301 (3.86), 364 (3.90), and 382 nm (3.98).

9-Methyl-9,10-dihydro-9-azaanthracen-10-one (*N*-methylacridone) (**5c**) was prepared by the oxidation of *N*-methylacridinium salt with potassium hexacyanoferrate (III) in aqueous alkaline solution, mp 208—209 °C (lit, 199 °C[30] and 203 °C[31]); IR (KBr): 1625 cm^{-1} (C=O); UV (CH_2Cl_2): λ_{max}=258 (log ε=4.75), 268 sh (4.50), 277 (4.41), 293.7 (3.98), 306 (3.77), 361 sh (3.70), 380 (4.01), and 400 nm (4.13).

9-Ethyl-9,10-dihydro-9-azaanthracen-10-one (*N*-ethylacridone) (**5d**) was also prepared from *N*-ethylacridinium salt, mp 162.5—163.0 °C (lit,[31] 159 °C); IR (KBr): 1625 cm^{-1} (C=O); UV (CH_2Cl_2): 258 (log ε=4.84), 268 sh (4.54), 277 (4.45), 294 (3.87), 306 (3.76), 363 sh (3.81), 381 sh (4.12), and 401 nm (4.26).

10*H*-9-oxaanthracen-10-one (xanthone) (**5e**) was a commercial material, mp 173.0—174.0 °C (from EtOH); IR (KBr): 1670 cm^{-1} (C=O); UV (CH_2Cl_2): λ_{max}=239 (log ε= 4.70), 261.5 (4.15), 277 sh (3.68), 286.5 sh (3.69), 327 sh (3.81), and 341.5 nm (3.89).

10*H*-9-thiaanthracen-10-one 9-oxide (**5f**) was prepared by the oxidation of **5b** with *m*-chloroperbezoic acid (1.33 eq.) in dichloromethane at room temperature and separated from **5b** and its sulfone by dry column chromatography (SiO_2/CH_2Cl_2), yield 50% together with 30% of sulfone, mp 205—206 °C (lit,[32] 199—201 °C); IR (KBr): 1675 (C=O), 1040, and 1095 cm^{-1} (SO); UV(CH_2Cl_2): λ_{max}=284 sh (log ε= 4.17) and 340 nm (3.67).

10*H*-9-thiaanthracen-10-one 9,9-dioxide (**5g**) was prepared by the oxidation of **5b** with *m*-chloroperbenzoic acid (2 eq.) in dichloromethane at room temperature, yield 90%; mp 190.0—191.0 °C (lit,[33] 185.5—186 °C); IR (KBr): 1680, 1310, 1300, 1170, and 1145 cm^{-1} (SO_2); UV (CH_2Cl_2): λ_{max}=286 sh (log ε=3.96); (CH_3CN): λ_{max}=229.5 (log ε= 4.32), 237 sh (4.23), 254 sh (3.88), 263 (3.89), and 283 nm (3.89).

9-Fluorenone (**5h**) was a commercial material, mp 83.0—84.0 °C (from PhH-EtOH); IR (KBr): 1700 cm^{-1} (C=O); UV (CH_2Cl_2): λ_{max}=250.5 (log ε=4.91), 259 (5.15), 284.5 sh (3.84), 296 (3.90), 311.5 sh (3.72), 327.5 sh (3.57), 358 sh (2.43), 378 (2.50), and 398 sh nm (2.46).

Tetraphenylcyclopentadienone (**5i**) was prepared by the reported method, mp 218—220 °C (lit,[34] mp 218—220 °C); UV (CH_2Cl_2): λ_{max}=262 (log ε=4.46), 340 (3.88), and 510 nm (3.03); (CH_3CN): λ_{max}=260 (log ε=4.40) and 338 nm (3.79); (CH_3CN with HBF_4): λ_{max}=258.5 (log ε= 4.40), 337 (3.81), and 502 nm (3.09).

7*H*-benz[d,e]anthracen-7-one (**5j**) was a commercial material, mp 169.0—170.0 °C (from PhH-EtOH); UV (CH_2Cl_2): λ_{max}=231.5 (log ε=4.60), 237 (4.56), 242 (4.51), 254 (4.46), 276 sh (4.06), 285 (4.07), 310 (4.03), 338 sh (3.66), 355 sh (3.86), 389 (4.13), and 407 sh (4.06).

10,10-Dibenzyl-9(10*H*)-anthracenone was prepared by refluxing 9(10*H*)-anthracenone and benzyl chloride with aq. sodium hydroxyde in THF, mp 232.0—233.0 °C. IR (KBr): 1650 cm^{-1} (C=O).

*Preparation of 2-Phosphonio-1,3-dithiole Salts (**2**). General Procedure*: Tertiary phosphine (10 mmol) was added to a stirred solution of 1,3-dithiolylium tetrafluoroborate (**1**: 10 mmol) in dry acetonitrile (50 ml) at room temperature. After stirring for 2 h, the solvent was evaporated to about 10 ml under reduced pressure. Dry ether (50 ml) was added to the residue and the precipitates were collected, washed with ether, and recrystallized from ethanol.

2-Triphenylphosphonio-1,3-benzodithiole tetrafluoroborate (**2a**), yield 87%; mp 211.5—212.5 °C (dec); IR (KBr): 1140—1020 and 520 (BF_4^-), 1430, 770, 760, 750, 740, 730, 720, 700, and 690 cm^{-1}; ^1H-NMR (DMSO-d_6): δ 6.7—7.3 (m, 5H, aromatic and 2-CH), and 7.3—8.2 (m, 15H, aromatic).

Found: C, 59.94; H, 4.05%. Calcd for $C_{25}H_{20}BF_4PS_2$: C, 59.78; H, 4.01%.

2-Tributylphosphonio-1,3-benzodithiole tetrafluoroborate (**2b**), yield 90%; mp 166.5—168.0 °C; IR (KBr): 1140—1020 and 520 (BF_4^-), 1440, and 760 cm^{-1}; ^1H-NMR (DMSO-d_6): δ 0.5—2.5 (m, 27H, *n*-Bu), 6.42 (bs, 1H, PCH), and 7.0—7.6 (m, 4H, aromatic).

Found: C, 51.30; H, 7.52%. Calcd for $C_{19}H_{32}BF_4PS_2$: C, 51.59; H, 7.29%.

4,5-Dimethyl-2-triphenylphosphonio-1,3-dithiole tetrafluoroborate (**2c**), yield 84%; mp 175.0—177.0 °C (dec); IR (KBr): 1120—1140 and 520 (BF_4^-), 1430, 750, 730, 720, and 690 cm^{-1}; ^1H-NMR (DMSO-d_6): δ 1.30 (s, 6H, 4- and 5-Me), 7.35 (bs, 1H, 2-CH), and 7.2—8.4 (m, 15H, aromatic).

Found: C, 57.29; H, 4.65%. Calcd for $C_{23}H_{22}BF_4PS_2$: C, 57.51; H, 4.62%.

*Preparation of 2-Dialkoxyphosphinyl-1,3-dithiole (**3**). General Procedure*: Trialkyl phosphite (10 mmol) and sodium iodide (1.5 g, 10 mmol) were added successively to a stirred solution of 1,3-dithiolylium tetrafluoroborate (10 mmol) in dry acetonitrile (50 ml) under a nitrogen atmosphere at room temperature . The reaction took place rapidly and was slightly exothermic. Stirring was continued for about 30 min, and the solvent was evaporated *in vacuo*. The residue was extracted with dichloromethane (30 ml×3) after addition of water (50 ml). The combined extracts were

dried over anhydrous magnesium sulfate and dichloromethane was removed under reduced pressure. The residue was recrystallized from ethyl acetate or ethanol to give 2-dialkoxyphosphinyl-1,3-dithiole.

2-Dimethoxyphosphinyl-1,3-benzodithiole (**3a**), yield 80%; mp 122.0—123.0 °C (from EtOH); IR (KBr): 1260 (P=O), 1050, and 1035 cm^{-1} (P-O-C): ^{1}H-NMR ($CDCl_3$): δ 3.63 (d, J_{POCH}=10.4 Hz, 6H, $POCH_3$), 4.75 (d, J_{PCH}=5.8 Hz, 1H, PCH), and 6.7—7.3 (m, 4H, aromatic); ^{31}P-NMR ($CDCl_3$): δ_P −19 ppm; MS: *m/e* 262 (M^+, 8%), 153 ($M^+-P(O)(OMe)_2$, 100), and 77 (Ph^+, 21).

Found: C, 41.01; H, 4.14; S, 24.40%. Calcd for $C_9H_{11}O_3PS_2$: C, 41.21; H, 4.23; S, 24.45%.

2-Diethoxyphosphinyl-1,3-benzodithiole (**3b**), yield 95%; mp 115.5—116.5 °C (from EtOH); IR (KBr): 1250 (P=O), 1050, and 1030 cm^{-1} (P-O-C); ^{1}H-NMR ($CDCl_3$): δ 1.22 (t, J_{HCCH}=6.8 Hz, 6H, $POCCH_3$), 4.15 (dq, J_{POCH}=7.7, J_{HCCH}=6.8 Hz, 4H, $POCH_2$), 4.89 (d, J_{PCH}=5.2 Hz, 1H, PCH), and 6.9—7.3 (m, 4H, aromatic). The triplet signal at δ 1.22 of $POCCH_3$ was irradiated to give a doublet signal at δ 4.15 for $POCH_2$ with a coupling constant of 7.7 Hz. MS: *m/e* 290 (M^+, 4.4%), 153 ($M^+-P(O)(OEt)_2$, 100), and 77 (Ph^+, 23).

Found: C, 45.43; H, 5.25; S, 22.21%. Calcd for $C_{11}H_{15}O_3PS_2$: C, 45.51; H, 5.21; S, 22.09%.

4,5-Dimethyl-2-dimethoxyphosphinyl-1,3-dithiole (**3c**); After usual work-up, the product was submitted to dry column chromatography over neutral alumina (activity III) with dichloromethane. The fraction (R_f 0.2—0.4) was eluted with ethyl acetate to give 83% yield of **3c**. This compound has low melting point (<20 °C), and is so hygroscopic and sensitive to air in an oily state or in solution that it could not be purified enough for elemental analysis. IR (neat): 1255 (P=O), 1180, 1055, and 1030 cm^{-1}; ^{1}H-NMR (CCl_4): δ 1.83 (s, 6H, 4,5-dimethyl), 3.80 (d, J_{POCH}=10.4 Hz, 6H, $POCH_3$), and 4.73 (d, J_{PCH}=4.5 Hz, 1H, PCH).

Found: C, 33.52; H, 5.23%. Calcd for $C_7H_{13}O_3PS_2$: C, 34.99, H, 5.45%.

2-Dimethoxyphoshinyl-4-phenyl-1,3-dithiole (**3d**), yield 90%; mp 87.0—88.0 °C (from AcOEt); IR (KBr): 1255 (P=O), 1180, 1065, and 1040 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 3.89 (d, J_{POCH}=10.5 Hz, 6H, $POCH_3$), 5.06 (d, J_{PCH}=4.5 Hz, 1H, PCH), 6.24 (s, 1H, 5-CH), and 7.2—7.5 (m, 5H, aromatic); MS: *m/e* 288 (M^+, 9.4%), 179 ($M^+-P(O)(OMe)_2$, 100); metastable ion, found: 111.3, calcd for 288→179: 111.25.

Found: C, 45.82; H, 4.55; S, 21.91%. Calcd for $C_{11}H_{13}O_3PS_2$: C, 45.82; H, 4.54; S, 22.24%.

Wittig Reaction of (1,3-Benzodithiol-2-ylidene)triphenylphosphorane (Method A). General Procedure: To a suspension of 2-triphenylphosphonio-1,3-benzodithiole tetrafluoroborate (**2a**) (1.005 g, 2.0 mmol) in THF (50 ml) was added butyllithium in hexane (1.5 ml, 2.3 mmol) at −78 °C under a nitrogen atmosphere with stirring. Stirring was continued for 2.0—2.5 h to give a dark red solution of (1,3-benzodithiol-2-ylidene)triphenylphosphorane (*A*). A carbonyl compound (2.0 mmol) was added at −78 °C. Immediately the dark red color of the solution turned yellow. The mixture was allowed to get warm to room temperature and the solvent was evaporated under reduced pressure. The residue was extracted with dichloromethane (30 ml×3) after addition of water (50 ml). The combined extracts were dried over anhydrous magnesium sulfate, dichloromethane was removed under reduced pressure, and the residue was submitted to dry column chromatography over silica gel (activity III) with carbon tetrachloride as a developing solvent. The fraction of R_f value 0.7—0.9 was eluted with dichloromethane or ether to give 2-alkylidene-1,3-benzodithiole (**4**) and the fraction of R_f value 0.1—0.2 was eluted with ethyl acetate to give triphenylphosphine oxide.

Reaction of **2a** with *p*-anisaldehyde gave triphenylphosphine oxide, yield 75%, mp 155.0—156.0 °C (from AcOEt), and 2-(*p*-methoxyphenylmethylene)-1,3-benzodithiole (**4b**), yield 77%; mp 144.5—145.5 °C (from ErOH-Et_2O); IR (KBr): 1250, 1180, and 1040 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 3.83 (s, 3H, OCH_3), 6.51 (s, 1H, olefinic), and 6.8—7.6 (m, 8H, aromatic); MS: *m/e* 272 (M^+, 88%), 257 (M^+-Me, 100), and 229 (257−CO, 26).

Found: C, 66.17; H, 4.38; S, 23.36%. Calcd for $C_{15}H_{12}OS_2$: C, 66.14; H, 4.44; S, 23.54%.

Reaction of **2a** with *p*-tolualdehyde gave triphenylphosphine oxide (74%) and 2-(*p*-tolylmethylene)-1,3-benzodithiole (**4c**), yield 75%; mp 149.5—151.0 °C (from EtOH); IR (KBr): 1580, 1550, 1445, 1430, 1130 and 930 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 2.33 (s, 3H, Me), 6.51 (s, 1H, olefinic), and 6.9—7.5 (m, 8H, aromatic); MS: *m/e* 256 (M^+, 100%), 140 ($C_6H_4S_2^{+\cdot}$, 14), 128 (M^{2+}, 14), and 115 ($M^+-C_6H_5S_2$, 20).

Found: C, 70.52; H, 4.58; S, 24.88%. Calcd for $C_{15}H_{12}S_2$: C, 70.27; H, 4.72; S, 25.01%.

Reaction of **2a** with benzaldehyde gave triphenylphosphine oxide (72%) and 2-benzylidene-1,3-benzodithiole (**4d**), yield 74%; mp 133.0—134.5 °C (from EtOH); IR (KBr): 1580, 1470, and 1430 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 6.60 (s, 1H, olefinic) and 7.0—7.6 (m, 9H, aromatic); MS: *m/e* 242 (M^+, 100%), 165 (M^+-Ph, 18), 140 ($C_6H_4S_2^{+\cdot}$, 39), 121 (M^{2+}, 37), and 108 (140−S, 18).

Found: C, 69.25; H, 4.10; S, 26.33%. Calcd for $C_{14}H_{10}S_2$: C, 69.38; H, 4.16; S, 26.46%.

Reaction of **2a** with *p*-chlorobenzaldehyde gave triphenylphosphine oxide (79%) and 2-(*p*-chlorophenylmethylene)-1,3-benzodithiole (**4e**), yield 82%; mp 190.0—190.8 °C (from EtOH); IR (KBr): 1580, 1540, and 1100 cm^{-1}; ^{1}H-NMR ($CDCl_3$ with CF_3CO_2H[35]): δ 5.05 (s, 2H, benzyl proton), 7.1—7.7 (m, 4H, aromatic), and 7.8—8.7 (m, 4H, aromatic); MS: *m/e* 278 (M^+ for ^{37}Cl, 47%), 277 (M^+-1, 24), 276 (M^+, for ^{35}Cl, 100), 240 (M^+-HCl, 24), and 140 ($C_6H_4S_2^{+\cdot}$, 47).

Found: C, 60.52; H, 3.21; S, 22.89; Cl, 12.99%. Calcd for $C_{14}H_9S_2Cl$: C, 60.75; H, 3.28; S, 23.17; Cl, 12.81%.

Reaction of **2a** with cinnamaldehyde gave triphenylphosphine oxide (80%) and 2-(3-phenyl-2-propenylidene)-1,3-benzodithiole (**4f**), yield 78%; mp 148.0—149.0 °C (from EtOH-Et_2O); IR (KBr): 1570, 1540, 960, and 950 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 5.9—6.8 (m, 3H, olefinic) and 6.8—7.5 (m, 9H, aromatic); MS: *m/e* 268 (M^+, 94%), 140 ($C_6H_4S_2^{+\cdot}$, 23), 134 (M^{2+}, 20), and 128 ($M^+-C_6H_4S_2^{+\cdot}$, 100).

Found: C, 71.60; H, 4.39; S, 24.02%. Calcd for $C_{16}H_{12}S_2$: C, 71.60; H, 4.51; S, 23.89%.

Reaction of **2a** with *p*-dimethylaminobenzaldehyde did not proceed and a red color of the phosphorane did not disappear up to room temperature. Therefore, the solution was refluxed for 30 min, when the solution slightly darkend. Many products were observed by TLC, however, the expected product (**4a**) could not be isolated.

Wittig-Horner Reaction of 2-Dimethoxyphosphinyl-1,3-benzodithiole (3a) (Method B). General Procedure: Butyllithium in hexane (1.5 ml, 2.3 mmol) was added to a stirred solution of 2-dimethoxyphosphinyl-1,3-benzodithiole (**3a**) (524.6 mg, 2.0 mmol) in THF (20 ml) at −78 °C under a nitrogen atmosphere. After 10 min, a carbonyl compound (2.0 mmol) was added to the yellow solution of the resulting phosphonate carbanion (*B*). The mixture was stirred for 10 min at −78 °C, allowed to get warm to room temperature,

and THF was evaporated under reduced pressure. The residue was extracted with dichloromethane (30 ml×3) after addition of water (50 ml). The combined extracts were dried over anhydrous magnesium sulfate, dichloromethane removed under reduced pressure, and the residue was recrystallized from an appropriate solvent to give the corresponding 2-alkylidene-1,3-benzodithiole (1,4-benzodithiafulvene) (**4**).

Reaction of **3a** with *p*-dimethylaminobenzaldehyde gave 2-(*p*-dimethylaminophenylmethylene)-1,3-benzodithiole (**4a**), yield 95%; mp 145.0—146.0 °C (from EtOH); IR (KBr): 1600, 1510, 1440, and 1360 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 2.97 (s, 6H, N-CH_3), 6.47 (s, 1H, olefinic), and 6.6—7.4 (m, 8H, aromatic); MS: *m/e* 285 (M^+, 100%), 270 (M^+ —Me, 28), 240 (M^+ —Me_2NH, 10), and 142.5 (M^{2+}, 26): metastable ion, found: 255.5, calcd for 285→270: 255.7.

Found: C, 66.81; H, 5.21; N, 4.82: S, 22.60%. Calcd for $C_{16}H_{15}NS_2$: C, 67.33; H, 5.30; N, 4.91; S, 22.47%.

Reaction of **3a** with *p*-tolualdehyde gave 2-(*p*-tolylmethylene)-1,3-benzodithiole (**4c**), yield 94%; mp 150.0—151.0 °C (from EtOH).

Reaction of **3a** with *trans*-2-butenal gave 2-(2-butenylidene)-1,3-benzodithiole (**4g**), yield 95%; mp 72.0—73.0 °C (from ethanol–hexane); IR (KBr): 1540, 1440, 1430, and 960 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 1.79 (d, J_{HCCH}=6.0 Hz, 3H, CH_3), 5.2—6.3 (m, 3H, olefinic), and 6.9—7.4 (m, 4H, aromatic); MS: *m/e* 206 (M^+, 100%), 205 (M^+—H, 31), 179 (205—C_2H_2, 39), and 140 ($C_6H_4S_2^{+\cdot}$, 39).

Found: C, 63.53; H, 4.83; S, 31.00%. Calcd for $C_{11}H_{10}S_2$: C, 64.03; H, 4.89; S, 31.08%.

Reaction of **3a** with cyclopentanone gave 2-cyclopentylidene-1,3-benzodithiole (**4h**), yield 96%; mp 105.5—107.0 °C (from EtOH); IR (KBr): 1440, 1420, and 1120 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 1.4—2.6 (m, 8H, aliphatic)and 6.7—7.4 (m, 4H, aromatic); MS: *m/e* 220 (M^+, 100%), 219 (M^+—H, 31), 192 (M^+—C_2H_4, 97), 179 (M^+—C_3H_5, 14), 166 (M^+—C_4H_6, 23), and 153 (M^+—C_5H_7, 29).

Found: C, 65.43; H, 5.44; S, 29.04%. Calcd for $C_{12}H_{12}S_2$: C, 65.41; H, 5.49; S, 29.10%.

Reaction of **3a** with cyclohexanone gave 2-cyclohexylidene-1,3-benzodithiole (**4i**), yield 98%; mp 96.0—97.5 °C (from EtOH); IR (KBr): 1420, 1120, and 740 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 1.2—1.8 (m, 6H, 3′-CH_2, 4′-CH_2 and 5′-CH_2), 1.8—2.2 (m, 4H, 2′-CH_2 and 6′-CH_2), and 6.7—7.3 (m, 4H, aromatic); MS: *m/e* 234 (M^+, 100%), 233 (M^+—H, 21), 205 (233—C_2H_4, 39), 179 (M^+—C_4H_7, 31), 166 (M^+—C_5H_8, 31), and 153 (M^+—C_6H_9, 53).

Found: C, 66.37; H, 6.28; S, 27.24%. Calcd for $C_{13}H_{14}S_2$: C, 66.62; H, 6.02; S, 27.36%.

Reaction of **3a** with 3,5,5-trimethyl-2-cyclohexen-1-one gave 2-(3,5,5-trimethyl-2-cyclohexenylidene)-1,3-benzodithiole (**4j**), yield 87%; mp 99.0—100.0 °C (from EtOH); IR (KBr): 1560, 1540, 1440, 1420, and 1120 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 0.95 (s, 6H, 5′,5′-dimethyl), 1.7—1.95 (m, 5H, 3′-CH_3 and 4′-CH_2), 1.97 (s, 2H, 6′-CH_2), 5.85—5.95 (m, 1H, 2′-CH), and 6.9—7.4 (m, 4H, aromatic). The multiplet signal at δ 1.7—1.95 was irradiated to give a singlet signal at δ 5.9 for 2′-CH. Protonation occurred at 3′-position, giving a conjugated cation; ^{1}H-NMR ($CDCl_3$ with CF_3CO_2H): δ 1.02 (s, 3H, 5′-CH_3), 1.20 (s, 3H, 5′-CH_3), 1.29 (d, J_{HCCH}=6.8 Hz, 3H, 3′-CH_3), 1.5—1.75 (m, 2H, 4′-CH_2), 2.47 (br s, 2H, 6′-CH_2), 2.6—2.9 (m, 1H, 3′-CH), 7.58 (br s, 1H, 2′-H), and 7.8—8.5 (m, 4H, aromatic). MS: *m/e* 274 (M^+, 100%), 259 (M^+—Me, 36), 231 (259—C_2H_4, 13), 153 (M^+—C_9H_{13}, 44), and 121 (C_9H_{13}, 23); metastable ion, found, 244.9, calcd for 274→259: 244.8.

Found: C, 69.95; H, 6.61; S, 23.05%. Calcd for $C_{16}H_{18}S_2$: C, 70.02; H, 6.61; S, 23.37%.

Reaction of **3a** with benzylideneacetone gave 2-(1-methyl-3-phenyl-2-propenylidene)-1,3-benzodithiole (**4k**), yield 96%; mp 170.0—171.0 °C (from EtOH); IR (KBr): 955, 750, and 695 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 1.99 (s, 3H, 1′-CH_3), 6.44 (d, J_{HCCH}=16 Hz, 1H, olefinic), 7.03 (d, J_{HCCH}=16 Hz, 1H olefinic), and 7.0—7.7 (m, 9H, aromatic); MS: *m/e* 282 (M^+, 100%), 153 (M^+—PhC_4H_4, 30), 142 (M^+—$C_6H_4S_2$, 71), and 141 (142—H, 44); metastable ion, found: 71.6, calcd for 282→142: 71.5.

Found: C, 72.14; H, 4.89; S, 22.39%. Calcd for $C_{17}H_{14}S_2$: C, 72.30; H, 5.00; S, 22.71%.

Reaction of **3a** with *p*-methylacetophenone gave 2-(1-*p*-tolylethylidene)-1,3-benzodithiole (**4l**), yield 92%; mp 80.0—81.0 °C (from EtOH); ^{1}H-NMR ($CDCl_3$): δ 2.15 (s, 3H, 2′-CH_3), 2.38 (s, 3H, ArMe), and 6.8—7.5 (m, 8H, aromatic); MS: *m/e* 270 (M^+, 100%), 269 (M^+—H, 31), 255 (M^+—Me, 8), 179 (M^+—tolyl, 17), and 153 (M^+—C_9H_9, 33); metastable ion, found: 240.9, calcd for 270→255: 240.8.

Found: C, 70.96; H, 5.18; S, 23.86%. Calcd for $C_{16}H_{14}S_2$: C, 71.07; H, 5.22; S, 23.71%.

Reaction of **3a** with acetophenone gave the crude product which was submitted to dry column chromatography over silica gel with carbon tetrachloride as an eluent to afford oily 2-(1-phenylethylidene)-1,3-benzodithiole (**4m**), yield 94%; IR (neat): 3050, 1590, 1435, 1130, and 1035 cm^{-1}; ^{1}H-NMR (CCl_4): δ 2.09 (s, 3H, CH_3) and 6.7—7.5 (m, 9H, aromatic); MS: *m/e* 256 (M^+, 100%), 255 (M^+—H, 17), 179 (M^+—Ph, 12), and 153 (M^+—C_8H_7, 11); metastable ion, found: 125.1, calcd for 256→179: 125.16.

Found: C, 70.12; H, 4.67; S, 24.88%. Calcd for $C_{15}H_{12}S_2$: C, 70.27; H, 4.72; S, 25.01%.

Reaction of **3a** with *p*-chloroacetophenone gave 2-(1-*p*-chlorophenylethylidene)-1,3-benzodithiole (**4n**), 91%; mp 97.0—98.0 °C (from hexane); IR (KBr): 1580, 1480, 1425, 1095, and 1015 cm^{-1}; ^{1}H-NMR (CCl_4): δ 2.10 (s, 3H, CH_3) and 6.7—7.4 (m, 8H, aromatic); MS: *m/e* 292 (M^+, for ^{37}Cl, 39%), 291 (M^+—H, 30), 290 (M^+, for ^{35}Cl, 100), 289 (M^+—H, 30), 255 (M^+—Cl, 12), and 153 (M^+—C_8H_6Cl, 31); metastable ion, found 224.2, calcd for 290→255: 224.2.

Found: C, 62.25; H, 3.72; S, 22.07%. Calcd for $C_{15}H_{11}S_2Cl$: C, 61.95; H, 3.81; S, 22.05%.

Reaction of **3a** with 4,4′-dimethoxybenzophenone gave 2-[bis(*p*-methoxyphenyl)methylene]-1,3-benzodithiole (**4o**), yield 96%; mp 105.0—106.0 °C (from ethyl acetate and hexane); IR (KBr): 1600, 1495, 1240, 1170, 1030 cm^{-1}; UV (CH_2Cl_2): λ_{max}=247 (logε=4.55), 256 sh (4.49), 326 nm (4.35); ^{1}H-NMR (CCl_4): δ 3.78 (s, 6H, OCH_3), 6.78 (d, J=8.6 Hz, 4H, aromatic), 7.00 (br s, 4H, aromatic), and 7.20 (d, J=8.6 Hz, 4H, aromatic); MS: *m/e* 378 (M^+, 100%) and 363 (M^+—Me, 43); metastable ion, found: 349.0, calcd for 378→363: 348.6.

Found: C, 69.76; H, 4.60; S, 17.21%. Calcd for $C_{22}H_{18}O_2S_2$: C, 69.81; H, 4.79; S, 16.94%.

Reaction of **3a** with benzophenone gave 2-(diphenylmethylene)-1,3-benzodithiole (**4p**), yield 80%; mp 96.0—97.0 °C (from ethyl acetate and hexane); IR (KBr): 1570, 1535, 1435, and 1130 cm^{-1}; UV (CH_2Cl_2): λ_{max}=244 (log ε=4.51), 252 sh (4.43), and 329 nm (4.34); MS: *m/e* 318 (M^+, 100%) and 178 (M^+—$C_6H_4S_2$, 36).

Found: C, 75.15; H, 4.29; S, 20.09%. Calcd for $C_{20}H_{14}S_2$: C, 75.43; H, 4.43; S, 20.14%.

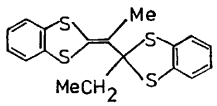
Reaction of **3a** with 4,4′-dichlorobenzophenone gave 2-[bis(*p*-chlorophenyl)methylene]-1,3-benzodithiole (**4p**), yield 95%; mp 113.0—114.0 °C (from EtOH); IR (KBr): 1480, 1100, and 1020 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 7.1 (br s, 4H, aromatic) and 7.3 (br s, 8H, aromatic); MS: *m/e* 390 (M^+,

for two ^{37}Cl, 18%), 389 (17), 388 (M^+, for one ^{37}Cl and one ^{35}Cl, 68), 387 (23), and 386 (M^+ for two ^{35}Cl, 100); ESCA: $S_{2P\,3/2}=163.1\pm0.15$ eV.

Found: C, 61.98; H, 3.42; S, 16.70; Cl, 18.50%. Calcd for $C_{20}H_{12}S_2Cl_2$: C, 62.02; H, 3.12; S, 16.56; Cl, 18.31%.

Reaction of **3a** with 3-buten-2-one gave crude 2-(1-methyl-2-propenylidene-1,3-benzodithiole (**4r**), yield 53%; mp 87.0—89.0 °C (from ethanol and hexane); IR (KBr): 1595, 1440, and 1425 cm^{-1}; ^1H-NMR ($CDCl_3$): δ 1.86 (s, 3H, CH_3), 4.8—5.3 (m, 2H, olefinic CH), 6.2—6.8 (m, 1H, olefinic CH), and 6.8—7.4 (m, 4H, aromatic); MS: *m/e* 206 (M^+, 100%), 205 (M^+-H, 31), 179 ($M^+-C_2H_3$, 26), 166 ($M^+-C_3H_4$, 91), and 153 ($M^+-C_4H_5$, 21); metastable ion, found: 133.9, calcd for 206→166: 133.8. This compound was not so stable as to give an analytically pure sample.

Reaction of **3a** with acetaldehyde in 1.0 mmol scale gave a crude product (170 mg). However, purification by preparative thin-layer chromatography (SiO_2/CCl_4) afforded only a trace amount of a dimeric compound. The structure of the compound was proposed to be shown below from its ^1H-NMR spectral data. ^1H-NMR (CCl_4): δ 1.07 (t, J= 7 Hz, 3H, $-C-CH_3$), 1.99 (s, 3H, CH_3), 2.42 (q, J=7 Hz, 2H, CH_2-C), and 6.7—7.6 (m, 8H, aromatic).



Reaction of **3a** with 9(10*H*)-anthracenone gave a reaction mixture which was submitted to dry column chromatography over neutral alumina with dichloromethane to give 9,10-anthracenedione (73%, mp 285 °C) together with recovered **3a** (41%).

Reaction of **3a** with 10,10-dibenzyl-9(10*H*)-anthracenone did not take place even under reflux for 30 min. A large amount of the ketone was recovered (70—80%).

Reaction of 2-dimethoxyphosphinyl-4-phenyl-1,3-dithiole (**3d**) with 4,4'-dichlorobenzophenone in 1.0 mmol scale gave 4-phenyl-2-[bis(*p*-chlorophenyl)methylene]-1,3-dithiole, yield 83%; mp 183.5—185.0 °C (from methanol and hexane); IR (KBr): 1480, 1100, 1090, and 1020 cm^{-1}; ^1H-NMR ($CDCl_3$): δ 6.40 (s, 1H, olefinic) and 7.2—7.5 (m, 13H, aromatic); MS: *m/e* 416 (M^+ for two ^{37}Cl, 15%), 415 (16), 414 (M^+, for one ^{37}Cl and one ^{35}Cl, 74), 413 (22), and 412 (M^+ for two ^{35}Cl, 100).

Found: C, 64.07; H, 3.20; Cl, 16.65%. Calcd for $C_{22}H_{14}S_2Cl_2$: C, 63.92; H, 3.41; Cl, 17.15%.

Reaction of **3a** with dibenzo[a,d]cyclohepten-5-one (**5a**) gave 2-(dibenzo[a,d]cyclohepten-5-ylidene)-1,3-benzodithiole (**6a**), yield 83%; mp 179.0—180.0 °C (from EtOH); IR (KBr): 1570, 1440, 1425, and 1125 cm^{-1}; UV (CH_2Cl_2): λ_{max}=232 (log ε=4.73), 273 (4.39), 299 (4.37), and 340 sh nm (4.15); ^1H-NMR ($CDCl_3$): δ 6.83 (s, 2H, olefinic), 7.00 (s, 4H, aromatic), 7.2—7.7 (m, 8H, aromatic); MS: *m/e* 342 (M^+, 100%), 308 (M^+-H_2S, 16), 234 ($M^+-C_6H_4S$, 13), 202 ($M^+-C_6H_4S_2$, 35), and 189 ($M^+-C_7H_5S_2$, 35); ESCA: $S_{2P\,3/2}=163.3\pm0.15$ eV.

Found: C, 77.38; H, 3.93; S, 18.54%. Calcd for $C_{22}H_{14}S_2$: C, 77.16; H, 4.12; S, 18.72%.

Reaction of **3a** with 10*H*-9-thiaanthracen-10-one (**5b**) gave 10-(1,3-benzodithiol-2-ylidene)-10*H*-9-thiaanthracene (**6b**), yield 88%; mp 219.0—220.0 °C (from EtOH); IR (KBr): 1525, 1445, 1425, and 1125 cm^{-1}; UV (CH_2Cl_2): λ_{max}=243.5 (logε=4.69), 270.5 sh (4.16), 312 sh (4.05), and 363 nm (4.36); MS: *m/e* (M^+, 100%); ESCA: $S_{2P\,3/2}=162.9\pm0.15$ eV.

Found: C, 68.73; H, 3.54%. Calcd for $C_{20}H_{12}S_3$: C, 68.93; H, 3.47%.

Reaction of **3a** with 9-methyl-9,10-dihydro-9-azaanthracen-10-one (**5c**) in 1.0 mmol scale gave 9-methyl-10-(1,3-benzodithiol-2-ylidene)-9,10-dihydro-9-azaanthracene (**6c**) yield 62%; mp 210.0—211.0 °C (from EtOH). Refluxing of the mixture (30 min) was necessary to effect the reaction. IR (KBr): 1455, 750, and 740 cm^{-1}; UV (CH_2Cl_2): λ_{max}=238 (logε=4.77), 262.5 sh (4.26), 314 (4.18), 395 nm (4.30); ^1H-NMR ($CDCl_3$): δ 3.39 (s, 3H, $N-CH_3$) and 6.8—7.7 (m, 12H, aromatic); MS: *m/e* 345 (M^+, 100%), 330 (M^+-Me, 77), 222 ($330-C_6H_4S$, 10), and 172.5 (M^{2+}, 12); ESCA: $S_{2P\,3/2}=162.9\pm0.15$ eV.

Found: C, 72.90; H, 4.38; N, 4.31; S, 18.68%. Calcd for $C_{21}H_{15}NS_2$: C, 73.01; H, 4.38; N, 4.05; S, 18.56%.

Reaction of **3a** with 9-ethyl-9,10-dihydro-9-azaanthracen-10-one (**5d**) in 1.0 mmol scale gave 9-ethyl-10-(1,3-benzodithiol-2-ylidene)-9,10-dihydro-9-azaanthracene (**6d**), yield 56%; mp 205.0—206.0 °C (from EtOH). Refluxing of the mixture was necessary to effect the reaction. IR (KBr): 1455, 1445, and 1260 cm^{-1}; UV (CH_2Cl_2): λ_{max}=238 (logε= 4.73), 263 sh (4.26), 314 (4.18), and 399 nm (4.28); ^1H-NMR ($CDCl_3$): δ 1.43 (t, J=6.8 Hz, 3H, $N-C-CH_3$), 4.03 (q, J= 6.8 Hz, 2H, $N-CH_2-C$), and 6.9—7.7 (m, 12H, aromatic); MS: *m/e* 359 (M^+, 72%), 330 (M^+-Et, 100), and 296 ($330-H_2S$, 9); metastable ion, found: 303.3, calcd for 359→330: 303.3.

Found: C, 73.60; H, 4.78; N, 3.84; S, 17.50%. Calcd for $C_{22}H_{17}NS_2$: C, 73.50; H, 4.77; N, 3.90; S, 17.84%.

Reaction of **3a** with 10*H*-9-oxaanthracen-10-one (**5e**) gave 10-(1,3-benzodithiol-2-ylidene)-10*H*-9-oxaanthracene (**6e**), yield 84%; mp 202.0—203.0 °C (from EtOH); IR (KBr): 1440, and 1265 cm^{-1}; UV (CH_2Cl_2): λ_{max}=255 sh (log ε= 4.44), 300 (4.01), and 370 nm (4.42); MS: *m/e* 332 (M^+, 100%) and 166 (M^{2+}, 29); ESCA: $S_{2P\,3/2}=163.2\pm0.15$ eV.

Found: C, 72.50; H, 3.48; S, 19.36%. Calcd for $C_{20}H_{12}OS_2$: C, 72.26; H, 3.64; S, 19.29%.

Reaction of **3a** with 10*H*-9-thiaanthracen-10-one 9-oxide (**5f**) in 1.0 mmol scale gave 10-(1,3-benzodithiol-2-ylidene)-10*H*-9-thiaanthracene 9-oxide (**6f**), yield 75%; mp 246.0—247.5 °C (from EtOH); IR (KBr): 1090 and 1040 (S=O) cm^{-1}; MS: *m/e* 364 (M^+, 48%), 348 (M^+-O, 76), 316 (M^+-SO, 39), 212 ($M^+-C_7H_4S_2$, 85), and 196 ($M^+-C_7H_4OS_2$, 100).

Found: C, 65.05; H, 3.05%. Calcd for $C_{20}H_{12}OS_3$: C, 65.90; H, 3.32%.

Reaction of **3a** with 10*H*-9-thiaanthracen-10-one 9,9-dioxide (**5g**) in 1.0 mmol scale gave 10-(1,3-benzodithiol-2-ylidene)-10*H*-9-thiaanthracene 9,9-dioxide (**6g**), yield 92%; mp 315.0—316.0 °C (from EtOH); IR (KBr): 1570, 1520, 1300 (SO_2, asym.), 1170, and 1165 (SO_2, sym) cm^{-1}; UV (CH_2Cl_2): λ_{max}=402 nm (logε=4.24); (MeCN): λ_{max}=265 (logε=4.06), 295.5 (3.72), 318.5 (3.76), and 396 nm (4.32); MS: *m/e* 380 (M^+, 100%) and 316 (M^+-SO_2, 7).

Found: C, 62.57; H, 2.99%. Calcd for $C_{20}H_{12}O_2S_3$: C, 63.13; H, 3.18%.

Reaction of **3a** with 9-fluorenone (**5h**) gave 2-(9-fluorenylidene)-1,3-benzodithiole (**6h**), yield 96%; mp 205.0—206.0 °C (from EtOH and $CHCl_3$). This compound was only slightly soluble in usual solvents such as benzene, chloroform, ethanol, and dimethyl sulfoxide. IR (KBr): 1540, 1440, and 775 cm^{-1}; UV (CH_2Cl_2): λ_{max}=251 (logε=4.98), 298 (4.00), 309 (4.02), 329 sh (4.07), 388 (4.68), 402 sh nm (4.66); (MeCN): λ_{max}=248.5 (log ε=4.83), 273 sh (3.88), 296.5 sh (3.66), 307.5 sh (3.71), 326 sh (3.79), 385 (4.52), and 400 sh nm (4.49); ESCA: $S_{2P\,3/2}=163.4\pm0.15$ eV; MS: *m/e* 316 (M^+, 100%) and 158 (M^{2+}, 29).

Found: C, 75.76; H, 4.12; S, 20.30%. Calcd for $C_{20}H_{12}S_2$: C, 75.91; H, 3.82; S, 20.27%.

Reaction of **3a** with tetraphenylcyclopentadienone (**5i**) gave 2-(tetraphenylcyclopentadienylidene)-1,3-benzodithiole (**6i**), yield 75%; mp 383—385 °C (from $CHCl_3$ and EtOH). This compound was only slightly soluble in usual solvents. IR (KBr): 1475, 1460, and 885 cm^{-1}; UV (CH_2Cl_2): λ_{max}= 247 sh (logε=4.45), 255.5 (4.50), 274 sh (4.39), and 435 nm (4.60); (MeCN): λ_{max}=244.5 sh (logε=4.33), 253 (4.38), 272 sh (4.24), and 430 nm (4.45); (MeCN with HBF_4): λ_{max}=232 sh (logε=4.43), 314 sh (3.75), and 532 nm (4.44); MS: *m/e* 520 (M^+, 100%).

Found: C, 82.70; H, 4.86; S, 11.71%. Calcd for $C_{36}H_{24}S_2$: C, 83.04; H, 4.65; S, 12.32%.

Reaction of **3a** with 7*H*-benz[d,e]anthracen-7-one (**5j**) gave 2-(7*H*-benz[d,e]anthracen-7-ylidene)-1,3-benzodithiole (**6j**), yield 80%; mp 256.0—257.0 °C (from $CHCl_3$ and EtOH); IR (KBr): 830, 770, and 735 cm^{-1}; UV (CH_2Cl_2): λ_{max}= 247.5 sh (logε=4.66), 272 sh (4.38), 318 (4.40), and 424 nm (4.49); MS: *m/e* 366 (M^+, 100%), 332 (M^+-H_2S, 14), and 183 (M^{2+}, 47).

Found: 78.37; H, 3.58; S, 17.36%. Calcd for $C_{24}H_{14}S_2$: C, 78.65; H, 3.85; S, 17.50%.

Reaction of **3a** with 9,10-anthracenedione in 1.0 mmol scale gave yellow crystals of 9,10-bis(1,3-benzodithiol-2-ylidene)-9,10-dihydroanthracene, yield 73%; mp 262.0—263.0 °C (from EtOH); UV (CH_2Cl_2): λ_{max}=237 (log ε= 4.34), 273 sh (3.77), 352 sh (3.78), 395 sh (3.89), and 416 nm (3.97); ESCA: $S_{2P\ 3/2}$=162.9±0.15 eV; MS: *m/e* 480 (M^+, 100%) and 240 (M^{2+}, 51).

Found: C, 69.70; H, 3.16; S, 26.28%. Calcd for $C_{28}H_{16}S_4$: C, 69.96; H, 3.36; S, 26.68%.

General Synthesis of Phosphonates from Heteroniaanthracene Cations and Their Use in Wittig-Horner Reaction

Kiyofumi ISHIKAWA, Kin-ya AKIBA,* and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received April 11, 1978)

Heteroaromatic cations such as 9-heteroniaanthracene (acridinium, xanthylium, and thioxanthylium) and 1-thionianaphthalene (thiochromenylium) ions reacted with trimethyl phosphite in the presence of sodium iodide in acetonitrile at room temperature to give the corresponding phosphonates (**2** and **4**) respectively in 76—92% yields. The phosphonates were deprotonated with butyllithium in THF at −78 °C, and the resulting carbanions reacted with *p*-tolualdehyde, cinnamaldehyde, and 4,4′-dichlorobenzophenone to afford the corresponding exomethylene containing heterocyclic compounds, respectively, in 52—96% yields. However, the phosphonate carbanions derived from **2** did not react with cycloalkanones and butanal.

The reactions of heteroaromatic cations with a wide variety of nucleophiles have been investigated extensively. However, there are only a few reports on the reactions with phosphorus nucleophiles such as phosphines and phosphites.[1] Evenmore, the utilization of the expected reaction products (*e.g.*, phosphonium salts or phosphonates) as reagents for carbonyl olefination has been described only by two reports, one on the use of the phosphonium salt obtained from pyrylium perchlorate[1a], and the other on that of phosphonates obtained from acridinium salts.[1f]

The preceding paper and its preliminary reports showed that 1,3-dithiolylium salts reacted with phosphines or phosphites to give the corresponding phosphonium salts or phosphonates in high yields and that they, especially the latter, could be used in Wittig-Horner reaction to give various derivatives of 1,4-dithiafulvenes and fulvalenes in high yields.[2] Consequently, versatile utility in the synthesis of heterocyclic compounds was expected for analogous phosphonates, if they could be prepared from heteroaromatic cations and trialkyl phosphite.

We report here a general synthesis of the phosphonates[3] from heteroaromatic cations such as acridinium, xanthylium, thioxanthylium, and thiochromenylium ions, and their use in Wittig-Horner reaction.

Results and Discussion

Preparation of Phosphonates from Heteroaromatic Cations. Under a nitrogen atmosphere at room temperature, trimethyl phosphite was added at once to a stirred solution of 9-heteroniaanthracene salt (acridinium, xanthylium, or thioxanthylium salts) (**1a**—**f**) in dry acetonitrile, then immediately sodium iodide was added,

TABLE 1. YIELDS, MP, AND IR SPECTRAL DATA OF THE PHOSPHONATES (**2**)

Compound	Yield (%)	Mp (°C)	IR (KBr) (cm^{-1}) $\nu_{P=O}$	ν_{P-O-C}	
2a	85	170.0—171.0	1225	1055(as)	1030(s)
2b	85	98.0—99.0	1270 or 1240	1045(as)	1020(s)
2c	92	100.0—100.5	1260 or 1250	1060(as)	1020(s)
2d	76	147.0—148.0	1240	1060(as)	1030(s)
2e	90	132.0—133.0	1255	1050(as)	1020(s)
2f	87	194.0—195.0	1245	1055(as)	1025(s)

and the solution was stirred for 1 h. Usual treatment of the mixture gave the corresponding phosphonate (**2a**—**f**) in high yields. The results are shown in Table 1.

The structure of **2a**—**f** was confirmed by means of elemental analyses, IR, ^{1}H-NMR, and mass spectra.

As shown in Table 1, the IR spectra of **2a**—**f** showed strong absorption bands at 1225—1270 (P=O), 1045—1060, and 1020—1030 cm^{-1} (P-O-C). The IR spectrum of **2a** showed also a sharp absroption band at 3270 cm^{-1} (NH).

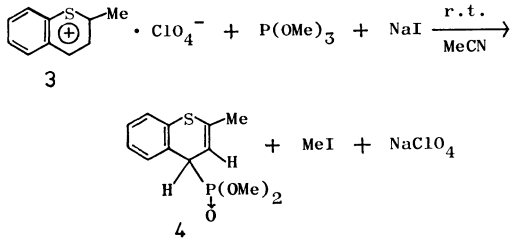
All **2a**—**f** gave reasonable ^{1}H-NMR spectra, each of which showed a doublet signal at δ 3.46—3.53 due to $POCH_3$ (J_{POCH}=10.5 Hz), and a doublet signal at δ 4.49—4.69 with a relatively large value of coupling constnat (J=24.8—28.7 Hz) assignable to PCH. This fact will be discussed later.

The ^{31}P-NMR spectrum of **2e** exhibited a signal at δ_P −24 ppm supporting the phosphonate structure.[4]

The mass spectra of the phosphonates (**2a**—**f**) showed the parent peak (3—6%), the base peak assignable to $M^+-P(O)(OMe)_2$, and the metastable peak due to the direct fragmentation of the parent ion to the $M^+-P(O)(OMe)_2$ ion.

As described above, it was ascertained first that the Michaelis-Arbuzov reaction of 9-heteroniaanthracene salt (**1a**—**f**) with trimethyl phosphite proceeded easily even at room temperature in the presence of sodium iodide in acetonitrile, similarly to the case of 1,3-dithiolylium salt.[2]

Furthermore, 2-methyl-1-thionianaphthalene perchlorate [(2-methyl)thiochromenylium perchlorate] (**3**) was also allowed to react with trimethyl phosphite under the same conditions to give 4-dimethoxyphosphinyl-2-methyl-4*H*-1-thianaphthalene (**4**; yield 91%) exclusively.



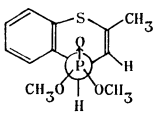
Scheme 2.

The structure of **4** was confirmed by means of elemental analysis, IR, ^{1}H-NMR, and mass spectra, and was also supported by the result of its reaction with 4,4'-dichlorobenzophenone described later. The isomeric structure, 2-dimethoxyphosphinyl-2-methyl-2*H*-1-thianaphthalene was ruled out based on the ^{1}H-NMR spectral data.

The IR spectrum of **4** showed strong absorptions at 1240 (P=O), 1055, and 1025 cm^{-1} (P–O–C).

The phosphonate (**4**) exhibits a rather complex ^{1}H-NMR spectrum compared with those of **2** due to the presence of an asymmetric carbon atom at the 4-position, however, it is fully assigned as shown in Table 2.

Table 2. ^{1}H-NMR spectral data of the phosphonate (**4**) (in $CDCl_3$)



δ 2.06 (3H, ddd, J_{PCCCCH}=6.0, J_{HCCCH}=1.4, J_{HCCCCH}=0.9 Hz, 2-C-CH_3);
3.61 (3H, d, J_{POCH}=10.4 Hz, $POCH_3$);
3.72 (3H, d, J_{POCH}=10.4 Hz, $POCH_3$);
4.18 (1H, qdd, J_{PCH}=28.5, J_{HCCH}=6.8, J_{HCCCCH}=0.9 Hz, 4-CH);
5.62 (1H, qdd, J_{HCCH}=6.8, J_{PCCH}=4.2, J_{HCCCH}=1.4 Hz, 3-CH);
7.18 (4H, br s, aromatic H)

There are two significant features in relation to the coupling constants between phosphorus and hydrogen: (a) the J_{PCH} value (28.5 Hz) is one of the largest ones ever known and is much larger than J_{PCCH} (4.2 Hz), usually the reverse should be the case,[5] and (b) the long range coupling between phosphorus and 2-C–CH_3 (J_{PCCCH}=6.0 Hz) is exceptionally large. These facts were confirmed by comparison of the spectra obtained at 60 MHz and at 100 MHz. Moreover, the 2-C–CH_3 signal was irradiated to give double doublet signals for 3-CH and 4-CH with the coupling constants shown above.

The mass spectrum of **4** showed the parent peak at *m/e* 270 (5%), the base peak at *m/e* 161 assignable to $M^+-P(O)(OMe)_2$, and the metastable peak at *m/e* 96.0 due to the direct fragmentation of the parent ion to the $M^+-P(O)(OMe)_2$ ion.

Chemical shifts and coupling constants of PCH of related phosphonates are shown in Table 3. These facts can be summarized as follows: i) coupling constants (J_{PCH}) of phosphonates of 1,3-dithioles lie around 5 Hz, these of 1,3-oxathioles around 8 Hz, those of 1,3-dioxoles around 30 Hz, and those of 1-hetera-2,5-cyclohexadienes around 27 Hz and ii) an electronegative group increases the coupling constants.

Table 3. Chemical shifts and coupling constants of PCH of related phosphonates (in $CDCl_3$)

Compound		PCH (δ)	J_{PCH} (Hz)
		4.75	5.8
		4.73	4.5

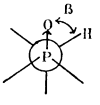
	X=OTs	5.62	15.5

a) In CCl_4.

Costisella and Gross suggested recently that there is a relationship similar to Karplus equation between the value of J_{PCH} and the dihedral angle (β) for phosphinyl-containing compounds.[6b] However, bond lengths (C–H and C–P) and bond angle ($\angle$HCP) should also be important factors and detailed discussion cannot be given here.



Wittig-Horner Reaction of the Phosphonates. Under a nitrogen atmosphere at −78 °C, butyllithium in hexane was added to stirred solution of the phosphonate (**2a**, **b**, **e**, or **f**) in tetrahydrofuran (THF). The resulting carbanion was allowed to react with a carbonyl compound to give the exo-methylene-containing compound (**5**) in a high yield. The reaction with *p*-tolu-

Table 4. Yields and mp of 5 and 6

Product	X	R^1	R^2	Yield (%)	Mp (°C)

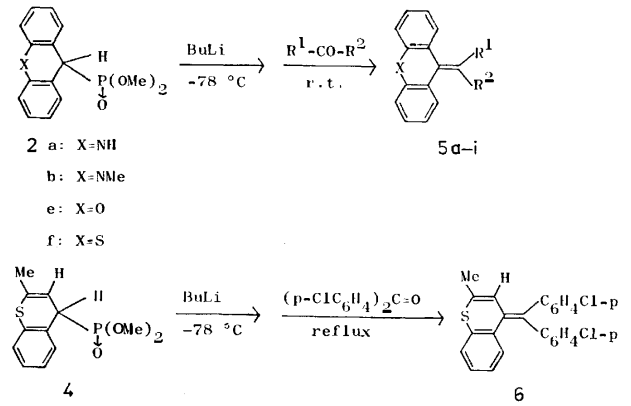
a) See the text.

aldehyde and cinnamaldehyde took place rapidly at low temperature (—78 °C to room temperature) but that with 4,4′-dichlorobenzophenone was effected in refluxing THF. The phosphonate (**4**) was also deprotonated and the resulting carbanion reacted with 4,4′-dichlorobenzophenone to give 4-[bis(*p*-chlorophenyl)methylene]-2-methyl(thiochromene) (**6**). The reaction of **2f** and 4,4′-dichlorobenzophenone did not proceed even under reflux, and the starting materials were recovered (**2f**; 58%; ketone, 73%).[7] The results are shown in Table 4.



Scheme 3.

The structures of **5** and **6** were confirmed by means of elemental analyses, IR, ^{1}H-NMR, and MS. The molecular ion peak is in each case the most intense peak in the mass spectra except for **5e** (M^+, 63%; M^+—Ph, 100%). The structure of **5a** was confirmed to be 9-(*p*-methylbenzyl)acridine formed by prototropy of the initially produced benzylidene type compound (absence of NH in IR and presence of a methylene group in NMR).

Furthermore, the reaction of the phosphonate carbanion derived from **2b** or **2e** with cycloalkanones (*e.g.*, cyclohexanone or cyclopentanone) and butanal was tried, however, the expected product could not be obtained even under reflux and the starting material (**2b** or **2e**) was recovered exclusively. The inertness of the reaction seems to be attributable chiefly to steric hindrance between the peri-hydrogens of the phosphonate (**2**) and the α-methylene hydrogens of a carbonyl compound.

Experimental

All the melting points are not corrected. IR spectra were measured with a Hitachi EPI-G2 spectrometer, ^{1}H-NMR spectra with Hitachi R-20B, Hitachi R-24 (60 MHz), and JEOL JNM-4H-100 (100 MHz) spectrometers (TMS as an internal standard), and MS with a Hitachi RMU-6L mass spectrometer at 70 eV. ^{31}P-NMR spectra were measured with a Hitachi R-20B-R-204-PB (24.3 MHz) spectrometer using 85% phosphoric acid as an external standard.

*Materials: 9-Azoniaanthracene Salts (Acridinium Salts) (**1a—d**).* Each 9-azoniaanthracene salt was prepared by the reaction of 9-azaanthracene (aciridine) with RX in good yields.

Compound	R	X	Mp (°C)
1a	H	Cl	220.5—222 (dec)[1c),a)]
1b	Me	$MeSO_4$	207—208 (dec)[8),a)]
1c	Et	$EtSO_4$	275—277 (dec)[8),a)]
1d	$PhCH_2$	Br	225—227 (dec) [lit,[9] 209 (dec)]

a) Melting points were not indicated for **1a**, **1b**, and **1c** in the literatures.

9-Oxoniaanthracene perchlorate (xanthylium perchlorate) (**1e**) was prepared by the treatment of 10*H*-9-oxaanthracen-10-ol (mp 125—126 °C, lit,[10] 124—126 °C), which was obtained by the reduction of xanthone (5.89 g, 0.03 mol) with sodium borohydride (2.3 g) in refluxing absolute methanol (150 ml), with 70% perchloric acid (20 ml) in dry ether (200 ml) at —78 °C, mp 237 °C (dec) (lit,[11] mp 225—226 °C), total yield 7.40 g (88%).

9-Thioniaanthracene perchlorate (thioxanthylium perchlorate) (**1f**) was prepared from thioxanthone (6.4 g, 0.03 mol) by the same procedure as **1e** in total ylied of 6.14 g (69%), mp 229—230 °C (dec) (lit, mp 217—219 °C[12], 229 °C[13]).

2-Methyl-1-thionianaphthalene perchlorate (**3**) was prepared from 2-methyl-4*H*-1-thianaphthalen-4-one[14] (5.28 g, 0.03 mol) by the same procedure as **1e** in total yield of 5.70 g (73%), mp 143—145 °C. This compound was colored blue due to the presence of a small amount of impurity (*e.g.*, cyanine dye) but was used for the next step without further

purification because of its instability.

Michaelis-Arbuzov Reaction of Heteroaromatic Cations with Trimethyl Phosphite. General Procedure: Trimethyl phosphite (1.2 ml, 10 mmol) was added to a stirred solution of heteroaromatic cation (10 mmol) in dry acetonitrile (50 ml) at room temperature under nitrogen and then followed with dry sodium iodide (1.5 g, 10 mmol). After the mixture had been stirred for 1 h, the solvent was evaporated under reduced pressure. Water (50 ml) was added to the residue and the product was extracted with dichloromethane (30 ml×3). The combined extracts were dried over anhydrous magnesium sulfate and the solvent was removed under reduced pressure. Recrystallization of the residue from ethyl acetate and ether gave the corresponding phosphonate. Dry column chromatography (neutral alumina) was often used for purification.

Reaction of 9-azoniaanthracene chloride (**1a**) with trimethyl phosphite gave 10-dimethoxyphosphinyl-9,10-dihydro-9-azaanthracene (**2a**), yield 85%, mp 170.0—171.0 °C (from AcOEt); IR (KBr): 3270 (NH), 1480, 1225 (P=O), 1055, and 1030 cm^{-1} (P–O–C); ^{1}H-NMR ($CDCl_3$): δ 3.53 (d, J_{POCH}=10.5 Hz, 6H, $POCH_3$), 4.58 (d, J_{PCH}=24.9 Hz, 1H, PCH), and 6.5—7.4 (m, 9H, aromatic and NH); MS: *m/e* 289 (M^+, 4%), 180 ($M^+-P(O)(OMe)_2$, 100), 179 (180 −H, 15), and 152 (180−CH_2N, 5); metastable ion, found: 112.1 calcd for 289→180: 112.1; found: 128.4, calcd for 180→152: 128.36.

Found: C, 62.19; H, 5.66; N, 4.62%. Calcd for $C_{15}H_{16}NO_3P$: C, 62.28; H, 5.58; N, 4.84%.

Reaction of 9-methyl-9-azoniaanthracene methyl sulfate (**1b**) with trimethyl phosphite gave 10-dimethoxyphosphinyl-9-methyl-9,10-dihydro-9-azaanthracene (**2b**), yield 85%, mp 98.0—99.0 °C (from AcOEt and Et_2O); IR (KBr): 1580, 1470, 1240 (P=O), 1045, and 1020 cm^{-1} (P–O–C); ^{1}H-NMR ($CDCl_3$): δ 3.39 (s, 3H, NCH_3), 3.49 (d, J_{POCH}=10.5 Hz, 6H, $POCH_3$), 4.55 (d, J_{PCH}=26.1 Hz, 1H, PCH), and 6.7—7.5 (m, 8H, aromatic); MS: *m/e* 303 (M^+, 6%), 194 ($M^+-P(O)(OMe)_2$, 100), and 179 (194−Me, 17); metastable ion, found: 124.2, calcd for 303→194: 124.21; found: 165.2, calcd for 194→179: 165.16.

Found: C, 63.11; H, 6.05; N, 4.53%. Calcd for $C_{16}H_{18}NO_3P$: C, 63.36; H, 5.98; N, 4.62%.

Reaction of 9-ethyl-9-azoniaanthracene ethyl sulfate (**1c**) with trimethyl phosphite gave 10-dimethoxyphosphinyl-9-ethyl-9,10-dihydro-9-azaanthracene (**2c**), yield 92%, mp 100.0—100.5 °C (from PhH and CH_2Cl_2); IR (KBr): 1590, 1260 or 1250 (P=O), 1060, and 1020 cm^{-1} (P–O–C); ^{1}H-NMR ($CDCl_3$): δ 1.38 (t, J=6.8 Hz, 3H, N-C-CH_3), 3.46 (d, J_{POCH}=10.5 Hz, 6H, $POCH_3$), 3.99 (q, J=6.8 Hz, 2H, N-CH_2-C), 4.52 (d, J_{PCH}=25.5 Hz, 1H, PCH), and 6.7—7.5 (m, 8H, aromatic); MS: *m/e* 317 (M^+, 6%), 208 ($M^+-P(O)(OMe)_2$, 100), 180 (208−C_2H_4, 22), and 152 (180−CH_2N, 4); metastable ion, found: 136.5, calcd for 317→208: 136.48; found 155.8, calcd for 208→180: 155.77; found 128.4, calcd for 180→152: 128.36.

Found: C, 64.16; H, 6.44; N, 4.57%. Calcd for $C_{17}H_{20}NO_3P$: C, 64.35; H, 6.35; N, 4.41%.

Reaction of 9-benzyl-9-azoniaanthracene bromide (**1d**) with trimethyl phosphite gave 9-benzyl-10-dimethoxyphosphinyl-9,10-dihydro-9-azaanthracene (**2d**), yield 76%, mp 147.0—148.0 °C (from AcOEt); IR (KBr): 1470, 1240 (P=O), 1060, and 1030 cm^{-1} (P–O–C); ^{1}H-NMR ($CDCl_3$): δ 3.52 (d, J_{POCH}=10.5 Hz, 6H, $POCH_3$), 4.62 (d, J_{PCH}=25.7 Hz, 1H, PCH), 5.18 (s, 2H, N–CH_2–Ph), and 6.5—7.5 (m, 13H, aromatic); MS: *m/e* 379 (M^+, 6%), 270 ($M^+-P(O)(OMe)_2$, 100), and 179 (270−$PhCH_2$, 19); metastable ion, found: 192.4, calcd for 379→270: 192.35.

Found: C, 69.58; H, 5.98; N, 3.51%. Calcd for $C_{22}H_{22}NO_3P$: C, 69.65; H, 5.85; N, 3.69%.

Reaction of 9-oxoniaanthracene perchlorate (**1e**) with trimethyl phosphite gave 10-dimethoxyphosphinyl-10*H*-9-oxaanthracene(**2e**), yield 90%, mp 132.0—133.0 °C (from AcOEt and Et_2O) (lit,[15] 128—129 °C); IR (KBr): 1475, 1255 (P=O), 1050, and 1020 cm^{-1} (P–O–C); ^{1}H-NMR ($CDCl_3$): δ 3.53 (d, J_{POCH}=10.5 Hz, 6H, $POCH_3$), 4.49 (d, J_{PCH}=24.8 Hz, 1H, PCH), and 6.9—7.5 (m, 8H, aromatic): ^{31}PNMR ($CDCl_3$): δ_P−24 ppm; MS: *m/e* 290 (M^+, 3%), and 181 ($M^+-P(O)(OMe)_2$, 100).

Reaction of 9-thioniaanthracene perchlorate (**1f**) with trimethyl phosphite gave 10-dimethoxyphosphinyl-10*H*-9-thiaanthracene (**2f**), yield 87%, mp 194.0—195.0 °C (from AcOEt and Et_2O); IR (KBr): 1245 (P=O), 1055 and 1025 cm^{-1} (P–O–C); ^{1}H-NMR ($CDCl_3$): δ 3.52 (d, J_{POCH}=10.5 Hz, 6H, $POCH_3$), 4.69 (d, J_{PCH}=28.7 Hz, 1H, PCH), and 7.1—7.5 (m, 8H, aromatic); MS: *m/e* 306 (M^+, 5%) and 197 ($M^+-P(O)(OMe)_2$, 100).

Found: C, 58.63; H, 5.06; S, 10.55%. Calcd for $C_{15}H_{15}O_3PS$: C, 58.82; H, 4.94; S, 10.47%.

Reaction of 2-methyl-1-thioniaanaphthalene perchlorate (**3**) with trimethyl phosphite gave 4-dimethoxyphosphinyl-2-methyl-4*H*-1-thianaphthalene (**4**), yield 91%, mp 99.0—100.0 °C (from AcOEt); IR (KBr): 1240 (P=O), 1055, and 1025 cm^{-1} (P–O–C); ^{1}H-NMR ($CDCl_3$): δ 2.06 (ddd, J_{PCCCCH}=6, J_{HCCCH}=1.4, J_{HCCCCH}=0.9 Hz, 3H, 2-C-CH_3), 3.61 (d, J_{POCH}=10.4 Hz, 3H, $POCH_3$), 3.72 (d, J_{POCH}=10.4 Hz, 3H, $POCH_3$), 4.18 (qdd, J_{PCH}=28.5, J_{HCCH}=6.8, J_{HCCCH}=0.9 Hz, 1H, 4-CH), 5.62 (qdd, J_{HCCH}=6.8, J_{PCCH}=4.2, J_{HCCCH}=1.4 Hz, 1H, 3-CH), and 7.18 (br s, 4H, aromatic); (100 MHz, in $CDCl_3$): δ 2.06 (ddd, 3H, 2-C-CH_3), 3.61 (d, 3H, $POCH_3$), 3.72 (d, 3H, $POCH_3$), 4.18 (qdd, 1H, 4-CH), 5.62 (qdd, 1H, 3-CH), and 7.18 (br s, 4H, aromatic). The 2-C-CH_3 signal at δ 2.06 was irradiated to give double doublet signals for 3-CH (δ 5.62) and 4-CH (δ 4.18) with the coupling constants shown above.

MS: *m/e* 270 (M^+, 5%), 161 ($M^+-P(O)(OMe)_2$, 100), 128 (161−SH, 10), and 155 (161−CH_2S, 6); metastable ion, found: 96.0, calcd for 270→161: 96.0; found 101.8, calcd for 161→128: 101.76.

Found: C, 53.17; H, 5.84; S, 11.37%. Calcd for $C_{12}H_{15}O_3PS$: C, 53.33; H, 5.59; S, 11.86%.

Witting-Horner Reaction of the Phosphonates Derived from Heteroaromatic Cations. General Procedure: To a stirred solution of a phosphonate (1.0 mmol) in THF (10 ml), butyllithium in hexane (0.75 ml, 1.15 mmol) was added at −78 °C under nitrogen. The solution colored yellow or yellowish brown due to the resulting carbanion. After 10 min, a solution of a carbonyl compound (1.0 mmol) in THF (5—10 ml) was added. Stirring was continued for 10 min at −78 °C and the mixture was then allowed to get warm to room temperature. When the carbonyl compound was not an aldehyde but a ketone, the reaction mixture was heated under reflux for 30 min. The solvent was evaporated under reduced pressure and the mixture was extracted with dichloromethane (20 ml×3) after addition of water (50 ml). The combined extracts were dried over anhydrous magnesium sulfate, the solvent was evaporated, and the residue was recrystallized to give the corresponding product.

Reaction of **2a** with *p*-tolualdehyde gave 9-(*p*-methylbenzyl) acridine (**5a**), yield 53%, mp 164.0—166.0 °C (dec) (from MeOH); IR (KBr): 1510, 770, 760, and 740 cm^{-1}; ^{1}H-NMR (CCl_4): δ 2.24 (s, 3H, CH_3), 4.89 (s, 2H, CH_2), 6.95 (s, 4H, aromatic), and 7.1—8.4 (m, 8H, aromatic); MS: *m/e* 283 (M^+, 100%), 282 (M^+−H, 49), 268 (M^+−Me, 50), 267 (268−H, 38), 141 (282^{2+}, 15), and 134 (268^{2+}, 31).

Reaction of **2e** with *trans*-3-phenyl-2-propenal gave 9-(3-phenyl-2-propenylidene)xanthene (**5f**), yield 91%, mp 91.0—92.0 °C (from EtOH); IR (KBr): 1595, 1450, 1310, 1270, 945, 770, 765, 750, and 695 cm^{-1}; ^1H-NMR (CCl_4): δ 6.4—7.8 (m, aromatic and olefinic); MS: *m/e* 296 (M^+, 100%), 295 (M^+-H, 86), 219 (M^+-Ph, 97), and 218 (296—Ph, 46).

Found: C, 89.02; H, 5.21%. Calcd for $C_{22}H_{16}O$: C, 89.16; H, 5.44%.

Reaction of **2f** with *trans*-3-phenyl-2-propenal gave 9-(3-phenyl-2-propenylidene)thioxanthene (**5g**), yield 92%, mp 165.0—166.0 °C (from EtOH); IR (KBr): 1455, 1430, 970, 765, 740, and 690 cm^{-1}; ^1H-NMR (CCl_4): δ 6.4—7.8 (m, aromatic and olefinic); MS: *m/e* 312 (M^+, 100%), 311 (M^+-H, 68), 235 (M^+-Ph, 78), 234 (311—Ph, 40), 221 (235—CH_2, 26), and 202 (235—SH, 11).

Found: C, 84.85; H, 5.00; S, 10.22%. Calcd for $C_{22}H_{16}S$: C, 84.58; H, 5.16; S, 10.26%.

Reaction of **2b** with 4,4′-dichlorobenzophenone gave 10-methyl-9-[bis(*p*-chlorophenyl)methylene]-9,10-dihydroacridine (**5h**), yield 52%, mp 257.0—258.0 °C (from EtOH); IR (KBr): 1590, 1455, 1350, 1095, 820, 810, and 755 cm^{-1}; ^1H-NMR (CCl_4 and $CDCl_3$, 1:1): δ 3.50 (s, 3H, N-CH_3) and 6.4—7.5 (m, 16H, aromatic); MS: *m/e* 431 (M^+ for two ^{37}Cl, 12%), 430 (25), 429 (M^+ for one ^{37}Cl and one ^{35}Cl, 80), 428 (44), and 427 (M^+ for two ^{35}Cl, 100).

Found: C, 75.95; H, 4.48; N, 3.32; Cl, 16.98%. Calcd for $C_{27}H_{19}NCl_2$: C, 75.71; H, 4.47; N, 3.27; Cl, 16.55%.

Reaction of **2e** with 4,4′-dichlorobenzophenone gave 9-[bis(*p*-chlorophenyl)methylene]xanthene (**5i**), yield 95%, mp 209.0—210.0 °C (from MeOH); IR (KBr): 1440, 1250, 1090, 1015, 825, 760, and 755 cm^{-1}; MS: *m/e* 418 (M^+ for two ^{37}Cl, 14%), 417 (20), 416 (M^+ for one ^{37}Cl and one ^{35}Cl, 68), 415 (32), 414 (M^+ for two ^{35}Cl, 100), 378 (M^+-HCl, 28), and 342 (378—HCl, 17).

Found: C, 75.49; H, 3.63; Cl, 16.95%. Calcd for $C_{26}H_{16}OCl_2$: C, 75.19; H, 3.88; Cl, 17.07%.

Reaction of **2f** with 4,4′-dichlorobenzophenone gave no expected product and the starting materials (4,4′-dichlorobenzophenone, 73%, and **2f**, 58%) were recovered. Moreover, 10*H*-9-thiaanthracen-10-one was detected by thin-layer chromatography (SiO_2/CH_2Cl_2).

Reaction of **2b** or **2e** with cycloalkanones (*e.g.*, cyclohexanone and cyclopentanone) did not take place under general procedure and the color of the carbanion (**2b**, brown; **2e**, orange) disappeared, when the solution was refluxed. However, the expected product could not be obtained and the starting material (**2b** or **2e**) was recovered.

Reaction of **4** with 4,4′-dichlorobenzophenone in refluxing THF for 30 min gave 2-methyl-4-[bis(4-chlorophenyl)methylene]-4*H*-1-thianaphthalene (**6**), yield 78%, mp 158.5—159.5 °C (from MeOH); IR (KBr): 1480, 1095, 825, 760, and 750 cm^{-1}; ^1H-NMR ($CDCl_3$): δ 1.99 (br s, 3H, 2-C-CH_3), 6.52 (br s, 1H, 3-CH), and 6.7—7.9 (m, 12H, aromatic); MS: *m/e* 398 (M^+ for two ^{37}Cl, 18%), 397 (20), 396 (M^+ for one ^{37}Cl and one ^{35}Cl, 72), 395 (31), 394 (M^+ for two ^{35}Cl, 100), 358 (M^+-HCl, 20), and 344 (358—CH_2, 17).

Found: C, 69.58; H, 3.84%. Calcd for $C_{23}H_{16}SCl_2$: C, 69.88; H, 4.08%.

Macrocyclic Enzyme Model Systems. Catalytic Activity of Cyclic Peptides Involving Hydrophobic Segments†

Yukito MURAKAMI,* Akio NAKANO, Kiyoshi MATSUMOTO, and Kiyoshi IWAMOTO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received April 13, 1978)

In order to develop an effective hydrolase model, BCP-1 was synthesized and its kinetic behavior investigated. The corresponding linear hexapeptide was prepared by the solid phase method and subjected to cyclization by the azide method. BCP-1 enhanced the hydrolysis of *p*-nitrophenyl carboxylates bearing a long alkyl chain. The pH-rate profile for the hydrolysis of *p*-nitrophenyl hexadecanoate (PNPP) as effected by BCP-1 was not of a bell-shaped type but a sigmoid, from which the kinetic pK_a value was estimated as 12.3. The initial reaction rate was found to level off beyond a certain range of substrate concentration (saturation-type kinetics), the kinetic data being analyzed on the basis of Michaelis-Menten scheme. The large hydrophobic binding ability of BCP-1 toward PNPP (K_m(app) $\simeq 10^{-6}$ M) was attributed to its double-layered bicyclic structure. The Hammett plot for the hydrolysis of substituted phenyl hexadecanoates gave a satisfactory linear correlation. Consequently, the acyl transfer from the bound substrate to the imidazole anion of the histidyl residue of BCP-1 was referred to the rate-determining step. The large negative entropy change for the acyl transfer step seems to indicate that the Michaelis complex does not have a conformation favorable for such acyl transfer process. The catalytic effectiveness (k_{cat}/K_m(app)) for the BCP-1 catalysis in PNPP hydrolysis is comparable to that for enzymatic hydrolysis.

Catalytic functions of macrocyclic compounds such as cycloamyloses,[1] cyclophanes,[2] and cyclic peptides[3] have been investigated in order to explore the possibility of developing novel and efficient enzyme models. Cyclic peptides would simulate enzyme functions in a more favorable manner among these model systems since all enzymes are polypeptides. A few cyclic peptides so far synthesized were constructed only with α-amino acids, their hydrolase-like functions being much lower than those of real enzymes. The low efficiency may be primarily attributed to the network formation in their interior cavity by intramolecular hydrogen bonding, so that the hydrophobic binding ability can not be exercised. Such extensive intramolecular hydrogen bonding has been observed for cyclic hexapeptides by means of NMR[4] and CD[5] measurements.

In the present study, we designed cyclic peptides which bear long-chain alkyl segments in their skeleton to reduce the extent of intramolecular hydrogen bonding interaction, providing an efficient hydrophobic cavity for binding substrates. CP-1 was designed as a papain model with the aid of a space-filling molecular model (CPK model) so that the cyclic peptide has both an imidazole group of L-His and a thiol group of L-Cys at the juxtaposition within hydrogen bonding distance. In spite of this interesting aspect, CP-1 was not obtained but its dimeric form with a disulfide bond (BCP-1) was isolated. BCP-1 has only imidazole moieties as active functional groups and is considered to exist as a double-layered structure in aqueous media due to strong hydrophobic interaction between the two cyclic skeletons. We have investigated the esterase-like activity of BCP-1 in the ester hydrolysis for which the model compound would show a profound binding ability toward the substrates. In order to clarify the catalytic mechanism involved in the ester hydrolysis effected by BCP-1, other related compounds BCP-2 and CP-3 were also prepared and their kinetic effects studied.

† Contribution No. 483 from this Department.

CP-1, *cyclo*-glycyl-L-cysteinylglycyl-L-histidyl-6-aminohexanoyl-ω-aminoundecanoyl; BCP-1, *S,S'*-bis(*cyclo*-glycyl-L-hemicystylglycyl-L-histidyl-6-aminohexanoyl-ω-aminoundecanoyl); BCP-2, *S,S'*-bis(*cyclo*-glycyl-L-hemicystyl-6-aminohexanoyl-L-alanylglycyl-ω-aminoundecanoyl); CP-3, *cyclo*-glycyl-L-alanyl-6-aminohexanoyl-L-histidylglycyl-ω-aminoundecanoyl.

Experimental

The synthetic procedures for the protected CP-1 (PCP-1) and BCP-1 are outlined in Scheme. 1. The linear hexapeptide hydrazide (**4**) was prepared by the solid phase method[6] and subjected to cyclization by the azide method.

Chloromethylated Styrene-2% Divinylbenzene Copolymer[7] (**1**). Copolystyrene-2%divinylbenzene (Protein Research Foundation, 100—200 mesh; 48 g) was made to swell in chloroform (300 ml) by stirring at room temperature for 2.5 h and was then cooled down to 0 °C. A solution of anhydrous stannic chloride (7.5 ml) in chloromethyl methyl ether (50 ml) was added to this mixture at 0 °C in 30 min, and stirred for 1 h at the same temperature. The mixture was filtered and the solid recovered was washed with dioxane-water (3 : 1 by volume, 1 litre) and subsequently with dioxane-3M HCl

Scheme 1. Synthetic procedures for BCP-1: Hex, 6-aminohexanoyl: Und, ω-aminoundecanoyl; Boc, *t*-butoxycarbonyl; Bzl, benzyl; P, styrene-2%divinylbenzene copolymer.

(3 : 1 by volume, 1 litre). The cream-colored beads were washed further with water first and then with aqueous dioxane, the dioxane content of which was increased gradually up to 100%. After the beads had been washed with pure dioxane, they were washed with dioxane-methanol with gradual increase in methanol content and finally with pure methanol. No abrupt change in solvent composition was made during the course of washing. The product was dried *in vacuo* at 100 °C: yield 53.2 g; 1.98 mmol Cl/g.

N-t-*Butoxycarbonyl-ω-aminoundecanoyl Resin (2)*. A solution of *N-t*-butoxycarbonyl-ω-aminoundecanoic acid[8] (8.94 g, 29.7 mmol) and triethylamine (3.3 ml, 24.0 mmol) in 40 ml of dry ethanol was mixed with **1** (100—200 mesh, 10.0 g). The mixture was stirred under reflux for 144.5 h and filtered to recover the resin, which was subsequently washed thoroughly with ethanol, hot ethanol, aqueous ethanol, water, aqueous methanol, and methanol, and then dried *in vacuo*; the content of ω-aminoundecanoic acid by nitrogen analysis, 0.80 mmol/g (conversion 40.4%).

N-t-*Butoxycarbonylglycyl*-S-*benzyl*-L-*cysteinylglycyl*-N^{Im}-*benzyl*-L-*histidyl-6-aminohexanoyl-ω-aminoundecanoyl Resin (3)*. A portion of **2** (4.0 g, 3.2 mmol) was coupled first with *N-t*-butoxycarbonyl-6-aminohexanoic acid[8] (Table 1) with a Shimadzu peptide synthesizer APS-80. The subsequent coupling reactions were carried out in a similar manner; modifications with regard to solvents and reagents are shown in Scheme 1. Additional washing with a solvent for the corresponding coupling reaction was carried out for the subsequent coupling steps between treatment Nos. 10 and 11 in Table 1. *N-t*-Butoxycarbonyl-N^{Im}-benzyl-L-histidine[9] and *N-t*-butoxycarbonyl-*S*-benzyl-L-cysteine[10] were prepared according to the procedures reported.

N-t-*Butoxycarbonylglycyl*-S-*benzyl*-L-*cysteinylglycyl*-N^{Im}-*benzyl*-L-*histidyl-6-aminohexanoyl-ω-aminoundecanoic Acid Hydrazide (4)*. To a suspension of protected linear hexapeptide resin **3** (4.85 g) in *N,N*-dimethylformamide (30 ml) was added freshly prepared anhydrous hydrazine (bp 113.5 °C; 5.0 ml, 157 mmol). The mixture was stirred at room temperature for 48 h, and filtered to separate the resin which was subsequently washed with *N,N*-dimethylformamide (100 ml). The filtrate and washings were combined and evaporated *in vacuo*, and the residue was treated with water (200 ml) in order to isolate the insoluble product (610 mg). The crude material was purified on a column (2.5 × 81.0 cm) of Sephadex LH-20 with methanol as an eluent: yield 560 mg (18.2% based on *N-t*-butoxycarbonyl-ω-aminoundecanoyl resin); ninhydrin test, positive; hydrazide test, positive; R_f with 1-butanol–water–acetic acid (4:2:1), 0.89; mp 144—147 °C. IR (KBr disc): 3280 (NH str.); 2910 and 2840 (CH str.); 1635 (C=O str.); 770, 730, and 700 cm^{-1} (CH bend. of benzene). NMR (DMSO-d_6, TMS): δ 1.23 (22H, s, $-NHCH_2-(CH_2)_{n-2}CH_2CO-$), 1.38 (9H, s, $(CH_3)_3CO-$), 2.02 (4H, broad, $-NHCH_2(CH_2)_{n-2}CH_2CO-$), 2.85 (2H, broad,

–NHCH(CH$_2$SCH$_2$Ph)CO–), 3.00 (4H, broad, –NHCH$_2$–(CH$_2$)$_{n-2}$CH$_2$CO–), 3.50 (4H, s, –NHCH$_2$CO–), 3.68 (2H, broad, –NHCH(CH$_2$ImCH$_2$Ph)CO–), 3.75 (2H, s, –SCH$_2$–Ph), 4.50 (2H, broad, –CH–), 5.12 (2H, s, N^{Im}-CH$_2$Ph), 6.85 (1H, s, imidazolyl H), 7.30 (10 H, s, phenyl H's), 7.62 (1H, s, imidazolyl H), 7.83—8.60 (6H, broad, –NH–), and 9.00 (2H, broad, –NHNH$_2$). Found: C, 60.83; H, 7.76; N, 14.20%. Calcd for $C_{49}H_{74}N_{10}O_8S$: C, 61.10; H, 7.74; N, 14.54%.

cyclo-*Glycyl*-S-*benzyl*-L-*cysteinylglycyl*-N^{Im}-*benzyl*-L-*histidyl*-6-*aminohexanoyl*-ω-*aminoundecanoyl* (**5**, *PCP-1*). Linear hexapeptide hydrazide **4** (884 mg, 0.98 mmol) was dissolved in freshly prepared 2M hydrogen chloride in dry methanol (60 ml), and the mixture was stirred at room temperature for 3 h and then evaporated *in vacuo*. The residue was triturated in anhydrous ether, washed with the same solvent, and dried *in vacuo* at 40 °C to give pale yellow crystals. To the product dissolved in dry *N,N*-dimethylformamide (70 ml) was added freshly prepared 1.85 M hydrogen chloride in dry tetrahydrofuran (35 ml) and isopentyl nitrite (0.5 ml, 3.69 mmol) at −30 °C. After the reaction mixture being allowed to stand at −30 °C for 90 min, the absence of residual hydrazide in it was confirmed. A mixture of 0.3 M iron(III) chloride in 0.1 M acetic acid and 0.2 M potassium hexacyanoferrate(III) in 0.1 M acetic acid was used for detection. The mixture was diluted with dry *N,N*-dimethylformamide (540 ml) at −60 °C, followed by addition of dry triethylamine (21.7 ml, 155.4 mmol). The reaction mixture was allowed to stand at −10 °C for 48 h with stirring, and evaporated *in vacuo*. The residue was treated with water (200 ml) in order to recover the insoluble product. The crude product was purified by chromatography on columns of Amberlite IR-45 (1.5×27 cm) and Amberlite IRC-50 (1.5×27 cm) with dichloromethane–methanol–*N,N*-dimethylformamide–water (32:17:5:6 by volume), and then on a column of Sephadex LH-20 (2.5×81.0 cm) with methanol to give a white solid: yield 165.2 mg; mp(dec) 207—210 °C; ninhydrin test, negative; hydrazide test, negative. IR (KBr disc): 3300 (NH str.); 2920 and 2860 (CH str.); 1640 (C=O str.); and 770, 730, and 700 cm^{-1} (CH bend. of benzene). NMR (DMSO-d_6, TMS): δ 1.25 (22H, s, –NHCH$_2$(CH$_2$)$_{n-2}$CH$_2$CO–), 2.08 (4H, broad, –NHCH$_2$–(CH$_2$)$_{n-2}$CH$_2$CO–), 2.85 (2H, broad, –NHCH(CH$_2$SCH$_2$–Ph)CO–), 3.07 (4H, broad, –NHCH$_2$(CH$_2$)$_{n-2}$CH$_2$CO–), 3.42 (4H, s, –NHCH$_2$CO–), 3.65(2H, broad, –NHCH–(CH$_2$ImCH$_2$Ph)CO–), 3.80 (2H, s, –SCH$_2$Ph), 4.50 (2H, broad, –CH–), 5.22 (2H, s, N^{Im}-CH$_2$Ph), 7.00 (1H, s, imidazolyl H), 7.38 (10H, s, phenyl H's), 7.85 (1H, s, imidazolyl H), and 7.96—8.58 (7H, broad, –NH–). Mol wt: osmometry (methanol), 830; calcd for $C_{44}H_{62}N_8O_6S$, 831.1. Found: C, 62.16; H, 7.61; N, 12.82%. Calcd for $C_{44}H_{62}N_8O_6S\cdot H_2O$: C, 62.24; H, 7.63; N, 13.20%.

S,S′-*Bis*(cyclo-*glycyl*-L-*hemicystylglycyl*-L-*histidyl*-6-*aminohexanoyl*-ω-*aminoundecanoyl*) (*BCP-1*). To a solution of the protected cyclic peptide (**5**) (100 mg, 0.12 mmol) in liquid ammonia (100 ml, distilled in the presence of sodium metal) was added a small amount of sodium metal with stirring until the blue color of the solution remained for at least 2 min. In order to quench the excess sodium metal, a small amount of ammonium chloride was added to the solution which was subsequently evaporated to dryness *in vacuo* at room temperature. The residue was then treated with water (100 ml). The insoluble product was recovered by filtration, washed thoroughly with water, and dried *in vacuo* to give a white solid: yield 52.5 mg (67%); ninhydrin test, negative; Pauly test, positive; nitroprusside test, negative; Ellman test, negative. IR (KBr disc): 3300 (NH str.); 2920 and 2860 (CH str.); 1645 cm^{-1} (C=O str.). NMR (DMSO-d_6, TMS): δ 1.23 (22H, s, –NHCH$_2$(CH$_2$)$_{n-2}$CH$_2$–CO–), 2.10 (4H, broad, –NHCH$_2$(CH$_2$)$_{n-2}$CH$_2$CO–), 2.80 (2H, broad, –NHCH(CH$_2$S–)CO–), 3.13 (4H, s, –NHCH$_2$(CH$_2$)$_{n-2}$CH$_2$CO–), 3.38 (4H, s, –NHCH$_2$CO–), 3.65 (2H, s, –NHCH(CH$_2$Im)CO–), 4.46 (2H, broad, –CH–), 6.80 (1H, s, imidazolyl H), and 7.54 (1H, s, imidazolyl H). Amino acid analysis: Hex, 0.9 (1); His, 1.0 (1); Gly, 1.9 (2); Cys, 0.8 (1). The product showed very limited solubility in water and in most organic solvents; molecular weight determination by vapor pressure osmometry was not possible. Found: C, 54.21; H, 7.77; N, 16.09%. Calcd for $C_{60}H_{98}N_{14}O_{12}S_2\cdot 2H_2O$: C, 53.87; H, 7.84; N, 16.75%.

Other Cyclic Peptides. *cyclo*-Glycyl-L-cysteinyl-6-aminohexanoyl-L-alanylglycyl-ω-aminoundecanoyl (CP-2) and CP-3 were prepared in a manner similar to that described for BCP-1. Elimination of the protecting group in the last step of the CP-2 synthesis was performed with anhydrous hydrofluoric acid.

CP-2: white powder; ninhydrin negative, nitroprusside positive, and Ellman positive at pH 8. IR (KBr disc): 3295 (NH str.); 2920 and 2850 (CH str.); 1625 and 1540 cm^{-1} (C=O str.). NMR (DMSO-d_6, TMS): δ 1.22 (22H, s, –NHCH$_2$(CH$_2$)$_{n-2}$CH$_2$CO–), 2.15 (4H, broad, –NHCH$_2$(CH$_2$)$_{n-2}$CH$_2$CO–), 2.77 (2H, broad, –CH$_2$SH), 3.04 (4H broad, –NHCH$_2$(CH$_2$)$_{n-2}$CH$_2$CO–), 3.63 (4H, s, –NHCH$_2$CO–), and 4.58 (2H, broad, –CH–). Amino acid analysis: Gly, 2.2 (2); Ala, 1.1 (1); Cys, 1.0 (1); Hex, 1.1 (1). BCP-2 was prepared by air-oxidation of CP-2 before use until nitroprusside test turned out to be completely negative.

CP-3: white powder; ninhydrin negative, and Pauly positive; R_f with 1-butanol–water–acetic acid (4 : 2 : 1 by volume), 0.53. IR (KBr disc): 3280 (NH str.); 2920 and 2850 (CH str.); 1640 and 1550 cm^{-1} (C=O str.). NMR (methanol-d_4, TMS): δ 1.32 (22H, s, –NHCH$_2$(CH$_2$)$_{n-2}$–CH$_2$CO–), 2.26 (4H, broad, –NHCH$_2$(CH$_2$)$_{n-2}$CH$_2$CO–), 3.79 (4H, s, –NHCH$_2$CO–), 4.26 (2H, broad, –CH–), 6.91 (1H, s, imidazolyl H), and 7.67 (1H, s, imidazolyl H). Amino acid analysis: Gly, 2.2 (2); Ala, 1.1 (1); His, 1.0 (1); Hex, 0.7 (1). Found: C, 56.79; H, 8.22; N, 17.02%; M^+, 619. Calcd for $C_{30}H_{50}N_8O_6\cdot H_2O$: C,56.58; H, 8.23; N, 17.59%; mol wt ($C_{30}H_{50}N_8O_6$), 618.81.

Substrates. Substituted phenyl esters were prepared by the general method[11] from acid chlorides and substituted phenols in the presence of a trace amount of magnesium and confirmed by IR and NMR spectroscopy. Analytical and physical data for the esters are given in Table 2.

Kinetic Measurements. Rates of phenol liberation from a substituted phenyl ester were measured either with a Union Giken high sensitive spectrophotometer SM-401 or with a Hitachi 124 spectrophotometer at the following wavelengths: *p*-cyanophenyl hexadecanoate, 275 nm; *p*-acetylphenyl hexadecanoate, 330 nm; *m*-nitrophenyl and *p*-nitrophenyl hexadecanoate, and other *p*-nitrophenyl esters, 400 nm. Each run was initiated by adding a dioxane solution(30 μl) of a substrate ester to a mixture of a reaction medium (3.0 ml) and a *N,N*-dimethylformamide solution (30 μl) of a catalyst, which was pre-equilibrated at an appropriate temperature in a thermostatted cell set in the spectrophotometer. The reaction temperature was maintained constant within an accuracy of ±0.1 °C. The reaction medium was prepared as follows: 10.0 ml of 1.0 M aqueous potassium chloride, 10.0 ml of an appropriate aqueous buffer, and 10.0 ml of dry dioxane were placed in a 100-ml volumetric flask; and subsequently the flask was filled with deionized and distilled water. Aqueous buffer solutions used are as follows:

1/10 M potassium dihydrogenphosphate-1/20 M sodium borate for pH 6—9, 1/20 M sodium borate-1/20 M sodium carbonate for pH 10—11, and 1/10 M sodium hydroxide —1/10 M sodium hydrogenphosphate for pH 11—12. pH Measurements were carried out with a TOA HM-9A pH meter equipped with a TOA GC-125 combined electrode after calibration with a combination of appropriate aqueous standard buffers.

Results and Discussion

Catalytic Effects and Substrate Specificity. The catalytic efficiency of BCP-1 in the hydrolysis of *p*-nitrophenyl esters of some carboxylic acids has been investigated by the kinetic method in 10.0%(v/v) dioxane–1.0%(v/v) *N*,*N*-dimethylformamide–water at μ 0.10 (KCl). Apparent pseudo-first-order rate constants were obtained from the initial stage of the reaction by measuring the amount of liberated *p*-nitrophenol. The first-order kinetics was found to hold at least up to 65% conversion of the substrate under the conditions [S]>[E]; S and E stand for substrate and catalyst species, respectively. The kinetic data are summarized in Table 3. The result shows BCP-1 only catalyzes the hydrolysis of *p*-nitrophenyl esters bearing a long alkyl chain such as *p*-nitrophenyl hexadecanoate (PNPP) and dodecanoate (PNPL). In order to observe the catalytic effect by BCP-1, the substrate is required to involve a bulky group of suf-

ficient hydrophobicity as observed for the paracyclophane catalysis.[2] The rate constants for the hydrolysis of PNPP in the presence of various synthetic catalysts are summarized in Table 4. Among the synthetic cyclic peptides employed, only BCP-1 showed a significant catalytic activity toward PNPP. On the other hand, PCP-1 and BCP-2 inhibited the alkaline hydrolysis of PNPP. This indicates that both cyclic compounds can incorporate PNPP into their cyclic skeletons, preventing the hydroxide attack on the bound substrate. It seems that hydrophobicity provided by the single layered structure of CP-3 in aqueous media is not sufficient to incorporate PNPP. The apparent second-order rate constant (k_c/[E]) for the hydrolysis catalyzed by BCP-1 is larger than that for imidazole catalysis by 4.2×10^4 fold. The high catalytic efficiency of BCP-1 is attributed to the binding capability of its hydrophobic cavity toward the substrate of hydrophobic character.

pH-Dependence of Kinetic Behavior. The pH-rate profile is not the bell-shaped type observed in enzymatic reactions,[12] but a sigmoid as shown in Fig. 1. This indicates that BCP-1 has a functional group or groups which can be activated by deprotonation above pH 12. The active functional group is referred to the anionic imidazole group of the histidyl residue: pK_a (graphically estimated), 12.3. Relative to the corresponding pK_a value for imidazole (14.5 at 25 °C and μ 0.5 in aqueous medium),[13] the pK_a value obtained for BCP-1 is somewhat lower. The intramolecular hydrogen bonding between two imidazole groups in the single molecule may act to reduce the pK_a value since these two imidazole groups in BCP-1 can be placed at the juxtaposition within their hydrogen bonding distance according to the CPK model. The access of these groups would be enhanced by the intramolecular hydrophobic interaction between the two cyclic skeletons. Our attempt to determine the pK_a of the imidazole group of L-His residue of BCP-1 by spectrophotometric or potentiometric titration was not successful due to its limited solubility. Overberger *et al.* observed that the solvolysis rate of *p*-nitrophenyl acetate is enhanced by homopolymers of 4-vinylimidazole and 5-vinylbenzimidazole. They attributed the rate enhancement to the reduction of pK_a of the polymers brought about by internal hydrogen bonding interaction.[14]

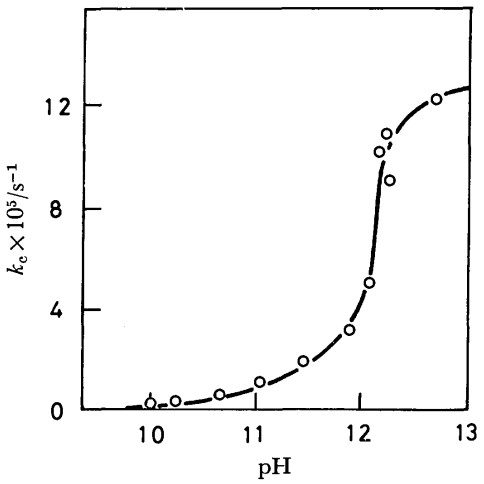

Fig. 1. pH-Rate profile for the BCP-1 catalyzed hydrolysis of *p*-nitrophenyl hexadecanoate (PNPP) in 10.0% (v/v) dioxane–1.0% (v/v) *N*,*N*-dimethylformamide–water at 40.0±0.1 °C and μ 0.10 (KCl); $k_c=k_{obsd}-k_{hyd}$. Initial concentrations: PNPP, 0.985×10^{-5} M; BCP-1, 0.49×10^{-6} M.

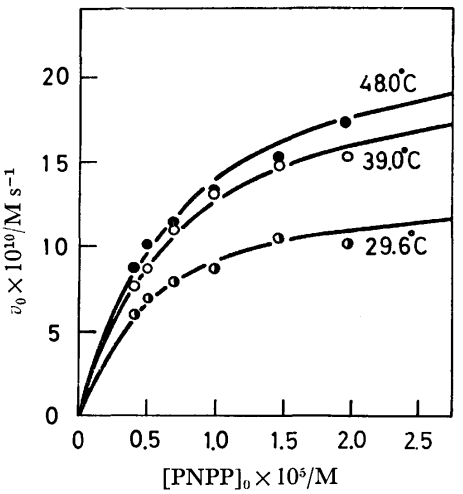

Fig. 2. Saturation-type kinetics for the hydrolysis of *p*-nitrophenyl hexadecanoate as catalyzed by BCP-1 in 10.0% (v/v) dioxane–1.0% (v/v) *N*,*N*-dimethylformamide–water at pH 12.35 and μ 0.10 (KCl): initial concentration of BCP-1, 0.49×10^{-6} M; v_0, initial reaction velocity; $[PNPP]_0$, initial concentration of PNPP.

Michaelis-Menten Analysis. The initial hydrolysis rate (v_0) as catalyzed by BCP-1 was determined at various concentrations of PNPP. The initial rate was found to level off beyond a certain range of substrate concentration (saturation-type kinetics) as seen in Fig. 2. The kinetic data were analyzed in terms of the Michaelis-Menten kinetics based on the overall reaction pathway given by the following:

$$\begin{array}{ccccccc} E + S & \overset{K_S}{\rightleftharpoons} & (ES) & \xrightarrow{k_2} & (ES)' & \xrightarrow{k_3} & E + P_2 \\ & & \downarrow{\scriptstyle k_{hyd}} & & + & & \\ & & P_1 + P_2 & & P_1 & & \end{array} \quad (1)$$

where P_1 and P_2 stand for the alcohol and the acid moiety, respectively, formed in the hydrolysis of ester substrate S; (ES) and (ES)′ are the Michaelis-type complex and the acylated catalyst, respectively; k_2 and k_3 refer to the rate constants for acylation and deacylation steps performed on the catalyst, respectively. For the three-step kinetic model, apparent Michaelis constant K_m(app) and catalytic coefficient k_{cat} are defined by Eqs. 2 and 3, respectively, on the basis of the steady-state approximation, where $K_s=[E][S]/[ES]$.

$$K_m(\text{app}) = \frac{k_3}{k_2+k_3}K_S \quad (2)$$

$$k_{cat} = \frac{k_2k_3}{k_2+k_3} \quad (3)$$

The rate of *p*-nitrophenolate (P_1) liberation was found

to follow the apparent first-order kinetics for at least 65% conversion of PNPP when [S]>[E], no detectable induction period being observed for all runs of the present study. The observations are consistent with a reaction mechanism which involves complex formation between the substrate and the catalyst followed by the rate-determining acyl-transfer step (k_2) to form acylated catalyst (ES)'. The catalyst species was regenerated through the final fast deacylation step (k_3); so-called turnover behavior was observed. In order to confirm that the acylation step is rate determining, the kinetic data obtained under [S]>[E] for the hydrolysis of substituted phenyl esters of hexadecanoic acid were treated in terms of Hammett equation. A good linear correlation (Fig. 3) indicates that the acylation step is rate determining: Eqs. 2 and 3 can be simplified as $K_m(\text{app})=K_s$ and $k_{cat}=k_2$, respectively. The evaluated ρ-value (3.5) is quite large for the ordinary nucleophilic displacement reaction at the substituted phenyl ester bond. This high sensitivity may result from a tight interaction of the ester bond with the anionic nucleophile in the desolvated cage. It seems that the reaction center is located in the hydrophobic cavity of BCP-1. The Michaelis-Menten parameters obtained by the Lineweaver-Burk plots are given in Table 5.

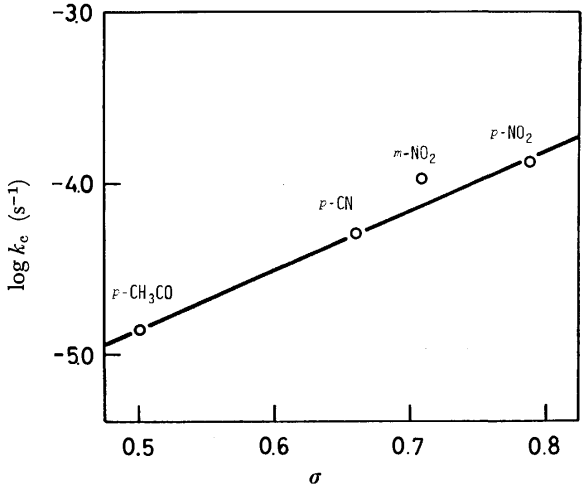

Fig. 3. Correlation of apparent catalytic rate constant k_c with Hammett σ. All runs were carried out in 10.0%(v/v) dioxane-1.0%(v/v) *N,N*-dimethylformamide-water at pH 12.30, 40.0±0.1 °C, and μ 0.10 (KCl). Initial concentrations: BCP-1, 0.49×10^{-6} M; PNPP, 0.985×10^{-5} M; MNPP, 0.984×10^{-5} M; PCPP, 0.984×10^{-5} M; PAPP, 0.981×10^{-5} M.

Nakajima and Okawa investigated the catalytic behavior of *cyclo*(His-Gly-Cys-D-Phe-Gly)$_2$ in the hydrolysis of *p*-nitrophenyl acetate:[3e] $k_{cat}=2.8\times10^{-3}$ s^{-1}, $K_m(\text{app})=2.7\times10^{-3}$ M, $k_{cat}/K_m(\text{app})=1.04$ M^{-1} s^{-1} at pH 7.73 and 24.0 °C. The k_{cat} value for their cyclic peptide is comparable to that for BCP-1 of the present study. However, the $k_{cat}/K_m(\text{app})$ value of the cyclic decapeptide is much smaller than that of BCP-1 by an order of 5×10^2, most likely due to the lower hydrophobic effect of the former. The importance of the hydrophobic effect for incorporation of the bulky substrate was further confirmed by a solvent effect study on the BCP-1 catalyzed hydrolysis. The catalytic ability of BCP-1 completely disappeared when the content of dioxane was raised to 20% (v/v) in reaction media.

The thermodynamic parameters for the substrate-binding process (Table 6) indicate that the formation of a substrate-catalyst complex is primarily controlled by the entropy effect for which the hydrophobic interaction between BCP-1 and PNPP is responsible. In reference to the activation parameters for both BCP-1 catalyzed and alkaline hydrolyses of PNPP, the rate enhancement by BCP-1 (k_{cat}) over the corresponding alkaline hydrolysis (k_{hyd}) is attributed to the enthalpy effect. The unfavorable entropy change is more than compensated by the enthalpy change. The unfavorable entropy effect in the pseudo-intramolecular acyl-transfer was unexpected and might be due to particular steric conformation in the Michaelis-type complex not favorable for the subsequent acylation reaction.

Effect of Mercury(II) Ion. An appropriate metal ion is expected to show a unique effect on the reactivity of BCP-1 since the catalyst has several donor atoms. The mercuric ion gave no effect in the hydro-

lysis of PNPP without BCP-1, but considerably retarded the reaction with cooperation of the cyclic peptide (Table 7). The reaction rate was reduced below the catalyst-absence level (k_{hyd}). The result suggests that BCP-1 deactivated by the coordination of the mercuric ion at its imidazole group still holds a significant ability to bind the substrate.

Substrate-Binding Ability of BCP-1 and PCP-1. PCP-1 retarded the alkaline hydrolysis of PNPP by incorporating the substrate into its cavity in line with the kinetic pathway expressed by the following:

$$\begin{array}{ccccc} S + C & \overset{K_b}{\rightleftharpoons} & (SC) & \xrightarrow{k_{in}} & P \\ & & \downarrow{\scriptstyle k_{hyd}} & & \\ & & P & & \end{array} \qquad (4)$$

where cyclic peptide C and substrate S yield association complex (SC) with binding constant K_b, and the free and bound substrates undergo hydrolysis with rate constants k_{hyd} and k_{in}, respectively. The observed pseudo-first-order rate constant (k_{obsd}) is given by

$$k_{obsd} = \frac{k_{hyd} + k_{in}K_b[C]_0}{1 + K_b[C]_0}, \qquad (5)$$

where $[C]_0$ stands for the initial concentration of PCP-1. Equation 5 can be rearranged to give

$$\frac{1}{k_{hyd} - k_{obsd}} = \frac{1}{k_{hyd} - k_{in}} + \frac{1}{(k_{hyd} - k_{in})K_b[C]_0}. \qquad (6)$$

A good linear relationship has been obtained by plotting $1/(k_{hyd} - k_{obsd})$ against $1/[C]_0$. The values of k_{in} and K_b obtained are 1.68×10^{-4} s^{-1} and 8.47×10^4 M^{-1}, respectively, at pH 12.3, 40.0±0.1 °C, and μ 0.10. The hydrolysis constant for the bound PNPP is smaller than that for the free ($k_{hyd}=2.91\times10^{-4}$ s^{-1}) by 1.7-fold. The binding constant for the complex of PCP-1 and PNPP is smaller than that for the complex of BCP-1 and PNPP by 1.6-fold. BCP-2 also retarded the alkaline hydrolysis of PNPP to a similar extent to that observed for PCP-1 (Table 4). CP-3 did not give out any meaningful effect on the alkaline hydrolysis of PNPP. The result indicates that the hydrophobic effect provided by the CP-3 cavity is not enough to incorporate PNPP.

Conclusion. Since CP-3 has no catalytic activity in the hydrolysis of PNPP, depth of the single-layered cyclic peptide does not seem to provide sufficient hydrophobic effect to incorporate a hydrophobic substrate. On the other hand, BCP-1, being a double-layered bicyclic species, provides a strong hydrophobic cavity. The efficient hydrophobic nature of the double-layered cyclic peptide was further substantiated by investigation on the substrate-binding property of BCP-2. Although we were not successful in developing an efficient papain model, the thiol group of L-Cys residue not being left active upon disulfide-bond formation during the course of CP-1 synthesis, the apparent second-order rate constant (k_{cat}/K_m(app)) for the PNPP hydrolysis effected by BCP-1 is comparable to those for the papain-catalyzed hydrolysis of esters and amides.[15] The overall rate enhancement by BCP-1 is apparently provided by a much stronger hydrophobic binding ability than that of papain and chymotrypsin toward the present particular substrate. In order to develop a more effective hydrolase model, the steric control needs to be exercised toward a bound substrate, so that the unfavorable entropy effect observed in the acylation step of the present study would be markedly improved.

This work was partially supported by the Kurata Foundation. The authors are indebted to Drs. Motosuke Kikutani and Masatsune Ishiguro, Faculty of Pharmaceutical Sciences, Nagasaki University, for the amino acid analysis.

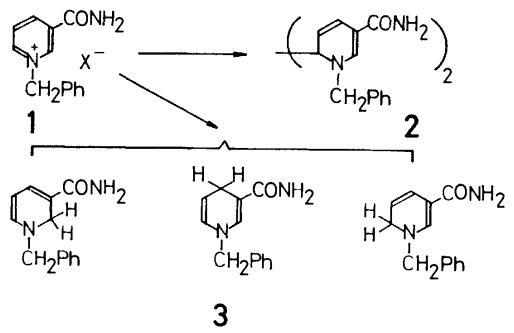
Photoreduction of 1-Benzyl-3-carbamoylpyridinium Chloride in Aqueous Ammonia[1)]

Teruo MATSUURA,* Toshio ITAHARA, Toshiaki OTSUKI, and Isao SAITO
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606
(Received April, 18 1978)

Irradiation of 1-benzyl-3-carbamoylpyridinium chloride (BNA$^+$Cl$^-$) in the presence of ascorbic acid in 28% aqueous ammonia gives the corresponding 1,4-dihydronicotinamide as the major product. The spectroscopic behavior of BNA$^+$ in aqueous ammonia and the adduct formation between BNA$^+$ and chloroform are also described.

Among various reactions of *N*-alkylpyridinium salts containing electronwithdrawing groups as models for the biological oxido-reductions involving nicotinamide coenzymes, NAD(P)$^+$, the chemical or electrochemical reduction of 1-alkyl-3-carbamoylpyridinium salts has received considerable attention, where 1,2-,[2)] 1,4-,[3,4)] and 1,6-dihydronicotinamides[5)] are formed two-electron transfer and a 6,6'-dihydro dimer[3)] by one-electron transfer. Relatively few attention has been drawn to



the photochemical reduction of NAD$^+$ or its analogs, which may serve as a model for the electron transport in photosynthetic system. Earlier workers have shown that photolysis of NAD$^+$ or its analog, 1-benzyl-3-carbamoylpyridinium chloride (**1**; BNA$^+$Cl$^-$), in the presence of ascorbic acid appreciably gives a reduced nicotinamide detected by its absorption spectrum, only in aqueous pyridine containing ammonia[6,7)] or in the presence of NADP reductase in aqueous solution.[8,9)] Kano and Matsuo have recently found that BNA$^+$Cl$^-$ (**1**) is photoreduced in the presence of diethylamine and/or ethylenediaminetetraacetic acid in aqueous solution to give 6,6'-dihydrodimer **2** as the main product(15—19%).[10,11)] We now report that the photoreduction of **1** in the presence of ascorbic acid in aqueous ammonia gives 1-benzyl-3-carbamoyl-1,4-dihydropyridine (**3**).

Results and Discussion

Irradiation of a 2×10^{-2} M solution of BNA$^+$Cl$^-$ (**1**) in 28% aqueous ammonia in the presence of an excess of ascorbic acid with a high-pressure mercury lamp (Pyrex) under nitrogen for 12 h gave the known 1,4-dihydro compound **3**[12)] in 22% yield, as the major component of the chloroform extract of the reaction mixture. TLC analysis of the chloroform extract revealed the presence of a trace of nicotinamide (**4**), but no other dihydronicotinamides and dihydrodimers. The aqueous layer contained a complex mixture of products from which no pure compound could be isolated. The photoreaction of **1** under various conditions was examined (Table 1). The characteristic features of the photoreduction are as follows. (1); Catechol could be used as a reducing agent instead of ascorbic acid, although the yield of **3** was lower. (2); The kind of the counter anion of BNA$^+$ appears to give no effect; the photolysis of BNA$^+$Br$^-$ under the same conditions gave virtually the same result. (3); When various amines were used instead of ammonia, only a trace of **3** was detected and the yield of **4** somewhat increased. Upon irradiation in 30% aqueous trimethylamine under similar conditions, **3** was found to be recovered almost unchanged. This result indicates that **3**

might not be formed in the photolysis of **1** in the presence of trimethylamine. (4); Replacemnet of ammonia by sodium hydroxide gave a complex mixture of products including a trace of **3**. These results indicate that the presence of ammonia are essential for the photochemical formation of the 1,4-dihydronicotinamide **3**.

Recently, Ohnishi has reported that treatment of **1** with aqueous ammonia in the dark gives **3** in small yield.[13] This finding prompted us to carry out a control experiment under similar conditions. Thus, when **1** was treated with 28% aqueous ammonia for 12 h in the dark, **3** was found to form in 7% yield in a complex mixture of products. This result indicates that the major portion of the compound **3** formed under the irradiation is resulted from a photochemical process.

In order to gain informations on the role of ammonia in the photochemical formation of **3**, the spectroscopic and chemical behaviors of BNA$^+$Cl$^-$ (**1**) in aqueous ammonia were examined. At a low concentration (4×10^{-5} M), **1** apparently undergoes chemical transformation at least with three steps. The ultraviolet absorption spectra of **1** with or without ammonia in aqueous solution are shown in Fig. 1. The absorption maximum at 258 nm of **1** in aqueous solution increased with increased amount of added ammonia and a new maximum appeared at 323 nm (stage I). The intensity of the latter absorption strongly depends upon ammonia concentration, as shown by the fact that the 323 nm maximum does not appear at ammonia concentrations of below 15% w/v. Acidification of the strong ammonia solution of **1** with hydrochloric acid gave rise to a spectrum identical with that of **1** in aqueous solution, indicating that the change into stage I is reversible.

When the ammonia solution at stage I was kept on standing at room temperature for several hours, a spectral change occurred gradually to reach a new spectrum having a maximum at 345 nm (stage II) with three isosbestic points at 273, 294, and 334 nm (Fig. 2). The spectral change of stage I to stage II

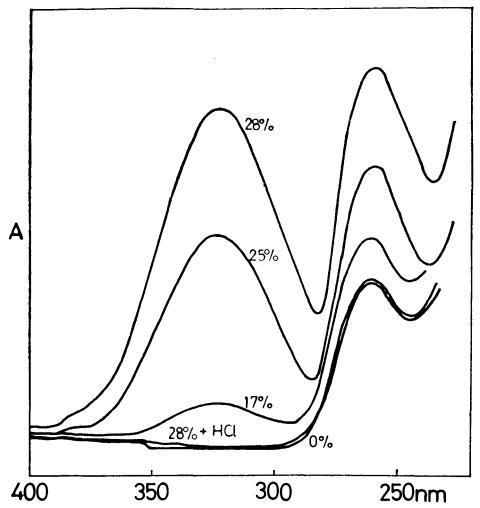

Fig. 1. UV spectra of BNA$^+$Cl$^-$ (**1**) in aqueous solution and in aqueous ammonia solution with different concentrations. BNA$^+$Cl$^-$: 4.0×10^{-5} M. Ammonia concentrations are shown by w/v %.

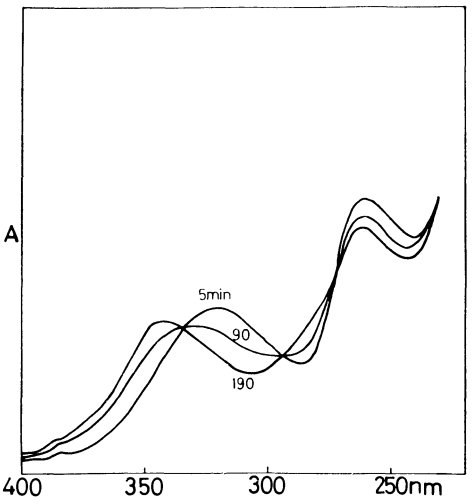

Fig. 2. UV spectral change of a solution of BNA$^+$Cl$^-$ (**1**) in 23% aqueous ammonia at 5, 90, and 190 min after dissolution. BNA$^+$Cl$^-$: 4.0×10^{-5} M.

was highly sensitive to the concentration of **1**. Thus, at higher concentrations of **1** the change became obscure, suggesting the occurrence of bimolecular reactions of the transient species having the 345 nm maximum. In fact, a 0.16 M solution of **1** in 28% aqueous ammonia became turbid and deposited an yellowish brown precipitate in a few hours (stage III). Figure 3 shows the spectra of the freshly prepared precipitate and the aqueous filtrate, suggesting a complex nature of stage III. These results may be simply summarized as the following scheme:

$$\text{NBA}^+\text{Cl}^- + \text{NH}_3\ \text{aq} \rightleftharpoons \text{stage I} \rightarrow \text{stage II} \rightarrow \text{stage III}$$

Since the photolysis of **1** in aqueous ammonia was done at a relatively high concentration (2×10^{-2} M), the reduction product **3** seems to originate from some of the intermediate species corresponding to these three stages.

Various attempts were made to isolate the species formed in the stages I, II, and III, but were unsuccessful because of their instability. During these attempts, it was found that when a 0.27 M solution of **1** in 28%

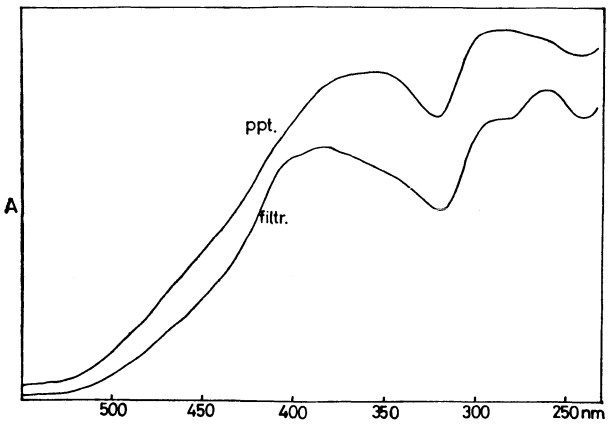

Fig. 3. UV spectra of the precipitate and the filtrate obtained from a solution of BNA$^+$Cl$^-$ (**1**) in 28% aqueous ammonia after standing for 12 hr. BNA$^+$Cl$^-$ (2.0 g) in 28% aqueous ammonia (50 ml).

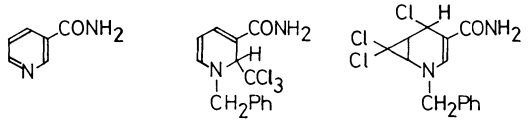
aqueous ammonia is stirred with chloroform for 3 h, two adducts between BNA^+ and the trichloromethanide anion, **5** (19%) and **6** (15%) are obtained from the chloroform layer. The structure of the latter product was assigned as **6** which had already been reported by Gündel.[14] The structure **5** was assigned by comparing its spectral data with those of the known 2,6-dichlorobenzyl analog.[14] Similar adduct formation between pyridinium salts and the trihalomethanide anions has been reported.[14-16]



4 **5** **6**

Because of the failure to identify any of the intermediate species in stages I, II, and III, the nature of the present photoreduction remains unknown. However, on the basis of the probable equilibrium of ammonia in water, $NH_3+H_2O \rightleftharpoons NH_4^+ + OH^-$ ($K_B=[NH_4^+][OH^-]/[NH_3]_t=1.75\times10^{-5}$ (25°)), where $[NH_3]_t$ denotes the total concentration of ammonia,[17] NH_3 would be able to act as a nucleophile rather than OH^-. Therefore, it seems reasonable to assume that adducts, **7a**, **8a**, and **9a**, which are formed between **1** and ammonia, play a role in the formation of the 1,4-dihydronicotinamide **3**. Comparing the absorption maxima at stages I (323 nm), II (345 nm), and III (350—400 nm) in Figs. 2 and 3 with those of *N*-(2,6-dichlorobenzyl)dihydronicotinamides, **7b** (ca. 420 nm), **8b** (350 nm), and **9b** (355 nm),[2,5] *N*-(2,6-dichlorobenzyl)-2-trichloromethyl-1,2-dihydronicotinamide (**7c**) (364 nm),[14] *N*-benzyl-4-trichloromethyl-1,4-dihydronicotinamide (**8d**) (365 nm),[14] and **5** (360 nm), there appeared rather difficult to assign the structures of the adducts in stages I, II, and III. However, considering from the difference between stages I and II in their absorption maxima, the adducts in stage I and II may be assigned as **8a** and **7a** (or **9a**) respectively. The precipitates of stage III may be very likely to consist of a mixture of the adducts and/or their decomposition products. The relatively low yield of the 1,4-dihydronicotinamide **3** may have resulted from the simultaneous occurence of side reactions of the adducts. A similar formation of the unstable adducts from **1** or its analogs by the action of a nucleophile such as the hydroxide anion,[18,19] amines,[13] and formate,[20] has been claimed. Such adducts are considered to be interconvertible, although the nature of the reaction is usually complex.

Experimental

All the melting points are uncorrected. UV, IR, NMR, and mass spectra were measured on a Shimadzu UV-200, a JASCO IRA-1, an NEVA T-60 (TMS, internal standard), and a Hitachi RMS-4 spectrometers, respectively. BNA^+ (**1**) was prepared by the known method.[21]

Photoreduction of 1-Benzyl-3-carbamoylpyridinium Chloride (1). A solution of **1** (1.0 g) and ascorbic acid (1.0 g) in 28% aqueous ammonia (180 ml) was irradiated internally with a 100 W high-pressure mercury lamp (Pyrex housing) under nitrogen for 12 h. The photolysate was extracted with chloroform. Evaporation of the chloroform extracts gave a solid (0.19 g) which on TLC (silica gel; chloroform) showed a major spot of *N*-benzyl-1,4-dihydronicotinamide (**3**) and a minute spot of nicotinamide (**4**). Recrystallization of the solid from aqueous ethanol gave crystals which were identical with an authentic sample of **3**[12] (NMR, IR, and TLC). Attempts to isolate pure products from the aqueous layer were unsuccessful.

Photolysis of **1** and the corresponding bromide (BNA^+Br^-) was carried out (Table 1). A solution of the pyridinium salts (1.0 g) and ascorbic acid or pyrocatechol (1.0 g) in a given solvent (180 ml) was irradiated under similar conditions. The photolysate was worked up as above.

Dark Reaction of 1 with Aqueous Ammonia. A solution of **1** (1.0 g) in 28% aqueous ammonia (180 ml) was kept on standing at room temperature under nitrogen for 12 h. After evaporating ammonia *in vacuo*, the mixture was extracted with chloroform. The chloroform layer was dried (Na_2SO_4) and evaporated to give a reddish brown solid (419 mg), which was found to contain **3** by TLC (silica gel; EtOAc–MeOH (10:1)). The NMR analysis of the solid with *t*-butyl alcohol as an internal standard showed that the yield of **3** was less than 7%.

Reaction of 1 with Chloroform in Aqueous Ammonia. A solution of **1** (2.0 g) in 28% aqueous ammonia (30 ml) was stirred with chloroform (60 ml) at room temperature for 3 h. The chloroform layer was dried (Na_2SO_4) and evaporated to give an yellowish brown solid (1.65 g), which was chromatographed on a silica gel column (Wakogel C-200). Elution with chloroform–ethyl acetate (2:3) yielded *N*-benzyl-2-trichloromethyl-1,2-dihydronicotinamide (**5**) as a pale yellow solid (0.50 g; 19%), which was recrystallized from benzene–cyclohexane as pale yellow crystals; mp 118—123 °C; λ_{max}^{EtOH} 360 nm (ε 5500); MS, *m/e* (rel int.) 213 (41) (M^+-CCl_3), 91 (65) ($PhCH_2^+$), 85 (100), 83 (65); NMR ($CDCl_3$), δ 4.80 (s, 2H, benzyl protons), 5.27 (dd, 1H, 5-H, J=6.6, 6.6 Hz), 5.70 (broad, 2H, NH_2, D_2O-exchangeable), 5.73 (d, 1H, 2-H, J=1.8 Hz), 6.58 (dd, 1H, 6-H, J=6.6, 1.8 Hz), 7.03 (d, 1H, 4-H, J=6.6 Hz), 7.32 (m, 5H, phenyl protons).

Found: C, 51.28; H, 4.05; Cl, 30.83; N, 8.27%. Calcd for $C_{14}H_{13}Cl_3N_2O$: C, 50.70; H, 3.95; Cl, 32.08; N, 8.45%.

Further elution with the same solvent yielded 5,7,7-trichloro-4-carbamoyl-2-benzyl-2-azabicyclo[4.1.0]hept-3-ene (**6**) as a pale yellow solid (0.41 g; 15%), which was recrystallized from ether–petroleum ether as colorless needles; mp 55—60 °C (containing 1 equivalent mole of ether of crystallization) (lit,[14] mp 130—131 °C, from dichloromethane); λ_{max}^{EtOH} 263 nm (ε 4400), 313 (4400); MS, *m/e* (rel int.) 213 (54) (M^+-CCl_3), 91 (100) ($PhCH_2^+$), 85 (23), 83 (35); NMR ($CDCl_3$), δ 1.20 (t, 6H, CH_2-CH_3, J=6 Hz), 3.49 (q, 4H, -O-CH_2-CH_3, J=6 Hz), 4.53 (s, 2H, benzyl protons), 4.55 (d, 1H, 5-H, J=6 Hz), 5.21 (dd, 1H, 6-H, J=6, 7.2 Hz), 5.60 (broad, 2H, NH_2, D_2O-exchangeable), 6.38 (dd, 1H, 1-H, J=7.2, 1.2 Hz), 7.24 (m, 5H, phenyl protons), 7.33 (d, 1H, 3-H,

J=1.8 Hz). (Found: C, 53.03; H, 5.65; N, 7.04; O, 8.19%. Calcd for $C_{14}H_{13}Cl_3N_2O \cdot C_2H_5OC_2H_5$: C, 53.28; H, 5.71; N, 6.90; O, 7.89%.)

Preparation of D:B-Friedoolean-5(10)-en-1-one and Related Compounds. A Comment on the Structure of "Glut-5(10)-en-1-one" from *Euphorbia Nerifolia*[1]

Eri AKIYAMA, Yoshihiko MORIYAMA, Tatsushi MURAE, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received April 19, 1978)

In order to examine the structure, "glut-5(10)-en-1-one", proposed for a new triterpene from *Euphorbia nerifolia*, this ketone (≡D : B-friedoolean-5(10)en-1-one) was prepared. Oxidation of D : B-friedoolean-5(10)-ene with chromium trioxide-pyridine complex gave the allylic oxidation products, D : B-friedoolean-5(10)-en-1-one, D : B-friedoolean-5(10)-en-6-one, and D : B-friedoolean-5(10)-ene-1,6-dione. The spectral data and physical constants of the synthetic ketone (D : B-friedoolean-5(10)-en-1-one) were not identical with those of the new triterpene; this requires revision of the structure of this natural triterpene. Oxidation of D : B-friedoolean-5(10)-en-3-one enol acetate under the same conditions to give D : B-friedooleane-1,5(10)-dien-3-one is also described.

From the stems and leaves of *Euphorbia nerifolia* Linn. (Euphorbiaceae), a new triterpene, $C_{30}H_{48}O$, mp 312—314 °C, $[\alpha]_D$ +50°, was isolated together with 3α- and 3β-hydroxyfriedelanes and taraxerol by Row *et al.*[2] Based on the spectral data, this new compound was inferred to be a pentacyclic triterpene ketone conjugated with a tetrasubstituted double bond. Catalytic reduction of the ketone into glut-5(10)-ene (**1**≡D : B-friedoolean-5(10)-ene**) and investigation on the UV spectra of both the ketone and its 2,4-dinitrophenylhydrazone led to the conclusion that the new triterpene is glut-5(10)-en-1-one (**2**≡alnus-5(10)-en-1-one≡D : B-friedoolean-5(10)-en-1-one**).[2]

However, the proposed structure for this triterpene is very questionable, because the UV absorption at 218 nm (log ε 3.87) and three weak bands at 880, 840, and 810 cm^{-1} in the IR spectrum described for this compound,[2] could not be compatible with the proposed structure. In this paper, we describe an unambiguous synthesis of D:B-friedoolean-5(10)-en-1-one (**2**) by oxidation of D:B-friedoolean-5(10)-ene (**1**)[3] with chromium trioxide–pyridine complex[4] and that the synthetic triterpene (**2**) is different from the natural one, indicating that the structure for the natural triterpene from *Euphorbia nerifolia* should be revised.

D:B-Friedoolean-5(10)-ene (**1**), prepared by the Huang-Minlon reduction of D:B-friedoolean-5(10)-en-3-one (**3**),[3,5] was subjected to oxidation with chromium trioxide–pyridine complex[4a] according to Ratcliffe's modified procedure[4b] to give a complex mixture, from which two ketones (**2** and **4**) and a diketone (**5**), together with the unchanged starting material (**1**) were isolated by column chromatography on alumina and subsequent separation by preparative TLC on silica gel.

Since the carbonyl moiety in these ketones (**2** and **4**) was shown to be conjugated with a tetrasubstituted double bond from the spectral measurement (*vide infra*), these ketones were inferred to be the allylic oxidation products at C-1 and C-6, respectively. The Huang-Minlon reduction of both **2** and **4** gave the same hydrocarbon as the starting D:B-friedoolean-5(10)-ene (**1**). Thus the position of the tetrasubstituted double bond in both **2** and **4** was determined to be between C-5 and C-10.

The more polar ketone (**2**), $C_{30}H_{48}O$, mp 257.5—259 °C, $[\alpha]_D$ −53°, showed the UV absorption at 249 nm (ε 19100), IR absorption band at 1660 cm^{-1}, and complex signals (4H) due to $-CO-CH_2-$ and $-\overset{|}{C}=\overset{|}{C}-CH_2-$ groupings at δ 2.0—2.7 in the PMR spectrum, while the other (**4**), $C_{30}H_{48}O$, mp 243—245 °C, $[\alpha]_D$ −11°, the UV absorption at 250 nm (ε 10800), IR absorption band at 1655 cm^{-1}, and complex signals (4H) due to $-CO-CH_2-$ and $-\overset{|}{C}=\overset{|}{C}-CH_2-$ groupings at δ 2.0—2.5 in the PMR spectrum. In the PMR measurement using Eu(fod)$_3$-d_{27} for a 7% (w/v) solution of **4** in $CDCl_3$ in a molar ratio (**4**/the shift reagent) of 1:1, two of the four protons which had given the complex signals at δ 2.0—2.5, appeared at δ_A 12.40 and δ_B 11.92 as an AB part of an ABX-type signal, respectively, and *one* proton corresponding to the X-part was also observed at δ_X 6.42. On irradiation at δ_A 12.40 and δ_B 11.92, the signals due to H_X changed into a singlet like and a doublet, respectively. Irradiation at δ_X 6.42 changed the signal due to the AB-part into an AB quartet. These observations confirmed the presence of the grouping $-CO-CH_AH_B-\overset{|}{C}H_X-$ (J_{AB}=18, J_{AX}=12, and J_{BX}=6 Hz) and therefore the less polar

** In this paper, friedooleanane nomenclature was used.

Table 1. The CD spectral data for the enones (**2** and **4**)

Compound	Observed cotton effect			Predicted sign		
	R-Band	K-Band		Enone helicity	Allylic axial chirality contribution	α'-Axial chirality contribution
2	$[\theta]_{330}+2000$	$[\theta]_{242}-34500$	$[\theta]_{213}+14300$	+	4α-CH_3 (+) 6α-H (−)[a] 9β-CH_3 (−)[a]	2α-H (+)
4	$[\theta]_{350}-3300$	$[\theta]_{268}+1900$	$[\theta]_{225}-15700$	−	1β-H (+)[b] 4α-CH_3 (+)[b] 9β-CH_3 (−)	7β-H (−)

a) Contribution of 9β-CH_3 and 6α-H may be greater than that of 4α-CH_3.
b) Contribution of 4α-CH_3 and 1β-H may overcome that of 9β-CH_3.

ketone (**4**) could be formulated as D : B-friedoolean-5(10)-en-6-one. Thus the structure of the polar ketone (**2**) was concluded to be D : B-friedoolean-5(10)-en-1-one.

The diketone (**5**), $C_{30}H_{46}O_2$, was identified to be D : B-friedoolean-5(10)-ene-1,6-dione based on the spectral data. This received support by the fact that each of the ketones **2** and **4** gave the same diketone (**5**) on oxidation under the same conditions as above.

The circular dichroism data (Table 1) for the enones (**2** and **4**) could be interpreted by the enone helicity rule[6] for the R-band Cotton effect, and by the allylic axial chirality contribution rule[7] and the α'-axial chirality contribution rule[7] for the K-band Cotton effect.

If an additional double bond is introduced between C-2 and C-3 in the D:B-friedoolean-5(10)-ene framework, it would be expected that the C-1 methylene group might be more susceptible to the allylic oxidation than the C-6 methylene group. D : B-Friedoolean-5-(10)-en-3-one (**3**) was converted into the corresponding enol acetate (**6**), which was subjected to the oxidation under the same conditions as above. However, the expected allylic oxidation product (**7**) could not be obtained, but only a dienone (**8**) was isolated in about 50% yield. The dienone (**8**), mp 217—219 °C, was shown to be identical with D:B-friedooleane-1,5(10)-dien-3-one.[3,8] Goldblum and Mechoulam[9] reported a novel oxidative rearrangement leading to α-benzoyloxy ketones in allylic oxidation of various enol benzoates with sodium chromate in acetic acid. The formation of the 1,5(10)-dien-3-one (**8**) could be explained by the same mechanism as described by Mechoulam.[9]

In conclusion, the spectral data and physical constants of the synthetic ketone, D:B-friedoolean-5(10)-en-1-one (**2**) are clearly shown to be different from those of the natural triterpene*** described by Row *et al.*[2] Therefore the structure proposed for the natural triterpene should be revised.

Experimental

IR spectra were measured using a Hitachi EPI-G2 spectrometer. UV spectra were determined on a Hitachi EPS-3 spectrometer. CD measurements were carried out on a JASCO Model J-20 spectrometer. Optical rotations were measured on a JASCO DIP-SL polarimeter. Mass spectra were taken on a Hitachi RMU-6 Tokugata mass spectrometer with a direct inlet system operating at 70 eV. PMR spectra were measured using a JEOL 4H-100 (100 MHz) or a Hitachi R-20 (60 MHz) spectrometer. Chemical shifts were expressed in δ downfield from TMS as an internal standard, and coupling constants in Hz. HPLC analyses were carried out at room temperature using a Liquid Chromatograph Model ALC/GPC 202/401 (Waters Assoc.) with a UV detector (column: μ-Porasil 1/8 (inch) × 1 (foot); solvent system: 25% CH_2Cl_2-hexane; flow rate: 0.4 ml/min; pressure: *ca.* 500 psi). TLC was carried out on Kieselgel G nach Stahl, Kieselgel GF_{254} nach Stahl, and Kieselgel 60 PF_{254} (E. Merck, Darmstadt). For column chromatography, Wakogel C-200 (Wako Pure Chem. Ind.) and Activated Alumina (Showa Chem.) were used. Melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and were uncorrected.

*Oxidation of D:B-Friedoolean-5(10)-ene (**1**).* Chromium trioxide (2.5 g) was added to a mixture of pyridine (4 ml) and dichloromethane (70 ml) with stirring for 15 min.[4b] To the solution, D:B-friedoolean-5(10)-ene[3,5] [**1**; 1.04 g, prepared from D:B-friedoolean-5(10)-en-3-one (**3**)] in dichloromethane (100 ml) was added. The reaction mixture was stirred at room temperature for 21 h. Ether (*ca.* 300 ml) was added and the ethereal layer was washed with 5% aqueous sodium hydroxide solution, 5% hydrochloric acid, and then with saturated aqueous sodium hydrogencarbonate solution, and dried over sodium sulfate. Evaporation of the solvent gave a residue (1.3 g) which was dissolved in petroleum ether, passed through a column of alumina (100 g), and eluted with the following solvents (each 100 ml). Petroleum ether, frs 1—3; benzene, frs 7—15. On evaporation, fractions 1—3 gave the starting material (**1**; 64 mg), fractions 7 and 8 gave a mixture of 1,6-dione (**5**) and 6-one (**4**), and fractions 11—15 gave a mixture of 6-one (**4**) and 1-one (**2**). These mixtures were subjected to separation by preparative TLC (developed with benzene-hexane, 1 : 1) giving rise to **2** (85 mg), **4** (195 mg), and **5** (98 mg).

*D : B-Friedoolean-5(10)-en-1-one (**2**).* Mp 257.5—259 °C (recrystallized from ethyl acetate), $[\alpha]_D$ −53° (*c* 0.73, $CHCl_3$); IR (KBr) 1660 cm^{-1}; UV (EtOH) λ_{max} 249 nm (ε 19100); PMR ($CDCl_3$) δ 0.97, 1.05, 1.10, 1.14 (each s, 3H, *t*-Me), 1.00, 1.20 (each s, 6H, 2×*t*-Me), and 2.0—2.7 (4H, complex); CD (*c* 0.094, dioxane): Table 1; MS *m/e* (%) 424 (M^+; 100), 409 (37), 245 (41), 205 (62), 191 (85), 177 (78), and 163 (57); MW Found: *m/e* 424.3756. Conversion of D : B-Friedoolean-5(10)-en-1-one (2) and -6-one (4) into D : B-Friedoolean-5(10)-ene-1,6-dione (5). D : B-Friedoolean-5(10)-en-1-one (**2**; 14 mg) in dichloromethane (3 ml) was oxidized with chromium trioxide-pyridine complex[4b] (chromium trioxide 100 mg, pyridine 0.2 ml, and dichloromethane 2.4 ml) at 30 °C for 5 days. The reaction mixture was worked up as before and a mixture of D : B-friedoolean-5(10)-ene-1,6-dione (**5**) and the unchanged starting material (**2**) was obtained. Although separation of the mixture was not attempetd, HPLC examination showed that the mixture consisted of **5** and **2** (their retention times 24 min and 30 min, respectively) in a ratio of 5 : 1. And the mixture gave an overlapped mass spectrum of **5** and **2** in the same ratio.

D : B-Friedoolean-5(10)-en-6-one (**4**; 18.7 mg) in dichloromethane (3 ml) was treated with the same reagent[4b] (chromium trioxide 50 mg, pyridine 0.1 ml, and dichloromethane 1.2 ml) under the same conditions as above. After usual treatment, separation by preparative TLC gave D:B-friedoolean-5(10)-ene-1,6-dione (**5**; *ca.* 2 mg) and a minute quantity of the starting 6-one (**4**). The IR spectrum of the former product (**5**) was shown to be identical with that of D:B-friedoolean-5(10)-ene-1,6-dione (**5**).

Wolff-Kishner Reduction of D : B-Friedoolean-5(10)-en-1-one (2) and -6-one (4) under Forced Conditions. D : B-Friedoolean-5(10)-en-1-one (**2**; 15 mg) was treated with diethylene glycol (5 ml), sodium (100 mg), and anhydrous hydrazine[10] (1 ml) under a nitrogen atmosphere according to the Barton's procedure.[11] The reaction product was subjected to separation by column chromatography of silica gel (5 g) impregnated with silver nitrate (1.25 g) using petroleum ether as eluent. D : B-Friedoolean-5(10)-ene (**1**; 4 mg) was obtained as the major reduction product and the mp, IR, and MS were all in accord with those of an authentic specimen.

The Wolff-Kishner reduction of D : B-friedoolean-5(10)-en-6-one (**4**; 45.4 mg) was effected under the same conditions as above to give D : B-friedoolean-5(10)-ene (**1**; 10 mg), whose IR spectrum was identical with that of an antheutic sample.

D : B-Friedoolean-5(10)-en-3-one Enol Acetate (6). A mixture of D:B-friedoolean-5(10)-en-3-one (**3**; 170 mg), isopropenyl acetate (12 ml), and *p*-toluenesulfonic acid (40 mg) was heated and distilled slowly. After 2 ml of the solvent was distilled off, the reaction mixture was refluxed for 17 h. Usual treatment gave a residue, which was dissolved in benzene-ether (10 : 1), passed through a column of alumina (5 g), and eluted with the same solvents. Recrystallization from ethyl acetate afforded the enol acetate (**6**; 168 mg), mp 241—243 °C; IR (KBr) 1760, 1210, and 905 cm^{-1}; PMR ($CDCl_3$) δ 2.15 (3H, s; -OAc), 2.76 (2H, d, J=4 Hz; $C_{(1)}$-H_2), and 5.31 (1H, t, J=4 Hz; C=C-H); MS *m/e* (%) 466 (M^+; 8), 451 (35), 424 (41), 409 (11), 406 (13), 205 (91), 136 (100), 121 (91), and 109 (91); Found: C, 82.39; H, 10.61%. Calcd for $C_{32}H_{50}O_2$: C, 82.35; H, 10.80%.

Oxidation of Enol Acetate (6). D : B-Friedoolean-5(10)-en-3-one enol acetate (**6**; 100 mg) in dichloromethane (12 ml) was treated with the chromium trioxide-pyridine complex[4b] (chromium trioxide 235 mg, pyridine 0.8 ml, and dichloromethane 12 ml) at room temperature for 1.25 h with stirring. Usual workup and recrystallization from chroloform-methanol afforded D:B-friedooleane-1,5(10)-dien-3-one (**8**; 45 mg), mp 217—219 °C (lit,[3] 216—217 °C; lit,[8] 212.5—215 °C); IR (KBr) 1675, 1620, and 812 cm^{-1}; UV (EtOH) λ_{max} 323 nm (ε 5470) [lit,[3] 322 nm (ε 5500); lit,[8] 320 (ε 5000)]; PMR ($CDCl_3$) δ 2.3 (2H, m; $C_{(6)}$-H_2), 6.0 and 7.1 (2H, ABq, J=10 Hz; CH=CH-C=O); MS *m/e* (%) 422 (M^+; 23), 407 (13), 205 (52), and 109 (100).

Department of Chemical Engineering, College of Engineering, University of Osaka Prefecture, Mozu-Ume, Sakai, Osaka 591

(Received October 26, 1977)

A new chemical precipitation process that had been developed for the removal of heavy metals was extended to the removal of phosphate and COD substances. For simulated wastewater contaminated with heavy metal, phosphate, and COD substances, removal experiments were undertaken in a batch, stirred vessel by using the lime sulfurated solution as a single coagulant. The coagulant, the main component of which is CaS_x, decomposes in water on contact with air or CO_2 gas, and liberates H_2S, CaS_2O_3, $CaCO_3$, $CaSO_4$, and solid sulfur particles. While heavy metals are precipitated as metal sulfides or hydroxides, phosphate is precipitated as calcium phosphate and COD substances are sorbed on the surfaces of the precipitates and they removed. The experimental findings are as follows: (1) The simulated wastewater contaminated simultaneously with phosphate and cadmium ions can be treated better than that contaminated only with the phosphate ion. Also, the CaS_x process is found to be more effective than the $Ca(OH)_2$ process for the removal of phosphate. (2) The removal percentages of COD substances ranged from 40% to 90% according to the sort of substance. The COD removal can be attained by the sorption of the substances mainly on the liberated solid sulfur particles, and partly on the calcium salts.

Wastewater issuing from communities and various industries is often contaminated simultaneously with many sorts of chemical species. Therefore, it is advantageous to develop a wastewater treatment process that can treat these contaminants by a single procedure. As the contaminants, phosphate and nitrogen compounds as well as heavy metals and COD substances have occasioned much public discussion. For the removal of nitrogen compounds, biological denitrification processes have recently been developed and have been playing very important role in the protection of the environment. As for the phosphate removal, however, there are only a few processes that can be practically applied. They are the precipitation processes of phosphate by injecting calcium hydroxide, aluminum sulfate, or iron salts into the wastewater.

In this paper, a new precipitation process is proposed for the removal of phosphate together with heavy metal and COD substances. This process has already been tested for the removal of heavy metals from simulated wastewater.[1,2] By utilizing the lime sulfurated solution as a single coagulant, the apparent reaction kinetics for the removal of heavy metals (Hg^{2+}, Cd^{2+}, Pb^{2+}, Cu^{2+}, Zn^{2+}, Cr^{3+}, and Cr(VI)) has been studied by us.[1] We have also discussed the conditions necessary for the precipitation of heavy metals at various initial concentrations from various examples of simulated wastewater with a variety of pH's and temperatures by injecting different amounts of the coagulant at several agitating speeds.[2] Sufficient removal below the water quality standards in our country has been ascertained for the heavy metals, which are precipitated as metal sulfides by the H_2S and CaS_2O_3 that are liberated on the decomposition of CaS_x by air or CO_2 gas, or as metal hydroxides by the strong alkaline base of the CaS_x solution. Accompanied by the decomposition of CaS_x in water, calcium ion and solid sulfur particles are also liberated. The phosphate ion in the wastewater can be expected to be precipitated as calcium phosphate by the calcium ion. Good removal may also be anticipated for the COD substances that may be sorbed on the solid sulfur particles and the other precipitates.

In the present study, experiments were carried out for the removal of phosphate, heavy metal, and some COD substances from the simulated wastewater. Discussion was also made for their removal percentages.

† Present address: Ataka Kogyo Co., Ltd., Sueyoshibashi, Minami-ku, Osaka 542.

Experimental

Apparatus. The batch stirred vessel utilized in this experiment was the same as that used in the previous works.[1,2] The agitating speed of the impeller was fixed at 10 Hz. The vessel was immersed in a constant-temperature bath at 25 °C. Gas (air or CO_2) was blown into the vessel at a rate of 500 cm^3/min.

Method. For the phosphate contamination, distilled water containing potassium dihydrogenphosphate was used as simulated wastewater. As examples of COD contamination, water solutions of acetone, CMC (carboxymethylcellulose), and Methyl Violet were provided. After the start of a run by blowing in air or CO_2 gas, sample liquors were taken at predetermined time intervals. For the concentration determination with heavy metal, phosphate, and acetone, the liquors were filtered by means of No. 5C filter paper. The heavy metal concentration was determined by means of an atomic absorption spectrophotometer. The phosphate was detected according to JIS-K0102. The acetone was developed by a gas chromatograph (F. I. D.). For the measurement of the CMC concentration, a Stokes viscometer was applied to the liquor filtered by membranes of various pore sizes after the viscosity had been calibrated against the CMC concentration. In the case of Methyl Violet, the centrifugal separation of the precipitates in the liquor was executed at 4,000 G for 10 min, because Methyl Violet is a kind of dye and so, if filtered, it might be sorbed on the filter paper. The supernatant liquors were examined by means of a spectrophotometer in order to determine their concentrations of residual Methyl Violet.

Results and Discussion

Removal of Phosphate. Figure 1 shows the removal of the phosphate ion, PO_4^{3-}, by means of the CaS_x process and the $Ca(OH)_2$ process. The ordinate indicates the residual PO_4^{3-} concentration after aeration for 180 min in order to decompose CaS_x in the case of the CaS_x process. The $Ca(OH)_2$ process does not need aeration. The abscissa implies the mole ratio of Ca^{2+} in the CaS_x or in the $Ca(OH)_2$ added per PO_4^{3-}.

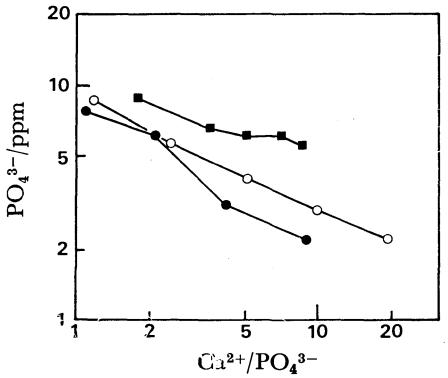

Fig. 1. Residua PO_4^{3-} concn against mole ratio of Ca^{2+} in CaS_x or in $Ca(OH)_2$. Initial concn of PO_4^{3-}=25 ppm, initial pH=6 and final pH=6.2. ■: PO_4^{3-} by $Ca(OH)_2$ process, ○: PO_4^{3-} by CaS_x process with aeration, ●: $PO_4^{3-}+Cd^{2+}$ by CaS_x process with aeration, initial concns are 25 ppm.

The initial concentrations of PO_4^{3-} and Cd^{2+} are both 25 ppm. For the simulated wastewater contaminated only with phosphate, the CaS_x process can treat PO_4^{3-} more effectively than the $Ca(OH)_2$ process for the same ratio of Ca^{2+}/PO_4^{3-}. This better removal of the CaS_x process can be thought to be due to the coprecipitation of calcium phosphate with the solid sulfur particles and calcium salts ($CaCO_3$ and $CaSO_4$) which are liberated from CaS_x. When the wastewater is contaminated simultaneously with PO_4^{3-} and Cd^{2+}, the removal is more effective. As a reason for this effective removal, the precipitation of PO_4^{3-} by Cd^{2+} may be considered. The residual Cd^{2+} concentration was determined to be 0.01 ppm, *i.e.*, far below the effluent standard of 0.1 ppm, for the treatment by the CaS_x process of the simulated wastewater contaminated simultaneously with Cd^{2+} and PO_4^{3-}.

Removal of COD Substances. The percentage of the removal of acetone whose initial cencentration was 1500 ppm was measured for the CaS_x process. The resulting removal percentage of the acetone is shown in Fig. 2 against the mass ratio of sulfur in the CaS_x added per acetone. A removal of more than 40% can be realized by the use of the CaS_x process. The peak of the removal percentage at a mass ratio of about 0.8 may be explained as follows. With the decrease in the quantity of the coagulant, the particle size of the solid sulfur liberated from CaS_x is reduced, as was found in a previous work.[2] The finer particles have a larger surface area in sum total, and so they can sorb more acetone. The removal percentages of acetone by

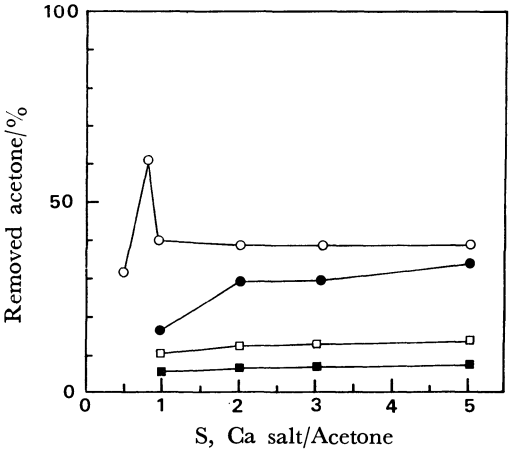

Fig. 2. Removal percentage of acetone against mass ratio of sulfur in CaS_x or of precipitated sulfur and of calcium salts, per acetone. Initial concn of acetone=1500 ppm.

the precipitated sulfur particles and calcium salts ($CaCO_3$(precipitated), $CaSO_4$) are also shown in Fig. 2, since the sulfur particles and the salts are components of the precipitates of the CaS_x process.[1,2] The precipitated sulfur particles used in the experiment of Fig. 2 were prepared by the decomposition of a CaS_x solution (1,000 ppm) with 0.1 M-HCl. The precipitates were filtered by No. 5C and washed with distilled water in order to dissolve the $CaCl_2$. The dried cake of the sulfur particles was assured to have a purity of more than 99.5% of sulfur. Figure 2 shows that the precipitated sulfur particles can sorb about 30% of acetone, while the removal percentages with $CaCO_3$ and $CaSO_4$ are, respectively, 10 and 5%. The CaS_x process can remove about 40% of the acetone, while the precipitated sulfur sorbs 30%. The colloidal sulfur particles generated by the CaS_x process may sorb more acetone by means of some force such as the attractive force by the surface charge,[7] though the mechanism is not evident at present.

In Fig. 3, the residual concentrations of CMC are plotted against the pore size of the membrane filters used for the filtration of sample liquors. R is defined as the mass ratio of S in CaS_x per CMC. Without CaS_x injection, a part of the CMC, with so long a molecular length, was removed only by filtration with the membrane whose pore size was less than 0.5 μm. The initial concentration of CMC was 60 ppm. The residual concentration of CMC was about 12 ppm for the case of R=25 by aeration with a 0.45 μm membrane, as is shown in Fig. 3. The removal percentage for this case is about 75%. The apparent particle size of the precipitates (S, $CaCO_3$, and $CaSO_4$ with CMC) for the removal of CMC by the CaS_x process was measured by using membranes with various pore sizes like a standard sieve mesh. The apparent particle size distributions are shown in Fig. 4. These distributions are obtained by weighing the masses of the membranes and the cakes, after a processing time of 60 min using the CaS_x process. Aeration gives a little larger

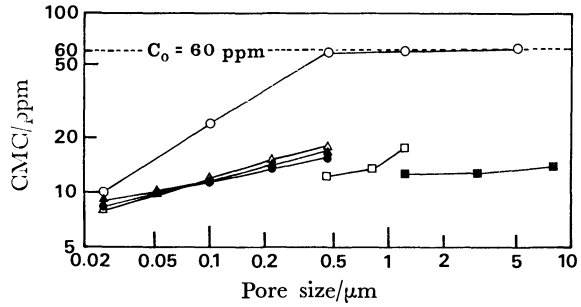

Fig. 3. Residual CMC concn against pore size of membrane. Initial concn of CMC=60 ppm.
○: Only by membrane filtration, ▲: R(mass ratio of S in CaS_x per CMC)=6.25 with aeration, ●: R=12.5 with aeration, □: R=25 with aeration, ■: R=50 with aeration, △: R=25 with CO_2 blowing.

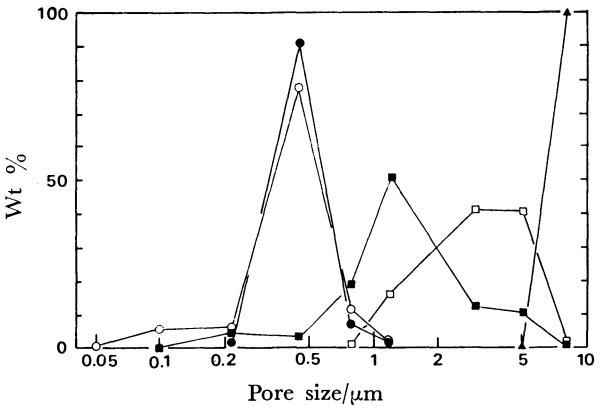

Fig. 4. Apparent particle size distributon of the precipitates formed on the removeal of CMC by CaS_x process.
○: R=6.25 with aeration, ●: R=12.5 with aeration, □: R=25 with aeration, ▲: R=50 with aeration, ■: R=25 with CO_2 blowing.

particle size than CO_2 blowing for the same R value of 25. The R value of more than 50 gives a particle size sufficient for the easy separation of the precipitates in the case of CMC processing by the CaS_x process. The particle size shown in Fig. 4 is rather finer than that observed for heavy-metal removal by the CaS_x process, as was reported in a previous paper.[2] This finer particle size may be due to the emulsifying characteristics of the CMC.

Figure 5 shows the removal of Methyl Violet. The initial concentration of 5 ppm was reduced within 0.1 ppm. The removal percentage is about 80% to 90%. The precipitates separated centrifugally were as violet in their color as if they had been dyed. On the other hand, a tentative experiment was carried out for the removal of Methyl Violet by the iron(III) hydroxide process. The removal percentage was only about 1%.

Figures 6 and 7 show photographs of the precipitates taken by means of an electron microscope when CaS_x decomposes in contact with air. Figure 6 shows the precipitates as cake caught on the fibril of No. 5C filter paper. A magnified photograph of the precipitates is shown in Fig. 7. Figures 8 and 9 (magnified) show precipitates obtained by the decomposition of CaS_x with CO_2 gas blowing. Figures 6 to 9 are cases when the substance is precipitated from the water which does not contain any contaminants but 1 cm^3 of the CaS_x solution per dm^3 of distilled water. Photographs of the precipitates when the water is contaminated with 25 ppm of Cd^{2+} and when the mole ratio of S in the CaS_x added per Cd^{2+} is equal to 25 are shown in Figs. 10 to 11 (magnified). While iron(III) hydroxide precipitates are known to be amorphous, the precipitates of the CaS_x process are found to be spheres, and so they have the advantage of easy filtration. Particle properties of the CdS precipitated from aqueous solution

of $Cd(NO_3)_2$ or $CdSO_4$ by adding $Na_2S_2O_3$ or H_2S have been studied recently by Hashimoto *et al.*[5] They have shown that the CdS particles are spherical in shape and that the diameter becomes the bigger for the higher concentration of Cd^{2+}. Since the solid sulfur particles formed in the CaS_x process are also spherical in shape as may be seen in Figs. 6 and 7, it is scarcely possible to distinguish CdS from solid sulfur in Figs. 10 and 11. The cubes in Fig. 10 are probably $CaCO_3$ as is shown in Ref. 6. Coagulation between $CaCO_3$ (cubes) and the other precipitates(spheres: solid sulfur and CdS) can clearly be recognized in Fig. 10. Most of the spheres may consist of solid sulfur particles, which have porous or irregular surfaces, as may be seen in Figs. 7, 9, and 11. These porous or irregular surfaces may work favorably to sorb organic COD substances. CO_2 decomposition gives more irregular surfaces than

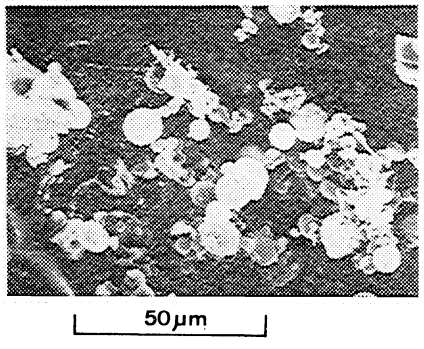

Fig. 10 Precipitates of Cd^{2+} processing by CaS_x process with blowing a gas which contains 97% of air and 3% of CO_2 gas. Initial concn of Cd^{2+}=25 ppm and mole ratio of S in CaS_x per Cd^{2+}=25.

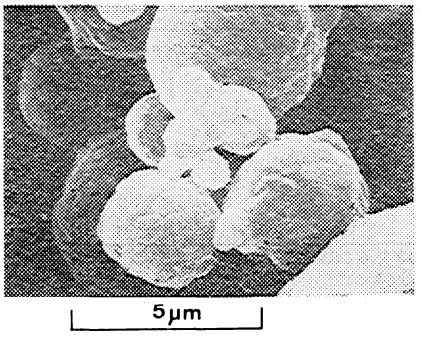

Fig. 11. Magnification of a part of Fig. 10.

that by aeration. The reason for this is not evident, but the fact that the CO_2 blowing gives rise to the rapid decomposition of CaS_x[1] may be connected with this irregularity.

The removal of heavy metals when the target material was simultaneously contaminated with COD substances was experimented within several cases. However, heavy-metal removal is not so severely affected by the simultaneous contamination with the COD substances used in the present experiments. This tendency may be explained by the fact that the COD substances were removed by the sorption on the solid sulfur particles and other precipitates, while the heavy metals were precipitated by reacting with H_2S and CaS_2O_3. The CMC might give finer particle sizes of the precipitates and so a lower removal percentage of heavy metals. However, so long as the No. 5C filter paper was employed for the separation of the precipitates, the heavy-metal removal was not affected by the COD contamination in the CaS_x process. It was shown by an auxiliary experiment that No. 5C filter paper had apparent pore sizes equivalent to membranes of between about 0.1 and 0.2 μm, and that the precipitates of the heavy metal sulfides or hydroxides were larger than these pore sizes. COD substances that form soluble-metal compounds, such as EDTA (ethylenediamine tetraacetic acid), citric acid, and tartaric acid, may affect the removal of heavy metals.[3]

An experiment was made at removing NH_3 in water by means of the CaS_x process. The initial NH_3 concentration of 25 ppm was reduced to 1 ppm after 60 min of aeration by the injection of CaS_x at an amount 25 times that of NH_3 in mole ratio. If the nitrogen compounds in the sewage are reduced as far as to free NH_3, a good removal can be realized by means of the CaS_x process. This good removal may be attributed mainly to the stripping of NH_3 from water to the exhaust-gas phase, as in the NH_3 stripping process,[4] or partly to the sorption of NH_3, though the reason for this is not evident, on the surfaces of the precipitates, for the odors of the exhaust gas and the sludge are that of NH_3 and the exhaust gas has a stronger odor than the sludge.

Conclusion

The CaS_x process is simple in its operation and makes it possible to remove various contaminants simultaneously. Thus, a good effect can be expected in water-

pollution control. The CaS_x process can also be applied to the advanced treatment of sewage which usually contains COD/BOD substances, phosphate, ammonia, and a trace of heavy metals.

The authors wish to express their appreciation of their useful discussions with Mr. Kiyochika Yahikozawa of Shinshu University, Prof. Dr. Ryuzo Ito of Osaka University, Profs. Drs. Takataro Suda and Yoshiki Sanoh of Shinshu University, and Assoc. Prof. Dr. Kei Miyanami of the University of Osaka Prefecture.

Studies in Isodielectric Media. The Standard Potentials of Ag–AgCl and Ag–AgBr Electrodes in 1,2-Ethanediol–2,2′-Oxydiethanol Mixtures at 25 °C

P. SIVAPRASAD and C. KALIDAS*

Department of Chemistry, Indian Institute of Technology, Madras 600036, India

(Received September 16, 1977)

Standard potentials of Ag–AgCl and Ag–AgBr electrodes in various compositions of 1,2-ethanediol–2,2′-oxydiethanol (ethylene glycol–diethylene glycol) mixtures at 25 °C are reported. The free energies of transfer of the hydrogen halides from ethylene glycol to the mixtures were evaluated on mole fraction scale. The transfer free energies of H^+ and the halide ions were determined employing the ferrocene reference method. The results suggest that the basicity of the mixtures increases with the addition of diethylene glycol and that it is more basic than ethylene glycol.

Studies in isodielectric solvent mixtures have provided valuable information[1,2] on solute-solvent interactions in mixed solvents in recent years. In particular, such investigations enable one to study the influence of the chemical effect of the solvents on the thermodynamics of transfer between different solvents, for the electrostatic effects arising out of the difference in the dielectric constants of the solvent components are expected to be small in these media. Although a few emf studies in isodielectric media have been made,[3,4] no measurements have been reported in the binary mixtures of glycols. Since the dielectric constants of ethylene glycol (EG) and diethylene glycol (DEG) at 25 °C are 41.20 and 31.20 respectively and those of their mixtures are expected to be between these limits, all these solvents should serve approximately as isodielectric media. In continuation of our earlier work on the thermodynamic behaviour of electrolytes and ions in glycolic solvents,[5,6,7] the present work therefore deals with the determination of standard potentials of the silver–silver chloride and silver–silver bromide electrodes in 20 to 80 wt % EG–DEG mixtures at 25 °C. The cell (1) was used for the determination of the standard potential of the Ag–AgCl electrodes.

$$\text{Pt, } H_2\text{(g, 1 atm)/HCl(m) solvent/AgCl, Ag} \qquad (1)$$

and the buffered cell (2)

$$\text{Pt, } H_2\text{(g, 1 atm)/HOAc(m1), NaOAc(m2), KX(m3) solvent/AgX, Ag} \qquad (2)$$

containing acetic acid (HOAc), sodium acetate (NaOAc) and potassium bromide (KBr) with X=Br was used for determining the standard potentials of Ag–AgBr electrode. The dissociation constant of acetic acid required in the evaluation of the standard potentials of Ag–AgBr electrode in these solvents was determined as described later.

Experimental

EG (LR, BDH) and DEG (LR, BDH) were purified by the methods described earlier.[5,8] The preparation of the stock acid solutions was as described elsewhere.[8]

Ag–AgCl and Ag–AgBr electrodes were of the thermal electrolytic type and were prepared according to the method of Janz and Ives.[9] The preparation of the hydrogen electrode and the experimental set up employed in EMF measurements are similar to those described in detail in earlier work.[5] The cells were thermostated with an accuracy of ±0.05 °C during equilibration. The cells normally attained equilibrium 5—6 h after the start of hydrogen bubbling in all the mixtures and constancy of emf values to ±0.1 mV over a period of half an hour was considered as an adequate criterion of equilibrium. The vapour pressures of the solvents being very small, no vapour pressure correction was applied to the emf data. The transfer free energy of proton in these mixtures was determined by employing the ferrocene reference method according to the procedure described earlier.[10]

Results and Discussion

The standard molal potentials ${}_sE^\circ_m$ of the cell (1) in different solvent mixtures were obtained by extrapolation of the function

$$E^{\circ\prime} = E + 2k\log m - 2kA'm^{1/2}/(1+aB'm^{1/2}) - 2k\log(1+0.002\,mM_{xy}) = {}_sE^\circ_m - 2k\,b\,m \qquad (3)$$

to zero molality. In the above equation,

$$k = 2.303\,RT/F, \qquad (4)$$

m is the molality of HCl, A' and B' are the Debye-Hückel constants on the molality scale, a is the ion size parameter, b is the coefficient occurring in the activity coefficient expression as a function of molality and M_{xy} is the mean molar mass of the mixed solvent as defined earlier.[5] In determining ${}_sE^\circ_m$, a=5 Å was used as this was found to give good linear plots with the least slope. The standard potentials of the Ag–AgCl electrode on molar (${}_sE^\circ_c$) and mole fraction scales (${}_sE^\circ_N$) were calculated from (${}_sE^\circ_m$) with the help of usual relationships given earlier.[5] All these values at 25 °C are given in Table 1.

The standard potentials (${}_sE^\circ_m$) of the Ag–AgBr electrode at 25 °C in different solvent mixtures were obtained from a plot of the function $E^{\circ\prime}$ defined by

$$E^{\circ\prime} = E - 2.303\frac{RT}{F}\mathrm{p}K_{(\mathrm{HOAC})} + 2.303\frac{RT}{F}\log\frac{m\,\mathrm{HOAC}\;m\,\mathrm{Br}^-}{m\,\mathrm{OAC}^-} = {}_sE^\circ_m - 2.303\frac{RT}{F}\log\frac{\gamma\mathrm{HOAC}\;\gamma\mathrm{Br}^-}{\gamma\mathrm{OAC}^-} = {}_sE^\circ_m + f(\mu) \qquad (5)$$

against μ, the ionic strength, by extrapolating to μ=0. $E^{\circ\prime}$ values were computed by using the values of $\mathrm{p}K_{(\mathrm{HOAC})}$ and the measured EMF values of cell (2) with X=Br for various buffer compositions. $\mathrm{p}K_{(\mathrm{HOAC})}$ values required in Eq. 5 were obtained from measurements

40	−415	−936	−39	−376	−897
60	569	−454	−268	837	−186
80	2162	569	−922	3084	1491
100	2635	1785	−1267	3902	3052

on cell 2 with X=Cl and utilizing the ${}_sE^\circ_m$ values of Ag–AgCl electrode in these solvents obtained with cell (1). In calculating $E^{\circ\prime}$, it was assumed that KBr and NaOAc are completely dissociated in all the solvents, and that the dissociation of HOAc is so small that it does not affect the effective concentration of HOAc and OAc^-. The ${}_sE^\circ$ values on different scales are also presented in Table 1.

The transfer free energy of proton, $\Delta G^\circ_{H^+}$ in these mixtures was determined as described earlier from the relation

$$\Delta G^\circ_{cell} = F({}_sE^\circ_N - {}_{EG}E^\circ_N) = \Delta G^\circ_{FIC^+(el)} - \Delta G^\circ_{H^+}, \quad (6)$$

where ${}_sE^\circ_N$ and ${}_{EG}E^\circ_N$ represent the standard potentials of the cell

$$\frac{\text{Pt, } H_2\text{(g, 1 atm)}}{H^+ \text{ in the solvent}} \;\Big|\; \frac{FiC^+, FOC\ 1:1 \text{ in the solvent}}{\text{Pt}} \quad (7)$$

in the solvent and EG respectively on the mole fraction scale.

$\Delta G^\circ_{FIC^+(el)}$ which represents the electrostatic transfer free energy of the ferricinium ion from EG to the solvent was determined from the Born equation using the dielectric constants of the solvent mixtures (our unpublished results) determined by us.

The standard free energy change, ΔG°_t, for the transfer of one mole of HX from the standard state in one reference solvent to the standard state in another can be calculated from the standard potential data of the Ag–AgX electrodes in different solvents. Considering EG as the reference solvent, $\Delta G^\circ_{t(HX)}$ for HCl and HBr were computed by

$$\Delta G^\circ_t = F({}_{EG}E^\circ_N - {}_sE^\circ_N), \quad (8)$$

where ${}_{EG}E^\circ_N$ and ${}_sE^\circ_N$ are the standard potentials in EG and the solvent mixtures respectively. They are recorded in Table 2 and are accurate to ±90 J. The free energies of transfer of H^+, and the halide ions are also given in Table 2. The ΔG°_t values for both acids are found to have small negative values initially, pass through a minimum at about 20 wt % DEG and then increase (become positive) with the further addition of DEG. Thus while the transfer of HCl and HBr from EG to the mixed solvents is thermodynamically favourable upto about 40 wt % DEG, the transfer process is not favoured at higher compositions of DEG. For any solvent the values for HBr are more negative than for HCl indicating that the transfer is relatively easier for HBr than for HCl. The nature of the variation of ΔG°_t with solvent composition suggests that two opposing factors must operate so as to give the observed minimum in the EG rich region. The transfer free energies of the proton together with the data for the halide ions (Table 2) in these solvent mixtures lend support to the above conclusion because $\Delta G^\circ_{t(H^+)}$ and $\Delta G^\circ_{t(Cl^-)}$ clearly vary in opposite directions. However, it is seen that the changes in $\Delta G^\circ_{t(X^-)}$ predominate over that of $\Delta G^\circ_{t(H^+)}$ and thus govern the overall variation of $\Delta G^\circ_{t(HX)}$ with the solvent composition.

In general, the basicity of the solvent mixtures increases with increasing proportion of DEG and also DEG is more basic than EG. These results are in agreement[10] with the conclusions arrived on the basis of proton medium effects determined by the ferrocene reference method in DEG–water and EG–water mixtures earlier.

Variation of Transport Properties as Functions of Temperature and Composition in Glass-forming Melts — An Isoenergic Equation

Nurul ISLAM,* Satendra KUMAR, and Kunwar Pal SINGH
Department of Chemistry, Aligarh Muslim University, Aligarh 202001, India
(Received November 24, 1977)

Measurements of density, ρ, viscosity, η, and electrical conductance, Λ, in glass-forming molten mixtures of manganese(II) chloride–tetrabutylammonium bromide were made as functions of temperature and composition. The non-Arrhenius temperature dependence of transport properties has been discussed in terms of equations based on the free-volume model. Composition dependence of viscosities has been explained satisfactorily through a parabolic equation, $\eta=p+qN+rN^2+sN^3$, where p, q, r, and s are the empirical parameters and N is the mole fraction of the solute. The minimum in the viscosity isotherms has been observed at $N=-q/2r$. A better applicability of isoenergic equation, $Y(=\phi$ or $\Lambda)=(A_{0Y}-Q_{1Y}N)c^{-1/2}(T_{0(0)}+Q_2N)^{-1/2}\exp[-k_{1Y}/(T_{0(0)}+Q_2N)\text{-}(c-1)]$ over an isothermal equation (both based upon free volume model) in explaining the transport process in all the glass-forming melts has been emphasized.

Temperature dependence of transport properties starting from very high temperatures where it is of Arrhenius' type passes through the middle region from T_g to $2T_g$ where it becomes of non-Arrhenius' type, and once again it is of Arrhenius' type at low temperatures. Such dependence in the middle region has been studied by several workers in terms of equations based upon free-volume and configurational entropy models; of these based upon the former are

$$Y = A_{1Y}T^{-1/2}\exp[-k_{1Y}/(T-T_0)], \quad (1)$$

$$Y = A_{2Y}\exp[-k_{2Y}/(V-V_0)], \quad (2)$$

where symbols have their usual significances. Equally important composition dependence has been described by considering the variation of the empirical parameters, A_Y and T_Y with concentration of these equations. Angell[1,2] proposed an isothermal equation by assuming A_Y and k_Y as composition independent and only T_0 varying linearly with concentration, which is of the form

$$Y = A_{1Y}T^{-1/2}\exp[-k_{1Y}/Q_2(N_0\delta-N)], \quad (3)$$

where N is the concentration in mol%, Q_2 is the slope of T_0 *versus* N plots, and N_0, the characteristic composition at which the isothermal temperature, T becomes the glass transition temperature, T_g of the system. Recently, a linear decrease of A_{1Y} terms[3,4] with composition has been observed and Eq. 3 was modified[5] accordingly in order to account for that, and is of the form

$$Y = (A_{0Y}-Q_{1Y}N)T^{-1/2}\exp[-k_{1Y}/Q_2(N_0-N)]. \quad (4)$$

Q_{1Y} is the negative slope of A_Y *versus* N plots and A_{0Y} the preexponential term for the pure solvent. This equation was satisfactorily employed to explain the composition dependence of transport properties of several molten salt mixtures.[5,6] However, such an isothermal equation may only be employed within the temperature limits ranging between the T_0's of the solvent and the solute. Beyond this range N_0 will have values which are either less than zero or more than 100 mol% and such values may not have any physical meaning whatsoever. To overcome these difficulties an expression based upon configurational entropy model was suggested in an earlier paper,[7] in which the use of isentropic condition, $c=T/T_0$ was made based upon the definition of configurational entropy[8] as $S_c=\Delta C_p \ln(T/T_0)$ where ΔC_p is the difference in heat capacities of liquid and glassy state. Assuming ΔC_p as almost composition invariant at equal values of T/T_0, the entropy may also be considered as constant. However, we remain unable to give sufficient support to this assumption that ΔC_p is compostiion independent. Therefore, another modified expression based upon free volume model has been suggested here to explain more satisfactorily the composition dependence of transport properties of glass-forming melts. Tetrabutylammonium bromide–$MnCl_2$ system has been selected here for further studies of such behavior. The system under consideration is of importance, as its viscosities show an abnormal composition dependence. Such behavior of viscosity has been explained through a parabolic equation as well as modified free-volume expression.

Experimental

Tetrabutylammonium bromide (Fluka) was used as solvent in molten state and anhydrous $MnCl_2$[9] as solute. The experimental techniques used and the precision of measurements are similar to those reported earlier.[7,10] Also the ranges of composition and temperature measurements are the same as reported in a previous paper.[7]

Results and Discussion

The measured densities of the system under investigation have been least-squares fitted to a linear function of the form $\rho=a-bT$ (K) and the values of computed parameters are given in Table 1.

a) Fluidity data are within parentheses.

Temperature Dependence of Fluidities and Conductances. The conductance and fluidity data (Table 2) show non-Arrhenius temperature dependence and therefore least-squares fitted to Eqs. 1 and 2. The empirical parameters of these Eqs. along with standard deviations in $\ln \phi$ and $\ln \lambda$ are given in Table 3. Linear plots (Fig. 1) of $\log(\phi T^{1/2})$ and $\log(\lambda T^{1/2})$ *versus* $1/(T-T_0)$ show the applicability of Eq. 1 to explain the temperature dependence. Further, the plots of ϕ and λ *versus* $(V-V_0)$ were found to be non-linear signifying the inability of the Hildebrand equation,[11] $Y(=\phi$ or $\lambda)=B(V-V_0)/V_0$, to explain the transport behavior in the present system. However, linear plots (Fig. 2) of $\log \phi$ and $\log \lambda$ *versus* $1/(V-V_0)$ demonstrate a better fit of these data to Doolittle Eq. 2. Empirical parameters of this equation are given in Table 3 along with standard deviations in $\ln \phi$ and $\ln \lambda$.

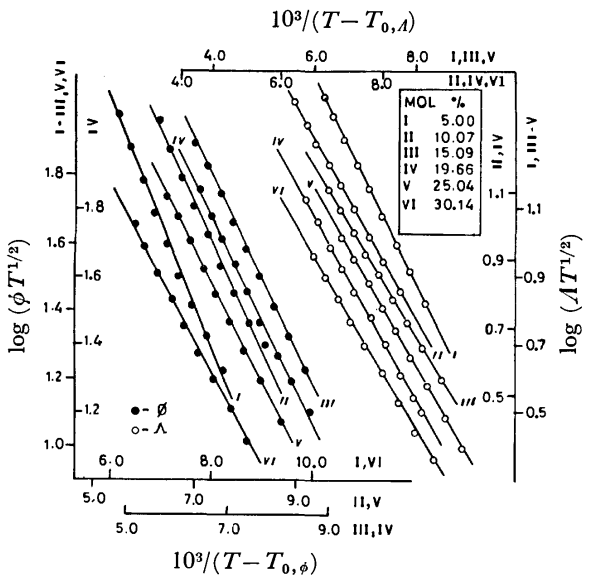

Fig. 1. Plots of $\log(YT^{1/2})$ *vs.* $1/(T-T_0)$ for TBAB-$MnCl_2$ melts.

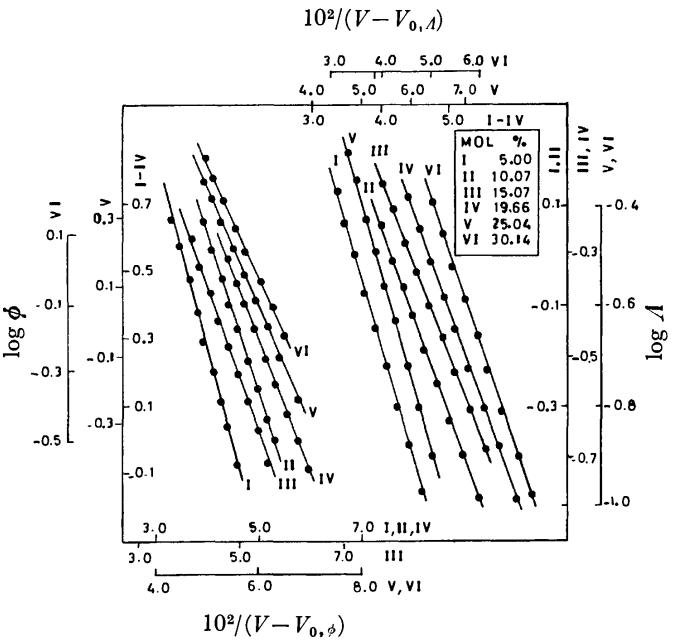

Fig. 2. Plots of $\log Y$ *vs.* $1/(V-V_0)$ for TBAB-$MnCl_2$ melts.

Both Eqs. 1[12] and 2[13] based upon the free volume approach are similar to one another. The parameter A_{2Y} of Doolittle Eq. is expected to depend on composition as in the case of A_{1Y} of free-volume model. Similarly k_{2Y} in the exponential term is related to k_{1Y} as being composition independent. Moreover, values of $T_{0,\phi}$ and $T_{0,\Lambda}$ and $V_{0,\phi}$ and $V_{0,\Lambda}$ obtained from Eqs. 1 and 2, respectively, are very close to one another thereby indicating the thermodynamic nature of glass transition temperature, T_0 and intrinsic volume, V_0 rather than kinetic. $k_\phi \approx 700$ K and $k_\Lambda \approx 600$ K seem

a) Fluidity data are within parentheses.

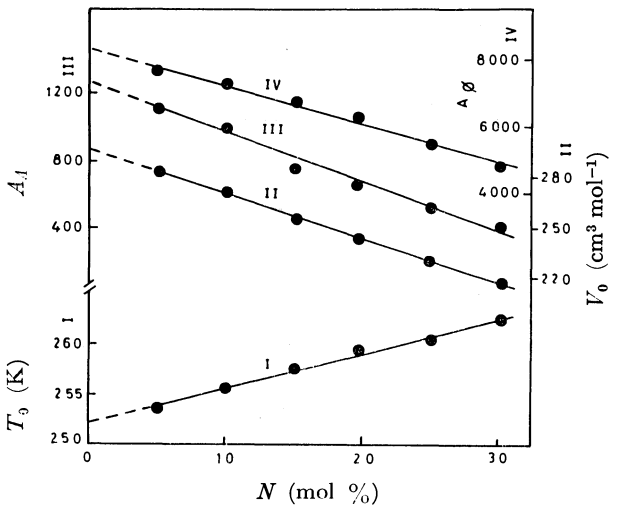

Fig. 3. Variation of T_{0Y}, $V_{0,\phi,A}$, and A_{1Y} with composition for TBAB-$MnCl_2$ melts.

to be very close to the values assigned to them as being universal constants.

The values of the preexponential factors of both Eqs. 1 and 2 decrease linearly with concentration (Fig. 3). Although there is a marked difference in the magnitude of A_Y terms of these equations which may be due to the absence of $T^{-1/2}$ in the preexponential term in Eq. 2. According to Cohen and Turnbull,[14] the A_Y terms may be expected to show direct dependence on $r/m^{1/2}$, where r and m are the effective radius and mass, respectively of the component particles of the system. In the present system there is a decrease in average molar mass by the addition of $MnCl_2$ to the molten TBAB, hence one can predict an increase in A_Y terms with increase in [$MnCl_2$]. However, an opposite trend has been obtained in the variation of A_Y with composition and may be represented as

$$A_Y = A_{0Y} - Q_{1Y}N, \tag{5}$$

where A_{0Y} is the value of the preexponential term for the pure solvent and Q_{1Y} gives the negative slopes of A_Y *versus* N plots.

An alternative explanation may be accorded for such a change in A_Y terms. According to Maxwell

$$Y = \frac{1}{\tau G}, \tag{5}$$

where τ is the relaxation time of the flowing entities and G is the rigidity modulus of the system. Using Eyring's expression, Eq. 6 may be written as

$$Y = \frac{1}{G\tau_0} \exp\left[-E_Y/RT\right], \tag{7}$$

in which τ_0 is the period of vibration of the flowing entity in its equilibrium position and E_Y is the activation energy for the transport process. R and T have their usual significances. Comparing Eqs. 1 and 7 we may obtain

$$A_{1Y} = \frac{T^{1/2}}{\tau_0 G}. \tag{8}$$

The above expression implies that A_Y is a function of rigidity of the system and as the concentration increases the rigidity of the system may increase. Moreover, the transition probability decreases with increasing concentration, in other words, the relaxing species will vibrate for a longer time in its equilibrium position with an increase in concentration. Accordingly, this may account for the linear decrease of A_Y terms with increasing [$MnCl_2$]. Further, the larger value for the slope of the linear plot of A_ϕ *versus* N than that of A_A *versus* N implies that A_ϕ decreases more rapidly than A_A with increase in concentration. Therefore, conductance appears to be less prone to the change in rigidity of the system than the fluidity.

In the system under investigation as well as in a variety of other[3,5,12,15] systems T_0 shows a linear relationship with mol % of solute (Fig. 3) which may be expressed as

$$T_0 = T_{0(0)} + Q_2N, \tag{9}$$

where $T_{0(0)}$ is the glass transition temperature for the pure solvent and Q_2 is the slope of T_0 *versus* N plot. This linear increase of T_0 with composition can be explained by considering that T_0 depends upon coulombic interactions or cohesive energy of the system.[12] The interactions increase with increase in [Mn^{2+}] thereby increasing T_0 values. In other words, an increase in T_0 with an increase in [$MnCl_2$] may be

Table 4. Computed parameters for Eqs. 10 and 11 for Walden product of TBAB–$MnCl_2$ melts

attributed to an increase in net cohesion in the system due to complex formation which leads to an eventual supercooling to glassy state. Therefore, it appears that in the absence of crystallization, addition of an excess amount of solute to any ionic solution results in glass formation and a sharp increase in viscosity may result, and such a concentration will be the glass transition composition, N_0. Also the linear increase in $T_{0,\gamma}$ with increase in [$MnCl_2$] may be due to the decrease in average mass of the system with the addition of $MnCl_2$ to TBAB melts.[7] Moreover, the values of $V_{0,\phi}$ and $V_{0,\Lambda}$ (Fig. 3) appear to decrease with increase in [$MnCl_2$] which may be due to the close packing of the system.

Temperature Dependence of Walden's Product. The temperature dependence of Walden's product, $\Lambda\eta$ may be represented through expressions[5] essentially based upon Eqs. 1 and 2 of the form

$$\Lambda\eta = A_3 \exp\left[k_3/(T-T_0)\right], \tag{10}$$

and

$$\Lambda\eta = A_4 \exp\left[k_4/(V-V_0)\right], \tag{11}$$

where A_3, k_3, A_4 and k_4 are empirical constants. The best fit values of these parameters are given in Table 4. The simultaneous representation of the temperature dependences of Λ and η appears to be more sound due to their interdependent nature.

The temperature dependence of $\Lambda\eta$ product may also be expressed satisfactorily by Frenkel's equation[16]

$$\Lambda^n\eta = \text{constant}, K. \tag{12}$$

This is apparent from its recent application to the $\Lambda\eta$ products of $CoCl_2$–$Ca(NO_3)_2.3.91H_2O$ molten mixtures.[5] Computed parameters for Eq. 12 are given in Table 5 for the present system. Here n is the ratio of E_ϕ/E_Λ, which is found to be greater than one. It may be further emphasized that failure of Walden's rule in molten salts may be due to the higher activation energies for viscous flow than ionic and is likely due to the difference in the availability of the species for relaxation in the two processes.

30.14	1.0635	1.7522	0.015

Composition Dependence of Fluidities and Conductances. A regular decrease in electrical conductance with increase in composition is observed (Table 2) which may be attributed to the removal of more mobile anions as a result of complex formation and simultaneous decrease in free volume. While an increase in fluidity is observed as the concentration of $MnCl_2$ increases from ≈5 to ≈10 mol % and then decreases with further increase in concentration. The minimum at ≈10 mol % of Mn^{2+} appears to flatten as the temperature increases (Fig. 4). Such an unexpected trend in the viscosity isotherms has earlier[3] been observed in the molten TBAI+$CoCl_2$ systems. Similar abnormal behavior of viscosity as well as conductance isotherms has also been reported in several other binary molten mixtures.[15,17,18]

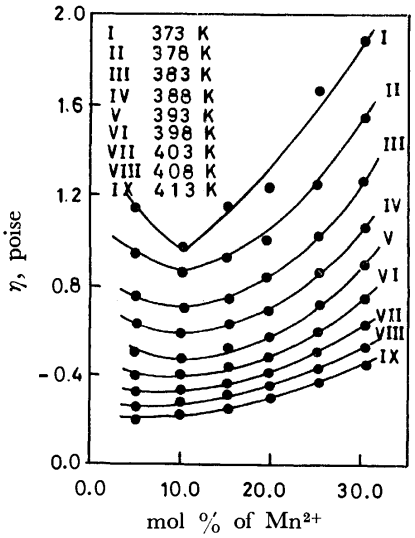

Fig. 4. Viscosity, η isotherms for TBAB–$MnCl_2$ melts.

The decrease in the viscosity in concentration range up to ≈10 mol % of $MnCl_2$ may be attributed to the decrease in electrostatic force holding a solvent ion-pair together due to the presence of free metal ions in its neighborhood. Such a dissociation with increase in concentration of solute at constant temperature depends upon the number of free metal ions and the thermal energy of the solvent.[19] The minimum in the viscosity isotherms corresponds to a point where dissociation is maximum. Furthermore, when the dissociation of solvent molecules (TBAB) increases

with increase in [$MnCl_2$], the solvent anions, *i.e.*, Br^- ion formed in this way form a complex species with the free metal ion as $MnBr_4^{2-}$, the presence of which has been supported by its ligand-field bands.[10] The complex species formed associates with the solvent cation, Bu_4N^+. Such a simultaneous complexation and association at higher concentrations may increase the viscosity of the system from ≈ 0.1 to ≈ 0.30 mole fraction of $MnCl_2$. This abnormal nature of viscosity isotherms has been empirically described by least-squares fitting the data to a polynomial equation of the form

$$\eta = p + qN + rN^2 + sN^3, \quad (13)$$

where p, q, r, and s are empirical constants, using POLRG computer program. This computer program is similar to that reported by Easteal and Hodge[17] and can fit the data to polynomials up to seventh degree. The computed values of the empirical constants are presented in Table 6 along with the standard deviation from the observed η. It is apparent from the table that in most of the cases the polynomial is quadratic and the expected minimum at the mole fraction, $N=-q/2r$ fairly coincides with those of the viscosity isotherms, *viz.* ≈ 0.1 (Fig. 4).

The conventional activation eneriges, E_ϕ and E_Λ were computed from the corresponding derivatives of Eq. 1. A regular decrease in activation energies, E_ϕ and E_Λ with temperature was obtained which may be due to the thermal expansion of the system thereby decreasing the interionic forces or, in other words, lowering the height of the potential energy barrier for the flow processes.

Table 6. Computed parameters for Eq. 13 for the viscosity of TBAB-$MnCl_2$ melts

T (K)	p	q	r	s	Std dev in η

413.0	0.2282	−0.434	3.95	—	0.005

On the other hand, an abnormal behavior in the composition dependence of E_ϕ has been observed. E_ϕ decreases initially with an increase in the concentration of $MnCl_2$ and passes through a minimum at ≈ 10 mol % of $MnCl_2$ and then increases with further increase in [$MnCl_2$] as observed in the case of Bu_4NI–$CoCl_2$ melts.[3] The decrease in activation energy for viscous flow up to ≈ 10 mol % may be due to the dissociation of solvent molecules which results in an ease to viscous flow. Furthermore, the increase in E_ϕ following minimum may be due to the complexation and association as discussed above. However, at equal values of T/T_0 the corrected activation energies ($E_Y + 1/2RT$) of the molten salt systems may be considered as constant,[2,20] which may be termed as an isoenergic condition. Therefore, the fluidities and conductances may be plotted *versus* composition at constant T/T_0 values. The significance of such plots is that a better quantitative illustration of the composition dependence of transport properties may be made at equal T/T_0 values by accounting for the composition dependence of individual parameters in Eq. 1. At T/T_0=constant, c, Eq. 1 becomes

$$Y = A_{1Y}(cT_0)^{-1/2} \exp\left[-k_{1Y}/T_0(c-1)\right]. \quad (14)$$

The values of fluidities and equivalent conductances at constant T/T_0 ratios ranging from 1.4 to 2.1 were calculated from Eq. 14 and are in turn least-squares fitted to the equation obtained by substituting the linear variations of A_Y and T_0 with composition, in Eq. 14 as

$$Y = (A_{0Y} - Q_{1Y}N)c^{-1/2}(T_{0(0)} + Q_2N)^{-1/2} \exp\left[-k_{1Y}/(T_{0(0)} + Q_2N)(c-1)\right]. \quad (15)$$

Table 7. Computed parameters for Eq. 15 (c=1.4 to 2.1) for the fluidities[a] and equivalent conductances of TBAB-$MnCl_2$ melts

Volues of c	A_{0Y}	Q_{1Y}	k_{1Y} (K)	$T_{0(0)}$ (K)	Q_2	Std dev in ln Y
1.4	1278.0	27.52	607.8	251.5	0.368	0.098
	(8229.0)	(103.20)	(703.8)	(251.2)	(0.375)	(0.097)

a) Parameters for fluidity are within paratheses.

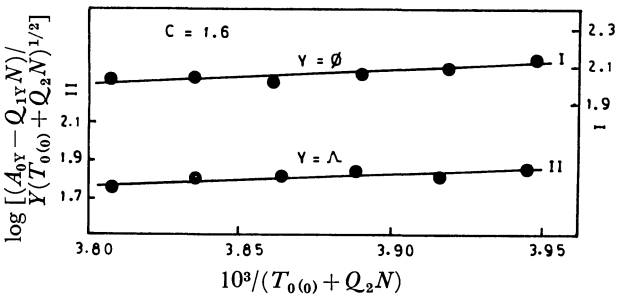

Fig. 5. Plots of $\log[(A_{0Y}-Q_{1Y}N)/Y(T_{0(0)}+Q_2N)^{1/2}]$ *vs.* $1/(T_{0(0)}+Q_2N)$ for TBAB-$MnCl_2$ melts.

Reasonably good fits were obtained at different c values and the computed values of the parameters are given in Table 7. The successful applicability of Eq. 15 to explain composition dependence of transport properties in the system under investigation may be emphasized by linear plots (Fig. 5) of $\log[(A_{0Y}-Q_{1Y}N)/Y(T_{0(0)}+Q_2N)^{1/2}]$ *versus* $1/(T_{0(0)}+Q_2N)$ which pass through the origin. The computer fitted values of the parameters A_{0Y}, Q_{1Y}, k_{1Y}, Q_2, and $T_{0(0)}$ were found to be very close to those obtained from the corresponding plots (Fig. 3). Thus the value of $T_{0(0)}$ obtained from Eq. 15 is in good resemblance with that obtained by extrapolating the plot of T_0 *versus* N to zero mol% of $MnCl_2$.

It may be concluded that the isoentropic conditions used in the earlier paper[7] [TBAX (X=Cl, I)-$MnCl_2$ systems] and the isoenergic conditions used in the present system, satisfactorily represent the composition dependence of viscosities and conductances in the glass-forming melts irrespective of the geometry of the complex species present. However, the latter conditions seem to be more satisfactory because of having sound experimental base and may be employed over wide range of temperature without depending on the T_0's of the solvent and solute.

The authors are thankful to Professor W. Rahman, Head of the Department of Chemistry, for providing necessary facilities. Financial assistance of CSIR (India) to two of us (S. K. and K. P. S.) is gratefully acknowledged.

20) The corrected activation energies, E_{corr}, for conductance and viscous flows were obtained as $E_{corr}/Rk_{1Y}=[T/(T-T_0)]^2$ from the derivatives of Eq. 1, where R is the gas constant and k_{1Y} is the empirical constant in Eq. 1. If we take T_0 as the corresponding temperature scale instead of absolute temperature, T then at the constant value of T/T_0 we have $E_{corr}/Rk_{1Y}=[(T/T_0/(T/T_0-1)]^2$. Therefore, E_{corr}/Rk_{1Y} may have a constant value at equal T/T_0 values.

A Molecular Orbital Treatment of the Electronic Spectra of Linear and Cross Conjugated Systems. Thienyl Phenyl Ketones and *N*-Thenylideneanilines

R. Abu-Eittah* and R. Hilal

Department of Chemistry, Faculty of Science, University of Cairo, Giza, Cairo, Egypt

(Received July 25, 1977)

The electronic absorption spectral measurements as well as MO calculations have been conducted on representatives of a cross conjugated system, thienyl phenyl ketones, and a linear conjugated system, *N*-thenylideneanilines. Results have proved that, although the two systems may be "π"-isoelectronic yet, their electronic spectra differ substantially. The nodal properties of the molecular orbitals of the two systems explain nicely their differences in conjugation. Steric factors play no roll concerning the differences in the spectra of the two systems.

The conformational analysis of composite molecules is a subject of increasing importance yet, the difficulties encountered in the experimental determination of their structure[1-3] turn the attention to the theoretical procedures. Most composite molecules possess a "complex-type" of orbital interactions[4] which are not treated explicity in most theoretical treatments; one such complicated interaction is the cross-conjugation[5] in these molecules.

The aim of the present investigation is to examine the effect of cross and linear conjugation on the electronic spectra of a series of typical composite molecules, namely, 2-thienyl phenyl ketones and *N*-thenylideneanilines.

Qualitative interpretation of the spectra of 2-thienyl phenyl ketone was reported by Koper and Boer[6,7] whereas the spectra of *N*-thenylideneanilines have not been investigated before, although they were synthesized and showed wide applicability.[8]

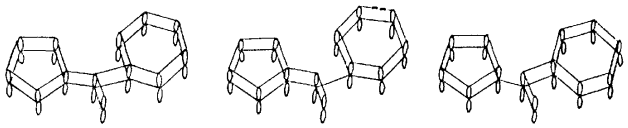
Experimental

Solvents and apparatus used are described before.[9] 2-Thienyl phenyl ketones were prepared by stirring thiophene and the appropiate aroyl chloride in the presence of anhydrous aluminum chloride at low temperature.[10] The mixture is then refluxed, cooled and poured on ice and extracted with ether. Vacuum distillation and crytallization from petroleum ether gave pure products with melting points identical to those reported.[10]

N-(2-Thenylidene)anilines were prepared by azeotropic condensation of thiophene-2-aldehyde with the corresponding aniline. The products were purified by vacuum distillation.

Results and Discussion

I. Electronic Absorption Spectra. (A) 2-Thienyl Phenyl Ketones: In the composite molecule 2-thienyl phenyl ketone, a competition is assumed to exist between the thienyl and phenyl moieties for conjugation with the carbonyl group. If the two moieties interact equally with the carbonyl group *e.g. via* both the resonance and electron repulsion integrals, then Conformer I will predominate and the electronic spectrum of the composite molecule should differ substantially from that of its subsystems. On the other hand, if one moiety enjoys greater overlap with the $2p_z$ orbital of the carbonyl carbon atom then conformers II or III will predominate. In the latter case the interaction of the phenyl ring with



I II III

the thienyl ketone (II) or the thienyl ring with the phenyl ketone (III) will be *via* electron repulsion terms only. Rotation about the sigma bond joining the two subsystems (in Conformers II and III) could lead to a nonplanar conformation for the composite molecule.

Figure 1 shows the electronic absorption spectra of 2-thienyl phenyl ketone, which consists mainly of two overlapping transitions. This spectrum is very much similar to that of 2-acetylthiophene indicating that the interaction of the phenyl group with the thienyl ketone group is not substantial. Consequently, Conformer II is a predominant one. If the phenyl ring aquires a plane perpendicular to the plane of the rest of the molecule, the n_0 electrons would be conjugated with the "π"

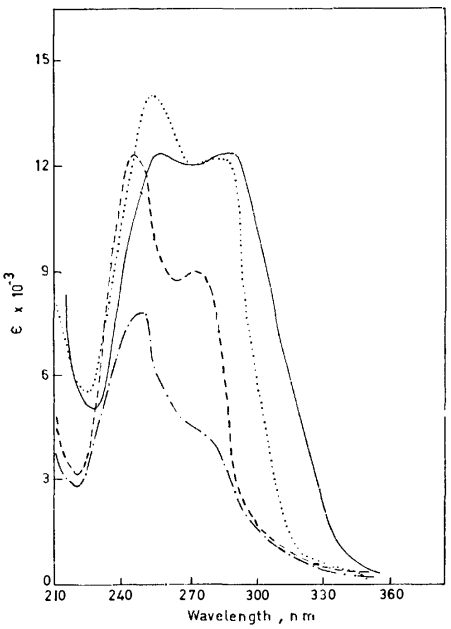


Fig. 1. Electronic absorption spectra.
——: 2-Thienyl phenyl ketone in ethanol, ·····: 2-thienyl phenyl ketone in cyclohexane, ----: 2-acetylthiophene in ethanol, -·-·-: 3-acetylthiophene in ethanol.

system of the benzene nucleus. This explains the absence of an n-π^* transition in the spectra of such a molecule.

To confirm the above results, the spectra of *p*-methoxyphenyl 2-thienyl ketone and *p*-nitrophenyl 2-thienyl ketone were investigated (Fig. 2). The spectrum of the *p*-methoxy derivative is slightly different from that of 2-thienyl phenyl ketone; bands are slightly red shifted and intensified. This effect is expected only if the phenyl ring is not planar with the rest of the molecule. The band at 220 nm most probably corresponds to the ^1L_a of the *p*-methoxyphenyl moiety.[11] Although the ionization potential of anisole[12] (8.4 eV) is less than that of thiophene (9.1 eV) yet, conjugation is still between the carbonyl group and the thiophene nucleus.

The spectrum of *p*-nitrophenyl 2-thienyl ketone (Fig. 2) is different in many respects from that of the parent compound. The first band appears at ≈294 nm (3000) and the second band at 252 nm (21000). These bands compare very well with the corresponding transitions of *p*-nitroacetophenone (297 nm (2300) and 258 nm (16000)). This leads one to suggest that in *p*-nitrophenyl 2-thienyl ketone conjugation extends on the nitro group, the benzene nucleus, and the carbonyl group. It is interesting to remember that this was not the case in either the unsubstituted ketone or in the *p*-methoxy derivative. Rationalization of these results is easily found when considering the symmetry properties of the molecular orbitals of the subsystems, which will be discussed in the next section.

In the case of 2-acetylthiophene, 2-thienyl phenyl ketone and *p*-methoxyphenyl 2-thienyl ketone, the band at 280 nm has a pronounced "charge-transfer" character indicating that in all of them the donor site is the same, *i.e.* the thienyl moiety. For the *p*-nitro derivative this band has a λ_{max} at 294 nm in cyclohexane and 303 nm in methanol indicating that the donor and acceptor sites are different.

Table 1 gives the values of the molar extinction coefficients, band maxima and oscillator strengths of the observed transitions for the studied thienyl phenyl ketones in cyclohexane as a solvent.

(B) N-*(2-Thenylidene)anilines*: Thenylideneaniline is "π"-isoelectronic with 2-thienyl phenyl ketone. If the two compounds possess the same type of "π" conjugation their spectra would be similar. Comparison of Figs. 1 and 3 shows that this is not entirely the case, though the spectra of 2-acetylthiophene and *N*-(2-thenylidene)methylamine (Fig. 4) are very much similar. Consequently, there must be a substential difference in the degree of interaction of the phenyl group with the rest of the molecule in the two systems, 2-thienyl phenyl ketone and *N*-(2-thenylidene)aniline.

The features of the spectra of *N*-(2-thenylidene)aniline and *N*-(2-thenylidene)methylamine are completely different contrary to the case of 2-thienyl phenyl ketone

and 2-acetylthiophene. The spectrum of *N*-(2-thenylidene)aniline (Fig. 3) is characterized by the presence of overlapping transitions and consists mainly of two band systems whose intensities and positions vary in different ways as one goes from polar to nonpolar solvents. This suggests that they correspond to different electronic transitions. These results confirm a near planar structure for the thenylideneaniline.

The complications of the spectrum of *N*-(2-thenylidene)aniline makes it necessary to examine the spectra of some of its derivatives before any conclusion can be made. The spectra of *o*- and *p*-chloro, methoxy and nitro derivatives of *N*-(2-thenylidene)aniline are examined (Figs. 5—7). The general features of the spectra are similar to those of the parent compound. Substitution has perturbed all the observed transitions. Since the planar conformer is an adequate description of

thenylideneanilines; the observed bands correspond to transitions to "mixed-states" of the subsystems as well as a significant contribution of "charge-transfer" configurations.

II. Molecular Orbital Calculations. (A) 2-Thienyl Phenyl Ketone: The SCF wave functions of the molecule are determined assuming that the participation of the sulfur atom d-orbitals is trivial. The resonance integral terms are calculated using the relation[13]

$$\beta_{uv} = [S_{uv}/(1+S_{uv})][(I_u+I_v)/2]. \quad (1)$$

The electron repulsion terms are calculated using Nishimoto-Mataga[14] equation.

The self-consistent molecular orbitals of the composite molecule A-B are those of the separate constituents A and B. The extent of interaction between the two subsystems is determined by the value of the resonance integral β_{uv} and repulsion integrals γ_{uv} (atom u on A and atom v on B). The general expression for the interaction between two different singly excited configurations $^1\psi_{a-b}$ and $^1\psi_{c-d}$ is given by[15]

$$\langle {}^1\psi_{a-b}|\hat{H}|{}^1\psi_{c-d}\rangle = 2(cd|ab)-(ca|bd),$$

where $\hat{H}$ is the total Hamiltonian for the system.

Application to the Planar Conformer: The SCMO's of benzene are symbolized by the lower case letters (θ's), those of thienyl ketone by (y's). The corresponding states are symbolized by upper case letters (θ, Y). The singly excited states of benzene are

$$\Theta_\beta = (1/2)^{1/2}(\theta_3^{-1}\theta_4-\theta_2^{-1}\theta_5);\ \Theta_\beta = (1/2)^{1/2}(\theta_3^{-1}\theta_5+\theta_2^{-1}\theta_4),$$
$$\Theta_p = (1/2)^{1/2}(\theta_3^{-1}\theta_4-\theta_2^{-1}\theta_5);\ \Theta_\alpha = (1/2)^{1/2}(\theta_3^{-1}\theta_5+\theta_2^{-1}\theta_4).$$

For the 2-thienyl ketone the energies of the different configurations, $y_4^{-1}y_5$, $y_4^{-1}y_6$, $y_4^{-1}y_7$, $y_3^{-1}y_5$, $y_3^{-1}y_6$, $y_3^{-1}y_7$, are computed by the usual procedure[18] and the configuration interaction matrix of 2-thienyl ketone is solved. The form of the wave functions corresponding to the singly excited states of 2-thienyl ketone are available on request.

In the planar conformer the resonance integral β_{uv} is not zero and will mix together configurations which differ by the position of just one electron. The integrals to be evaluated are

$$\int \psi_o \hat{H}_{core} \psi_a^{-1} \psi_b \quad d\tau = (2)^{1/2} \int \psi_a(i) \hat{H}_i^{core} \psi_b(i) d\tau_i,$$
$$\int \psi_c^{-1} \psi_a \hat{H}_{core} \psi_c^{-1} \psi_b \quad d\tau = \int \psi_a(i) \hat{H}_i^{core} \psi_b(i) d\tau_i,$$
$$\int \psi_a^{-1} \psi_c \hat{H}_{core} \psi_b^{-1} \psi_c \quad d\tau = -\int \psi_a(i) \hat{H}_i^{core} \psi_b(i) d\tau_i.$$

The above integrals will be zero unless ψ_a belongs to one subsystem and ψ_b to the other. To calculate the electronic states of 2-thienyl phenyl ketone one has to consider the interaction between (1) ground state and "charge-transfer" states, (2) "charge-transfer" states to produce "charge-resonance" wave functions, (3) locally excited configurations and charge-resonance, and (4) locally excited configurations of the two subsystems.

To begin with, the charge-transfer (CT) configurations, $y_4^{-1}\theta_4$, $\theta_3^{-1}y_5$, $y_4^{-1}\theta_5$, $\theta_2^{-1}y_5$, are combined to produce the charge-resonance wave functions (CR's)

$$CR_I = (1/2)^{1/2}(\theta_3^{-1}y_5+y_4^{-1}\theta_4),$$
$$CR_{II} = (1/2)^{1/2}(\theta_3^{-1}y_5-y_4^{-1}\theta_4),$$
$$CR_{III} = (1/2)^{1/2}(\theta_2^{-1}y_5+y_4^{-1}\theta_5),$$
$$CR_{IV} = (1/2)^{1/2}(\theta_2^{-1}y_5-y_4^{-1}\theta_5).$$

The interaction terms between the fifteen different states, namely, the ground state, the four CR's, and the ten singly excited states localized on the two subsystems (Θ's and Y's) are computed (mathematical procedure is given before[16]). The interaction matrix is solved and the resultant energies and state wave functions of the ground and first three excited states are

		eV
(1)	$0.9855\psi_o-0.06226CR_I+0.05667CR_{II}$ $+0.1003CR_{III}$,	−0.137
(2)	$0.4948Y_1-0.5946Y_2+0.1434Y_3$ $+0.1958\Theta_\alpha+0.0480\Theta_P+0.0828CR_I$ $-0.4239CR_{II}+0.2136CR_{III}-0.3014CR_{IV}$,	3.375
(3)	$-0.7051Y_1-0.4095Y_2-0.3853\Theta_\alpha$ $-0.1499\Theta_\beta-0.1411\Theta_\beta-0.2313CR_I$ $-0.2094CR_{II}-0.3035CR_{III}-0.2796CR_{IV}$,	3.998
(4)	$0.1232Y_1-0.2018Y_2+0.0887Y_3$ $+0.6519\Theta_\alpha+0.1610\Theta_p+0.4835CR_I$ $+0.3205CR_{II}-0.1500CR_{III}-0.4319CR_{IV}$.	4.050

The calculated value 3.5 eV for the transition energy of the planar conformer of 2-thienyl phenyl ketone is significantly lower than the experimental one (4.4 eV). This is a strong evidence that either the planar conformer is a poor description of the molecule, or the molecule is planar but conjugation is not extending over the entire molecule. The spectrum of the molecule indi-

cates that conjugation extends only on the thienyl and carbonyl groups *i.e.* not including the benzene nucleus.

Application to the Perpendicular Conformer: The interaction between locally excited states Y's and Θ's is computed adopting the ZDO approximation. The matrix elements are computed for the ten states (six Y's and four Θ's) of 2-thienyl phenyl ketone. Solving this matrix, the energies and state wave functions are obtained. The first three are

	eV
(1) $-0.9985Y_1-0.0893\Theta_\alpha-0.0883\Theta_p$,	4.29
(2) $-0.9960Y_2+0.0862\Theta_\alpha+0.0127\Theta_\beta$,	4.59
(3) $0.0870Y_1+0.0870Y_2-0.1325Y_3$ $+0.9829\Theta_\alpha+0.0129\Theta_p$.	4.90

Comparison with experiment is postponed till we consider the "π"-isoelectronic *N*-(2-thenylidene)aniline.

(B) N-*(2-Thenylidene)aniline.* Computations are carried out in a similar way to that followed in the case of 2-thienyl phenyl ketone. Two conformers were considered, the *cis-* and the *trans-* planar ones. The numerical values of the parameters used are[17] (eV)

$$\alpha_C = -11.16;\ \alpha_N = -14.12;\ \alpha_S = -23.12,$$
$$\gamma_{CC} = 11.13;\ \gamma_{NN} = 12.34;\ \gamma_{SS} = 11.19.$$

The wave functions and the corresponding energies are given in Tables 2 and 3.

Comparison with Experiment: Table 4 compares the experimental and theoretically computed transition energies. For the 2-thienyl phenyl ketone values obtained for the perpendicular conformer agree satisfactorily with the experimental ones. On the other hand, planar conformers are good description for the *N*-(2-thenylidene)anilines with the *trans*-configuration nearer to reality than the *cis*-one.

Table 2. State function and energy of the ground and first four excited states for the *cis*-conformer of *N*-(2-thenylidene)aniline

Discussion and Conclusions

The spectra shown in Figs. 1 to 7 and the results of molecular orbital calculations (Table 4) indicate that, in 2-thienyl phenyl ketone, "π" conjugation does not extend over the entire molecule. This happens in two situations, (i) the phenyl ring lies in a plane perpendicular to that of the rest of the molecule, or (ii) the whole molecule is planar but the "cross-conjugation" behavior is pronounced; the net result would be the same. Drawing the molecules using Pauling atomic radii shows no sign of steric hinderance. Results at hand can not firmly differentiate between a perpendicular conformer and a planar "cross-conjugated" one. Also computations with a more sophisticated method would not be able to do so. Results of the theoretical treatment of 2-thienyl phenyl ketone shows a good agreement between the perpendicular conformer and the spectra. The wave functions of the excited states are merely those of either the thienyl ketone or the phenyl moieties of the molecule and mixing of states can be considered negligible.

Extensive interaction exists between the thienyl and phenyl groups with the azomethine group in the case

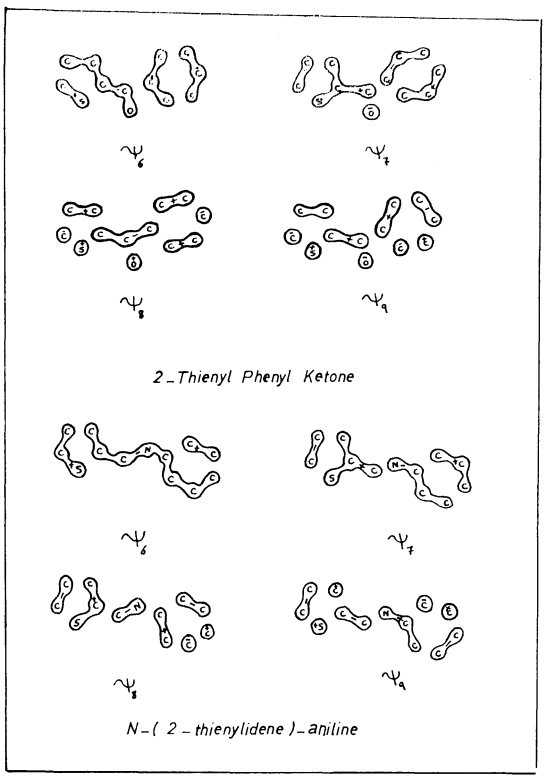

Fig. 8. The nodal properties of the highest two occupied and lowest two vacant MO's of 2-thienyl phenyl ketone and *N*-(2-thenylidene)aniline.

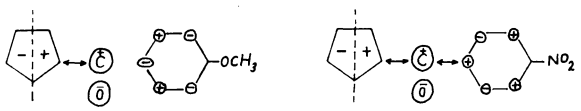

Fig. 9. The nodel properties of the highest two occupied and lowest two vacant MO's of 2-thienyl phenyl ketone.

of *N*-(2-thenylidene)anilines. Examination of Tables 2 and 3 indicates clearly that the wave functions of the excited states of the composite molecule represent mixed-states resulting from extensive interaction between the states of the two subsystems. As a result, the observed transitions can not be assigned to localized ones.

The cross-conjugation behavior is very nicely seen when considering the nodal properties of the molecular orbitals. Figure 8 represents the hieghest two occupied and lowest two vacant SCFMO's of 2-thienyl phenyl ketone and *N*-(2-thenylidene)aniline. Although a planar conformer is considered for both compounds with comparable resonance integrals yet, the antibonding character between the phenyl and carbonyl groups is pronounced in the molecular orbitals of 2-thienyl phenyl ketone as reflected in the values of the mobile "π"-bond order between the carbonyl carbon and the two competing moieties *i.e.* 2-thienyl and phenyl, which are 0.4100 and 0.1964 respectively. On the other hand, bonding character between the azomethine group and both the 2-thienyl and phenyl nuclei is pronounced ("π"-bond orders are 0.3324 and 0.2980 respectively). Hence, classification of the two compounds as cross and linear conjugated ones is reflected quite well in their electronic properties.

(Received April 26, 1977)

Complexes of Co(II), Ni(II), Cu(II), Ru(II), Rh(III), Pd(II), Pt(II), and Au(I) with 2*H*-1,2,4-triazole-3-thiol have been prepared. Probable structures have been proposed for the complexes on the basis of visible and infrared spectra, magnetic susceptibility, and chemical analysis. Crystal field parameters have been calculated wherever possible.

In the course of studies on metal complexes derived from the ligands having the skeletal unit NH–C(=S)–, the ligand 2*H*-1,2,4-triazole-3-thiol, whose *N*-substituted derivatives are of great biochemical interest,[1-3] has been found to be a good complexing agent. The isolation and characterization of complexes with the metal having d^{10} configuration have been described.[4] In this paper, the synthesis and structural studies of the complexes of Co(II), Ni(II), Cu(I/II), Ru(II), Rh(III), Pd(II), Pt(II), and Au(I) are reported.

Experimental

All the chemicals were or Analar or chemically pure grade.

Preparation of the Ligand. *(a) 2H-1,2,4-Triazole-3-thiol (I)*: The ligand in the H form and its sodium salt were prepared by the method given in literature.[4,5]

(b) Deuterated form of 2H-1,2,4-Triazole-3-thiol: About 0.1 g of the ligand was dissolved in 25 ml D_2O. The resulting solution was refluxed for *ca.* 4 h, heated to dryness, and kept overnight in a desiccator.

General Method of Preparation of Complexes. Conditions for preparation and analytical data of the complexex are given in Table 1. All the complexes were prepared by mixing an aqueous solution of an appropriate metal salt (sulfate or chloride) with an alcoholic solution of the ligand. The mixed solutions were heated on a water bath or refluxed, whereby the complexes of all the metal ions were precipitated out. The complexes were separated by centrifuging the slurry and were washed with methanol or ethanol and ether, and dried in a vaccum desiccator.

Analyses. Sulfur, chloride (wherever present), and metal ions were analysed by the standard methods[6-8] after fusion in a Parr-bomb by Na_2O_2 and KNO_3. Analyses of carbon, hydrogen, and nitrogen were carried out in the Microanalytical Section of the Indian Institute of Technology, Kanpur, India.

Magnetic Susceptibility. Magnetic susceptibility was determined at room temperature with a Gouy balance. Mercurytetrathiocyanatocobaltate(II) was used as a magnetic

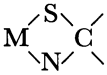
susceptibility standard. Diamagnetic corrections were made by the method given in literature.[9] Electronic spectral bands and their assignments are given in Table 2.

Spectra. Visible and ultraviolet spectra were recorded in Nujol mulls with a Cary-14 spectrophotometer in the range 1600—300 nm. Infrared spectra were taken with a Perkin-Elmer 521 Grating Spectrophotometer in the range 4000—250 cm^{-1}, using Nujol mulls and KBr pellets. The major infrared bands are given in Table 3.

Results and Discussion

The ligand in solution exists in either thiol or thioxo form, behaving as a weak dibasic acid. In either form it has four bonding sites (three N's and one S). It can thus behave as a mono, bi, tri, or tetradentate towards one or more metal ions. However, a chelate ion is difficult to envisage, because of a four membered



ring, where C and N belong to a five membered heterocycles. We, thus, expect bridge configurations through the ligands which are bonded to two or more metal atoms. The formation of polymeric complexes is more likely to occur. This is also suggested by poor solubility of the complexes (except that of Pt(II)) in water or in organic solvents. Methods like NMR, molecular weight or conductivity measurements could not be used for their structural studies.

Magnetic Moments. The magnetic moments of Ni(II) and Co(II) (green) complexes (Table 2) are close to those of other octahedral complexes.[10] The value of Co(II) (pink) complex was slightly lower than the normal octahedral complexes but somewhat higher than the distorted tetrahedral complexes.[10,11] The distortion in the octahedral arrangement in the latter may thus be comparable to that of green complex.[11]

The complexes of Au(I), Rh(III), and Pd(II) are dia-

magnetic. This is what would be expected if they assume linear, octahedral, and square planar configurations, respectively.

The diamagnetism of the ruthenium complex is rather unexpected since $RuCl_3 \cdot xH_2O$ was used as the starting material for its synthesis. This could be due to either the presence of ruthenium in +2 oxidation state or spin pairing through NCS group. The former seems to be more probable since Ru(III) is a relatively powerful oxidizing agent and might be reduced to Ru(II) by the ligand during the course of the reaction.

Platinum complex was also found to be diamagnetic indicating the presence of platinum of +2 or +4 state. It is probable that platinum(IV) is reduced by the ligand to +2 state during the course of preparation.[12]

The magnetic moment of copper complex (0.9 B.M.) was found to be lower than that expected for one electron. Possibly Cu(II) ions were partially reduced to +1 state during the course of preparation, so that the complex obtained contains copper both in +2 and +1 states. This is also suggested by the black coloration of the complex where the charge transfer between Cu(I) and Cu(II) may be taking place through NCS group of the ligand. When the complex was decomposed in pyridine in N_2 atmosphere, the pyridine complex of Cu(II) of the type $Cu(py)_xL_y$ where $x<4$ was formed in solution, indicating at least a part of copper to be present in +2 state in the complex. Although a similar anomalous magnetic moment of Cu(II) in some copper complexes was interpreted in terms of antiferromagnetic interactions, either by forming σ or δ bond between two copper ions or by superexchange phenomenon through NCS group, a consideration of the reducing power of the ligand and the oxidizing power of the Cu^{2+} suggest that the partical quenching of paramagnetism in the complex is not due to such effects.

Visible Spectra. The visible spectra of all the complexes showed bands around 410 and 390 nm. The bands were also observed, slightly on the higher wave number side, in the spectrum of the ligand. They are thus due to ligand molecule (possibly arising from transition $n \rightarrow \pi^*$ or $\pi \rightarrow \pi^*$ of NCS group).

The positions of the bands in the spectrum of $NiL_2 \cdot 3H_2O$ (Table 2) are characteristic of those found for octahedral complexes of Ni(II)[11] which supports the octahedral structure of the complex. The bands at 950 and 640 nm are unsymmetrical, possibly owing to a slight distortion[12] from the O_h symmetry towards a rhombic or tetragonal one. From the positions of these bands the values of $10Dq$, B, β, and the position of the band due to $^3A_{2g} \rightarrow {}^3T_{1g}$ were calculated[13] to be 10160 cm^{-1}, 870 cm^{-1}, 0.85, and 10160 cm^{-1}, respectively, assuming O_h symmetry (approximately). The calculated value (10160 cm^{-1}) is quite close to that found experimentally (10530 cm^{-1}) which supports assignments. The value of β (0.85) indicates that the bonds between the ligand and the metal ion are essentially ionic having a small degree of covalence.[14]

In the assignment of the bands of $CoL_2 \cdot 3H_2O$ (assuming approximately octahedral symmetry) (Table 2), fitting the positions of the bonds give Dq, B and β as 860, 750 cm^{-1}, and 0.74 and places the $^4T_{2g}(F) \rightarrow {}^4T_{1g}(F)$ absorption band at 6480 cm^{-1} (near IR region) which could not be observed in our spectrum. Some splitting was found in the bands at 540 and 585 nm. This indicates that the orbital degenerate terms T_{1g} and T_{2g} are split because of the lowering of the symmetry of the complex from O_h.

The spectrum of $CoL \cdot 3H_2O$ showed a very broad weak band at 500 nm with shoulders at 530, 490, 470. The intensities of these shoulder bands were found to be nearly equal to each other as indicated by their respective optical densities. Apparently there is practically no symmetry in the complex, the degenerate terms *e.g.*, T_{1g} and T_{2g}, being split completely into non-degenerate ones. The evidence in support of the lowering of symmetry also comes from the magnetic moment values (4.5 B.M.), which is too low for an octahedral Co(II) ion.

The spectrum of copper complex showed a continuous absorption from 800 nm down to 450 nm followed by three, bands at 440, 410, and 395 nm. If copper in the complex is present in +2 state, we should expect one, three, and four bands in O_h, D_{4h}, and D_{2h} symmetry respectively. The continuous absorption and the presence of 440 nm band together with the magnetic evidence supports the view that copper in the complex exists in two mixed valence states. The band at 440 nm may then be assigned to mixed valence state band similar to that present in other mixed valence state copper complex.[15] It is the origin of the very dark coloration of this complex (dark brown to black) which is also characteristic of a mixed valence complex.

The spectrum of gold complex showed no band except the ligand bands at 410 and 395 nm. This suggests the oxidation state of gold as +1, which is also indicated by the formulla AuL where one of the two protons of NH groups is deprotonated.

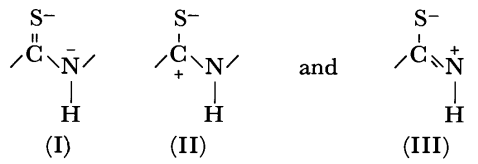
The spectrum of ruthenium complex is similar to that of copper with ligand bands at 410 and 390 nm, no d-d band appearing in the visible region owing to intense absorption.

The bands at 650 and 480 nm in the spectrum of PtL_4Cl_2, and at 735 and 530 nm in the PdL_2 spectra were found to be much weaker than the other bands. In a d^8 system, we expect six transitions in D_{4h} symmetry (three spin allowed and three weak spin forbidden bands)[16] (Table 2). The values of parameters calculated from the positions of these bands are as follows: PdL_2: $\Delta_1=23800$ cm^{-1}, $\Delta_2=7200$ cm^{-1}, $\Delta_3=2900$ cm^{-1}, $B=200$ cm^{-1}, $C=3300$ cm^{-1}; PtL_4Cl_2: $\Delta_1=25300$ cm^{-1}, $C=3300$ cm^{-1}. In the case of Pd, the calculated frequency for the band due to $^1A_{1g} \rightarrow {}^1B_{1g}$ was found to be 29700 cm^{-1} which is close to the value found experimentally (30000 cm^{-1}), supporting our assignments. In case of Pt, owing to the lack of data, some of the parameters have not been calculated.

The spectrum of Rh complex showed no band except at 410 and 395 nm. However, there was a continuous strong absorption whose intensity decreased gradually from 650 to 400 nm. The weak d-d bands are possibly obscured by the intense charge transfer band (L→M) present in the visible region. No information regarding the structure of the complex has been obtained from

the visible spectral studies.

Infrared Spectra. The ligand is best described as a resonance hydrid of the structures:



(I) (II) (III)

Metal coordination through sulfur will lead to a decrease in the thiocarbonyl stretching force constant and an increase in CN force constant. Coordination to nitrogen, on the other hand, would increase the contribution of structure I to the ground state of the complexes and cause an increase in the thiocarbonyl frequencies and decrease in CN and NH stretching frequencies.[17,18]

In order to determine the coordination sites in the complexes, we have classified the spectra of the complexes into the following four groups (A to D):

(A) Spectra of Ni(II), Co(II), Cu(II), Pd(II), Rh-(III), and Au(I).

(1) The positions of those bands having contributions from νCN (1480, 1320, 1275 cm^{-1}) shifted towards higher wave number (+20 cm^{-1}) suggesting the increase in CN bond order.

(2) The shifts in the positions of bands at 1080 and 960 cm^{-1} were small (±10 cm^{-1}). There also appeared a band around 1020 cm^{-1} which may be due to two different types of νCN.

(3) The positions of the bands arising mainly from νCS, *viz.*, 650 and 550 cm^{-1} shifted to lower wave numbers (−20 cm^{-1}).

(4) The positions of the bands arising from νNH, δNH and τNH remained practically constant, their relative intensities decreasing.

(5) In the spectra of Ni(II), Co(II), Cu(II), and Rh(II) the characteristic bands due to νOH and δOH were present around 3400 cm^{-1} (broad) and 1650 cm^{-1} (medium) respectively.

All the above shifts can be explained by the assumption that the metal ion is coordinated to one of the NH groups after deprotonation and the thiocarbonyl sulfur with relatively strong interaction.

(B) Spectra of Pt(II).

(1) All the bands having contributions from νNH, δ NH and τNH were split with the separation ±10 cm^{-1} around the positions found in the spectrum of the ligand.

(2) The positions of νCN bands shifted to higher wave numbers and were split (10—20 cm^{-1}).

(3) The positions of the νCS bands shifted to lower wave number. The band at 500 cm^{-1} was broad while that of 525 cm^{-1} was split.

These observations can be explained if the platinum ion in the complex is assumed to be bonded separately with four thiocarbonyl sulfur atoms of the four ligand molecule arranged in a square planar arrangement to form an ionic complex $[PtL_4]Cl_2$.

In such a bonding scheme we should expect the interaction between νCN bands and δNH bands in one ligand molecule to give asymmetric and symmetric modes of vibration.

(C) Spectrum of Ru(II). The spectrum of ruthenium is quite complicated, but the positions and shifts of the bands appear to be similar to those of the combined spectra of Group A (*e.g.*, Ni(II) or Co(II)) and Group B (Pt(II)) complexes, with the bands at 3000, 3150, 1570, 1550, 1500, 1335, 1360, 1290(br), 1200(br), 1075, 1060, 980, 970, 695, and 680 cm^{-1}). It is therefore assumed that two of the three ligand molecules are linked with thiocarbonyl sulfur and nitrogen after deprotonation, while the third ligand molecule is linked with thiocarbonyl sulfur strongly and nitrogen without deprotonation weakly. This is in line with the charge balance in the complex where ruthenium atom is assumed to be in +2 oxidation state.

(D) Spectra of Cu(II/I) and Co(II) (pink). Since it is improbable for cobalt to be reduced in +1 state by the ligand, the formula indicates that both the NH groups of the ligand are deprotonated. Owing to the presence of broad bands due to water molecule around 3300 and 1600 cm^{-1}, the band due to νNH could not be confirmed. However, no band at 690 cm^{-1} assigned to τNH appeared in the spectrum of the complex, suggesting the possibility of complete deprotonation. Further in the finger print region bands were rather broad and no definite conclusion regarding their structure could be drawn. The general pattern in the shifts of the band positions are similar to those of Group A, suggesting at least a linkage of the ligand through nitrogen and thiocarbonyl sulfur.

On the basis of these data the following structures were assigned:

(i) $NiL_2(H_2O)_3$, $CoL_2(H_2O)_3$, $CoL(H_2O)_3$, $RhL_3(H_2O)_2$, RuL_3, $CuL(H_2O)_2$: Octahedron with bonding through thiocarbonyl sulfur and –NH nitrogen, the latter after deprotonation. Except for Rh and Ru complexes water molecules are also coordinated.

(ii) PdL_2: Square planar with bonding through thiocarbonyl sulfur and –NH nitrogen, the latter after deprotonation.

(iii) PtL_4Cl_2: Square planar with bonding through thiocarbonyl sulfur.

(iv) AuL: Linear with bonding through thiocarbonyl sulfur and –NH nitrogen, the latter after deprotonation.

Topological Properties of Benzenoid Systems. IV.[1] On Aihara's Resonance Energy

Ivan GUTMAN

Department of Chemistry, Faculty of Sciences, University of Kragujevac, 34000 Kragujevac, R. Domanovića 12, Yugoslavia

(Received December 22, 1977)

Different mathematical properties of a resonance energy, recently defined by Aihara (This Bulletin, **50**, 2010 (1977)), are presented.

In a recent paper[2] Aihara defined a new resonance energy, *RE**, by

$$RE^* = K\sum_{k=1}^{m} X_k, \tag{1}$$

where X_k denotes the roots of the equation $A(X)=0$, arranged in descending order. The polynominal $A(X)$ is defined by

$$A(X) = \sum_{k=0}^{m} (-1)^k r(k) X^{2m-2k},$$

where $r(k)$ denotes the resonant sextet numbers.[3] The main properties of *RE** and its relation to the resonance energy of Dewar and that of Herndon were determined.[2] The present paper reports an attempt to establish further relations for this new concept, in order to clarify its mathematical meaning; Aihara's notations have been used. Sometimes notations $RE^*=RE^*(G)$, $A(X)=A(G, X)$ and $r(k)=r(G,k)$ are used to indicate quantities corresponding to a particular benzenoid molecule G.

Aihara noted[2] that in certain cases the X_k values become complex numbers. Equation 1 should thus be modified as

$$RE^* = K\sum_{k=1}^{m} x_k, \tag{1'}$$

where x_k is the real part of X_k. In the following this generalized definition of *RE** is considered. Equation 1′ is reduced to Eq. 1 when all X_k values are real.

*Identities, Bounds and Approximate Topological Formulas for RE**. There is a formal analogy between Eqs. 1 and 1′ and the definition of the total π-electron energy (E) in Hückel molecular orbital (HMO) theory. A number of known results for E can thus be applied and changed into relations valid for *RE**. For this it is important to recognize the analogy between $A(X)$ and the HMO characteristic polynominal.[2]

Let us denote the first derivative of the polynomial $A(X)$ by $A'(X)$ and a complex variable by z. Then according to Coulson,[4] the sum of the form (Eq. 1′) fulfills the equations

$$RE^* = \frac{K}{2\pi i}\int_C \left[2m - \frac{z\,A'(z)}{A(z)}\right] dz \tag{2}$$

and

$$RE^* = \frac{K}{2\pi}\int_{-\infty}^{+\infty} \left[2m - \frac{iX\,A'(iX)}{A(iX)}\right] dX, \tag{3}$$

where i is the imaginary unit, the contour C in Eq. 2 being chosen to encircle the non-negative part ($Re\ z \geqslant 0$) of the complex plain. Note that the polynominal $A(X)$ is constructed in such a manner that all its roots differ from zero.

Equation 3 is further transformed into[5]

$$RE^* = \frac{K}{2\pi}\int_{-\infty}^{+\infty} f(X)dX, \tag{4}$$

where

$$f(X) = X^{-2}\ln\sum_{k=0}^{m} r(k)X^{2k} = X^{-2}\ln B(X^2)$$

and $B(X)$ is the sextet polynomial of Hosoya and Yamaguchi.[2,3]

Let G_1 and G_2 be two benzenoid systems and let their A-polynomials be of the order $2m_1$ and $2m_2$, respectively. Then another result of Coulson[6] gives the identity

$$RE^*(G_1) - RE^*(G_2) = \frac{K}{2\pi}\int_{-\infty}^{+\infty} \ln\left[(-X^2)^{m_2-m_1}\frac{A(G_1, iX)}{A(G_2, iX)}\right] dX. \tag{5}$$

Three topological parameters of benzenoid systems are of importance in the following discussion. They are $r(G, 1)$—the number of resonant sextets in G, m—the maximal number of mutually resonant sextets in G and $r(G, m)$—the number of ways in which m resonant sextets are selected in G. Although no simple and general procedure exists for calculating these quantities, it is not difficult to determine them from an inspection of the molecular network of a benzenoid system.[7]

The significance of m, $r(1)$ and $r(m)$ becomes evident if one remembers that they play formally the same role in $A(X)$, as the number of carbon atoms, the number of carbon-carbon bonds and the algebraic structure count in the HMO characteristic polynomial.[8] Thus it is easy to transform the known[9] lower and upper bounds for E into bounds for *RE**. Hence we get

$$\begin{aligned} &r(1) - mr(m)^{1/m} \leq mr(1) - (RE^*/K)^2 \leq \\ &\leq (m-1)[r(1) - mr(m)^{1/m}]. \end{aligned} \tag{6}$$

A special case of the relation (Eq. 6) is the simple formula

$$m \leq RE^*/K \leq \sqrt{mr(1)}\ .$$

A class of approximate topological formulas for *RE** is obtained using a general method[10] which we will apply to Eq. 4. Similar conclusions can be reached from Eqs. 3 and 5.

The integrand $f(X)$ in Eq. 4 is a bell-shaped function, showing the following asymptotic behavior.

$$f(X) \approx \begin{cases} r(1) & \text{for } |X| \to 0 \\ 2m\, X^{-2} \ln X & \text{for } |X| \to \infty \end{cases} \quad (7)$$

Moreover, we have

$$f(1) = \ln SC, \quad (7')$$

since $B(1) = r(0) + r(1) + \cdots\cdots + r(m)$ is equal to the structure count (SC) of the benzenoid system under consideration.[3]

If another function $g(X)$ fulfills the relations (Eqs. 7 and 7'), then the expression $\frac{K}{2\pi}\int_{-\infty}^{+\infty} g(X)\, dX$ is expected[10] to give a good estimate of RE^*. A suitable function of this type is

$$g(X) = \frac{T^2 r(1) + m \ln(1+X^2)}{T^2 + X^2},$$

with

$$T^2 = (\ln SC - m \ln 2)/(r(1) - \ln SC).$$

Straightforward integration yields

$$RE^*/K \approx \frac{1}{2} T\, r(1) + m \frac{\ln(1+T)}{T}. \quad (8)$$

It can be shown that the above relation is suitable for numerical calculations. However, we are herewith mainly interested in the topological properties of Eq. 8, namely in the finding of the main structural factors which contribute to RE^*. We see that RE^* is grossly determined by three structural parameters $r(1)$, m, and SC. Since Eq. 8 does not depend explicitly on $r(m)$, we conclude that this quantity has only a second order influence on the value of RE^*. The functional dependence of RE^* on $r(1)$, m, and SC is rather complicated. In order to get a qualitative insight into this dependence, one can use the fact that T is small, which results in an essential simplification of Eq. 8.

$$RE^*/K \approx m + \frac{1}{2} T\, r(1) \quad (9)$$

Hence the main contribution to RE^* comes from the maximal number of mutually resonant sextets (m), while the number of simply resonant sextets ($r(1)$) has a smaller effect. An inspection of both Eqs. 8 and 9 suggests that RE^* is proportional to ln SC, but the functional dependence between RE^* and ln SC does not seem to be linear.

RE^*'s of Non-Branched Cata-Condensed Benzenoid Systems. For every non-branched cata-condensed benzenoid (NBCCB) system[11] G with n hexagons, an acyclic graph T with $n+1$ vertices can be constructed, such that its characteristic polynominal $P(T, X)$ fulfills the relation[12]

$$X^{n+1-2m} A(G, X) = P(T, X). \quad (10)$$

It follows from this relation that $RE^*(G)/K = E(T)/2$. Hence Aihara's resonance energy (in terms of K) of a NBCCB molecule is equal to half of the Hückel energy (in terms of β) of a particular acyclic graph. This simple result enables us to apply the numerous relations known for acyclic graphs and their Hückel energy[13] to the theory of RE^*. A few selected examples are given.

The way in which an "L, A-sequence" is associated with a NBCCB system and the procedure of the construction of the graph T have been reported.[12] As an example, in the case of a linear polyacene with n hexagons (an L^n-system), the corresponding T-graph is the star S_{n+1} with $n+1$ vertices. The characteristic polynomial of the star reads[13]: $P(S_{n+1}, X) = X^{n+1} - nX^{n-1}$. Consequently, it is $E(S_{n+1}) = 2\sqrt{n}$ and $RE^*(L^n) = \sqrt{n}K$. This latter result is equivalent to Aihara's Eq. 15.[2]

By a similar argument we obtain general formulas for the RE's of further classes of NBCCB molecules given below, where n denotes the total number of hexagons. RE^* is expressed in terms of K.

$$RE^*(L^n) = \sqrt{n}$$

$$RE^*(L^a A L^b) = \sqrt{n + 2\sqrt{ab}} \qquad (a+b+1=n)$$

$$RE^*(L^a A^2 L^b) = \sqrt{n + 2\sqrt{ab} + n - 2} \qquad (a+b+2=n)$$

$$RE^*(L^a (AL^a)^b) = \sum_{j=1}^{b+1} \sqrt{a + \cos^2 \frac{\pi j}{b+2}} \qquad (a+b+ab=n)$$

$$RE^*(LA^{n-2}L) = \begin{cases} \operatorname{cosec} \frac{\pi}{2n+4} - 1 & \text{if } n \text{ is odd} \\ \operatorname{cotg} \frac{\pi}{2n+4} - 1 & \text{if } n \text{ is even} \end{cases}$$

$$RE^*(L^2A^{n-3}L) = \begin{cases} \operatorname{cotg} \frac{\pi}{2n+4} & \text{if } n \text{ is odd} \\ \operatorname{cosec} \frac{\pi}{2n+4} & \text{if } n \text{ is even} \end{cases}$$

$$RE^*(L^2A^{n-4}L^2) = \begin{cases} \operatorname{cosec} \frac{\pi}{2n+4} + 1 & \text{if } n \text{ is odd} \\ \operatorname{cotg} \frac{\pi}{2n+4} + 1 & \text{if } n \text{ is even} \end{cases}$$

The T-graph associated with a NBCCB system of the type L^n and $LA^{n-2}L$ is the star S_{n+1} and the path P_{n+1}, respectively, with $n+1$ vertices.[12] It has been proved[13] that for all acyclic graphs T with $n+1$ vertices, $E(S_{n+1}) \leq E(T) \leq E(P_{n+1})$. This implies that among NBCCB systems with n hexagons, the linear polyacene (L^n) has minimal and the angular polyacenes ($LA^{n-2}L$) have maximal values of RE^*.

Kinetics and Mechanism of the Oxidation of Alcohols by Pyridinium Chlorochromate

Kalyan K. BANERJI
Department of Chemistry, University of Jodhpur, Jodhpur 342001, India
(Received January 9, 1978)

The kinetics of the oxidation of ten primary alcohols by pyridinium chlorochromate has been studied. The main product of the oxidation is the corresponding aldehyde. The reaction is of first order with respect to the concentration of the alcohol and oxidant. The reaction is catalysed by acid, the catalysed reaction being nearly first order in acidity. The kinetic isotope effect, k_H/k_D is 5.71 at 303 K for ethanol. The reaction does not induce polymerisation of acrylonitrile. The reaction constant ρ^* for the uncatalysed and acid-catalysed oxidations have the values −1.93 and −1.75 at 303 K respectively. Probable mechanisms are discussed.

Pyridinium chlorochromate (PCC) is a complex of chromium trioxide, pyridine and hydrochloric acid.[1] Corey and Suggs[1] reported that this complex converts alcohols to carbonyl products in yields over 80%. There seems to be no previous report on the mechanism of this useful reaction. The present paper deals with the oxidation of some primary alcohols in 1 : 1 (v/v) dichloromethane–nitrobenzene solution and evaluates the reaction constant.

Results

The rate laws and other experimental data were obtained for all the alcohols investigated. Since results are similar, only those of ethanol are reproduced.

The oxidation of ethanol by PCC results in the formation of acetaldehyde as the main product, which is isolable in 75±5% yield as its 2,4-dinitrophenylhydrazone.

Stoichiometry. Excess of PCC was allowed to react with 0.08 M of ethanol at various acidities and the unreacted oxidant estimated. For some runs the carbonyl product was estimated, using an excess of the alcohol. The overall reaction corresponds to

$$3RCH_2OH + 2Cr(VI) \longrightarrow 3RCHO + H^+ + 2Cr(III). \quad (1)$$

Rate Laws. When the alcohol is in excess, the rate of disappearence of PCC follows first rate laws. The rate constant is independent of the initial concentration of PCC (Table 1). The reaction is of first order with respect to the alcohol concentration also (Table 2). The reaction is catalysed by acid. The catalysed reaction being nearly first order in acidity. The actual order is 0.88±0.02 (Table 3). Because of the non-aqueous nature of the solvent, constant ionic strength could not be maintained.

TABLE 1. OXIDANT DEPENDENCE OF THE REACTION RATE

[EtOH] 0.10 M	Temp 303 K				
10^3 [PCC] M	2.0	4.0	6.0	8.0	10.0
$10^6 k_1$ s^{-1}	10.0	9.73	10.6	10.0	9.84

TABLE 2. SUBSTRATE DEPENDENCE OF THE REACTION RATE

[PCC] 0.002 M	Temp 303 K				
[EtOH] M	0.05	0.10	0.20	0.40	0.80
$10^6 k_1$ s^{-1}	5.13	10.0	20.7	41.0	78.3

TABLE 3. ACIDITY DEPENDENCE OF THE REACTION RATE

[EtOH] 0.10 M	[PCC] 0.002 M		Temp 303 K		
[TsOH] M	0.05	0.10	0.20	0.30	0.40
$10^6 k_1$ s^{-1}	14.4	18.9	27.0	38.1	44.9

TABLE 4. DEPENDENCE OF THE REACTION RATE ON SOLVENT COMPOSITION

[EtOH] 0.10 M	[PCC] 0.002 M		[TsOH] 0.10 M		Temp 303 K
Percentage of nitrobenzene	30	40	50	60	70
Dielectric constant	16.8	19.4	22.0	24.5	27.1
$10^6 k_1$ s^{-1}	50.1	28.2	18.9	13.5	10.6

The rate of the oxidation of ethan-1,1-d_2-ol and ethanol at 303 K are 10^5k=1.75 and 10.0 l mol^{-1} s^{-1} respectively. The kinetic isotope effect, k_H/k_D is 5.72 at 303 K.

Effect of Solvent Composition. The acid-catalysed oxidation of ethanol was studied in solutions containing varying proportion of dichloromethane and nitrobenzene (Table 4). Increasing proportion of nitrobenzene in the solution reduces the rate.

The oxidation of ethanol, in an atmosphere of nitrogen, failed to induce polymerisation of acrylonitrile. In control experimetns, with the alcohol absent, the concentration of PCC does not change.

TABLE 5. RATE CONSTANTS FOR THE UNCATALYSED OXIDATION OF PRIMARY ALCOHOLS, RCH_2OH, BY PYRIDINIUM CHLOROCHROMATE

Substituent (R)	$10^6 k$ l mol^{-1} s^{-1}

$MeOCH_2$	24.0	34.7	50.1	72.5
$BrCH_2$	3.16	5.07	7.76	12.3
$CClCH_2$	2.95	4.68	7.24	11.5

The uncatalysed and acid-catalysed oxidation of the primary alcohols were studied at different temperatures (Tables 5 and 6) and the activation parameters evaluated (Table 7). The average error limits in the values of ΔH^*, ΔS^*, and ΔF^* (at 303 K) are ± 6 kJ mol^{-1}, ± 10 J mol^{-1} K^{-1}, and ± 7 kJ mol^{-1} respectively.

Discussion

A near constancy of the free energy of activation shows that the same mechanism is operative in all the alcohols. The free energy of activation of the acid-catalysed oxidation is consistently lower than that of the uncatalysed reaction but are of the same order indicating that the mechanisms of the two reactions are essentially similar.

The linear increase in the oxidation rate with acidity suggests involvement of a protonated Cr(VI) species in the rate-determining step. Involvement of such species are well known in chromic acid oxidation.[2] The kinetic isotope effect suggests that the rate-determining step involves a C–H bond rupture.

The activation enthalpies and entropies of both the uncatalysed and acid-catalysed reactions are linearly related (r=0.9993 and 0.9991 respectively). The correlations were tested and found genuine by applying Exner's criterion.[3] The isokinetic temperatures computed from these polts are 436 and 502 K respectively. Current views do not attach much physical significance to isokinetic temperature,[4] though a linear correlation is usually a necessary condition for the validity of linear free energy relationships.

Dielectric constants for dichloromethane–nitrobenzene mixtures are not available, but can be estimated approximately from the dielectric constants of the pure solvents.[5] The estimated dieletctric constants of the solvent mixtures are recorded in Table 4. A plot of $\log k_1$ against the inverse of dielectric constant is a straight line with a positive slope. This indicates an interaction between a dipole and a positive ion.[6] This accords with the observation regarding involvement of a protonated Cr(VI) species in the rate-determining step.

The oxidation rates of the primary alcohols correlate well with Taft's σ^* values with negative reaction constants (Table 8).

A hydrogen abstraction mechanism may be discounted in view of the failure to induce polymerisation of acrylonitrile and the magnitude of the reaction constant. In most hydrogen abstraction reactions the reaction constants have small magnitude.[7] The large negative reaction constant together with the substantial deuterium isotope effect indicate a considerable carbonium ion character in the transition state. The above results points to a hydride-ion transfer in the rate-determining step. The hydride transfer may take place directly (Scheme 1) or may involve the prior formation of a chromate ester (Scheme 2). The similarity in the rate laws with chromic acid oxidations[2] suggests a chromate ester formation. However, the observed kinetic isotope effect is rather

large for the non-linear transition state implied in Scheme 2. The present data, thus do not enable one to distinguish between the two mechanisms. Chromate ester formation is not likely to be very much susceptible to structural influence.[8,9] The large negative reaction constant can thus arise only out of the differential effects of the substituents on the rate-determining step.

Scheme 2.

Experimental

Materials. The preparation and specification of the alcohols used have been described earlier.[10] Isotopic purity of ethan-1,1-d_2-ol, as determined by NMR, was 89±5%. The oxidant was prepared by the method of Corey and Suggs.[1] *p*-Toluenesulfonic acid (TsOH) was used as a source of hydrogen ions. The solvents were purified and dried in the usual manner.[11] All reagents were of analytical grade.

Product Analysis. Acetaldehyde was characterised and estimated by the isolation of its 2,4-dinitrophenylhydrazone.

Kinetic Measurements. The reactions were carried out under pesudo-first-order conditions by keeping a large excess of the alcohol over PCC. The temperature was kept constant to ±0.1 K. The reactions were followed iodometrically. The rate constant were computed from the plots of log [oxidant] against time and were reproducible within ±4%. The solvent was dichloromethane–nitrobenzene —1:1 (v/v)—, unless otherwise stated. The reaction mixtures were homogenous in the solvent systems used. The rate for the deuterated alcohol was corrected for the ordinary alcohol present.

Polarization Dispersion in the Resonance Raman Spectra of EDA Complexes with TCNE and TCNB

Masao TAHARA,* Susumu MATSUZAKI,† and Shiro MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Midori-ku, Yokohama 227

† *Department of Chemistry, Faculty of Science, Kumamoto University, Kumamoto 860*

(Received February 6, 1978)

Synopsis. Polarization dispersion of the $\nu_{C\equiv N}$ Raman line of the *N,N*-dimethylaniline–TCNB complex indicated that the two CT absorption bands are assignable to different acceptor orbitals, in contrast with those of TCNE complexes.

The resonance Raman effect (RRE) can be used to probe the nature of electronic excited states, and its faculty is fully exhibited by investigating the excitation profile and polarization dispersion. Charge transfer (CT) excited states of electron-donor-acceptor (EDA) complexes can suitably be investigated by RRE, as was demonstrated by Kaya *et al.*[1] for the complexes of tetracyanoethylene (TCNE) with benzene homologues. They observed the RRE of $\nu_{C=C}$ and $\nu_{C\equiv N}$ of complexed TCNE by exciting radiations within the first CT absorption band, and concluded that some increase of equilibrium C=C and C≡N distances from the ground to CT excited states was responsible for the resonant intensity of those lines.

It has been known that two CT absorption bands appear in the complexes with strong electron acceptors such as chloranil and TCNE.[2] Those CT bands have been explained by the two CT configurations (illustrated in Fig. 1a) distinguished by the difference in electron-donating orbitals. On the other hand, Iwata *et al.*[3] showed that the two CT absorption bands observed for some complexes of 1,2,4,5-tetracyanobenzene (TCNB), though quite similar to the TCNE case, were more reasonably interpreted by another multi-CT scheme (shown in Fig. 1b) in which two CT configurations are distinct in the electron-accepting orbitals of TCNB. In order to investigate the validity of these multi-CT schemes further, the RRE has been measured for the *N,N*-dimethylaniline–TCNB complex and some TCNE complexes.

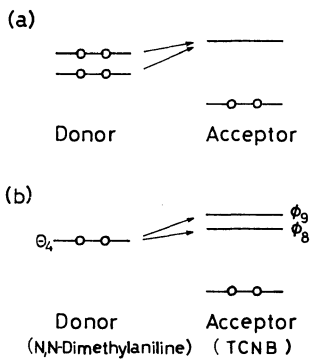

Fig. 1. Schematic diagram of CT excited states a) naphthalene–TCNE, and b) *N,N*-Dimethylaniline–TCNB complexes.

Experimental

Commercially obtained samples were used after appropriate purification, with the exception of TCNB, which was synthesized from pyromellitic acid and purified by sublimation. Raman spectra were recorded on JRS-S1 and JRS-400D spectrometers using exciting radiations from Ar^+ (457.9…514.5 nm), Kr^+(530.9, 568.2, 647.1 nm), and He–Ne (632.8 nm) lasers. The measurement was carried out on donor-excess solutions by using a rotating cell. The intensity and depolarization ratio were determined by checking with appropriate internal standards; these were solvent CH_2Cl_2 for TCNE and purposely added CCl_4 for TCNB.

Results and Discussion

Figure 2 shows the excitation profiles and polarization dispersions measured on $\nu_{C=C}$ (1560 cm^{-1}) and $\nu_{C\equiv N}$ (2230 cm^{-1}) of TCNE in the solution of naphthalene–TCNE complex. About 80% of TCNE is bound to form the complex[2] in the present donor-excess condition, so that the non-resonant intensity from free TCNE may be unimportant. The $\nu_{C\equiv N}$ Raman band

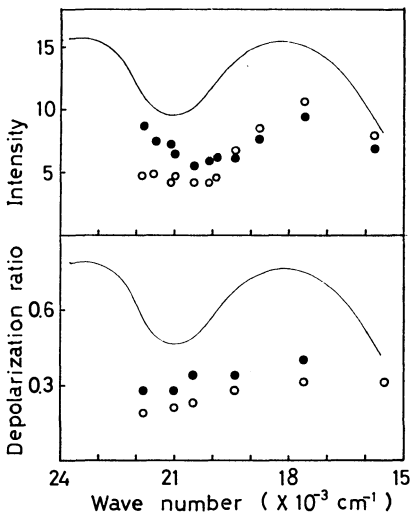

Fig. 2. Excitation profile and polarization dispersion of naphthalene–TCNE complex, naphthalene=0.1 mol/l, TCNE=0.005 mol/l in CH_2Cl_2 solution. (○): $\nu_{C=C}$(1560 cm^{-1}), (●): $\nu_{C\equiv N}$(2230 cm^{-1}), (——); absorption.

includes both A_g and B_{1g}** C≡N stretching modes. Since the ρ value is rather close to 1/3, which is the value expected for a Franck-Condon type resonance enhancement of the A_g mode, the depolarized B_{1g} intensity does not seem to be appreciably resonant in the CT band region. If the B_{1g} mode were resonant due to a vibronic coupling of the CT levels, the ρ plot should have shown generally higher values than that observed and tended upward at the high frequency side as in observed for the intensity plot. The slight dispersive trend of ρ observed for both $\nu_{C=C}$ and $\nu_{C\equiv N}$ may possible be caused by the interference of contributions from the first and second CT levels. Such an interference can take place because those CT transition moments may not be exactly parallel to each other on account of the mixing with locally excited states. Similar measurements have been carried out for the TCNE complexes of durene and pyrene, which also have two CT absorption bands in the visible; similar features of the depolarization ratio were found.

Figure 3 shows the results of the corresponding observations on *N,N*-dimethylaniline–TCNB complex.*** It is remarkable that the ρ ($\nu_{C\equiv N}$) increases towards the CT absorption maximum up to about 0.7 at a 514.5 nm excitation, while ρ ($\nu_{C=C}$) is kept nearly constant at about 1/3. This indicates that the depolarized $\nu_{C\equiv N}$ (B_{1g}) line is quite resonant in this system. The RRE intensity of a non-totally symmetric mode normally originates from vibronic coupling; thus,

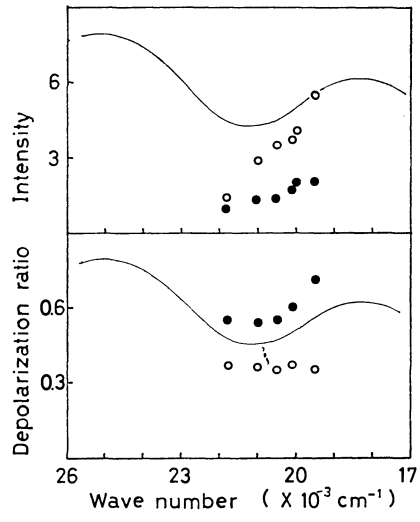

Fig. 3. Excitation profile and polarization dispersion of *N,N*-dimethylaniline–TCNB complex, TCNB= 0.007 mol/l in *N,N*-dimethylaniline solution. (○): $\nu_{C=C}$(1542 cm^{-1}), (●): $\nu_{C\equiv N}$(2240 cm^{-1}), (——): absorption.

** Representation of the D_{2h} group of TCNE.

*** Several other donors tried at the same time were not suitable enough to allow significant observation, because of insufficient solubility, CT band locations remote from available laser lines, apparent interference from intense locally excited absorptions, *etc.*

the above case may be most reasonably understood by the coupling of the first and second CT states illustrated in Fig. 1b, as will be descrived below. The contribution to a Raman tensor from a vibronic coupling of ψ_e and ψ_s states is proportional to the integral $\int \psi_e^*(\partial H/\partial Q_a)_0\ \psi_s d\tau$,[5] where Q_a is a normal coordinate. The integral can be reduced to a single electon one such as

$$\int \psi_e^*(H\partial/\partial Q_a)_0 \psi_s d\tau_1 \cdots d\tau_N = \int v^a(1)\rho_{es}(1)d\tau_1, \qquad (1)$$

where v^a is the potential from a set of point dipoles produced by the nuclear displacement of mode a and ρ_{es} is the transition density defined by

$$\rho_{es}(1) = N\int \psi_e^*(1, \cdots, N)\psi_s(1, \cdots, N)d\tau_2 \cdots d\tau_N. \qquad (2)$$

Now, let us assume that the CT states of *N,N*-dimethylaniline–TCNB complex can be represented by

$$\psi_{CT1} = \Phi(\theta_4^{-1}\phi_8), \qquad \psi_{CT2} = \Phi(\theta_4^{-1}\phi_9), \qquad (3)$$

$$\Phi(\theta_4^{-1}\phi_k) = (1/\sqrt{2})[|\theta_1 \cdots \phi_4\bar{\phi}_k \cdots \bar{\phi}_7| + |\theta_1 \cdots \phi_k\bar{\theta}_4 \cdots \bar{\phi}_7|], \qquad (4)$$

where θ and ϕ represent the MO's of *N,N*-dimethylaniline and TCNB respectively, as shown in Fig. 1b. It is readily shown that

$$\rho_{CT1,CT2} = \phi_8\phi_9, \qquad (5)$$

which signifies that the transition density is spacially localized on the TCNB moiety. Then the significant coupling of the CT states (3) can take place only by the vibrational modes of the TCNB moiety, as is obvious from Eq. 1, providing that the mode a belongs to the same representation of TCNB symmetry (D_{2h}) as $\rho_{CT1,\ CT2}$ does. Since

$$\Gamma(\phi_8) \times \Gamma(\phi_9) = A_u \times B_{1u} = B_{1g},$$

the $\nu_{C\equiv N}$ (B_{1g}) mode meets the above requirement. On the other hand, it is obvious by a similar consideration that the transition density between the two CT configurations of Fig. 1a is one-sided on the donor molecule, so that the vibronic coupling by acceptor modes may be quite unlikely.

On the basis of above discussion, the present RRE result may be thought of as further evidence for the multi-CT schemes of Figs. 1a and b proposed for TCNE and TCNB complexes.

Temperature Effects on CD Spectra of α-Cyclodextrin Complexes with *m*- and *p*-Nitrophenol

Kazuaki HARATA

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221

(Received March 17, 1977)

Synopsis. The CD spectra of α-cyclodextrin complexes with *m*- and *p*-nitrophenol were measured at 10, 30, 50, and 70 °C in aqueous solutions of various α-cyclodextrin concentrations. The CD intensity of both complexes was decreased to 14—61% of the intensity measured at 10 °C with the increase of temperature to 70 °C, but no significant change was observed in the spectral shape. The thermodynamic parameters for the complex formation were determined.

α-Cyclodextrin (α-CDx) forms inclusion complexes with *m*-nitrophenol (*m*-NP) and *p*-nitrophenol (*p*-NP). The structure of the *p*-nitrophenol complex in aqueous solutions has been investigated by CD[1,2] and NMR[3,4] spectra. Recent X-ray analyses revealed the detailed structure of the *m*-nitrophenol and *p*-nitrophenol complexes.[5,6] In the crystalline states, the *m*-nitrophenol molecule has been suggested to be more loosely bound to the α-cyclodextrin ring than the *p*-nitrophenol molecule. In the presnet study, the CD spectra of these complexes were meausred at various temperatures in order to investigate the α-cyclodextrin interaction with *m*- and *p*-nitrophenol in aqueous solutions.

Experimental

α-Cyclodextrin (G.R., Tokyo Kasei Co.) was crystallized from water and dried *in vacuo* over phosphorus pentaoxide at room temperature. *m*- and *p*-nitrophenol (G.R., Tokyo kasei Co.) were used without further purification. Solutions were prepared with deionized water, and the concentrations of *m*- and *p*-nitrophenol were adjusted to 9.66 and 8.81×10^{-4} mol, respectively. The concentration of α-cyclodextrin was varied from 0.001 to 0.054 mol. The CD spectra were recorded at 10, 30, 50, and 70 °C on a JASCO J-40A circular dichrograph with a J-DPZ data-processor by use of a 1 mm quartz cell. The temperature was regulated by using a Tokyo Rico TC-100 thermo-controller with an accuracy of ±0.5 °C inside the cell.

Results and Discussion

The CD spectra of α-cyclodextrin complexes with *m*- and *p*- nitrophenol are shown in Figs. 1 and 2. The CD intensity in these spectra decreased gradually with the increase of the temperature, although no significant change is observed in the spectral shape. The intensity changes for various molar ratios of [α-CDx]/[guest] ([C]/[G]) were measured at 280 nm for the *m*-nitrophenol complex and at 340 nm for the *p*-nitrophenol complex, as shown in Figs. 3 and 4. At 10 °C, the intensity of both complexes increased rapidly with the increase of the concentration of α-cyclodextrin up to the [C]/[G] value of 10, but only a small intensity enhancement was observed at the

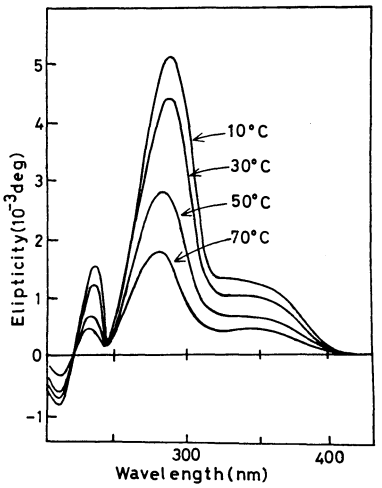

Fig. 1. The CD spectra of α-cyclodextrin–*m*-nitrophenol complex at 10, 30, 50, and 70 °C. The concentrations of α-cyclodextrin and *m*-nitrophenol are 1.8×10^{-2} and 9.66×10^{-4} mol, respectively, and a 1 mm cell was used.

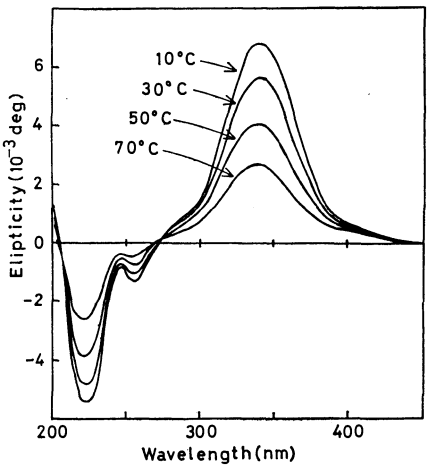

Fig. 2. The CD spectra of α-cyclodextrin–*p*-nitrophenol complex at 10, 30, 50, and 70 °C. The concentrations of α-cyclodextrin and *p*-nitrophenol are 1.8×10^{-2} and 8.81×10^{-4} mol, respectively, and a 1 mm cell was used.

[C]/[G] values greater than 20. On the other hand, at 70 °C, the CD intensity changes more slowly, and showed a gradual increase. When the temperature was raised from 10 to 70 °C, the CD intensity of the *m*-nitrophenol complex fell to 54% at the highest [C]/[G] value, while the intensity decreased to 14% at the lowest [C]/[G] value. A similar intensity change was observed in the *p*-nitrophenol complex. The in-

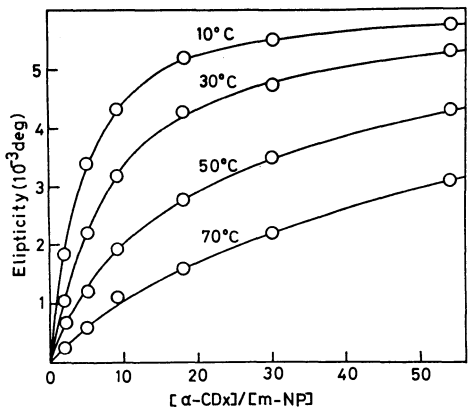

Fig. 3. Plot of the CD intensity measured at 280 nm against the [α-CDx]/[*m*-NP] ratio. The concentration of *m*-nitrophenol is 9.66×10^{-4} mol.

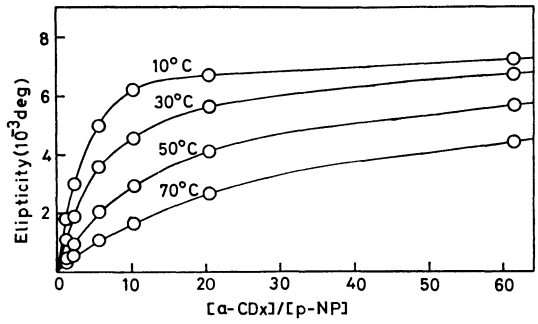

Fig. 4. Plot of the CD intensity measured at 340 nm against the [α-CDx]/[*p*-NP] ratio. The concentration of *p*-nitrophenol is 8.81×10^{-4} mol.

tensity at 340 nm fell to 61% in the solution with a [C]/[G] value of 61 and to 19% in that with a value of 1.

The dissociation constants of the complexes were determined by the Rose-Drago method,[7] on the assumption that α-cyclodextrin forms only a 1:1 complex. This assumption may be supported by the fact that no significant spectral shift or change of the spectral shape, but only an intensity decrease was found with increasing temperature or with decreasing [C]/[G] value. The observed intensity change gave a good fit to the equilibrium equation for the 1:1 stoichiometry. The results are shown in Table 1. The dissociation constants of the *m*-nitrophenol complex were 1.6—2.0 times greater than the corresponding values of the *p*-nitrophenol complex. In both complexes, about a ten-fold increase of the dissociation constants was observed when the temperature was raised from 10 to 70 °C. The enthalpy and entropy changes (ΔH and ΔS) for the complex formation were estimated: −33(1) kJ mol^{-1} and −70(4) J K^{-1} mol^{-1} for the *m*-nitrophenol complex and −30(1) kJ mol^{-1} and −56(3) J K^{-1} mol^{-1} for the *p*-nitrophenol complex, where values in parentheses are standard deviations. The ΔH and ΔS values of the *p*-nitrophenol complex are in good agreement with the values of −31 kJ mol^{-1} and −63 J·K^{-1} mol^{-1} determined by Lewis and Hansen.[8] These thermodynamic parameters indicate that *m*-nitrophenol is bound to α-cyclodextrin as strongly as *p*-nitrophenol. X-ray studies,[5,6] however, indicated that *m*-nitrophenol is more loosely bound to α-cyclodextrin than *p*-nitrophenol. In the crystalline complexes, the *p*-nitrophenol molecule deeply penetrates into the α-cyclodextrin ring and is rigidly fixed, while only a partial inclusion of the guest molecule is observed in the *m*-nitrophenol complex. On the other hand, NMR studies[2,3] have suggested that *p*-nitrophenol molecule is not deeply inserted into the α-cyclodextrin ring. In the *m*-nitrophenol complex, the deep penetration of the guest molecule is impossible because of the steric hindrance. If *m*- and *p*-nitrophenol form complexes in aqueous solutions in the same manner as found in the crystalline complexes, it seems likely that the structural difference between the two complexes will affect the enthalpy of the complex formation.[6] A possible explanation for the observed thermodynamic parameters may be that the *p*-nitrophenol molecule is only partially and loosely included in the α-cyclodextrin ring in aqueous solutions, as suggested from the NMR studies.

Table 1. Dissociation constants and free energies for the complex formation

Values in parentheses are standard deviations.

The Polarographic Behavior of 6-Mercaptopurine in Aqueous Solutions

Toshio YAO,* Junji UDA, Tamotsu WASA, and Soichiro MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozuumemachi, Sakai 591

(Received February 16, 1978)

Synopsis. The polarographic reduction of 6-mercaptopurine at the dropping mercury electrode took place in two steps; they were a two-electron process producing the 1,6-dihydro derivative, followed by a further two-electron process producing the 1,2,3,6-tetrahydro derivative. An anodic wave corresponding to the reaction with the mercury of the electrode material was observed at a relatively low potential, and its analytical utility for the determination of 6-mercaptopurine is suggested.

The electrochemical reduction of purines and pyrimidines, which are important components of nucleic acids, have been investigated in aqueous[1-3] and nonaqueous solutions.[4-6]

Mercaptopurines containing exocyclic sulfur are often anticarcinogens. In particular, 6-mercaptopurine is being used as an anti-leukemia agent. The present work was carried out in order to study the polarographic behavior of 6-mercaptopurine and its applicability to the polarographic determination of this compound.

Experimental

Chemicals. The 6-mercaptopurine(6-MP) was obtained from the Sigma Chemical Company and was recrystallized from water. The other chemicals were of a reagent grade and were used without further purification.

Apparatus. The polarograms were recorded using a Yanagimoto P-8 type Polarograph. The dropping mercury electrode (DME) had the following characteristics: mercury flow rate, m, 2.30 mg/s, and drop time, t, 3.25 s, with an open circuit under the mercury head of 70 cm, in 1 mol/dm^3 $HClO_4$. A saturated calomel electrode was employed as a reference electrode, and a platinum wire, as a counter electrode, A mercury pool electrode was also used for the controlled potential electrolysis and the coulometric measurements.

Results and Discussion

Polarography and Controlled Potential Electrolysis.

Cathodic Waves: It is known[1] that purine, which is the model compound of 6-MP, exhibits two pH-dependent waves when in an acidic solution, but none when in a neutral or alkaline solution. Similarly, 6-MP exhibits two cathodic waves at fairly negative potentials. The diffusion-current constant (I_d) and the half-wave potential of 6-MP as a function of the pH values are shown in Fig. 1.

At pH values below 4.5, two relatively close polarographic waves(wave I and II) were observed. The half-wave potentials of the two waves shifted linearly towards a negative potential with an increase in the pH; $E_{1/2}$(*vs.* SCE)/V$=-0.680-0.120$ pH for the I wave and $E_{1/2}$ (*vs.* SCE)/V$=-1.016-0.061$ pH for the II wave. The I_d values for both the waves, particularly

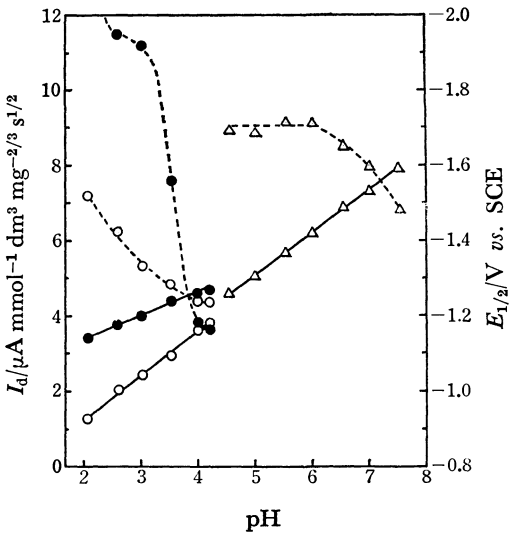

Fig. 1. Effect of pH on the diffusion-current constant (I_d) and half-wave potential of the reduction waves of 0.2×10^{-3} mol/dm^3 6-MP.
○: Wave I, ●: wave II, △: wave III.
(——: $E_{1/2}$, ----: I_d)

that for the II wave, were very large in highly acidic solutions (pH 0—3), but were kept constant at pH values around 4. It is known that the first wave of purine is attributable to a two-electron diffusion-controlled process. The I_d value for this wave was 3.60 μA mmol^{-1} dm^3 mg$^{-2/3}$ s$^{1/2}$. At pH 4.02, the I_d values for the I and II waves of 6-MP were *ca.* 4.4 and 3.8 μA mmol^{-1} dm^3 mg$^{-2/3}$ s$^{1/2}$, corresponding to a two-electron reduction process.

At pH values above 4.5 these two waves merged, and the resulting composite wave(wave III) had a pH dependence of $E_{1/2}$(*vs.* SCE)/V$=-0.746-0.113$ pH. The I_d value of the III wave remained almost constant up to pH *ca.* 6; its value corresponded to a four-electron reduction step. At pH values above 6.0, however, the height of the III wave decreased gradually with an increase in the pH. Since the pK_a of 6-MP was determined to be 7.6 by utilizing the UV absorption method of Shugar and Fox,[7,8] this decrease in the wave-height seems to imply that 6-MP dissociates into an electroinactive ion in solutions above pH *ca.* 7.

The coulometric measurements at the controlled potentials were performed in order to determine the number of electrons involved in the overall electron-transfer reactions. The controlled potential electrolysis at a potential on the crest of the I wave in the Britton-Robinson buffer (pH 4.02) indicated that 2.1 ± 0.2 electrons were transferred per molecule of 6-MP. A coulometric n value for the II wave gave an unusually high value. Also, the electrolytic current remained at a high value throughout the electrolysis

and the pH of the solution increased. This behavior indicates that a major part of the current is a catalytic reduction of hydrogen ions, rather than being due to the reduction of 6-MP itself. Also, the electrolysis at a potential on the crest of the II wave resulted in the liberation of H_2S (detected by lead acetate paper), but no such liberation was detected in the case of the electrolysis at a potential on the crest of the I wave. At pH 6.00 the coulometric n value of the III wave was 5.8±0.4, and the liberation of H_2S was detected just as in the case of the electrolysis at a potential on the crest of the II wave. This discrepancy between the polarographic and coulometric n values may be explained by a ECE mechanism comprised of a slow chemical reaction (liberation of H_2S) which does not occur during the lifetime of a mercury drop, but which becomes important under conditions of prolonged electrolysis.

It is known[1] that purine is reduced in two steps at the DME; the first step is a two-electron reduction to 1,6-dihydropurine, while the second is a further two-electron reduction to 1,2,3,6-tetrahydropurine, which is then hydrolyzed by water to [(5-aminoimidazol-4-ylmethyl)amino]methanol. The mechanisms for the reduction of 6-MP were also proposed. The values of αn_a and of P(the number of hydrogen ions involved in the rate-determining step) were calcualted for the I wave on the basis of the wave-slope($E_{1/4}$-$E_{3/4}$) and the slope of the $E_{1/2}$-pH plots.[9] An average αn_a value of 1.05 and an average P value of 2.13 were determined. Also, the I wave was a two-electron process judging from its I_d values. These facts suggest the hydrogenation of a double bond. Thus by analogy with the first step of purine, the I wave of 6-MP is probably a two-electron process, producing the 1,6-dihydro derivative(**1**). The II wave would then seem to result from a further two-electron reduction to the 1,2,3,6-tetrahydro derivative(**2**) of 6-MP. The UV absorption spectrum of a solution obtained by controlled-potential electrolysis on the crest of the II wave is essentially superimposed on that of the product of the complete electrolysis at a potential on the crest of the second wave of purine, indicating the identity of the two products. The formation of identical products in the reduction processes of 6-MP and purine requires the elimination of the 6-mercapto group from the **2** of 6-MP; this can be explained from the facts that the n values obtained coulometrically at a potential on the crests of the II and III waves were both *ca.* 6 and the liberation of H_2S was detected during the electrolysis. These experimental results seem to indicate that the **2** produced by a four-electron reduction of 6-MP evolves H_2S by means of a relatively slow chemical reaction to produce 2,3-dihydropurine(**3**), which then undergoes a further two-electron reduction to produce 1,2,3,6-tetrahydropurine(**4**), which is probably hydrolyzed to [(5-aminoimidazol-4-ylmethyl)-amino]methanol (**5**) as an end product.

Anodic Waves: An anodic wave of 6-MP was also observed at the DME over the pH range of 2—12. The relationship between the half-wave potentials and the pH was composed of two straight lines. At pH values below 7.6, the anodic wave shifted linearly towards negative potentials with an increase in the pH; $E_{1/2}$(*vs.* SCE)/V=0.140—0.060 pH. At pH values above 7.6, however, the half-wave potential of the anodic wave was independent of the pH; $E_{1/2}$= −0.324 V *vs.* SCE. The pH values at the intersection of these two lines was 7.66, which agreed very closely with the pK_a value (7.60) determined by the UV absorption method,

The height of the anodic wave remained almost constant at the I_d value corresponding to a one-electron faradaic process. The anodic current was proportional to the square root of the height of the mercury head, and the temperature coefficient was 1.3% per degree, indicating that the anodic current was controlled by diffusion.

However, this anodic wave was not observed in this potential range when a platinum electrode was used as the working electrode.

From these experimental results, it seems that the anodic wave of 6-MP does not correspond to the oxidation of 6-MP itself, but to the following reaction of 6-MP with the DME:

$$\mathrm{pH}<\mathrm{p}K_a \quad \mathrm{RSH} + \mathrm{Hg} \longrightarrow \mathrm{RSHg} + \mathrm{H^+} + \mathrm{e},$$

$$\mathrm{pH}>\mathrm{p}K_a \quad \mathrm{RS^-} + \mathrm{Hg} \longrightarrow \mathrm{RSHg} + \mathrm{e}$$

(RSH : 6-MP).

Analytical Application. Compared with the cathodic waves of 6-MP, the anodic wave of this compound was observed at a relatively low potential and was well-defined over the wide pH range of 2—12. The height of this wave in the Britton-Robinson buffer was proportional to the concentrations ranging (5×10^{-5}—10^{-3})mol/dm^3. The satisfactorily wide range of this linear relation suggests that the polarographic method may have analytical utility for the determination of 6-MP, which is being used as an anti-leukemia agent.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (9), 2741—2742 (1978)

The Preparation of 2,2′-Bipyridinedicarbonato and Dicarbonato-1,10-phenanthroline Complexes of Cobalt(III)

Yayoi IDA, Kiyoyuki IMAI, and Muraji SHIBATA*

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received April 26, 1978)

Synopsis. Two new dicarbonato complexes, K[Co$(CO_3)_2$(bpy)]·$2H_2O$ and K[Co$(CO_3)_2$(phen)]·H_2O, have been prepared by the method starting from the $[Co(CO_3)_3]^{3-}$ complex and resolved by means of diastereoisomer formation.

The preparative method starting from a green solution of potassium tricarbonatocobaltate(III) has been characterized by the successive replacement of the CO_3^{2-} ion in the starting material with other ligands, and various dicarbonato complexes which are products of the first-step replacement have been reported; such complexes as *cis*-$[Co(CO_3)_2(NH_3)_2]^-$, $[Co(CO_3)_2(en)]^-$, *cis*-$[Co(CO_3)_2(NO_2)_2]^{3-}$, *cis*-$[Co(CO_3)_2(CN)_2]^{3-}$, and *cis*- and *trans*-$[Co(CO_3)_2(py)_2]^-$ are those examples,[1] and have been used as convenient intermediates for further synthesis.[1,2] The present work was undertaken in order to prepare dicarbonato complexes of 2,2′-bipyridine (bpy) and 1,10-phenanthroline (phen) by reactions of the green solution with these ligands. By the way, the preparation of (mono)carbonato complexes from the green solution has been reported by Kashiwabara *et al.*[3]

Experimental

To a cold, green solution of tricarbonatocobaltate(III) ($Co(NO_3)_2·6H_2O$, 5.8 g, 0.02 mol scale), we added 2,2′-bipyridine (3.1 g, 0.02 mol) dissolved in 50 cm^3 of methanol, after which the mixture was stirred at room temperature for 1 h. To the resulting violet solution we added 100 cm^3 of ethanol, and the whole was cooled in an ice bath for 2 h. The solution was then filtered to remove the by-products, which contained a small amount of the bis(bipyridine)-carbonato complex. To the filtrate we added ether, and then the green, oily portion produced was removed by decantation. The supernatant was kept in a refrigerator overnight to deposit the crude product. Recrystallization of the product was performed from warm water (*ca.* 35 °C) by the addition of a small amount of ethanol. The yield was *ca.* 1.5 g. Found: C, 35.14; H, 2.96; N, 6.71%. Calcd for K[Co$(CO_3)_2(C_{10}H_8N_2)$]·$2H_2O$: C, 35.13; H, 2.95; N, 6.83%.

The corresponding dicarbonatophenanthroline complex was prepared in the manner described above except for the use of 1,10-phenanthroline instead of 2,2′-bipyridine. The yield was *ca.* 1.5 g. Found: C, 39.47; H, 2.30; N, 6.49%. Calcd for K[Co$(CO_3)_2(C_{12}H_8N_2)$]·H_2O: C, 39.54; H, 2.61; N, 6.59%.

The K[Co$(CO_3)_2$bpy]·$2H_2O$ compound (4.1 g, 0.01 mol) was dissolved in a warm solution of $(-)_{589}$[Co$(NO_2)_2(en)_2$]-$(C_2H_3O_2)$[4] (0.005 mol in 20 cm^3 H_2O, *ca.* 40 °C), and then the mixture was cooled in an ice bath. After the side of the vessel had been scratched for a while, the whole was kept in an ice bath for 1 h. The crystals thus obtained were recrystallized from warm water (*ca.* 35 °C). The less soluble diastereoisomer was found to be $(-)_{589}$[Co$(NO_2)_2$-$(en)_2$]·$(+)_{589}$[Co$(CO_3)_2$(bpy)]. The yield was *ca.* 1 g. Found: C, 28.87; H, 4.60; N, 17.43%. Calcd for [Co$(NO_2)_2(C_2H_8N_2)_2$]·[Co$(CO_3)_2(C_{10}H_8N_2)$]·$3H_2O$: C, 29.10; H, 4.58; N, 16.97%.

The resolution of the $[Co(CO_3)_2(phen)]^-$ complex was achieved with $(-)_{589}$[Co(ox)$(en)_2$]$(C_2H_3O_2)$[5] in a manner similar to that used for the bipyridine complex. The less soluble diastereoisomer contained the $(-)_{589}$ form of the complex. The yield was *ca.* 1 g. Found: C, 38.12; H, 3.73; N, 13.22%. Calcd for [Co$(C_2O_4)(C_2H_8N_2)_2$]·[Co$(CO_3)_2$-$(C_{12}H_8N_2)$]: C, 38.35; H, 3.86; N, 13.42%.

By the way, two known carbonato complexes, $[CoCO_3(bpy)_2]^+$ and $[CoCO_3(phen)_2]^+$, as well as two known tris complexes, $[Co(bpy)_3]^{3+}$ and $[Co(phen)_3]^{3+}$, could be prepared by the reactions of the $[Co(CO_3)_3]^{3+}$ complex and the ligands in stoichiometric amounts; in the case of the latter complexes, activated charcoal was used.

The absorption spectra were measured with a Hitachi 323 recording spectrophotometer. The CD spectra were recorded with a JASCO J-40CS automatic recording spectropolarimeter equipped with a JASCO Model J-DPZ data processor for CD, and with the samples converted into potassium salts by means of the ion-exchange technique. For the measurement of the optical rotation, a JASCO Model DIP-SL automatic polarimeter was used.

Results and Discussion

The absorption and CD spectra are shown in Fig. 1. The maximum of the first absorption band is observed

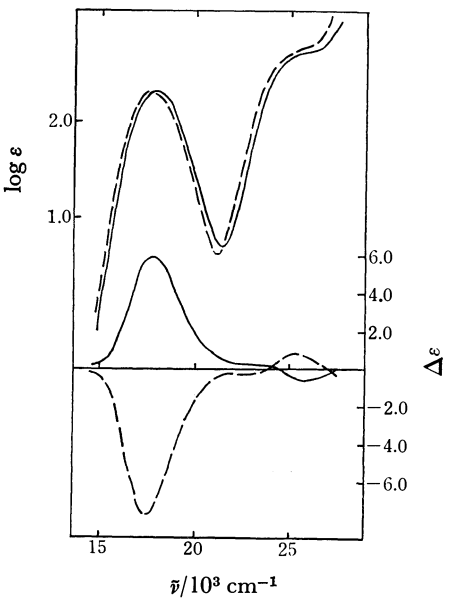

Fig. 1. Absorption and CD spectra of
—— $(+)_{589}$[Co$(CO_3)_2$(bpy)]$^-$ and
—— $(-)_{589}$[Co$(CO_3)_2$(phen)]$^-$.

at 17800 cm^{-1} ($\log\varepsilon=2.18$) for the bpy complex and at 17600 cm^{-1} ($\log\varepsilon=2.18$) for the phen complex. The second absorption band is observed as a shoulder at *ca.* 25600 cm^{-1} (log ε, *ca.* 2.38) for the bpy complex and as one at *ca.* 25400 cm^{-1} (log ε, *ca.* 2.40) for the phen complex.

Recently, we studied the CD spectra of the $[Co(O,O)_2(N)_2]^-$-type complexes ($O,O=CO_3^{2-}$, ox^{2-} and mal^{2-}; $(N)_2$=en, $2NH_3$ and 2py) and found that the related $(+)_{589}[Co(CO_3)_2(en)]^-$, $(-)_{589}[Co(CO_3)_2(NH_3)_2]^-$ and $(+)_{589}[Co(CO_3)_2(py)_2]^-$ complexes exhibit only one CD peak in the first absorption band region; 17600 cm^{-1} ($\Delta\varepsilon=-1.91$) for the en complex, 17800 cm^{-1} ($\Delta\varepsilon=-2.32$) for the NH_3 complex, and 18400 cm^{-1} ($\Delta\varepsilon=+2.94$) for the py complex.[6] The absolute configurations of these complexes were assigned on the basis of the (+) sign of the CD peak referring to Λ, and the (−) sign, to Δ.[6] The CD spectra of the present dicarbonato complexes also exhibit only one CD peak in the first band region; 17700 cm^{-1} ($\Delta\varepsilon=+5.93$) for the bpy complex and 17500 cm^{-1} ($\Delta\varepsilon=-7.72$) for the phen complex. From these CD signs, the Λ configuration is given to the $(+)_{589}[Co(CO_3)_2(bpy)]^-$ complex and the Δ configuration to the $(-)_{589}[Co(CO_3)_2(phen)]^-$ complex. The large $\Delta\varepsilon$ values observed for the present complexes may be attributed to the chelating bpy or phenligand. In an aqueous solution, the $(-)_{589}[Co(CO_3)_2(phen)]^-$ complex racemized with a half-life of *ca.* 7 h at room temperature. In this connection, the $(-)_{589}[Co(CO_3)_2(NH_3)_2]^-$ complex racemized with a half-life of *ca.* 3 min.[7]

Cyclopentadienyl- and Pentamethylcyclopentadienylbis(isocyanide)cobalt(I)[1]

Yasuhiro YAMAMOTO,* Takaya MISE, and Hiroshi YAMAZAKI
The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received February 28, 1978)

Synopsis. Compounds, η-$C_5H_5Co(RNC)_2$ and η-$Me_5C_5Co(RNC)_2$ were prepared from $Co_2(RNC)_8$ and C_5R_5H (R=H, CH_3), and from η-$C_5H_5Co(CO)_2$ and isocyanide.

The cobalt complexes having cyclopentadienyl or pentamethylcyclopentadienyl group as a ligand, η-$C_5H_5CoL_2$ (L=CO,[2] phosphorus ligands[3]) η-$Me_5C_5Co(CO)_2$[4] and η-$C_5H_5Co(CO)L$ (L=PPh_3,[5] RNC[6]) have been known. The chemical reactions of these complexes have been widely provided. However, analogous η-$R_5C_5Co(RNC)_2$ has not been known yet. We here report the preparation and reactions of this type of complexes.

The two methods for the preparation are; (1) the reaction of octakis(isocyanide)dicobalt(0) with cyclopentadiene or pentamethylcyclopentadiene, and (2) the reactions of η-$C_5H_5Co(CO)_2$ with isocyanide. The reaction of $Co_2(2,6\text{-}Me_2C_6H_3NC)_8$ with cyclopentadiene in toluene at 120 °C gave two products, dark brown complex **1a** formulated as η-$C_5H_5Co(2,6\text{-}Me_2C_6H_3NC)_2$ and unknown brown organic compound **2**[7] formulated as $(C_5H_6)(C_9H_9N)_4$.

$$Co_2(RNC)_8 + C_5H_6 \rightarrow \eta\text{-}C_5H_5Co(RNC)_2 + (C_5H_6)(RNC)_4. \quad (1)$$

The chemical shifts of the *ortho*-methyl resonances of coordinated isocyanides were independent of the concentration of free $2,6\text{-}Me_2C_6H_3NC$ added in the NMR spectra of η-$C_5H_5Co(2,6\text{-}Me_2C_6H_3NC)_2$, suggesting the absence of dissociation. When $Co_2(2,6\text{-}Me_2C_6H_3NC)_8$ was treated with pentamethylcyclopentadiene, only η-$Me_5C_5Co(2,6\text{-}Me_2C_6H_3NC)_2$ **1b** was formed.

The reaction of η-$C_5H_5Co(CO)_2$ or η-$Me_5C_5Co(CO)_2$ with excess 2,6-xylyl isocyanide proceeded with substitution of a carbon monoxide at room temperature to give η-$R_5C_5Co(CO)$ $(2,6\text{-}Me_2C_6H_3NC)$ (**3a**: R=H, **3b**: R=CH_3) (Eq. 2). Upon heating at 120 °C, the further displacement of CO took place to afford **1a**, although no displacement of CO occurred in the case of pentamethylcyclopentadienyl analog. This is due to the results that back-bonding Co(3d)→C≡O(π^*) in **3b** is more extensive than that in **3a**, as shown in the C≡O stretching frequencies of **3a** (1956 cm^{-1}) and **3b** (1924 cm^{-1}) (Table 1).

Compounds **3a** and **3b** were regenerated together with a small amount of η-$R_5C_5Co(CO)_2$, when **1a** and **1b** were treated with CO (Eq. 3). These reactions were formally reversible.

$$\eta\text{-}C_5H_5Co(CO)_2 + RNC \rightarrow \eta\text{-}C_5R_5(CO)(RNC) + CO \quad (2)$$

$$\eta\text{-}C_5H_5Co(CO)(RNC) + RNC \rightleftharpoons \eta\text{-}C_5H_5Co(RNC)_2 + CO \quad (3)$$

Compound **1c** was also prepared from η-$C_5H_5Co(CO)_2$ and mesityl isocyanide. However, when η-$C_5H_5Co(CO)_2$ was treated with aliphatic isocyanides such as *t*-butyl or cyclohexyl isocyanide under similar conditions, one mole of CO was substituted to produce η-$C_5H_5Co(CO)(RNC)$,[6] without producing bis(isocyanide) derivative.

Table 1. Infrared spectra of **1** and **3**

	Compound	IR (cm^{-1})[a] ν(N≡C)	ν(C≡O)
1a	η-$C_5H_5Co(2,6\text{-}Me_2C_6H_3NC)_2$	2068 1990	
1b	η-$C_5Me_5Co(2,6\text{-}Me_2C_6H_3NC)_2$	2052 1942	
1c	η-$C_5H_5Co(2,4,6\text{-}Me_3C_6H_2NC)_2$	2053 1989	
3a	η-$C_5H_5Co(CO)(2,6\text{-}Me_2C_6H_3NC)$	2075	1956
3b	η-$C_5Me_5Co(CO)(2,6\text{-}Me_2C_6H_3NC)$	2038	1924

a) Measured in benzene.

The reaction of **1a** with iodine in a 1:1 molar ratio took place readily to give $[\eta\text{-}C_5H_5Co(2,6\text{-}Me_2C_6H_3NC)I]I$, and that with an excess of iodine gave $[\eta\text{-}C_5H_5Co(2,6\text{-}Me_2C_6H_3NC)_2I]I_3$. The similar type of complex, $[\eta\text{-}Me_5C_5Co(2,6\text{-}Me_2C_6H_3NC)_2I]I_3$, was also obtained from **1b** and iodine.

Compound **1a** reacted readily with TCNE to give the olefin complex η-$C_5H_5Co(2,6\text{-}Me_2C_6H_3NC)$(TCNE), whereas no reaction occurred on treatment with dialkyl maleate. When **1a** was treated with azobenzene at 120 °C, the reaction led to recovery of **1a**, contrasted with the reaction leading to the formation of η-$C_5H_5Co(o\text{-}N(Ph)NHC_6H_4)$ from η-$C_5H_5Co(CO)_2$[8] or η-$C_5H_5Co(CO)$(*t*-BuNC) and azobenzene.

The relatively low reactivity of η-$C_5H_5Co(RNC)_2$ may be due to the steric hindrance and no dissociation of ligands.

Experimental

*Preparation of η-$Me_5C_5Co(2,6\text{-}Me_2C_6H_3NC)_2$ **1b** from $Co_2(2,6\text{-}Me_2C_6H_3NC)_8$[9] and Me_5C_5H.* A mixture of pentamethylcyclopentadiene (0.45 ml, 2.65 mmol) and $Co_2(2,6\text{-}Me_2C_6H_3NC)_8$, prepared from $Co_2(CO)_8$ (0.18 g, 0.53 mmol) and $2,6\text{-}Me_2C_6H_4NC$ (0.69 g, 5.3 mmol), *in situ* was heated in toluene at 120 °C. After 4 h, the solvent was removed in vacuo and the residue was chromatographed on alumina. Eluting with hexane–benzene (1:1) gave dark red crystals of η-$Me_5C_5Co(2,6\text{-}Me_2C_6H_3NC)_2$ **1b** (0.175 g, 36%, mp (N_2) ≈108 °C(dec)), which was crystallized from hexane at −30 °C. NMR(C_6H_5Cl): δ 1.95 (bs, Me_5C_5) and 2.25 (bs, 12H, CH_3). Found: C, 73.13; H, 7.34; N, 6.05%. Calcd for $C_{28}H_{33}N_2Co$: C, 73.67; H, 7.29; N, 6.14%.

*Preparation of η-$C_5H_5Co(2,6\text{-}Me_2C_6H_3NC)_2$ **1a** from η-$C_5H_5Co(CO)_2$ and 2,6-Xylyl Isocyanide.* A mixture of η-$C_5H_5Co(CO)_2$ (0.90 g, 5.0 mmol) and 2,6-xylyl isocyanide (2.0 g, 1.53 mmol) in toluene (15 ml) was heated at 120 °C. After

6 h, the solvent was removed in vacuo and the residue was chromatographed on alumina, using hexane-benzene (1:1). The solvent was removed in vacuo, and the brown residue was crystallized from hexane at −30 °C to afford the title complex (1.7 g, 88%, mp(N_2) 94—97 °C(dec)). Mass spectrum M^+ 386 (386.39) Found: C, 71.49; H, 6.01; N, 7.26%. Calcd for $C_{23}H_{23}N_2Co$: C, 71.50; H, 6.00; N, 7.25%. Compound **1c** (72%; mp 72—74 °C(dec)) was prepared from η-$C_5H_5Co(CO)_2$ and mesityl isocyanide by the procedure similar to the method (2). Found: C, 72.41; H, 6.58; N, 6.81%. Calcd for $C_{25}H_{27}N_2Co$: C, 72.45; H, 6.57; N, 6.76%.

Preparation of η-$C_5H_5Co(CO)$ *(2,6-*$Me_2C_6H_3NC$*).* A mixture of η-$C_5H_5Co(CO)_2$ (0.18 g, 1.0 mmol) and 2,6-xylyl isocyanide (0.30 g, 2.3 mmol) in toluene (15 ml) was kept at room temperature for 5 h. The work-up of the reaction mixture gave the title compound (0.25 g, 92%, mp 70—71 °C(dec)). Mass M^+ 283(283.22). Found: C, 63.52; H, 4.89; N, 5.03%. Calcd for $C_{15}H_{14}OCo$: C, 63.61; H, 4.92; N, 4.95%.

Reaction of η-$R_5C_5Co(2,6$-$Me_2C_6H_3NC)_2$. *a) With Iodine*: To a solution of η-$C_5H_5Co(2,6$-$Me_2C_6H_3NC)_2$ (0.09 g, 0.23 mmol) in benzene (5 ml) was added iodine (0.09 g, 0.35 mmol) in benzene (5 ml) at room temperature. After 45 min, the resulting black brown crystals (0.065 g, 44%; mp 143—145 °C (dec)) were filtered off, which were crystallized from CH_2Cl_2-hexane. The complex contains one molecule of CH_2Cl_2 in crystallization. IR(KBr): 2189 (N≡C) cm^{-1}. NMR($CDCl_3$): δ 2.54 (s, CH_3) 6.27 (bs, C_5H_5), and 7.16 (bs, C_6H_3) ppm. Found: C, 40.19; H, 3.33; N, 3.97%. Calcd for $C_{24}H_{25}N_2Cl_2I_2Co$: C, 39.75; H, 3.48; N, 3.86%.

[η-$C_5H_5Co(2,4,6$-$Me_3C_6H_2NC)_2I$]I (83%, mp ≈160 °C (dec)) was prepared by the procedure similar to that mentioned above. IR(KBr): 2178 (N≡C) cm^{-1}. NMR($CDCl_3$): δ 2.33 (s, *p*-Me), 2.51 (s, *o*-Me) 6.30 (bs, C_5H_5) and 6.92 (s, C_6H_2) ppm. Found: C, 44.70; H, 4.02; N, 4.26%. Calcd for $C_{25}H_{27}N_2I_2Co$: C, 44.94; H, 4.07; N, 4.19%.

[η-$Me_5C_5Co(2,6$-$Me_2C_6H_3NC)_2I$]I_3 (mp 166—168 °C(dec)) was obtained from **1b** and an excess of I_2 in hexane. IR(KBr): 2151 and 2165 (N≡C) cm^{-1}. NMR($CDCl_3$): δ 2.21 (s, Me_5C_5), 2.47 (s, *o*-Me), and *ca.* 7.18 (m, C_6H_3). Found: C, 34.85; H, 3.46; N, 2.67; I, 51.40%. Calcd for $C_{28}H_{33}N_2I_4Co$: C, 34.88; H, 3.45; N, 2.91; I, 52.62%.

[η-$C_5H_5Co(2,6$-$Me_2C_6H_3NC)_2I$]I_3 (mp 105 °C (dec)). IR(KBr): 2185 (N≡C) cm^{-1}. Found: C, 30.14; H, 2.54; N, 3.01%. Calcd for $C_{23}H_{23}N_2I_4Co$: C, 30.90; H, 2.59; N, 3.13%.

b) With Tetracyanoethylene (TCNE): A solution of TCNE (0.04 g, 0.31 mmol) in benzene (3 ml) was added to a solution of **1a** (0.12 g, 0.31 mmol) in benzene (5 ml) at room temperature and stirred for 1 h. The mixture was chromatographed on alumina. Eluting with CH_2Cl_2 gave brown crystals of η-$C_5H_5Co(2,6$-$Me_2C_6H_3NC)$(TCNE) (0.46 g, 39%, mp >300 °C). IR(benzene): 2220 (C≡N) and 2152 (N≡C) cm^{-1}. Found: C, 62.43; H, 3.69; N, 18.35%. Calcd for $C_{20}H_{14}N_5Co$: C, 62.67; H, 3.68; N, 18.27%.

The Use of Zinc/Silver Couple in the Cyclocoupling Reaction of Polybromo Ketones and Furan

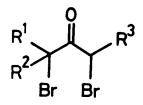
Tsuneo SATO and Ryoji NOYORI*

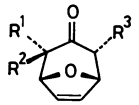
Department of Chemistry, Nagoya University, Chikusa, Nagoya 464

(Received May 18, 1978)

Synopsis. The title 3+4→7 reaction, followed by Zn/Cu couple reduction in methanol, affords 8-oxabicyclo-[3.2.1]oct-6-en-3-ones in satisfactory yields.

During the course of our recent project on *C*-nucleoside synthesis,[1] the need arose for the large-scale preparation of the oxabicyclic product **5** by the reductive cyclocoupling reaction of $\alpha,\alpha,\alpha',\alpha'$-tetrabromoacetone (**1**) and furan.[2] Among various reducing agents, Zn/Ag couple[3] was found to be an effective reagent for such purpose. Thus reaction of **1** and furan in THF with the aid of Zn/Ag couple and subsequent treatment of the product with Zn/Cu couple[5] in methanol gave rise to **5** in 55% yield. The yield of the present 3+4 cyclocoupling reaction was not as high as that of the iron carbonyl promoted reaction[4] but these reaction conditions may be suitable for the medium- to large-scale synthesis of **5** because of the operational simplicity and from economical point of view. Use of Zn/Cu couple[5] or activated Zn[6] in place of Zn/Ag couple resulted in decrease in product yield.[7] THF was the best among solvents so far examined. Zn/Ag couple could be employed also in the reaction of the polybromo ketones **2**—**4** and furan.





1, $R^1=R^3=Br$; $R^2=H$ **5**, $R^1=R^2=R^3=H$
2, $R^1=R^3=Br$; $R^2=CH_3$ **6**, $R^1=CH_3$; $R^2=R^3=H$
3, $R^1=R^2=CH_3$; $R^3=Br$ **7**, $R^1=R^2=CH_3$; $R^3=H$
4, $R^1=R^3=CH_3$; $R^2=H$ **8**, $R^1=R^3=CH_3$; $R^2=H$

Experimental

The brominated ketones **1**—**4**[8] and Zn/Cu couple[5] were made by the known methods. Zn/Ag couple was prepared by the Heathcock's procedure using 65 mg of $AgOCOCH_3$ per g of Zn.[3a] Solvent THF was freshly distilled from sodium/benzophenone in a recycling still. All reactions were carried out under argon atmosphere. Filtration was carried out using a Celite 545 pad. Unless otherwise stated, concentration of solutions containing nonvolatile materials was achieved on a rotary evaporator (30—40 mmHg) at room temperature. Drying of organic solutions was performed over anhydrous Na_2SO_4. All melting and boiling points are uncorrected.

8-Oxabicyclo[3.2.1]oct-5-en-3-one (5). A mixture of Zn/Ag couple (29.3 g, 0.450 g-atom) and furan (210 ml, 3.00 mol) in dry THF (450 ml) was placed in a 2-litre three-necked flask and cooled at −10 °C. A solution of **1** (112 g, 0.300 mol) in dry THF (200 ml) was added dropwise over a period of 2 h with stirring and then the resulting mixture was allowed to warm up to room temperature and stirred for 12 h. The insoluble materials were removed by filtration and the filtrate was concentrated. The tarry brown residue was chromatographed on a silica gel column (E. Merck, 700 g, 1:20 to 1:5 hexane/ethyl acetate mixture as eluent) to give crude 2α,4α-dibromo-8-oxabicyclo[3.2.1] oct-6-en-3-one[4] as yellowish crystals (55 g). Recrystallization from hexane gave a pure sample melting at 126.5—127 °C. The dibromo adduct was dissolved in saturated NH_4Cl solution in CH_3OH (1.3 litre) and to this was added portionwise Zn/Cu couple (120 g, 1.85 g-atom) over 10 min at room temperature. The suspension was stirred for an additional 1 hr and filtered. The filtrate was divided into four portions and each portion was diluted with water (200 ml) and saturated Na_2H_2edta solution (300 ml). Extraction was then performed with CH_2Cl_2 successively (300 ml and then 200 ml×2). The combined extracts were dried and CH_2Cl_2 was removed by distillation at atmospheric pressure through a 40-cm Vigreux column. Finally the residue was subjected to light suction by an aspirator at room temperature to leave the bicyclic compound **5**, contaminated with a small amount of CH_2Cl_2, as a pale yellow liquid (20.4 g, 95% pure by NMR analysis[4]). Overall yield based on **1** was 55%. Pure crystalline sample of **5**, mp 37—39 °C, was obtained by bulb-to-bulb distillation (50—80 °C/0.01 mmHg).

2α-Methyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (6). A mixture of Zn/Ag couple (29.3 g, 0.450 g-atom) and furan (210 ml, 3.00 mol) in THF (450 ml) was cooled at −10 °C and to this was added a solution of **2** (116 g, 0.300 mol) in THF (200 ml) in a dropwise manner over 1.5 h. The reaction mixture was stirred at the same temperature for 1 h and then at room temperature for 17 h, and filtered. The filtrate was concentrated and chromatographed on a column of silica gel (700 g, 1:20 to 1:5 hexane/ethyl acetate) to give 2,4-dibromo-2-methyl-8-oxabicyclo[3.2.1] oct-6-en-3-one as a pale yellow solid (54 g). Mp 78—79 °C (from hexane). This adduct, dissolved in saturated NH_4Cl solution in CH_3OH (1.2 litre), was treated with Zn/Cu couple (120 g, 1.85 g-atom) with stirring at room temperature for 1 h and filtered. The resulting solution was worked up with aqueous Na_2H_2edta and CH_2Cl_2 in the same fashion as described in the preparation of **5**. The combined CH_2Cl_2 solutions were dried and concentrated with a Vigreux column at atmospheric pressure and then with an aspirator (30—40 mmHg, room temperature) to afford **6** (21.9 g, contaminated with 7% of CH_2Cl_2 as determined by NMR[4]). The overall yield was 53% based on **2**. Pure sample of **6** was obtained by bulb-to-bulb distillation (70—100 °C/0.02 mmHg).

2,2-Dimethyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (7). To a cooled (−10 °C) mixture of Zn/Ag couple (29.3 g, 0.450 g-atom), furan (210 ml, 3.00 mol), and THF (450 ml) was added a solution of **3** (96.6 g, 0.300 mol) in THF (200 ml) over a period of 1.5 h. The mixture was then stirred at room temperature for 19 h, filtered, and concentrated. The resulting tarry residue was chromatographed (silica gel 700 g, 1 : 20 to 1 : 5 hexane/ethyl acetate) to give 2,2-dimethyl-4α-bromo-8-oxabicyclo[3.2.1]oct-6-en-3-one as crystalline solid (38 g). Mp 95—96 °C (from hexane). The

bromide was dissolved in CH_3OH saturated with NH_4Cl (1.4 litre) and treated with Zn/Cu couple (100 g, 1.54 g-atom) at room temperature for 1 h. The reaction mixture was filtered and the filtrate was worked up with aqueous Na_2H_2-edta and CH_2Cl_2 as described above. The combined organic layers were dried and concentrated using a Vigreux column. Subsequent light suction by an aspirator (30—40 mmHg, at room temperature) left **7** of 93% purity (NMR analysis,[4] 22.5 g, 50% overall yield based on **3**), the only impurity being CH_2Cl_2. Its bulb-to-bulb distillation (80—110 °C/0.05 mmHg) afforded pure sample of **7**, mp 46—47 °C.

2α,4α-Dimethyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (8). A mixture of Zn/Ag couple (19.6 g, 0.300 g-atom), furan (140 ml, 2.00 mol) and THF (300 ml) was stirred at −10 °C, to which a solution of **4** (48.8 g, 0.200 mol) in THF (150 ml) was added dropwise over a period of 1 h. Then the mixture was allowed to warm up to room temperature and stirred for an additional 12 h. The insoluble precipitate was removed by filtration and the filtrate was concentrated. Chromatography of the residue on a silica gel column (500 g, 1:20 to 1:5 hexane/ethyl acetate) afforded **8** as a colorless liquid (24.2 g, 80% yield), identical with authentic sample.[4] No other stereoisomers were formed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (9), 2747—2748 (1978)

Synthesis of 5-(Substituted methyl)-6,8-dimethyl-4-chromanones[1)]

Akira NINAGAWA* and Haruo MATSUDA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received February 17, 1978)

Synopsis. 5-(Substituted methyl)-6,8-dimethyl-4-chromanones were synthesized from the reactions of 5-hydroxymethyl-6,8-dimethyl-4-chromanone with nucleophilic reagents in acid media, and the reactions of its 5-halomethyl derivatives with ethoxide or phenoxide nucleophiles.

In previous papers,[2)] polymers having 4-chromanones have been synthesized since 4-chromanones are useful ultraviolet absorbers.

In this paper, the syntheses of 5-(substituted methyl)-6,8-dimethyl-4-chromanones from the reactions of 5-hydroxymethyl-6,8-dimethyl-4-chromanone(**1**) with nucleophilic reagents in the presence of acid catalysts are presented. In addition, 5-(substituted methyl)-6,8-dimethyl-4-chromanones have been prepared from 5-halomethyl derivatives of **1**.

Results and Discussion

*Reactions of **1** with Nucleophilic Reagents.* The reactions of **1** with nucleophilic reagents in acidic media were carried out and reaction conditions are shown in Table 1.

The chlorination of **1** in dioxane solution in the presence of hydrochloric acid as the catalyst and nucleophilic reagent gave 5-chloromethyl-6,8-dimethyl-4-chromanone(**3a**). Similarly, the bromination of **1** in dioxane in the presence of hydrobromic acid afforded 5-bromomethyl-6,8-dimethyl-4-chromanone(**3b**). The methanolysis of **1** in a mixture of methanol and dioxane with perchloric acid as the catalyst gave 5-methoxymethyl-6,8-dimethyl-4-chromanone(**3c**). The ethanolysis of **1** in ethanol in the presence of perchloric acid gave 5-ethoxymethyl-6,8-dimethyl-4-chromanone(**3d**).

The reactions of **1** with phenol and *p*-cresol in ethanol gave 5-(4-hydroxybenzyl and 2-hydroxy-5-methylbenzyl)-6,8-dimethyl-4-chromanones(**3e** and **3f**), respectively. The reaction of **1** with *p*-cresol gave a mixture of **3f** and **3d** in the mole ratio of 8:9, which was measured by the peak area in the ^{1}H-NMR spectrum. The low yield of **3f** is due to the lower fractionation of **3f** from the reaction mixture. When a mixed solution of dioxane and ethanol was used, the reaction gave **3f** along with a small amount of resinous product. No formation of **3d** was detected. With increasing ratio of dioxane to ethanol, the resinous product increased. When dioxane solvent was used solely in the reaction of **1** with *p*-cresol, phenol, and *p*-*t*-butylphenol, 5-substituted methyl compounds were not isolated from the reaction mixtures. It was found that the reaction was affected markedly by the character of the solvents, dioxane causing a remarkable effect in the yield of products.

The reaction of **1** with excess 2,6-di-*t*-butylphenol in dioxane gave 5-(4-hydroxy-3,5-di-*t*-butylbenzyl)-6,8-dimethyl-4-chromanone(**3h**).

Thiophenol and *p*-thiocresol gave 5-phenylthiomethyl and 5-(*p*-tolylthiomethyl) compounds(**3i** and **3j**), respectively, in larger yields than in the cases of phenol and *p*-cresol.

The results shown in Table 1 indicate that the yield of the products are largely dependent on the nucleophilicity[3)] of reagents and the stability of the oxonium ion(**2**)[1)] in acidic solvents.

*Synthesis of **4d**, **4k**, and **4m** from 5-Halomethyl Derivatives (**3a** and **3b**).* The reaction of **3b** with sodium ethoxide gave **4d** quantitatively, but the use of **3a** under similar conditions gave the starting material. The reactions of **3a** with phenol and *p*-cresol gave 5-phenoxymethyl and 5-(*p*-tolyloxymethyl) derivatives (**4k** and **4m**), respectively.

Experimental

Melting points are uncorrected. IR spectra were obtained using KBr pellets in a Hitachi EPI-G2 spectrophotometer. ^{1}H-NMR spectra were recorded on a JEOR Model PS-100 spectrometer with tetramethylsilane as the internal standard. Mass spectra were obtained on a Hitachi RUM-6 mass spectrometer operating at 70 eV.

Materials. **1** was prepared by the reported method,[1)] mp 95—97 °C [lit,[1)] mp 95—97 °C].

*Reactions of **1** with Nucleophilic Reagents.* The following procedure for the preparation of 5-(substituted methyl)-6,8-dimethyl-4-chromanone is representative.

A mixture of **1** and hydrochloric acid in dioxane was stirred at 80 °C for 6 h. After completion of the reaction, the reaction mixture was poured into water, and then extracted with chloroform. The chloroform layer was washed

† *Chemistry Department, Faculty of Science, Cairo University, Cairo, Egypt*

(Received December 14, 1977)

Synopsis. A formalism is presented for studying intramolecular cycloadditions in terms of their corresponding perturbation density matrices. The effect of hetero-atom on a particular intramolecular cycloaddition is discussed.

Although the conversion of benzene into prismance (I) might formally be considered as a ($\pi 2_s + \pi 2_a + \pi 2_a$) intramolecular cycloaddition, and inspite of the fact that such a process is thermally "allowed," Reaction 1[1] and the related ones, Reaction 2 and 3, as well as the corresponding cycloreversions are not observed in the ground state.[2] On the other hand, derivatives of the oxa analogue (IV) of quadricyclene (III) are smoothly transformed into the corresponding oxepines when heated[3] (backward of Reaction 4 in Fig. 1). Conservations of orbital symmetry do not provide a clear explanation of such intramolecular cycloadditions. In this note a formalism is given in which such reactions are quantitatively described.

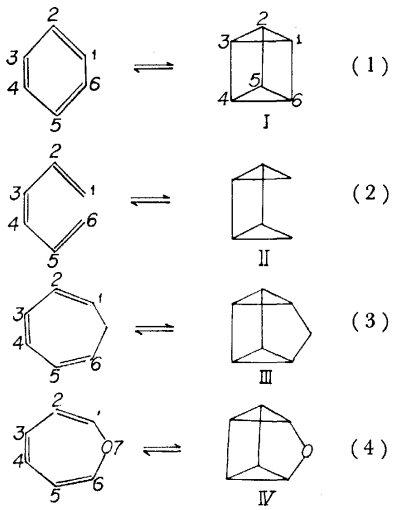

Fig. 1.

For a particular intramolecular cycloaddition reaction, calculations proceed as follows:

(1) An $n \times n$ perturbation matrix, P, is written to describe the particular intramolecular process, where n is the number of p-orbitals in conjugation in the starting polyene. The elements of such a matrix will vanish except those at positions where sigma resonance integrals change from a value of zero to some finite value as a result of overlap during the process.

(2) The initial perturbation ΔE which is a measure of the feasibility of a particular cycloaddition is given by

$$\Delta E = 1/2 \sum_{i=1}^{n/2} e_i \langle \phi_i | P | \phi_i \rangle = \sum_{r>s} \sum C_{ir} C_{is} \gamma_{rs}, \quad (1)$$

where

$$\gamma_{rs} = \langle \chi_r | P | \chi_s \rangle = \begin{cases} -|\gamma| & \text{(r, s; interacting)} \\ 0 & \text{(otherwise).} \end{cases}$$

In Eq. 1, e_i is the number of electrons in the ith MO. The eigenvectors $|\phi_i\rangle$ and $\langle \phi_i|$ are the SCF column and row vectors of the ith MO. The factor of 1/2 avoids counting a particular interaction twice. Matrix elements such as $\langle \phi_i | P | \phi_i \rangle$ form the main diagonal in the corresponding "perturbation density matrix."

TABLE 1. INITIAL PERTURBATIONS[a] ΔE FOR STUDIED INTRAMOLECULAR CYCLOADDITION REACTIONS (Fig. 1)

Reaction	Contribution to ΔE from	ΔE_{total}	Exptl.
1	ϕ_1, $\Delta E_1 = -1.000$		
	ϕ_2, $\Delta E_2 = 1.000$		
	ϕ_3, $\Delta E_3 = 0.6667$	0.6667	Not observed
2, 3	ϕ_1, $\Delta E_1 = -3.6370$		
	ϕ_2, $\Delta E_2 = -0.7282$		
	ϕ_3, $\Delta E_3 = 4.3880$	0.0228	Not observed
4	ϕ_1, $\Delta E_1 = -0.1654$		
	ϕ_2, $\Delta E_2 = -2.0588$		
	ϕ_3, $\Delta E_3 = -0.6988$		
	ϕ_4, $\Delta E_4 = 2.7304$	−0.1926	Observed

a) All values are divided by $|\gamma|$. A negative ΔE implies stabilization of the system and *vice-versa*.

Table 1 outlines the results of calculations using a previously described version of the SCF-PPP method.[4] The following points are worth observing:

(1) While the dominating interactions are always contributed by HOMO, one should not draw a conclusion based upon such an interaction alone. Rather, all interactions must be considered. Reaction 4 is particularly illustrative of this point.

(2) Examination of Reactions 2 and 3 on one hand and Reaction 4, on the other, makes it clear that the HOMO provides the most destabilizing component to the cycloaddition process and that such destabilization is decreased upon introduction of the hetero-atom in the molecule. In simple terms one might say that the introduction of an oxygen atom in quadricyclene (III), "buffers" an "energy-raising" component into the transition state of its cycloreversion.

Interaction of Synthetic Polypeptides with Lipids in Monolayers

Takuya YAMASHITA, Akira SHIBATA, and Shinsuke YAMASHITA*

Faculty of Pharmaceutical Sciences, Tokushima University, Shomachi, Tokushima 770

(Received October 3, 1977)

The interaction of polypeptide (benzyloxycarbonyl derivatives of basic poly(α-amino acid), benzyl esters of acidic poly(α-amino acid), and poly(L-leucine)) and lipid (fatty acids, fatty alcohols and cholesterol) at the air–water interface was investigated. From the additivity rule of mean molecular areas and the work of collapse of the monolayers, it was found that the characteristic interaction occurs in the polymer rich region (less than 0.2 lipid mol fraction), and that the interaction is stronger for the polymer with higher helical content. The interaction was found to take place between side chains of polypeptides and lipids, and to be mainly of hydrophobic nature. The components in mixed polypeptide–cholesterol monolayers exhibit characteristic miscibilities depending upon the chemical composition of polymer side chains. The polarized infrared spectra of collapsed films consisting of single or mixed components indicate that the polymer component is aligned in a direction parallel to the compressing barrier.

Lipid-protein interactions are of great interest for understanding the structure and function of biological membranes. Spread monolayers provide one of the most promising means for studying molecules in fixed orientations, constituting an important model system for many naturally-occurring phenomena which involve surfaces or oriented arrays of molecules. The monolayer approach has been found very useful for understanding molecular aspects of lipid-protein interactions presumably occurring in biomembranes.[1–3] Synthetic polypeptides are useful as a simple model of proteins. A number of investigations on the physicochemical and biological properties have been carried out.[4]

Recently, the interactions of lipid monolayers spread at the air–water interface with synthetic polypeptides dissolved in the subsolution have been investigated.[5–8] For poly(L-lysine) and stearic acid system, the maximum interaction occurs at a pH value where polypeptide is in the helical conformation, and the helical conformation of the poly(L-lysine) molecule can be stabilized by electrostatic interaction with the ionized stearic acid monolayer.[7] On the other hand, from studies on various combinations of lipid monolayers (phosphatidyl serine, DL-α-dipalmitoyllecithin) and synthetic polypeptides-(poly(L-aspartic acid), poly(L-glutamic acid), poly(L-lysine)), in the subsolution, it has been found that the interaction between lipids and polypeptides at the interface is essentially hydrophobic.[8] The interactions have also been studied by using mixed monolayers of synthetic polypeptides and lipids. The mixed monolayer approach is particularly useful for studying the surface compatibility of polypeptides and lipids.[9–11] No interactions are detected probably owing to the quite different steric arrangement of the two components at the interface.[9,10] On the other hand, the formation of 5:1 and 1:1 (residue: molecule) complexes for poly-(DL-leucine) and sodium octadecyl sulfate system and 1:1 complex for poly(DL-phenylalanine) and sodium octadecyl sulfate system has been also reported.[11]

The purpose of this investigation is to establish the existence or nonexistence of interactions between synthetic polypeptides and lipids, and to clarify the nature of the interaction at the interface.

Experimental

Poly(δ-benzyloxycarbonyl-L-ornithine) (PLO(Z)), poly-(ε-benzyloxycarbonyl-L-lysine) (PLL(Z)), poly(L-leucine) (PLLeu), poly(β-benzyl-L-aspartate) (PBLA), poly(γ-benzyl-L-glutamate) (PBLG), and poly(γ-benzyl-DL-glutamate) (PBDLG-1, PBDLG-2) were prepared by the polymerization of the *N*-carboxy anhydrides of respective amino acids. The molecular weights determined from the viscosities at 25 °C in *N*,*N*-dimethyl-formamide (DMF)[12] or dichloroacetic acid (DCA)[13] are given in Table 1. Infrared spectra indicate that, with the exception of PBDLG-1 and PBDLG-2, these polymers are in the α-helical conformation in the solid state. The helical content of poly(γ-benzyl-DL-glutamates) was more than 90% regular α-helix for PBDLG-1, and 13% regular α-helix and 60% perturbed α-helix for PBDLG-2. No β-conformation was found for PBDLG-1 and PBDLG-2. The regular α-helix and perturbed α-helix have been designated by Tsuboi *et al.*[14] The perturbed α-helix portion in a polypeptide molecule contains an antipode residue, the sequence length being relatively short.

Table 1. Molecular weights of polypeptide samples

Polymer	[η]	*MW*
PLO(Z)	2.17(DMF)	3.5×10^5
PLL(Z)	2.40(DMF)	3.8×10^5
PBLA	0.28(DCA)	4.0×10^4
PBLG	1.67(DCA)	3.1×10^5
PBDLG-1	0.34(DCA)	5.0×10^4
PBDLG-2	0.40(DCA)	6.0×10^4
PLLeu: $\eta_{sp}/c=4.56$ ($c=0.2\%$ TFA)		

Lipids employed were myristic acid (C_{14} acid), stearic acid (C_{18} acid), 1-tetradecanol (C_{14} alcohol), 1-octadecanol (C_{18} alcohol), and cholesterol. These materials were purified either by fractional distillation or by recrystallization, and were chromatographycally pure.

The spreading solvents (DMF, dichloromethane (DCM) and trifluoroacetic acid (TFA)) were distilled under nitrogen atmosphere. The subsolution, 0.01 M HCl, was made up from twice distilled water and distilled 6 M HCl.

The spreading solvents were DCM for PBLA- and PBG (PBLG, PBDLG-1 and PBDLG-2)-lipid systems, a 9:1 (v/v) mixture of DCM and DMF for PLO(Z)- and PLL(Z)-lipid

systems, and a 9: 1 (v/v) mixture of DCM and TFA for PLLeu. When a 0.3 cm^3 solvent was deposited on water surface, a 10 to 1 compression of the surface produced less than 0.1 dyn/cm film pressure. The solutions of polypeptide and lipid were prepared separately, and mixed in the desired ratio immediately before spreading. The spreading solution was deposited from a micrometer syringe onto the surface of subsolution, and left to stand for 15 min. Polypeptide or lipid concentration in the spreading solution was 4—6 mg/10 cm^3. Unless otherwise stated, the initial spreading-area was 50 $Å^2$ (0.5 nm^2)/residue or molecule. The trough (65×15×1 cm) and compressing barriers were made of Teflon. The film was compressed at a rate of 10 mm/min (1 $Å^2$/residue or molecule/min). The surface pressure was measured by the Wilhelmy method. Measurements were carried out at 25 °C.

The polarized infrared spectra of collapsed films were measured by a JASCO DS-701G spectrometer. The monolayer was spread and compressed until collapse under the same conditions as in the case of surface pressure measurement. In order to remove the monolayer, it was compressed between two Teflon barriers, until the separation was about 1.5 cm. The polymer was then removed by drawing a stainless steel net across the trough between the barriers. The transferred collapsed film was dried at room temperature.

Results

Figure 1 shows the surface pressure-area (π-A) curves for PLO(Z), PLL(Z), PLLeu, PBLA, and PBG's. Plateaux or inflections are seen in the curves. The plateau or inflection which is characteristic of a number of synthetic polypeptide monolayers is associated with the collapse or transition of the monolayer in the α-helical conformation from a two-dimensional oriented state to a three-dimensional disoriented state.[4,15] The limiting areas extrapolated to zero surface pressure for the steep region are 22.5 $Å^2$/residue for PLO(Z), 23.8 $Å^2$/residue for PLL(Z) and 20.7 $Å^2$/residue for PBLA. When the monolayers were formed at the various spreading areas (40—60 $Å^2$/residue), the π-A curves were reproducible to ±0.2 $Å^2$/residue in repeated experiments. The areas are in good agreement with those reported by other workers.[4,16-19] The limiting area for PLLeu is 17.4±0.3 $Å^2$/residue which is smaller than that reported by Yamashita (19 $Å^2$/residue).[20] According to Malcolm,[21] the result may be associated with the difficult spreading of PLLeu.

The π-A curves of PBLG, PBDLG-1 and PBDLG-2 are shown in Fig. 1-b. The limiting area and monolayer transition pressure are 21.6 $Å^2$/residue and about 5.3 dyn/cm for PBLG, 21.0 $Å^2$/residue and 7.8 dyn/cm for PBDLG-1, and 20.8 $Å^2$/residue and 8.1 dyn/cm for PBDLG-2. The transition pressure of PBLG is much lower than that of PBDLG-1 and PBDLG-2. This might be related to the conformational difference between monolayers of PBLG and PBDLG's at the air–water interface. The difference in transition pressures of PBDLG-1 and PBDLG-2 is quite small. For PBG's, it has been reported that the temperature coefficient of transition pressure is dependent upon the regular α-helix content: the negative value of temperature coefficient is smaller for PBDLG-1 than for PBDLG-2 (regular α-helix content; PBDLG-1>PBDLG-2).[22] The height of transition pressure may be reversed at higher temperature. The monolayer of PBLG is more expanded than that of PBDLG-1 and PBDLG-2 (Fig. 1-b). The compressibility at close packed area is 0.027 for PBLG, 0.014 for PBDLG-1, and 0.015 for PBDLG-2.

The π-A curves of various lipids are shown in Fig. 2. C_{14} acid gives an expanded monolayer. On the other hand, the monolayers of C_{18} acid, C_{14} alcohol, C_{18} alcohol, and cholesterol are of condensed type. The film of cholesterol is highly incompressible.

As typical examples, the π-A curves of mixed PLO(Z)–C_{14} acid and mixed PLO(Z)–cholesterol monolayers are shown in Fig. 3. Two transition points are shown to

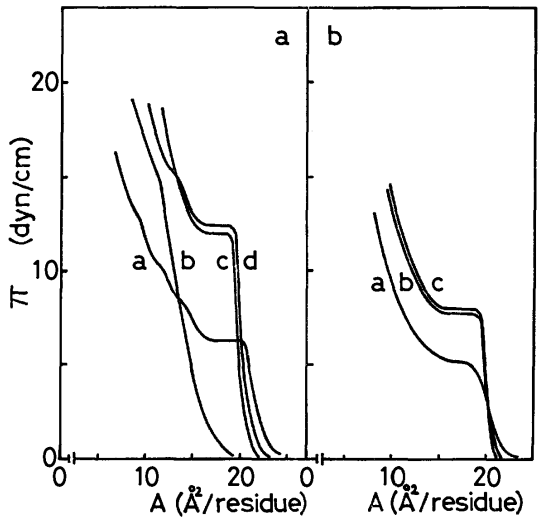

Fig. 1. Surface pressure-area curves of polypeptide monolayers on 0.01 M HCl at 25 °C. 1 dyn=10^{-5} N, 1 Å=0.1 nm. a) a: PLL(Z), b: PLLeu, c: PBLA, d: PLO(Z). b) a: PBLG, b: PBDLG-1, c: PBDLG-2.

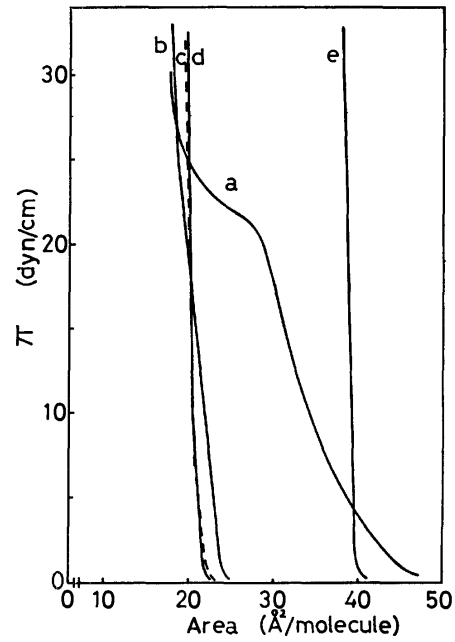

Fig. 2. Surface pressure-area curves of lipid monolayers on 0.01 M HCl at 25 °C. a: C_{14} acid, b: C_{18} acid, c: C_{14} alcohol, d: C_{18} alcohol, e: cholesterol.

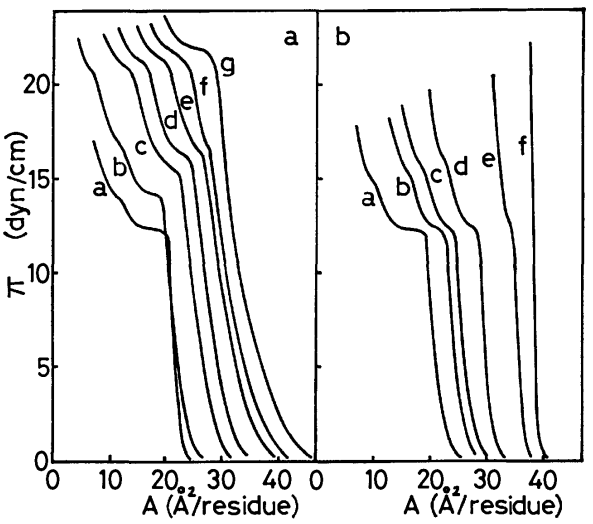

Fig. 3. Surface pressure-area curves of mixed monolyers on 0.01 M HCl at 25 °C. a) PLO(Z)–C_{14} acid, a: 1: 0, b: 4: 1, c: 7: 3, d: 1: 1, e: 3: 7, f: 1: 4, g: 0: 1, b) PLO(Z)-cholesterol, a: 1: 0, b: 4: 1, c: 7: 3, d: 1: 1, d: 1: 1, e: 1: 4, f: 0.: 1 (residue mol: mol).

exist (Fig. 3-a). The surface pressure at the lower point increases with increase in C_{14} acid mol fraction, while the higher point (about 22 dyn/cm) is independent of the mol fraction of C_{14} acid. The lower transition point is evidently caused by the polymer component. Discussion will be limited to this lower transition point or pressure. For mixed PLO(Z)–C_{14} acid system, up to C_{14} acid mole fraction of 0.5, the transition pressure caused by the polymer component increases steeply, the increase becoming gradual beyond this mole fraction. No significant change in transition pressure is observed for the mixed PLO(Z)–cholesterol system (Fig. 3-b).

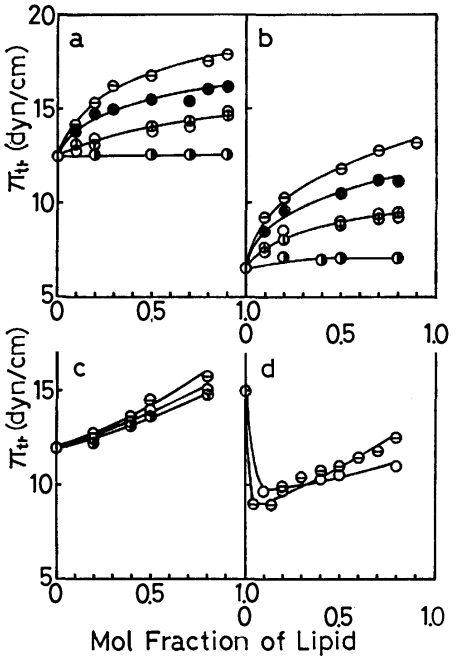

Fig. 4. Transition pressure of mixed monolayers as a function of lipid mole fraction at 25 °C.
a) PLO(Z)-lipid, b) PLL(Z)-lipid, c) PBLA-lipid, d) PLLeu-lipid, ⊖: polypeptide–C_{14} acid. ○: polypeptide–C_{18} acid, ●: polypeptide–C_{14} alcohol, ⓘ: polypeptide–C_{18} alcohol, ◑: polypeptide–cholesterol.

Figure 4 shows the relationship between the transition pressure and the composition of lipid in mixed monolayers for PLO(Z)–lipid, PLL(Z)–lipid, PBLA–lipid and PLLeu–lipid systems. From Figs. 4-a and 4-b, we see that no difference in transition pressures between PLO(Z)–C_{18} acid and PLO(Z)–C_{18} alcohol molayers and between PLL(Z)–C_{18} acid and PLL(Z)–C_{18} alcohol monolayers. In addition, the transition pressures for mixed PLL(Z)–lipid systems are larger than those for mixed PLO(Z)–lipid systems. PLO(Z) has less methylene group as compared with PLL(Z).

The transition pressure for PBLA–lipid systems (Fig. 4-c) differs remarkably from PLO(Z)–lipid and PLL(Z)–lipid systems. The difference in transition pressure among PBLA–C_{14} acid, PBLA–C_{18} acid and PBLA–cholesterol is small. There is an inflection point at about 15 dyn/cm for a monolayer of PLLeu (Fig. 1). For mixed monolayers of PLLeu and either C_{14} acid or C_{18} acid (Fig. 4-d), we see that the transition pressure decreases remarkably with the addition of a small amount of lipid, becoming minimum at about 0.2 lipid mole fraction.

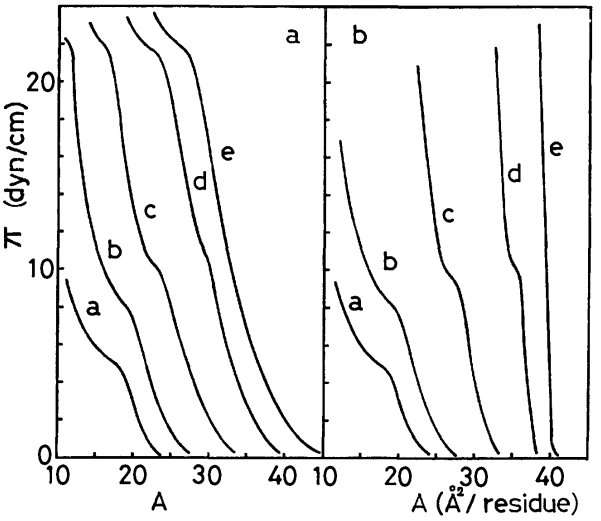

Fig. 5. Surface pressure-area curves of mixed monolayers on 0.01 M HCl at 25 °C. a) PBLG–C_{14} acid, b) PBLG–cholesterol. a: 1: 0, b: 4: 1, c: 1: 1, d: 1: 4, e: 0: 1 (residue mol: mol).

Figure 5 shows the π-A curves of mixed PBLG–C_{14} acid and mixed PBLG–cholesterol monolayers. It was found that the π-A curves for mixed monolayers of C_{14} acid, and either PBDLG-1 or PBDLG-2 also shows a similar tendency to that for mixed PBLG–C_{14} acid monolayers.

Figure 6 shows the relationship between the transition pressure and the composition of lipid for mixed monolayer of PBG with C_{14} acid, C_{18} acid or cholesterol. The increment of the transition pressure is in the order of α-helical content of polymers in solid state. With exception of mixed PBLG–cholesterol monolayers, the change in transition pressure is considerably small

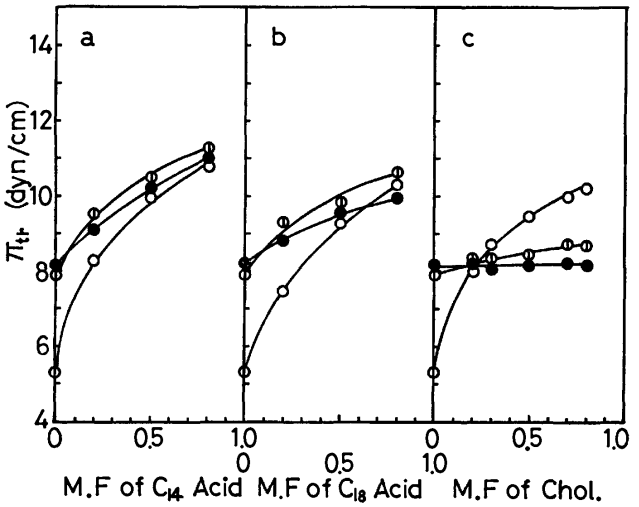

Fig. 6. Transition pressure of mixed monolayers as a function of lipid mole fraction at 25 °C.
a) PBG–C_{14} acid, b) PBG–C_{18} acid, c) PBG–cholesterol. ○: PBLG–lipid, ⓘ: PBDLG-1–lipid, ●: PBDLG-2–lipid.

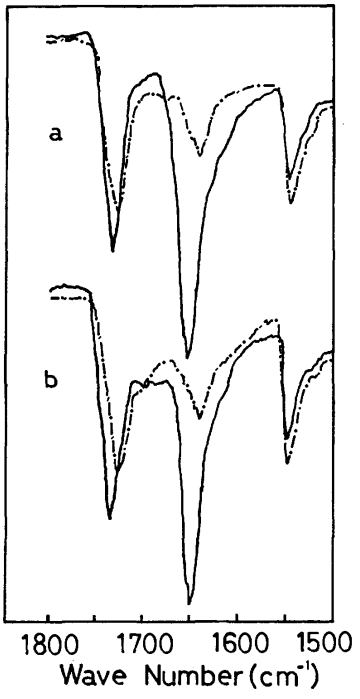

Fig. 7. Polarized IR spectra of collapsed films transferred onto a stainless steel net. a) PBLG, b) PBLG–C_{14} acid mixture (4: 1(residue mol: mol)). ——: Electric vector parallel to the barrier used to collapes the film, –•–•: electric vector perpendicular.

(PBDLG-1) or practically absent (PBDLG-2).

As a typical example, the polarized infrared spectra for collapsed films of PBLG and a 4: 1 (residue mol: mol) mixture of PBLG and C_{14} acid are shown in Fig. 7. The amide I and amide II bands (about 1650 cm^{-1} and about 1550 cm^{-1}) suggest that the polymer is in α-helical conformation. Dichroism is also observed at about 1730 cm^{-1} (assignable to stretching of the ester C=O bond of the side chain). A similar tendency was observed for other single and mixed films.

Discussion

Polypeptide–Lipid Interaction. One way to explain the interaction occurring in mixed monolayers is the application of the surface phase rule.[23,24] If a polypeptide and a lipid are completely miscible in the monolayer and the new three-dimensional phase begins to appear at the transition point, the transition pressure should vary with composition. If, on the other hand, the monolayer components are immiscible, the transition pressure is independent of composition. As can be seen in Figs. 4 and 6, the mixed systems of cholesterol with PLO(Z), PLL(Z), PBDLG-1 or PBDLG-2 are immiscible, other systems forming homogeneous miscible monolayers.

In general, the interaction between two different lipid components results in a deviation from the additivity rule of molecular areas only if one or both components form expanded monolayer. The additivity rule is also satisfied if two components are completely immiscible.

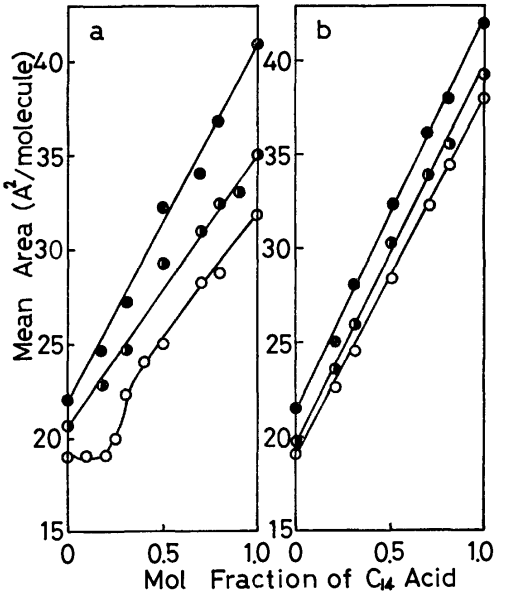

Fig. 8. Mean molecular areas of mixed monolayers as a function of lipid mole fraction at 25 °C.
a) PLO(Z)–C_{14} acid (●: 3 dyn/cm, ◑: 7 dyn/cm, ○: 10 dyn/cm), b) PBLG–C_{14} acid (●: 2 dyn/cm, ◑: 4 dyn/cm, ○: 5 dyn/cm).

Figure 8 shows the plots of mean molecular (residual) areas of mixed PLO(Z)–C_{14} acid and PBLG–C_{14} acid monolayers as a function of the composition under constant pressure. The maximum deviation can be seen at about 0.2 mole fraction of C_{14} acid at the pressure near the transition point of PLO(Z) (Fig. 8-a). A similar maximum deviation was observed for mixed PLL(Z)–C_{14} acid monolayer. No deviation can be seen for mixed PBLG–C_{14} acid monolayer (Fig. 8-b). No deviation was found for other mixed polypeptide–lipid systems (PLO-(Z)– and PLL(Z)–C_{18} acid, PLO(Z)– and PLL(Z)–cholesterol, PBDLG-1– and PBDLG-2–C_{14} acid, PBDLG-1– and PBDLG-2–cholesterol). From the results of two-

dimentional phase rule and additivity rule, it was found that for the miscibility between two component the side chain composition of polypeptide is important.

The results given in Fig. 4 indicate that the hydrophobic portion of lipid and polypeptide side chains is much more important for the interaction than the hydrophilic portion. The transition pressures of mixed PLO(Z)–C_{14} acid and PLL(Z)–C_{14} acid monolayers are higher than those of PLO(Z)–C_4 alcohol and PLL(Z)–C_{14} alcohol monolayers, respectively. This suggests that the state of monolayers of lipid is also important; C_{14} acid and C_{14} alcohol form a expanded monolayer and a condensed monolayer, respectively, at 25 °C. There is a considerable difference in the transition pressure between PBLA–lipid and PLO(Z)–lipid (or PLL(Z)–lipid) systems. It is of interest that in mixed PBLA–cholesterol system the transition pressure increase with lipid composition. On the contrary, in the case of mixed PLO(Z)–cholesterol and PLL(Z)–cholesterol systems, the change in transition pressure is practically absent. This suggests that for interaction the size and shape of lipid molecules (fatty acids, fatty alcohols and cholesterol) are important.

The work of collapse of mixed monolayers may provide a further information concerning the polypeptide-lipid interaction. The work of collapse, W, is given by

$$W = \pi_{tr} \cdot \Delta A,$$

where π_{tr} is the transition pressure, and ΔA is the difference between initial and final areas of collapse.

Figure 9 shows the work of collapse as a function of lipid mole fraction. Corresponding to the results shown in Fig. 4-c, the PBLA–lipid systems differ a great deal from other mixed systems. The work of collapse decreases with lipid mole fraction. As shown in Fig. 9-b, there is a remarkable difference in W values between PBLA and PBLG. The difference in side chain length would mainly affect the work of adhesion to water.[19] A significant difference in solution and solid properties has been reported between PBLA and PBLG.[25] It can be seen that with exception of PBLA–lipid systems, the maximum work of collapse is found at about 0.2 lipid mol fraction in agreement with the maximum deviation from the additivity rule of molecular areas for PLO(Z) (or PLL(Z))–C_{14} acid system at the pressure near the transition point of polypeptides. At about 0.2 lipid mole fraction, the cohesive force might be reinforced as a result of the formation of the 4: 1 complex (residue: molecule) of polypeptide and lipid in monolayers. Although no deviation from the molecular areas is found for PLLeu–C_{14} acid and PLLeu–C_{18} acid systems, the relationship between the transition pressure and the mol fraction of lipid suggests that the 4: 1 complex is also formed in these systems.

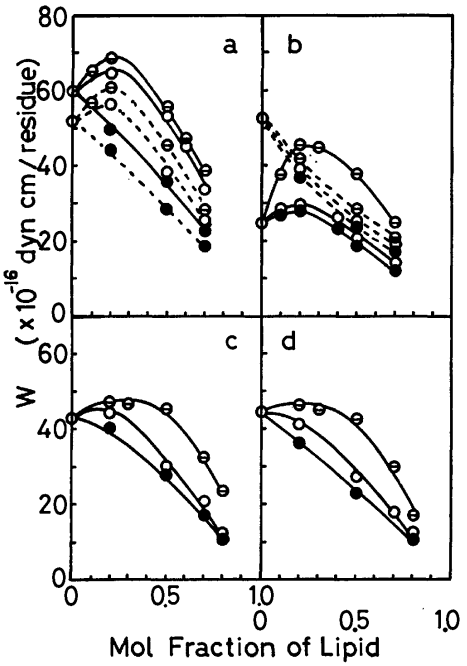

Fig. 9. Work of collapse for mixed monolayers as a function of lipid mole fraction at 25 °C.
a) PLO(Z)-lipid(——), PLL(Z)-lipid(——-), b) PBLG-lipid(——), PBLA-lipid(----), c) PBDLG-1-lipid, d) PBDLG-2-lipid. ⊖: polypeptide–C_{14} acid, ○: polypeptide–C_{18} acid, ●: polypeptide–cholesterol.

The drastic decrease in transition pressure of PLLeu with the incorporation of small amounts of C_{14} acid and C_{18} acid also suggests that the hydrophobic interaction is important (Fig. 4-d). As a result of hydrophobic interaction between polypeptide side chains and lipids, the adhesive force of PLLeu decreases remarkably, the film collapsing more easily than in the case of PLLeu alone.

The dichroism (amide I band) shown in Fig. 7 indicates that the horizontally oriented polypeptide molecules at the interface are aligned in a direction parallel to the compressing barrier. The dichroism at about 1730 cm^{-1} suggests that the side chain is considerably ordered at the interface. This might favor the polypeptide–lipid interaction at close packed state in the monolayer.

The discussion given above is summarized as follows: 1) the interaction between polypeptide and lipid is mainly of hydrophobic nature, 2) the interaction is considered to depend on the orientation and the chemical composition of polypeptide side chains and on the size, shape and state of lipid molecules in the monolayer.[26] In connection with the number of residue in a turn of the α-helix (3.6 residues), the intermolecular complex between polypeptide and lipid is formed at a molar ratio of 4: 1 (0.2 lipid mole fraction).

Effect of Conformation on Interactions. The effect of polypeptide conformation on the polypeptide–lipid interaction was investigated by using PBG's of different α-helical content in solid state.

As shown in Fig. 6, the change in transition pressure of mixed PBG–fatty acid monolayer is in order PBLG> PBDLG-1>PBDLG-2. Thus, it is assumed that PBLG interacts most strongly with the lipids. The interaction is the weakest for PBLG-2. It is of interest that this order corresponds to the helical content in the solid state. The maximum interaction of lipid monolayers with polypeptides occurs when the polypeptides dissolved in the subsolution in the α-helical conformation.[5,6,8]

If we assume that a PBLG monolayer is in the α-helical

conformation[15,27] and a perturbed helix portion of PBDLG is unfolded at the interface owing to relatively weak stability of the helix.[22,28] PBLG might become more hydrophobic than PBDLG's, since the polypeptide main chain is considerably shielded from the interaction with water molecules. This can be seen from the fact that the transition pressure of a monolayer of PBLG is much lower than that of PBDLG (Fig. 1-b).

The PBLG monolayer is more compressible than the PBDLG monolayers. Because of a highly rigid nature of the polypeptide main chain of the α-helix compared with other conformations. The high compressibility of a PBLG monolayer can be ascribed to the flexibility of side chains. The flexible side chains of PBLG might undergo rearrangement more easily into position favorable to the interaction with normal alkyl chain of a fatty acid. The state of a lipid monolayer and the flexibility of side chains of a polypeptide seem to affect the degree of interaction. C_{14} acid interacts more strongly than C_{18} acid with PBG.

The influence of cholesterol on the PBG monolayers is much more pronounced than that of fatty acids. PBLG interacts characteristically with cholesterol. However, PBDLG-1 and PBDLG-2 interact with considerable difficulty. Cholesterol does not interact with benzyloxycarbonyl derivatives of basic poly(α-amino acid). The interaction of cholesterol with synthetic polypeptides in monolayers depends upon the chemical composition of side chains of a polymer. The present study indicates that the conformation of a polymer is also important for the interaction. The change in transition pressure is in the order PBLG–cholesterol > PBDLG-1–cholesterol > PBDLG-2–cholesterol. This corresponds to the helical content of respective polymers.

From the work of collapse shown in Figs. 9-b, -c, and -d, it can be seen that the strong interaction between two components takes place at about 0.2 lipid mole fraction for PBLG–fatty acid and PBLG–cholesterol systems. For PBDLG–lipid systems except PBDLG–cholesterol systems, a specific interaction is found in a polymer rich region (less than 0.2 mole fraction of a lipid). This might indicate that side chains in the helical region in a polymer molecule is an interacting site.

The above arguments are summerized as follows: 1) the flexibility of polypeptide side chains is related to the conformation of a polypeptide at the interface, 2) the hydrophobic interaction of PBG's and lipids in monolayers is considerably affected by the conformation of a polymer, and the interaction is stronger when the α-helical content in the film is higher. This seems to be important in relation to the nature of lipid-protein interactions in biomembranes.

Effect of Water Structure on Mixed Synthetic Polypeptide-Lipid Monolayers

Akira SHIBATA, Shinsuke YAMASHITA, and Takuya YAMASHITA*

Faculty of Pharmaceutical Sciences, Tokushima University, Shomachi, Tokushima 770

(Received October 3, 1977)

The effect of water structure on the interaction of synthetic polypeptides with fatty acids in monolayers at the air-water interface was investigated. It was found that SCN^-, F^-, and urea exert a remarkable effect upon the hydrophobic interaction in monolayers. SCN^- and urea disrupt the hydrated structure biult up around the hydrocarbon moieties of polypeptides and lipids at the interface. On the other hand, the presence of F^- as a structure maker tends to stabilize the hydrophobic bonding. The infrared spectra of polymer components were practically identical for the collapsed films in the absence and presence of SCN^-, F^-, and urea.

The hydrophobic bonding is important in stabilizing macromolecular structures such as proteins and biological membranes.[1] Water is considered to affect the properties and structure of biopolymers at the interface. Recent evidence suggests that the water adjacent to interfaces significantly differs from bulk water.[2]

In relation to the structure of water at the interfacial region, we have reported the effects of monovalent anions on the surface pressure-area (π-A) curves of poly(ε-benzyloxycarbonyl-L-lysine).[3] The effects of anions on increasing the surface pressure were in the order $SCN^->Br^->Cl^->F^-$ in line with that of these anions as breakers of water structure.[4]

The action of urea on macromolecular structures closely resembles that of chaotropic ions in which both unfolding and denaturation are strongly favored. It is not clear if the action of urea is similarly mediated by a modification in the structure of water. However, there is widespread belief that in the presence of urea, hydrophobic bonding is weakened.[5]

The purpose of this work is to clarify the effect of SCN^-, F^-, and urea on the interaction of polypeptides and lipids in relation to the structure of water at the interfacial region.

Experimental

Synthetic polypeptides used in the present study were poly(δ-benzyloxycarbonyl-L-ornithine) (PLO(Z)), poly(ε-benzyloxylcarbonyl-L-lysine) (PLL(Z)), poly(γ-benzyl-L-glutamate) (PBLG), and poly(γ-benzyl-DL-glutamate) (PBDLG) (13% regular α-helix and 60% perturbed α-helix). Lipids used were myristic acid (C_{14} acid) and stearic acid (C_{18} acid). Polypeptides, lipids, and spreading solvents were the same as those used in the preceding work.[6] Salts and urea solutions were treated with activated charcoal in order to remove surface-active contaminants, and were used as a subsolution after being adjusted to contain 0.01 M HCl. A 10 to 1 compression of the surface of the salt or urea subsolutions, after being left to stand for 10 min, produced less than 0.1 dyn/cm film pressure.

The surface pressure was measured by the Wilhelmy method at 25±0.5 °C. The films were compressed at a rate of 1 Å²/residue/min.

The polarized infrared spectra of collapsed films were measured with a JASCO DS-701G instrument.[6]

Results

Figure 1 shows the π-A curves for PBLG, PBDLG, PBLG–C_{14} acid and PBDLG–C_{14} acid mixtures (1: 1 (residue mol: mol)) spread on 0.01 M HCl, and on 2 M KSCN and 2 M KF subsolutions containing 0.01 M HCl. The transition pressures for PBLG and PBDLG monolayers are much higher on the subsolution containing KSCN than on 0.01 M HCl. On the other hand, in the presence of KF, the film transition pressure becomes slightly lower. In the presence of KSCN, film expansion is observed for PBLG and PBDLG. The effect of KF on exapansion is quite small. Similar tendencies were observed for the mixed monolayers.

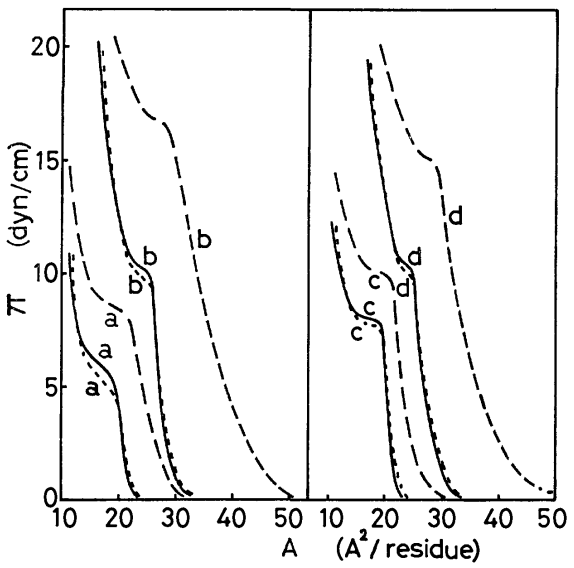

Fig. 1. Surface pressure-area curves of single and mixed monolayers on 0.01 M HCl(——), 2 M KSCN(— —) and 2 M KF(----) at 25 °C. 1 dyn=10^{-5} N, 1 Å=0.1 nm. a: PBLG, b: PBLG–C_{14} acid (1: 1(residue mol: mol)), c: PBDLG, d: PBDLG–C_{14} acid (1: 1(residue mol: mol)).

Figure 2 shows the π-A curves for PLO(Z), PLL(Z), PBLG and PBDLG spread on 0.01 M HCl and 2 M urea subsolutions together with those for C_{14} acid and C_{18} acid monolayers. The transition pressure of polypeptide monolayers increases in the presence of urea. Expansion of polypeptide and lipid monolayers is also observed. The monolayer behavior in the presence of urea is similar to that of KSCN.

Figure 3 shows the film transition pressure, π_{tr}, and the limiting area extrapolated to zero surface pressure for the steep region, A_0, against urea and KSCN concentrations. Up to the concentration of 6 M urea

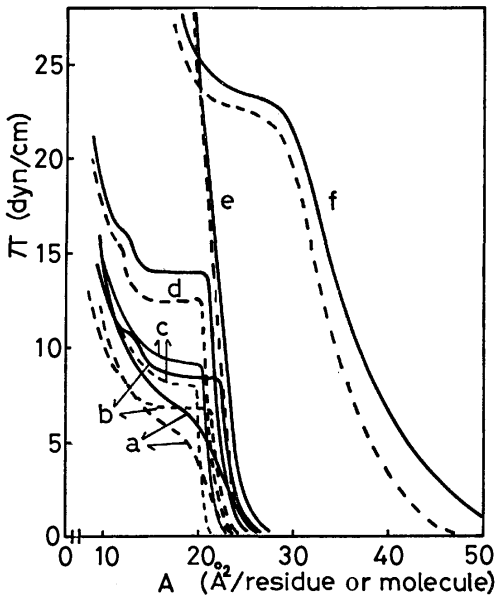

Fig. 2. Surface pressure-area curves of polypeptide and lipid monolayers on 0.01 M HCl(-----) and 2 M urea (——) at 25 °C. a: PBLG, b: PLL(Z), c: PBDLG, d: PLO(Z), e: C_{18} acid, f: C_{14} acid.

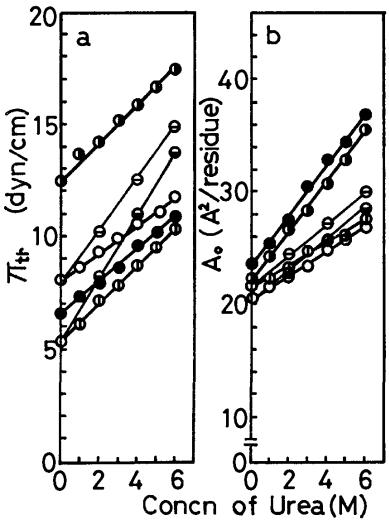

Fig. 3. Transition pressure, a, and limiting area, b, of polypeptide monolayers as a function of urea and KSCN concentration at 25 °C. Urea; ◑: PLO(Z), ●: PLL(Z), ⓘ: PBLG, ○: PBDLG. KSCN; ◒: PBLG, ⊖: PBDLG.

and KSCN, π_{tr} and A_0 increase linearly. The effect of KSCN on π_{tr} and A_0 is much larger than that of urea.

As a typical example of mixed monolayers, Fig. 4 shows the π-A curves for mixed PLO(Z)-C_{14} acid monolayer on 0.01 M HCl and 2 M urea subsolutions. The transition pressures caused by the polymer components increase with increase in lipid mol fraction irrespective of the absence and presence of urea.

Figure 5 shows the polarized infrared spectra of collapsed films of PBLG formed on the subsolutions in the absence and presence of urea, KSCN and KF. In the α-helical amide I (about 1650 cm^{-1}) and amide

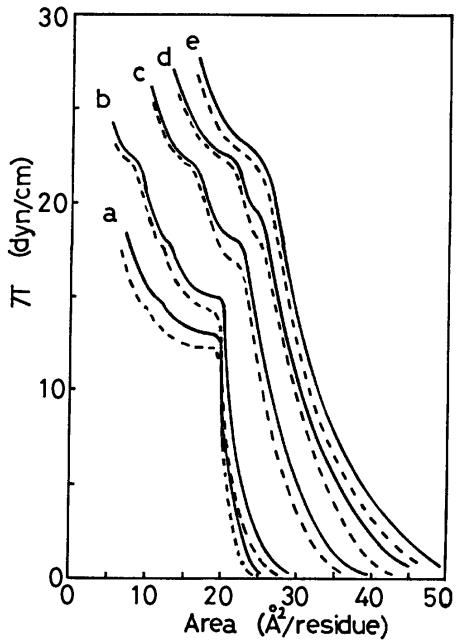

Fig. 4. Surface pressure-area curves of mixed monolayers of PLO(Z) with C_{14} acid on 0.01 M HCl(——) and 2 M urea(——) at 25 °C. a: 1: 0, b: 4: 1, c: 1: 1, d: 1: 4, e: 0: 1 (residue mol: mol).

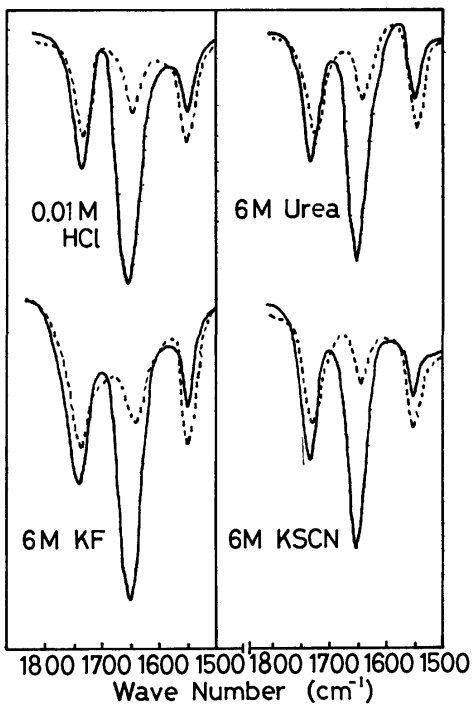

Fig. 5. Polarized IR spectra of collapsed films of PBLG formed on 0.01 M HCl, 6 M urea, 6 M KF and 6 M KSCN subsolutions. ——: Electric vector parallel to the barrier used to collapse the film, -----: electric vector perpendicular.

II (about 1550 cm^{-1}) regions, the spectra are practically identical with each other. Dichromism is also observed at about 1730 cm^{-1} (assignable to stretching of the ester C=O bond of the side chain). Similar results were

obtained for the other single and mixed monolayers. This suggests that polypeptide molecules are aligned in a parallel direction to the compressing barrier, irrespective of the kind of subsolution. The highly ordered alignment of polypeptide molecules may be favorable for the interaction between polypeptide and lipid.

Discussion

Effect of Salts. The order of film expansion is KSCN>KF≥0.01 M HCl (Fig. 1). This suggests that salts are transferred into the interface relative to the surface without monolayer. Fatty acid and fatty alcohol monolayers expand in the presence of salts[7] and urea.[8] Ralston and Healy gave an expansion for fatty alcohol monolayer in terms of interfacial water structure.[7] The film transition pressure is related to the collapse of monolayers from a two-dimensional oriented state to a three-dimensional disoriented state.[9,10]

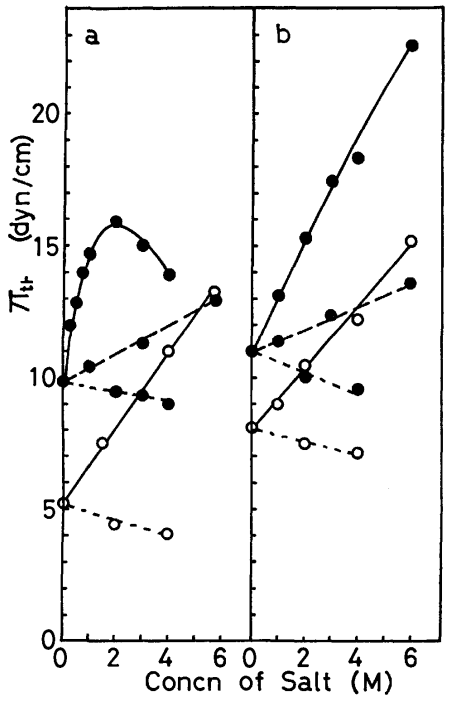

Fig. 6. Transition pressure of single and mixed monolayers as a function of concentration of KSCN(——), KF(----) and urea(——) at 25 °C. a) ○: PBLG, ●: PBLG–C_{14} acid (1: 1 (residue mol: mol)). b) ○: PBDLG, ●: PBDLG–C_{14} acid(1: 1(residue mol: mol)).

Figure 6 shows the transition pressure as a function of salts and urea concentrations for PBLG, PBDLG together with PBLG– and PBDLG–C_{14} acid mixtures (1: 1 (residue mol: mol)) spread on KSCN or KF subsolution. The transition pressures of PBLG and PBDLG increase linearly with increase in KSCN concentration. The hydrated structure around the hydrocarbon moieties of the side chains of polypeptides disrupted by SCN^- ion preferentially accumulated on the surface. As a result of the disruption, the affinity of the hydrocarbon moieties to water might increase.[1,11,12] The increment of transition pressure appears to be caused by destabilized hydrophobic bonding as a result of breakdown of the water structure. From the relationship between the transition pressure and the KSCN concentration in Fig. 3, the value of $d\pi_{tr}/dC$ for PBLG is larger than that of PBDLG. This can be attributed to the difference in the conformation in monolayer states between PBLG and PBDLG. In the conformation of synthetic polypeptides in monolayers, the α-helical conformation is reported to be one of the stable conformations.[9] Other conformations can also exist depending upon conformation in the solid state[13] or solution[14] and stability of the helix.[15,16] In the presence of KF, contrary to the case of KSCN, the transition pressure decreases linearly with the concentration for polypeptide monolayers. The decrease of transition pressure (Fig. 6) indicates that the adhesive force of polypeptide to water becomes weak with the formation of hydrated structure at the interface by the action of F^- as a maker of water structure.[4]

For mixed PBLG–C_{14} acid monolayer, there is a maximum value in transition pressure at 2 M KSCN. On the other hand, for mixed PBDLG–C_{14} acid monolayer, the transition pressure increases linearly. This can be associated with the difference in the stability of the hydrophobic bonding between two mixed systems. In analogy with SCN^-, the presence of urea also gives rise to the increase of transition pressure and the expansion in single and mixed monolayers. For PBLG– and PBDLG–C_{14} acid mixtures (1: 1 (residue mol: mol)), the effect of SCN^- on transition pressure is more remarkable than that of urea (Fig. 6). For PBLG–C_{14} acid mixture in particular, the transition pressure gives a maximum value at 2 M KSCN, while in the presence of urea, the pressure increases linearly with concentration. A remarkable difference in the increment of transition pressure is also observed for PBDLG–C_{14} acid mixture, suggesting that the effect of SCN^- on the hydrophobic interaction is much larger than that of urea. In the presence of KF, the decrease in transition pressure is small (about 1 dyn/cm at 4 M KF), little difference between PBLG and PBDLG monolayers, and between mixed PBLG–C_{14} acid and mixed PBDLG–C_{14} acid monolayers being observed. This suggests that the hydrophobic bonding tends to be stabilized by the action of F^-.

The results suggest that the action of ions (SCN^- and F^-) takes place on water and not primarily on the monolayer components itself. The monolayer behavior on salt subsolutions is closely related to the interfacial water structure.

Effect of Urea. It would be enlightening to elucidate the effect of urea in the polypeptide monolayers.

Film characteristics of synthetic polypeptides are given in Table 1. Film compressibility extrapolated to zero surface pressure, δ, is shown in the absence and presence of urea, together with the increment of limiting area and transition pressure against the urea concentration (dA_0/dC and $d\pi_{tr}/dC$). The change in limiting area of polypeptide with increase in the concentration of urea can be attributed to the penetration of a polypeptide monolayer by urea in the subsolution. The

TABLE 1. FILM CHARACTERISTICS OF SYNTHETIC POLYPEPTIDES

Polypeptide	dA_0/dC (Å²/residue/M)	$d\pi_{tr}/dC$ (dyn/cm/M)	δ ((dyn/cm)$^{-1}$) 0.01 M HCl	δ ((dyn/cm)$^{-1}$) 6 M urea
PLO(Z)	2.47	0.83	0.0131	0.0202
PLL(Z)	2.42	0.72	0.0144	0.0205
PBLG	1.12	0.81	0.0270	0.0333
PBDLG-2	1.18	0.60	0.0151	0.0284

increments of the limiting areas of PBLG and PBDLG against urea concentration differ a great deal from those of PLO(Z) and PLL(Z). This suggests that the surface activity of urea depends on the difference in the composition and geometrical arrangement of side chains between benzyloxycarbonyl derivatives of basic poly(amino acid) and benzyl esters of acidic poly(amino acid).

In the presence of 6 M urea, the film compressibility of a polypeptide increases considerably. The film transition pressure increases with urea concentration. This indicates that the affinity of hydrophobic moieties of polypeptide side chains to water and the side chain flexibility increase with the penetration by urea as a breaker of water structure.[4,17,18] The value of $d\pi_{tr}/dC$ for PBLG (0.81) is larger than that for PBDLG (0.60). This suggests that urea molecules mainly affect the side chains in the α-helical region of a polypeptide molecule.

Any deviation of mixed monolayer behavior from the additivity rule of molecular area might give useful information as regards the miscibility and interaction in the film. Figure 7 shows the mean molecular areas of mixed PLL(Z)–C_{14} acid and mixed PLL(Z)–C_{18} acid monolayers as a function of lipid mole fraction in the

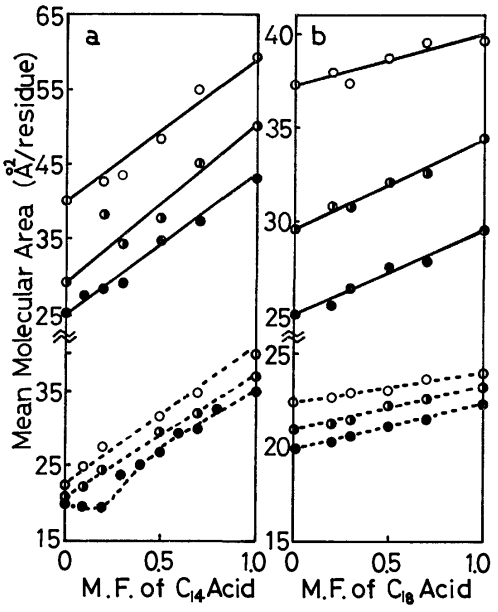

Fig. 7. Mean molecular area of mixed monolayers as a function of lipid mole fraction at 25 °C. ----: 0.01 M HCl, ——: 6 M urea. a) PLL(Z)–C_{14} acid (○: 2 dyn/cm, ◑: 4 dyn/cm, ●: 6 dyn/cm). b) PLL(Z)–C_{18} acid(○: 2 dyn/cm, ◑: 4 dyn/cm, ●: 6 dyn/cm).

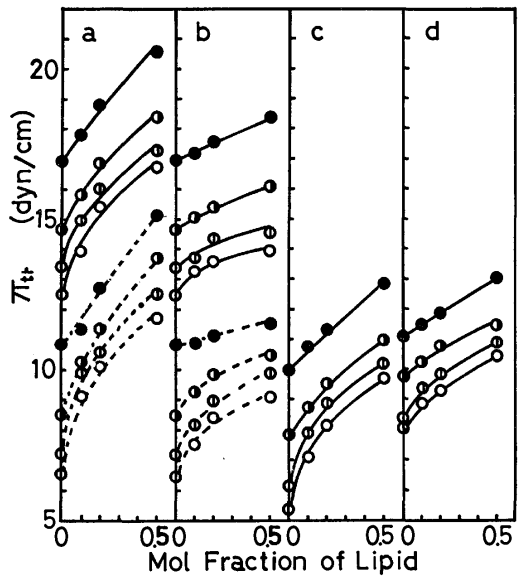

Fig. 8. Transition pressure of mixed monolayers as a function of lipid mole fraction in various concentration of urea at 25 °C. a) PLO(Z)–C_{14} acid (——), PLL(Z)–C_{14} acid(----). b) PLO(Z)–C_{18} acid (——), PLL(Z)–C_{18} acid(----). c) PBLG–C_{14} acid. d) PBDLG–C_{14} acid. ●: 6 M urea, ◑: 3 M urea, ⓘ: 1 M urea, ○: 0.01 M HCl.

absence and presence of 6 M urea. When PLL(Z) is mixed with C_{14} acid which forms an expanded monolayer, the maximum negative deviation is observed at about 0.2 mole fraction of the acid in the absence of urea. However, no deviation from the additivity rule takes place in the presence of 6 M urea. A similar tendency was observed for mixed PLO(Z)–C_{14} acid monolayers.

When there is no deviation from the additivity rule of mean molecular areas, it is difficult to determine the miscibility in the film. Figure 8 shows the transition pressure as a function of lipid mole fraction for mixed monolayers of fatty acid with PLO(Z), PLL(Z), PBLG or PBDLG for various concentrations of urea. The film transition pressure caused by the polymer component increases with C_{14} acid mole fraction (Fig. 8-a). The surface phase rule[19,20] predicts that two film components are miscible in the presence and absence of urea in the subsolutions. In the presence of 6 M urea, the transition pressure increases linearly with lipid mole fraction. This suggests that an ideal surface mixture of PLO(Z) (or PLL(Z)) and C_{14} acid is formed in the film at high concentration of urea.

The molecular area additivity rule[6] holds in other mixed monolayers such as PLO(Z) with C_{18} acid, PLL(Z) with C_{18} acid, PBLG with C_{14} acid, and PBDLG with C_{14} acid. On the other hand, the film transition pressure against lipid mole fraction for these mixed monolayers indicates that the film components are miscible, irrespective of urea concentration (Figs. 8-b, -c, and -d).

The formation of an ideal surface mixture can be ascribed to the breaking of hydrated structure around the hydrophobic moieties of polypeptide and lipid by the action of urea. As a result, the affinity of polypeptide

side chains and a nonpolar portion of the lipid to water[21] and the flexibility of polypeptide side chains increase. This might be supported by the film expansion (Figs. 2 and 4) and the increased compressibility of polypeptide monolayers in the presence of urea (Table 1).

From the conformational aspects of polypeptide monolayers, the action of urea on the interactions of PBLG–lipid and of PBDLG–lipid in monolayers are of interest. The perturbed α-helix portion of PBDLG molecule might be unfolded in the monolayer state owing to the relatively weak stability of the helix.[15,16] The interaction of PBDLG and lipid is weak as compared with that of PBLG and lipid.[5] The results shown in Figs. 8-c and -d indicate that the change in transition pressure against C_{14} acid mole fraction is smaller for PBDLG than for PBLG. This supports the view that the perturbed helix is unstable in monolayers. Urea molecules predominantly attack the hydrophobic moieties around the regular helix.

N,N,N',N'-Tetramethyl-*p*-phenylenediamine (TMPD) fluorescence lifetimes in 2-methyltetrahydrofuran (MTHF) glass at 77 K (13.5 ns) and in ethanol glass at 77 K (12.3 ns) and 4 K (11.5 ns) were measured using 347 nm excitation from a frequency doubled ruby laser. Trapped electrons and $TMPD^+$ were generated in these matrices by photoionization and the recombination fluorescence stimulated by 694 nm laser light was found, within an experimental limit of 1 ns, to occur with the same lifetime as the directly excited fluorescence. A convolution analysis indicates that the electron-cation recombination lifetimes are ≤ 1 ns in all these matrices at the temperatures given. It is also suggested that a lower limit for the electron mobility of 0.005 $cm^2\ V^{-1}\ s^{-1}$ is implied by these data.

Electrons have been trapped in a variety of organic glasses and their electronic and geometric structures have been extensively studied.[1] Both bound-bound and bound-continuum transitions seem to occur depending on the matrix and on the exciting light energy. However, little is known about the excited state lifetimes because no luminescence is observed. Indirect laser photobleaching methods suggest that the excited state lifetime is ≤ 6 ps in liquid water[2] and <10 ps in aqueous glass at 77 K.[3]

Another approach to obtain the excited state lifetime of trapped electrons is to measure the recombination lifetime of laser stimulated recombination luminescence. In this method the trapped electrons are produced by photoionization of an aromatic solute whose excited states luminesce.[4,5] The closest localized electrons to the solute cations recombine with them isothermally by tunneling[6] to produce isothermal recombination luminescence. More distant localized electrons can be optically stimulated to recombine with the solute cation. If the optical excitation of the trapped electron is energetic enough to excite the electron to the conduction state of the matrix, the total recombination lifetime will consist of four parts: (a) the lifetime of the localized continuum or quasi-continuum state of the electron, (b) the electron lifetime in the conduction state, (c) the lifetime of the localized continuum state of the excited solute, and (d) the lifetime of the fluorescent state of the solute. Contribution (b) can be estimated from electron mobility data if known. We expect (c) to be short compared to (d) because lifetimes are generally shorter for more highly excited states. Thus a delay of the recombination fluorescence lifetime beyond the directly excited fluorescence lifetime of the solute (contribution d) may yield information about the excited electron state lifetime.

This type of experiment was initially tried for *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) in 3-methylpentane (3 MP) glass at 77 K, although the focus was on an estimate of lifetime (c) and contributions (a) and (b) were not considered.[7] The recombination fluorescent lifetime and an upper limit of 1 ns on the electron-cation recombination step was deduced.

In the present work we have extended this type of experiment to polar matrices, 2-methyltetrahydrofuran (MTHF) and especially ethanol, and have made measurements at both 4 and 77 K in ethanol. New information is obtained on the natural fluorescent lifetimes of TMPD under these various conditions, but even in these polar matrices only upper limit for the electron-cation recombination step can be deduced.

Experimental

Chemicals were purified as described previously.[5,6] A Korad Pockel cell switched ruby laser was used for excitation. The 694 nm output energy was about 1 J per pulse of half-width 15—25 ns. For fluorescence lifetime measurements the laser output frequency was doubled to 347 nm. For recombination fluorescence, trapped electrons were first generated by photoionizing TMPD (7×10^{-4} mol/dm^3) with 320 ± 20 nm light from a filtered mercury lamp; then within 3—10 min fluorescence was stimulated with a 694 nm laser pulse. Laser induced emission was detected through a Bausch and Lomb monochromator at 400 ± 10 nm with a 1P28 photomultiplier for nanosecond response[8] and photographed on a 7904 Tektronix scope. Temperature at 77 K was controlled by cold helium gas in a Dewar. At 4 K the sample was in a Dewar for liquid helium in which the sample position was not shielded by liquid nitrogen. Samples were prepared in 3 mm i.d. pyrex tubes.

Results and Discussion

The directly excited TMPD fluorescence intensity *vs.* time is similar to the laser pulse profile but its peak is typically shifted by 7—10 ns from the laser pulse peak. Accurate fluorescence lifetimes thus required a deconvolution procedure. For greater accuracy a Laplace transform method was used.[9] The fluorescence lifetime τ_f was determined from

$$\bar{L}(p)/\bar{G}(p) = (p/I_0) + (I_0\tau_f)^{-1}, \quad (1)$$

where I_0 is the initial fluorescence intensity after instantaneous excitation, p is the Laplace transform parameter $\bar{G}(p)$ is the Laplace transform of the observed fluorescence curve, $\bar{L}(p)$ is the Laplace transform of the 347 nm laser pulse and exponential decay for the fluorescence

† Present address: Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060.

was assumed. The left side of Eq. 1 was calculated by a computer program and plotted *vs.* p to give a linear plot from which τ_f was obtained. The τ_f values obtained in this way are estimated to be accurate to $\pm 10\%$ which is thus the effective time resolution of the apparatus with the deconvolution procedure (*i.e.* $\approx$1 ns). The values of τ_f were checked by convoluting the exponential fluorescence decay with laser pulse to simulate the observed fluorescence curves; agreement was excellent in all cases. The fluorescence lifetimes are summarized in Table 1.

Table 1. Fluorescence decay times of TMPD in various matrices

Matrix	T/K	Decay time[a]/ns
Ethanol	Room	9.3, 7.1[b]
Ethanol	77	12.3
Ethanol	4	11.5
MTHF	77	13.5
Cyclohexane	Room	4.3[b]
3-Methylpentane	77	7.4$\pm$1.1[c]

a) Estimated error $\pm 10\%$ except where noted. b) I. B. Berlman, "Handbook of Fluorescence Spectra of Aromatic Molecules," 2nd ed, Academic Press, New York (1971), pp. 168—169. c) Ref. 7.

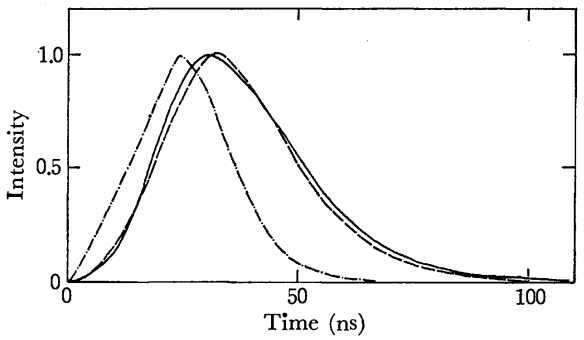

Fig. 1. Intensity *vs.* time profile of the 694 nm laser pulse (-·-) and the recombination fluorescence (——) in ethanol glass at 77 K containing 7×10^{-4} mol/dm^3 TMPD which was previously photoionized by UV light. The dashed curve is calculated TMPD fluorescence convoluted from the 694-nm laser pulse and an exponential fluorescence decay with a liferime of 12.3 ns.

The same deconvolution analysis gives recombination fluorescence lifetime within 10% of the direct fluorescence lifetimes. This is shown pictorially in Fig. 1. The laser stimulated recombination fluorescence for TMPD in ethanol at 77 K is shown in Fig. 1 as is the 694 nm laser pulse profile. The fluorescence calculated from the 694 nm laser pulse and the fluorescence lifetime is seen to coincide, within experimental uncertainty, with the recombination fluorescence. Similar results are obtained for TMPD in ethanol at 4 K and in MTHF at 77 K.

Excited TMPD$^+$ is not expected to contribute to the recombination fluorescence at 400 nm. This was verified by observing no emission from ethanol glass containing 4×10^{-5} to 2×10^{-4} mol/dm^3 TMPD$^+$ ClO_4^- and excited by 694 nm light. Direct excitation of TMPD by 694 nm laser light *via.* double quantum absorption was negligible, since no emission was observed when ethanol glass containing 7×10^{-4} mol/dm^3 TMPD was irradiated by 694 nm laser pulse.

The coincidence of the directly excited and the recombination fluorescence lifetimes indicated that the electron-cation recombination process occurs within $\approx$1 ns which is our estimated time resolution with the deconvolution procedure. Thus the more polar matrices (MTHF and ethanol) show the same upper limit as the nonpolar 3-methylpentane (3MP) matrix.[7]

The upper limit of $\approx$1 ns corresponds to the upper limits for each of the three possible contributions: lifetime of localized continuum states of excited electron (a) and of excited solute (c) and lifetime of the electron in the conduction state (b). From the upper limit of the conduction state lifetime, cation field and recombination distance one can estimate the lower limit of the electron mobility. Assuming the average recombination distance of 10 nm the field independent electron mobilities in MTHF and ethanol matrices are $\mu>0.005$ cm^2 V^{-1} s^{-1} based on the 1 ns upper limit and the increase in cation field as the recombination distance decreases.** This limit is consistent with the reported drift mobility of 0.055 cm^2 V^{-1} s^{-1} for MTHF glass at 77 K.[10]

The same lower limit on electron mobility is implied for ethanol glass at both 77 and 4 K unless tunneling recombination dominates (see below). This implication is particularly interesting at 4 K since it indicates that the electron mobility remains relatively high to quite low temperature.

In 3MP and MTHF the 694 nm light is energetic enough to excite the trapped electron to the conduction state as indicated by photoconductivity data.[1] However in ethanol the 694 nm (1.8 eV) light appears insufficient to excite the trapped electron to the conduction state since the photoionization threshold is 2.3$\pm$0.1 eV.[11] If the trapped electron is sufficiently close to the cation the Coulomb potential can distort the electron potential well and cause the recombination threshould to be less than the photoionization threshould. However, at separation distances of $\approx$3.0 nm this difference should be within the experimental uncertainty of $\pm$0.1 eV. In fact, the same threshold for electron loss is observed from photoconductivity, photobleaching and stimulated luminescence methods.[1]

Let us see whether tunneling recombination from an

** The average recombination distance can be estimated from a tunneling model for the recombination process[6] prior to laser stimulation. The tunneling rate constant k is given by the equation, $\log k = 15 - 0.44 d V_b^{1/2}$, assuming a simple one dimentional tunneling model with a square barrier of height V_b and width d. The V_b values can be taken as the electron trap depth in MTHF (1.6 eV) and in ethanol (2.3 eV).[1] Then at 200 s which is the average time between photoionization and laser excitation, one finds distances of 3.1 nm (MTHF) and 2.6 nm (ethanol). The average recombination distance will be several times greater than the minimum recombination distance thus estimated and we assume 10 nm. Assuming a dielectric constant of 2 the cation field at 10 nm is 7.2×10^4 V cm^{-1}.

excited state of the electron in ethanol can account for the observed recombination time. With a barrier height of 2.3 −1.8=0.5 eV, the simple tunneling model[6] predicts tunneling from 1.9 nm or less within 1 ns. However, the same tunneling model predicts that all electrons within 2.6 nm will have tunneled through the full 2.3 eV barrier in ethanol during the ≈200 s between photoionization and laser excitation. Thus there will not be any electron left within 1.9 nm of the cation at the time of laser excitation and the tunneling mechanism seems improbable. It is necessary to reduce the barrier height to 0.25 eV or less for the tunneling distance in 1 ns to be >2.7 nm and to make the tunneling mechanism a possible alternative.

A second possibility is that a few of the electrons constituting the 1 eV wide absorption band in ethanol are in shallow enough traps to be excited to the conduction state by 694 nm light. Since fluorescence is a more sensitive detection technique than photoconductivity it may be possible to observed such a small population of electrons if they exist. The observation that the stimulated fluorescence in ethanol glass is 1—2 orders of magnitude weaker than that in MTHF glass may support this suggestion.

We conclude that the localized continuum state lifetimes of trapped electrons and excited TMPD in 3MP and MTHF glasses are ≤1 ns at 77 K and in ethanol glass are ≤1 ns between 4 and 77 K. Likewise the electron conduction state lifetime is ≤1 ns which suggests a lower limit to the electron mobility of 0.005 $cm^2 V^{-1} s^{-1}$ in these matrices.

This work was supported by the U. S. Energy Research and Development Administration through contract number E(11-1)-2086. We thank Dr. S. A. Rice for comments on the Laplace transform analysis. One of the authers, LK thanks Prof. H. Yoshida of Hokkaido University for his cooperation and support while this work was completed.

(Received November 17, 1977)

Formation and reactivity of oxygen adsorbates on the surface of α-Fe_2O_3 were investigated in the temperature range 0—600 °C by means of a temperature programmed desorption (TPD) technique. At least four different states of adsorbed oxygen were indicated by four TPD peaks, the maxima of which appeared at 50—300 (α), 350—360 (β), 480—490 (γ), and >600 °C (δ), respectively. Mode of preparation hardly affected the essential nature of oxygen adsorption (or desorption) except the relative amounts of respective desorptions. Of these adsorbates, α, whose desorption peak shifts over a wide temperature range depending upon adsorption conditions, was interpreted to be molecular oxygen (O_2 or O_2^-) bonded to the oxide surface with an extraordinarily broad heterogeneity, while β and γ species were tentatively assigned to O_2^- and O^-, respectively, adsorbed on different sites. The activation energies of desorption were 23.8 and 54.6 kcal/mol for β and γ, respectively. On exposure to gaseous hydrogen, β species as well as α turned more reactive than γ, though γ was also reactive at higher temperatures. The reaction of β and α species with hydrogen at lower temperatures gave rise to an increase in γ adsorption. This is accounted for by assuming a reaction in which the molecular adsorbates (α and β) react with hydrogen to leave the atomic adsorbates (γ) behind.

For an understanding of catalytic oxidation of reactants over metal oxide catalysts, it is important to know the kinds of oxygen adsorbates present on the oxide surface, their binding energies and populations, and how the structure or the preparation method of oxide catalysts affects the oxygen adsorption.

The problems might be best examined by use of a temperature programmed desorption (TPD) technique,[1] which adopts programmed heating of a catalyst surface covered with adsorbates. If all the adsorbates are in a given energy state, the increasing desorption probability with a rise in temperature results in a peak in the desorption flux; otherwise more than one peak are expected. The desorption temperature, peak shape and the variation of desorption temperature with the initial surface coverage are all related to the properties of adsorbates so that we can determine several adsorption (desorption) characteristics from the TPD chromatograms.[2] By this technique we studied oxygen adsorption on nickel oxide[3] and Cu(II) ion exchanged Y-type zeolite,[4] and revealed the existence of several modes of oxygen adsorbates on these adsorbents. We have applied the same technique to the investigation of oxygen adsorption on α-Fe_2O_3.

Ferric oxide, with the standard heat of formation ($-\Delta H_f^\circ$) of a moderate magnitude, exhibits high catalytic activity and selectivity for the oxidative dehydrogenation of butene to butadiene.[5] The correlation of the oxidation state of iron oxide with their catalytic activity has been discussed.[6,7] Fe_2O_3 is a n-type semiconductor in contrast to the p-type of NiO. It is of interest to compare the behavior of the two oxides. Recently, Halpern and Germain[8] examined the desorption of oxygen from powdered oxides of first transition metals by means of flash desorption. For Fe_2O_3 they obtained a spectrum with three desorption peaks at *ca.* 60, 250, and 550 °C. However, the limination of the method, *i.e.*, very rapid and non-linear heating (*ca.* 30 °C/s in average), prevented them from investigating the phenomenon in sufficient detail. The purpose of the present study is to clarify the formation, nature and reactivity of several modes of oxygen adsorbates on the surface of α-Fe_2O_3.

Experimental

Apparatus. The TPD apparatus is essentially the same as that used previously.[3] It consists of two parts; one in which sample conditioning and oxygen adsorption under specified conditions are carried out in the conventional manner, the other in which adsorbates on the sample undergo thermal desorption into a helium carrier under programmed heating. The concentration of the desorbed gas was monitored and recorded with a thermal conductivity detector.

Materials. Helium gas of ultra-high-purity grade (> 99.995%) was supplied from Air Products and Chemicals. Before use, helium was passed through a liquid nitrogen cold trap in order to remove a trace amount of moisture. Oxygen gas was also dried before use by liquefaction and vaporization in a cold trap.

Ferric oxide samples were prepared by calcining ferric hydroxide, ferric nitrate or ferric oxalate, the corresponding sample being denoted by Fe_2O_3-I, II, or III, respectively. The calcination conditions and BET surface areas are summarized in Table 1. All the samples were identified to be α-Fe_2O_3 by X-ray powder diffraction. They were sieved to 20—60 mesh for TPD experiments.

Methods and Procedures. Ferric oxide, 1 g, was put into the TPD cell. Each fresh sample was evacuated for more than 2 h at 600 °C untill no more water was condensed in a liquid

Table 1. Ferric oxide samples

Catalyst	Starting materials	Calcination conditions	Surface area (m^2/g)
Fe_2O_3-I	$Fe(OH)_3$	600 °C, 5 h	5.5
Fe_2O_3-II	$Fe(NO_3)_3 \cdot 9H_2O$	600 °C, 5 h	6.6
Fe_2O_3-III	$FeC_2O_4 \cdot 2H_2O$	600 °C, 5 h	1.9

nitrogen trap connected to the cell. The sample was then repeatedly subjected to a series of routine TPD procedures consisting of sample pretreatment, oxygen adsorption and temperature programmed desorption. As pretreatment, the sample was exposed to 100 Torr of oxygen for 1 h followed by evacuation ($<10^{-5}$ Torr) at 600 °C for 1 h. Oxygen was usually adsorbed according to one of the following ways.

Procedure I: After being cooled to the desired temperature, the sample was exposed to an oxygen atmosphere (100 Torr) for 1 h and then evacuated for 15 min before further cooling down to 10 °C within 30 min *in vacuo*.

Procedure II: On the introduction of 100 Torr of oxygen at 600 °C, the sample was made to cool at a rate of *ca.* 10 °C/min down to 10 °C, at which the system was evacuated for 15 min.

After these manipulations, a carrier gas (helium) was diverted to flow through the reactor at a rate of 30 cm³/min and the programmed heating was started. The heating rate was 21±1 °C/min unless specified otherwise. The thermally desorbed oxygen was recorded as a TPD chromatogram, its amount being evaluated from the peak area of the chromatogram.

In order to examine the reactivity of adsorbed oxygen toward hydrogen, various amounts of hydrogen were injected in a pulse at specified temperatures, with a helium carrier (30 cm³/min). After ten min from the hydrogen pulse, the sample was cooled to 10 °C and heated up to take a TPD chromatogram. In all these runs, a liquid nitrogen trap was equipped between the TPD cell and the detector in order to separate off water vapor desorbed from the reacted surface. The monitored gas was identified to be oxygen alone throughout the experiments by gas chromatography and mass spectroscopy.

Results and Discussion

Desorption Chromatograms of Oxygen from Fe_2O_3. Desorption chromatograms of oxygen from Fe_2O_3 were found to vary with the sample preparation and conditions of oxygen adsorption. Figures 1 and 2 show typical examples obtained for Fe_2O_3-I and II, respectively, after oxygen adsorption was performed at various temperatures by Procedure I (all runs except 1 and 6) or II (runs 1 and 6) as indicated. Although the amounts

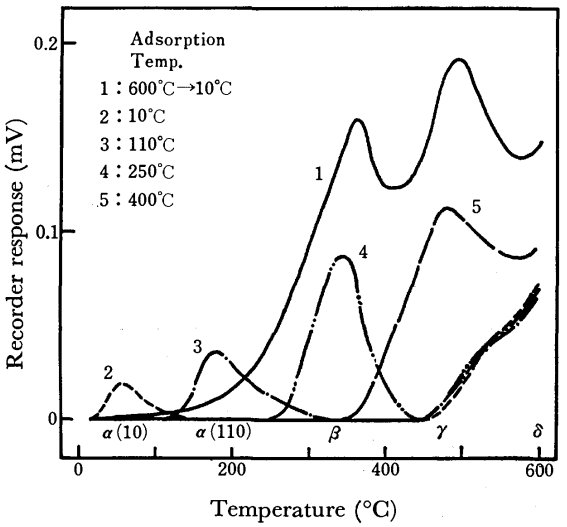

Fig. 1. TPD chromatograms of oxygen adsorbed on Fe_2O_3-I.

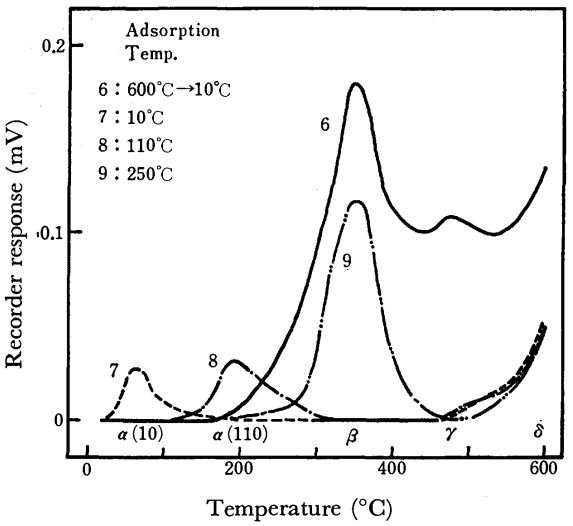

Fig. 2. TPD chromatograms of oxygen adsorbed on Fe_2O_3-II.

of oxygen desorption are dependent upon sample preparation to some extent, oxygen desorption is reproducible in the same temperature range irrespective of the sample preparation if oxygen has been adsorbed under the same conditions. The change in adsorption temperature T_{ad}, however, cause pronounced effects on TPD chromatograms, since it affects the states and concentrations of adsorbed oxygen. Thus, for various T_{ad} values five desorption peaks appear whose maxima appear respectively at 50—70 (α_{10}), 180—200 (α_{110}), 350—380 (β), 480—490 (γ), and >600 °C (δ). The subscripts attached to α for the first two peaks denote T_{ad}. The peaks are assigned to the same kind of oxygen species adsorbed on a heterogeneous surface. The desorption peak δ appears invariably in all the chromatograms with similar shapes and magnitudes, suggesting that it is a sort of desorption of lattice oxygen from Fe_2O_3 toward a non-stoichiometric oxide. In contrast, the other peaks change in magnitude markedly with the conditions of oxygen adsorption and can be attributed to adsorbed oxygen species. β and γ peaks, which also appear in chromatograms 1 and 6, can be assigned to respective kinds of oxygen adsorbates. On the other hand, a marked feature of the α species is the desorption temperature shifts over a wide range from room temperature to *ca.* 300 °C, depending on T_{ad}.

The amounts of desorbed (or adsorbed) oxygen per unit surface area (V_d) were determined from the

Table 2. Amounts of desorbed oxygen from the ferric oxides

Adsorption temp (°C)	Desorption peak	Amount of desorbed oxygen (cm³/m²)		
		Fe_2O_3-I	Fe_2O_3-II	Fe_2O_3-III
10	α(10)	1.88×10^{-4}	2.19×10^{-4}	4.86×10^{-4}
110	α(110)	4.34×10^{-4}	3.00×10^{-4}	3.96×10^{-4}
250	β	9.22×10^{-4}	1.07×10^{-3}	1.80×10^{-3}
400	γ	1.73×10^{-3}		3.81×10^{-3}
600→10	β+γ+δ[a]	4.39×10^{-3}	3.15×10^{-3}	1.18×10^{-2}

a) Total oxygen desorbed below 600 °C.

desorption peak areas, data for the three samples being summarized in Table 2. For runs in which Procedure II was used for oxygen adsorption, only the total amounts of oxygen desorbed below 600 °C ($\beta+\gamma+\delta$) are given. The amounts are in the order $\alpha_{10} \lesssim \alpha_{110} < \beta < \gamma$, differing somewhat with sample. We can estimate the surface coverage from these values. The amount of $\beta+\gamma+\delta$, for example, is 4.39×10^{-3} cm^3/m^2 or 1.18×10^{13} oxygen molecules/cm^2 for Fe_2O_3-I. If we assume that the adsorbent surface is (0001) or (11$\bar{2}$0) plane of α-Fe_2O_3 which contains 4.55×10^{14} or 2.92×10^{14} surface iron atoms/cm^2, respectively, the above value corresponds to only *ca.* 0.02 or 0.04 O_2 molecules per surface iron atom, respectively. This suggests that some sort of surface defect is responsible for the oxygen adsorption. There is little possibility that oxygen adsorbs on a surface impurity, since the desorption of oxygen is inherent for each oxide and the amount of desorbed oxygen seems to be related with the heat of oxide formation ($-\Delta H_f^\circ$).[9]

It is interesting to compare the adsorptive properties of Fe_2O_3 (a n-type semiconductor) and NiO (a p-type semiconductor). The TPD experiments show that the surface coverage of adsorbed oxygen is nearly the same for both oxides. This suggests that, contrary to the accepted view, the type of semiconductor has little effect on the amount of adsorbed oxygen.

Sample preparation affects only the relative amounts of desorption peaks, the essential nature of the oxygen desorption (or adsorption) remaining unaffected. Thus the experiments were performed only with Fe_2O_3-I. Interconversion between the oxygen adsorbates is negligible during the course of evacuation, cooling, and heating applied. For instance, chromatogram 4 which shows a single desorption peak, β, indicates that none of β adsorbates were converted into γ, α_{110}, or α_{10} during the TPD experiments. Similar conclusions can be drawn from the other runs.

Characterization of Desorption Peaks. Oxygen desorption below 350 °C was investigated in detail. Figure 3 shows the effect of oxygen adsorption temperature (T_{da}) on the TPD chromatogram. In each case

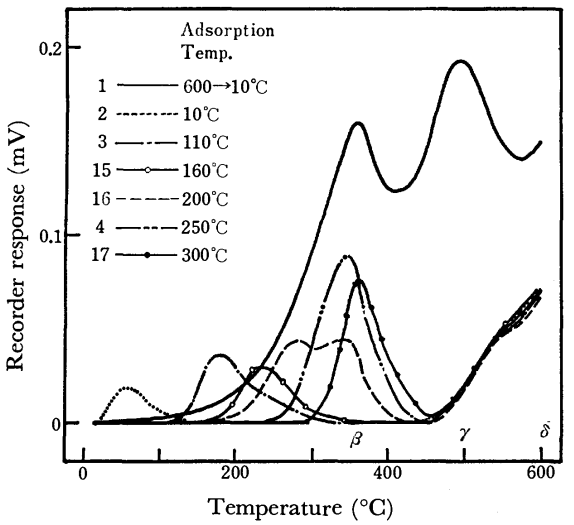

Fig. 3. Effect of the adsorption temperature on TPD chromatograms of oxygen.

of T_{ad}=10, 110, and 160 °C, a single desorption peak appears below 400 °C; oxygen desorption starts at a temperature near T_{ad}, reaches a maximum around a temperature 40—80 °C higher than T_{ad} and then decreases with a very long tailing. With T_{ad}=200 °C, however, there appear two desorption peaks with maxima at 280 and 350 °C, the former apparently being of the same feature as the above and the latter assignable to β desorption. Further increase in T_{ad} to 250 °C again gives rise to a single desorption peak (β) at 350 °C. This indicates that the desorption peak at the lower temperature region shifts continuously with T_{ad}. Such a phenomenon can not be explained in terms of the change in the kind of adsorbed species, but is best understood in terms of a single kind of adsorbate (α) desorbing from the oxide surface with a broad heterogeneity, though the actual nature of the adsorption sites is not clear. It is assumed that, while α adsorbates can take continuous adsorption states with broadly dispersing bonding energies, at a given T_{ad} only α species with a certain range of bonding energies are formed. In connection with such behavior of α desorption, it is noted that remarkable leadings are seen, prior to the β peak (Figs. 1 and 2, runs 1 and 6). These are considered to be partly contributed by the broadly dispersed α desorption. The β peak maxima (350—360 °C) are scarcely affected at all by adsorption conditions, showing little heterogeneity associated with it.

Interactions between oxygen adsorbates were studied as follows.

(1) The sample on which oxygen had been adsorbed at 110 °C was further exposed to an oxygen atmosphere (100 Torr) at 10 °C for 1 h. The results coincided with these in chromatogram 3, indicating that the presence of α_{110} inhibits adsorption in α_{10}. Probably the oxide surface had been saturated with α_{110}, no more room being left for α_{10}.

(2) After β species was adsorbed in the same way as for chromatogram 4, the sample was further exposed to 100 Torr of oxygen at 110 °C for 1 h. The chromatogram obtained showed two desorption peaks of α_{110} and β. The amount of α_{110}, 2.1×10^{-4} cm^3/m^2, was about a half of that for chromatogram 3, whereas that of β, 9.1×10^{-4} cm^3/m^2, was almost the same as for chromatogram 4. Suppression of α_{110} as compared with chromatogram 3 suggests a steric or electrostatic hindrance by β species.

(3) A sample, exposed to 100 Torr of oxygen at 600 °C for 1 h in advance, was cooled down to 10 °C at a rate of *ca.* 10 °C/min in the same atmosphere, with pause at 400 °C for 1 h. The resulting chromatogram was in precise agreement with chromatogram 1. This shows that all the adsorption sites for β and γ are fully occupied in chromatogram 1 (Procedure II), and that β and γ do not interact with each other, or in other words, they adsorb on independent adsorption sites.

For β and γ species, the activation energies of desorption were measured on the basis of the equations derived by Cvetanovic and Amenomiya.[1] When the sample temperature increases linearly with time at a heating rate b and desorption takes place from a homogeneous surface without appreciable readsorption,

we obtain Eqs. 1 and 2, for the first order and second order desorptions, respectively.[2,10,11]

$$2\ln T_M - \ln b = \frac{E_d}{RT_M} + \ln\frac{E_d v_m}{Rk_0} \quad (1)$$

$$2\ln T_M - \ln b = \frac{E_d}{RT_M} + \ln\frac{E_d v_m^2}{2Rk_0} - \ln v_m\theta_M \quad (2)$$

Here T_M is the temperature of the desorption peak maximum, v_m the amount of adsorbate at the full surface coverage, θ_M the surface coverage at the peak maximum, and k_0 and R are constants. In the first order desorption, when T_M is measured as a function of b, E_d can be obtained from the plots of $(2\ln T_M - \ln b)$ *vs.* $1/T_M$. For the second order desorption, the computer simulation analyses of TPD chromatograms[12] show that θ_M is little affected by b if the initial surface coverage is kept constant. Based on Eq. 2, the conditions allow us to evaluate E_d of the second order desorption also from the same plots as above. This means that we can estimate E_d, at least as an approximation, from the same plots without knowing exact desorption orders. Recently Konvalinka *et al.* reached the same conclusion by computer simulation analyses.[13] Such an approximation is permissible only for the homogeneous surface.[14]

Table 3. Temperature programmed desorption of β and γ oxygen

b heating rate, T_M peak temperature, and V_d desorbed amount.

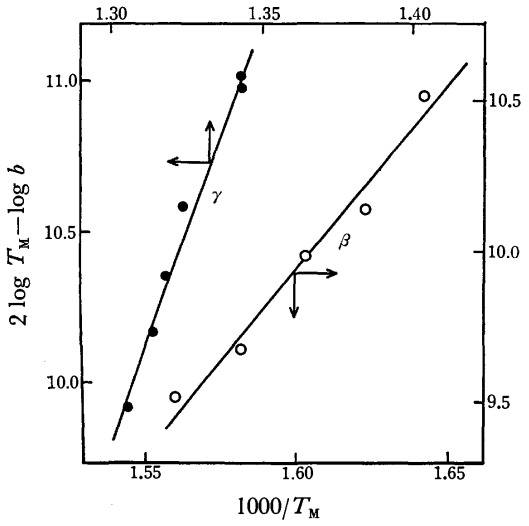

Fig. 4. Activation energy of desorption for β and γ adsorbates.

The analyses were applied to β and γ desorption. In order to obtain respective desorption peaks in adequate magnitudes, oxygen adsorption was performed by Procedure II for β, and by Procedure I for γ at 410 °C. In the analyses of β, the contribution of α adsorbates to the leading part was disregarded. The results are summarized in Table 3. For both cases of β and γ, T_M increases with increase in b. The plot of $(2\ln T_M - \ln b)$ *vs.* $1/T_M$ gave straight lines in agreement with the above equations (Fig. 4). From the slopes, the activation energies for β and γ were determined to be $E_d(\beta)=23.8$ and $E_d(\gamma)=54.6$ kcal/mol, respectively.

The desorption orders for β and γ remain undetermined. Phenomenologically, differentiation of the desorption order can be made according to whether or not T_M is independent of the amount of adsorbates (V_d) at a constant heating rate. No experiments were carried out for the sake of confirmation. However, there is some evidence that β and γ desorption are of the first and second order, respectively. Figure 3 shows that T_M of β desorption is almost unchanged with a change in magnitude of the desorption peak (runs 1, 4, 16, and 17), suggesting the first order desorption. On the other hand, T_M of γ desorption shifts to the higher side with a decrease in V_d (Figs. 6 and 7), indicating the second order desorption.

Winter[15] has studied the isotopic exchange reaction of oxygen over α-Fe_2O_3 pretreated in various ways, and found that the activation energy of the reaction is 19—27 kcal/mol at 260—400 °C. The value is in good agreement with $E_d(\beta)$. It appears that the rate determining step of the reaction is the desorption of molecular oxygen from the surface, in line with Winter's suggestion.

Reaction of Adsorbed Oxygen with Hydrogen. The oxygen adsorbates were found to react easily with hydrogen. After oxygen adsorption by Procedure II, the sample was brought in contact with a hydrogen pulse (0.025—0.200 cm³ (STP)) at selected temperature.

The effect of the pulse (reaction) temperature on the TPD chromatogram is shown in Fig. 5. The hydrogen pulse, 0.05 cm³, is twice the amount necessary to convert all the adsorbed oxygen into H_2O. The left part of the peak β disappears at 80 °C or below. α adsorbates are consumed simultaneously under these conditions, since this part is partly contributed by the α desorption as mentioned above. With an increase in temperature up to 188 °C, increasing amounts of β are consumed. Such consumption of β adsorbates (and α in part) is coupled with a roughly proportional increase in γ desorption. Thus the γ desorption becomes the largest after the hydrogen pulse at 188 °C. It was cinfirmed that the γ species also reacts with hydrogen above 300 °C.

The effect of the amount of hydrogen pulse at 125 °C on TPD chromatogram is shown in Fig. 6. Increase in pulse amount up to 0.2 cm³ causes γ desorption to increase at the expense of β (and α), in a similar manner to that above. Since the injection of 1.0 cm³ of hydrogen gave a chromatogram almost the same as chromatogram 30, it is concluded that γ adsorbates are inactive to hydrogen at 125 °C. Whilst all the adsorbates are

able to react with hydrogen under adequate conditions, α and β adsorbates are much more reactive than γ.

Why does the γ adsorbates increase coupled with the consumption of β (and α)? For each run in Figs. 5 and 6, the amounts of decrease in $\beta(V_{dec})$ and increase in $\gamma(V_{inc})$ were determined from the respective peak areas. It was found that the relation $V_{inc}/V_{dec} \simeq 1/2$ holds in all runs (Table 4). To account for this relation, we assume that α and β adsorbates are molecular while γ is atomic, and that the molecular species reacts with hydrogen at 50—188 °C to leave the atomic species (γ) behind. The reaction may be represented as follows, if the electronic states of adsorbates are disregarded.

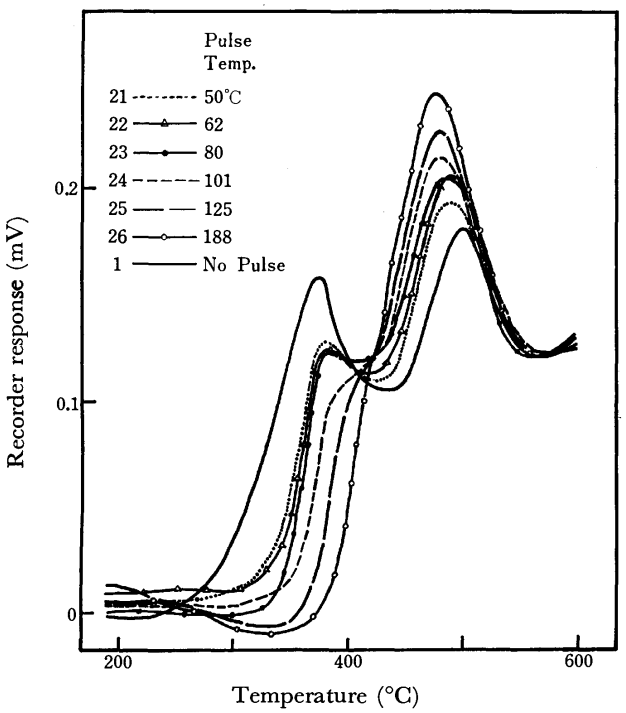

Fig. 5. TPD chromatograms of oxygen adsorbed on Fe_2O_3-I after the reaction with hydrogen pulsed at various temperature.

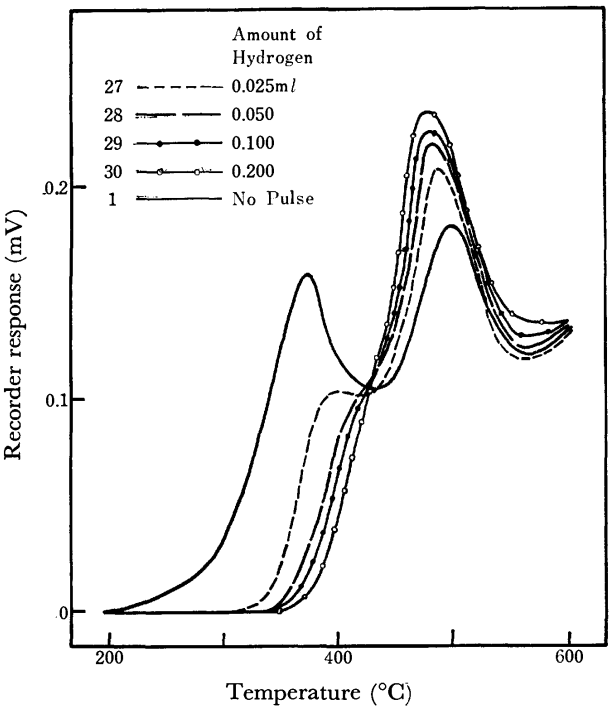

Fig. 6. Influence of the pulse amounts of hydrogen on TPD chromatograms of oxygen adsorbed on Fe_2O_3-I.

Table 4. Reaction of oxygen adsorbed on Fe_2O_3-I with hydrogen

Run No.	Reaction temp (°C)	Amount of hydrogen pulse (cm^3)	Decrease in β, V_{dec} (cm^3/m^2)	Increase in γ V_{inc} (cm^3/m^2)	$\frac{V_{inc}}{V_{dec}}$

30	125	0.200	1.79	1.14	0.64

$$O_2(ad) + H_2 \longrightarrow O(ad) + H_2O$$

Since adsorption in γ must have been saturated after the oxygen adsorption by Procedure II, the increase of adsorbates indicates that additional sites for γ adsorption are created by the above reaction. It was confirmed that oxygen adsorption by Procedure II after the pulse reaction gave precisely the same TPD chromatogram as in run 1. This indicates that the surface can be brought back reversibly to the original state during the course of adsorption. It seems that the hydrogen pulse creates additional γ sites to accommodate atomic oxygens. It is possible that β sites are made to turn into γ sites tempolarily due to the chemical reaction involved.

The assumption that α and β adsorbates are molecular is not unreasonable, considering that they form or desorb at relatively low temperatures. β desorption shows a feature of the first order desorption in which the desorption temperature is little affected by the surface coverage. In contrast, the desorption temperature for γ is dependent on the surface coverage as exemplified by chromatograms in Figs. 5 and 6, a feature of the second order desorption or the dissociative adsorption. The plots of log V_{dec} *vs.* inverse of the pulse temperature give a straight line. From the slope, the activation energy for the above reaction was obtained as 4.5 kcal/mol, which may correspond to the energy of rupturing O–O bond in the molecular adsorbates.

There is no definite evidence to indicate the electronic states of α, β, and γ adsorbates. However, many metal oxides have been known to adsorb oxygen as O_2 or O_2^- at relatively low temperatures, while adsorption as O^- or O^{2-} is favored at higher temperatures. At present, we assume tentatively that α, β, and γ adsorbates are O_2 or O_2^-, O_2^-, and O^-, respectively.

The reactivity of adsorbed oxygen exhibits very interesting features not so far foreseen, though the assumption used to interpret them needs further verifica-

tion. This kind of information would be important for the understanding of catalytic oxidations.

The Phosphorescence Spectra of 1,4-Naphthoquinone and Its Alkyl Derivatives in Solutions at 77 K

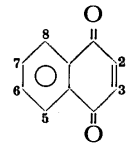
Akira KUBOYAMA

National Chemical Laboratory for Industry, Shibuya-ku, Tokyo 151

(Received November 28, 1977)

The phosphorescence spectra of 1,4-naphthoquinone (NQ), 2-methyl-, 2,6-dimethyl-, 2,6-diisopropyl-, and 2,6-di-*t*-butyl-NQ's in various kinds of solutions at 77 K were studied. The phosphorescence bands of NQ and 2,6-di-*t*-butyl-NQ in all the solutions and those of the other NQ's in saturated hydrocarbon solutions are assigned to the n,π^* band. In the ethanol solution, 2-methyl-NQ shows a dual phosphorescence, the lifetimes of which are different and which depends on the excitation wavelength. In the Daifloil solutions, 2-methyl- and 2,6-dimethyl-NQ's also show a dual phosphorescence. In the toluene solutions, these two NQ's show remarkably broad phosphorescence bands. These facts are discussed on the basis of the electronic structures at the excited states of these NQ's.

Heretofore, we have studied the n,π^* phosphorescence spectra of various kinds of quinones in solutions at 77 K.[1-3] In many organic solvents, 1,4-naphthoquinone (NQ) shows n,π^* phosphorescence at 77 K, while 2,3-dimethyl-NQ shows no n,π^* phosphorescence. In this connection, it is interesting to study the phosphorescence spectra of other NQ alkyl derivatives. However, few studies of the phosphorescence spectra of NQ alkyl derivatives have been reported.[4] In this work, we have studied the phosphorescence spectra of NQ, 2-methyl-, 2,6-dimethyl-, 2,6-diisopropyl-, and 2,6-di-*t*-butyl-NQ's in various kinds of solutions at 77 K.



(NQ)

Experimental

Measurements. The phosphorescence spectra and their lifetimes in solutions at 77 K have been measured using an Aminco-Bowman spectrofluorophotometer in the manner described in previous papers.[1-3] Hg 313 and 365 nm lines of a Hanovia 150W xenon-mercury lamp were used as the exciting light. Two photomultipliers, HTV R106 and R105UH, were used for the measurements of phosphorescence spectra and their lifetimes respectively. The spectral response of the photomultiplier tube and the spectral transmittance of the monochromator have not been taken into account. The concentrations of sample solutions ranged from 10^{-3} to 10^{-5} mol/dm^3. The solvents used were normal paraffins (hexane, heptane, and octane), methylcyclohexane, ethanol, Daifloil (polymers of trifluorochloroethylene), and toluene. Except for the case of normal paraffins, all the solutions formed the glass state at 77K.

Materials. Commercially-available NQ was purified by active-carbon treatment in cyclohexane (mp 124.3—125.3 °C). Commercially-available 2-methyl-NQ was purified by the zone-melting method (mp 106.8—107.4 °C). 2,6-Dimethyl-, 2,6-diisopropyl-, and 2,6-di-*t*-butyl-NQ's[5,6] were synthesized from 2,6-dimethyl, 2,6-diisopropyl, and 2,6-di-*t*-butylnaphthalenes respectively. 2,6-Dimethyl-NQ was purified by vacuum sublimation, and the others, by recrystal lization from ethanol (mp 138.0—139.0 °C, 62.5—63.5 °C, and 84.0—85.0 °C respectively). Spectro-grade hexane, heptane, methylcyclohexane, and toluene of the Dozin Yakukagaku Co., spectro-grade octane of the Tokyo Kasei Kogyo Co., analytical-grade ethanol of the Wako Junyaku Kogyo Co., and Daifloil #1 (mean molecular weight 500) of the Daikin Kogyo Co. were used without further purification.

Results

The phosphorescence spectra of all the NQ's in the saturated hydrocarbon solutions slowly cooled were too weak to be observed, while those in other solutions slowly cooled were almost the same in all respects as those in these solutions rapidly cooled. Therefore, in this paper the phosphorescence spectra of the sample solutions rapidly cooled are reported. The main phosphorescence spectra obtained are shown in Figs. 1—7. The wavelengths of the main peaks and the observed lifetimes of the phosphorescence spectra are shown in Tables 1 and 2 respectively. No phosphorescence spectrum can be observed for 2,6-di-*t*-butyl-NQ in the normal paraffin solutions. The spectrum of 2,6-dimethyl-NQ in the toluene solution is similar to that of 2-methyl-NQ in Fig. 7.

Discussion

First, the phosphorescence spectra of the saturated hydrocarbon solutions of the NQ's will be discussed. They may be assigned to the n,π^* phosphorescence

band, based on their main progressions of the C-O stretching vibration and their short lifetimes, as may be seen in Figs. 1—3 and Tables 1 and 2.[7] In the methylcyclohexane solutions, as may be seen in Table 1, the phosphorescence bands of 2-methyl- and 2,6-dimethyl-NQ's show a blue shift, in comparison with that of NQ, while that of 2,6-diisopropyl-NQ shows no shift and that of 2,6-di-t-butyl-NQ shows a considerable red shift. The blue shift in the cases of 2-methyl- and 2,6-dimethyl-NQ's is characteristic of the n,π^* transition.[8] The red shift in the case of 2,6-di-t-butyl-NQ may be due to the interaction between the t-butyl group and the lone-electron-pair of the carbonyl group located close to it. The shorter lifetime of the phosphorescence band of 2,6-di-t-butyl-NQ than those of the other NQ's, as may be seen in Table 2, may also be due to the same reason.

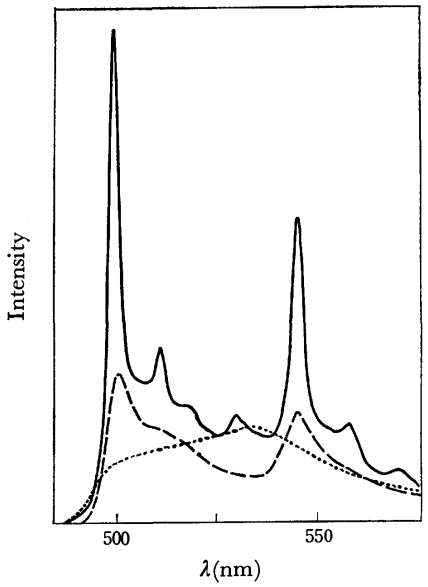

Fig. 3. Phosphorescence spectra of 2,6-(i-Pr)$_2$-NQ in solutions, 77 K.
——: Hexane, ——: heptane, ·····: octane.

As for the Shpol'skii effect,[9] sharp spectra are observed in the normal paraffin solutions, as may be seen in Figs. 1—3. In the heptane solutions of 2-methyl- and 2,6-dimethyl-NQ's, two closely located phosphorescence bands are observed, as in the case of anthraquinone[2] previously reported. It is noticeable that, in 2,6-diisopropyl-NQ, the heptane solution alone shows a sharp band.

Let us turn to the phosphorescence spectra of the

TABLE 2. OBSERVED LIFETIMES OF THE PHOSPHORESCENCE BANDS (ms)

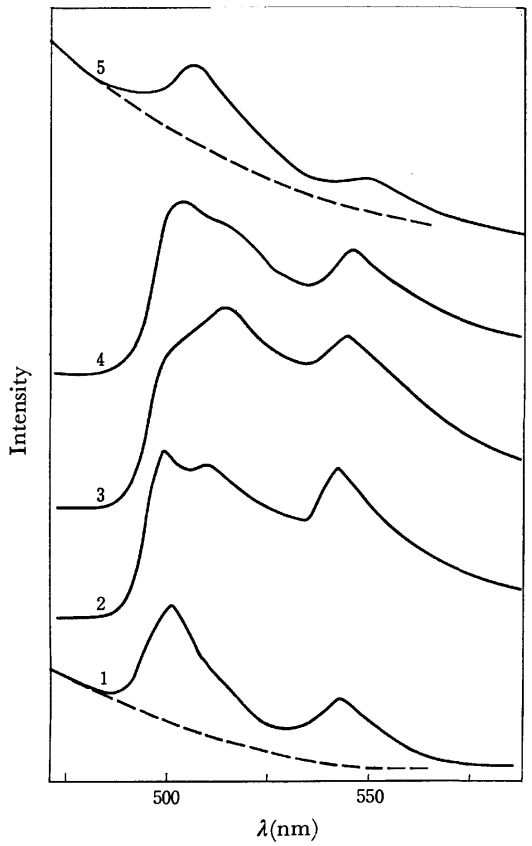

Fig. 4. Phosphorescence spectra of the NQ's in the ethanol solutions, 77 K.
1: NQ, 2: 2-Me-NQ, 3: 2,6-Me_2-NQ, 4: 2,6-(i-Pr)$_2$-NQ, 5: 2,6-(t-Bu)$_2$-NQ.

NQ's in the ethanol solutions. The phosphorescence bands of the NQ's except for 2,6-dimethyl-NQ are assigned to the n,π^* band in the ethanol solutions, since they show clear vibrational structures of the C–O stretching mode and have short lifetimes (Fig. 4 and Tables 1 and 2). The phosphorescence spectrum of 2,6-dimethyl-NQ shows no vibrational structure of the C–O stretching mode and may be assigned to the π,π^* band. From the comparison between Curves 2 and 3 in Fig. 5, we can see that the intensity of the shortest wavelength peak decreases for 2-methyl-NQ with a decrease in the turning-rate of the sector. This means that 2-methyl-NQ shows two closely located phosphorescence bands (the so-called dual phosphorescence[10]) with different lifetimes. The one containing the shortest wavelength sharp peak has a shorter lifetime than the other and may be assigned to the n,π^* band. The other band, which is broad and which shows no C–O stretching vibrational structure, may be assigned to the π,π^* band. In Table 2, the lifetime for 2-methyl-NQ in the ethanol solution is that of the broad band.

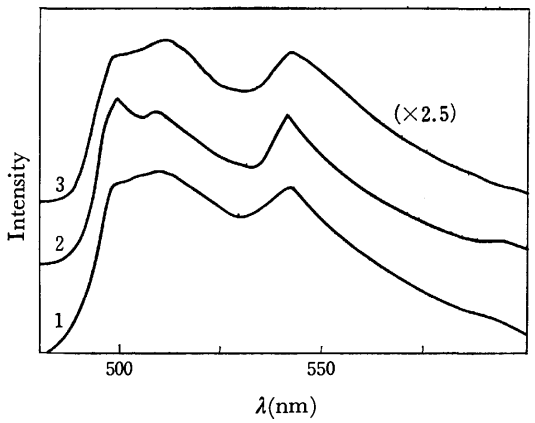

Fig. 5. Phosphorescence spectra of 2-Me-NQ in the ethanol solution, 77 K.
1: 313 nm line ex., sector fast, 2: 365 nm line ex., sector fast, 3: 365 nm line ex., sector slow.

It is considered that the lowest ^{3}(n,π^*) and $^3(\pi,\pi^*)$ levels are higher and lower respectively for 2-methyl-NQ than for NQ[11] as a result of the methyl-group substitution, and that in each quinone these levels are higher and lower respectively in the ethanol solution than in the saturated hydrocarbon solutions, as a result of the hydrogen-bond formation[1] between ethanol and the quinone. Consequently, in the ethanol solution of 2-methyl-NQ, the lowest ^{3}(n,π^*) and $^3(\pi,\pi^*)$ levels may reasonably be assumed to be very close. The above-mentioned dual phosphorescence may result from this closeness of the lowest ^{3}(n,π^*) and $^3(\pi,\pi^*)$ levels of 2-methyl-NQ in the ethanol solution. It is uncertain at this stage whether the two phosphorescences have their origin in like molecules or in differently solvated species. In 2,6-dimethyl-NQ, considering the case of 2-methyl-NQ, the lowest $^3(\pi,\pi^*)$ level may be somewhat lower than the lowest ^{3}(n,π^*) level in the ethanol solution because of the two methyl-group substitution, so only the π,π^* phosphorescence band is observed. The short lifetimes of the phosphorescence bands assigned to the π,π^* band in Table 2 may result from the mixing of the phosphorescent $^3(\pi,\pi^*)$ states with the nearby ^{3}(n,π^*) states.

In 2-methyl-NQ, as may be seen from a comparison between Curves 1 and 2 in Fig. 5, the phosphorescence spectra observed by the two kinds of excitations, the 313 and 365 nm line excitations, where the former corresponds to the excitation to the $^3(\pi,\pi^*)$ state, and the latter to the excitations to both the ^{3}(n,π^*) and $^3(\pi,\pi^*)$ states,[16,17] are different. From this fact it may be concluded that a part of the quinone molecules excited to the $^3(\pi,\pi^*)$ state at the 313 nm line excitation directly transfer to a high-energy triplet state through the intersystem crossing.

Since all the phosphoresence bands of the NQ's in the Daifloil solutions show clear progressions of the C–O stretching vibration and short lifetimes (Tables 1 and 2), these bands may be assigned to the n,π^* band. The phosphorescence band of NQ in the Daifloil solution shows a more considerable blue shift than do those in the saturated hydrocarbon solutions (Table 1). This blue shift may be mainly due to the n-σ type charge-transfer interaction between the lone-pair orbitals of the carbonyl groups of NQ and the σ^*-orbitals of the C–Cl bonds of Daifloil.[3]

The phosphorescence spectrum of 2,6-dimethyl-NQ in the Daifloil solution depends on the turning-rate of the sector (Fig. 6). A similar situation is also observed

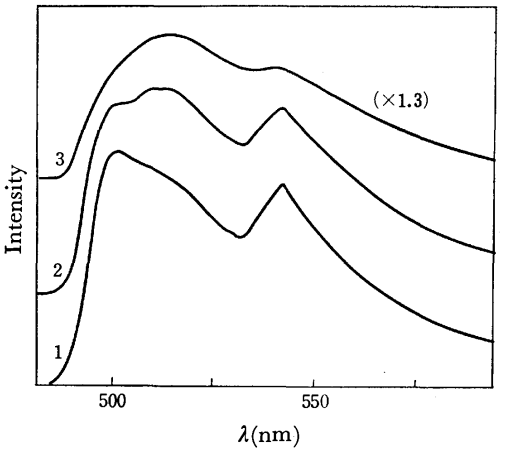

Fig. 6. Phosphorescence spectra of 2,6-Me_2-NQ in the Daifloil solution, 77 K.
1: No sector, 2: sector fast, 3: sector slow.

for 2-methyl-NQ. Therefore, as may be seen in Fig. 6, a dual phosphorescence which consists of a sharp band and a broad band appears in these two NQ's in the Daifloil solutions, as in the case of 2-methyl-NQ in the ethanol solution. The lifetimes for these two NQ's in the Daifloil solutions in Table 2 are those of the broad bands. In this case, the phosphorescence spectra do not depend on the exciting wavelength.

As for the phosphorescence spectra of the NQ's in the toluene solutions, as may be seen in Fig. 7 and Tables 1 and 2, their lifetimes are all short; those of NQ and 2,6-di-*t*-butyl-NQ show a clear vibrational structure

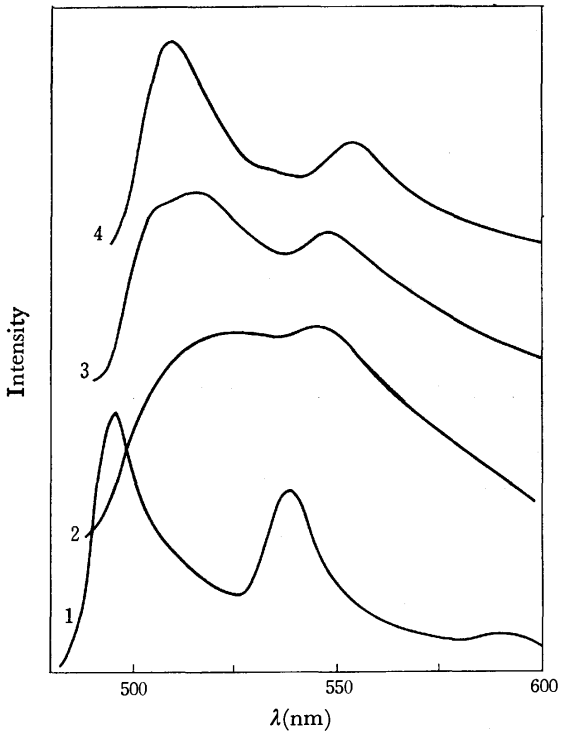

Fig. 7. Phosphorescence spectra of the NQ's in the toluene solutions, 77 K.
1: NQ, 2: 2-Me-NQ, 3: 2,6-(i-Pr)$_2$-NQ, 4: 2,6-(t-Bu)$_2$-NQ.

of the C–O stretching mode, while those of the other NQ's do not show it. Especially those of 2-methyl- and 2,6-dimethyl-NQ's show almost no structure. The former may reasonably be assigned to the n,π^* band, but the latter may be assigned to the π,π^* band, which has the n,π^* character to some extent, in view of their short lifetimes.

The phosphorescence band of NQ in the toluene solution shows a larger blue shift than those in the ethanol and Daifloil solutions (Table 1) as a result of the π-π type charge-transfer interaction between toluene and NQ.[1] As for the above-mentioned phosphorescence bands of 2-methyl- and 2,6-dimethyl-NQ's in the toluene solutions, the phosphorescent π,π^* states may mix with the triplet charge-transfer states also, for they are remarkably broad. On the other hand, the phosphorescence band of NQ in the toluene solution does not show such a broadening. The reason for this may be that, in NQ, it is difficult for the phosphorescent n,π^* state to mix with the triplet charge-transfer state because of the small overlapping between the donor π-orbital of toluene and the n-orbital of the carbonyl oxygen atoms of NQ.

As for the observed lifetimes of the phosphorescence bands of the NQ's in Table 2, those for all the NQ alkyl derivatives except for 2,6-di-*t*-butyl-NQ are, in each kind of solution, a little longer than that for NQ. The short lifetimes in the case of 2,6-di-*t*-butyl-NQ have been discussed before. It is noticeable that the observed lifetimes are, in each quinone, regularly in the following order of solvents: toluene>Daifloil>ethanol>heptane.

11) NQ is thought to have two low-energy $^3(n, \pi^*)$ levels, the energy difference between which is several hundreds cm^{-1}, as in the case of *p*-benzoquinone.[2] In the text, the $^3(n, \pi^*)$ level corresponds to the lower one of them, while the higher one is neglected in order to simplify the discussion. According to the CNDO/S+CI calculations,[13,14] the lowest $^1(n, \pi^*)$ state of NQ is the $^1A_2$ state, so the lowest $^3(n, \pi^*)$ state may also be the $^3A_2$ state, considering the case of *p*-benzoquinone.[12] On the other hand, the lowest $^3(\pi, \pi^*)$ state is the $^3B_2$ state, according to both the CNDO/S+CI[13,14] and P-P-P[15,16] calculations.

Relaxation Phenomena after an Area Strain on the Adsorbed Surfaces of Aqueous Solutions of Poly(oxyethylene) Dodecyl Ethers

Masao NAKAMURA* and Shinichi TAKEUCHI

Department of Chemistry, Faculty of Science, Tokai University, Kitakaname, Hiratsuka 259-12

(Received December 10, 1977)

The relaxations were observed after suddenly dilating or compressing the equilibrium surfaces of aqueous solutions of poly(oxyethylene) dodecyl ethers, $C_{12}H_{25}(OC_2H_4)_nOH$ ($n=5$ and 7), at 303 K. The relaxation is expressed as the Maxwell model, with a Hookean surface-area modulus and a Newtonian surface-area viscosity, if the absolute value of an area strain is less than 0.3. The surface-area modulus is dependent upon the amount of surfactant molecules adsorbed in the surface, Γ, regardless of the sign of the area strain. The relaxation time, τ_c, in the case of compression is dependent on Γ, and τ_d in the case of dilation depends on the monodispersed concentration of the surfactant in the bulk solution, C. The surface dilational viscosity, η_0^A, has a maximum around the concentration at which the surface reaches the saturated adsorption. The rate constants for the adsorption and desorption were estimated by determining empirically the functions of $1/\tau_d$ and $1/\tau_c$ with respect to C and Γ respectively.

The rheological properties, especially the resistances against an area strain, of an interface containing adsorbed surfactants have been pointed out as important factors in stabilizing some dispersions through the resistance against the rupture of the interface.[1,2] In a previous paper[3] there has been proposed a concept that a liquid surface with adsorbed surfactant molecules behaves as a two-dimensional open system, in which the number of surfactant molecules changes during the processes, involving some area strains. Thus, when the surface is dilated, an adsorption of surfactant molecules proceeds from the bulk solution to cover the lack in the surface. On the other hand, when the surface is compressed, an excess of surfactant molecules desorbs into the bulk solution. It is the purpose of the present paper to determine quantitatively both the surface-area modulus and the surface-area viscosity of the surface adsorbed with surfactants and, further, relate them to the molecular behavior characterized by the two-dimensional open system. For this purpose, measurements were made of the stress relaxation, with the area strain kept constant, either positive or negative, after suddenly dilating or compressing the surface in equilibrium with the bulk solution at a constant temperature of some nonionic surfactants. That is, the system was simple as possible.

Experimental

The nonionic surfactants, poly(oxyethylene) dodecyl ethers $C_{12}H_{25}(OC_2H_4)_nOH$ ($n=5$ and 7), were kindly provided by Nihon Surfactant Kogyo K.K.; they had a purity above 99% and no distribution of polymerization in the hydrophilic part, as verified by gas chromatography.[4] The solvent was obtained by distilling the alkaline permanganate solution in ion-exchanged water after refluxing for 15 h.

An equilibrium surface was obtained by filling a Langmuir-type trough with a solution, maintaining the temperature constant at 303 K, after sweeping the surface 6 times in 1 h with three glass barriers coated with paraffin; the trough was then allowed to stand for *ca.* 15 h. The area, A_0, of the equilibrium surface was changed suddenly to another area, A, by moving one of the two barriers which had confined the area. As the result, the surface underwent an area strain, $\Delta A/A$ ($\Delta A=A-A_0$). According to the direction of the movement of the barrier, the surface was either dilated or compressed, the sign of area strain being positive or negative. When the area strain was maintained constant, the surface pressure, π, which had deviated as a result of the sudden change in the area, converged gradually to the equilibrium value, π_e. Such phenomena were measured by the Wilhelmy method using a torsion balance with a glass plate.[5] The surface pressure was determined at a precision within ± 0.05 mN m^{-1}, particularly by controlling the level of the surface to avoid any changes in the position of the plate due to the change in the surface level which accompanies the movement of the barrier.

Results and Discussion

The relations of the surface pressure, π, with the time, t, after sudden area strains are shown in Fig. 1 when, for example, the surface of a solution of 3.56×10^{-2} mol m^{-3} of $n=5$ is dilated with various proportions. As may be seen in the figure, π converges to an equal value if the area strain does not exceed 0.67. The converged value was regarded as the equilibrium surface pressure, π_e, of the surface at that temperature. The stress corresponding to the area strain at time t is the

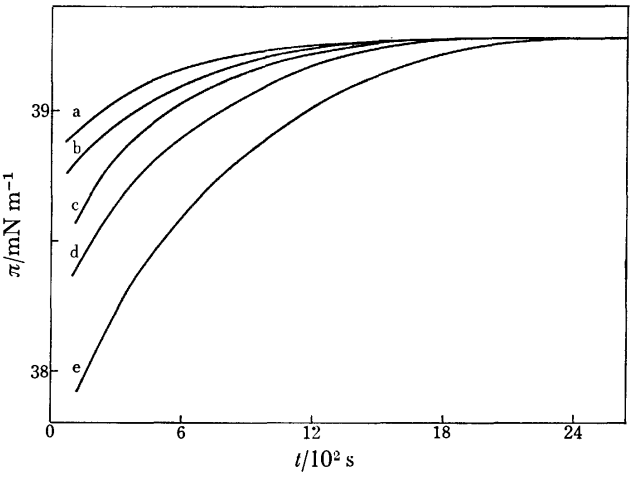

Fig. 1. Surface pressure change with time after sudden area strain for the equilibrium surface of aq $C_{12}H_{25}(OC_2H_4)_5OH$ soln of 3.56×10^{-2} mol m^{-3} at 303 K. Area strain: a 0.15, b 0.2, c 0.3, d 0.44, e 0.67.

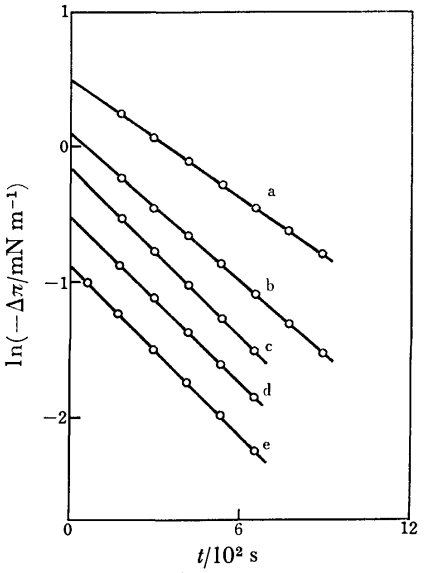

Fig. 2. Stress relaxation plots for the curves in Fig. 1.

difference in the surface pressure from the equilibrium value, $\Delta\pi=\pi-\pi_e$, which has the sign opposite to the strain; it is negative in the case of the dilation and positive in the compression.

The curves in Fig. 1 show the stress relaxation when the area strain is kept constant. The natural logatithm of the absolute value of the stress, which is estimated from the curves in Fig. 1, decreases linearly with time t, as is shown in Fig. 2. The relations between $\Delta\pi$ and t can be expressed by

$$\Delta\pi = K\exp(-t/\tau) \quad (1)$$

for each area stress, where K is the initial stress and τ is the relaxation time; these values are obtained from the value extrapolated to $t=0$ and the slope of the straight line in Fig. 2 respectively.

Equation 1 corresponds correctly to the relaxation of the Maxwell model with the surface-area modulus, ε^A, and the surface-area viscosity, η^A, when the model undergoes a constant area strain, $\Delta A/A$.[6] Accordingly, K, τ, ε^A, and η^A are connected with each other by

$$K = -\varepsilon^A(\Delta A/A), \quad (2)$$

and

$$\tau = \eta^A/\varepsilon^A. \quad (3)$$

Since K has the sign opposite to $\Delta A/A$, as has been mentioned above, ε^A is always positive. Both ε^A and η^A can be obtained from the measured K and τ by applying Eqs. 2 and 3. As a result of repeated measurements of the surfaces with an equal bulk concentration, as is shown in Fig. 3, it may be concluded that both ε^A and η^A are independent of the area strain, $\Delta A/A$; they are, therefore, Hookean and Newtonian respectively if the area strain is less than 0.3. Only if the absolute value of the area strain does not exceed 0.3 were ε^A and η^A confirmed to be Hookean and Newtonian for any surface under investigation, with either the dilation or compression of the surface.

The equilibrium surface tension, σ_e, which was estimated by subtracting the converged surface pressure, π_e, in the relaxation curve from the surface tension of pure water at 303 K, 71.15 mN m^{-1}, [7] is plotted against

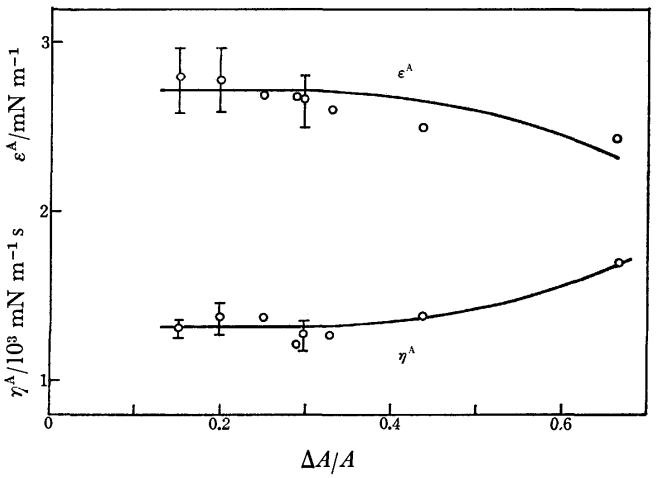

Fig. 3. Surface-area modulus ε^A and surface-area viscosity η^A *vs.* area strain plots for $C_{12}H_{25}(OC_2H_4)_5OH$ soln of 3.56×10^{-2} mol m^{-3}.

□ ■: compression

the logarithm of concentration, C, in Fig. 4. All the plots fall on a single curve for $n=5$ and 7, whether π_e is measured by means of the dilation or the compression of the surface. This means that the measured relaxation process is a process approaching a final state, irrespective of the dilation or compression, *i.e.*, it is approaching a true equilibrium state. The concentrations at the break points, corresponding to the critical micelle concentration, CMC, are 4.5 and 5.9×10^{-2} mol m^{-3} for $n=5$ and 7, smaller than the values at 6.8 and 6.9×10^{-2} mol m^{-3} at 278 K measured by Ohba and Takahashi for the same substances,[4] but the differences are not so great in the surface tension. The CMC value for $n=5$ determined by van Voorst Vader *et al.*[8] is 12×10^{-2} mol m^{-3}, far larger and rather close to the value found by our preliminary experiments using the drop-weight method. These facts indicate that the break point on the surface tension *vs.* log C curve, corresponding to the CMC, has a tendency to be smaller in concentration as the surface tension approaches the equilibrium value.

The surface-area modulus, ε^A, increases with an

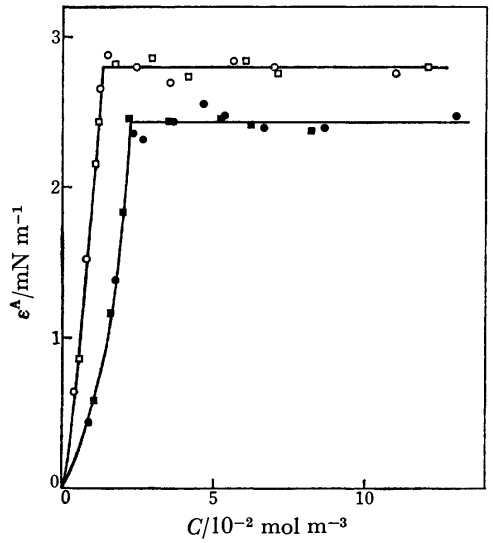

Fig. 5. Surface-area modulus *vs.* bulk concn plots. Marks are the same as in Fig. 4.

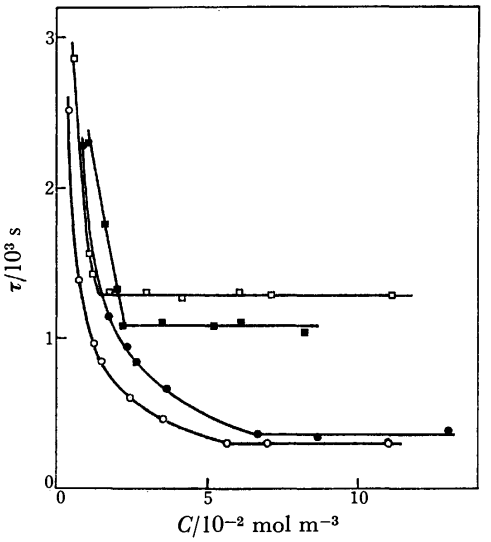

Fig. 6. Relaxation time *vs.* bulk concn plots. Marks are the same as in Fig. 4.

increase in the bulk concentration, C, and reaches a constant value at a concentration, shown in Fig. 5, in which the values do not differ between the cases of dilation and compression. The concentration at which ε^A becomes constant corresponds exactly to the concentration at which σ_e changes into the linear region in Fig. 4, for both $n=5$ and 7. When the Gibbs adsorption equation is applied to the curves in Fig. 4, such concentrations are found to be equal to those at which the surface is saturated with the surfactant molecules, because the amount of adsorption or surface excess is proportional to the tangent of the σ_e *vs.* log C curve. These facts reveal that ε^A increases with an increase in the amount of adsorption on the surface, Γ, and becomes constant when the surface is saturated, even if the concentration increases as the micelles appear in the bulk solution. ε^A can, therefore, be determined only by the state of the surface. The independence of ε^A of the dilation or compression indicates that the initial state of the surface immediately after the area strain applied is the same for both directions of the strain. Taking into account, in addition, the fact that the process converges to the same state, irrespective of the sign of the area strain, it may be concluded that the initial state corresponds to a state of the surface in the lack of surfactant molecules when dilated and to a state with an excess of them in the case of compression, and that ε^A is, therefore, equal to the reciprocal of the compressibility of the adsorbed film when it is assumed to be insoluble.[9] Thus, ε^A reflects the properties characterized by the two-dimensional closed system.

On the other hand, the relaxation time when the surface is dilated, τ_d, is significantly different from the relaxation time when it is compressed, τ_c. Both of them tend to decrease with an increase in the bulk concentration, C, and to attain a constant value. However, the constant value and the concentration of its attainment are quite different between τ_d and τ_c, as is shown in Fig. 6. Thus, the concentration needed for τ_c to become constant is equal to that for ε^A, at which concentration the surface is saturated. The decrease in τ_c in the lower-concentration region may, then, be attributed to the increase in the amount of adsorption on the surface with an increase in the concentration. On the other hand, the concentration at which τ_d is unchanged is in good agreement with the break point in Fig. 4, *i.e.*, the CMC, at which the monodispersed molecules are saturated in the bulk solution. τ_d is affected not by the saturation of the surface with surfactant molecules, but by the monodispersed concentration in the bulk solution.

Since τ_c and τ_d depend only upon the amount of adsorption of the surfactant molecules on the surface, Γ, and only upon the monodispersed concentration of surfactant molecules in the bulk solution, C, respectively, it may be concluded that the measured relaxation processes are the desorption process of the surfactant molecules in excess in the surface due to a negative area strain in the case of compression, and the adsorption process of the surfactant molecules to supply the lack in the surface due to a positive area strain in the case of dilation. Thus, the characteristics of the adsorbed film as an open system appear specifically in the relaxation time against the area strain.

The surface dilational viscosity, η_d^A, and the surface compressional viscosity, η_c^A, which were estimated from ε^A and either τ_d or τ_c according to Eq. 3, are plotted against the bulk concentration, C, in Fig. 7. η_c^A increases with C and has a constant value in the saturated adsorption region. On the other hand, η_d^A increases with C in the dilute region, but decreases in the saturated adsorption region up to the CMC. As a consequence, there appears a maximum in η_d^A around the concentration at which the surface becomes saturated. An adsorbed film, and thus some dispersions stabilized by such a film may be expected to become most stable against the surface-area changes around such a concentration. When a periodical area strain is given to a surface by repeating the dilation and compression in turn, an equal area viscosity has often been assumed for both processes symmetrically.[10] Such an assumption is not consistent with the present results.

If both the adsorption and desorption processes of

surfactant molecules are represented by a single relaxation process, as in the present results, the activated adsorption mechanism[11] would be more fitting than the diffusion-controlled mechanism,[12] which has been assumed by most authors since Ward and Tordai,[13] because the former mechanism needs a single exponential term with respect to time, while the latter needs plural such terms, according to Sutherland.[14] The reciprocal of the relaxation time would correspond to the rate for the process. When the reciprocal of τ_d is plotted against the bulk concentration below the CMC, curves are obtained for $n=5$ and 7, as is shown in Fig. 8. These curves may be approximated by

$$1/\tau_d = k_d \cdot C^{0.8}, \quad (4)$$

by expressing both axes with the logarithmic scale and by drawing two straight lines for $n=5$ and 7 parallel to each other; here k_d may be regarded as the rate

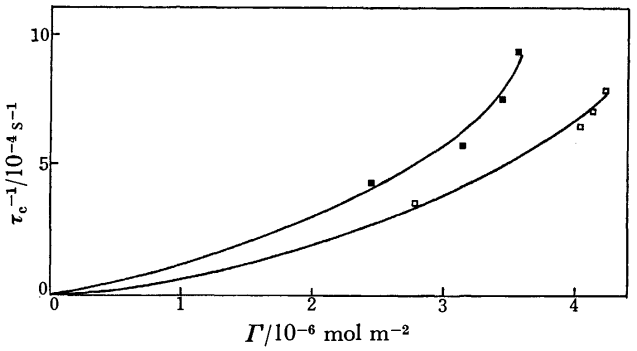

Fig. 9. Reciprocal of relaxation time when compressed *vs.* adsorption amount in the surface plots.
□: $n=5$, ■: $n=7$.

Table 1. Rate constants for the adsorption, k_d, and desorption, k_c, of $C_{12}H_{25}(OC_2H_4)_nOH$ at 303 K

n	$k_d \times 10^2$	$k_c \times 10^{-7}$
5	3.5	4.2
7	2.0	6.5

constant for the adsorption process. On the other hand, if the reciprocal of τ_c is plotted against the amount of adsorption of the surfactant molecules, Γ, evaluated by applying the Gibbs adsorption equation to the curves in Fig. 4, then the curves shown in Fig. 9 are obtained for $n=5$ and 7. The curves may be approximated by

$$1/\tau_c = k_c \cdot \Gamma^2, \quad (5)$$

by treating them similarly to the relation between τ_d and C, where k_c is the rate constant for the desorption process. As is shown in Table 1, the degree of polymerization of poly(oxyethylene) chain, n, has a reverse effect on k_d and k_c. This reveals that the rate-determinig steps can be different for the adsorption and desorption processes.

The authors wish to express their heartly thanks to Professor Mitsuo Muramatsu of Tokyo Metropolitan University for his helpful advice in the preparation of the paper.

Hydrogen Bond of 4-Amino-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one Derivatives with Alcohols. I. Experimental Considerations

Akira FUJIMOTO and Kozo INUZUKA*

Department of Applied Science, Faculty of Technology, Tokyo Denki University, Kanda, Chiyoda-ku, Tokyo 101

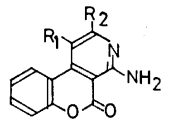
(Received December 21, 1977)

The hydrogen bond between 4-amino-5*H*-[1]benzopyrano[3,4-*c*]-pyridin-5-one (benzopyranopyridine) derivatives including their related compounds (pyridine, aniline, and coumarin) and alcohols (methanol and ethanol) is discussed experimentally in detail. The formation of a hydrogen bond between the nitrogen atom of the benzopyranopyridine ring and the hydroxyl group of methanol was investigated by IR spectral measurements. The equilibrium constants for the formation of hydrogen-bonded 1:1 complexes were determined from the UV spectral data. The enthalpy changes accompanying complex formation were obtained from a knowledge of the temperature dependence of the equilibrium constants. The values of the enthalpy changes range approximately from 4.5 to 5.2 kcal/mol in the benzopyranopyridine–ethanol systems. It may be concluded that the hydrogen bond of the benzopyranopyridine–ethanol system occurs mainly at the nitrogen atom of benzopyranopyridine ring, because the thermodynamic properties for hydrogen bond formation between benzopyranopyridine and ethanol showed a striking resemblance to those of the pyridine–ethanol system. In addition, the presence of an intramolecular hydrogen bond between the amino and carbonyl groups of benzopyranopyridine derivatives was confirmed by means of IR spectra.

The hydrogen bond of organic compounds has been studied by many workers in recent years.[1] However, the hydrogen bond of 4-amino-5*H*-[1]benzopyrano-[3,4-*c*]pyridin-5-one (benzopyranopyridine) derivatives has not been investigated except in the benzopyranopyridine derivative–acetic acid systems.[2] In this paper the hydrogen bond between the benzopyranopyridine derivatives and alcohols was investigated in detail by means of IR and UV spectra. The spectra for the systems of the related compounds of benzopyranopyridine derivatives (pyridine, aniline, and coumarin) and alcohols were also measured. Some discussions were made of the hydrogen bond by comparing the IR and UV spectra of the benzopyranopyridine–alcohol systems with those of the related compound–alcohol systems.

Experimental

Six benzopyranopyridine derivatives **1**—**6** (Fig. 1) were prepared by the methods described by Sakurai *et al.*[3]



1	R_1= CH_3	R_2=H
2	R_1= n-C_5H_{11}	R_2=H
3	R_1= n-C_9H_{19}	R_2=H
4	R_1= H	R_2=CH_3
5	R_1= H	R_2=n-C_5H_{11}
6	R_1= H	R_2=n-C_9H_{19}

Fig. 1. Benzopyranopyridine derivatives; 4-amino-1-methyl-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one (**1**), 4-amino-1-*n*-pentyl-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one (**2**), 4-amino-1-*n*-nonyl-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one (**3**), 4-amino-2-methyl-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one (**4**), 4-amino-2-*n*-pentyl-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one (**5**), and 4-amino-2-*n*-nonyl-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one (**6**).

These compounds were purified by recrystallization from ethanol several times and then by sublimation *in vacuo* at *ca.* 230 °C. Pyridine was refluxed over barium oxide and distilled. Aniline was dried over potassium hydroxide for a long time, and then fractionated under reduced pressure. Coumarin was recrystallized from ethanol and ligroin several times. The purifications of methanol, ethanol, carbon tetrachloride, and isooctane (2,2,4-trimethylpentane) were done in the usual ways.[4]

The IR and UV spectra were measured using the Hitachi Model 215 infrared spectrophotometer and Hitachi Model 323 spectrophotometer, respectively. All the infrared absorption measurements were carried out at room temperature in carbon tetrachloride solution. All the UV absorption spectra were measured in isooctane solution. The temperature of the UV absorption cells was regulated by use of the Komatsu-Yamato Model CTR-120 electronic cooling circulator within the temperature range between 10 and 50 °C.

Results and Discussion

The compounds **1** and **4** which have the simplest structure among the benzopyranopyridine derivatives synthesized by Sakurai *et al.*[3] are soluble only in carbon tetrachloride (6×10^{-3} mol/l) and isooctane (4×10^{-5} mol/l) at room temperature. However, **2**, **3**, **5**, and **6** have higher solubility in these solvents than **1** and **4** at room temperature. Consequently, the IR and UV spectra of these compounds were measured more easily than those of **1** and **4**. On the basis of these data of **1**—**6** the intermolecular interaction between the benzopyranopyridine derivatives and alcohols was investigated in the non-polar solvents.

First, the formation of an intramolecular hydrogen bond by the benzopyranopyridine derivative was studied by the IR spectral measurement in CCl_4 solution. The asymmetric (ν_{as}) and symmetric (ν_s) stretching frequencies for the NH_2 group of a primary amine can be expressed by the following empirical equation:[5]

$$\nu_s = 345.5 + 0.876\nu_{as}, \quad (1)$$

where ν_s is attributed to the lower frequency and ν_{as}

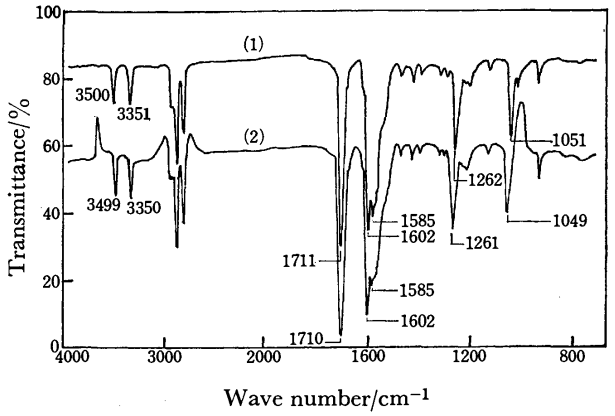


Fig. 2. IR spectra of **6** (1) and the **6**–methanol system (2) in carbon tetrachloride solution. Concentration of **6**: 1.2×10^{-2} mol/l. Concentration of methanol: 9.9×10^{-2} mol/l.

to the higher one. As is shown in Fig. 2, the two bands of the amino group of **6** appear at 3500 and 3351 cm^{-1}. The value of ν_s calculated using Eq. 1 with the value of ν_{as} (3500 cm^{-1}) became 3412 cm^{-1}. This value is higher than the observed value (3351 cm^{-1}). A similar example has been seen for the NH_2 group of *o*-nitroaniline[6] in chloroform. In the case of the *o*-nitroaniline, the corresponding bands appear at 3510 and 3380 cm^{-1}. The observed value (3380 cm^{-1}) for the symmetric frequency is lower than the calculated value (3420 cm^{-1}). This discrepancy in the two values of *o*-nitroaniline may be attributed to an intramolecular hydrogen bond between the NH_2 and NO_2 groups. On the analogy of *o*-nitroaniline, the discrepancy between the calculated and observed frequency values of **6** would be due to the formation of an intramolecular hydrogen bond between the NH_2 and C=O groups. The formation of the intramolecular hydrogen bond of benzopyranopyridine derivative is further confirmed by the following experimental results:

(1) The IR absorption bands of the NH_2 and C=O groups of **6** were measured in concentration from 2.1×10^{-3} to 4.3×10^{-1} mol/l, but there was no variation in the frequencies of these bands.

(2) The C=O stretching vibration of **6** appeared at 1711 cm^{-1} (Fig. 2), while the C=O bands of coumarin appeared at 1757 and 1742 cm^{-1} (Fig. 5). The decrease in the C=O frequency of **6** may be attributed to an intramolecular hydrogen bond.

Another consideration of this intramolecular hydrogen bond will be given in a subsequent paper[7] in further detail.

Benzopyranopyridine has four positions (the ring nitrogen atom, the oxygen atoms of carbonyl group and coumarin ring, and the hydrogen atom of amino group) for the hydrogen bond formation with alcohol. Therefore, there are four kinds of 1 : 1 hydrogen-bonded complexes in the benzopyranopyridine–methanol system. The IR spectral techniques were employed to determin which hydrogen-bonded complex is predominant among the four complexes. The IR spectrum of the **6**–methanol system is presented in Fig. 2. The position of the IR absorption bands corresponding to the NH_2 and C=O groups, and that of the absorption bands of each type (1262, 1051 cm^{-1}) shifted to the lower frequency side by about 1—2 cm^{-1}, and the intensity of these absorption bands did not change, compared with the IR spectrum of **6**. Nevertheless, the absorption band at 1585 cm^{-1} corresponding to the stretching vibration of the benzopyranopyridine ring disappeared, while a new shoulder was observed at 1590 cm^{-1} (Fig. 3)

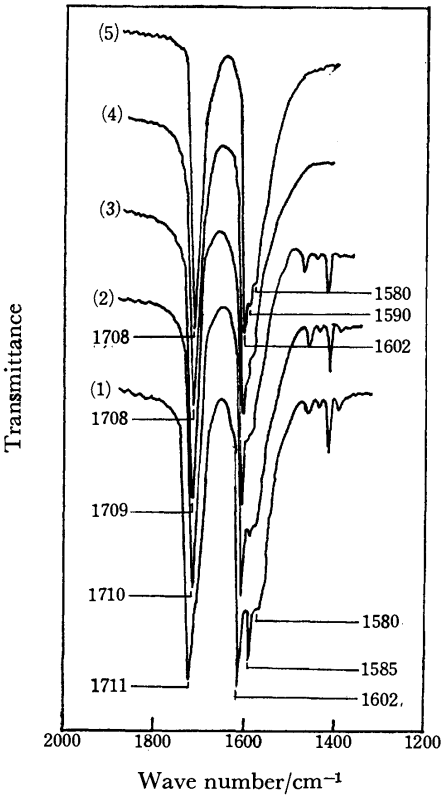

Fig. 3. IR spectra of **6** in carbon tetrachloride solution at room temparature in the presence of methanol of various concentrations. Concentration of **6**: 1.2×10^{-2} mol/l. Concentrations of methanol (mol/l): (1) 0, (2) 9.9×10^{-2}, (3) 4.0×10^{-1}, (4) 2.5, (5) 5.0.

after an addition of methanol. In the IR spectra of the systems of each compound from **1** to **5** and of methanol a similar new shoulder was observed near 1590 cm^{-1}. Furthermore, when ethanol was used in the place of methanol, the new shoulder band was observed near 1590 cm^{-1}. This result indicates that there is no difference between the two alcohols with respect to the hydrogen bond with benzopyranopyridine.

The IR spectra of the pyridine–methanol system were measured and compared with those of the benzopyranopyridine–methanol system. The spectra of this system are shown in Fig. 4. The two absorption peaks corresponding to the stretching vibration of the pyridine ring at 1597 and 1577 cm^{-1} disappeared with an increase of methanol concentration, while a new peaks appeared at 1590 cm^{-1}. The present results of the pyridine–methanol system are compatible with those reported by Takahashi *et al.*[8] (Fig. 4). In high concentrations of methanol, the two absorption bands of the NH_2 group of **6** could not be observed owing to the

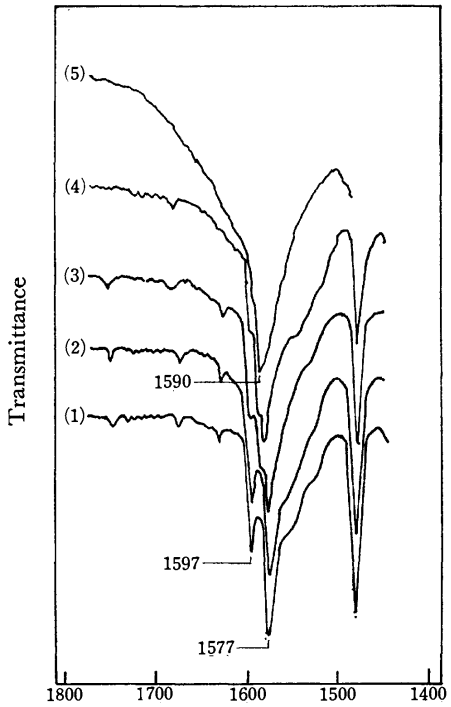

Fig. 4. IR spectra of pyridine in carbon tetrachloride solution at room temperature in the presence of methanol of various concentrations. Concentration of pyridine: 1.3×10^{-1} mol/l. Concentrations of methanol (mol/l): (1) 0, (2) 9.9×10^{-2}, (3) 2.5×10^{-1}, (4) 4.5×10^{-1}, (5) 5.0.

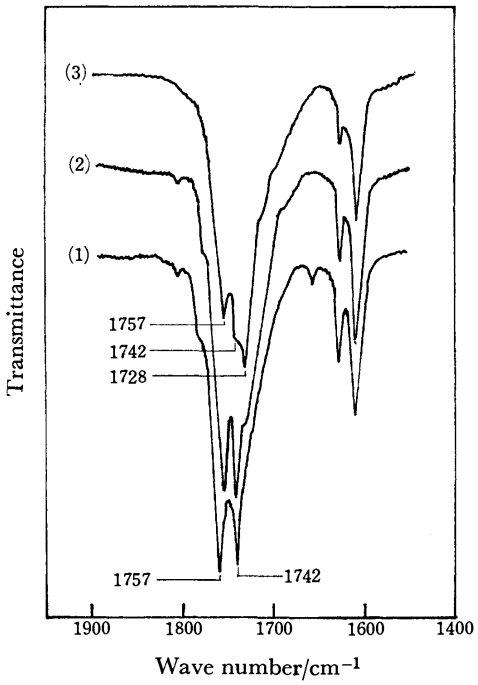

Fig. 5. IR spectra of coumarin in carbon tetrachloride solution at room temperaure in the presence of methanol of various concentrations. Concentration of coumarin: 2.0×10^{-2} mol/l. Concentrations of methanol (mol/l): (1) 0, (2) 8.7×10^{-1}, (3) 3.5.

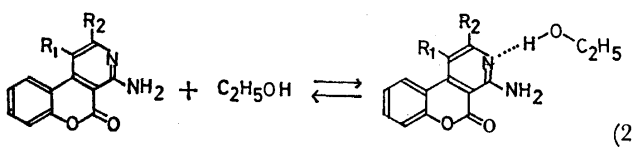
overlap of an intense absorption band of the OH group of the alcohol. However, the absorption bands of this amino group were observed in the concentration range of 0 to 3×10^{-1} mol/l. The corresponding bands of the amino group shifted to the lower frequency side with increasing methanol concentration. But this spectral shift was smaller than that of the amino group for the aniline–methanol system. It is thought that the hydrogen-bonded species formed between the amino group of benzopyranopyridine and the hydroxyl group of alcohol is negligibly small in concentration.

The C=O absorption bands of coumarin were observed at 1757 and 1742 cm^{-1}, as shown in Fig. 5. When methanol was added to the coumarin system, a new band appeared at 1728 cm^{-1}. This band may be due to the formation of a hydrogen bond between the C=O group of coumarin and the OH group of methanol. However, in the case of the benzopyranopyridine derivative–methanol system the C=O absorption band of **6** at 1711 cm^{-1} shifts by 3 cm^{-1} (Fig. 3). This spectral shift is very small compared with that of the coumarin–methanol system. Therefore, the C=O group of benzopyranopyridine is weaker than that of coumarin in hydrogen bonding ability. Another example is found in the salicylaldehyde–*n*-butyl alcohol system. The C=O stretching vibration of salicylaldehyde appears at 1668 cm^{-1} in CCl_4 solution and 1667 cm^{-1} in *n*-butyl alcohol solution.[9] Its C=O stretching frequency changes only by 1 cm^{-1} in *n*-butyl alcohol solution. The reason may be attributed to the intramolecular hydrogen bond of the C=O group. With increasing concentration of methanol, the absorption band at 1051 cm^{-1} of **6**, which may be assigned to the ether type absorption, was hidden by the intense absorption band of the OH group of alcohol, while the absorption band at 1261 cm^{-1} corresponding to the ether type of **6** was not so effected by an addition of methanol. This result suggests that the hydrogen-bonded complex formed at the oxygen atom of the coumarin ring may be negligible. From the above experimental results, it may be concluded that the hydrogen-bonded species formed at the nitrogen atom of the benzopyranopyridine ring is the most predominant among the four hydrogen-bonded ones.

The equilibrium constant (K), enthalpy changes ($-\Delta H$), and entropy changes ($-\Delta S$) were obtained by means of the UV spectroscopic method, as given below. As is partly shown in Figs. 6 and 7, remarkable changes are produced in the UV spectra of **3** and **6** by the addition of ethanol to the isooctane solution. It may safely be assumed that these spectral changes are due to the formation of a hydrogen-bonded species between the benzopyranopyridine derivatives and alcohols. In this case the hydrogen bond is represented by the following equilibrium:



(2)

where benzopyranopyridine derivative acts as a proton acceptor and ethanol as a proton donor. No considera-

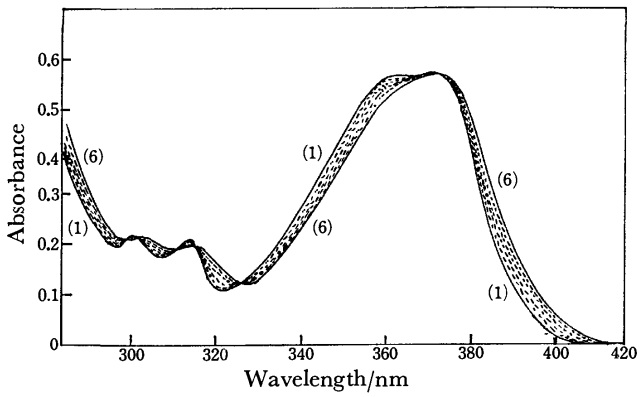


Fig. 6. UV spectra of **3** in isooctane solution at 25.0 °C in the presence of ethanol of various concentrations. Concentration of **3**: 6×10^{-5} mol/l. Concentrations of ethanol (mol/l): (1) 0, (2) 7.0×10^{-2}, (3) 1.0×10^{-1}, (4) 5.0×10^{-1}, (5) 1.0, (6) 2.0.

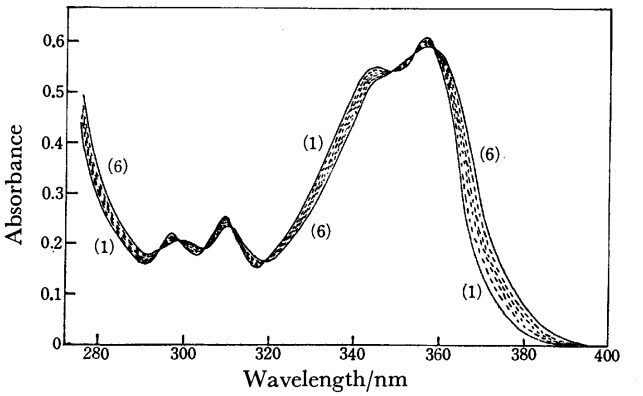

Fig. 7. UV spectra of **6** in isooctane solution at 27.0 °C in the presence of ethanol of various concentrations. Concentration of **6**: 5.3×10^{-5} mol/l. Concentrations of ethanol (mol/l): (1) 0, (2) 7.0×10^{-2}, (3) 1.0×10^{-1}, (4) 5.0×10^{-1}, (5) 1.0, (6) 2.0.

tion is given here to the hydrogen-bonded form in which one benzopyranopyridine is associated with two or more ethanols, because several clear isosbestic points are observed from the UV spectra. The **1**–ethanol and **2**–ethanol systems showed a remarkable resemblance to the **3**–ethanol system in spectral behavior. However, the spectral changes of the **4**–ethanol and **5**–ethanol systems were similar to that of the **6**–ethanol system.

The equilibrium constants K of the hydrogen bonding reactions were obtained by the use of

$$1/(\varepsilon-\varepsilon_f) = [1/\{K(\varepsilon_b-\varepsilon_f)\}](1/C) + [1/(\varepsilon_b-\varepsilon_f)],^{10)} \quad (3)$$

where ε_f is the molar absorption coefficient of the non-hydrogen-bonded or free solute species, and ε_b is that of the hydrogen-bonded species. ε is the molar absorption coefficient observed for a solution in which the initial concentration of ethanol is C. All these absorption coefficients refer to a given wavelength.

The enthalpy changes $(-\Delta H)$ accompanying hydrogen-bond formation can be obtained from a knowledge of the variation of K with temperature, according to the well known-equation,

$$-\Delta H = R[\mathrm{d}\ln K/\mathrm{d}(1/T)]. \quad (4)$$

In the present experiment the values of K were determined for each system at five points of temperature within the range from 10 to 50 °C. The free energy changes ΔG were calculated by

$$\Delta G = -RT\ln K. \quad (5)$$

The entropy changes were obtained from

$$\Delta G = \Delta H - T\Delta S. \quad (6)$$

Table 1. Thermodynamic properties of hydrogen-bond formation in benzopyranopyridine derivative–ethanol systems (1 cal=4.184 J)

Compd	K[a]	$-\Delta H$	$-\Delta S$
	l mol^{-1}	kcal mol^{-1}	cal K^{-1} mol^{-1}
1	2.90	4.6	13.3
2	3.05	4.5	12.9
3	3.00	4.7	13.6
4	3.35	5.0	14.4
5	4.05	5.2	14.7
6	3.25	5.0	14.4
Pyridine	1.60	4.2	13.2
Aniline	0.35	2.1	9.2
Coumarin	1.01	3.8	12.7

a) The values were interpolated at 25.0 °C.

The values of K, $-\Delta H$, and $-\Delta S$ for the systems of benzopyranopyridine derivatives, pyridine, aniline, and coumarin with ethanol are given in Table 1. From Table 1 it is found that the $-\Delta H$ values are *ca.* 4.6 kcal/mol for the 1-alkyl derivative–ethanol systems, and *ca.* 5.1 kcal/mol for the 2-alkyl derivative–ethanol systems. The values of K, $-\Delta H$, and $-\Delta S$ of 2-alkyl derivative–ethanol systems are slightly larger than those of 1-alkyl derivative–ethanol systems. The nitrogen atom of 2-alkyl derivatives is activated by the nearest-neighbour alkyl group which is situated at the

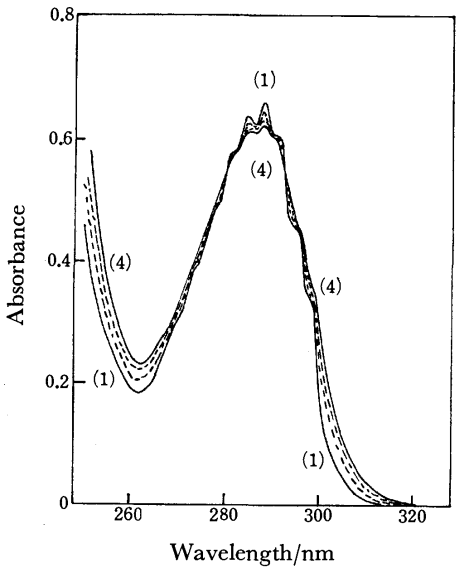

Fig. 8. UV spectra of aniline in isooctane solution at 24.8 °C in the presence of ethanol of various concentrations Concentration of aniline: 2.3×10^{-4} mol/l. Concentrations of ethanol (mol/l): (1) 0, (2) 1.0×10^{-1}, (3) 5.0×10^{-1}, (4) 2.0.

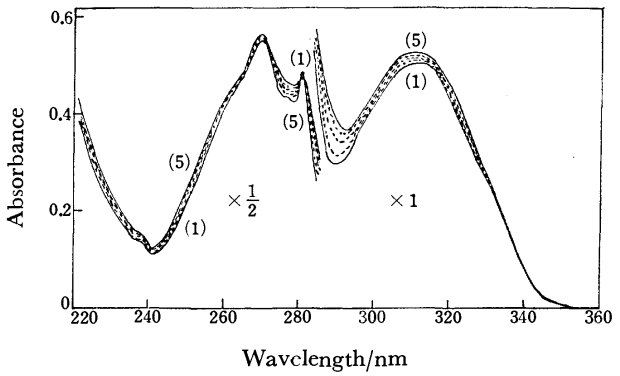

Fig. 9. UV spectra of coumarin in isooctane solution at 28.0 °C in the presence of ethanol of various concentrations. Concentration of coumarin: 2.3×10^{-4} mol/l. Concentrations of ethanol (mol/l): (1) 0, (2) 1.0×10^{-1}, (3) 3.0×10^{-1}, (4) 5.0×10^{-1}, (5) 1.0.

α-position with respect to the ring nitrogen atom, but the 1-alkyl group which is substituted at the β-position cannot activate the ring nitrogen atom.

The UV spectral change of the aniline–ethanol system was not so large when ethanol was added in a fairly large amount (Fig. 8). The $-\Delta H$ of this system is smaller than that of benzopyranopyridine derivative–ethanol system. This result indicates that the hydrogen-bonded complex formed between the amino group of benzopyranopyridine and ethanol is not so important. The UV spectra for the coumarin–ethanol system is shown in Fig. 9. The value of $-\Delta H$ for the coumarin–ethanol system is 3.8 kcal/mol. This value indicates that the carbonyl group of coumarin has a fairly strong hydrogen bonding ability. However, in the case of benzopyranopyridine the hydrogen bonding ability of its carbonyl group is not so strong as that of the carbonyl group of coumarin, because the carbonyl group of benzopyranopyridine is already occupied by an intramolecular hydrogen bond.

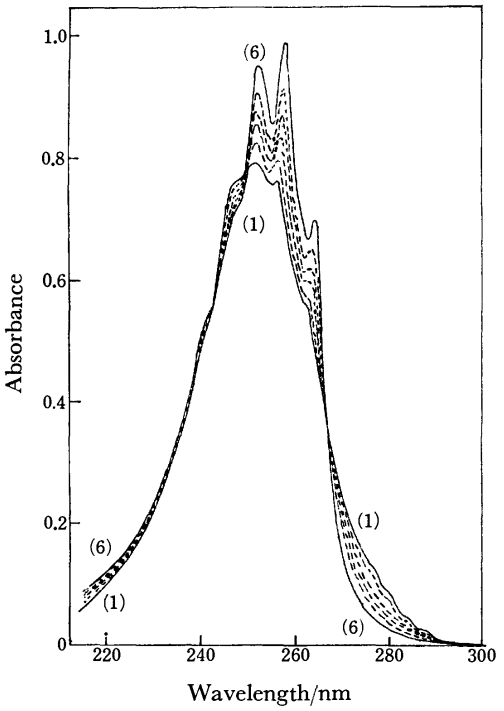

Fig. 10. UV spectra of pyridine in isooctane solution at 19.2 °C in the presence of ethanol of various concentrations. Concentration of pyridine: 4.4×10^{-4} mol/l. Concentrations of ethanol (mol/l): (1) 0, (2) 7.0×10^{-2}, (3) 2.0×10^{-1}, (4) 5.0×10^{-1}, (5) 1.0, (6) 2.0.

The UV spectral data of the pyridine–ethanol system is presented in Fig. 10. As is listed in Table 1, the values of K, $-\Delta H$, and $-\Delta S$ for the pyridine–ethanol system obtained by this study are 1.60 l/mol, 4.2 kcal/mol, and 13.2 kcal/(K mol), respectively. These values are in fair agreement with the K (2.31 l/mol), $-\Delta H$ (4.4 kcal/mol), and $-\Delta S$ (11.7 cal/(K mol))[11] for the pyridine–methanol system obtained by the IR spectral experiment. It is to be noted that these values of the pyridine–ethanol system are approximately equal to those of the benzopyranopyridine–ethanol system, although the values of K and $-\Delta H$ for the benzopyranopyridine–ethanol system are slightly larger than those of the pyridine–ethanol system. This is because the nitrogen atom of the benzopyranopyridine ring is activated by the adjacent alkyl and amino groups. In addition, as the π-conjugation of the benzopyranopyridine molecule is larger than that of the pyridine molecule, the hydrogen bond makes the benzopyranopyridine–ethanol system more stable than the pyridine–ethanol system.

This work was supported by grants from the Tokyo Denki University Research Fund. The authors would like to express their sincere thanks to Drs. Takeshi Oishi and Akio Sakurai of the Institute of Physical and Chemical Research for their kindness concerning the IR spectroscopic measurements.

Hydrogen Bond of 4-Amino-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one Derivatives with Alcohols. II. Theoretical Considerations

Kozo INUZUKA* and Akira FUJIMOTO

Department of Applied Science, Faculty of Technology, Tokyo Denki University, Kanda, Chiyoda-ku, Tokyo 101

(Received December 21, 1977)

In a previous paper the experimental considerations on the hydrogen bonding between benzopyranopyridine derivatives including related compounds (pyridine, coumarin, and aniline) and alcohols were made, and the thermodynamic constants for the formation of the hydrogen-bonded complexes were obtained from UV spectroscopic studies. In this paper the molecular orbital calculation by the CNDO/2 method was conducted to further clarify the experimental results. Several conclusions were drawn from the present calculation: (1) Benzopyranopyridine has an intramolecular hydrogen bond between its amino and carbonyl groups. (2) The hydrogen bond energy of 2-alkyl benzopyranopyridines with alcohol is larger than that of the 1-alkyl compounds. (3) Benzopyranopyridine has four positions for hydrogen bond formation with alcohol, that is, the ring nitrogen atom, the carbonyl group, the ring oxygen atom, and the amino group. The ring nitrogen atom gave rise to the largest hydrogen bond energy among the four positions. Therefore, the corresponding hydrogen-bonded complex plays an important role in the benzopyranopyridine–alcohol system. (4) The hydrogen bond energy depended on the charge density of the atom which gave rise to the hydrogen bond with alcohol. Especially, substitution of the electron donating group such as amino and methyl groups at the position which increases the charge density of the atom giving rise to a hydrogen bond with alcohol increases the hydrogen bond energy.

Recently, the CNDO/2 method developed by Pople *et al.*[1] has been applied to elucidate the enthalpy and equilibrium distance of hydrogen bond formation. These studies[2–6] look successful and are encouraging. In a previous paper[7] the hydrogen bond between 4-amino-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one (abbreviated to benzopyranopyridine) derivatives including related compounds (pyridine, coumarin, and aniline) and alcohols (methanol and ethanol) was discussed experimentally using the IR and UV spectral data.

In this paper the molecular orbital calculation by the CNDO/2 method was carried out to further clarify the experimental results and to compare the calculated results with the experimental ones.

Methods of Calculation and Molecular Models

The CNDO/2 method developed by Pople *et al.*[1] was used. The method has been described in detail in the literature.[1]

The molecule of benzopyranopyridine was assumed to be planar and the model substituted by a methyl group is shown in Fig. 1. The bond distance and bond angle of the molecular model used for the present calculation is as follows:

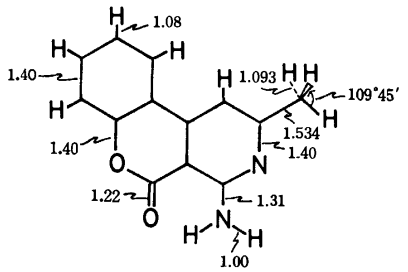

Fig. 1. A molecular model of methyl-substituted 4-amino-5*H*-[1]benzopyrano-[3,4-*c*]pyridin-5-one used for the present calculation.

Water:[8] O–H 0.9572 Å, ∠HOH 104.52°

Results and Discussion

Electronic Properties of Benzopyranopyridine Derivatives in the Ground State. The CNDO/2 method was applied to compounds **1** and **4** which correspond to the 1- and 2-methyl benzopyranopyridines and compound **7** which corresponds to the unsubstituted benzopyranopyridine in order to elucidate the total energies, dipole moments, π-bond orders of carbonyl groups, total charge densities, and π-charge densities. The calculated results are shown in Table 1 and Fig. 2. Methyl-substitution makes

Table 1. Total energies, dipole moments and π-bond orders of carbonyl group of 4-amino-1-methyl-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one (**1**), 4-amino-2-methyl-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one (**4**), and 4-amino-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one (**7**)

Compound	Total energy (a. u.) E_T	Dipole moment (D) μ	π-Bond order $P_{C=O}$
1	−160.1193	3.643	0.822
4	−160.1734	3.995	0.819
7	−151.4720	3.735	0.821

compound **4** more stable than compound **1** by 34 kcal/mol. The π-bond order of the carbonyl group of compound **1** is a little larger than that of compound **4**, but it is almost equal to that of compound **7**. These results suggest that the carbonyl stretching frequency of compound **1** may be a little higher than that of compound **4**, but it may be equal to that of compound **7**. The observed carbonyl stretching vibration of compound **1** appears at 1708 cm^{-1} in CCl_4 solution, but the corresponding one of compound **4** at 1706 cm^{-1}. The IR spectrum of compound **7**, however, is unavailable for comparison because the synthesis has not been successful. There is no difference in the carbonyl stretching

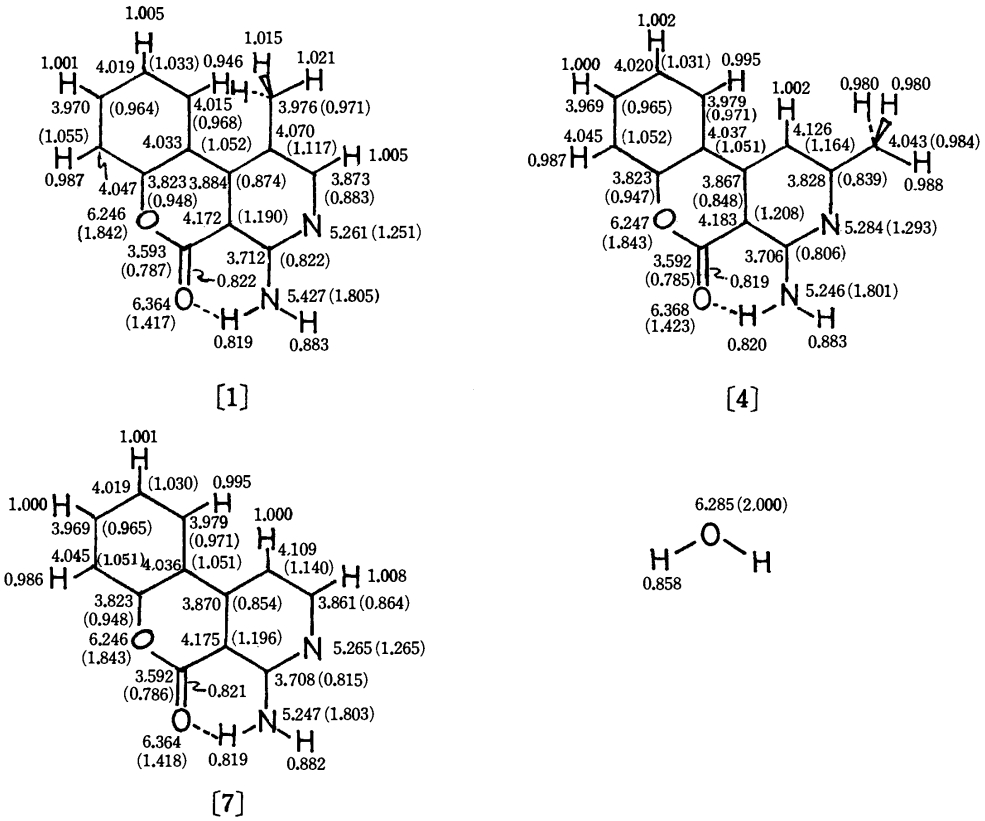

Fig. 2. Total charge densities and π-charge densities of **1**, **4**, **7**, and water.

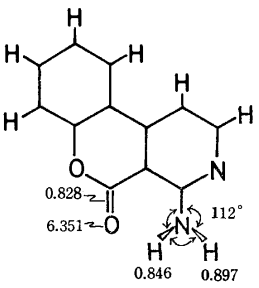
frequency of compounds **2**, **3**, **5**, and **6**[7] which have an alkyl group longer than the methyl group.

The calculated dipole moment of **1** is smaller than that of **4** but it is approximately equal to that of compound **7**. In Fig. 2 the effect of methyl substitution on the charge density of **7** is mainly limited to that of the pyridine ring. It is significant that the 2-methyl-substitution increases the charge density of the ring nitrogen atom while the 1-methyl-substitution decreases the charge density compared with that of **7**.

Intramolecular Hydrogen Bond. (i) The charge density on the two hydrogen atoms of the amino group of compounds **1**, **4**, and **7** are 0.882—0.883 and 0.819—0.820, respectively. The former values correspond to the charge density of the hydrogen atom adjacent to the ring nitrogen atom and the latter values to the hydrogen atom of the opposite side (Fig. 2). The charge densities of the hydrogen atoms of the amino group of 2-aminopyridine are 0.883 and 0.882, the former value corresponding to the values 0.882—0.883 of compounds **1**, **4**, and **7**, and the latter values to the values 0.819—0.820. The charge densities of the hydrogen atom near the ring nitrogen atom is almost equal in the four compounds, even if they are different in molecular structure. However, the charge density of the hydrogen atom of the opposite side is different in 2-aminopyridine and benzopyranopyridine derivatives. The large decrease in charge density from 0.882—0.883 to 0.819—0.820 may be attributed to the intramolecular hydrogen bonding between the carbonyl and amino groups, because the charge density of the hydrogen atom concerned with hydrogen bond formation decreases to a large extent due to the charge migration.

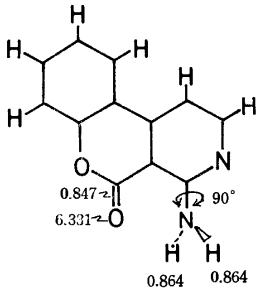
(ii) The carbonyl stretching vibration of the six benzopyranopyridine derivatives in a previous paper[7] appeared in the range of 1706 to 1711 cm^{-1}. The corresponding one of coumarin, which is split into two peaks shows a large difference appearing at 1757 and 1742 cm^{-1}. The large decreases in the carbonyl stretching frequencies of benzopyranopyridine derivatives may be largely attributed to intramolecular hydrogen bonding.

(iii) The two models **8** and **9** were used to investigate the effect of intramolecular hydrogen bonding in the charge densities of the oxygen atom of the carbonyl group and the hydrogen atoms of the amino group and on the π-bond order of the carbonyl group. Model **8** has a non-planar amino group with three valence angles of 112° with respect to the nitrogen atom. Model **9** has a planar amino group twisted by 90° about the C–N bond. If an intramolecular hydrogen bond exists between the oxygen atom of the carbonyl group and the hydrogen atom of the amino group, it may be weaker in **8** than in **7** but it may be broken in **9**. The values of the charge densities and π-bond order of the carbonyl group and the charge densities of the hydrogen atoms of the amino group are shown in the models **8** and **9** with the total energies. The model **8** is higher in energy than **7** with a planar amino group by 1.52 kcal/mol. The 2-aminopyridine with a non-planar amino group and three valence angles of 112° is more stable than that with a planar amino group by 4.22



−151.4718a.u.

[8]



−151.4369a.u.

[9]

kcal/mol. The charge density of the oxygen atom of the carbonyl group of **8** decreases more than that of **7**. At the same time the charge density of the hydrogen atom of the amino group of the **8** increases more than that of the **7**. These trends are more conspicuous in **9** than in **8**. Added to this the π-bond order of carbonyl groups increases in the order from **7** to **9**. These results suggest that an intramolecular hydrogen bond exists between the carbonyl and amino groups.

Intermolecular Hydrogen Bond. Benzopyranopyridine has four positions which give rise to the hydrogen bond with alcohol, that is, the ring nitrogen atom, the carbonyl group, the ring oxygen atom, and the amino group. Each of these charge densities of the atom in the four positions shown in Fig. 2 are almost equal to each other except for the ring nitrogen atom among the three compounds. The charge density on the ring nitrogen atom of compound **4** is larger than that of compounds **1** and **7**, but the charge densities of the ring nitrogen of the latter two compounds are approximately equal. From this result it may be expected that the hydrogen bond energy of compound **4** may be larger than that of compounds **1** and **7**, but approximately equal in **1** and **7**, if there is hydrogen bond formation between the ring nitrogen atom and alcohol. However, if hydrogen bonding between the remaining three positions and alcohol occurs, it is expected that there will be no interpretable differences in energy of the corresponding hydrogen bonds among the three compounds.

In order to calculate the four kinds of hydrogen bond energies for the benzopyranopyridine–alcohol system the following models were used as shown in Fig. 3. In order to simplify the present calculation a water molecule was used in place of alcohol, and the unsubstituted benzopyranopyridine used.

Model A: The equilibrium distance between the ring nitrogen atom and the hydrogen atom of water, 1.6 Å of model A corresponds to the value determined for the pyridine–water system. The two molecules lie in the same plane and the O–H bond of water lies along the n-orbital of the ring nitrogen atom.

Model B: The equilibrium distance between the oxygen atom of the carbonyl group and the hydrogen atom of water, 1.6 Å and bond angle between the carbonyl axis and hydroxyl bond, 60° were used for model B refering to the values determined for the *s-trans*-acrylaldehyde–water system. The equilibrium distance 1.6 Å and bond angle 60° correspond to the conformation with the maximum hydrogen bond energy.

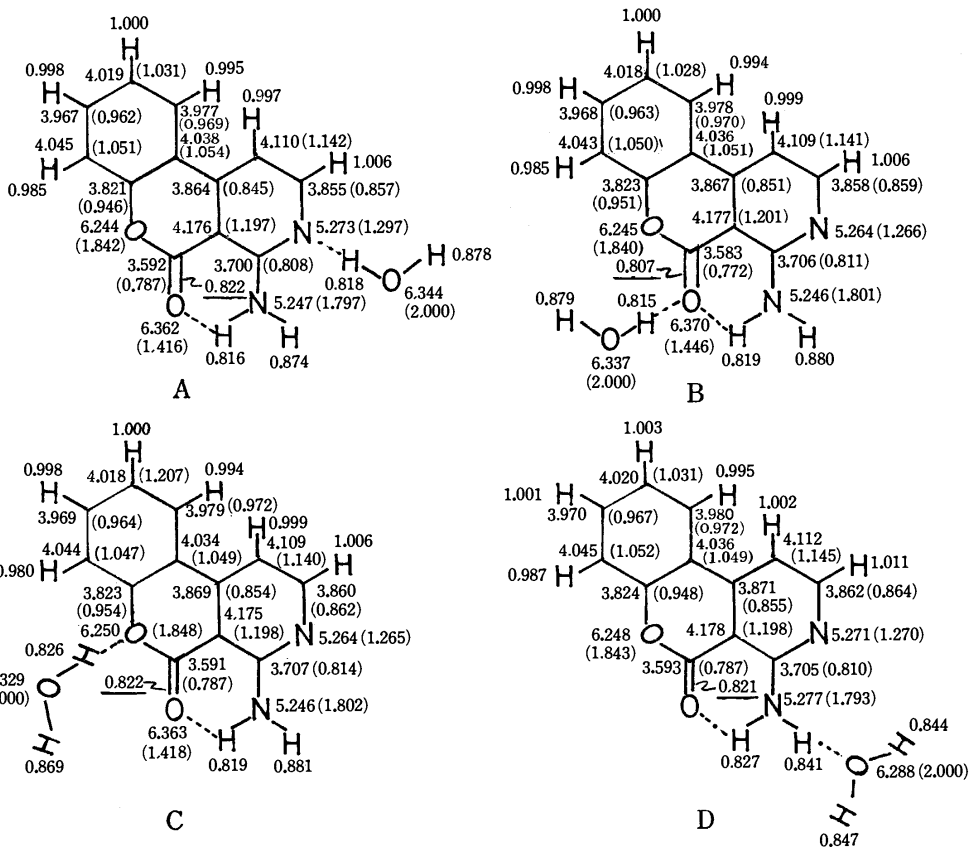


Fig. 3. Hydrogen-bonded complex models between **7** and water.

Model C: The two molecules were assumed to lie in the same plane refering to the calculated results of conformation of the hydrogen-bonded complex for the tetrahydrofuran (THF)–water and THF–methanol systems.[9] The equilibrium distance between the ring oxygen atom and the hydrogen atom of water, 1.6 Å which was determined for the coumarin–water system was used.

Model D: The equilibrium distance between the hydrogen atom of the amino group and the oxygen atom of water, 1.6 Å which was determined for the 2-aminopyridine–water system was used.

Table 2. Hydrogen bond energies, dipole moments and π-bond orders of carbonyl group of the hydrogen-bonded 1:1 complexes formed between 4-amino-5*H*-[1]benzopyrano[3,4-*c*]pyridin-5-one and water

Hydrogen-bonded complex	Hydrogen bond energy $-\Delta H$ (kcal/mol)	Hydrogen bond energy $-\Delta H_c$ (kcal/mol)	Dipole moment μ (D)	π-Bond order $P_{C=O}$
A	9.41	4.99	6.291	0.822
B	7.96	4.22	6.432	0.807
C	6.61	3.51	3.828	0.822
D	5.04	2.69	2.883	0.821

The calculated hydrogen bond energy, dipole moment, and π-bond order of the carbonyl group for the four models are listed in Table 2. The calculated hydrogen bond energies are larger than the observed energies in a previous paper.[7] The same methods was applied to the pyridine–methanol system to compare the calculated hydrogen bond energy with the observed value. The calculated value was 8.29 kcal/mol while the observed value was 4.4 kcal/mol.[10] The values $-\Delta H_c$ in Table 2 were corrected by multiplying by the factor 4.4/8.29 to the values $-\Delta H$ on the assumption that the same ratio applies to the present calculated and observed values. The corrected value $-\Delta H_c$ is better than the uncorrected value for a comparison with the observed value.

The calculated hydrogen bond energy of model A is the largest among the four models. The order of hydrogen bond energy from model A to D seems reasonable. The ratio of the models from A to D in equilibrium concentration at 300 K was evaluated by use of the values $-\Delta H_c$ assuming the Boltzmann distribution. The calculated ratio, A: B: C: D became 0.72: 0.20: 0.06: 0.02. These values suggest that the hydrogen bond such as model A is the most important one. The numerical values of the Boltzmann distribution ratio indicate the possibility of model B, however it is not significant. The hydrogen-bonded complexes such as models C and D may be negligible.

The observed average hydrogen bond energy for 1-alkyl benzopyranopyridines was about 4.6 kcal/mol, while that of 2-alkyl ones was about 5.1 kcal/mol. This indicates that the 2-alkyl substituted benzopyranopyridines are larger in hydrogen bond energy than the 1-alkyl compounds. The calculated value 4.99 kcal/mol may correspond to the observed value 4.6 kcal/mol for 1-alkyl benzopyranopyridines as discussed in the previous section. The hydrogen bond energy 3.8 kcal/mol, observed for the coumarin–ethanol system[7] was assigned to the energy of the hydrogen bond formation between the carbonyl group and alcohol from the IR spectrum, since coumarin showed a sharp carbonyl band split into two peaks located at 1757 and 1742 cm^{-1} in CCl_4 solution while a new band appeared at 1728 cm^{-1} by an addition of methanol to coumarin.[7] The observed value 3.8 kcal/mol corresponds well to the calculated value 4.22 kcal/mol for model B.

Experimentally, the presence of the hydrogen bond such as model A was confirmed by IR spectrum but the remaining species, like the models B, C, and D were not clearly determined.[7]

The calculation of π-bond order indicates that the hydrogen bond formation between carbonyl and hydroxyl groups gives rise to large decreases in the π-bond order of the carbonyl group in model B as shown in Table 2. This suggests that a large carbonyl frequency shift due to hydrogen bond formation may be expected. However, experimentally a small frequency shift (1—2 cm^{-1}) was observed in addition of methanol in large amounts. The small shift suggests that the intramolecular hydrogen bond disturbs the hydrogen bond formation. The formation of the hydrogen-bonded complex such as model B may be difficult because model B may correspond to the 1: 2 complex with respect to the carbonyl group. The entropy change $|-\Delta S|$ for the formation of the 1: 2 complex may become larger than that for the 1: 1 complex.

The calculated energy $-\Delta H_c$ for the coumarin–water hydrogen-bonded complex between the ring oxygen atom and hydroxyl group such as model C became 3.44 kcal/mol. If the observed value 3.8 kcal/mol for the coumarin–ethanol system is assigned to the energy value for the formation between the ring oxygen atom and alcohol, it is difficult to explain the large frequency shift in the carbonyl vibration, because the above coumarin-water model makes no change in the π-bond order of the carbonyl group.

The calculated hydrogen bond energy 2.69 kcal/mol for model D shows a good correspondence to the observed value 2.1 kcal/mol for the aniline–alcohol system where it is expected a hydrogen bond is formed between the amino group of aniline and ethanol.[7]

Charge Density Distribution in Hydrogen-Bonded Complex. In model A there are variations of the charge densities in the pyridine ring and water, in which the charge densities of the α- and γ-carbon atoms of the pyridine ring decrease but the charge density of the nitrogen atom increases. The charge density of water increases by 0.039. This increase denotes that the charge migration occurs from the proton acceptor to the donor. Locally, the charge variation occurs such as $\overset{-}{N}\cdots\overset{+}{H}\text{–}\overset{-}{O}$ on the atoms of the hydrogen bridge. In model B the large charge density variation occurs mainly in the carbonyl group and in water. In model B also the charge density increases in water by 0.031 the same as in model A. In model C the charge density increases in water by 0.023 and in model D it decreases by 0.021 and the charge migration occurs from water to benzo-

pyranopyridine. In models A to C the amount of the charge migration is proportional to the hydrogen bond energy, while in model D the direction of the charge migration is reverse to that of the other three models.

This work was supported by grants from the Tokyo Denki University (T. D. U.) Research Fund. The authors especially wish to acknowledge the assistance of the staffs of the T. D. U. Computing Center in the present work.

Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812

(Received January 27, 1978)

Liquid membrane electrodes selective to alkyl sulfate ions were devised for octyl, decyl, and dodecyl sulfate ions, and employed in the study of micellar solutions. A nitrobenzene solution of hexadecyltrimethylammonium–alkyl sulfate complex was used as the liquid membrane. The membrane potential-logarithmic concentration showed a maximum at the critical micelle concentration (CMC), an increase with the Nernstian slope at the lower concentrations and a decrease at the higher concentrations. Below CMC, the presence of excess inorganic salt did not alter the Nernstian slope, *i.e.*, the liquid membrane was more highly permselective to alkyl sulfate ions than to inorganic anions. From a simple thermodynamic consideration of a micellar solution based on the pseudo phase model of the micelle, the change in the activity of alkyl sulfate ions and the dissociation of the micelle were discussed. It has been deduced that the concentration of the singly dispersed surfactant ions above CMC is reduced with concentration, except for the presence of a large excess of added electrolyte, and that the degree of dissociation of the micelle is unaltered even when the excess electrolyte is added.

The surfactant ion activity in surfactant solutions has been studied by using solid exchange membranes, including the cation-selective glass electrode.[1–6] Botré *et al.*[1] used the solid ion exchange membranes of both negative and positive types and evaluated the degree of association of the counterions with micelles in aqueous solutions of sodium laurate and dodecylamine hydrochloride. Satake *et al.*[2] used the sodium glass electrode for estimating the degree of association of Na ions in the micelles of sodium alkyl sulfates. Further, Sasaki *et al.*[3] determined the mean activity of sodium dodecyl sulfate in aqueous solutions by using both the sodium ion response glass electrode and the solid anion exchange membrane.

On the other hand, only a few studies[7–9] have been performed with a liquid membrane electrode with a response only for surfactant ions, although various ion-selective electrodes using liquid membranes have recently been devised.[10–13] By virtue of the response only for a particular ion, the use of the liquid membrane would be superior to the solid ion exchange membrane in the study of surfactant solutions. In this respect, new information can be obtained by applying the surfactant ion selective liquid membrane to the study of micellar solutions.

This paper is concerned with the study of the selective permeability coefficient of various surfactant ions as well as the states of surfactant ions in the solution.

Experimental

Materials. The surfactants used were sodium alkyl sulfate (SAS) with chain length C_8 to C_{12}, *i.e.*, sodium octyl sulfate (SOS), sodium decyl sulfate (SDeS), and sodium dodecyl sulfate (SDS). The purified alcohol was obtained by fractional distillation and sulfated with chlorosulfuric acid, then neutralized with sodium hydroxide solution and recrystallized from ethanol. The crystalline sodium alkyl sulfate was finally purified by the solvent extraction with diethyl ether for 48 h. The purity of specimen was confirmed by the absence of a minimum in the surface tension *vs.* concentration curve. Hexadecyltrimethylammonium bromide (HTAB) of guaranteed grade was used after recrystallization from redistilled water. The membrane material, hexadecyltrimethylammonium–alkyl sulfate complex (HTA–AS), was prepared by mixing HTAB solution with SAS solution and washing the precipitate with distilled water. The nitrobenzene solution of HTA–AS was used as the liquid membrane which is denoted as the AS membrane. All the other reagents were of guaranteed grade and used without further purification.

Membrane Potential Measurement. An Orion model 801A digital ion analyzer was used for measuring the membrane potential of the following concentration cell:

$$\begin{array}{l}\text{Calomel}\,\|\,\text{Satd } NH_4Cl\text{ Agar}\,\|\,10^{-3}\text{ mol dm}^{-3}\text{ SAS Ref. Soln}\,\|\\ 10^{-4}\text{ mol dm}^{-3}\text{ HTA–AS in Nitrobenzene}\,\|\,\text{SAS Soln with varying Concn}\,\|\\ \text{Satd } NH_4Cl\text{ Agar}\,\|\,\text{Calomel}\end{array} \quad \text{(A)}$$

where the left half cell including the AS membrane may be termed the AS ion selective electrode. For the study of the selectivity of some inorganic and alkyl sulfates (AS) ions to the dodecyl sulfate (DS) ion electrode, the following cell was used:

$$\begin{array}{l}10^{-3}\text{ mol dm}^{-3}\text{ SDS Ref. Soln}\,\|\,10^{-4}\text{ mol dm}^{-3}\text{ HTA–DS in Nitrobenzene}\,\|\\ 10^{-3}\text{ mol dm}^{-3}\text{ SAS or}\\ 10^{-3}\text{ mol dm}^{-3}\text{ Inorganic Anion}\end{array} \quad \text{(B)}$$

For the study of the effect of electrolyte, a constant concentration of NaCl was added to the test solution with varying concentrations of surfactant. The potential reached a steady value (± 0.2 mV) within 10 min. The measurements were carried out at 25.0 ± 0.1 °C.

Results and Discussion

In Fig. 1, typical response curves for the AS electrodes are shown for SOS, SDeS, and SDS. The kink point in the response curve agreed with the values of CMC in the literature.[14] The values of CMC observed were: SDS, 8.0×10^{-3} mol dm^{-3}; SDeS, 3.3×10^{-2} mol dm^{-3}; SOS, 1.2×10^{-1} mol dm^{-3}. Below CMC, the membrane potential V obeyed the Nernst equation,

$$V = \frac{RT}{F} \ln \frac{C_{AS}}{C_{AS}^{\circ}}, \quad (1)$$

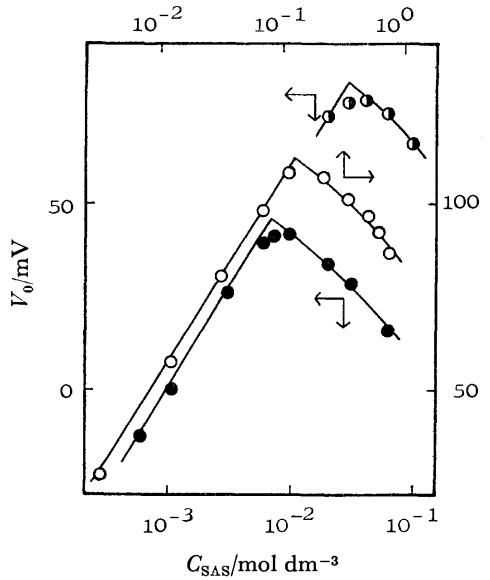

Fig. 1. Response curves of HTA–DS and HTA–DeS and HTA–OS liquid membrane for SDS, SDeS, and SOS solutions with 10^{-3} mol dm^{-3} SDS, SDeS, and SOS reference solutions, respectively.
●: SDS, ◑: SDeS, ○: SOS.

where $C_{AS}°$ and C_{AS} denote the concentration of AS ion in the reference solution and the test solution, respectively. This indicates that the AS electrode is ideally permselective to AS ions and the change in the activity coefficient of AS ions as well as the interference by Na ions may be ignored. Above CMC, the decrease in the potential with increasing SAS concentration, an indicative of the decrease in the apparent surfactant ion activity, was observed.

The selectivities of some inorganic and alkyl sulfate ions to the DS electrode were examined by using the cell systems (B). The selectivity was calculated according to the following equation for the membrane potential V:

$$V = \frac{RT}{F} \ln K^{pot.}_{DS,X} \frac{a_X}{a_{DS}}, \qquad (2)$$

where a_X and a_{DS} denote the activity of X ion and that of DS ion, respectively, and $K^{pot.}_{DS,X}$, the selectivity of X ion to DS ion. In estimating the selectivities, the activity coefficients were assumed to be unity, since the concentrations of sodium alkyl sulfates and inorganic salts were low. The selectivities are summarized in Table 1. It is seen in Table 1 that chloride and bromide ions hardly interfere with the response of the DS electrode to DS ions. On the other hand, the responses of the DS electrode to perchlorate and thiocyanate ions are more or less greater than those to halide anions. Thus, these inorganic anions may interfere with DS ions in the response to the DS electrode. It is known that the perchlorate and thiocyanate ions dissolve considerably in the organic solvent.[15] This may be responsible for the higher selectivities of these inorganic ions, since the selectivity is given by the product of the ratio of transport coefficients and that of partition coefficients. The selective permeability coefficients of the homologous alkyl sulfate ions increased by a factor of about 10 with the increase in alkyl chain length by two methylene groups.

Table 1. Selective permeability coefficients

Examined salt	$K^{pot.}_{DS,J}$
STS(C_{14})	10
SDS(C_{12})	1
SDeS(C_{10})	2.8×10^{-1}
SOS(C_8)	1.2×10^{-2}
$NaClO_4$	4.4×10^{-2}
KSCN	2.8×10^{-2}
KBr	1.1×10^{-3}
NaCl	6.0×10^{-4}

This agrees with the Traube rule and reflects the greater partition coefficient of a surfactant of longer chain length in the organic solvent. The longer the chain length, the greater the selectivity; thus tetradecyl sulfate (TS) ion, which has more carbon atoms than DS ion, exhibited greater response to the DS electrode, as shown in Table 1.

The selective permeability coefficient of Cl ion is of the order of 10^{-4}. This implies that even though Cl ions coexist in the test solutions of cell system (B), there would be little influence on the response of the AS electrode to AS ions. Thus, using the cell system (B), the study of the effect of added electrolytes in aqueous SAS solutions was performed. In Figs. 2 to 4, the response curves for SAS solutions in the presence of 0.1 and 0.01 mol dm^{-3} NaCl are shown together with those for the salt-free systems. For all the cases of the surfactants with alkyl chain length from C_8 to C_{12}, CMC of each surfactant solution in the presence of NaCl agreed well with that in the literature.[14] It is also shown in these figures that the presence of inorganic salt more or less decreased the membrane potential below CMC. Furthermore, the longer the chain length, the greater the decrease in the potential. This tendency was also enhanced as the added amount of electrolytes increased. This may reflect a decrease in the activity

of surfactant ion caused by the added electrolyte. Mukerjee *et al.*[16,17] suggested the existence of a detergent dimer below CMC, on the basis of conductivity measurements of the SDS solution. In the present study, however, there was no sign of the dimerization of surfactant ions, because the concentration dependence of the membrane potential possessed the Nernstian slopes. The potential equation may be given by

$$V = \frac{RT}{F} \ln \frac{a_{AS}}{a_{AS}^{\circ}}, \quad (3)$$

where a_{AS} denotes the activity of AS ions in the presence of NaCl, and a_{AS}°, the activity of AS ions in the 10^{-3} mol dm^{-3} SAS solution without added electrolyte. Equation 3 becomes

$$V = \frac{RT}{F} \ln \frac{C_{AS}}{C_{AS}^{\circ}} + \frac{RT}{F} \ln \frac{\gamma_{AS}}{\gamma_{AS}^{\circ}}, \quad (4)$$

where γ_{AS} and γ_{AS}° denote the activity coefficients of AS ions in the presence and the absence of NaCl, respectively. Thus, the decrement due to the added electrolyte may be ascribed to the decrease in the activity coefficient of AS ions caused by the added electrolyte. Since the Nernstian slope was unaltered even in the presence of the added electrolyte, the AS electrode may be regarded as ideally permselective to singly dispersed AS ions. In the absence of electrolyte, Eq. 4 is reduced to Eq. 1.

Above CMC, a decrease of the membrane potential was observed; this tendency was accelerated by increasing the amount of the added electrolyte or the chain length. These phenomena may be attributed to the change in the activity of surfactant ions.

The chemical potential of the surfactants in the bulk phase μ_b and that, μ_m, in the micellar phase are described as follows:

$$\mu_b = \mu_b^{\circ} + RT \ln a_{Na} a_{AS}, \quad \mu_m = \mu_m^{\circ} + RT \ln a_m, \quad (5)$$

where a_{AS}, a_{Na}, and a_m denote the activity of the surfactant ion, Na ion, and NaAS in the micelle, respectively; μ_b° and μ_m° are the standard chemical potential for the dissociated surfactant and the micelle. Taking the micelle as a pseudo phase, the activity of the micelle may be set at unity. Since the singly dispersed surfactants are equilibrated with the micelles, we have from Eq. 5,[18,19]

$$a_{Na} a_{AS} = \text{const.} \quad (6)$$

We may conclude that the response of the AS electrode to the micellar AS ions can be ignored, since the potentials never increase with surfactant concentrations. The potential should increase if the AS electrode responds to the micellar AS ions. The fact that the potential is kept constant in the large excess of added electrolyte, as shown in Figs. 2 and 3, supports this view.

Below CMC, the activity coefficient of AS ions may be regarded as a constant. Thus, the potential decrease above CMC implies the decrease in the concentration of singly dispersed surfactant ion providing that the activity coefficient does not change appreciably above CMC. On the other hand, since the potential remains constant in the presence of a large excess of electrolyte, a_{AS} as well as C_{AS} remains constant in this region. This can be deduced from Eq. 6, *i.e.*, in the presence of a large excess of electrolyte, a_{Na} may be regarded as a constant and hence a_{AS} becomes constant. Furthermore the activity coefficient of singly dispersed surfactant ions may be regarded as a constant due to the large excess of inorganic electrolyte, and thus C_{AS} might be constant. These conclusions agree with those obtained by Sasaki *et al.*[3,4] from the gel filtration data.

It is usually assumed that above CMC the concentration of singly dispersed surfactant ions is kept constant even though the total analytical concentration of surfactant increases. This hypothesis should be true only in the presence of a large excess of added electrolyte.

On the other hand, the activity of Na ions in the bulk phase may be expressed by

$$a_{Na} = \gamma_{Na}[C_S + C_{AS} + \alpha(C - C_{AS})], \quad (7)$$

where C_S, C_{AS}, and C denote the concentration of the added NaCl, that of the singly dispersed surfactant ions, and the total analytical concentration of surfactant, respectively; γ_{Na} is the activity coefficient of Na ions, and α, the degree of dissociation of the micelle. A similar relation is proposed by Botré *et al.*,[1] for a system with no added salt. Subtracting the potential at CMC, V^*, from V by the use of Eq. 3, we have

$$V - V^* = \frac{RT}{F} \ln \frac{a_{AS}}{a_{AS}^*}, \quad (8)$$

where the asterisk refers to CMC.

Comparing this with Eq. 6, we obtain

$$V - V^* = \frac{RT}{F} \ln \frac{a_{Na}^*}{a_{Na}}. \quad (9)$$

Assuming that γ_{Na} does not change appreciably above CMC, we have, from Eqs. 7 and 9,

$$V - V^* = \frac{RT}{F} \ln \frac{C_S + C_{AS}^*}{C_S + C_{AS} + \alpha(C - C_{AS})}, \quad (10)$$

where C_{AS}^* denotes CMC.

In the presence of a large excess of added salt, C_{AS}^*, C_{AS}, and $(C - C_{AS})$ can be ignored as compared with C_S, and thus $V = V^*$, which agrees with the experimental results.

TABLE 2. DEGREE OF DISSOCIATION OF MICELLE CALCULATED ACCORDING TO Eqs. 8 AND 10

SAS	SDS	SDeS	SOS
α	0.20	0.23	0.27

For other cases, the potential decreases with concentration above CMC. As pointed out previously, C_{AS} can be evaluated according to Eq. 8, if γ_{AS} is assumed to be constant. Table 2 shows the values of α calculated according to Eqs. 8 and 10 by assuming a constant activity coefficient of AS ions. This table indicates that the value of α is approximately constant for a given surfactant. This coincides with the additivity rule for the counterions of the polyelectrolyte in the presence of added electrolyte.[20]

Theoretical Studies on the Electronic Structure of the H_2S Anion Radical

Shinichi NAGATA,*,† Tokio YAMABE, and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 604

(Received February 23, 1978)

The electronic structure of the H_2S anion radical has been investigated by means of the non-empirical unrestricted Hartree-Fock method. The most stable conformation of this radical has been obtained at bond length R(S–H) = 1.550 Å and bond angle θ (<HSH) = 160°. These values are relatively larger in comparison with observed values of the neutral molecule (R = 1.335 Å and θ = 92.2°). ESR hyperfine coupling constants and excitation energies have also been examined through analyses of the electronic structure of the most stable conformation of this radical. Furthermore, the dissociation process, $H_2S \rightarrow H_2 + S^-$ or $HS^- + H$, has been discussed.

There have been a number of studies on the electronic structure of sulfur compounds from both theoretical and experimental aspects.[1] Most of the theoretical investigations on simple molecules such as H_2S have been done employing the *ab initio* SCF method and discussed the role of the vacant 3d-orbitals of sulfur.[2] Previous studies[2] seem to have led to the conclusion that the 3d-orbitals of sulfur with normal valences do not greatly contribute to the molecular properties in the ground state. This has, however, led to an improvement in the quality of the calculation. Recently, Schwenzer and Schaefer[3] also came to similar conclusions for the ground electronic state of the hypervalent molecules, SH_4 and SH_6, although they pointed out that the contribution of the 3d-orbitals is larger for SH_6 and SH_4 than SH_2. However, the contribution of the 3d-orbitals cannot be neglected in the ground state as well as the excited one as indicated from the theoretical studies of Hillier *et al.*[2b] and Bendazzoli *et al.*[2c]

Experimental studies on the H_2S anion radical have been few compared to H_2S or H_2S^+,[4] since it is difficult to produce the H_2S anion radical. For example, the radiation method[5] showed that H_2S reacts with an e^- at a higher rate ($k = 1.35 \times 10^{10}\ M^{-1}\ s^{-1}$) and produces predominantly H and HS^- with minor fractions H_2 and S^-. In 1966, Bennett *et al.*[6] reported the ESR spectrum of the H_2S anion radical in the reaction between an alkali-metal atom and H_2S or D_2S at 77 K. Theoretical studies on the H_2S anion radical followed: Cook *et al.*[7] performed the non-empirical calculation using the mixed basis method with d-orbitals and found poor agreement between the theoretical and experimental values of ESR hyperfine coupling constants of sulfur nuclei. Claxton *et al.*[8] carried out the *ab initio* UHF calculation on the same molecule with minimal Gaussian basis set and expressed considerable doubt on the interpretation of the ESR spectrum assigned to the H_2S anion radical by Bennett *et al.*[6] An inexplicable discrepancy between their calculation[8] and Cook's result[7] was reported.

In the present paper, the *ab initio* UHF calculation on the H_2S anion radical has been performed in the LCAO MO approximation with spin annihilation to obtain the pure doublet spin state. SCF atomic orbitals used for this calculation are the minimal basis set of Csizmadia *et al.*,[9] minimal STO-3G basis,[10] and larger basis of "double ζ" quality (4-31 G).[11] The primary purposes of this work are (1) to determine the stable conformation of the H_2S anion radical in both the $^2B_2$ and the $^2A_1$ states, taking the correlation of the Walsh diagram into consideration; (2) to calculate and examine the molecular properties of ESR hyperfine coupling constants and excitation energies; (3) to investigate the formation of solvated electrons in the system of H_2S and electrons as experimentally observed in H_2O, or the dissociation towards $H + HS^-$ or $H_2 + S^-$ of the H_2S anion radical.

Method of Calculation

The UHF calculations have been performed based on the minimal Gaussian-type orbitals (MGTO) by Csizmadia *et al.*,[9] STO-3G,[10] and 4-31 G[11] basis sets. The exponent values of the STO's, ζ, are the same as reported previously.[9,10] In the STO-3G expansion, the values of the exponents (α_m) and coefficients (d_m) of the GTO's were taken from Stewart[12] ($\chi_r = \mathrm{STO}(\zeta) = \sum_{m=1} d_m\ \mathrm{GTO}(\alpha_m)$). For the 4-31 G basis set the bases for the valence shells were split into inner and outer parts over the smaller minimal set, and the standard scale factors presented by Hehre *et al.*[11] were used. Consideration of the total energies, orbital energies, charge densities, and spin densities was made with the results obtained after the single annihilation.[13]

Excitation energies of the H_2S anion radical were calculated from the following equations[14] using values of ε, J, and K obtained from the calculation of H_2S equivalent with the geometry of the H_2S anion radical:

$$\Delta E_{p\to k} = \varepsilon_k - \varepsilon_p,$$

$$\Delta E_{i\to p} = \varepsilon_p - \varepsilon_i - 2J_{pi} + K_{pi} + J_{pp},$$

$$\Delta E_{i\to k}(1) = \varepsilon_k - \varepsilon_i - (J_{pi} - K_{pi}/2) - (J_{ki} - 2K_{ki}) + (J_{pk} - K_{pk}/2),$$

$$\Delta E_{i\to k}(2) = \varepsilon_k - \varepsilon_i - (J_{pi} - K_{pi}/2) - J_{ki} + (J_{kp} + K_{kp}/2),$$

where, i, p, and k denote the doubly occupied, singly occupied, and virtual orbitals, respectively.

Results and Discussion

(1) The calculations of the H_2S anion radical were performed with MGTO,[9] STO-3G,[10] and 4-31 G[11] basis sets, varying the angle θ (<HSH) from 92.2

† Present address: Research Institute of Marine Cargo Transportation, Kobe University of Mercantile Marine, Higashinada-ku, Kobe 658.

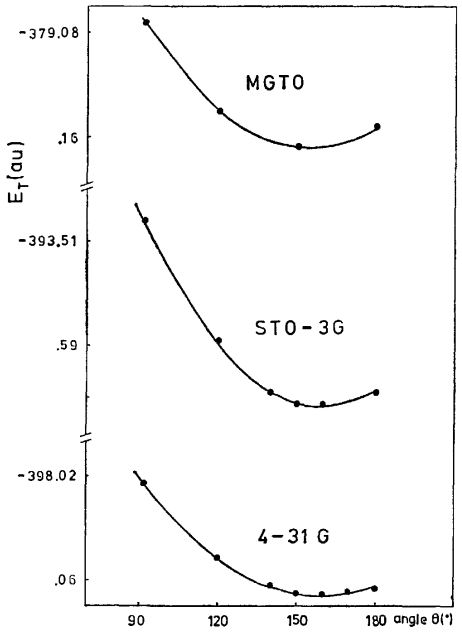

Fig. 1. Total energies of H_2S anion radical, with the angle variation, calculated by MGTO, STO-3G, and 4-31 G basis.

(experimentally determined for H_2S)[15] to 180°, fixing the bond distance at 1.335 Å.[15] The results obtained are shown in Fig. 1, and demonstrate the superiority of the STO-3G and 4-31 G basis sets in comparison with the MGTO basis. Consequently the results obtained from the STO-3G and 4-31G basis will be discussed later. It is worth noting that the H_2S anion radical is most stable at $\theta=160°$ in these basis sets. Here, it should be remembered that the calculations of this anion radical reported previously[7,8] were conducted using the same geometry as H_2S (92.2°).

The ground and lowest excited states of the H_2S anion radical are the $^2B_2$ and $^2A_1$ states, respectively. The $^2B_2$ and $^2A_1$ states are equivalent with the entrance of one electron into the $3b_2$ orbital (lowest unoccupied

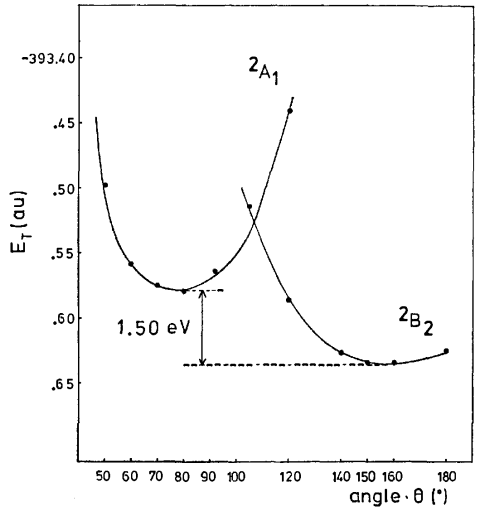

Fig. 2. Total energies of $^2B_2$ and $^2A_1$ states with the variation of angle θ.

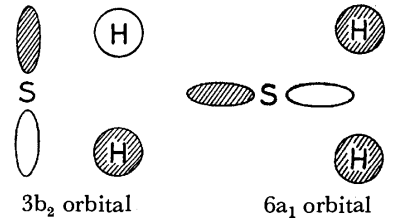

Fig. 3. Orbital shapes of $3b_2$ and $6a_1$ orbitals of H_2S molecule (angle θ(<HSH)=92.2°).

molecular orbital (LUMO)) and the $6a_1$ orbital (LUMO +1), respectively. Energy changes for both states as a function of the angle θ are shown in Fig. 2, which were obtained from the calculation of STO-3G basis. The $^2B_2$ state is energetically more stable compared to the $^2A_1$ state by 1.50 eV. Interestingly, the angle θ has become larger for the former and smaller for the latter than that of the H_2S molecule (92.2°). Examination of the extension of $3b_2$ and $6a_1$ orbitals and the relationship of the chemical bonds of H_2S (see Fig. 3) showed that the $3b_2$ and $6a_1$ orbitals are antisymmetric and symmetric on the lane bisecting the angle θ (<HSH), respectively. Accordingly excess electrons of H_2S^- entering into the $3b_2$ and $6a_1$ orbitals may decrease the electronic repulsion between the hydrogen atoms and form a bond between them, respectively. Such considerations are consistent with the calculated results of the most stable conformation of $^2B_2$ and $^2A_1$ states of the H_2S anion radical.

It is interesting and important to consider the correlation between the total energies and orbital energies from the Walsh diagram[16] of both states. Figure 4 shows the one-electron orbital energy changes of H_2S as a function of the angle θ. This figure demonstrates that the electron occupancy into the $3b_2$ orbital makes the angle θ larger, while in the case of the $6a_1$ orbital the reverse is indicated, *i.e.*, the angle θ becomes smaller. The present qualitative consideration is in good agree-

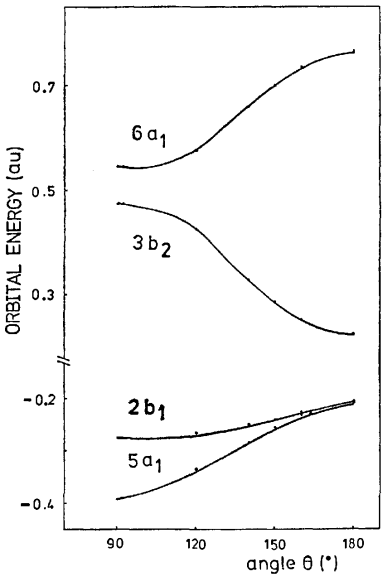

Fig. 4. Orbital energy diagram of H_2S from 90 to 180° calculated by STO-3G basis set.

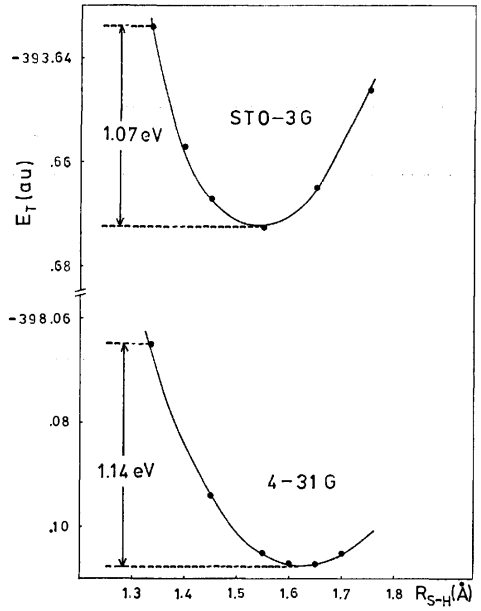

Fig. 5. Total energies of H_2S anion radical (angle θ(<HSH)=160°) with the variation of R(S–H).

ment with the changes of total energies (Fig. 2) and also appears to be interpretable for the H_2S cation radical which has been treated in a previous paper,[4] that is, the $^2B_1$ and $^2A_1$ states of the H_2S cation radical are most stable for θ=92.9 and 127° in accord with the observed values obtained from the emission spectra,[17] respectively.

Subsequently the changes in the total energy of the H_2S anion radical for the variation of R(S–H) were examined, since the excess electron on H_2S may lead to molecular deformation caused by decreasing the electronic repulsion between hydrogen and hydrogen or sulfur atoms. As expected, Fig. 5 clearly shows the minimum energy of the anion radical at R(S–H)=1.650 Å from the calculation of 4-31 G basis and 1.550 Å from STO-3G basis, respectively. Namely, the total energy decreases *ca.* 1.14 and 1.07 eV by the lengthening of the S–H bond, 0.315 and 0.215 Å, in comparison with R(S–H)=1.335 Å of H_2S, respectively.

Table 1. Calculated hyperfine coupling constants (G) of H_2S anion radical (angle (<HSH)=160°) by STO-3G and 4-31 G basis

	STO-3G	4-31 G	Exptl[a]
a_H	187.27	327.60	±7.7±0.3
a_S	159.35	−207.24	±60.0±2.0

a) Ref. 6.

(II) The molecular properties of ESR hyperfine coupling constants (a_H and a_S) of the H_2S anion radical are given in Table 1 which represents the calculated hyperfine coupling constants by both basis sets, where the following results for both a_H and a_S are indicated, *i.e.*, the calculated values are far larger than observed ones. This discrepancy between theory and experiment may be the same as that pointed out in the previous studies.[7,8] The authors obtained good agreement with the experimental values (a_H) for the H_2S cation radical[4] by the use of the same basis set as the present one. Furthermore, Claxton *et al.*[8] were also successful in the calculation of hyperfine coupling constants on many kinds of radicals except for the H_2S anion radical. Taking these results into consideration, the authors have joined Symons[18] and Claxton *et al.* in entertaining considerable doubt on the interpretation of the ESR spectrum assigned to the H_2S anion radical. This discussion will be made in a later section.

Table 2. Calculated excitation enegies (eV) of H_2S anion radical (angle θ (<HSH)=160°) by STO-3G and 4-31 G basis sets

	STO-3G	4-31 G	Exptl[a]
$\Delta E(9\rightarrow10)$[b]	6.28	1.79	1.22—1.77
$\Delta E(8\rightarrow10)$	7.81	2.81	3.10
$\Delta E(10\rightarrow11)$	11.24	9.14	
$\Delta E(9\rightarrow11)^{(1)}$	14.69	8.05	
$\Delta E(9\rightarrow11)^{(2)}$	17.68	10.52	

a) Ref. 6. b) 9, 10, and 11 denote the highest occupied, singly occupied, and lowest unoccupied molecular orbitals of H_2S anion radical, respectively.

An attempt was made to calculate the excitation energies of the H_2S anion radical, with reference to the experiments of Bennett *et al.*,[6] the details of which are given in the preceding section. The results calculated by using both basis sets are tabulated in Table 2. The absorption band found experimentally[6] at 1.22—1.77 eV may be assigned to the $2b_1\rightarrow3b_2$ transition, *i.e.*, from the lone pair electrons of sulfur to the anti-bonding orbital of the S–H bond. Such a large red shift of this band compared to H_2S is due to the fact that the σ^*_{S-H} orbital lowers, to a large extent, by the presence of an excess electron. The next band at 3.10 eV may be assigned to the $5a_1\rightarrow3b_2$ transition, that is, from the σ_{S-H} orbital to the σ^*_{S-H} one. Similarly, the red shift of this band compared to that of H_2S may be ascribed to the lowering of the σ^*_{S-H} orbital as mentioned above. Since the intensity of these absorption bands has not been experimentally determined as yet, there is no alternative except to discuss in terms of the excitation energy. In the present calculation, the $2b_1\rightarrow3b_2$ transition is theoretically forbidden (f=0.0). On the contrary, the intensity of the $5a_1\rightarrow3b_2$ band is considerably large (f=0.117, calculated) because of the symmetry allowance between both states. The excitation energies calculated by the 4-31 G basis were in good accordance with the experimental ones,[6] but those of STO-3G basis are somewhat larger, which is mainly due to the higher-energy location of virtual orbitals obtained from this basis.

(III) In the preceding section, the electronic structures and molecular properties of the H_2S anion radical were discussed. It is interesting to consider this anion radical as a reaction product of H_2S+e^- and the starting molecule for dissociation into $H+HS^-$. At the outset, it is supposed that the electron outside H_2S is describable by placing the diffuse s-type orbital outside

TABLE 3. CALCULATED HYPERFINE COUPLING CONSTANTS (G) AND CHARGE DENSITIES OF H_2S ANION RADICAL (angle θ ($<$HSH)=160 AND 92.2°) WITH OUTER 2s-TYPE ORBITAL ($\xi_{2s}=0.1$)[a]

a) Calculations were carried out using STO-3G basis set. b) Between sulfur atom of H_2S and diffuse 2s-type orbital on the line bisecting the angle θ($<$HSH).

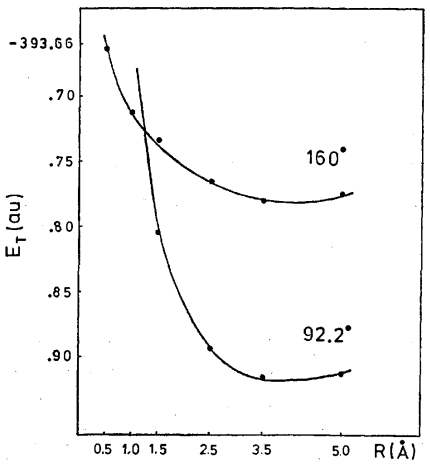

Fig. 6. Total energies of H_2S anion radical (angle θ($<$HSH)=92.2 and 160°) in the condition of locating the diffuse 2s-type orbital.

t, that is, on the bisector of the angle θ and the opposite side of the pσ orbital of sulfur on the H_2S plane. The calculated results for two kinds of angle ($<$HSH), 92.2 and 160°, are shown in Fig. 6 and Table 3, which were obtained from the calculation consisting of both STO-3G basis and diffuse 2s type orbital. From these, it can be rationalized that the H_2S+e^- system is impelled to destabilize as the e^- approaches H_2S. At the same time, one can easily recognize that in the distant region (>1.5 Å) between H_2S and e^- this system retains the original form of H_2S (92.2°) and separated electron, but that the approach of the e^- to H_2S in the region less than 1.5 Å tends to make the angle θ open (see the point of intersection of Fig. 6). As a consequence, the H_2S+e^- system is inclined to form the H_2S anion radical in the region less than 1.5 Å. Such a tendency may also be explained from the change of charge densities on the outer orbital (Table 3), *i.e.*, the excess electron of the H_2S anion radical may be regarded as flowing into the diffuse orbital placed outside the region over 1.5 Å, and delocalizing by the orbital hybridization in the region less than 1.5 Å, respectively.

Here, it should be remembered that the minimum energy was found at *ca.* 4 Å in both cases of 92.2 and 160°, implying that the H_2S anion radical is highly reactive and that H_2S forms a kind of solvated electron in this region as observed in the case of H_2O.[5] Hyperfine coupling constants and charge densities calculated by the addition of outer orbitals are given in Table 3, from which the remarkable decrement of a_H and a_S values with the separation of e^- are seen. The hyperfine coupling constants of H_2S anion radical are far larger than the experimental ones[6] and hence the possibility of the formation of a solvated electron or trapped electron for the H_2S+e^- system cannot be neglected.

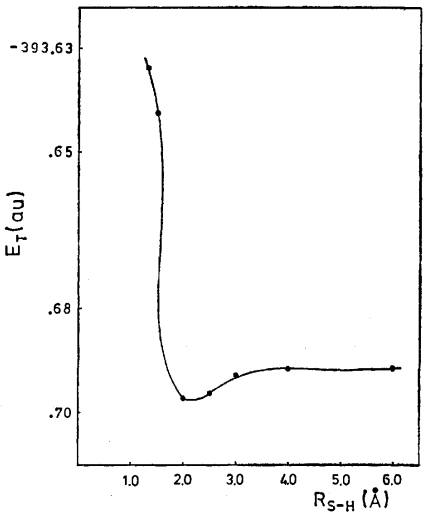

Fig. 7. Total energies accompanied with the dissociation reaction of $H_2S^- \rightarrow HS^- + H$.

Finally the dissociation process of the H_2S anion radical to HS^-+H will be discussed. Figure 7 suggests that the H_2S anion radical tends to separate such as HS^-+H through weak bonding at R(S–H)=2.2 Å.[20] Taking these results into account, the process may be as follows; the separated system of H_2S+e^-, which is originally stable, begins to interact to form a quasi-stable anion radical which dissociates into $H+HS^-$, probably because of an excess electron entered into the antibonding orbital of the S–H bond of the b_2 symmetry. The process leading to the formation of H_2+S^- may be explained in terms of the dissociation through the $^2A_1$ state due to an excess electron in the $6a_1$ orbital, since the bonding nature between the hydrogen atoms is indicated from the analysis of the charge density contour maps.

Conclusion

The present calculation on the H_2S anion radical indicates that the most stable conformation is the $^2B_2$ state with $\theta=160°$ and that the bond length of R(S–H) increases a little compared with that of H_2S. These results on the bond angle and bond length seem to be reasonable from the Walsh diagram and chemical reasoning. The H_2S anion radical itself, however, is very unstable and tends to dissociate as discussed. Consequently, more accurate experiments will make more detailed discussion on the H_2S anion radical possible, as Bennett *et al.*[6] obtained the ESR spectrum assigned to this anion radical. Moreover, the possibility of the formation of a solvated electron for the H_2S+e^- system should be examined from both theoretical and experimental aspects.

Thermodynamic Study on the Adsorption of 1-Octadecanol at Hexane/Water Interface

Norihiro MATUBAYASI,*,† Kinsi MOTOMURA, Makoto ARATONO, and Ryohei MATUURA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received March 8, 1978)

The interfacial tension γ between water and hexane solution of 1-octadecanol has been measured as functions of temperature T, pressure p, and mole fraction of 1-octadecanol in hexane x_1^0 by the pendant drop method. The curves of γ *vs.* T, γ *vs.* p, and γ *vs.* x_1^0 show noticeable break points. Calculated thermodynamic quantities such as energy changes, entropy changes, and volume changes associated with the adsorption show the points of discontinuity at a certain temperature, pressure, and composition, corresponding to the above breaking points. It has been clarified that the first order phase transition between the expanded and condensed states takes place at the interface like that of monomolecular films spread on water surfaces. The expanded state is characterized by a relatively high energy, high entropy, and large volume, while the condensed state by low energy, low entropy, and small volume.

In a previous paper, the structure and properties of adsorbed films of 1-tetradecanol at the hexane/water interface were clarified by applying the thermodynamic treatment developed previously.[1,2] As an extension of the work, the adsorbed films of 1-octadecanol at the same interface was studied, and it was expected that a longer chain alcohol exhibits a phase transition from an analogy with the insoluble monolayer spread on water surface. There has been little data to suggest the phase transition at the liquid/liquid interface, and, in particular, the analysis appears to be insufficiently rigorous thermodynamically.[4-10] The major purpose of this work was to confirm that the phase transition really takes place in the adsorbed film and to clarify the type of the phase transition thermodynamically.

Experimental

1-Octadecanol used was purified by distillation and the purity checked by gas-liquid chromatography; only one peak was obtained. Water distilled three times from $KMnO_4$ solution was used as the aqueous phase. Hexane was dehydrated and the impurities removed by passing hexane through an activated alumina column. Interfacial tension measurements were performed by the pendant drop method, the detailed descriptions of which have been previously reported.[2,3]

Results

To calculate the entropy change Δs, the volume change Δv of the interface formation, and the interfacial density of 1-octadecanol Γ_1^{II}, data of the variations of interfacial tension with temperature T, pressure p, and mole fraction of 1-octadecanol in hexane x_1^0 are required. The interfacial tension was measured at 293.15, 295.65, 298.15, 300.65, and 303.15 K over the pressure range from 0.1 to 150 MPa, and concentration up to 2.3×10^{-3} mol fraction. In Figs. 1 and 2 the interfacial tension is plotted against the pressure at constant concentration and at constant temperature, 303.15 and 298.15 K. It is seen that the interfacial tension increases linearly with increasing pressure at low concentration, like the case of the 1-tetradecanol solution.[2] At an intermediate concentration, however, it decreases abruptly at a certain pressure which is dependent on the concentration of 1-octadecanol in hexane. The broken lines in Figs. 1 and 2 are obtained by connecting these break points. This behavior was not observed for 1-tetradecanol over the same range of temperature, pressure, and concentration.[2] At a high concentration, the interfacial tension decreases with the increase in pressure up to a point at which the crystallization of 1-octadecanol solution starts. It is clearly demonstrated in the Figures that the break point is affected by temperature. Figure 3 showes the variation of interfacial tension γ with temperature T at constant concentration, and pressure of 0.1 MPa. At low concentration a linear relation is obtained between γ and T and the slope varies from negative to positive with the increase in concentration in a similar manner to that of 1-tetradecanol. At high concentration, however, the γ *vs.* T curve has a break point. It is found that the decrease in

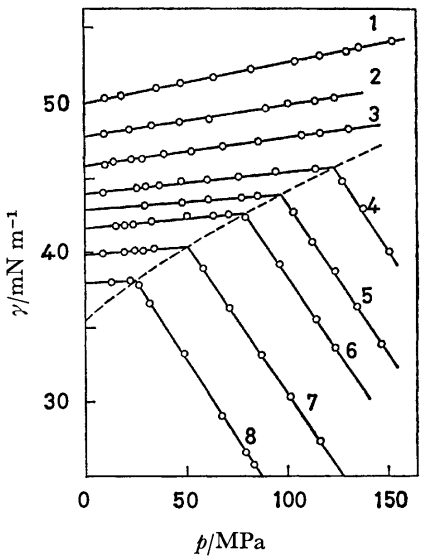

Fig. 1. Interfacial tension *vs.* pressure curves at constant mole fraction of octadecanol in hexane at 303.15 K. 1: $x_1^0=0$, 2: 1.04×10^{-4}, 3: 3.08×10^{-4}, 4: 6.31×10^{-4}, 5: 8.82×10^{-4}, 6: 1.08×10^{-3}, 7: 1.60×10^{-3}, 8: 2.38×10^{-3}.

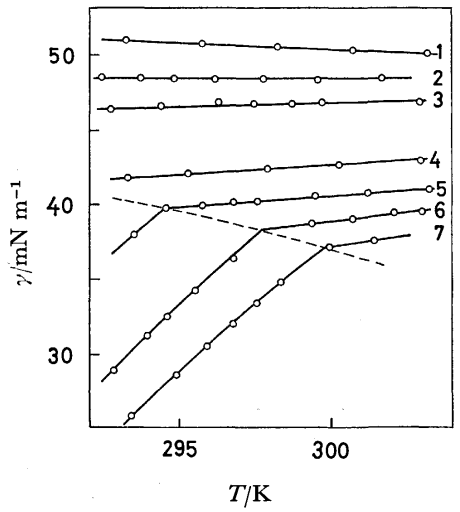

Fig. 3. Interfacial tension *vs.* temperature curves at constant concentration under 0.1 MPa. 1: $x_1^0=0$; 2: 1.33×10^{-4}, 3: 2.55×10^{-4}, 4: 8.05×10^{-4}, 5: 1.26×10^{-3}, 6: 1.68×10^{-3}, 7: 2.32×10^{-3}.

temperature and increase in concentration gives rise to the break in the curve. At any pressure similar figures as that in Fig. 3 can be drawn with the aid of the above γ *vs.* p curves. No striking difference was observed, but the temperature of the break point increase with the increase in pressure.

The interfacial tension γ can be plotted as a function of the concentration x_1^0 of 1-octadecanol in hexane at any temperature and pressure. In order to show that the break points in the γ *vs.* p curves clearly reflect those in the γ *vs.* x_1^0 curves, the behavior is illustrated in Fig. 4 at the temperatures of 293.15, 298.15, and 303.15 K at a constant pressure of 80 MPa.

At 0.1 MPa, the γ *vs.* x_1^0 curve breaks only at low temperature, and at 150 MPa, it breaks in a lower

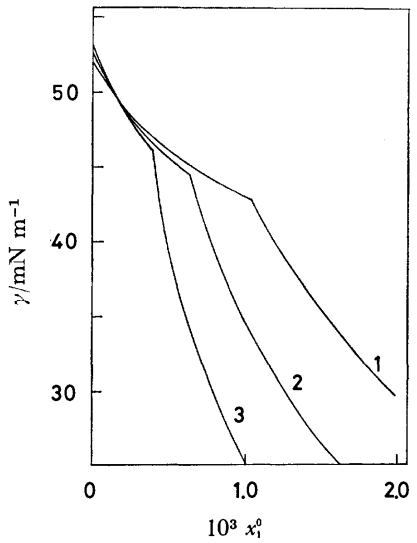

Fig. 4. Interfacial tension *vs.* concentration curves at constant temperature under 80 MPa. 1: 303.15 K, 2: 298.15 K, 3: 293.15 K.

concentration range. It seems appropriate to show the behavior of the break point in figures at 80 MPa, and in the following section the data at 80 MPa will be used for the thermodynamic discussion.

Discussion

Over the range of experimental conditions, the interfacial tension varies almost linearly with temperature and pressure, apart from the characteristic break points observed. It is conceivable that the phase transition in the interfacial film causes an abrupt change in the curves. Lutton *et al.*[8] also observed that the γ *vs.* T curve exhibits a break point for the system of triglyceride oil solutions of propylene glycol monoester and monoglyceride and water. They suggested that the behavior observed could be accounted for in terms of a melting of the surfactant monolayer adsorbed at the interface. Hutchinson[4-6] studied the adsorption of myristic acid at the cyclohexane/water interface and observed that the interfacial pressure *vs.* area per molecule curve displayed a transition. He assumed that the transition takes place between the liquid expanded and the liquid condensed films. A similar observation for 1-octadecanol in the cyclohexane/mercury system was made by Ambawani *et al.*[9] In order to understand the mechanism, it is necessary to analyze the experimental results thermodynamically.

For the system under consideration, it may be assumed that the mutual solubility of hexane and water is in fact negligible and 1-octadecanol is soluble only in hexane. In comformity with this view, the thermodynamic treatment applied to the adsorption of 1-tetradecanol at the hexane/water interface is applied in this study.[2] Since the measurements were made on the solution of solute mole fraction below 2.3×10^{-3}, the solution was regarded as an ideal one. The interfacial density of 1-octadecanol is given by the equation

$$\Gamma_1^{\mathrm{H}} = -(x_1^0/RT)(\partial\gamma/\partial x_1^0)_{T,p}. \quad (1)$$

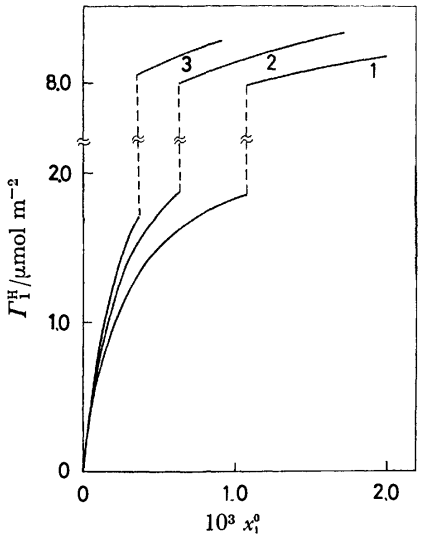

Fig. 5. Interfacial density *vs.* concentration curves at constant temperature under 80 MPa. 1: 303.15 K, 2: 298.15 K, 3: 293.15 K.

Figure 5 shows Γ_1^H as a function of x_1^0 at various temperatures and at 80 MPa. The discontinuous change on the Γ_1^H *vs.* x_1^0 curve indicate a phase transition in the adsorbed film of 1-octadecanol.

To further elucidate the adsorption, the relationships between the interfacial pressure π and the area per molecule A are given in Fig. 6 at three temperatures at 80 MPa, and in Fig. 7 at four pressures at 303.15 K. The isothermal and isobaric π *vs.* A curves show typical phase transition between the expanded and condensed films. Further, the intermediate region between both states become narrow with increasing temperature at constant pressure or with decreasing pressure at constant temperature. This behavior is comparable with that of the myristic acid monomolecular film spread at the air/water interface.[11]

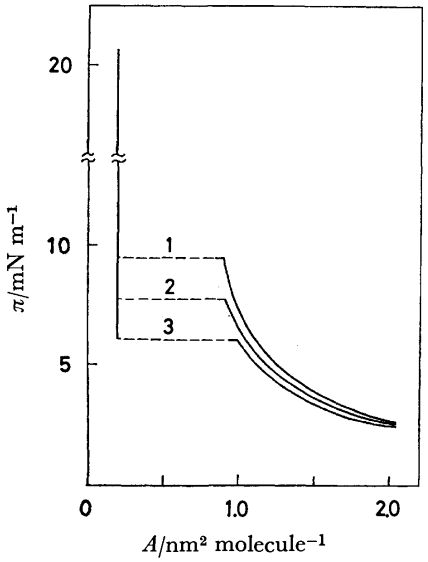

Fig. 6. Interfacial pressure *vs.* area curves at constant temperature under 80 MPa. 1: 303.15 K, 2: 298.15 K, 3: 293.15 K.

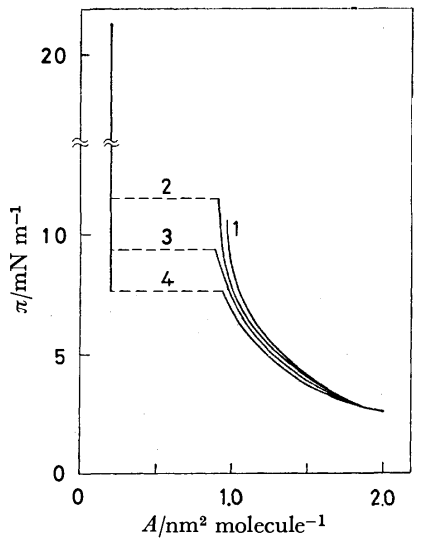

Fig. 7. Interfacial pressure *vs.* area curves at constant pressure at 303.15 K. 1: 0.1 MPa, 2: 40 MPa, 3: 80 MPa, 4: 120 MPa.

Entropy and volume changes of interface formation are given by the equations

$$\Delta s = -(\partial\gamma/\partial T)_{p,x_i'} \tag{2}$$

and

$$\Delta v = (\partial\gamma/\partial p)_{T,x_i'}. \tag{3}$$

In Figs. 8 and 9, the values of Δs and Δv are plotted as functions of concentration at 293.15, 298.15, and 303.15 K and at a constant pressure 80 MPa. In the expanded state, Δs and Δv are independent of temperature and pressure within the precision of the observations. Both the positive values of Δs and Δv for the system of pure hexane and water indicate that the contact between hexane and water causes increases in entropy and volume. With increasing concentration both values decreases gradually. This means that the adsorption of 1-octadecanol at the interface makes a negative contribution to Δs and Δv and that the partial molar entropy and volume of the adsorption are negative, as in the case of

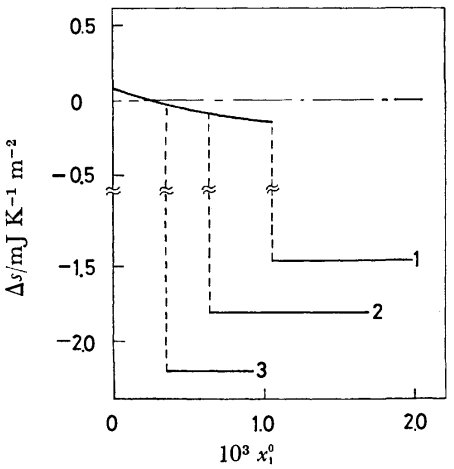

Fig. 8. Entropy change *vs.* concentration curves at constant temperature under 80 MPa. 1: 303.15 K, 2: 298.15 K, 3: 293.15 K.

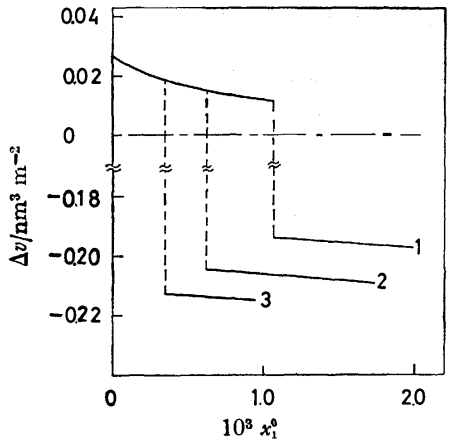

Fig. 9. Volume change *vs.* concentration curves at constant temperature under 80 MPa. 1: 303.15 K, 2: 298.15 K, 3: 293.15 K.

1-tetradecanol. In the condensed state, on the other hand, it is apparent that both Δs and Δv are dependent on temperature and are characterized by remarkably negative values.

The striking discontinuities in the Δs *vs.* x_1^0 and Δv *vs.* x_1^0 curves indicate that the break points in the γ *vs.* T and γ *vs.* p curves are the first order phase transition points, and at these points the expanded and condensed films coexist. With reference then to the gas-liquid equilibrium, the expanded state is favored by relatively high entropy and large volume and the condensed state by low entropy and small volume. Thus the increase in pressure and the decrease in temperature favor the condensed state.

It has been known that the differentials of interfacial tension in the condensed and expanded phases are expressed respectively as

$$d\gamma = -\Delta s^c dT + \Delta v^c dp - \Gamma_1^{H\cdot c}(\partial\mu/\partial x_1^0)dx_1^0 \quad (4)$$

and

$$d\gamma = -\Delta s^e dT + \Delta v^e dp - \Gamma_1^{H\cdot e}(\partial\mu/\partial x_1^0)dx_1^0, \quad (5)$$

where the condensed and expanded states are denoted by the superscript c and e, respectively. From these equations, it may be seen that

$$(\partial\gamma^{eq}/\partial T)_p = -(\Delta s^c/\Gamma_1^{H\cdot c} - \Delta s^e/\Gamma_1^{H\cdot e})/(1/\Gamma_1^{H\cdot c} - 1/\Gamma_1^{H\cdot e}) \quad (6)$$

and

$$(\partial\gamma^{eq}/\partial p)_T = (\Delta v^c/\Gamma_1^{H\cdot c} - \Delta v^e/\Gamma_1^{H\cdot e})/(1/\Gamma_1^{H\cdot c} - 1/\Gamma_1^{H\cdot e}). \quad (7)$$

The left-hand sides of these equations can be easily obtained as the slopes of the broken lines of Figs. 2 and 3, and the right-hand side may be calculated by the quantities derived above. The values of both sides of Eq. 6 at 298.15 K and at 80 MPa are 0.37 and 0.45 mJ K^{-1} m^{-2}, and those of Eq. 7 are 0.71 and 0.81 mm^3 m^{-2}, respectively. Taking into account the precision of the right hand sides of equations, the agreement is not unsatisfactory. Then this fact supports that the phase transition in the adsorbed film of 1-octadecanol is the first order phase transition.

The energy change associated with the adsorption

Table 1. Comparison of thermodynamic quantities at 303.15 K and 80 MPa

$10^3 x_1^0$	State of film	γ / mJ m^{-2}	$T\Delta s$ / mJ m^{-2}	$p\Delta v$ / mJ m^{-2}	Δu / mJ m^{-2}
0.0	*e*	52.02	27.3	2.10	77.2
0.2	*e*	48.74	6.6	1.66	53.8
0.4	*e*	46.63	−9.1	1.40	36.1
0.6	*e*	45.15	−21.2	1.22	22.7

1.2	*c*	39.92	−452	−15.7	−395
1.4	*c*	36.88	−455	−15.8	−402
1.6	*c*	34.18	−455	−15.8	−405
1.8	*c*	31.87	−455	−15.9	−407
2.0	*c*	29.81	−457	−16.0	−411

may be obtained at any temperature, pressure, and composition with the aid of the relation

$$\Delta u = \gamma + T\Delta s - p\Delta v. \quad (8)$$

In Table 1, values of Δu, γ, $T\Delta s$, and $p\Delta v$ at 303.15 K and at 80 MPa are given. It is seen that in the expanded state the values of Δu decrease with increase in concentration in a similar way as in the case of 1-tetradecanol.[2] In the condensed state the adsorption of 1-octadecanol remarkably lowers the hexane/water interface energy.

All work prior to this has been carried out without taking into account the effect of pressure on interfacial tension provided that it has no pronounced effect on the properties of the condensed phase. For the system investigated in this study, the term $p\Delta v$ makes a relatively smaller contribution to Δu than $T\Delta s$ as shown in Table 1, and in fact has only a negligible contribution at atmospheric pressure. But it is important to investigate the effect of pressure on interfacial tension which will provide important data concerning the volumetric properties of the interface as discussed above.

This work was supported in part by a Scientific Research Grant from the Ministry of Education, Japan (No. 147010).

Nuclear Quadrupole Resonance Study of β-Chloroisocrotonic Acid

Kiyoshi ICHIMURA,* Nobuo NAKAMURA, and Hideaki CHIHARA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560
(Received March 9, 1978)

^{35}Cl nuclear quadrupole resonance frequencies have been measured in powders of β-chlorocrotonic acid and β-chloroisocrotonic acid to be 34.966 and 34.261 MHz, respectively, at 78 K. Zeeman effect experiments were conducted on a single crystal of β-chloroisocrotonic acid and the asymmetry parameter of the electric field gradient has been determined to be 0.174±0.016 at 78 K. The π-electron density on the chlorine site has been estimated from the asymmetry parameter according to Bersohn and discussed on the basis of the semi-empirical Pariser-Parr-Pople molecular orbital treatment.

The electronic structure of organic compounds has been examined extensively by electronic spectra, photoelectron spectroscopy and other experimental techniques and the results of these experiments have been used to check the theoretically elucidated atomic and molecular wave functions and *vice versa*. It is still difficult to obtain good wave functions for such heavy atoms as chlorine, bromine, *etc.* which may play very important roles in determining the molecular and crystal structure as well as the reactivity of simple organic compounds.

Pure nuclear quadrupole resonance (NQR) is a powerful tool to examine the electronic structure of the ground state of molecules in crystals and has been applied to numerous organic compounds which contain quadrupole nuclei such as nitrogen, chlorine, bromine, and iodine. This method can be more effective to determine the molecular wave functions if the nuclear quadrupole coupling constant e^2Qq and the asymmetry parameter η of the electric field gradient (EFG) at the resonating nucleus can be measured, but it is necessary to do Zeeman effect experiments on single crystals to obtain η in the case of chlorine and bromine. Although the electronic structure of the chemical bonds between halogens and the carbon atoms in simple halogen-substituted ethylenes has been studied by the NQR method,[1] only semi-quantitative discussions have been possible because of the lack of precise e^2Qq and η in these compounds. The difficulty in obtaining e^2Qq and η stems mainly from the difficulty in growing large single crystals of halogen-substituted olefinic compounds.

The purpose of the present paper is to measure e^2Qq and η of ^{35}Cl precisely in a single crystal of β-chloroisocrotonic acid which contains a typical olefinic C–Cl bond and to discuss the electronic structure of this substance in detail. The bond parameters of the olefinic system elucidated by a semi-empirical molecular orbital method based on the Pariser-Parr-Pople theory are also evaluated.

Experimental

A mixture of ethyl β-chloroisocrotonate and ethyl β-chlorocrotonate was prepared from ethyl acetoacetate and PCl_5 in benzene solution according to methods in the literature.[2,3] The esters were separated by fractionation, and hydrolyzed with hydrochloric acid to give the free acids. The crystals of the acids thus precipitated were collected, and purified by sublimation *in vacuo*. β-chloroisocrotonic acid (hereafter abbreviated as CICA) and β-chlorocrotonic acid (CCA) were identified by high resolution NMR, the melting points being 56 and 90 °C, respectively. A single crystal of the CICA (approximately $1\times2\times3.5$ cm^3) was grown from a solution of water–methanol system.

The ^{35}Cl NQR frequencies were measured between 20 and 80 K, and at 196 and 291 K by using a Dean-type super-regenerative spectrometer on a powdered specimen. The uncertainty in the frequency measurement was within ±1 kHz. Single crystal Zeeman effect experiments were conducted at the liquid nitrogen and at the room temperatures. The zero-splitting loci of the ^{35}Cl resonance line were determined on an oscilloscope by rotating the magnetic field about two mutually orthogonal axes. Details of the apparatus and the method of the frequency determination and the Zeeman measurements have been previously described.[4]

The analysis of the data of the Zeeman effect measurement was performed by using a high-speed electronic computer (NEAC-2200) which has been programmed by Mano.[5]

Results and Discussion

Description of the Crystal Structure. CICA crystallizes in a monoclinic system with the space group $P2_1/c$ and contains four molecules in the unit cell. Two molecules in the unit cell are connected to each other by hydrogen bonds and form a plane dimer.[6] The center of symmetry lies at the center of the dimer, therefore all the chlorines are at equivalent sites in the crystal. The crystal structure of CCA has not been determined.

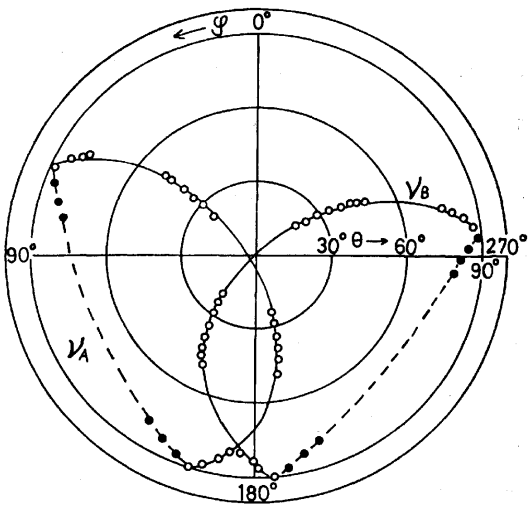

Fig. 1. Zero-splitting loci due to two C–Cl bonds at room temperature. The zero-splitting loci above and below the plane of the paper are distinguished by open and closed circles.

Table 1. Nuclear quadrupole resonance frequencies, quadrupole coupling constants, asymmetry parameters and the direction cosines of principal Z-axis of electric field gradient tensors in a laboratory-fixed coordinate system

The standard deviations are given in parentheses.

Resonance line	Temperature/K	Frequency/MHz	e^2Qqh^{-1}/MHz	η	Direction cosines		
					X_L	Y_L	Z_L
ν_A	291	33.605	66.88 (0.34)	0.172 (0.005)	−0.5397	−0.6151	0.5748
ν_B	291	33.605	66.86 (0.27)	0.177 (0.004)	−0.3822	0.7451	0.5466
ν_A	78	34.261	68.23 (1.10)	0.160 (0.016)	−0.5339	−0.6042	0.5916
ν_B	78	34.261	68.11 (1.10)	0.190 (0.016)	−0.3728	0.7576	0.5358

^{35}Cl Nuclear Quadrupole Resonance. ^{35}Cl NQR frequencies in CICA were 34.372±0.001 MHz at 20 K and 33.605±0.001 MHz at 291 K. The resonance frequency of CICA decreases monotonously with increasing temperature as expected by the Bayer-Kushida theory[7,8] and no phase transition was found over the whole temperature range of the measurement. The temperature coefficient $d\nu/dT$ was 2.00±0.25 (Hz K^{-1}) at 50 K which is comparable to that in *trans*-$C_2H_2Cl_2$.[9] The result of the Zeeman effect study on CICA crystal is shown in Fig. 1. In this figure one may see the location of the two zero-splitting cones in the laboratory-fixed coordinate system. These cones are related to each other by the two-fold screw axis. From these experimental results the nuclear quadrupole coupling constants, the asymmetry parameters and the direction cosines of the principal axes of the electric field gradient tensors were calculated by fitting these zero-splitting data to the relation[10]

$$\sin^2\theta = \frac{2}{3-\eta\cos 2\varphi}, \tag{1}$$

where θ and φ are the polar and the azimuthal angles of the direction of the Zeeman field with respect to the principal coordinate system of the EFG tensors. The number of data collected were 92 for Cl_1 and 99 for Cl_2 at room temperature. The results of the analysis are recorded in Table 1.

The angle between the two principal Z-axes of EFG with different orientations was calculated to be 93.3° which agrees well with 93.1° obtained by the X-ray analysis.[6] It can be seen from Table 1 that the η and the direction cosines of the principal axes X, Y, and Z at 78 K and room temperature were nearly the same.

Semi-empirical Molecular Orbital Treatment of the NQR Parameters. According to the Townes-Dailey theory the electric field gradient *eq* and the asymmetry parameter η of a free molecule may be expressed in terms of the population difference of the outer p-electron orbitals. If we assume that the population difference of the p_x, p_y, and p_z orbitals are U_x, U_y, and U_z, then

$$q = q_p\left(U_z - \frac{U_x+U_y}{2}\right), \tag{2}$$

and

$$\eta = \frac{3(U_y-U_x)}{U_x+U_y-2U_z} = \frac{3q_p}{2q}(U_y-U_x) = \frac{3e^2Qq_p(U_y-U_x)}{2e^2Qq}, \tag{3}$$

where eq_p is the field gradient due to one p-electron in the valence shell and the Z-axis is assumed to coincide with the C–Cl bond. By putting e^2Qq_p/h=109.6 MHz,[11] e^2Qq/h=68.18 MHz, η=0.174, and U_y=2 (the population in the chlorine p_y orbital perpendicular to the π-bond between two carbons), U_x was calculated to be 1.93 for the partially π-bonded chlorine orbital p_x in CICA. Here we have neglected the intermolecular contribution to η.

Grabe[12] calculated the values of U_x for several chlorine-substituted ethylenes by means of a semi-empirical molecular orbital theory proposed by Pariser, Parr, and Pople.[13] In order to examine the reliability of the parameters presented by Grabe we applied the Pariser-Parr-Pople method to CICA. In the calculation the usual assumptions have been adopted as follows:

$$S_{\mu\nu} = \langle\mu|S|\nu\rangle = \delta_{\mu\nu}$$

$$\alpha_\mu = \langle\mu|H^{core}|\mu\rangle \neq 0$$

$$\beta_{\mu\nu} = \langle\mu|H^{core}|\nu\rangle \begin{cases} \neq 0 \text{ when } \mu \text{ and } \nu \text{ are the neighbors} \\ = 0 \text{ when } \mu \text{ and } \nu \text{ are not the neighbors} \end{cases}$$

$$\langle\alpha\beta|r_{ab}^{-1}|\mu\nu\rangle = \delta_{\alpha\mu}\delta_{\beta\nu}\gamma_\mu$$

The same notations as in Ref. 12 were used here. The core integral was assumed to be

$$\alpha_\mu = W_\mu - (n_\mu-1)\gamma_{\mu\mu} - \sum_{\mu\neq\nu} n_\nu\gamma_{\mu\nu}.$$

The other parameters were taken as

$$\beta_{\mu\nu} = \beta_0 + \delta_{\mu\nu}{}^\beta(R_{\mu\nu}-R_0),$$

$$W_\mu = W_0 + \sum_\nu \Delta W_\mu(\nu),$$

$$\gamma_{\mu\nu} = \gamma_0 + \delta_{\mu\nu}{}^\gamma(R_{\mu\nu}-R_0),$$

$$\Delta W_\mu(\nu) = \Delta W_\mu{}^0(\nu) + \delta_{\mu\nu}{}^W(R_{\mu\nu}-R_0),$$

where R_0 is the reference distance and $R_{\mu\nu}$ is the real distance between atoms μ and ν. These parameters were determined according to Refs. 12, 14—16 by using the crystal structure data. The ionization potential

Table 2. Ionization potential and π-orbital population in β-chloroisocrotonic acid

I_p/eV (calcd)	π-electron density	
9.62	C_{methyl}	1.961
10.19	C_β	0.946
11.75	C_α	1.049
12.68	$C_{carboxyl}$	0.606
13.55	Cl	1.964
	$O_{carbonyl}$	1.587
	$O_{hydroxyl}$	1.885

and the orbital populations calculated by using these parameters are given in Table 2. As there are no available experimental data on the ionization potential of CICA, the values in Table 2 cannot be evaluated at the present stage.

We now compare the π-electron density in CICA with those in other olefinic compounds. The π-electron densities on the chlorines in vinyl chloride and *cis*-dichloroethylene in the gaseous state have been deduced to be 1.94[17] and 1.95,[18] respectively, from microwave measurements. These values agree fairly well with 1.97 calculated for these compounds by the Pariser-Parr-Pople method.[12] In the case of CICA the agreement between the experimental π-electron density 1.93 and the calculated one, 1.96, is comparable to the cases of vinyl chloride and *cis*-dichloroethylene. The experimental π-electron density in CICA is the smallest of these three olefinic compounds, suggesting that the conjugation of the π-orbitals extends over the whole molecule and makes it easy to form strong π-bonding between the C_β and the terminal chlorine atom. There may be some contribution to η at the chlorine site from the intermolecular interactions which cannot be estimated at the present stage.

The authors wish to thank Dr. Koichi Mano for the computer program for the analysis of the Zeeman data. They are also grateful to Mr. Tokutsuka Kiichi for his help in programming the molecular orbital calculation.

The Enantioselective Dehydrogenation of Racemic Secondary Alcohols Catalyzed by Dimeric Ruthenium(II) Chiral Diphosphine Complexes

Katsutoshi OHKUBO,* Ikuhiro TERADA, and Kohji YOSHINAGA

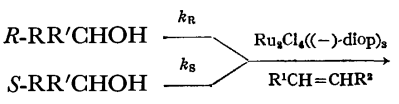
Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received March 13, 1978)

The asymmetric dehydrogenation of racemic alcohols by an effective $Ru_2Cl_4((-)\text{-diop})_3$ (diop=2,3-*O*-isopropylidene-1,4-bis(diphenylphosphino)butane) was investigated with and without unsaturated hydrogen acceptors at 120—195 °C, with particular reference to the enantioselective factors and the reaction mechanism. The magnitude of enantioselectivity was substantially affected by the structures of the alcohols and of the hydrogen acceptors and by the reaction temperature; the hydrogen acceptors ($R^1CH=CHR^2$: $R^1 \neq H$ and $R^2 \neq H$) contributed to the enhancement of the selectivity through the newly formed asymmetric centers which result from their coordination to the chiral Ru(II) complex. The activation parameters (ΔH^* and ΔS^*) obtained from the linear Arrhenius dependence of the rate constants of each enantiomer (*R*- or *S*-alcohol) established an isokinetic relationship, and the defference in the parameters of the each enantiomer ($\Delta\Delta H^*$ and $\Delta\Delta S^*$) also showed a satisfactorily linear correlationship between them. It is deduced from the present study that the enantioselection of *R*- and *S*-alcohols occurs at different coordination distances toward the chiral Ru(II) complex between the enantiomers under asymmetric circumstances.

Enantio-differentiating reactions with chiral transition-metal complexes have currently received considerable attention in the asymmetric hydrogenation (of prochiral olefins) which was originally developed in 1968.[1,2] Asymmetric induction by chiral metal complexes, especially by rhodium(I) chiral phosphine complexes, in the hydrogenation of prochiral olefins has been extensively investigated by taking notice of the structural effects of chiral ligands or of prochiral olefins on the optical yields of chiral products;[3-13] enantiomeric excesses of 95—96% are now possible in the asymmetric hydrogenation of α-(acylamino)acrylic acids by [Rh(1,5-cyclooctadiene)biphosphine]$^+BF_4^-$ (biphosphine=1,2-bis[(*o*-methoxyphenyl)phenylphosphino]ethane).[7,12]

On the other hand, the catalytic enantioselection of racemates with chiral metal complexes is also of interest and significant in connection with the asymmetric synthesis of chiral compounds with metal complexes. In our laboratory, Ru(II) chiral phosphine complexes were found catalytically effective for the enantioselective dehydrogenation of racemic alcohols with or without hydrogen acceptors.[14] Ru(II) chiral phosphine complexes have hitherto been the objects of only a limited investigation in terms of an examination of their asymmetric catalyses. In regard to chiral phosphine ligands, a diphosphine of (+)- or (−)-2,3-*O*-isopropylidene-1,4-bis(diphenylphosphino)butane (diop) has recently been accepted as an efficient chiral ligand when used in the rhodium-[5,8,15-24] and ruthenium-[25,26] catalyzed asymmetric hydrogenation of prochiral olefins, and it is also extensively used as a polymer-attached active phosphine ligand.[27-30] Therefore, we examined the efficiency of the diphosphine (diop) as a chiral ligand of ruthenium in the enantioselective dehydrogenation of racemic secondary alcohols (RR'CHOH) by $Ru_2Cl_4((-)\text{-diop})_3$[5] with and without unsaturated hydrogen acceptors ($R^1CH=CHR^2$):



$$RR'C{=}O + R^1CH_2CH_2R^2 \quad (1)$$

where k_R and k_S denote, respectively, the pseudo-first-order rate constants for *R* and *S* enantiomers.

In the present work, some isolated crystalline complexes, such as $RuCl_2((+)\text{-bmpp})_3$ (bmpp=benzylmethylphenylphosphine) and an *in situ* prepared complex of $RuCl_2((+)\text{-nmdp})_3$ (nmdp=neomenthyldiphenylphosphine), were also used in Reaction 1 instead of the dimeric $Ru_2Cl_4((-)\text{-diop})_3$ complex for the sake of comparison.

Experimental

Materials. (−)-*O*-2,3-Isopropylidene-1,4-bis(diphenylphosphino)butane (diop) was prepared by Kagan's method,[5] and the chiral phosphines of (−)-*o*-methoxyphenylmethylphenylphosphine (*o*-ampp), (−)-propylmethylphenylphosphine (pmpp), and (+)-benzylmethylphenylphosphine (bmpp) were prepared according to Mislow *et al.*[31] (+)-Neomenthyldiphenylphosphine (nmdp) was made by means of Morrison's method.[32] $Ru_2Cl_4((-)\text{-diop})_3$ was supplied by James *et al.*,[25] and $RuCl_2$ $((+)\text{-nmdp})_3$ was prepared *in situ* from $[(+)\text{-nmdp}]_0/[RuCl_2(PPh_3)_3]_0=6$. The other complexes, $RuCl_2((-)\text{-ampp})_2(PPh_3)$, $RuCl_2((-)\text{-pmpp})_3$, and $RuCl_2((+)\text{-bmpp})_3$, were made according to the phosphine-exchange method;[33] $RuCl_2\text{-}(PPh_3)_4$ and the chiral phosphine (in their molar ratio of 1:4) were refluxed in hexane for 1—10 h in a nitrogen atmosphere until a change in the solution color was observed, and satisfactory elementary analyses were obtained for the isolated crystalline complexes, as is shown below: $Ru_2Cl_4((-)\text{-diop})_3$: ^1H NMR ($CDCl_3$) δ 0.86 (s, 6H), 1.57 (broad, 12H), 3.02 (broad, 6H), 6.98 (m, 2OH), 7.18 (m, 40H). Found: C, 60.78; H, 5.73; Cl, 7.58%. Calcd for: C, 60.72; H, 5.22; Cl, 7.72%. $RuCl_2((-)\text{-ampp})_2(PPh_3)$: ^1H NMR ($CDCl_3$) δ 1.54 (d, 6H, J=4 Hz), 3.75 (s, 6H), 7.25 (m, 33H). Found: C, 61.80; H, 5.14; Cl, 7.82%. Calcd for: C, 61.74; H, 5.03; Cl, 7.94%. $RuCl_2((-)\text{-pmpp})_3$: ^1H NMR ($CDCl_3$) δ 0.80 (broad, 3H), 1.77 (broad, 7H), 7.23 (m, 5H). Found: C, 53.82; H, 6.57; Cl, 10.35%. Calcd for: C, 53.74; H, 6.77; Cl, 10.58%. $RuCl_2((+)\text{-bmpp})_3$: ^1H NMR ($CDCl_3$) δ 1.60 (broad, 3H), 3.45 (broad, 2H), 7.02 (m, 5H), 7.32 (m, 5H). Found: C, 62.01; H, 5.64; Cl, 8.61%. Calcd for: C, 61.92; H, 5.57; Cl, 8.70%.

Reaction Procedure and Optical Analysis. The dehydrogenation of freshly distilled secondary alcohols (1-phenyl-

ethanol and 1-phenyl-1-propanol) by the Ru(II) chiral phosphine complex was carried out without solvents at 120—195 °C in a N_2 atmosphere in the absence or in the presence of unsaturated hydrogen acceptors such as benzylideneacetone. After a desired conversion of the reaction was obtained, the unreacted alcohol was fractionally distilled under reduced pressure and then subjected to optical-rotation measurements. In the dehydrogenation of achiral alcohols such as benzyl alcohol with the Ru(II) chiral phosphine complexes at 120—195 °C, it was confirmed that the distilled alcohols include no optically active contaminants, such as the chiral Ru(II) complex, chiral ligands, and their decomposed products. To determine the optical purity of the alcohol enriched in one of the enantiomers, the average value of the optical rotations measured four times with a highly sensitive UNION PM-101 polarimeter was used as the observed one. The distribution of reaction products was followed by gas-chromatographic analyses, and some side reaction products, such as the racemic or meso bis(α-methylbenzyl) ether obtained from the dehydrogenation of 1-phenylethanol, were identified by means of 60 MHz ^{1}H NMR after their fractional collection by gas chromatography.

Results and Discussion

Pseudo-first-order Enantioselective Reaction. When the asymmetric dehydrogenation of the alcohol (8.34×10^{-2} mol) by using $Ru_2Cl_4((-)\text{-diop})_3$ (2 mM) or $RuCl_2L^*_3$ (L*=chiral ligand) (4 mM) was carried out with a hydrogen acceptor (6.84×10^{-2} mol) at 120—195 °C, the optical purity (O.P.) of the unreacted alcohol (RR'CHOH), obtained by fractional distillation without any optically active contaminants, increased with an increase in the conversion (Conv.), obeying pseudo-first-order rate law up to Conv. $\simeq$65% with a constant k_R/k_S ratio, which reflects the enantioselectivity (Table 1).

$$k_R = (\ln [R]_0/[R])/t$$
$$= \ln (10^4/(100-\text{Conv.})(100-\text{O.P.}))/t \quad (2a)$$
$$k_S = (\ln [S]_0/[S])/t$$
$$= \ln (10^4/(100-\text{Conv.})(100+\text{O.P.}))/t \quad (2b)$$

where $[R]_0$ and $[S]_0$ mean, respectively, the initial concentrations of the *R* and *S* enantiomers, and where *t* is the reaction time. As is indicated in Table 1, the present chiral Ru(II) catalyst produced acetophenone as the main dehydrogenation product of 1-phenylethanol, with a quantitative saturation of the unsaturated hydrogen acceptor, but small amounts of racemic and meso bis(α-methylbenzyl) ether (^{1}H NMR($CDCl_3$) δ 1.46 (d, 6H, J=6.4 Hz), 4.53 (q, 2H, J=6.4 Hz), 7.29 (s, 10H) and δ 1.40 (d, 6H, J=6.4 Hz), 4.25 (q, 2H, J=6.4 Hz), 7.31 (s, 10H)) were also detected, together with negligible amounts of styrene and ethylbenzene. The formation of such a side product of the ether was remarkably accelerated by RhCl((−)-diop) (prepared *in situ* from $[\text{diop}]_0/[(RhCl(C_2H_4)_2)_2]_0=3$); hence, the ruthenium–diop complex is superior to the rhodium–diop complex in terms of the promotion of the hydrogen transfer from the racemic alcohols to hydrogen acceptors, with a higher enantioselection of the former.

Efficiency of diop as a Chiral Ligand. In order to confirm the actual efficiency of diop as a chiral ligand of the Ru(II) complex in comparison with other chiral phosphine ligands, we examined the asymmetric dehydrogenation of 1-phenyl-1-propanol in the presence of benzylideneacetophenone at 165 °C with $Ru_2Cl_4((-)\text{-diop})_3$, $RuCl_2((-)\text{-ampp})_2(PPh_3)$, $RuCl_2((-)\text{-pmpp})_3$, $RuCl_2((+)\text{-bmpp})_3$, and $RuCl_2((+)\text{-nmdp})_3$. Although the enantioselective ability of the dimeric $Ru_2Cl_4((-)\text{-diop})_3$ complex is not directly comparable with those of the other monomeric derivatives ($RuCl_2L^*_3$ or $RuCl_2L^*_2(PPh_3)$: L*=chiral ligand), among the complexes tested, the diop ligand substantially brought about the highest activity for the binuclear $Ru_2Cl_4((-)\text{-diop})_3$ complex in the dehydrogenation and enantioselection of racemic 1-phenyl-1-propanol (Table 2). One could suppose, here, that the low enantioselective ability of $RuCl_2L^*_3$ (or $RuCl_2L^*_2(PPh_3)$), including the Mislow phosphine ligand (L*), was the result of the incomplete racemization of L* at 165 °C, even as the metal complexes. However, this is not true, because the $RuCl_2L^*_3$ (or $RuCl_2L^*_2(PPh_3)$) complex appreciably increased its dehydrolyzing and enantioselective ability even at temperatures higher than 165 °C; for example, $RuCl_2((-)\text{-ampp})_2(PPh_3)$ resulted in O.P.(Conv.)=0.80% (50.5%), $k_R=6.59\times10^{-6}$ s^{-1}, $k_S=8.33\times10^{-6}$ s^{-1}, and $k_R/k_S=1.023$ at 185 °C in the same reactions in Table 2. Presumably, the slightly higher temperature promotes the dissociation of the chlorine atom from the Ru(II) complex so as to make active sites and that of

Table 1. Enantioselective dehydrogenation of 1-phenylethanol (8.34×10^{-2} mol) by $Ru_2Cl_4((-)\text{-diop})_3$ (2 mM) with benzylideneacetone (6.84×10^{-2} mol) at 165 °C

the hydrogen attached to the α-carbon in the alcohol.

Structural Effect of Hydrogen Acceptors. The addition of hydrogen acceptors to the reaction system substantially enhanced the enantioselection of the racemic alcohol by the chiral Ru(II) complex in comparison with that in the same reaction without hydrogen acceptors, and a structural effect of hydrogen acceptors on the enantioselectivity defined by k_R/k_S was observed (Table 3). Such a structural effect of hydrogen acceptors has also been reported in the enantioselective dehydrogenation of 1-phenylethanol by $RhCl((+)\text{-nmdp})_3$ prepared *in situ*[34] or by $RuCl_2((+)\text{-nmdp})_3$.[35] There are two possible explanations of such a structural effect of the hydrogen acceptors on the selectivity: (a) the change in the type of hydrogen acceptor affects the equilibrium of the $Ru_2Cl_4((-)\text{-diop})_3$ complex in the solution, if there is an equilibrium of the complex, and (b) the coordination of the unsaturated hydrogen acceptor ($R^1CH{=}CHR^2$) to the chiral Ru(II) complex gives rise to newly formed asymmetric centers, as is shown below:

$$R^1CH{=}CHR^2\ (R^1{\neq}H \text{ and } R^2{\neq}H) + (Ru) \rightleftharpoons \underset{R^1\overset{*}{C}H\text{——}\overset{*}{C}HR^2}{\overset{(Ru)}{\diagup\ \diagdown}}\ (I) \qquad (3)$$

where (Ru) denotes a catalytically active species supplied from $Ru_2Cl_4((-)\text{-diop})_3$.

The equilibrium of the bridged dimer complex of $(diop)Cl_2Ru\text{-}P\text{-}P\text{-}RuCl_2(diop)$ (P-P=diop) in solutions has not yet been established, but one species which can be obtained from the dimeric complex is $(diop)Cl_2RuP$ (P=ligand produced by the dissociation of P-P). Even though an equilibrium between $(diop)Cl_2Ru\text{-}P\text{-}P\text{-}RuCl_2\text{-}(diop)$ and $(diop)Cl_2RuP$ could be expected in solutions, it seems unreasonable to explain the effect of $R^1CH{=}CHR^2$ on the selectivity only on the basis of the (a) explanation. On the other hand, the (b) explanation seems plausible because such newly formed asymmetric centers induced by the coordination of olefins to chiral metal complexes (*viz.*, platinum amine one) have

a) e.c. of *R*-(−)-$MeCH_2CH(Me)CO_2H$ formed=21.0%.

already been confirmed.[36-38] Although, in the case of the platinum amine complexes, Reaction 3 has been established only at temperatures much lower than 120—195 °C,[36-38] the newly formed asymmetric centers in the (I) intermediate might not be completely diminished *via* the epimerization,[36-37] even in the present temperature range. The possibility of Reaction 3 is also supported by the fact that the prochiral (*E*)-α-methylcrotonic acid used as a hydrogen acceptor instead of achiral olefins was converted into a chiral species (*R*-(−)-$MeCH_2CH(Me)CO_2H$) in an enantiomeric excess of 21.0% in the dehydrogenation of 1-phenylethanol by $Ru_2Cl_4((-)\text{-diop})_3$ at 165 °C with O.P.= 4.85%(Conv.=68.4%) of *S*-(−)-1-phenylethanol (Table 3). This double asymmetric-transfer hydrogenation with Ru(II) chiral phosphine complexes seems promising; the details of an investigation which is now in progress will be presented in a succeeding paper.

In connection with the above structural effect of hydrogen acceptors on the enantioselectivity, the change in the type of hydrogen donor(RR'CHOH) also affected the magnitude of the selection by $Ru_2Cl_4((-)\text{-diop})_3$ (Table 4); the change from 1-phenylethanol to 1-phenyl-1-propanol affected the selectivity substantially.

Reaction Mechanism. If the induced asymmetry in the (I) intermediate plays an important role in the enhancement of the enantioselectivity, the coordination of the hydrogen acceptor to the chiral metal complex is required before the coordination of the alcohol to the complex can proceed; that is, the reaction between the alcohol and the (I) intermediate should be realized. In this regard, the increase in the concentration of the hydrogen acceptor with respect to that of the alcohol resulted in a monotonous acceleration of the reaction rate up to $[R^1CH{=}CHR^2]_0/[RR'CHOH]_0 \simeq 1$, but the excess concentration of $R^1CH{=}CHR^2$ ($[R^1CH{=}CHR^2]_0/[RR'CHOH]_0 > 1$) retarded the reaction (Fig. 1). This probably implies that the increase in the $R^1CH{=}CHR^2$ concentration raises the concentration of the (I) intermediate, which reacts with the alcohol in the following way:

$$\text{(I)} + RR'CHOH \xrightarrow{-H^+} \left[RR'CHO\text{—}(Ru)\begin{matrix}{}^{*}CHR^1\\ |\\ {}^{*}CHR^2\end{matrix}\right]$$

$$\longrightarrow \left[RR'C{=}O\text{—}(Ru)\begin{matrix}H\\ {}^{*}CHR^1\\ |\\ {}^{*}CHR^2\end{matrix}\right]^{+}$$

$$\longrightarrow \left[RR'C{=}O\text{—}(Ru\text{-}H)\begin{matrix}{}^{*}CHR^1\\ |\\ {}^{*}CHR^2\end{matrix}\right]$$

$$\longrightarrow [RR'C{=}O\text{—}(Ru)\text{-}{}^{*}CHR^1CH_2R^2]$$

$$\xrightarrow{H^+} RR'C{=}O + R^1CH_2CH_2R^2 + (Ru) \qquad (4)$$

In the case of the excess concentration of $R^1CH{=}CHR^2$, the shielding of active sites of the (I) intermediate by $R^1CH{=}CHR^2$ depresses the reaction between the (I) intermediate and RR'CHOH in Reaction 4. The reaction between the (I) intermediate and RR'CHOH starts *via* the deprotonation of RR'CHOH. The deprotonation process, which corresponds to the rate-determing step, can be explained by the basicity effect on the rate enhancement in the dehydrogenation of alcohols; the dehydrogenation of ethanol by $[Ru_2Cl_3(PEt_2Ph)_6]Cl$ is enhanced by potassium hydroxide,[39] and the transfer hydrogenation of benzylideneacetophenone by $PhCH(Me)O^-Na^+$ with $RuCl_2(PPh_3)_3$ is markedly accelerated as compared with the same reaction including PhCH(Me)OH instead of $PhCH(Me)O^-Na^+$.[40]

Activation-Parameter Relationships. The rate of the dehydrogenation of RR'CHOH by the (I) intermediate is dependent on the reaction temperature between the enantiomers; hence, the enantioselectivity defined by k_R/k_S comes to be affected by the temperature (Table 3). The temperature dependence of the rate constant for each enantiomer can be expressed by the linear Arrhenius relationship (Fig. 2); the activation param-

eters ($\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$) obtained for the series of experiments shown in Table 3 are summarized in Table 5. The activation parameters which reflect those for the rate-determining hydrogen-abstraction process in Reaction 4 established an isokinetic relationship well; that is, the smaller $\Delta H^{\ddagger}$ values for one of the enantiomers always require negatively larger $\Delta S^{\ddagger}$ values (Fig. 3). Such an isokinetic relationship is also obtained from the

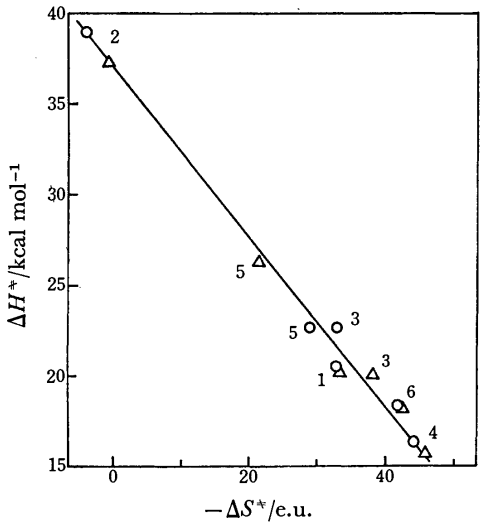

Fig. 3. An isokinetic relationship of the present reaction (numbers are the same as in Table 5). ○: R, △: S.

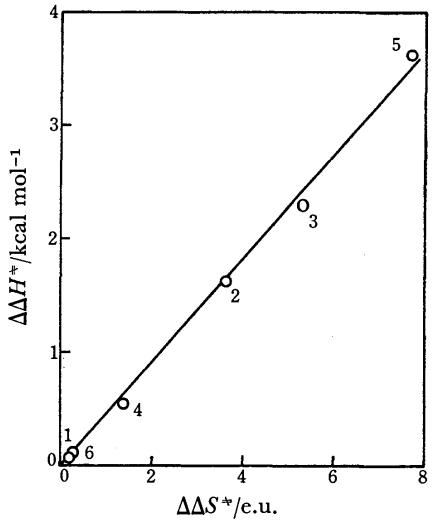

Fig. 4. Correlation between the $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ values (numbers are the same as in Fig. 3).

reaction steps common to the present reaction, especially from the transition state shown in Reaction 4. The difference in the electronic factors reflected in $\Delta H^{\ddagger}$ between the *R* and *S* enantiomers ($\Delta H^{\ddagger}_R$ and $\Delta H^{\ddagger}_S$ respectively) leads to the idea that the coordination distance between the oxygen atom and the Ru metal in the transition state might be different between the enantiomers; the shorter coordination distance makes the $\Delta H^{\ddagger}$ value smaller, while requiring a negatively larger $\Delta S^{\ddagger}$ one. If this is true, the difference between the $\Delta H^{\ddagger}_R$ and $\Delta H^{\ddagger}_S$ values, $\Delta\Delta H^{\ddagger}$, will be correlated with that between the $\Delta S^{\ddagger}_R$ (for *R* enantiomer) and $\Delta S^{\ddagger}_S$ (for *S* one) values, $\Delta\Delta S^{\ddagger}$. In this respect, there is a linear correlationship between the $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ values with the intersect of zero (Fig. 4). It may be deduced, therefore, that the enantioselective coordination of *R*- and *S*-RR'CHOH to the chiral complex occurs at a different coordination distance between the enantiomers under asymmetric circumstances (*viz.*, stereochemical influences of chiral ligands).

Physical Properties and Constitution of the 5,6: 11,12-Bis(epidithio)-naphthacene-Iodine Complexes (TTT-I_n)

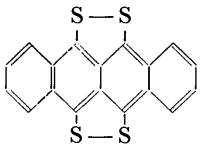
Tamotsu INABE and Yoshio MATSUNAGA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 16, 1978)

The electrical resistivity of the 5,6: 11,12-bis(epidithio)naphthacene(TTT)–iodine system was examined using polycrystalline compactions. The room-temperature resistivity reaches a minimum of 0.3 ohm cm at the composition of the well-studied metallic phase, TTT–$I_{1.5}$, and a shoulder as large as 200 ohm cm occurs at the composition of the other metallic phase, TTT–$I_{2.7}$. The apparent activation energy for semiconduction at the latter composition is as much as 0.13 eV, indicating some semiconductor behavior in directions other than the needle axis. The appearance of the latter phase is also manifested by a drastic increase in the Seebeck coefficient near this composition, which corresponds to a change in the amount of charge per TTT molecule from 0.68 to 0.85. The diffuse reflection spectra were recorded for TTT–$I_{1.53}$ and TTT–$I_{2.79}$. The resemblance between the spectrum of the iodine-rich complex and that of TTT–Br is noted.

It has been known for some time that 5,6: 11,12-bis(epidithio)naphthacene(TTT[1]) can produce highly



conducting ionic molecular complexes and also cation radical salts. The former group consists of the complexes with *o*-haloanils,[2-4] tetracyanoethylene,[2,3] tetracyanoquinodimethane,[5-8] and bis(1,2-ethylenedithiolato)nickel(II),[9] while the latter includes halides and thiocyanate.[10] Recently, there has been a great deal of interest in TTT–$I_{1.5}$, which is among the most conducting organic compounds so far developed.[11-14] Here, we wish to report the electrical properties of TTT–I_n as functions of the composition. Earlier, similar studies were made on the four semiconducting thiazine–iodine systems.[15] The location of electrical singularities was shown to be a powerful tool for elucidating the constitution of organic compound-iodine systems. For instance, we demonstrated that a shoulder in the resistivity-composition isotherm, a decrease in the activation energy for semiconduction by a factor of two, and a change in the sign of the Seebeck coefficient from negative to positive can be observed at a composition of two molecules of phenothiazine to five atoms of iodine and that the incorporation of a half mole of iodine to this compound gives rise to a resistivity minimum.

Experimental

Materials. TTT was synthesized following the method reported by Marschalk and Stumm and recrystallized three times from trichlorobenzene.[16] Samples were prepared by grinding the weighed TTT and iodine or the weighed sample of a less iodine content and iodine in an agate mortar in the presence of a small amount of benzene. The iodine contents were determined by microanalysis. Two additional samples were prepared by the reaction between TTT and iodine in boiling nitrobenzene and benzene respectively. Their compositions were TTT–$I_{1.53}$ and TTT–$I_{2.79}$.

Measurements. The electrical resistivities and Seebeck coefficients of polycrystalline compactions were recorded as functions of the temperature from −120 to 20 °C by the procedures described in our previous paper.[17] The diffuse reflectance of samples diluted with sodium chloride was measured by means of a Beckman DK 2A spectroreflectometer in the range from 325 to 2500 nm. The reference was pure sodium chloride. The spectrum was then plotted using the Kubelka-Munk function.

Results and Discussion

Electrical Properties. In Fig. 1, the logarithm of electrical resistivity at 20 °C is plotted against the number of iodine atoms per TTT molecule, *n*. Two shaded circles indicate that these samples were made by the reaction in boiling nitrobenzene or benzene; therefore, they were supposed to be more homogeneous than the others. It must be emphasized that the shaded circles fit in well to the resistivity-composition isotherm made with open circles. A minimum resistivity of about 0.3 ohm cm is found at $n=1.5$. Then the resistivity reaches a shoulder at $n=2.7$, the value being about 200 ohm cm. Although Buravov *et al.* have reported a phase corresponding to $n\simeq 1$,[11] no singularity due to this phase could be detected in our isotherm. Kamaras

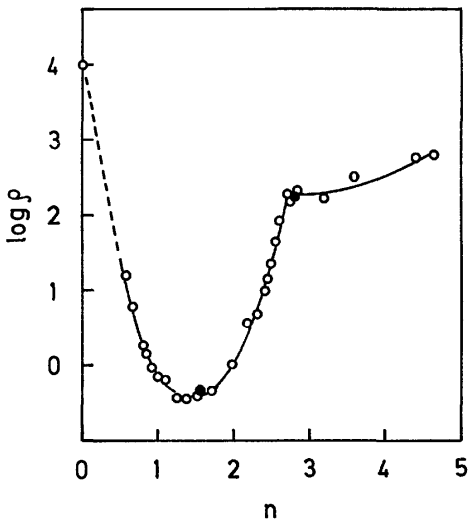


Fig. 1. Electrical resistivity at 20 °C plotted against the iodine content (*n* I atoms/TTT molecule).

et al. have noted that the phase can be obtained only occasionally, together with TTT and TTT–$I_{1.5}$;[13] therefore, the amount of TTT–I in our samples may be too small to show any singularity.

Now we wish to summarize briefly the electrical behavior of mixtures. If two coexisting phases are strictly stoichiometric and mechanically mixed without interaction, Lichtenecker's logarithmic mixing rule may apply for the resistivity.[18,19] The composition of a distinct compound may correspond to a minimum in the resistivity-composition isotherm when its resistivity is the lowest in the system or to an abrupt change in the slope when its resistivity is not the lowest. If the incorporation of a marked stoichiometric imbalance is conceivable for a phase, the electrical behavior may depend quite differently upon the composition. When additional carriers are introduced by the imbalance, the stoichiometric composition may be indicated by a maximum in the resistivity-composition isotherm. When the effect of an excess of one of the components on the resistivity is small or when the stoichiometric phase is incapable of existence, a shoulder may be observed instead of a maximum.

The composition of the well-studied TTT–$I_{1.5}$ phase has been reported to vary within narrow limits, from $n=$ 1.50 to 1.56;[14,20] therefore, the appearance of a resistivity minimum at this composition seems to be more likely than that of a maximum. Even if a maximum exists, the presently-observed resistivity values around $n=1.5$ arise essentially from contact between the crystals and are probably much larger than the maximum value. All the reported resistivity values along the needle axis are of the order of 0.001 ohm cm.[11–13] The electrical behavior found for the phase around $n=2.7$ is clearly of a nonstoichiometric type, and is in agreement with the observation made by Kamaras *et al.*, namely, the composition of their recrystallized samples ranges from $n=2.6$ to 2.9.[13] The sharp edge appearing in Fig. 1 shows that the ideal composition of this phase is $n=2.7$ and also that the incorporation of an excess of TTT considerably lowers the resistivity. This large effect seems to agree qualitatively with the observation by Kamaras *et al.* again. They have examined about twenty crystals in this phase and have found resistivity values along the needle axis scattered by a factor of 16. However, it must be added that the values in Fig. 1 are three orders of magnitude greater than the reported values, namely, from 0.01 to 0.2 ohm cm. This disagreement suggests that the anisotropy in the TTT–$I_{2.7}$ phase is anomalously large and is much larger than that in the TTT–$I_{1.5}$ phase.

The temperature dependence of the resistivity, ρ, follows the typical semiconductor behavior: $\rho=\rho_0 \exp(E_a/kT)$. The activation energy for semiconduction, E_a, thus obtained is plotted against n in Fig. 2. As the single crystal resistivities measured along the needle axes in both the TTT–$I_{1.5}$ and TTT–$I_{2.7}$ phases are known to be metallic in the temperature range from 200 to 300 K, the activation energy observed with the polycrystalline compactions must be attributed to the activation energy for semiconduction in the directions other than the needle axis and, at least in part, to contact between the crystals. The small activation energy found near $n=1.5$ may be mostly due to the latter; however, the value as large as 0.13 eV found for the TTT–$I_{2.7}$ phase arises undoubtedly from the semiconductor behavior along the axes other than the needle axis.

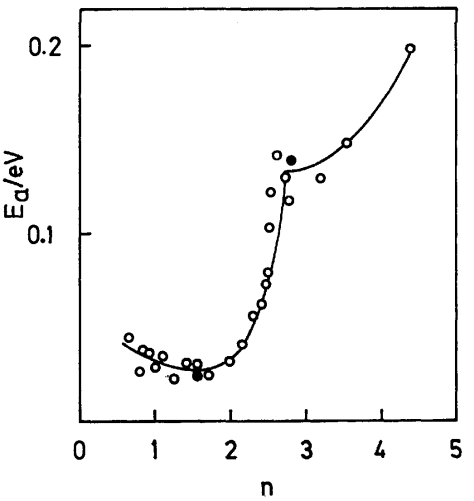

Fig. 2. Activation energy for semiconduction plotted against the iodine content.

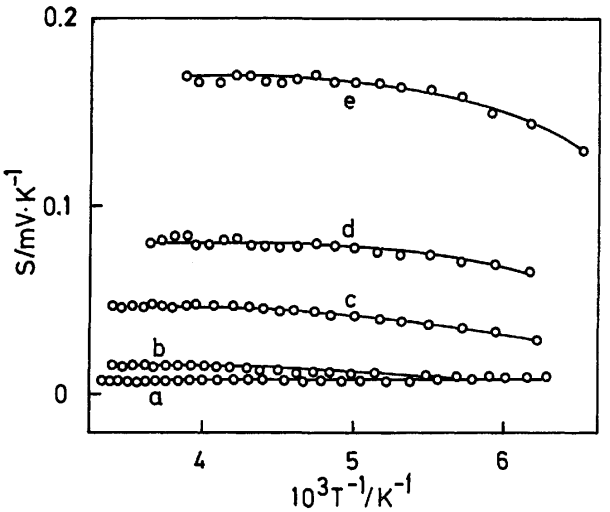

Fig. 3. Seebeck coefficient of the TTT–iodine complexes; a) $n=1.71$, b) 2.59, c) 2.84, d) 3.20, and e) 3.58.

The Seebeck coefficients of all the samples are positive throughout the examined temperature range, and tend to saturate at high temperatures (see Fig. 3). Similar behavior, but with the opposite sign, has been known to be characteristic of TCNQ salts with metallic conductivity.[21] According to the theory of Beni,[22] their Seebeck coefficients in the high temperature limit, $S(T\to\infty)$, are given by the equation,

$$S(T\to\infty) = -\frac{k}{|e|}\ln 2(1-\gamma)/\gamma,$$

where γ is the carrier concentration defined by the ratio of the number of carriers to the number of sites, in other words, the amount of negative charge per TCNQ molecule. Following the proposal by Beni *et al.* that the above equation is the most direct way of

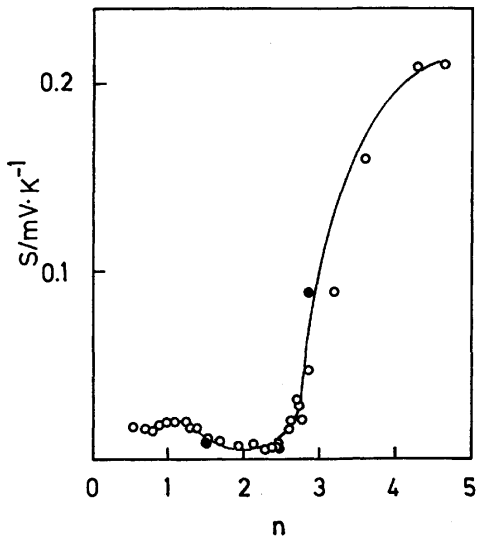

Fig. 4. Seebeck coefficient at −20 °C plotted against the iodine content.

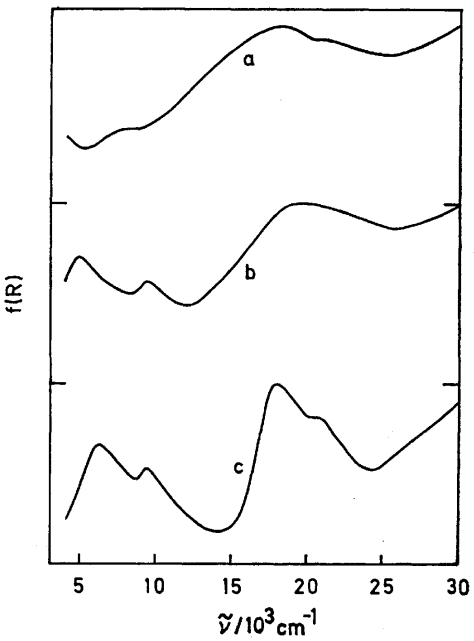

Fig. 5. Diffuse reflection spectra of a) TTT-$I_{1.53}$, b) TTT-$I_{2.79}$, and c) TTT-Br.

determining the value of γ,[23] we earlier found 0.52—0.55 for the high-conductivity 1:2 salts and 0.60—0.62 for the 2:3 salts by measurements on the polycrystalline compactions.[24] These values agree reasonably well with the expected ones, namely, 1/2 and 2/3. The high-temperature limit for the Seebeck coefficient is governed entirely by the entropy change per added carrier and is expected to be independent of the charge sign.[25] Consequently, the Beni equation may be employed for the estimation of the amount of positive charge per TTT molecule, because both TTT-$I_{1.5}$ and TTT-$I_{2.7}$ phases are known to be metallic. The positive coefficients are indicative of the γ values larger than 2/3. The value estimated for the TTT-$I_{1.5}$ phase is 0.68 and that for the TTT-$I_{2.7}$ phase, 0.80—0.85. If all the iodine atoms in these phases exist as triiodide ions, the expected γ values are 1/2 and 9/10 respectively. The $S(T\rightarrow\infty)$ value for the former γ is $-60\ \mu V\ K^{-1}$ and that for the latter is $+130\ \mu V\ K^{-1}$. Thus, the estimated amount of charge per TTT molecule in the TTT-$I_{1.5}$ phase is significantly larger than the expected one. If one assumes that a part of the iodine is in the form of iodide ions, I^-, and that $\gamma=2/3$ for the sake of simplicity, the constitution at $n=1.5$ may be expressed by the formula: $(TTT^+)_{2/3}(TTT^0)_{1/3}(I_3^-)_{5/12}(I^-)_{1/4}$. The abrupt increase of the Seebeck coefficient in a narrow range of $n=2.6$ to 3.0 shown in Fig. 4 corresponds to the change of γ from 0.68 to 0.85. The temperature-dependence of the Seebeck coefficient in the range above $n=3$ is similar to that below $n=3$. Tentatively applying the Beni equation to the range near $n=3$, it is concluded that the TTT molecule does not attain a unit positive charge even at the highest iodine content. Therefore, the TTT-$I_{2.7}$ phase may contain a higher polyiodide ion, possibly a pentaiodide ion, or an iodine molecule in addition to the triiodide ion.

Electronic Spectra. In Fig. 5, the Kubelka-Munk plots of diffuse reflectance are presented for samples TTT-$I_{1.53}$ and TTT-$I_{2.79}$. Each spectrum in the region below $10\times10^3\ cm^{-1}$ consists of two peaks; however, their locations are markedly dependent on the composition. The TTT-$I_{1.5}$ phase shows one peak below $4\times10^3\ cm^{-1}$, the limit of the spectroreflectometer employed, and the other at about $7.5\times10^3\ cm^{-1}$, while the TTT-$I_{2.7}$ phase shows peaks at 4.8×10^3 and $9.4\times10^3\ cm^{-1}$. The presence of two peaks in the infrared region is characteristic of solid TTT cation radical salts.[26] For comparison, the spectrum of TTT-Br taken from our previous work is added to Fig. 5. This bromide has been reported to exhibit a resistivity of 50 ohm cm at 25 °C by Perez-Albuerne *et al.*[10] Here, the peaks are located at 6.2×10^3, 9.5×10^3, and $18.0\times10^3\ cm^{-1}$, with a shoulder at $20\times10^3\ cm^{-1}$. As the appearance of such low-energy absorption bands attributable to electronic transitions are common to low-resistivity organic compounds, it is strange that no absorption has been noted below $10\times10^3\ cm^{-1}$ in the spectra of samples TTT-$I_{1.6}$ and TTT-$I_{2.8}$ presented by Kamaras *et al.*[13] Although the lowest energy band in the TTT-$I_{2.7}$ phase is shifted a little to the lower-energy side compared with that in the TTT-Br, the close resemblance in the spectral features of these two may be noted. In agreement with the high γ value estimated on the basis of the Seebeck coefficient, this resemblance suggests that the major fraction of TTT molecules is in the form of monopositive ions. The strong peak with a shoulder in the visible region shown by the solid TTT-Br is the cause of the dark red color and characterizes the TTT^+ ion. However, this peak cannot be identified in the spectra of black-colored TTT-$I_{1.53}$ and TTT-$I_{2.79}$ because of overlap with strong absorption bands due to triiodide and/or polyiodide ion.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 234028).

Intramolecular Charge Transfer in the Polar Fluorescent State of 1- and 2-Acylanthracenes

Takashi TAMAKI

Research Institute for Polymers and Textiles, Sawatari, Kanagawa-ku, Yokohama 221

(Received March 22, 1978)

The absorption and emission spectra of 1- and 2-aroyl- and acetylanthracenes were measured in various solvents. The emission spectra moved to longer wavelengths and their forms changed from the structured ones to the structureless ones with increasing solvent polarity, while the absorption spectra showed no appreciable changes under the same conditions. These emissive features became more distinguished with increasing electron-withdrawing ability of the aroyl group. The dipole moments of the fluorescent state as estimated from the Lippert-Mataga formula were 7—16 D for these compounds. The assignments of the low-lying excited states are described in terms of the electronic transitions of the parent anthracene, ^1L_a and ^1L_b, which undergo perturbation by the substitution.

In a recent study on the photoaroylation of anthracene (**1**) with benzoyl chloride, and its *p*- or *m*-substituted compounds, the ketone products formed were found to be positionally selective, the product distribution being different from that of the thermal Friedel-Crafts benzoylation.[1] This positional selectivity has attracted our continuing attention. Since the product distribution obtained is inconsistent with that theoretically expected from the reactivity calculated, which is acceptable for a non-interacting aromatic molecule, we tentatively postulate a specific intermolecular interaction between the reactants to ensure the positional selectivity. In fact, a strong interaction was evidenced by the efficient quenching of the fluorescence of **1** by these aroyl chlorides. Furthermore, the Hammett treatment of the quenching rate constant was indicative of an exciplex formation.

To further elucidate the electronic interaction of **1** with the aroyl system, we planned to study the spectral and emissive behaviors of aroylanthracenes, in which the constituents are intimately combined. The information about the intramolecular interaction may be helpful to account for the mechanisms of the intermolecular interaction concerned.

The introduction of a substituent group into an aromatic ring, in general, leads to a spectral deformation due to degradation of the molecular symmetry and due to effective electronic conjugation with the group.[2] It is well known that the absorption spectra of the anthracene derivatives, except for the meso substitution, are quite different from that of the parent (**1**).[3-5] The factors influencing the spectra are also discussed.

Experimental

Aroylanthracenes (**2c** and **3b—f**) were prepared in similar ways to those described in a preceding paper.[1b] The preparation of acetylanthracenes (**2a** and **3a**) was carried out after Luttinghaus and Kacer.[6] The emission spectra were measured in an air atmosphere, using a Hitachi MPA-2A spectrophotofluorometer. The sample absorbance in a 1-cm square quartz cell was made to be 0.1 at the exciting wavelength (390 nm), so that the reabsorption was negligible and that the relative emission intensities were comparable with each other.

Solvents used were spectro- or G.R. grade reagents (the numbers in parentheses refer to those presented in the figures): hexane (1), cyclohexane (2), carbon tetrachloride (4), dioxane (5), dibutyl ether (6), dipropyl ether (7), chloroform (8), butyl acetate (10), ethyl acetate (11), dichloromethane (13), 1,2-dichloroethane (14), pyridine (15), *t*-butyl alcohol (16), and 2-propanol (17) were used as commercially available; benzene (3), diethyl ether (9), tetrahydrofuran (12), acetone (18), *N,N*-dimethylformamide (19), ethanol (20), acetonitrile (21), and methanol (22) were dried by standard procedures and purified by fractional distillation.

The measurements of the fluorescence polarization spectra were made in a glycerol solution in order to minimize the rotational relaxation. The monitoring wavelength was 520 nm.

Results and Discussion

Absorption Spectra. The absorption spectra of 1- (**2c**) and 2-benzoylanthracene (**3c**) in hexane are shown in Fig. 1. The intense absorption bands in the short wavelength region (<300 nm) may consist of the transition bands which originate from the constituent aromatic moieties. In this region, the anthryl and the phenyl rings give intense progressions, which are assigned to the ^1B_b and the ^1L_a band, respectively.[2] The assignment of the short wavelength bands was not undertaken in this study.

In the longer wavelength region, above 300 nm, the absorption spectra are quite different from that of the parent anthracene (**1**), in which a progression of the ^1L_a transition alone is prominent. As is shown in Fig. 1, the compounds (**2c** and **3c**) give two electronic transition bands, which are closely overlapping each other in the former spectrum and clearly separate in the latter spectrum. These bands are conveniently named as I and II, according to the sequence of their peak energy

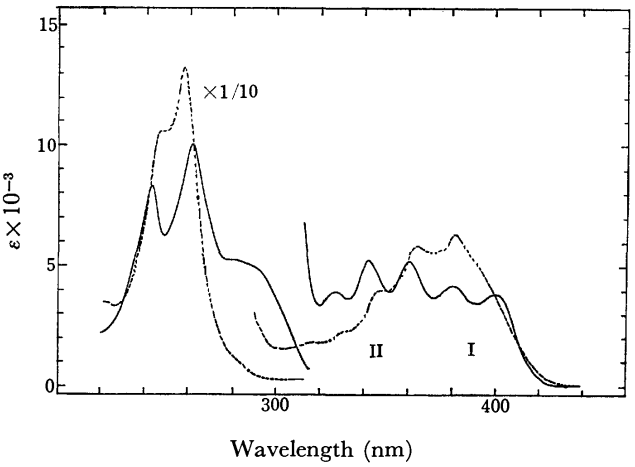

Fig. 1. Absorption spectra of 1-benzoylanthracene (——) and 2-benzoylanthracene (——) in hexane.

(see Fig. 1). The absorption spectra of acetylanthracenes (**2a** and **3a**) are the same as those of the corresponding benzoylanthracenes. Such spectral deformation is rather common to the anthracene to which a powerful substituent group attaches.[2,4,5] Thus, the general form of the absorption spectrum is fundamentally dependent on the aromatic C-position at which the substitution occurs.

It is of special interest to clarify the roots of the I and II transition bands. Although a few papers have discussed the problem, the arguments among articles are confused because the fundamental dissimilarity to the parent spectrum prevents one from deducing conclusive assignments of the transition bands with certainty.[2,4,5] So far, the most plausible assignment arises from the resonance theory,[3,4] which claims that a substituent group largely affects the aromatic transition band lying in the same direction as that of the extending conjugation. Since an 1-substituent group lies nearly along the short axis of an aromatic molecule, it primarily influences the transverse-polarized ^1L_a band. Likewise, since a 2-substituent group lies nearly along the long axis, the longitudinally polarized ^1L_b band is mainly subjected to its influence. These substituent effects are well accepted for naphthalene derivatives: the 1-substitution gives rise to large bathochromic and hyperchromic shifts of the ^1L_a band, and the 2-substitution causes the similar shifts of the ^1L_b band.[2]

Suzuki and Baba have discussed the assignment of the electronic transition bands of anthrol and anthrylamine in terms of such substitution perturbation.[4] On the assumption that the degradation of the molecular symmetry due to substitution would lead to the emergence of the ^1L_b transition, which is forbidden in the parent spectrum, they ascribed the lowest (I) and the second (II) bands of the 1-derivatives to the perturbed ^1L_a and ^1L_b bands, respectively, and those of the 2-derivatives to the perturbed ^1L_b and ^1L_a bands, respectively. These assignments are also favored in the cases of the acylanthracenes studied here, because their absorption spectra have close resemblances to those of the corresponding anthrols or anthrylamines.

Judging from the MO treatments of the parent

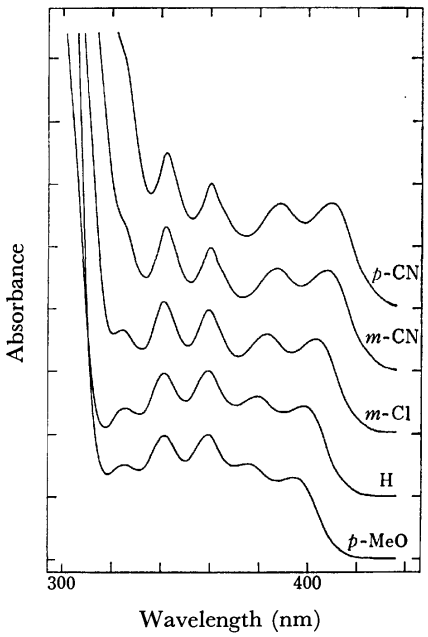

Fig. 2. Absorption spectra of 2-(substituted benzoyl)-anthracene in hexane.

spectrum, which suggest that the transition energy of the forbidden band (^1L_b) is slightly higher than that of the predominant band (^1L_a),[7] it appears striking that the former band extensively emerges on the lower frequency side of the latter band, when the substituent group is introduced at the 2-position of **1**. To examine this for the cases of the compounds concerned, we measured the absorption spectra of the series of 2-aroylanthracenes, which have a *p*- or *m*-substituent group on the benzoyl ring. As is shown in Fig. 2, the I band is apparently dependent on the substituent group, whereas the II band is little affected, its peak positions lying at the same wavelengths (325, 342, and 360 nm) for these compounds. The peak positions of their longest wavelength bands and their peak height ratio are listed in Table 1. The results indicate that the bathochromic and presumably hyperchromic effects on the I band become larger with increasing electron-withdrawing ability of the substituent group. The peak energy of the I band is well correlated with the Hammett substituent constant, σ. The ρ value obtained is 2.3, a value close to that derived from the inductive effect on the electron-abstracting process of the benzoyl system.[8]

These spectral features are quite consistent with the transition-band assignments in view of the resonance theory. It appears likely that the substituent perturba-

tion extends the spectral deformation, which was first generated from the degradation of the aromatic symmetry.

Solvent Effects on the Emission Spectra. The increase of the solvent polarity degradates the vibrational structure of the I band, with a slight broadening of the band, while the II band undergoes only a slight red-shift without changing its fundamental form. In contrast with these small changes of the absorption spectra, the emission spectra are greatly dependent on the solvent properties, as is shown in Fig. 3. The emission spectra in non-polar solvents are equal to the mirror image of the I band. When the solvent is changed from non-polar to polar, they are converted into structureless bands with large Stokes' shifts. Neverthless, their excitation spectra in all cases are in good agreement with the absorption spectra.

Lippert and Mataga have independently developed the theoretical treatments for solvent-induced changes of the excited electronic structure.[9] In the theory, the emission energy is to a good approximation correlated with the quasimacroscopic parameter for solvent polarity, $f(\varepsilon, n)=2(\varepsilon-1)/(2\varepsilon+1)-(n^2-1)/(2n^2+1)$, in which ε and n are the dielectric constant and refractive index of the continuum medium, respectively. As is shown in Fig. 4, the peak energy in most solvents used is in good correlation with the parameter, $f(\varepsilon, n)$, although the deviation from the plots is observed for some solvents, which specifically interact with the solute. The protic solvents in particular induce anomolous red-shifts, presumably due to formation of the hydrogen bond. The excess of stabilization energy for the hydrogen bond is of the order of 1500 cm^{-1}, as estimated from the difference between the frequencies of the peak maxima in acetonitrile and in methanol, which are of the same polarity. Further discussions for the cases of the protic solvents will not be made.

The emission energy plots obtained for all compounds examined give curvatures which have at least two slopes, as is shown in Fig. 4. The slope in the non-polar region is nearly horizontal and that in the polar region is definitely negative. The inflection appears at the intermediate-polarity solvent, ethyl ether. This solvent dependence indicates that the fluorescent state of **2** and **3** becomes highly polar with increasing the solvation, while the ground state is little affected. In Table 2 are liested the values of the dipole moment in the fluorescent state, as calculated from the Lippert-Mataga formula on the assumption that the radius of the solvent cavity is 5 Å, approximately what would be expected from the molecular model. The values of the dipole moment are 7 D for **2**, 9 D for **3a**, and 10 D for **3c**.

As is shown in Fig. 4b, the peak shift in the polar region is very sensitive to the substituent group of the benzoyl phenyl ring. The greater the electron-withdrawing ability of the substituent group, the more the peak moves to the longer wavelengths and the greater the value of the dipole moment calculated (Table 2).

Table 2. Dipole moments in polar fluorescent states

Compound	Dipole moment (debye)	Compound	Dipole moment (debye)
2a	7	**3c**	10
2c	7	**3d**	12
3a	9	**3e**	13
3b	9.5	**3f**	16

From these results, it appears probable that the charge transfer occurs from the anthryl ring to the acetyl or benzoyl moiety in the excited equilibrium state.

In this connection, it was observed that *N,N*-dimethylaniline, which is an electron donor, strongly quencehd the fluorescence of the compounds (**2** and **3**) to give an exciplex emission in non-polar solvents. On the other hand, an electron acceptor such as dicyanobenzene had no such quenching ability. These facts support the assertion that the anthryl ring is greatly electron-deficient in the excited state owing to the charge transfer to the substituent group.

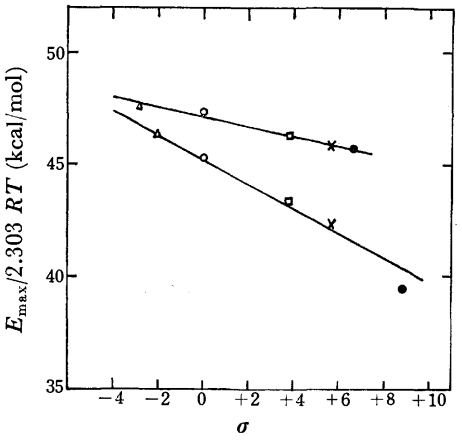

Fig. 5. Hammett correlation of the emission peak maxima of 2-(substituted benzoyl)anthracene in hexane (upper plots) and in acetonitrile (lower plots).

The Hammett plots for the emission energy of **3b—f** are shown in Fig. 5. The emission energy in hexane shows a linear Hammett correlation, with ρ equal to that obtained from the similar plots of the absorption energy. While the inductive contribution is importtant for the electronic transition processes in the non-polar solvents, the emission energy in acetonitrile requires an exalted substituent constant, σ^-, to give a linear Hammett correlation, which suggests the validity of the resonance contribution for the stabilization of the polar fluorescent state. The ρ value obtained for the acetonitrile solution is 5.5, a value so high as to be consistent with the charge transfer required in a large electron-demand process.

The solvent dependence of the emission intensity is complicated, as is shown in Fig. 6. Generally speaking, the emission intensity increases with increasing the solvent polarity, and then decreases in a highly polar region. Very weak emission in non-polar solvents may correspond to the case of 9-benzoylanthracene, which is non-fluorescent because of rapid radiationless decay through a thermally activated intersystem crosssing to the upper triplet state in a slightly higher energy level than that of the lowest excited singlet state.[10] It appears likely that the energy gaps between the relevant electronic levels of the compounds (**2** and **3**) are so large that the radiative transition rate is comparable to the radiationless decay rate. If this energy gap is more enlarged when the fluorescent state moves

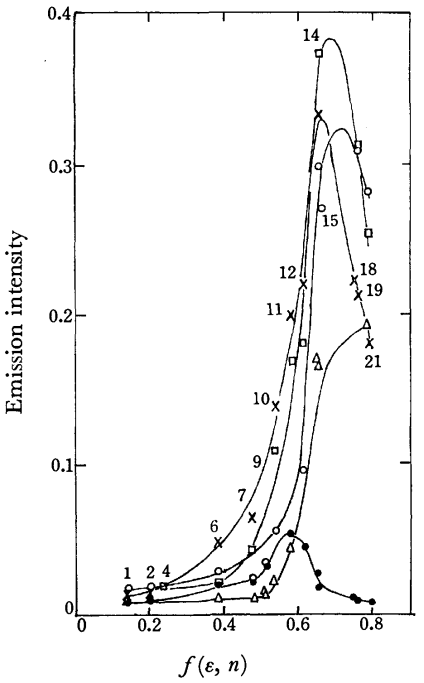

Fig. 6. Solvent effects on the emission intensity of 2-(substituted benzoyl)anthracene: *p*-MeO (△), H (○), *m*-Cl (□), *m*-CN (×), *p*-CN (●).

to the lower frequency region with increasing the solvation, the radiative probability would increase at the expense of the intersystem-crossing probability. The decrease of the emission intensity in highly polar solvents is remarkable for the compounds (**3**), which have a powerful substituent group such as a cyanobenzoyl group. This suggests that a complete charge separation would be accomplished for these highly solvated compounds, resulting in the decrease of the radiative transition probability.

The excitation-polarization spectra of **2a** and **3a** in glycerol are shown in Fig. 7. When the I band is excited, the degree of the polarization obtained is *ca.* 0.3 suggesting that this band corresponds to the emitting band. If the rotational relaxation is severly inhibited, the polarization degree would become close to the maximum value, 0.5.[11] The excitation of the II band leads to the decrease of the polarization, which supports

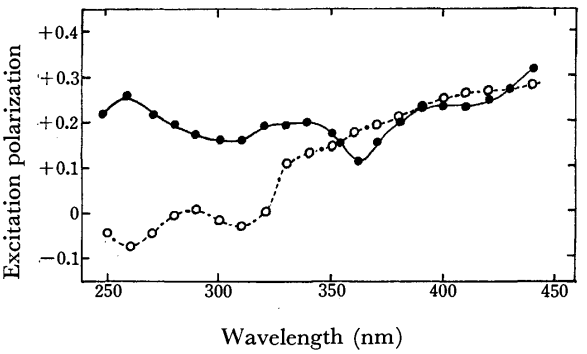

Fig. 7. Excitation polarization spectra of 1-acetylanthracene (-----) and 2-acetylanthracene (——) in glycerol. Monitoring wavelength, λ 520 nm.

the idea that the transition moments of the I and II bands are oriented at large angles to each other. While the polarization behaviors of these long wavelengths bands are similar for all compounds examined, the situation of the short wavelengths bands is quite different for the polarization spectra of **2** and of **3**: the former shows a negative polarization (*ca.* −0.1), but the latte shows a large positive polarization (*ca.* 0.25). The dissimilarity in the polarization spectra may reflect the difference in the mutual orientation of the exciting and emitting transition moments of these compounds. The exciting band of acetylanthracene (**2a** and **3a**) in this short wavelength region is ascribed to the anthryl ^1B_b band, although the contribution of the phenyl ^1L_a transition to excitation is unclear in the cases of benzoylanthracene (**2c** and **3c**). Since the ^1B_b band lies along the long axis,[7] the results for the polarization provide a possible orientation of the I band of **2** and **3**, which is approximately in line with the consequences of the transition-band assignments based on the absorption spectra.

The emissive features of aroylanthracenes are informative to account for the mechanisms of the intermolecular interaction between **1** and the aroyl chlorides:[1] 1) the charge transfer in the polar fluorescent state is related to an intermolecular exciplex formation; and 2), the inversion of the excited states in 2-benzoylanthracene is indicative of the validity of the ^1L_b state in determining the positional selectivity in the photoaroylation.

A Study on the Anode Effect in KF-2HF System. III. Influence of Bath Temperature and Surface Tension and Addition of Fluoride Particles on the Occurrence of the Anode Effect

Hiroki IMOTO, Kazuo UENO, and Nobuatsu WATANABE*

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received March 24, 1978)

The decomposition reaction of the graphite fluoride film formed on the edge plane of pyrolytic graphite, carbon, and graphite electrodes was faster in a KF·HF bath (250 °C) than in a KF·2HF bath (100 °C) due to the higher temperature of KF·HF bath. The critical current densities (CCD's)[1] were about 0.1 A/cm² for the layer and edge planes of pyrolytic graphite, carbon, and graphite electrodes in the KF·HF bath, and the CCD for each electrode was larger in the KF·HF bath than in the KF·2HF bath. The anode effect took place easily on the glassy carbon electrode in the KF·2HF bath. However, the anode effect did not take place in liquid hydrogen fluoride due to its very low surface tension, although the graphite fluoride film was formed on the electrode surface. The zeta-potential of aluminum fluoride particles in liquid hydrogen fluoride containing 0—20 mol of potassium fluoride/l and that of magnesium fluoride particles in liquid hydrogen fluoride were almost zero at 0 °C. From the results it is not proper that the effect of the addition of dispersed particles upon the anode effect is explained by the view of electrostatic force of the particles proposed so far.[2]

The anodic behavior of four kinds of electrodes (graphite, carbon, pyrolytic graphite, and glassy carbon) have been investigated in KF·2HF bath.[2-4] It has been suggested that the occurrence of the anode effect is influenced by the wettability of the anode surface with the bath and the kinetic balance of the rates of the formation and decomposition reaction of the graphite fluoride, $(CF)_n$,[5] film on the anode. The wettability and the kinetic balance vary with the surface tension and the operating temperature of the bath, respectively. Table 1 shows the surface tensions of the KF–HF system. The surface tension of liquid hydrogen fluoride (LHF, 0 °C) is much lower than that of KF·2HF melt (100 °C). The surface tension of KF·HF melt (250 °C) is almost the same as that of KF·2HF melt. Therefore, in the present study, LHF and KF·HF melt were used as baths for investigating the influence of the surface tension and the temperature of the baths on the occurrence of the anode effect.

TABLE 1. SURFACE TENSION OF KF–HF SYSTEM

	LHF[a]	KF·2HF[b]	KF·HF[c]
Temperature (°C)	0	100	245

The addition of lithium fluoride, nickel fluoride, aluminum fluoride, calcium fluoride,[6] magnesium fluoride[7] particles to the KF·2HF bath is effective for preventing the anode effect. This effect has been explained on the basis of the zeta-potential of the fluoride particles.[2] In order to confirm the explanation proposed, the zeta-potentials of aluminum fluoride (AlF_3) and magnesium fluoride (MgF_2) particles dispersed in KF–HF system were measured at 0 °C.

Experimental

The cell was kept at 100 and 250 °C for KF·2HF and KF·HF baths, respectively. A platinum rod was used as a reference electrode in both baths. Further detailed descriptions of the apparatus and the procedure for the measurement in the KF·2HF bath have been given in previous papers.[4,8] The measurement in the KF·HF bath was the same as that in the KF·2HF bath. The electrolytic cell for LHF was identical to that reported before[9] and cooled at 0 °C in ice bath. The Cu/CuF_2 electrode was used as a reference electrode, and a nickel plate as a counter electrode. Small amounts of potassium fluoride were added to LHF as a supporting electrolyte. LHF in the cell was dehydrated by pre-electrolysis with nickel electrodes for 2 days. The glassy carbon electrode was connected with a nickel lead by winding fine copper wires. The nickel lead and all parts of the glassy carbon except for the working electrode surface were protected with perflon paint[10] and Teflon (poly(tetrafluoro-

ethylene)) tape. Before ESCA measurement, the electrode of pyrolytic graphite was washed with LHF in order to remove the KF·HF remaining on the electrode. The ESCA spectrum of C 1s electron for the electrode has two peaks at 284 and 288.5 eV.[8] The former peak corresponds to the binding energy of the C 1s electron for the carbon atom which has only the C–C bond, and the latter peak corresponds to the one for the carbon atom with C–F bond. The height of the peaks at 284 and 288.5 eV were represented by h_0 and h_1, respectively and the value of $h_1/(h_0+h_1)$ was adopted as the relative amount of $(CF)_n$ on the electrode surface. The zeta-potential of particles dispersed in the KF–HF system was measured using a microelectrophoresis apparatus as shown in Fig. 1. The cell was specially designed for the corrosive hydrogen flouride, that is, the microscopic observation tube (3) was made of transparaent poly(trifluorochloroethylene) and the other parts were made of Teflon. The parts (1), (2), and (3) in Fig. 1 were kept at 0 °C in a cold air bath. The potential gradient between the nickel electrodes (2) was varied from 0 to 2.7 V/cm.

Results and Discussion

Effect of the Temperature of Bath. Figure 2 shows the *I-V* curves obtained by the linear potential sweep method for the layer plane (G_L) and edge plane (G_E) of the pyrolytic graphite electrodes in the KF·HF bath at 250 °C. The potential of the electrode G_L or G_E was swept from 0 to 7.0 V *vs.* Pt (forward sweep) and subsequently from 7 to 3.5 V (backward sweep). Two peaks were observed on both curves (a) and (b) on the forward sweep. This may be explained in terms of formation of two kinds of $(CF)_n$ films on the anode surface,[3] that is, the $(CF)_n$ film which has extremely low surface energy is formed at the second peak, and the current decreases rapidly with increasing potential. But the current restored on the backward sweep only on the electrode G_E, indicating that decomposition took place easily on the electrode. The peak current densities on the forward (second peak) and the backward sweeps were represented by P_f and P_b, respectively. The value of P_b/P_f for the electrode G_E was about twice as large in the KF·HF bath as in the KF·2HF bath, because the former cell temperature was about 150 °C higher than the latter one and therefore the $(CF)_n$ film easily decomposed in the KF·HF bath.[11] On the other hand, the current was hardly restored on the backward sweep on the electrode G_L, which means that the $(CF)_n$ film on the electrode G_L was hardly decomposed.

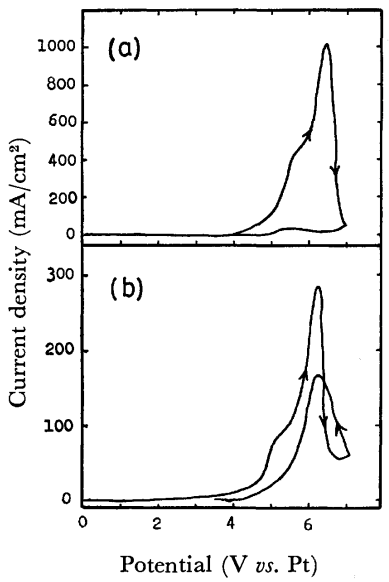

Fig. 2. *I-V* curves (potential sweep) in KF·HF bath at 250 °C.
Anode: (a) electrode G_L, (b) electrode G_E, potential sweep rate: 50 mV/s.

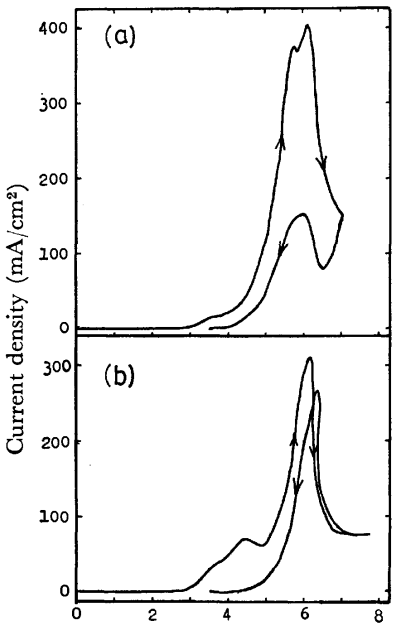

Fig. 3. *I-V* curves (potential sweep) in KF·HF bath at 250 °C.
Anode: (a) graphite, (b) carbon, potential sweep rate: 50 mV/s.

Figure 3 shows the *I-V* curves for the commercial carbon and graphite electrode. The values of P_b/P_f for the graphite and carbon electrodes were two and three times larger in the KF·HF bath than in KF·2HF bath, respectively. Consequently, the rate of decomposition of the $(CF)_n$ film on the anode surface is faster in KF·HF bath than in the KF·2HF bath when the electrode G_E and the carbon and graphite electrodes are used as anodes.

Figure 4 shows the potential sweep rate dependence of the P_f value for the four kinds of electrodes mentioned above. The dependence of the P_f values for these electrodes on the potential sweep rate showed the same tendency in both the KF·2HF and the KF·HF baths. Only the peak current density for the electrode G_L increased with the potential sweep rate much more than those for the other electrodes. From previous discussion,[4] this indicates that the covering rate of the electrode surface with the $(CF)_n$ was slower on the electrode G_L than on the other electrodes. Furthermore, the peak current densities for the four kinds of electrodes were independent of potential sweep rate within the

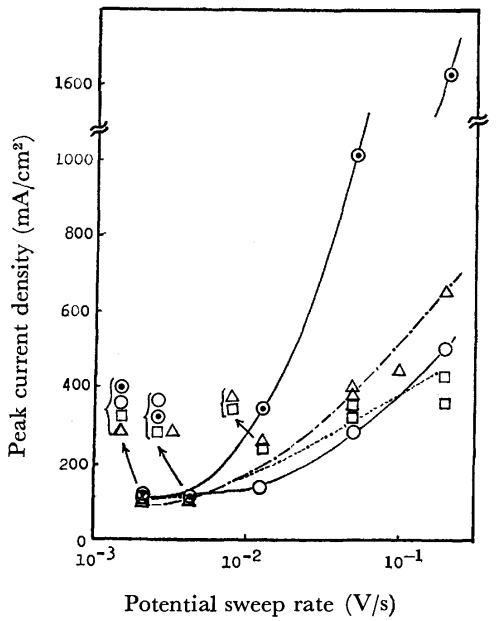

Fig. 4. Dependence of peak current densities on potential sweep rate in KF·HF bath (250 °C).
⊙ Electrode G_L, ○ electrode G_E, △ graphite, □ carbon.

region of low sweep rate. As the steady state condition was established within the region, the critical current densities (CCD's)[1] were found to be about 0.1 A/cm² for all electrodes from the peak current densities. The CCD's for the carbon, graphite, G_L, and G_E electrodes in the KF·2HF bath were 80, 25, 20, and 55 mA/cm², respectively. From the results, the KF·HF bath has advantages for operating the fluorine cell at higher current density compared with the KF·2HF bath.

When the electrode G_L or G_E was potentiostatically polarized in the KF·HF bath, the current reached a stationary value within 10 min. The ESCA spectra of C 1s electron for these electrodes were obtained after the polarization. The potential dependence of the values of $h_1/(h_0+h_1)$ is shown in Fig. 5. The potential

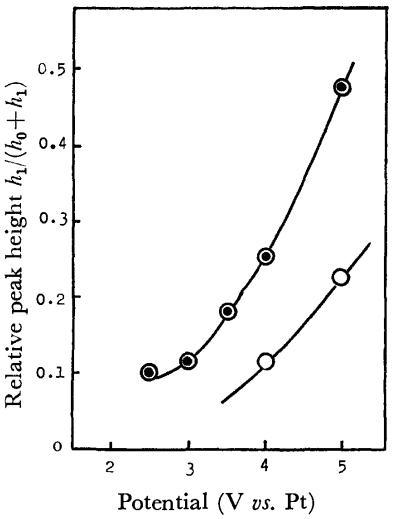

Fig. 5. Potential dependence of ESCA spectra of C 1s electron for pyrolytic graphite anode surface.
⊙ Electrode G_L, ○ electrode G_E.

dependence of the amount of the $(CF)_n$ film formed on the electrode G_L in the KF·HF bath was similar to that in the KF·2HF bath. However the $(CF)_n$ film was hardly observed on the electrode G_L polarized at lower potential than 3.5 V, although the $(CF)_n$ film was formed on the electrode polarized at 2 V in the KF·2HF bath. These facts suggest that the $(CF)_n$ formed on the electrode G_E at lower potential was easily decomposed due to the higher temperature of the KF·HF bath and the film on the electrode G_L was thermally more stable than that on the electrode G_E. These results may support the interpretation of the *I-V* curves described above.

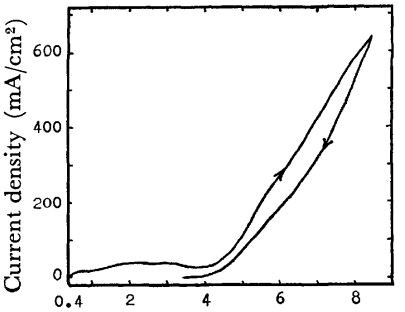

Fig. 6. *I-V* curve (potential sweep) in liquid hydrogen fluoride at 0 °C.
Electrode: glassy carbon, potential sweep rate: 12.5 mV/s.

Effect of Surface Tension of Bath. Only the polarization curve of the glassy carbon electrode could be obtained even in the LHF bath.[12] Figure 6 shows *I-V* curve for the glassy carbon electrode obtained by the linear potential sweep method at the potential between 0.4—8.4 V (the potential is converted into the potential *vs.* hydrogen electrode only in this section). The *I-V* curve obtained in the LHF bath was significantly different from that obtained in the KF·2HF bath, since the current increased with increasing potential without the anode effect becoming apparent. On the other hand, the current decreased rapidly at about 5.5 V with increasing potential due to the anode effect in the KF·2HF bath. The ESCA spectrum of C 1s electron for the surface of the glassy carbon electrode polarized at 4.9 V for 10 min in the LHF bath indicated the existence of the $(CF)_n$ film on the electrode surface. When the $(CF)_n$ film is formed on the glassy carbon electrode by the anodic polarization in the KF·2HF bath, the anode effect takes place, because the elctrode does not come into direct contact with the bath due to the high surface tension of the bath. However, the anode effect does not take place in the LHF bath in spite of the formation of the $(CF)_n$ film on the electrode, because the electrode surface comes into contact with the bath due to the very low surface tension of the LHF bath. The results verify the mechanism of the occurrence of the anode effect proposed,[2,13,14] and agree with the fact that when the carbon anode is used, the CCD's are 50—60 and 60—80 mA/cm² in KF·2HF (100 dyn/cm, 90 °C) and KF·3HF (75 dyn/cm, 80 °C) baths, respectively.[2]

Effect of Addition of Fluoride Particles. The following explanation was proposed[15,16] to account for the suppressive effect of fluoride particles on the anode effect. If the fluorine gas bubbles generated on the anode have negative charges, it is difficult for the bubbles to be separated from the anode because of the electrostatic attractive forces. If the colloidal fluoride particles have positive charges, they would be absorbed on the fluorine bubbles to neutralize the negative charges of the bubbles. Consequently the electrostatic force between the fluorine gas bubbles and the anode becomes remarkably weak and the fluorine gas bubbles can be readily separated from the anode surface. The zeta-potential of AlF_3 and MgF_2 particles dispersed in the KF–HF system were measured. The zeta-potentials of AlF_3 in LHF containing 0—20 mol of potassium fluoride/l and of MgF_2 in LHF were almost zero at 0 °C. Therefore, the zeta-potentials of AlF_3 and MgF_2 particles are thought to be almost zero in the KF·2HF bath of which the ionic strength is very high. From the results, it was found that the suppressive effect of the dispersed fluoride particles upon the anode effect cannot be accounted for in terms of the electrostatic interaction proposed so far.

Conclusion

1) The rate of decomposition of the graphite fluoride film formed on the edge plane of pyrolytic graphite, carbon, and graphite anodes was faster in the KF·HF bath than in the KF·2HF bath, and each critical current density for the pyrolytic graphite, carbon, and graphite electrodes was higher in the KF·HF bath than in the KF·2HF bath.

2) The anode effect did not take place in liquid hydrogen fluoride due to the very low surface tension of liquid hydrogen fluoride, which verifies the mechanism of the anode effect in KF·2HF bath proposed so far.

3) It was found that the suppressive effect of the dispersed fluoride particles upon the anode effect cannot be explained from the view of electrostatic force proposed so far.

Studies on Aqueous Solutions of Guanidinium Salts. VIII. Free Energy of Mixing of Guanidinium Bromide and Tetrabutylammonium Bromide in Aqueous Solution at 25 °C

Koichiro MIYAJIMA, Hiromitsu YOSHIDA, and Masayuki NAKAGAKI*

Faculty of Pharmaceutical Sciences, Kyoto University Yoshida-Shimoadachi-cho, Sakyo-ku, Kyoto 606

(Received March 18, 1978)

Osmotic and activity coefficients have been determined by the isopiestic comparison method on the water–guanidinium bromide–tetrabutylammonium bromide system at 25 °C. The values of the excess free energy change of mixing and the interaction parameter g_0 on Friedman's formalism were large and negative in magnitude. These results have been discussed in terms of the mixed ion pairing and structural change of water.

Guanidinium salts and their related compounds are well known as protein denaturants, but the mechanism of the denaturation remains ambiguous. Two types of mechanism have so far been postulated, one is the direct interaction between the acid amide groups of proteins and denaturants leading to the destruction of the hydrogen bond between the acid amide groups and the other is the indirect interaction between proteins and denaturants through the change of water structure which stabilizes the natural conformation of protein in the aqueous solution. Robinson and Jencks[1] investigated the former mechanism by examining the effect of several perturbants on the activity coefficient of acetyltetraglycine ethyl ester. By measuring the solubility they concluded that the non-hydrophobic interaction made a major contribution to the effectiveness of perturbants in protein denaturation in aqueous solution. Kauzmann[2] and Tanford[3] suggested that the hydrophobic bond played an important role in the stability of tertiary or higher structures of proteins. In the aqueous ternary systems containing urea and hydrocarbons, urea increased the solubility of the latter.[4] Similarly the decrease in the activity coefficient of tetrabutylammonium bromide (Bu_4NBr) and a positive enthalpy of transfer were obtained for the water–urea–tetraalkylammonium salt system.[5,6] Potassium bromide, on the other hand, increased the activity coefficient of tetrapropylammonium bromide in the aqueous ternary system.[7] These results were discussed in terms of the changes of the hydrophobic interactions by the structure breaking of potassium bromide and urea.[5–7] Based on the similartities of molecular shape, size and functional groups between urea and the guanidinium ion (Gu^+), the authors postulated[8] that the mechanism of the structure breaking by the guanidinium ion was similar to that by urea rather than by large alkali metal ions such as potassium and caesium ions. The differences would be more pronounced in aqueous solutions containing structure making solutes such as tetraalkylammonium salts than in pure water. The excess thermodynamic function of mixing in aqueous electrolyte solutions has been studied mainly on inorganic salt mixtures, several cases containing tetraalkylammonium salt as a component. The free energy change of mixing of Bu_4NBr and guanidinium bromide (GuBr) has been studied by the isopiestic comparison method and the results discussed in terms of the interionic interaction and the hydrophobic hydration.

Experimental

Materials. Guanidinium bromide was obtained by concentrating the aqueous solution of guanidine neutralized with hydrobromic acid. The crystal obtained was recrystallized twice or more from acetone and dried *in vacuo* before use. Tetrabutylammonium bromide was purchased from Wako Junyaku Co., Ltd. and recrystallized twice or more from the mixed solvent (ethyl acetate: diethyl ether=3: 1).

Method. Measurements of osmotic coefficients were carried out by the isopiestic comparison method at 25±0.02 °C using the same apparatus as reported previously.[9] In order to calculate the molality of each ternary solution, buoyancy corrections were made adopting the densities of the solid as 1.894 for GuBr, 1.152 for Bu_4NBr, and unity for the aqueous solutions. Both GuBr and Bu_4NBr were used as reference solutes. The experimental determination of the isopiestic concentration were precise to within 0.5%.

Theory

Activity Coefficient. Mckay and Perring's method[10] was used to evaluate the activity coefficients of each component in the ternary solution which was prepared by mixing two kinds of 1 : 1 electrolyte solutions. Under the conditions of equal vapour pressure among the three solutions, *i.e.* of GuBr (solute B), Bu_4NBr (solute C) and a mixture of both of them, the relation of Eq. 1 holds.

$$\nu_B M_B \phi_B = \nu_C M_C \phi_C = \nu m \phi, \quad (1)$$

where ν_B and ν_C are the number of moles of ions formed from 1 mol of solute B and C, M_B and M_C are the molality of solute B and C in the binary solutions which have the corresponding osmotic coefficients ϕ_B and ϕ_C, respectively. ν is the number of ions formed from 1 mol of pseudo-binary salt $(1-x)Gu^+xBu_4N^+Br^-$ and m is the total molality of the ternary solution which has the corresponding osmotic coefficient ϕ. x is the ionic mole fraction of electrolyte C in the mixture defined as

$$x = m_C/m = I_C/I, \quad (2)$$

where I_C and I are the ionic strengths of electrolyte C and the total one of the mixed electrolyte, respectively. The activity coefficient of solute B (γ_B) in the ternary solution may be obtained from the following equations:

$$\ln \gamma_B = \ln \Gamma_B + \ln R_B + \int_0^{M_B\phi_B} f(m, M_B, x)\, d(M_B\phi_B) \quad (3)$$

and

$$f(m, M_B, x) = \left(\frac{\partial m}{\partial \ln x}\right) \Big/ m^2 + 1/m - 1/M_B, \quad (4)$$

where Γ_B is the activity coefficient of solute B in the binary solution in equilibrium with the ternary solution, R_B is the isopiestic ratio (M_B/m). Approximating R_B to[10]

$$R_B = 1 - a_B x - b_B x^2, \quad (5)$$

Eq. 3 reduces to

$$\ln \gamma_B = \ln \Gamma_B + \ln R_B + x^2 \int_0^{M_B\phi_B} \frac{b_B}{M_B} d(M_B\phi_B). \quad (6)$$

The activity coefficient of solute C can also be obtained from the same procedure.

Free Energy of Transfer ΔG^{tr} at Constant Mole Fraction (N). Using the activity coefficient of each solute in a ternary solution calculated by the above method, the free energy of transfer of one component from the binary to the ternary solution at constant mole fraction (N) can be obtained[11] as follows. In the case of solute C being transferred from water to a solution containing solute B, the free energy of transfer is defined as

$$\Delta G_C^{tr} = \nu_C RT \ln (f_C^*/f_C^0), \quad (7)$$

where f_C^* and f_C^0 are the activity coefficients of solute C in mole fraction scale in the ternary and the binary solutions, respectively. They are defined by

$$f_C^0 = \gamma_C^0(1+0.001 M_A \nu_C m_C^0), \quad (8)$$

$$f_C^* = \gamma_C(1+0.001(\nu_C m_C' + \nu_B m_B)), \quad (9)$$

and

$$m_C' = (1+0.001 M_A \nu_B m_B) m_C^0, \quad (10)$$

where m_C^0 and γ_C^0 are the molality and the molal activity coefficient of solute C in the binary solution, while m_C' and γ_C are the corresponding quantities in the ternary solution, having the same mole fraction (N_C) as the binary solution. M_A is the molecular weight of water. Free energy of transfer of solute B was also obtained from the same method.

Excess Free Energy Change on Mixing Solution at Constant Ionic Strength $\Delta_m G^{ex}$. $\Delta_m G^{ex}$ is defined by[12]

$$\Delta_m G^{ex}(x, I) = G^{ex}(x, I) - xG^{ex}(1, I) - (1-x)G^{ex}(0, I), \quad (11)$$

where $G^{ex}(1, I)$ and $G^{ex}(0, I)$ are the excess free energies of binary solutions of solute C and B, respectively. $G^{ex}(x, I)$ is the corresponding quantity in the ternary solution of which the total ionic strength equals I and the fraction of ionic strength is x. The excess free energy of pseudo-binary salt solutions is defined by

$$G^{ex}(x, I) = \nu RTI(\ln \gamma_\pm + (1-\phi)), \quad (12)$$

where $\gamma_\pm$ and ϕ are the mean activity coefficient and osmotic coefficient of the solute, respectively, R being the gas constant and T the absolute temperature. By applying the Gibbs-Duhem relation to Eq. 12, one obtains

$$G^{ex}(x, I) = -2\nu IRT \int_0^{\sqrt{I}} \frac{1-\phi}{\sqrt{I}} d\sqrt{I}. \quad (13)$$

The integration of Eq. 13 was carried out by computer program assuming Relation 14 between ϕ and I at the same fraction x.

$$\phi = 1 - \sum_{i=1}^{5} q_i I^{i/2} \quad (q_1 = 0.3902). \quad (14)$$

Theoretically, $\Delta_m G^{ex}(x, I)$ would be expressed as a power series of the ionic strengths of each component in the mixed solution and those coefficients of the power series are related to the magnitudes of various interactions of ions. Friedman's extention based on Mayer's ionic cluster expansion theory has been adopted which yields the following expression:

$$\Delta_m G^{ex}(x, I) = I^2 RTx(1-x)(g_0 + g_1(1-2x) + \cdots), \quad (15)$$

where g_i is the interaction parameter. The first two interaction parameters of Eq. 15 were determined graphically by plotting $\Delta_m G^{ex}(x, I)/I^2 RTx(1-x)$ against x.

Results

Isopiestic Solutions. The isopiestic and related data are shown in Table 1. The second column gives the molalities of the reference GuBr solutions (M_B) having the osmotic coefficients ϕ_B. The next two columns show the molalities of GuBr (m_B) and those of Bu_4NBr (m_C), respectively, in the ternary solutions being isopiestic with the reference solution. The fifth shows the ionic mole fraction of solute C (x), the sixth

the isopiestic ratio (R_B).

Activity Coefficients. The activity coefficients of guanidinium bromide (γ_B) and tetrabutylammonium bromide (γ_C) for various ionic mole fractions obtained from Mckay and Perring's method are shown in Figs. 1 and 2, respectively. Each activity coefficient decreased as the total molality increased. In the system of the common ion mixing, the log γ curves for each electrolyte in aqueous ternary solutions with constant ionic mole fraction plotted against the total molality are usually located between those curves for the two binary systems. Put another way, the higher log γ values of the two electrolytes decreases on moving from the binary system to the ternary one, and *vice versa*. As shown in Fig. 1, the log γ values of guanidinium bromide in the H_2O–GuBr–Bu_4NBr system obeyed this rule in the concentration range studied, since the log γ values of GuBr

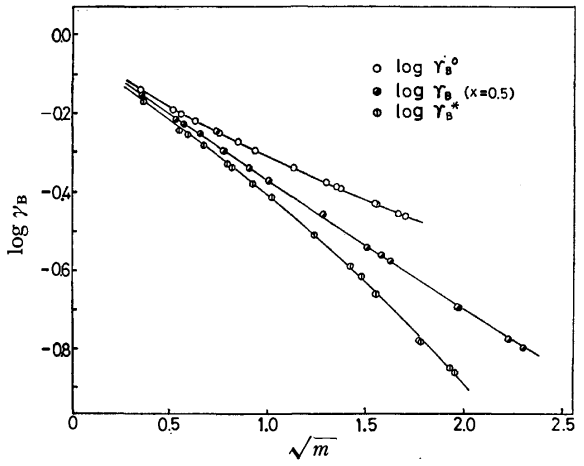

Fig. 1. Activity coefficient of GuBr (solute B) γ_B, plotted against $\sqrt{m}$. γ_B^0 is the activity coefficient in binary solution of solute B. γ_B^* is the activity coefficient of solute B in the solution containing only solute C (trace activity coefficient of B).

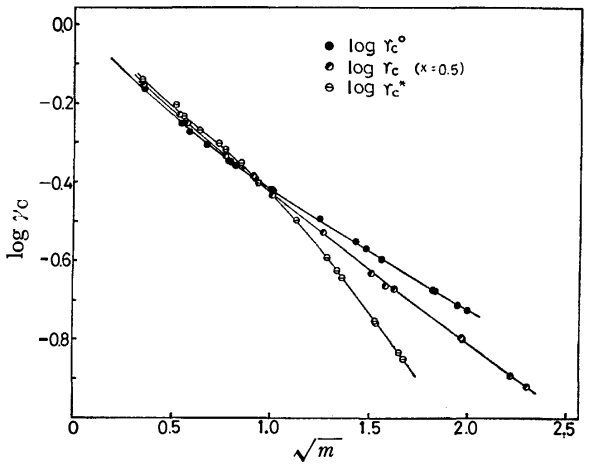

Fig. 2. Activity coefficient of Bu_4NBr (solute C) γ_C, plotted against $\sqrt{m}$. γ_C^0 is the activity coefficient in binary solution of solute C. γ_C^* is the activity coefficient of solute C in the solution containing only solute B (trace activity coefficient of C).

(log γ_B^0) were higher than those of Bu_4NBr (log γ_C^0) in each binary solution at the same molalities. As seen in Fig. 2, the activity coefficients of Bu_4NBr (log γ_C) in this ternary system were higher than those in the binary solution (log γ_C^0) below 1 molal, while the log γ_C values were lower than log γ_C^0 above 1 molal. Therefore the two curves cross each other around 1 molal. In order to express more clearly the influence of one electrolyte on the activity coefficient of the other in the ternary system, extended Harned's equation have been proposed as follows:[13,14]

$$\log \gamma_B = \log \gamma_B^0 - \alpha_B m_C - \beta_B m_C^2 = \log \gamma_B^0 - \alpha_B mx - \beta_B m^2 x^2 \quad (16)$$

and

$$\log \gamma_C = \log \gamma_C^0 - \alpha_C m_B - \beta_C m_B^2 = \log \gamma_C^0 - \alpha_C m(1-x) - \beta_C m^2(1-x)^2, \quad (17)$$

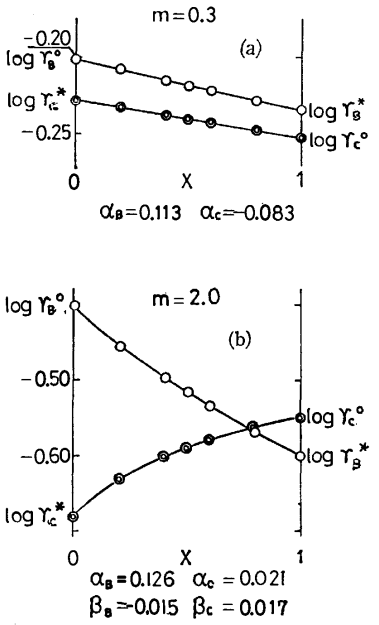

Fig. 3. (a) The variation of two activity coefficients against x at the total molality of 0.3. (b) The variation of two activity coefficients against x at the total molality of 2.0.

where α and β are the empirical constants which represent the type and magnitude of interionic interactions. In Figs. 3-a and 3-b, the relation between the activity coefficient of each salt and the mole fraction of Bu_4NBr (x) are shown at total molality $0.3m$ and $2.0m$, respectively. In Fig. 3-a, log γ_B decreases almost linearly with the increase of x, log γ_C increases from log γ_C^0 to log γ_C^* (trace activity coefficient of Bu_4NBr) linearly as x decreases from 1 to 0. The values of α_B and α_C were 0.113 and -0.083, respectively, and the values of β were nearly zero. As seen in Fig. 3-b, however, an abnormal change appeared when the total molality was at $2.0m$. The values of log γ_B decreased with the increase of value of x, while log γ_C decreased with the decrease of x. Therefore, the two curves were non-linear and the values of α_B and α_C were 0.126 and 0.021, respectively, while β_B and β_C were -0.015 and 0.017, respectively. Curves of this type which cross have so far been rarely reported in aqueous ternary solutions containing two kinds of inorganic electrolytes.

Free Energy of Transfer ΔG^{tr}. It is difficult to distinguish whether the change of the activity coefficient are based on salting-out, salting-in or "mutual" effect by plotting the activity coefficients at constant x against total molality. In the case of ΔG^{tr}, it is distinguishable because the free energy of transfer can be calculated from Eqs. 7—10, converting the activity coefficients to those in the mole fraction scale. They are shown in Tables 3-a and 3-b. Negative values of ΔG^{tr} were obtained for each electrolyte and the absolute value of ΔG^{tr} for each electrolyte increased with the molality of the other.

Excess Free Energy Change of Mixing $\Delta_m G^{ex}$. The osmotic coefficients of pseudo-binary salts (ϕ) for various ionic mole fraction x are shown in Table 2. These

values were read from the ϕ-I curves obtained by a least squares fit to Eq. 14. $\Delta_m G^{ex}$ at constant ionic strength was obtained from Eqs. 13 and 11 as shown in Fig. 4. The curves are nearly parabolic but the minimum point is slightly displaced towards the right from the

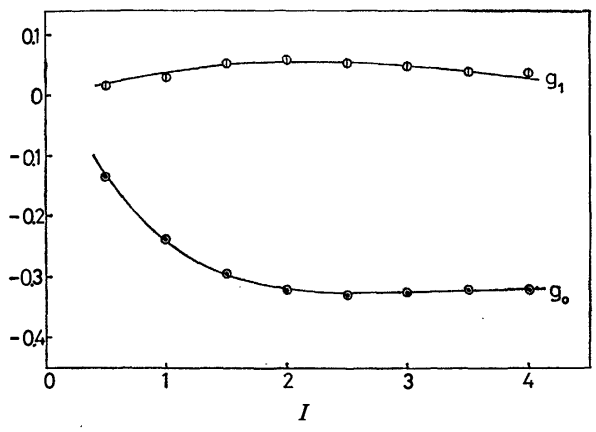

Fig. 5. Interaction parameters g_0 and g_1 plotted against I.

vertical line of $x=0.5$. The value of $\Delta_m G^{ex}$ at the minimum decreases as the total ionic strength increases. The interaction parameters g_0 and g_1 obtained from Eq. 15 are shown in Fig. 5 and Table 4. The negative values of g_1 slightly increased up to about $I=2.0$ and decreased with the increase of I.

Discussion

In most aqueous ternary systems containing two kinds of inorganic electrolytes with a common anion, the relation between log γ and the concentration of each electrolyte obeys "Harned's rule" for a wide range of concentration.[14] This means that the values the interaction parameter for a mixed cation pair corresponds almost to the arithmetic mean value of those for like cation pairs.[15] As shown in Fig. 3-a, the system of H_2O–GuBr–Bu_4NBr showed a similar behavior at low concentration to the aqueous ternary systems with two kinds of inorganic electrolytes, although the slopes of the log γ *vs.* x curves were considerably larger. However, as seen in Fig. 3-b, when the total molality increased, the log γ *vs.* x curves were quite different from those of Fig. 3-a. This implies that Harned's rule does not hold at high concentration, that is, the attractive interaction between Bu_4N^+ and Gu^+ increases and dominates the other pair interactions. This salting-in effect is expressed in terms of the free energy of transfer ΔG^{tr} similar to that of the H_2O–urea–Bu_4NBr system. The values of ΔG^{tr} for Bu_4NBr in the H_2O–GuBr–Bu_4NBr system are almost twice as large as those in the H_2O–urea–Bu_4NBr system.[5] This result is closely related to the effective concentration of these solutes in the denaturation of proteins in aqueous solutions. As seen in Fig. 4, the values of $\Delta_m G^{ex}$ are all negative and depend parabolically on x at all ionic strengths, suggesting that the g_0 terms are more important than the g_1 terms in the concentration region studied.[7] However the skewness of the curves at high ionic strength shows that the g_1 terms cannot be ignored. As shown in Fig. 5 and Table 4, the positive g_1 values increased as the concentration increased up to around 2.0*m* and decreased above this concentration. However the magnitudes of g_0 are 6 or 10 times larger than those of g_1. In the symmetrical mixture of electrolyte, g_0 and g_1 are expressed as[16]

$$g_0 = (g^{B^+C^+} - g^{B^+B^+} - g^{C^+C^+}) + I(g^{B^+C^+Br^-} - g^{B^+B^+Br^-} - g^{C^+C^+Br^-}) + \text{triplet type of same cations} \quad (18)$$

and

$$g_1 = I(g^{B^+C^+C^+} - g^{B^+B^+C^+} + g^{B^+B^+B^+} - g^{C^+C^+C^+}), \quad (19)$$

where B^+ and C^+ are Gu^+ and Bu_4N^+, respectively, and g^{ij} is the interaction parameter of free energy of ions i and j, g^{ijk} is the same quantity of three ions i, j, and k. Though it will be of great interest to find the values of g^{ij} and g^{ijk}, it is quite impossible using this experimental approach. The g_0 coefficients listed in Table 4 are related to the coefficient of Harned's equation[12] as

$$g_0 = -2.303((\alpha_B+\alpha_C) + I(\beta_B+\beta_C)) + \cdots. \quad (20)$$

The pairwise interaction parameter in Eq. 18, $(g^{B^+C^+} - g^{B^+B^+} - g^{C^+C^+})$ corresponds to $-2.303\ (\alpha_B+\alpha_C)$. The values of this ion pair term at 0.3*m* and 2.0*m* are -0.069 and -0.339, respectively. The sign and magnitude of the values at 2.0*m* are almost the same as those of g_0 in Table 4 suggesting that the pairwise interaction is quite important at this concentration. The negative sign of the pairwise interaction term implies that the mixed cation pair Gu^+–Bu_4N^+ is more favored over the like ion pairs Gu^+–Gu^+ and Bu_4N^+–Bu_4N^+. In a previous paper,[17] it was reported that guanidinium bromide formed a crystalline complex with tetrabutylammonium bromide at high concentrations in aqueous solutions. From this fact and the large negative values of the pairwise interaction term in Eq. 18 at moderate concentrations, it seems plausible that the formation of mixed cation pair, Gu^+–Bu_4N^+ makes an important contribution to the mutual salting-in. However, Friedman's treatment is not sufficiently rigorous in which water is regarded as a continuum solvent with the dielectric constant of 80. Therefore the interionic interaction through the change of water structure caused by the addition of ions has to be considered. This effect may work as an attractive or repulsive force between ions. Previously,[9] the guanidinium ion was reported to be a structure breaker ion, while Bu_4N^+ was regarded as a hydrophobic structure maker which formed the clathrate hydrate in aqueous solution. As pointed out in a previous paper,[8] the interaction between Gu^+ and Bu_4N^+ decreases the water structure around Bu_4N^+. This effect also makes a negative contribution to g_0 values even if these two kinds of cations do not form a mixed ion pair.

It is interesting to compare $\Delta_m G^{ex}$ and ΔG^{tr} of this system and those of the H_2O–KBr–Pr_4NBr[7] and H_2O–urea–Bu_4NBr[5] systems. In the H_2O–KBr–Pr_4NBr system, $\Delta_m G^{ex}$ *vs.* x curves are usually parabolic as in the case of this system, but the sign of $\Delta_m G^{ex}$ is opposite. Wen[6] and Wood[18] concluded from the measurements of free energy and heats of mixing that Pr_4N^+–Pr_4N^+ was favored over the mixed ion pair in that system. Both the potassium[20] and guanidinium ions are classified as structure breakers but the mechanism of the breaking of the water structure should be quite different from each other,[7,8] since the effects of those ions toward hydrophobic hydration are quite different. On the other hand, ΔG^{tr} of Bu_4NBr from water to the aqueous solutions of urea and GuBr are both negative and the magnitudes of ΔG^{tr} are comparable to each other.

These results suggest that the shape, size, and functional groups play important roles in the effect of organic solutions on hydrophobic hydration at high concentration. The next stage, in progress now, is to measure the heat of mixing of these salts in aqueous solution.

Multiple Transmission Method of Time Domain Spectroscopy

Hiroshi SATO,* Koichi ITOH, and Hiroaki TAKAHASHI

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku, Tokyo 160

(Received March 27, 1978)

A new multiple transmission method of time domain spectroscopy was developed. A small amount of the sample (0.6 cm^3) is needed in this measurement. The dielectric dispersion and absorption curves of 1-propanol, 1-butanol, and 1-pentanol have been obtained as recorder traces of the spectra stored in the minicomputer. Three dielectric parameters, ε_∞, ε_0, and τ, are estimated for these alcohols.

Time domain spectroscopy (the TDS method), which was initially proposed by Fellner-Feldegg in 1969,[1] has a great advantage over the usual frequency domain method; it can considerably reduce the time needed in obtaining continuous spectra of the dielectric constant and loss. Recently several other groups have developed various ways of measurement and analysis for the TDS method, *viz.*, the thin sample method[2,3] and the methods of lumped capacitance,[4-6] multiple reflection,[7,8] and multiple transmission.[9]

In this report, we shall describe a new measurement system for the multiple transmission method, which requires only a small amount of the sample (0.6 cm^3). The results of the measurements, using this system, of the dielectric dispersion and absorption were found to be in fair agreement with those of the preceding works.

Experimental

Principle. When an annular disk of the dielectric sample is inserted in the coaxial lines, the characteristic impedance of the line changes at Point A (Fig. 1). After having been propagated through the coaxial lines, the electromagnetic waves reach the sample, where these waves are partially reflected and partially transmitted. Suppose that the input voltage is represented by a function of the time $v(t)$, and the transmitted voltage from the disk by $r(t)$. The total transmission coefficient $S(\omega)$ at a given angular frequency, ω, will be expressed in terms of Fourier transforms of $v(t)$ and $r(t)$ as follows:

$$S(\omega) = \frac{\int_0^\infty r(t) \exp(-j\omega t)\,dt}{\int_0^\infty v(t) \exp(-j\omega t)\,dt}. \quad (1)$$

On the other hand, $S(\omega)$ is related to the dielectric constant of the sample, $\varepsilon(\omega)$, by the following formula:[10]

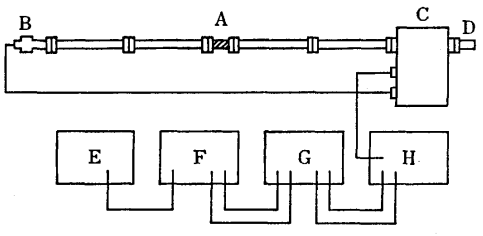

Fig. 1. Block diagram of the measurement system.
A: Sample cell, B: pulse generator, C: sampler, D: 50Ω termination, E: recorder, F: minicomputer, G: interface, H: sampling oscilloscope.

$$S(\omega) = \frac{(1-\rho^2(\omega)) \exp(-(\omega l/c) j\sqrt{\varepsilon(\omega)})}{1-\rho^2(\omega) \exp(-(2\omega l/c) j\sqrt{\varepsilon(\omega)})}, \quad (2)$$

where $\rho(\omega)$ is the reflection coefficient of the air-dielectric interface and is given by $(1-\sqrt{\varepsilon(\omega)})/(1+\sqrt{\varepsilon(\omega)})$, and where l is the thickness of the sample, and c, the velocity of light.

Apparatus. The main instruments for measurements and analyses are: (a) the Hewlett-Packard 180 TDR system with a 28 ps pulse generator, (b) GR 900-L30 precision air lines, and (c) the Melcom 70 minicomputer. The sampling oscilloscope in the system was modified in such a way as the time base could be swept externally. The measurement system used in the present work is shown schematically in Fig. 1.

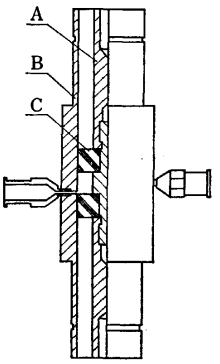

Fig. 2. Cross section of a dielectric specimen-holder.
A: Inner conductor (outer diam. 0.6204 cm), B: outer conductor (inner diam. 1.4288 cm), C: Teflon window (outer diam. 1.43 cm, inner diam. 0.43 cm, thickness 0.50 cm).

Details of Part A in Fig. 1 are shown in Fig. 2. The inner and outer conductors are the precision inner conductor rod (GR 900-9508) and the outer conductor tube (GR 900-9509), respectively. The thickness of the sample cell is 5.00 mm, and its volume is about 0.6 cm^3. The inner conductor is undercut to minimize the reflection at the surface of the Teflon. The cell is connected with the measurement system by means of two GR 900 BT precision connectors.

Measurements and Analyses. The two wave forms, $v(t)$ and $r(t)$, recorded by the oscilloscope are sampled at equal intervals along the time axis, and stored in the core memory of the minicomputer. The two signals relating to $v(t)$ and $r(t)$ are obtained when the cell is empty and when it is filled with the sample, respectively. The number of sampling points is about 1024, and the sampling interval, about 5 ps.

In order to analyze the data, the transmitted signal, $r(t)$, should have the same time origin as the input signal, $v(t)$. A set of five data-points is chosen for this reason from the steepest part of the transient, either $v(t)$ or $r(t)$, and a least-

squares approximation is applied to fit the set of data to a straight line. The point at which this straight line intersects the voltage base-line is assumed to be the time reference point.

The Fourier transforms of $v(t)$ and $r(t)$ were obtained by the Samulon method.[11] The results of calculation, however, sometimes become unsatisfactory when the iteration procedure is employed in solving a complicated function such as Eq. 2. In such a case, different damping factors were used for the real and imaginary part — for example, 1.0 for the real part and 0.3 for the imaginary part; then consistent and converged values were obtained for all calculations.

To determine the limiting high- and low-frequency dielectric constants ε_∞, ε_0, and the relaxation time τ, the Debye equation,

$$\varepsilon(\omega) = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{1 + j\omega\tau} \tag{3}$$

was fitted to the data by the least-squares method.

All the calculations were carried out by using a Melcom 70 minicomputer and programs written in an assembler language.

Results and Discussion

Figure 3 shows an example of the input and transmitted signals observed for 1-propanol at room temperature. Each signal was an average of thirty-two scans. This average procedure reduced the jitter noise generated by the measurement system.

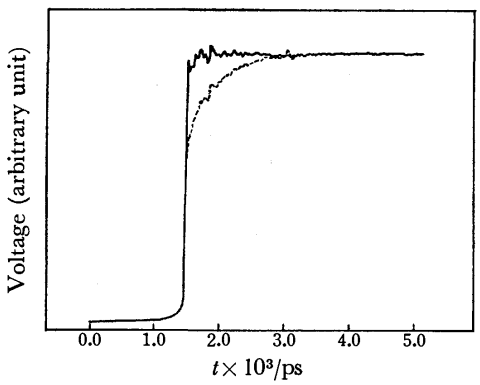

Fig. 3. Changes of the input (——) and transmitted voltages (– – –) with time, t.

From Fig. 3, the dielectric dispersion and absorption spectra are obtained (see the upper curves in Fig. 4). All the curves shown in Fig. 4 are direct recorder traces of the spectra stored in a minicomputer.

It has been reported that aliphatic normal alcohols show the second and third dielectric dispersions in the high frequency region.[12] The single Debye equation, however, was fitted to our data in the 0.1—2.5 GHz frequency region to obtain the limiting high- and low-frequency dielectric constants, ε_∞, ε_0, and the relaxation time, τ, because our measurement values were not so accurate as to give many parameters in the Budo equation.[13] The ε_∞, ε_0, and τ values for 1-propanol obtained are summarized in Table 1, together with the literature values. The dielectric measurements were also carried out on 1-butanol and 1-pentanol. The ε_∞, ε_0, and τ values obtained for these alcohols are recorded in Table 2.

Proton Diffusion in the Premelted State of 1-Hexadecanol

Norio MURASE,*,† Teruyuki FUJITA, Naotake MORIKAWA,** and Shozo KOGA

The Institute of Applied Microbiology, The University of Tokyo, Bunkyo-ku, Tokyo 113

***Radioisotope Centre, The University of Tokyo, Bunkyo-ku, Tokyo 113*

(Received March 27, 1978)

Proton diffusion in the α-phase of polycrystalline 1-hexadecanol was studied using $C_{16}H_{33}O^3H$ and $C_{15}H_{31}$-$^{14}CH_2OH$. It was found that hydroxyl proton diffuses translationally more easily than the whole molecule. A value of $(7\pm5)\times10^{-7}$ cm²/s was obtained for the diffusion coefficient of the hydroxyl proton in the α-phase. This fast diffusion is ascribed to the presence of molecular rotation involving hydrogen-bond networks in the α-phase of the crystal. Since the mechanism for the proton diffusion seems to be the same as that for the protonic conduction in this α-phase, proton mobility can be calculated from the diffusion coefficient, assuming that molecular rotation makes the rate determining step in both processes.

It has been shown in the literatures that proton conduction takes place in the premelted state (α-phase) of 1-hexadecanol (cetyl alcohol) through hydrogen bridges by way of the Grotthus mechanism.[1-3] Proton conduction is observed neither in the liquid state nor in the lower temperature solid phase of the alcohol. For the proton conduction to occur in solid, the presence of hydrogen-bond networks and their reorientation ability along the applied electric field are needed.[1,4-7] In the α-phase of 1-hexadecanol the molecules are known to be rotating around their hydrocarbon chains.[1,8] For further analysis of the mechanism of the proton conduction, it is necessary to know about the value of the proton mobility. There have been few data obtained about it so far on account of the small mobility and the occurence of electrode polarization, *etc.*[9-12] This study was made to obtain the diffusion coefficient of proton in the α-phase of 1-hexadecanol and also to calculate from it the value of the proton mobility.[13-16]

Experimental

1-Hexadecanol(guaranteed grade) used was obtained from Tokyo Kasei Co., Ltd. (Tokyo), and was used without further purification in this experiment. Two types of radioactive tracer were used in this experiment; tritiated 1-hexadecanol ($C_{16}H_{33}O^3H$), in which hydroxyl protons were tritium-labeled, and [1-^{14}C]-labled 1-hexadecanol ($C_{15}H_{31}$-$^{14}CH_2OH$).

Tritiated 1-hexadecanol was prepared by mixing 2 grams of melted 1-hexadecanol with 2 ml of tritiated water (100 mCi/ml) in an evacuated vessel (10^{-4} mmHg), followed by repeated annealing. The labeled alcohol was separated from the water and kept sealed in an evacuated flask until it was used for the experiment. The activity, obtained by this preparation, was about 3 μCi/mg and was ascertained before each experiment.

[1-^{14}C]1-Hexadecanol was obtained from the Radiochemical Centre(Amersham) as benzene solution whose radioactivity was 55.4 μCi/mg.

In order to distinguish the diffusion of the hydroxyl protons from that of the whole molecules, ^{14}C, ^3H-double labeled 1-hexadecanol was used. This double-labeled specimen was prepared in an evacuated vessel by mixing tritiated 1-hexadecanol with ^{14}C-labeled one in the liquid state and also sealed in the evacuated vessel. Its activity was 1.7 μCi/mg for ^3H and 2.4×10^{-1} μCi/mg for ^{14}C in the mixed state, respectively. During the measurement of diffusion coefficient, all handlings were carried out in a glove box where the atmosphere was replaced by nitrogen gas dried with P_2O_5. This is to prevent the tritium of 1-hexadecanol from being exchanged with protons of water molecules in the atmosphere followed by being re-exchanged with hydroxyl protons of other alcohol molecules at a distance.

A cyclinder-form cell made of polyethylene, the size of which was 1 cm in diameter and about 4 cm in height, was closed at one end and filled with melted 1-hexadecanol. The cell was put in an aluminium box and the temperature of the total system was controlled using thermister at 47 ± 0.5 °C where 1-hexadecanol takes α-phase. Two or three drops of melted double-labeled 1-hexadecanol were dropped on the flat surface of the alcohol kept in the α-phase using a warmed glass syringe. The whole cell was immediately covered with the lid of acrylic resins and separated completely from the surroundings. After keeping the sample in this state for 2 weeks, it was sectioned, weighed and assayed for radioactivity using a liquid scintillation counter. The composition of the scintillation solution used in this experiment was dioxane 1 dm³, naphthalene 100 g, 2,5-diphenyloxazole 1 g, *p*-bis(4-methyl-5-phenyl-2-oxazolyl)benzene 0.25 g.

Results and Discussion

The equation which described the tracer diffusion from an infinitely thin surface layer into a semi-infinitely thick solid is given by

$$C(x,t)=\frac{C_0}{\sqrt{\pi Dt}}\exp\left(-\frac{x^2}{4Dt}\right), \quad (1)$$

where $C(x,t)$ is the concentration of the tracer at a distance of x into the solid at time t, C_0 is the initial concentration of the tracer present and D is the diffusion coefficient. The diffusion coefficient can, therefore, be obtained from a plot of $\ln C$ *vs.* x^2. From the measurement of the ^3H-diffusion rate, it was found that $\ln C$-x^2 plots were almost linear except for their initial part where possible existence of micro-cracks through the thin specimens gave larger values. Carbon-14-labeled molecules did not diffuse at all during the same period of experiments. These results are shown in Fig. 1 and Table 1.

Since a cold sample used as a blank test in parallel run showed no radioactivity, the water vapor in the environment seemed to have been almost perfectly removed. The proton diffusion observed in this experi-

15	60.1	<0.1
25	28.4	<0.1
35	20.8	<0.1

a) Initial activity was 1.7 μCi/mg for ^3H and 2.4×10^{-1} μCi/mg for ^{14}C, respectively.

ment is considered to have taken place through the bulk without involving proton exchanges with water vapor in the atmosphere. Moreover, tritium diffusion through the partially molten spots in the sample can be ignored, because the ^{14}C-labeled molecules had scarcely diffused despite the temperature was kept just below the melting point. It was concluded, therefore, that hydroxyl protons diffuse rather fast and independently of the whole molecule in the α-phase of the alcohol, presumably *via* the hydrogen-bond networks extending through the crystals.

The diffusion coefficient, D, was calculated in accordance with Eq. 1 as

$$D = (7\pm5)\times10^{-7}\ \mathrm{cm^2/s}. \quad (1)$$

Measurements of the diffusion coefficient for proton using radioisotope as a tracer have been reported with other crystals such as ice,[14,15] imidazole,[16] and pivalic acid.[13] In the plastic phase of pivalic acid, it was reported that the diffusion coefficient of carboxyl protons is about 10^{-7} cm^2/s at 25 °C, which is approximately 10^2 times faster than that of the whole molecules. The diffusion coefficient is related to the mobility of charge carrier by Einstein's equation

$$\mu kT = qD, \quad (2)$$

where μ is the mobility, k is the Boltzmann constant, and q is the charge of the ion. Using this equation, the proton mobility in the α-phase of 1-hexadecanol is calculated as follows from the value of the diffusion coefficient obtained in this experiment.

$$\mu = (3\pm2)\times10^{-5}\ \mathrm{cm^2\ V^{-1}\ s^{-1}}.$$

It seems that Eq. 2 can only be applied when the independent charged-particles diffuse through the material. Charge transfer is not necessarily involved in the present diffusion process because diffusion can also be effected by some non-ionic exchange mechanism. However, if the rate-determining step in both the electric conduction and the concentration diffusion through the hydrogen-bond networks is not in the proton transfer process, but in the process of molecular rotation or reorientation of the hydrogen-bonded portion,[5] then Eq. 2 can be used to evaluate the effective mobility for the electric conduction of 1-hexadecanol in the α-phase.

The G-value of Nitrogen Atoms Produced in the γ-Radiolysis of Liquid Nitrogen and the Ozone Formation in the γ-Irradiated Liquid Nitrogen Solution of Oxygen

Akihiko MATSUMOTO, Rei YUGETA, Hidetoshi KARASAWA, and Shin SATO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 7, 1978)

The γ-radiolyses of liquid nitrogen solutions of nitrogen oxide and of oxygen gave nitrogen dioxide and ozone, respectively, as the main products. Over the solute concentrations from 0.01 to 0.1 mol l^{-1}, the G-values of both products were constants: $G(NO_2)=3.3$ and $G(O_3)\approx 7$. The G-value of nitrogen dioxide in the former solution probably corresponds to the G-value of nitrogen atoms from liquid nitrogen. For the formation of ozone in the latter solution, a possible reaction mechanism is discussed. Dinitrogen oxide was found as a minor product, the G-value being about 0.1 for both solutions.

The γ-radiolysis of liquid nitrogen containing a certain solute is one useful method for the investigation of the reactions of nitrogen atoms with the solute molecule or the radicals eventually produced from the solute in the solution, although this method is restricted by the solubility of the solute in liquid nitrogen. In previous papers,[1] we used several hydrocarbons as the solute and observed various nitrogen-containing compounds as the products; however, because of the complexity of the reactions occurring in the solution, we could not precisely determine the G-values of active species produced in the γ-irradiated liquid nitrogen.

In the study of active nitrogen in the gas phase, it is now well known that the titration using nitrogen oxide is one of the best methods for determining the concentration of nitrogen atoms.[2] We, therefore, attempted to study the γ-radiolysis of liquid nitrogen containing nitrogen oxide in the hope that the G-value of nitrogen atoms could be determined.

The formation of ozone in the γ-irradiated liquid nitrogen containing oxygen has long been known; however, the G-value of ozone did not seem to be measured. Since the technique used for the determination of the G-value of nitrogen dioxide can be applied for the estimation of ozone yield, the G-value of ozone from the liquid nitrogen solution of oxygen has also been measured.

Experimental

The dried high-purity nitrogen supplied by the Nihon Sanso Co. was used after having been passed through sulfuric acid. The research grade nitrogen oxide and oxygen were purchased from the Takachiho Shoji Co.

The procedures of preparation and of γ-irradiation at 77 K of the samples were the same as those previously reported.[1] The dose rate was 1.06×10^6 R h^{-1} and the irradiation time ranged from 20 min to 2 h. The absorbed dose was estimated by the Fricke dosimetry.

After the γ-irradiation, the inside of the sampling tube was slowly pumped out at 77 K. Usually two hours were taken for complete evacuation. When nitrogen oxide was used as the solute, the pumping was stopped at the pressure of 0.1 Torr, in order to prevent the pumping-out of nitrogen oxide. The products thus obtained were subjected to analysis.

In the case of the solution of nitrogen oxide, the observed products were nitrogen dioxide and a small amount of dinitrogen oxide. The amount of nitrogen dioxide was estimated by the optical density at 450 nm using a Hitachi Model 200-20 spectrophotometer. Since an excess amount of nitrogen oxide was present in the analyzing vessel, the following two equilibrium reactions had to be taken into account:

$$NO + NO_2 \rightleftarrows N_2O_3,$$

$$2NO_2 \rightleftarrows N_2O_4.$$

The equilibrium constants were taken from the literature.[3,4]

The analysis of dinitrogen oxide was made by a gaschromatograph equipped with a 5 m dimethyl sulfolane column of 20% w/w on celite. Before introducing the products into the gaschromatograph, nitrogen dioxide was separated by the distillation at -120 °C.

When oxygen was used as the solute, the formation of nitrogen dioxide could not be observed. The observed products were ozone and a small amount of dinitrogen oxide. Since ozone is easily decomposed at room temperature, the following procedure was used for the measurement. After the evacuation of the γ-irradiated solution at 77 K, a known amount of nitrogen oxide was introduced into the sampling tube. Then the liquid nitrogen Dewar flask was removed, so that all molecules of ozone should have been converted into nitrogen dioxide according to the stoichiometric reaction:

$$O_3 + 3NO = 3NO_2.$$

Then the amount of nitrogen dioxide was measured as stated above.

Results

Figure 1 shows the G-value of nitrogen dioxide as a function of the amount of nitrogen oxide introduced

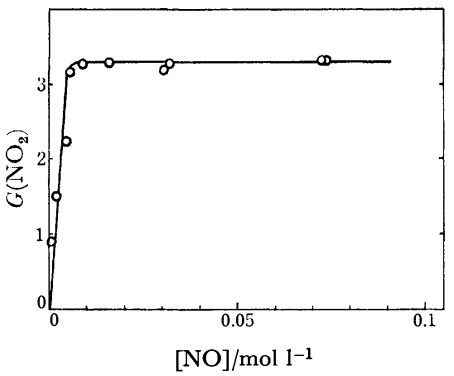

Fig. 1. The G-value of nitrogen dioxide as a function of the concentration of nitrogen oxide.

Table 1. The measurement of dinitrogen oxide

	Liquid N_2/cm³	Solute/ 10^{-3} M	Irradiation time/min	$G(N_2O)$
Nitrogen oxide	30	6.6	60	0.10
	30	6.2	30	0.13
Oxygen	10	6.7	20	0.09
	20	11.4	20	0.08
	10	33.0	30	0.10

in liquid nitrogen. Below 0.01 mol l^{-1}, the yield of nitrogen dioxide was about equal to a half of the amount of nitrogen oxide introduced. At the concentrations higher than 0.01 mol l^{-1}, the following G-values were obtained: $G(NO_2)=3.3$ and $G(N_2O)=0.1$. Table 1 summarizes the results of the measurement of dinitrogen oxide.

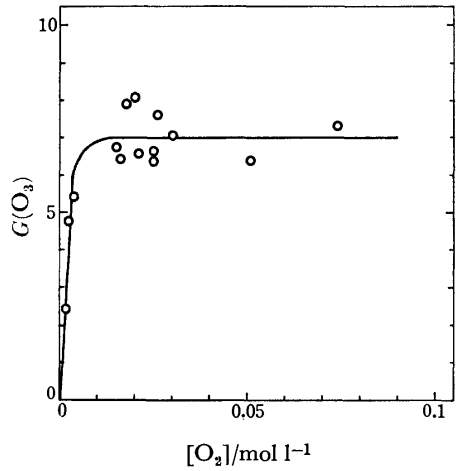

Fig. 2. The G-value of ozone as a function of the concentration of oxygen.

Figure 2 shows the G-value of ozone as a function of the amount of oxygen introduced in liquid nitrogen. Although the data are a little scattered, the following G-values were obtained at the concentrations higher than 0.01 mol l^{-1} of oxygen: $G(O_3)=7.0\pm0.5$ and $G(N_2O)=0.1$.

Discussion

The formation of nitrogen dioxide in the γ-irradiated liquid nitrogen containing nitrogen oxide can be simply explained by the following reactions:

$$N + NO \longrightarrow N_2 + O, \quad (1)$$

$$O + NO \longrightarrow NO_2. \quad (2)$$

This reaction mechanism is consistent with the fact that at the concentrations lower than 0.01 mol l^{-1}, the yield of nitrogen dioxide is equal to a half of the amount of nitrogen oxide introduced in liquid nitrogen. If the above mechanism is the only process for the formation of nitrogen dioxide, the value of 3.3 is the G-value of nitrogen atoms from liquid nitrogen.

Since the ionization potential of nitrogen oxide is lower than that of nitrogen, a charge transfer from nitrogen molecule ion to nitrogen oxide is possible; the neutralization reaction of the nitrogen oxide ion thus produced may form nitrogen and oxygen atoms. These atoms will produce nitrogen dioxide through Reactions 1 and 2. However, if the neutralization of nitrogen molecule ions and the charge transfer from nitrogen molecule ion to nitrogen oxide are in competition, a very high concentration of the positive ion interceptor, nitrogen oxide in the present case, must be necessary to suppress the neutralization completely.[5] According to Fig. 1, only 0.01 mol l^{-1} is enough to saturate the G-value of nitrogen dioxide. This is incompatible with the formation of nitrogen dioxide through the charge transfer from nitrogen molecule ion to nitrogen oxide.

Another possible mechanism is the energy transfer reaction from excited nitrogen molecules to nitrogen oxide. However, this reaction is believed not to occur even in the gas phase reaction of active nitrogen at room temperature.[2]

Consequently it may be concluded that the G-value of nitrogen atoms from liquid nitrogen is 3.3.

In the γ-radiolyses of liquid nitrogen solutions of hydrogen and of various hydrocarbons,[1] the sum of the G-values of nitrogen containing products we could observe did not exceed 1.5, while the present experiment suggested $G(N)=3.3$. This difference may be due to the fact that back reactions, such as

$$NH + NH \longrightarrow N_2 + H_2, \quad (3)$$

$$RN + NH \longrightarrow N_2 + RH, \quad (4)$$

$$RN + RN \longrightarrow N_2 + R_2, \quad (5)$$

are important processes when hydrogen and hydrocarbons are used as solutes. Here, R stands for hydrocarbon radicals.

For the formation of ozone in the γ-irradiated liquid nitrogen containing oxygen, we tentatively considered the following reaction mechanism:

$$N_2 \rightsquigarrow N_2^+ + e^-, N_2^*, \quad (6)$$

$$N_2^* + O_2 \longrightarrow N_2 + 2O, \quad (7)$$

$$e^- + O_2 \longrightarrow O_2^-, \quad (8)$$

$$N_2^+ + O_2^- \longrightarrow N_2 + 2O, \quad (9)$$

$$O + O_2 \longrightarrow O_3. \quad (10)$$

Here, N_2^* is the excited state of nitrogen molecule, probably $^3\Sigma_u^+$ state.[1] The direct participation of nitrogen atoms was ignored because the reaction between nitrogen atoms with oxygen molecule to form nitrogen oxide is known to be a slow reaction.[6] This is consistent with the experimental result that no nitrogen dioxide formation could be observed in this solution.

It may be worthwhile to mention here that the bond dissociation energy of O_2 (5.15 eV) is much smaller than that of NO (6.54 eV) and also smaller than the excitation energy of the lowest excited state $^3\Sigma_u^+$ of nitrogen (6.17 eV).

Although an oxygen molecule is a good electron scavenger, 0.01 mol l^{-1} of oxygen concentration is not high enough to scavenge all the electrons ejected into the solution.[7] Consequently, the main process of the ozone formation probably consists of Reactions 7 and

10 at low concentrations of oxygen. If so, the G-value of N_2^* becomes 3.5. As possible origins of N_2^*, the following three processes have to be considered: the direct formation due to the γ-irradiation, the neutralization reaction of nitrogen molecule ions, and the recombination reaction of nitrogen atoms. The specific allotment of each contribution is beyond our present knowledge.

Phosphorescence Emissions and Nonradiative Properties of Vapors of Aromatic Carbonyl Compounds at Low Pressure

Takao ITOH, Hiroaki BABA,* and Takeshi TAKEMURA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received April 17, 1978)

The phosphorescence quantum yields of benzaldehyde, acetophenone, *p*-fluorobenzaldehyde, *p*-chlorobenzaldehyde, and benzophenone vapors, measured at low pressure down to the order of 10^{-3} Torr as a function of excitation wavelength, are essentially constant in the region of excitation energy corresponding to the $S_1(n, \pi^*)$ state, whereas the yields decrease very sharply as the excitation energy is raised to the value corresponding to the S_2 (π, π^*) state. This indicates that the nonradiative pathway in the carbonyl compound varies according to the type of the singlet state to which the molecule is initially excited. When excited to the S_1 and S_2 states, the molecule passes to the phosphorescent triplet state and a decomposing state, respectively. Two mechanisms are suggested and examined for understanding the nonradiative properties of the carbonyl compound vapors: (I) The internal conversion $S_2 \rightarrow S_1$ is slow compared with the conversion from S_2 to the decomposing state; (II) the vibrational energy redistribution in S_1 between the vibrational mode populated through $S_2 \rightarrow S_1$ and the mode to be populated optically is slow compared with the conversion from the former mode to the decomposing state.

In the vapor phase at low pressure, organic molecules often show photochemical or photophysical properties that cannot be observed in the condensed phase.[1,2] The photochemical reactivity of benzaldehyde and acetophenone in the vapor phase is known to be very sensitive to the excitation energy or to the nature of the electronic state excited.[3,4] The vapor-phase phosphorescence yields of benzaldehyde and benzophenone also are known to be sensitive to the excitation energy.[5,6]

In a previous paper,[7] it was reported preliminarily that the phosphorescence quantum yield of benzaldehyde vapor varies, depending on the type of singlet state to which the benzaldehyde molecule is initially excited. That is, the quantum yield is essentially constant in the region of excitation energy corresponding to the $S_1(n,\pi^*)$ state, but it decreases very sharply as the energy is raised to the value corresponding to the $S_2(\pi,\pi^*)$. Since the excited-electronic-state dependence of the molecular emission property is of prime importance in connection with the mechanism of radiationless transition, we have extended this sort of study to various derivatives of benzaldehyde. The present paper reports the emission and excitation spectra of acetophenone, *p*-fluorobenzaldehyde, *p*-chlorobenzaldehyde, and benzophenone vapors at low pressure, down to the order of 10^{-3} Torr, in comparison with the corresponding spectral data on benzaldehyde. It is shown that, in all the molecules studied, the phosphorescence quantum yields decrease greatly on changing the excitation from $S_0 \rightarrow S_1$ to $S_0 \rightarrow S_2$.

Experimental

Benzaldehyde and acetophenone obtained from Nakarai Chemicals, Kyoto and *p*-fluorobenzaldehyde from Aldrich Chemical Company were purified by means of repeated vacuum distillations. *p*-Chlorobenzaldehyde obtained from Tokyo Chemical Industry was purified by repeated vacuum sublimations. Benzophenone from Nakarai Chemicals was vacuum sublimated and zone-refined. Carbon tetrachloride from Merck was used as a foreign gas without further purification. All the sample vapors were degassed in a mercury-free vacuum system, and their pressures were determined from the intensities of the $S_0 \rightarrow S_3$ absorption spectra. It was confirmed that no impurity emission was detected from the sample vapors.

Emission and excitation spectra were measured with a high-sensitivity spectrophotometer[8] equipped with a Hamamatsu TV R-585 photomultiplier, using the photon-counting method. Absorption spectra were measured with a Hitachi EPS-3, a Shimadzu MPS-5000, or a Cary-15 spectrophotometer. For most of the emission measurements, square 10-mm path length quartz cells were used. A spherical 160-mm path length cell with quartz windows was also used for benzaldehyde and *p*-fluorobenzaldehyde at very low pressure ($<$7 mTorr).

The excitation spectra were obtained with a 1- or 2-nm bandwidth for the excitation monochromator and a 19-nm bandwidth for the emission monochromator, and were corrected for the spectral intensity distribution of the exciting light by the use of an aqueous solution of rhodamine B as a quantum counter. The spectral measurements were conducted at 85 °C for benzophenone and at room temperature for the other compounds.

Results

The vapor-phase emission spectra of the carbonyl compounds studied are shown in Figs. 1 and 2. These

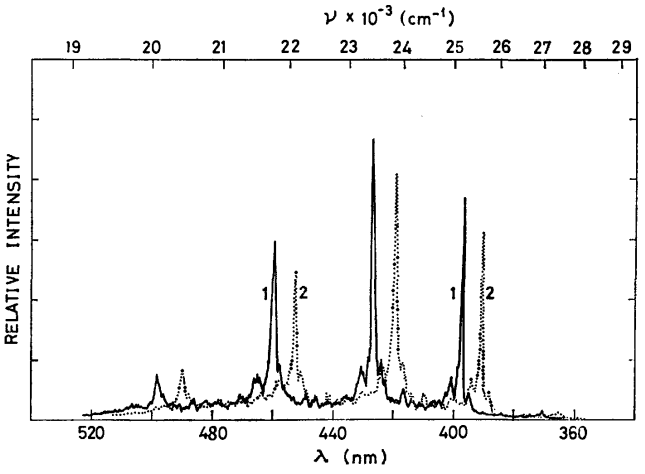

Fig. 1. Vapor-phase emission spectra of (1) benzaldehyde (bandwidth, 0.3 nm) and (2) *p*-fluorobenzaldehyde (bandwidth, 0.4 nm). The spectra are not corrected for the spectral response of the monochromator-photomultiplier system.

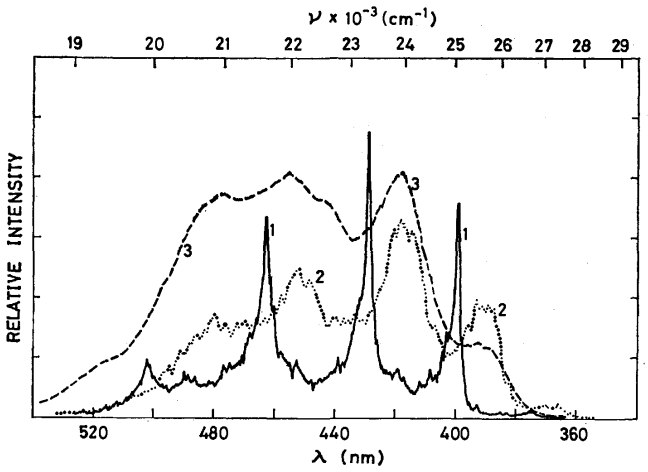

Fig. 2. Vapor-phase emission spectra of (1) *p*-chlorobenzaldehyde (bandwidth, 0.9 nm), (2) acetophenone (bandwidth, 1.2 nm), and (3) benzophenone (bandwidth, 1.0 nm). The spectra are not corrected for the spectral response of the monochromator-photomultiplier system.

spectra consist mainly of phosphorescence, accompanied by very weak E-type delayed fluorescence at shorter wavelengths. The spectral shapes were found to be independent of the pressure and excitation energy within the limit of experimental error.

Figures 3(a)—7(a) show corrected phosphorescence excitation spectra at different pressures of the vapors of the carbonyl compounds, together with the vapor-phase absorption spectra. In the presence of high-pressure carbon tetrachloride as a foreign gas, the excitation spectrum agrees well with the corresponding absorption spectrum for all the carbonyl compounds, except for benzophenone. The absorption spectrum of benzophenone in the long wavelength region is not known because of its low vapor pressure. However, its corrected excitation spectrum in the presence of high-pressure carbon tetrachloride resembles the absorption spectrum in isopentane solution. It is assumed, therefore, that the former excitation spectrum can be used as a substitute for the vapor-phase absorption spectrum. In the case of pure carbonyl compound vapors at low pressure, the intensities of the corrected excitation spectra are markedly low in the S_2 region, as compared with the absorption spectra.

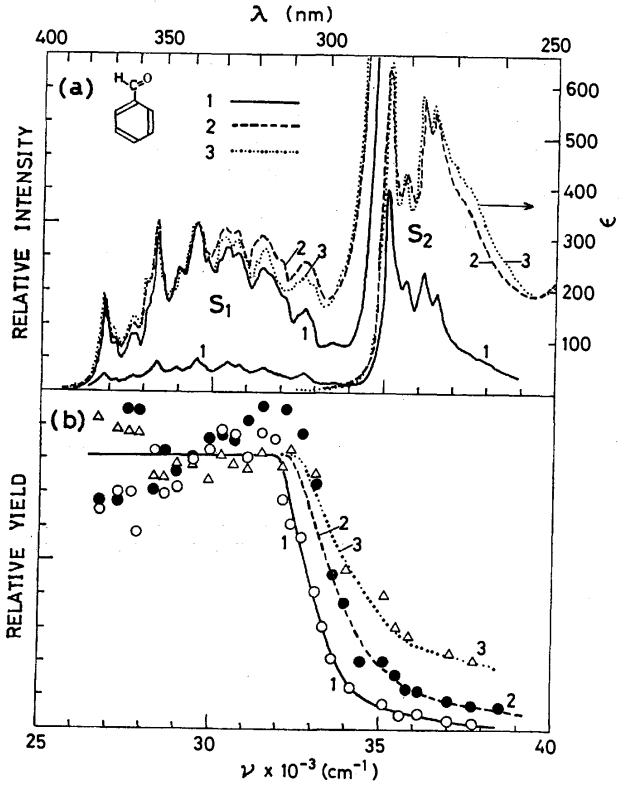

Fig. 3. (a) Phosphorescence excitation spectra at different pressures (1 and 2) and absorption spectrum (3) of benzaldehyde vapor. (1) 3 mTorr; (2) 500 mTorr of benzaldehyde in the presence of added CCl_4 (≈100 Torr). Higher-intensity spectra are obtained by multiplying the ordinate values of the corresponding lower-intensity spectra by factors of 5 and 20, respectively, for curve 1 and for curves 2 and 3. (b) Plots of phosphorescence quantum yields of benzaldehyde vapor *vs.* excitation energy at different pressures. (1) 2 mTorr; (2) 4 mTorr; (3) 10 mTorr.

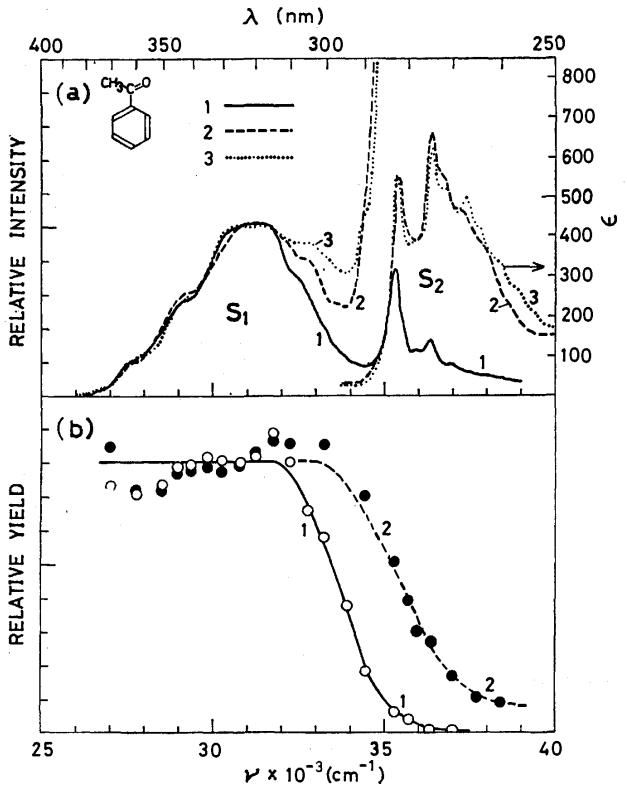

Fig. 4. (a) Phosphorescence excitation spectra at different pressures (1 and 2) and absorption spectrum (3) of acetophenone vapor. (1) 20 mTorr; (2) 30 mTorr of acetophenone in the presence of added CCl_4 (≈200 Torr). Higher-intensity spectra are obtained by multiplying the ordinate values of the corresponding lower-intensity spectra by a factor of 10 for curves 2 and 3. (b) Plots of phosphorescence quantum yields of acetophenone vapor *vs.* excitation energy at different pressures. (1) 20 mTorr; (2) 220 mTorr.

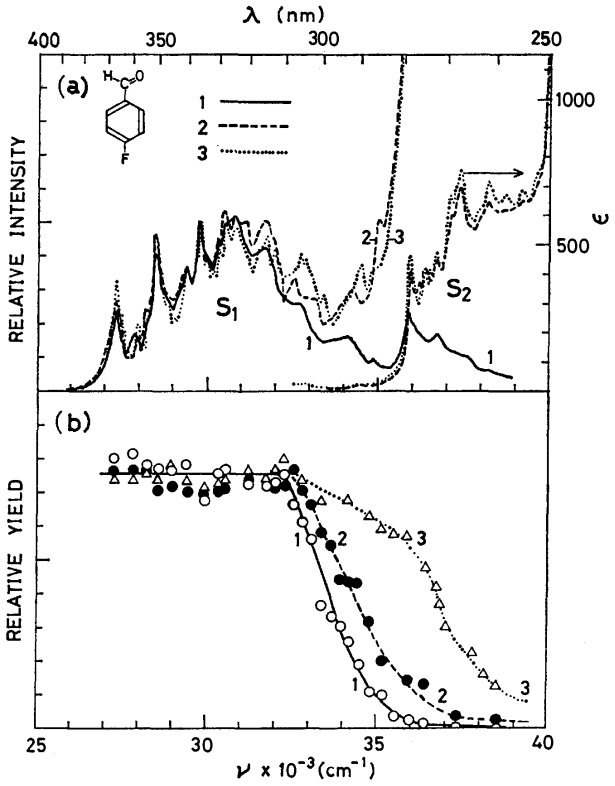

Fig. 5. (a) Phosphorescence excitation spectra at different pressures (1 and 2) and absorption spectrum (3) of *p*-fluorobenzaldehyde vapor. (1) 7 mTorr; (2) 300 mTorr of *p*-fluorobenzaldehyde in the presence of added CCl_4 (≈100 Torr). Higher-intensity spectra are obtained by multiplying the ordinate values of the corresponding lower-intensity spectra by a factor of 20 for curves 2 and 3. (b) Plots of phosphorescence quantum yields of *p*-fluorobenzaldehyde vapor *vs.* excitation energy at different pressures. (1) 7 mTorr; (2) 30 mTorr; (3) 100 mTorr.

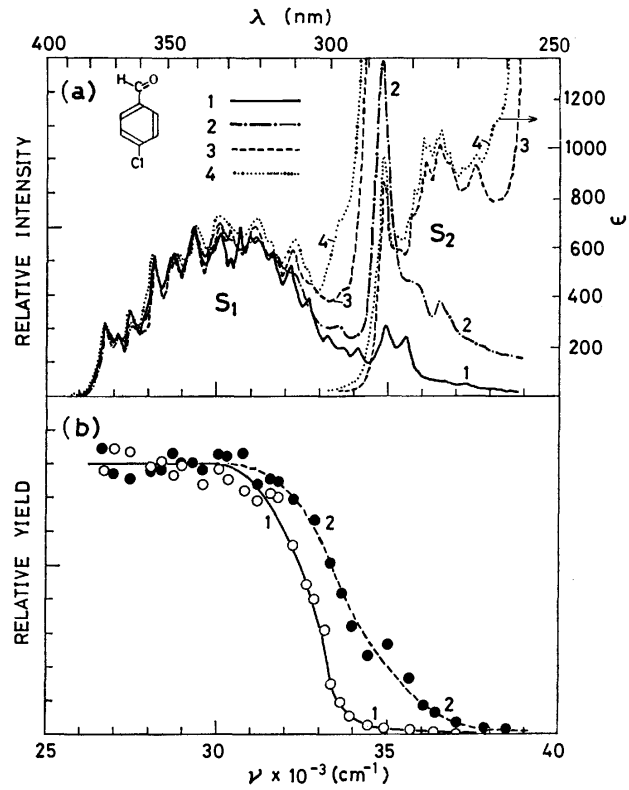

Fig. 6. (a) Phosphorescence excitation spectra at different pressures (1, 2, and 3) and absorption spectrum (4) of *p*-chlorobenzaldehyde vapor. (1) 9 mTorr; (2) 40 mTorr; (3) 50 mTorr of *p*-chlorobenzaldehyde in the presence of added CCl_4 (≈400 Torr). Higher-intensity spectra are obtained by multiplying the ordinate values of the corresponding lower-intensity spectra by a factor of 20 for curves 3 and 4. Since the molar extinction coefficients (ε) of this compound could not be determined directly because of its low vapor pressure, the ε values in the vapor phase were estimated from those in isopentane solution. (b) Plots of phosphorescence quantum yields of *p*-chlorobenzaldehyde vapor *vs.* excitation energy at different pressures. (1) 9 mTorr; (2) 60 mTorr.

Relative phosphorescence quantum yields are plotted against the excitation energy in Figs. 3(b)—7(b) for different pressures of the carbonyl compound vapors; in each of the figures the average values of the yields in the S_1 region are normalized to a common magnitude. These plots were obtained from comparison of the intensities of absorption and corrected excitation spectra. It should be emphasized that although the phosphorescence quantum yields, Φ_P, are essentially constant in the whole range of excitation energy corresponding to the S_1 state, they undergo an abrupt, step-like change when the excitation energy is raised to the value corresponding to S_2.

Figure 8 shows plots of $\Phi_P(S_2^0)/\Phi_P(S_1)$ against the pressure, p, for benzaldehyde, acetophenone, and *p*-fluorobenzaldehyde. Here, the Φ_P values obtained by excitation into the S_1 state and into the zero-point vibrational level of the S_2 state are denoted by $\Phi_P(S_1)$ and $\Phi_P(S_2^0)$, respectively; since in each of the carbonyl compounds $\Phi_P(S_1)$ is approximately constant regardless of the magnitude of the excess vibrational energy, the vibrational level excited is not specified in the case of $\Phi_P(S_1)$. As p is reduced to zero, the ratios $\Phi_P(S_2^0)/\Phi_P(S_1)$ appear to approach zero. This pressure dependence of the quantum yield ratios is consistent with the observation that the step-like changes of Φ_P, caused by changing the excitation from $S_0 \rightarrow S_1$ to $S_0 \rightarrow S_2$, become more pronounced as p is lowered (see Figs. 3(b)—7(b)).

The pressure dependence of $\Phi_P(S_1)$ and $\Phi_P(S_2^0)$ was already shown in the previous paper[7] for benzaldehyde; both $\Phi_P(S_1)$ and $\Phi_P(S_2^0)$ have a value of about 0.02 at 0.8 Torr. It was found that the phosphorescence quantum yields of other carbonyl compounds are comparable to that of benzaldehyde, when p is relatively large.

Discussion

We have measured the phosphorescence excitation spectra of carbonyl compounds at pressures lower than previous authors employed. The results show that Φ_P decreases very sharply as the excitation energy is raised

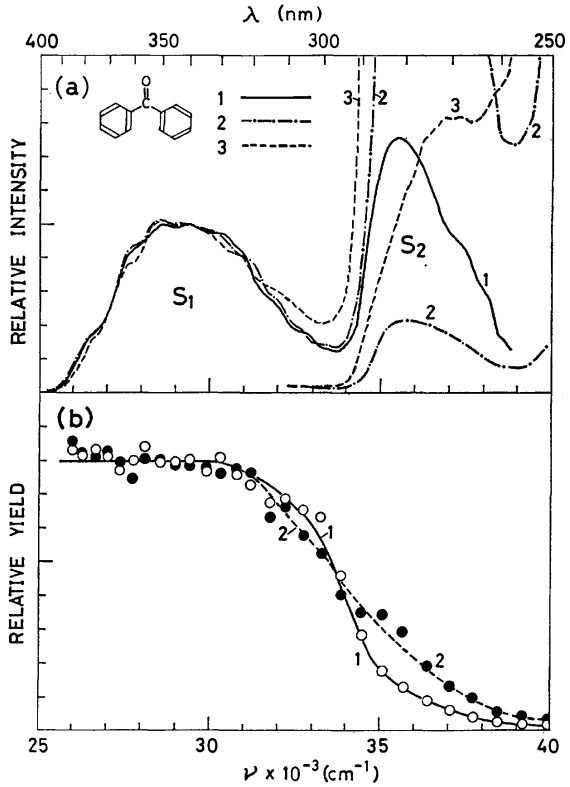

Fig. 7. (a) Phosphorescence excitation spectra at different pressures of benzophenone vapor. (1) 1 mTorr; (2) 110 mTorr; (3) 20 mTorr of benzophenone in the presence of added CCl_4 (≈400 Torr). Higher-intensity spectra are obtained by multiplying the ordinate values of the corresponding lower-intensity spectra by a factor of 10 for curves 2 and 3. (b) Plots of phosphorescence quantum yields of benzophenone vapor *vs.* excitation energy at different pressures. (1) 1 mTorr; (2) 110 mTorr.

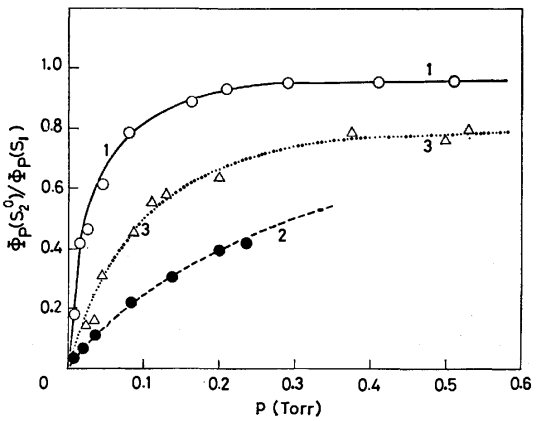

Fig. 8. Plots of $\Phi_P(S_2^0)/\Phi_P(S_1)$ *vs.* p for (1) benzaldehyde, (2) acetophenone, and (3) *p*-fluorobenzaldehyde.

to the value corresponding to the S_2^0 level, and that $\Phi_P(S_2^0)$ appears to approach zero as p is reduced to zero.

Berger *et al.*[3,4] studied the photochemistry of benzaldehyde and acetophenone vapors by determining the quantum yields of photoproducts as well as the lifetimes and quantum yields of phosphorescence emissions over a range of pressures and of excitation wavelengths. They reported that the molecules excited to the S_2 state decompose with unit probability at low pressure to produce carbon monoxide and benzene from benzaldehyde, and methyl and benzoyl radicals from acetophenone, but that excitation to the S_1 state does not result in such decomposition. They concluded also that the decomposition occurs from the excited vibrational levels of triplet states of these molecules.

It is possible that a decomposing level which leads to the step-like change of Φ_P may be situated accidentally near the S_2^0 level. For all the carbonyl compounds studied, however, Φ_P shows a sharp decrease when the excitation energy approaches the value corresponding to the S_2^0 level. This can be most clearly seen by comparing the excitation energy dependence of Φ_P of *p*-fluorobenzaldehyde (S_2^0, 35970 cm^{-1}) with that of *p*-chlorobenzaldehyde (S_2^0, 34970 cm^{-1}). In fact, on going from the former to the latter molecule, the starting point of the sharp decrease of Φ_P is red-shifted by about 1000 cm^{-1} (Figs. 5 and 6). It is, therefore, reasonable to consider that Φ_P varies according to the nature of the singlet electronic state to which the molecule is initially excited.

The pressure dependence of Φ_P suggests that the decomposition process occurs *via* a long-lived state such as a triplet, as will be explained in detail later. This decomposing state will hereafter be named an intermediate state, and will be denoted by Im. It is inferred that the state Im is relaxed to the phosphorescent state by collision.

Kinetic Considerations. The radiative and nonradiative properties of the vapors of the carbonyl compounds can be explained by the kinetic scheme illustrated in Fig. 9. For S_1 excitation,

$$S_1^v \xrightarrow{k_1} T_1^v, \tag{1}$$

$$T_1^v + S_0 \xrightarrow{k_2} T_1^0 + S_0, \tag{2}$$

and for S_2 excitation,

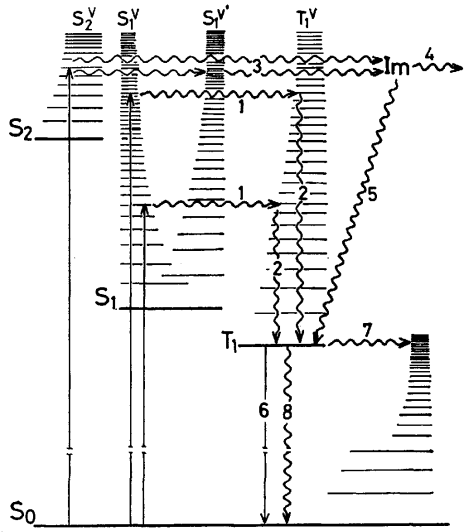

Fig. 9. A schematic diagram showing photophysical and photochemical processes in the carbonyl compound vapors.

$$S_2^v \xrightarrow{k_3} \text{Im}, \quad (3)$$

$$\text{Im} \xrightarrow{k_4} \text{Products}, \quad (4)$$

$$\text{Im} + S_0 \xrightarrow{k_5} T_1^0 + S_0. \quad (5)$$

Processes 1 and 3 represent intersystem crossing from S_1^v to T_1^v and overall conversion from S_2^v to Im, respectively. Here, S_1^v and S_2^v mean the optically populated vibrational levels in S_1 and S_2, respectively, and T_1^v is the vibrational level in T_1 populated as a result of the crossing from S_1^v; $v=0$ corresponds to the zero-point vibrational level for each of the electronic states. Process 4 is the decomposition of the carbonyl compounds in the Im state. The resulting products in benzaldehyde and acetophenone have already been mentioned. No information is available as to the decomposition products in *p*-fluorobenzaldehyde, *p*-chlorobenzaldehyde, and benzophenone, but similar cleavage is expected to occur also in these compounds. Processes 2 and 5 represent, respectively, collisional deactivation of T_1^v and Im to T_1^0; here, T_1^0 means lower vibrational levels of T_1, including the zero-point level. Since the shapes of the observed phosphorescence spectra are independent of the pressure, the emission originates only from the T_1^0 state.

The molecule in the T_1^0 state resulting from process 2 or 5 is deactivated in the following ways:

$$T_1^0 \xrightarrow{k_6} S_0 + h\nu, \quad (6)$$

$$T_1^0 \xrightarrow{k_7} S_0, \quad (7)$$

$$T_1^0 + S_0 \xrightarrow{k_8} 2S_0. \quad (8)$$

Process 7 represents the pressure-independent intersystem crossing from T_1^0 to the ground state, and process 8 the self-quenching. In this model, the quenching of the excited molecule by the cell wall is not taken into account for the sake of simplicity, although such a wall effect cannot be neglected in the measurement at very low pressure.

In the case of S_2 excitation, process 3 is followed exclusively by the decomposition process 4 when p is very small, but at large p values process 5 competes favorably with the decomposition. On the other hand, optical excitation to the S_1 state, *i.e.* excitation to S_1^v, does not lead to the decomposition.[3,4] These observations account for the fact that the quantum yield ratios $\Phi_P(S_2^0)/\Phi_P(S_1)$, which are zero at $p\simeq 0$, increase with increasing pressure (see Fig. 8).

In terms of the kinetic scheme mentioned above, $\Phi_P(S_1^v)$ and $\Phi_P(S_2^v)$ as functions of p are given by

$$\Phi_P(S_1^v) = \Phi_{ISC}(S_1^v \rightarrow T_1^v)\kappa, \quad (9)$$

$$\Phi_P(S_2^v) = \Phi(S_2^v \rightarrow \text{Im})\frac{k_5 p}{k_4 + k_5 p}\kappa, \quad (10)$$

where

$$\kappa = \frac{k_6}{k_6 + k_7 + k_8 p},$$

and $\Phi_{ISC}(S_1^v \rightarrow T_1^v)$ and $\Phi(S_2^v \rightarrow \text{Im})$ are the quantum yields of the intersystem crossing $S_1^v \rightarrow T_1^v$ and the overall conversion $S_2^v \rightarrow$ Im, respectively. It follows from Eqs. 9 and 10 that

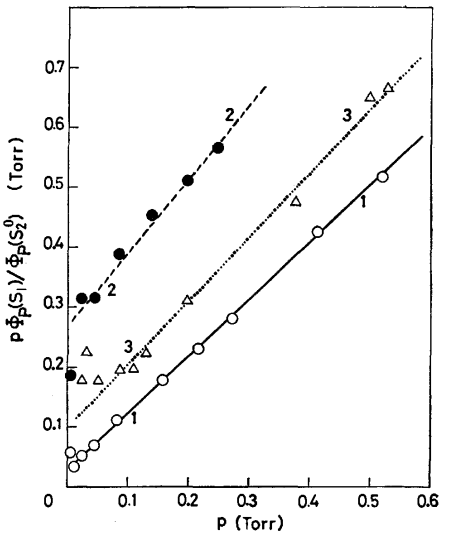

Fig. 10. Plots of $p\Phi_P(S_1)/\Phi_P(S_2^0)$ *vs.* p for (1) benzaldehyde, (2) acetophenone, and (3) *p*-fluorobenzaldehyde.

$$p\frac{\Phi_P(S_1^v)}{\Phi_P(S_2^v)} = \frac{\Phi_{ISC}(S_1^v \rightarrow T_1^v)}{\Phi(S_2^v \rightarrow \text{Im})}\left(\frac{k_4}{k_5} + p\right). \quad (11)$$

The experimental data given in Fig. 8 are analyzed on the basis of Eq. 11 for benzaldehyde, acetophenone, and *p*-fluorobenzaldehyde, with the results shown in Fig. 10. Thus, the plots of $p\Phi_P(S_1)/\Phi_P(S_2^0)$ against p give straight lines, as may be expected from Eq. 11. From the intercepts and slopes of the straight lines, the values of k_4/k_5 and $\Phi_{ISC}(S_1 \rightarrow T_1^v)/\Phi(S_2^0 \rightarrow \text{Im})$ are evaluated, respectively, to be 0.03 Torr and 0.95 for benzaldehyde, 0.23 Torr and 1.20 for acetophenone, and 0.10 Torr and 1.06 for *p*-fluorobenzaldehyde.

Berger *et al.*[3] pointed out that the decomposition of benzaldehyde occurs in two states with different lifetimes, but the linear plot in Fig. 10 appears to indicate that only a single state participates in the decomposition so far as the pressure region employed in Fig. 10 is concerned.

The Intermediate State and Nonradiative Processes. In terms of the kinetic model, the lifetime of the intermediate state is given by

$$\tau_{Im} = \frac{1}{k_4 + k_5 p}. \quad (12)$$

The value of the collisional deactivation rate constant, k_5, may be assumed to be equal to or less than that of the bimolecular rate constant for collision, k_c. On the basis of the hard sphere model, the k_c values are estimated to be 1.07×10^7, 1.13×10^7, and 1.02×10^7 Torr^{-1} s^{-1}, respectively, for benzaldehyde (5.5 Å), acetophenone (5.8 Å), and *p*-fluorobenzaldehyde (5.6 Å), with the molecular diameters given in parentheses. If k_5 is assumed to be equal to k_c, the value of k_4 can immediately be obtained by using the k_4/k_5 values which have already been determined. In this way the lifetimes at zero pressure, $\tau_{Im}(=1/k_4)$, are found to be 3.1×10^{-6}, 3.8×10^{-7}, and 9.8×10^{-7} s for benzaldehyde, acetophenone, and *p*-fluorobenzaldehyde, respectively.

The fact that fluorescence is not observed from S_1 and S_2 means that the lifetimes of these singlet states

are very short ($<1\times10^{-9}$ s), and therefore Im cannot be the S_1 nor S_2 state. Taking this into account, Im should be one of the following states: (1) a dissociative vibrational mode in T_1, denoted by $T_1^{v'}$, which is different from T_1^v in nature; (2) a higher triplet state, $T_j(j>1)$; (3) a reaction intermediate which cannot be identified as any of the excited states of the initial carbonyl compound.

As has been shown, the phosphorescence quantum yield of the carbonyl compound vapor varies according to the nature of the singlet state (S_1 or S_2) to which the molecule is initially excited. This indicates that the molecule excited to S_2 takes a nonradiative pathway different from the one taken by the molecule excited to S_1. According to the kinetic scheme already mentioned, the excitation to S_2^v is followed by the overall $S_2^v\rightarrow$Im conversion, whereas the molecule excited to S_1^v converts to T_1^v.

Two mechanisms, (I) and (II), are conceivable for the overall $S_2^v\rightarrow$Im conversion. (I) S_2^v converts to Im without passing through S_1, *i.e.* $S_2^v\rightarrow$Im. (II) S_2^v converts to Im *via* $S_1^{v'}$, *i.e.* $S_2^v\rightarrow S_1^{v'}\rightarrow$Im, where $S_1^{v'}$ represents the vibrational mode in S_1 populated as a result of the $S_2\rightarrow S_1$ internal conversion; $S_1^{v'}$ is in general different from S_1^v in nature (see Fig. 9). In the former mechanism the $S_2^v\rightarrow S_1^{v'}$ conversion should be slow compared with the $S_2^v\rightarrow$Im conversion, while in the latter the vibrational energy redistribution between $S_1^{v'}$ and S_1^v should be slow compared with the $S_1^{v'}\rightarrow$Im conversion.

We have mentioned three possible states (1)—(3) for Im and two mechanisms (I) and (II) for $S_2^v\rightarrow$Im. It is at present difficult to know which state is most probable and which mechanism is more important. If Im is $T_j(j>1)$ or a reaction intermediate, the mechanism (I) will be more important, because the $S_2\rightarrow S_1$ internal conversion in the carbonyl compounds studied is expected to be relatively slow owing to the large energy separation ($\approx$8000 cm^{-1}) between S_2^0 and S_1^0. When Im is $T_1^{v'}$, the mechanism (I) corresponds to the process $S_2^v\rightarrow T_1^{v'}$. If this process occurs directly, its rate must be slow because of the large energy gap between S_2^0 and T_1^0, so that the mechanism (II) will become favorable compared with (I). It is possible, however, that the process $S_2^v\rightarrow T_1^{v'}$ may occur *via* a higher-energy triplet state. In any case, in order that $T_1^{v'}$ may be a candidate for Im, both the intersystem crossing $S_1^v\rightarrow T_1^{v'}$ and the vibrational energy redistribution between T_1^v and $T_1^{v'}$ should occur only slowly; otherwise the optical excitation to S_1^v would lead to the decomposition reaction.

(Received April 20, 1978)

The standard redox potentials of five R^-/R^+ redox couples that can be considered as candidates for the reference redox couple, *i.e.*, the anion/cation couples of tris(2,2′-bipyridine)iron(II), tris(2,2′-bipyridine)ruthenium(II), cobaltocene, perylene, and 9,10-diphenylanthracene, have been determined in acetonitrile, dimethyl sulfoxide, *N,N*-dimethylformamide and propylene carbonate by means of polarography and voltammetry. The results confirmed that the standard potentials of these redox couples are independent of the solvents studied so that they can be used as solvent-independent reference points for potential comparisons. The solvent activity coefficients of the silver ion have been estimated on the basis of these reference redox couples.

The evaluation of single-ion solvent activity coefficients, ${}^{o}\gamma^{s}_{ion}$, for the transfer of ions from a reference solvent (superscript o) to another solvent (superscript s) is one of the most interesting problems of solution chemistry. Since the problem is not accessible to exact thermodynamics, extrathermodynamic procedures must be followed. Thus various extrathermodynamic procedures have been proposed by several authors for the estimation of the solvent activity coefficients of single ions. The current status of this field has been comprehensively reviewed in several recent papers.[1-6]

In a previous paper,[7] two of the authors (M.S. and R.T.) proposed that the standard redox potential, $E^{\circ}_{R^-/R^+}$, of the R^-/R^+ redox couple may work as a solvent-independent reference point in various solvents if the R^-/R^+ redox couples, being named the reference redox couples, have the following chemical features: a) the R^+ and R^- ions are very large in size with the charge shielded by large organic groups, and b) the charge distribution in the R^+ ion is the same or very nearly the same as that in the R^- ion. It was also pointed out that the standard redox potentials can be estimated from polarographic reversible half-wave potentials of R/R^+ and R^-/R couples and that this approach should give an accurate and convenient estimation of single-ion solvent activity coefficients.

In this study the standard redox potentials of several R^-/R^+ redox couples that can be considered as candidates[7] for the reference redox couple (*i.e.*, the anion/cation couples of tris(2,2′-bipyridine)iron(II), tris(2,2′-bipyridine)ruthenium(II), cobaltocene, perylene and 9,10-diphenylanthracene) have been determined in acetonitrile (AN), dimethyl sulfoxide (DMSO), *N,N*-dimethylformamide (DMF), and propylene carbonate (PC) by means of polarography and voltammetry. Furthermore the solvent activity coefficients of the silver ion have been estimated on the basis of these R^-/R^+ reference redox couples. An estimation of the absolute electrode potentials of the silver/silver ion electrodes in nonaqueous solvents has been attempted.

Experimental

Chemicals. Commercial PC(a Merk product for synthesis) was dried over molecular sieves 5A for several days and fractionally distilled twice under vacuum. The central 70% fraction of the distillate was collected from each distillation and stored under a nitrogen atmosphere after dry nitrogen gas had been passed through the distillate for several hours. Spectro grade DMF was stirred with molecular sieves 4A overnight and distilled under vacuum. The central 60% fraction was collected and stored under a nitrogen atmosphere after dry nitrogen gas had been passed though the distillate for one hour. Spectro grade DMSO was dried over molecular sieves 5A for two days and twice distilled under vacuum. The central 70% fraction was collected in each distillate and stored under a nitrogen atmosphere. Analytical grade AN was refluxed over phosphorus pentaoxide (5 g/l) for 15 min and distilled at the rate of 100 ml/h. The central 80% fraction of the distillate was refluxed over CaH_2(2 g/l) for half an hour and fractionally distilled through Widmer's fractional distillation column at the rate of 100 ml/h. The central 80% fraction was collected and dried over anhydrous sodium carbonate. Just before use the dried AN was fractionally distilled through a 1 m column packed with stainless steel helices.

Tetraethylammonium perchlorate (TEAP) was prepared and purified by the method previously described.[8] The salt was vacuum-dried at 100 °C for 24 h and stored in a desiccator. Just before use the salt was again vacuum-dried at 100 °C for two hours. Commercial silver perchlorate was purified by repeated recrystallization with dried thiophene-free benzene[9] and vacuum-dried at 60 °C, both processes being carried out in the dark. Silver nitrate of analytical grade (a product of Wako Pure Chemicals) was used without further purification. Rubidium perchlorate was prepared by the equimolar addition of perchloric acid to an aqueous solution of rubidium bromide, which was then purified by repeated recrystallization with twice distilled water and vacuum-dried at 100 °C for 24 h. Tris(2,2′-bipyridine)iron(II) perchlorate ($Fe(bpy)_3(ClO_4)_2$) and tris(2,2′-bipyridine)ruthenium(II) bromide ($Ru(bpy)_3Br_2$) were kindly supplied by Dr. T. Matsumura-Inoue of Nara University of Education. Reagent grade perylene was purified by repeated recrystallization with toluene. Analytical grade 9,10-diphenylanthracene (DPA) (a product of Nakarai Chemicals for scintillation use) was used without further purification. Cobalticenium hexafluorophosphate (Cp_2CoPF_6) was prepared according to Wilkinson's procedure[10] with a slight modification,[11] and purified by repeated recrystallization from a 2:1 methanol–acetone mixture.

Electrochemical Measurements. Dc polarograms and cyclic voltammograms were measured with a potentiostat, Yanaco

Model PE-21-TB2S, equipped with a function generator, YHP 3310B. Ac polarographic measurements were performed with a lock-in amplifier, NF LI-572B, equipped with the above potentiostat system. Double potential-step measurements[12] for chemical kinetics following charge transfer were carried out with the same system as the dc polarograph. The data were recorded using both a transient memory, Union Giken System 71-02, and an X-Y recorder, Yokogawa 3077.

All voltammetric measurements were performed in Cell A under potentiostatic conditions. A three electrode system consisting of a working electrode (dropping mercury, platinum plane button, or hanging mercury drop electrode), a coiled platinum wire auxiliary electrode, and a nonaqueous silver/silver ion reference electrode, at room temperature (25±1 °C) under a dry nitrogen atmosphere was used.

Cell A: Hg (or Pt) | 0.5—1 mM depolarizer; 0.2 M TEAP; solvent s || 1 mM $AgNO_3$ or $AgClO_4$; (10 mM $AgNO_3$ in DMF); 0.2 M TEAP; solvent s | Ag

The half cells in Cell A were interconnected through sintered glass. The platinum working electrode (area 7.9×10^{-3} cm^2), sealed in glass, was polished with emery paper (#3000) and then immersed in an aqueous iron(II) sulfate solution for approximately half an hour. It was then washed in distilled water, dried, and pre-immersed in the solution to be studied. Good experimental reproducibility was obtained by using this procedure. The hanging mercury drop electrode was a Metrohm mercury drop electrode E 410. As the reference electrode an Ag/1 mM $AgNO_3$(or $AgClO_4$), 0.2 M TEAP, s, electrode was used for the measurements in s=PC, DMSO or AN. The potential of the reference electrode was found to be stable and reproducible for at least 2 h after the electrode's preparation. However, the Ag/1 mM $AgNO_3$ electrode was unstable in DMF and this was most likely due to the reduction of the silver ion by the solvent[13] (the potential of the electrode which was left standing for 4 hours was about 20 mV more negative compared to that of the freshly prepared electrode). Therefore an Ag/10 mM $AgNO_3$, 0.2 M TEAP, DMF electrode was used for the measurements in DMF. This electrode was found to be satisfactorily stable and gave reproducible results for at least 2 h after the preparation. For these reasons the reference electrodes were freshly prepared for each measurement, and the measurements were finished within 2 h after the preparation. The data in DMF obtained with the above reference electrode were converted to those referred to the Ag/1 mM $AgNO_3$, 0.2 M TEAP, DMF electrode by using the emf value of the following freshly prepared cell:

Ag | 1 mM $AgNO_3$; 0.2 M TEAP; DMF || 10 mM $AgNO_3$; 0.2 M TEAP; DMF | Ag

Results

Nonaqueous electrochemistry of $Fe(bpy)_3^{2+}$,[14,15] $Ru(bpy)_3^{2+}$,[15] Cp_2Co^+,[11,16,17] DPA,[18] and perylene[18] has been studied by many authors. These studies have revealed that in aprotic dipolar media these compounds give one-electron reversible reduction or oxidation steps, involving redox couples R/R^+ and R^-/R, defined by the equations: $R^+ + e = R$ and $R + e = R^-$. These compounds are also of relatively large size. For these reasons the above compounds were selected as the candidates for the R^-/R^+ reference redox couple.

Electrochemical Reduction of $Fe(bpy)_3^{2+}$ and $Ru(bpy)_3^{2+}$. These complexes[14,15] gave four reduction waves in aprotic media. The second and third reduction steps were assigned to the redox reactions of $M(bpy)_3^{2+} + e = M(bpy)_3$ and $M(bpy)_3 + e = M(bpy)_3^-$, respectively. In general the behavior of these complexes in the four solvents as investigated in this study was found to agree with data obtained by previous authors. The dc half-wave potentials, $E_{1/2}$, of these reduction steps conformed, within experimental error, to the corresponding ac peak

potentials, E_p^{AC}, and the half-wave potentials, $E_{1/2}^{CV}$, calculated from the cyclic voltammetric (CV) peak potentials. The conventional criteria of the reversibility, such as the dc polarographic slope, $\Delta E(\equiv E_{1/4}-E_{3/4})$, CV anodic-cathodic peak separation, ΔE_p^{CV}, ac polarographic half-width, ΔE_p^{AC}, *etc.*, showed that the second and third reduction steps are a reversible one-electron process in all the solvents studied. Some experimental results are shown in Table 1.

Electrochemical Reduction of Cp_2Co^+. Previous work[16,17] has revealed that this compound gives two reduction waves in AN and that the first reduction step corresponds to a simple reversible one-electron reduction from the cobaltocene cation to neutral cobaltocene:

$$Cp_2Co^+ + e \rightleftarrows Cp_2Co \qquad E_1 \qquad (a)$$

Regarding the reduction mechanisms of the second step, there are several points of disagreement between the two previous papers.[16,17] In contrast to the earlier report by Gubin *et al.*[17] that the second reduction step is a one-electron irreversible process, Geiger[16] has recently reported that in AN the neutral cobaltocene formed at the first reduction step is reduced by an ECE mechanism;

$$Cp_2Co + e \rightleftarrows Cp_2Co^- \qquad E_2 \qquad (b)$$

$$Cp_2Co^- \longrightarrow Z \qquad (c)$$

$$Z + e = Z^- \qquad E_3 \qquad (d)$$

where the intermediate Z is more reducible than the cobaltocene. He also showed that the rate of the chemical reaction (c) was relatively slow ($k\approx 0.1$ s^{-1} in AN). In addition the redox reaction (b) was shown to be highly reversible in AN.[11] The polarographic data on this compound in AN, DMF, and PC found here were consistent with the reduction mechanism proposed by Geiger.[16] The polarographic limiting current of the second reduction step, $i_l^{(2)}$, was slightly larger than that of the first reduction step, $i_l^{(1)}$, and the ratio, $i_l^{(2)}/i_l^{(1)}$, when corrected for drop time, decreased and approached unity with increasing mercury column height, as shown in Table 2. A plot of log $[i/(i_l-i)]$ *vs.* E for the second wave gave a straight line with a slope of 59 mV. On CV, the cathodic peak height of the second reduction step, $i_{cp}^{(2)}$, was not proportional to the square root of the scan rate, in contrast to the behavior of the first reduction step. As the scan rate increased the ratio $i_{cp}^{(2)}/i_{cp}^{(1)}$, $i_{cp}^{(1)}$ being the cathodic peak height of the first step, decreased and approached unity ($i_{cp}^{(2)}/i_{cp}^{(1)}\approx 1$ at $v\geq 0.5$ V/s). The peak potential of the second cathodic peak was practically invariant with the change in the scan rate. These results can be interpreted by assuming the ECE mechanism[19-22] with a slow chemical reaction (c). The rate constant of the chemical reaction (c) was estimated from the polarographic limiting currents[20,22] as given in Table 2. Analysis of the CV data yielded a rate constant of the same order of magnitude; $k=0.1$ to 0.2 s^{-1} in these solvents. The dc polarographic theory[22] for the ECE mechanism predicts that, for $k=0.2$ s^{-1} or less, the observed half-wave potential of the second step will agree with the reversible half-wave potential of the Cp_2Co/Cp_2Co^- couple within a few millivolts when $E_3\geq E_2$. Thus it can be concluded that the deviation of the observed half-wave potential from the true reversible half-wave potential of this redox couple (b) will be negligibly small in AN, DMF, and PC. It was also found that the ac peak potential of the second step agreed with the corresponding dc half-wave potential. On the other hand, this compound gave three reduction waves in DMSO. The first reduction step was found to represent a one-electron reversible reduction from the cobaltocene cation to cobaltocene. The second and third reduction steps appeared irreversible, showing no corresponding anodic peaks on the CV curves at $v=1$ V/s. Thus, the reversible half-wave potential of the Cp_2Co/Cp_2Co^- couple in DMSO could not be determined.

Electrochemical Oxidation and Reduction of DPA and Perylene. It has been reported that DPA and perylene undergo reversible one-electron oxidations and reductions to produce reasonably stable cation and anion radicals,[18] respectively. For this reason these compounds were also selected as candidates for the R⁻/R⁺ reference redox couple. All polarographic and voltammetric data obtained in this study indicated that the first reduction steps of these compounds are reversible one-electron reductions to anion radicals, which are highly stable in all four solvents studied. On the other hand, these compounds were found to undergo reversible one-electron oxidations to produce stable cation radicals in AN and PC only. In DMSO, DPA gave no oxidation wave within the limits of anodic potential range, whereas perylene gave an irreversible oxidation wave in this solvent, showing no corresponding cathodic peak on the CV curves at $v=1$ V/s. In DMF, DPA gave an oxidation wave, which was most likely complicated by a succeeding chemical reaction of the cation radical. Thus in CV, the ratio of cathodic to anodic peak current, i_{cp}/i_{ap}, increased with the increasing voltage scan rate. Also the anodic to cathodic peak

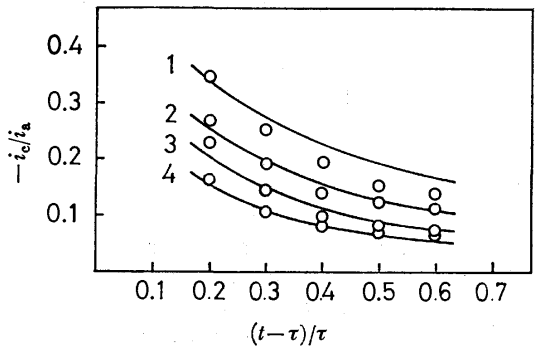

Fig. 1. Plots of $-i_c/i_a$ *vs.* $(t-\tau)/\tau$ for the oxidation step of DPA in DMF containing 0.2 M TEAP at 25 °C. Solid lines represent theoretical curves for $k=3.7\ s^{-1}$ and points are experimental results; (1) $\tau=0.192$ s; (2) $\tau=0.295$ s; (3) $\tau=0.384$ s; (4) $\tau=0.491$ s.

separation increased as the voltage scan rate was increased. These results indicate that this oxidation step is a quasi-reversible one-electron oxidation succeeded by a chemical reaction. To estimate the reversible half-wave potential of the DPA/DPA$^+$ couple in this solvent, an attempt was made to determine the rate constant of the succeeding chemical reaction, using the double potential step method developed by Shwarz and Shain.[12] The initial dc potential was set at 0.49 V *vs.* the Ag/10 mM $AgNO_3$ electrode, and the anodic polarization step of 0.99 V was applied for a given interval, τ, followed by the cathodic polarization at 0.49 V. Typical results, corrected for the base current, for different intervals are shown in Fig. 1. The points represent the experimental results and the solid lines represent the theoretical curves for $k=3.7\ s^{-1}$. Therefore, based on the theory,[23] in CV the deviation of the observed anodic peak potential of this compound from the supposed anodic peak potential of a hypothetical redox couple, either reversible or quasi-reversible, without succeeding chemical reaction should be less than 1 mV at $v=1$ V/s. Thus the reversible half-wave potential was estimated from the CV data at $v\geq 1$ V/s, as follows. According to Matsuda and Ayabe,[24] the anodic peak potential, E_p(quasi), of a quasi-reversible oxidation step can be written as

$$E_p(\text{quasi}) = E^r_{1/2} + (RT/nF)\Xi(\Lambda),$$

where $E^r_{1/2}$ is the reversible half-wave potential and Λ is a function of the electrochemical kinetic parameters, k_s and α, and the voltage scan rate, v. The parameter Λ can be estimated from the CV peak separation, ΔE_p, by using a working curve of $\Psi(\equiv\Lambda/\sqrt{\pi})$ *vs.* ΔE_p calculated by Nicholson.[25] Using this Λ value, the $\Xi(\Lambda)$ value can be obtained and consequently the $E^r_{1/2}$ value.[24] The results are summarized in Table 3, assuming $\alpha=0.5$. The values of $E^r_{1/2}$ estimated at various scan rates were constant, indicating that the value of $E^r_{1/2}$ estimated by this method is reliable. In DMF, perylene gave an oxidation wave, however the oxidation appeared irreversible and showed no corresponding cathodic peak on the CV curves.

Table 4 summarizes the reversible half-wave potentials of R/R$^+$ and R$^-$/R redox couples of the five compounds studied and of the rubidium ions in PC, DMF, AN and DMSO. In addition the corresponding reversible half-wave potentials of the five R$^-$/R$^+$ redox couples, $E^r_{1/2}$(R$^-$/R$^+$), which were calculated by

$$E^r_{1/2}(R^-/R^+) = (E^r_{1/2}(R/R^+) + E^r_{1/2}(R^-/R))/2,$$

are illustrated.

Discussion

As described previously,[7] the standard redox potential of the R$^-$/R$^+$ redox couple, $E^\circ_{R^-/R^+}$, measured against a silver/silver ion reference electrode can be expressed by

$$E^\circ_{R^-/R^+}: R^+ + 2e = R^-, \quad (1)$$

$$E^\circ_{R^-/R^+} = (E^\circ_{R/R^+}+E^\circ_{R^-/R})/2 = (A+I)/2F-(G^s(R^-)-G^s(R^+))/2F + \Delta G^s(Ag/Ag^+)/F, \quad (2)$$

where E°_{R/R^+} and $E^\circ_{R^-/R}$ are the standard redox potentials of the redox couples, R/R^+ and R^-/R, respectively, as defined by

$$E^\circ_{R/R^+}: R^+ + e = R, \quad (3a)$$

$$E^\circ_{R^-/R}: R + e = R^-. \quad (3b)$$

In Eq. 2, A and I respectively represent the electron affinity and ionization potential of the neutral molecule R derived from R^+ or R^- by the above redox reaction (3a) or (3b), $G^s(R^i)$ $(i=+, -)$ is the solvation energy of the ion R^i, and $\Delta G^s(Ag/Ag^+)$ is the free energy change of the reference electrode reaction,

$$Ag^+ + e = Ag \quad (3c)$$

in solvent, s. When R^+ and R^- are very large in size with the charge shielded by large organic groups and the charge distribution in the R^+ ion is the same or nearly the same as that in the R^- ion, it can be assumed that

$$\Delta G^s_{R^-/R^+} = G^s(R^-) - G^s(R^+) = 0. \quad (4)$$

Then $E^\circ_{R^-/R^+}$ should be solvent-independent;

$$E^\circ_{R^-/R^+} = (A+I)/2F + \Delta G^s(Ag/Ag^+)/F. \quad (5)$$

The half-wave potential $E^r_{1/2}(R^-/R^+)$ is related to the standard potential $E^\circ_{R^-/R^+}$ by

$$E^r_{1/2}(R^-/R^+) = E^\circ_{R^-/R^+} + (RT/2F)\ln(f_+\sqrt{D_-}/f_-\sqrt{D_+}),$$

where f_+ and f_- are the activity coefficients and D_+ and D_- the diffusion coefficients of R^+ and R^-, respectively. It is quite reasonable to assume $f_+=f_-$ and $D_+=D_-$ for the R^-/R^+ couple, so that $E^r_{1/2}(R^-/R^+)$ equated to $E^\circ_{R^-/R^+}$ is a very good approximation (see Table 4).

According to the molecular orbital theory the sum of A and I should be constant for alternant aromatic hydrocarbons. Thus Eq. 5 predicts that for a given solvent $E^\circ_{R^-/R^+}$ of alternant aromatic hydrocarbons should be constant independent of the species of alternant aromatic hydrocarbon. Results in Table 4 show this is the case with perylene and DPA in PC and AN, indicating the validity of Eq. 4 for alternant aromatic hydrocarbons in nonaqueous solvents.[49]

From Eq. 2 the difference $\Delta^I E^{II}(s)$ between the $E^\circ_{R^-/R^+}$'s of two couples, I and II, in a solvent, s, is given by

$$\Delta^I E^{II}(s) = E^\circ_{R^-/R^+}(I, s) - E^\circ_{R^-/R^+}(II, s) = (A_I+I_I)/2F - (A_{II}+I_{II})/2F - (\Delta G^s_{R^-/R^+}(I)-\Delta G^s_{R^-/R^+}(II))/2F. \quad (6a)$$

Accordingly, if $\Delta^I E^{II}(s)$ were found to be independent of the solvent s for any pair of redox couples, I and II, it must hold that $\Delta\Delta^I G^{II}(s)=\Delta G^{s'}_{R^-/R^+}(I)-\Delta G^s_{R^-/R^+}(II) \approx 0$, because $\Delta\Delta^I G^{II}(s)$, if appreciable, should be dependent on the solvent s. The last condition means that $\Delta G^s_{R^-/R^+}(I)\approx\Delta G^s_{R^-/R^+}(II)\approx\Delta G^s_{R^-/R^+}(III)\approx\cdots$, which in turn implies that all these $\Delta G^s_{R^-/R^+}$'s are negligibly small or that Eq. 4 is valid, because $\Delta G^s_{R^-/R^+}(I)$, $\Delta G^s_{R^-/R^+}(II)$, $\Delta G^s_{R^-/R^+}(III)$,$\cdots$, if appreciable, should be dependent on the redox couples I, II, III, $\cdots$, respectively. In conclusion, if $\Delta^I E^{II}(s)$ is independent of the solvent s, Eq. 4 is valid, so that

$$\Delta^I E^{II}(s) = (A_I+I_I)/2F - (A_{II}+I_{II})/2F. \quad (6b)$$

A similar argument leads to the conclusion that if the difference $\Delta^{s'}E^{s''}(I)$ between the $E^\circ_{R^-/R^+}(I)$'s of a redox couple, I, in any two solvents, s' and s'', is independent of the redox couple I, Eq. 4 is valid, so that $\Delta^{s'}E^{s''}(I)$ should indicate the solvent activity coefficient, ${}^{s'}\gamma^{s''}$, of the ion involved in the reference electrode reaction, as shown by

$$\Delta^{s'}E^{s''}(I) = E^\circ_{R^-/R^+}(I, s') - E^\circ_{R^-/R^+}(I, s'') = (\Delta G^{s'}(Ag/Ag^+) - \Delta G^{s''}(Ag/Ag^+))/F = (RT/F)\ln {}^{s'}\gamma^{s''}_{Ag^+}. \quad (7)$$

Thus the validity of the five R^-/R^+ redox couples employed here as the reference R^-/R^+ redox couple can be checked. Table 5 shows the values of $\Delta^I E^{II}(s)$ obtained with pairs of the five redox couples in the solvents studied. Table 6 summarizes the $\Delta^{s'}E^{s''}(I)$ values for various solvent pairs measured against the silver/silver ion electrode. These results show that the theoretical predictions (6b) and (7) are satisfied within experimental error by all the five R^-/R^+ redox couples. In particular, it is noteworthy that the hydrocarbon and metal complex systems give practically the same

results although they are quite different in their chemical structures.

Regarding the charge distribution in the hydrocarbon ions, it can be confidently assumed that the π-electron spin-density distributions are the same for the monocation and monoanion of an alternant aromatic hydrocarbon. The pairing theorem[26,27] predicts that the π-electron spin-density distributions should be the same for the cation and anion of an alternant aromatic hydrocarbon. Some experimental results[28,29] seem to show that this theorem holds to a high degree of approximation for alternant hydrocarbon ions. Significant differences observed between the ESR spectra of the positive and negative hydrocarbon ions have been interpreted[30,31] in terms of the variation of the σ-π parameter, Q^{H}_{CH}, in McConnell's relation. Therefore it is quite reasonable to assume that[7] the charge distributions in the cation and anion radicals of perylene and DPA are very nearly the same. In fact, this assumption has been adopted by Case and his coworkers[32] in their estimation of the surface potential of acetonitrile. Parker,[33] in his studies on the energetics of electrode reactions of aromatic hydrocarbons, has also proceeded on this assumption. On the other hand the charge distributions in the cations of the bipyridine complexes seem somewhat different from those in the corresponding anions, since in the first three one-electron reduction steps of the bipyridine complexes each added electron may occupy one of the three vacant π^*-orbitals localized mainly in the ligand molecules.[15] This difference in charge distribution between the R^+ and R^- ions fortunately seems to result in a small effect (probably less than 0.01 eV)[7] on the difference of solvation energy, as indicated by the above $\Delta^{I}E^{II}$(s)- and $\Delta^{s'}E^{s''}$(I)-tests. Recently Ogata, Fujisawa, and Tanaka[50] have proposed a $Co(bipy)_3^{3+}/Co(bipy)_3^{2+}$ couple as a candidate for the reference redox couple.

The Born equation for the free energy of ion solvation was first modified by Latimer, Pitzer, and Slansky[34] and later by numerous other authors.[3,6] This was done by introducing the empirical radius corrections specific to the solvent s, R_+(s) and R_-(s) for cations and anions, respectively. This correction should imply supplemental energies of ion solvation which are not involved in the simple Born equation. These supplemental energies may consist of a part of electrostatic energy of solvation due to ion-multipole interactions, as discussed by Buckingham,[35] and a part of non-electrostatic (or van der Waals') interaction energy of solvation. The latter is dependent on the orientation of solvent molecules in the first solvation sheath. Thus, in the modified Born equation the difference in the solvation free energy between two oppositely charged ions having the same radius should be reflected in the difference between R_+(s) and R_-(s). According to Strehlow,[6] $R_+(AN)=0.072$ and $R_-(AN)=0.061$ nm, which will result, for example, in $\Delta G^{AN}_{R^-/R^+}=0.02$ eV for the metal bipyridine complex redox couples.[7] Although Tanaka and Ogata[51] and Nedermeijer-Denessen, de Ligny, and Remijnse[36] have recently shown that the existence of R_+(s) and R_-(s) which are valid for *all* kinds of ions in a specified solvent, s, is questionable, this estimation of $\Delta G^{S}_{R^-/R^+}$ based on the empirical radius corrections as well as the discussion on the $\Delta^{I}E^{II}$(s)- and $\Delta^{s'}E^{s''}$(I)-test described above shows that the error, introduced by assuming $\Delta G^{S}_{R^-/R^+}=0$ (Eq. 4) for the redox couples investigated here, is probably not larger than ± 0.01 eV. Thus it may be concluded that the standard potentials of the R^-/R^+ redox couples studied here are solvent-independent within an error of ± 0.01 V.

To estimate the solvent activity coefficient of an ion at $\mu=0$, μ being the ionic strength, it is necessary to know the dependence of the activity coefficient on the ionic strength in each solvent. Table 7 shows $\Delta E^{r}_{1/2}$(exptl) as the difference of two experimental values of $E^{r}_{1/2}(R^-/R^+)$ at two different concentrations of the supporting electrolyte, *i.e.*, 0.05 and 0.2 M TEAP, referred to Ag/1 mM Ag^+ in 0.05 and 0.2 M TEAP, s, electrodes, respectively. Since $E^{r}_{1/2}(R^-/R^+)\approx E^{\circ}_{R^-/R^+}$ the difference $\Delta E^{r}_{1/2}$(exptl) should be equated to the difference of the two reference electrodes, which is expressed by $\Delta E^{r}_{1/2}=(RT/F)\ln[f^{+}_{Ag}(0.05\ M)/f^{+}_{Ag}(0.2M)]$. Table 7 shows $\Delta E^{r}_{1/2}$(calcd) as the difference calculated by this equation with the Davies equation, $\log f=-A[\sqrt{\mu}/(1+\sqrt{\mu})-0.3\ \mu]$.[37] Good agreement between $\Delta E^{r}_{1/2}$(exptl) and $\Delta E^{r}_{1/2}$(calcd) indicates that the Davies equation is applicable to estimate the ionic activity coefficients of the silver ion in the solvents studied. Thus the solvent activity coefficients of the silver ion were corrected for $\mu=0$ using the Davies equation. Table 8 gives the solvent activity coefficients of the silver ion at $\mu=0$, $(RT/F)\ln {}^{S'}\gamma^{S''}_{Ag^+(\mu=0)}$, in molality scale, as obtained by this procedure. Table 8 also gives for comparison the solvent activity coefficients estimated on the basis of other extrathermodynamic assumptions by other authors.[41,46-48] The $(RT/F)\ln {}^{S'}\gamma^{S''}_{Ag^+(\mu=0)}$ values in molarity scale[47,48] were conventionally converted to the values in molality scale by

a) Calculated by Eq. 8 (see text).

$$\ln {}^{s'}\gamma^{s''}_{Ag^+(\mu=0)}(\text{molal}) + \ln (d^{s'}_{o}/d^{s''}_{o}) = \ln {}^{s'}\gamma^{s''}_{Ag^+(\mu=0)}(\text{molar}),$$

where $d^{s'}_{o}$ and $d^{s''}_{o}$ are the densities of pure solvents, s′ and s″, respectively. Assumption 1, the reference electrolyte method,[38] equates the solvent activity coefficients of tetraphenylarsonium cation and tetraphenylboride anion, $\log {}^{o}\gamma^{s}_{Ph_4As^+} = \log {}^{o}\gamma^{s}_{Ph_4B^-}$. Assumption 2, based on Strehlow's ferrocene scale, equates the solvent activity coefficients of ferrocene and ferricinium cation.[39] Assumption 3 neglects the liquid junction potential in a cell composed of a nonaqueous salt bridge of tetraethylammonium picrate.[40] Assumption 4 is based on the solvent activity coefficient of rubidium ion calculated by a modified Born equation.[41] The internal coherency of the solvent activity coefficient of the silver ion estimated by these assumptions seems generally satisfactory in these four solvents. In particular, good agreement is seen between the results reported here and those based on assumptions 1 or 4. Such a correspondence, considering the similarities between assumption 1 and ours, would be expected. The modified Born equation with appropriate empirical parameters seems to give a reasonable estimation to the differences in the solvation free energies of large alkali ions between two solvents.

When electron affinity and ionization potential data are available for the neutral compounds R, the free energy change of the reference electrode reaction, $\Delta G^{s}(Ag/Ag^+)$, by Eq. 5 can be calculated. At present the experimental data are not available, but theoretical values of the electron affinity and ionization potential for perylene are available: $(A+I)_{perylene} = 8.23$ eV[42] or 8.68 eV.[43] Alternatively, for the $(A+I)$ value of perylene, the average value of the experimental data of $(A+I)$ for several other alternant aromatic hydrocarbons can be used, since the molecular orbital theory[44] predicts that the $(A+I)$ for alternant aromatic hydrocarbons should be constant, and available experimental results support this relationship: $(A+I)^{ex}_{av} = 8.22$ eV.[32] Assuming 8.22 eV for the $(A+I)$ of perylene, $\Delta G^{s}(Ag/Ag^+)$ by Eq. 5 was calculated and the results are summarized in Table 9. Table 9 also gives the values of the standard free energy change (in molality scale) of the reference electrode reaction, $\Delta G^{os}(Ag/Ag^+)$, conventionally calculated by

$$\Delta G^{os}(Ag/Ag^+) = \Delta G^{s}(Ag/Ag^+) + RT \ln [f_{Ag^+} C_{Ag^+}/d_o],$$

where d_o is the density of the pure solvent and C_{Ag^+} the molar concentration of the silver ion involved in the reference electrode. In the calculations it was also assumed that 1 mM silver salt contained in the reference electrode solution was perfectly dissociated in all the solvents studied. Table 10 shows the values of $(A+I)$ of the compounds used here as the R^-/R^+ reference redox couple which were calculated from Eq. 5 by taking 8.22 eV for the $(A+I)$ of perylene.

a) Reference value.

Recently Trasatti[45] has recalculated the absolute potential of the standard hydrogen electrode using the more reliable value of the hydration free energy of protons; $\varepsilon^{\circ}_{abs} = 4.31 \pm 0.04$ V. This value agreed well with those estimated from the calculated absolute potentials of several alkali metal/alkali metal ion electrodes in water. Thus the absolute electrode potential of an Ag/Ag^+ half-cell in water can be calculated; $\Delta G^{ow}(Ag/Ag^+) = -5.11$ eV. From this the solvent activity coefficients for the transfer of the silver ion from water to nonaqueous solvent can be calculated by

$$(RT) \ln {}^{w}\gamma^{s}_{Ag^+(\mu=0)} = \Delta G^{ow}(Ag/Ag^+) - \Delta G^{os}(Ag/Ag^+). \quad (8)$$

The results are given in Tables 8 and 9. These values agree well with those estimated on the basis of the modified Born equation,[41,46] but deviate by about −0.05 V from those estimated by the reference electrolyte method.[48] Note that the determination of solubilities of the reference electrolyte in water is sometimes associated with inaccuracy.[47]

Addendum. After completion of this work,[52] a paper was published by C. Madec and J. Courtot-Coupez,[53] which contains experimental results that confirm that the R^-/R^+ system of alternant aromatic hydrocarbons can be used as a solvent-independent reference for potential comparisons.[7]

We are grateful to Dr. Takeko Matsumura-Inoue of Nara University of Education for her kind gift of bipyridine complexes used in this work. This work was supported by a grant from the Japanese Ministry of Education.

Crystal Structures of *N*-(Benzyloxycarbonyl)prolylleucine Ethyl Ester and *N*-(*t*-Butoxycarbonyl)prolylleucine Benzyl Ester

Harumasa SUGINO, Isao TANAKA,* and Tamaichi ASHIDA

Department of Applied Chemistry, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 24, 1978)

The molecular structures of *N*-(benzyloxycarbonyl)prolylleucine ethyl ester and *N*-(*t*-butoxycarbonyl)-prolylleucine benzyl ester, were determined by the X-ray method. The former belongs to the orthorhombic system $P2_12_12_1$ with $Z=4$, $a=9.917(3)$, $b=21.960(3)$, and $c=9.956(1)$ Å; the latter belongs to the monoclinic system $P2_1$ with $Z=2$, $a=10.475(1)$, $b=17.910(1)$, $c=6.303(1)$ Å, and $\beta=90.213(7)°$. Both structures were determined by the direct method; the final R indexes are 0.062 for the former and 0.072 for the latter. An extended conformation found in both dipeptides shows that in terms of the Pro–Leu unit alone this conformation is preferable to the folded β-turn conformation such as is found in longer peptides. The leucyl side chain conformations found in peptides or amino acids were also studied. For the residues occurring in the peptides the $C'-C^{\alpha}-C^{\beta}-C^{\gamma}-C^{\delta 1}$ trans-zigzag conformation was found overwhelmingly, without any obvious relationships to the main chain torsion angles. On the other hand, for the C-termini leucyl residues and leucines the $N-C^{\alpha}-C^{\beta}-C^{\gamma}-C^{\delta 2}$ trans-zigzag conformation was rather preferred and the ϕ values were restricted to a narrow range.

Several linear oligopeptides containing the Pro–Leu sequence have been studied by the X-ray method. They are benzyloxycarbonyl(Z)–Gly–Pro–Leu–Gly–Pro,[1] Z(*o*-Br)–Gly–Pro–Leu–Gly–Pro,[2] Z(*p*-Br)–Gly–Pro–Leu–Gly,[3] *t*-butoxycarbonyl(Boc)–Pro–Leu–Gly,[4] *S*-benzyl–Cys–Pro–Leu–Gly–NH_2,[5] Pro–Leu–Gly–NH_2,[6] and Z–Gly–Pro–Leu.[7] All the oligopeptides but the last two have the β-turn of type I[8] with a 4→1 hydrogen bond, in which Pro and Leu residues are located at the second and third sites of the β-turn. On the other hand, the Pro–Leu parts in Pro–Leu–Gly–NH_2 and Z–Gly–Pro–Leu take more extended forms, somewhat similar to the poly(L-proline) II.

In this study, Z–Pro–Leu–OEt(ethyl ester) and Boc–Pro–Leu–OBzl(benzyl ester), which cannot have an intramolecular hydrogen bond of the β-turn, were prepared and their crystal structures were worked out by the X-ray method.

Experimental

Z–Pro–Leu–OEt and Boc–Pro–Leu–OBzl were prepared from the corresponding N-protected proline and the C-protected leucine.

The X-ray diffraction data were collected on a Hilger and

TABLE 1. CRYSTAL AND EXPERIMENTAL DATA

		Z–Pro–Leu–OEt	Boc–Pro–Leu–OBzl
Molecular formula		$C_{21}H_{30}N_2O_5$	$C_{23}H_{34}N_2O_5$
Molecular weight		390.48	418.53
Crystal system		Orthorhombic	Monoclinic

Watts four circle diffractometer with Ni-filtered Cu $K\alpha$ radiation and ω-2θ step scan. Lorentz and polarization factors were applied, but no absorption corrections were made. The crystal and experimental data are listed in Table 1.

Structure Determination and Refinement

Both structures were determined by the direct method using the program *MULTAN*[9] and refined by the block-diagonal least-sequares method with the program *HBLS* V.[10] Since the ($\bar{2}01$) reflection of Boc–Pro–Leu–OBzl suffered much from extinction, it was omitted from the refinement. The final R values were 0.062 for Z–Pro–Leu–OEt and 0.072 for Boc–Pro–Leu–OBzl. The minimized function was $\sum\omega(\Delta F)^2$, with $\omega=0.0$ for $|F_o|=0$, and $\omega=(\sigma^2(F)+a|F_o|+b|F_o|^2)^{-1}$ for $|F_o|>0$, where $\sigma(F)$ was the standard deviation based on the counting statistics. The parameters were: $a=-0.157$ and $b=0.008$ for Z–Pro–Leu–

OEt, and $a=-0.073$ and $b=0.004$ for Boc–Pro–Leu–OBzl.

All the atomic scattering factors were taken from International Tables for X-Ray Crystallography.[11] The calculations were made on FACOM 230-60 and 75 of Nagoya University. The final positional and thermal parameters are also listed in Tables 2 and 3.[12]

Results and Discussion

Bond Lengths and Angles. The bond lengths and angles of the two molecules (Figs. 1 and 2) are in

a) All the torsion angles for the L-isomers are listed. b) Type I, II, and III have the trans-zigzag chains of C'–C^α–C^β–C^γ–$C^{\delta 1}$, N–C^α–C^β–C^γ–$C^{\delta 2}$, and C'–C^α–C^β–C^γ–$C^{\delta 2}$, respectively. c) In cases of C termini leucyl residue and leucine amino acid, ψ means the torsion angle N–C^α–C'–O.

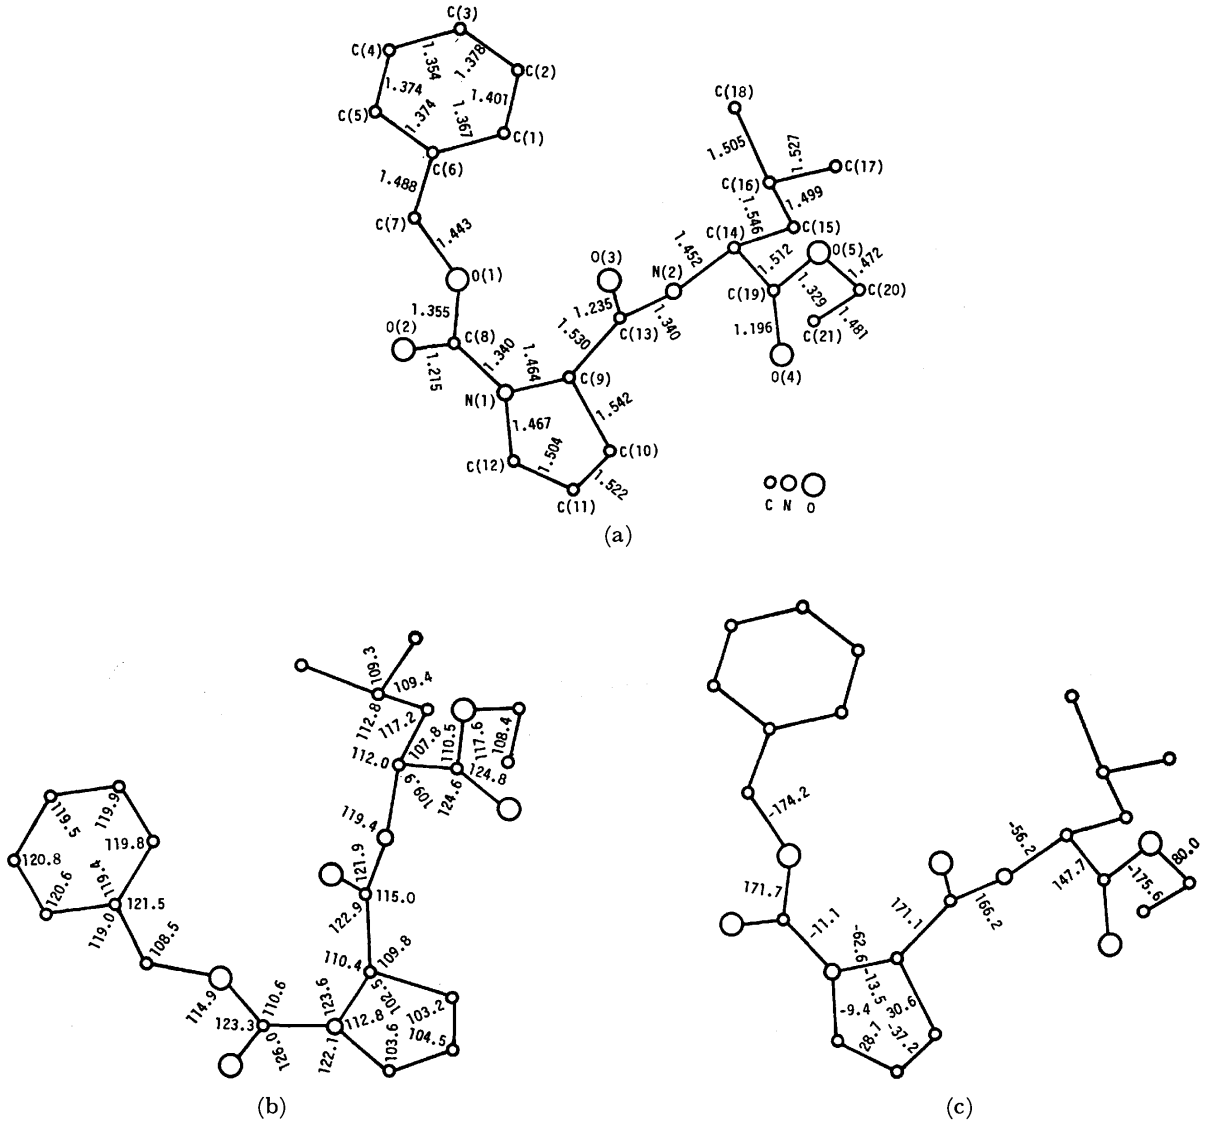

Fig. 1. (a) Bond lengths (Å), (b) angles (°), and (c) torsion angles (°) for Z–Pro–Leu–OEt.

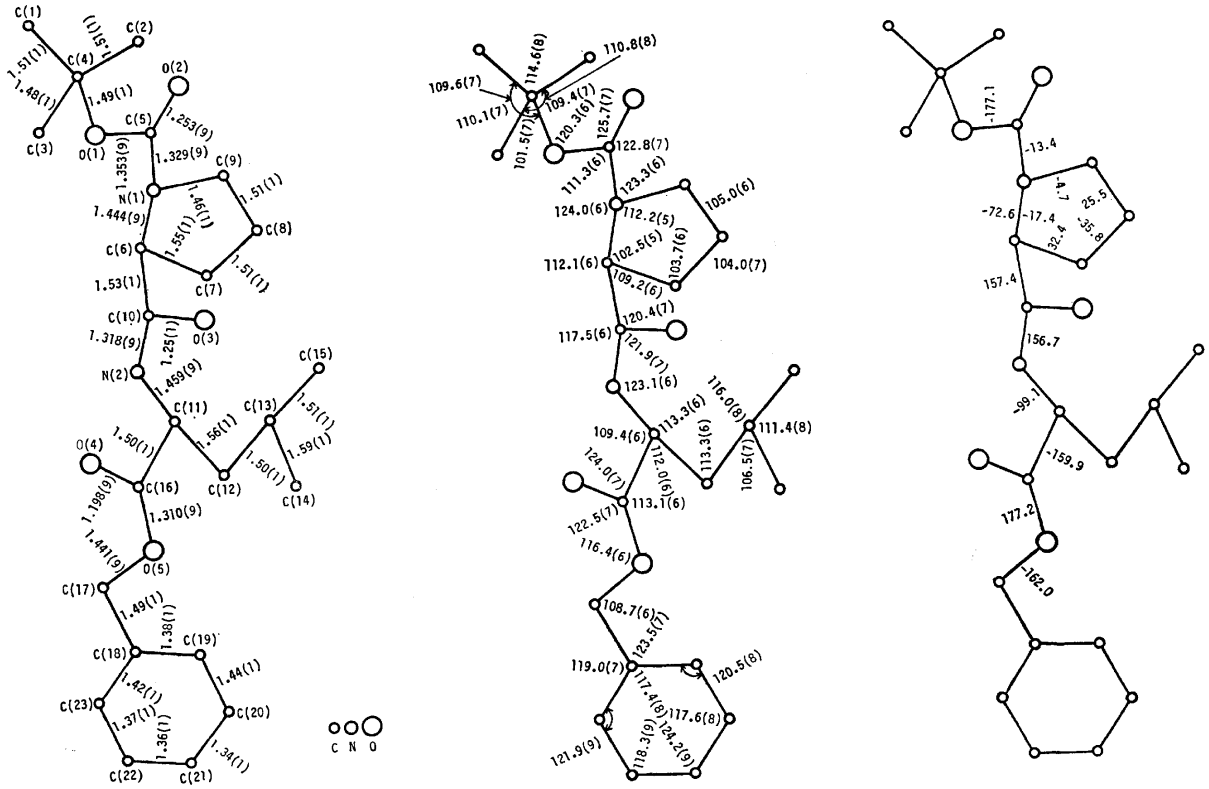
accordance with the average values of the peptides, within the experimental error. Seemingly abnormal large values observed at the C^{β} atoms of the leucyl residues (117.2° in Z–Pro–Leu–OEt and 113.3° in Boc–Pro–Leu–OBzl) are common to all the leucines so far studied. They are attributed to the steric repulsion between the peptide plane and the bulky leucyl side chain.[3]

Prolyl Side Chain. Both pyrrolidine rings are designated as C^{γ}-*endo*, conformation B by the definition of Balasubramanian *et al.*[13] But following the more detailed classification by Ashida and Kakudo,[14] they can be distinguished as C_2–C^{γ}-*endo* for Z–Pro–Leu–OEt and an intermediate state between C_2–C^{γ}-*endo* and C_s–C^{γ}-*endo* for Boc–Pro–Leu–OBzl.

Leucyl Side Chain. Most of the side chain conformations of the leucyl residues so far analyzed can be classified into three trans-zigzag conformations, *i.e.* C′ to $C^{\delta 1}$(type I), N to $C^{\delta 2}$(type II), and C′ to $C^{\delta 2}$(type III).[4] (see Table 4 footnote) The two molecules in this study take a type I conformation.

The main chain torsion angles (ϕ,ψ) and the leucyl side chain conformations are presented in Table 4. For the leucyl residues occurring in the peptides, type I is found overwhelmingly, without any obvious relationships to the main chain torsion angles. On the other hand, for the C termini leucyl residues and leucines, type II is rather preferred and the ψ values seem to be restricted to a narrow range.

Peptide Chain. The main chain torsion angles are shown in Figs. 1 and 2. Both of the peptides analyzed in this study, Z–Pro–Leu–OEt and Boc–Pro–Leu–OBzl, take an extended conformation, in contrast to the folded β-turn conformation of the longer peptides so far analyzed. This observation suggests that an extended conformation is preferable to the folded conformation for the simple Pro–Leu unit. The folded conformation has only been found with the 4⟶1 hydrogen bond. The conformational difference between the dipeptides and the longer peptides suggests an important role for the semi-local interactions, such as the 4⟶1 hydrogen bond, in the folding of peptide chains.



(a) (b) (c)

Fig. 2. (a) Bond lengths (Å), (b) angles (°), and (c) torsion angles (°) for Boc–Pro–Leu–OBzl.

Crystral Structure. The crystal structures of the two compounds are shown in Figs. 3 and 4. Although there is no close relationship between the two structures, the hydrogen bonds between the carbonyl oxygen atom of the oxycarbonyl group and the nitrogen atom of the leucyl residue are commonly observed. This fact, together with the clustering of the Boc or Z group and the other hydrophobic groups in each crystal, suggests that the two N-protecting groups, Boc and Z, play a similar role in crystal packing.

The authors would like to express their sincere thanks to Prof. J. Tanaka of Nagoya University for his very kind permission to use the diffractometer. A part of the cost of this research was covered by a Scientific Research Grant from the Ministry of Education, to which the authors' thanks are due.

The Theoretical Study of External Magnetic Field Effect on Chemical Reactions in Solution

Hisaharu HAYASHI and Saburo NAGAKURA*

The Institute of Physical and Chemical Research, Wako, Saitama, 351

(Received April 8, 1978)

External magnetic field effects on chemical reactions in solution are studied theoretically and consequently reactions through radical pairs are shown to be controlled by a magnetic field. Some conditions necessary for the occurrence of the magnetic field effects are discussed, the effects being classified into three types: (1) the electronic Zeeman effect ($\Delta g\beta H$), (2) the hyperfine interaction effect, and (3) the mixed effect.

Recently, magnetic field effects on dynamical processes of excited states have been extensively studied. The phenomena can be divided into two classes; intramolecular and intermolecular cases. The intramolecular phenomena include magnetic field effects on radiative[1] and nonradiative[2] decay processes, predissociation,[3] and reactivity of triplet sublevels.[4] The intermolecular phenomena are related with the selection rule of reactions induced by the collision of excited molecules or radicals with some spin multiplicities (*i.e.* triplet+triplet, triplet+doublet, doublet+doublet *etc.*). In actuality, the intermolecular magnetic field effect has been observed with delayed fluorescence,[5] photoconductivity,[6] chemiluminescence,[7] chemically induced dynamic electron and nuclear polarization (CIDEP and CIDNP).[8]

Concerning external magnetic field effects upon chemical reactions through excited states, reliable studies have scarcely been done. A magnetic field effect upon photo-decomposition has been observed with iodine molecules in gas phase.[3] Gupta and Hammond[9] reported magnetic field effects on some photoisomerization reactions through exciplexes in solution.[10]

Recently, the yields of some excited states produced by pulse radiolysis[11] and laser photolysis[12,13] have been found to be affected by a magnetic field. The Novosibirsk group[14,15] found an external magnetic field effect on the yield ratio of a cage product to a free radical product in some thermal reactions between alkyl lithium and alkyl halide. We also found an external magnetic field effect on the reaction yields of both the cage product and the free radical products in the singlet sensitized photolysis of dibenzoyl peroxide in solution.[16]

In this paper, we have developed a theory for the external magnetic field effect on chemical reactions through radical pairs in solution on the basis of the general formula for the spin hamiltonian of a weakly coupled radical pair which was developed in a previous paper[17] and was used as one of the basic theories for CIDNP.[8] The purpose of the present study is to clarify the conditions necessary for the magnetic field control of chemical reactions.

Theory

It has already been shown that the singlet-triplet conversion in a radical pair in solution is affected by an external magnetic field when the energy separation between the singlet and triplet ground states, $|2J|$, is comparable to or smaller than the difference between the Zeeman energies of the component radicals or their hyperfine energies.[8] Therefore in this paper, we consider only a separated radical pair in solution. In the previous paper,[17] we obtained the matrix elements between the singlet $|S_0; M\rangle$ and triplet $|T_m; M'\rangle$ ($m=0, \pm1$) ground states of a radical pair. It can be expressed in general as follows:

$$v^m_{M',M} = \langle T_m; M'|H_{st}|S_0; M\rangle, \tag{1}$$

where H_{st} in the second-order matrix element representing the interaction between the orbitally degenerate singlet and triplet states,[17] and M and M' stand for the sets of the nuclear states of the singlet and triplet ground states, respectively. The non-vanishing elements for the separated radical pair in solution are given as follows:

$$\langle T_m; M_i^a, M_j^b|H_{st}|S_0; M_i^a, M_j^b\rangle = v_N + (1-m^2)[(g^a-g^b)\beta H+\sum A_i^a M_i^a-\sum A_j^b M_j^b]/2, \tag{2}$$

$$\langle T_{\pm1}; M_i^a \mp 1, M_j^b|H_{st}|S_0; M_i^a, M_j^b\rangle = \mp A_i^a[I_i^a(I_i^a+1)-M_i^a(M_i^a\mp1)]^{1/2}/(8)^{1/2}, \tag{3}$$

$$\langle T_{\pm1}; M_i^a, M_j^b \mp 1|H_{st}|S_0; M_i^a, M_j^b\rangle = \pm A_j^b[I_j^b(I_j^b+1)-M_j^b(M_j^b\mp1)]^{1/2}/(8)^{1/2}. \tag{4}$$

Here g^ν (ν=a or b) is the average value of the three principal values of the g^ν tensor, A_k^ν is the Fermi contact term of the k-th nucleus, and H is the strength of the external magnetic field. As is shown in Appendix, v_N is the usual matrix element for radiationless transition between the singlet and triplet ground states of the radical pair. This corresponds to the radiationless transition rate constant for a large molecule and may safely be assumed to be much samller than the second term on the right-hand side of Eq. 2 for the separated radical pair in solution as is shown in Appendix. Thus, we disregard v_N hereafter in the present paper.

According to the radical pair theory of CIDNP derived by Kaptein,[18] the yield, $P^\Gamma(H)$ (Γ=S(singlet), T(triplet), or F(free radical)) of the cage product through the singlet ground state[19] of a radical pair formed from a Γ-precursor is given for the case where the singlet-triplet transition rate, $k^m_{M',M}$ is small ($k^m_{M',M}=(1/\hbar)\ |v^m_{M',M}| \ll 1/t_d$):

$$P^S(H) = (\lambda/N)\sum_m\sum_M\sum_{M'}(p-x^m_{M',M}), \tag{5}$$

$$P^T(H) = (\lambda/3N(1-p))\sum_m\sum_M\sum_{M'}x^m_{M',M}, \tag{6}$$

$$P^F(H) = (\lambda/4N)\sum_m\sum_M\sum_{M'}[1+\{p(1-\lambda)+\lambda x^m_{M',M}\}/(1-p\{1-\lambda(1-\lambda)/2\})]. \tag{7}$$

Here $k^m_{M',M}$ is the transition rate between $|S_0; M\rangle$ and

$|T_m; M'>$, t_d is the lifetime of the radical pair, λ is the probability for recombination during a singlet encounter, p is the total probability of at least one reencounter appearing in Noyes' reencounter function, $f(t)=m_0t^{-3/2}\exp(-m_0p^2/t)$[20] where m_0 is a constant with the dimension of $s^{1/2}$. N is the number of the nuclear states, $|S_0; M>$, and $x^m_{M'.M}$ is given as follows:[18]

$$x^m_{M'.M} = m_0\pi^{1/2}(v^m_{M'.M})^2(\omega^m_{M'.M})^{-3/2}, \quad (8)$$

where

$$\omega^m_{M'.M} = [\{J+m(g^a+g^b)\beta H/2\}^2+(v^m_{M'.M})^2]^{1/2}. \quad (9)$$

For the case of large $k^m_{M'.M}$ we need a numerical calculation[11-13] for evaluation $P^T(H)$. But for the extreme case where $k^m_{M'.M}$ is very large ($k^m_{M'.M}\gg t_d^{-1}$, $(1/\hbar|J|)$, the singlet–triplet conversion rate is so fast that $|S_0; M>$ and $|T_m; M'>$($m=0$, ±1 for the zero field and $m=0$ for high field) are assumed to exist in equilibrium with each other. Therefore, we can derive the following equations for $P^T(0)$ and $P^T(H_\infty)$:

$$P^S(0) = p\lambda(1+p(1-\lambda/4)+\cdots)/4$$
$$= p\lambda/[4(1-p(1-\lambda/4))], \quad (10)$$
$$P^S(H_\infty) = p\lambda(1+p(1-\lambda/2)+\cdots)/2$$
$$= p\lambda/[2(1-p(1-\lambda/2))], \quad (11)$$
$$P^T(0) = P^S(0), \quad (12)$$
$$P^T(H_\infty) = p(1+p(1-\lambda/2)+\cdots)/6$$
$$= p\lambda/[6(1-p(1-\lambda/2))]. \quad (13)$$

Here $H_\infty\gg 2v^m_{M'.M}/(g^a+g^b)\beta$. In the above evaluation, we assumed, for simplicity, that the radicals escaped from the cage disappear so fast that no cage product is formed through the free radicals.

In order to compare the theory with experiments, we define the relative change in the yield for the cage product, $R^T(H)$, and that for the i-th free radical product, $Q^T_i(H)$, as follows:

$$R^T(H) = [P^T(H)-P^T(0)]/P^T(0), \quad (14)$$
$$Q^T_i(H) = [F^T_i(H)-F^T_i(0)]/F^T_i(0). \quad (15)$$

Here $F^T_i(H)$ is the yield of the i-th free radical product and can be expressed with the fraction, f_i, for giving the product from the escaped radical:

$$F^T_i(H) = f_i[1-P^T(H)]. \quad (16)$$

Therefore, $Q^T_i(H)$ can be rewritten as

$$Q^T_i(H) = -R^T(H)P^T(0)/(1-P^T(0)). \quad (17)$$

This equation means that $Q^T_i(H)$ is independent of f_i and has the opposite sign to $R^T(H)$.

Types of External Magnetic Field Effects on Chemical Reactions

As mentioned above, the matrix elements between the singlet and triplet states of a separated radical pair are expressed by the difference between the g factors and hyperfine interactions of the component radicals. Here we classify the external magnetic field effects on chemical reactions into the following three types: (1) effect of $\Delta g\beta H$ ($\Delta g=g^a-g^b\neq0$ and $A_i^a=A_j^b=0.$), (2) effect of hyperfine interactions ($\Delta g=0$, $A_i^a\neq0$, and $A_j^b\neq0.$), and (3) mixed effect of $\Delta g\beta H$ and hyperfine interactions.

Effect of Electronic Zeeman Interaction ($\Delta g\beta H$). In this case, the following equations hold:

$$v^0_{M'.M} = \Delta g\beta H/2\delta_{M'.M} = v\delta_{M'.M}, \quad (18)$$
$$v^{\pm1}_{M'.M} = 0. \quad (19)$$

These equations show that the conversion occurs only between $|S_0; M>$ and $|T_0; M>$. At first, we consider a reaction through a singlet precursor. For a small v ($(1/\hbar)v\gg t_d^{-1}$), $R^S(H)$ can be given as follows:

$$R^S(H) = -fx/p. \quad (20)$$

Here f is the fraction with which a cage product is given through separated pairs,[21] $x=m_0\pi^{1/2}v^2\omega^{-3/2}$, and $\omega^2=J^2+v^2$. For $v\ll|J|$ (case a) and $v\gg|J|$ (case b), x can be approximated to be $m_0\pi^{1/2}v^2|J|^{-3/2}$ and $m_0\pi^{1/2}v^{1/2}$, respectively. Thus we can derive the following equations:

$$\text{(case a)} \quad R^S(H) = -fm_0\pi^{1/2}(\Delta g\beta H)^2/(p|J|^{3/2}), \quad (21)$$
$$\text{(case b)} \quad R^S(H) = -fm_0\pi^{1/2}(\Delta g\beta H)^{1/2}/p. \quad (22)$$

For the extreme case where H is very large (case c), $R^S(H)$ can be given with the aid of Eqs. 5 and 11 as follows:

$$\text{(case c)} \quad R^S(H) = 1/[2(1-p(1-\lambda/2))]-1. \quad (23)$$

Equations 21—23, clearly show that $R^S(H)$ is proportional to H^2 at low fields and $H^{1/2}$ at higher field, but it saturates at much higher fields. This is shown in Fig. 1.

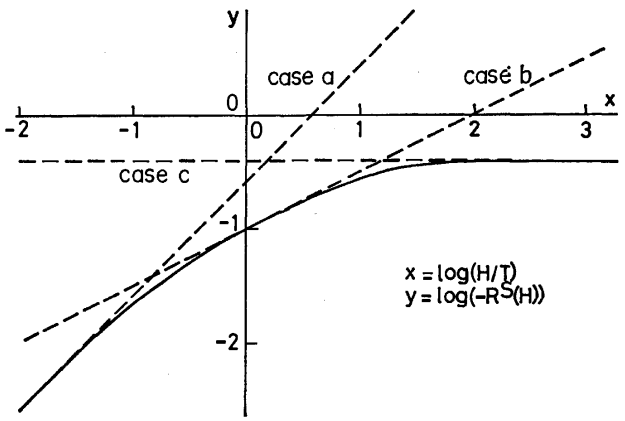

Fig. 1. The calculated contribution of the electronic Zeeman effect to the magnetic field dependence of $R^S(H)$: ——, plot of $\log(-R^S(H))$ *versus* $\log H$ for the whole magnetic field region; ——, plots of $\log(-R^S(H))$ *versus* $\log H$ for cases a, b, and c.

An example of this type of the magnetic field effect is the singlet sensitized photo-decomposition reaction of dibenzoyl peroxide in toluene.[16] It was observed that the yield of phenyl benzoate, the cage product of the reaction, decreased proportionaly to the square root of the applied field strength. This means that the reaction shows a case b type magnetic field effect. From the slope of the observed $R^S(H)$ for phenyl benzoate, *versus* $H^{1/2}$, fm_0/p was determined to be 1.08×10^{-6} $s^{1/2}$ with the aid of Eq. 22. Since $f\lesssim1$, $0.5<p<1$, and $m_0\approx10^{-6}$ $s^{1/2}$,[18] the theoretical value of fm_0/p agrees well with the experimental value.

As for the free radical products (2-methylbiphenyl, 4-methylbiphenyl, and 1,2-diphenylethane) in the

reaction, their $Q_i^S(H)$ values were observed to be independent of f_i and increased by 2% in the presence of 4.3 T field.[16] Since $R^S(4.3\ T)$ and $P^S(0)$ were observed to be -0.08 and 0.12, respectively, for phenyl benzoate,[16,25] $Q_i^S(4.3\ T)$ was calculated to be 0.01 with the aid of Eq. 17. This value also agrees with the observed one (0.02)[16] within the limitations of experimental error.

Next, let us consider reactions through a triplet precursor. For a small v, $P^T(H)$ can be evaluated as follows:

$$P^T(H) = fx/[3(1-p)]. \quad (24)$$

This shows that $P^T(H)$ has the opposite sign to $R^S(H)$ (see Eq. 20). In the extreme case where v is very large, $P^T(H)$ is given by Eq. 13. The reaction showing an external magnetic field effect of this type has not yet been observed. We are now studying the triplet sensitized photo-decomposition reaction of dibenzoyl peroxide. This reaction may be the example of this type.

Effect of Hyperfine Interactions. The effects of hyperfine interactions on some reaction intermediates have been studied by Brocklehurst,[11] Michel-Beyerle *et al.*,[12] and Schulten *et al.*.[13] They evaluated numerically the effects for some ideal cases. Although it is impossible to derive a simple analytical expression for the effect, its qualitative features correspond fairly well to the extreme case where $k^m_{M',M}$ is very large. For this case, the singlet-triplet conversion occurs between $|S_0; M>$ and $|T_m; M'>$ ($m=0, \pm1$ for zero field and $m=0$ for high field, H_∞). Thus $P^\Gamma(H_\infty)$ for this case are given by Eqs. 10—13. According to these equations, the yield of the cage product from the singlet (triplet) precursor increases (decrease) on the application of a strong external magnetic field. Actually, H_∞ is less than 0.1 T for many cases.[11-13] On the other hand, the yield of each free radical product from the singlet (triplet) precursor is proved to decrease (increase) on the application of the field.

For a smaller $k^m_{M',M}$, the change in the yield of each product on the application of a strong field shows the same tendency as that for the strong limit case. But the degree of the change may be smaller than that of the strong limit case because of the diffusion of the radical pair to free radicals. An example of this type of the effect is the thermal reaction of benzylic chloride with butyllithium studied by Sagdeev *et al.*[14]

Mixed Effect of $\Delta g\beta H$ and Hyperfine Interactions. Although it is also difficult to obtain a simple analytical form for this case, qualitative analysis can be done for small $|J|$ ($|J| \ll v^m_{M',M}$) as follow. (1) At zero field, the conversion between $|S_0; M>$ and $|T_m; M'>$ ($m=0, \pm1$) occurs through hyperfine interactions. (2) At a higher field, H_1, where $A/g\beta \ll H_1 \ll A/\Delta g\beta$, and A and g are the orders of hyperfine interactions and g factors of the component radicals, respectively, only the conversion between $|S_0; M>$ and $|T_0; M>$ occurs through hyperfine interactions. Therefore, the yield of the cage product from the singlet (triplet) precursor is shown to increase (decrease) on the application of the field, H_1. (3) at a much higher magnetic field, H_2 (where $A/\Delta g\beta \ll H_2$), the conversion between $|S_0; M>$ and $|T_0; M>$ occurs through $\Delta g\beta H_2$ and hyperfine interactions as shown by Eq. 2. Thus the yield of the cage product at H_2 through the singlet (triplet) precursor is concluded to be smaller (larger) than that at H_1. From Eq. 16, the magnetic field dependence of $F^\Gamma_i(H)$ is also shown to be inverse to that of $P^\Gamma(H)$.

This type of the effect has been observed for the cage and free radical products in the thermal reaction of decafluorodiphenylchloromethane with butyllithium[15] and some free radical products (dimethylbiphenyls and tolyl benzoates) in the photo-decomposition reaction of dibenzoyl peroxide.[26]

The mixed effect at a high field, H ($H>H_1$) can easily be evaluated by taking the matrix element, $v^0_{M,M}$, between $|S_0; M>$ and $|T_0; M>$ as follows:

$$v^0_{M,M} = [(g^a - g^b)\beta H + \sum A_i^a M_i^a - \sum A_j^b M_j^b]/2. \quad (25)$$

In this case, with a method similar to that used for the electronic Zeeman effect, $P^S(H)$ can be given for small $v^0_{M,M}$ as follows:

$$P^S(H) = (\lambda/N)\sum_M (p - fx^0_{M,M}), \quad (26)$$

where

$$x^0_{M,M} = m_0\pi^{1/2}(v^0_{M,M})^2(\omega^0_{M,M})^{-3/2}$$

and

$$(\omega^0_{M,M})^2 = J^2 + (v^0_{M,M})^2.$$

In order to compare the theory with experiments, we define $R^S_{H_1}(H)$ as follow:

$$R^S_{H_1}(H) = [P^S(H_2) - P^S(H)]/[P^S(H_2) - P^S(0)]. \quad (27)$$

When H and H_2 are large enough, $P^S(H)$ and $P^S(H_2)$ can be evaluated by Eq. 26, and $P^S(0)$ can be assumed to be equal to λp. In actuality the $R^S_{4.3T}(H)$ values were calculated for phenyl benzoate in the photo-decomposition reaction of dibenzoyl peroxide, the high magnetic field approximation being adopted and the observed hyperfine coupling constants for *ortho*-(1.74 mT), *meta*-(0.59 mT), and *para*-(0.19 mT) protons of the phenyl radical[24] being used. Since no hyperfine structure was observed for the benzoxyl radical,[22] we did not consider its hyperfine interaction. The calculated $R^S_{4.3T}(H)$ values for various J values are plotted

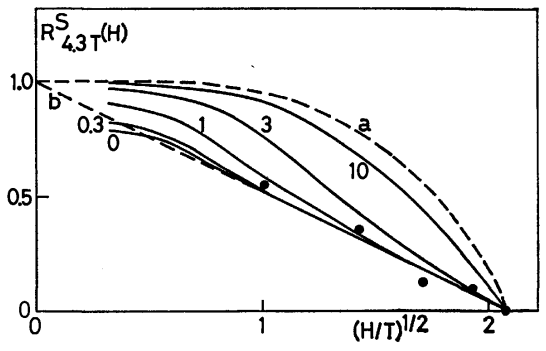

Fig. 2. The dependence of $R^S_{4.3T}(H)$ *versus* $H^{1/2}$ for phenyl benzoate as the photo-decomposition product of dibenzoyl peroxide: ——, the calculated dependence considering both the electronic Zeeman effect and the hyperfine interaction effect; $|J|=0$, 0.3, 1, 3, and 10 mT, for curves 0, 0.3, 1, 3, and 10 respectively; ----, the calculated dependence for case a (curve a) and for case b (curve b) considering only the electronic Zeeman effect: ●, the observed $R^S_{4.3T}(H)$ values for phenyl benzoate.[16]

as the function of $(H)^{1/2}$ in Fig. 2 (solid lines). In this figure are also shown the experimental results of phenyl benzoate (filled circle) and the $R^{S}(H)$-$H^{1/2}$ relationship corresponding to cases a and b of the electronic Zeeman effect (broken lines).

The $R^{S}_{4.3T}(H)$-$H^{1/2}$ plots for $|J|=0$ and $|J|=0.3$ mT agree well with curve b corresponding to case b. This means that in the small $|J|$ region the effect of the hyperfine interactions can safely be disregarded for this reaction compared with that of $\Delta g\beta H$. With increasing $|J|$, the $R^{S}_{4.3T}(H)$ dependence against H gradually deviates from curve b and approaches curve a corresponding to case a. The observed data fit to the curves for $|J|=0$ and $|J|=0.3$ mT (0.281×10^{-3} cm^{-1}). This shows that the magnetic field effect upon formation of phenyl benzoate is mainly due to the electronic Zeeman ($\Delta g\beta H$) effect.

Discussion

The magnetic field effect upon intramolecular processes of an excited state observed for small molecules in gas phase[2,3] is interpreted in terms of the enhancement of the non-radiative decay from the state into a quasi-continuum by the Zeeman interaction and also by the energy shift and broadening of rovibronic levels due to the Zeeman effect.[27,28]

A magnetic field effect on the dynamical process of an exciplex itself has been observed in solid phase[29] or in polymer.[30] This is the case where the acceptor and donor stay separately for a considerable time. In non-viscous solution, it seems difficult to observe any magnetic field effect on the dynamical process of an exciplex itself. The magnetic field effect in non-viscous solution, however, has been observed for reactions through the ion pair after exciplex formation.[12,13] This effect can be explained in terms of the radical pair theory treated in this paper. Recently, Hata observed a magnetic field effect on the photo-isomerization of isoquinoline *N*-oxide.[31] This might be due to a level-crossing[26] in an intermediate radical pair.

We summarize the conditions necessary for the magnetic field control of chemical reactions through raidcal pairs. (1) The magnetic field effect can be observed for reactions which proceed mainly through separated pairs, where $v^{m}_{M'.M}\gg v_{N}$. It is believed that the reaction through close pairs shows no magnetic field effect.[18] (2) The conversion rate $k^{m}_{M'.M}$ between $|S_0; M\rangle$ and $|T_m; M'\rangle$ should not be much smaller than the separation rate of radical pair to free radicals. As is shown in Eqs. 2—4, $k^{m}_{M'.M}$ is large when Δg, hyperfine constants, and the number of the nuclei giving the hyperfine interactions are large. The second condition is the same as that necessary for CIDNP.[8,18] On the other hand, the first condition is not necessary for CIDNP because even a small amount of the product through a separated pair can give the strong CIDNP signal. The magnetic field effect on chemical reactions is useful not only for the determination of the reaction mechanism but also for the control of the product yields. This paper will give a theoretical guidance to the future investigation of the magnetic field effect upon chemical reactions.

We wish to thank Professor K. Tokumaru and Dr. H. Sakuragi, The University of Tsukuba and Dr. Y. Tanimoto, Kanazawa University for their stimulating discussions. We are also indebted to Dr. N. Kanamaru, The Nagoya University and Dr. N. Nishi, The University of Tokyo for valuable comments on radiationless transitions.

Appendix

Since we use a pure-spin BO representation[32] in this paper, the matrix elements between the singlet and triplet states for the usual radiationless transition ($H'_{mr,nt}$) and the hyperfine and electronic Zeeman interactions ($H^{s}_{mr,nt}$) can be written as follows:

$$\begin{aligned}H'_{mr,nt} &= \langle{}^1\psi_{mr}|H_{LS}|{}^3\psi_{nt}\rangle \\ &+ \sum\langle{}^1\psi_{mr}|T_N|{}^1\psi_{ts}\rangle\langle{}^1\psi_{ts}|H_{LS}|{}^3\psi_{nt}\rangle/(E_n-E_t) \\ &+ \sum\langle{}^1\psi_{mr}|H_{LS}|{}^3\psi_{ts}\rangle\langle{}^3\psi_{ts}|T_N|{}^3\psi_{nt}\rangle/(E_n-E_t),\end{aligned} \tag{A-1}$$

$$\begin{aligned}H^{s}_{mr.nt} &= \langle{}^1\psi_{mr}|H_{SI}|{}^3\psi_{nt}\rangle \\ &+ \sum\langle{}^1\psi_{mr}|H_{LZ}|{}^1\psi_{ts}\rangle\langle{}^1\psi_{ts}|H_{LS}|{}^3\psi_{nt}\rangle/(E_n-E_t) \\ &+ \sum\langle{}^1\psi_{mr}|H_{LS}|{}^3\psi_{ts}\rangle\langle{}^3\psi_{ts}|H_{LZ}|{}^3\psi_{nt}\rangle/(E_n-E_t),\end{aligned} \tag{A-2}$$

with

$${}^1\psi_{mr}(q, Q) = {}^1\phi_m(q, Q)\Lambda_{mr}(Q), \tag{A-3}$$

$${}^3\psi_{nt}(q, Q) = {}^3\phi_n(q, Q)\Lambda_{nt}(Q), \tag{A-4}$$

$${}^{\mu}\psi_{ts}(q, Q) = {}^{\mu}\phi_t(q, Q)\Lambda_{ts}(Q), \quad (\mu=1 \text{ or } 3), \tag{A-5}$$

where q and Q denote the sets of electronic, $\phi(q,Q)$, and vibrational, $\Lambda(Q)$, states, respectively. Here H_{LS}, H_{SI}, and H_{LZ} are the spin-orbit, hyperfine, and electronic Zeeman interaction terms, respectively, and T_N is the nuclear kinetic-energy term. Matrix elements v_P and v_F corresponding to the radiationless transitions $S_0\leftarrow T_1$ and $T_1\leftarrow S_1$, respectively, and the matrix element v_R corresponding to the singlet-triplet conversion of a separated radical pair can be given for a large molecule:

$$v_P = \sum_r\sum_t\sum_s(H'_{mr,n0}+H^{s}_{mr,n0}), \tag{A-6}$$

$$v_F = \sum_t\sum_t\sum_s(H'_{m0,nt}+H^{s}_{m0,nt}), \tag{A-7}$$

$$v_R = \sum_t\sum_s(H'_{m0,n0}+H^{s}_{m0,n0}). \tag{A-8}$$

Here we used a low-temperature approximation.

Concerning evaluation of v_P, $H'_{mr,n0}$ is usually approximated to be propotional to its Franck-Condon facter, $\langle\Lambda_{mr}|\Lambda_{n0}\rangle$[32], and $H^{s}_{mr.n0}$ can also be shown to be propotional to it. Thus v_P can be approximated as follows:

$$v_P = \sum_r(h'_{mn}+h^{s}_{mn})\langle\Lambda_{mr}|\Lambda_{n0}\rangle, \tag{A-9}$$

where $h'_{m,n}$ and h^{s}_{mn} are the propotional coefficients of $H'_{mr,n0}$ and $H^{s}_{mr.n0}$ respectively. They can be determined by the electronic wave functions at the equilibrium position for Q. Since βH is 0.467 cm^{-1} for $H=1$ T, and vibronic couplings are usually estimated larger than 100 cm^{-1}, h^{s}_{mn} can safely be ignored in the evaluation of v_P for usual experimental conditions. In a similar way, $H^{s}_{m0.nt}$ can also be shown to be disregarded for estimating v_F.

Concerning evaluation of v_R, $H^{s}_{m0.n0}$ is shown to be proportional to its Franck-Codon factor which may be assumed to be equal to unity for a separated raidcal pair. Therefore, $H^{s}_{m0.n0}$ in Eq. A-8 can be replaced by h^{s}_{mn} as are shown in Eqs. 2—4. On the other hand, $H'_{m0,n0}$, can be assumed to be much

smaller than $H^{S}_{m0,n0}$ as is shown below. The first order term in $H'_{m0,n0}$ vanishes since the singlet and triplet ground states have the same electronic structure. The second order terms are shown to be proportional to the following integral according to the promoting mode, Q_k:

$$\langle\chi_n^{k0}(0)|\mathbf{O}^1(Q_k)|\chi_i^{ks}(v_i^{ks})\rangle\langle\chi_i^{ks}(v_i^{ks})|\chi_m^{k0}(0)\rangle.$$

Here $\chi_p^{kq}(v_p^{kq})$ is the q-th vibrational wave function of the k-th promoting mode in the p-th electronic state with the vibrational quantum number, v_p^{ks}, and $\mathbf{O}^1(Q_k)$ is a linear operator according to Q_k Since $|\chi_n^{k0}(0)\rangle$ is nearly the same as $|\chi_m^{k0}(0)\rangle$ for the radical pair, the above integral vanishes for a harmonic oscillator. Thus this integral can safely be assumed to be much smaller than h^{S}_{mn}/h'_{mn}. Therefore, $H'_{m0,n0}$ in Eq. A-8 can safely be disregarded in estimating v_R, as is assumed in this paper. Of course there may be the case where it can not be disregarded.

Electronic Structures and Spectra of Aminoacetophenones and Related Compounds

Ryoichi NAKAGAKI,† Saburo NAGAKURA,*,†,†† Takayoshi KOBAYASHI,†† and Suehiro IWATA††

†*The Institute for Solid State Physics, The University of Tokyo, Minato, Tokyo 106*

††*The Institute of Physical and Chemical Research, Wako, Saitama 351*

(Received June 10, 1978)

The $S_n \leftarrow S_0$ and $S_n \leftarrow S_1$ transition bands were measured with *m*- and *p*-dimethylaminoacetophenones and related compounds in order to clarify the characters of the excited singlet states. The observed spectra were reasonably interpreted by the use of the theoretical results based on the composite molecule method. The longest wavelength band ($S_1 \leftarrow S_0$) of the meta isomer has mainly the local excitation (LE) character of aniline ($^1B_2 \leftarrow {}^1A_1$), while that of the para isomer is ragarded as the intramolecular charge-transfer band. In the para isomer the LE transition corresponding to $^1B_2 \leftarrow {}^1A_1$ is covered by the intense CT band. The $S_n \leftarrow S_1$ transitions of the meta isomer are almost of LE character, whereas those of the para isomer are of back CT nature. This is mainly attributed to the difference in the character of S_1.

The π-electron systems of organic compounds containing electron donor and electron acceptor group have been extensively studied from the standpoint of intramolecular charge-transfer interaction.[1-13] Disubstituted benzene molecules, D–C_6H_4–A, where D and A represent an electron donor and an electron acceptor, respectively, are typical intramolecular donor-acceptor systems and exhibit characteristic absorption spectra. The spectra have been interpreted by the composite molecule method (the molecules in molecule method) for nitroanilines, nitrophenols, cyanophenols, and other compounds.[4,7,14,15] More recently, McGlynn and coworkers studied the luminescence spectra and kinetic parameters of cyanoanisoles, fluorobenzonitriles, cyanoanilines, and nitroanilines.[16-18] The $T_n \leftarrow T_1$ transitions of aminobenzenes and cyanobenzenes were measured and discussed in terms of intramolecular charge-transfer interaction.[19,20]

In the present work, the $S_n \leftarrow S_0$ and $S_n \leftarrow S_1$ (transient) absorption spectra of aminoacetophenones and related compounds have been measured in order to clarify the characters of the excited states. The $S_n \leftarrow S_0$ and $S_n \leftarrow S_1$ transitions of aminoacetophenones were analyzed with the aid of the theoretical results based on the composite molecule method, in which the intramolecular charge-transfer interaction of the aminophenyl group with the carbonyl group was considered.

Experimental

Materials. Commercially available *m*- and *p*-aminoacetophenones (*m*- and *p*-AAP), *p*-dimethylaminobenzaldehyde (*p*-DMABA), *N*,*N*-dimethyl-*p*-nitroaniline (*p*-DMNA) were chromatographed from benzene on activated alumina and recrystallized from the same solvent. The meta and para isomers of dimethylaminoacetophenone (*m*- and *p*-DMAAP) and *p*-dimethylaminobenzonitrile (*p*-DMABN) were synthesized according to the methods described in literature,[21-23] and purified in the same manner as mentioned above.

Measurements. Visible and ultraviolet absorption spectra were measured on a Cary 14 recording spectrophotometer. Emission spectra were measured with a Spex 1700-II grating monochromator equipped with an EMI 6256S photomultiplier and a PAR 128 lock-in amplifier. The fluorescence quantum yield was determined by the use of a Shimadzu RF-502 spectrofluorometer, 2,5-diphenyloxazole with the quantum yield of 1.00 in cyclohexane[24] being used as the standard. A method for the determination of fluorescence lifetimes was the same as described previously.[25]

For the measurement of transient absorption spectra two methods were employed; the one is an ordinary N_2 laser photolysis method (method I), the details of which were already reported,[25] and the other is a method using superradiant fluorescence from solution as an analyzing light source (method II).[26] The transient absorption spectra obtained by the latter method were superposition of the $S_n \leftarrow S_1$ and $T_n \leftarrow T_1$ transitions. Even for fluorescent compounds method II is applicable to the measurement of the $S_n \leftarrow S_1$ transition bands. In method II, dyes used were as follows: 3-cyano-7-hydroxy-4-methylcoumarin, coumarin 1 (7-dimethylamino-4-methylcoumarin), coumarin 30 (3-(2′-methyl-1-benzimidazolyl)-7-diethylaminocoumarin), 7-diethylamino-4-(trifluoromethyl)-coumarin, Brilliant Sulfaflavine, Uranine, Rhodamine 6G, Rhodamine B, Cresyl Violet perchlorate–Rhodamine 6G mixture, and Cresyl Violet perchlorate–Rhodamine B mixture.

For the measurement of the transient absorption spectra the concentration of the solution was adjusted so that the absorbance at 337.1 nm was $\approx$1.0 in 1 mm light-path.

Theoretical

Molecular Geometry of Aminoacetophenones. In carrying out the MO calculations on aminoacetophenones the following assumptions were made concerning the molecular geometry; the molecules are planar, the phenyl rings are equilateral hexagonals with the C–C distance of 1.397 Å,[27] and the angle between the double bond of the carbonyl group and the single bond linked to the phenyl ring is 120°. Other atomic distances were taken from the data on *p*-aminoacetophenone determined by X-ray crystal analysis:[28] namely, the C–C distance in the single bond between the carbonyl and the phenyl group is 1.468 Å, the C–O distance in the carbonyl double bond is 1.215 Å, and the C–N distance is 1.376 Å.

Configuration Interaction Calculation. In the present treatment aminoacetophenones are considered to be composite molecules consisting of an electron donor, aminophenyl group, and an electron acceptor, carbonyl group. The π-electron energy and wave functions of several electron configurations; the ground (G) configuration, the locally excited (LE) configura-

tions within the aminophenyl group, and the charge-transfer (CT) configurations in which an electron in the occupied orbital of the donor is transferred into the anti-bonding orbital of the acceptor. The diagonal energies corresponding to the local excitations of aminophenyl group were taken from the spectroscopic data on anilines and *N*-alkylated derivatives in the previous paper.[9]

To evaluate the off-diagonal elements between LE and CT configurations, the accurate wave functions for the LE's of aminophenyl groups were required. At first, the LCAO SCF MO's of the π-electron systems of aniline and *N*,*N*-dimethylaniline, $\phi_i (i=1\text{—}7)$, were calculated by the aid of the Pariser-Parr-Pople method.[29] The wave functions for the ground and excited states of aniline and *N*,*N*-dimethylaniline were obtained by considering CI among electron configurations constructed from the SCF MO's. The configurations considered in the CI calculation are given below: for A_1 symmetry, 28 configurations, that is, the ground, 5 singly excited, 14 doubly excited, and 8 triply excited configurations, and for B_2 symmetry, 25 configurations, that is, 5 singly excited, 12 doubly excited, and 8 triply excited configurations. From the resultant excited wave functions the lowest 3 wave functions with A type symmetry and the lowest 3 wave functions with B type symmetry were picked up as LE configurations for the further CI calculations of energy levels and wave functions of aminoacetophenones.

The molecular orbitals of the carbonyl group obtained by Tanaka were used in the present calculation.[30]

The CT configurations taken in the CI calculation for aminoacetophenones were given below:

$$\text{CT(4-A)} = (\phi_4^{-1}\text{A}),\ \text{CT(3-A)} = (\phi_3^{-1}\text{A}),\ \text{and}$$
$$\text{CT(2-A)} = (\phi_2^{-1}\text{A}).$$

Here, A denotes the anti-bonding orbital of the acceptor, carbonyl group, and ϕ_i the *i*-th occupied orbital of aniline, the highest occupied orbital being ϕ_4. The energies of the CT configurations were evaluated by the equation,

$$E(\text{CT}) = I_P(\phi_i) - E_A(\text{C=O}) - C,$$

where $I_P(\phi_i)$ is the ionization potential of the donor, E_A(C=O) is the electron affinity of the acceptor, and C is the coulombic interaction energy between the donor and acceptor groups. The values of I_P were taken from the photoelectron spectroscopic data,[31,32] the affinity E_A was assumed as -1.2 eV,[5] and C values were calculated by using the values of two center Coulomb repulsion integrals (rr|ss), which were evaluated according to the Pariser-Parr method.[29]

The off-diagonal matrix elements of the total electronic Hamiltonian were evaluated by the aid of the formulations by Pople[33] and by Longuet-Higgins and Murrell.[3] They were given in terms of $\beta_{C\text{-}C=O}$, the core resonance integral between the ring carbon and the carbonyl carbon. Actual calculations were made by changing $\beta_{C\text{-}C=O}$ as a parameter from -1.50 eV to -1.90 eV by a step of 0.10 eV. Consequently, the results were found to be insensitive to the parameter. The energies and wave functions for $\beta_{C\text{-}C=O}$ of -1.90 eV are shown in Table 1.

Table 1. The energy levels and wave functions of *m*- and *p*-dimethylaminoacetophenone

(*m*-DMAAP)

$W_0 = -0.23$ eV

a) In cyclohexane. b) In 1,1,1,3,3,3-hexafluoro-2-propanol (HFP).

Results and Discussion

The $S_n \leftarrow S_0$ Transition Bands of m- *and* p-*Dimethylaminoacetophenones.* In cyclohexane, the $n\pi^*$ band of *m*-DMAAP or *p*-DMAAP was observed as a weak tail (log $\varepsilon \leq 2$) at the longer wavelength side of the lowest $\pi\pi^*$ or CT band. In polar solvents, however, it was found to be covered by the intense $\pi\pi^*$ or CT band.

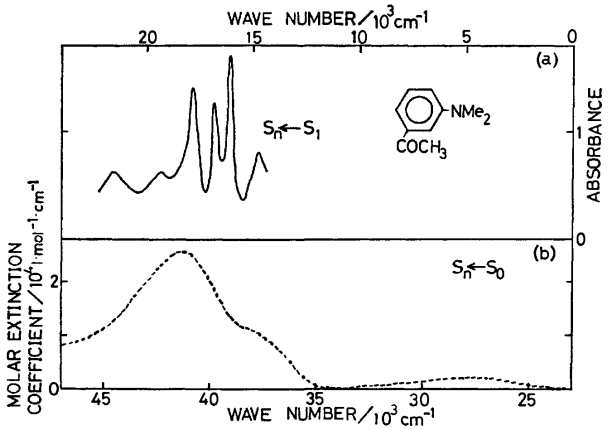

Fig. 1. (a) Upper: the transient absorption spectrum of *m*-DMAAP in ethanol at room temperature obtained by method II. The transition energy is indicated on the upper abscissa in the units of 1000 cm^{-1}. (b) Lower: the absorption spectrum of *m*-DMAAP in ethanol at room temperature. The transition energy is indicated on the lower abscissa in the units of 1000 cm^{-1}.

In the absorption spectrum of ethanolic solution of *m*-DMAAP (Fig. 1-b), we can see four $\pi\pi^*$ transition bands: three bands at 27600, 37800, and 41300 cm^{-1} and an additional tail at higher energy side (45000 cm^{-1}). In cyclohexane solution of *p*-DMABA or *p*-DMAAP (Fig. 3 or 4), two bands were observed in the region, 28000—47000 cm^{-1}.

The intense long wavelength band of *p*-DMAAP or *p*-DMABA shows the increasing red-shift on going from the nonpolar solvent, cyclohexane, to the polar ones: cyclohexane<acetonitrile<ethanol<water<1,1,1,3,3,3-hexafluoro-2-propanol (HFP) (see Figs. 2-b, 4, and 5). The largest red-shift was observed in HFP solution, in spite of the rather low dielectric constant and refractive index of this solvent (16.62 at 25 °C and 1.2750 at Na D line) compared with those of ethanol (24.3 and 1.3618), acetonitrile (37.5 and 1.3437), and water (78.54 and 1.3330). This fact indicated that the red-shift observed in HFP is mainly due to hydrogen bonding.[34] In the HFP solution of *p*-DMAAP or *p*-DMABA, four $\pi\pi^*$ or CT bands were observed: *e.g.* for *p*-DMABA, one strong band at 27400, and three bands at $\approx$33000, $\approx$39800, and $\approx$43500 cm^{-1} (Fig. 3). Formation of strong hydrogen bonds between the solute, *p*-DMAAP or *p*-DMABA, and the solvent, HFP, causes the large red-shift of some of the absorption bands. On the other hand, the bands less sensitive to the hydrogen bonding show small solvent shift. As the result the two bands observed in cyclohexane split into four components in strongly hydrogen bonding HFP.

results at least semi-quantitatively (see Table 2).

The S_n←S_1 Transitions of m- *and* p-*Dimethylaminoacetophenones.* The transient absorption spectrum of *m*-DMAAP is given in Fig. 1, together with the S_n←S_0 spectrum. The T_n←T_1 transition of *m*-DMAAP was not detected by method I in the region, 14300—27800 cm^{-1}. Therefore, the transient absorption spectrum obtained by method II is purely attributed to the S_n←S_1 transitions. From the consideration of the observed frequencies of the S_n←S_0 transition bands, the S_n←S_1 band at 17000 cm^{-1} is safely assigned to the S_3←S_1 transition. This band shows vibrational structures, suggesting that this transition is largely of forbidden character. The oscillator strength of the S_3←S_1 transition was calculated to be 0.07, by assuming that the molecular geometry in the excited state is the same as that in the ground state. This theoretical prediction is consistent with the observed result.

The transient spectra of *p*-DMAAP are given in Fig. 2-a. Very similar transient spectra are also obtained for *p*-DMABA. The T_n←T_1 spectrum of *p*-DMAAP was observed by method I, and the transient spectrum measured by method II was found to be composed of the S_n←S_1 and the T_n←T_1 transition bands. The S_n←S_1 transition band appears at 16700 cm^{-1} for *p*-DMAAP and may be assigned to the S_3←S_1 or S_4←S_1 transitions from the consideration of the observed frequencies of the S_n←S_0 transition bands of *p*-DMAAP (Table 2). The oscillator strength was evaluated to be 0.03 and 0.50 for the S_3←S_1 and S_4←S_1 transitions, respectively, in the same assumption as mentioned above. Hence, the S_4←S_1 assignment was preferred.

The Characters of the Lowest Excited Singlet States of m- *and* p-*Dimethylaminoacetophenones.* The kinetic parameters for the lowest excited singlet states were determined in EPA (5:5:2) at 77 K. The results are as follows: for *m*-DMAAP, τ_f(fluorescence lifetime)=54 ns and ϕ_f(fluorescence quantum yield)=0.85, and for *p*-DMAAP, τ_f=3.5 ns and ϕ_f=0.64. From these values the fluorescence radiative rate constants are calculated to be 1.7×10^7 s^{-1} for *m*-DMAAP, and 1.8×10^8 s^{-1} for *p*-DMAAP. This fact, together with the spectral difference between the absorptions of *m*-DMAAP and *p*-DMAAP (lower figures of Figs. 1 and 2) shows that the lowest excited states of both isomers have different electronic structures. According to the present theoretical consideration, the longest wavelength band of *m*-DMAAP originates mainly from the local excitation of aniline ($^1B_2$←$^1A_1$), while that of *p*-DMAAP or *p*-DMABA is assigned as the CT band which is associated with the charge-transfer configuration (ϕ_4←^{1}A). The theoretical result is supported by the fact that the longest wavelength band of *p*-DMAAP or *p*-DMABA has the transition moment nearly parallel to the molecular long axis.[35] Thus it is concluded that the S_1 state of the meta-isomer has the LE character within *N,N*-dimethylaniline, while that of the para-isomer the CT character.

Let us consider the spectral difference in the S_n←S_1 transitions between the meta- and para-isomers on the basis of the above-mentioned nature of the S_1 states. The final states of the S_n←S_1 transition bands, S_3 of the meta-isomer and S_4 of the para-isomer are nearly of the same nature: LE of *N,N*-dimethylaniline ($^1A_1$←$^1A_1$) perturbed by CT(4-A). Hence, the S_n←S_1 transition band can be interpreted as the LE band for the meta-isomer and as the back CT band for the para-isomer.

The Characters of Lower-lying Excited States of Several Related Aniline Derivatives. The spectra of dimethylaminoacetophenones are correlated with those of aminoacetophenones and other aniline derivatives containing various acceptor groups.

The two isomers of aminoacetophenone, *m*-AAP and *p*-AAP exhibit absorption spectra similar to those of the corresponding *N,N*-dimethylated compounds, *m*-DMAAP and *p*-DMAAP. Concerning the S_1←S_0 transition, the decrease of the transition energy and the increase of the oscillator strength were observed alkylation of the amino group. This observation is reasonably interpreted in terms of the CT interaction. The red-shift and intensification of the longest wavelength band due to alkylation can be interpreted in terms of the lowering of the ionization potential of the electron donor.

In the region, 24000—47000 cm^{-1}, the para-substituted *N,N*-dimethylanilines show four bands of CT or LE character (Figs. 4 and 5). The two lower-lying states are closely located and characterized by CT from *N,N*-

dimethylaniline to the acceptor substituent and also by LE corresponding to $^1B_2 \leftarrow {}^1A_1$ of *N,N*-dimethylaniline. From the absorption maxima of the para-substituted *N,N*-dimethylanilines (Table 3), we can see that the red-shift of the intense CT band is associated with the increase in the electron affinity of the acceptor substituent and the resultant increase in the CT character in S_1. The transition energies of the LE bands seem to remain unchanged by replacing the substituent on the para position. Thus we can expect that the reversal occurs in the order of the two lower-lying states by changing the acceptor substituent group: in cyclohexane, the S_1 state of the cyanoaniline is of LE, while the S_1 state of the nitroaniline is of CT. The reversal is also observed by changing solvents. In nonpolar solvents, the lowest excited singlet state of the cyano-substituted aniline is mainly of LE character, and a reversal of the order of the two lower-lying states occurs by replacing a nonpolar solvent, cyclohexane by polar solvents, such as acetonitrile, ethanol, water, and HFP. Concerning carbonyl-substituted *N,N*-dimethylanilines in the nonpolar solvents the weak LE band is located slightly above the strong CT band and cannot be discernible, while it can be observed separately in HFP.

Table 4. Wave numbers of $T_n \leftarrow T_1$ transitions, ν_{max}, S-T separations, $\Delta\nu_{ST}$, and phosphorescence lifetimes, τ_p for *p*-substituted *N,N*-dimethylanilines, *p*-$(H_3C)_2N$–C_6H_4–X

NO_2	19400[a]	3750[c]	0.22 ± 0.02[c]

a) This work, in ethanol at room temperature. b) This work, in EPA (5:5:2) at 77 K. c) Ref. 36, in EPA (5:5:2) at 77 K. d) Ref. 37, in ethanol at 93 K. e) Ref. 38, in EPA (5:5:2) at 77 K.

The wave numbers of the $T_n \leftarrow T_1$ transitions, the values of S-T separation, and the phosphorescence lifetimes are given in Table 4 for various para-substituted *N,N*-dimethylanilines. The lifetime data indicate that the lowest excited triplet states are of $\pi\pi^*$ character. Since each CT triplet state has the same energy as the corresponding CT singlet state in the zero differential overlap approximation, the decrease of S-T splitting values shows clearly the increase of the CT character in T_1. The increasing CT character in T_1, reflecting the order of the electron affinity of the acceptor substituent, is parallel to the red-shift of the $T_n \leftarrow T_1$ transitions. The decrease of the phosphorescence lifetimes can be qualitatively interpreted in terms of the enhancement of spin-orbit coupling by the intramolecular CT interaction in the same manner as in anilines.[39-41]

We wish to thank Dr. Kazuo Shibata and Dr. Yorinao Inoue, The Institute of Physical and Chemical Research, for their kindness in putting the spectrofluorometer (Shimadzu RF-502) at our disposal.

Reduction of Calcium Interference on Barium Using the Nitrogen-Shielded Nitrous Oxide-Acetylene Flame in Atomic Absorption Spectroscopy†

Hisao KAWAMURA

Division of Radioecology, National Institute of Radiological Sciences, Isozaki, Nakaminato, Ibaraki 311-12

(Received November 15, 1977)

The interference effects of calcium on barium in atomic absorption spectroscopy, *i.e.*, background absorption and noise effect having been attributed to the CaOH green band were further studied. The behavior of the interfering calcium hydroxide radical and the barium atom itself was studied in relation to the distribution of natural species, OH and CN, using conventional and nitrogen-shielded nitrous oxide–acetylene flames. A remarkable reduction in the calcium interference was demonstrated using a nitrogen-shielded version of moderately fuel-rich flames. This effect was attributed to the suppression of CaOH formation which was brought about by an improvement in the reducing nature of the flame with shielding.

The calcium interference effects on barium, *i.e.*, background absorption and noise effect have been attributed to the molecular absorption and emission spectra of CaOH, and remain as major obstacles in the determination of this element in biological and geological materials, necessitating the removal of calcium in atomic absorption spectroscopy using nitrous oxide–acetylene flames.[1-3] Correcting for background absorption using a continuum source[4] appears impracticable due to the noisy signal of barium in the presence of calcium.[1] Gas-shielded burners have been used but with only limited information available on the behavior of the interferent.[5] It is difficult to meet the conditions for maximum barium absorbance and minimum calcium interference. The behavior of the barium atom in relation to the interfering CaOH radical in the nitrous oxide–acetylene flames does not appear to have been studied although the atomization of elements has often been discussed.[6-9]

Assuming that the oxides and hydroxides of alkaline earth elements in flames are in equilibrium with the oxidizing natural species,[10] making the flames more reducing may result in a reduction of the calcium hydroxide formation. In this paper, the distribution of barium atoms and CaOH radicals in the nitrous oxide–acetylene flames, as influenced by flame stoichiometry and inert gas shielding, has been studied as well as the distribution of OH and CN radicals. The CaOH population in a moderately fuel-rich nitrous oxide–acetylene flame has been clearly shown to be further suppressed by nitrogen shielding which results in a reduction in the calcium interference effects under optimum conditions for atomizing barium.

Experimental

A Perkin-Elmer Model 403 atomic absorption spectrophotometer was used. A barium hollow cathode lamp of maximum current 30 mA d.c. was operated at 26 mA as in previous work.[1] An Osram 64633 iodine-filled tungsten lamp was used at approximately 10 V a.c. with air cooling. A Perkin-Elmer nitrous oxide burner head was used with two types of laboratory-made gas shielding apparatuses, shown in Fig. 1. The first type (a) was fitted to the burner tightly covering the cooling fin and, in this way, the vertical holes encircling the head formed in the cooling block ensured laminar flow of the shielding gas. When the second type (b) was used, the burner head was removed from the cooling fin and fitted to this apparatus. Pure nitrogen or argon (99.9995% purity) was used as the shielding gas.

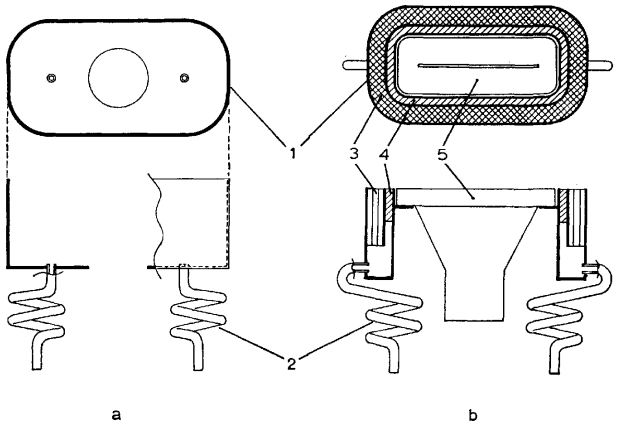

Fig. 1. Schematic diagram of burner with nitrogen shielding apparatus.
1: 1-mm thick brass box, 2: inert gas inlet, 4-mm diam. copper tube, 3: array of 2-mm diam. aluminum tubes 25 mm in length, 4: asbestos packing, 5: nitrous oxide burner head removed of cooling fin.

The position of the burner assembly was displaced manually by adjusting the installed racking mechanism stepwise by 2.5 and 0.43 mm in the vertical and horizontal directions, respectively. The flow rate of nitrous oxide was kept constant throughout the experiments, 13.2 dm^3/min (40.0 divisions of the flow meter reading at 30.0 psi). The acetylene flow rate was changed in seven steps from 7.36 to 8.33 dm^3/min (58.5 to 65.5 divisions at 8.0 psi). Thus, the nitrous oxide-to-acetylene flow ratio or molar ratio of the mixed gases as denoted by ρ[6] was lowered stepwise from 1.79 to 1.58. The setting of the flow meters was periodically checked during the course of measurements. Flow rates were read on the calibration graph revised by the manufacturer[11] neglecting possible small variations among flow meters of the same specification.

† This work was announced in part at the 22nd Annual Meeting of the Japan Society for Analytical Chemistry, November 23—26, 1973, Fukuoka, and at the 26th International Congress of Pure and Applied Chemistry, September 4—10, 1977, Tokyo.

The mask for the transmitting window on the right-hand side of the burner housing[1] was replaced with one having a 12-mm diam. circular aperture. When observing the spatial distribution of emission signal, another mask with a 4.5-mm diam. circular hole was attached to the window. Spatial resolution in the barium atom absorbance measurement was estimated as approximately 1.4 and 3.0 mm in the horizontal and vertical directions, respectively, measured at the focal plane close to the center of the burner slot. Spatial resolution in the emission study was estimated by viewing the filament of a small tungsten valve at the end of the slot nearer to the monochromator at 554 nm, as 1.3 and 4.7 mm in the horizontal and vertical directions, respectively.

The emission and absorption of CaOH was measured at 554 nm with a spectral band width of 0.4 nm, while 0.14 nm was used in recording the spectral profile. Flame background emission on aspirating distilled water at 554 nm, consisting of a C_2 band and continuum, was substracted.

The emission intensity of OH was measured using the 306.4 nm head with a spectral band width of 0.2 nm. The net intensity was obtained by substracting the contribution of the continuum, measured at 305 nm.

The OH and CN absorbances were measured using the Osram lamp by scanning each band with the head at 306.4 and 388.3 nm, respectively, employing a 0.07 nm spectral band width.

All emission and absorption measurements were carried out on aspirating either distilled water or salt solutions containing hydrochloric acid (0.1 mol dm^{-3}). Reagents used were of analytical grade, except for the Johnson Matthey "Specpure" barium carbonate and calcium carbonate.

Results and Discussion

Practically no difference was found between the two types of shielding apparatuses and between nitrogen and argon, with respect to the shielding effects on the CaOH emission intensity and flame stability. At a nitrogen flow rate of 13.5 dm^3/min, virtual suppression of the CaOH emission was achieved. Noise in emission and absorption measurements was found to increase above this flow rate.

Distribution of OH and CN in the Nitrous Oxide–Acetylene Flames as Influenced by Nitrogen Shielding. Spatial Distribution of the OH Emission Band: The distribution of the OH emission band in conventional and nitrogen-shielded flames of approximately optimum stoichiometry for barium atom absorbance ($\rho=1.67$) is shown in Fig. 2. The emission intensity in the central part of the flame, corresponding to the interconal zone, was remarkably depressed with nitrogen shielding (Fig. 2b) while the red feather, about 15 mm in height in the conventional flame, was elongated to about 30 mm in the nitrogen-shielded version. In the outer zone, the OH emission grew more intense up the flame to form broad maxima on both sides of the flame at about 15 mm from the burner top in the non-shielded flame. The emission in this region was strongly suppressed with nitrogen shielding. The observed large reduction in the OH emission band intensity with nitrogen shielding in the interconal and outer zones, shows that the suppressed formation of OH at the boundary of the interconal zone and the suppressed diffusion of OH to the center of the flame[12] are caused by the depression in secondary combustion reactions due to the lack of entrained air. The persisting OH band emission in the primary reaction zone may be explained by the formation of the species and its strong chemiluminescence in

this region.[10]

Vertical Distribution of the OH Absorption Band: The vertical absorbance profile of OH was studied. The results shown in Fig. 3 show the less pronounced effect of nitrogen shielding than that on OH emission. The absorbance was reduced by 57% at 10 mm when $\rho=1.67$. A dip in absorbance just above the primary reaction zone was observed suggesting the presence of OH scavenging reactions involving carbon-containing species, 2C or C_2,[13] and C_2 and CH.[14]

Vertical Distribution of CN Absorption Band: The front of the CN absorbance profile moved up the flame along with decreasing ρ in the conventional and nitrogen-shielded flames as shown in Fig. 4. This approximately corresponded to the elongation of the red zone. A remarkable enhancement effect due to nitrogen shielding was observed above 5 mm, but hardly observable at 2.5 mm. The enhancement factor was 3 at 12.5 mm when $\rho=1.67$. The enhancement mechanism for CN absorbance is thought to be depression on shielding in the partial pressure of oxidizing species, O, OH, and H_2O[15] which rapidly consume CN.

From the results of the distribution of OH and CN, it was confirmed that the reducing nature of the interconal region of fuel-rich nitrous oxide–acetylene flames could be further enhanced by nitrogen shielding.

Absorbance Profile of Barium Atom in the Nitrous Oxide–Acetylene Flames as Influenced by Nitrogen Shielding. The barium absorbance in the fuel-rich nitrous oxide-acetylene flames in the presence and absence of an ionization suppressor as influenced by ρ and nitrogen shielding was studied. The results at typical ρ values are shown in Figs. 5 and 6. The addition of potassium at a concentration of 1000 μg cm^{-3} caused a shift in optimum height due to build-up of neutral atoms which were otherwise depleted through ionization. The optimum ρ value in the conventional flames was

1.66—1.67 on the ionization suppression. These results seem to differ from the published data.[6]

With the nitrogen-shielded flame of ρ 1.67, the rapid decrease of barium atom absorbance up the flame changed to show enhanced and markedly broader profiles. The optimum ρ was found to be slightly shifed to the lean side. These results suggest that free barium atoms are protected by the enhanced reducing atmosphere of the interconal zone of the shielded flames, in spite of a decrease in flame temperature on shielding reported in the literature.[16]

When the flame became extremely fuel-rich and slightly luminous with excessive carbon ($\rho=1.58$), the absorbance decreased and the vertical profile was found to be quite different from those at higher ρs. The absorbance increased again at higher positions above 12.5 mm in the conventional flame and this was found to disappear when the flame was shielded. In these flames, it was inferred that the flame temperature was too low to sufficiently atomize barium, due to deficiency of oxidant. Barium, mostly in the bound state under these conditions, may respond to changes in flame temperature rather than to the reducing nature of flames. A certain increase in temperature above the primary reaction zone between 15 and 25 mm has been reported in an unshielded fuel-rich nitrous oxide-acetylene flame while in the nitrogen-shielded counterpart, a sharp drop in temperature has been observed in the same region.[16] It is interesting to consider possible bound forms of barium in these conditions. Oxide and hydroxide cannot account for this since CaOH, having a similar energy of dissociation, 4.0±0.4 eV, to that of BaOH, 4.64±0.09 eV,[10] was suppressed according to the molecular absorption study described later. A possibility of incomplete solute vaporization due to the added potassium chloride was rejected since essentially the same phenomenon was observed in the absence of the potassium salt (Fig. 6, $\rho=1.58$). It may

be inferred that carbon-containing barium compounds[6] are responsible for this phenomenon.

Distribution of CaOH in the Nitrous Oxide–Acetylene Flames as Influenced by Nitrogen Shielding. Vertical Profile of CaOH Emission Band: The emission band spectra of the CaOH green band in the fuel-rich nitrous oxide–acetylene flames as influenced by argon shielding are shown in Fig. 7a. The emission lines near 560 nm having been observed[1] were identified as the seven calcium atom lines lying between 558.2 and 560.3 nm the occurrence of which has been described in arc and spark;[18] this was proved by their distribution in flames and response to flame conditions.

As shown in Fig. 8a, the emission intensity of CaOH in the flames was gradually decreased when ρ was lowered. A small maximum between 5 and 7.5 mm and a minimum around 10 mm above the burner top was observed and the intensity was observed to remarkably increase further up the non-shielded flame. By shielding the flame with nitrogen, the CaOH emission was generally reduced, especially beyond 10 mm in height (Fig. 8b).

CaOH Absorbance Profile as Influenced by Flame Shielding: The suppressing effect of argon shielding on the CaOH absorption band in the flame is shown in Fig. 7b.

As shown in Fig. 9, the absorbance signal decreased as ρ was lowered. However, on shielding the flames, the absorbance was remarkably reduced further beyond 10 mm while being unchanged at 5 mm.

It may be concluded that the background absorption and noise effect due to calcium may be minimized by employing a moderate ρ value, *i.e.*, 1.67 required for maximum barium atom absorbance in the nitrogen-shielded flame.

Spatial Distribution of CaOH Emission Intensity: The distribution of CaOH emission intensity in the transverse section of the flames of ρ 1.67 was studied to investigate the occurrence of CaOH with respect to flame structure. The results are shown in Fig. 10. In the outer mantle of the conventional flame, a large build-up of the CaOH emission intensity was found up the flame (Fig. 10a). The central part of the flame up to 15 mm of weaker intensity was observed to correspond to a space inside

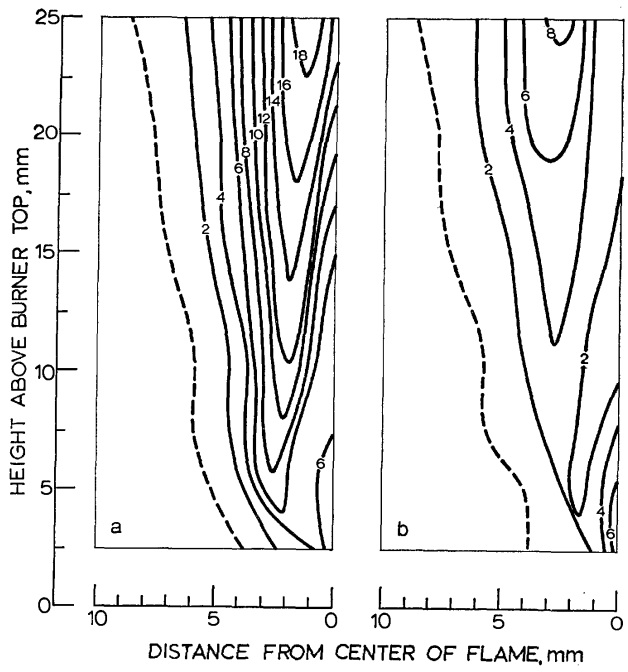

Fig. 10. Spatial distribution of CaOH emission intensity in the N_2O–C_2H_2 flames of ρ 1.67.

----Boundary of CaOH emission.
Figures on contour lines represent intensity in arbitrary unit.

the red feather, or the interconal zone. A small island-like region of strong CaOH emission was observed near the primary reaction zone. In the shielded flame, the emission band was suppressed throughout the flame, with the central part of weaker intensity being enlarged (Fig. 10b). The whole pattern of spatial distribution of the CaOH emission band may be compared with that of OH (Fig. 2).

These results suggest that CaOH, produced in the primary reaction zone, is markedly subjected to depopulation in the interconal zone of the nitrogen-shielded nitrous oxide-acetylene flames. This may be due to reactions with carbon-containing species, *i.e.*, C_2, CH,

etc., as well as the suppression of oxidizing species, *i.e.*, O, OH, and H_2O.

Effect of Nitrogen Shielding on the Background Absorption and Signal-to-Noise Ratio in the Barium Absorbance Signal in the Presence of Calcium. For the purpose of determining barium in the absence of calcium, an accord in conditions of the flame stoichiometry and height for maximum barium atom absorbance and those for minimum CaOH absorbance and emission intensity, is favorable. This may be due to the similarity in dissociation energies of the monoxide and hydroxide of barium and calcium.

TABLE 1. THE EFFECT OF NITROGEN SHIELDING ON BARIUM ATOM ABSORBANCE AT 553.6 nm IN THE PRESENCE OF CALCIUM OF VARIOUS CONCENTRATIONS IN THE NITROUS OXIDE–ACETYLENE FLAME

5000	0.102	0.30	0.143	0.82

10 μg cm^{-3} Ba+1000 μg cm^{-3} K. Observation height 17 mm.

The background absorption and relative S/N ratio in the presence of different concentrations of calcium were measured employing optimum flame stoichiometry, ρ 1.67, and the results are shown in Table 1. A height of 17 mm above the burner top was adopted for the purpose of comparison with previous work.[1] Using the nitrogen-shielded flame, the background absorbance due to calcium was substantially eliminated and the relative S/N ratio was found to be little affected by calcium in various concentration levels. This effect was also proved at an optimum height for the practical determination. As shown in Fig. 11, the interfering effects of calcium at concentrations of 2000 μg cm^{-3} were essentially eliminated.

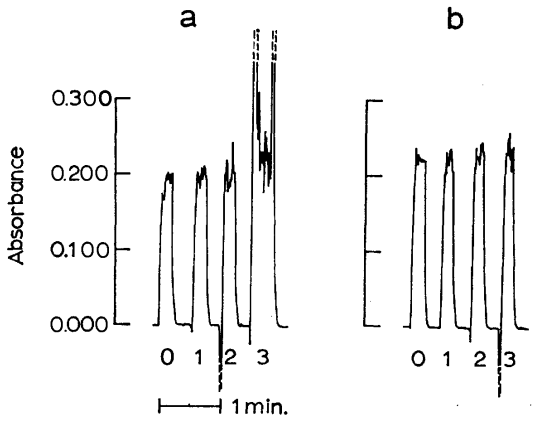

Fig. 11. Effect of nitrogen shielding on barium atom absorbance in the presence of calcium.

Conclusion

The nitrogen shielding of a fuel-rich nitrous oxide–acetylene flame remarkably reduced the spectral interference and the noise effect of calcium on the barium determination by atomic absorption spectroscopy. Spectroscopically, this was shown to be due to the suppression of CaOH radical formation by the enhanced reducing nature of the flame of an optimum oxidant-to-fuel flow ratio for maximum barium atom absorbance. By using this technique, the chemical separation of barium from calcium will be unnecessary or, at least, the time and tedious labor for perfect removal of calcium will be saved in the analysis of biological and geological materials of high calcium contents.

The Synthesis of Hydrated Rare Earth Carbonate Single Crystals in Gels

Hisanobu WAKITA

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Nishi-ku, Fukuoka 814

(Received July 29, 1977)

Hydrated rare earth carbonate single crystals were obtained in metasilicate gels. The formulas of the crystals were determined to be $(RE)_2(CO_3)_3 \cdot 8H_2O$ (RE=La, Pr) and $(RE)_2(CO_3)_3 \cdot 4.54H_2O$ (RE=Nd), and the crystal structures were determined to be of the lanthanit type.

Rare earth elements, having ionic radii larger than neodymium, were crystallized in lanthanite-type hydrated normal carbonates, $(RE)_2(CO_3)_3 \cdot 8H_2O$, whereas, rare earth elements with ionic radii smaller than neodymium were crystallized in tengerite-type hydrated normal carbonates, $(RE)_2(CO_3)_3 \cdot 2—3H_2O$.[1] The differences in the hydration numbers of, and in the ionic radii of rare earth elements in the lanthanite and tengerite type structures, seem to characterize differences in their structures and properties. Since these carbonates have been prepared as powders, accurate structural and chemico-physical data have not been obtained.[2] Shinn and Eick[3] obtained a single crystal of hydrated lanthanum carbonate, $La_2(CO_3)_3 \cdot 8H_2O$, by slow hydrolysis of lanthanum trichloroacetate. They determined the crystal structure of this crystal and found that it contains 4 formula units in an orthorhombic cell of space group Pccn with lattice parameters of $a=8.984\pm0.004$, $b=9.580\pm0.004$, and $c=17.00\pm0.01$ Å, and has a density, $\rho_{obsd}=2.72\pm0.02$ g cm^{-3}, which is very similar to the calculated value, $\rho_{calcd}=2.732$ g cm^{-3}.

Crystalline rare earth carbonates are generally obtained by the hydrolysis of trichloroacetates of rare earth elements, but they usually precipitate as a powder.[2] Henisch *et al.*[4] synthesized single crystals of various slightly soluble materials by means of a silica gel technique. Their results indicated that this technique could be adapted to the crystal growth of rare earth carbonates.

In this study, the crystal growth of hydrated normal rare earth carbonates by the gel method was attempted at various temperatures and with various ratios of rare earth ions and precipitant.

Experimental

Synthesis of the hydrated normal rare earth carbonates was carried out by the reaction between carbonates and rare earth salts in sodium metasilicate gels. Two methods have been examined for this purpose.[5] In the first the gel containing the carbonate was used. Aqueous mixtures of sodium metasilicate and various kinds of carbonates were prepared and the pH was adjusted. As carbonates, 0.008—0.2 M aqueous solutions of Na_2CO_3, $(NH_4)_2CO_3$, $NaHCO_3$, and NH_4HCO_3 were used. After the gel had set, rare earth salt solution was placed on top of the gel and allowed to diffuse. An aqueous solution of 0.008—0.2 M rare earth was prepared from $RECl_3$(RE= La, Ce, Nd, Sm, Gd, Dy, Ho, Yb, Sc). The gels were made from analytical grade $Na_2SiO_3 \cdot 9H_2O$. A 0.23 M Na_2SiO_3 aqueous solution, adjusted to a pH between 7 and 8 with dilute hydrochloric acid, was set in reaction tube and left overnight at room temperature. A simple test tube (25×200 mm) was used as the reaction tube. In the second method, each reagent, rare earth salt solution and carbonate solution, was diffused into the gel from each side of a U-tube (25×200 mm) or double tube. It appears that neither method has any significant advantage. Well-shaped crystals up to 2 mm in size were grown in 12 to 16 weeks. Well-shaped crystals were taken out of the tube and, after dissolving the gel with concentrated alkali solution, were washed with water, air-dried, and subjected to chemical, X-ray diffractometric, and thermal analyses.

Results and Discussion

In the test tube, milky precipitates appeared at the upper growth front and with time penetrated down into the gel. In the cases of lanthanum, praseodymium, and neodymium, well-shaped crystals separated from these milky precipitates after several weeks. Figure 1 shows a micrograph of a praseodymium carbonate crystal. The green, clear-cut crystals cleaved parallel to (001). In the cases of lanthanoids heavier than neodymium, well-shaped crystals did not appear even after several months. Sometimes, spherulites of the carbonates (RE=Nd) were obtained.

Factors Which Influence Crystal Growth. The following experiments were carried out in order to investigate the various factors which influence the growth behavior of neodymium carbonate: the temperature, the concentration of rare earth (in this case of neodymium) and carbonate ions, and the growth period of the crystals. In Fig. 2-a, r, the penetration depth[7,8] of the crystal-growth front is plotted against the square root of the diffusion time. It is observed in Fig. 2-a that r increases linearly with the increase of the square root of t until the diffusion time reaches 49 h. Over 49 h the slope

	Concentration of neodymium mol/l	System's temepratures °C	Molar ratios of Na_2SiO_3: $(NH_4)_2CO_3$
A	0.1	35	3 : 1
B	0.1	25	3 : 1
C	0.1	30	3 : 1
D	0.1	30	2 : 1
E	0.2	25	3 : 1
F	0.1	25	3 : 1

Added volumes of neodymium ion are 0.5 ml. The pH of the gels is 7.4.

changed with time. During the period in which the linear relationship is maintained, the penetration rates obey a first order kinetic relationship. Beyond 49 h, because masses of the precipitate interfere with the diffusion of neodymium ions, this linear relationship breaks down. In Figs. 2-a, 2-b, and 2-c, the penetration rates were plotted against changes in temperature, concentration of the precipitant, and concentration of neodymium salt, respectively. As for sparingly soluble salts such as the rare earth carbonates, the penetration rates are primarily criteria of the diffusion rates. In the synthesis of single crystals of slightly soluble salts, it is important to have a controlled supply of the reactant; that is, the diffusion rates are to be controlled. Well-shaped and large crystals were produced under the following conditions: the temperature was at 25 °C, Na_2SiO_3: $(NH_4)_2CO_3$ was 3: 1 and the concentration of neodymium ion was 0.2 M.

TABLE 1. CHEMICAL ANALYSIS OF SYNTHESIZED RARE EARTH CARBONATES
(Quantities are molar ratios.)

RE	RE_2O_3 :	CO_2 :	H_2O
La	1.00	3.00	8.04
Pr	1.00	2.99	7.90
Nd	1.00	2.99	4.54
Sm	1.00	2.85	2.85
Gd	1.00	2.76	2.59

Chemical Analysis. Carbon, hydrogen, and rare earth elements of the crystals obtained were analysed using elemental analytical techniques. The carbonates obtained from this method are liable to be contaminated by sodium and silicon because sodium metasilicate gel were used. However, no sodium and silicon were detected from these carbonates by either flame analysis or EPMA. The results of the chemical analyses of air-dried carbonates are given in Table 1; the molar ratios of the first two correspond to $RE_2(CO_3)_3 \cdot 8H_2O$ (RE= La, Pr), the next to $RE_2(CO_3)_3 \cdot 4.54H_2O$ (RE=Nd), and last two to $RE_2(CO_3)_3 \cdot 2—3H_2O$ (RE=Sm, Gd), respectively. The absence of OH^- ions was demonstrated by infrared spectroscopy. Molar ratios are not whole numbers, this anomaly was described in a previous paper.[1] Carbonates of holmium, ytterbium, and scandium could not be analysed, because they were very fine powdered samples and they could not be separated from the gels. Cerium carbonate was not analysed because it was amorphous and contaminated.

X-Ray Diffraction Analyses. The X-ray powder diffraction data of these carbonates are shown in Table

2. This table indicates that the X-ray powder data of lanthanum, praseodymium, and neodymium are almost identical to that of lanthanite, while the data for samarium and gadolinium are almost identical to that of tengerite. A single crystal of the neodymium carbonate was employed in taking Weisenberg and precession photographs in order to determine the cell parameters and the space group. Systematic absence occured for $h00$, $0k0$, and $00l$ when h, k, or $l=2n+1$, for $0kl$ and $h0l$ when $l=2n+1$ and for $hk0$ when $h+k=2n+1$. Therefore, Pccn is a possible space group. The lattice parameters obtained from powder diffractometric data are: $a=8.97$ (calculated from 200), $b=9.49$ (calculated from 020), and $c=17.18$ (calculated from 002) Å. The density (2.76 g cm^{-3}) calculated for four formula units was in agreement with the density obtained by the heavy liquid method (2.75 g cm^{-3}). The crystalline carbonate of cerium was not obtained by this method. Perhaps cerium(III) in the starting solution had been oxidized in cerium(IV) during the diffusion. No report of a carbonate of cerium(IV) was found in the literature surveyed. Because the carbonates were not separated from the gels, no X-ray powder diffraction peaks of the carbonates of holmium, ytterbium, and scandium were obtained. This is the first report of samarium and gadolinium carbonates crystallizing with the tengerite type structure at such low temperatures (≈25 °C) and that neodymium carbonate crystallizes with a lanthanite type structure.

Thermal Analyses. The thermal analysis of the carbonates of lanthanite type was carried out with a heating rate of 10 °C/min in air. The results of the thermogravimetric analysis, TGA, and differential scanning calorimetry, DSC, of the carbonates of lanthanum and neodymium are shown in Fig. 3. The decomposition processes of neodymium and lanthanum carbonate were similar. On the TGA curve for the neodymium carbonate, there is initially a loss of water, which corresponds to the formation of anhydrous carbonate. This step is also prominent for the lanthanum compound. The DSC curve in Fig. 3 shows that the endothermic effects in the 100—200 °C range corresponds to the formation of the anhydrous carbonate. The continuous raising of the temperature leads to the formation of some intermediate phases, shown in the following schemes:

$$Nd_2(CO_3)_3\cdot 8H_2O \xrightarrow{ca.\,150\,^\circ C} Nd_2(CO_3)_3 \xrightarrow{ca.\,450\,^\circ C} Nd_2O(CO_3)_2 \xrightarrow{ca.\,750\,^\circ C} Nd_2O_3 \quad (1)$$

$$La_2(CO_3)_3\cdot 8H_2O \xrightarrow{ca.\,150\,^\circ C} La_2(CO_3)_3 \xrightarrow{ca.\,450\,^\circ C} La_2O_2(CO_3) \xrightarrow{ca.\,700\,^\circ C} La_2O_3 \quad (2)$$

The intermediate phases appearing at *ca.* 450 °C were different with each carbonate sample, despite the fact that the initial compositions of these compounds were identical. The results of the thermal analysis of samarium and gadolinium carbonates obtained were similar to that of tengerite.[6]

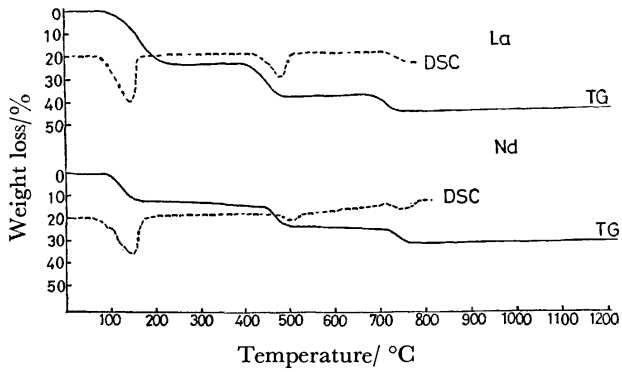

Fig. 3. Thermal analyses of lanthanum and neodymium carbonates.

I wish to express my deep gratitude to Professor Isao Masuda, Fukuoka University and Professor Kozo Nagashima, The University of Tsukuba, for their encouragement through the course of this work.

The Formation of Trapped Electrons upon the Thermal Dehydration-condensation of Hydrated Hydrogenorthophosphates

Hiroshi KAWAZOE,* Masaru NISHINO, Hideo HOSONO, Kei ISOZAKI, Kazuo AMETANI,† Masahiko IMAI,† and Takafumi KANAZAWA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received September 19, 1977)

Radical formation was found in the thermal dehydration-condensation process of hydrated hydrogenorthophosphates (HHP). It was considered that the intermediate radical reacted with lattice defects, thus resulting in the generation of trapped electrons. The gray coloration and the ESR sensitivity of the heated HHP were assigned to the formation of the trapped electron.

Some hydrated hydrogenorthophosphates (HHP), such as $MgHPO_4 \cdot 3H_2O$ (DMP3) and $Mg(H_2PO_4)_2 \cdot 2H_2O$, turn gray in the course of the thermal dehydration-condensation (D-C) reaction, resulting in a pyro- or meta-phosphate formation. These colored materials are bleached before the completion of the reaction; they change into white polycrystalline powders of pyro- or meta-phosphate. These facts suggest that a color center forms in the reaction process. In the present work, the nature of the color center was studied by means of ESR- and electronic-spectroscopies. The change in the concentration of the center with the reaction time was determined. The role of the center in the reaction was then discussed on the basis of these measurements.

Experimental

All the chemicals used here were guaranteed-grade reagents produced by Kanto Chemicals, Ltd. These reagents, *i.e.*, $MgHPO_4 \cdot 3H_2O$, $NaH_2PO_4 \cdot 2H_2O$, $Na_2HPO_4 \cdot 12H_2O$, $CaHPO_4 \cdot 2H_2O$, $Ca(H_2PO_4)_2 \cdot H_2O$, $KH_2PO_4 \cdot nH_2O$, and K_2HPO_4, were used as the starting samples without further purification. The $Mg(H_2PO_4)_2 \cdot 2H_2O$ sample was synthesized from MgO and H_3PO_4.[1)]

Thermogravimetric and differential thermal analyses were made to determine the temperatures of dehydration and crystallization of their dehydrated phosphate samples.

Electron spin resonance measurements were carried out for the materials obtained by thermal treatment with varying temperatures and times for HHP. The spectra were recorded on a JEOL JES-PE spectrometer at an X band microwave frequency. The concentrations of an unpaired spin in the heated samples were measured by using a double-mode cavity, with a known amount of polycrystalline DPPH as a reference.

A visible-UV spectrum was taken on a Shimadzu UV-200 spectrometer for the colored HHP dissolved in a sodium metaphosphate glass matrix.

The crystallinities of heat-treated DMP3, *i.e.*, a fraction of the $Mg_2P_2O_7$ crystal, at 700 °C at various times were determined by comparing the X-ray diffraction intensity for the (022) of $Mg_2P_2O_7$ in the sample with that in the calibration curve. This curve was obtained from mixtures of crystalline $Mg_2P_2O_7$ and amorphous $MgHPO_4$ in various mixing ratios.

Results and Discussion

Nature of the ESR Center. The electron spin resonance spectra for the samples obtained by the thermal treatment of several HHP are shown in Fig. 1. The heating temperatures and times noted in the figure were the conditions under which the most intense absorptions were observed for the respective HHP. All HHP excepting for K_2HPO_4 showed ESR absorptions of a singlet type, no other signals were recognized. The features of the singlets were regarded as the same for all the samples, even though the absorption intensities for the respective phosphates were different from one another. Three common natures of the absorptions were recognized: the first, no hyperfine structure; the second, a line width of 1—2 G measured at a peak-to-peak width in the derivative curve, and the last, a nearly isotropic spectroscopic splitting tensor with a value equivalent to that of a free electron (g=2.002). In the

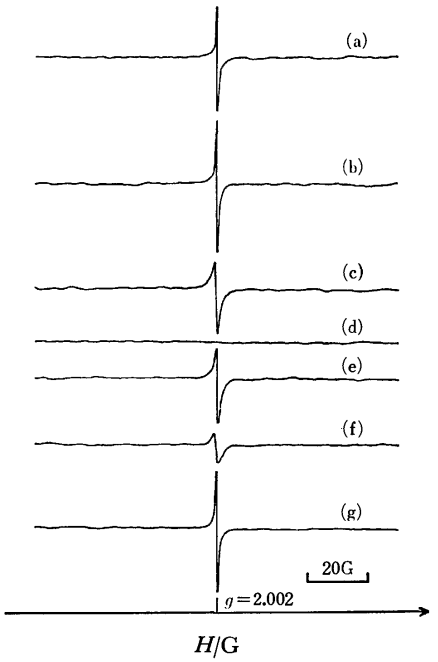

Fig. 1. ESR spectra for hydrated hydrogenorthophosphates heat-treated under the conditions shown below, a: $NaH_2PO_4 \cdot 2H_2O$, at 500 °C for 1 h, b: $Na_2HPO_4 \cdot 12H_2O$, at 500 °C for 1 h, c: $KH_2PO_4 \cdot nH_2O$, at 500 °C for 1 h, d: K_2HPO_4, at 200—800 °C for 0.5—10 h, e: $Ca(H_2PO_4)_2 \cdot H_2O$, at 400 °C for 1 h, f: $CaHPO_4 \cdot 2H_2O$, at 300 °C for 1 h, g: $Mg(H_2PO_4)_2 \cdot 2H_2O$, at 700 °C for 1 h. The spectra were recorded at 25 °C.

cases of $CaHPO_4 \cdot 2H_2O$, $KH_2PO_4 \cdot nH_2O$, and $Ca(H_2PO_4)_2 \cdot H_2O$, the g tensor was slightly anisotropic; *i.e.*, $g_{\parallel}=2.0025$ and $g_{\perp}=2.0023$. It should be noticed that K_2HPO_4 contains no water of crystallization. It may be expected, therefore, that lattice defects formed by the dehydration of HHP contribute to trapping the unpaired electron. Similar ESR centers were found in SiO_2, MgO, and CaS, all subjected to an explosive shock.[2] The color of these powdered materials was also gray.

We found that metaphosphate glasses are good trappers of these electrons. Sodium metaphosphate containing a small amount of HHP (1% in wt) was fused at 700 °C for 10 min and then quenched by using two plates of stainless steel. The glasses thus obtained were gray in color, but transparent to visible light. These glasses are suitable for the photo-bleaching and the measurement of an electronic spectrum. An electron spin resonance spectrum measured on the glass is shown in Fig. 2(b). The same singlet as that obtained by heating HHP (Fig. 1) reappeared. A unique difference between the spectrum of heated HHP (a) and that of HHP-doped metaphosphate glass (b) was a remarkable increase in the absorption intensity (in the order of 10^1—10^3) for the glass.

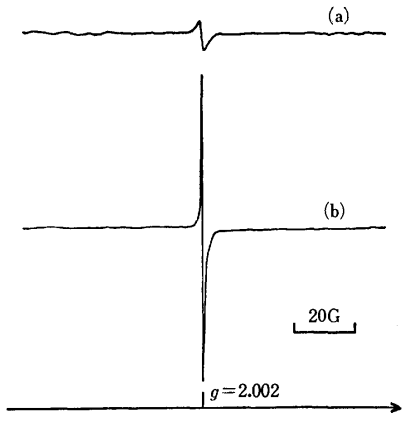

Fig. 2. ESR spectra of $CaHPO_4 \cdot 2H_2O$. a: Heated at 300 °C for 1 h in air and b: dissolved in sodium metaphosphate melt at 700 °C and quenched to form glass. The spectra were obtained at 25 °C. The concn of $CaHPO_4 \cdot 2H_2O$ was 1 wt %.

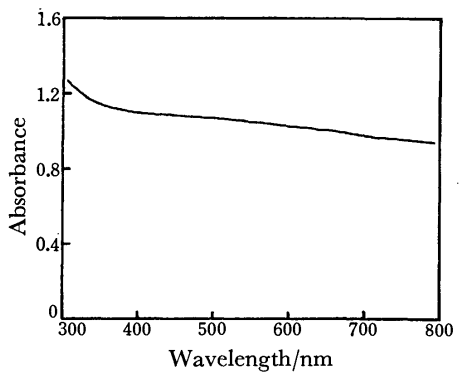

Fig. 3. Visible-UV spectrum of ESR center dissolved in sodium metaphosphate glass matrix.

Figure 3 shows the UV-visible spectrum for the glass containing DMP3. There was no characteristic peak, but a considerably intense absorption was seen over the range of wavelengths measured. If the lattice defect which is trapping an electron is assumed to make a three-dimensional, square-well potential, the difference between the energy levels for a trapped electron depends on the linear dimensions of the well. The size of the defects may be expected to be distributed in these amorphous matrices, and the absorption frequency may also be anticipated to have a wide distribution.

It is well known that DMP3 releases three water molecules at 180 °C and changes into $Mg_2P_2O_7$ gradually liberating one more water molecule by a condensation reaction between two $HOPO_3^{2-}$ ions at temperatures above 300 °C.[3] The process of the reaction should not, however, be viewed as so simple as is illustrated by the above scheme. In solid matrices the reaction does not always take place homogeneously; the extent of the reaction and the kind of the reaction products may be different for local sites and for sites in bulk specimens. For example, the condensation process of two $HOPO_3^{2-}$ ions is accompanied by the formation of the isolated amorphous MgO and "overcondensed" magnesium tetrametaphosphate.[4] The ESR spectrum obtained at 25 °C is displayed in Fig. 4 for the DMP3 sample,

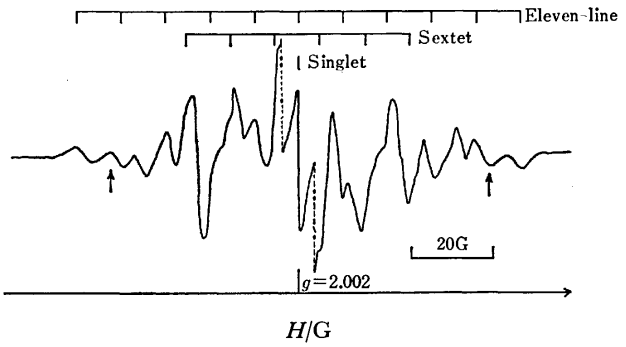

Fig. 4. ESR spectrum of DMP3 heated at gradually increasing temperatures up to 700 °C. Measurement was conducted at 25 °C. Signal gain for the central part is 1/10 of that for the outer parts. The expected locations of the singlet, sextet and eleven-line are also shown.

heated at gradually increasing temperatures with a small rate up to 700 °C. This spectrum was assigned to an F center in MgO.[5] It is expected that 53% of all magnesium-oxygen octahedra should have ^{24}Mg and ^{26}Mg ($I=0$), since the only abundant (10.05%) isotope with a nonzero nuclear spin is ^{25}Mg ($I=5/2$). One should see a single narrow line for an electron in a negative-ion vacancy with such an environment. There are also centers with one or two ^{25}Mg ions around one electron, and these should give a six- or an eleven-line hyperfine pattern centered upon the strong component. Such centers constitute 36 and 10% of the total number respectively. The contributions of those centers with 3, 4, and 5 ^{25}Mg neighbors can be neglected because of their small populations. For the unit intensity of the central line, one should have an intensity of 0.11 for the

sextet and $0.0052n$ for the group of eleven lines, where $n=1, 2, 3, 4, 5, 6, 5, \cdots, 1$. In the figure, the absorptions responsible for the F center with 0, 1, and 2 ^{25}Mg are classified. A nerly isotropic hyperfine coupling tensor was assumed. The locations and intensities of the members of the sextet were in satisfactory agreement with the expection. However, the fourth and eighth members of the eleven lines diminished. This might be due to the interference of the two adjacent members of the more intense sextet. Furthermore, the locations of the second and tenth members were shifted, because the absorptions which are marked by arrows and which are not assignable overlapped with the member lines. The locations and intensities of the other members of the eleven lines were in fair agreement with the expectation. The hyperfine coupling constant was found to be 11 ± 1 G, which is larger than those ($A=5$ G and $A=3.5$ G) found in the single crystal of MgO.[5]

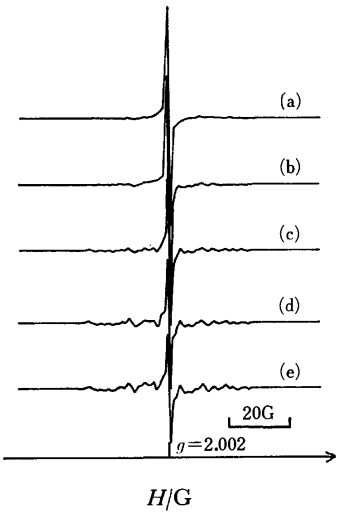

Fig. 5. ESR spectra for $MgHPO_4 \cdot 3H_2O$ heated at 700 °C for 1 h. The spectra were measured at a: −100 °C, b: −30 °C, c: 50 °C, d: 150 °C, and e: 245 °C.

The absorption profile shown in Fig. 4 changed gradually when the measuring temperature was varied. The spectra measured at different temperatures are illustrated in Fig. 5. The increase in the intensities of the sextet and eleven lines with an increase in the temperature was clearly recognized, whereas an inverse change was seen in the intensity of the central line. The change was found to be reversible. This fact suggests that an electron transfered from an F center in MgO to a lattice defect at lower temperatures, since the strong central line contains the contributions of the trapped electron in a lattice defect, besides that of the F center with no ^{25}Mg ion.

We may conclude here that a lattice defect formed in the reaction process acts as an electron-trapping site. The energy levels for the trapped electrons differ from site to site, corresponding to the distribution of the linear dimensions of the electron-trapping defects. Thus, the electronic spectrum for the electron has no peaks centered on a specific wavelength, but shows a rather wide absorption over the range of visible light.

Mechanism of Formation of Trapped Electrons. A major problem remaining is the mechanism of the dehydration-condensation reaction of HHP. In this article we wish to discuss the process by which an ESR center forms.

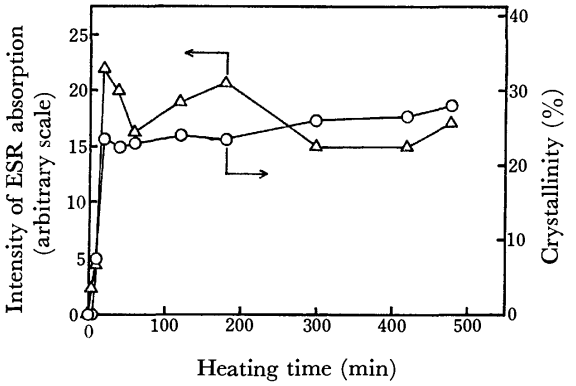

Fig. 6. Changes in ESR absorption intensity and crystallinity of $Mg_2P_2O_7$ with heating time. Specimens were $MgHPO_4 \cdot 3H_2O$ heated at 700 °C. The maximum concn of the trapped electron was ≈100 ppm.

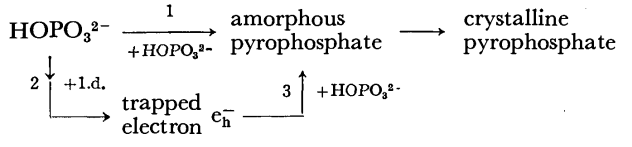
This center emerged during the decomposition of $HOPO_3^{2-}$ ions. The intensities of ESR absorption and the crystallinities of magnesium pyrophosphate for DMP3 heated at 700 °C for various times are given in Fig. 6. The two properties changed similarly in the initial stage (≲20 min), but they varied inversely afterwords. The initial variations in the two features are considered to be due to the release of water of crystallization and the successive decomposition of $HOPO_3^{2-}$ ions. The latter stage of the changes in the crystallinity is viewed as a rearrangement of the resultant amorphous magnesium pyrophosphate to form a crystalline lattice. The slow extinction of the trapped electron (20 min≲) is probably due to the reaction of the electron with fragment ions. The value of the initial crystallinity (≈25%) depends on the experimental conditions. In this experiment, the samples initially equilibrated at room temperature were placed in an electric furnace maintained at 700 °C. The lattice structure of the HHP subjected to an abrupt temperature rise was destroyed by the vaporization of the water of crystallization. The resulting amorphous hydrogen-orthophosphate, containing many cavities or voids among its constituent ions, was suitable for trapping an electron, but unsuitable for forming crystalline pyrophosphate. In the initial heating times, parallel changes in the two properties were recognized. The minimum temperature of heat-treatment generating the detectable ESR absorption for the respective HHP were also the lowest temperatures for the formation of the condensed phosphates. These two facts indicate that the trapped electron emerges during the decomposition of the $HOPO_3^{2-}$ ions.

It can be supposed that the D-C reaction between two $HOPO_3^{2-}$ ions proceeds at least partly through the formation of radicals at elevated temperatures, and that the trapped electron results from the reaction between the radical and the lattice defect. Distinct mechanisms

have been proposed for the D-C reaction of $CaHPO_4 \cdot 2H_2O$ at higher temperatures and at lower temperatures.[6] No intermediate radical expected to be generated during the reaction, such as $H^\bullet$, $^\circ_\bullet OH$, $^\circ_\bullet OPO_3^{2-}$, and $^\circ_\bullet PO_3^{2-}$, was detected directly by the ESR method, but one of the derivatives of phosphine was found.[7] It may, therefore, be inferred that atomic hydrogen, $H^\bullet$, forms upon the reaction. One possible mechanism of forming a trapped electron is the process shown below:



Here, l.d. expresses a lattice defect. The 1 process was regarded as the direct radical condensation corresponding to the initial crystallinity shown in Fig. 6:

$$HOPO_3^{2-} \longrightarrow H^\bullet + {}^\circ_\bullet OPO_3^{2-}$$

$$H^\bullet + HOPO_3^{2-} + {}^\circ_\bullet OPO_3^{2-} \longrightarrow H_2O + P_2O_7^{4-}.$$

The 2 stage was viewed as the formation of the trapped electron:

$$H^\bullet + \text{l.d.} \longrightarrow e_h^- + H^+ \quad \text{or}$$

$$H^\bullet + HOPO_3^{2-} \longrightarrow H_2O + {}^\circ_\bullet PO_3^{2-}$$

$${}^\circ_\bullet PO_3^{2-} + \text{l.d.} \longrightarrow PO_3^- + e_h^-.$$

The 3 reaction was considered to be the extinction of the e_h^- of forming the $P_2O_7^{4-}$ ions:

$${}^\circ_\bullet OPO_3^{2-} + e_h^- + PO_3^- \longrightarrow P_2O_7^{4-}.$$

Other side reactions, such as the formation of a hydrogen molecule ($H^\bullet + H^\bullet \rightarrow H_2$) and the substitution of a hydrogen for an oxygen in a PO_4 tetrahedron, may be possible.

The "Overcondensation" of Phosphate Ions and the Formation of Conjugate Metal Oxide upon the Thermal Dehydration-condensation of Hydrogenorthophosphates

Hiroshi KAWAZOE,* Kazuo AMETANI,† Masahiko IMAI,† and Takafumi KANAZAWA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

†*Tokyo Metropolitan Isotope Research Center, Fukazawa, Setagaya-ku, Tokyo 158*

(Received September 19, 1977)

On the thermal reaction of H_3PO_4 or $NH_4H_2PO_4$ with metal salts, such as Na_2CO_3 or $Mg(OH)_2$, the "overcondensation" of the phosphate anions and the conjugate formation of metal oxide were observed. The "overcondensation" was defined as a formation reaction of the phosphate with a larger polymerization degree than that of the product to be expected from the [MO or M_2O]/[P_2O_5] mole ratio of the starting mixtures. The "overcondensed" tetrametaphosphate and the conjugate oxide, magnesium oxide, were detected on the thermal condensation of $MgHPO_4 \cdot 3H_2O$ and of a mixture of $NH_4H_2PO_4$ or H_3PO_4 and $Mg(OH)_2$. The "overcondensed" tripoly- and trimeta-phosphate were found in the course of the formation reaction of Na pyrophosphate from a mixture of Na_2CO_3 and $NH_4H_2PO_4$.

A free electron was found to be trapped in a lattice defect formed during the dehydration-condensation (abbreviated as D-C) reaction of hydrated hydrogen-orthophosphates.[1] Especially, on the thermal condensation of $MgHPO_4 \cdot 3H_2O$ (DMP3), an ESR center which may be assigned to the trapped electron at an oxygen vacancy in MgO (the so-called F center) was detected. The magnesium oxide was considered to arise upon the reaction. The formation of MgO must be accompanied by the formation of the condensed phosphate, which has a greater polymerization degree than that of pyrophosphate. Therefore, it may be supposed that the thermal condensation reaction progresses through the separation of metal oxide and the "overcondensation" of phosphates. This "overcondensation" is defined as the formation reaction of the condensed phosphates with a larger polymerization degree than that of the product to be expected from the mole ratio of the starting sample, [MO or M_2O]/[P_2O_5].

It is the purpose of the present paper to examine whether or not a pair of conjugate reactions, the "overcondensation" of phosphates and the isolation of metal oxide, generally occurs on the D-C of orthophosphates. The condensation reactions of some sodium- and magnesium-orthophosphates to the respective pyrophosphates were done, and the "overcondensed" phosphates were identified by means of X-ray diffraction or ESR spectroscopy for irradiated samples. The formation of amorphous magnesium oxide was verified by using the ESR technique for the Mn(II)-doped samples.

Experimental

In order to obtain the intermediates in the reaction, a mixture of metal salt and phosphate or phosphoric acid was placed in a high-alumina crucible and heated in an electric furnace at several fixed temperatures. The thermal reactions for preparing the respective pyrophosphates were as follows:

$$2Na_2CO_3 + 2NH_4H_2PO_4 \longrightarrow Na_4P_2O_7 + 2NH_3 + 2CO_2 + 3H_2O$$

$$2Mg(OH)_2 + 2NH_4H_2PO_4 \longrightarrow Mg_2P_2O_7 + 2NH_3 + 5H_2O$$

$$2Mg(OH)_2 + 2H_3PO_4 \longrightarrow Mg_2P_2O_7 + 5H_2O$$

$$2MgHPO_4 \cdot 3H_2O \longrightarrow Mg_2P_2O_7 + 7H_2O.$$

All the chemicals used except DMP3 were guaranteed-grade reagents (Kanto Chemicals, Ltd.). The magnesium hydrogenphosphate trihydrate was produced by the reaction of $Mg(OH)_2$ with H_3PO_4 and was used as one of the starting samples for magnesium pyrophosphate (MP) preparation. The magnesium salts doped with Mn(II) were also prepared in order to examine whether or not the isolated MgO deposits in the course of the reaction. The manganese carbonate was dissolved in phosphoric acid or added to a mixture of powdered $Mg(OH)_2$ and $NH_4H_2PO_4$. The mole ratio of Mn/Mg was 1×10^{-4}.

The measurement of the X-ray diffraction were made for the powdered samples to check changes in the structure of the phosphates during the thermal reaction.

The measurements of the ESR absorption were carried out for the γ-irradiated specimens (^{60}Co source, for two hours at a dose rate of 0.5 Mrad/h) and Mn(II)-doped samples on a JEOL JES-PE-3X ESR spectrometer, mainly at room temperature.

Results and Discussion

"Overcondensed" Phosphates Detected by the X-Ray Powder Diffraction Method. Figure 1 shows the X-ray diffraction patterns of the specimens obtained by a thermal treatment of a mixture of Na_2CO_3 and $NH_4H_2PO_4$. The pattern for the material heated at 300 °C (d) was attributed to that of sodium tripolyphosphate (Form II).[2] A successive heating up to 520 °C (b) resulted in the crystallization of sodium trimetaphosphate[3] in addition to tripolyphosphate. The degradation of the "overcondensed" phosphates, *i.e.*, tripoly- and trimeta-phosphates, into sodium pyrophosphate occurred above 620 °C (a).[4]

The X-ray diffraction patterns for the heat-treated magnesium salts are shown in Fig. 2. As may be seen in the figure, the diffraction patterns were identical for the two cases starting from different phosphates, *i.e.*, ammonium dihydrogenphosphate and phosphoric acid. The crystalline material formed by heating at 730 °C (b, e) was identified as not magnesium pyrophosphate, but magnesium tetrametaphosphate.[5,6] In this stage

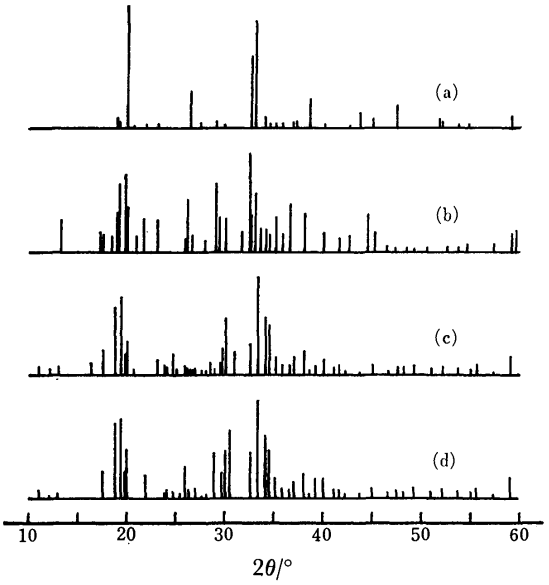

Fig. 1. X-Ray diffraction patterns of the mixture of Na_2CO_3 and $NH_4H_2PO_4$ (1: 1 in mole ratio) heated at a: 620, b: 520, c: 400, and d: 300 °C.

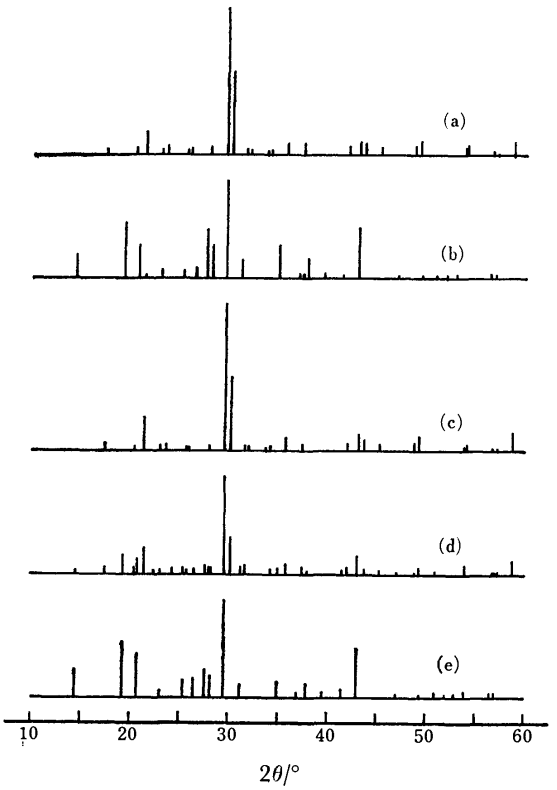

Fig. 2. X-Ray diffraction patterns of the mixtures of $Mg(OH)_2$ and a phosphate (MgO/P_2O_5 mole ratio=2) heated at a: 1075 °C for 2 h, b: 730 °C for 15 h, c: 1075 °C for 2 h, d: 920 °C for 2 h, and e: 730 °C for 15 h. Orthophosphoric acid was used as a starting reagent for a and b, whereas $NH_4H_2PO_4$ was utilized for c, d, and e.

of the reaction, no other crystalline phosphates were found. The tetrametaphosphate changed into MP at higher temperatures (a, c, d).[7] The results are summarized in Table 1. It may be inferred from these results that the formation of "overcondensed" phosphates with a larger polymerization degree than that of pyrophosphate takes place in the course of the condensation of orthophosphates. The condensation through the formation of the "overcondensed" phosphates must be the predominant path, since the crystallinity of the samples obtained by heating at lower temperatures was quite high (in the order of 10%) and no detectable signal of pyrophosphate formation was seen in the diffraction patterns. It may be noted that the formation of the oxides in the heated samples was not detected by the X-ray method because of the relatively low crystallinity of MgO and the unstability of Na_2O.

Detection of the Amorphous "Overcondensed" Phosphates and Amorphous Magnesium Oxide by the ESR of Mn(II). We made a prediction that the "overcondensation" is accompanied by the isolation of metal oxide. The utilization of ESR of incorporated Mn(II) made it possible to examine the formation of amorphous magnesium oxide. The ESR spectra for Mn(II)-doped samples are shown in Fig. 3. Only the fine-structure component responsible for the $M=1/2\leftrightarrow-1/2$ transition with six hyperfine structure lines produced by ^{55}Mn ($I=5/2$) had a detectable strength of the signals. The (a) and (c) spectra were taken as the references; (a) was the well-known pattern of Mn(II) in the MgO host crystal,[8] while (c) was the absorption due to Mn(II) in polycrystalline magnesium tetrametaphosphate.[9] The (b) pattern, taken from the specimen heated at 730 °C, may be regarded as a close superposition of the other two spectra, (a) and (c). An extra peak found near $g=2.002$ is attributable to the electron trapped in a lattice defect.[1] It may, therefore, be

a) Samples obtained by mixing the reagents shown in this table.

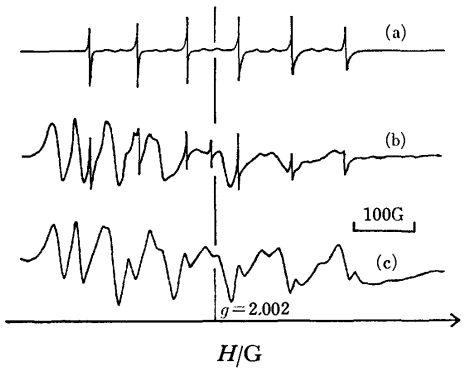

Fig. 3. ESR spectra of Mn(II) in various host crystals. a: In MgO, b: in the specimen obtained by heating 1:1 mixture of $Mg(OH)_2$ and $NH_4H_2PO_4$ at 730 °C and c: in $Mg_2P_4O_{12}$.

concluded that the "overcondensation" of phosphate ions and the isolation of magnesium oxide proceed simultaneously in the course of the D-C reactions of orthophosphate with magnesium salt.

No trace of the "overcondensation" of phosphates or of the isolation of MgO crystals was seen by X-ray diffraction when DMP3 was used as the starting sample. The process of the D-C reaction of DMP3 to MP is well established:[10]

$$MgHPO_4 \cdot 3H_2O \xrightarrow[-3H_2O]{1\ 180\,^\circ C} \text{amorph. } MgHPO_4 \xrightarrow[-H_2O]{2\ \text{above } 300\,^\circ C}$$

$$\text{amorph. } Mg_2P_2O_7 \xrightarrow{3\ \text{above } 450\,^\circ C} \text{cryst. } Mg_2P_2O_7.$$[11]

In the above reaction, the conversion to crystalline MP is slow at temperatures lower than about 900 °C. If amorphous "overcondensed" phosphate forms competitively with amorphous MP in Stage 2, it is undetectable by X-ray diffraction. In order to confirm the formations of the "overcondensed" phosphate and its conjugate oxide, ESR measurements were carried out on Mn(II)-doped DMP3 heated at 700 °C for several hours, which was still gray-colored and which exhibited the weak X-ray diffraction characteristic of crystalline MP. The results are shown in Fig. 4(a). The signals represented as F may be attributable to the F center in magnesium oxide.[12] The peaks labelled by M may be interpreted as resulting from the Mn(II) in the MgO host lattice. This fact strongly supports the formation of the isolated magnesium oxide. The manganese ions, of course, occupy also the sites of Mg ions in the condensed phosphates. Thus, the absorption responsible for these Mn(II) ions would be expected to appear. However, the environment of Mn(II) ions was considered to be distorted or to be widely distributed in these amorphous phosphates, and the resultant absorption was too broad to be shown in the figure. The underlying vague absorption (not shown in the figure) was assigned to these manganese ions.

In order to detect the counterpart of the isolated MgO, that is, the "overcondensed" phosphates, the measurements of ESR absorption were made on γ-irradiated samples which had been obtained by heating DMP3 doped with Mn(II) at 730 °C for 15 h in order to bleach out the trapped electron. The representative

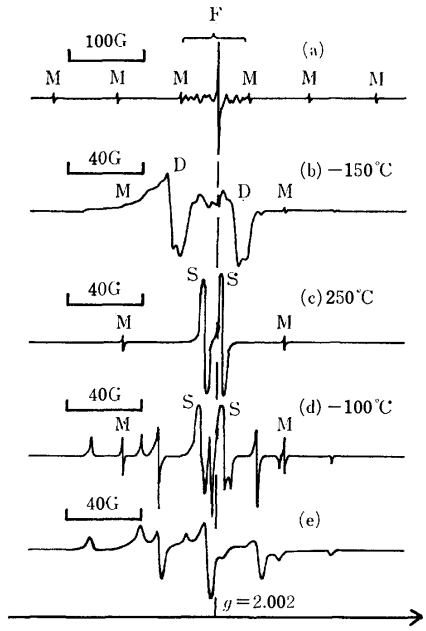

Fig. 4. ESR spectra for $MgHPO_4 \cdot 3H_2O$. a: Mn(II)-doped sample heated at 700 °C. b, c, d: Specimens obtained by heating DMP3 doped with Mn(II) at 730 °C for 15 h and by irradiating with γ-ray at a liquid nitrogen temperature. The spectrum b was recorded without intervening warming up to room temperature and c was measured at 250 °C. The spectrum d was obtained at −100 °C after bleaching out (at 300 °C) the intense signals arising from PO_4^{2-} radicals. e: γ-irradiated $Mg_2P_4O_{12}$ obtained by heating 1:1 mixture of $NH_4H_2PO_4$ and $Mg(OH)_2$ at 1100 °C. Signal gain for c and d is ten times larger than that for b.

spectra are shown in Fig. 4 (b, c, d). The (b) spectrum was recorded without intervening warming up to room temperature after irradiation at the temperature of liquid nitrogen and (c) was measured at 250 °C. The (d) spectrum was obtained at −100 °C after bleaching out (at 300 °C) the intense signals arising from PO_4^{2-} radicals. The intense doublet seen in the (b) pattern (labelled by D) is identified as the PO_4^{2-} radical.[13] At present, the nature of the radical responsible for the doublet, S, in the (c) pattern is not clear, but a little should be mentioned about this center. This absorption was found to arise generally by the irradiation to pyrophosphates and to be stable up to 300 °C. The remarkable peak of the trapped electron was also visible near the g value of a free electron. The (e) spectrum was recorded on the γ-irradiated specimen obtained by heating a 1:1 mixture of $NH_4H_2PO_4$ and $Mg(OH)_2$ at 1100 °C. The crystalline component in this sample was magnesium tetrametaphosphate. This spectrum was attributed to the radical (U) formed by the irradiation to the tetrametaphosphate crystal or its glass.[14] The center was formed only in the irradiated tetrametaphosphate and was not detected in other related, irradiated magnesium phosphates. The spectrum broadened beyond detection at above 200 °C because of the relatively short relaxation time. Three types of

ESR centers are recognized in the (d) pattern. The first is the unknown center (the doublet, S), the second, the radical (U) in the tetrametaphosphate host lattice, and the last, Mn(II) in the MgO host matrix.

It may, therefore, be concluded that the "overcondensation" of phosphates and the counterpart isolation of MgO occur also in the course of the D-C reaction of DMP 3.

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565

(Received December 24, 1977)

Di(2-ethylhexyl)phosphoric acid† (D2EHPA or HX) extracts lanthanoids (Ln) from a moderately acidic solution by cation exchange reaction: $Ln^{3+}+m(HX)_n \rightleftarrows LnX_3 \cdot 3HX+3H^+$. From the mode of extraction m is estimated to be 3 in benzene diluent, and smaller than 3 in heptane diluent. The change of the relative extractability with the atomic number of lanthanoids is in line with what is expected from the concept of the tetrad effect proposed by Peppard *et al.* When the hydrogen ion concentration is very high, the main reaction is solvation: $Ln^{3+}+3A^-+q(HX)_n \rightleftarrows LnA_3 \cdot 4HX$. In benzene diluent q is 2 and n is 2, while q is 1.6—1.7 in heptane diluent. It can be attributed to the difference in the association degree of D2EHPA that m or q is smaller in heptane than in benzene.

Di(2-ethylhexyl)phosphoric acid† (D2EHPA or HX) extracts a lanthanoid by a cation exchange reaction expressed by

$$Ln^{3+}_{(aq)} + 3(HX)_{2(org)} \rightleftarrows LnX_3 \cdot 3HX_{(org)} + 3H^+_{(aq)}, \quad (1)$$

where the subscripts (aq) and (org) represent the aqueous and organic phase, respectively.[1,2] In a saturated aliphatic hydrocarbon, however, the extraction behavior of the lanthanoids differs slightly from what is expected from Eq. 1.[3,4] The association degree of D2EHPA is higher than 2 in such a solvent.[5] Sato and Ueda assumed that the extracted species is different from that described in Eq. 1.[4] Assuming that a lanthanoid is extracted only by a cation exchange reaction, the distribution ratio of the lanthanoid is expected to decrease with the increase in acid concentration in aqueous phase. However, in the extraction of metals by a dialkyl phosphoric acid the distribution ratio increases with the acid concentration in the region in which acid concentration is very high.[6-8] This suggests that some other reactions occur. We have studied the distribution equilibria of some lanthanoids with D2EHPA.

Experimental

Materials. D2EHPA (Union Carbide Corporation) was purified[9] and then diluted with heptane or benzene to the desired concentration. The lanthanoid salt solutions were prepared as described for chloride solutions.[3]

Procedure. Equal volumes of organic D2EHPA solution and the aqueous lanthanoid solution were placed in an Erlenmeyer flask with a glass stopper. The flask was shaken vigorously for 15 min, allowed to stand for 30 min, and again shaken for 10 min. After the flask had been allowed to stand for 30 min or longer, the glass stopper was replaced by the glass stopcock used for separation of the two liquids, and the two phases were separated. All the equilibration procedures were carried out at 20.0±0.2 °C.

Determination of Equilibrium Data. The lanthanoids and yttrium extracted into the organic phase were recovered by back-extracting four times with equal volumes of 6M hydrochloric or nitric acid solution. The concentrations of lanthanoids and yttrium were determined by EDTA titration with Xylenol Orange as an indicator. The concentration of hydrogen ion in the aqueous solution was determined by titration with a standard solution of sodium hydroxide with Bromophenol Blue as an indicator. The concentration of D2EHPA in organic solution was determined by titration with a standard sodium hydroxide solution in an ethanol–water (4: 1 volume ratio) solvent with a pH meter. The concentration of D2EHPA was determined as the monomer unit. The distribution ratio of a lanthanoid is defined to be the ratio of the concentration of the lanthanoid in the organic phase to that in the aqueous phase.

† Bis(2-ethylhexyl) hydrogenphosphate in IUPAC notation.

Results and Discussion

Figure 1 shows the variation of the distribution ratios of dysprosium and europium with the concentration of

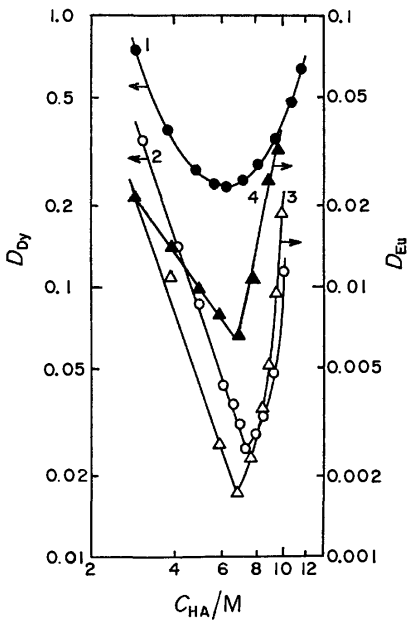

Fig. 1. Relationship between the distribution ratio, D, and the concn of the acid or the anion in the aq phase in the extraction of Eu or Dy by 1 M D2EHPA in heptane.
1: 0.05 M $Dy(NO_3)_3$–HNO_3 system, HA: HNO_3, 2: 0.05 M $DyCl_3$–HCl system, HA: HCl, 3: 0.05 M $EuCl_3$–HCl system, HA: HCl, 4: 0.05 M $EuCl_3$–HCl–LiCl system, C_{HCl}=2.88 M, $C_{HA}=C_{HCl}+C_{LiCl}$. 1M= 1 mol/dm³.

hydrochloric or nitric acid in aqueous phase. With the increase in the concentration of acid the distribution ratio decreases in the lower acid concentration region and increases in the higher concentration ragion, exhibiting a minimum at acid concentration 6—8 M. Similar data were obtained in other systems. From the extraction behavior we see that D2EHPA extracts a lanthanoid mainly by a cation exchange reaction in the low acid concentration region and by some other reactions in the high acid concentration region.[6]

Low Acid Concentration Region. The cation exchange reaction for the extraction of a trivalent lanthanoid by D2EHPA can be expressed as follows, taking into account the association degree of D2EHPA, n.

$$Ln^{3+}_{(aq)} + m(HX)_{n(org)} \rightleftarrows LnX_3 \cdot xHX_{(org)} + 3H^+_{(aq)}, \quad (2)$$

where the ratio of D2EHPA to the lanthanoid in the extracted species is $(3+x)$, and $m \times n$ is equal to $(3+x)$. Three hydrogen ions are transferred into the aqueous phase per each lanthanoid extracted.[3]

It was confirmed that Eq. 1 is valid in benzene diluent. The association degree of D2EHPA was found cryoscopically to be nearly equal to 2. The plot of log D *vs.* log C_{HX} shows that the distribution ratio of the lanthanoid is of third power with respect to D2EHPA concentration.

Table 1. Extractant dependency of the extraction of Eu by D2EHPA in heptane

Series	$C_{HA,I}$[a] / M[f]	$C_{Eu,I}$[b] / M[f]	Extractant dependency[c] estimated for $x=3$	$x=2$
1[d]	0.50	0.05	2.16	2.17
2[d]	0.40	0.05	2.12	2.20
3[d]	0.40	0.14	2.25	2.25
4[d]	0.076	0.208	2.28	2.73
5[e]	0.194	0.05	2.23	2.38

a) The initial concentration of hydrochloric or nitric acid in aq phase. b) The initial concentration of Eu in aq phase. c) Estimated from the slope of the plot of $\lg D_{Eu}$ *vs.* $\lg C_{HX}$ (C_{HX}: 0.1—1.0 M). d) $EuCl_3$–HCl system. e) $Eu(NO_3)_3$–HNO_3 system. f) 1 M=1 mol/dm^3.

The extractant dependency estimated for the extraction of europium with D2EHPA in heptane is given in Table 1. The equilibrium concentration, C_{HX}, was estimated by the equation $C_{HX}=C_{HX,I}-(3+x)C_{Eu(org)}$, derived from Eq. 2, where $C_{HX,I}$ and $C_{Eu(org)}$ are the initial concentration of D2EHPA and the equilibrium concentration of europium in the organic phase, respectively. In the estimation the cases $x=3$ and $x=2$ were assumed.[3,10] Mason *et al.* proposed an equation in which x is 2 and m is 2.5 regarding D2EHPA as dimeric in heptane. When x is 3, the estimated dependency is nearly equal for all the series. On the other hand, when x is 2 the dependency differs a great deal for series 4 from those for the others. Thus it is reasonable to assume x to be 3 rather than 2. Eq. 2 can be rewritten as

$$Ln^{3+}_{(aq)} + m(HX)_{n(org)} \rightleftarrows LnX_3 \cdot 3HX_{(org)} + 3H^+_{(aq)}. \quad (3)$$

The extractant dependency for the nitrate system (series 5) is nearly equal to that for chloride systems (Table 1) suggesting that there is no serious difference in the extraction reaction between the two systems. The values of the extractant dependency are considerably smaller than 3, the value obtained for the benzene system. The difference in value of the two systems may be explained in terms of the difference of the association degree of D2EHPA, since the ratio of D2EHPA to a lanthanoid in the extracted species is 6 in both systems, though the effect of the activity coefficient should be taken into account for discussion. The extractant dependency for several lanthanoids and yttrium is given in Table 2.

Table 2. Extractant dependency of the extraction of lanthanoids (Ln) and yttrium

	Extractant dependency
La	2.40
Pr	2.26
Nd	2.22
Sm	2.15
Eu	2.16
Gd	2.18
Tb	2.12

Y	2.11

Extraction conditions: C_{HX}=0.1—1.0 M, $C_{Ln,I}$=0.02—0.05 M, C_{HCl}=0.15—2 M. 1 M=1 mol/dm^3.

Figure 2 shows the relative extractability of several lanthanoids and yttrium. The relative extractability was estimated from the difference of the distribution ratios normalized to an identical condition. The average separation factor for the adjacent lanthanoids is evaluated to be 2.28, which is in rough accord with that reported by Pierce *et al.*[11] The relative extractability is not a smooth function of the atomic number, Z, of the lanthanoid. The shape of the curve is in fair agreement with that expected from the concept of the tetrad effect proposed by Peppard *et al.*[12] A tendency similar to the concept was also reported by Siekierski.[13] The relative extractability of yttrium seems to be between holmium and erbium; that of holmium was not determined in this study.

In order to check the validity of the relations stated above with regard to the distribution equilibrium, the equilibrium values calculated by the use of the following equations were compared with the actual extraction isotherms.[3]

$$D = K' \times \frac{C^a_{HX}}{C^3_{H^+}}, \quad C_{HX} = C_{HX,I} - 6C_{Ln(org)}, \text{ and}$$

$$C_{H^+} = C_{H^+,I} + 3C_{Ln(org)}$$

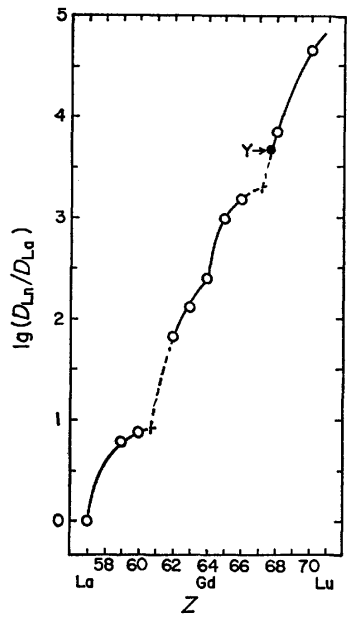

Fig. 2. Variation of the distribution ratio, D, with the atomic number, Z, of lanthanoids in the extraction from the chloride solutions by 1M D2EHPA in heptane. $C_{LnCl_3,i}=0.02$—0.05M, $C_{HCl}=1$M, $C_{HX}=0.5$ M. 1M=1 mol/dm³.

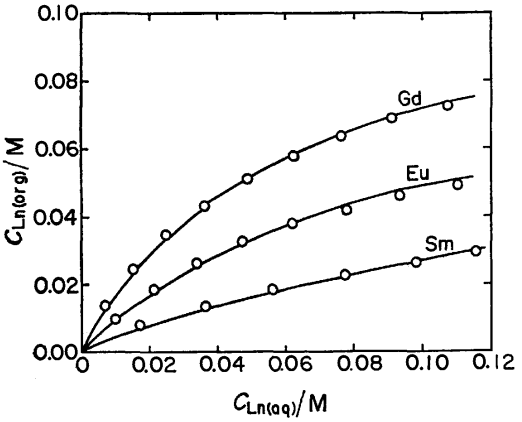

Fig. 3. Distribution equilibria for $SmCl_3$–HCl–, $EuCl_3$–HCl–, and $GdCl_3$–HCl–1M D2EHPA in heptane systems.
$[H^+]=1$M. The solid curves represent the calculated values. 1M=1 mol/dm³.

In the calculation the constant K' was evaluated from the equilibrium data observed for the system where $C_{Ln,i}=0.1$ M†† and $C_{H^+}=1$ M.†† $C_{H^+,i}$ represents the initial concentration of hydrogen ion. For the value of a, the extractant dependency given in Table 2 was used. Figure 3 shows the extraction isotherms for the $SmCl_3$–HCl–, $EuCl_3$–HCl–, and $GdCl_3$–HCl–D2EHPA in heptane systems. The calculated values are denoted by three curves and the experimental values by open circles. The validity of the relations is demonstrated by the agreement between the calculated and observed values.

†† Throughout this paper, 1M=1 mol/dm³.

High Acid Concentration Region. Solvation is a predominant reaction at high acidity, which is expressed by

$$Ln^{3+} + 3A^- + q(HX)_n \rightleftarrows LnA_3 \cdot qnHX, \quad (4)$$

where A^- represents an anion.[4,7] This indicates that the effect of the concentration of a mineral acid on the extraction by solvation is essentially attributed to the corresponding anion. It is demonstrated by the similarity in shape of curves 3 and 4 (Fig. 1), though a little difference can be attributed to the difference in HCl concentration. The shapes of the curves can be explained as follows. (i) Increase in HCl concentration causes decrease in the amount of the extraction of europium by the cation exchange reaction, since the extraction reaction is of inverse third power dependence on the hydrogen ion concentration. (ii) Increase in chloride concentration depresses the extraction of a lanthanoid by the cation exchange reaction, since the concentration of the trivalent lanthanoid ion, one reactant in Eq. 2, decreases by complexing between the lanthanoid and chloride. (iii) Increase in chloride concentration increases the amount of the extraction of the lanthanoid by the solvation expressed by Eq. 4. The extractant dependency of the extraction of lanthanoids from highly acidic solutions where the lanthanoids are extracted almost only by solvation is given in Table 3. The

Table 3. Extractant dependency of the extraction of lanthanoids

Dy	HNO_3	12.0	Heptane	1.63
Dy	HCl	10.5	Heptane	1.73
Eu	HCl	10.0	Heptane	1.70

a) The initial concentration of the acid in aq phase. b) 1 M=1 mol/dm³. c) Estimated from the slope of the plot of lg D_{Ln} *vs.* lg C_{HX} ($C_{Ln,i}=0.05$ M, $C_{HX}=0.1$—1.0 M).

extractant dependency is about 2.0 both for the nitrate and the chloride systems when benzene is a diluent, and Eq. 4 can be rewritten for such systems as follows since D2EHPA is practically dimeric in benzene.

$$LnA_3 + 2(HX)_2 \rightleftarrows LnA_3 \cdot 4HX \quad (5)$$

On the other hand the dependency is smaller in heptane diluent as in the case of the cation exchange reaction.

Cobalt(IV) Ammine Complexes with 5-Nitrosalicylato or Similar Ligands. IV.[1] Preparation, ^{1}H-NMR, ^{13}C-NMR, and IR Spectra

Yoshihisa YAMAMOTO

Faculty of Pharmaceutical Science, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02

(Received January 5, 1978)

The ^{1}H-NMR spectrum of the 5-nitrosalicylatotetraamminecobalt(IV) complex did not show the signals of phenyl protons of the salicylato ligand, but did show those of ammine protons at 3.7 (s, 6H) and 3.3 ppm (s, 6H). The ^{13}C-NMR peaks could not be observed because of the paramagnetism. The ^{1}H-NMR spectra of the salicylatotetraamminecobalt(III) complexes showed peaks at 3.96 (s, 6H), 3.65 (s, 3H), and 3.38 ppm (s, 3H) for the ammine protons and at 6.7—8.1 ppm (m, 4H) for the phenyl protons of the salicylato ligand. Their ^{13}C-NMR spectra showed seven signals for the salicylato ligand. The IR peaks assignable to the rocking deformation vibration were observed at 830—855 cm^{-1} for the ammine ligands of 5-nitrosalicylatotetraamminecobalt(IV) complexes and at 820—840 cm^{-1} for those of salicylatotetraamminecobalt(III) complexes, in conformity with the view that the former complexes are actually cobalt(III) complexes of a free radical nature.

The previous papers have been concerned with the preparation[2,3] and some physical properties[4] of cobalt(IV) ammine complexes with 5-nitrosalicylato and similar ligands. The delocalization of an electron hole over the cobalt and 5-nitrosalicylato ligand system of the "cobalt(IV)" ammine complex ion with 5-nitrosalicylato or similar ligands was inferred from the magnetic susceptibility[4] and the electrical resistivity.[4] The present paper will deal with the results of measurements of the ^{1}H-NMR, ^{13}C-NMR, IR-spectra and the isolation of 5-nitrosalicylatotetraamminecobalt(IV) dinitrates and 5-nitrosalicylatotetraamminecobalt(III) nitrate.

Results and Discussion

Formation of the Complexes. The salicylatotetraammine cobalt complexes studied in this research, together with the abbriviations adopted in this paper, are listed in Table 1. The **2a**—**2c** complexes are oxidized and changed to the **1a**—**1c** complexes respectively, but the **2d** complex is not oxidized with 60% nitric acid. The **1g** and **1h** complexes have been synthesized for the first time. The **1h** complex has been prepared only from the **1g** complex by metathesis. The **1g** and **1h** complexes are green and paramagnetic. Their absorption spectra show a characteristic peak at 660 nm (log $\varepsilon \approx 4$) as do other cobalt(IV) ammine complexes with 5-nitrosalicylato or similar ligands. The **1g** complex has the electrical resistivity of 10^{11} Ω cm.

The **3a** and **3b** complexes are orange and are insoluble in most organic solvents, but are soluble in water and dimethyl sulfoxide. Neither the **3a** complex nor the **3b** complex changes to a green, paramagnetic complex, **1h** and **1a** with 60% nitric acid respectively. The **3a** and **3b** complexes were characterized by the measurement of the magnetic susceptibility (diamag.), the absorption spectra (510 nm, $\varepsilon \approx 190$), the ^{1}H-NMR spectra [ammine protons (12H), and the 5-nitrosalicylato ligand protons (3H)] and equivalent conductance (114 S cm^2 for the **3a** complex). These data show that the **3a** and **3b** complexes are cobalt(III) complexes of the low-spin type.

NMR Spectra. The ^{1}H-NMR spectrum of the **1d** complex was measured in 1.8 M deuteriosulfuric acid at room temperature. The spectrum, as is shown in Fig. 1, did not show peaks of the phenyl protons of the salicylato ligand, but did show those of the ammine protons, the chemical shifts of which are close to those of the **2a** complex. The chemical shift of the methyl

II; $[(NH_3)_4Co(OOC)(O)C_6H_3(NO_2)]Cl_2\cdot 3H_2O$ in 1.8M D_2SO_4.

Standard: External TMS in $CDCl_3$.

protons of the salicylato ligand in the **1e**, **1f**, and **2b—2d** complexes did not show any appreciable change, either, as is shown in Table 2. The measurements of the ^{13}C-NMR spectra of the **1a**, **1c**, and **1d** complexes were attempted in several solvents, at varying concentrations at low and at room temperature. The spectra did not show the expected signals because of the paramagnetism of those complexes. These results lead to the conclusion that, in the **1a—1h** complexes, the electron hole is not distributed over the ammine ligands and the methyl group of substituted 5-nitrosalicylato ligand, though it seems to be delocalized over the chelate ring containing the cobalt atom and the benzene ring of the 5-nitrosalicylato ligand.

^{1}H-NMR spectrum of the **2a** complex showed three singlets of ammine groups and a multiplet of the salicylato ligand in the expected integral ratio (3:3:6:4) at room temperature, as is shown in Fig. 1. The singlet (3.38 ppm) at the highest field was assigned to the protons of the ammine ligand in a position *trans* to the carboxyl oxygen of the salicylato ligand in the **2a** complex. The singlet at 3.65 ppm is assigned to the protons of the ammine ligand in a position *trans* to the phenolic oxygen, which is less electronegative than the carboxyl oxygen, while that at 3.96 ppm is assigned to the protons of two ammine ligands in positions *cis* to the salicylato ligand. The multiplet (6.7—8.1 ppm) at the lowest field was assigned to the protons of the salicylato ligand. The above assignment was made in view of the following: studies of pentaammineaniono-cobalt(III) ions, $[Co(NH_3)_5X]^{n+}$ (X: Cl, Br, OH ···), have been reported by Buckingham,[5] Jolly,[6] and Clifton,[7] who described that the chemical shift of the NH_3 group in a position *trans* to the electronegative atom (X) is at higher fields than those of NH_3 groups in a position *cis* to the electronegative atom. The chemical shift of the NH_3 group in a position *trans* to the electronegative atom (HSO_4^-) is at higher field than that of the NH_3 group in a position *trans* to other electronegative atoms (H_2O, Cl, ···).[6] Marzilli[8] and Hawkins[9] also reported the case of sarcosinatotriethylenetetraminecobalt(III) ions in which the proton signals of the NH_2 group in a position *trans* to the coordinated carboxyl oxygen of sarcosinato ligand appeared at higher fields than those of the NH_2 group in a position *cis* to the coordinated carboxyl oxygen.

The ^{13}C-NMR spectra of the **2a** complex were measured in heavy water at room temperature. The assignment of the salicylato ligand of the complex was attempted by means of a consideration of the assignment of salicylaldehyde[10] and methylsalicylate.[10] Two signals, C-1 and C-3, of the salicylato ligand overlapped, as is shown in Table 3, but they split when the pH was

Abbreviations: L^a: salicylic acid, L^b: 3-methylsalicylic acid, L^c; 4-methylsalicylic acid, L^d: 5-Methylsalicylic acid, L^e: salicylaldehyde,[10] and L^f: 5-nitrosalicylic acid.

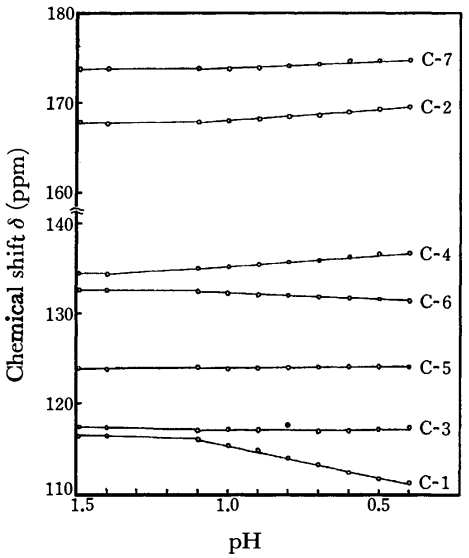

Fig. 2. ^{13}C-NMR chemical shift *vs.* pH of the complex **2a**.

$[(NH_3)_4Co(OOC\text{-}C_6H_4\text{-}O)]Cl\cdot H_2O$ in D_2O and HCl.

Standard: MeOH (δ=49.8 ppm).

lowered below 1.1 by the addition of hydrochloric acid. In hydrochloric acid, the carbon signal of C-5 did not shift, that of C-3 shifted slightly to a higher field, C-6 shifted to a higher field, and those of C-2, C-4, and C-7 shifted to a lower filed, as is shown in Fig. 2. This observation seems to be due to the hydrogen bonding[11,12] between the lone pairs of the carbonyl oxygen atom of the salicylato ligand and proton of hydrochloric acid.

The ^1H-NMR spectra of the **3a**—**3b** complexes are similar to those of the **2a**—**2d** complexes. The ^{13}C-NMR spectra of the **3a**—**3b** complexes in DMSO-d_6 are shown in Table 3. The chemical shifts of the substituted carbon atom of the salicylato ligand both in the **2b**—**2c** complexes and in the free ligands, L^b-L^d, L^f, move to a lower field upon the substitution of methyl and nitro groups. These shifts are coincident with the data reported by Levy and Nelson.[13,14] The exceptions are the carbon signals of the C-5 position of the 5-methyl- or 5-nitrosalicylato ligands in the **2d** and **3a**—**3b** complexes which do not shift to a lower field.

IR Spectra. It was reported by Nakamoto,[15] Wilmshuist[16] and Svatos[17] that the rocking deformation vibration of metal ammine complexes, which appears as a broad band, is influenced by the oxidation state of the metal in the ammine complex. Thus, it appears at 650 cm^{-1} in hexaamminecobalt(II) chloride[17-19] and at 827 cm^{-1} in hexaamminecobalt(III) chloride.[17-19] The rocking deformation vibration was observed as a broad band at 830—855 cm^{-1} for the **1a**—**1f** complexes, at 820—840 cm^{-1} for the **2a**—**2d** complexes, and at 828—840 cm^{-1} for the **3a**—**3b** complexes, showing little difference among these complexes. From the above facts, the most reasonable conclusion seems that the ammine ligands in the **1a**—**1f** complexes are similar to those of the **2a**—**2d** complexes and that the **1a**—**1f** complexes have a free radical nature in which the electron hole is delocalized over the 5-nitrosalicylato ligand and the cobalt ion in agreement with magnetic susceptibility,[4] the electrical resistivity[4] and the NMR spectra of the **1a** and **1d**—**1f** complexes. The situation might be similar to the cases of μ-peroxo and μ-hyperoxo dicobalt complexes, both of which have the rocking deformation band of ammine at around 800 cm^{-1} and are considered to contain trivalent cobalt.[20,21]

Experimental

Measurements. The NMR spectra were measured with a FX-60 (JEOL) for ^{13}C-NMR and JNM-PMX-60 (JEOL), R-40 (Hitachi) for ^{1}H-NMR. The IR spectra were measured with a JASCO spectrophotometer, DS 402-G, and an EPI 238 Hitachi apparatus in potassium bromide disks for the **1a—1h** and **2a—2d** complexes and in Nujol mulls for the **3a—3b** complexes. The visible absorption spectra were recorded with Shimadzu MPS-5000 recording spectrophotometer. The electrical resistivity was measured with a Toa Denpa Kogyo Microvolt ammeter. The magnetic susceptibilities were measured by the Gouy method with a magnetic balance (Shimadzu) at room temperature. The pH was measured with a Toa Electronics pH-meter, HM-5B.

Preparation of Complexes. *The **1a**, **1b**, **1c**, **1d**, **1e**, and **1f** complexes* were prepared as has been described in previous papers.[2,3] *The **2a**, **2b**, **2c**, and **2d** complexes* were prepared by Morgan and Smith's method.[22]

*5-Nitrosalicylatotetraamminecobalt(IV) Picrate Dihydrate (**1g**).* An aqueous solution of 0.8 g (1.89 mmol) of the **1a** complex was slowly added to an aqueous solution of 0.87 g (3.79 mmol) of picric acid, and mixture was stirred. The precipitated green complex was filtered off, washed with water, and dried. Yield: 0.94 g (62.3%), Found: C, 28.49; H, 2.87; N, 19.41%. Calcd for $CoC_{19}H_{23}N_{11}O_{21}$ (*MW*: 800.39) C, 28.51; H, 2.90; N, 19.25%. The absorption maximum in the visible spectrum was at 660 nm ($\varepsilon=12700$) in water.

*5-Nitrosalicylatotetraamminecobalt(IV) Nitrate Hemihydrate(**1h**).* 0.5 g (0.62 mmol) of the **1g** complex was dissolved in 60% nitric acid, and some picric acid was precipitated. The solution was then filtered with a glass filter (G4), and the filtrate was added to acetone. The precipitated green complex was filtered off, washed and dried. Yield: 0.20 g (72.7 %), Found: C, 19.47; H, 3.80; N, 21.66%. Calcd for $CoC_7H_{16}N_7O_{11.5}$: (*MW*: 441.18) C, 19.06; H, 3.65; N, 22.22%. Visible absorption peaks: 450 nm ($\varepsilon=3700$) and 660 nm ($\varepsilon=14100$) in 60% nitric acid.

*5-Nitrosalicylatotetraamminecobalt(III) Nitrate Monohydrate(**3a**).* The **1a** complex was precipitated by the addition of acetone to a 60% nitric acid solution of 3.0 g (9.5 mmol) of the **2a** complex according to the method presented in a previous paper.[2] The **3a** complex was isolated from this orange-colored acetone solution, recrystallized from water, and dried. Yield: 0.96 g (18.5%), Found: C, 21.82; H. 4.53; N, 21.90%. Calcd for $CoC_7H_{17}N_6O_9$: (*MW*: 387.52) C, 21.70; H, 4.42; N, 21.69 %. The visible absorption peak was 510 nm ($\varepsilon=196$) in water.

*5-Nitrosalicylatotetraamminecobalt(III) Chloride Dihydrate Hydrochloric Acid (**3b**).* 0.4 g (1.03 mmol) of the **3a** complex was dissolved in 30% hydrochloric acid. The precipitate formed by the addition of acetone was filtered off, washed, and dried. Yield: 0.26 g (58.2%), Found: C, 20.34; H, 4.85; N, 16.27; Cl, 17.62%. Calcd for $CoC_7H_{20}N_5O_7Cl_2$: (*MW*; 416.12) C, 20.21; H, 4.84; N, 16.83; Cl, 17.04%. The visible absorption peak was 512 nm ($\varepsilon=185$) in 35% hydrochloric acid.

The author wishes to express his gratitude to Professor Masayasu Mori of Osaka City University for his discussion and to Dr. Genetsu Matsubayashi of Osaka University for the NMR spectra.

Trimethylenediamine Complexes. VI.[1] Kinetic and Equilibrium Studies of Ligand Substitution Reactions of the *trans*-Aquabis(diamine)sulfito- and *trans*-Bis(diamine)-hydroxosulfitocobalt(III) Complexes

Yoshiaki Ito, Akira Terada, and Shinichi Kawaguchi*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received January 20, 1978)

Substitution reactions of the *trans*-$CoSO_3$ (H_2O or OH) (en or tn)$_2$ complex with Cl^-, Br^-, CH_3COO^-, N_3^-, NO_2^-, NCS^-, CN^-, and SO_3^{2-} have been studied by the spectrophotometric method. The equilibrium constant of anation $K^X_{H_2O}$ spans many orders of magnitude, *e.g.* from 1.24 for bromide to 1.23×10^7 M^{-1} for cyanide in the case of the en complex, and is correlated to the electron donor constant E_n which was defined by Edwards. The kinetics of the substitution reactions is adequately interpreted by virtue of the reversible **D** mechanism *via* a five-coordinate intermediate $CoSO_3(AA)_2^+$. Release of the ligand X^{n-} from *trans*-$CoSO_3(X)(tn)_2^{(1-n)+}$ proceeds 10—25 times faster than from the corresponding bis(ethylenediamine) complex, and the kinetic ring-size effect is attributed to the larger stability of the en complex as compared with the tn complex at the ground state.

Although cobalt(III) complexes are usually inert,[2] two groups of complexes are known to perform rapid ligand substitution. One is those containing unsaturated macrocyclic(N_4) ligands, which have been shown to enhance the rate of ligand substitution at the metal center by many orders of magnitude.[3] The increasing degree of unsaturation in the encircling macrocycle is considered to enhance softness of the central metal ion, thus stabilizing five-coordinate intermediates and increasing the rates of ligand displacement.[4]

The other group of rather labile cobalt(III) complexes contain S-bonded ligands such as sulfite[5] and sulfinate,[6] σ-bonded organo ligands,[7] and P-bonded phosphonate ligands[8] which exert a significant labilizing effect on the trans ligand. By comparing activation enthalpies, Stranks and Yandell[9] concluded that the labilizing effect of the sulfite ligand in the *trans*-aqua(or hydroxo)-bis(ethylenediamine)sulfitocobalt(III) complex arises from stabilization of the five-coordinate intermediate in the dissociative (**D**) reaction pathway. On the other hand Palmer and Deutsch attributed the trans labilizing effect of the sulfinate ligand in *trans*-bis(dimethylglyoximato)methanol(*p*-toluenesulfinato)cobalt(III) to its trans influence, that is a ground-state weakening of the trans bond.[6]

The present paper is concerned with the reactions of *trans*-$CoSO_3(Y)(AA)_2^{(1-m)+}$ with various nucleophiles X^{n-}, where AA=ethylenediamine(en) or trimethylenediamine(tn), Y^{m-}=OH^- or H_2O, and X^{n-}=Cl^-, Br^-, CH_3COO^-, NO_2^-, N_3^-, NCS^-, SO_3^{2-}, or CN^-. The equilibrium and kinetic studies of these reactions have revealed that they proceed *via* the **D** mechanism, and afforded a quantitative relationship between the electron-donating properties of X^{n-} and the formation constants of *trans*-$CoSO_3(X)(AA)_2^{(1-n)+}$.

Experimental

Preparation of Complexes. trans-*Aquabis(ethylenediamine)-sulfitocobalt(III) Perchlorate Monohydrate,* $[CoSO_3(H_2O)(en)_2]ClO_4\cdot H_2O$, was prepared by the method of Baldwin[10] and recrystallized twice from water containing sodium perchlorate and a trace amount of perchloric acid. It contained one molecule of crystalline water contrary to Baldwin's anhydrous compound. Found: C, 12.17; H, 5.10; N, 14.55%. Calcd for $C_4H_{20}N_4O_9SClCo$: C, 12.17; H, 5.11; N, 14.20%.

trans-*Aquasulfitobis(trimethylenediamine)cobalt(III) Perchlorate Monohydrate,* $[CoSO_3(H_2O)(tn)_2]ClO_4\cdot H_2O$, was prepared by a similar method. The compound $CoCl(SO_3)(tn)_2\cdot H_2O$[11] (14 g) was dissolved in a dilute perchloric acid solution (pH=4) and a trace amount of insoluble material was filtered off. About three times molar amount of sodium perchlorate was added to this solution and the mixture was kept standing at 0 °C in the dark to give light brown thin crystals. The precipitate was filtered off, washed with ethanol and acetone successively, and dried over silica gel. The yield was 43% (7.4 g), and the compound was recrystallized twice from water containing sodium perchlorate and a trace amount of perchloric acid. Found: C, 16.91; H, 5.65; N, 13.22%. Calcd for $C_6H_{24}N_4O_9SClCo$: C, 17.05; H, 5.72; N, 13.25%.

trans-*Aquasulfitobis(trimethylenediamine)cobalt(III) Nitrate Hemihydrate,* $[CoSO_3(H_2O)(tn)_2]NO_3\cdot 1/2H_2O$, was derived from the perchlorate. The perchlorate (1 g) was dissolved in cold water (7 ml), and treated with a slightly excess amount of pulverized silver nitrate. After filtration of silver chloride, two drops of concentrated nitric acid, 0.3 g of ammonium nitrate and 50 ml of ethanol were added to the solution and the mixture was kept in a refrigerator. A light brown precipitate was recrystallized twice from ethanol–water (5:1 by volume), washed with ethanol and acetone successively, and then air-dried. The yield was 18% (0.2 g). Found: C, 19.06; H, 6.27; N, 18.62%. Calcd for $C_6H_{23}N_5O_{7.5}SCo$: C, 19.15; H, 6.16; N, 18.61%.

Sodium Disulfitobis(trimethylenediamine)cobaltate(III) Trihydrate, $Na[Co(SO_3)_2(tn)_2]\cdot 3H_2O$, was prepared by a previous method.[11] Found: C, 16.06; H, 6.09; N, 12.48%. Calcd for $C_6H_{26}N_4O_9S_2CoNa$: C, 16.22; H, 5.90; N, 12.61%.

All the nucleophilic reagents are sodium salts of A. R. grade.

Measurements. The ionic strength was adjusted with sodium perchlorate to 1.00 M. The hydrogen ion concentration was determined by means of a Beckman "Century" SS-1 pH meter with a Beckman 39301 glass electrode and a Beckman 39402 B-4U calomel electrode. A saturated solution of sodium chloride was employed in place of potassium chloride for the calomel electrode in order to prevent precipitation of potassium perchlorate, and a 4.302×10^{-3} M solution of perchloric acid (μ=1.00 M) was used as a reference solution.

Absorption spectra were recorded on a Hitachi EPS-3T spectrophotometer and NMR spectra on a JOEL C-60 HL

spectrometer. IR spectra were measured in Nujol with JASCO IR-E (4000—600 cm^{-1}) and Hitachi EPI-L (700—200 cm^{-1}) Infrared Spectrophotometers. Reactions were followed by the stopped-flow method with a Union Stopped-Flow, Rapid-Scan Spectrophotometer RA-1300.

Results

Characterization of the Aqua Sulfitobis(trimethylenediamine)-cobalt(III) Complex. The IR spectrum of $[CoSO_3(H_2O)(tn)_2]ClO_4\cdot H_2O$ in Nujol shows a single sharp band at 899 cm^{-1} which is assigned to the CH_2 rocking vibration, suggesting a trans structure.[12] The proton NMR spectrum in a 0.3 M D_2SO_4–D_2O solution at 25 °C displays three signals at 1.73 (4H), 2.59 (8H), and 3.67 (8H) ppm from DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate). They are assigned to the β-CH_2, α-CH_2, and NH_2 protons, respectively, of the trimethylenediamine ligands $NH_2CH_2(\alpha)CH_2(\beta)CH_2(\alpha)NH_2$. Usually the amine protons in a *trans*-bis(diamine)cobalt(III) complex resonate as a single peak, whereas those in a *cis* isomer exhibit two bands.[13,14] The trans structure of $CoSO_3(H_2O)(tn)_2^+$ is thus supported by the NMR data, too.

In order to inspect IR spectra in the 1200—1000 cm^{-1} region, the perchlorate anion in the outer sphere, which has absorption in this region, was replaced by the nitrate ion. $[CoSO_3(H_2O)(tn)_2]NO_3\cdot 1/2H_2O$ shows absorption bands assignable to the sulfite ligand at 1120(s), 1092(s, br), 980(vs), 628(vs, br), and 524(sh) cm^{-1}. The frequencies are higher as compared with those of free sulfite ion, suggesting S-bonding to the cobalt atom.[15] The S-bonding of the sulfite ligands has been ascertained by X-ray analysis for $[CoSO_3(NH_3)_5]Cl\cdot H_2O$,[16] *trans*-$[CoSO_3(H_2O)(en)_2]ClO_4\cdot H_2O$,[17] *trans*-$[CoSO_3(H_2O)$(quarterpyridine)$]NO_3\cdot H_2O$,[18] and *trans*-$[CoSO_3(NCS)(en)_2]\cdot 2H_2O$.[19]

Equilibrium Studies. The pK_a value of *trans*-$CoSO_3(H_2O)(en)_2^+$ was reported by Stranks and Yandell to be 9.45 at 25 °C.[9] Now pK_a of *trans*-$CoSO_3(H_2O)(tn)_2^+$ was determined to be 9.10 ± 0.05 at 25.0 °C and $\mu=$ 1.00 M from the customary acid-base titration curve using 0.05 M NaOH as the base titrant.

$$trans\text{-}CoSO_3(H_2O)(AA)_2^+ \rightleftharpoons trans\text{-}CoSO_3(OH)(AA)_2 + H^+ \quad (1)$$

Equilibrium constants of the anation reactions of $CoSO_3(H_2O)(AA)_2^+$ with various ligands (X^{n-}) spanned many orders of magnitude, and were measured by the following three methods at 25.0 °C and $\mu=1.00$ M. The complex concentration was kept much smaller as compared with $[X^{n-}]$ in the case of (i) and (ii), and with $[OH^-]$ in (ii) and (iii).

(i) Substitution with Chloride, Bromide and Acetate Ions: Anation reactions of *trans*-$CoSO_3(H_2O)(en)_2^+$ with chloride at pH 3.46, bromide at pH 3.45 and acetate ions at pH 3.19—5.01,[20] and of *trans*-$CoSO_3(H_2O)(tn)_2^+$ with these anions at pH 3.40, 4.45, and 3.84—4.90,[20] respectively, proceed to attain equilibria

$$trans\text{-}CoSO_3(H_2O)(AA)_2^+ + X^{n-} \rightleftharpoons trans\text{-}CoSO_3(X)(AA)_2^{(1-n)+} + H_2O. \quad (2)$$

The spectral change in either case exhibits isosbestic points at 223, 247, and 276 nm (Cl^-); 255 and 286 nm (Br^-); 241 and 269 nm (CH_3COO^-) in the case of the en complex, and at 236, 257, and 283 nm (Cl^-); 265 and 290 nm (Br^-); 242, 254, and 274 nm (CH_3COO^-) for the tn complex.

The equilibrium constant of each reaction is expressed by

$$K^X_{H_2O} = \frac{[RX]}{[ROH_2][X^{n-}]} = \left(\frac{A-A_{ROH_2}}{A_{RX}-A}\right)\frac{1}{[X^{n-}]}, \quad (3)$$

where RX and ROH_2 denote *trans*-$CoSO_3(X)(AA)_2^{(1-n)+}$ and *trans*-$CoSO_3(H_2O)(AA)_2^+$, respectively, and A is the absorbance of a solution equilibrated at given concentrations of the complex (c_M) and X^{n-}(c_X), and $A_{ROH_2}=\varepsilon_{ROH_2}c_M$, $A_{RX}=\varepsilon_{RX}c_M$. All quantities except $K^X_{H_2O}$ and ε_{RX} are observable, since $[X^{n-}]=c_X$ when $c_X \gg c_M$. Eq. 3 is transformed into

$$\frac{1}{A-A_{ROH_2}} = \frac{1}{A_{RX}-A_{ROH_2}} + \frac{1}{(A_{RX}-A_{ROH_2})K^X_{H_2O}}\cdot\frac{1}{[X^{n-}]}. \quad (4)$$

By plotting the left side tem against $[X^{n-}]^{-1}$, a straight line is obtained for each reaction (Eq. 2), and values of the equilibrium constant $K^X_{H_2O}$ and the molar extinction coefficient ε_{RX} of the anation product are calculated from the slope and intercept of the straight line. The results are included in Table 1.

(ii) Substitution with Azide, Nitrite, Thiocyanate, and Sulfite Ions: Basic solutions are suitable for investigation of these reactions, which are reversible and exhibit the following isosbestic points: 455 nm(NO_2^-), 486 and 556 nm (NCS^-) for AA=en and 474 nm (NO_2^-), 391, 402, and 507 nm (NCS^-), 498 nm(SO_3^{2-}) for AA=tn. In the reactions with azide ions no isosbestic points were observed in the 340—700 nm region.

$$trans\text{-}CoSO_3(OH)(AA)_2 + X^{n-} \rightleftharpoons trans\text{-}CoSO_3(X)(AA)_2^{(1-n)+} + OH^- \quad (5)$$

The equilibrium constant K^X_{OH} of Reaction 5 is defined by

$$K^X_{OH} = [RX][OH^-]/[ROH][X^{n-}], \quad (6)$$

where ROH stands for *trans*-$CoSO_3(OH)(AA)_2$. In a similar manner to Eq. 4, the spectral data are related to K^X_{OH} and ε_{RX} by Eq. 7, of which values are included in Table 1.

$$\frac{1}{A-A_{ROH}} = \frac{1}{A_{RX}-A_{ROH}} + \frac{1}{(A_{RX}-A_{ROH})K^X_{OH}}\cdot\frac{[OH^-]}{[X^{n-}]} \quad (7)$$

(iii) Substitution with Cyanide Ion: In a basic solution, the reversible replacement by the cyanide ion also proceeds according to Eq. 5, and the spectral change displays isosbestic points at 364, 380 and 440 nm in the case of the en complex and at 366, 396 and 456 nm for the tn complex. Since the values of K^{CN}_{OH} are large enough to complete reactions in the presence of excessive cyanide, the molar extinction coefficients ε_{RX} of *trans*-$CoSO_3(CN)(AA)_2$ were determined under these conditions. Then the equilibrium constant K^X_{OH} was calculated by Eq. 6 using

$$[RX] = (A-\varepsilon_{ROH}c_M)/(\varepsilon_{RX}-\varepsilon_{ROH}),$$
$$[ROH] = (\varepsilon_{RX}c_M-A)/(\varepsilon_{RX}-\varepsilon_{ROH}),$$
$$[X^{n-}] = c_X - [RX],$$

Table 1. Equilibrium constants for the substitution reactions of *trans*-$CoSO_3(H_2O)(AA)_2^+$ and *trans*-$CoSO_3(OH)(AA)_2$ with nucleophiles X^{n-} at 25.0 °C and μ=1.00 M ($NaClO_4$)

where c_X is the total concentration of cyanide ions.

The equilibrium constants $K^X_{H_2O}$ and K^X_{OH} can be converted into each other by virtue of the interrelation

$$\log K^X_{H_2O} = \log K^X_{OH} - pK_a - \log K_w, \quad (8)$$

and are collected in Table 1. Here, log K_w=−13.80 at 25.0 °C and μ=1.00 M($NaClO_4$).[21]

Kinetic Studies. The substitution Reaction 5 was followed spectrophotometrically by the stopped-flow method. Azide, nitrite, thiocyanate, sulfite and cyanide ions were used as the nucleophile X^{n-}, and the reaction with sulfite ion was studied only with the trimethylenediamine complex, since the corresponding reaction with the ethylenediamine complex was previously reported by Stranks and Yandell.[9]

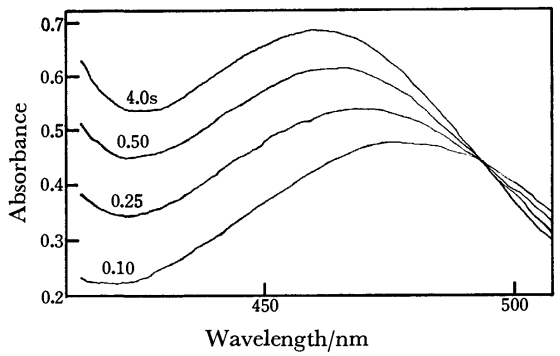

Fig. 1. The spectral change in the course of reaction between *trans*-$CoSO_3(OH)(tn)_2$ and SO_3^{2-} at 23.0 °C and μ=1.00 M ($NaClO_4$) with c_M=2.990×10^{-3} M, $c_{Na_2SO_3}$=0.116 M and c_{OH}=33.59×10^{-3} M. The reaction is in equilibrium after 4 s.

As an example of the results, the spectral change during the reaction of *trans*-$CoSO_3(OH)(tn)_2$ with sulfite is displayed in Fig. 1. The reaction attains an equilibrium 4 s after the commencement and an isosbestic point is observed at 494 nm which nearly coincides with that observed in the equilibrium study (498 nm). Concentrations of sulfite and hydroxide ions were both varied in the region of large excess over the complex. In the case of other nucleophiles, on the other hand, [OH^-] was kept constant and only [X^{n-}] was changed. In either case the plot of log $|A_\infty - A_t|$ against time gave a straight line over about 90% conversion.

Figures 2 and 3 show that the pseudo first order rate constant k_{obsd} increases linearly with [X^{n-}]/[OH^-] in conformity with the equation

$$k_{obsd} = k_f([X^{n-}]/[OH^-]) + k_r. \quad (9)$$

Ligand substitution reactions of several cobalt(III) sulfite complexes have been reported to proceed *via* the **D** mechanism,[5,9] and the present rate Eq. 9 is also compatible with the following reversible **D** mechanism.

$$\textit{trans}\text{-}CoSO_3(OH)(AA)_2 \underset{k_{OH}}{\overset{k_{-OH}}{\rightleftharpoons}} CoSO_3(AA)_2^+ + OH^- \quad (10)$$

$$CoSO_3(AA)_2^+ + X^{n-} \underset{k_{-X}}{\overset{k_X}{\rightleftharpoons}} \textit{trans}\text{-}CoSO_3(X)(AA)_2^{(1-n)+} \quad (11)$$

Assuming that the stationary state approximation is applicable to the five-coordinate intermediate $CoSO_3(AA)_2^+$, then

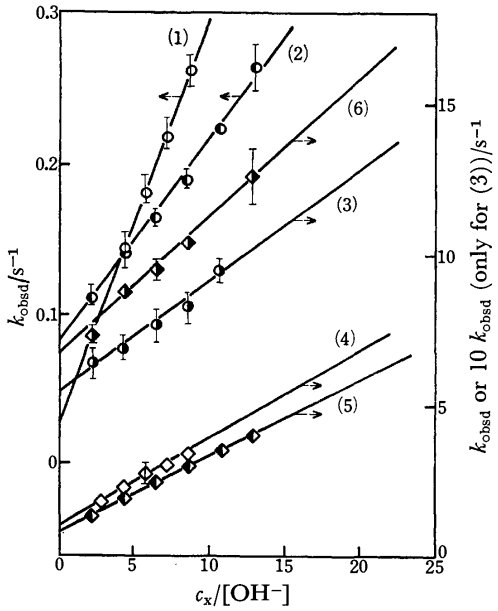

Fig. 2. Linear plots of the pseudo first order rate constants k_{obsd} for attaining the equilibrium, *trans*-$CoSO_3(OH)(AA)_2+X^{n-}\rightleftharpoons$*trans*-$CoSO_3(X)(AA)_2^{(1-n)+}+OH^-$ at 25.0 °C and $\mu=1.00$ M ($NaClO_4$) against $c_X/[OH^-]$. Lines 1 (NCS^-), 2 (NO_2^-) and 3 (N_3^-) are for the en complex, and 4 (NCS^-), 5 (NO_2^-) and 6 (N_3^-) are for the tn complex. $[OH^-]=0.0353$ M and $c_M=(1.500—1.657)\times10^{-3}$ M.

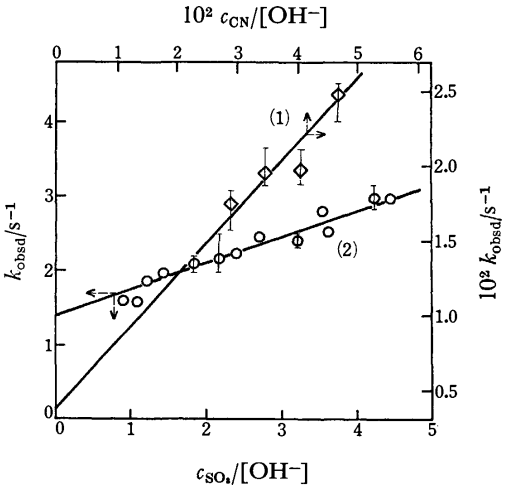

Fig. 3. Linear plots of the pseudo first order rate constants k_{obsd} for attaining the equilibrium, *trans*-$CoSO_3(OH)(tn)_2+X^{n-}\rightleftharpoons$*trans*-$CoSO_3(X)(tn)_2^{(1-n)+}+OH^-$ at 25.0 °C and $\mu=1.00$ M ($NaClO_4$) against $c_X/[OH^-]$, 1: $X^{n-}=CN^-$, $[OH^-]=0.03530$ M and $c_M=2.08\times10^{-5}$ M; 2: $X^{n-}=SO_3^{2-}$, $[OH^-]=0.02203$—0.08089 M, and $c_M=1.500\times10^{-3}$ M. Each point represents an average of at least five measurements.

$$k_{obsd}=\frac{k_Xk_{-OH}[X^{n-}]+k_{OH}k_{-X}[OH^-]}{k_{OH}[OH^-]+k_X[X^{n-}]}. \quad (12)$$

If $k_{OH}[OH^-]\gg k_X[X^{n-}]$ over the concentration range employed, Eq. 12 is reduced to

$$k_{obsd}=\frac{k_Xk_{-OH}}{k_{OH}}\frac{[X^{n-}]}{[OH^-]}+k_{-X}, \quad (13)$$

which is of the same form as Eq. 9, leading to

$$k_f=k_Xk_{-OH}/k_{OH},\quad k_r=k_{-X}. \quad (14)$$

In Table 2 are listed values of k_f, k_r, and the equilibrium constant for Reaction 5 which is calculated by

$$(K_{OH}^X)_{kin}=k_f/k_r,$$

and is to be compared with K_{OH}^X determined at the equilibrium state.

The reaction of *trans*-$CoSO_3(OH)(tn)_2$ with sulfite was studied at several temperatures other than 25.0 °C to obtain the rate data listed in Table 3. Eyring plots of k_f and k_r afforded good straight lines leading to $\Delta H^*=16.7\pm0.4$ kcal·mol^{-1} and $\Delta S^*=-2.1\pm1.2$ cal·K^{-1}·mol^{-1} for the dissociation of a sulfite ion from *trans*-$Co(SO_3)_2(tn)_2^-$.

For the reaction of *trans*-$CoSO_3(OH)(en)_2$ with cyanide, the equilibrium constant is so large and the rate is so small that determination of the forward and

backward rates in the above manner was difficult. Alternatively the cyanide concentration was kept in large excess to render the reaction irreversible. In this case the pseudo first order rate constant is expressed by

$$k_{obsd} = k_{CN}k_{-OH}[CN^-]/(k_{OH}[OH^-]+k_{CN}[CN^-]), \quad (15)$$

which is transformed into

$$\frac{1}{k_{obsd}} = \frac{1}{k_{-OH}} + \frac{k_{OH}}{k_{CN}k_{-OH}}\left(\frac{[OH^-]}{[CN^-]}\right). \quad (16)$$

A plot of the observed rate data according to Eq. 16

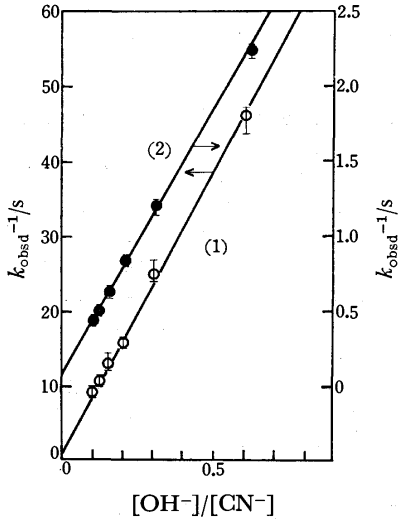

Fig. 4. The plot of $1/k_{obsd}$ *vs.* $[OH^-]/[CN^-]$ for the reaction *trans*-$CoSO_3(OH)(AA)_2+CN^-\rightarrow$*trans*-$CoSO_3(CN)(AA)_2+OH^-$ at 25.0 °C and $\mu=1.00$ M ($NaClO_4$). 1: AA=en, $[OH^-]=0.03656$ M and $c_M=4.485\times10^{-4}$ M. 2: AA=tn, $[OH^-]=0.03657$ M and $c_M=4.400\times10^{-4}$ M.

gave a straight line displayed in Fig. 4, which also contains another plot for the reaction of *trans*-$CoSO_3(OH)(tn)_2$ performed in a similar condition for the sake of comparison. The intercepts and slopes of these straight lines gave the following constants: $k_{-OH}=1.19\pm0.81$ s^{-1}(AA=en) and 13.9 ± 2.7 s^{-1}(AA=tn), $k_{CN}/k_{OH}=(1.12\pm0.80)\times10^{-2}$(AA=en) and $(2.02\pm0.42)\times10^{-2}$(AA=tn) at 25.0 °C and $\mu=1.00$ M. Furthermore, by combining the value of slope $k_{OH}/k_{CN}k_{-OH}$ with that of the equilibrium constant K_{OH}^{CN} listed in Table 1, k_{-CN} was calculated to be $(2.41\pm0.23)\times10^{-5}$ s^{-1} for the en complex. The value of $k_f=k_{CN}k_{-OH}/k_{OH}=0.280\pm0.004$ s^{-1} for the tn complex, which was calculated from the slope of the straight line (2) in Fig. 4, nearly coincides with that obtained in the reversible condition (Table 2).

Division of the k_f value in Table 2 by $k_{-OH}=1.19\pm0.81$ (AA=en) or 13.9 ± 2.7 (AA=tn) s^{-1} affords k_X/k_{OH} (*cf.* Eq. 14) which is shown in Table 4. The ratio indicates that the nucleophilic reactivity of hydroxide ion toward $CoSO_3(AA)_2^+$ is 30—90 times larger than that of other nucleophiles examined. The hydroxide ion was also reported to be at least 4×10^5 times more reactive than H_2O toward $CoSO_3(en)_2^+$,[9] and 8×10^3 times more reactive than NH_3 toward $CoSO_3(NH_3)_4^+$.[22] It was suggested[5a] that the high reactivity of OH^- might reflect a Grotthus-type mechanism.

Discussion

Linear Free Energy Relations (LFER) have been widely used to sort out the various factors that contribute to the rate and equilibrium of organic[23] and inorganic[24] reactions. On the supposition that nucleophilic character of a reagent is a combination of several factors, Edwards proposed an equation

$$\log(K/K_0) = \alpha E_n + \beta H, \quad (17)$$

where K and K_0 are the rates or equilibrium constants of reactions of a particular substrate with a nucleophile and water, respectively, α and β are two substrate constants, and E_n and H are electron donor constant and basicity constant, respectively.[25] Recently Tanaka related the formation constant K_{ML}^L of a complex ML with the Edwards' parameters by

$$\log K_{ML}^L = \log K_{os(M,L)} + \alpha E(L) + \beta H(L), \quad (18)$$

where $K_{os(M,L)}$ denotes the formation constant of an outer-sphere complex [M, L].[26]

Equation 18 was derived on the basis of the Eigen

Table 4. The rate of X^{n-} release (k_{-X}) from *trans*-$CoSO_3(X)(AA)_2^{(1-n)+}$ and the reactivity ratio of X^{n-} and OH^- (k_X/k_{OH}) toward $CoSO_3(AA)_2^+$ at 25.0 °C and $\mu=1.00$ M ($NaClO_4$)

($\mathbf{I_d}$) mechanism, the rate of dissociation of the ligand L from the complex ML being assumed to be inversely proportional to both the electron donating property and the Brønsted basicity of the leaving group L. The present reactions, on the other hand, are presumed to proceed *via* the **D** mechanism and contribution of the outer-sphere complex as in Eq. 18 need not be considered.

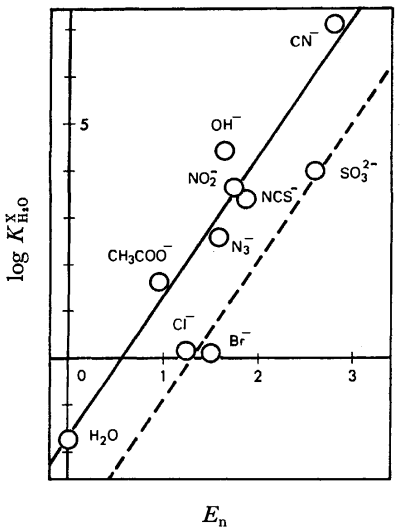

Fig. 5. A plot of log $K^X_{H_2O}$ for Reaction 2 (AA=en) against the electron donor constant E_n of X^{n-}.

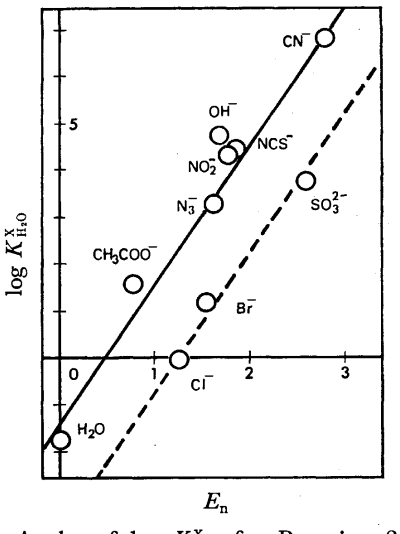

Fig. 6. A plot of log $K^X_{H_2O}$ for Reaction 2 (AA=tn) against the electron donor constant E_n of X^{n-}.

In Figs. 5 and 6 are plotted log $K^X_{H_2O}$ (Eq. 3) against E_n of a nucleophile X^{n-}. For both the en and tn complexes LFER holds and data for the ligands containing O, N, or C as donor atom lie on a straight line in conformity with

$$\log K^X_{H_2O} = \alpha E_n + \gamma. \quad (19)$$

The value of substrate constant α is nearly the same for the en(3.0) and tn(2.9) complexes, indicating the similarity of the two complexes in the electron-donor discrimination. The value of intercept γ is -1.6 for the en complex and -1.4 for the tn complex, both being near to $\log K^{H_2O}_{H_2O} = -\log [H_2O] = -1.74$ which is obtained by merely substituting X^{n-} in Eq. 3 with H_2O. Thus Eq. 19 coincides with Eq. 17 under the conditions of $\beta=0$, indicating that the $CoSO_3(AA)_2^+$ moiety is soft enough to render the stability constant of *trans*-$CoSO_3(X)(AA)_2^{(1-n)+}$ depend not on the Brønsted basicity but on the electron donating property of X^{n-}. In fact the set of values of α and β for $CoSO_3(AA)_2^+$ (3.0, 0) is comparable with those for Ag^+ (3.60, -0.09), Cu^+ (3.92, 0.18), and CH_3Hg^+ (4.21, 0.11)[27] which are typically soft according to Pearson's classification.[28] Usually Co(III) is hard, but in the present compounds the sulfite ion is soft and makes Co(III) prefer a soft ligand at the sixth coordination site trans to SO_3^{2-}. This may be an example of chemical symbiosis proposed by Jørgensen.[29]

In Figs. 5 and 6 Cl^-, Br^-, and SO_3^{2-} remarkably deviate from the straight line established by the other ligands, and lie on another straight line (dotted) paralleling the former. Such a behavior can not be rationalized at the present stage of investigation. Tanaka[26,30] succeeded in estimating the formation constant of a mixed ligand complex MAL and a $1:n$ complex ML_n by introducing additional terms $\sum_i\sum_j \delta_{ij}X_i(A)Y_j(L)$ into Eq. 18 in order to take into account the effect of interaction between donor atoms X_i and Y_j in the coexisting ligand and entering one. In the present case effect of the nitrogen atoms in en and tn on the O, N, or C atom in the entering ligand might be similar, but that on the Cl, Br, or S atom might be much larger in the repulsive sense partly because of the larger size of the latter donor atoms (the atomic radius: N=0.74, C=0.772, O=0.74, S=1.04, Cl=0.99, Br=1.14 Å[31]). A similar situation is also noticed when we correlate the equilibrium constants for the substitution of H_2O

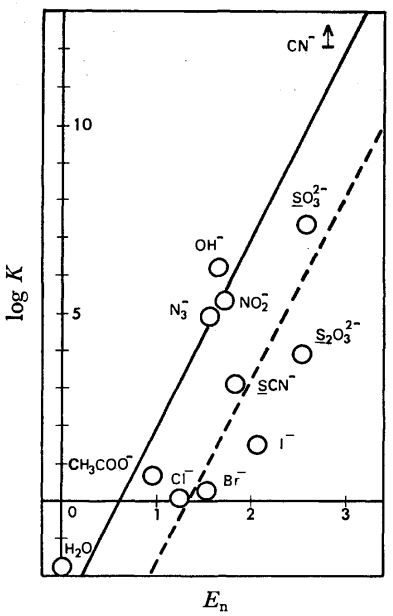

Fig. 7. Relation of the equilibrium constant K for anation of aquacobalamin with the electron donor constant E_n of a nucleophile. Data from Ref. 32 are plotted.

in aquacobalamin which were determined by Pratt and his collaborators[32] with the E_n value of each nucleophile (Fig. 7).

In a previous paper[33] it was reported that the rate of nitrite release from $Co(NO_2)_4(tn)^-$ is 4.5 times and the rate of aqua ligand release from $Co(NO_2)_3(H_2O)(tn)$ is 7.2 times larger than those of the corresponding en complexes. Now Table 4 indicates that the ratio $(k_{-X})_{tn}/(k_{-X})_{en}$ for *trans*-$CoSO_3(X)(AA)_2^{(1-n)+}$ amounts to 10—25 except for the cyano complex. The larger kinetic ring-size effect in the present case may be due to the increase in number of the chelate ring. The enthalpy of activation for the sulfite release from *trans*-$Co(SO_3)_2(en)_2^-$ was reported[9] to be 20.5 ± 0.6 kcal·mol^{-1} and that for the corresponding reaction of *trans*-$Co(SO_3)_2(tn)_2^-$ was now obtained as 16.7 ± 0.4 kcal·mol^{-1}. Holmes and Williams determined the thermodynamic functions of the copper(II) and nickel(II) complexes of en and tn.[34] In either case the en complex is more stable than the tn complex, and the difference in the enthalpy of formation of $M(en)_2(H_2O)_2^{2+}$ and $M(tn)_2(H_2O)_2^{2+}$ amounts to 2.69 kcal·mol^{-1} in the case of the Cu(II) complex and 3.85 kcal·mol^{-1} for Ni(II). A similar amount of excess ground-state stabilization may be offered to *trans*-$Co(SO_3)_2(en)_2^-$ as compared with *trans*-$Co(SO_3)_2(tn)_2^-$ and may be responsible for the excess $\Delta H^{\neq}$ of 3.8 kcal·mol^{-1}. Thus the kinetic ring-size effect seems to stem from the energy difference at the ground state. This is the same conclusion as that drawn in a previous paper.[33]

The cyanide release from *trans*-$CoSO_3(CN)(tn)_2$ is 149 ± 80 times faster than from the corresponding en complex (Table 4). An enormous difference in the aquation rate of the en and tn complexes of the type *trans*-$CoBr_2(AA)_2^+$ and *trans*-$CoCl_2(AA)_2^+$ has previously been reported, $k(tn)/k(en)$ being 680[35] and 1666[36] at 25 °C, respectively. The $k(tn)/k(en)$ for the *trans*→*cis* isomerization of $Co(H_2O)_2(AA)_2^{3+}$ was also recorded as 1450, while the rate ratio for the similar isomerization of $Co(OH)_2(AA)_2^+$ was only 13.[35] Reasonable explanation for these abnormal kinetic ring-size effect is quite difficult.

The authors wish to thank Mr. Junichi Gohda for the elemental analysis and are also grateful to the Ministry of Education for Grant-in-Aid.

(Received January 23, 1978)

As a part of potentiometric studies of the complexing of univalent cations in acetonitrile with other solvents by the use of a cation-sensitive glass electrode, investigations were carried out of the complexing of the ammonium ion in acetonitrile with such solvents as water, methanol, *N*-methylformamide, *N,N*-dimethylformamide, *N,N*-dimethylacetamide, dimethyl sulfoxide, 1-methyl-2-pyrrolidone, and hexamethylphosphoric triamide, and also with dibenzo-18-crown-6. Prior to the study of the complexing, the cation-sensitive glass electrode was confirmed to respond in a Nernstian way to the change in the ammonium-ion activity which occurs due to the change of the solvent (solvent effect). The ammonium ion in acetonitrile formed complexes of mono- and di-solvated species with methanol and water. Formations of up to tri-solvated species were formed with DMF, DMA, and DMSO, and up to tetra-solvated species with 1-methyl-2-pyrrolidone and NMF. With HMPA, even penta-solvated species were formed. The complex formation constants of the mono-solvated ammonium ion, β_1 (mol^{-1} dm^3), were 1.$_7$ with methanol, 5.6 with DMF, 14 with DMSO, 17 with DMA, 31 with 1-methyl-2-pyrrolidone, 3.0×10^2 with NMF, and 1.2×10^3 with HMPA. The association constant of ammonium perchlorate in acetonitrile was determined conductometrically to be 25 mol^{-1} dm^3.

Recently, the complexing of univalent cations with other solvents has been investigated in acetonitrile (AN) by using such techniques as nuclear magnetic resonance,[1] infrared spectroscopy,[2] conductometry,[3] and potentiometry,[4-6] but few reports have appeared concerning the complexing of the ammonium ion in acetonitrile. In the present paper, we have studied the complexing of the ammonium ion in acetonitrile with other dipolar solvents, such as water, methanol, *N*-methylformamide (NMF), *N,N*-dimethylformamide (DMF), *N,N*-dimethylacetamide (DMA), dimethyl sulfoxide (DMSO), 1-methyl-2-pyrrolidone, and hexamethylphosphoric triamide (HMPA), and with dibenzo-18-crown-6, by using a potentiometric method similar to that used in the previous reports.[4-6] The emf of the following cell was measured:

Ag|0.005 M $AgNO_3$, 0.01 M Et_4NClO_4(AN)‖
0.1 M Et_4NClO_4(AN)‖10^{-3} M NH_4ClO_4,
0.01 M Et_4NClO_4(AN+D)|Cation-sensitive
Glass Electrode ··· Cell I

where D denotes the solvents added and where M=mol dm^{-3}. The formation constants, β_x in $(mol^{-1}\ dm^3)^x$, for Reaction 1 were obtained by analyzing the emf data under assumptions similar to those in the previous reports.[4-6]

$$NH_4^+{}_s + xD = NH_4^+{}_{xD} \quad (1)$$

$$\beta_x = \frac{(NH_4^+{}_{xD})}{(NH_4^+{}_s)[D]^x} \quad (2)$$

In Eq. 1, $NH_4^+{}_s$ shows ammonium ions solvated only with acetonitrile and $NH_4^+{}_{xD}$ those complexed by molecules of D in AN+D. In Eq. 2, $(NH_4^+{}_s)$ and $(NH_4^+{}_{xD})$ are the activities, and [D], the concentration, of the respective species in the molar scale.

Experimental

Apparatus. Most of the apparatus and experimental techniques used for the potentiometric determination of the complex formation constants were the same as those in the previous reports.[4-6] A Horiba No. 1826A-05T glass electrode was used to determine the acid dissociation constant of the pyridinium ion in acetonitrile. The conductance was measured with a universal bridge model 4255A of the Yokogawa-Hewlett-Packard Co., Ltd. Polarograms were measured with a three-electrode polarograph, Yanagimoto P8-PS. All these measurements were carried out at 25 °C.

Reagents. The ammonium perchlorate was prepared by introducing ammonia into a solution of perchloric acid, purified by recrystallizing from water, and dried *in vacuo* at 110 °C. The pyridinium perchlorate was prepared by passing evaporated pyridine into an aqueous solution of perchloric acid and purified by recrystallizing it from ethanol. It was dried at room temperature under a high vacuum with P_2O_5. The dibenzo-18-crown-6, which has been prepared by the method of Pedersen,[7] was recrystallized from chloroform. The 1-methyl-2-pyrrolidone was a product of Wako Chemicals Co., Ltd., and was purified according to the method of Sears *et al.*[8] The DMA[9] was purified by distillation, first from BaO, next from CaH_2, and finally without any additives. The other solvents and reagents used in this experiment were the same as those described in the previous reports.[4-6]

Results

Response of the Cation-sensitive Glass Electrode to the Activity of the Ammonium Ion. The cation-sensitive glass electrode used in this study showed a response of a slope of 56 mV for the ammonium-ion concentration between 10^{-2} and 10^{-4} M in acetonitrile − 0.01 M Et_4NClO_4. If correction is made for the change in the salt-effect activity coefficient, which is calculated by using the Debye-Hückel equation: $\log f = -AI^{1/2}/[1+BaI^{1/2}]$, assuming $A=1.64$ $mol^{-1/2}$ $dm^{3/2}$, $B=4.86\times10^8$ $mol^{-1/2}$ $dm^{1/2}$, and $a=5\times10^{-8}$ cm, the slope of the response to $pa_{NH_4^+}$ becomes 58.5 mV, which is very near to the Nernstian slope of 59.16 mV.

In order to confirm that the glass electrode also

responds to the change in the activity of the ammonium ion due to the solvent effect, the emfs of Cell II were measured in various solvents, D, and were compared with the polarographic half-wave potentials of the ammonium ion, which were measured in 10^{-3} M NH_4ClO_4–0.01 M Et_4NClO_4(D) by using a salt bridge and a reference electrode similar to those in Cell II.

Ag|0.005 M $AgNO_3$, 0.01 M Et_4NClO_4(AN)‖
0.1 M Et_4NClO_4(AN)‖10^{-3} M NH_4ClO_4,
0.01 M Et_4NClO_4(D)|Cation-sensitive Glass Electrode ··· Cell II

(D denotes AN, DMF, DMA, and DMSO)

The results are shown in Fig. 1. For D solvents such as acetonitrile, DMF, DMA, and DMSO, the values on the abscissa agree fairly well with the values on the coordinate. Because the polarographic behavior of the ammonium ion is nearly reversible in these solvents, these results can be considered to confirm the Nernstian response of the glass electrode to the effect of the solvent on the activity of the ammonium ions. For other solvents, the polarographic behavior of the ammonium ion was not reversible or did not give a well-defined wave, and so a comparison as in Fig. 1 was impossible. However, it would be reasonable to assume that even in these solvents the glass electrode can respond in a Nernstian way to the effect of the solvent on the ammonium-ion activity.

Complexing of the Ammonium Ion in Acetonitrile with Other Solvents. From the emf measurement of Cell I, the values of the complex formation constants of the ammonium ion in acetonitrile with other solvents, such as water, methanol, NMF, DMF, DMA, DMSO, 1-methyl-2-pyrrolidone, and HMPA, were obtained by the method used in the previous papers.[4-6] The results are summarized in Table 1. The values of β_1 in Table 1 seem to be reliable within $\pm 10\%$ for aprotic solvents. However, for β_1 in the cases in which D was a protic solvent and for β_2 to β_5, the reliability seems to be somewhat less because of the deviations from the ideal conditions assumed in calculating these values.[4] The formation constants with water are shown in parentheses

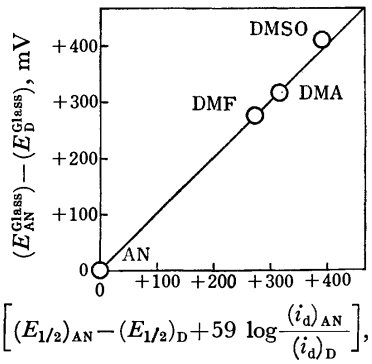

Fig. 1. Relation between the emf of Cell II and the half-wave potential of the ammonium ion in different solvents. Both referred to the values in acetonitrile.

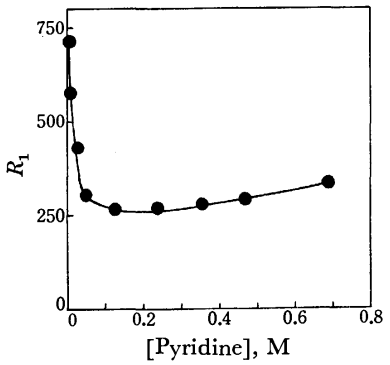

Fig. 2. The exceptional relation of R_1-[D] for the case in which D=pyridine (see text).

Table 1. Complex formation constants, β_x in $(mol^{-1}\ dm^3)^x$, of the ammonium ion in acetonitrile with other solvents and a crown ether (at 25 °C)

Ligand	Max. concn of ligand added (M)	β_1	β_2	β_3	β_4	β_5

	0.2	1.2×10^3	2.0×10^5	3.9×10^6	$4._7\times 10^7$	2×10^8
Dibenzo-18-crown-6	0.03	4.9×10^3	1.1×10^5			
	0.03	5.0×10^3	8.7×10^4			

a) See text for the values in parentheses.

in Table 1. This is because the potential of the glass electrode was not stable enough when water was titrated in Cell I. When pyridine was used as the D solvent, the relation between R_1** and the concentration of pyridine added to Cell I (Fig. 2) was peculiar and an extremely big R_1 value was obtained at a small concentration of pyridine. The complex formation constants of the ammonium ion in acetonitrile with dibenzo-18-crown-6 were determined by adding a solution of 6.25×10^{-2} M crown ether to a solution of 5×10^{-3} M NH_4ClO_4 in acetonitrile–5×10^{-2} M Et_4NClO_4. These results are also shown in Table 1.

The Acid Dissociation Constant of the Pyridinium Ion. The acid dissociation constant of the pyridinium ion (pyH^+) in acetonitrile was determined by measuring the emf of Cell III:

Ag|0.005 M $AgNO_3$, 0.01 M Et_4NClO_4(AN)‖
0.1 M Et_4NClO_4(AN)‖4×10^{-3} M $pyHClO_4$,
x M pyridine(AN)|Glass Electrode ··· Cell III

The Horiba 1826A-05T glass electrode in Cell III was calibrated in a 5×10^{-3} M picric acid–5×10^{-3} M tetraethylammonium picrate buffer solution in acetonitrile by using the pK_a value of 11.0[10] for picric acid. The pyridine concentration added to Cell III was varied from 2.00×10^{-4} to 2.74×10^{-2} M. The pa_{H^+} value was calculated by assuming a response of 59.16 mV/pa_{H^+} and the pK_a value (K_a in mol dm^{-3}) was obtained from the simple Henderson equation by making a correction for the change in the activity coefficient according to the Debye-Hückel limiting law, $-\log f=1.64\{I/(\text{mol dm}^{-3})\}^{1/2}$. As is shown in Table 2, a pK_a value of 12.60 ± 0.01 was obtained. The pK_a value was also determined in the presence of an indifferent electrolyte of 1.0×10^{-2} M Et_4NClO_4 in Cell III, a pK_a value of 12.53 was thus obtained, which is in fairly good agreement with the literature data of 12.33.[11]

Table 2. The dissociation constants of the pyridinium ion from the glass electrode measurements

[pyH^+] M×10³	[Pyridine] M×10³	E mV	log f	pa_{H^+}	$pK_a^{pyH^+}$
4.00	0.200	17.5	-0.10_4	11.40	12.60
4.00	0.500	−5.9	-0.10_4	11.80	12.60

3.99	3.83	−57.5	-0.10_4	12.67	12.59
3.98	4.78	−63.2	-0.10_4	12.77	12.59
3.98	5.73	−68.5	-0.10_3	12.86	12.60
3.97	6.68	−73.2	-0.10_3	12.94	12.61
3.97	7.65	−76.4	-0.10_3	12.99	12.60
3.95	11.5	−87.1	-0.10_3	13.17	12.61
3.92	19.2	−101.2	-0.10_3	13.41	12.62
3.89	27.4	−110.8	-0.10_2	13.57	12.62

** R_1 is obtained by the use of the relation $R_1=\{10^{(E_{AN}-E_{AN-D})/59.16}-1\}/[D]$, where E_{AN} and E_{AN-D} are the emfs of Cell I in the absence and in the presence respectively of the D solvent. In ordinary cases, the following relation holds: $R_1=\beta_1+\beta_2[D]+\beta_3[D]^2+\cdots$.[4]

Determination of the Association Constant of the Ammonium Perchlorate. The conductometric measurements of the ammonium perchlorate in acetonitrile were carried out at (25±0.01) °C at ammonium-perchlorate concentrations from 4.20×10^{-4} to 3.33×10^{-2} M. The association constant and the molar conductivity of ammonium perchlorate, obtained with the Schedolovsky equation, were 25 mol^{-1} dm^3 and 200.$_6$ S cm^2 mol^{-1} respectively. By using the molar ionic conductivity, $\lambda_0(ClO_4^-)$, of 103.7 S cm^2 mol^{-1} [12] in acetonitrile, $\lambda_0(NH_4^+)$ can be calculated to be 96.$_9$ S cm^2 mol^{-1}, which is between the λ_0 (H^+) value of 99 S cm^2 mol^{-1} [13] and the $\lambda_0(Me_4N^+)$ value of 94.5 S cm^2 mol^{-1}. [12]

Discussion

From the results in Fig. 1, it may be considered that the cation-sensitive glass electrode can respond well to the activity of the ammonium ion in solvents of different species or compositions.

The ammonium ion in acetonitrile behaves as a Lewis acid, and the complex formation constant, β_1, increases with the solvent basicity. The values in Table 1 show that the complexing of the ammonium ion in acetonitrile with other solvents is generally more extensive than in the cases of the sodium and thallium(I) ions and that it is roughly comparable to the case of the lithium ion[5]. Kolthoff and Coetzee[14] indicated, as the results of their polarographic measurements, that the free energy of the solvation of the ammonium ion is considerably larger in water than in acetonitrile. Coetzee and Padmanabhan reported similar results.[11] The complex formation constants of the ammonium ion with water are, as is shown in Table 1, fairly large and are comparable to the complex formation constants with DMF. For sodium and thallium(I) ions, on the other hand, the formation constants with water are smaller than those with DMF.[4,6]

The formation constants of the ammonium ion with dibenzo-18-crown-6 (Table 1) are considerably larger than the polarographic results of Angelis *et al.*[15] They obtained the formation constant of 3.1×10^2 in a 0.1 M tetrabutylammonium perchlorate–acetonitrile solution, but they mentioned that the validity of their value may be somewhat in doubt since the electrode-reaction kinetics of the ammonium ion may be influenced by the adsorption of the polyether complex. The existence of the 2:1 crown ether–NH_4^+ complex seems to be reasonable if we consider the fact that the Pauling crystal diameter of the ammonium ion (2.96 Å) and the diameter of the cavity of dibenzo-18-crown-6 (2.6 Å according to Corey-Pauling-Koltun atomic models and 3.2 Å according to Fisher-Hirschfelder-Taylor atomic models).[16]

When pyridine was used as the D solvent in Cell I, a peculiar change in the glass electrode potential was observed, as is shown by the R_1 value in Fig. 2. Because the acid dissociation constants of the ammonium and pyridinium ions in acetonitrile are, as pK_a values, 16.5[11] and 12.6 respectively, the NH_4^++py→NH_3+pyH^+ reaction should occur to some extent. However our attempt to explain the behavior of the glass-electrode potential in terms of the above reaction was unsuccessful.

More complicated phenomena, including homo- and hetero-conjugations between ammonium ions and pyridine, may be occurring.[11]

The association of the univalent cation under investigation with the perchlorate ion may affect, at least theoretically, the complex formation constants of the cation with other solvents.[4-6] The association constant of the ammonium perchlorate in acetnitrile, which was determined conductometrically, was *ca.* 25 mol^{-1} dm^3, somewhat smaller than that of the thallium(I) perchlorate.[17] We determined the complex formation constant of the ammonium ion in acetonitrile with DMSO in the presence of varing concentrations of Et_4NClO_4 from 0 to 0.1 M. However no appreciable change in the formation constant was observed with the change in the concentration of Et_4NClO_4. These results suggest that the association of the ammonium ion with the perchlorate ion, which was detected by conductometric measurement, does not significantly affect the potentiometric results of the formation constants of complexes between the ammonium ion and solvent molecules.

The authors wish to thank Mr. Eiji Kubota of Shinshu University for his kindness in analyzing the conductivity data with a computer. They also wish to thank the staff of the Tokyo University Computation Center and the Shinshu University Remote Batch Computation Center for the use of their computers.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 247031).

Synthesis, Reactions and Catalytic Properties of Stable Alkoxocopper, Phenoxocopper and Related Copper Complexes Containing Triphenylphosphine Ligands

Minoru KUBOTA and Akio YAMAMOTO

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received February 14, 1978)

A variety of new alkoxocopper and phenoxocopper(I) complexes containing triphenylphosphine ligands have been prepared by the reactions of methylbis(triphenylphosphine)copper(I) etherate (I) with the corresponding alcohols and phenols. The isolated complexes were characterized by elemental analysis, IR and NMR spectroscopy and chemical reactions. The reactions of the alkoxocopper and phenoxocopper complexes with alkyl halides and acyl halides or carboxylic anhydrides yield ethers and carboxylic esters, respectively. The stoichiometric exchange reactions of the alkoxo group in the alkoxocopper complexes with carboxylic esters proceed smoothly and the alkoxocopper complexes were found to act as excellent catalysts for the transesterifications between carboxylic esters and alcohols. The exchange reactions take place also between the alkoxocopper complexes and phenols or thiols producing phenoxocopper or alkylthiocopper complexes with the liberation of alcohols. Amides and nitromethane react with the alkoxocopper complexes releasing alcohols to give *N*-bonded amidocopper and *O*-bonded acinitrocopper complexes, respectively. The thermolysis of the alkoxocopper complexes in various solvents were studied and the mechanism and the factors influencing the course of thermolysis discussed.

The versatility of alkyl- and arylcopper(I) reagents in organic syntheses has been well established[1] but the utility of alkoxo- and phenoxocopper(I) complexes has been less explored.[2] There are only a few reported examples of well characterized alkoxocopper compounds. Poorly characterized copper methoxide has been reported to be thermally unstable and explosive.[3] *t*-Butoxocopper provides the most stable example amongst the known alkoxocopper compounds without ligands and the reactions of copper *t*-butoxide have been studied.[5-7] Other primary and secondary alkoxides are less stable and they have been prepared by heterogeneous reactions *in situ* and characterized only through indirect means.[8] Copper phenoxide is more stable than the alkoxide and substituted and unsubstituted phenoxocopper compounds have been prepared and utilized for ether and ester syntheses.[9] Copper(II) alkoxides, copper(II) methoxides[3a,10] and copper(II) acetylacetonate methoxide[11] are known.

The remarkable stabilizing effect of tertiary phosphines on the thermal stability of alkylcopper compounds has been reported before.[12,13] The reactions of alcohols with the alkylcopper(I) complexes having tertiary phosphine ligands led to the preparation of a variety of stable alkoxocopper(I) complexes having tertiary phosphine ligands. The stabilizing effect of the tertiary phosphine ligands was also evident in the alkoxocopper complexes which provide convenient materials for studying the properties of the synthetically useful alkoxocopper complexes and allow examination of the mechanism of thermolysis of the alkoxocopper complexes and to compare the results with the thermolysis behavior of the alkylcopper complexes. This paper describes the synthesis and properties of the alkoxocopper complexes containing triphenylphosphine.

Results and Discussion

Synthesis of Alkoxocopper(I) Complexes with Triphenylphosphine Ligands. Methylbis(triphenylphosphine)-copper etherate, $CH_3Cu(PPh_3)_2 \cdot 0.5Et_2O$ (I)[12] reacts with alcohols and phenols to give alkoxo- and phenoxocopper complexes (II—XI) containing triphenylphosphine ligands. Some complexes include diethyl ether as the solvent of crystallization.

$$CH_3Cu(PPh_3)_2 \cdot 0.5Et_2O + ROH \xrightarrow{Et_2O} ROCu(PPh_3)_m(Et_2O)_n + CH_4 \quad (1)$$

R = Me (II), Et (III), Pr^n (IV), CH_2=CH-CH_2- (V), Pr^i (VI), $PhCH_2$- (VII)

Ethylene glycol reacts at one of the hydroxyl groups producing hydroxyethoxocopper complex (VIII):

$$CH_3Cu(PPh_3)_2 \cdot 0.5Et_2O + HOCH_2CH_2OH \xrightarrow{Et_2O} HOCH_2CH_2OCu(PPh_3)_2 + CH_4 \quad (2)$$

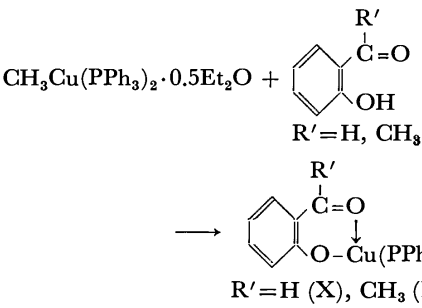
(VIII)

Phenol reacts similarly with I to give the known phenoxocopper complex prepared by different route.[9]

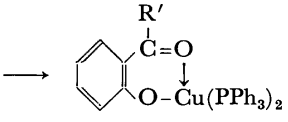
$$CH_3Cu(PPh_3)_2 \cdot 0.5Et_2O + PhOH \xrightarrow{Et_2O} PhOCu(PPh_3)_2 + CH_4 \quad (3)$$

(IX)

o-Formyl- and *o*-acetyl-substituted phenols afford six-membered chelates:



$R' = H, CH_3$



$R' = H$ (X), CH_3 (XI)

These reactions, 1—4, proceed smoothly at −10 to 0 °C evolving 1 mol equiv. of methane per mol of I to give white or yellow precipitate of II—XI in high yields.

Table 1 summarizes the yields, melting points, analytical results and molecular weights of the isolated copper complexes and Table 2 shows the relevant NMR and IR data. The alkoxocopper complexes are sensitive to oxygen and water but their thermal stabilities are substantially enhanced in comparison with the alkoxocopper compounds without triphenylphosphine as exemplified by the high melting point (dec) 65 °C of $CH_3OCu(PPh_3)_2 \cdot 0.5Et_2O$ compared with CH_3OCu which explodes on heating. The decomposition temperature of the series of alkoxocopper complexes rises with increasing alkyl chain length, a similar trend being observed in the thermal stabilities of alkylcopper complexes.[12] Albeit the alkoxocopper complexes have high decomposition temperatures in the solid state, they are less stable in solution and decompose in benzene at about 0 °C preventing the cryoscopic determination of the molecular weight in benzene. The reaction of I with ethylene glycol was expected to yield a bridged ethylene glycol derivative of copper. The molecular weight and analytical data of VIII together with the presence of the free ν(OH) band at 3300 cm^{-1} in the IR spectrum indicated that one of the two OH groups of ethylene glycol remains intact after reaction with I.

The phenoxocopper complexes showed much higher decomposition temperatures than the alkoxocopper complexes. The formation of the six-membered chelates in X and XI was deduced on the basis of the shifts of the ν(C=O) bands to lower frequencies (35 and 40 cm^{-1}) from those of the free salicylaldehyde and *o*-hydroxyacetophenone. These alkoxocopper complexes containing triphenylphosphine may also be obtained by the reaction of lithium or sodium alkoxide with bromobis(triphenylphosphine)copper, but the yield was poor and the purification of the product was more difficult than that of the complexes prepared by Eq. 1.

The phenoxocopper complex was prepared by the reaction of cuprous oxide with phenol in the presence of triphenylphosphine giving a yield of 59% based on copper.

$$Cu_2O + 2PhOH + 4PPh_3 \xrightarrow{75\,^\circ C \text{ in toluene}} 2PhOCu(PPh_3)_2 + H_2O$$
IX

The reaction required a higher temperature and a longer reaction period than the preparation starting from I.

The preparation of alkoxocopper complexes higher than butoxocopper was also attempted using I but the reaction was too slow to give the corresponding alkoxocopper complexes without the decomposition of the alkoxocopper complexes formed.

Reactions of Alkoxocopper Complexes. One of the features of the alkoxocopper complexes is the ability to exchange the alkoxo group. The alkoxo group bound to copper can be readily displaced by other components to give new organic copper complexes. The reactions appear to proceed smoothly, particularly when the product is more stable than the starting alkoxocopper complex. Thus, ethoxocopper complex III reacts with 1.5 equivalents of phenol in diethyl ether at 0 °C to

a) vs=very strong, s=strong, m=medium, w=weak.

produce the more thermally stable phenoxocopper complex IX in high yield:

$$\underset{\text{III}}{EtOCu(PPh_3)_2} + PhOH \longrightarrow \underset{\text{IX (78\%)}}{PhOCu(PPh_3)_2} + \underset{\text{(85\%)}}{EtOH}$$

Such alcohol exchange reactions have been extensively utilized in the preparation of new alkoxides of Al, Ge, Sn, Ti, Zr, Hf, Nb, Ta, Fe, La, Th, U, and Pu.[14]

Similarly thiols react smoothly with the ethoxocopper complex with the liberation of ethanol:

$$EtOCu(PPh_3)_2 + EtSH \longrightarrow \underset{\text{XII (82\%)}}{EtSCu(PPh_3)_2} + \underset{\text{(89\%)}}{EtOH}$$

An amide also is exchanged with the alkoxocopper complex quite readily. Complex III reacts with an equivalent amount of acetanilide in diethyl ether at 0 °C to produce the thermally stable (acetanilido-*N*)-bis(triphenylphosphine)copper (XIII) and ethanol:

$$EtOCu(PPh_3)_2 + PhNHCOCH_3 \longrightarrow \underset{\text{XIII (65\%)}}{\begin{matrix}Ph\\ \diagdown\\ \quad N\text{–}Cu(PPh_3)_2\\ \diagup\\ CH_3CO\end{matrix}} + \underset{\text{(72\%)}}{EtOH}$$

The ν(C=O) band in XIII was observed at 1685 cm^{-1}

with scarcely any shift from that of the free acetanilide suggesting the *N*-bonded structure.

Furthermore, the alkoxocopper complex reacts with active methylene compounds such as nitromethane and acetylacetone to afford the known complexes XIV and XV:[15,16]

$$\underset{\text{III}}{EtOCu(PPh_3)_2} + CH_3NO_2 \longrightarrow (CH_2NO_2)Cu(PPh_3)_2 + EtOH$$
$$\text{XIV (82\%)} \qquad (87\%)$$

$$EtOCu(PPh_3)_2 + Hacac \longrightarrow (acac)Cu(PPh_3)_2 + EtOH$$
$$\text{XV (74\%)} \qquad (80\%)$$

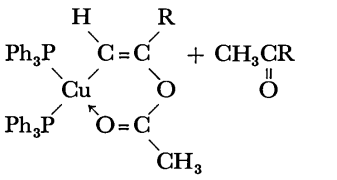
The reactive alkoxocopper complexes function as a transesterification reagent for various carboxylic esters. The reaction of the ethoxocopper complex III with methyl methacrylate, for example proceeds smoothly below room temperature to yield ethyl methacrylate and the methoxocopper complex II in high yields:

$$EtOCu(PPh_3)_2 + CH_2{=}C(CH_3)COOMe \longrightarrow CH_2{=}C(CH_3)COOEt + MeOCu(PPh_3)_2\cdot 0.5Et_2O$$
$$(89\%) \qquad\qquad \text{II (78\%)}$$

Related transesterification reactions between carboxylic esters and metal alkoxides such as tin,[17] aluminium,[18] zirconium, hafnium,[19] and titanium[19,20] are known.

In the transesterification reaction of carboxylic esters with alkoxocopper and phenoxocopper complexes it has been noted that reactive alkoxocopper complexes such as methoxo- and ethoxocopper complexes undergo transesterification with a variety of carboxylic esters but the more stable complexes are less reactive. Thus, the phenoxocopper complex failed to react with ethyl acetate, benzyl acetate, allyl acetate, and vinyl acetate, whereas the ethoxocopper complex III underwent the transesterification with all of these esters to give excellent to moderate yields. The reactions of III with vinyl and isopropenyl acetates proceed beyond the simple transesterification and give the known C-bonded 1-acetoxyvinyl and 1-acetoxy-1-methylvinylcopper complexes[21] together with by-product acetatocopper complex in high yields:

$$EtOCu(PPh_3)_2 + CH_2{=}C(R)OCOCH_3 \quad (R=H,\ CH_3)$$
$$\xrightarrow{CH_3COOEt} [CH_2{=}CROCu(PPh_3)_2] \xrightarrow{CH_2=C(R)OCOCH_3}$$



$$R=H\ (XVI),\ CH_3\ (XVII)$$

Furthermore, the alkoxocopper complexes serve as excellent catalysts for transesterification between various esters and alcohols. The transesterification reactions of alkyl methacrylates, alkenyl acetates, alkyl acetates, alkyl benzoates, aryl acetates, alkyl carbonates, and alkyl phosphites with alcohols are catalyzed by small amounts of the alkoxocopper complexes under very mild conditions.

$$CH_2{=}C(CH_3)COOMe + EtOH \xrightarrow[-5\,^\circ C]{EtOCu(PPh_3)_2} CH_2{=}C(CH_3)COOEt + MeOH$$
$$\text{conversion} = 73\%$$

Since the catalytic reactions proceed cleanly under mild and neutral conditions, the alkoxocopper complexes provide some synthetic utility.

Reactions of organic halides with copper alkoxides without the tertiary phosphine ligands have been examined by Whitesides[8] and Hashimoto,[9] and the formation of various ethers has been reported. The alkoxo- and phenoxocopper complexes prepared in the present study react readily with organic halides producing ethers.

$$\underset{\text{III}}{EtOCu(PPh_3)_2} + Bu^nCl \xrightarrow{-5\,^\circ C,\ Et_2O} CH_3OBu^n \quad (36\%)$$

$$\underset{\text{VIII}}{HOCH_2CH_2OCu(PPh_3)_2} + MeI \xrightarrow{-30\text{--}10\,^\circ C} HOCH_2CH_2OMe \quad (76\%)$$

$$\underset{\text{IX}}{PhOCu(PPh_3)_2} + MeI \xrightarrow{\text{room temp}} PhOMe \quad (99\%)$$

The reactions of the alkoxocopper complexes with acyl chloride have been further examined. Complex III reacts readily with propionyl chloride to produce ethyl propionate in good yield:

$$EtOCu(PPh_3)_2 + CH_3CH_2COCl \longrightarrow CH_3CH_2COOEt \quad (82\%)$$

Reaction of the ethoxocopper complex III with acetic anhydride also produces ethyl acetate and the known acetatocopper complex XVI in good yields.

$$EtOCu(PPh_3)_2 + (CH_3CO)_2O \longrightarrow CH_3COOEt + CH_3COOCu(PPh_3)_2$$
$$76\% \qquad\qquad \text{XVIII (72\%)}$$

Similar reactions of metal alkoxides with acyl halides and acid anhydrides have been reported.[22,23]

Thermal Decomposition of Alkoxocopper Complexes. In contrast to the copper alkoxides without tertiary phosphine the thermal stabilities of the present alkoxocopper complexes with triphenylphosphine ligands are considerably enhanced. For a comparison of the thermolysis behavior of simple copper alkoxides with that of phosphine-stabilized alkoxocopper complexes the thermolysis products in various media were examined and compared with those reported by Whitesides (Table 3).

Table 3. Thermal decomposition of alkoxocopper complexes[a)]

Complex	Solvent (H donor ability)[b)]	Alcohol/[c)] Carbonyl	Product balance, %

$PhOCu(PPh_3)_2$ (IX)	in the solid state[e)]	only PhOH	89

a) Alkoxocopper complexes (0.20 g) in 2 ml of various solvents were heated at the boiling points or at 100 °C for 30 min in a closed system. b) The method used to estimate these numbers is described in Ref. 8. c) "Alcohol/carbonyl" in the ratio of the alcohol- and carbonyl-containing products derived from the alkoxo moiety of the alkoxocopper complexes. d) Ethyl benzene (10% per Cu) was detected. e) The phenoxocopper complex was heated above decomposition point in a closed system for 30 min.

The alkoxocopper complexes liberate alcohols, aldehydes or ketones on thermolysis, the former being produced in higher yields relative to those of the carbonyl-containing products. Two principal pathways are possible in the thermolysis of the secondary and primary alkoxocopper complexes. One involves the β-elimination mechanism forming aldehyde and copper hydride which may further react with another alkoxocopper complex to produce an alcohol. The other involves the homolytic splitting of the Cu–O bond producing alkoxy radicals which either disproportionate to the alcohol and aldehyde or abstract hydrogen from the solvent to generate the alcohol. Table 3 indicates the effects of solvents with different hydrogen atom donating abilities on the alcohol/carbonyl ratio. It can be seen that an effective hydrogen donor such as tetrahydrofuran significantly increased the ratio. The result as a whole agrees with the result of Whitesides who used copper alkoxide without the tertiary phosphine ligands and is compatible with the homolytic cleavage of the RO–Cu bond, although the formation of a "free radical" in the homolysis remains to be established. In the benzyloxocopper complex VII the decomposition behavior seems to be somewhat different from that of the rest of the complexes. Furthermore, when the thermolysis was carried out in the presence of styrene, a significant amount of ethylbenzene was produced. The result may be taken as an indication of the presence of β-hydrogen elimination in thermolysis of VII.

Experimental

All preparations, recrystallizations and reactions of copper complexes were carried out under deoxygenated nitrogen, argon, or in a vacuum. Solvents were dried by the usual procedures, distilled and stored under argon or nitrogen. IR spectra were recorded on a Hitachi Model 295 spectrometer using KBr discs under nitrogen. ^{1}H-NMR spectra were recorded with a Japan Electron Optics Lab. JNM-PS 100 spectrometer (TMS as internal standard). Evolved gas was analyzed with a Hitachi RMU 5B mass-spectrometer and a Shimadzu GC-5B gas chromatograph, and the volume measured with a Toepler pump. The microanalysis of carbon, hydrogen and nitrogen was performed by Mr. T. Saito in this laboratory with a Yanagimoto CHN Autocorder Type MT-2.

Preparation of Methoxobis(triphenylphosphine)copper(I) Etherate (II) and Related Alkoxocopper Complexes III, IV, V, VI, and VII. Methanol (109 μl, 3.2 mmol) was added to the methylcopper complex, $CH_3Cu(PPh_3)_2 \cdot 0.5Et_2O$ (I) (1.732 g, 2.706 mmol) suspended in diethyl ether (5 ml). After stirring the yellow suspension at -10 to 0 °C for a day a white precipitate was produced with the evolution of methane (0.92 mol per mol of Cu). The white precipitate was recrystallized from a mixture of diethyl ether and methanol to give II (1.047 g).

Other alkoxocopper complexes: III, IV, V, VI, and VII were prepared by the reaction of I with the corresponding alcohols in a similar way to that for II.

Preparation of (2-Hydroxyethoxo)bis(triphenylphosphine)copper (VIII). Ethylene glycol (16 mmol) was added to I(1.682 g, 2.63 mmol) suspended in diethyl ether (5 ml). After stirring the yellow suspension at -10 °C for 0.5 h a white precipitate was produced with the evolution of methane (0.92 mol per mol of Cu). The white precipitate was recrystallized from a mixture of toluene and ethylene glycol to give VIII (1.279 g).

Preparation of Phenoxobis(triphenylphosphine)copper (IX). Phenol (0.188 g, 2 mmol) was added to I (1.280 g, 2 mmol) suspended in diethyl ether (10 ml). The yellow suspension was stirred at 0 °C for 20 min to produce a white precipitate with the evolution of 1.0 mol of methane per Cu. Recrystal-

lization of the precipitate from toluene afforded white crystals of IX (0.653 g).

Preparation of IX from Cu_2O, PhOH, and PPh_3. A mixture of Cu_2O (0.143 g, 1 mmol), PhOH (0.190 g, 2 mmol), and PPh_3 (1.05 g, 4 mmol) in toluene (10 ml) was heated at 75 °C for 10 h. The gray precipitate produced was recrystallized from toluene to give $PhOCu(PPh_3)_2$ (IX) (0.803 g, yield 59% based on Cu_2O).

Preparation of (o-Formylphenoxo)bis(triphenylphosphine)copper (X) and (o-Acetylphenoxo)bis(triphenylphosphine)copper (XI). Salicylaldehyde (1.5 mmol) was added to I (0.944 g, 1.475 mmol) suspended in diethyl ether (10 ml). On stirring the yellow emulsion at −10—0 °C for 1 h an orange precipitate was produced with the evolution of methane (0.86 mol per mol of Cu). The precipitate was recrystallized from toluene to give orange crystals of X (0.899 g).

Complex XI (0.549 g) was prepared by the reaction of I (0.64 g, 1 mmol) with *o*-hydroxyacetophenone (1 mmol) in a similar way to the preparation of complex X.

Reaction of III with Phenol. Phenol (0.48 mmol) was added to III (0.20 g, 0.32 mmol) suspended in diethyl ether (2 ml). After stirring the white suspension at −5 to 0 °C for 10 h a clear supernatant and precipitate were produced. The formation of ethanol (yield 85% per Cu) was confirmed in the supernatant by GLC analysis. The precipitate was recrystallized from toluene to give white crystals of IX (0.168 g, yield 78%) which was identified on the basis of its IR spectrum.

Reaction of III with Ethanethiol. The reaction of III (0.20 g, 0.32 mmol) with ethanethiol (0.48 mmol) in diethyl ether (2 ml) at −5 to 0 °C for 10 h produced a white precipitate and released ethanol (yield 89% based on Cu). The precipitate was crystallized from toluene to give white crystals of XII (0.168 g, yield 82%); mp 139 °C (dec). Found: C, 70.4; H, 5.3; S, 5.1%. Calcd for $C_{38}H_{35}P_2SCu$: C, 70.4; H, 5.4; S, 4.9%. IR(KBr): 2950 w, 2900 w, 2850 w, 1235 m cm^{-1} and other absorptions due to PPh_3 ligands. ^{1}H-NMR (C_6D_6, r.t.): δ 1.2 (t, 3H), 2.8 (q, 2H), 7.1 (m, 18H, *m,p*-phenyl), 7.5 (m, 12H, *o*-phenyl).

Reaction of III with Acetanilide. The reaction of III (0.100 g, 0.158 mmol) with acetanilide (0.158 mmol) in diethyl ether (2 ml) at 0 °C for 24 h liberated ethanol (yield 72% based on Cu) to give a precipitate which on recrystallization from a mixture of diethyl ether and toluene afforded white crystals of XIII (0.074 g, yield 65%). Complex XIII, mp 151 °C (dec). Found: C, 72.7; H, 5.5; N, 2.4%. $C_{34}H_{38}ONP_2Cu$ calcd for: C, 73.2; H, 5.3; N, 1.9%. IR(KBr): 1680 m, 1585 m, 1510 s, 1490 s, 1450 w, 1240 m, 940 m, 800 m, 580 w, cm^{-1} and other absorptions to PPh_3. ^{1}H-NMR (C_6D_6, r. t.): δ 2.16 (s, 3H), 7.0 (m, 23H, 18H of *m,p*-phenyl of PPh_3 and 5H of phenyl), 7.6 (m, 12H, *o*-phenyl of PPh_3).

Reaction of III with Nitromethane and Acetylacetone. Nitromethane (1 ml) was introduced into a Schlenk type flask containing III (0.100 g, 0.158 mmol) in diethyl ether (1 ml) by a trap-to-trap distillation in a vacuum. After stirring the white emulsion at −20 to 0 °C for 24 h a white precipitate was produced with liberation of ethanol (yield 87% per Cu). The precipitate was repeatedly washed with THF and dried in a vacuum to give the white complex XIV (0.084 g, yield 82%) which was characterized as nitromethanidobis(triphenylphosphine)copper(I) on the basis of its IR and ^{1}H-NMR spectra. $(CH_2NO_2)Cu(PPh_3)_2$ (XIV), IR(KBr): ν(C=N), 1562 s, 1550 m; $\nu(NO_2$, asym), 1250 s; $\nu(NO_2$, sym), 952 s cm^{-1}. ^{1}H-NMR (CD_2Cl_2): δ 5.76 (s, 2H, CH_2), 7.1 (m, 30H, $2PPh_3$).

The reaction of III (0.20 g, 0.32 mmol) with acetylacetone (1 ml) was carried out in a similar way to give a white precipitate with the liberation of ethanol (80% per Cu). Recrystallization from diethyl ether gave acetylacetonatobis(triphenylphosphine)copper(I) (0.163 g, yield 74%).[16] (acac)Cu$(PPh_3)_2$ (XV), IR(KBr): ν(C=O), 1598 vs cm^{-1}. ^{1}H-NMR (C_6D_6): δ 2.04 (s, 6H, $2CH_3$), 5.56 (s, 1H), 7.1 (m, 18H, *m,p*-phenyl), 7.7 (m, 12H, *o*-phenyl).

Exchange Reaction of III with Methyl Methacrylate. A suspension of III (0.20 g, 0.32 mmol) in diethyl ether (2 ml) was treated with methyl methacrylate (0.32 mmol) at −5 °C for 12 h. Formation of ethyl methacrylate (yield 89% based on Cu) was confirmed by gas chromatographic analysis. The precipitate formed after the reaction was characterized as II (yield 78%) on the basis of its IR spectrum.

Reaction of III with Vinyl Acetate and Isopropenyl Acetate. Vinyl acetate (2 ml) was introduced into a Schlenk type flask containing III (0.20 g, 0.32 mmol) by a trap-to-trap distillation in a vacuum. After stirring the white emulsion at −5 to 0 °C for 12 h, ethyl acetate (yield 97% based on Cu), acetaldehyde (yield 15% based on Cu) and a small amount of polyvinyl acetate were produced besides a white precipitate. The precipitate was recrystallized from THF to give white crystals (174 mg, yield 81% based on Cu) of 1-acetoxyvinylbis(triphenylphosphine)copper[21](XVI) which was identified by IR and ^{1}H-NMR spectroscopy. Complex XVI, IR(KBr): ν(C=O) 1605 cm^{-1}. ^{1}H-NMR (C_6D_6): δ 1.92 (s, 3H, CH_3); 5.23 (d, 1H, J=7 Hz, =CH); δ 7.0 (m, 18H, *m,p*-phenyl); 7.6 (m, 12H, *o*-phenyl); 8.62 (d, 1H, J=7 Hz, =CH).

The reaction of III (0.20 g, 0.32 mmol) with isopropenyl acetate (2 ml) was carried out in a similar way to that of vinyl acetate to produce ethyl acetate, acetone and a precipitate (180 mg) containing 1-acetoxy-1-methylvinylbis(triphenylphosphine)copper[21](XVII) and acetatobis(triphenylphosphine)copper[21] (XVIII) which were identified by IR and ^{1}H-NMR spectroscopy. Complex XVII, IR(KBr): ν(C=O) 1595 cm^{-1}. ^{1}H-NMR (C_6D_6): δ 2.0 (s, 6H, $OCOCH_3$ and CH_3); 5.42 (s, 1H); 7.0 (m, 18H, *m,p*-phenyl); 7.6 (m, 12H, *o*-phenyl). Complex XVIII, IR(KBr): ν(OCO, asym), 1550; ν(OCO, sym), 1413; δ(OCO, sym), 667 cm^{-1}. ^{1}H-NMR (C_6D_6): δ 2.36 (s, 3H, CH_3); 7.0 (m, 18H, *m,p*-phenyl); 7.6 (m, 12H, *o*-phenyl).

Catalytic Transesterification Reaction Using III. Complex III (0.100 g, 1.06 mmol) was dissolved in a mixture of methyl methacrylate (0.73 ml, 6.77 mmol) and ethanol (5 ml) and the solution stirred at −5 °C for 24 h. Ethyl methacrylate was identified by gas chromatographic analysis of the reaction mixture (yield 73%).

Reaction of Alkoxocopper Complexes with Alkyl Halides. A measured amount of an alkyl halide was introduced into a Schlenk type flask containing the alkoxocopper complex by a trap-to-trap distillation in a vacuum or by means of a syringe at −30 °C. The reaction mixture was stirred for 12 to 24 h below 0 °C. The amount of ether formed in the reaction was determined by means of gas chromatography.

Reaction of III with Propionyl Chloride. Propionyl chloride (0.458 mmol) was added to III (0.20 g, 0.32 mmol) suspended in diethyl ether (2 ml). After stirring the white suspension at −5 °C for 2 h ethyl propionate (yield 82% per Cu) was produced.

Reaction of III with Acetic Anhydride. Acetic anhydride (0.458 mmol) was added to III (0.20 g, 0.32 mmol) suspended in diethyl ether (2 ml). After stirring the white suspension at −5 °C to r.t. for 24 h a white precipitate and ethyl acetate (yield 76% per Cu) were produced. The precipitate was crystallized from THF to give white crystals which were characterized as $CH_3COOCu(PPh_3)_2$ (XVIII) (yield 72%) on the basis of its IR and ^{1}H-NMR spectra.

Mixed Ligand Complexes of Copper(II)-1-(2-Pyridylazo)-2-naphthol with Bidentate Ligands

Hiroko WADA,* Kazuyoshi IKUTA, and Genkichi NAKAGAWA*

Laboratory of Analytical Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received February 23, 1978)

Formation constants of mixed ligand complexes of copper(II)–1-(2-pyridylazo)-2-naphthol chelate (Cu(pan)) with bidentate ligands, which accelerate the rate of color change of 1-(2-pyridylazo)-2-naphthol (PAN) indicator in copper(II)–EDTA titrations, were determined by the spectrophotometric method in 5 or 10% v/v dioxane–H_2O at μ=0.1 (KNO_3) and at 25 °C. The overall formation constants ($\log K^{\text{pan.L}}_{\text{Cu(pan)L}}$=log ([Cu(pan)L]/[Cu][L][pan]) are 21.26 (5% dioxane) for 2,2′-bipyridine, 21.64 (10% dioxane) for ethylenediamine, 22.80 (5% dioxane) for 8-hydroxy-5-quinolinesulfonic acid, 19.39 (10% dioxane) for glycine, and 20.68 (10% dioxane) for iminodiacetic acid. These ligands coordinate with Cu(pan) chelate as bidentate ligands, and the mixed ligand complexes may have a distorted octahedron structure. Thus the Cu–pan bond in the mixed ligand complex is weakened.

In the EDTA-titration of copper(II), 1,10-phenanthroline, 2,2′-bipyridine, ethylenediamine, 8-quinolinol, glycine, and iminodiacetic acid accelerate the rate of the color change of 1-(2-pyridylazo)-2-naphthol (PAN) indicator.[1] In a previous work[2] the mechanism of the acceleration by 1,10-phenanthroline was elucidated: *i.e.* the mixed ligand complex of Cu(pan) chelate with 1,10-phenanthroline is formed and undergoes a faster substitution with EDTA than does Cu(pan) chelate. In the present paper the composition and the formation constants of the mixed ligand complexes of Cu(pan) chelate with 2,2′-bipyridine(bpy), ethylenediamine-(en), 8-hydroxy-5-quinolinesulfonic acid(Hoxs), glycine (Hgly), and iminodiacetic acid (H_2ida) are reported.

Experimental

Reagents. The copper(II) solution and the Hpan solution were the same as those used in previous work.[2] Reagent grade chemicals were purified by recrystallization. A 2,2′-bipyridine dioxane solution, and ethylenediamine aqueous solution, a glycine aqueous solution, a 8-hydroxy-5-quinolinesulfonic acid alkaline aqueous solution, and an iminodiacetic acid aqueous solution were used. The ionic strength was maintained constant with potassium nitrate. Dioxane was purified as described in the previous paper.[2] Buffer solutions: 0.02 M 2-morpholino-1-ethanesulfonic acid (MES)–NaOH buffer for pH 4—7, and 0.01 M disodium tetraborate–HNO_3 or NaOH buffer for pH 7.5—11 were used.

Apparatus. A Hitachi 124 Spectrophotometer, a Hitachi 356 Two-wavelength Spectrophotometer, a Radiometer PHM 26 pH meter equipped with a Radiometer G202B glass electrode and a K401 calomel electrode (saturated KCl), and a Hitachi-Horiba F-5 pH meter equipped with an Orion 94-29A copper(II) ion-selective electrode or a Hitachi-Horiba 1026-05T glass electrode and a Hitachi-Horiba 2080-05T calomel electrode (3.3 M KCl) were used. These glass electrodes were calibrated with the two standard buffers: 0.025 M KH_2PO_4 +0.025 M Na_2HPO_4 and 0.05 M $KH_3(C_2O_4)_2\cdot 2H_2O$, 0.05 M $KHC_6H_4(COO)_2$, 0.05 M $Na_2B_4O_7\cdot 10H_2O$ or saturated (25 °C) $Ca(OH)_2$.

Procedure. All measurements were carried out in 5 or 10% v/v dioxane–water media, depending upon the solubility of mixed ligand complexes, at an ionic strength of 0.1 M (KNO_3) and at 25±1 °C. The acid dissociation constants and the formation constants of copper(II) complexes of the ligands (bpy, en, Hoxs, Hgly, H_2ida) were determined under the same conditions as those employed for the determination of the formation constants of mixed ligand complexes. All constants determined are written in the form of mixed constants involving hydrogen ion activity.

Determination of the Acid Dissociation Constants of the Ligands and the Formation Constants of the Cu(II) Complexes. The acid dissociation constant of protonated 2,2′-bipyridine (Hbpy) was determined by a spectrophotometric method. The acid dissociation constants of protonated ethylenediamine (H_2en), 8-hydroxy-5-quinolinesulfonic acid (H_2oxs), glycine (H_2gly), and iminodiacetic acid (H_2ida), and the formation constants of Cu–ida complexes were determined by the pH-tritration with a NaOH standard solution. The formation constants of Cu–bpy, Cu–en, Cu–oxs, and Cu–gly complexes were determined by the potentiometric method with a copper(II) ion-selective electrode.[3] The acid dissociation constants of the ligands and the formation constants of the copper(II) complexes are summarized in Table 1.

Determination of the Formation Constants of the Mixed Ligand Complexes. The formation constant of a mixed ligand complex is defined by Eq. 1. Charges are omitted for simplicity.

TABLE 1. EQUILIBRIUM CONSTANTS OF LIGANDS (L)
25 °C, μ=0.1 (KNO_3)

Ligand (L)	pk_1	pk_2	Method[a]	$\log\beta_{\text{CuL}}$	$\log\beta_{\text{CuL}_2}$	$\log\beta_{\text{CuL}_3}$	Method[a]	Dioxane (%)
bpy	4.37		3	8.59	14.09	17.84	2	5
en	7.14	9.98	1	10.56	19.55		2	10
Hoxs	3.90	8.82	1, 3	11.86	21.87		2	5
Hgly	2.52	9.40	1	8.12	14.71		2	10
H_2ida	2.86	9.51	1	10.93	16.67		1	10

a) Method 1: pH titration, Method 2: potentiometry with Cu(II) ion-selective electrode, Method 3: spectrophotometry.

$$\beta_{Cu(pan)L_n} = \frac{[Cu(pan)L_n]}{[Cu(pan)][L]^n}, \quad (1)$$

where L represents the free ligand. The conditional formation constant of Cu–pan complexes, taking into account the formation of mixed ligand complexes, is given by

$$K_{(Cupan)'} = \frac{[(Cupan)']}{[Cu'][pan']} = \frac{K_{Cupan}\alpha_{Cupan(L)}}{\alpha_{Cu(L)}\alpha_{pan(H)}}, \quad (2)$$

where

$$[(Cupan)'] = [Cu(pan)] + [Cu(pan)L] + [Cu(pan)L_2] + \cdots + [Cu(pan)L_n], \quad (3)$$

$$K_{Cupan} = \frac{[Cu(pan)]}{[Cu][pan]}, \quad (4)$$

$$\alpha_{Cupan(L)} = 1 + \sum_{n=1}^{n} \beta_{Cu(pan)L_n}[L]^n, \quad (5)$$

$$\alpha_{Cu(L)} = 1 + \sum_{m=1}^{m} \beta_{CuL_m}[L]^m, \quad (6)$$

$$\alpha_{pan(H)} = 1 + \frac{[H]}{k_2} + \frac{[H]^2}{k_1 k_2}. \quad (7)$$

β_{CuL_m} is the overall formation constant of CuL_m, and k_1 and k_2 are the acid dissociation constants of H_2pan.

The total concentration of Cu–pan complexes [(Cupan)'] can be obtained from the absorbance at the wavelength where the absorbance of the mixed ligand complex is equal to that of Cu(pan) chelate. [Cu'] and [pan'] are calculated by means of the following equations:

$$[Cu'] = C_{Cu} - [(Cupan)'], \quad (8)$$

$$[pan'] = C_{Hpan} - [(Cupan)'], \quad (9)$$

where C_{Cu} and C_{Hpan} represent the analytical concentrations of Cu and Hpan, respectively. Thus the values of $K_{(Cupan)'}$ are obtained at the various concentrations of the ligand and the various pHs of the solutions.

On the other hand the concentration of free ligand L is calculated by

$$[L] = \frac{[L']}{\alpha_{L(H)}}, \quad (10)$$

where

$$\alpha_{L(H)} = 1 + \frac{[H]}{k_p} + \frac{[H]^2}{k_p k_{p-1}} + \cdots + \frac{[H]^p}{k_p \cdots k_2 k_1},$$

and [L'] represents the total concentration of the ligand not combined with copper, and $k_1, k_2, \cdots k_p$ are the acid dissociation constants of the ligand. In this work a large excess of the ligand compared with copper and Hpan was used; thus [L'] is approximately equal to the initial concentration of the ligand C_L. $\alpha_{Cu(L)}$ and $\alpha_{pan(H)}$ are calculated from the concentration of L and the pH of the solution by means of Eqs. 6 and 7, respectively.

Thus $K_{Cupan}\alpha_{Cupan(L)}$ can be written as Eq. 11 and evaluated from $K_{(Cupan)'}$ by the use of Eq. 2.

$$K_{Cupan}\alpha_{Cupan(L)} = K_{Cupan}(1 + \sum_{n=1}^{n} \beta_{Cu(pan)L_n}[L]^n) \quad (11)$$

From the plots of $\log K_{Cupan}\alpha_{Cupan(L)}$ *vs.* log [L] the formation constants of Cu(pan) and $Cu(pan)L_n$ complexes were obtained by the curve fitting method.

Results

2,2'-Bipyridine. Under the conditions: C_{Cu}= 0.223—11.1×10^{-5} M, C_{Hpan}=1.01—20.2×10^{-6} M, C_L=3.00—500×10^{-4} M, pH 8.18—9.07, dioxane 5% v/v, the absorption spectra were measured. Some of them are shown in Fig. 1. By the addition of 2,2'-bipyridine the absorption maximum of Cu(pan) chelate shifted from 550 to 540 nm, and the absorbance at λ_{max} decreased with increasing the concentration of 2,2'-bipyridine, because the replacement of Cu(pan) chelate by 2,2'-bipyridine proceeds together with the formation of the mixed ligand complex. The isosbestic point of the curves 2—8 at 502 nm indicates the existence of the mixed ligand complex and Hpan in the presence of 2,2'-bipyridine. From the absorbances at 545 nm the total concentration of Cu–pan complexes and then the values of $K_{(Cupan)'}$ were calculated. A plot of $\log K_{Cupan}\alpha_{Cupan(L)}$ *vs.* the logarithm of free 2,2'-bipyridine concentration log [bpy] yielded a straight line with a slope of 1.0 (Fig. 2). Thus, over the concentration range of 2,2'-bipyridine from 10^{-4} to 10^{-1} M a mixed ligand complex

		16.00[b]				10
		15.58[c]				5
		15.99[c]				10

Hpan: pk_1=2.87, pk_2=11.55 (dioxane 5%) pk_1=2.90, pk_2=11.68 (dioxane 10%). a) In the presence of Hoxs. b) In the presence of en, H_2ida, or Hgly. c) In the absence of auxiliary complexing agents.

Cu(pan)(bpy) is formed, as in the case of 1,10-phenanthroline. The value of log $K^{pan.bpy}_{Cu(pan)bpy}$ was obtained from the value of log $K_{Cupan\alpha Cupan(L)}$ at log[bpy]=0 (Table 2).

Ethylenediamine. By the addition of ethylenediamine the absorption maximum of Cu(pan) chelate shifted to 548 nm. Increasing the concentration of free ethylenediamine caused the formation of the mixed complex and the substitution with ethylenediamine to proceed. Under the conditions: $C_{Cu}=2.14—12.9\times10^{-4}$ M, $C_{Hpan}=9.97—10.2\times10^{-6}$ M, $C_L=1.57—12.1\times10^{-2}$ M, pH 6.08—10.22, dioxane 10% v/v, the absorbances at 549 nm were measured. As shown in Fig. 3, the values of log $K_{Cupan\alpha Cupan(L)}$ became higher than that of log K_{Cupan} when the concentration of free ethylenediamine exceeded 10^{-6} M, and a straight line with a slope of 1.0 was obtained at concentrations higher than 10^{-4} M. Thus a mixed ligand complex Cu(pan)(en) is formed.

8-Hydroxy-5-quinolinesulfonic Acid. In this case Cu-oxs chelate is extremely stable, so the substitution of Cu(pan) chelate with oxs proceeded even at a low concentration of oxs. Hence the following experimental conditions were employed: $C_{Cu}=1.6—488\times10^{-5}$ M, $C_{Hpan}=2.94—32.2\times10^{-6}$ M, $C_L=0.378—113\times10^{-4}$ M, pH 3.58—11.00, dioxane 5% v/v. A plot of log $K_{Cupan\alpha Cupan(L)}$ *vs.* log [oxs] is shown in Fig. 2. The formation of a mixed ligand complex Cu(pan)(oxs) was observed.

Glycine. In this case the absorption maximum of Cu(pan) chelate shifted to the shorter wavelength (545 nm) with increase in the concentration of free glycine. The absorbances at 547.5 nm were measured under the conditions: $C_{Cu}=4.29\times10^{-6}—1.07\times10^{-3}$ M, $C_{Hpan}=3.00—9.01\times10^{-6}$ M, $C_L=1.62—19.8\times10^{-2}$ M, pH 5.84—9.28, dioxane 10% v/v. The results are shown in Fig. 3 and Table 2.

Iminodiacetic Acid. The absorption spectrum was slightly shifted to the shorter wavelengths compared with that of Cu(pan) chelate. The experiments were carried out under the conditions: $C_{Cu}=8.00—80.0\times10^{-5}$ M, $C_{Hpan}=0.923—1.18\times10^{-5}$ M, $C_L=3.62—45.3\times10^{-3}$ M, pH 5.14—9.66, dioxane 10% v/v. The results are shown in Fig. 3 and Table 2.

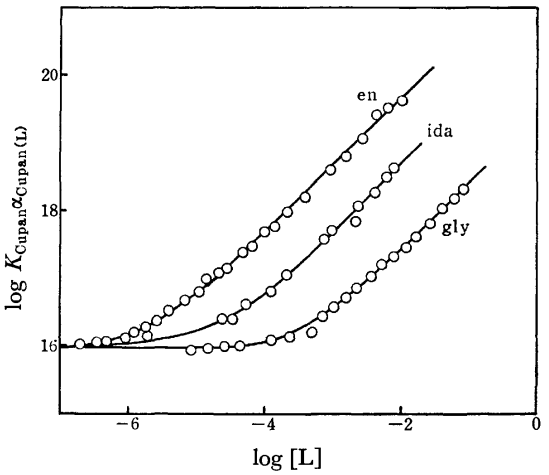

Fig. 3. Plots of log $K_{Cupan\alpha Cupan(L)}$ *vs.* log [L]. Solid lines are the theoretical curves calculated with the values obtained by curve fitting.

Discussion

In all cases, the replacement of Cu(pan) chelate by auxiliary complexing agents takes place before the complete formation of the mixed ligand complex. Thus, it was assumed that the molar absorptivity of the mixed ligand complex is the same as that of Cu(pan) chelate at the middle wavelength of these two absorption maxima, as observed in the case of 1,10-phenanthroline.[2] Since the plots of log $K_{Cupan\alpha Cupan(L)}$ *vs.* log [L] fitted well with a normalized curve plotting y *vs.* log x for $y=\log(1+x)$, and since in the case of 8-hydroxy-5-quinolinesulfonic acid, ethylenediamine, iminodiacetic acid, and glycine the formation constants of Cu(pan) chelate obtained from the horizontal parts of the curves were in good agreement with the values obtained in the absence of auxiliary complexing agents[4] (Table 2), the above assumption should be correct. In each case at higher concentrations of free ligand a straight line with a slope of 1.0 was obtained; hence one molecule of ligand coordinates with one molecule of Cu(pan) chelate.

To compare the formation constants of Cu(pan) and Cu(pan)L, $K^{pan}_{Cu(pan)L}$ was calculated from $K^{pan.L}_{Cu(pan)L}$, as

$$K^{pan}_{Cu(pan)L}=\frac{[Cu(pan)L]}{[CuL][pan]},$$

and values of Δlog K defined by Sigel[5] were calculated:

$$\Delta\log K=\log K^{pan}_{Cu(pan)L}-\log K_{Cupan}.$$

In all cases Δlog K are negative (Table 2). Therefore, by the formation of the mixed ligand complex the bonds between copper and pan may be weakened.

Tabata and Tanaka determined the formation constants of mixed ligand complexes of copper(II)-4-(2-pyridylazo)resorcinol (Cu(par)) chelate with unidentate ligands(L) such as SCN^-, Cl^-, Br^-, I^-, NH_3, pyridine, CH_3COO^- and N_3^-.[6] Comparing the values of $K^L_{Cu(pan)L}$ obtained in this work with those of $K^L_{Cu(par)L}$ by Tabata and Tanaka, $K^L_{Cu(pan)L}$ for 1,10-phenanthroline, 2,2'-bipyridine, and 8-hydroxy-5-quinolinesulfonic acid are much larger than $K^L_{Cu(par)L}$ for pyridine. $K^L_{Cu(pan)L}$ for

ethylenediamine, and iminodiacitic acid are also greater than $K^{L}_{Cu(par)L}$ for NH_3, while in the case of glycine $K^{L}_{Cu(pan)L}(=10^{3.40})$ is of the same order as $K^{L}_{Cu(par)L}$ $(=10^{3.51})$ for NH_3. On the other hand, in the EDTA titration of copper(II) with PAN indicator the rate of the color change is accelerated with glycine,[1] but glycine methyl ester slows down the rate of color change, as does pyridine.** Thus glycine may coordinate with Cu(pan) chelate as a bidentate ligand. The calculated $\Delta\log K$ value for iminodiacetic acid was small, if iminodiacetic acid were to act as a terdentate ligand; thus iminodiacetic acid may coordinate as a bidentate ligand with the amine nitrogen and one of the carboxyl oxygen atoms.

All ligands examined in this study coordinate with Cu(pan) chelate as bidentate ligands and the mixed ligand complexes may have a distorted octahedron structure. This is the reason why 1,10-phenanthroline, 2,2′-bipyridine, ethylenediamine, 8-hydroxy-5-quinolinesulfonic acid, glycine, or iminodiacetic acid accelerates the rate of color change of PAN indicator in copper(II)-EDTA titrations.

** The formation constant of the mixed ligand complex of Cu(pan) with glycine methyl ester could not be determined, because of the small solubility in H_2O–dioxane.

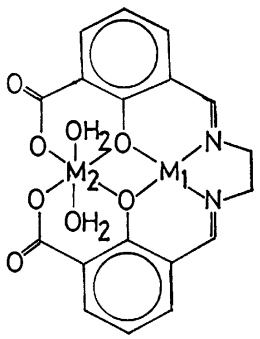
(Received April 13, 1978)

The crystal structure of hetero-metal binuclear complex, CuCo(fsaen)·3H$_2$O, with *N,N'*-bis(3-carboxysalicylidene)ethylenediamine (H_4fsaen) was determined by the single-crystal X-ray diffraction method. The crystals are trigonal, space group $P3_221$, $a=b=12.845(2)$, $c=9.962(1)$ Å, $V=1423.5(4)$ Å^3, and $Z=3$. The structure was solved by the heavy atom method and refined by the block-diagonal least-squares method to an *R* factor of 0.028. The copper atom is coordinated by two nitrogen atoms and two phenolic oxygen atoms in a square-planar manner. The cobalt atom is coordinated by two equatorial carboxyl oxygen atoms, two equatorial phenolic oxygen atoms and two axial water oxygen atoms in a distorted octahedral geometry. The detailed structure determined is in conformity with the magnetic and spectral properties previously reported.

In the previous papers of this series,[2,5] it was shown that the Schiff bases derived from 3-formylsalicylic acid and diamines are binucleating ligands with coordinative selectivity. By use of these ligands, many hetero-metal binuclear complexes have been synthesized and characterized on the basis of elemental analyses, IR, electronic spectra, and magnetic measurements over the temperature range.[1-4] However, no direct proof of the structure has been given yet. Therefore, it is desired to establish the basic structure of these hetero-metal binuclear complexes. In this study, the crystal structure of CuCo(fsaen)·3H$_2$O which is one of those hetero-metal binuclear complexes was analyzed by the single-crystal X-ray diffraction method, where H_4fsaen represents *N,N'*-bis(3-carboxysalicylidene)ethylenediamine.

According to the previous paper,[3] the electronic spectrum of CuCo(fsaen)·3H$_2$O was interpreted in terms of the planar copper(II) in the "inside" coordination site and the octahedral cobalt(II) in the "outside" coordination site. On the basis of the magnetic property, it was assumed that the ground state of the cobalt(II) is orbitally singlet and, hence, the geometry around the cobalt atom is slightly distorted from the regular octahedron. Hence, in view of this assumption, it is interesting to provide the detailed structural data of this complex obtained by the X-ray analysis.



Experimental

CuCo(fsaen)·3H$_2$O was prepared by the method previously reported.[3] Crystals suitable for an X-ray study were obtained as red-purple prisms by crystallization from a dilute aqueous solution.

Preliminary Weissenberg photographs showed that the complex crystallizes in a trigonal system. The cell parameters and intensities were measured on a Syntex P$\bar{1}$ automated four-circle diffractometer with monochromated Mo $K\alpha$ radiation ($\lambda=0.71073$ Å). The crystal was ground to a sphere (radius 0.152 mm). The cell parameters were determined by the least-squares refinement based on the 15 reflections in the range of $17<2\theta<38°$. The values are $a=b=12.845$ (2), $c=9.962$ (1) Å, and $V=1423.5$ (4) Å^3. The density $D_m=1.84$ g/cm^3 obtained by floatation in hexane–1,2-dibromoethane solution agrees well with the density $D_C=1.85$ g/cm^3 calculated for three molecules per unit cell. The crystallographic data are given in Table 1.

Table 1. Crystal data

Molecular formula	CuCo($C_{18}H_{12}N_2O_6$)·3H$_2$O
Molecular weight	528.8
Crystal system	Trigonal
Space group	$P3_121$ or $P3_221$
$a=b=12.845(2)$, $c=9.962(1)$ Å	
$V=1423.5(4)$ Å^3	
$Z=3$	
$D_m=1.84$ g/cm^3	
$D_c=1.85$ g/cm^3	
$\mu=21.1$ cm^{-1} (for Mo $K\alpha$)	

Intensity data were collected by the θ-2θ scan technique with a variable scan rate of 4.0 to 24.0°/min. Three standard reflections were monitored every 50 reflections, and their intensities showed a good stability. A total of 4493 reflections with $2\theta<48°$ were collected. The intensities were corrected for the Lorentz and the polarization effects, but corrections for absorption were not applied on account of $\mu r=0.32$. 839 independent reflections with $|F_o|\geq 2.5\sigma(F_o)$ were considered as "observed" and were used for the structure analysis.

Solution and Refinement of the Structure

The observed Laue symmetry of the reflections is $\bar{3}$ml. The observed setting of the symmetry, $I(hkl)=I(khl)$, and the systematic absences of $00l$ for $l\neq 3n$ indicate that either of the two enantiomorphous space groups $P3_121$ or $P3_221$ is possible.

The structure was solved by the heavy atom method. The positions of the copper and cobalt atoms were

determined by a three-dimensional Patterson synthesis. The copper and cobalt atoms were located on the twofold axes in the special positions. The successive Fourier syntheses and the difference Fourier syntheses revealed all the nonhydrogen atoms. Refinement was carried out by the block-diagonal least-squares method. One of the water oxygens, O(5) was found to be positionally disordered, with a half-occupancy of the two positions related by the twofold axis. Being introduced anisotropic thermal parameters, the block-diagonal least-squares refinement yielded a discrepancy factor $R_1=\sum||F_o|-|F_c||/\sum|F_o|=0.046$. At this stage, a difference Fourier map revealed all the hydrogen atoms. The refinement was performed for both the enantiomorphous space groups $P3_121$ and $P3_221$. The final discrepancy factors were : $R_1=0.038$ and $R_2=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}=0.059$ for space group $P3_121$; $R_1=0.028$ and $R_2=0.045$ for space group $P3_221$. As has been pointed out,[6,7] the best refinement should correspond to the correct configuration. Accordingly, the hypothesis of space group $P3_121$ can be rejected at a confidence level higher than 99.5%.[9] A further check on the $P3_221$ configuration was carried out in comparing the intensities of Friedel pairs. Table 2 lists observed and calculated intensity relations between some *hkl* and $\bar{h}\bar{k}l$ reflections. Inspecting these relations, one can confirm that $P3_221$ is the correct space group for the crystal studied here.

In the least-squares refinement the function minimized was $\sum w(|F_o|-k|F_c|)^2$, and the weighting scheme was $w=(10+|F_o|+0.01|F_o|^2)^{-1}$.[8] The final shift in the atomic parameters of the nonhydrogen atoms averaged 0.05σ with the maximum of 0.26σ. Atomic scattering factors for Cu, Co, O, N, C_{val}, and H, and the anomalous dispersion corrections, $\Delta f'$ and $\Delta f''$ for Cu

and Co, were taken from International Tables for X-Ray Crystallography.[9] The final difference Fourier map showed no important features, the highest peak being 0.3 e/Å^3.

The final positional and thermal parameters with their estimated standard deviations are given in Tables 3 and 4.***

The calculations were carried out at the Computer Center of Kyushu University, by the use of the UNICS-II program system.

Description of the Structure and Discussion

The molecular structure obtained is shown in Fig. 1. As has been expected, the molecule is a binuclear complex in which two metal atoms (M_1 and M_2) are coordinated by fsaen^{4-}. Metal atoms, M_1 and M_2, lie on the twofold axis. The molecule has the C_2 symmetry on this twofold axis. The "inside" metal atom, M_1, is coordinated by two nitrogen atoms of the ethylenediamine and two phenolic oxygen atoms in the typical square-planar manner. The "outside" metal atom, M_2, is octahedrally coordinated by two equatorial carboxyl oxygen atoms, two equatorial phenolic oxygen atoms, and two axial water oxygen atoms. Therefore, we can conclude that M_1=Cu and M_2=Co, since no alternative assignment is compatible with the magnetic and spectral properties as were already discussed in the previous paper.[3] The bond distances and angles with their estimated standard deviations are listed in Tables 5 and 6, respectively. Some least-squares planes with the deviations of atoms from the planes are given in Table 7. The Cu–O distance (1.909(5) Å) and the Cu–N distance (1.915(6) Å) are of the normal in-plane coordination. The Co–O distance (2.065(4) Å) of the bridging oxygen atom is slightly longer than that (1.995(5) Å) of the terminal oxygen atom. This relation had also been observed in the structures of some other binuclear complexes with Schiff bases.[10-12] As seen in Table 5, the Co–O(1) distance is considerably longer than the Cu–O(1) distance. This is consistent with a fact that Co–O distances are generally longer than Cu–O ones.[13] The axial Co–O distance (2.137(5) Å) is somewhat longer than that of the in-plane coordination. As seen in Table 6, the in-plane O–Co–O angles considerably deviate from right angle (77.1(2), 86.2(2), and 110.7(2)°), whereas the apical O–Co–basal O angles are 86.6(2), 89.5(2), and 92.2(2)°. As seen in Table 7, four coordinating atoms around the copper atom are almost coplanar with the deviations within ±0.02 Å. On the other hand, four equatorial atoms around the cobalt atom deviate from the mean plane by ±*ca.* 0.07 Å and show a slight distortion toward the tetrahedron. Accordingly the coordination geometry about

I) y, x, −z. a) Equations have the form $AX+BY+CZ=D$ where X, Y, and Z are Cartersian axes lying along $\boldsymbol{a}\times\boldsymbol{c}^*$, $\boldsymbol{b}$, and $\boldsymbol{c}^*$, respectively.

the cobalt atom evidently deviates from a regular octahedron, so that the orbital degeneracy of the ground state ($^4T_{1g}$) in O_h symmetry is removed. The first excited state may possibly be thermally nonaccessible, thereby the cryomagnetic behavior of CuCo(fsaen)·3H$_2$O being expressed by the Van Vleck equation based on the Heisenberg model with $S_1=1/2$ and $S_2=3/2$.

The unit cell contains three binuclear molecules and three uncoordinated crystal water molecules. The carboxyl oxygen O(3) and the water oxygen O(4) coordinated to the cobalt atom of the adjacent molecule are hydrogen-bonded and the O(3)···O(4) distance is 2.699(8) Å. The crystal water is in the vicinity of the carboxyl oxygen O(2) by hydrogen bonding with the O(5)···O(2) distance of 2.86(1) Å. The absolute configuration of the packing is that of a left-handed helical sequence of molecules, the axis of the helix being the c axis. Each binuclear molecule points its "outside" moiety toward the inside of the helix in which the crystal water molecules are housed.

The authors wish to express sincere thanks to Dr. Yoshihiko Kushi of Hiroshima University for his helpful advice and discussion. They are also grateful to Dr. Shigeaki Kawano of Kyushu University for use of the UNICS-II program. Thanks are also due to Dr. Yuzo Nishida of Kyushu University for the help in data collection, and to Mr. Naoyuki Torihara for helping us in the preparation of the complex.

A Dimeric Structure of Dimethyllead(IV) Complexes with ONO Tridentate Schiff-base Ligands and the Interaction of These Complexes with Donor Solvents

Tetsuro MAJIMA and Yoshikane KAWASAKI*

Department of Petroleum Chemistry, Osaka University, Yamadakami, Suita, Osaka 565

(Received April 14, 1978)

From measurements of the molecular weights, dimethyllead(IV) complexes with ONO tridentate Schiff-base ligands, 2-(2-oxidobenzylideneamino)phenolatos, were found to have dimeric six-coordinate structure in $CHCl_3$, in which either one of the two oxygen atoms in the ligands bridges the lead atoms. The $^2J(^{207}Pb\text{–}CH_3)$ values increase and the $\delta(Pb\text{–}CH_3)$ values shift to a higher magnetic field with an increase in the donor strength of the solvents. Linear relationships between the $^2J(^{207}Pb\text{–}CH_3)$ and $\delta(Pb\text{–}CH_3)$ values and Hammett's σ values of the substituents on the Schiff-base ligands were obtained. These results suggest that the complexes form monomerically as a result of coordination with one and/or two solvent molecules in such donor solvents as DMSO and HMPA, and that the $^2J(^{207}Pb\text{–}CH_3)$ values is dependent mainly on the change in the positive charge on the lead atom: the change in the mean excitation energy, ΔE, in the Fermi contact term.

In a series of spectroscopic studies of several dimethyllead(IV) complexes of 8-quinolinols,[1] β-diketones,[2] benzoates,[3] and quadridentate Schiff bases,[4] we have found that these dimethyllead(IV) complexes are monomeric and take a six-coordinate configuration in non-coordinating solvents, $CHCl_3$ and CH_2Cl_2, and that in such donor solvents as DMSO and HMPA, the lead atom is coordinated with a solvent molecule as the seventh ligand. In both types of solvents, the C–Pb–C skeleton is always linear. On the other hand, Bosco and Cefalù[5] have prepared a dimethyllead(IV) complex with a ONO tridentate Schiff-base ligand and claimed that the complex has a five-coordinate configuration. The C–Pb–C skeleton of the complex is not linear, judging from the following observations: 1) the molecular weight in acetone shows a monomeric value, and 2) the spin-spin coupling constant, $^2J(^{207}Pb\text{–}CH_3)$, in $CDCl_3$ is very small (132 Hz) as compared with those of usual six-coordinate dimethyllead(IV) complexes (*ca.* 150 Hz) with the linear C–Pb–C skeleton.[1–4,6] However, a possibility that the coordination of an acetone molecule to the lead atom gives the monomeric value can not be disregarded, since we have elucidated from spectroscopic studies[3] that acetone interacts more or less strongly with dimethyllead(IV) complexes. Moreover, the configuration of the C–Pb–C skeleton in dimethyllead(IV) complexes, as ascertained in a series of our studies,[1–4,7,8] is not correlated directly with the $^2J(^{207}Pb\text{–}CH_3)$ values. Therefore, we have reinvestigated the molecular weights of the some dimethyllead(IV) complexes with ONO tridentate Schiff-base ligands in $CHCl_3$, in which the possibility of the coordination of solvent molecules to the lead atom seems negligibly small.

	complex; $(CH_3)_2PbL$
L=**1**: X=Z=H, Y=NO_2	(complex I)
L=**2**: X=Y=H, Z=NO_2	(complex II)
L=**3**: X=Y=Z=H	(complex III)

L=**5**: X=OCH_3, Y=Z=H	(complex V)
L=**6**: X=OCH_3, Y=CH_3, Z=H	(complex VI)

We also wish to report on the effects of the substituents on the Schiff-base ligands and of the donor strength of solvents upon the $^2J(^{207}Pb\text{–}CH_3)$ and the $\delta(Pb\text{–}CH_3)$ values.

As the planar ONO tridentate Schiff-base ligands, 2-(2-oxidobenzylideneamino)phenolates, L=**1**—**6**, were used.

Experimental

Materials. The dimethyllead dichloride was prepared by the chlorination of tetramethyllead in ethyl acetate at −10 °C.[9] The Schiff bases, 2-(2-hydroxybenzylideneamino)phenols (H_2L), were prepared by dehydration reactions between the corresponding *o*-aminophenols and salicylaldehydes by refluxing in alcoholic solutions. The solvents were reagent grade and were purified according to the standard method except for $CDCl_3$, which was used as supplied.

Preparation of the Complexes, I—VI. The dimethyllead complexes, $(CH_3)_2PbL$, I—VI, with the corresponding ligands, **1**—**6** respectively, were prepared according to the following procedures. A dry methanol solution (20 dm) of sodium salts of an appropriate Schiff base (Na_2L), prepared from sodium methoxide in methanol (Na; 0.5 g, 20 mmol) and H_2L (10 mmol), was added, drop by drop, into dimethyllead dichloride (2.5 g, 10 mmol) in dry methanol (30 dm). The mixture was then stirred for a few hours. The precipitates were filtered, washed by benzene and methanol, and recrystallized from methanol (I and IV), *N*,*N*-dimethylformamide/methanol(II), or dichloromethane/hexane (III, V, and VI). Elemental analyses of the lead of all the complexes were carried out by decomposition with concentrated sulfuric and nitric acids.[10]

Molecular-weight and Conductivity Measurements. The molecular weights in $CHCl_3$ (0.5 wt %) were measured by means of a Mechrolab vapor pressure osmometer at 25 °C. The molar conductances in DMSO were measured by means of a Yokogawa F-225A Universal bridge and a cell with the cell constant of 0.377 cm^{-1} at 25±0.1 °C. The specific conductance of DMSO used was $\kappa=4.2\times10^{-7}$ Ω^{-1} cm^{-1}. The molar conductances (Λ_m) of IV—I in DMSO (10^{-3} mol·dm^{-3}) were 1.1—1.9 Ω^{-1} cm^2 mol^{-1} (Table 1). All the complexes were found to be non-electrolytes.

a) In DMSO. b) In $CHCl_3$. c) Decomposed. d) Sublime. e) 1605 cm^{-1} in the solid state, reported by Bosco and Cefalù.[5]

IR and ^1H NMR Spectra. The IR Spectra were recorded on a Hitachi 225 spectrophotometer. ^1H NMR studies were carried out on a JEOL-PS-100 spectrometer operating at 100 MHz. All the data were obtained in 4 wt % or in saturated solutions. The chemical shifts were measured relative to TMS as the internal standard at the ambient temperature.

The analytical data, physical properties, and IR and ^1H NMR spectral data for the complexes, I—VI, are given in Tables 1 and 2.

Results and Discussion

The color, melting point, ν(C=N), and δ(Pb–CH_3) and $^2J(^{207}Pb–CH_3)$ values of III obtained by us (Tables 1 and 2) are in good agreement with those reported by Bosco and Cefalù.[5] As can be seen from Table 1, the molecular weights of I—VI were twice the values produces by the use of the $(CH_3)_2PbL$ formula. These results indicate that either one of the two oxygen atoms of the ligand bridges the lead atoms, resulting in the formation of a six-coordinate configuration (**A**), in which the C–Pb–C skeleton may be linear, although a distorted octahedral structure with a slightly bent C–Pb–C skeleton is possible. A similar dimeric structure is found in the case of $[(CH_3)_2Pb(ox)X]_2$ (ox=8-quinolinolato, X=Cl and Br), in which the halogen atoms bridge two lead atoms.[11] These results are in marked contrast to those for dimethyltin(IV) complexes; *i.e.*, the dimethyltin complexes of **1**, **3**, and **4**[12] and $(CH_3)_2Sn(ox)X$ (X=Cl and Br)[13] have the five-coordinate and distorted trigonal bipyramidal structures, with a bent C–Sn–C skeleton.

The bridging of the oxygen atom in Complex I—VI is weak and is easily severed by a solvent molecule, forming a six-coordinate configuration (**B**) in donor solvents, since a monomeric value was observed for III in such weak donor solvent as acetone.[5] The dimethyllead species may have a six-coordinate configuration with an acetone molecule as the sixth ligand (**B**). The existence of seven-coordinate ones (**C**) can not be excluded, especially in such strong donor solvents as DMSO and HMPA. The $^2J(^{207}Pb–CH_3)$ values of V and VI in DMSO and HMPA are comparable to those of $(CH_3)_2Pb(ox)_2$ in DMSO (176.4 Hz),[1] in which the seven-coordinate configuration was assumed, and of an isolated seven-coordinate complex, $(CH_3)_2Pb(gbha)(H_2O)$ (gbha=2,2′-(ethanediylidenediimino)diphenolato) (176—178 Hz).[8]

The $^2J(^{207}Pb–CH_3)$ values of III and IV in $CDCl_3$ (133.6 and 135.0 Hz respectively) are smaller than those of many other six-coordinate complexes (*ca.* 150 Hz).[1-4,6] Those of I and II with an electron-withdrawing nitro group on the ligands are much smaller: 120.7 and 123.1 Hz respectively. On the other hand, those of V and VI with an electron-releasing methoxyl group (155.0 and 156.7 Hz respectively) are larger than those of I—IV, and have values similar to that of $(CH_3)_2Pb(acac)_2$ (acac=acetylacetonato) (154.7 Hz), having a six-coordinate configuration with a linear C–Pb–C skeleton.[14] The independence of the $^2J(^{207}Pb–CH_3)$ values on the configuration of the C–Pb–C skeleton may better be understood by the linear relationship between these values and Hammett's σ values of the substituents on the phenyl ring of the ligands for I—IV (Fig. 1).

a) δ_1, δ_2, ^2J, and ^3J are δ(Pb–CH_3) (ppm), δ(Pb–N=CH) (ppm), $^2J(^{207}Pb–CH_3)$ (Hz), and $^3J(^{207}Pb–N=CH)$
d) Obscured by the solvent peaks.

This relationship indicates that the $^2J(^{207}Pb–CH_3)$ values decrease with an increase in the electron-withdrawing character of the substituent on the ligand. The electron-withdrawing group leads to an increase in the polarization in $Pb^{\delta+}–O^{\delta-}$ bonds, resulting in an increase in the positive charge on the lead atom. Indeed, the δ(Pb–CH_3) values are found to shift to a lower magnetic field in this order: IV, III, II, and I (Fig. 1). Similarly, an increase in the $^2J(^{207}Pb–CH_3)$ values and a higher magnetic-field shift of the δ(Pb–CH_3) values with an increase in the donor strength of the solvents (Table 2) can also be explained by the decrease in the positive charge on the lead atom with the increase in the donor strength of the solvents. These results are consistent with our previous assumption[1,3,4,7,15] that the change in the mean excitation energy, ΔE, in the Fermi contact term plays a dominant role in determining the $^2J(^{207}Pb–CH_3)$ value for dimethyllead(IV) complexes. Therefore, the small $^2J(^{207}Pb–CH_3)$ value can not be connected directly with the conclusion that the C–Pb–C skeleton is bent in the dimethyllead(IV) complexes. This is substantiated by the observation that the $^2J(^{207}Pb–CH_3)$ values of the dimethyllead(IV) cation, $(CH_3)_2Pb^{2+}$, with a linear C–Pb–C skeleton, are very smaller, ranging from 101 to 132 Hz in several strong acids.[7]

It should also be noted that the amount of variation in the $^2J(^{207}Pb–CH_3)$ values upon a change in the solvent from $CDCl_3$ to HMPA are in this order: I, II (*ca.* 50 Hz)>III, IV (*ca.* 30 Hz)>V, VI (*ca.* 20 Hz). These values are attributable to the fact that the strength of coordination of the solvent molecule to the lead atom differs from complex to complex, probably increasing with an increase in the positive charge on the lead atom.

As in the case of $(CH_3)_2Pb(saln)\cdot CH_3OH$,[4] we have also obtained the spin-spin coupling constants between the lead nucleus and the azomethine proton, $^3J(^{207}Pb–N=CH)$, in the case of I and II, although Bosco and Cefalù did not report these values.[5] The couplings were not detected in the other complexes, since the azomethine proton signals of the complexes are broad (with a half-height width of 4—8 Hz). The broadenings are presumed to be due to the coupling with the lead nucleus. By comparison with the values of $(CH_3)_2Pb(saln)\cdot CH_3OH$ (23.4—29.3 Hz),[4] those of I and II (5.0—15.5 Hz) are quite small and change remarkably along with the coordinating ability of the solvents. Therefore, the above results suggest that the coordination of the nitrogen atom to the lead atom in I—VI is weaker than in $(CH_3)_2Pb(saln)\cdot CH_3OH$. On the other hand, the $^3J(^{119}Sn–N=CH)$ values of $(CH_3)_2SnL$ (L=**3**) decrease with an increase in the donor strength of the solvents, although the $^2J(^{119}Sn–CH_3)$ values increase.[11]

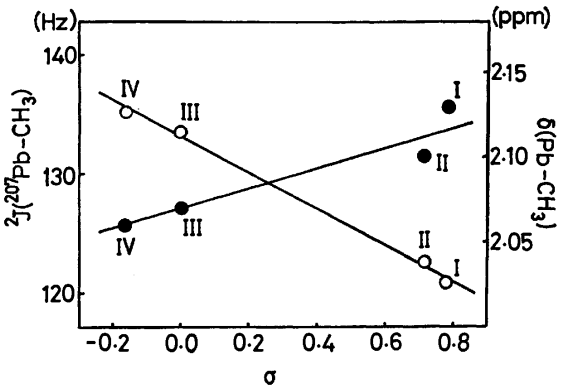

Fig. 1. Plots of the $^2J(^{207}Pb–CH_3)$ (—○—) and the δ(Pb–CH_3) values (—●—) in $CDCl_3$ *vs.* Hammett's σ for $(CH_3)_2PbL$, I—IV.

In conclusion, Complexes I—VI have a dimeric six-coordinate structure (**A**) in such non-coordinating solvents as $CHCl_3$ and CH_2Cl_2. On the other hand, in such donor solvents as DMSO and HMPA the complexes form a monomeric six- and/or seven-coordinate structure, (**B**) and/or (**C**), with one or two donor solvent molecules. In either solvent, the C–Pb–C skeleton is linear and is perpendicular to the coordination plane. Therefore, the results are fundamentally different from those for the dimethyltin(IV) complexes, in which the C–Sn–C skeleton is quite flexible.

Department of Chemistry, National Defense Academy, Hashirimizu, Yokosuka 239

†Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received April 17, 1978)

An ultrasonic absorption study has been carried out on aqueous acidic solutions of mercury(II) acetate. The absorption data shows a single-relaxation phenomenon in the frequency range of 15—95 MHz. On the other hand, the results of the pH measurement indicate that the only mecury(II) acetate complexes conceivable in solution are of the HgL^+ and HgL_2 forms (L^- denotes the acetate ion); the succesive formation constants of these complexes, together with the mercury(II) hydrolysis constants, are also determined. The equilibrium constants reported are: 2.1×10^3 for K_1, 4.9×10^3 for K_2, 6×10^{-4} for K_{h1}, and 1.0×10^{-3} for K_{h2}, at 30 °C and $I=1$. On the basis of the above results, the ultrasonic relaxation absorption is ascribed to the complex formation reaction: $HgL^+ + L^- \rightleftarrows HgL_2$. The rate constants and the volume change of this reaction are determined to be: $k_f^\circ = 7.8\times10^9$ M^{-1} s^{-1}, $k_b^\circ = 1.6\times10^6$ s^{-1}, and $\Delta V = 18$ cm^3 mol^{-1}, at 30 °C.

It is well known[1] that the rate of a metal-complex formation reaction in an aqueous solution is controlled by the water release from the metal and that the rate constant of this step depends strongly on the nature of the metal ion, *e.g.*, on the charge, the electronic configuration, the ionic radius, and the coordination number. Although many studies[2] have provided us with much information about the complexation kinetics for most "labile" metals, few kinetic studies about mercury(II) complexes[2,3] have been made up to the present. This is because some experimental difficulties exist in the studies; *e.g.*, mercury(II) exhibits a considerable hydrolysis-tendency, and it is one of the most labile of metals.

The purpose of the present study is to obtain kinetic information on mercury(II) acetate complexes through an elucidation of ultrasonic absorption in aqueous mercury(II) acetate solutions. The kinetic analysis of the absorption data requires an exact knowledge about the nature of complexes in solution and about the formation constants. The literature[4-6] gives little information on these constants, and so the present study included a determination of them by means of a pH measurement method.

Experimental

Equilibrium Measurements. The formation constants of the mercury(II) acetate complexes were obtained from the pH measurements. A Hitachi-Horiba Expandomatic pH meter, Model F-7SS, with general-purpose glass and calomel electrodes was used and calibrated with standard buffer solutions. The pH values were determined to an accuracy of ±0.005 unit. Sample solutions were prepared from mercury(II) acetate and stock solutions of nitric acid and/or acetic acid; the ionic strength was kept constant at $I=1$ by the addition of $NaNO_3$. The concentrations of the acid solutions were determined by titrating with standard NaOH.

The experiments were carried out for three kinds of systems. The first contains 0.001—0.4 M mercury(II) acetate and 0.01—0.4 M nitric acid; pH=1.0—3.1. The second contains 0.15—0.5 M mercury(II) acetate, 0.02—0.1 M nitric acid, and 0.25 M acetic acid; pH=2.0—2.6. The third contains 0.005—0.4 M mercury(II) acetate and 0.07—0.25 M acetic acid; pH =2.7—3.3. The dissociation constant of acetic acid was also obtained from the pH measurement of solutions containing 0.025—0.9 M acetic acid and 0.01—0.2 M sodium acetate ($I=1$ with $NaNO_3$); the pH value lay in the 3.3—4.5 range.

The concentrations of hydrogen ions in the solutions were calculated from the measured pH values by using an apparent activity coefficient, γ_H, which was determined by the pH measurement of solutions containing nitric acid at various concentrations and sufficient amounts of $NaNO_3$ to maintain the ionic strength at unity. All the pH measurements were carried out at 30.0 ± 0.5 °C.

Kinetic Measurement. Sample solutions were prepared from mercury(II) acetate and sodium acetate. The pH values of the solutions were adjusted by the addition of perchloric acid; no supporting electrolytes were added. The ultrasonic absorption was measured in the frequency range of 5—95 MHz by the pulse technique[7] at 30.00 ± 0.05 °C.

The relaxation absorption spectra were represented by the single-relaxation equation:

$$\frac{\alpha}{f^2} = \frac{A}{1+(f/f_r)^2} + B, \tag{1}$$

or:

$$(\alpha'\lambda) = \left(\frac{\alpha}{f^2} - B\right)cf = \frac{2\mu_m(f/f_r)}{1+(f/f_r)^2}, \tag{2}$$

where α is the ultrasonic absorption coefficient; f, the frequency of the sound; f_r and A, the relaxation frequency and amplitude, respectively; B, the high-frequency value of α/f^2; $(\alpha'\lambda)$, the excess absorption per wavelength; c, the velocity of sound, and μ_m $(=cAf_r/2)$, the maximum excess absorption per wavelength.

The values of f_r, A, and B were determined by fitting the data to Eq. 1. A least-squares fit was obtained by using a routine in which the root-mean-square percentage deviation between the experimental and calculated α/f^2 values was minimized.

Results and Discussion

The Formation Constants of Mercury(II) Acetate Complexes. In the mercury(II) acetate systems studied, the following equilibria may exist:

$$HL \overset{K_H}{\rightleftarrows} H^+ + L^-, \tag{3}$$

$$Hg(OH)_{m-1}^{3-m} \overset{K_{hm}}{\rightleftarrows} Hg(OH)_m^{2-m} + H^+, \quad m=1, 2, \tag{4}$$

$$HgL_{n-1}^{3-n} + L^- \overset{K_n}{\rightleftarrows} HgL_n^{2-n}, \quad n=1, 2, \cdots N, \tag{5}$$

where L^- denotes the acetate ion and where K_H is the dissociation constant of acetic acid; the K_{hm}'s are the mercury(II) hydrolysis constants, and the K_n's, the formation constants of the complexes. Then, the average number, $\bar{n}$, of acetate ions bound to the central metal may be defined by[8]

$$\bar{n} = \frac{\sum_n n\beta_n[L^-]^n}{1+\sum_n \beta_n[L^-]^n}, \quad \beta_n = K_1K_2 \cdots K_n, \tag{6}$$

where the brackets indicate the molar concentration at equilibrium and where the summation is to be carried out for all the whole values of n from 1 to N.

In the first place, the data analysis was tried by ignoring the hydrolysis Reactions 4 from the above equilibria. Then, we could evaluate $[L^-]$ and $\bar{n}$ by means of the following relations:[6]

$$[L^-] = K_H(\sum \text{acid} - [H^+])/[H^+], \tag{7}$$

$$\bar{n} = \{\sum L - (1+[H^+]/K_H)[L^-]\}/\sum Hg, \tag{8}$$

where $\sum Hg$ and $\sum L$ are the total stoichiometric concentrations of mercury(II) and acetate ions, respectively, and where $\sum$acid is the sum of those of nitric and acetic acids. The dissociation constant, K_H, was determined from the measured hydrogen-ion concentrations of the acetic acid–sodium acetate system by means of the relation: $pK_H = p[H^+] + \log\{(C_1 - [H^+])/(C_2 + [H^+])\}$, were C_1 and C_2 are the stoichiometric concentrations of acetic acid and sodium acetate, respectively. The K_H value obtained is shown in Table 1; it was used for the evaluation of $[L^-]$ and $\bar{n}$ (Eqs. 7 and 8).

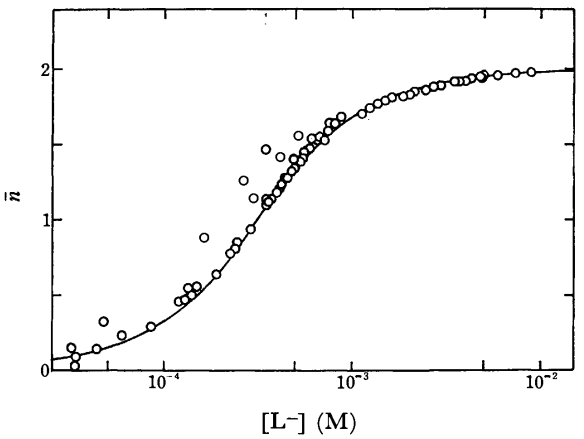

Fig. 1. Graph of $\bar{n}$ *vs.* $[L^-]$ for the mercury(II) acetate system at 30 °C and $I=1$. Open circle refers to the $\bar{n}$ and $[L^-]$ values determined approximately by Eqs. 7 and 8. The solid curve expresses the $\bar{n}$ value calculated by Eq. 6 using the K_1 and K_2 values in Table 1.

As is shown in Fig. 1, a graph of the $\bar{n}$ *vs.* $[L^-]$ plot thus obtained forms almost a single curve except for some data in the low $[L^-]$ region which exhibit somewhat large deviations from the curve. Probably these deviations reflect the fact that the effect of the hydrolysis reactions cannot be ruled out in this region. Furthermore, the fact that the $\bar{n}$ value increases as a whole with an increase in $[L^-]$ and tends to an asymptotic value of 2 in the high $[L^-]$ region indicates that the only mercury(II) acetate complexes conceivable in solution are of the HgL^+ and HgL_2 forms.

Since graphical methods for determining equilibrium constants[9] may not be simply applied to the present systems, the data analysis was carried out as follows. From the equilibria (3—5) with $m=1, 2$ and $n=1, 2$, we obtain the following conservation relations:

$$\sum Hg = [Hg^{2+}]\left(1+\frac{K_{h1}}{[H^+]}+\frac{K_{h1}K_{h2}}{[H^+]^2}+K_1[L^-]+K_1K_2[L^-]^2\right), \tag{9}$$

$$\sum L = [L^-]\left(1+\frac{[H^+]}{K_H}\right)+[Hg^{2+}](K_1[L^-]+2K_1K_2[L^-]^2), \tag{10}$$

$$\sum \text{acid} = [H^+]\left(1+\frac{[L^-]}{K_H}\right)-[Hg^{2+}]\left(\frac{K_{h1}}{[H^+]}+\frac{2K_{h1}K_{h2}}{[H^+]^2}\right). \tag{11}$$

If a set of values is given to the four parameters, K_{h1}, K_{h2}, K_1, and K_2, the values of $[Hg^{2+}]$ and $[L^-]$ may be evaluated from the known values of $\sum Hg$, $\sum L$, and $[H^+]$ by using Eqs. 9 and 10. Then, Eq. 11 enables us to calculate $\sum$acid. Therefore, the values of the equilibrium constants were determined by repeating a number of similar calculations, in which the values of the parameters were varied independently, and finally by obtaining a set of values which minimize the root-mean-square percentage deviation between the experimental and calculated $\sum$acid values. The calculations were carried out by using a computer program. The values of the equilibrium constants obtained are shown in Table 1. The calculated $\sum$acid values agree with the experimental values within $\pm 3\%$. The $\bar{n}$ value was recalculated by means of Eq. 6 using the K_1 and K_2 values in Table 1; it is shown by a solid line in Fig. 1. The calculated curve is consistent with the $\bar{n}$ *vs.* $[L^-]$ plot which was obtained approximately by means of Eqs. 7 and 8.

Table 1. Equilibrium constants for the aqueous mercury(II) acetate system at 30 °C and $I=1$

Dissociation constant of acetic acid	$K_H = (3.19\pm0.07)\times10^{-5}$
Mercury(II) hydrolysis constants	$K_{h1} = (6\pm2)\times10^{-4}$ $K_{h2} = (1.0\pm0.4)\times10^{-3}$
Formation constants of mercury(II) acetate complexes	$K_1 = (2.1\pm0.1)\times10^3$ $K_2 = (4.9\pm0.3)\times10^3$

The K_{h1} and K_{h2} values in Table 1 are within the ranges of those reported by the earlier workers.[4] On the other hand, the results obtained for mercury(II) acetate complexes are very different from those reported by Banerjea and Singh.[6] They reported the presence of four kinds of complexes (*i.e.*, $n=1$—4) in solution and obtained these values: 3.59×10^5, 5.54×10^3, 9.6×10^3, and 6.1×10^3 for K_1, K_2, K_3, and K_4, respectively, at 30 °C and $I=1$. Their K_1 value is larger by almost two orders of magnitude than the corresponding one in Table 1, though their K_2 value is close to that obtained here. For comparison, the $\bar{n}$ value was calculated by means of Eq. 6 using their four equilibrium constants; it ranges from 1.1 to 4 in the $[L^-]$ range in Fig. 1,

TABLE 2. EXPERIMENTAL CONDITIONS AND ULTRASONIC RELAXATION PARAMETERS FOR THE AQUEOUS MERCURY(II) ACETATE SYSTEM[a] AT 30 °C

Sample No.	∑L (M)	pH	Equilibrium concentrations of species (10^{-2} M)[b]							f_r (MHz)	A	B

a) Each solution contains 0.500 M ∑Hg. b) I=0.2—1.3.

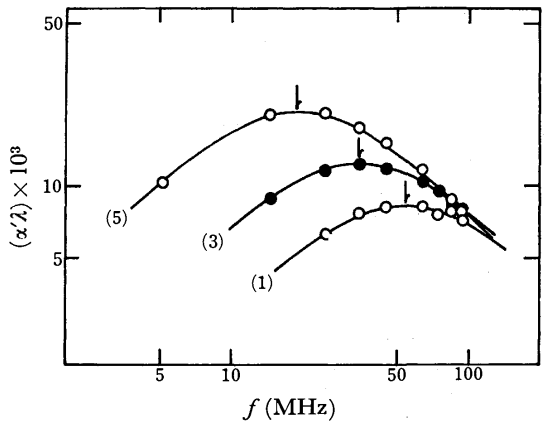

Fig. 2. Graph of $(\alpha'\lambda)$ *vs.* f for the mercury(II) acetate system containing $HClO_4$ in a definite concentration (*ca.* 0.2 M), at 30 °C. The arrow indicates the relaxation frequency. The number in parentheses refers to the sample number in Table 2.

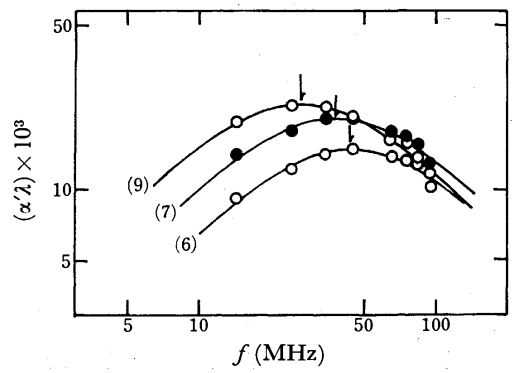

Fig. 3. Graph of $(\alpha'\lambda)$ *vs.* f for the mercury(II) acetate system in a definite pH (2.46), at 30 °C. The arrow indicates the relaxation frequency. The number in parentheses refers to the sample number in Table 2.

being too large to be consistent with the present results.

Ultrasonic Absorption of Mercury(II) Acetate Solutions. The experimental conditions and the adsorption parameters obtained are summarized in Table 2. The data consist of those from two kinds of systems. One contains $HClO_4$ in a definite concentration of *ca.* 0.2 M (sample No. 1—5), while the other has been adjusted to a definite pH of 2.46 (sample No. 6—11). Representative absorption curves for these systems are shown in Figs. 2 and 3, where the excess absorption per wavelength $(\alpha'\lambda)$ is plotted against f.

The equilibrium concentrations of species in solution were evaluated from the ∑Hg, ∑L, and pH values in Table 2, together with the values of the equilibrium constants which were calculated from those in Table 1 by using Meites' equation[10] for the activity coefficients of ions. Calculations by a recurrence method resulted in self-consistent values for the equilibrium concentrations, the ionic strength, the activity coefficients, and the corrected equilibrium constants. The results are also shown in Table 2.

The kinetic analysis of the absorption data was carried out by associating the relaxation process with one of the equilibria (3—5). An examination of the concentration dependence of the observed relaxation frequency showed that only the following reaction is consistent with the experimental data (furthermore, all the species in this reaction are considered to be of a reasonable order of magnitude over the whole concentration range studied):

$$HgL^+ + L^- \underset{k_b}{\overset{k_f}{\rightleftarrows}} HgL_2. \qquad (12)$$

The relaxation frequency associated with this reaction is expressed by

$$2\pi f_r = k_f^\circ\{\gamma_\pm^2([HgL^+]+[L^-])+1/K_2^\circ\}, \qquad (13)$$

where $\gamma_\pm$ is the mean activity coefficient of HgL^+ and L^-, and where the superscript (o) indicates the quantities at I=0. In the above expression, the equilibrium relation of $K_2^\circ=k_f^\circ/k_b^\circ$ is employed. As is shown in Fig. 4, a graph of the f_r *vs.* $\{\gamma_\pm^2([HgL^+]+[L^-])+1/K_2^\circ\}$ plot gives a straight line passing through the point of origin, and the rate constant, k_f°, was obtained from the slope of this line. The values of k_f° and k_b° $(=k_f^\circ/K_2^\circ)$ are shown in Table 3. The maximum excess absorption per wavelength corresponding to Eq. 13 is given by

$$\mu_m = \frac{(\pi\Delta V)^2}{2RT\beta_s}\left\{\frac{1}{[HgL^+]}+\frac{1}{[L^-]}+\frac{1}{[HgL_2]}\right\}^{-1}, \qquad (14)$$

where R is the gas constant; T, the absolute temperature

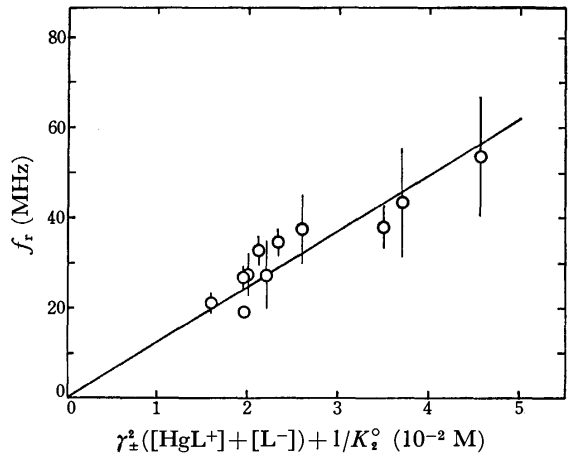

Fig. 4. Graph of f_r *vs.* $\{\gamma_\pm^2([HgL^+]+[L^-])+1/K_2^\circ\}$ for the mercury(II) acetate system at 30 °C. The vertical lines indicates the uncertainty intervals given in Table 2.

Table 3. Kinetic results for the formation of $Hg(CH_3CO_2)_2$ at 30 °C

Rate constants	$k_f^\circ=(7.8\pm0.9)\times10^9$ $M^{-1}s^{-1}$
	$k_b^\circ=(1.6\pm0.2)\times10^6$ s^{-1}
Volume change	$\Delta V=18\pm2$ cm^3 mol^{-1} [a]

a) Effective value in the I range of 0.2—1.3.

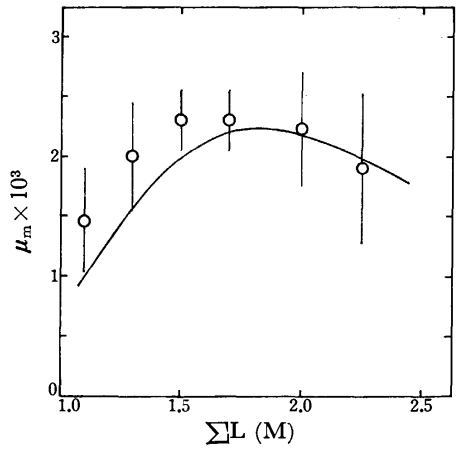

Fig. 5. Graph of μ_m *vs.* $\sum L$ for the mercury(II) acetate system under the conditions of $\sum Hg=0.500$ M, pH=2.46, and 30 °C. The vertical lines indicate the uncertainty intervals obtained from the data in Table 2. The solid curve expresses the μ_m value calculated by Eq. 14 using the ΔV value in Table 3.

and β_s, the adiabatic compressibility of the solution; ΔV is the volume change of the complex formation reaction 12. The ΔV value was determined by Eq. 14; it is also shown in Table 3. Figure 5 shows the observed μ_m values plotted against $\sum L$ for the solutions of $\sum Hg=0.5$ M and pH=2.46, while the calculated μ_m value is also shown by the solid line. The calculated curve expresses fairly well the concentration dependence of the observed μ_m value. These results indicate that the observed relaxation absorption is associated with Reaction 12.

By an electric-field-dispersion method, Eigen and Eyring[3] obtained the rate constant, $(5—10)\times10^9$ M^{-1} s^{-1} (at 24—25 °C and $I\approx0$), for the $HgCl_2$ formation reaction. The similarity of the k_f° value in Table 3 to the above value indicates that the formation reactions of the mercury(II) complexes proceed *via* the Eigen mechanism,[11,12] which involves the loss of a water molecule in the rate-determining step. By assuming that the outer-sphere association process reaches equilibrium much faster than the ligand substitution, the complex formation rate constant, k_f, may be expressed in terms of the association constant, K_o, of the outersphere complex and the rate constant, k_o, of ligand substitution; *i.e.*, $k_f=K_ok_o$. For Reaction 12, the K_o value was estimated to be 1.3 (at $I=0$) by means of the Fuoss equation,[13] in which the center-to-center distance between the reaction partners was assumed to be 5 Å. Then, the k_f° value in Table 3 gives $k_o=6\times10^9$ s^{-1}, which is in line with the corresponding values reported for the d^{10} cations:[1] *i.e.*, $(2.5—3)\times10^7$ s^{-1} for Zn^{2+}, $(2.5—4)\times10^8$ s^{-1} for Cd^{2+}, and 2×10^9 s^{-1} for Hg^{2+}, at 20 °C.

The Solution Behavior of Thenoyltrifluoroacetone in Alcoholic Solvents

Hidenori SHIBUYA, Hitoshi WATARAI, and Nobuo SUZUKI*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received April 17, 1978)

The solution behavior of thenoyltrifluoroacetone (TTA) has been investigated in a series of higher alcohols which are often used in solvent extraction by means of UV and NMR spectrometries. It was experimentally confirmed that TTA exists in the enol and hemiacetal forms in dehydrated alcohol, while in wet alcohol we should also take a hydrate form into consideration. The fractions of the species at equilibrium were determined, and their dependencies on the water concentration and on the solvent properties, *i.e.*, the dielectric constant and the solubility parameter, were examined. The interconversion rate between the enol and hemiacetal forms were also observed as a function of the water concentration.

The identification of the chemical form of a partitioning species is one of the most important problems in fundamental research into solvent extraction. TTA (4,4,4-trifluoro-1-(2-thienyl)-1,3-butanedione) has been extensively used as a powerful extractant for metal ions, especially for heavy metals.[1] The predominant form of TTA in the inert solvents commonly used in solvent extraction is known to be the enol form, and in aqueous solvents, the hydrate form.[2-4] In addition, it has been reported that TTA reacts with methanol.[5] However, there is no information on whether TTA reacts with the higher alcohols used in solvent extraction. Recently, Suzuki *et al.*[6] observed that the partition rate of TTA between higher alcohol and water is very slow compared to that between an inert solvent and water. This fact seems to suggest a specific interaction between TTA and higher alcohol.

In the present study, a quantitative investigation has been carried out on the chemical equilibrium and the kinetic behavior of TTA in eleven higher alcohols by means of UV and ^{19}F and ^{1}H NMR spectrometries.

Experimental

Materials. The TTA (Dojindo G. R.) was purified by vacuum sublimation. The purity was checked by mp measurement (43.2—43.8 °C, lit, 42.5—43.2 °C[1]). Commercially purchased alcohols were fractionally distilled over calcium oxide or calcium sulfate. The purified TTA and alcohols were stored in a silica-gel desiccator. The dioxane was purified by the ordinary method.[7] The deuterated methanol (CD_3OD, 99%), dehydrated methanol, and perchloric acid were all reagent-grade. Redistilled water was used throughout.

Determination of Water Concentration. The concentration of water in alcohol was determined by the Karl-Fischer method. Water-saturated alcohol was prepared by placing a diluted aqueous solution (pH=3.5) of perchloric acid in contact with purified alcohol for several days in a thermostated room at 25 °C. The determination was repeated three times for each sample.

NMR Measurement. A deuterated methanol solution of TTA (1M) was prepared one day before measurement. The ^{1}H NMR spectra of the solution were taken on a Varian A-60 NMR apparatus. An alcohol solution of TTA (0.3M) was prepared for each alcohol at 25±0.5 °C. In order to establish the equilibration, the solutions were allowed to stand for four days in the case of dehydrated solutions and for two or three days in the case of water-containing solutions. The ^{19}F NMR spectra of the solutions were taken on a JEOL-PS-100 NMR apparatus at 94 MHz and 25±2 °C. The signal integration of a resonance peak was repeated at least four times. As an internal standard of the chemical shift, tetramethylsilane was used for the ^{1}H NMR and fluorotrichloromethane for the ^{19}F NMR.

Kinetic Measurements. The interconversion rate among the species of TTA was measured by observing the decrease in the enol concentration photometrically; 50 μl of a dioxane solution of TTA (0.003 M) was spiked into 5 ml of alcohol in a quartz cell, and the subsequent decrease in the transmittance at 340 nm (absorption maximum of enol form) was recorded on a Hitachi 356 UV-VIS spectrophotometer at 25±0.2 °C.

Results and Discussion

Chemical Species of TTA in Alcoholic Solvents. The ^{1}H NMR spectra of the deuterated methanol solution of TTA are shown in Fig. 1. The two multiplets at 7.76 and 7.10 ppm are assigned to the thienyl group, and the singlet at 6.48 ppm, to the α-proton of the enol form. The quartet at 3.34 ppm with a coupling constant of

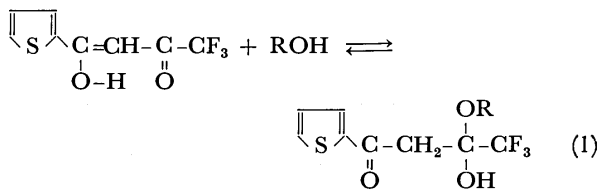
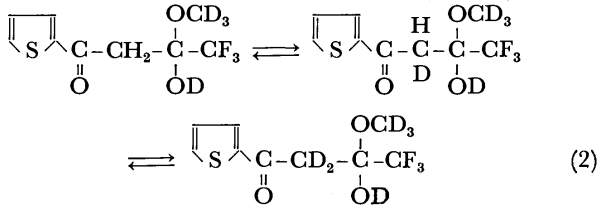
A: Dehydrated methanol solution,
B: water-saturated 1-hexanol solution.

J=15.7 cps and the doublet at 3.52 and 3.12 ppm are thought to be assignable to species other than the enol form. The ^{19}F NMR spectra of a dehydrated methanol solution of TTA is shown in Fig. 2(A). Two singlet signals were observed at 77.2 and 83.6 ppm. In the other dehydrated alcohols also, similar spectra were observed except for the cases of 2-octanol and 3-methyl-1-butanol. These results show that TTA is in two forms in dehydrated alcohols, *viz.*, enol and hemiacetal produced by a reaction with alcohol:



(1)

The hemiacetal form has two α-protons which are not equivalent because of the effect of the asymmetric carbon atom at the adjacent position. Since the α-protons belong to the AB-type group, they may be expected to show a quartet. Consequently, the quartet at 3.34 ppm can be assigned to the α-protons of the hemiacetal form. The doublet in Fig. 1 can be explained by considering a proton-deuteron exchange in one of the α-protons as follows:



(2)

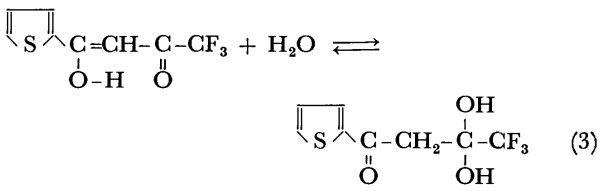
In this way, the NMR spectra of methanol solution of TTA can be thoroughly interpreted by considering the enol and the hemiacetal forms.

The ^{19}F NMR spectra of a water-saturated 1-hexanol solution of TTA are shown in Fig. 2(B). Three singlet signals, at 77.6, 84.1, and 88.2 ppm, were observed. In the other water-saturated alcohols, similar spectra were obtained except for the cases of 2-octanol and 3-methyl-1-butanol. The signal of 88.2 ppm, which appears only in wet alcohol, is assigned to the hydrate form, because the signal becomes progressively larger as the water concentration increases. The other two signals are consistent with the signals assigned to the enol and hemiacetal forms in dehydrated alcohol.

The equilibrium fraction of each species was determined from the integrated intensity of the corresponding signal of the ^{19}F spectra. In Table 1, the fractions of the TTA species in hydrated and water-saturated alcohols are listed, together with the solubility of water, the dielectric constant, and the solubility parameter.

Solvent Effect on the Equilibria among the Three Species.

From the NMR spectra, it was found that TTA in dehydrated alcohol exists as an equilibrium mixture of the enol (E) and hemiacetal (A) forms. Furthermore, Table 1 shows that the ratio of E% to A% is not greatly affected by the solvent employed, while in water-saturated alcohols the fraction of the hydrate form (H) depends on the solvent. Since the hydration reaction is expressed by the following equation:



(3)

the fraction of the hydrate form can be expected to depend on the water concentration. In Table 2, the fractions of the three forms in 1-butanol containing water in various concentrations are listed. A linear correlation between ln [H]/[E] and ln X_W (mole fraction of water) was obtained in the mole-fraction range from 0.136 to 0.514, as is shown in Fig. 3. However, the plots for water-saturated alcohols are appreciably scattered from the line obtained for aqueous 1-butanol, hence, it is found that the water concentration is the primary, but not the only, factor governing the fraction of the hydrate form. It is considered that

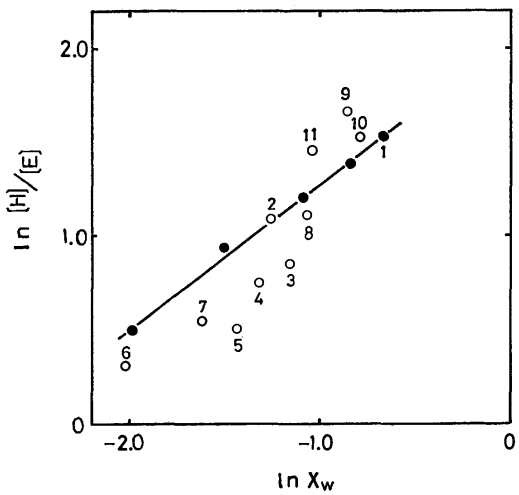

Fig. 3. Dependence of the enol-hydrate equilibrium constant on water mole fraction in alcohol; ●, aqueous 1-butanol, ○, water-saturated alcohols. The numbers in this figure correspond to those in Table 1.

alcohols affect the solubilities of both water and the hydrate form. Therefore, we also examined the influence of the physical properties of alcohols on the fraction ratio of [H]/[E].

Bernstein and Powling[8] have accounted for the influence of the solvent on the keto-enol tautomerism of β-diketones in terms of Onsager's model, which consideres the different energies of the electrostatic interaction of each tautomer with its surroundings. According to the relationship established in their work, the enthalpy of hydration, ΔH, may be represented as follows:

$$\Delta H_{\text{gas}} = \Delta H_{\text{solution}} + \left(\frac{\varepsilon-1}{2\varepsilon+1}\frac{1}{V_0}\right)_{\text{solvent}}(\mu_H^2-\mu_E^2), \quad (4)$$

where μ_H and μ_E are the dipole moments of the hydrate form and the enol form respectively, and where V_0 and ε are the molar volume and the dielectric constant of alcohol respectively. Equation 4 suggests the correlation between the free energy of the hydration, which is equal to $-RT$ ln [H]/[E], and $(\varepsilon-1)/V_0(2\varepsilon+1)$. In Fig. 4, ln [H]/[E] is plotted against the solvent quantity $(\varepsilon-1)/V_0(2\varepsilon+1)$. The plots almost follow a straight line, and the positive sign of the slope means that $\mu_H > \mu_E$.

Recently, the solubility parameter concept has been applied to the interpretation of the solvent effect of alcohols on the partition equilibrium of TTA.[6] Accord-

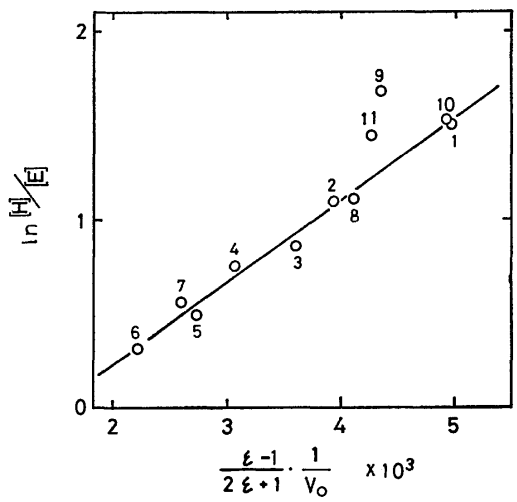

Fig. 4. Correlation between the enol-hydrate equilibrium constant and the solvent quantity $(\varepsilon-1)/V_0(2\varepsilon+1)$. The numbers in this figure correspond to those in Table 1.

ing to the solubility parameter theory, the equilibrium constant of the hydration reaction can be represented approximately by

$$\ln [H]/[E] = \frac{V_E}{RT}(\delta_H-\delta_E)(2\delta_0-\delta_E-\delta_H) + \text{const}, \quad (5)$$

where V_E is the molar volume of the enol form and where δ_H, δ_E, and δ_0 are the respective solubility parameters of the hydrate form, the enol form, and the water-saturated alcohol. The influence of water on the solubility parameter of the water-saturated alcohols is not serious in most alcohols, except for the cases of 1-butanol and 2-methyl-1-propanol, in which the next equation can be used for correction:

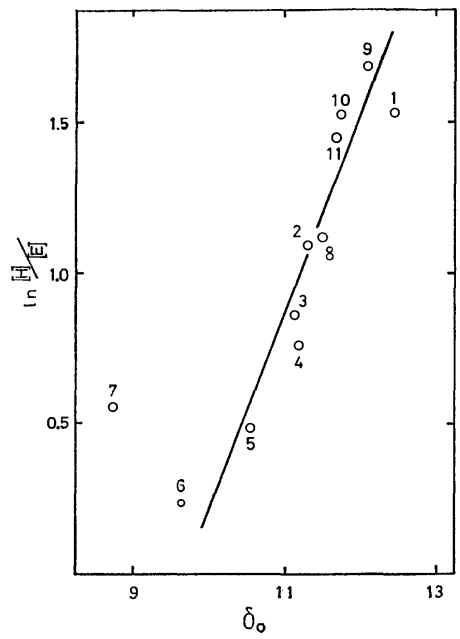

Fig. 5. Correlation between the enol-hydrate equilibrium constant and the solubility parameter of alcohol. The numbers correspond to those in Table 1.

$$\delta_0 = \phi_s\delta_s + \phi_a\delta_a, \quad (6)$$

where ϕ_a and ϕ_s are the respective volume fractions of water and alcohol and where δ_a and δ_s are the respective solubility parameters of water (23.4 $cal^{1/2}$ $cm^{-3/2}$) and alcohol. In Fig. 5, ln [H]/[E] is plotted against the solubility parameter of the alcohol. In most alcohols, the plots follow a straight line. The positive sign of the slope means that $\delta_H > {}_E\delta$, which corresponds to the result of $\mu_H > \mu_E$. From above results, we can state that the fraction of the hydrate form increases with the solvent quantity, ε or δ.

Inversion Rate of the Hemiacetal Form. The observed first-order rate constant (k) in dehydrated alcohol is the sum of the forward rate constant (k_a) and the reverse rate constant (k_e) in Eq. 2, *i.e.*, $k=k_a+k_e$. The enolization rate constant is calculated by means of the following relation:

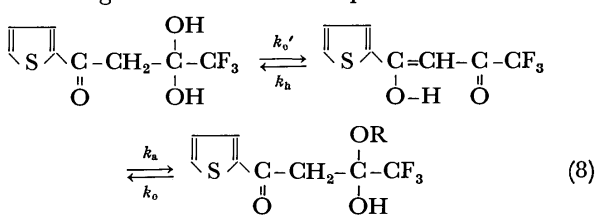
$$k_e = fk, \quad (7)$$

where f is the enol fraction. The observed rate constant and the calculated enolization rate constant are listed in Table 3 for several alcoholic systems. The rate constant in 2-methyl-1-propanol is smaller than the others. This may be the result of the steric effect in the transition state.

Table 3. Observed interconversion rate constant (k) between the enol and hemiacetal forms and the estimated enolization rate constant (k_e) of TTA in alcoholic solutions

Solvent	Mole fraction of water	$k\times10^3$ (min^{-1})	$k_e\times10^3$ (min^{-1})
1-Butanol	0.000	2.39	0.70
	0.025		2.31
	0.049		3.72
	0.133		8.96
	0.234		20.7
1-Pentanol	0.000	3.48	1.11
1-Hexanol	0.000	11.7	4.00
1-Octanol	0.000	3.96	1.34
2-Methyl-1-propanol	0.000	1.07	0.29

In the case of a water-containing alcoholic solution, the following reaction can be expected to occur:



(8)

The rate equation for the above reaction may be described as

$$-\frac{d}{dt}[E] = (k_h+k_a)[E]-k_e'[H]-k_e[A]. \quad (9)$$

When the hydration rate is fast and the equilibrium between the enol form and the hydrate form is instantly established, Eq. 9 becomes

$$-\frac{d}{dt}[E] = \left(\frac{k_a}{1+K}+k_e\right)([E]-[E]_{eq}), \quad (10)$$

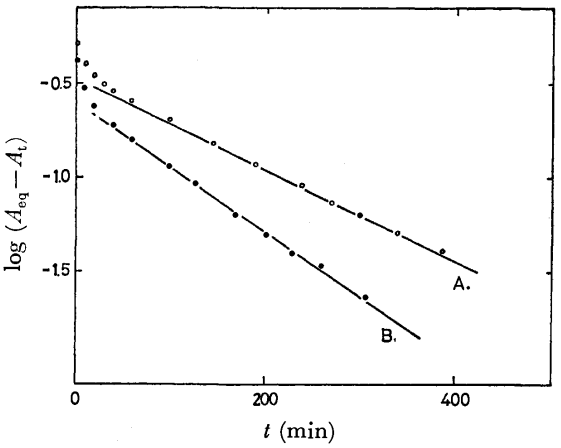


Fig. 6. Absorbance change of the enol form in aqueous 1-butanol solution; A, $X_w=0.025$, B, $X_w=0.049$.

where K is the equilibrium constant, $K=[H]_{eq}/[E]_{eq}$. The integration of Eq. 10 gives the final equation:

$$\log([E]_{eq}-[E]) = -\frac{k_a+(1+K)k_e}{2.30(1+K)}t + \text{const.} \quad (11)$$

Typical absorbance changes of the enol form observed in the aqueous 1-butanol solutions are shown in Fig. 6. The fast-reaction part and the subsequent slow-reaction part are clearly seen. The fast-reaction is connected with the hydration reaction. From the slope of the slow-reaction part, the rate constant of the enol-hemiacetal reaction was obtained. The rate constant for the process from the hemiacetal form to the enol form was calculated from the following reaction:

$$k_e = (1+K)fk. \quad (12)$$

The obtained values for k and k_e are listed in Table 3. The value of k_e increases with the water concentration. In Fig. 7, log ($k_e-k_e^\circ$) is plotted against the molar concentration of water, where k_e° denotes the enolization rate constant in dehydrated 1-butanol. A linear correlation with a slope of 0.92 was obtained. The result suggests that one water molecule participates in the

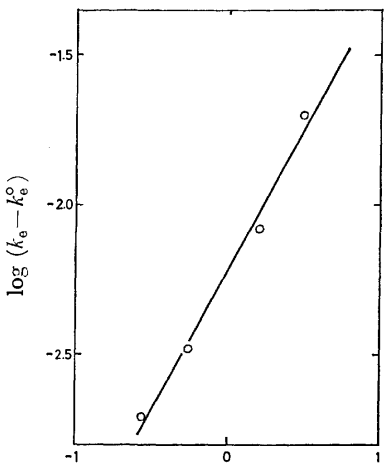

Fig. 7. Water concentration dependence of the enolization rate constant of the hemiacetal form in aqueous 1-butanol.

transformation from the hemiacetal form to the enol form. Takada *et al.*[9] examined the water-concentration dependence of the hydration rate of TTA in both dioxane and acetonitrile and suggested the third order in water. Bell *et al.*[10] have reported that three water molecules participate in the hydration of 1,3-dichloroacetone and that the water can be replaced by either carboxylic acid or 2,6-dichlorophenol. In the present system also, it can reasonably be expected that one water and some alcohol molecules participate cooperatively in the enolization process of the hemiacetal form.

From the results that the fraction of the hemiacetal forms is 20—30% for most water-saturated alcohols and that the inversion rate to the enol form is very slow, it can be expected that the hemiacetal form plays an important role in the kinetics and mechanism of metal extraction with TTA in an alcohol/water system.

Anodic Voltammetry and Its Analytical Application to the Detection and Simultaneous Determination of Hypoxanthine, Xanthine, and Uric Acid

Toshio YAO,* Yoichi TANIGUCHI, Tamotsu WASA, and Soichiro MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozuumemachi, Sakai 591

(Received April 21, 1978)

The voltammetric oxidation of hypoxanthine, xanthine, and uric acid was investigated by means of linear-sweep voltammetry, cyclic voltammetry, and controlled-potential coulometry. Hypoxanthine, xanthine, and uric acid each gave a single oxidation peak at a different potential, with a stationary glassy carbon electrode, over the wide pH range of 0—13. Hypoxanthine was initially oxidized in a two-electron step to xanthine, which was then further oxidized in a two-electron step to uric acid, as well as the enzymatic oxidation. All three substances were strongly adsorbed on the surface of the glassy carbon electrode, so that the concentration *vs.* anodic peak current curves were not linear. The adsorption on the electrode was very dependent on the pH, and especially at pH values around neutrality the anodic peaks were ill-defined. However, in such acid solutions as H_3PO_4 and H_2SO_4, the voltammetric oxidation was a diffusion-controlled process and the differences between the peak potentials were most pronounced (*ca.* 400 mV). Consequently, it was possible to determine simultaneously three hydroxypurine bases by using 1 M H_2SO_4 or 1 M H_3PO_4 as a supporting electrolyte, without prior treatment or separation procedures.

The electrochemical oxidation and reduction of biologically important compounds have been investigated with much interest. It is important to understand fully their redox behavior in considering the methabolism and analytical determination of biologically important compounds. Several works[1-3] have suggested a possible parallelism between the modes of electrochemical behavior and the biological transformation, *e.g.*, the enzymatic oxidation.

The electrochemical reduction of purine bases, which are important components of nucleic acids, has been investigated in both aqueous[4-6] and nonaqueous solutions[7,8] at the dropping mercury electrode (DME). However, in aqueous solutions none of the purine bases except adenine were easily reduced at the DME.

A few studies of the electrochemical oxidation of purine bases have been done at the pyrolytic graphite electrode (PGE)[9-11] and the glassy carbon electrode (GCE).[12] Both adenine and guanine gave a anodic peak at different potentials over a wide pH range. Our own previous paper[12] described a method whereby adenine, guanine, and their nucleosides could be determined simultaneously by linear-sweep voltammetry using a stationary planar GCE.

In the present work, the oxidation behavior of three hydroxypurine bases (hypoxanthine, xanthine, and uric acid) was investigated by means of linear-sweep voltammetry, cyclic voltammetry, and controlled-potential coulometry. The mutual relation of the primary oxidation process of each of these hydroxypurine bases was investigated. Also, in order to develop a satisfactory analytical method of the three hydroxypurine bases it was found necessary to investigate in some detail the adsorption behavior on the GCE. This paper will describe the oxidation behavior and a method for the simultaneous determination of hypoxanthine, xanthine, and uric acid.

Experimental

Chemicals. The hypoxanthine, xanthine, and uric acid were all obtained from the Wako Pure Chemical Co. The other chemicals were of a reagent grade and were used without further purification.

Apparatus. The anodic voltammograms were recorded using a Yanagimoto P-8 type Polarograph. Cyclic voltammograms were obtained with a versatile solid-state instrument constructed in this laboratory following the design of Goolsby and Sawyer,[13] with the triangular voltage sweeps supplied by a NF circuit design block Co. Model FG-104T function generator. The current-voltage curves were recorded on a IWATSU Model DS-5016 dual-beam oscilloscope equipped with a camera. Controlled-potential coulometry was done with a NICHIA NP-1 type potentiostat, and a glassy carbon beaker (40 ml in volume, Tokai Electrode Co.) was used as the working electrode.

A three-electrode voltammetric cell maintained at (25±0.1) °C was used for all the experiments. A saturated calomel electrode (SCE) was employed as a reference electrode, while a platinum wire was employed as a counter electrode. A working electrode was constructed from a 3-mm glassy carbon rod (Grade GC-20, Tokai Electrode Co.). The rod was cut into a length of 10 mm and was sealed in one end of a glass tube (3 mm in diameter) with epoxy cement. The end of the glass tube-carbon rod assembly was polished with 400-grade emery paper until it was quite smooth. Then, by polishing with 1500-grade emery paper and then with a paste of CeO_2 on asphalt pitch, the surface of the electrode was brought to a mirror finish.

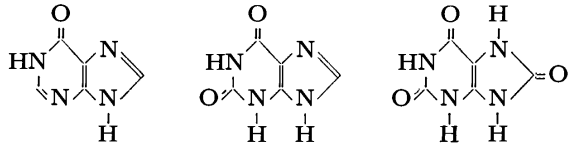
Voltammetric Procedure. In order to obtain reproducible results, a standard pretreatment procedure was applied before recording each voltammogram. The GCE was polished for 30 s with 1500-grade emery paper and then with a paste of CeO_2 on asphalt pitch until the surface of the electrode was brought to a mirror finish. The surface of the electrode was then washed with a fine spray of distilled water. Any water remaining on the electrode surface and the shaft of the electrode was removed by touching the surface very gently with a piece of soft absorbent paper. The test solutions were not deaerated. The voltage scan was commenced after quiescency

for about 20 s at the starting potential (usually 0.0 V *vs.* SCE).

At least three replicate voltammograms were recorded for each test solution. A current-voltage curve of the background solution was recorded in the same way, while the peak current was obtained by arithmetrically subtracting the observed background current at the peak potential from that of the test solution.

Results and Discussion

Linear-Sweep Voltammetry. *Effect of pH*: Hypoxanthine, xanthine, uric acid each gave an oxidation peak at a stationary GCE over the wide pH range of 0—13. The anodic voltammograms recorded at various pH values are shown in Fig. 1 for uric acid and in Fig. 2



Hypoxanthine Xanthine Uric acid

for xanthine. The oxidation peaks of uric acid and xanthine tended to become ill-defined with the increase in pH, and their peak currents decreased gradually. Similar behavior was also observed for hypoxanthine.

The half-peak potentials ($E_{p/2}$) of the oxidation peaks of the three hydroxypurine bases (uric acid, xanthine, and hypoxanthine), as is shown in Fig. 3, shifted linearly towards negative potentials with the increase in pH; $E_{p/2}$ (*vs.* SCE)/V=0.69—0.050 pH for uric acid, $E_{p/2}$ (*vs.* SCE)/V=1.08—0.059 pH for xanthine, and $E_{p/2}$(*vs.* SCE)/V=1.50—0.068 pH for hypoxanthine. The analytical significance of these experimental results lies in the fact that the voltammetric oxidation peak-potential for each of the three hydroxypurine bases is quite different at each of the pH values studied.

GCE geometric area: 7.1 mm², scan rate: 3.3 mV/s.
----: i_p, —— : $E_{p/2}$.

The peak current of the oxidation peaks gradually decreased with the increase in pH, as is shown in Fig. 3, particularly in the case of hypoxanthine. This experiment was undertaken at a relatively low concentration (0.1 mM) of the hydroxypurine bases. When the depolarizer concentration was fairly high (1.0 mM), the pH values were found to have a pronounced effect on the peak current of the hydroxypurine bases. That is, the peak current decreased extremely at the pH values

around neutrality, as is shown in Fig. 4 for hypoxanthine. However, the peak current was relatively constant in the Britton-Robinson buffer at pH 2.1 and in acid solutions (1 M H_2SO_4, $HClO_4$, and H_3PO_4) as supporting electrolytes. Also, in electrolytes containing chloride ions such as HCl, the oxidation peak of hypoxanthine was masked by the facile oxidation of the chloride ion in the background electrolyte. Similar relationships between the peak current and the pH values were also obtained for the oxidation peaks of xanthine and uric acid.

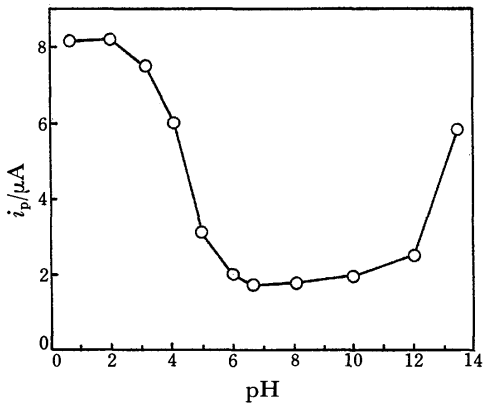

Fig. 4. The effect of pH on the peak current of 1.0 mM hypoxanthine.
GCE geometric area: 7.1 mm², scan rate: 3.3 mV/s.

Effect of the Scan Rate: In order to study the adsorption of the hydroxypurine bases on the stationary GCE, the effect of the voltage scan rate on the peak current of each hydroxypurine base was examined.

For a linear diffusion-controlled peak, the peak current function, $i_p/ACV^{1/2}$, should be a constant[14] in spite of the variation in the scan rate, where A is the area of the electrode surface; C, the bulk concentration of depolarizer; and V, the scan rate. In 1 M H_2SO_4 or H_3PO_4, the peak current function for each of the three hydroxypurine bases was almost independent of the scan rate. In the electrolyte solution with pH values around neutrality, however, the peak current functions increased with the increase in the scan rate, especially in the case of hypoxanthine. This behavior is typical of an electrode process where the reactant is adsorbed on the electrode,[15] but in 1 M H_2SO_4 or H_3PO_4 the voltammetric oxidation is a diffusion-controlled process.

Effect of the Concentration: In the 0.5 M phosphate buffer (pH 6.6), the relationship between the peak current and the concentration were nearly linear for both xanthine and uric acid, but non-linear for hypoxanthine, as is shown in Fig. 5. The peak potential was also dependent on the concentration and slightly shifted to more positive values with the increase in the concentration. Over the concentration range of 0.02—0.2 mM, this shift was about 14 mV for uric acid, 29 mV for xanthine, and 55 mV for hypoxanthine. In the Britton-Robinson buffer with pH values of 8—10, hypoxanthine showed a post-peak at a more positive potential than the main peak at concentrations above *ca.* 1 mM. This post-peak appeared at rather variable potentials.

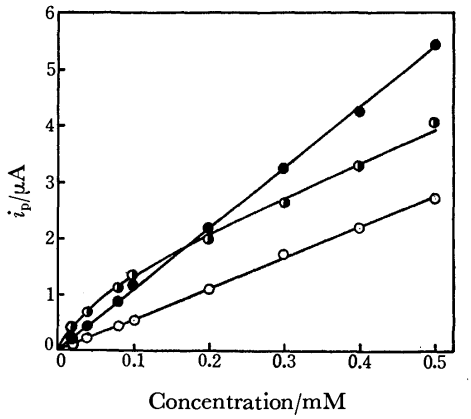

Fig. 5. The relationships between the peak current and the concentration in 0.5 M phosphate buffer (pH 6.6).
○: Uric acid, ●: xanthine, ◑: hypoxanthine.

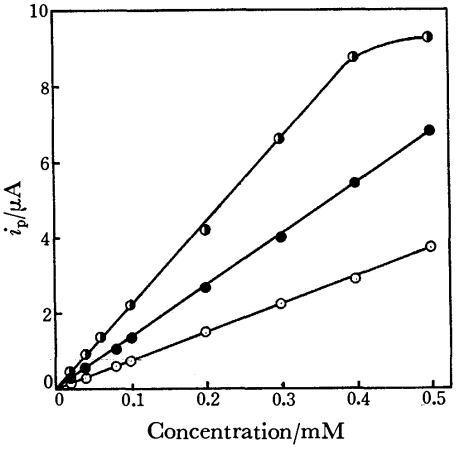

Fig. 6. The relationships between the peak current and the concentration in 1 M H_3PO_4.
○: Uric acid, ●: xanthine, ◑: hypoxanthine.

However, in such acid solutions as 1 M H_3PO_4 and H_2SO_4, each of these hydroxypurine bases showed a good linear relationship between the peak current and the concentrations ranging from 0.02 to 0.4 mM, as is shown in Fig. 6. Also, the peak potential was independent of the concentration.

These effects of the concentration and the pH on the peak current imply that the adsorption of the depolarizer on the GCE is very dependent on the pH, but in 1 M H_3PO_4 or H_2SO_4 solutions the voltammetric oxidation is a diffusion-controlled process.

Mutual Relation of Primary Oxidation Processes. Cyclic voltammograms at fast scan rates were recorded for each of the three hydroxypurine bases. The results are shown in Fig. 7. Scanning from 0.0 V at a clean electrode toward a positive potential, only a single anodic peak was observed for hypoxanthine. The principle point of interest in this voltammogram is that two new and small anodic peaks (Peaks I and II) were observed on the second sweep toward the positive potential, Peak I at 0.65 V and Peak II at 0.99 V (*vs.* SCE) in the Britton-Robinson buffer at pH 2.1. However, the peak potentials of these new peaks were

TABLE 1. COULOMETRIC *n* VALUES FOR THE CONTROLLED-POTENTIAL ELECTROLYSIS OF OXYPURINE BASES IN 1 M H_3PO_4

Oxypurine bases	Applied potential (V *vs.* SCE)	$n^{a)}$
Uric acid	0.80	2.21
Xanthine	1.20	4.16
Hypoxanthine	1.60	5.88

a) Average value of triplicate determinations.

dependent on the pH of electrolyte solutions. At various pH values, the peak potentials for these two anodic peaks, I and II, were the same as those of the anodic peaks for the oxidation of uric acid and xanthine respectively. Similarly, xanthine showed a new anodic peak on the second sweep toward the positive potential. This peak appeared at almost the same peak potential as the anodic peak of uric acid.

Controlled-potential coulometry for each of three hydroxypurine bases was carried out in 1 M H_3PO_4. The electrolysis was continued until all of the depolarizers were completely oxidized. Typical coulometric data are presented in Table 1; the *n* value for uric acid was about two, for xanthine it was four, and for hypoxanthine it was six.

In summary, the cyclic voltammetric and coulometric data suggest that hypoxanthine is initially oxidized in a two-electron step to produce xanthine, which is then further oxidized in a two-electron step to produce uric acid. It is also known[16] that uric acid is oxidized in a two-electron process to produce 4,5-dihydroxy-4,5-dihydrouric acid, which is unstable and which fragments predominantly to allantoin, but a very small fraction is further oxidized to parabanic acid. Hypoxanthine is also enzymatically oxidized to uric acid *via* xanthine by the action of the xanthine oxidase. Thus, it is interesting that the electrochemical oxidation is very similar to the enzymatic oxidation.

Analytical Application. The anodic voltammograms for the mixtures of uric acid, xanthine, and hypoxanthine were recorded in three electrolyte solutions (Fig. 8). In 1 M H_2SO_4 three successive well-defined oxidation peaks were observed, but in the 0.5 M phosphate buffer and 1 M NaOH solutions the three peaks were ill-defined, as a result that the increase in the pH of the electrolyte solutions made the voltammetric peaks sensitive to the adsorption of depolarizers on the GCE. Accordingly, for the detection and quantitative determination of the three hydroxypurine bases, the use of a 1 M H_2SO_4 or H_3PO_4 solution as the supporting electrolyte was suitable. In order to test the quantitative method developed here, the voltammograms for some mixtures of three hydroxypurine bases were recorded in 1 M H_2SO_4 at a stationary GCE. The concentration of each hydroxypurine base was determined by the calibration-curve method from the respective heights of the resulting voltammetric oxida-

tion peaks. Some typical analytical results are shown in Table 2. Clearly this method is readily capable of determining simultaneously each component in mixtures of the three hydroxypurine bases.

The principal advantage of the proposed method is the rapidity of analysis. The speed of analysis is aided by the fact that no prior treatment or separation procedure is needed. Furthermore, as dissolved oxygen does not interfere with the anodic voltammetry, no deaeration is required.

Preparation and Solid-phase Thermal *cis-α* ⟷ *cis-β* Isomerization of the Chromium(III) Triethylenetetramine Complexes[1)]

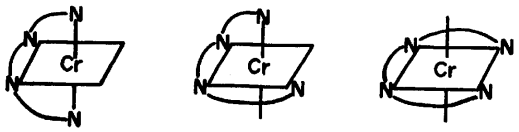
Ryokichi TSUCHIYA,* Akira UEHARA, Kazuhiko NOJI, and Hitoshi YAMAMURA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received April 24, 1978)

Heating of a mixture of $CrCl_3 \cdot 6H_2O$ and triethylenetetramine (trien) produced violet products which gave *cis*-α-$[Cr_2(OH)_2trien_2]X_4 \cdot 2H_2O$ and *cis*-α-$[Cr(OH)(H_2O)trien]X_2 \cdot H_2O$ (X=Cl, Br or I) on treatment with aqueous NaX solutions. *cis*-α-$[CrCl_2trien]Cl \cdot 2H_2O$ were obtained in the presence of a trace amount of water. Absolutely dry conditions are necessary for the preparation of *cis*-β-$[CrCl_2trien]Cl$. The thermally induced reversible *cis*-α↔*cis*-β isomerization was detected in the complexes *cis*-α-$[Cr(OH)(H_2O)trien]Cl_2 \cdot H_2O$ and *cis*-β-$[CrCl_2trien]Cl$ by means of derivatography and high-temperature IR spectroscopy. The former *cis*-α-hydroxoaqua complex was found to be converted irreversibly into *cis*-β-form above 225 °C in the solid-phase. The *cis*-β-form obtained readily isomerized to *cis*-α-form in aqueous media. The dimeric *cis*-α-$[Cr_2(OH)_2trien_2]^{4+}$ was converted gradually into the monomeric *cis*-α-$[Cr(OH)(H_2O)trien]^{2+}$ in water.

Three geometrically possible isomers are expected for the chromium(III)–triethylenetetramine (trien) complexes: *cis*-α, *cis*-β, and *trans*-forms (Fig. 1). In the case of the cobalt(III)[2-8] and rhodium(III)[9,10] complexes, the three geometrical isomers as well as other conformational isomers, especially of the dihalogeno complexes [Co or Rh Cl_2 trien]$^+$ have been reported. As regards the chromium(III) complexes, however, only *cis*-α-form is known[11,12] except for the recent report by Fordyce *et al.*[13] on *cis*-β-$[CrCl_2trien]Cl$. This is partly because the *cis*-β complexes are apt to undergo rapid aquation and isomerization in aqueous media. Special care is thus necessary for preparation of the *cis*-β complexes. Difficulties might be overcome if hydrous chromium(III) salts could be used in the preparation of the desired complexes.



cis-α *cis*-β *trans*

Fig. 1. Geometrically possible isomers of the Cr(III)–trien complexes.

We have attempted to prepare the Cr(III)–trien complexes by the reaction of $CrCl_3 \cdot 6H_2O$ and trien in a matrix state in order to clarify the solid-phase *cis*-α↔*cis*-β thermal isomerization of the complexes obtained. The survey of the isomerization in the solid-phase enables us to predict the possibility of the formation of *cis*-β complexes hardly obtainable in the presence of water.

Experimental

Preparation of Complexes. cis-α-*Di-μ-hydroxo-bis(triethylenetetraminechromium(III)) Iodide Dihydrate,* cis-α-$[Cr_2(OH)_2trien_2]I_4 \cdot 2H_2O$ *(bluish violet).* 30 g (0.11 mol) of chromium(III) chloride hexahydrate and 18 g (0.12 mol) of trien were triturated in a mortar of 12 cm diameter and heated at 180 °C for 6 h in an air-bath. The resulting violet masses were crushed. Excess ethanol was added to extract unreacted trien. After the extraction had been repeated 2 or 3 times, the bluish violet products were dissolved in 200 ml of hot water. Greenish residues were then removed by filtration. To the violet filtrate, 30 g (0.2 mol) of sodium iodide was added. Bluish violet crystals were soon separated out. The crystals had to be quickly recrystallized from water, otherwise the following hydroxoaqua complex was obtained. Yield about 20 g.

Found: C, 14.62; H, 4.15; N, 11.76%. Calcd for $C_{12}H_{42}O_4N_8I_4Cr_2$: C, 14.79; H, 4.08; N, 11.95%.

cis-α-*Hydroxoaquatriethylenetetraminechromium(III) Chloride Monohydrate,* cis-α-*[Cr(OH)(H$_2$O)trien]Cl$_2$·H$_2$O (pink).* The violet filtrate was allowed to stand in a refrigerator overnight without addition of NaI, pink products being obtained. Recrystallization was carried out from water. Yield 3 g.

The complex was also obtained when the aqueous solution of the di-μ-hydroxo complex was allowed to stand overnight.

The corresponding bromide and iodide were obtained as monohydrates by addition of NaBr and NaI, respectively, to the aqueous solution of *cis*-α-$[Cr(OH)(H_2O)trien]Cl_2 \cdot H_2O$.

The *cis*-α complex was converted irreversibly into *cis*-β-form above 225 °C in the solid-phase. Isomerization makes it possible to prepare the *cis*-β complex. However, we could not purify the product because of the absence of a suitable solvent. Recrystallization from water always gave *cis*-α-form.

cis-α-*Dichlorotriethylenetetraminechromium(III) Chloride Dihydrate,* cis-α-*[CrCl$_2$trien]Cl·2H$_2$O (violet) and* cis-β-*Dichlorotriethylenetetramine Chloride,* cis-β-*[CrCl$_2$trien]Cl (violet).* These

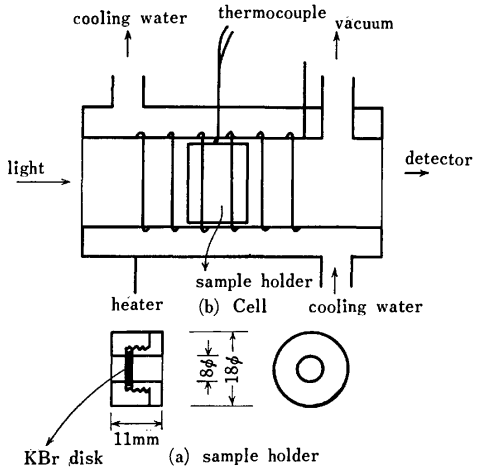


Fig. 2. Devices for measuring IR spectra at elevated temepartures.
(a) Sample holder, (b) cell.

were prepared from *cis*-α-[Cr(ox)trien]Br·nH$_2$O (n=3 or 0 respectively) according to the method of Fordyce *et al.*[13] slightly modified and identified by means of elemental analysis and IR spectroscopy. The striking difference in preparation between the *cis*-α and *cis*-β complexes is that the former can be obtained even in the presence of a trace amount of water, while water should be absolutely avoided in the preparation of the latter.

Instruments. Derivatograms, IR and UV spectra, and molar conductivities were measured by the same apparatus as reported.[14] The IR spectra at elevated temperatures were monitored with a temperature-controlled cell (Fig. 2). The cell was then set up on a JASCO A-3 IR spectrophotometer. The 9 mm diam KBr disk prepared in the usual way was loaded in the steel holder (Fig. 2-(a)), which was then put in a cell regulated at the desired constant temperatures (Fig. 2-(b)). The sample (KBr disk) temperature was measured and controlled with a SINYO RIKA DIGICON-1200 equipped with an alumel-chromel thermocouple.

Results and Discussion

IR Spectra. The band due to the NH asymmetric bending vibration in the region 1550—1600 cm^{-1} is diagnostically useful for distinguishing *cis*-α from *cis*-β complexes: *cis*-α has one band, *cis*-β 2 or 3 bands in this region.[2,12,13] Figure 3 shows the IR spectra of *cis*-α-[CrCl$_2$trien]Cl·2H$_2$O, *cis*-α-[Cr(ox)trien]Br·3H$_2$O, *cis*-α-[Cr(OH)(H$_2$O)trien]Cl$_2$·H$_2$O and *cis*-β-[CrCl$_2$trien]Cl. The spectrum of *cis*-α-[Cr$_2$(OH)$_2$trien$_2$]I$_4$·2H$_2$O is omitted since it is essentially the same as that of *cis*-α-[Cr(OH)(H$_2$O)trien]Cl$_2$·H$_2$O. The numerical data for the samples before, during and after heating at appropriate temperatures are summarized in Table 1. All the *cis*-α complexes have a sharp band, while the *cis*-β complex has three distinctive peaks. Noticeable changes could be detected in the IR spectra of *cis*-α-[Cr(OH)(H$_2$O)trien]Cl$_2$·H$_2$O and *cis*-β-[CrCl$_2$trien]Cl at elevated temperatures. The changes thermally reversible may come from the reversible *cis*-α↔*cis*-β isomerization of these complexes.

Electronic Spectra. *Hydroxo Complexes*: The absorption maxima due to d-d transition of each complex are summarized in Table 2. The dimeric structure for *cis*-α-[Cr$_2$(OH)$_2$trien$_2$]I$_4$·2H$_2$O is supported by the appearance of the band at about 36.6×10^3 cm^{-1} (log

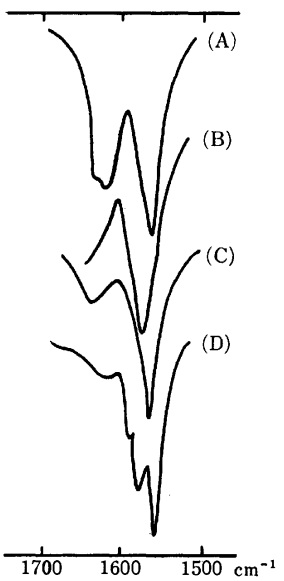

Fig. 3. IR spectra.
(A) *cis*-α-[CrCl$_2$trien]Cl·2H$_2$O, (B) *cis*-α-[Cr(ox)trien]Br·3H$_2$O, (C) *cis*-α-[Cr(OH)(H$_2$O)trien]Cl$_2$·H$_2$O, (D) *cis*-β-[CrCl$_2$trien]Cl.

$\varepsilon\approx4.1$) assignable to the bridging OH groups.[15] The absorption maxima of the complex in water shift gradually to higher wavenumber regions. After being left to stand they became similar to those of *cis*-α-[Cr(OH)(H$_2$O)trien]Cl$_2$·H$_2$O, suggesting that the dimeric di-μ-hydroxo complex is gradually converted into the monomeric complex in water.

Dichloro Complexes: The electronic spectra of *cis*-α-[CrCl$_2$trien]Cl·2H$_2$O and *cis*-β-[CrCl$_2$trien]Cl were measured both in dry methanol and in 0.1 mol dm^{-3} hydrochloric acid. The resemblance in color between the *cis*-α and *cis*-β complexes is recognizable from the similarity of their electronic spectral data in dry methanol used for preventing aquation of the complexes. However, both the complexes differ remarkably from each other in hydrochloric acid solution. As seen in Table 2, the first band (18.3×10^3 cm^{-1}) of the *cis*-β complex shifts to higher wavenumber regions (19.2×10^3 cm^{-1}) within only 3 minutes after the complex was dissolved in 0.1 mol dm^{-3} hydrochloric acid, the

a) The complex gave the specific band at about 36.6×10^3 cm^{-1} (log $\varepsilon \approx 4.1$) due to the di-μ-hydroxo group. b) Measured 3 min after the complex was dissolved. c) The data are closely similar to those of *cis*-α-[CrCl(H_2O)trien]$^{2+}$ reported previously.[13]

spectrum being quite similar to those of *cis*-α-[CrCl(H_2O)trien]$^{2+}$.[13] On the other hand, only a slight shift was observed in the case of the *cis*-α complex ($18.5 \times 10^3 \rightarrow 18.6 \times 10^3$ cm^{-1}). The *cis*-α complex was also found to be finally aquated to form *cis*-α-[CrCl(H_2O)trien]$^{2+}$. These results indicate that the *cis*-β complex aquates and isomerizes quite rapidly as compared with the *cis*-α complex.

Thermally Induced cis-α↔cis-β *Isomerization in the Solid-phase.* Reversible *cis*-α↔*cis*-β isomerization was found to be thermally induced in the complexes *cis*-α-[Cr(OH)(H_2O)trien]$Cl_2 \cdot H_2O$ and *cis*-β-[$CrCl_2$trien]Cl. Figure 4 shows the derivatograms of both the complexes measured in a nitrogen stream at a heating rate of 1 °C min^{-1}.

As seen from the TG curve of *cis*-α-[Cr(OH)(H_2O)trien]$Cl_2 \cdot H_2O$, the complex evolves 1 mol of water at 50—135 °C, remaining unchanged up to 295 °C, and then decomposes in a complicated way. Two small but distinct endothermic peaks are observed in the DTA curve after the dehydration step. The original pink color of the complex becomes slightly violet at the first endothermic peak (*ca.* 160 °C), the violet tone returning to the original pink color upon cooling at room temperature. The reversibility was repeatedly found in each step between the first (160 °C) and the second (225 °C) DTA peaks. However, thermochromism becomes irreversible above the temperature of the second DTA peak.

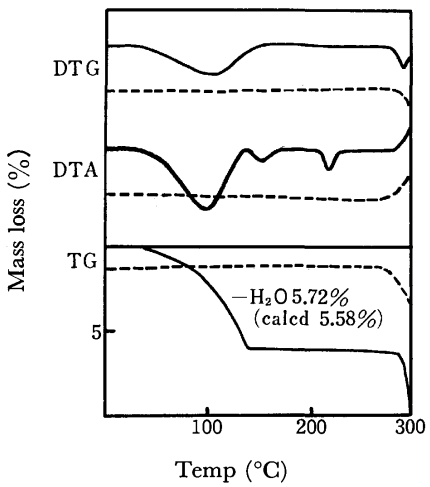

Fig. 4. Derivatograms of *cis*-α-[Cr(OH)(H_2O)trien]$Cl_2 \cdot H_2O$ (——) and *cis*-β-[$CrCl_2$trien]Cl (----).

The thermochromic behavior was monitored by measuring IR spectra below and above respective DTA peaks. As seen from Table 1, the complex exhibits one sharp band at room temperature, and three bands (1592, 1575, and 1556 cm^{-1}) at 160 °C. The three bands were quenched when the complex was cooled to room temperature, its original one band being recovered. Such IR spectral changes were reversible between the first (160 °C) and the second (225 °C) DTA peaks. The changes became irreversible above 230 °C (Table 1). The results suggest that the complex undergoes reversible *cis*-α↔*cis*-β isomerization at 160—225 °C, being converted into *cis*-β-form irreversibly above 225 °C. This implies that the heating of the *cis*-α complex above 225 °C furnishes a useful method for preparing *cis*-β complex which is hardly obtained in solution. However, the *cis*-β complex thus obtained could not be purified.

cis-α-[Cr(OH)(H_2O)trien]$Cl_2 \cdot H_2O$ underwent no olation upon heating, although hydroxoaqua Co(III) and Cr(III) complexes usually evolve the coordinated water to form the corresponding di-μ-hydroxo complexes.[16]

On the other hand, the violet color of *cis*-β-[$CrCl_2$trien]Cl became faintly bluish above 70 °C, and the bluish tone returned to the initial violet when the complex was cooled to room temperature. The change was also reversible. No change was found in both the TG and DTA curves up to 285 °C, above which the complex began to decompose (Fig. 4).

Monitoring of the IR spectra revealed that the band due to the NH asymmetric bending vibration appears as three peaks (1591, 1578, and 1561 cm^{-1}) and as one sharp peak (1581 cm^{-1}) at room temperature and at a temperature above 70 °C, respectively. The one sharp peak, however, returned to three peaks when the complex was allowed to stand at room temperature. Such a spectral change was also reversible, suggesting the occurrence of the reversible *cis*-β↔*cis*-α isomerization. Fordyce *et al.*[13] reported that the *cis*-β complex does not isomerize to *cis*-α-form even after the complex was held at 120 °C for 24 h. Their results are understandable in view of our finding that the isomerization is reversible in the temperature region from 70 °C to the decomposition temperature (285 °C). In contrast to *cis*-α-[Cr(OH)(H_2O)trien]$Cl_2 \cdot H_2O$, no clear isomerization temperature was observed in the DTA curve of *cis*-β-[$CrCl_2$trien]Cl. This might be due to a small difference in their relative enthalpies between *cis*-β and *cis*-α complexes.

The isomerization of *cis*-α-[Cr(OH)(H_2O)trien]$Cl_2 \cdot H_2O$ is completed at about 225 °C to give the *cis*-β complex, whereas the isomerization of *cis*-β-[$CrCl_2$trien]Cl remains to be reversible until the complex begins to decompose. This might be interpreted as follows: two

adjacent coordination sites in octahedral environment are occupied by OH and H_2O in *cis*-α-[Cr(OH)(H_2O)-trien]$Cl_2 \cdot H_2O$, and two chloride ions in *cis*-β-[$CrCl_2$-trien]Cl. The size of Cl ion is considerably greater than that of OH or H_2O. If isomerization takes place through twist-mechanism, the size of Cl ion hinders the completion of isomerization. Thus the *cis*-β dichloro complex might decompose prior to reaching the completion-temperature of isomerization. On the contrary, the completion-temperature (about 225 °C) of the isomerization of *cis*-α-[Cr(OH)(H_2O)trien]$Cl_2 \cdot H_2O$ is far lower than the decomposition temperature (295 °C).

Induced Circular Dichroism Spectra of Some Achiral and Racemic Cobalt(III)-Amine Complexes in Aqueous (*R,R*)-Tartrate and (*R,R*)-Tartratoantimonate(III) Solutions

Katsuhiko MIYOSHI, Chang Eon OH, Hiroshi NAKAZAWA, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received May 1, 1978)

The induced circular dichroism (ICD) spectra were measured in the first d-d transition region for the following cobalt(III)-amine complexes in aqueous solutions of (*R,R*)-tartrate and (*R,R*)-tartratoantimonate(III) anions; $[Co(en)_n(NH_3)_{6-2n}]^{3+}$ (n=0—3) and *cis*-$[Co(en)_2(RNH_2)_2]^{3+}$ (R=methyl and ethyl). It was found that a single negative CD band was induced for all the complexes in (*R,R*)-tartrate solution, while a single positive one was induced for most of them in (*R,R*)-tartratoantimonate(III) solution; the ICD developed in it was composed of a single negative band for $[Co(en)_3]^{3+}$ and of two bands with opposite sign for *trans*-$[Co(en)_2(NH_3)_2]^{3+}$ and *cis*-$[Co(en)_2(EtNH_2)_2]^{3+}$. The ICD spectra obtained for racemic complexes were interpreted in terms of differential interactions of Λ- and Δ-enantiomers with (*R,R*)-tartrate or (*R,R*)-tartratoantimonate(III), and an attempt was made to correlate the sign of their ICD spectra with their chromatographic behavior on an SP-Sephadex ion-exchanger with these chiral anions as an eluent.

When a racemic or achiral metal complex is mixed with a chiral substance in solution, relatively weak circular dichroism (CD) is induced in the d-d transition region of the complex. If the racemic complex is optically labile, this phenomenon is referred to as the Pfeiffer effect and has been ascribed to a displacement of the chiral equilibrium between the enantiomers of the complex. On the other hand, CD is similarly induced even if the complex is optically stable or inherently achiral, and it is called induced circular dichroism (ICD).

Mason and Norman[1] were the first to report this phenomenon for a transition metal complex in aqueous diethyl (*R,R*)-tartrate. Since then, special attention has been paid to $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$ to elucidate the mechanism leading to the ICD in achiral and racemic metal complexes.[2-4] In the present paper, an attempt is made to correlate the sign of the ICD spectra developed for a series of racemic cobalt(III)-amine complexes in aqueous (*R,R*)-tartrate and (*R,R*)-tartratoantimonate(III) solutions with their chromatographic behavior on an SP-Sephadex ion-exchanger with these chiral anions as an eluent.

Experimental

Preparation of the Complexes. *(1)* cis-$[Co(en)_2(NH_3)_2]Br_3\cdot H_2O$ *and* trans-$[Co(en)_2(NH_3)_2](NO_3)_3$: $[Co(CO_3)(en)_2]NO_3$[5] was added to concentrated nitric acid, which was then evaporated to dryness on a water bath. The resulting nitrato complex was dissolved in dimethylsulfoxide (DMSO), through which NH_3 gas was bubbled until the color of the DMSO solution changed to orange yellow. The precipitate formed by the addition of ethanol was dissolved in hot water. Less soluble *trans*-$[Co(en)_2(NH_3)_2](NO_3)_3$ was precipitated on cooling and was collected by filtration. The filtrate was loaded on an SP-Sephadex C-25 ion-exchanger and was eluted with sodium phosphate (0.05 M) to remove the *trans*-isomer completely. The addition of sodium bromide to the effluent led to the precipitation of the desired *cis*-isomer as bromide salt. Found: C; 12.05, H; 5.61, N; 32.13%. Calcd for *trans*-$[Co(en)_2(NH_3)_2](NO_3)_3$: C; 12.03, H; 5.51, N; 31.58%. Found: C; 10.32, H; 5.17, N; 17.54%. Calcd for *cis*-$[Co(en)_2(NH_3)_2]Br_3\cdot H_2O$: C; 10.20, H; 5.10, N; 17.83%. Optical resolution of the *cis*-isomer was performed after the method described in the literature.[6] The value of $\Delta\varepsilon$ at 492 nm was +0.575 and −0.561 for the Λ- and Δ-enantiomers, respectively (*cf.* 0.42 reported by McCaffery *et al.*[7]).

(2) cis-$[Co(en)_2(RNH_2)_2](NO_3)_3$ ($R=CH_3$ *and* C_2H_5): These were prepared from $[Co(CO_3)(en)_2]NO_3$ and the corresponding amines by the same method as described above. The yield of *trans*-isomers was so low that only *cis*-isomers were collected. *cis*-$[Co(en)_2(CH_3NH_2)_2]^{3+}$ was partially resolved *via* diastereomeric salt formation with *d*-α-nitrocamphoronate. Found: C, 16.78; H, 6.20; N, 29.82%. Calcd for *cis*-$[Co(en)_2(CH_3NH_2)_2](NO_3)_3$: C, 16.86; H, 6.09; N, 29.51%. Found: C, 20.25; H, 6.92; N, 26.75%. Calcd for *cis*-$[Co(en)_2(C_2H_5NH_2)_2](NO_3)_3\cdot H_2O$: C, 20.29; H, 6.77; N, 26.64%.

(3) $[Co(en)(NH_3)_4]I_3$: *trans*(*Cl*),*cis*(*N*)-$[Co(Cl)_2(en)(NH_3)_2]Cl$[8] was dissolved in DMSO, through which NH_3 gas was bubbled. The orange yellow crystal precipitated by the addition of ethanol was dissolved in a minimum amount of water. The iodide salt was obtained upon the addition of sodium iodide to the solution. Found: C, 4.50; H, 3.66; N, 14.84%. Calcd for $[Co(en)(NH_3)_4]I_3$: C, 4.23; H, 3.52; N, 14.79%.

(4) $[Co(NH_3)_6]Cl_3$ *and* $[Co(en)_3]Cl_3\cdot 3H_2O$: These were prepared by well-established methods.

Chromatographic Resolution and Measurements. Chromatographic resolution of racemic complexes was carried out in the same manner as described by Kojima *et al.*[9] CD spectra were recorded on a JASCO J-40CS spectropolarimeter and ICD spectra were measured for aqueous sodium (*R,R*)-tartrate (0.1 M) or sodium (*R,R*)-tartratoantimonate(III) (0.1 M) solution containing 0.01 M of each complex. When the association constant was obtained by recording the CD intensities, the cell compartment was temperature-controlled at 25±0.2 °C.

Results and Discussion

In Figs. 1 and 2 are shown the ICD spectra obtained in the first d-d transition region for all the complexes examined in aqueous (*R,R*)-tartrate ((*R,R*)-tart^{2-}) and (*R,R*)-tartratoantimonate(III) (Sb_2(*R,R*)-tart$_2^{2-}$) solutions, respectively.

Achiral Complexes. The ICD spectra for achiral

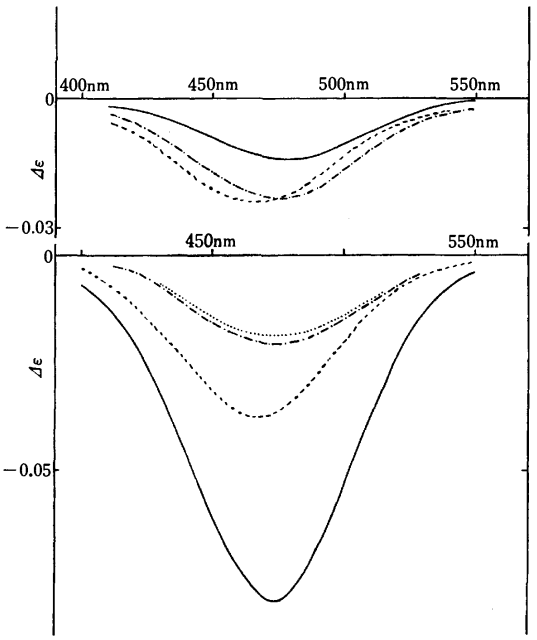

Fig. 1. ICD spectra in aqueous (*R,R*)-tart^{2-} solution. Upper curves; $[Co(NH_3)_6]^{3+}$(——), $[Co(en)(NH_3)_4]^{3+}$ (-•••-), *trans*-$[Co(en)_2(NH_3)_2]^{3+}$(– – –). Lower curves; *rac*-$[Co(en)_3]^{3+}$(——), *rac-cis*-$[Co(en)_2(NH_3)_2]^{3+}$(– – –), *rac-cis*-$[Co(en)_2(MeNH_2)_2]^{3+}$ (-•••-), *rac-cis*-$[Co(en)_2(EtNH_2)_2]^{3+}$ (……).

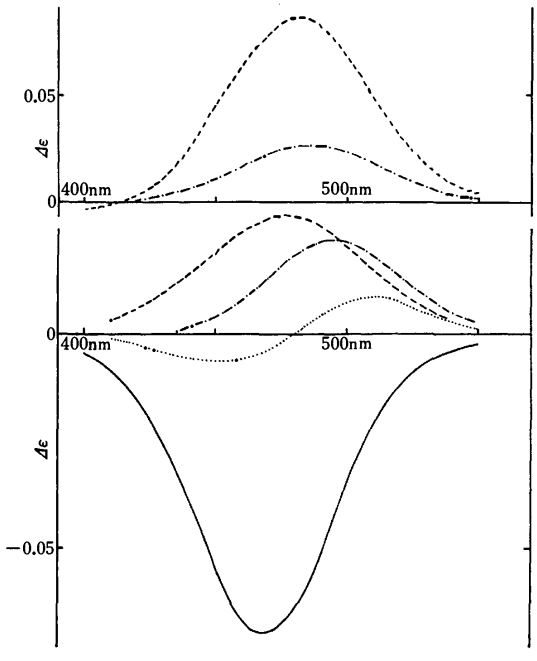

Fig. 2. ICD spectra in aqueous $Sb_2(R,R)$-$tart_2^{2-}$ solution. Upper curves; $[Co(en)(NH_3)_4]^{3+}$(-•••-), *trans*-$[Co(en)_2(NH_3)_2]^{3+}$(——). Lower curves; *rac*-$[Co(en)_3]^{3+}$(——), *rac-cis*-$[Co(en)_2(NH_3)_2]^{3+}$(– – –), *rac-cis*-$[Co(en)_2(MeNH_2)_2]^{3+}$(-•••-),*rac-cis*-$[Co(en)_2(EtNH_2)_2]^{3+}$ (……).

complexes are shown in the upper parts of Figs. 1 and 2. It is seen that, in (*R,R*)-tart^{2-} solution, a single negative CD band is induced, and its intensity decreases in the following order; *trans*-$[Co(en)_2(NH_3)_2]^{3+}$ $\gtrsim [Co(en)(NH_3)_4]^{3+} \gg [Co(NH_3)_6]^{3+}$. This order is tentatively ascribed to the difference in the degree of hydration of these complexes, because hydration of these amine complexes *via* their N–H groups are known to have a profound influence on their association behavior with various anions.[10] In contrast, Taniguchi *et al.*[11] reported the reversed order in acetone containing diethyl (*R,R*)-tartrate and interpreted it in terms of the number of N–H groups on the complexes available for hydrogen bonding with diethyl (*R,R*)-tartrate.

In $Sb_2(R,R)$-$tart_2^{2-}$ solution, on the other hand, $[Co(en)(NH_3)_4]^{3+}$ has a single positive ICD band, but *trans*-$[Co(en)_2(NH_3)_2]^{3+}$ has an additional small, negative band at the higher energy side of a dominant positive band. Since $[Co(NH_3)_6]^{3+}$ forms sparingly soluble precipitate with $Sb_2(R,R)$-$tart_2^{2-}$, the ICD measurement is impossible for this complex. A noteworthy fact is that the magnitude of the ICD is much greater for *trans*-$[Co(en)_2(NH_3)_2]^{3+}$ than for $[Co(en)(NH_3)_4]^{3+}$. This fact may be also interpreted in terms of the degree of hydration of these complexes and suggest some contribution to the ICD from a conformational change of en chelate rings caused by the association with $Sb_2(R,R)$-$tart_2^{2-}$, as Bonsnich pointed out.[12] However, it is difficult at this stage to offer precise explanation to the mechanism of the ICD developed in these achiral complexes.

Racemic Complexes. The ICD spectra for racemic complexes are shown in the lower parts of Figs. 1 and 2. In (*R,R*)-tart^{2-} solution, a single negative CD band is induced for all the racemic complexes just like for achiral complexes. On the other hand, different ICD patterns are developed in $Sb_2(R,R)$-$tart_2^{2-}$ solution; a single positive band is induced for *cis*-$[Co(en)_2(NH_3)_2]^{3+}$ and *cis*-$[Co(en)_2(MeNH_2)_2]^{3+}$, and two bands with opposite sign for *cis*-$[Co(en)_2(EtNH_2)_2]^{3+}$, but the ICD for $[Co(en)_3]^{3+}$ is composed of only a single negative band like in (*R,R*)-tart^{2-} solution.

It is now well known that the CD spectrum of $[Co(en)_3]^{3+}$ is appreciably affected by the addition of (*R,R*)-tart^{2-} [2,13] or $Sb_2(R,R)$-$tart_2^{2-}$;[14] the absolute intensity is decreased and increased for the E and A_2 components, respectively. Since *Λ*-$[Co(en)_3]^{3+}$ has positive E and negative A_2 components in the first d-d transition region, and the sign of the ICD for racemic $[Co(en)_3]^{3+}$ is negative in both (*R,R*)-tart^{2-} and Sb_2-(*R,R*)-$tart_2^{2-}$ solutions, the CD change caused by the addition of these chiral anions must be greater for the *Λ*-enantiomer than for the *Δ*-enantiomer. This is easily confirmed experimentally.[14,15] If it is assumed that a greater CD change is brought about by the stronger association with (*R,R*)-tart^{2-} or $Sb_2(R,R)$-$tart_2^{2-}$, these anions are expected to have a greater affinity for *Λ*-$[Co(en)_3]^{3+}$. This has been actually verified by some workers.[2,14,16]

Recently a number of cationic metal complexes have been resolved on an SP-Sephadex ion-exchanger with (*R,R*)-tart^{2-} or $Sb_2(R,R)$-$tart_2^{2-}$ as an eluent. Present authors[14] and Searle[17] have explicitly evoked that the strength of ion association of metal complexes with the chiral eluent is the most important factor determining the elution order in ion exchange chromatography.

Table 1. Elution order and sign of induced CD

	Chromatography	Induced CD (affinity)
$Na_2(R,R)$-tart		
$[Co(en)_3]^{3+}$	Λ	negative (Λ)
cis-$[Co(en)_2(NH_3)_2]^{3+}$	(Λ)	negative (Λ)
cis-$[Co(en)_2(MeNH_2)_2]^{3+}$	(Λ)	negative (Λ)
cis-$[Co(en)_2(EtNH_2)_2]^{3+}$	(Λ)	negative (Λ)
$Na_2Sb_2(R,R)$-$tart_2$		
$[Co(en)_3]^{3+}$	Λ	negative (Λ)
cis-$[Co(en)_2(NH_3)_2]^{3+}$	Λ	positive (Δ)
cis-$[Co(en)_2(MeNH_2)_2]^{3+}$	(Δ)	positive (Δ)
cis-$[Co(en)_2(EtNH_2)_2]^{3+}$	(Δ)	positive (Δ) [a]

a) See the text.

Then, it is in principle possible to predict the elution order from the sign of the ICD spectra if the above-mentioned assumption is generally valid.

In Table 1 is summarized the sign of the ICD developed for a series of racemic complexes in (R,R)-$tart^{2-}$ and $Sb_2(R,R)$-$tart_2^{2-}$ solutions. From the discussion presented above, negative and positive ICD corresponds to a greater affinity for the Λ- and Δ-enantiomer, respectively, as shown in the parentheses, since the Λ-enantiomers of these complexes have in common a dominant positive CD band (E component) at the longer wavelength region and its intensity is all diminished by the addition of (R,R)-$tart^{2-}$ or $Sb_2(R,R)$-$tart_2^{2-}$. Also listed under the heading of "chromatography" in Table 1 is the absolute configuration of the enantiomer eluted first by (R,R)-$tart^{2-}$ or $Sb_2(R,R)$-$tart_2^{2-}$ on an SP-Sephadex. The symbol Λ or Δ is parenthesized when the chromatographic resolution is incomplete under our experimental conditions. It is seen in Table 1 that, when (R,R)-$tart^{2-}$ is used, the resulting elution order is in complete agreement with the prediction from the sign of the ICD spectra for all the complexes.

When $Sb_2(R,R)$-$tart_2^{2-}$ is used, the Λ-enantiomer is eluted first for $[Co(en)_3]^{3+}$, in accord with the prediction from its ICD spectrum. Similarly the elution order for *cis*-$[Co(en)_2(MeNH_2)_2]^{3+}$ and *cis*-$[Co(en)_2(EtNH_2)_2]^{3+}$ is in agreement with the order expected from their ICD spectra, though the Δ-enantiomers are eluted first, as seen in Table 1. However, the ICD spectrum exceptionally fails to predict the elution order for *cis*-$[Co(en)_2(NH_3)_2]^{3+}$; its ICD is positive, suggesting a greater affinity of $Sb_2(R,R)$-$tart_2^{2-}$ for the Δ-enantiomer, but actually the Λ-enantiomer is eluted first. In order to solve this apparent discrepancy, the CD spectra of Λ- and Δ-*cis*-$[Co(en)_2(NH_3)_2]^{3+}$ were measured in water as well as in aqueous (R,R)-$tart^{2-}$ and $Sb_2(R,R)$-$tart_2^{2-}$ solutions, and they are shown in Figs. 3 and 4, where dotted curves correspond to the CD spectra in the presence of (R,R)-$tart^{2-}$ or $Sb_2(R,R)$-$tart_2^{2-}$. It is clearly seen that the CD change is greater for the Λ-enantiomer in (R,R)-$tart^{2-}$ solution, while it is greater for the Δ-enantiomer in $Sb_2(R,R)$-$tart_2^{2-}$ solution. Since the ICD spectrum is a simple sum of the two dotted curves, the ICD spectra of *cis*-$[Co(en)_2(NH_3)_2]^{3+}$ shown in Figs. 1 and 2 are completely reproduced here. That is to say, it is explicitly demonstrated in Figs. 3 and 4 that differential CD changes between the Λ- and Δ-enantiomers upon the addition of (R,R)-$tart^{2-}$ or $Sb_2(R,R)$-$tart_2^{2-}$ are responsible for the appearance of

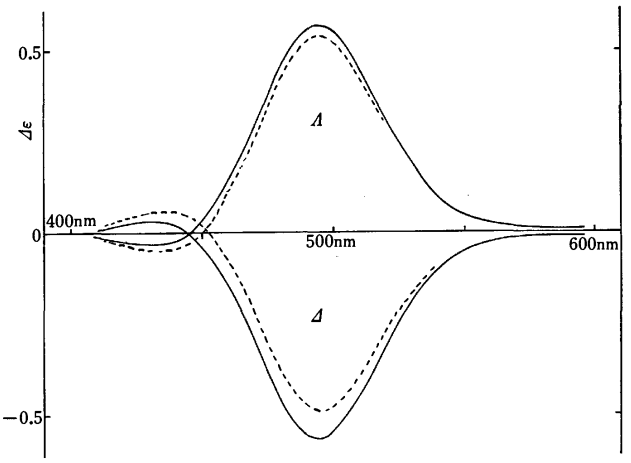

Fig. 4. CD spectra of Λ- and Δ-*cis*-$[Co(en)_2(NH_3)_2]^{3+}$ (4×10^{-3} M) in water (solid curves) and in 0.04 M aqueous $Sb_2(R,R)$-$tart_2^{2-}$ solution (dotted curves).

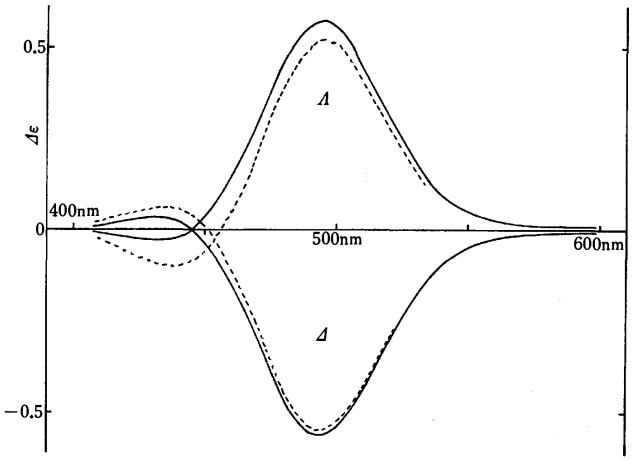

Fig. 3. CD spectra of Λ- and Δ-*cis*-$[Co(en)_2(NH_3)_2]^{3+}$(4×10^{-3} M) in water (solid curves) and in 0.04 M aqueous (R,R)-$tart^{2-}$ solution (dotted curves).

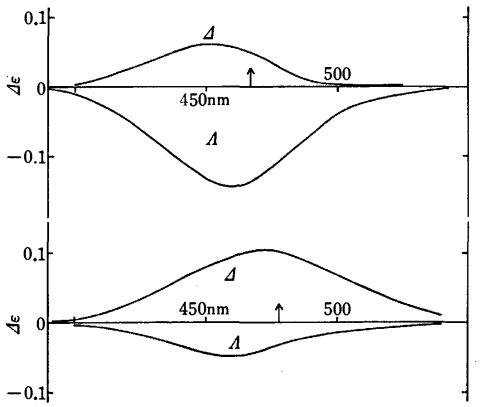

Fig. 5. Differential CD spectra of Λ- and Δ-*cis*-$[Co(en)_2(NH_3)_2]^{3+}$ (4×10^{-3} M) in 0.1 M aqueous (R,R)-$tart^{2-}$ solution (upper curves) and in 0.1 M aqueous $Sb_2(R,R)$-$tart_2^{2-}$ solution (lower curves).

the ICD for *cis*-$[Co(en)_2(NH_3)_2]^{3+}$. The same should hold for other racemic complexes.

This is more clearly confirmed in Fig. 5, where the difference CD spectra (the difference between the dotted and solid curves in Fig. 3 or 4) are depicted for *cis*-$[Co(en)_2(NH_3)_2]^{3+}$ both in (*R*,*R*)-tart^{2-} and Sb_2(*R*,*R*)-$tart_2^{2-}$ solutions, and the position of a small arrow corresponds to the wavelength at which the ICD has a maximum intensity. It should be noted here that the difference CD spectrum of the *Λ*-enantiomer differs from that of the *Δ*-enantiomer not only in magnitude but also in pattern in both (*R*,*R*)-tart^{2-} and Sb_2(*R*,*R*)-$tart_2^{2-}$ solutions. Therefore, it is concluded that both (*R*,*R*)-tart^{2-} and Sb_2(*R*,*R*)-$tart_2^{2-}$ interact with one enantiomer of the complex in a different fashion from the other. The same is found true for $[Co(en)_3]^{3+}$. If the peak positions of difference CD spectra for *Λ*- and *Δ*-enantiomers differ greatly from each other, the resulting ICD spectrum is expected to have two components with opposite sign. This is probably the case with *cis*-$[Co(en)_2(EtNH_2)_2]^{3+}$ in Sb_2(*R*,*R*)-$tart_2^{2-}$ solution. Judging from the relative intensities of the two ICD components of this complex (Fig. 2), it is supposed the *Δ*-enantiomer is subject to a greater CD change in Sb_2(*R*,*R*)-$tart_2^{2-}$ solution, so that "positive (*Δ*)" is inserted in the last column of Table 1 for this complex.

Now, we have to solve one important problem why *Λ*-*cis*-$[Co(en)_2(NH_3)_2]^{3+}$ is eluted first by Sb_2(*R*,*R*)-$tart_2^{2-}$ on an SP-Sephadex, despite the fact that it gives rise to a greater CD change for the *Δ*-enantiomer, as shown in Fig. 5. For this purpose, the association constants of *Λ*- and *Δ*-*cis*-$[Co(en)_2(NH_3)_2]^{3+}$ with (*R*,*R*)-tart^{2-} and Sb_2(*R*,*R*)-$tart_2^{2-}$ were obtained by measuring their CD intensities in aqueous solutions. Experimental details have been described earlier.[14] Since the CD change of *cis*-$[Co(en)_2(NH_3)_2]^{3+}$ was small as compared with that of $[Co(en)_3]^{3+}$, somewhat higher concentrations of *Λ*- or *Δ*-*cis*-$[Co(en)_2(NH_3)_2]Cl_3$ and Na_2(*R*,*R*)-tart or K_2Sb_2(*R*,*R*)-$tart_2$ had to be employed, so that sodium perchlorate was not added to adjust the ionic strength. Instead, the amounts of the complex and the chiral anion were appropriately varied to maintain a constant ionic strength. The final plots of $C_M(C_A-x)/(\Delta CD/2)$ *vs.* (C_A-x) obtained by a successive approximation[14] are shown in Fig. 6, and the derived association constant K_A and the value of molar CD change $(\Delta\varepsilon_{MA}-\Delta\varepsilon_M)$ are listed in Table 2. For comparison, the corresponding values for $[Co(en)_3]^{3+}$ obtained previously[14,16] are also given here.

It is seen in Table 2 that the association constant K_A of *cis*-$[Co(en)_2(NH_3)_2]^{3+}$ with (*R*,*R*)-tart^{2-} is slightly greater for the *Λ*-enantiomer, in accord with the result of present chromatography that the *Λ*-enantiomer is eluted first by (*R*,*R*)-tart^{2-}, but only incomplete resolution is attained. On the other hand, the K_A value of the *Λ*-enantiomer with Sb_2(*R*,*R*)-$tart_2^{2-}$ is almost twice as great as that of the *Λ*-enantiomer. Then, it is natural that complete chromatographic resolution is effected with the *Λ*-enantiomer eluted first by Sb_2(*R*,*R*)-$tart_2^{2-}$. As a result, it follows that the *Λ*-enantiomer associates favorably with Sb_2(*R*,*R*)-$tart_2^{2-}$ in such a fashion that its CD spectrum is not appreciably affected in comparison with the *Δ*-enantiomer, as is indicated by the values of their molar CD change $(\Delta\varepsilon_{MA}-\Delta\varepsilon_M)$. In contrast, for $[Co(en)_3]^{3+}$, both the K_A and $(\Delta\varepsilon_{MA}-\Delta\varepsilon_M)$ values are greater for the *Λ*-enantiomer, so that the ICD spectra provide a correct prediction of the elution order

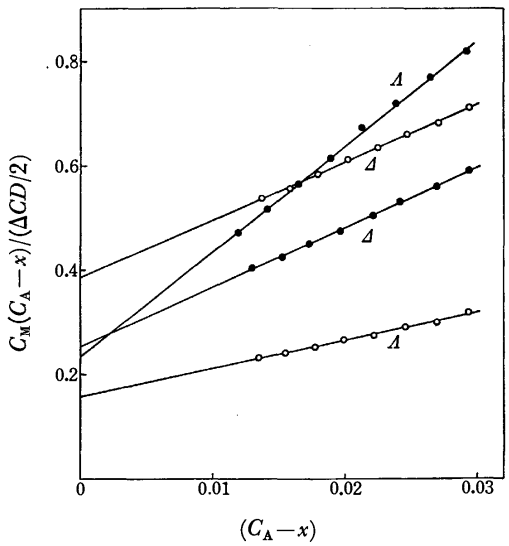

Fig. 6. Final plots of $C_M(C_A-x)/(\Delta CD/2)$ *vs.* (C_A-x) for *cis*-$[Co(en)_2(NH_3)_2]^{3+}$-(*R*,*R*)-tart^{2-}(○) and -Sb_2-(*R*,*R*)-$tart_2^{2-}$(●) system in water.

Table 2. Association constant K_A and molar CD change at 25 °C[a]

	nm[b]		K_A	$(\Delta\varepsilon_{MA}-\Delta\varepsilon_M)$
(*R*,*R*)-tart^{2-}				
cis-$[Co(en)_2(NH_3)_2]^{3+}$	446	*Λ*	32±1	0.192±0.005
		Δ	28±1	0.092±0.002
$[Co(en)_3]^{3+}$	430	*Λ*	13.0±0.1	0.85±0.01
		Δ	10.5±0.4	0.66±0.03
Sb_2(*R*,*R*)-$tart_2^{2-}$				
cis-$[Co(en)_2(NH_3)_2]^{3+}$	446	*Λ*	85±3	0.050±0.001
		Δ	45±1	0.088±0.001
$[Co(en)_3]^{3+}$	430	*Λ*	46.6±0.7	0.251±0.003
		Δ	25.6±0.9	0.197±0.006

a) Ionic strength is 0.1 adjusted by sodium perchlorate for $[Co(en)_3]^{3+}$ and is 0.08 without sodium perchlorate for *cis*-$[Co(en)_2(NH_3)_2]^{3+}$, so that the direct comparison of the two systems is almost meaningless. b) Wavelength at which CD changes were measured.

in both (*R*,*R*)-tart^{2-} and Sb_2(*R*,*R*)-$tart_2^{2-}$ solutions.

In this way, the ICD spectra are found useful to predict the elution order of several racemic complexes on an SP-Sephadex ion-exchanger with (*R*,*R*)-tart^{2-} or Sb_2(*R*,*R*)-$tart_2^{2-}$ as an eluent. Similar experiments on other metal complexes are now under way to extend the applicability of the ICD spectra to ion exchange chromatography.

Pyrolytic Sulfurization Gas Chromatography. III. Simultaneous Determination of the Atomic Ratio between C, H, O, and N in a Metallo-organic Compound

Tadashi HARA,* Kaoru FUJINAGA, and KATSUYA TSUJI

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received May 12, 1978)

Simultaneous determination of the atomic ratio between C, H, O, and N in a metallo-organic compound containing transition element is possible by the pyrolytic sulfurization gas chromatographic method, addition of reducing agent being unnecessary. Analytical results of metallo-organic compounds depend on the characteristics of their metal oxides. A few organophosphorus compounds were analyzed. The formation of water could be predicted from the atomic ratio of carbon to oxygen in a compound.

Simultaneous determination of the atomic ratio between C, H, O, and N in a sample can be achieved with the usual organic compounds[1] by pyrolytic sulfurization gas chromatography (PSGC).[2] The present study has been carried out to confirm whether PSGC can be applied to the analysis of various metallo-organic compounds containing transition elements. The affinity of metallic elements for oxygen is so strong that quantitative release of oxygen from their oxides is difficult. Simultaneous determination of oxygen with C, H, and N is impossible by the conventional methods. The oxygen in the metallo-organic compound has been determined either by subtracting the total amount of C, H, N, and metal oxide from the weight of a smple or by estimating the oxygen separately from the determination of C, H, and N. The former method is apt to introduce a relatively large error and is not applicable to samples containing molybdenum, cadmium, and so on, the oxides of which are volatile under the analytical conditions. The latter method has a disadvantage in that some reducing agent must be added to the sample in order to liberate oxygen from the combustion residues.

However, the present PSGC method based on a sulfur combustion technique, is characterized by converting the metal in a compound into sulfide, even in the case where the metal oxide is more stable than the corresponding sulfide since carbon atoms in the compound act as the reducing agent, releasing the whole oxygen in the sample. It is possible to determine the atomic ratio without a special procedure such as addition of reducing agent.

Experimental

Apparatus and Reagents. The reagents and apparatus used were the same as those reported[1] except that peak areas of the gas chromatogram were read out by use of a Shimadzu digital integrator ElA. A definite amount of sample was taken with a Shimadzu microbalance MDP-5.

Procedure. The preparation and reaction conditions of sample as well as conditions of gas chromatographic analysis are similar to those reported.[1]

Samples. The following samples were prepared by the methods found in literature for their gravimetric analyses: magnesium oxalate, $MgC_2O_4 \cdot 2H_2O$;[3] cobalt(II) oxalate, $CoC_2O_4 \cdot 2H_2O$;[3] copper(II) oxalate, CuC_2O_4;[4] cadmium oxalate, CdC_2O_4;[5] bis(8-quinolinolato)magnesium, $Mg(C_9H_6ON)_2$;[6] oxobis(8-quinolinolato)titanium(IV), $TiO(C_9H_6ON)_2$;[6] dioxobis(8-quinolinolato)molybdenum(VI), $MoO_2(C_9H_6ON)_2$;[6] dioxobis(8-quinolinolato)tungsten(VI), $WO_2(C_9H_6ON)_2$;[6] bis(8-quinolinolato)copper(II), $Cu(C_9H_6ON)_2$;[6] dioxo(8-quinolinol)bis(8-quinolinolato)uranium(VI), $UO_2(C_9H_6ON)_2(C_9H_7ON)$;[6] bis(8-quinolinolato)zinc(II), $Zn(C_9H_6ON)_2$;[6] bis(8-quinolinolato)manganese(II), $Mn(C_9H_6ON)_2 \cdot 2H_2O$;[6] tris(8-quinolinolato)iron(III), $Fe(C_9H_6ON)_3$;[6] bis(8-quinolinolato)cobalt(II), $Co(C_9H_6ON)_2 \cdot 2H_2O$;[6] bis(8-quinolinolato)nickel(II), $Ni(C_9H_6ON)_2$;[6] tris(8-quinolinolato)aluminium, $Al(C_9H_6ON)_3$;[6] tris(8-quinolinolato)lanthanum(III), $La(C_9H_6ON)_3$;[6] bis(8-quinolinolato)cadmium(II), $Cd(C_9H_6ON)_2 \cdot 2H_2O$;[6] tris(8-quinolionlato)chromium(III), $Cr(C_9H_6ON)_3$;[7] bis(2,3-butanedione dioximato)palladium(II), $Pd(C_4H_7O_2N_2)_2$;[8] bis(2,3-butanedione dioximato)nickel(II), $Ni(C_4H_7O_2N_2)_2$;[8] (benzoin oximato)copper(II), $Cu(C_{14}H_{11}O_2N)$;[8] bis(anthranilato)copper(II), $Cu(C_7H_6O_2N)_2$;[8] bis(anthranilato)zinc(II), $Zn(C_7H_6O_2N)_2$;[8] bis(anthranilato)nickel(II), $Ni(C_7H_6O_2N)_2$;[8] bis(anthranilato)manganese(II), $Mn(C_7H_6O_2N)_2$;[8] bis(anthranilato)cobalt(II), $Co(C_7H_6O_2N)_2$;[8] bis(anthranilato)cadmium(II), $Cd(C_7H_6O_2N)_2$;[8] bis(salicylaldehyde oximato)copper(II), $Cu(C_7H_6O_2N)_2$.[8] The composition and purity of samples were confirmed by the C and H analysis carried out in the Elemental Analysis Center of Pharmaceutical Department for Kyoto University (Table 1). The experimental results were in fair agreement with the theoretical values. Naphthalene, thiourea, sucrose, cyanoguanidine, bis(2,4-pentanedionato)magnesium, and tris(2,4-pentanedionato)iron(III) for elemental analysis were of reagent grade, the other reagents being commercial products. The metal oxides were of analytical grade and treated at 950 °C before use.

Results and Discussion

Reactivity of Metal Oxide. The reactivity between metal oxide and sulfur was investigated prior to the analysis of metallo-organic compounds. The reaction of silver nitrate ($AgNO_3$) as a reference substance seems to proceed completely in accordance with Eq. 1, since 1) a large, positive value of ΔG°_{1200K} in Eq. 1, 642.6 kJ·mol^{-1} was obtained from the thermodynamic data[9] by means of Ulich's approximate equation, 2) $AgNO_3$ produced only nitrogen molecule (N_2) and sulfur dioxide (SO_2) as reaction products, and 3) proportionality holds between the amount of $AgNO_3$ and the peak area of SO_2. The reactivity of metal oxide is expressed in terms of α, which refers to the mole ratio of SO_2 from the metal oxide, M_mO_n against that from

$AgNO_3$. Thus, the reactivity of metal oxide in Eq. 2 is approximately estimated by Eq. 3, where $A°(SO_2)$ and $A(SO_2)$ refer to the peak areas of SO_2 obtained with a mol of $AgNO_3$ and b mol of M_mO_n, respectively. The oxides of molybdeneum(VI),

$$AgNO_3 + S_2 = \frac{1}{2}Ag_2S + \frac{1}{2}N_2 + \frac{3}{2}SO_2 \quad (1)$$

$$\frac{3}{2}a = A°(SO_2),$$

$$M_mO_n + xS_2 = M_mS_n + \frac{n}{2}SO_2 \quad (2)$$

$$\frac{n}{2}b\alpha = A(SO_2),$$

TABLE 2. RELATIVE CONVERSIONS OF METAL OXIDES

Metal oxide	Relative conversion[a] α	Metal oxide	Relative conversion α
MgO	0	Fe_2O_3	1.1
CaO	0.67	NiO	0.33

Cr_2O_3	0.70	Mn_3O_4	0.96

a) Estimated by Eq. 3.

$$\alpha = \frac{A(SO_2)3a}{A^\circ(SO_2)nb}, \quad (3)$$

manganese(II, III), iron(III), copper(II), zinc(II), and bismuth(III) react quantitatively with sulfur (Table 2). The oxides of calcium(II), uranium(VI), vanadium(V), tungsten(VI), and nickel(II) react with sulfur to some extent, oxygen being liberated as SO_2. However, the oxides of magnesium(II), titanium(IV), aluminium-(III), and silicon(III) are barely reduced by sulfur under the experimental conditions.

The value of ΔG°_{1200K} for Eq. 2 gives a measure of the reactivity of metal oxide with sulfur. The results shown

a) Metal atoms were neglected in the composition of metallo-organic compounds since they could not be determined.

in Table 3 correspond fairly well to those in Table 2. Since the ΔG° value of magnesium(II) oxide, titanium(IV) oxide, and silicon(III) oxide among the metal oxides are positive and large, it is understandable that these metal oxides show no reactivity to sulfur.

Analysis of Various Metallo-organic Compounds. Various metallo-organic compounds containing transition elements were analyzed (Table 4). Almost all the complex salts gave satisfactory results, but the complex salts of Ti, U, and Al gave a fairly negative error in the oxygen value. Because of the high stability and the difficult reduction of the oxides of titanium(IV), aluminium(III), and uranium(VI), the oxygen atom in their complex salts seems to be partly transferred into the residues, giving rise to error.

Magnesium(II) oxide does not react with sulfur, but bis(8-quinolinolato)magnesium(II)reacts quantitatively with sulfur to give an exact oxygen value without producing magnesium(II) oxide. In order to clarify the difference in the two cases, study was carried out on a series of magnesium salts (Table 5). Bis(2,4-pentanedionato)magnesium(II) as well as bis(8-quinolinolato) magnesium(II) gave expected results, while oxalate and acetate of magnesium(II) gave fairly low oxygen values (Table 5). This can be attributed to the shortage of carbon atom necessary for the prevention of the formation of magnesium(II) oxide. In conclusion, the present method gives satisfactory oxygen values when the number of carbon atom exceeds that of oxygen atom in magnesium compound.

Analysis of Organophosphorus Compounds. Various organophosphorus compounds were analyzed (Table 6). Carbon-rich compounds such as triphenylphosphine oxide give satisfactory oxygen values, while carbon-poor compounds such as guanidine phosphate gives fairly low oxygen value, which may be ascribed to the formation of polyphosphoric acid. It seems that carbon atoms prevent oxygen atoms from the formation of polyphosphoric acid as in magnesium compounds. Inorganic phosphorus compounds did not react quantitatively with sulfur, the whole amount of oxygen not being liberated.

Decomposition of Water. By the present method, N_2, carbon dioxide, hydrogen sulfide, carbonyl sulfide, water, SO_2, and carbon disulfide can be determined simultaneously under the experimental conditions. Since the tailing phenomenon is observed on the water peak, it is desirable to avoid the formation of water for accurate determination. The formation of water was observed with magnesium(II) oxalate tetrahydrate, magnesium(II) acetate tetrahydrate, and cobalt(II) oxalate dihydrate but not with the other componds containing water of crystallization such as sodium citrate dihydrate and oxalic acid dihydrate. It seems that water is decomposed with an increasing number of carbon atom

in the compound to form hydrogen sulfide and carbonyl sulfide similarly as in magnesium compounds. As shown in Fig. 1, no water is formed when the atomic ratio of carbon to oxygen exceeds 0.5, while excess oxygen which is not consumed by carbon forms SO_2 when the above ratio is less than 0.5, followed by the reaction between SO_2 and hydrogen sulfide and by the formation of water. The formation of water from SO_2 and hydrogen sulfide can be easily understood from the previous results.[2]

Analysis of Alkali Metal Compounds. It should be emphasized that organic alkali metal salts give satisfactory results. In the conventional elemental analysis using an oxygen combustion technique, alkali and alkaline earth metal compounds are apt to be converted into their carbonates. Vanadium(V) oxide has been added to prevent the formation of carbonate for the analysis of carbon. There are many alkali and alkaline earth metal compounds the analysis of which are of great importance. The present method provides a convenient tool for the elemental analysis, since no special procedure such as the addition of vanadium(V) oxide is necessary.

Aminocyclitols. 36. Chlorination and Dechlorination of Aminocyclitol and Inositol Derivatives. Preparation of Dideoxy- and Trideoxystreptamines[1a,b]

Seiichiro OGAWA,* Yuji HONGO, Hitoshi FUJIMORI, Keiji IWATA, Akira KASUGA, and Tetsuo SUAMI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received September 27, 1977)

Chlorination of four aminocyclitol and six inositol derivatives with sulfuryl chloride gave the chloro substitution products, which were then dechlorinated by hydrogenolysis with Raney nickel or by treatment with tributyltin(IV) hydride giving the corresponding deoxy compounds. Several useful aminocyclitols, including 2,4-dideoxy- and 2,4,5-trideoxystreptamines, were prepared from 2-deoxystreptamine derivatives by these procedures.

The reaction of sulfuryl chloride with hexopyranoses and hexopyranosides had been extensively studied by Jones *et al.*[2] The mechanism and selectivity of the nucleophilic substitution of sulfate esters by chloride ions have been well established by both steric and electronic effects.[3] In the present paper, the reactions of aminocyclitol and inositol derivatives with sulfuryl chloride, and the preparation of dideoxy- and trideoxystreptamines by dechlorination of the corresponding chloro deoxy compounds are reported.

Inositol Derivatives. Treatment of 1,4,5,6-tetra-*O*-acetyl-*myo*-inositol (**1**)[4] with 3 mol equiv of sulfuryl chloride in pyridine at −10 °C for 0.5 h and subsequently at 5 °C overnight gave tetra-*O*-acetyl-2,3-dichloro-2,3-dideoxy-*myo*-inositol (**5**) in 45% yield. The structure of **5** was confirmed on the basis of the following evidence. In the ^{1}H NMR spectrum of **5** in deuteriochloroform ($CDCl_3$), the signals due to H-2 and H-3 were coupled and appeared as a triplet (δ 4.66) and a double doublet (δ 4.28) having 3-Hz splitting, and 3- and 10-Hz splitting, respectively. Hydrogenolysis of **5** with Raney nickel T-4[5] in ethanol in the presence of Amberlite IR-45 (OH^-) gave the known tetra-*O*-acetyl-1,3/2,4-cyclohexanetetrol (**9**)[6] in 67% yield.

Under similar conditions, the 3-*O*-benzoyl (**2**),[7] 3-*O*-mesyl (**3**),[7] and 3-*O*-tosyl derivatives (**4**)[8] of **1** were readily chlorinated to give the corresponding chloro deoxy compounds (**6**, **7**, and **8**) with inversion of configuration. Compound **6** could be hydrogenolyzed with Raney nickel analogously as described above to give the deoxy derivative (**10**) in 80% yield. Compounds **7** and **8** however gave **9** as the main product, together with a trace of the deoxy compounds (**11** and **12**), resulting from a cleavage of both the chlorine and sulfonyloxyl groups under these reduction conditions. Removal of only the chlorine atom of **8** was effected by treatment with tributyltin(IV) hydride in toluene in the presence of α,α′-azobisisobutyronitrile[9] and **12** was obtained in 87% yield.

1,2-*O*-Cyclohexylidene-3,4,6-tri-*O*-tosyl-*myo*-inositol (**13**)[10] was similarly chlorinated to give the known chloro deoxy compound (**14**)[11] in 76% yield, which was subsequently reduced with tributyltin(IV) hydride to give the deoxy compound (**15**) in 55% yield.

1,4-Di-*O*-benzoyl-2,3-*O*-cyclohexylidene-*myo*-inositol (**16**),[11] when treated with sulfuryl chloride, gave the monochloro substitution product (**17**) in 62% yield. The acetyl derivative (**18**) of **17** was obtained by the conventional way. Acid hydrolysis of **17** followed by acetylation gave the penta-*O*-acetyl-chlorodeoxyinositol (**19**), which was reduced with tributyltin(IV) hydride to the known penta-*O*-acetyl-1,5/2,3,4-cyclohexanepentol (**20**)[12] in 77% yield. These results indicated that the C-5 hydroxyl group of **16** was selectively displaced by a chloride ion *via* the sulfate ester, establishing the structure of **17** as 1,4-di-*O*-benzoyl-5-chloro-2,3-*O*-cyclohexylidene-5-deoxy-*neo*-inositol.

18 R^1=H, R^2=Cl, R^3=Ac

19 R=Cl
20 R=H

According to the above results, it was noted that an isolated hydroxyl group and both of the vicinal hydroxyl groups in the *cis*-relationship were easily displaced by chloride ions with inversion of configuration, but only one of the vicinal hydroxyl groups in the *trans* position was able to be displaced.

Aminocyclitol Derivatives. Deoxygenation of streptamine and 2-deoxystreptamine has been undertaken to prepare the deoxy derivatives of biological importance. Readily available 2-deoxystreptamine derivatives (**21**, **22**, **23**, and **33**) and streptamine derivative (**38**) were used as the starting materials.

Chlorination of 1,2-*O*-isopropylidene-(1,3/2,4,6)-4,6-bis(ethoxycarbonylamino)-1,2,3-cyclohexanetriol (**22**)[13] with 3 mol equiv of sulfuryl chloride in pyridine gave 1,2-*O*-isopropylidene-(1/2,3,4,6)-3-chloro-4,6-bis(ethoxycarbonylamino)-1,2-cyclohexanediol (**24**) in 63%

yield. The structure was confirmed by ^{1}H NMR, which revealed a narrow triplet at δ 4.69 attributable to H-3, indicating an inversion of the configuration at C-3. On treatment with 50% aqueous acetic acid at 80 °C followed by acetylation, **24** gave the di-*O*-acetyl derivative (**26**) in 83% yield. Similarly, the *N,N'*-diacetyl (**21**)[14] and *N,N'*-bis(benzyloxycarbonyl) derivatives (**23**)[14] of *O*-isopropylidene-2-deoxystreptamine were treated with sulfuryl chloride followed by mild acid hydrolysis and acetylation which gave the corresponding chloro deoxy compounds (**25** and **27**) in 48 and 34% yields, respectively.

Hydrogenolysis of **25** and **27** with Raney nickel in ethanol gave the deoxy compounds (**28** and **32**) in 56 and 89% yields, respectively. Compound **28** was shown to be identical with an authentic sample of tetra-*N,O*-acetyl-(1,3,5/2)-3,5-diamino-1,2-cyclohexanediol (2,4-dideoxystreptamine).[15] Hydrolysis of **28** with boiling 6 M hydrochloric acid gave the crystalline dihydrochloride (**29**) in 74% yield, which was further characterized by conversion into the *N,N'*-bis(ethoxycarbonyl) (**30**) and *N,N'*-bis(benzyloxycarbonyl)derivatives (**31**). Compound **30** was identical with the compound derived from **24** by mild acid hydrolysis and hydrogenolysis.

32 R^1=Ac, R^2=Cbz

The chlorination of *N,N'*-bis(ethoxycarbonyl)-2-deoxystreptamine (**33**)[13] was attempted to obtain the other chloro deoxy compounds. However, **33** gave, after acetylation, the cyclic sulfate ester (**34**, 28%) as the major product, together with **26** (17%). Thus, on chlorination, successive treatment with methanolic ammonia, and acetylation, **33** gave **26** in 61% yield.

In addition, the introduction of an amino function into 2-deoxystreptamine was carried out by reacting **26** with an azide ion. Treatment of **26** with an excess of sodium azide in *N,N*-dimethylformamide gave the azido deoxy compound (**35**) in 34% yield, which was reduced with Raney nickel to the 4-amino-4-deoxy derivative of 2-deoxystreptamine characterized as the *N*-acetyl derivative (**36**). Hydrolysis of **36** with boiling 48% hydrobromic acid followed by acetylation gave penta-*N,O*-acetyl-(1,3/2,4,6)-3,4,6-triamino-1,2-cyclohexanediol (**37**) whose ^{1}H NMR spectrum in dimethyl-d_6 sulfoxide revealed the presence of three equatorial acetamido groups [δ 1.76 (1) and 1.78 (2)] and two equatorial acetoxyl groups [δ 1.91 (1) and 1.92 (1)], establishing the proposed structure.

1,2-*O*-Isopropylidene-(1,3,5/2,4,6)-4,6-bis(ethoxycarbonylamino)-1,2,3,5-cyclohexanetetrol (**38**), when treated with sulfuryl chloride, gave two monochlorides (**39** and **40**) and one dichloride (**41**), which after separation by silica-gel chromatography gave yields of 19, 31, and 4%, respectively. Differentiation of **39** from **40** has been done by comparison of the ^{1}H NMR spectra. Thus, **39** showed two peaks of 2:1 ratio attributable to the three acetyl groups, while **40** showed three peaks for three individual acetyl groups. Finally, **40** was found to be identical with an authentic sample.[1a]

(1,2,3,5/4,6)-4,6-Bis(ethoxycarbonylamino)-1,2,3,5-cyclohexanetetrol (**42**) prepared from hexa-*N,O*-acetyl-*myo*-inosadiamine-4,6[16] by hydrolysis and subsequent ethoxycarbonylation was treated with 2,2-dimethoxypropane in *N,N*-dimethylformamide in the presence of an acid catalyst to give the 1,2-*O*-isopropylidene derivative, which was converted into 1,5-di-*O*-acetyl-2,3-*O*-isopropylidene-(1,2,3,5/4,6)-4,6-bis(ethoxycarbonylamino)-1,2,3,5-cyclohexanetetrol (**43**) in 25% overall yield. Chlorination of the hydroxy compound derived from **43** by *O*-deisopropylidenation gave the dichloro dideoxy compound (**44**) in 41% yield. The ^{1}H NMR spectrum of **44** was shown to be very similar to that of **5**, the protons attached to the carbon atoms bearing chlorine atoms. Dechlorination of **44** gave di-*O*-acetyl-(1,3/2,4)-2,4-bis(ethoxycarbonylamino)-1,3-cyclohexanediol (**45**) in 71% yield. The ^{1}H NMR spectrum supported the proposed structure.

Chlorination of **30** gave one monochloro substitution product (**46**) in 44% yield. The presence of the chlorine atom on C-1 was demonstrated by the appearance of the double doublet (δ 4.89) having 3.5- and 10-Hz

splitting due to H-2. Dechlorination of **46** gave (1/2, 4)-1-acetoxy-2,4-bis(ethoxycarbonylamino)cyclohexane (**47**) in 63% yield, which was *O*-deacetylated to give *N,N'*-bis(ethoxycarbonyl)-2,4,5-trideoxystreptamine (**48**).

Experimental[17]

1,4,5,6-Tetra-O-*acetyl-2,3-dichloro-2,3-dideoxy*-myo-*inositol (5).* To a solution of 1,4,5,6-tetra-*O*-acetyl-*myo*-inositol (**1**)[4] (1 g) in dry pyridine (30 ml) was added sulfuryl chloride (0.7 ml, 3 molar equiv) at −15 °C with agitation. After stirring at the same temperature for 1 h, the reaction mixture was kept at 5 °C overnight. An insoluble matter was filtered off and washed with pyridine. The filtrate and washings were combined and evaporated to dryness, the residue dissolved in chloroform (30 ml), and the solution washed successively with aqueous sodium hydrogencarbonate and water, dried over anhydrous sodium sulfate and evaporated to dryness. The residue was crystallized from ethanol to give 0.48 g (45%) of **5**: mp 159—161 °C. Recrystallization from ethanol gave a pure sample: mp 160—160.5 °C; ^{1}H NMR ($CDCl_3$) δ 2.00 (s, 6), 2.07 (s, 3), and 2.11 (s, 3) (OAc), 4.28 (dd, 1, $J_{2,3}$=3 Hz, $J_{3,4}$=10 Hz, H-3), 4.66 (t, 1, $J_{1,2}$=3 Hz, H-2), 5.05 (dd, 1, $J_{1,6}$=10 Hz, H-1), 5.25 (t, 1, $J_{4,5}=J_{5,6}$=8 Hz, H-5), 5.50 (dd, 1) and 5.65 (dd, 1) (H-4 and H-6).

Found: Cl, 18.64%. Calcd for $C_{14}H_{18}O_8Cl_2$: Cl, 18.41%.

1,2,3,4-Tetra-O-*acetyl-5*-O-*benzoyl-6-chloro-6-deoxy*-scyllo-*inositol (6).* To a solution of 1,4,5,6-tetra-*O*-acetyl-3-*O*-benzoyl-*myo*-inositol (**2**)[7] (2 g) in dry pyridine (40 ml) was added sulfuryl chloride (1.3 ml, 3.5 molar equiv) at −10 °C with agitation. After 1 h at this temperature, the solution was stirred for a further 2.5 h at 5 °C. Then the reaction mixture was processed as described for the preparation of **5.** The product was crystallized from chloroform–ethanol to give 1.2 g (55%) of **6**: mp 241—244 °C; ^{1}H NMR ($CDCl_3$) δ 1.90 (s, 3), 2.04 (s, 3), 2.06 (s, 3), and 2.13 (s, 3) (OAc), 4.21 (t, 1, $J_{1,6}=J_{5,6}$=9 Hz, H-6).

Found: C, 53.27; H, 4.87; Cl, 7.70%. Calcd for $C_{21}H_{23}O_{10}Cl$: C, 53.57; H, 4.92; Cl, 7.53%.

1,2,3,4-Tetra-O-*acetyl-6-chloro-6-deoxy-5*-O-*mesyl*-scyllo-*inositol (7).* 1,4,5,6-Tetra-*O*-acetyl-3-*O*-mesyl-*myo*-inositol (**3**)[7] (0.51 g) was treated with sulfuryl chloride (0.4 ml, 2 molar equiv) in pyridine (15 ml) as described for the preparation of **5.** The crude product was crystallized from ethanol to give 0.26 g (49%) of **7**: mp 187.5—189 °C; ^{1}H NMR (Me_2SO-d_6) δ 1.98 (s, 3), 2.05 (s, 3), and 2.07 (s, 3) (OAc), 3.18 (s, 3, mesyl CH_3).

Found: C, 40.40; H, 4.65%. Calcd for $C_{15}H_{21}O_{11}SCl$: C, 40.49; H, 4.76%.

1,2,3,4-Tetra-O-*acetyl-6-chloro-6-deoxy-5*-O-*tosyl*-scyllo-*inositol (8).* 1,4,5,6-Tetra-*O*-acetyl-3-*O*-tosyl-*myo*-inositol (**4**)[8] (5 g) was treated with sulfuryl chloride (2.4 ml, 3 molar equiv) in pyridine (150 ml) as described for the preparation of **5.** The crystalline product was recrystallized from chloroform–ethanol to give 4.1 g (79%) of **8**: mp 200—201 °C; ^{1}H NMR ($CDCl_3$) δ 2.01 (s, 6), 2.06 (s, 3), and 2.08 (s, 3) (OAc), 2.47 (s, 3, tosyl CH_3), 4.00 (t, 1, $J_{1,6}=J_{5,6}$=10 Hz, H-6).

Found: C, 48.53; H, 4.88%. Calcd for $C_{26}H_{25}O_{11}SCl$: C, 48.42; H, 4.84%.

Tetra-O-*acetyl-1,3/2,4-cyclohexanetetrol (9).* A solution of **5** (0.1 g) in dioxane (10 ml) was hydrogenated in a Parr shaker apparatus in the presence of Raney nickel T-4[5] and Amberlite IR-45 (2 ml) under pressure (3.4 kg/cm^2) at room temperature for 2 days. The catalyst and resin were filtered off and the filtrate evaporated to dryness. The product was recrystallized from ethanol to give 0.06 g (67%) of **9**: mp 124.5—127 °C (lit,[6] 125.5—127 °C), identical with an authentic sample in all respects.

Dechlorination of 6. a) A solution of **6** (0.2 g) in ethanol (60 ml) was hydrogenated with Raney nickel catalyst as described above at room temperature overnight. The crude product was crystallized from ethanol to give 0.1 g (52%) of 1,2,3,4-tetra-*O*-acetyl-5-*O*-benzoyl-1,3,5/2,4-cyclohexanepentol (**10**): mp 168—169 °C; ^{1}H NMR ($CDCl_3$) δ 1.96 (s, 3) and 2.04 (s, 9) (OAc).

Found: C, 57.82; H, 5.52%. Calcd for $C_{21}H_{24}O_{10}$: C, 57.78; H, 5.55%.

b) Compound **6** (1 g) was treated with tributyltin(IV) hydride (1 ml) in toluene (30 ml) in the presence of α,α'-azobisisobutyronitrile (10 mg) at 80—90 °C under a stream of nitrogen for 3 h. The solution was evaporated to give a crystalline residue that was pulverized with ethanol and the crude crystals were collected by filtration. Recrystallization from ethanol gave 0.74 g (80%) of **10**: mp 168—170 °C.

Dechlorination of 7. A solution of **7** (1 g) in dioxane (20 ml) was hydrogenated with Raney nickel at room temperature overnight as described in the preparation of **9.** The product was crystallized from ethanol to give a crystalline mixture, which was fractionated on a silica gel column (40 g) with 1: 5 2-butanone–toluene. The main fraction was evaporated to give a syrup that crystallized from chloroform–ethanol to give 0.28 g (39%) of **9**: mp 124—126 °C. The minor component was crystallized from ethanol to give 0.04 g (4%) of 1,2,3,4-tetra-*O*-acetyl-5-*O*-mesyl-1,3,5/2,4-cyclohexanepentol (**11**): mp 218.5—219 °C; ^{1}H NMR ($CDCl_3$) δ 2.04 (broad s, 12, four OAc), 3.08 (s, 3, mesyl CH_3).

Found: C, 44.08; H, 5.36; S, 8.06%. Calcd for $C_{15}H_{22}O_{11}S$: C, 43.90; H, 5.40; S, 7.81%.

Dechlorination of 8. a) Compound **8** (0.2 g) was hydrogenated in dioxane (5 ml) in the presence of Raney nickel and Amberlite IR-45 (OH^-) (4 ml) at room temperature overnight. The product was crystallized from ethanol–ether to give 0.07 g (57%) of **9**: mp 134—135 °C, identical with an authentic sample[6] in all respects.

b) Compound **8** (3 g) was treated with tributyltin(IV) hydride (3 ml) in toluene (60 ml) in the presence of α,α'-azobisisobutyronitrile (30 mg) at 80—90 °C under a stream of nitrogen for 2 h. The reaction mixture was processed as described in the preparation of **10** to give crude crystals, which were recrystallized from chloroform–ethanol to give 2.34g (87%) of 1,2,3,4-tetra-*O*-acetyl-5-*O*-tosyl-1,3,5/2,4-cyclohexanepentol (**12**): mp 157.5—158.5 °C; ^{1}H NMR ($CDCl_3$) δ 1.84 (s, 3), 2.00 (s, 3), 2.02 (s, 3), and 2.05 (s, 3) (OAc), 2.50 (s, 3, tosyl CH_3).

Found: C, 51.85; H, 5.40; S, 6.43%. Calcd for $C_{21}H_{26}O_{11}S$: C, 51.84; H, 5.39; S, 6.59%.

5-Chloro-1,2-O-*cyclohexylidene-5-deoxy-3,4,6-tri*-O-*tosyl*-neo-*inositol (14).* To a solution of 1,2-*O*-cyclohexylidene-3,4,6-tri-*O*-tosyl-*myo*-inositol (**13**)[10] (0.5 g) in dry pyridine (15 ml) was added sulfuryl chloride (0.18 ml, 3 molar equiv) at −15 °C and the reaction mixture allowed to stand at this temperature for 1 h. The brown mixture was then poured into ice water and the solution evaporated to dryness. The residue was crystallized from ethanol to give 0.38 g (76%) of **14**: mp 182—183.5 °C (lit,[11] 182—183.5 °C). The IR spectrum was imposable with that of an authentic sample.

1,2-O-*Cyclohexylidene-5-deoxy-3,4,6-tri*-O-*tosyl*-myo-*inositol (15).* Compound **14** (0.2 g) was dechlorinated with tributyltin(IV) hydride in toluene as described in the preparation of **10.** The crude product was crystallized from chloroform–ethanol to give 0.11 g (55%) of **15**: mp 171—174 °C; ^{1}H NMR ($CDCl_3$) δ 2.48 (s, 9, three tosyl CH_3).

Found: C, 56.22; H, 5.41; S, 13.46%. Calcd for $C_{33}H_{38}$-

$O_{11}S_3$: C, 56.07; H, 5.42; S, 13.61%.

1,4-Di-O-benzoyl-5-chloro-2,3-O-cyclohexylidene-5-deoxy-neo-*inositol (17).* To a solution of 1,4-di-*O*-benzoyl-2,3-*O*-cyclohexylidene-*myo*-inositol (**16**)[11] (1 g) in dry pyridine (30 ml) was added sulfuryl chloride (1.04 ml, 6 molar equiv) at −15 °C and the mixture stirred at this temperature for 1 h and subsequently at 5 °C for 3 h. The reaction mixture was processed as described in the preparation of **5**, crude product being crystallized from ethanol to give 0.65 g (62%) of **17**: mp 194—196 °C.

Found: C, 63.89; H, 5.52; Cl, 7.51%. Calcd for $C_{26}H_{27}O_7Cl$: C, 64.13; H, 5.59; Cl, 7.28%.

Compound **17** (0.2 g) was treated with acetic anhydride (5 ml) and pyridine (5 ml) at room temperature overnight. The reaction mixture was evaporated and the residue crystallized from ethanol to give 0.19 g (87%) of the acetyl derivative (**18**): mp 180—181°C.

Found: C, 63.64; H, 5.50; Cl, 6.83%. Calcd for $C_{28}H_{29}O_8Cl$: C, 63.57; H, 5.53; Cl, 6.70%.

Penta-O-acetyl-5-chloro-5-deoxy-neo-*inositol (19).* A mixture of **18** (0.53 g), 12 M hydrochloric acid (30 ml), and ethanol (30 ml) was refluxed overnight, and then evaporated to give a crystalline product (0.16 g): mp 240—250 °C. Without further purification, the product was treated with acetic anhydride (10 ml) and pyridine (15 ml) at 60 °C for 2 h. The reaction mixture was evaporated and the residue crystallized from ethanol to give 0.14 g (82%) of **19**: mp 180—183 °C; ^{1}H NMR ($CDCl_3$) δ 1.99 (s, 6), 2.10 (s, 6), and 2.17 (s, 3) (OAc).

Found: C, 46.77; H, 5.08; Cl, 8.96%. Calcd for $C_{16}H_{21}O_{10}Cl$: C, 47.01; H, 5.18; Cl, 8.67%.

Penta-O-acetyl-1,5/2,3,4-cyclohexanepentol (20). Compound **19** (0.1 g) was dechlorinated with tributyltin(IV) hydride (0.3 ml) as described in the preparation of **10**. The product was crystallized from ethanol to give 0.07 g (77%) of **20**: mp 186—187 °C (lit,[12] 182 °C); ^{1}H NMR ($CDCl_3$) δ 1.45 (broad dd, 1, $J_{1,6ax\ (5,6ax)}=10$ Hz, $J_{6gem}=12$ Hz, H-6ax), 2.01 (s, 6), 2.03 (s, 6), and 2.18 (s, 3) (OAc), 2.50 (td, 1, $J_{1,6eq\ (5,6eq)}=5$ Hz, H-6eq), 4.99 (dd, 2, $J_{1,2\ (4,5)}=10$ Hz, $J_{2,3\ (3,4)}=2.5$ Hz, H-2 and H-4), 5.33 (dt, 2, H-1 and H-5), 5.65 (t, 1, H-3). (Found: C, 50.95; H, 5.74%).

1,2-O-Isopropylidene-(1/2,3,4,6)-3-chloro-4,6-bis(ethoxycarbonylamino)-1,2-cyclohexanediol (24). To a solution of 1,2-*O*-isopropylidene-(1,3/2,4,6)-4,6-bis(ethoxycarbonylamino)-1,2,3-cyclohexanetriol (**22**)[13] (0.57 g) in chloroform (5 ml) and pyridine (10 ml) was added sulfuryl chloride (0.4 ml, 3 molar equiv) at −15 °C, and the reaction mixture kept at 4 °C overnight. The mixture was processed as described in the preparation of **5**. The product was crystallized from ethyl acetate–ether to give 0.38 g (63%) of **24**: mp 189—190 °C; ^{1}H NMR ($CDCl_3$) δ 1.25 (t, 6, $J=7.5$ Hz, two ethoxycarbonyl CH_3), 1.46 (s, 6, two isopropylidene CH_3), 4.16 (q, 4, two ethoxycarbonyl CH_2), 4.69 (t, 1, $J_{2,3}=J_{3,4}=3$ Hz, H-3).

Found: C, 49.15; H, 6.71; N, 7.46; Cl, 9.92%. Calcd for $C_{15}H_{25}N_2O_6Cl$: C, 49.38; H, 6.91; N, 7.68; Cl, 9.72%.

Di-O-acetyl-(1/2,3,4,6)-3-chloro-4,6-bis(ethoxycarbonylamino)-1,2-cyclohexanediol (26). A mixture of **24** (1 g) in 50% aqueous acetic acid (80 ml) was heated at 70—80 °C for 2 h. The reaction mixture was evaporated to give a crystalline product that was directly treated with acetic anhydride and pyridine in the usual manner. The product was crystallized from ethyl acetate–ether to give 0.93 g (83%) of **26**: mp 154—155 °C; ^{1}H NMR ($CDCl_3$) δ 1.24 (t, 3) and 1.26 (t, 3) ($J=7$ Hz, ethoxycarbonyl CH_3), 2.07 (s, 3) and 2.11 (s, 3) (OAc), 4.15 (q, 2) and 4.18 (q, 2) (ethoxycarbonyl CH_2), 4.71 (m, 1, H-3).

Found: C, 47.05; H, 6.08; N, 6.77; Cl, 8.53%. Calcd for $C_{16}H_{25}N_2O_8Cl$: C, 47.00; H, 6.16; N, 6.85; Cl, 8.67%.

Di-O-acetyl-(1/2,3,4,6)-4,6-diacetamido-3-chloro-1,2-cyclohexanediol (25). 1,2-*O*-Isopropylidene-(1,3/2,4,6)-4,6-diacetamido-1,2,3-cyclohexanetriol (**21**)[14] (1 g) was treated with sulfuryl chloride in chloroform and pyridine as described in the preparation of **24**. The product was heated with 1 M hydrochloric acid (20 ml) at 70 °C for 20 min. The mixture was evaporated and the residual product acetylated in the usual manner to give, after crystallization from ethanol, 0.58 g (48%) of **25**: mp 223—224 °C; ^{1}H NMR (Me_2SO-d_6) δ 1.76 (s, 3), 1.85 (s, 3), 1.95 (s, 3), and 2.03 (s, 3) (OAc), 4.75 (broad s, 1, H-3), 5.14—5.25 (m, 2, H-1 and H-2).

Found: C, 48.09; H, 5.94; N, 7.84; Cl, 10.09%. Calcd for $C_{14}H_{21}N_2O_6Cl$: C, 48.21; H, 6.07; N, 8.03; Cl, 10.16%.

1,2-Di-O-acetyl-(1/2,3,4,6)-4,6-bis(benzyloxycarbonylamino)-3-chloro-1,2-cyclohexanediol (27). 1,2-*O*-Isopropylidene-(1,3/2,4,6)-4,6-bis(benzyloxycarbonylamino)-1,2,3-cyclohexanetriol (**23**)[13] (0.8 g) was chlorinated as described in the preparation of **24**. The product was treated with acid and acetylated as described above. Purification using a silica gel column (40 g) with 1:10 2-butanone–toluene gave 0.31 g (34%) of **27**: mp 128.5—129.5 °C; ^{1}H NMR (Me_2SO-d_6) δ 1.90 (s, 3) and 2.06 (s, 3) (OAc), 4.89 (m, 1, H-3), 5.17 (broad s, 4, two benzyloxycarbonyl CH_2).

Found: C, 58.78; H, 5.28; N, 5.08; Cl, 6.77%. Calcd for $C_{26}H_{29}N_2O_8Cl$: C, 58.59; H, 5.48; N, 5.26; Cl, 6.65%.

(1,3,5/2)-3,5-Bis(ethoxycarbonylamino)-1,2-cyclohexanediol [N,N′-*Bis(ethoxycarbonyl)-2,4-dideoxystreptamine*] *(30).* A mixture of **24** (0.16 g) in dioxane (5 ml) and 50% aqueous acetic acid (20 ml) was heated at 70 °C for 2 h, and then evaporated to dryness. The residue was crystallized from ethyl acetate to give 0.14 g (96%) of the dihydroxy compound: mp 120—123 °C. This compound was hydrogenated in ethanol (10 ml) as described in the preparation of **9** at room temperature for 27 h. The product was crystallized from ethanol to give 0.068 g (54%) of **30**: mp 185—186 °C; ^{1}H NMR (Me_2SO-d_6) δ 1.11 (t, 6, $J=7$ Hz, two ethoxycarbonyl CH_3), 3.78—4.15 (m, 4, two ethoxycarbonyl CH_2).

Found: C, 49.26; H, 7.39; N, 9.42%. Calcd for $C_{12}H_{22}N_2O_6$: C, 49.64; H, 7.64; N, 9.65%.

Di-O-acetyl-(1,3,5/2)-3,5-diacetamido-1,2-cyclohexanediol (N,N′-*Diacetyl-2,4-dideoxystreptamine*) *(28).* Compound **25** (0.4 g) was hydrogenated in ethanol (20 ml) as described in the preparation of **9** at room temeprature overnight. The product was crystallized from ethanol–ether to give 0.21 g (65%) of **28**: mp 247—249 °C (lit,[15] 231.5—233 °C). This compound was identified with an authentic sample[15] by comparison with IR and ^{1}H NMR spectra, and shown to be more homogeneous.

Di-O-acetyl-(1,3,5/2)-3,5-bis(benzyloxycarbonylamino)-1,2-cyclohexanediol (32). Compound **27** (0.075 g) was dechlorinated with tributyltin(IV) hydride (0.3 ml) as described in the preparation of **10**. The crude crystals were recrystallized from chloroform–petroleum ether to give 0.062 g (89%) of **32**: mp 180—182 °C; ^{1}H NMR ($CDCl_3$) δ 1.94 (s, 3) and 2.00 (s, 3) (OAc), 5.10 (broad s, 4, two benzyloxycarbonyl CH_2).

Found: C, 62.26; H, 6.04; N, 5.68%. Calcd for $C_{26}H_{30}N_2O_8$: C, 62.64; H, 6.07; N, 5.62%.

(1,3,5/2)-3,5-Diamino-1,2-cyclohexanediol Dihydrochloride (2,4-Dideoxystreptamine Dihydrochloride) (29). Compound **28** (0.46 g) was refluxed with 6 M hydrochloric acid (20 ml) for 3.5 h. The reaction mixture was evaporated and the residual syrup crystallized from ethanol–methanol–water to give 0.24 g (74%) of **29**: mp 247—249 °C (dec.).

Found: C, 32.69; H, 7.18; N, 12.72; Cl, 32.20%. Calcd for $C_6H_{16}N_2O_2Cl_2$: C, 32.89; H, 7.36; N, 12.78; Cl, 32.36%.

Compound **29** (0.44 g) was treated with ethyl chloroformate (0.76 ml) in acetone (12 ml) and water (12 ml) containing

sodium carbonate (2.2 g) under vigorous agitation at room temeprature overnight. The mixture was neutralized with 1 M hydrochloric acid and evaporated to dryness. The residue was extracted with hot dioxane (20 ml), the extract evaporated and crystallized from ethanol to give 0.45 g (78%) of **30**: mp 185—186 °C, identical with the compound obtained before.

(1,3,5/2)-3,5-Bis(benzyloxycarbonylamino)-1,2-cyclohexanediol [N,N'-*Bis(benzyloxycarbonyl)-2,4-dideoxystreptamine*] *(31)*. The crude **29** obtained from **28** (0.16 g) was treated with 30% toluene solution of carbobenzyloxy chloride (1.1 ml) in acetone (4 ml) and water (2 ml) in the presence of sodium hydrogencarbonate (0.19 g) at 5 °C overnight. The resulting crystals were collected and recrystallized from ethanol to give 0.15 g (73%) of **31**: mp 204—205 °C.

Found: C, 63.45; H, 6.46; N, 6.39%. Calcd for $C_{22}H_{26}N_2O_6$: C, 63.75; H, 6.32; N, 6.76%.

Chlorination of (1,3/2,4,6)-4,6-Bis(ethoxycarbonylamino)-1,2,3-cyclohexanetriol (33).[13] a) To a solution of **33** (1 g) in pyridine (40 ml) was added sulfuryl chloride (1.1 ml, 4 molar equiv) at −15 °C with stirring, and the mixture was kept at 4 °C for 4 h. TLC indicated the formation of two components (R_f 0.81 and 0.51, in 5:1 benzene–ethanol). The reaction mixture was processed as described in the preparation of **5** and the product acetylated in the usual manner. The mixture of two components (R_f 0.56 and 0.51, in 2:1 benzene–ethyl acetate) was fractionated using a silica-gel column (100 g) with 3:1 and 5:1 benzene–ethyl acetate as the eluate. The first fraction (R_f 0.56) was evaporated and crystallized from chloroform–ethyl acetate to give 0.33 g (28%) of (1/2,3,4,6)-3-chloro-4,6-bis(ethoxycarbonylamino)-1,2-cyclohexanediol 1,2-cyclic sulfate (**34**): mp 183 °C (dec) after melting and resolidification at 105—110 °C; ^{1}H NMR (Me_2SO-d_6) δ 1.19 (t, 6, J=7.5 Hz, two ethoxycarbonyl CH_3), 4.06 (q, 4, two ethoxycarbonyl CH_2), 5.06 (t, 1, $J_{1,2}=J_{1,6}=10$ Hz, H-1), 5.64 (dd, 1, $J_{2,3}=3$ Hz, H-2); IR 3300 (NH), 1700 and 1540 (amide), 1390 cm^{-1} (sulfate).

Found: C, 36.96; H, 4.79; N, 7.19%. Calcd for $C_{12}H_{14}N_2O_8SCl$: C, 37.24; H, 4.95; N, 7.24%.

The second fraction (R_f 0.51) was evaporated and crystallized from ethyl acetate–petroleum ether to give 0.23 g (17%) of **26**: mp 154—155 °C, identical with the compound obtained before.

b) Compound **33** (3 g) was treated with sulfuryl chloride (3.3 ml) in pyridine (100 ml) as described above. The syrupy mixture thus obtained was treated with methanol (100 ml) saturated with ammonia at 5 °C at room temperature for 4 days. The reaction mixture evaporated to dryness and the residue treated with 1 M hydrochloric acid (50 ml) at 80 °C for 15 h. Then the mixture was neutralized with sodium carbonate (2.6 g) and evaporated to give solid residue, which was extracted with hot dioxane (50 ml). The extract was evaporated and the residual product acetylated in the usual manner. The product was purified by passage through a short alumina column with chloroform and crystallized from ethyl acetate–petroleum ether to give 2.46 g (61%) of **26**: mp 153—155 °C.

Di-O-acetyl-(1,3/2,4,6)-3-azido-4,6-bis(ethoxycarbonylamino)-1,2-cyclohexanediol (35). A mixture of **26** (2 g), sodium azide (3.65 g), and *N,N*-dimethylformamide (30 ml) was heated at 100 °C under stirring overnight. An insoluble matter was filtered off and the filtrate evaporated to dryness. The residue was treated with acetic anhydride (20 ml) and pyridine (20 ml) at room temperature overnight. The reaction mixture was evaporated, and the residual product dissolved in chloroform and filtered through a short alumina column. The filtrate was evaporated and crystallized from chloroform–ether to give 0.86 g (34%) of **35**: mp 155—156 °C; ^{1}H NMR ($CDCl_3$) δ 1.23 (t, 3) and 1.27 (t, 3) (J=7 Hz, ethoxycarbonyl CH_3), 2.07 (s, 3) and 2.13 (s, 3) (OAc), 4.12 (q, 2) and 4.18 (q, 2) (ethoxycarbonyl CH_2).

Found: C, 46.14; H, 6.01; N, 16.84%. Calcd for $C_{16}H_{25}N_5O_8$: C, 46.26; H, 6.07; N, 16.86%.

Di-O-acetyl-(1,3/2,4,6)-3-acetamido-4,6-bis(ethoxycarbonylamino)-1,2-cyclohexanediol (36). Compound **35** (0.76 g) was treated with methanolic ammonia (20 ml) at room temperature overnight. The mixture was evaporated to give a white powder, which was hydrogenated in ethanol (20 ml) with Raney nickel as described in the preparation of **9**. The product was acetylated in the usual manner and crystallized from ethanol to give 0.42 g (54%) of **36**: mp 267—268 °C.

Found: C, 49.97; H, 6.56; N, 9.83%. Calcd for $C_{18}H_{29}N_3O_9$: C, 50.11; H, 6.77; N, 9.74%.

*Penta-*N,O-*acetyl-(1,3/2,4,6)-3,4,6-triamino-1,2-cyclohexanediol (37)*. Compound **36** (0.045 g) was refluxed with 48% hydrobromic acid (2 ml) for 3 h. The reaction mixture was evaporated and the residue dissolved in water. The solution was passed through a short column of Dowex 1×2 (OH^-) and the eluate was evaporated to give the free base, which on acetylation gave 0.032 g (83%) of **37**: mp 298—303 °C (dec); ^{1}H NMR (Me_2SO-d_6), see text.

Found: C, 51.65; H, 6.62; N, 11.34%. Calcd for $C_{16}H_{25}N_3O_7$: C, 51.74; H, 6.79; N, 11.34%.

1,2-O-Isopropylidene-(1,3,5/2,4,6)-4,6-bis(ethoxycarbonylamino)-1,2,3,5-cyclohexanetetrol (38). 1,5-Di-*O*-acetyl-2,3-*O*-isopropylidene-(1,3,5/2,4,6)-4,6-bis(ethoxycarbonylamino)-1,2,3,5-cyclohexanetetrol[18] (1 g) was treated with methanol (50 ml) saturated with ammonia at 5 °C. After standing at room temperature overnight, the reaction mixture was evaporated to dryness and the residue crystallized from ethanol to give 0.64 g (78%) of **38** as tiny needles: mp 228—230 °C, after sintering and resolidifying at 200—203 °C.

Found: C, 49.57; H, 7.03; N, 7.74%. Calcd for $C_{15}H_{26}N_2O_8$: C, 49.72; H, 7.23; N, 7.73%.

Chlorination of 38. To a solution of **38** (2 g) in pyridine (50 ml) was added sulfuryl chloride (2.7 ml, 4 molar equiv) at −20 °C with stirring, and then the mixture was kept at 4 °C for 6 h. The reaction mixture was diluted with chloroform (100 ml) and the solution washed successively with aqueous sodium hydrogencarbonate and water. After drying over anhydrous sodium sulfate, the organic layer was evaporated to give a syrup, which was dissolved in dioxane (10 ml) and heated with 50% aqueous acetic acid (10 ml) at 80 °C for 2 h. The reaction mixture was evaporated to dryness and the residue treated with acetic anhydride (10 ml) and pyridine (10 ml) at room temperature overnight. TLC indicated the formation of three components (R_f 0.58, 0.37, and 0.25 in 3:1 benzene–ethyl acetate). The reaction mixture was evaporated and the residual product was chromatographed on silica gel (100 g) with 4:1 benzene–ethyl acetate as an eluent.

The fraction (R_f 0.58) was evaporated and crystallized from ethanol to give 0.1 g (4%) of di-*O*-acetyl-(1/2,3,4,5,6)-3,5-dichloro-4,6-bis(ethoxycarbonylamino)-1,2-cyclohexanediol(**41**): mp 200—202 °C; ^{1}H NMR (Me_2SO-d_6) δ 1.19 (t, 6, J=7 Hz, two ethoxycarbonyl CH_3), 2.08 (s, 6, two OAc), 4.06 (q, 4, two ethoxycarbonyl CH_2), 4.72 (dd, 1, J=*ca.* 3 Hz, H-3 or H-5), 7.69 (d, 2, J=7 Hz, 2NH).

Found: C, 43.20; H, 5.29; N, 6.19; Cl, 16.00%. Calcd for $C_{16}H_{24}N_2O_8Cl_2$: C, 43.35; H, 5.46; N, 6.32; Cl, 15.99%.

The fraction (R_f 0.37) was evaporated and crystallized from ethanol to give 0.49 g (19%) of tri-*O*-acetyl-(1,3/2,4,5,6)-5-chloro-4,6-bis(ethoxycarbonylamino)-1,2,3-cyclohexanetriol (**39**): mp 195—196 °C; ^{1}H NMR (Me_2SO-d_6) δ 1.18 (t, 6, J=7 Hz, two ethoxycarbonyl CH_3), 1.92 (s, 3) and 1.97 (s, 6) (OAc), 4.07 (q, 4, two ethoxycarbonyl CH_2), 7.26 (d, 2, J=8

Hz, 2NH).

Found: C, 46.59; H, 5.69; N, 6.00; Cl, 7.77%. Calcd for $C_{18}H_{27}N_2O_{10}Cl$: C, 46.31; H, 5.38; N, 6.00; Cl, 7.59%.

The fraction (R_f 0.25) was evaporated and crystallized from ethanol to give 0.81 g (31%) of tri-*O*-acetyl-(1,3,5,6/2,4)-6-chloro-3,5-bis(ethoxycarbonylamino)-1,2,4-cyclohexanetriol (**40**): mp 183—184 °C; ^{1}H NMR (Me_2SO-d_6) δ 1.13 (t, 3) and 1.18 (t, 3) (J=7 Hz, ethoxycarbonyl CH_3), 1.97 (s, 6) and 2.03 (s, 3) (OAc), 3.99 (q, 2) and 4.05 (q, 2) (ethoxycarbonyl CH_2), 6.94 (d, 1) and 7.19 (d, 1) (J=8 Hz, NH). (Found: C, 46.57; H, 5.56; N, 6.06; Cl, 7.76%). This compound was identified with an authentic sample[1a] (mp 180—182 °C).

(1,2,3,5/4,6)-Bis(ethoxycarbonylamino)-1,2,3,5-cyclohexanetetrol [N,N′-*Bis(ethoxycarbonyl)*-myo-*inosadiamine-4,6*] (**42**). Hexa-*N,O*-acetyl-*myo*-inosadiamine-4,6[16] (1.33 g) was treated with 6 M hydrochloric acid (30 ml) at reflux temperature for 2 h. The reaction mixture was evaporated and the crude dihydrochloride obtained treated with ethyl chloroformate (1.2 ml) in 1 M sodium hydroxide solution (15 ml) at room temperature overnight. After neutralization with 1 M hydrochloric acid, the mixture was evaporated to dryness and the residue extracted with hot dioxane (30 ml). The extract was evaporated and the crystals recrystallized from dioxane to give 0.73 g (80%) of **42**: mp 247.5—248.5 °C.

Found: C, 45.01; H, 6.84; N, 8.39%. Calcd for $C_{12}H_{22}N_2O_8$: C, 44.71; H, 6.88; N, 8.69%.

Compound **42** was acetylated in the conventional way. The crude product was crystallized from ethanol to give the tetra-*O*-acetyl derivative: mp 247—248.5 °C; ^{1}H NMR ($CDCl_3$) δ 1.23 (t, 6, J=7 Hz, two ethoxycarbonyl CH_3), 2.02 (s, 6), 2.07 (s, 3), and 2.20 (s, 3) (OAc), 4.10 (q, 4, two ethoxycarbonyl CH_2), 4.21 (q, 2, $J_{1,6(3,4)}=J_{4,5(5,6)}=J_{4,NH(6,NH)}$ =10.5 Hz, H-4 and H-6), 5.07 (t, 1, H-5), 5.09 (dd, 2, $J_{1,2(2,3)}$ =2.5 Hz, H-1 and H-3), 5.23 (d, 2, 2NH), 5.62 (t, 1, H-2).

Found: C, 48.92; H, 6.22; N, 5.53%. Calcd for $C_{20}H_{30}N_2O_{12}$: C, 48.97; H, 6.17; N, 5.71%.

1,5-Di-O-acetyl-2,3-O-isopropylidene-(1,2,3,5/4,6)-4,6-bis(ethoxycarbonylamino)-1,2,3,5-cyclohexanetetrol (**43**). Compound **42** (0.4 g) was dissolved in *N,N*-dimethylformamide (20 ml), and 2,2-dimethoxypropane (5 ml) and *p*-toluenesulfonic acid (10 mg) were added. The mixture was heated at 80 °C for 10 min and then treated with Amberlite IRA-400 (OH^-) after cooling. The solution was evaporated and crystallized from ethanol to give 0.15 g (34%) of the *O*-isopropylidene derivative: mp 190—191 °C; ^{1}H NMR (Me_2SO-d_6) δ 1.22 (t, 6, J= 7 Hz, two ethoxycarbonyl CH_3), 1.33 (s, 3) and 1.53 (s, 3) (isopropylidene CH_3), 4.12 (q, 4, two ethoxycarbonyl CH_2).

A 0.1-g portion of the crystals was acetylated in the usual manner and the product crystallized from ethanol to give 0.1 g (74%) of **43**: mp 221—222 °C; ^{1}H NMR ($CDCl_3$) δ 1.22 (t, 6, J=7 Hz, two ethoxycarbonyl CH_3), 1.36 (s, 3) and 1.64 (s, 3) (isopropylidene CH_3), 2.05 (s, 3) and 2.13 (s, 3) (OAc), 4.11 (q, 4, two ethoxycarbonyl CH_2), 4.43 (t, 1, $J_{1,2}=J_{2,3}$=3 Hz, H-2), 4.95 (t, 1, $J_{4,5}=J_{5,6}$=10 Hz, H-5), 5.00 (d, 1, J= 10 Hz) and 5.19 (d, 1, J=9 Hz) (NH), 5.20 (dd, 1, $J_{1,6}$=11 Hz, H-1).

Found: C, 51.38; H, 6.89; N, 6.35%. Calcd for $C_{19}H_{30}N_2O_{10}$: C, 51.12; H, 6.77; N, 6.27%.

Di-O-acetyl-(1,3/2,4,5,6)-4,5-dichloro-2,6-bis(ethoxycarbonylamino)-1,3-cyclohexanediol (**44**). Compound **43** (0.057 g) was heated with 90% aqueous acetic acid (10 ml) at 80 °C for 30 min. The mixture was evaporated to give a syrupy dihydroxy compound. Without further purification, the product was treated with sulfuryl chloride (0.05 ml) in pyridine (5 ml) at 5 °C overnight. The reaction mixture was processed as described in the preparation of **5**. The product was recrystallized from ethanol to give 0.023 g (41%) of **44**: mp 218—219 °C; ^{1}H NMR ($CDCl_3$) δ 1.21 (t, 3) and 1.24 (t, 3) (J=7 Hz, ethoxycarbonyl CH_3), 2.07 (s, 3) and 2.10 (s, 3) (OAc), 4.11 (q, 2) and 4.15 (q, 2) (ethoxycarbonyl CH_2), 4.35 (dd, 1, $J_{3,4}$=10 Hz, $J_{4,5}$=3 Hz, H-4), 4.63 (t, 1, $J_{5,6}$=3 Hz, H-5), 5.14 (d, 1) and 5.26 (d, 1) (J=9 Hz, NH), 5.26 (t, 1, $J_{1,2}=J_{1,6}$=10 Hz, H-1), 5.38 (t, 1, $J_{2,3}$=10 Hz, H-3).

Found: C, 43.26; H, 5.41; N, 6.28; Cl, 15.95%. Calcd for $C_{16}H_{24}N_2O_8Cl_2$: C, 43.34; H, 5.46; N, 6.32; Cl, 16.00%.

Di-O-acetyl-(1,3/2,4)-2,4-bis(ethoxycarbonylamino)-1,3-cyclohexanediol [*Di-O-acetyl*-N,N′-*bis(ethoxycarbonyl)-4,5-dideoxystreptamine*] (**45**). Compound **44** (0.21 g) was hydrogenated in ethanol (15 ml) as described in the preparation of **9**. The product was crystallized from ethyl acetate–ether to give 0.13 g (71%) of **45**: mp 170 °C; ^{1}H NMR (Me_2SO-d_6) δ 1.15 (t, 6, J=7.5 Hz, two ethoxycarbonyl CH_3), 1.91 (s, 3) and 1.97 (s, 3) (OAc), 4.01 (q, 4, two ethoxycarbonyl CH_2), 4.71 (dd, 1, $J_{2,3}=J_{3,4}$=*ca.* 10 Hz, H-3).

Found: C, 51.33; H, 7.00; N, 7.48%. Calcd for $C_{16}H_{26}N_2O_8$: C, 51.13; H, 6.86; N, 7.28%.

(1,2/3,5)-2-Acetoxy-1-chloro-3,5-bis(ethoxycarbonylamino)cyclohexane (**46**). Compound **30** (0.09 g) was treated with sulfuryl chloride (0.15 ml) in pyridine (5 ml) at −20 °C for 10 min and then at 5 °C for 6 h. The reaction mixture was processed as described in the preparation of **5**. The product was acetylated in the usual manner and purified through a short column of alumina with chloroform. Recrystallization from chloroform–ether gave 0.047 g (44%) of **46**: mp 162—163 °C; ^{1}H NMR ($CDCl_3$) δ 1.21 (t, 6, J=7 Hz, two ethoxycarbonyl CH_3), 2.08 (s, 3, OAc), 4.10 (q, 4, two ethoxycarbonyl CH_2), 4.86 (dd, 1, $J_{1,2}$=3.5 Hz, $J_{2,3}$=10 Hz, H-2).

Found: C, 47.76; H, 6.42; N, 7.80; Cl, 10.07%. Calcd for $C_{14}H_{23}N_2O_6Cl$: C, 47.93; H, 6.61; N, 7.98; Cl, 10.11%.

(1/2,4)-1-Acetoxy-2,4-bis(ethoxycarbonylamino)cyclohexane (**47**). A solution of **46** (0.5 g) in ethanol (20 ml) was hydrogenated as described in the preparation of **9**. The product was crystallized from ethanol to give 0.28 g (63%) of **47**: mp 151—152 °C; ^{1}H NMR (Me_2SO-d_6) δ 1.17 (t, 1, J=7 Hz, two ethoxycarbonyl CH_3), 1.97 (s, 3, OAc), 4.03 (q, 4, two ethoxycarbonyl CH_2), 4.53 (ddd, 1, $J_{1,2}=J_{1,6ax}$=9 Hz, $J_{1,6eq}$=4 Hz, H-1).

Found: C, 52.89; H, 7.46; N, 8.99%. Calcd for $C_{14}H_{24}N_2O_6$: C, 53.15; H, 7.65; N, 8.85%.

(1/2,4)-2,4-Bis(ethoxycarbonylamino)-1-cyclohexanol [N,N′-*Bis(ethoxycarbonyl)-2,4,5-trideoxystreptamine*] (**48**). Compound **47** (0.22 g) was treated with methanolic ammonia (20 ml) at room temperature overnight. The reaction mixture was evaporated and recrystallized from ethanol–ether to give 0.17 g (88%) of **48**: mp 133—136 °C.

Found: C, 52.41; H, 7.98; N, 10.15%. Calcd for $C_{12}H_{22}N_2O_5$: C, 52.54; H, 8.09; N, 10.29%.

The authors wish to thank Dr. Shigeru Nishiyama for the preparation of compound **37** from **36**. This work was carried out with financial support from the Ministry of Education.

The Linearity of the Substituent-induced Carbon-13 Chemical Shifts of α-Carbons with Charge Densities in Aromatic Side Chains. Semi-empirical Calculations for 4-Substituted Derivatives of Styrenes, α-Methylstyrenes, and Biphenyls

Jun NIWA

College of General Education, Nagoya University, Chikusa, Nagoya 464

(Received October 31, 1977)

The contributions to ^{13}C shifts from the diamagnetic term of the neighboring carbon atom and from the "ring-current" have been estimated by means of the equations given in a previous paper (J. Niwa, *Bull. Chem. Soc. Jpn.*, **48**, 118 (1975)). A semi-empirical expression has been derived for the substituent-induced ^{13}C chemical shift in an aromatic side chain by considering such contributions in addition to the local diamagnetic and paramagnetic terms of the carbon atom in question. The applicability of the expression has been examined for α-carbons of 4-substituted derivatives of styrenes and α-methylstyrenes, and for 1′-carbons of 4-substituted biphenyls.

The linearity of ^{13}C nuclear shielding with electron density is widely accepted on the basis of the Karplus and Pople LCAO-MO theory of diamagnetism.[1] The attempt to interpret the ^{13}C chemical shift induced by substituents (SCS) along the lines of their approach has been successfully performed for the *para*-carbon of the benzene ring.[2] The SCS of the terminal carbon of a conjugated aromatic side chain can also be treated in the same way, whereas that of α-carbon is not always directly correlated with the electron density; for example, in the ^{13}C shielding of α- and β-carbons for the series of substituted styrenes, α-carbon absorbs over a relatively narrow range, about 2 ppm, while β-carbon differs by 10 ppm. The trend of the latter is clear; an electron-withdrawing substituent decreases the β-carbon shielding, while an electron-releasing substituent increases it. This trend has been nicely correlated with the electron density. In contrast to the β-carbon, the electron-withdrawing substituent tends to increase the α-carbon shielding. The effect, however, is small and is not linearly correlated with the electron density, as is shown in Fig. 1. Its interpretation awaits a more refined theory of ^{13}C nuclear shielding.

The dominant factor governing the ^{13}C shielding must be the local paramagnetic term, σ^{AA}_{para}, but the magnetic contributions from the rest of the molecule may also not be ignored for the SCS, the range of which is relatively narrow; in the case of styrenes, the failure of the linearity of the SCS of the α-carbon with the electron density may be attributed to ignoring the contributions from the neighboring carbon atoms and the long-range shielding effect of the "ring-current."

The premises of the present approach are: (i) it is based on the Saika-Slichter expression for the nuclear magnetic shielding;[3] (ii) it continues the use of Pople's average excitation energy approximation for the paramagnetic term;[1] (iii) it considers the magnetic contribution from the neighboring carbon atom which is situated at the site near to the substituent, and (iv) it takes the long-range shielding effect of the "ring-current" into account. In our preceding paper,[4] we derived the equations for estimating the contributions from the diamagnetic term of the neighboring carbon atom and from the "ring-current." We can derive a semi-empirical expression for obtaining the ^{13}C SCS in an aromatic side chain by considering such contributions in addition to the local diamagnetic and the local paramagnetic terms of the relevant carbon atom.

The aim of the present paper is to demonstrate the validity of the predictions by an expression for a variety of substituents in the series of 4-substituted derivatives of styrenes, α-methylstyrenes, and biphenyls and, in particular, to examine the propriety of the expression for understanding and predicting the SCS of α-carbons of the styrenes and the α-methylstyrenes, and those of 1′-carbons of the biphenyls.

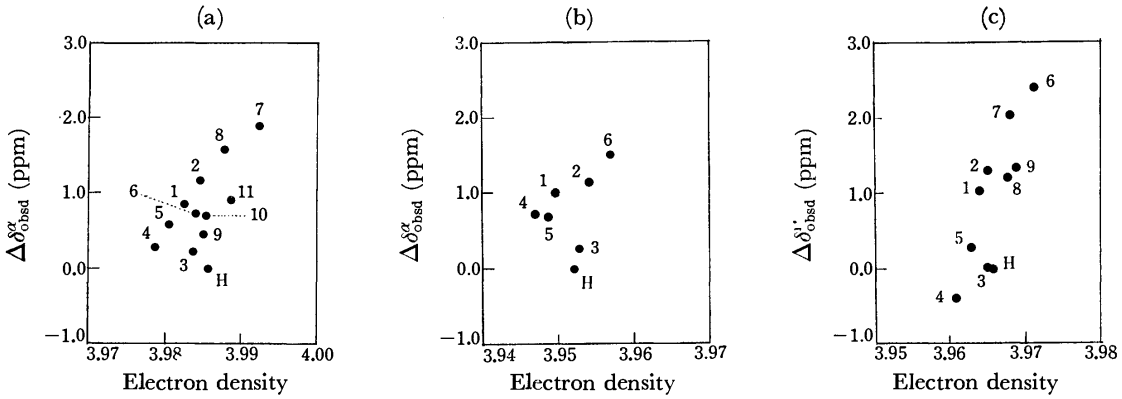

Fig. 1. Plots of $\Delta\delta_{obsd}$ against the electron density on α-carbon atom; (a) 4-substituted styrenes (b) 4-substituted α-methylstyrenes (c) 4-substituted biphenyls. Numbered points correspond to entries in Table 1.

Calculation, Results, and Discussion

The Saika-Slichter expression for obtaining a simple relationship for the nuclear magnetic shielding, σ^A, is given as[3]

$$\sigma^A = \sigma^{AA}_{dia} + \sigma^{AA}_{para} + \sum_{B\neq A}(\sigma^{AB}_{dia}+\sigma^{AB}_{para}) + \sigma^{A,ring}, \quad (1)$$

where σ^{AA} is the local diamagnetic and the local paramagnetic terms of the A atom in question; σ^{AB} is the contribution from currents on the B atom to the shielding of A, and $\sigma^{A,ring}$ is the contribution to the shielding of A from the "ring-current."

The local diamagnetic term, σ^{AB}_{dia}, is given by

$$\sigma^{AA}_{dia} = e^2/3mc^2\sum_i\langle r_i^{-1}\rangle, \quad (2)$$

where $\langle r_i^{-1}\rangle$ is the mean inverse distance of the i-th electron from a nucleus and where the summation is taken over all the electrons being considered; the diamagnetic shielding constant, σ_d', per 2s or 2p electron has been given by Yonezawa, Morishima, and Kato as[5]

$$\sigma_d'(2s \text{ or } 2p) = 4.45z^*,$$

where z^* is the "effective nuclear charge" estimated according to Slater's rules. The σ^{AA}_{dia} term has been defined in terms of the four valence electrons of a carbon atom:

$$\sigma^{AA}_{dia} = 4.45z^*q^A. \quad (3)$$

According to Pople's theory,[1] the zz-component of the local paramagnetic term, σ^{AA}_{para}, is given by

$$(\sigma^{AA}_{para})_{zz} = (-e^2\hbar^2/2m^2c^2\Delta E)\langle r^{-3}\rangle_{2p}\{(Q_{AA})_{zz} + \sum_{B\neq A}(Q_{AB})_{zz}\}, \quad (4)$$

where

$$(Q_{AA})_{zz} = 2-2(P_{xAxA}-1)(P_{yAyA}-1) + 2P_{xAyA}^2, \quad (5)$$

and

$$(Q_{AB})_{zz} = -2P_{xAxB}P_{yAyB} + 2P_{xAyB}P_{yAxB} \quad (6)$$

with corresponding expressions for other components. $\sum_{B\neq A}$ is a summation over all the atoms other than A, $\langle r^{-3}\rangle_{2p}$ is the mean inverse cube radius for carbon 2p orbitals, ΔE is the average electronic excitation energy, and $P_{\mu\nu}$ are elements of the charge density and the bond-order matrix in the MO theory of the unperturbed molecule. The suffixes xA, xB, yA, yB,$\cdots$ correspond to the various 2p atomic orbitals of the A and B atoms. The $\langle r^{-3}\rangle$ factor is given as[1,5]

$$\langle r^{-3}\rangle_{2p} = 1/24a_0^3\{3.25-0.35(P_{2p}-3)\}^3, \quad (7)$$

where a_0 is a Bohr radius and where $(P_{2p}-3)$ is the excess charge density of the 2p electron. The local paramagnetic term, σ^{AA}_{para}, becomes

$$\sigma^{AA}_{para} = -10.06/\Delta E\{3.25-0.35(P_{2p}-3)\}^3Q_{AB} \quad (8)$$

with $Q_{AB}=\sum_B\{(Q_{AA})_{\mu\mu}+\sum_{B\neq A}(Q_{AB})_{\mu\mu}\}$. The ΔE value has been assumed to be 8 eV to fit the chemical shifts observed for the α- and β-carbons of styrene and α-methylstyrene according to Pople's treatment.[1] In the same way, we have obtained 8.5 eV as the ΔE value for the 1′-carbon of biphenyl.

Table 1. Calculated and observed chemical shifts of α- and β-carbons in 4-substituted styrenes and 4-substituted α-methylstyrenes, and 1′-carbons in 4-substituted biphenyls[a]

a) All the values listed are relative to the unsubstituted compound, from the chemical shift of which upfield shifts are represented in ppm by positive values. b) For the α-carbon of styrene, σ_{dia}^{AA}: 57.733, σ_{para}^{AA}: −323.099 and for the β-carbon, σ_{dia}^{AA}: 58.262, σ_{para}^{AA}: −300.629. For the α-carbon of α-methylstyrene, σ_{dia}^{AA}: 57.459, σ_{para}^{AA}: −323.427 and for the β-carbon, σ_{dia}^{AA}: 58.453, σ_{para}^{AA}: −299.007. For the 1′-carbon of biphenyl, σ_{dia}^{AA}: 57.570, σ_{para}^{AA}: −325.839. c) Cited from Ref. 10, in which all the chemical shifts were measured in CCl_4 with 8% C_6D_{12}. d) The symbol A refers to the α-carbon (and the 1′-carbon), and the symbol B, to the C_1-carbon. e) The symbol A refers to the β-carbon, and the symbol B, to the α-carbon. f) The σ-values necessary to calculate the $\Delta\sigma^{A,ring}$, which had not been established from the reactivity data, were obtained from the correlation between the π-electron densities on *para*-carbons in monosubstituted benzenes and the known σ_π-values of the other substituents: $\sigma_\pi(-CH{=}CH_2)$, −0.05; $\sigma_\pi(-C{\equiv}CH)$, −0.005; $\sigma_\pi(SCH_3)$, −0.08; $\sigma_\pi(CO_2CH_3)$, 0.28. g) Cited from Ref. 12, in which all the chemical shifts were measured in acetone with 10% benzene.

The calculated values of the local diamagnetic (σ_{dia}^{AA}) and the local paramagnetic terms (σ_{para}^{AA}), relative to the unsubstituted compound, are summarized in Table 1. They are linearly correlated with the increments in the electron density on the carbon atom A:

$$\Delta\sigma_{dia}^{AA} + \Delta\sigma_{para}^{AA} = a\Delta q^A. \quad (9)$$

As has been shown in our preceding paper,[4] the diamagnetic contribution, σ_{dia}^{AB}, from the sp^2 hybridized carbon atom B to the A atom, to which the B atom is bonded, can be expressed as

$$\sigma_{dia}^{AB} = e^2/3mc^2\sum_I\langle r_{AB}^{-1}\rangle = e^2/3mc^2 r_{AB}^{-1}q^B, \quad (10)$$

where r_{AB}^{-1} is the inverse distance of the A atom from the point charge on the B atom and where q is the total (2s and 2p) electron density on the B atom. The expression of Eq. 10, relative to the unsubstituted compound, is given as

$$\Delta\sigma_{dia}^{AB} = b\Delta q^B. \quad (11)$$

The paramagnetic contribution, σ_{para}^{AB}, from the B atom has been calculated according to Pople's expression.[1] It remains almost constant for a series of compounds, so long as we assume the same average excitation energy and the same value of the integral $\langle r_{AB}^{-3}\rangle$ for the same series of compounds. Accordingly, the contribution of the paramagnetic term to the SCS can be ignored.

The "ring-current" effect on the SCS in an aromatic side chain can be expressed as[4,6]

$$\Delta\sigma^{A,ring} = -0.4f(\rho, z)|\sigma_\pi|, \quad (12)$$

where $f(\rho,z)$ is the Johnson-Bovey ring-current shift, which is expressed as a function of the geometric factor for the atom located at the cylindrical co-ordinates, ρ and z, and where σ_π is the Yukawa-Tsuno parameter for measuring the resonance ability of the substituent.

One might raise an objection that Eq. 12 should contain the magnetic contribution from the ring-carbon C_1, because the Johnson-Bovey ring-current

shift, $f(\rho,z)$, was originally estimated by measuring the difference in the ^1H chemical shift between benzene and ethylene; if so, according to the Saika-Slichter expression for the nuclear shielding, the $f(\rho,z)$ value for the ring proton might also contain the local diamagnetic term of the hydrogen atom, σ_{dia}^{AA}, and the magnetic contributions from the bonded carbon atom, σ_{dia}^{AB} and σ_{para}^{AB}, in addition to the effect of the "net" ring-current, $\sigma_{net.}^{A.ring}$,

$$\Delta\sigma = f(\rho,z) = \Delta\sigma_{dia}^{AA} + \Delta\sigma_{dia}^{AB} + \Delta\sigma_{para}^{AB} + \sigma_{net}^{A.ring}, \quad (13)$$

where $\Delta\sigma=\sigma(C_6H_6)-\sigma(C_2H_4)$. However, when the σ_{dia}^{AA} and σ_{net}^{AB} terms are calculated by means of the Eqs. 3 and 8 given in Ref. 4 and by using the CNDO/2 formalism:

$$\Delta\sigma_{dia}^{AA} = \sigma_{dia}^{AA}(C_6H_6) - \sigma_{dia}^{AA}(C_2H_4) = 0.355, \quad (14)$$

$$\Delta\sigma_{dia}^{AB} = \sigma_{dia}^{AB}(C_6H_6) - \sigma_{dia}^{AB}(C_2H_4) = -0.329. \quad (15)$$

The diamagnetic terms of benzene and ethylene almost cancel each other out; then Eq. 13 becomes

$$f(\rho,z) = \sigma_{para}^{AB}(C_6H_6) - \sigma_{para}^{AB}(C_2H_4) + \sigma_{net}^{A.ring}(C_6H_6). \quad (16)$$

Equation 16 shows that the $f(\rho,z)$ term does not depend on the nature of the resonating nucleus, A. The $f(\rho,z)$ term of monosubstituted benzene ($f(\rho,z)_X$) is given as

$$f(\rho,z)_X = \sigma_{para}^{AB}(C_6H_5X) - \sigma_{para}^{AB}(C_2H_4) + \sigma_{net}^{A.ring}(C_6H_5X). \quad (17)$$

On the other hand, the following relationship holds so long as we assume the same average excitation energy and the same value of the integral $\langle r_{AB}^{-3}\rangle$ for the same series of compounds:

$$\sigma_{para}^{AB}(C_6H_6) \fallingdotseq \sigma_{para}^{AB}(C_6H_5X). \quad (18)$$

Therefore, the difference in the $f(\rho,z)$ term between benzene and monosubstituted benzene is expressed as

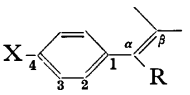
$$f(\rho,z)_X - f(\rho,z) = \sigma_{net}^{A.ring}(C_6H_5X) - \sigma_{net}^{A.ring}(C_6H_6) = \Delta\sigma_{net}^{A.ring}(C_6H_5X). \quad (19)$$

The $(f(\rho,z)_X - f(\rho,z))$ term was empirically expressed by Eq. 12 on the basis of the correlation between the ^1H SCS of *m*-substituted aromatic side chains and the Hammett σ_m values reported by Yamada *et al.*[6] We showed in our preceding paper[4] that Eq. 12 can reasonably be applied to the calculation of the ^1H SCS in aromatic side chain. Therefore, Eq. 12 can be applied, just as it is, to the calculation of the ^{13}C SCS in aromatic side chains.*

The values of $f(\rho,z)$ for the α- and β-carbons of the styrenes and the α-methylstyrenes and for the 1′-carbons of the biphenyls have been graphically estimated by utilizing the table of the Johnson-Bovey ring-current shift.[7]

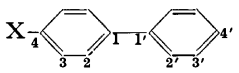
To estimate elements of the charge density and the bond-order matrix, the CNDO/2 formalism has been used.

The standard geometry of the styrenes is assumed to be planar in the present calculation.[8] The C_1–C_α bond length and the C_1–C_α–C_β valence angle are taken to be, respectively, 1.46 Å and 128°, and the phenyl-vinyl dihedral angle, θ, is taken to equal 0° on the basis of the MO calculations performed by Hehre, Radom, and Pople.[9] The geometry of α-methylstyrene may not be planar because of the steric repulsion between the phenyl ring and the methyl group of the side chain. For α-methylstyrene with an experimental dihedral angle $\theta=30°$, the C_1–C_α bond length is taken to be 1.46 Å and the C_1–C_α–C_β valence angle, to be 120°;[10] we have not attempted more rigorous energy optimizations. The respective values of the phenyl-phenyl dihedral angle and the C_1–$C_{1'}$ bond length of biphenyl are taken to be 45° and 1.48 Å.[11] The other bond angles and bond lengths for all the compounds are taken from the standard complications.[11] The carbons of the compounds examined were labeled as shown below:



R: H or CH_3

4-Subustituted styrenes and α-methylstyrenes



4-Substituted biphenyls

By combining Eqs. 3, 8, 10, and 12, we can calculate the ^{13}C SCS in an aromatic side chain. In Table 1, the calculated SCS values are compared with the observed SCS. In calculating the SCS of the α-carbon (and the 1′-carbon), the magnetic contribution from

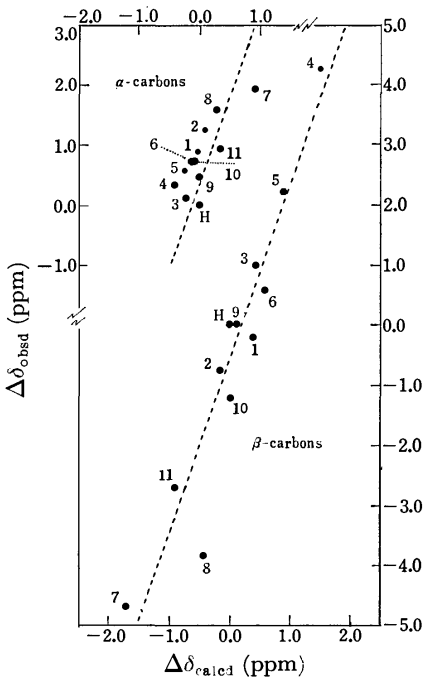


Fig. 2. Plots of $\Delta\delta_{obsd}$ against $\Delta\delta_{calcd}$ for α- and β-carbons of 4-substituted styrenes. Numbered points correspond to entries in Table 1.

* One of the referees expressed doubt about using the factor, −0.4 in Eq. 12 for the ^{13}C SCS because the factor was empirically estimated for the ^1H SCS; he advised determining the value of the factor, *c*, of the third term in the following equation by statistical treatment so as to make the slope of the correlation line between the observed and the calculated shift unity,

$$\Delta\delta_{calcd} = a\Delta q^A + b\Delta q^B + cf(\rho,z)|\sigma_z|,$$

where the values of *a* and *b* are taken from Table 2. However, this statistical treatment may result in overestimating the contribution of the 'ring-current' effect.

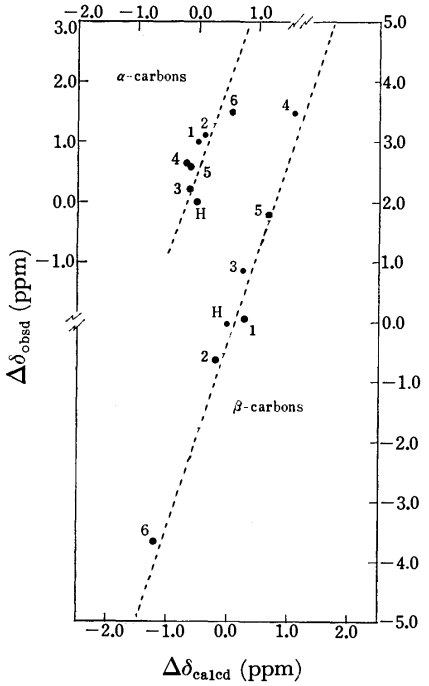

Fig. 3. Plots of $\Delta\delta_{obsd}$ against $\Delta\delta_{calcd}$ for α- and β-carbons of 4-substituted α-methylstyrenes. Numbered points correspond to entries in Table 1.

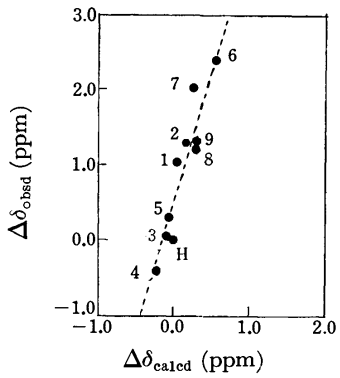

Fig. 4. Plots of $\Delta\delta_{obsd}$ against $\Delta\delta_{calcd}$ for 1'-carbons of 4-Substituted biphenyls. Numbered points correspond to entries in Table 1.

the β-carbon (and the 2'-carbon) has not been taken into account, because it may be small compared with that from the C_1-carbon. In Figs. 2—4, plots of the observed SCS are shown against the calculated SCS. As may clearly be seen in Table 1, the contributions from the diamagnetic term of the neighboring carbon atom, $B(\Delta\sigma^{AB}_{dia})$, and from the long-range shielding of the "ring-current" ($\Delta\sigma^{A,ring}$) can not be ignored in the case of the SCS of the α-carbons (and the 1'-carbon), while the local diamagnetic term ($\Delta\sigma^{AA}_{dia}$) can be ignored compared with the local paramagnetic term. The contributions of the $\Delta\sigma^{AB}_{dia}$ and the $\Delta\sigma^{A,ring}$ terms tend to almost cancel each other out in the case of the electron-withdrawing substituent, whereas both the $\Delta\sigma^{AB}_{dia}$ and the $\Delta\sigma^{A,ring}$ terms operate to cause a high-field shift in the case of the electron-releasing substituent.

We can express the SCS of the α-carbons of 4-substituted styrenes and α-methylstyrenes, and that of the 1'-carbons of 4-substituted biphenyls, by Eq. 20 in the same form as the expression derived for the ^1H SCS in an aromatic side chain, because the $\Delta\sigma^{AA}_{dia}$ and the $\Delta\sigma^{AA}_{para}$ terms are defined in terms of the electron density using Eq. 9:

$$\Delta\delta^{\alpha}_{calcd}(\text{or } \Delta\delta^{1'}_{calcd}) = a\Delta q^{A} + b\Delta q^{B} - 0.4f(\rho, z)|\sigma_{\pi}|. \quad (20)$$

The a, b, and $f(\rho,z)$ obtained are listed in Table 2.

TABLE 2. VALUES OF a, b AND $f(\rho, z)$ IN Eqs. 9, 11, AND 12 IN ppm

Compound		a	b	$f(\rho, z)$
Styrenes	α	124	6.43	−1.10
	β	121	7.01	−0.46
α-Methylstyrene	α	115	6.43	−1.10
	β	115	7.01	−0.49
Biphenyls	1'	108	6.35	−1.04

The results summarized in Table 1 show that the $\Delta\sigma^{AA}_{dia}$, the $\Delta\sigma^{AB}_{dia}$ and the $\Delta\sigma^{A,ring}$ terms do not make important contributions to the SCS of the β-carbons of the styrenes and the α-methylstyrenes. Therefore, the SCS of the β-carbon can be correlated only with the increments in the electron density on the β-carbon atom:

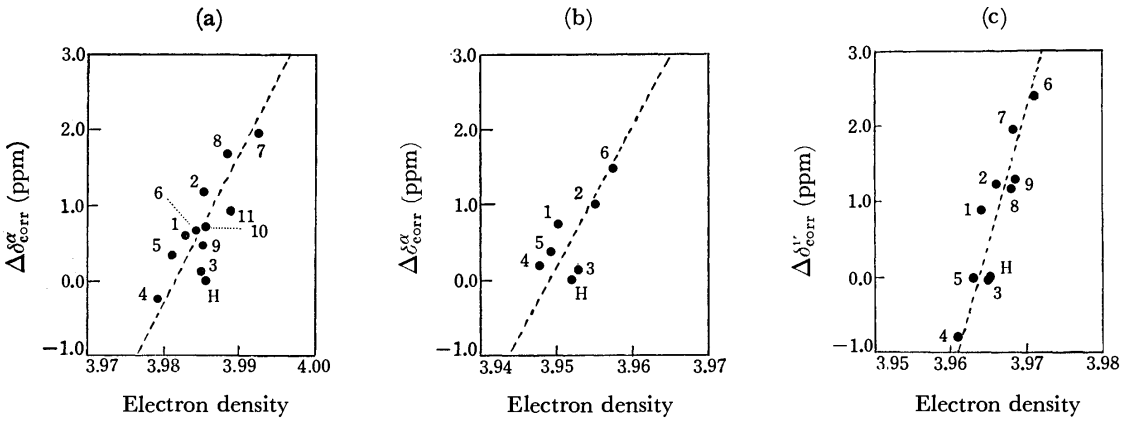

Fig. 5. Plots of $\Delta\delta_{corr}$ against the electron density on α-carbon (1'-carbon) atom; (a) 4-substituted styrenes (b) 4-substituted α-methylstyrenes (c) 4-substituted biphenyls. Numbered points correspond to entries in Table 1.

$$\Delta\delta^{\beta}_{\text{calcd}} = a\Delta q^{\text{A}}. \quad (21)$$

The calculated SCS values can reasonably reproduce all the observed SCS for the α- and β-carbons of the styrenes and the α-methylstyrenes, and for the 1'-carbons of the biphenyls, as is shown in Figs. 2—4. However, Figs. 2—4 also show that Eqs. 20 and 21 can not sufficiently reproduce the observed shifts. The shortcomings of Eqs. 20 and 21 may be attributed to adopting the same average excitation energy for all the derivatives in a series of compounds, as has been indicated by Bloor *et al.*,[2] who have calculated the SCS of ring-carbons of monosubstituted benzenes by the Karplus-Pople theory using $\delta^{13}\text{C(A)} = \sigma^{\text{AA}}_{\text{dia}} + \sigma^{\text{AA}}_{\text{para}}$**.

When the observed SCS of the α- and the 1'-carbons are corrected for the $\Delta\sigma^{\text{AB}}_{\text{dia}}$ and the $\Delta\sigma^{\text{A,ring}}$ terms, the corrected SCS values, $\Delta\delta^{\alpha}_{\text{corr}}$ (and $\Delta\delta^{\text{1'}}_{\text{corr}}$), come to be fairly well correlated with the electron densities on the α-carbons (and the 1'-carbons), as is shown in Fig. 5. This result implies that it may be appropriate to take the contributions of the $\Delta\sigma^{\text{AB}}_{\text{dia}}$ and the $\Delta\sigma^{\text{A,ring}}$ terms into consideration, so long as we interpret the SCS of α-carbon (and 1'-carbon) on the basis of the Saika-Slichter expression and Pople's average excitation energy approximation.

** For example, if it is permitted to assume empirically the appropriate ΔE value for each derivative within the range from 7.99 eV (for *p*-NMe_2) to 8.02 eV (for *p*-NO_2) for the α-carbons of the styrenes, the calculated shifts can reproduce the observed shifts fairly well. However, the MO Calculations (*e.g.*, the CNDO/2 and the INDO formalisms with the CI method) have not succeeded in reproducing the excitation energies to a degree of accuracy sufficient to examine the above assumption.

The CNDO/2 calculations were carried out on a FACOM-230 75 computer at the Nagoya University Computation Center.

Studies of the Isomerization of Unsaturated Carboxylic Acids. IV. Base-catalyzed Rearrangements of β,γ-Unsaturated Esters to α,β-Isomers

Mutsuji SAKAI,* Shūji NISHIKAWA, Haruo KOIKE, Yasumasa SAKAKIBARA, and Norito UCHINO
Department of Fiber Chemistry, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606
(Received December 23, 1977)

Dimethyl methylenesuccinate, dimethyl citraconate, and dimethyl mesaconate mutually rearranged in the presence of triethylamine at room temperature. The rearrangement was found dependent on the polarity of the solvent and the basicity of the amine, and the rate was found to be first-order in both ester and amine. A mechanism has been proposed from a kinetic study.

In the preceding paper of this series, it was reported that such unsaturated dicarboxylic esters as dimethyl methylenesuccinate (**1**), dimethyl citraconate (**2**), and dimethyl mesaconate (**3**) mutually rearranged at high temperatures and that rearrangement would proceed by the mechanism involving carbanion intermediates formed under the general-base catalysis of methanol used as a solvent.[1] According to the above mechanism, the addition of a base, *e.g.*, tertiary amines, may accelerate the rearrangement. The base-catalyzed rearrangements of other unsaturated esters to their isomers have been reported in the literature.[2-5]

This paper deals with the interconversion between **1**, **2**, and **3** in the presence of a tertiary amine. The rearrangement of an unsaturated monocarboxylic ester, methyl 3-butenoate (**4**), has also been examined and compared with that of **1**.

Experimental

All the boiling points are uncorrected.

Materials. The organic solvents and amines were purified by ordinary methods. The following compounds were prepared by the methods described in the literature: dimethyl methylenesuccinate (dimethyl methylenebutanedioate) (**1**),[1] bp 111 °C/13 Torr; dimethyl citraconate (dimethyl (*Z*)-2-methyl-2-butenedioate) (**2**),[1] bp 116°C/15 Torr; dimethyl mesaconate (dimethyl (*E*)-2-methyl-2-butenedioate) (**3**),[1] bp 118 °C/16 Torr; methyl 3-butenoate (**4**),[6] bp 108 °C; methyl (*Z*)-2-butenoate (**5**),[7] bp 119 °C (contaminated with 23% of **6**); methyl (*E*)-2-butenoate (**6**),[6] bp 120 °C; dimethyl ethylidenesuccinate,[8] bp 112 °C/15 Torr; dimethyl isopropylidenesuccinate,[8] bp 115 °C/14 Torr.

Procedure. A mixture of the ester (12 mmol), tertiary amine (12 mmol), and solvent (15 ml) was placed in a test tube fitted with a stopcock and kept in a thermostated bath. The mixture was stirred with a magnetic stirrer. Aliquots (1 ml) of the mixture were taken at regular intervals, treated with aqueous hydrochloric acid (3 ml), and extracted with benzene (2 ml). The benzene extracts were washed with sodium hydrogencarbonate and subjected to GLC analysis.

Kinetics. The initial rate constants were calculated from the plot of $\ln[\text{ester}]_0/[\text{ester}]_t$ against time. The activation parameters were obtained from the Arrhenius plot for the rate of the disappearance of ester.

Reaction in Methanol-d. A mixture of **1** (12 mmol), triethylamine (12 mmol), and methanol-*d* (15 ml) was stirred and kept at 50 °C in a thermostated bath, and at appropriate intervals aliquots of the mixture were taken. The aliquots were treated with aqueous hydrochloric acid and extracted with carbon tetrachloride. The carbon tetrachloride extracts were subjected to GLC and NMR analyses. The NMR spectra were recorded on a Varian T-60A spectrometer.

Analysis. The extracts were analyzed by GLC using a 90 m BDS capillary column with Yanagimoto G-80 for the esters (**1**, **2**, and **3**), and a 4.5 m DNP column with Yanagimoto GCG-220 for the esters (**4**, **5**, and **6**). It was confirmed that no rearrangement took place in the course of the treatment and gas chromatographic analysis.

Results

It was observed that the β,γ-unsaturated esters, **1** and **4**, rearranged to the α,β-isomers in the presence of the tertiary amine at ambient temperature and that the α,β-esters, **2** and **3**, rearranged to the β,γ-isomer. The gas chromatogram of the reaction mixture revealed that the mixture contained only three isomers of each ester; no by-product was detected.

Effects of Solvent and Amine. The initial relative rates for the rearrangement of **1** with various solvents and amines were measured. An equimolecular amount of amine to **1** was employed in order to accelerate the reaction. The reaction rate was found sensitive to the dielectric constant of the solvent, as shown in Table 1. In a polar solvent such as dimethyl sulfoxide (DMSO), **1** rearranged rapidly to **3**. In the case of a nonpolar solvent, cyclohexane, however, the rearrangement was quite slow.

The effect of amine on the rate is shown in Table 2. Methanol was used as a solvent, since some amines were not soluble in DMSO and acetonitrile. Tertiary

Table 1. Effect of solvent on the rearrangement of **1**[a]

Solvent	Dielectric constant, D	Relative rate[b]
DMSO	46.7	1.00
Sulfolane	44.0	1.04
Acetonitrile	37.5	0.349
Methanol	32.6	0.163
THF	7.6	0.0127
Cyclohexane	2.0	0.00319

a) Ester **1**, 12 mmol; triethylamine, 12 mmol; solvent, 15 ml; temp, 50 °C.
b) The rate for the disappearance of **1** in DMSO ($k=2.21\times10^{-4}$ l mol^{-1} s^{-1}) is taken as 1.00.

Table 2. Effect of amine on the rearrangement of 1[a]

Amine	pK_a	Relative rate[b]
Tributylamine	10.9	0.700
N,N-Dimethylcyclohexylamine	10.7	1.93
Triethylamine	10.7	1.00
N-Ethylpiperidine	10.4	0.542
N-Methylpiperidine	10.1	0.810
N,N-Dimethylbenzylamine	8.9	0.129
Triallylamine	8.3	0.0136
Pyridine	5.2	0
N,N-Dimethylaniline	5.1	0

a) Ester **1**, 12 mmol; amine, 12 mmol; methanol, 15 ml; temp, 50 °C. b) The rate for the disappearance of **1** in the presence of triethylamine ($k=3.60\times10^{-5}$ l mol^{-1} s^{-1}) is taken as 1.00.

amines were suitable bases for the test of the effect of amine on the rearrangement. When primary or secondary amines were used for the reaction in methanol, the aminolysis of **1** by diethylamine occurred. Tertiary amines appear to act as specific bases and general acids for the reaction. The reactivity of tertiary amines examined increased approximately with increase in basicity. The results listed in Table 2 indicate that a steric factor, in addition to an electronic one, participates in determining the reactivity of the amine with **1**.

Equilibria. The equilibria of the three isomers in DMSO containing triethylamine were examined. The results of the rearrangement are summarized in Table 3, and as may be seen, the equilibrium composition was found to be 34% for **1**, 4% for **2**, and 62% for **3**. Under identical conditions, the values in the rearrangement of methyl butenoate, attempted for a comparison, were 0% for **4**, 4% for **5**, and 96% for **6**. The esters, **4** and **5**, rearranged practically to **6**. The effect of the alkyl substituent on the rearrangement was also examined. γ-Substituted **1**, dimethyl ethylidenesuccinate and dimethyl isopropylidenesuccinate, did not rearrange to their isomers.

Kinetics. Kinetic measurements for the rearrangement of **1** and **4** were undertaken in the temperature range from 30 to 50 °C and in the concentration range of triethylamine from 0.12 to 12 mmol. The total esters were recovered quantitatively without any side reactions even after a prolonged reaction time. The rate of the rearrangement was found to be first-order in both ester and amine,

$$\text{rate} = k[\text{ester}][\text{amine}].$$

A good first-order plot for the disappearance of ester was obtained over a conversion of 20% in all cases of the esters, **1**, **2**, **3**, and **4**. The rate of the disappearance of **1** may be regarded as the rate from **1** to **3**, because the rate from **1** to **2** is much slower than that from **1** to **3** and because the rate of the reverse reaction[9] from **3** to **1** is neglected at the initial stage of the reaction. The rates of the disappearance of **2** and **3** may be taken as the rate from **2** to **1** and that from **3** to **1**, respectively, because the direct interconversion between **2** and **3** may be negligible (*vide infra*). The activation parameters, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, were 53.6 kJ mol^{-1} and −150 J K^{-1} mol^{-1} for **1**, 50.2 kJ mol^{-1} and −154 J K^{-1} mol^{-1} for **4**, respectively. In Table 4, these parameters are compared with those reported.[1,3] There are distinct differences between the values in the base-catalyzed and thermal rearrangements, the addition of a tertiary amine

Table 3. Equilibrium between 1, 2, and 3[a]

Starting ester	Time, h	Composition, %		
		1	**2**	**3**

120	12.5	82.4	5.1

a) Ester **2**, 12 mmol; triethylamine, 12 mmol; DMSO, 15 ml; temp, 50 °C.

accelerating the rearrangement significantly.

The steric effect of the ester group in methylenesuccinate on the rate was observed. The relative rate of diethyl and diisopropyl esters for **1** (1.0) were 0.75 and 0.36, respectively.

Deuterium Isotope Effect. When **1** was treated with triethylamine in methanol-*d* for 30 min, 50% of the hydrogen atoms in the α-methylene groups of the recovered **1** were replaced by deuterium atoms, whereas only 4% of **1** rearranged to **3**. The initial rate constant for the disappearance of **1** in methanol-*d*, k_{MeOD}, was measured and the ratio of k_{MeOH}/k_{MeOD} was found to be 2.5.

Scheme 1.

Discussion

Tertiary amines accelerated the rearrangement remarkably as expected. In view of the kinetic study, the same mechanism as described in the thermal rearrangement[1] is proposed for the base-catalyzed rearrangements of the unsaturated esters, **1**, **2**, **3**, and **4**, as shown in Scheme 1. The formation of **3** from the carbanion (**8**) is the rate-determining step for the rearrangement of **1** supported by the following results; the second-order reaction dependent on ester and amine, the rate dependence on the polarity of the solvent and the basicity of the amine, a facile hydrogen-deuterium exchange of the hydrogen atoms in the α-methylene group of the recovered **1**, and the deuterium isotope effect observed on the reaction. The last two observations especially support the following equation,

$$\mathbf{1} + NR_3 \overset{\text{fast}}{\rightleftharpoons} \mathbf{8} + HN^+R_3 \overset{\text{slow}}{\longrightarrow} \mathbf{3} + NR_3.$$

The rate for the formation of **2** is slower than that of **3**, since the carbanion **8** may be more stable than **7**. In the carbanion **7** (X=$-CO_2CH_3$), there is a mutual repulsion between the two *cis*-oxygen atoms of the methoxycarbonyl groups. However, for the rearrangement of methyl butenoate, **8** (X=–H) is less stable than **7**, which can thus produce a *trans*-isomer. The equilibrium between **5** and **6** lies entirely to the left under the conditions, consequently, the thermodynamically stable esters, **3** and **6**, are the most favored products in the equilibria. The equilibrium composition in the base-catalyzed rearrangements of **1**, **2**, and **3** agrees very closely with that reported in the thermal rearrangement.[1] A large negative value of entropy appears to indicate that the carbanion exists in a stabilized planar structure. However, carbanions from γ-alkylsubstituted methylenesuccinates may be unstable and/or return to starting esters, judging from the fact that the γ-alkylsubstituted methylenesuccinates do not rearrange to their isomers.

The direct *cis-trans* isomerization between **2** and **3**, another route in the rearrangement, may be negligible, because **1** predominated over **2** and **3** at the initial stage of the rearrangement of **3** and **2**, as shown in Tables 3 and 5, respectively. The *cis*-ester, **2**, rearranged consecutively to the *trans*-isomer, **3**, *via* **1**.

Thus, the mechanism reported in the thermal rearrangement using methanol as a solvent is strongly supported by the above description.

The authors wish to thank Mr. Tsutomu Kashiwaya (Toray Inc.) for his assistance in the experimental work.

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi 1-2-58, Shinagawa-ku, Tokyo 140

(Received January 10, 1978)

It has been found, from the ^1H NMR spectra that two esters exist in an intramolecularly hydrogen bonded form (**Z**) in $CDCl_3$ and DMSO solutions. Two amides, on the other hand, have been found to exist as a mixture of the **Z** and **E** isomers in DMSO solutions. H/D exchange at the olefinic site has been found to occur by the addition of D_2O to the DMSO solutions of the amides, but not in the cases of the esters. The amide configurations are discussed. An interpretation of the ^{13}C NMR spectra of these compounds is also given.

It was found that esters[1,2] and amides[3] of 3-(alkylamino)crotonic acid exist as mixtures of the **Z** and **E** isomers, with the **Z** form preferred in various solvents. The **Z-E** equilibrium was found to be solvent-dependent.[3] It was also found that the H/D exchange at the olefinic site of these compounds is closely related to the **Z-E** tautomerism, which was assumed to proceed through enamine⇌imine tautomerization. These properties of enamine derivatives are expected to depend upon the double-bond character of the olefinic linkage, which is determined by the combination of electron-donating and electron-withdrawing substituents on the opposite ends of the olefinic bond.

This paper will be concerned with the ^1H and ^{13}C NMR spectroscopic study of the four title compounds in $CDCl_3$ and DMSO solutions.

Experimental

Compound **1** was prepared by heating an equimolar mixture of ethyl acetoacetate and 2-aminopyrimidine at about 130 °C for 5 h. The volatile components were removed under reduced pressure, and the residue was extracted with hot cyclohexane. The concentration of the extract gave crude **1**, which was then purified by recrystallization from cyclohexane.

Compound **2** was prepared in a similar way.

Compounds **3** and **4** were prepared by the condensation of methylamine with the corresponding crotonamides; 2-acetoacetamidopyrimidine was commercially available, and 2-acetoacetamido-4-methylpyridine was derived from 2-amino-4-methylpyridine and ethyl acetoacetate.[4]

All four compounds gave satisfactory results of elemental analyses.

The ^1H NMR spectra were recorded on a Varian XL-100A-15 spectrometer at the CW mode at room temperature (*ca.* 28 °C), using TMS as the internal standard. The sample concentration was 50 mg/ml unless otherwise noted. The ^{13}C NMR spectra were taken under the FT mode under these conditions: spectrometer frequency, 25.16 MHz; spectral width, 5,500 Hz; aquisition time, 2 s; pulse width, 20 μs; pulse delay, 1.6—5.2 s; number of transients, 1000—10000; with or without proton-noise decoupling (10 W of rf power).

Results and Discussion

Assignment of NMR Spectra. In each of the ^1H NMR spectra of these four compounds in $CDCl_3$, there was a broad signal which was concentration-insensitive. This implies the amino structure (**Z**), including the intramolecular hydrogen bond, NH···OC.

In DMSO, the ^1H NMR spectra of **1** and **2** can be well explained in terms of one molecular species (**Z** form), whereas those of **3** and **4** can be explained by assuming two molecular species (**Z** and **E**) coexisting in the solution. A similar DMSO-induced isomerization has been reported for enamino ketones[5] and 1-carbamoyl-5-fluorouracil.[6] The ^1H chemical shifts are summarized in Table 1.

Amide Configurations. It is noteworthy that the olefinic proton of **3** resonates at a field lower by as great as 1.15 ppm than that of **4** in $CDCl_3$, and that the former signal shows an upfield shift, whereas the latter shows a downfield shift, with the solvent change from $CDCl_3$ to DMSO. This solvent change induced a great downfield shift of the amide signals of both the compounds. These observations can be well explained by assuming that **3** exists predominantly in a *s-cis* form in $CDCl_3$ and in a *s-trans* form in DMSO, because a similar phenomenon was observed for 2-acetamidopyrimidine[7] and 2-acetoacetamidopyrimidine.[8] On the other hand, it seems that the amide configuration of **4** is *s-trans* and solvent-independent.

a) Population (±5%). b) The figures in the upper row correspond to the *Z* isomer, and those in the lower, to the *E* isomer. c) Not identified because of the overlap with the *Z*-signals. d) Methyl substituent at the 4′-position.

Hydrogen-deuterium Exchange at the Olefinic Site. The addition of about 5% v/v D_2O to the DMSO solutions of **3** and **4** caused a gradual disappearance of the olefinic proton signal as well as of the amino and amide proton signals, whereas the addition of D_2O to the DMSO solutions of **1** and **2** induced the disappearance of the amino proton signal only. This means that the coexistence of the **Z** and **E** isomers in the DMSO solutions of **3** and **4** is essential to the H/D exchange at the olefinic site.

^{13}C NMR Spectra. The signal assignment was rather simple when the relative intensity and multiplicity in the proton-coupled ^{13}C spectra were taken into account (Table 2). The ring carbon, 2′, in these compounds can be identified by its rather large spin-coupling constant of about 12 Hz with the ring proton, 6′.[9]

Paired signals corresponding to the **Z** and **E** isomers were observed for **3** and **4** dissolved in DMSO; this is consistent with the results obtained from the ^1H NMR spectroscopic study.

The chemical-shift difference between the two isomers (**Z** and **E**) is appreciable for the carbonyl and the olefinic C-3 only. These two carbons are more deshielded in the **Z** form than in the **E** form, probably because of the enhanced polarization of the carbonyl group by the

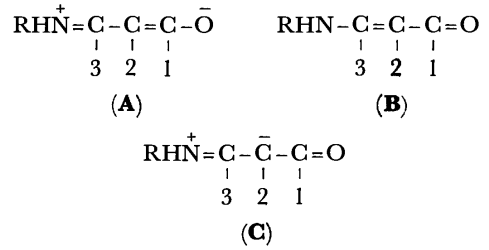
C-2′ means the ring carbon-2, for example. The values in parentheses correspond to the **E** isomer.

intramolecular hydrogen bonding. Another olefinic carbon, C-2, resonates at almost the same field in the either form of **Z** and **E**.

As has been mentioned before, it is very likely that the double-bond character of the C_2=C_3 linkage plays an important role in the isomerization and in the H/D exchange. An enhanced contribution of the canonical forms, **A** and **C**, to the ground state can be expected to reduce the double-bond character of the olefinic linkage and, as a consequence, to make the **Z-E** tautomerization as well as the H/D exchange easy.



(**A**) (**B**)

(**C**)

It is noteworthy that the ^{13}C chemical shifts of the C-2 and C-3 of **1** and **2** are systematically different from those of **3** and **4**; C-3 is more shielded in **1** and **2** than in **3** and **4**, but C-2 is, on the contrary, more shielded in **3** and **4**. Since there is no appreciable difference among the chemical shifts of the carbonyl carbons of the four compounds, the above systematic difference is probably to be ascribed to the different substituents at the 3-position, which influence both C-2 and C-3 mainly by a mesomeric mechanism. Therefore, the more shielded nature of the C-2 in **3** and **4** implies a higher contribution of the polar canonical form **C** than in **1** and **2**. This in turn means an easier formation of the transient imino form and an easier occurrence of H/D exchange.

The carbon-proton spin-spin coupling constants, $^{1}J_{CH}$'s, are given in Table 3. The $^{1}J_{CH}(2)$ values for **1** and **2** are slightly but definitely greater than those for **3** and **4**, reflecting a smaller *s* character of the C-2 hybrid orbital in **3** and **4**. This is consistent with the above argument that the contribution of the canonical form **C** is to be considered larger in **3** and **4** than in **1** and **2**.

Stereochemical Studies of the Electrolytic Reactions of Organic Compounds. V.† The Electro-reductive Cyclization of 1-Acyl-8-benzoylnaphthalenes to 1,2-Acenaphthenediols

Tsutomu NONAKA* and Mitsuo ASAI

Department of Electronic Chemistry, Tokyo Institute of Technology, Nagatsuta-machi, Midori-ku, Yokohama 227

(Received February 9, 1978)

The electrolytic reductions of several 1-acyl-8-benzoylnaphthalenes were carried out by means of controlled potential electrolysis at a mercury cathode in various catholytes. The isomeric ratio of the *cis*- and *trans*-1,2-acenaphthenediols thus formed depended on the kind of acyl group, supporting electrolyte, organic solvent in the catholyte, and cathode potential applied. The mechanism of the reductive cyclization is discussed from the stereochemical point of view, and it is proposed that the cyclization may occur not only by the intramolecular coupling of the biradical intermediate, but also by the intramolecular nucleophilic addition of the anionic part of the carbanion intermediate to its unreacted carbonyl group.

A number of studies of the stereochemistry of *vic*-diols produced by the electro-reductive dimerization of aromatic ketones and aldehydes have been performed. For instance, Stocker and Jenevein[1,2] found that the *dl*/*meso* ratio of the diol derived from acetophenone ranged from 1.0 to 1.4 in acidic media and from 2.5 to 3.2 in alkaline media, under a wide variety of electolytic conditions. These facts were explained as resulting from hydrogen bonding between radical intermediates in the transition state favorable for the formation of the *dl* isomer.

On the other hand, there have been a few papers[3-5] dealing with the stereochemistry of cyclic *vic*-diols produced by the electro-reductive cyclization of diketones. Gourley and Grimshaw[3] reported that the *cis*/*trans* ratios of the cyclic *vic*-diols produced by the reductive cyclization of 1,5-bis(4-methoxybenzoyl)-pentane and 1,5-bis(4-hydroxybenzoyl)pentane in an alkaline medium were 21.6 and 0.9 respectively. These facts were explained as resulting from hydrogen bonding favorable for the formation of the *cis* isomer in the case of the former, and to the strong electrostatic repulsion between the two negatively charged aromatic rings in the case of the latter. They also obtained cyclic *vic*-diols in such *cis*/*trans* ratios as 1.5 and 2.3 from 2,2′-bis(4-methoxybenzoyl)biphenyl and 2,2′-bis(4-hydroxybenzoyl)biphenyl respectively. However, these facts contradict the above theory. There is also an ambiguous point in the reductive dimerization of hydroxy ketones.[1,6]

In a previous work,[5] several aromatic diketones were electrolytically reduced under a variety of conditions, and it was found that the distribution of the products, which were cyclic and non-cyclic *vic*-diols and secondary alcohols, depended on the molecular structure of the diketones and on the electrolytic conditions. Of the diketones used, 1,8-dibenzoylnaphthalene (**1a**) gave only the corresponding cyclic *vic*-diol (1,2-acenaphthenediol, **2a**).

In this work, in addition to **1a**, three kinds of 1-acyl-8-benzoylnaphthalenes (**1b**—**d**) were subjected to electrolysis in order to clarify the mechanism of the reductive cyclization from the stereochemical point of view. The diacylnaphthelenes, **1b**—**d**, are characterized by their unsymmetrical molecular structures.

c: R=4-HO-C_6H_4
d: R=CH_3

Results and Discussion

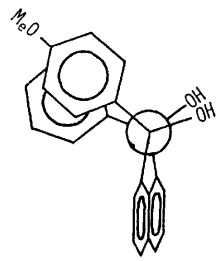
Synthesis of 1-Acyl-8-benzoylnaphthalenes (1a—d). 1,8-Dibenzoylnaphthalene (**1a**) was prepared according to the method of Beschke.[7] The routes of synthesizing the unsymmetrical diacylnaphthalenes (**1b**—**d**) were newly designed for this work.

At the first stage of the synthesis, 2-phenyl-2-hydroxy-1-acenaphthenone (**3**), which is an intermediate common to **1b**—**d**, was prepared from equimolar acenaphthenequinone and phenylmagnesium bromide in a 94% yield. The structure of the new compound, **3**, was determined by elemental analysis and by a study of the IR and mass spectra. At the second stage, **3** was converted into *trans*-1-phenyl-2-(4-methoxyphenyl)-1,2-acenaphthenediol (**2b**) and *trans*-rich 1-phenyl-2-methyl-1,2-acenaphthenediol (**2d**) by means of a Grignard reaction with 4-methoxyphenylmagnesium bromide and methylmagnesium iodide respectively. Finally, **2b** and **2d** were oxidized with chromium(VI) oxide to give 1-(4-methoxybenzoyl)-8-benzoylnaphthalene (**1b**) and 1-acetyl-8-benzoylnaphthalene (**1d**) respectively. 1-(4-Hydroxybenzoyl)-8-benzoylnaphthalene (**1c**) was prepared by the treatment of **1b** with boron tribromide.[8] The structures of the new compounds, **1b**—**d**, were established by elemental analysis and by a study of the IR and mass spectra.

† Part IV: *Bull. Chem. Soc. Jpn.*, **50**, 2965 (1977). Cathodic Crossed Hydrocoupling. Part 15. Part 14: *J. Chem. Soc., Perkin Trans. 2*, submitted for publication.

Determination of the Configuration of 1,2-Acenaphthenediol (2a—d). Since both *cis*-**2a**[7] and *trans*-**2a**[9] are known compounds, the measurement of their melting points served as the method of identification.

The diols, **2b—d**, are unknown compounds. The **2b** diol synthesized by the Grignard reaction differed from that synthesized by the magnesium reduction[10] of **1b** in its melting points, in the chemical shift of the methyl protons in the NMR spectra, and in the IR absorption bands of hydroxyl groups. Generally, the *cis* isomers of cyclic *vic*-diols, such as 1,2-acenaphthenediols and 9,10-dihydro-9,10-phenanthrenediols, showed higher melting points than the *trans* isomers.[9,10] Since the conformation of the phenyl and 4-methoxyphenyl groups of *cis*-**2b** shown in Scheme 1 seems to be more plausible than any other conformations in view of the steric requirement, the methyl protons of *cis*-**2b** are probably magnetically shielded by the phenyl group; consequently, a signal for the methyl protons would appear at a higher magnetic field in the NMR spectrum. From these considerations, the **2b** synthesized by the magnesium reduction, which melted at a higher temperature and which showed the NMR signal for methyl protons at a higher magnetic field than *trans*-**2b**, was considered to be the *cis* isomer. Both isomers also differed from one another in the IR spectrum in the OH-stretching band region. The *cis* isomer showed a broad band at about 3300 cm^{-1}. Such a low frequency seems to be the result of intramolecular hydrogen bonding. On the other hand, the *trans* isomer showed two sharper bands at 3550 and 3380 cm^{-1}. The higher-frequency band may be assigned to free hydroxyl groups, while the lower-frequency band may be the result of intermolecular hydrogen bonding.[12]



Scheme 1. Favorable conformation of *cis*-**2b**.

The *cis* and *trans* isomers of **2d** were separated by the fractional recrystallization of an isomeric mixture prepared by the Grignard reaction. The stereochemistry of the isomers was determined, similarly to the case of

a) Yield after purification. b) A vigorous hydrogen evolution was observed. c) A part of the 1,2-acenaphthenediol formed underwent acid-catalyzed pinacol rearrangement during electrolysis. d) A considerable amount of the unreacted naphthalene was recovered. e) The yield was not estimated.

2b, from considerations of their melting points and by a study of their IR and NMR spectra.

Determination of the Isomeric Formation Ratio of 1,2-Acenaphthenediols (2a—d). The isomeric ratio of **2a** formed in electrolysis was determined by fractional precipitation. The isomeric ratios of **2b** and **2d** were determined from the intensity of NMR signals for their methyl protons. Because the direct determination of the isomeric ratio of **2c** was difficult, the determination was carried out after **2c** was converted into **2b** with methyl sulfate. It was confirmed by a repetition of a methylation-demethylation cycle that no isomerization occurred during the methylation.

Electrolytic Results. The electrolytic conditions and results are summarized in Table 1. The *cis/trans* ratio of the 1,2-acenaphthenediols formed depended on the substituent of the starting naphthalenes, the cathode potential applied, the supporting electrolyte, and the organic co-solvent added to the catholyte to dissolve the naphthalenes. No by-products, such as 1-acyl-8-(hydroxymethyl)naphthalenes or 1,8-di(hydroxymethyl)naphthalenes, could be separated by column chromatography.

As is shown in Table 1, **1a** and **1b** gave the *cis*-rich diols in strongly acidic media, while **1c** gave the *cis* and *trans* diols in almost equal quantities. A part of the diol from **1c** was rearranged by sulfuric acid into the corresponding pinacolone during electrolysis. Since the pinacol rearrangement of *cis*- and *trans*-1,2-acenaphthenediols proceeds at almost the same rate in a medium containing water,[11] the *cis/trans* ratio measured after electrolysis probably corresponds to the real formation ratio of the isomers.

The formation of the thermodynamically stable *trans* isomer was predominant in strongly alkaline media.

In an weakly acidic solution, **1a—d** gave the *cis*-rich diols. The naphthalene, **1d**, which was condensed by water elimination into 3-phenyl-1-phenalenone in strongly acidic and alkaline media, could be electrolyzed only in this solution.

Polarography. The naphthalenes, **1a—d**, mostly showed very complicated multiple reduction waves in their polarograms. The half-wave potentials for the first waves only, therefore, can be estimated from the polarograms.

Table 2. Half-wave potentials of the polarographic first waves of 1-acyl-8-benzoylnaphthalene[a]

Compound	Supporting electrolyte	Organic co-solvent	$E_{1/2}$ V *vs.* SCE

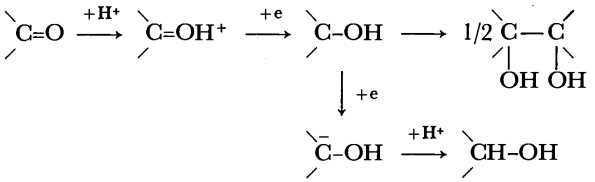
a) Measured in *ca.* 5×10^{-4} M of the concentration of the naphthalene in an electrolytic solution similar to one used for the macro electrolysis.

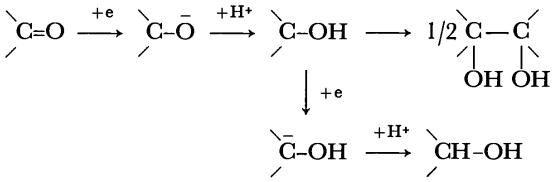
The reduction potential of an aromatic carbonyl compound generally depends on the substituents on its aromatic ring, and the dependence follows Hammet's rule.[13] For example, the polarographic half-wave potentials of 4-methoxy- and 4-hydroxybenzophenones are more negative by 100 and 170 mV respectively than that of unsubstituted benzophenone in an acidic medium. The half-wave potentials of **1a—d** were close to each other under the same conditions, as is shown in Table 2. This fact may suggest that the first one-electron transfer occurs at an unsubstituted benzoyl group in all of the naphthalenes.

Discussion of the Mechanism of the Reductive Cyclization from Stereochemical Aspects. The general reduction mechanism of carbonyl compounds was shown by Zuman[14,15] as follows:[16]

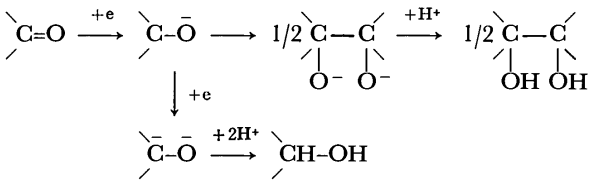
In acidic media;



in the medium pH-range;



and in alkaline media;

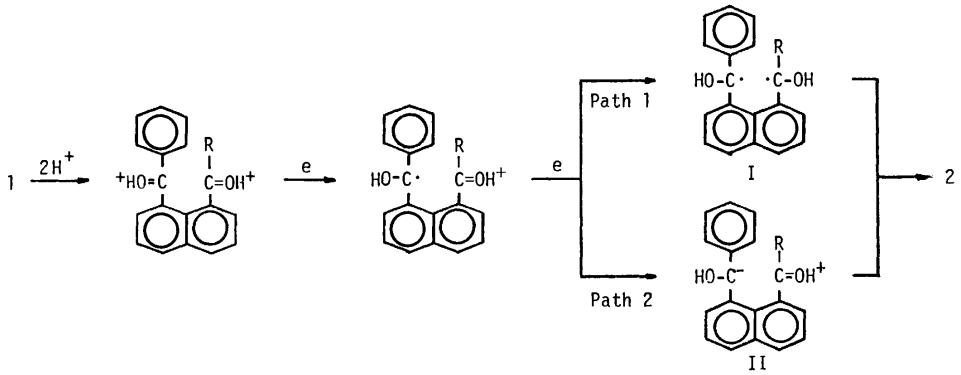


In the reduction of diketones, the second electron-transfer may occur not only at a radical carbon, but also at an unreacted carbonyl carbon. This problem could not be solved polarographically, because the naphthalenes, **1a—d**, showed multiple reduction waves which were ill-defined except for the first waves.

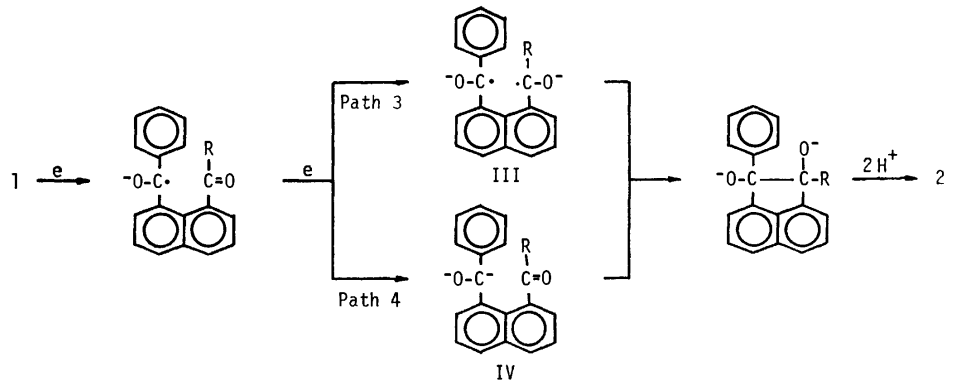
In Schemes 2, 3, and 4, two types of mechanisms for the cyclization are presented. One is based on the coupling of a biradical, and the other, on the nucleophilic addition of the carbanion.

Intramolecular hydrogen bonding in the intermediates would cause the formation of the *cis* isomer. The strength of the hydrogen bonding of a hydroxyl group with an other group containing an oxygen atom would increase in this order: $^+$HO=C, HO–C, O=C, and $^-$O–C, in view of the electron density on the oxygen atom.

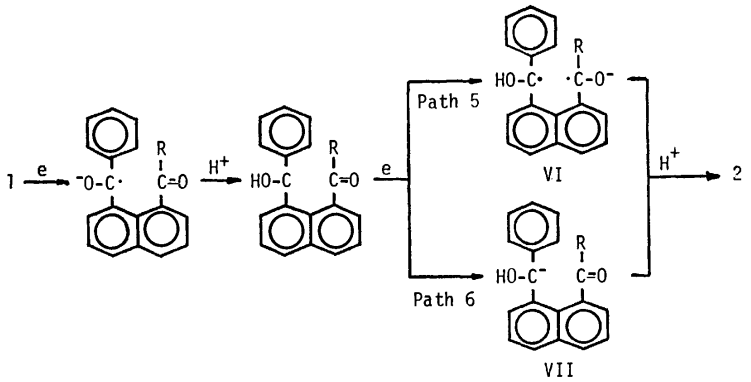
As is shown in Table 1, in a strongly acidic medium a marked substituent effect on the isomeric ratio was



Scheme 2. Possible mechanisms in strongly acidic solutions.



Scheme 3. Possible mechanisms in alkaline solutions



Scheme 4. Possible mechanisms in an weakyl acidic solution.

observed. An electron-releasing substituent on a substituted benzoyl group (R) would weaken the intramolecular hydrogen bonding in a carbanion intermediate (II) in Path 2 by promoting the protonation of the carbonyl group to decrease the ratio of the *cis* isomer, while such a substituent effect can not be expected in a biradical intermediate (I). The promotion of the protonation is essentially due to an increase in the basicity of the carbonyl group. The substituent effect observed suggests that Path 2 may be included in the cyclization process, but there is no experimental evidence for excluding Path 1. The influence of the cathode potential on the isomeric ratio may be explained as resulting from different potentials for the second electron-transfer in Paths 1 and 2, if the potential for the former is somewhat more positive than that for the latter. Whether the solvent effect is completely independent of the cathode potential is questionable.

In strongly alkaline media (see Scheme 3), where Paths 3 and 4 are possible, the *trans* isomers were predominantly formed. Since there is no contribution of hydrogen bonding in the cyclization process in either path, such electrolytic results seem reasonable. Path 3 may result in the formation of a larger amount of the *trans* isomer by the contribution of electrostatic repulsion between two negatively charged oxygen atoms than in Path 4. The exclusive formation of the *trans* isomers in the cases of **1a** and **1b** can be explained by Path 3.

Also, the formation of a small amount of the *cis* isomer in the case of **1c** may be explained as resulting from

another electrostatic repulsion, which would not be strong, between a phenolate anion (p-C_6H_4-O^-) and an oxygen anion at the opposite side of an intermediate (III) in Path 3. However, the influence of the cathode potential on the isomeric ratio can not be explained by Path 3. It seems that the reduction potential of a carbonyl group is more positive than that of the corresponding anion radical (Ċ–O^-) formed by one-electron transfer.[14,15] As the reduction potential of the carbonyl group shifts negatively when its basicity is increased by electron-releasing substituents,[13] the potential for the second electron-transfer in Path 3 may be very close to that in Path 4 in the case of **1c**, the substituent (p-C_6H_4-O^-) of which is a very strong electron-releasing group. The increase of the *cis* isomer in electrolysis at a more negative potential may be explained as resulting from the increase in the contribution of Path 4, which is competitive with Path 3, since in Path 4 the electrostatic repulsion should be weaker.

In acetic acid–sodium acetate, the manner of the substituent effect was similar to that in the alkaline media. Since the protonation of the carbonyl group would be very slight in this solution,†† the reduction mechanisms shown in Scheme 4 may be possible.[14] If the influence of the cathode potential on the isomeric ratio can be neglected compared with that of the substituent, Path 6 may be more favorable than Path 5 as an explanation of the electrolytic results. The predominant formation of the *cis* isomer in the case of **1d** may be the result of the overlapping of the strong electron-releasing and weak steric hindrance effects of the methyl group.

In summary it can be concluded from the above discussion that the nucleophilic addition process (Paths 2, 4, and 6) should be included in the reductive cyclization of 1,8-diacylnaphthalenes, without excluding the radical coupling process (Paths 1, 3, and 5); *i.e.*, the two processes are in competition with each other.

Experimental

*Synthesis of 1-Acyl-8-benzolylnaphthalenes (**1a—d**). 1,8-Dibenzoylnaphthalene (**1a**)*: *trans*-1,2-Diphenyl-1,2-acenaphthenediol (*trans*-**2a**) was prepared from one mole of acenaphthenequinone and two moles of phenylmagnesium bromide, and was then recrystallized from ethanol. Yield, 85%; mp 155—156 °C (lit,[7] 155—156 °C), and ν_{O-H} 3360 and 3420 cm^{-1}. The 1,2-acenaphthenediol obtained was oxidized with chromium (VI) oxide in acetic acid to give **1a** in a 30% yield. The crude product was recrystallized from a mixture of acetone and ethanol. Mp 187—190 °C (lit,[7] 190 °C), $\nu_{C=O}$ 1620 cm^{-1}, and *m/e* 336 (M^+). Found: C, 85.55; H, 4.56%. Calcd for $C_{24}H_{16}O_2$: C, 85.69; H, 4.79%.

*1-(4-Methoxybenzoyl)-8-benzoylnaphthalene (**1b**)*: A phenylmagnesium bromide solution, which has been prepared from 8.0 g of magnesium, 52.8 g of bromobenzene and 250 ml of THF, was added drop by drop, to 50 g of acenaphthenequinone suspended in 1500 ml of THF at room temperature. After stirring for 5 h, 50 ml of a saturated ammonium chloride solution was added to the reaction mixture, and then the resulting precipitates were filtered off. The filtrate was evaporated under reduced pressure. The residual red oil was extracted with 200 ml of benzene, and the benzene extract was washed with 500 ml of 5% sulfuric acid. The benzene solution was dried over anhydrous sodium sulfate and then evaporated to dryness under reduced pressure. The recrystallization of the residual solid from 2-propanol afforded 67 g (Yield 94%) of 2-phenyl-2-hydroxyl-1-acenaphthenone (**3**) as yellow plates. Mp 146—147 °C, $\nu_{C=O}$ 1710 cm^{-1}, ν_{O-H} 3500 cm^{-1}, and *m/e* 260 (M^+). Found: C, 83.31; H, 4.75%. Calcd for $C_{18}H_{12}O_2$: C, 83.06; H, 4.65%.

A 4-methoxyphenylmagnesium bromide solution, which had been prepared from 5.6 g of magnesium, 43.2 g of 4-methoxybromobenzene, and 200 ml of THF, was added to 20.0 g of **3** dissolved in 100 ml of THF. After stirring for 2 h, 20 ml of a saturated ammonium chloride solution was added to the reaction mixture, and then the resulting precipitates were removed by filtration. When the filtrate was evaporated, an oily substance remained. The oil was solidified by treatment with a small amount of methanol. The recrystallization of the solid from 2-propanol afforded 22.1 g (yield, 83%) of *trans*-1-phenyl-2-(4-methoxyphenyl)-1,2-acenaphthenediol (*trans*-**2b**)††† as white needles. Mp 111—112 °C, *m/e* 368 (M^+), ν_{O-H} 3380 and 3550 cm^{-1}, and δ for methyl protons 3.81 ppm. Found: C, 81.21; H, 5.23%. Calcd for $C_{25}H_{20}O_3$: C, 81.50; H, 5.47%.

Into 20.0 g of *trans*-**2b** dissolved in 100 ml of acetic acid we added drop by drop, 36.7 g of a 10% aqueous chromium(VI) oxide solution. After having been allowed to stand for 1.5 h, the reaction mixture was poured into cold water, and the resulting aqueous solution was repeatedly extracted with ether. The ethereal extract was washed with a saturated sodium carbonate solution and then with water. The ethereal solution was dried over anhydrous sodium sulfate and then evaporated. The resulting tar was solidified by treatment with a mixture of ethyl acetate and petroleum ether. The recrystallization of the solid from ethanol afforded 13.6 g (yield, 68%) of 1-(4-methoxybenzoyl)-8-benzoylnaphthalene (**1b**) as white needles. Mp 111—112 °C, $\nu_{C=O}$ 1650 and 1630 cm^{-1}, *m/e* 366 (M^+), and δ for methyl protons 3.86 ppm. Found: C, 81.96; H, 4.71%. Calcd for $C_{25}H_{18}O_3$: C, 81.95; H, 4.95%.

*1-(4-Hydroxybenzoyl)-8-benzoylnaphthalene (**1c**)*: In 500 ml of dichloromethane, 10.0 g of *trans*-**1b** was reacted with 20.0 g of boron tribromide at room temperature for 4 h. The reaction mixture was then poured into 500 ml of 5% sodium hydroxide. When the aqueous layer was neutralized with aqueous sulfuric acid, white solides were precipitated. Recrystallization from benzene afforded 8.0 g (yield, 80%) of **1c** as white needles. Mp 115 °C (dec), $\nu_{C=O}$ 1650 and 1630 cm^{-1}, ν_{O-H} 3260 cm^{-1}, and *m/e* 352 (M^+). Found: C, 81.74; H, 4.09%. Calcd for $C_{24}H_{16}O_3$: C, 81.80; H, 4.58%.

*1-Acetyl-8-benzoylnaphthalene (**1d**)*: A methylmagnesium iodide solution, which has been prepared from 4.2 g of magnesium, 25.0 g of methyl iodide, and 200 ml of ether, was added to 15.0 g of **3** dissolved in 50 ml of THF. The reaction mixture was refluxed for 3 h, and then a 100-ml portion of a saturated ammonium chloride solution was added. The organic layer was dried over anhydrous sodium sulfate and then evaporated. The residual red oil was solidified by treatment with a small amount of methanol. The recrystallization of the solid from a

†† It has been suggested, on the basis of the UV spectroscopic data, that a carbonyl compound is in protonation equilibrium in strongly acidic solutions.[17]

††† The *cis* isomer (*cis*-**2b**) was also prepared by the iodine-catalyzed magnesium reduction of **1b** in benzene at 80 °C. Yield, 100%; mp 177—178 °C, *m/e* 368 (M^+), and ν_{O-H} 3300 cm^{-1}, and δ for methyl protons 3.60 ppm. Found: C, 81.42; H, 5.24%.

mixture of methanol and water (2: 1 vol ratio) afforded 1.2 g (yield 8%) of *cis*-1-methyl-2-phenyl-1,2-acenaphthenediol (*cis*-**2d**) as prisms. Mp 161—162 °C, *m/e* 276 (M^+), ν_{O-H} 3300 cm^{-1}, and δ for methyl protons 1.00 ppm. Found: C, 82.25; H, 5.72%. Calcd for $C_{19}H_{16}O_3$: C, 82.58; H, 5.84%. On the other hand, the recrystallization from carbon tetrachloride of the solid obtained on evaporating the filtrate afforded 8.3 g (yield 52%) of *trans*-**2d** as white needles. Mp 111—112 °C, *m/e* 276 (M^+), ν_{O-H} 3320 and 3450 cm^{-1}, and δ for methyl protons 1.68 ppm. Found: C, 81.70; H, 5.84%.

A mixture of 3.0 g of *trans*-**2d**, 0.9 g of chromium(VI) oxide, 30 ml of acetic acid, and 9.1 ml of water was kept at 50 °C for 2 h. The reaction mixture was then poured into 70 ml of water and extracted with ether. The ethereal extract was washed with water and dried over anhydrous sodium sulfate. The red tar obtained by the evaporation of the ethereal solution under reduced pressure was solidified by treatment with a small amount of a mixture of ethyl acetate and petroleum ether. The subsequent recrystallization of the solid from 2-propanol afforded 2.8 g (yield 94%) of 1-acetyl-8-benzoylnaphthalene (**1d**) as white granules. Mp 110—111 °C, $\nu_{C=O}$ 1650 and 1680 cm^{-1}, and *m/e* 274 (M^+). Found: C, 83.26; H, 4.98%. Calcd for $C_{19}H_{14}O_2$: C, 83.19; H, 5.14%.

Conversion of ***1d*** *into 3-Phenyl-1-phenalenone.* To a DMF solution of **1d** we added a small amount of aqueous sulfuric acid or sodium hydroxide. After several minutes, the solution turned yellow. When a large amount of water was added to the solution, 3-phenyl-1-phenalenone was precipitated as yellow crystals. Mp 141—142 °C, $\nu_{C=O}$ 1630 cm^{-1}, and *m/e* 256 (M^+). Found: C, 89.39; H, 4.78%. Calcd for $C_{19}H_{12}O$: C, 89.04; H, 4.72%.

Electrolysis Procedure. An H-type electrolytic cell divided with a glass filter was used. A mercury pool (area, 12 cm^2) was used as the cathode, while the anode was a platinum disc (diameter, 2 cm). The catholyte and anolyte consisted of 60 ml of an organic solvent containing water in a concentration of 20 vol%. The supporting electrolytes were used in a concentration of 0.5 M except for sodium hydroxide, which was used in a concentration of 0.1 M. The starting diacylnaphthalene used for one run was 2.5 mmol. The catholyte was kept at 20 °C during the electrolysis, which was carried out by a controlled potential method.

Separation and Analysis of Products. General Procedure: After electrolysis, the catholyte was diluted with 300 ml of water and then neutralized with sulfuric acid or sodium hydroxide. The resulting solution was repeatedly extracted with ether, and the combined ethereal extract was dried over anhydrous sodium sulfate. The solids obtained by the evaporation of the ethereal solution were subjected to the following treatments for separation and analysis.

Electrolytic Products of ***1a***: The solid was dissolved in 30 ml of DMF, and the DMF solution was poured into 300 ml of water. When the resulting precipitate was recrystallized from ethanol, only unreacted **1a** crystallized out of the solution. The filtrate was evaporated, and the residue was recrystallized from acetic acid. The crystals thus obtained were *cis*-**2a**. The aqueous filtrate obtained at the first stage of this experiment was stored overnight in a refrigerator, and the resulting precipitate was filtered. The recrystallization of the precipitate from ethanol afforded pure *trans*-**2a**. The *cis*- and *trans*-**2a** thus obtained were identified with their authentic samples[7,9]** by mixed-melting point tests.

** The *cis* isomer (*cis*-**2a**) was also prepared using the method of Griegee.[9] Mp 174—175 °C (lit,[9] 176—177 °C) and ν_{O-H} 3220 cm^{-1}.

Electrolytic Products of ***1b***: Aliquorts of the solid obtained by the method described in *General Procedure* were subjected to NMR and IR spectroscopic analyses in order to determine the isomeric ratio of **2b** and to detect the unreacted **1b** respectively.

The unreacted **1b** was also recovered from the rest of the above solid by a method similar to that used in the case of **1a.** When the resulting isomeric mixture of **2b** was recrystallized from a small amount of aqueous methanol, *trans*-**2b** crystallized out of the solution. The crude *trans*-**2b** was recrystallized from 2-propanol. On the other hand, the recrystallization of the solids obtained by the evaporation of the methanolic filtrate from 2-propanol afforded *cis*-**2b**. The *cis*- and *trans*-**2b** thus obtained were identified with their authentic samples,†††,*** which were independently synthesized, by a mixed-melting point test.

Electrolytic Products of ***1c***: The solid obtained by the method described in *General Procedure* was dissolved in 100 ml of 0.5 M sodium hydroxide, and the resulting solution was stirred at room temperature for 12 h after the addition of 2.0 ml of dimethyl sulfate. The reaction mixture was repeatedly extracted with ether, and the combined ethereal extract was dried over anhydrous sodium sulfate. The subsequent evaporation of the etheral solution afforded methylated products‡ as white solids. These solids were analyzed much as in the case of **1b.** The methylated pinacol rearrangement product (2-phenyl-2-(4-methoxyphenyl)-1-acenaphthenone) was also detected using an IR spectroscopic method. This product was purely isolated by the use of a column chromatograph (silica gel, benzene). Mp 132—133 °C, $\nu_{C=O}$ 1720 cm^{-1}, *m/e* 350 (M^+), and δ for methyl protons 3.69 ppm. Found: C, 85.93; H, 5.05%. Calcd for $C_{25}H_{18}O_2$: C, 85.69; H, 5.18%.

Electrolytic Products of ***1d***: The solid obtained by the method described in *General Procedure* was subjected to the spectroscopic analyses of the products, and then unreacted **1d** was removed by a method similar to that used in the case of **1a** or **1b.** The recrystallization of the resulting isomeric mixture of **2d** from a mixture of methanol and water (2: 1 vol ratio) afforded *cis*-**2d.** On the other hand, the recrystallization from carbon tetrachloride of a solid obtained on evaporating the filtrate afforded *trans*-**2d.** The *cis*- and *trans*-**2d** thus obtained were identified with their authentic samples,‡‡ which were independently synthesized, by a mixed-melting point test.

The IR and NMR (90 MHz) spectra were measured in KBr tablets and in DMSO-d_6 solutions respectively, both at room temperature.

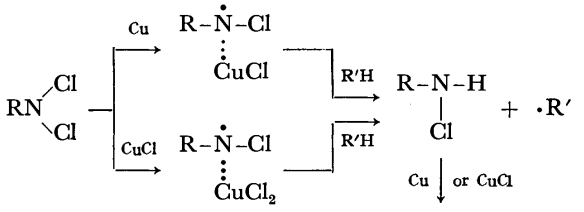
(Received February 10, 1978)

The reactions of *N,N*-dichlorourethane (**1**) with substrates, such as hydrocarbons and ethers, gave *N*-substituted urethanes (**3**) and urethane (**4**) in the presence of copper or copper(I) chloride. The reactions with aromatic hydrocarbons and cyclic ethers possessing an alkyl group at the α-position, however, gave no azepine and no alkoxyurethane respectively, in contrast to those of ethoxycarbonylnitrene generated from the azide. The reactions with the tertiary C–H bonds of *cis*- and *trans*-1,4-dimethylcyclohexanes proceeded non-stereospecifically, contrary to those of the nitrene. The reactions with alcohols led to high yields of **4**, accompanied by the corresponding aldehydes, but afforded no O–H insertion product. The addition of a radical inhibitor, nitrobenzene, reduced the yield of **3**, while it had no appreciable effect on the yield of **4**. Furthermore, the reactions of *N*-chlorourethane with hydrocarbons also gave **3** and **4**. These results suggest that the reaction of **1** with substrates proceeds not by a nitrene mechanism, but by a metal-radical mechanism.

The α-elimination of certain compounds has been reported as a method of generating a nitrene intermediate other than by the photolysis or thermolysis of azides. For example, *N*-(*p*-nitrophenylsulfonyloxy)-urethane[1] was thermolyzed to give ethoxycarbonylnitrene. The decomposition of chloramine-T[2] and dichloramine-T[3] in the presence of zinc dust has also been advanced as a method of generating the sufonylnitrene. These α-eliminations afforded the same products as those produced by the photolyses or thermolyses of the corresponding azides.

On the other hand, the thermolysis of *N,N*-dichloromethanesulfonamide in benzene afforded methanesulfonamide (82% yield), but not mesylaniline.[4] This finding suggests that the reaction involves no nitrene. We reported, prior to Ref. 4, the thermolysis of *N,N*-dichloromethanesulfonamide in the presence of copper.[5,6] Therefore, we tentatively advanced the idea that the reaction proceeded by means of a radical mechanism involving no sulfonylnitrene. In that mechanism, although an intervention of *N*-chloromethanesulfonamide was postulated (Scheme 1), further experimental evidence for the postulate was not yet found because of the difficulty of preparing the monochloramide.



Scheme 1.

In this study, *N,N*-dichlorourethane was employed instead of *N,N*-dichloromethanesulfonamide to obtain further corroborating evidence about the radical mechanism in the dihaloamide–metal system. When the urethane is employed, *N*-chlorourethane, whose intervention is assumed in the dichlorourethane–metal system, is easy to prepare and can be utilized for the present investigation.

Results and Discussion

Reaction of N,N-*Dichlorourethane (1) with Hydrocarbons and Cyclic Ethers in the Presence of Copper.* Copper powder was suspended in a substrate (**5**), and **1** was added, drop by drop, into the suspension in a stream of nitrogen. The yields of the products are listed in Table 1 and compared with those of the photolyses of ethyl azidoformate (**2**).[7,8]

Each of the reactions of **1** with substrates gave the *N*-substituted urethane (**3**) and urethane (**4**).

$$\underset{(1)}{Cl_2NCOOEt} + \underset{(5)}{R'H} \xrightarrow{Cu} \underset{(3)}{R'NHCOOEt} + \underset{(4)}{NH_2COOEt}$$

The products, **3** and **4**, correspond formally to those resulting from insertion into the C–H bonds and from the abstraction of the hydrogen atoms respectively by ethoxycarbonylnitrene. In the reactions with cyclic ethers, **5f**, **5g**, and **5h**, the α-substituted derivatives were isolated. The preferential formation of the α-substituted derivatives in these reactions paralles that in the direct[7] and sensitized[8] photolyses of **2**. The reactions of **1** with small-membered cyclic ethers, **5d** and **5e**, gave large quantities of colorless, viscous substances whose IR spectra showed the respective strong O–H stretching absorptions. Contrary to the reactions of **1**, the reactions of **2** with **5d** and **5e** gave two ring-opening products, **3d** and **3e** respectively. In the reactions of **1** with aromatic hydrocarbons, azepines, whose formation is a typical nitrene reaction, were not detected, although they were obtained in the photolyses of **2**. In the reaction with **5c**, the product with a side-chain C–H bond was preferentially obtained. The ring-opening products (**3d** and **3e**) in **5d** and **5e** are formed by only singlet ethoxycarbonylnitrene *via* an O–N ylide mechanism.[6] In addition, singlet ethoxycarbonylnitrene adds to aromatic double bonds to give the aziridines, followed by the cleavage of C–C bonds to give the azepines.[9] Therefore, the generation of the singlet nitrene from **1** must be ruled out.

Table 1. Reaction of **1** and **2** with hydrocarbons and ethers

Substrate (**5**)	Product (%)[a] **3**			**4**
(**a**)	(**a**)  NHR[b] 1.4 (32.0)			57.2 (15.0)
(**b**)	(**b**$_1$)  NHR 5.5 (1.7)	(**b**$_2$)  N–R ND[c] (20.8)		38.0 (7.6)
(**c**) 	(**c**$_1$)  CH_2NHR 21.6 (1.8)	(**c**$_2$)  CH_3 NHR 1.4 (2.9)	(**c**$_3$)  CH_3 NHR ND (1.1)	
	(**c**$_4$)  N–R CH_3 ND (6.7)	(**c**$_5$)  N–R CH_3 ND (9.0)	(**c**$_6$)  N–R CH_3 ND (6.2)	31.5 (5.0)
(**d**) 	(**d**) CH_2=$CHCH_2ONHR$ ND (21.0)			34.3 (12.0)
(**e**) 	(**e**) CH_2=$CHCH_2CH_2ONHR$ ND (28.0)			85.9 (23.0)
(**f**)	(**f**)  NHR 12.3 (25.0)			32.7 (21.0)
(**g**)	(**g**$_1$)  NHR 27.1 (25.0)	(**g**$_2$)  NHR ND (4.8)		32.0 (16.0)
(**h**)	(**h**)  NHR 30.2 (32.8)			68.7 (22.2)

( ) Indicates the values resulting from the photolyses of **2**.[8,9] a) Calculated on the basis of the **1** used. b) R: $COOC_2H_5$. c) ND: not detected.

Stereochemistry. In order to compare the reaction of **1** with that of **2** in stereochemical behavior, the reactions of **1** were carried out in *cis*- and *trans*-1,4-dimethylcyclohexanes (*cis*-**5** and *trans*-**5**).

As can be seen in Table 2, the reaction of **1** with either *cis*-**5** or *trans*-**5** gave a mixture of *cis*-**3** and *trans*-**3** (stereoisomer), though the yield was low. Such non-stereospecific formation has also been observed in the reaction of *N*,*N*-dichloromethanesulfonamide with *cis*-**5** or *trans*-**5**, where the tertiary sulfonamides are isolated in moderate yields.[5,6]

The stereospecific formation of *cis*-**3** or *trans*-**3** in the photolyses of **2**, as shown in Table 2, indicates that triplet ethoxycarbonylnitrene does not lead to the formation of **3**. Thus, the non-stereospecific formation in the reaction of **1** means that neither the singlet nor the triplet nitrene takes part in the formation of **3**.

Reaction of 1 with Alcohols. The reaction of **1** with ethanol and 1-butanol gave urethane in yields of 84 and 86% respectively, accompanied by the corresponding aldehydes. None of the O–H insertion products was detected in these reactions. On the other hand, the photolyses of **2** in ethanol and 1-butanol gave O–H insertion products in yields of 11 and 27% respectively, accompanied by urethane.[8] The O–H insertion products have been formed by a singlet nitrene *via* an O–N ylide intermediate, but not by a triplet nitrene *via* a radical mechanism.[8]

Reaction of 1 in the Addition of Radical Inhibitors. The above-mentioned results suggest that some radical species is involved in the reaction of **1**. Therefore, the reactions of **1** with toluene and tetrahydropyran were carried out in the presence of a radical inhibitor, nitrobenzene. The results are displayed in Table 3.

Breslow and Edwards reported the effect of radical inhibitors, such as nitrobenzene, *m*-dinitrobenzene, and sulfur, on the decomposition of **2** in cyclohexane.[12] That is, decompositions in the presence of these inhibitors

Table 2. Reaction of **1** and **2** with *cis*- and *trans*-1,4-dimethylcyclohexanes

Substrate (5)	Product (%)[a]		
	 (*cis*-**3**)	 (*trans*-**3**)	**4**
 (*cis*)	1.0(14.0)	2.0(ND[c])	50.8(18.0)
 (*trans*)	1.2(ND)	2.3(11.0)	56.6(16.0)

( ) Indicates the values resulting from the photolyses of **2**.[10] a) b) c) See Table 1, footnotes.

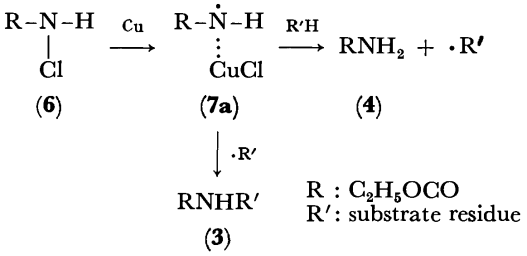
Table 3. Reaction of **1** with substrate in the presence of nitrobenzene

Substrate (5)	Radical inhibitor	Product (%)[a]			
		3			**4**
	presence	**c**$_1$ 8.4	**c**$_2$	1.3	31.1
	absence	21.6		1.4	31.5
	presence	**g**$_1$ 13.8			30.0
	absence	27.1			32.0

a) See Table 1, footnotes.

gave *N*-cyclohexylurethane and urethane in yields of 56—76 and 12—21% respectively, while those in their absence gave *N*-cyclohexylurethane and urethane in yields of 52 and 25% respectively. These additives led to increased yields of the insertion, but to decreased yields of the abstraction. They gave the following interpretation of the findings. A radical, HNCOOEt, produced by the hydrogen abstraction of the triplet nitrene can catalyze the singlet-triplet intersystem crossing. The reaction of the radical with the additive decreases its radical concentration, resulting in a slow singlet-to-triplet conversion and, therefore, in a high yield of the product from the singlet. Contrary to the decomposition of **2**, in the reaction of **1** the addition of nitrobenzene led to decreased yields of the *N*-substituted urethanes, while it had no appreciable effect on the yield of urethane.

Reaction of N-*Chlorourethane.* The reaction of *N*-chlorourethane (**6**) with dioxane in the presence of copper gave the expected *N*-substituted urethane, **3h**, and urethane in yields of 18.1 and 71.2% respectively.



Scheme 2.

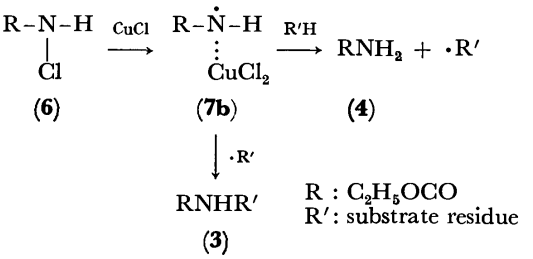
The reactions of **6** with either *cis*-**5** or *trans*-**5** gave a mixture of *cis*-**3** and *trans*-**3** non-stereospecifically, as in the case of **1**.

The decomposition of *N,N*-dichlorourethane (**1**) in the presence of copper leads to the formation of *N*-chlorourethane (**6**), as has been shown in Scheme 1. The chlorine atom of **6** is eliminated by copper to give a metal-radical complex (**7a**), as is shown in Scheme 2, followed by a hydrogen abstraction to give urethane (**4**). On the other hand, **7a** recombines with a substrate radical, ·R′, to afford the *N*-substituted urethane (**3**).

In the decomposition of the azide in hydrocarbons, the free HNCOOEt radical which resulted from triplet nitrene was not able to recombine with the substrate radical (·R′), but exclusively abstracted a hydrogen atom from the substrate. However, the HNCOOEt radical in the dichloramide– or chloramide–system may recombine with the substrate radical because of the stabilization produced by forming the metal-radical complex represented as **7a**.[6] In addition, a difference between the characteristics of the metal-radical and the free radical was shown also by the addition of the radical inhibitor, nitrobenzene. That is, the addition of the radical inhibitor caused a decreased yields of **3**, but had appreciable effect on the yield of **4** (Table 3). The substrate radical would be trapped by the inhibitor, while the metal-radical complex is not affected by the inhibitor, though the free radical can be captured by it.[12,13]

Reaction of **1** *and* **6** *in the Presence of Copper(I) Chloride.* As has been shown in Scheme 1, the copper-initiated decomposition of dichloramide should produce copper(I) chloride. This copper(I) chloride is expected to take part in the present reactions. The reaction of **1** with dioxane in the presence of copper(I) chloride gave the *N*-(1,4-dioxan-2-yl)urethane (**3h**) and urethane in yields of 6 and 64.4% respectively. The reactions with both *cis*-**5** and *trans*-**5** gave the *N*-substituted urethane isomer mixtures. The reaction of **6** with dioxane gave **3h** and urethane in yields of 9.6 and 65.4% respectively.

The reaction of **6** with a substrate in the presence



Scheme 3.

of copper(I) chloride is also outlined in Scheme 3. The metal-radical complex (**7b**) resulting from chlorine abstraction by copper(I) chloride abstracts a hydrogen atom from the substrate to give urethane. On the other hand, **7b** recombines with a substrate radical to afford **3**.

In Conclusion. In the absence of metals, the reactions of **1** with toluene and dioxane gave urethane in yields of 68 and 36% respectively, but not the C–H insertion products (**3**).

The formation of the insertion products from the chloramides is shown in Schemes 1—3, under the indispensable condition of the presence of copper or copper(I) chloride.

Experimental

The IR spectra were recorded on a Hitachi EP-S photometer and a Nippon Bunko (JASCO) Model IR-E photometer, while the NMR spectra were taken on Hitachi R-20 and Hitachi R-24 instruments, using tetramethylsilane as the internal standard. The gas chromatography (VPC) was done on Shimadzu GC-2C and Nippon Denshi (JEOL) JGC 20K units, employing as absorbents: A, 20% Apiezon Grease M on Neopak 1A (60—80 mesh); B, 20% Ucon Oil 5HB 2000 on Celite (60—80 mesh); C, 10% Polyethylene Glycol Succinate on Neopak 1A (60—80 mesh). The quantitative analyses of the products by VPC and the test for the stability of each product during VPC analysis have been done in the ways described in a previous paper.[14]

Materials. The *N,N*-dichlorourethane (**1**),[15] *N*-chlorourethane (**6**),[16] 2-methyloxetane,[7] and *cis*- or *trans*-1,4-dimethylcyclohexane (*cis*-**5** or *trans*-**5**)[17] were prepared by the methods already described. The propylene oxide, tetrahydrofuran, tetrahydropyran, 1,4-dioxane, cyclohexane, benzene, toluene, ethanol, and 1-butanol were used after purification by the methods recommended in the literature.[18]

Authentic Samples. The *N*-cyclohexylurethane (**3a**) was prepared by the method of Lwowski and Mattingly.[19] The *N*-phenylurethane (**3b**$_1$), *N*-benzylurethane (**3c**$_1$), *N*-(2-tolyl)-urethane (**3c**$_2$), and *N*-(4-tolyl)urethane (**3c**$_3$) were prepared from ethyl chloroformate and the corresponding amines in a way similar to that used in the preparation of *N*-cyclohexylurethane. **3a**: IR (Nujol, cm^{-1}): 3350, 1680, 1220. NMR (CCl_4, δ): 4.52 (NH, 1H, bs), 4.01 (2H, q), 3.40 (1H, m), 2.42—1.40 (ring-CH_2, 10H, m), 1.21 (3H, t). **3b**$_1$: IR (Nujol, cm^{-1}): 3350, 1700, 1240. NMR (CCl_4, δ): 7.80 (NH, 1H, bs), 7.64—6.75 (5H, m), 4.20 (2H, q), 1.21 (3H, t). **3c**$_1$: IR (Nujol, cm^{-1}): 3360, 1690, 1285. NMR (CCl_4, δ): 7.22 (5H, s), 5.36 (NH, 1H, bs), 4.21 (2H, d), 4.01 (2H, q), 1.67 (3H, t). **3c**$_2$: IR (Nujol, cm^{-1}): 3355, 1700, 1230. NMR (CCl_4, δ): 7.96—6.92 (4H, m), 6.68 (NH, 1H, bs), 4.20 (2H, q), 2.21 (3H, s), 8.71 (3H, t). **3c**$_3$: IR (Nujol, cm^{-1}): 3320, 1710, 1230. NMR (CCl_4, δ): 7.48—6.64 (5H, m), 4.10 (2H, q), 2.22 (3H, s), 1.19 (3H, t). The *cis* and *trans* isomers of *N*-(1,4-dimethylcyclohexyl)urethane (*cis*-**3** and *trans*-**3**) were prepared as follows. A mixture of the stereoisomers (*cis*-**3** and *trans*-**3**) was prepared from ethyl chloroformate and 1,4-dimethylcyclohexylamine (*cis-trans* mixture), which had been prepared in a way similar to that used in the preparation of 1-methylcyclohexylamine.[20] The urethanes were well separated into *cis* and *trans* isomers by using column B. The assignment of each stereoisomer was done by comparison with the products obtained from the stereospecific insertions of singlet ethoxycarbonylnitrene into the tertiary C–H bond of *cis*- and *trans*-1,4-dimethylcyclohexanes.[10] *cis*-**3**: IR (neat, cm^{-1}): 3340, 1710, 1230, NMR (CCl_4, δ): 4.80 (NH, 1H, bs), 4.22 (2H, q), 2.11—1.45 (ring-CH and CH_2, 9H, m), 1.38 (3H, s), 1.27 (3H, t), 0.98 (3H, d). *trans*-**3**: IR (neat, cm^{-1}): 3360, 1710, 1235. NMR (CCl_4, δ): 4.44 (NH, 1H, bs), 4.06 (2H, q), 2.50—1.40 (ring-CH and CH_2, 9H, m) 1.31 (3H, s), 1.22 (3H, t), 0.92 (3H, d). The IR and NMR spectral data of *N*-(2-tetrahydrofuryl)urethane (**3f**), *N*-(2-tetrahydropyranyl)urethane (**3g**$_1$), and *N*-(1,4-dioxan-2-yl)urethane (**3h**) have been described previously.[6,7]

Reaction of N,N-*Dichlorourethane (1) with Hydrocarbons and Ethers in the Presence of Copper.* Copper powder (4.8 g, 0.075 mol) was suspended in a substrate (0.5 mol of ethers and hydrocarbons), and *N,N*-dichlorourethane (**1**, 4 g, 0.025 mol) was added, drop by drop, into the suspension in a stream of nitrogen. The reactions with ethers and hydrocarbons were carried out at 20 and 50 °C respectively. After **1** had been added, the stirring was continued for about another 5 h, Then, the suspension was filtered, and the filtrate was concentrated under reduced pressure. The residue was analyzed by VPC on Columns B and C.

In Cyclohexane (5a), Benzene (5b), and Toluene (5c): **3a** (0.06 g), **3b**$_1$ (0.22 g), **3c**$_1$ (0.97 g), and **3c**$_2$ (0.06 g) were isolated.

In tetrahydrofuran (5f), Tetrahydropyran (5g), and 1,4-Dioxane (5h): **3f** (0.49 g), **3g**$_1$ (1.17 g), and **3h** (1.32 g) were isolated.

In cis-*1,4-Dimethylcyclohexane* (cis-*5*): *cis*-**3** (0.05 g) and *trans*-**3** (0.1 g) were isolated.

In trans-*1,4-Dimethylcyclohexane* (trans-*5*): *cis*-**3** (0.06 g) and *trans*-**3** (0.11 g) were isolated.

Reaction of 1 with Alcohols in the Presence of Copper. Copper powder (0.075 mol) was suspended in ethanol (0.5 mol) or 1-butanol (0.5 mol), and then **1** (4 g, 0.025 mol) was added, drop by drop, to the suspension kept at 5—7 °C in a stream of nitrogen. After the **1** had been added, the stirring was continued for about 5 h. Then, the suspension was filtered, and the excess substrate and the volatile product, aldehyde, were trapped in a flask immersed in a dry ice–methanol bath under reduced pressure. The trapped solution was added to a 2,4-dinitrophenylhydrazine solution, and the hydrazone was isolated.

Reaction of 1 with 5c and 5g in the Addition of Nitrobenzene. Copper powder (0.075 mol) was suspended in a mixture of substrate (0.5 mol) and nitrobenzene (0.025 mol), and then **1** (4 g, 0.025 mol) was added, drop by drop, into the suspension in a stream of nitrogen. The reactions with **5c** and **5g** were carried out at 50 and 20 °C respectively. Then, the reaction mixture was treated as has been described above. **3c**$_1$ (0.38 g) and **3c**$_2$ (0.06 g) were isolated in the reaction with **5c**, and **3g**$_1$ (0.6 g) was isolated in the reaction with **5g**.

Reaction of N-*Chlorourethane (6) with 5h and Hydrocarbons in the Presence of Copper.* Copper powder (0.075 mol) was suspended in a substrate (0.5 mol), and *N*-chlorourethane (**6**, 3.1 g, 0.025 mol) was added, drop by drop, into the stirred suspension at 20 °C (case of **5h**) or 50 °C (case of hydrocarbons) in a stream of nitrogen. Then, the reaction mixture was treated as has been described above.

In 5h: **3h** (0.8 g) was isolated.

In 5a: **3a** (0.08 g, 1.8%) and urethane (**4**, 50.0%) were isolated.

In cis-*5*: *cis*-**3** (0.06 g, 1.2%), *trans*-**3** (0.1 g, 2.1%), and **4** (50.4%) were isolated.

In trans-*5*: *cis*-**3** (0.05 g, 1.0%), *trans*-**3** (0.08 g, 1.6%), and **4** (63.7%) were isolated.

Reaction of 1 and 6 with 5h and Hydrocarbons in the Presence of Copper(I) Chloride. Copper(I) chloride (7.5 g, 0.075 mol) was suspended in a substrate (0.5 mol), and **1** or **6** (0.25 mol) was added to the suspension at 20 °C (case of **5h**) or 50 °C

(case of hydrocarbons) in a stream of nitrogen. Then, the reaction mixture was treated as has been described above.

In the Reaction of **1** *with* **5h**: **3h** (0.26 g) was isolated.

In the Reaction of **1** *with* cis-**5**: *cis*-**3** (0.06 g, 1.2%), *trans*-**3** (0.09 g, 1.8%), and **4** (62.0%) were isolated.

In the Reaction of **1** *with* trans-**5**: *cis*-**3** (0.09 g, 1.8%), *trans*-**3** (0.15 g, 3.0%), and **4** (54.8%) were isolated.

In the Reaction of **6** *with* **5h**: **3h** (0.42 g) was isolated.

Reaction of **1** *in the Absence of Copper.* The chloramide (**1**, 0.025 mol) was added, drop by drop, to **5h** (0.5 mol) kept at 20 °C or to **5c** (0.5 mol) kept at 50 °C in a stream of nitrogen. Then, the reaction mixture was treated as has been described above. Urethane was isolated in yields of 0.8 g and 1.51 g in **5h** and **5c** respectively.

Photolyses of Ethyl Azidoformate in Hydrocarbons. A solution of ethylazidoformate (0.02 mol) in hydrocarbon (0.5 mol) was irradiated using a low-pressure mercury lamp, with stirring and cooling at 0 °C until the evolution of nitrogen was no longer observed. The excess substrate was then removed under reduced pressure. The residue was analyzed by VPC on Colums B and C.

In 5a: **3a** (1.36 g) was isolated.

In 5b: $\mathbf{3b}_1$ (0.07 g) and *N*-(ethoxycarbonyl)azepine ($\mathbf{3b}_2$, 0.86 g) were isolated. $\mathbf{3b}_2$: IR (neat, cm^{-1}): 1715 (C=O), 1655 and 1630 (C=C). NMR ($CDCl_3$, δ): 6.12—5.18 (6H, m), 4.17 (2H, q), 1.25 (3H, t) (Found: C, 65.32; H, 6.62; N, 8.51%).

In 5c: $\mathbf{3c}_1$ (0.08 g), $\mathbf{3c}_2$ (0.13 g), $\mathbf{3c}_3$ (0.05 g), 2-methyl-*N*-(ethoxycarbonyl)azepine ($\mathbf{3c}_4$, 0.3 g), 3-methyl-*N*-(ethoxycarbonyl)azepine ($\mathbf{3c}_5$, 0.4 g), and 4-methyl-*N*-(ethoxycarbonyl)-azepine ($\mathbf{3c}_6$, 0.28 g) were isolated. $\mathbf{3c}_4$: IR (neat, cm^{-1}): 1710 (C=O), 1650 and 1630 (C=C). NMR ($CDCl_3$, δ): 6.35—5.63 (5H, m), 4.17 (2H, q), 2.07 (3H, s), 1.29 (3H, t) (Found: C, 67.21; H, 7.25; N, 7.76%). $\mathbf{3c}_5$: IR (neat, cm^{-1}): 1715 (C=O), 1660 and 1630 (C=C). NMR ($CDCl_3$, δ): 6.10—5.30 (5H, m), 4.22 (2H, q), 1.78 (3H, d, J=1.5 Hz), 1.32 (3H, t) (Found: C, 66.92; H, 7.41; N, 7.94%). $\mathbf{3c}_6$: IR (neat, cm^{-1}): 1720 (C=O), 1660 and 1630 (C=C). NMR ($CDCl_3$, δ): 6.10—5.14 (5H, m), 4.20 (2H, q), 1.80 (3H, s), 1.30 (3H, t) (Found: C, 67.30; H, 7.21; N, 7.95%). The IR and NMR data of $\mathbf{3c}_4$, $\mathbf{3c}_5$, and $\mathbf{3c}_6$ were assigned on the basis of those of 2-, 3-, and 4-methyl-*N*-(methoxycarbonyl)azepines.[21]

The authors are particularly indebted to Drs. Hisao Arakawa and Akira Matsumoto of the Science Education Institute of Osaka Prefecture for help in the preparation of this paper and for many useful suggestions.

Layered Compounds. LII.[1] Syntheses of Eleven Anthracenophanes

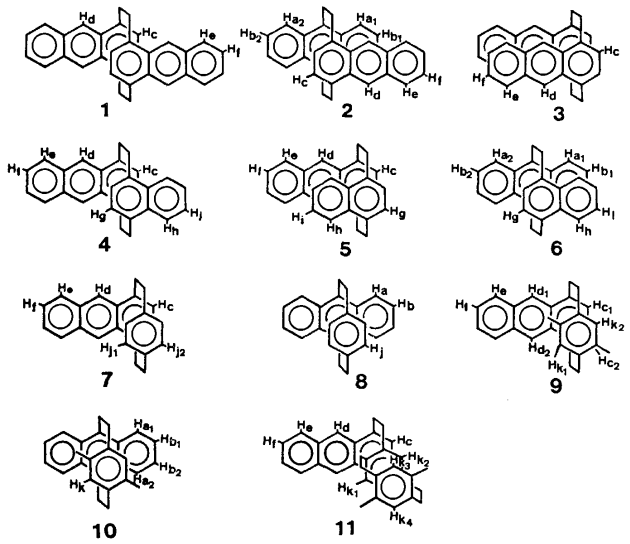
Akio IWAMA, Toshihiro TOYODA, Misaku YOSHIDA, Tetsuo OTSUBO, Yoshiteru SAKATA, and Soichi MISUMI*

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received February 20, 1978)

A series of layered cyclophanes where an anthracene ring is stacked in different modes with the same or other π-systems has been synthesized by the Hofmann elimination method or photodesulfurization for studying the transannular π-electronic interaction. Photochemical and thermal interconversions have been observed between *syn*-(1,4)anthracenophane and its isomer and have been discussed with reference to the X-ray crystal data. From the electronic spectra it has been established that the transannular interaction increases with overlapping between the two faced aromatic rings and that when the overlap between the two chromophores is the same, the interaction increases relative to the dimension of the faced chromophore.

Recently a wide variety of [2.2]phanes containing benzene or heteroaromatic rings has been synthesized in order to study the effect of transannular π-electronic interactions on their physical and chemical properties.[2] If one or two benzene rings are replaced by naphthalene or anthracene rings, which have a larger molecular surface and lower ionization potential than benzene, it is expected that such cyclophanes will show stronger transannular interactions. Various types of [2.2]naphthalenophanes[3] have been prepared for this purpose, but [2.2]anthracenophanes other than [2.2](9,10)-anthracenophane[4] have not been studied. Since the anthracene ring has a lower symmetry and more bridging points than the benzene ring, some isomeric anthracenophanes differing in stacking mode between the two chromophores are feasible. These isomers appear to be good models for studying the effect of the magnitude and/or the mode of overlapping between anthracene and other π-systems upon transannular π-electronic interaction. A series of anthracenophanes has been prepared along this line, *i.e.*, three isomers of both [2.2]anthracenophane (**1**—**3**) and [2.2]naphthalenoanthracenophane (**4**—**6**) and two isomers of both [2.2]paracycloanthracenophane (**7**, **8**) and its dimethyl derivative (**9**, **10**). In addition, a triple-layered anthracenophane **11** has also been synthesized.



Results and Discussion

Syntheses. A quaternary ammonium salt **12** was prepared from 4-methylanthracene-1-carboxylic acid **17** as shown in Scheme 2. The other quaternary ammonium hydroxides **13**—**16** were obtained according to methods previously reported.[3c,3g,5] The syntheses of all the new cyclophanes **1**—**11** except for **9** and **10** were conducted as shown in Scheme 1 by the pyrolysis of the corresponding ammonium hydroxide or an equimolar mixture of two different bases in boiling xylene in the presence of a catalytic amount of phenothiazine. Yields of cyclophanes were relatively low as expected for the 1,6-Hofmann elimination. The synthesis of **9** and **10** was carried out by the coupling of 9,10- or 1,4-bis(halomethyl)anthracene with 2,5-bis(mercaptomethyl)-*p*-xylene,[6] followed by photodesulfurization in triethyl phosphite.

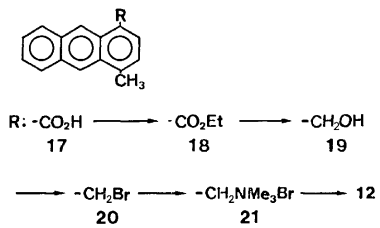
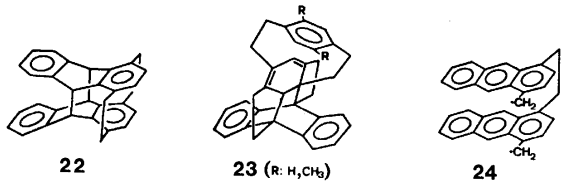


Scheme 2.

Separation and purification of the cyclophanes were achieved by careful column chromatography on silica gel and/or alumina followed by recrystallization. In the preparation of [2.2](1,4)anthracenophane and [2](1,4)naphthaleno[2](1,4)anthracenophane, both the *anti*- and *syn*-isomers, *i.e.*, **1** and **3**, and **4** and **5**, were isolated. The isomers are thermally stable and no interconversion between them was observed at room temperature. The structure of these isomers could be easily assigned by NMR analysis as described below. Pyrolysis of mixed ammonium bases, **13** and **15**, produced paracycloanthracenophane **8**. This was, however, not isolated in the reaction starting from [2.2]paracyclophane,[3c] probably due to an intramolecular Diels-Alder reaction as described below. Such instability of paracyclo(9,10)anthracenophane was observed in the attempted synthesis of the triple-layered (9,10)anthracenophane which is isomeric with **11**. Thus, the cross breeding reaction of **13** and **16** gave an unexpected, intramolecular Diels-Alder reaction product **23** instead of the desired triple-layered anthracenophane, the structure of which was determined by spectral data and X-ray crystallographic analysis.[5]



22 **23** (R: H,CH_3) **24**

Interconversion between 3 and 22. Pyrolysis of **12** and the succeeding work-up in the dark produced the *anti*- and *syn*-anthracenophanes (**1** and **3**). However, the same procedure in a bright room gave an unexpected mixture of **1** and its isomer **22**. The structure of **22** was confirmed by the absence of characteristic absorption bands in the electronic spectrum, NMR data, and finally by X-ray crystal structure analysis[1,7] as shown in Fig. 1. On the basis of the above results, it is reasonable to presume that the initially formed **3** might be isomerized to **22** by irradiation with scattered day light in the room, as in the photodimerization of anthracene to anthracene dimer (trivial name, dianthracene) (**25**). Irradiation with sunlight or monochromatic light (374 nm) of a solution of pure **3** gave immediately and quantitatively the photo-isomer **22**. The reverse reaction of **25** to anthracene is known to

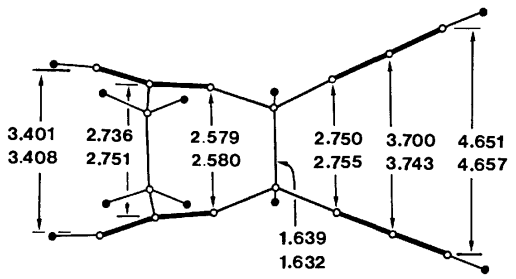


Fig. 1. Side view of **22**. Intramolecular nonbonding distances (Å) and single bond distances between bridgehead atoms are also given.

proceed at 200—270 °C.[8] The similar reverse reaction of **22** to **3** was performed under various pyrolytic conditions as shown in Tables 1 and 2. The optimum yield of **3** was achieved by heating **22** at 198—199 °C for 6 h under nitrogen stream (Table 1). However, when the pyrolysis was performed in solution (Table 2), a mixture of **1** and **3** was obtained and the ratio of **1**: **3** increased rapidly as the reaction proceeded. The difference in the pyrolytic reaction in the solid and in the solution can be understood as follows. In the solution an anthracene ring of biradical species **24**, which is formed by the homolytic cleavage of an sp^3-sp^3 single bond of **3**, can rotate to give thermodynamically stable *anti*-isomer **1**, while in the solid state the aromatic ring is unable to rotate due to less degrees of freedom for molecular motion and therefore more hindered *syn*-isomer **3** is afforded selectively. On the other hand, a photochemical interconversion was observed between **22** and **3**. Thus, when a solution of **22** in THF was exposed to monochromatic light (254 nm) for 10 min, **3** was observed in the resulting electronic spectrum and conversely, **3** to **22** by irradiation of 374 nm light.

The molecular structure of **22** and **3**[1] were determined by X-ray analysis, in order to clarify the reason for the easier interconversion between **22** and **3** than that between anthracene dimer and anthracene and to

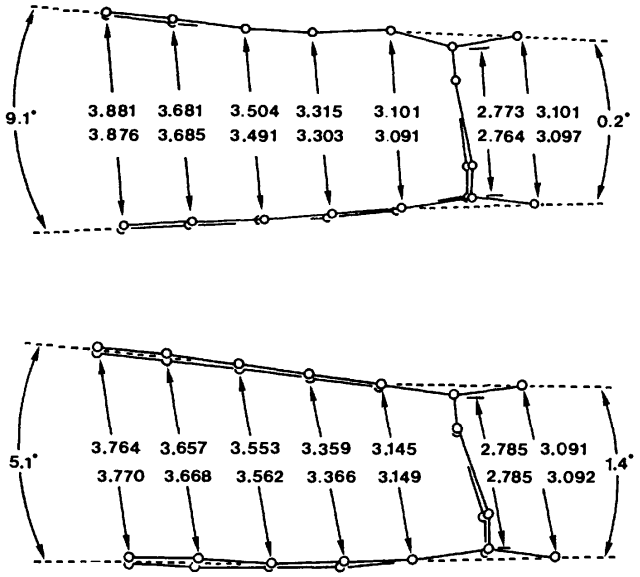

Fig. 2. Side view of the two anthracenophane molecules in crystal of **3**. Intramolecular nonbonding distances (Å) and dihedral angles are also given.

relate the structures of a series of anthracenophanes to their spectral data. Figure 1 shows marked elongation (1.632 and 1.639 Å) of the C_{sp^3}–C_{sp^3} bond in question from the normal value (1.54 Å) compared with the corresponding bond (1.61 Å) of anthracene dimer **25**,[9] indicating that there is greater strain in **22** causing easier breaking of the bond. Analysis of **3** showed two different anthracenophane molecules in each asymmetric unit of the crystal lattice. As seen in Fig. 2,[1] the non-bonding interatomic distances (3.315 and 3.303 Å) between the corresponding sp^2 carbon atoms in one of the two anthracenophane molecules are relatively shorter than the van der Waals distance, showing considerable overlap between the two $2P_z$ orbitals. In other words, it indicates easy formation of a covalent bond between the two carbon atoms. As a result the ready interconversion between **22** and **3** is understandable from the above analytical data.

NMR Spectra. NMR data of the compounds **1**—**11** are summarized in Table 3. The spectrum of *anti*-anthracenophane **1** was recorded in arsenic trichloride because of the low solubility in the usual

organic solvents. All the methylene proton signals appear separately as two groups of multiplets. The aromatic protons are assigned by reference to their coupling modes and the chemical shifts of non-layered compounds. The signals appear generally at higher field owing to the anisotropic effect of a faced aromatic ring or two benzene rings in the case of **11**, compared with those of the reference compounds. This effect was estimated by using the chemical shifts (Fig. 3) of the corresponding protons of 9,10- and 1,4-dimethylanthracenes, 1,4-dimethylnaphthalene, *p*-xylene, and durene as standards (Table 3). Of these values, marked upfield shifts (over 1 ppm) were observed for H_c's of **1**, **2**, and **4**, H_b, of **2**, H_g's of **4** and **6**, H_i of **5**, H_j, of **7**, H_j of **8**, H_k,'s of **9** and **11**, and H_k of **10**, all of which are located nearly above the center of the opposed aromatic ring. In triple-layered compound **11**, aromatic protons (H_{k_1}, H_{k_2}) of durene moiety absorb at higher field than the corresponding protons of double-layered compound **9** owing to the shielding effect of an additional benzene ring. *syn*- and *anti*-isomers [(**1** and **3**) and (**4** and **5**)] are easily distinguished by comparing the chemical shifts of H_c protons. Thus, H_c protons of the *anti*-forms (**1** and **4**) show high field shifts over 1 ppm, whereas those of the *syn*-forms (**3** and **5**) show only small high field shifts (0.48 ppm for **3**, 0.47 ppm for **5**). A slight down field shift was observed for H_e and H_f of **1** and H_f of **7**. These protons are situated far apart from the center of the opposite ring and hence, it is assumed that they are in the deshielding field of the transannular ring.

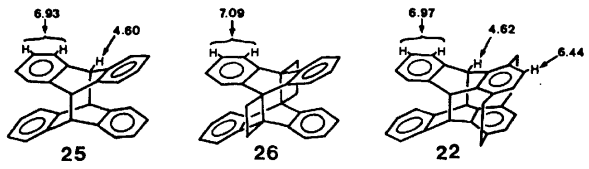

Fig. 4. NMR data of **22**, **25**, and **26** in $AsCl_3$.

NMR data of photo-adduct **22** are also shown in Fig. 4 together with those of two related compounds **25** and **26**. The chemical shifts of the corresponding protons reflect the similar molecular structure among the three compounds, *i.e.*, **22** (Fig. 1),[7] **25**,[9] and **26**.[10]

Electronic Spectra. The electronic spectra of anthracenophanes **1**—**11** are shown in Figs. 5—8 together with those of the reference compounds. Characteristic features of these spectra are eminent broadening of and considerable bathochromic and hypochromic shifts of ^1L_a band of anthracene chromophore compared with those of acyclic compounds, indicating obvious transannular π-electronic interaction. It may be easily understood from Fig. 6 that the magnitude of the transannular interaction is associated with the extent of overlap of the two chromophores. Thus, the longest wavelength bands of fully overlapped isomers **5** and **6** show large bathochromic shifts, while the spectrum of the least overlapped isomer **4** moderately resembles that of the reference compound. The same features are seen in Fig. 5. Anthracenophanes **2** and **3**, where two anthracene rings are stacked fully or appreciably, absorb in longer wavelength region than *anti*-isomer **1**.

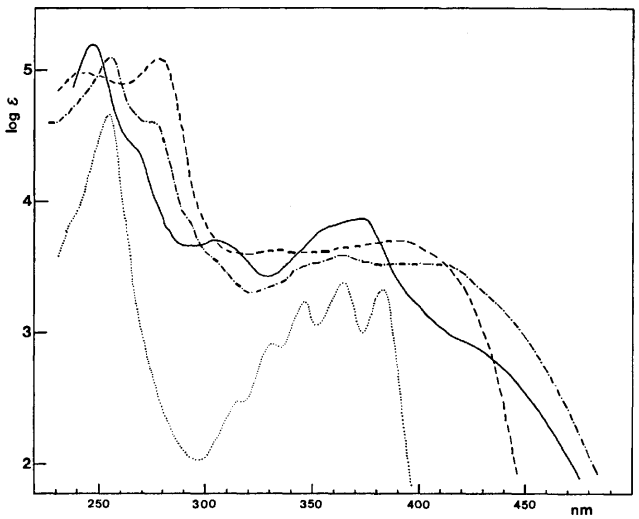

Fig. 5. Electronic spectra of **1** (----), **2** (·•·•·), **3** (——), and 1,4-dimethylanthracene (·····) in tetrahydrofuran. The curve of 1,4-dimethylanthracene is displaced downward by 0.5 log ε unit.

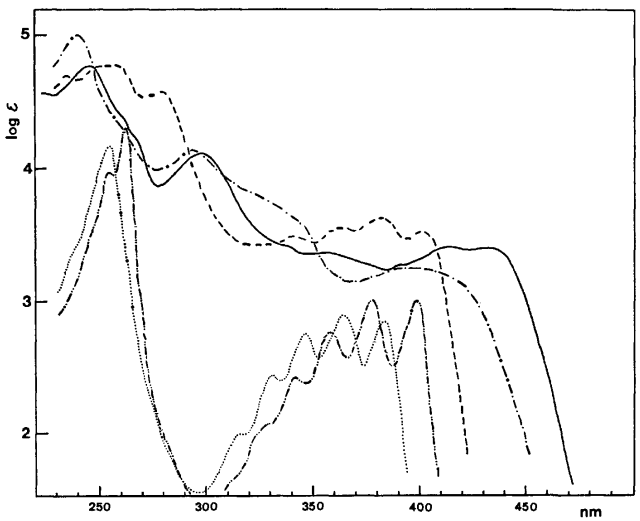

Fig. 6. Electronic spectra of **4** (----), **5** (·•·•·), **6** (——), 1,4-dimethylanthracene (·····), and 9,10-dimethylanthracene (-•••-) in tetrahydrofuran. The curves of two dimethylanthracenes are displaced downward by a log ε unit.

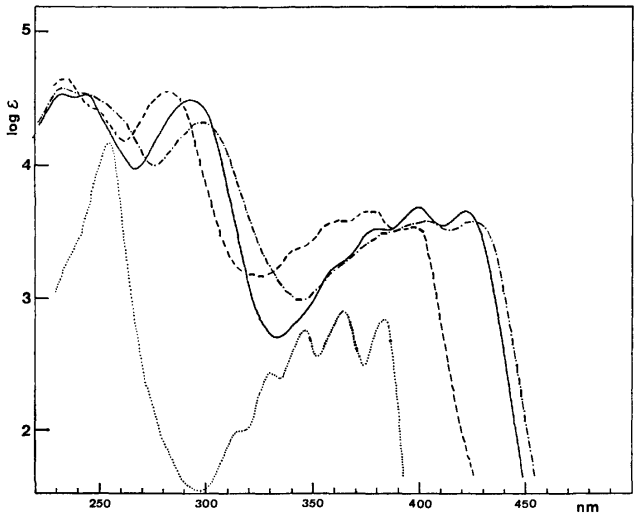

Fig. 7. Electronic spectra of **7** (----), **8** (——), **10** (·•··), and 1,4-dimethylanthracene (·····) in tetrahydrofuran. The curve of 1,4-dimethylanthracene is displaced downward by a log ε unit.

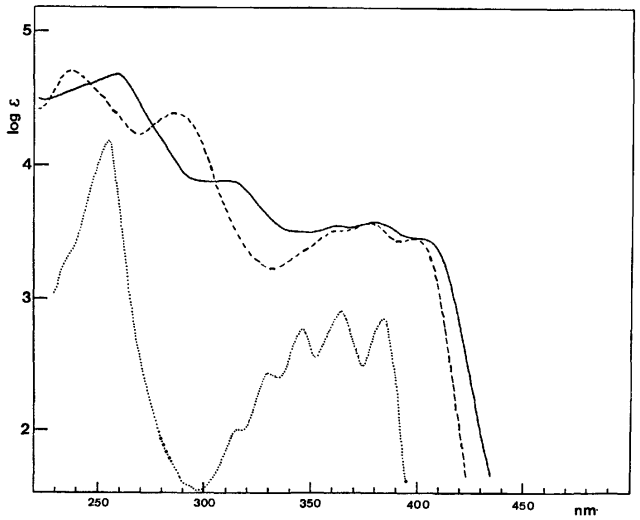

Fig. 8. Electronic spectra of **9** (----), **11** (——), and 1,4-dimethylanthracene (·····) in tetrahydrofuran. The curve of 1,4-dimethylanthracene is displaced downward by a log ε unit.

Let us consider an alternate groups of anthracenophanes, *i.e.*, compounds **1**, **4**, and **7**, which have the same degree of overlapping between the two faced rings and therefore probably the same degree of molecular strain. Of these three compounds, only **1** shows a structureless band in the region of 320—450 nm, indicative of extensive transannular interaction. The magnitude of the red shift of this band is largest for **1** and smallest for **7** compared with the reference compound. In other words, this implies that the transannular interaction increases in the order of **1**>**4**>**7**, that is, in the order of dimension of the faced chromophore. The same tendency is seen by comparing the spectrum of **2** with those of **5** and **6**. These observations may be interpreted by means of the exciton type interaction, which predicts that the smaller the difference in the transition energies of composite chromophores, the greater the configuration interaction between them; that is to say, the interaction is the strongest when the chromophores under consideration are the same. Theoretical treatment[11] of double-, triple-, and quadruple-layered cyclophanes has shown that their transannular bands in the longest wavelength region originate from the exciton interaction of composite chromophores with some degree of charge transfer character. Thus, it seems reasonable to assume the existence of similar excition interaction in anthracenophanes as above stated.

Triple-layered compound **11** absorbs at somewhat longer wavelength than double-layered one **9** (Fig. 8), indicating the increase of the transannular effect.

The fluorescence spectra of three isomeric anthracenophanes **1**—**3** are of particular interest in relation to the geometrical structure of excimers. This study has been reported in a separated paper.[12]

*4-Methyl-1-(bromomethyl)anthracene (**20**).* To a stirred suspension of $LiAlH_4$ (7.83 g) in dry ether (300 ml) was added dropwise a solution of **18** (74.8 g, 0.283 mol) in the same solvent (650 ml). After the addition was over, the mixture was stirred under reflux for 5 h, then at room temperature for 12 h. Water and 6 M aq HCl were successively added to the reaction mixture which was then extracted with ether and the organic layer was worked-up in the usual manner. Removal of the solvent gave yellow crystals (60.8 g, 96.8%) of **19**, which were used for the following reaction without further purification. To a stirred suspension of **19** (60.8 g, 0.274 mol) in CCl_4 (1 liter) was added a solution of PBr_3 (14 ml) in CCl_4 (200 ml). After the addition was over, the reaction mixture was heated at 50—53 °C for 10 h. Water (150 ml) was added and the mixture was extracted with CCl_4. The organic layer was worked-up in the usual manner and after recrystallization from CCl_4, pure **20** was obtained as yellow columns, 73.4% yield, mp 132.5—133.5 °C.

Found: C, 67.05; H, 4.34; Br, 27.79%. Calcd for $C_{16}H_{13}Br$: C, 67.38; H, 4.59; Br, 28.02%.

*(4-Methyl-1-anthrylmethyl)trimethylammonium Bromide (**21**).* An excess of trimethylamine (40 g) in ether was added with stirring to a cooled solution of **20** (49.2 g, 0.173 mol) in ether (5 l). After prolonged stirring, the resulting ppt was filtered, washed with ether, and dried. The yield of quaternary ammonium bromide **21** was 58.5 g (98.5%).

*Synthesis of **1**—**8** and **11** by the Hofmann Elimination Reaction.* All the coupling reactions of ammonium salts were undertaken according to the general procedure, which is described in detail for the case of (4-methyl-1-anthrylmethyl)trimethylammonium bromide **21** as follows.

An aq solution of **21** was passed through a column of anion exchange resin (Dowex 1-X8) to give an aq solution of ammonium base **12**. The soln thus obtained was added dropwise to a boiling solution of phenothiazine in xylene (0.2 g per 3 l of xylene) which was placed in a three-necked flask equipped with a condenser, mechanical stirrer, and water separator. After water separation was over, additional heating was continued for 24 h. The insoluble solid was filtered off and the filtrate dried over $MgSO_4$. The solvent was removed *in vacuo* until a small amount of the solvent was left. By this treatment *anti*-[2.2](1,4)anthracenophane **1** was precipitated from the solution. An additional amount of the compound **1** was obtained by benzene extraction of the insoluble solid above described. The total yield of **1** was about 60%. Recrystallization from xylene gave pure **1** as colorless prisms, dec over 300 °C.

Found: C, 93.95; H, 5.78%; M^+, 408. Calcd for $C_{32}H_{24}$: C, 94.08; H, 5.92%; M, 408.51.

The mother liquor was chromatographed on Al_2O_3 (Woelm, Activity I) to give **22** (1.9% yield). Recrystallization from AcOEt–EtOH gave pure **22** as colorless prisms, mp 242—243 °C with dec.

Found: C, 94.23; H, 5.82%; M^+, 408. Calcd for $C_{32}H_{24}$: C, 94.08; H, 5.92%; M, 408.51.

When the above reaction was carried out in the dark, **3** was obtained after filtration of the reaction mixture and evaporation of the solvent. Crude **3** was purified from the *anti*-isomer by the following manner. First it was recrystallized from benzene to give **3** containing 5% of **1**. Then, the crystals were dissolved in a minimum amount of benzene, the solution was frozen in a deep-freezer, and warmed up to room temperature. After most of the solid was dissolved, it was filtered as soon as possible to remove less soluble *anti*-isomer **1**. The above procedure was repeated once or twice and recrystallization from CCl_4 gave pure **3** as yellow plates, 250 °C dec.

Found: C, 93.91; H, 5.76%; M^+, 408. Calcd for $C_{32}H_{24}$: C, 94.08; H, 5.92%; M, 408.51.

Elemental analyses, melting points, recrystallization solvents, and yields of the other anthracenophanes are summarized in Table 4.

*5,8-Dimethyl-2,11-dithia[3.3]paracyclo(1,4)anthracenophane (**27**).* A solution of 1,4-bis(bromomethyl)anthracene[14] (1.82 g, 5.0 mmol) in benzene (300 ml) and a solution of 1,4-dimethyl-2,5-bis(mercaptomethyl)benzene[6] (0.99 g, 5.0 mmol) and sodium hydroxide (0.4 g) in 95% ethanol (50 ml) were added dropwise and simultaneously through dropping funnels into boiling ethanol (150 ml) over a period of 5 h under N_2 with vigorous stirring. After further heating and stirring for 18 h, the solvents were evaporated off and the residue was extracted with benzene. The benzene solution was passed through a short column of silica gel to yield a yellow solid. This was recrystallized from benzene to give pure dithiacyclophane **27** (1.09 g, 54.5%) as yellow prisms, dec>236 °C in a sealed tube.

Found: C, 78.06; H, 5.80; S, 15.92%; M^+, 400. Calcd for $C_{26}H_{24}S_2$: C, 77.95; H, 6.04; S, 16.01%; M, 400.58. NMR ($CDCl_3$, δ): 1.18 (s, 3, *endo*-Me), 2.38 (s, 3, *exo*-Me), 4.64—3.50 (m, 8, CH_2), 6.16 (s, 1, H_{k1}), 6.73 (s, 1, H_{k2}), 6.74 (AB, J=8 Hz, 1, H_{c1}), 7.04 (AB, J=8 Hz, 1, H_{c2}), 7.0—7.8 (m, 2, H_{f1} and H_{f2}), 7.8—8.4 (m, 2, H_{e1} and H_{e2}), 8.53 (s, 1, H_{d2}), 8.73 ppm (s, 1, H_{d1}).

*4,7-Dimethyl[2.2]paracyclo(1,4)anthracenophane (**9**).* A solution of dithiacyclophane **27** (2.0 g, 5.0 mmol) in benzene (400 ml) and triethyl phosphite (500 ml) was irradiated internally with a high pressure mercury lamp (400 W) for 9 h whilst a slow stream of N_2 was bubbled through. After removal of the solvents, the resulting solid was chromatographed on silica gel with benzene to yield the desired cyclophane **9** (1.24 g, 73.7%), yellow prisms from benzene, mp 235.0—235.5 °C with dec in a sealed tube.

Found: C, 92.59; H, 6.98%; M^+, 336. Calcd for $C_{26}H_{24}$: C, 92.81; H, 7.19%; M, 336.45.

*5,8-Dimethyl-2,11-dithia[3.3]paracyclo(9,10)anthracenophane (**28**).* A solution of 9,10-bis(chloromethyl)anthracene[15] (3.3 g, 12.0 mmol) in benzene (500 ml) and a solution of 2,5-bis(mercaptomethyl)-*p*-xylene (2.38 g, 12.0 mmol) and sodium hydroxide (1.0 g) in 90% ethanol were added dropwise and simultaneously through dropping funnels into boiling ethanol (200 ml) for 3.75 h under N_2. The mixture was refluxed for an additional 12 h and worked up in the same manner as in the synthesis of **27** to afford 3.06 g (63.7%) of **28**. It was recrystallized from benzene to give a yellow powder, dec>230 °C in a sealed tube.

Found: C, 77.94; H, 5.96; S, 15.79%; M^+, 400. Calcd for $C_{26}H_{24}S_2$: C, 77.95; H, 6.04; S, 16.01%; M, 400.58. NMR ($CDCl_3$, δ): 1.51 (s, 6, Me), 3.58 (AB, J=15 Hz, 2, CH_2 attached to durene moiety), 3.85 (AB, J=15 Hz, 2, CH_2 attached to durene moiety), 4.89 (bs, 4, CH_2 attached to anthracene moiety), 6.20 (s, 2, H_k), 7.3—7.8 (m, 4, H_{b1} and H_{b2}), 8.1—8.6 ppm (m, 4, H_{a1} and H_{a2}).

*4,7-Dimethyl[2.2]paracyclo(9,10)anthracenophane (**10**).* In the same manner as **9**, irradiation of a solution of disulfide **28** (4.0 g, 10 mmol) in 1 liter of benzene and triethyl phosphite (1:1) for about 5 h and purification by column chromatography on silica gel gave the cyclophane **10** (1.99 g, 59.2%), yellow needles from dichloromethane–petroleum ether, dec> 170 °C in a sealed tube.

Found: C, 92.15; H, 6.94%; M^+, 336. Calcd for $C_{26}H_{24}$: C, 92.81; H, 7.19%; M, 336.45.

We are greatly indebted to Mr. T. Fujino for microanalyses and to Mr. Y. Takai for NMR measurements. The present work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Synthesis of [2-Serine, 8-Valine]-Human Calcitonin[1,2]

Sukekatsu NOZAKI

Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro, Tokyo 171

(Received February 22, 1978)

The [2-serine, 8-valine]-analog of human calcitonin (**1**) was synthesized by the liquid phase method. Analog **1** was built up from five fragments with minimized protection for the side functional groups. These fragments were linked stepwise to the C-terminal fragments by the azide method. A gel filtration was effectively applied for the purification of the resulting peptide in each fragment condensation. Analog **1** had about the same hypocalcemic activity as that of human calcitonin. The result showed that the high activity of eel or salmon calcitonin 1 or 2 is not ascribable only to the amino acid sequence of their *N*-terminal decapeptide.

Among calcitonins isolated from various origins, salmon[3] and eel hormones[4] exhibit conspicuously high activity, about 20—50 times the hypocalcemic potency of any other calcitonin from mammalian species.[5-8] All the calcitonins so far isolated are composed of 32 amino acids with a disulfide bridge between two cysteinyl residues in positions 1 and 7. The structural homology of these calcitonins is found in the C-terminal prolinamide, glycine in position 28, and the region around the disulfide bridge; amino acids in positions 1, 3, 4, 5, 6, 7, and 9 are common to all the hormones. Salmon calcitonin 3 with methionine in position 8 exhibits the hormonal activity of one third of salmon calcitonin 2,[9] which has the same amino acid sequence but valine at this position. The oxidation of methionine in the same position as that of human calcitonin remarkably reduces the activity of the hormone,[7] but not the oxidation of the amino acid in position 25 of the porcine hormone.[5] Similarity in the N-terminal structure of calcitonins and the remarkable decrease of hormonal activity induced from the oxidation of methionine in position 8 suggests the presence of an "active site" around the disulfide bridge of the hormone.

Several analogs of human calcitonin have been synthesized but the structure-activity relationship of calcitonin has not been explained clearly.[10] To investigate the effect of variation of the primary structure around the disulfide bridge of the human hormone on its hypocalcemic activity, we synthesized [2-serine, 8-valine]-human calcitonin, **1** (Fig. 1), in which glycine in position 2 and methionine in position 8 of the original hormone are replaced by serine and valine, respectively. Analog **1** is a hybrid peptide consisting of the N-terminal decapeptide of eel calcitonin or salmon calcitonin (1 or 2), the hormones with the highest hypocalcemic potency, and the C-terminal decosapeptide amide of human calcitonin, the lowest potent hormone.

Results and Discussion

Analog **1** was built up from five subfragments prepared in the liquid phase method according to the routes illustrated in Schemes 1—5. The protection of the side functional groups of fragments was minimized in order to facilitate the application of various kinds of chromatography to the purification of elongated peptides. The subfragments were linked stepwise to the C-terminal fragments by Rudinger's modification of the azide method[11] as shown in Scheme 6. Each product of the azide coupling was purified after removal of its N-terminal protecting group. The restriction of the molecular size of the N-terminal fragment used in every coupling reaction to be sufficiently smaller than that of the resulting peptide made the gel filtration efficient in the purification of the product. When necessary, partition chromatography on Sephadex[12] was further applied to the purification of deprotected peptides. The yield and properties of N-protected intermediates are

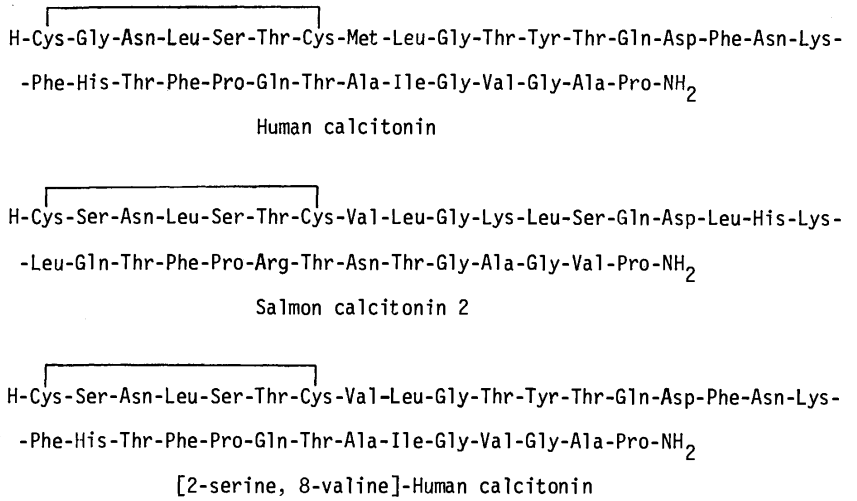

Fig. 1.

given in Table 1.

Positions 23—32. Acylation of free proline with benzyloxycarbonylalanine *p*-nitrophenyl ester followed by a gel filtration on Sephadex LH-20 yielded benzyloxycarbonylalanylproline (**2**) nearly in a theoretical yield. The mixed anhydride prepared from **2** and isobutyl chloroformate was ammonolyzed in tetrahydrofuran to give benzyloxycarbonylalanylprolinamide (**3**) in a 86% yield. This route is applicable to the preparation of a dipeptide containing prolinamide, since it is much more convenient for preparation of **3** than other ones starting with prolinamide or *via* ammonolysis of benzyloxycarbonylalanylproline ethyl ester. The azide formation from benzyloxycarbonylprolylglutaminylthreonylalnanylisoleucylglycine hydrazide (**18**) was slow. The amine component, valylglycylalanylprolinamide (**19**), should be added to the azide solution after the hydrazide is consumed completely, in order to avoid serious difficulties in the separation of the desired decapeptide amide (**20**) from the remaining hydrazide.

Positions 20—32. Benzyloxycarbonylhistidylthreonylphenylalanine hydrazide (**24**) was converted into the azide, which was allowed to couple with the C-terminal decapeptide amide (**25**). The product was hydrogenated and applied to a gel filtration. Further purification was performed by means of partition chromatography on Sephadex with the system of 1-butanol–acetic acid–water. The eluate was monitored at 254 nm, three compounds (peptide A, B, and C) being obtained after removal of the solvent. The amino acid compositions in acid hydrolysates of those peptides agreed with the theoretical value for peptide **26**. By aminopeptidase M digestion, however, peptide A left undigested core of threonylphenylalanylprolylglutaminylthreonylalanine,

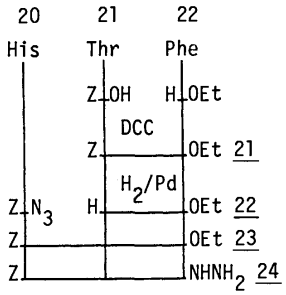
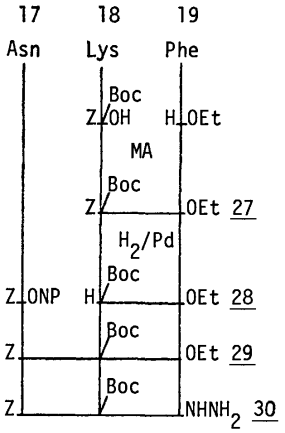


Scheme 2. Preparation of fragment positions at 20—22.



Scheme 3. Preparation of fragment positions at 17—19.

while peptides B and C gave the expected amino acid ratios. The results and other data[13] on aminopeptidase M from our laboratory suggest the presence of D-phenylalanine in peptide A. No difference was observed between peptide B and C on TLC with several solvent systems and between the results of Edman degradation. Peptide C was positive on Beilstein test, while B was negative. Thus, the two peptides, B and C, were thought to be the acetate and the hydrochloride, respectively, of the desired peptide (**26**) and were used for further elongation.

Positions 17—32. Rapid formation of cyclo-N^{ε}-*t*-butoxycarbonyllysylphenylalanyl occurred during the hydrogenolysis of N^{α}-benzyloxycarbonyl-N^{ε}-*t*-butoxycarbonyllysylphenylalanine ethyl ester (**27**) even in the presence of an equivalent amount of acetic acid. N^{ε}-*t*-butoxycarbonyllysylphenylalanine ethyl ester (**28**), the desired product, thus was obtained by use of excess acetic acid. The tridecapeptide (**26**) was acylated by the azide derived from benzyloxycarbonylasparaginyl-N^{ε}-*t*-butoxycarbonyllysylphenylalanine hydrazide (**30**). A gel filtration of the product after hydrogenolysis gave the hexadecapeptide amide (**31**).

Positions 8—32. Tyrosine was introduced to the peptide chain as *N*-benzyloxycarbonyl-*O*-benzyl ester. The protection of the side functional group was removed together with the N-protecting group prior to the further elongation. Benzyloxycarbonylvalylleucylglycine (**35**) was coupled with threonyltyrosylthreonine ethyl ester (**40**) by the two procedures. By the dicyclohexylcarbodiimide/*N*-hydroxysuccinimide method, the yield of the hexapeptide (**41**) was 69%, while the use of benzyloxycarbonylvalylleucylglycine *p*-nitrophenyl ester (**36**) improved the yield to 95%. In our preliminary experiments, benzyloxycarbonylvalylleucylglycylthreonyltyrosylthreonylglutaminyl-*β*-*t*-butylaspartylphenylalanine ethyl ester could not be converted into the hydrazide under mild conditions. The use of the protected hydrazide at the C-terminal of the nonapeptide made it difficult to find a suitable blocking group for *β*-carboxyl function of the aspartyl residue. The presence of the free *β*-carboxyl group in aspartylphenylalanine

Scheme 6. Preparation of [2-serine, 8-valine]-human calcitonin (**1**) by stepwise fragment condensation.

t-butoxyhydrazide (**44**), however, caused no difficulty for the construction of tripeptide (**45**) and the longer peptides. In the hydrogenolysis of the *t*-butoxycarbonylhydrazides, **43** and **45**, some by-products formed, especially after contact with hydrogen for a long time, but their amount was negligibly small when the hydrogenolysis was performed in a short period. The coupling of glutaminylaspartylphenylalanine *t*-butoxycarbonylhydrazide (**46**) with the azide derived from benzyloxycarbonylvalylleucylglycylthreonyltyrosylthreonine hydrazide (**42**) yielded protected nonapeptide (**47**). The *t*-butoxycarbonyl group of **47** was removed by concentrated hydrochloric acid. The use of trifluoroacetic acid for the deprotection unexpectedly gave a mixture showing multiple spots on TLC. Acylation of the hexadecapeptide amide (**31**) with the azide derived from **48** produced the pentacosapeptide amide, which was purified after removal of the N-protecting group by a gel filtration and succeeding partition chromatography on Sephadex to give **49**.

Positions 1—7. The azide prepared from *N-t*-butoxycarbonyl-*S*-benzylcysteinylserylasparaginylleucylserine hydrazide (**57**) was allowed to couple with threonyl-*S*-benzylcysteine ethyl ester (**59**) to yield the heptapeptide ester (**60**), which was led to the hydrazide (**61**) prior to the formation of disulfide bridge, lest the ester group should be ammonolysed during the course of sodium/ammonia treatment. After the removal of *S*-benzyl group, the thiols of cysteinyl residues were oxidized in a dilute solution by air to disulfide in a slightly basic region. In neutral or lower pH region, the thiol was not oxidized completely even after contact with air for a long time. Gel filtration on Sephadex LH-20 using DMF was successful for the purification of the product (**62**).

Positions 1—32. Two equivalent amount of the azide prepared from **62** was used for the acylation of pentacosapeptide amide (**49**). The *t*-butoxycarbonyl groups of the crude product were removed by concentrated hydrochloric acid treatment at −5 °C for 10 min to give **1**. Analog **1** was purified by gel filtration and carboxymethyl cellulose chromatography. The homogeneity of **1** was confirmed by tlc in several solvent systems and amino acid analyses of the acid hydrolysates, as well as of the aminopeptidase M digests.

Analog **1** exhibited hypocalcemic activity of 80—120 MRC units/mg. The potency is similar to or a little higher than that of human calcitonin but much lower than that of eel or salmon calcitonins. This suggests that the high activity of salmon or eel hormone is not ascribable only to the amino acid sequence of their N-terminal decapeptide and that the presence of methionine in position 8 of human calcitonin is not responsible by itself for the low potency of the hormone.

Experimental

Melting points are uncorrected. Amino acid analyses were carried out on a JLC-6AS automatic analyzer (JEOL) after acid hydrolysis with HCl of constant bp (110 °C, 16—20 h), or aminopeptidase M (Röhn and Haas Co.) digestion. The theoretical values of amino acid ratios are shown in parentheses after each result. Edman degradation was carried out with a JAC-47K automatic sequencer (JEOL). Biological activities were measured according to the method of Cooper *et al.*[15] The N-protected dipeptides, **5**,[16] **9**,[17] **21**, **27**, **32**,[18] **37**, **43**, **50**, **52**, and **58**, were prepared by the usual methods as shown in the Schemes. The longer peptides, **11**, **13**, **15**, **17**, **23**, **29**, **34**, **39**, **45**, and **54**, were synthesized by the stepwise elongation method. Compounds **8**[19] and **56** were prepared from the subfragments by the active ester method and the azide method, respectively. Hydrazides, **18**, **24**, **30**, **42**, **51**, **57**, and **61**, were obtained from the corresponding ethyl esters. The active esters, **7**[20] and **36**, were prepared from **6**[21] and **35** by the use of DDC. Compounds **6** and **35** were prepared from **5** and **34**, respectively, by saponification. The N-terminal free peptides, **10**, **12**, **14**, **16**, **19**, **22**, **33**, **38**, **40**, **44**, **46**, **53**, **55**, and **59**, were obtained by the usual catalytic hydrogenolysis of the corresponding benzyloxycarbonyl derivates. In TLC, silica gel G (Merck and Co.) plate (Sh), silica gel-precoated plate (Merck and Co.) (Sp) and cellulose-precoated plate (Avicel)(C) were used with the following solvent systems: chloroform–methanol, 95/15 (1a), 95/5 (1b); chloroform–methanol–acetic acid, 95/5/3 (2a), 36/4/1 (2b); 1-butanol–acetic acid–water, 4/1/1 (3a), 3/1/1 (3b), 10/1/1 (3c); 1-butanol–1 M acetic acid, 2/1 upper phase (4a), 1/1 upper phase (4b); 2-propanol–water, 4/1 (5); 1-butanol–pyridine–acetic acid–water, 16/3/1/4 (6); 2-butanol–15 M ammonia–water, 24/1/5 (7).

Cbz-Ala-Pro-OH (2). Cbz-Ala-ONP (6.50 g) was added to a suspension of proline (2.30 g) and triethylamine (2.78 ml) in DMF (50 ml). The mixture was stirred at room temperature for 4 days and the solvent was removed. The residue was dissolved in ethyl acetate and washed with 1 M HCl and water. An oil obtained after removal of solvent of the organic layer was dissolved in a small amount of ethanol. About half of the solution was applied onto a Sephadex LH-20 column (2.5×76 cm) and the product was eluted with ethanol. The colorless fractions containing the peptide were evaporated to give an oil. The rest of the ethanol solution was treated in the same way. The combined product was dried in reduced pressure; 5.70 g. R_f (Sh, 1b) 0.33.

Cbz-Ala-Pro-NH$_2$ (3). BCC (2.24 ml) was added with stirring to a solution of **2** (5.35 g) and *N*-methylmorpholine (1.69 g) in THF (200 ml) at −15 °C. After 5 min, dried ammonia was passed into the mixture at −15 °C for 20 min and then at ice-bath temperature for 1.5 h. The mixture was stirred for 2 h in the ice-bath and at room temperature for 2 days. The residue obtained after removal of the solvent was dissolved in chloroform–water (100 ml and 20 ml each), and the aqueous phase was extracted with chloroform (70 ml×2). The organic phases were combined and washed with water (10 ml×3). After removal of the chloroform the residue was recrystallized from ethyl acetate; 4.60 g. R_f (Sh, 2a) 0.67.

Cbz-Pro-Gln-Thr-Ala-Ile-Gly-Val-Gly-Ala-Pro-NH$_2$ (20). HCl/THF (3.08 M, 1.95 ml) was added dropwise to a suspension of **18** (1.47 g) in DMF (20 ml) at −40 °C. 1-Butyl nitrite (0.25 ml) was added to the suspension. The mixture was stirred for 40 min at −20 °C, and then cooled at −40 °C. Triethylamine (0.83 ml) was added to the azide solution followed by **19** (2 mM) and triethylamine (0.28 ml) in DMF (10 ml). The mixture was stirred at ice-bath temperature for 3 days. After removal of the solvent, the residue was triturated with water and the solid collected was washed with 1 M citric acid and water. The purified decapeptide amide was obtained by reprecipitation from DMF–ether; 1.69 g. R_f (Sh, 3a) 0.41, (Sh, 5) 0.52. Amino acid ratios in acid hydrolysate: Thr 0.88 (1), Glu 1.08 (1), Pro 2.05 (2), Gly 2.00 (2), Ala 2.08 (2), Val 1.01 (1), Ile 0.99 (1).

H-Pro-Gln-Thr-Ala-Ile-Gly-Val-Gly-Ala-Pro-NH_2 (25). The protected decapeptide amide, **20** (2.09 g), was hydrogenated in the presence of Pd black in DMF (200 ml) and water (40 ml) at 40—50 °C for 3 h. The mixture was diluted with additional water (40 ml) and the hydrogenolysis was continued at 40—50 °C for 3 h and at 70—80 °C for 1 h. After removal of the catalyst the solvent was evaporated to give a solid in a quantitative yield. R_f (Sh, 3b) 0.20.

H-His-Thr-Phe-Pro-Gln-Thr-Ala-Ile-Gly-Val-Gly-Ala-Pro-NH_2 Hydrochloride (26). HCl/THF (1.70 M, 5.56 ml) was added to a solution of **24** (2.40 mM, 1.32 g) in DMF (8 ml) at −40 °C. 1-Butyl nitrite (0.288 ml) was added dropwise and the mixture was stirred at −25 °C for 20 min and then cooled at −40 °C. To the azide solution thus obtained were added triethylamine (1.34 ml) and **25** (2.00 mM) in HMPA (10 ml) and DMF (6 ml). Stirring was continued at ice-bath temperature for 3 days and the solvent was removed. The residue was dissolved in water–saturated 1-butanol and washed with 5% $NaHCO_3$ and water. A syrup which remained after removal of the solvent was solidified by addition of ether. The solid (2.68 g) was hydrogenated in ethanol (100 ml) and water (20 ml) containing HCl. After removal of the catalyst and the solvent, the product was applied to a Sephadex G-10 column (3×32.5 cm) and eluted with water. Fractions of 5 ml each were collected and the desired peptide was obtained from fractions 13—20. The material from fractions 21—25 was rechromatographed on the same column, and an additional crop was obtained. Colorless powder (2.33 g), R_f (C, 4a) 0.18 and 0.14. A part of the product (0.996 g) was dissolved in a small amount of the upper phase of 1-butanol–acetic acid–water (5/1/5) and this was applied to a Sephadex G-25 column (3.5×42.5 cm) which had been equilibrated with the lower phase of the solvent system and then washed with the upper phase. The elution was carried out with the upper phase and the optical density of the eluate was observed at 254 nm to show three major peaks. Peptide A (0.119 g), B (0.079 g), and C (0.305 g) were obtained respectively from the fractions corresponding to the peaks. Peptide A: R_f (C, 4a) 0.18. Amino acid ratios in acid hydrolysate; His 1.17 (1), Thr 1.91 (2), Glu 1.02 (1), Pro 1.96 (2), Gly 1.99 (2), Ala 1.91 (2), Val 1.02 (1), Ile 1.01 (1), Phe 0.98 (1). Amino acid ratios in AP-M digest; His 1.00 (1), Thr 0.34 (2), Gln 0.15 (1), Gly 1.68 (2), Ala 0.48 (1), Val 0.90 (1), Ile 1.00 (1). Peptide B: R_f (C, 4a) 0.14. Amino acid ratios in acid hydrolysate; His 1.00 (1), Thr 1.89 (2), Glu 1.15 (1), Pro 2.17 (2), Gly 1.99 (2), Ala 1.98 (2), Val 0.93 (1), Ile 0.98 (1), Phe 0.91 (1). Amino acid ratios in AP-M digest; His 1.03 (1), Thr 1.88 (2), Gln 1.07 (1), Gly 2.08 (2), Ala 1.07 (1), Val 0.96 (1), Ile 0.91 (1). Peptide C: R_f (C, 4a) 0.14. Amino acid ratios in acid hydrolysate; His 1.07 (1), Thr 1.96 (2), Glu 1.14 (1), Pro 2.13 (2), Gly 1.93 (2), Ala 1.90 (2), Val 0.97 (1), Ile 0.96 (1), Phe 0.92 (1). Amino acid ratios in AP-M digest; His 1.03 (1), Thr 1.91 (2), Gln 1.12 (1), Gly 1.96 (2), Ala 1.05 (1), Val 0.96 (1), Ile 0.98 (1).

Peptide B (0.689 g) obtained by repeating a similar procedure was dissolved in 0.05 M HCl (24 ml). After removal of insoluble materials, the solvent was evaporated to give the hydrochloride, peptide C, as solid (0.644 g). Found: C, 47.96; H, 6.84; N, 15.94; Cl, 6.58%. Calcd for $C_{62}H_{95}O_{17}N_{18}\cdot 3HCl\cdot 5H_2O$: C, 47.46; H, 6.95; N, 15.95; Cl, 7.13%.

H-Lys(Boc)-Phe-OEt Acetate (28). The protected peptide (**27**) (7.50 g) was hydrogenated in ethanol (250 ml) and acetic acid (3.75 ml) to give the desired product. R_f (Sh, 3a) 0.75. However, when the hydrogenolysis was carried out with an equivalent amount of acetic acid, a product having high melting point and poor solubility was obtained. This was recrystallized from DMF and supposed to be cyclo-Lys(Boc)-Phe. R_f (Sh, 1a) 0.41. mp 246 °C. $[\alpha]_D^{20}$ −24.7° (*c* 0.6, DMF). (lit,[22]) mp 224—226 °C, $[\alpha]_D^{20}$ −24.7° (*c* 0.5, DMF). Found: C, 64.50; H, 7.90; N, 11.31%. Calcd for $C_{20}H_{28}O_4N_3$: C, 63.99; H, 7.78; N, 11.19%.

H-Asn-Lys(Boc)-Phe-His-Thr-Phe-Pro-Gln-Thr-Ala-Ile-Gly-Val-Gly-Ala-Pro-NH_2 Acetate (31). To the azide solution, prepared from **30** (0.36 mM, 0.237 g) in DMF (1 ml) as described for Z-His-Thr-Phe-N_3 in the preparation of **26**, was added a solution of **26** (0.30 mM, 0.410 g) and triethylamine (0.083 ml) in HMPA (3 ml) and DMF (3.5 ml). The mixture was stirred at ice-bath temperature for 4 days and the solvent was removed. The residue was washed and then solidified as in the preparation of **26**. The crude product (0.620 g) was hydrogenated in ethanol (50 ml) and water (10 ml) containing acetic acid (0.12 ml). After removal of the catalyst and the solvent, the product was applied to a Sephadex G-10 column (3×32.5 cm) and eluted with water. Fractions of 5 ml each were collected and the desired peptide was obtained from fractions 11—18. 0.375 g (57%). R_f (Sp, 6) 0.20 with a trace spot at 0.24, (Sp, 3a) 0.31 with a trace spot at 0.38. Amino acid ratios in acid hydrolysate: Asp 1.06 (1), Thr 1.94 (2), Glu 0.98 (1), Pro 1.94 (2), Gly 1.98 (2), Ala 1.97 (2), Val 1.01 (1), Ile 1.00 (1), Phe 2.01 (2), Lys 1.09 (1), His 1.09 (1).

Cbz-Val-Leu-Gly-Thr-Tyr-Thr-OEt (41). a) Triethylamine (0.695 ml) was added dropwise to an ice-cold solution of **36** (2.32 g) and **40** (5.0 mM) in DMF (20 ml). The mixture was stirred at room temperature for 2 days. After removal of the solvent the residue was dissolved in water–saturated 1-butanol and washed with 5% citric acid and water. The solvent was evaporated to give a solid, which was recrystallized from DMF–ether. 3.67 g. R_f (Sp, 1a) 0.27, (Sp, 2a) 0.08. b) DCC (0.825 g) in DMF (4 ml) was added in an ice-cold solution of **35** (1.69 g), **40** (3.76 mM) and HOSu (0.460 g) with triethylamine (0.523 ml) in DMF (25 ml). After 2.5 h, HOSu (0.460 g) was added and the mixture was stirred at room temperature overnight. The insoluble substances were removed and the filtrate was evaporated to give a solid, which was washed and reprecipitated from DMF–ether; 2.10 g (69%).

Cbz-Val-Leu-Gly-Thr-Tyr-Thr-Gln-Asp-Phe-NHNH-Boc (47). To an azide solution prepared from **42** (2.00 g) in DMF (8 ml) as in the preparation of **26** was added a solution of **46** (1.54 g) and triethylamine (0.417 ml) in DMF (12 ml). The mixture was stirred at ice-bath temperature for 4 days and the solvent was removed. After the usual treatment, the desired peptide was recrystallized from DMF–ether; 2.94 g. R_f (Sp, 3a) 0.69 (Sp, 6) 0.65. Amino acid ratios in acid hydrolysate: Asp 0.93 (1), Thr 2.05 (2), Glu 0.85 (1), Gly 0.95 (1), Val 0.99 (1), Leu 1.06 (1), Tyr 1.12 (1), Phe 1.06 (1).

Cbz-Val-Leu-Gly-Thr-Tyr-Thr-Gln-Asp-Phe-$NHNH_2$ Hydrochloride (48). The Boc-hydrazide (**47**) (0.30 g) was dissolved in ice-cold 12 M HCl. After 5 min, the solution was poured into NaCl-saturated water (30 ml) at ice-bath temperature. The resulting precipitate was collected and washed with saturated NaCl and with a small amount of water. The solid was dried *in vacuo* over NaOH pellets and recrystallized from DMF–ethyl acetate; 0.17 g. R_f (Sp, 3a) 0.51.

H-Val-Leu-Gly-Thr-Tyr-Thr-Gln-Asp-Phe-Asn-Lys(Boc)-Phe-His-Thr-Phe-Pro-Gln-Thr-Ala-Ile-Gly-Val-Gly-Ala-Pro-NH_2 (49). To the azide solution prepared from **48** (0.200 mM, 0.242 g) in DMF (0.8 ml) in the usual way was added a solution of **31** (0.173 mM, 0.320 g) and triethylamine (10% in DMF, 0.481 ml) in DMF (2.1 ml). The mixture was stirred at ice-bath temperature for 4 days and the solvent was

removed. The residue was dissolved in water-saturated 1-butanol and washed with water. The butanol solution was concentrated into a syrup, to which was added ether and the resulting precipitate was collected. 0.538 g. A part of the crude product (0.240 g) was hydrogenated in ethanol (50 ml) and water (10 ml) in the presence of acetic acid (0.09 ml). After removal of the catalyst and the solvent, the aqueous solution of the residue was applied to a Sephadex G-25 column (3×22 cm), and eluted with 0.05 M ammonium acetate. Fractions of 3 ml each were collected and the desired peptide was obtained from fractions 16—22. R_f (Sp, 3a) 0.47 with minor spots at 0.45 and 0.50. The peptide was further applied to a Sephadex G-25 column (3.5×41 cm), which had been equilibrated with 1-butanol−0.5 M acetic acid (1/1) in a similar way to that described in the preparation of **26**, and was eluted with the upper phase of the solvent system. Fractions of 3 ml each were collected and the purified peptide was obtained from fractions 52—68. 0.090 g. R_f (Sp, 6) 0.04, (Sp, 5) 0.74, (Sp, 3a) 0.43, (C, 4a) 0.05. Amino acid ratios in acid hydrolysate: Asp 1.96 (2), Thr 3.82 (4), Glu 1.91 (2), Pro 2.07 (2), Gly 3.18 (3), Ala 2.13 (2), Val 1.90 (2), Ile 1.04 (1), Leu 0.87 (1), Tyr 0.97 (1), Phe 3.01 (3), Lys 1.04 (1), His 1.11 (1).

*Boc-Cys(Bzl)-Ser-Asn-Leu-Ser-Thr-Cys(Bzl)-OEt (**60**).* To an azide solution prepared as usual from **57** (6.30 g) in DMF (50 ml) and THF (10 ml) was added a solution of **59** (9.25 mM) and triethylamine (1.29 ml) in DMF (50 ml). The mixture was stirred at ice-bath temperature for 3 days. Cold water (200 ml) was poured into the mixture and the resulting precipitate was collected and washed as usual; 6.00 g. R_f (Sh, 2b) 0.30 with a trace spot at 0.62. A part of the product (3.00 g) was applied to a silica gel column (3×38 cm) and eluted with chloroform-methanol (94/4). The purified peptide was obtained in a considerably low yield because of the strong adsorption of the peptide to the gel; 1.10 g. R_f (Sh, 2b) 0.30, (Sh, 3c) 0.75.

*Boc-Cys-Ser-Asn-Leu-Ser-Thr-Cys-NHNH$_2$ (**62**).* The heptapeptide hydrazide, **61** (0.256 g), was dissolved in liquid ammonia (about 50 ml). To the solution was added sodium in a small portions until the blue color of the solution remained for 10 min (0.087 g of sodium was required for a period of 25 min). NH_4Cl (0.282 g) was added to the mixture and the ammonia was evaporated under reduced pressure. The residue was dissolved in water (200 ml) and the solution (pH 8.05) was stirred vigorously in a stream of air for 3 h. The desired peptide was extracted with 1-butanol (40 ml×4, 20 ml×5). The combined organic phase was washed with water (20 ml) and acidified with acetic acid, and then the solvent was evaporated. The residue was applied to a Sephadex LH-20 column (3×32 cm) and eluted with DMF. Fractions of 3 ml each were collected and the desired peptide was located in fractions 21—24. The fractions were combined and concentrated to a small volume and ether was added. The resulting precipitate was collected and washed with ether; 0.139 g. R_f (Sp, 3a) 0.46 with a trace spot at 0.57. Amino acid ratios in the acid hydrolysate: Asp 1.14 (1), Thr 0.94 (1), Ser 1.94 (2), Cys_2 0.93 (1), Leu 1.11 (1).

*H-Cys-Ser-Asn-Leu-Ser-Thr-Cys-Val-Leu-Gly-Thr-Tyr-Thr-Gln-Asp-Phe-Asn-Lys-Phe-His-Thr-Phe-Pro-Gln-Thr-Ala-Ile-Gly-Val-Gly-Ala-Pro-NH$_2$ (**1**).* To the azide solution prepared from **62** (0.050 mM, 42.1 mg) in DMF (0.8 ml) was added a solution of **49** (0.025 mM, 71.7 mg) and triethylamine (10% in DMF, 0.07 ml) in DMF (0.6 ml). The mixture was stirred at ice-bath temperature for 4 days and the solvent was removed. The residue was solidified by the addition of ether. The solid was dissolved in 12 M HCl (1 ml) at −5 °C. After 10 min, ammonium hydrogencarbonate (950 mg) was added to the solution. The solution was diluted with water (about 12 ml), adjusted to pH 3.5 with formic acid and concentrated to about 5 ml volume. The resulting precipitate was separated (ppt fraction). The solution was applied to a Sephadex G-25 column (2.5×23 cm) and eluted with 0.05 M ammonium formate (pH 3.5). Fractions of 4 ml each were collected and the eluate in fractions 13—21 was lyophilized to give a solid. The crude product was further applied to a CM-cellulose column (Serva, 1.2×28 cm) and eluted with a linear gradient of ammonium formate buffer (0.01 M, pH 4.7—0.1 M, pH 5.2, 220 ml each). Fractions of 4 ml each were collected and the eluate in fractions 53—64 was lyophilized. The solid obtained was again desalted with a Sephadex G-10 column (1.5×14 cm) to give the desired peptide **1**; 2.27 mg. R_f (Sp, 3a) 0.45, (Sp, 6) 0.21, (Sp, 7) 0.17, (C, 4b) 0.21. $[\alpha]_{331}^{24}$ −1633° (*c* 0.2, 1 M acetic acid). Amino acid ratios in acid hydrolysate: His 0.98 (1), Lys 1.09 (1), Asp 3.16 (3), Thr 4.82 (5), Ser 2.19 (2), Glu 2.07 (2), Pro 2.24 (2). Gly 3.11 (3), Ala 2.22 (2), Cys_2 0.60 (1), Val 1.82 (2), Ile 1.11 (1), Leu 1.87 (2), Tyr 0.82 (1), Phe 2.96 (3). Average recovery of the amino acids was 90%. Amino acid ratios in AP-M digest: Asp 1.00 (1), Asn 1.99 (2), Thr 4.94 (5), Ser 2.13 (2), Gln 1.92 (2), Pro 0.11 (2), Gly 3.28 (3), Ala 1.53 (2), Cys_2 0.70 (1), Val 1.92 (2), Ile 1.36 (1), Leu 1.87 (2), Tyr 0.93 (1), Phe 2.35 (3), Lys 1.02 (1), His 1.12 (1). AP-M used in this analysis cleaved the peptide bond X-Pro (X=amino acid) very slowly. The low recoveries of Phe, Pro, and Ala are due to this. Hypocalcemic activity: 80—120 MRC units/mg. The product (18.96 mg), which still contained the amine component, positions 8—32, was recovered from the "ppt fraction" and the void volume fractions of CM-cellulose chromatography.

The author wishes to express his sincere thanks to Professor Ichiro Muramatsu for his kind guidance throughout this work. He also thanks the Research Laboratories of Toyo Jozo Co., Ltd. for the elemental and amino acid analyses, and for biological assay of the product. The sequence analyses of peptide **26** were kindly carried out in the Laboratory of JEOL Ltd.

An ESR Study of *N*-Benzoyl- and *N*-Pivaloyl-*N*-(arylthio)aminyls[1)]

Yozo MIURA,* Yosuke KATSURA, and Masayoshi KINOSHITA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received February 27, 1978)

N-Benzoyl-*N*-(arylthio)aminyls, ArCONSAr', and *N*-pivaloyl-*N*-(arylthio)aminyls, *t*-BuCONSAr, were generated in benzene by hydrogen-abstraction from *N*-benzoyl- and *N*-pivaloylbenzenesulfenamides. The hyperfine coupling constants (*hfcc*) for the radicals are in the range of 6.80—7.57 G for the nitrogen nucleus and 1.68—1.97 G for the *S*-phenyl ring protons. However, *hfcc* due to the benzoyl and pivaloyl protons were not detected. The *g*-values lie in the range of 2.0081—2.0084. On the basis of these ESR parameters, it is suggested that the acylaminyls exist in a π-electronic ground state and that the unpaired electron is located predominantly on the nitrogen atom ($2p_z$ orbital) and the phenylthio group. From the decay kinetic study of the radicals, it was found that *N*-benzoyl-*N*-(4-chlorophenylthio)aminyl persisted for more than 3 h in benzene at 24 °C, and *N*-pivaloyl-*N*-(4-chlorophenylthio)aminyl decayed only a little, even after 20 h.

Acylaminyls are of interest as an important intermediate in such photochemical reactions as Hoffmann-Löffler type intramolecular rearrangements.[2)] Some ESR spectroscopic investigations of acylaminyls have been undertaken for the purpose of determining whether they can best be classified as π or σ radicals.[3-6)] Acylaminyls are generally known as transient radicals and are easily converted into the corresponding nitroxides in the presence of oxygen. Thus, the unequivocal identification of the radicals by ESR spectroscopy is difficult, and other radicals have often been misassigned as acylaminyls. Recent ESR spectroscopic investigations of acylaminyls have shown that they exist in a π-electronic ground state.[3)]

In the past years we have studied some nitrogen-centered free radicals in which one or two divalent sulfur atoms are adjacent to the radical center.[7)] In this report we will describe an ESR study of a new class of acylaminyls, *N*-acyl-*N*-(arylthio)aminyls (**2**).

Results and Discussion

Preparation of N-*Acylbenzenesulfenamides (**1**).* The sulfenamides were prepared by the reactions of benzamides or pivalamide with benzenesulfenyl chlorides in THF or ether in the presence of triethylamine. In the reactions of pivalamides, sulfenamides were afforded in relatively good yields (*ca.* 50%), but with benzamides the yields were low (8—28%). The structures of **1** were identified by means of elemental and instrumental analyses.

$$\mathrm{RCNH_2} + \mathrm{ArSCl} \xrightarrow[\text{in THF (ether)}]{\mathrm{Et_3N}} \mathrm{RCNHSAr} + \mathrm{Et_3N \cdot HCl}$$

1

Generation of Radicals. Acylaminyls, **2**, were generated by two procedures: a) the photolysis of a benzene solution of **1** using a high-pressure mercury lamp and b) the thermolysis of a benzene solution containing **1** and di-*t*-butyl diperoxyoxalate. In the former procedure, the radicals **2** seem to be generated by hydrogen-abstraction from **1** by the amidyl radicals which are formed by the photoinduced S–N bond fission of **1** (Scheme 1).[8,9)]

$$\mathbf{1} \xrightarrow{h\nu} \mathrm{RCNH\cdot} + \mathrm{ArS\cdot}$$

$$\mathrm{ArS\cdot} + \mathbf{1} \longrightarrow \mathrm{RCNH_2} + \mathrm{RCNSAr}\ (\mathbf{2})$$

Scheme 1.

The ESR spectra of **2** generated by Procedures a and b were in complete agreement with each other.

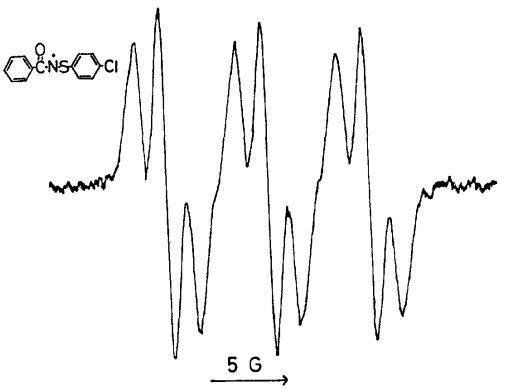

Fig. 1. An ESR spectrum of **2b** generated by photolysis of a benzene solution of **1b** at 24 °C.

The ESR spectrum (Fig. 1) of *N*-benzoyl-*N*-(4-chlorophenylthio)aminyl (**2b**) was split into a 1:1:1 triplet (7.16 G) by the interaction with one nitrogen nucleus, and each of the triplet was further split into a 1:2:1 triplet (1.72 G) by the interaction with two magnetically equivalent protons. The latter triplet is obviously due to the two ortho-protons in the *S*-phenyl ring, and no quartet splitting which could be expected on the basis of the benzoyl protons' participation could be detected. In order to confirm this assignment, an ESR spectrum of a *d*-labeled acylaminyl, **2g**, was measured. This ESR spectrum consisted of a simple 1:1:1 triplet (7.08 G), and no splitting due to the benzoyl protons was detected. The radicals **2c**, **2d**, and **2f** also showed spectra similar to that of **2b**. On the other hand, the spectra of *N*-benzoyl-*N*-(phenylthio)-aminyl (**2a**) and *N*-pivaloyl-*N*-(phenylthio)aminyl (**2e**) were constituted of 1:3:3:1 quartets (1.68—1.69 G)

Table 1. The ESR parameters for *N*-acyl-*N*-(arylthio)aminyls (**2**)[a]

	R–C(=O)–N•–S–R′		*S*-Phenyl ring			*g*-Value
	R	R′	a_N[b]	a_{o-H}[b]	a_{p-H}[b]	
2a	C_6H_5	C_6H_5	7.09	1.68	1.68	2.0081
2b	C_6H_5	4-ClC_6H_4	7.16	1.72	—	2.0083
2c	4-$CH_3OC_6H_4$	4-ClC_6H_4	7.38	1.73	—	2.0082
2d	4-$NO_2C_6H_4$	4-ClC_6H_4	6.80	1.97	—	2.0084
2e	*t*-C_4H_9	C_6H_5	7.49	1.69	1.69	2.0082
2f	*t*-C_4H_9	4-ClC_6H_4	7.57	1.69	—	2.0083
2g	C_6H_5	C_6D_5	7.08			2.0082

a) In benzene at 24 °C. b) In G.

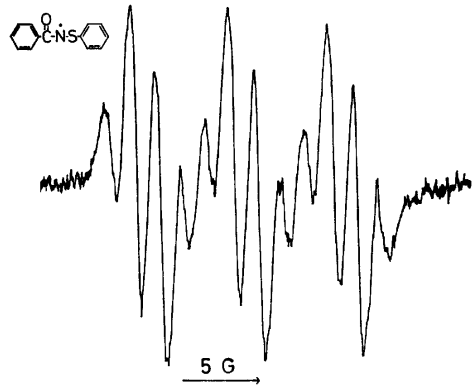

Fig. 2. An ESR spectrum of **2a** generated by photolysis of a benzene solution of **1a** at 24 °C.

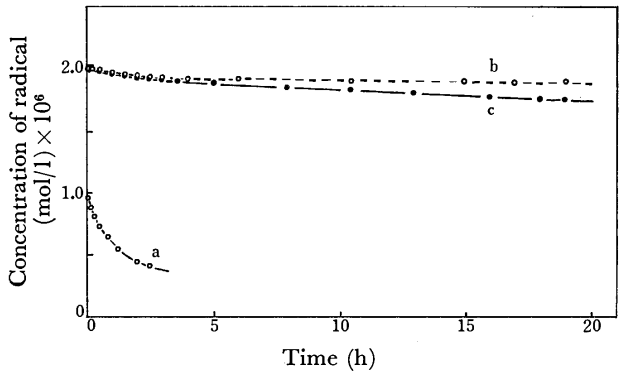

Fig. 3. Decay plots of *N*-acyl-*N*-(arylthio)aminyls (**2**) in benzene at 24 °C. a: **2b** in degassed benzene; b: **2f** in degassed benzene; c: **2f** in benzene saturated with air.

of a 1:1:1 triplet (7.09—7.49 G, see Fig. 2). The quartets were obviously due to the interaction with the magnetically equivalent two ortho- and one para-protons in the *S*-phenyl ring. The values of the coupling constants are listed in Table 1, together with the *g*-values.

It is well known that nitrogen-centered free radicals are easily converted into the corresponding nitroxides, even in the presence of such weak oxidants as atmospheric oxygen. In the present experiment, however, the possibility that **2** are identical with the corresponding nitroxides, **3**, may be excluded on the basis of the following points: 1) the *g*-values of **2** (2.0081—2.0084) are too high compared with those for nitroxides so far reported (*ca.* 2.006)[10] and 2) although, in *t*-BuNSAr, couplings due to the ring protons have never been detected,[11] in **2** relatively large couplings (a_H: 1.68—1.97 G) are observed.

3

Decay Kinetics. The decay kinetic study of **2** was carried out in benzene at 24 °C in the dark. The results are illustrated in Fig. 3. As can be seen from the figure, the radical **2b** persisted in degassed benzene for more than 3 h, and **2f** decayed only a little, even after one day. Moreover, the decay rate of **2f** was measured in benzene saturated with air in order to examine the influence of oxygen on the stability. As may be found from the figure, the decay rate is almost the same as that obtained under the degassed conditions, indicating that the life-time of the radical is little affected by oxygen. Since other acylaminyls are very short-lived and are significantly sensitive to oxygen,[3,12] these results are of interest.

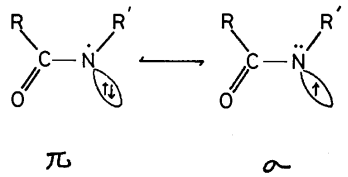

Fig. 4.

Consideration of ESR Parameters. Since, in acylaminyls, there is a carbonyl group which can potentially interact with the nitrogen lone-pair electrons, there has been considerable interest in determining whether they are π or σ radicals (Fig. 4). If in a σ-electronic ground state, they are expected to exhibit a large a_N value because the unpaired electron would reside in an orbital of an appreciable s character. Recent investigations of acylaminyls indicate that simple or *N*-alkoxyacylaminyls are π radicals, judging from the ESR parameters.[13]

With respect to the present radicals, the a_N values lie in the range of 6.80—7.57 G: they are considerably smaller than those observed for simple or *N*-alkoxyacylaminyls,[13] suggesting that **2** exist in a π-electronic ground state.

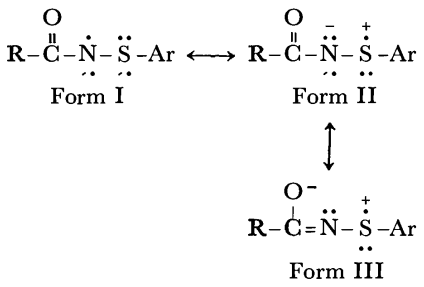
In **2a—d** and **2e**, no couplings due to the benzoyl protons were observed. Also, the replacement of the benzoyl groups in **2a** and **2b** by a pivaloyl group (**2a** or **2f**) increased the a_N values by only 0.4 G. Thus, in **2** there is a negligibly small delocalization of the unpaired electron onto the benzoyl aromatic ring.

When the a_H (1.68—1.97 G) and the *g*-values (2.0081—2.0084) for **2** are compared with those for *N*-(arylthio)-*t*-butylaminyls (**4**, a_H: 0.89—1.07 G, *g*-value: 2.0068—2.0072),[7] it is obvious that the extent of the delocalization of the unpaired electron onto the arylthio group in **2** is larger than in **4**. Since **4** is radical which the benzoyl or pivaloyl group in **2** is replaced by a *t*-butyl group with no ability to de-

4

localize an unpaired electron, it is reasonable to think that, in **2**, the unpaired electron is little delocalized onto the carbonyl group.

The small a_N values observed for **2**, compared with those of other acylaminyls,[13] can be well explained in terms of the contribution of the resonance forms II and III, which reduce the spin density on the nitrogen. The contribution of II and III leads to an increase in



Form I Form II

Form III

the spin density on the sulfur atom possessing a large spin orbit coupling parameter,[15] resulting in the large *g*-values for **2**.

The contribution of II and III may become more important by the introduction of electron-withdrawing substituents into the benzoyl group, resulting in a reduction in the magnitude of the a_N value. In the *p*-nitro-substituted acylaminyl, **2d**, the a_N value is reduced by 0.36 G compared with that for **2b**. On the contrary, the introduction of electron-donating substituents may lead to an increase in the magnitude of the a_N value. In the *p*-methoxy-substituted acylaminyl, **2c**, the a_N value is increased by 0.22 G compared with that for **2b**.

From the results and discussion, it may be concluded that the acylaminyls **2** exist in a π-electronic ground state, and the unpaired electron is located predominantly on the nitrogen atom ($2p_z$ orbital) and the arylthio group.

Experimental

All the melting points are uncorrected. The IR spectra were run on a JASCO Model IR-G spectrometer, and the NMR spectra were recorded with a Hitachi-Perkin Elmer R-20 spectrometer, using TMS as an internal standard. Benzene-d_5-thiol[16] and di-*t*-butyl diperoxyoxalate[17] were prepared by the reported methods. The benzene used as a solvent in the ESR measurements was purified by the usual method.[18]

General Procedure for Preparation of N-*Acylbenzenesulfenamides (1).* Benzenesulfenyl chloride (0.024 mol) in dry THF [50 ml, or dry ether (50 ml) in the cases of **1e** and **1f**] was added dropwise to a stirred solution of amide (0.020 mol) and triethylamine (0.030 mol) in dry THF [250 ml, or dry ether (500 ml) in the cases of **1e** and **1f**] at 0 °C. After addition of the sulfenyl chloride, the reaction mixture was stirred for 3 h at 0 °C, and then for 10 h at room temperature. After the triethylamine hydrochloride thus formed was filtered off, the filtrate was concentrated under reduced pressure to give a powdery residue, which was subjected to column chromatography [alumina (E. Merck, Darmstate, Art 1097), column size 20×3 cm, eluent: benzene/ethanol: 100/1]. The **1** thus separated was recrystallized from the appropriate solvents.

N-*Benzoylbenzenesulfenamide (1a).* Colorless plates with mp 122—124 °C (from benzene/hexane: 2/1). Yield: 14%. IR (KBr): 3250 (NH) and 1635 cm^{-1} (CO). NMR (DMSO-d_6): δ 7.15—8.11 (m, aromatic, 10H) and 10.25 (br s, NH, 1H). Found: C, 67.77; H, 4.64; N, 5.88%. Calcd for $C_{13}H_{11}NOS$: C, 68.09; H, 4.84; N, 6.11%.

N-*Benzoyl-4-chlorobenzenesulfenamide (1b).* Colorless plates with mp 138—139 °C (from benzene/hexane: 2/1). Yield: 15%. IR (KBr): 3250 (NH), 1640 cm^{-1} (CO). NMR (DMSO-d_6): δ 7.19—8.10 (m, C_6H_4 and C_6H_5, 9H) and 10.33 (br s, NH, 1H). Found: C, 59.10; H, 3.70; N, 5.18%. Calcd for $C_{13}H_{10}NOClS$: C, 59.20; H, 3.82; N, 5.31%.

N-*(4-Methoxybenzol)-4-chlorobenesulfenemide (1c).* Colorless needles with mp 178—179 °C (from benzene). Yield: 13%. IR (KBr): 3200 (NH), 1650 cm^{-1} (CO). NMR (DMSO-d_6): δ 3.87 (s, CH_3, 3H), 7.12 and 8.04 (d, J=8 Hz, CO-C_6H_4, 4H), 7.25 and 7.49 (d, J=8 Hz, *S*-C_6H_4, 4H), and 10.12 (br s, NH, 1H). Found: C, 57.35; H, 4.25; N, 4.77%. Calcd for $C_{14}H_{12}NO_2ClS$: C, 57.24; H, 4.12; N, 4.77%.

N-*(4-Nitrobenzoyl)-4-chlorobenzenesulfenamide (1d).* Light yellow needles with mp 169—170 °C (from benzene). Yield: 8%. IR (KBr): 3250 (NH), 1660 cm^{-1} (CO). NMR (DMSO-d_6): δ 7.34 and 7.39 (s, *N*-C_6H_4, 4H), 8.16 and 8.41 (d, J=8 Hz, CO-C_6H_4, 4H), and 10.61 (br s, NH, 1H). Found: C, 50.57; H, 2.89; N, 9.09%. Calcd for $C_{13}H_9N_2O_3ClS$: C, 50.57; H, 2.94; N, 9.07%.

N-*Pivaloylbenzenesulfenamide (1e).* Colorless needles with mp 102—103 °C (from hexane). Yield 58%. IR (KBr): 3200 (NH), 1650 cm^{-1} (CO). NMR (CCl_4): δ 1.16 (s, *t*-Bu, 9H), 7.12 (s, C_6H_5, 5H), and 7.79 (br s, NH, 1H). Found: C, 62.95; H, 7.38; N, 6.65%. Calcd for $C_{11}H_{15}NOS$: C, 63.12; H, 7.22; N, 6.69%.

N-*Pivaloyl-4-chlorobenzenesulfenamide (1f).* Colorless plates with mp 119—120 °C (from hexane). Yield: 43%. IR (KBr): 3200 (NH) and 1650 cm^{-1} (CO). NMR (CCl_4): δ 1.20 (s, *t*-Bu, 9H), 7.00 and 7.13 (d, J=8 Hz, C_6H_4, 4H), and 7.66 (br s, NH, 1H). Found: C, 53.81; H, 6.08; N, 5.64%. Calcd for $C_{11}H_{14}NOClS$: C, 54.20; H, 5.79; N, 5.75%.

N-*Benzoylbenzenesulfenamide-2,3,4,5,6-*d_5 *(1g).* Colorless plates with mp 126—128 °C (from benzene/hexane: 2/1). Yield 28%. IR (KBr): 3250 (NH) and 1660 cm^{-1} (CO). NMR (DMSO-d_6): δ 7.25—8.22 (m, C_6H_5, 5H) and 10.44 (br s, NH, 1H). Found: C, 66.25; H, 4.50; N, 6.18%. Calcd for $C_{13}H_6NOD_5S$: C, 66.63; H, 4.74; N, 5.98%.

Generation of Radicals. a) Sulfenamide **1** (5.0 mg) and benzene (0.20 ml) were placed in an ESR tube. The solution

was degassed by three freeze-and-thaw cycles, and then sealed. The solution was directly irradiated in the cavity of an ESR instrument with an 100W high-pressure mercury lamp (JES-UV-1); b) **1** (5.0 mg), di-*t*-butyl diperoxyoxalate (10.0 mg), and benzene (0.20 ml) were placed in an ESR tube. The solution was degassed by the procedure described above, and then sealed. The ESR spectra from the solution were recorded at 24° C.

Decay Kinetics. The decay kinetic study of **2** was carried out in benzene at 24 °C in the dark. The sample was prepared as follows: **1** (5.0 mg) and benzene (0.20 ml) were placed in an ESR tube, degassed by the procedure described above, and then sealed. The solution was directly irradiated for *ca.* 20 min in the cavity of an ESR instrument with the mercury lamp, and then the light was turned off. The decay rates were followed by monitoring the ESR signal intensities, and the integration of the signals was carried out with a JES-ID-2 integrator, using a benzene solution of 3,4-dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (1,3,5-triphenylverdazyl)[19] as a standard.

The ESR spectra were recorded on a JES-ME-3X spectrometer, with an X-band microwave unit and 100 kHz field modulation. The hyperfine coupling constants *(hfcc)* and *g*-values for **2** were determined by comparing them with the *hfcc* (a_N: 13.09 G)[20] and *g*-value (2.0057)[21] of Fremy's salt.

Sulfenylation Accompanied by Dealkoxycarbonylation of β-Keto Esters, Geminal Diesters, and α-Cyano Ester in Hexamethylphosphoric Triamide (HMPA)

Morio ASAOKA,* Kazutoshi MIYAKE, and Hisashi TAKEI

Department of Life Chemistry, Tokyo Institute of Technology, Nagatsutacho, Midori-ku, Yokohama 227

(Received February 27, 1978)

In the presence of sodium iodide, diphenyl disulfide reacted with geminal diesters, β-keto esters, and α-cyano esters in hexamethylphosphoric triamide (HMPA) at 150—160 °C to give alkyl phenyl sulfides and α-phenylthio esters, ketones, and nitriles, respectively, along with evolution of carbon dioxide.

It is well-known that geminal diesters, β-keto esters, and α-cyano esters undergo dealkoxycarbonylation when heated with salt, such as sodium chloride or sodium cyanide, in a wet polar aprotic solvent.[1,2] The dealkoxycarbonylation was thought to involve carbanion as an intermediate. Our investigation was undertaken in order to utilize such carbanion for synthetic purposes. We previously reported the intermolecular and intramolecular alkylation of such carbanion.[3] In the present paper, we wish to report sulfenylation of the carbanion, since the sulfenylated compounds are known to be useful intermediates for a variety of organic compounds.[4]

Results and Discussion

When a solution of diethyl malonate, diphenyl disulfide, and sodium iodide in HMPA was heated to 150—160 °C for 1 h, the evolution of carbon dioxide was observed and the disappearance of diethyl malonate was recognized by TLC. From the reaction mixture, ethyl phenyl sulfide and ethyl (phenylthio)acetate were isolated in 40 and 46% yields, respectively, and unreacted diphenyl disulfide was recovered. At the same time, the formation of ethyl acetate was also confirmed. In this reaction, 1.1 equivalents of sodium iodide (which can be regarded as a catalyst) was used, but when 0.2 equivalent of sodium iodide was used, the reaction was found to proceed very slowly.

In order to find the most suitable reaction conditions

$$\underset{\mathbf{1}}{CH_2(COOEt)_2} + \underset{\mathbf{2}}{(PhS)_2} \xrightarrow[HMPA]{NaI} \underset{\mathbf{3}}{PhSCH_2COOEt} + \underset{\mathbf{4}}{PhSEt} + CO_2$$

and to elucidate the reaction mechanism, several experiments were carried out, using a variety of catalysts and solvents or changing the ratio of the reactants. These results are summarized in Table 1.

In view of these results the most effective catalyst is sodium iodide and the most suitable solvent is HMPA. When DMSO or sulfolane was used instead of HMPA, the dealkoxycarbonylation of diethyl malonate was very slow and considerable amounts of unreacted diethyl malonate and diphenyl disulfide were recovered.

Some of possible reaction sequences are shown in the following equations:

$$\underset{\mathbf{1}}{CH_2(COOEt)_2} + X^- \longrightarrow \underset{\mathbf{5}}{[EtOOCCH_2COO^-]} + EtX \quad (1)$$

$$\mathbf{5} \longrightarrow \underset{\mathbf{6}}{[\bar{C}H_2COOEt]} + CO_2 \quad (2)$$

$$\mathbf{6} + PhSSPh \longrightarrow \underset{\mathbf{7}}{PhSCH_2COOEt} + PhS^- \quad (3)$$

Table 1. Effect of metal halide, solvent, and molar ratio of reactants

Molar ratio $CH_2(COOEt)_2$	$(PhS)_2$	MX	Solvent	Time h	Yield (%)[a] $PhSCH_2COOEt$	Others

1	1	1.0 (LiI)	HMPA	1.0	25		
1	1	1.2 (NaBr)	HMPA	1.1	21		
1	1	1.2 (KI)	HMPA	1.1	35		
1	1	1.1 (NaI)	HMPA	1.1	46		
1	2	1.2 (NaI)	HMPA	1.3	44[b]		
1	1	5 (NaI)	HMPA	0.8	45		
2	1	1 (NaI)	HMPA	1.0	82	Et(PhS)CHCOOEt	8
2	1	2 (NaI)	HMPA	1.0	84	Et(PhS)CHCOOEt	9
1	1	1 (NaI)	DMSO	1.0	13	$CH_2(COOEt)_2$	63
1	1	1 (NaCl)	DMSO	1.0	5	$CH_2(COOEt)_2$	75
1	1	1 (NaI)	sulfolane	1.0	12	$CH_2(COOEt)_2$	65

a) Yields were calculated based on diphenyl disulfide. b) Yield was calculated based on diethyl malonate.

$$\mathbf{6} + CH_2(COOEt)_2 \longrightarrow CH_3COOEt + \underset{\mathbf{8}}{\bar{C}H(COOEt)_2} \quad (4)$$

$$\mathbf{8} + PhSSPh \longrightarrow \underset{\mathbf{9}}{PhSCH(COOEt)_2} + PhS^- \quad (5)$$

$$PhS^- + EtX \longrightarrow PhSEt + X^- \quad (6)$$

$$\mathbf{9} + X^- \longrightarrow \underset{\mathbf{10}}{PhS\bar{C}HCOOEt} + EtX + CO_2 \quad (7)$$

$$\mathbf{10} + EtX \longrightarrow Et(PhS)CHCOOEt \quad (8)$$

As shown in Table 1, use of 2 equivalents of diethyl malonate caused a great increase of the yield, though addition of excess sodium iodide or diphenyl disulfide scarcely affected the yield. These facts suggest that proton transfer (Eq. 4) and the succeeding sulfenylation (Eq. 5) might be involved in the major pathway for the formation of ethyl (phenylthio)acetate and the direct sulfenylation (Eq. 3) might be less important in this case. The formation of ethyl α-(phenylthio)butyrate in the reaction using 2 equivalents of diethyl malonate also supports the importance of the pathway which involves proton transfer (Eqs. 5, 7, and 8).

When ethyl acetoacetate was used instead of diethyl malonate, (phenylthio)acetone (**11**) (47%) was obtained along with α,α-bis(phenylthio)acetone (**12**) (8%). The formation of α,α-bis(phenylthio)acetone also shows the occurrence of proton transfer.

$$CH_3COCH_2COOEt + (PhS)_2 \xrightarrow[HMPA]{NaI} \underset{\mathbf{11}}{PhSCH_2COCH_3} + \underset{\mathbf{12}}{(PhS)_2CHCOCH_3} + PhSEt + CO_2$$

In order to increase the yield of **11** and the ratio of **11** to **12**, the influence of reaction temperature was examined, using HMPA and NaI as solvent and catalyst. Though the ratio scarcely changed, the highest yield of **11** was obtained at 160 °C (Table 2).

Then the reactions of various geminal diesters, β-keto esters, and ethyl cyanoacetate were carried out in HMPA in the presence of sodium iodide at 155—160 °C. α,α-Disubstituted malonic esters and β-keto esters gave the desired sulfenylated products in better yields than geminal diesters, β-keto esters, and α-cyano ester all of which possess active hydrogen. These results are summarized in Table 3. The NMR and IR spectral data of the sulfenylated compounds are also listed in Table 4.

In conclusion, the sulfenylation accompanied by dealkoxycarbonylation was proved to be a useful method for the synthesis of sulfenylated compounds, especially in the case of α,α-disubstituted malonic esters and β-keto esters.

Experimental

Materials. Alkali halides were used after drying at 110—120 °C for several hours in vacuo. HMPA was distilled over sodium hydride under reduced pressure.

Typical Example of the Sulfenylation. A mixture of dimethyl α,α-dimethylmalonate (320 mg, 2 mmol), diphenyl disulfide (436 mg, 2 mmol), sodium iodide (360 mg, 2 mmol), and HMPA (2 ml) was heated at 165—170 °C for 1 h. The mixture was then cooled to room temperature, poured into water (50 ml), and extracted with two portions of ether (50 ml). The organic layer was washed with water and dried over anhydrous sodium sulfate. After removal of the solvent under reduced pressure, the residue was separated by silica gel TLC (hexane–ether 6: 1), to give methyl α-(phenylthio)-isobutylate (**23**) (298 mg, 71%); mp 41—43 °C, IR(KBr) 1730 cm^{-1} NMR (CCl_4) δ= 1.4 (6H, s), 3.55 (3H, s), and 7.1—7.5 (5H, m). Found: C, 62.78; H, 6.63; S, 15.47%. Calcd for $C_{11}H_{14}O_2S$: C, 62.84; H, 6.71; S, 15.22%.

Ethyl α-benzyl-α-(phenylthio)hydrocinnamate (**24**) and ethyl α-methyl-α-(phenylthio)pentanoate (**22**) were obtained from the corresponding disubstituted malonates in a similar manner. Ethyl α-benzyl-α-(phenylthio)hydrocinnamate (**24**). Found: C, 76.37; H, 6.47; S, 8.26%. Calcd for $C_{23}H_{24}O_2S$; C, 76.57; H, 6.43; S. 8.50%. Ethyl α-methyl-α-(phenylthio)pentanoate (**22**). Found: C, 67.07; H, 7.89; S, 12.34%. Calcd for $C_{14}H_{20}O_2S$: C, 66.64; H, 7.99; S, 12.68%.

Other sulfenylated compounds were also obtained by practically the same method as described above. Their structures were confirmed by comparison of their spectral and elemental analyses with those of the authentic samples prepared according to the reported procedures.[5)]

Synthesis of the Monoterpene Lactone from *Chrysanthemum flosculosum* L.

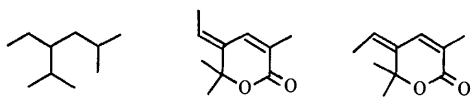
Shûichi YAMAGIWA, Hiroshi KOSUGI, and Hisashi UDA*

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-2, Sendai 980

(Received March 2, 1978)

The synthesis of a lactonic constituent [(*Z*)-5-ethylidene-5,6-dihydro-3,6,6-trimethyl-2*H*-pyran-2-one] isolated from *Chrysanthemum flosculosum* L. is described. Dehydration of 5-ethyl-5,6-dihydro-5-hydroxy-3,6,6-trimethyl-2*H*-pyran-2-one derived from 5-ethyl-5,6-dihydro-6,6-dimethyl-3-phenylthio-2*H*-pyran-2-one *via* methylation, oxidation, [2,3]sigmatropic rearrangement, and saponification, gave the geoisomeric [(*E*)-5-ethylidene] lactone. Photochemical isomerization of the ethylidene side-chain furnished the natural lactone. The geometry of the ethylidene group in both isomers has been rigorously established.

The santolinyl group of monoterpenoids possesses the carbon skeleton **1**, which does not conform to the isoprene rule.[1] A representative member of this group of natural products is the crystalline lactone isolated as a minor polar constituent from *Chrysanthemum flosculosum* L.[2,3] Bohlmann and Grenz have assigned structure **2** to this lactone, but have not established the geometry of the ethylidene side-chain.[3,4]

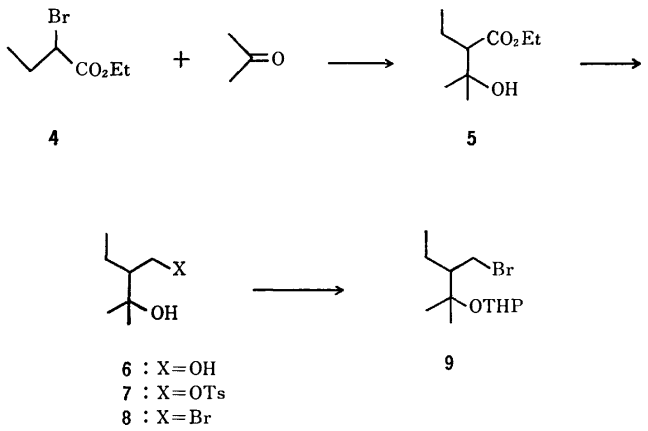


1 **2** **3**

The synthesis of both (*E*)- and (*Z*)-5-ethylidene isomers of this δ-lactone derivative, **2** and **3**, are reported which unambiguously establishes the structure of the natural lactone to be **3**. In view of the recent work on the reactions of (phenylthio)acetic acid and its ester,[5] and the rearrangement reactions of the α-phenylsulfinylacrylate derivatives,[6,7] the key intermediate chosen was the α-phenylthio-α,β-unsaturated δ-lactone **14**.

The Reformatsky reaction of ethyl α-bromobutyrate (**4**) with acetone in refluxing benzene gave the hydroxy ester **5** in 64% yield. Lithium aluminum hydride reduction of **5** afforded the glycol **6**, which was then transformed into the tetrahydropyranyloxy bromide **9** in 64% overall yield through the usual manner: monotosylation to **7**, substitution to the bromohydrin **8**, and finally tetrahydropyranylation (Scheme 1).

Methyl sodio(phenylthio)acetate (**10**), prepared from methyl (phenylthio)acetate by the action of sodium hydride in tetrahydrofuran and hexamethylphosphoric



4 **5**

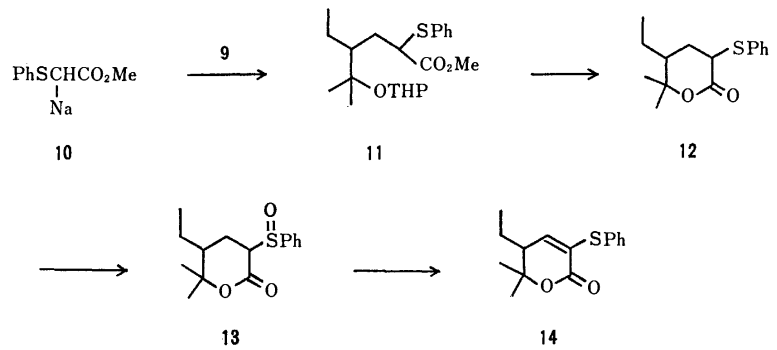
Scheme 1.

triamide, reacted well with the bromide **9** to produce the substitution product **11**. Hydrolysis and lactonization by treating with *p*-toluenesulfonic acid, initially in boiling aqueous tetrahydrofuran and then in boiling benzene gave a 72% yield of a stereoisomeric mixture of the δ-lactone **12**. The lactone **12** was treated with sodium periodate in dilute methanol to give the sulfoxide **13**. Exposure of **13**, without purification, to trifluoroacetic anhydride in dichloromethane directly provided the desired intermediate **14**, mp 73—74 °C, in 80% yield from **12** through the spontaneous elimination of trifluoroacetic acid from the initially formed Pummerer rearrangement product, α-phenylthio-α-trifluoroacetoxy lactone (Scheme 2). The structure of **14** was verified by its analytical and spectroscopic properties.

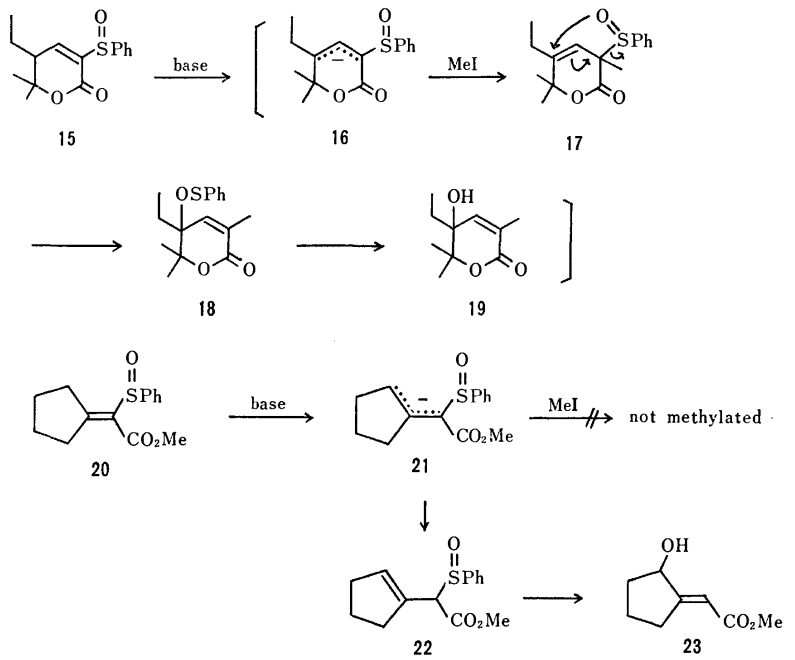
The planned synthesis of **2** or **3** involved the one-step introduction of a methyl group at the α-position and of



10 **11** **12**

13 **14**

Scheme 2.

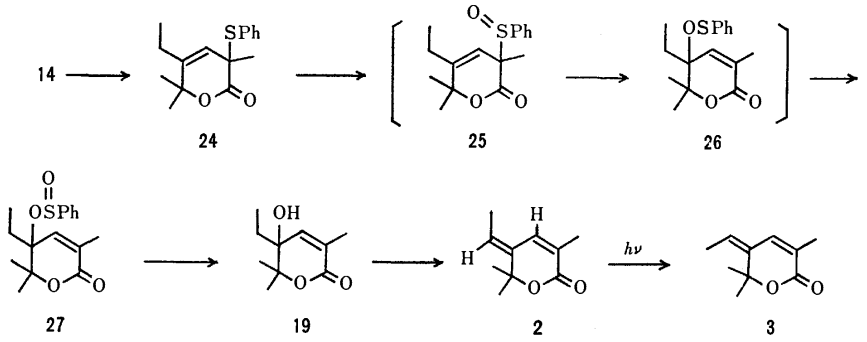


Scheme 3.

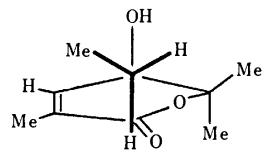
a hydroxyl group at the γ-position in the α-sulfinyl δ-lactone system **15** by applying the doubly double-bond migrating rearrangement reaction observed in the α-phenylsulfinylacrylate derivatives.[6,7] If the carbanion species **16** derived from **15** by an appropriate base reacts more rapidly with methyl iodide than the [2,3]-sigmatropic rearrangement of the sulfinyl group, the methylated sulfoxide **17** should be produced. Subsequent rearrangement and hydrolysis of the sulfenate **18** might give the precursor **19** of the natural product (Scheme 3). However, a number of preliminary experiments using methyl cyclopentylidene(phenylsulfinyl)acetate (**20**) as a model compound suggests that such a reaction process (alkylative rearrangement) is not applicable, since the migration of the double-bond of **20** and the [2,3]sigmatropic rearrangement of the resulting isomer **22** are extremely facile; methylation of the anion **21** did not take place, compound **23** being the only isolable product.[7]

The introduction of functional groups, methyl and hydroxyl, was then attempted in a stepwise manner (Scheme 4). Treatment of **14** with potassium *t*-butoxide in tetrahydrofuran and hexamethylphosphoric triamide and then with methyl iodide afforded the α-methylated product **24** in 72% yield. Oxidation of **24** with two equivalents of *m*-chloroperbenzoic acid in dichloromethane at 0 °C gave the rearranged sulfinyloxy lactone **27**. Compound **27** showed a very complicated pattern in the NMR spectrum, indicating that **27** was actually a mixture of diastereomers with respect to the γ-carbon and sulfur atoms. Compound **27** was treated with a catalytic amount of sodium methoxide in methanol to give a single crystalline hydroxy lactone **19**, mp 81—82 °C, in 65% yield from **24**; there was no indication of the presence of a translactonization product (γ-lactone). It should be noted that both the [2,3]sigmatropic rearrangement of the sulfoxide **25** and the oxidation of the resulting sulfenate **26** to the sulfinate **27** proceeded very rapidly. When one equivalent of *m*-chloroperbenzoic acid was employed in the oxidation of **24**, neither the sulfoxide **25** nor the sulfenate **26** was isolated; unchanged starting sulfide **24** and the sulfinate **27** were obtained in equal amounts.

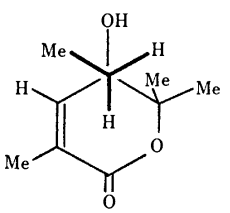
We now considered the conformation of the ethyl



Scheme 4.



19a



19b

group of **19** because this determined whether, at the next dehydration stage, the *E*- (**2**) or *Z*- (**3**) ethylidene group would be preferentially formed. Two conformations **19a** (quasi-equatorial ethyl) and **19b** (quasi-axial ethyl) are possible for the 2-pyrone ring of **19**. In both cases, if the conformation, in which the ring hydroxyl group and the one hydrogen atom of the ethyl-methylene are anti-periplanar, is the favorable one for dehydration, the methyl of the ethyl group would be apart from the gem-dimethyl group as a result of the severe steric interaction between these methyl groups. Furthermore, in the dehydration product the (*E*)-5-ethylidene isomer would be thermodynamically (or sterically) more stable than the (*Z*)-isomer due to the same steric interaction. Hence, dehydration of **19** would be expected to produce preferentially the isomer having the *E*-ethyliedne group.

Compound **19** was heated in boiling benzene containing a catalytic amount of *p*-toluenesulfonic acid and afforded a 63% yield of an unsaturated lactone **2** as the sole product. The lactone **2** was also obtained by treating **19** with thionyl chloride–pyridine at 0 °C. The spectral properties are fully in accord with the assigned structure **2** including the geometry of the ethylidene group. In the 100 MHz NMR spectroscopy, irradiation of the gem-dimethyl signal at δ 1.52 caused 11% of the NOE enhancement of the ethylidene olefinic proton signal at δ 5.72. Furthemore irradiation of the olefinic methyl signal centered at δ 1.92 resulted in 7% of the NOE enhancement of the ring olefinic proton signal at δ 7.00. Thus, the configuration of the ethylidene group of this lactone should be evidently *E*-geometry as expected.

It was found, however, that this compound **2** is oily and the spectral data (see Experimental section) is not entirely consistent with the reported values for the natural lactonic constituent. Consequently, the natural lactone must have the structure **3** possessing the *Z*-ethylidene side-chain, and the synthesis of **3** was achieved by photochemical isomerization. Irradiation of **2** in benzene with 100 W high-pressure mercury lamp through Pyrex provided the isomeric crystalline lactone **3**, mp 63.5—64.5 °C, in 73% yield. Although, the IR and UV absorption maxima [ν_{max} (CCl_4) 1710, 1640, and 1620 cm^{-1}; λ_{max} (EtOH) 276.5 nm (ε=17360)] are slightly different from the reported ones [ν_{max} (phase—not reported) 1725, 1650, and 1630 cm^{-1}; λ_{max} (solvent—not reported) 266.5 nm (ε=14900)], the melting point, the NMR spectrum [δ (CCl_4) 1.62 (s, 6H), 1.88 (s, 3H), 1.91 (d, J=7.0 Hz, 3H), 5.58 (q, J=7.0 Hz, 1H), and 6.42 (s, 1H)], and the mass spectrum [M^+ *m/e* 166 (35%), 151 (100%), and 123 (29%)] were consistent with the reported values for the natural lactone: mp 64.5 °C the NMR spectrum [δ (solvent—not reported) 1.60 (s, 6H), 1.87 (s, 3H), 1.89 (d, J=7.0 Hz, 3H), 5.57 (q, J=7.0 Hz, 1H), and 6.42 (s, 1H)], and mass spectrum [M^+ *m/e* 166 (25%), 151 (100%), and 123 (22%)].[8] From the present study, we conclude that the natural lactone has been assigned as (*Z*)-5-ethylidene-5,6-dihydro-3,6,6-trimethyl-2*H*-pyran-2-one.

Experimental

All the melting points were taken on a Yamato melting point apparatus and are uncorrected. Small amounts of liquid products were purified by evaporative short-path distillation; oil-bath temperatures are recorded. IR spectra were obtained with a Hitachi EPI-S2 or G2 spectrophotometer. A UV spectrum was taken on a Hitachi EPS-3T spectrometer. NMR spectra of solutions in carbon tetrachloride (unless otherwise indicated) were recorded with a JEOL PMX-60 (60 MHz) or PS-100 (100 MHz) instrument, with TMS as an internal standard; coupling constants are given in Hz. Mass spectra were taken with a Shimadzu LKB-9000 instrument. Microanalyses were carried out in the microanalytical laboratory of this Institute.

Tetrahydropyranyl Ether of 3-Bromomethyl-2-methyl-2-pentanol (8). To a slurry of zinc powder (11 g, 0.17 g atom) and iodine (a catalytic amount) in boiling anhydrous benzene (200 ml) was added dropwise over a period of 1 h a solution of ethyl α-bromobutyrate (26.5 g, 0.136 mol) and acetone (35 ml, 0.475 mol) in anhydrous benzene (40 ml), and the reaction mixture refluxed for 2 h. Dilute sulfuric acid (6 M, 150 ml) was added to the cooled reaction mixture, and the resulting solution vigorously stirred for 30 min at room temperature. The water layer was extracted twice with ether. The combined organic layers were washed twice with water and saturated brine, and dried. After removal of the solvent, the residual liquid was fractionated under reduced pressure, and the fraction of bp 62—63 °C/5 Torr (1 Torr≈133.322 Pa) collected to yield 15.22 g (64%) of ethyl 2-ethyl-3-hydroxy-3-methylbutyrate (**5**): IR (CCl_4) 3450, 1720 (sh), 1705, 1460, 1375, 1190, and 1160 cm^{-1}; NMR δ 0.89 (3H, t, J=7.0), 1.15 (6H, s), 1.27 (3H, t, J=7.0), 1.53 (2H, quint, J=7.0), 2.20 (1H, t, J=7.0), 2.81 (1H, s, OH), and 4.12 (2H, q, J=7.0).

To a slurry of lithium aluminum hydride (0.7 g, 18.5 mmol) in anhydrous ether (50 ml) was added dropwise a solution of **5** (1.74 g, 10 mmol) in anhydrous ether (20 ml) at room temperature under nitrogen, and the reaction mixture stirred for 30 min at room temperature. Ethyl acetate (10 ml) was added slowly to the mixture at 0 °C to decompose the excess hydride, and then a minimum amount of water was added until a jelly-like precipitate separated from the ether solution. The ether layer was decanted, and the precipitate thoroughly washed with ether. The combined ether solutions were evaporated under reduced pressure to give 1.32 g (100%) of 2-ethyl-3-methyl-1,3-butanediol (**6**): NMR δ 1.17 (3H, s), 1.28 (3H, s), 0.70—2.30 (6H, m), 3.74 (2H, m), and 4.70 (2H, m).

To a solution of **6** (660 mg, 5 mmol) in anhydrous pyridine (7 ml) was added portionwise *p*-toluenesulfonyl chloride (1.33 g, 7 mmol) at 0 °C, and the reaction mixture allowed to stand for 5 h at room temperature. Chopped ice was added to the mixture, and the resulting solution poured into a mixture of ether and water in a separatory funnel. The ether layer was washed with dilute HCl solution and twice with saturated brine. Evaporation of the ether left 1.22 g (86%) of 2-ethyl-3-hydroxy-3-methylbutyl *p*-toluenesulfonate (**7**): NMR δ 0.50—2.30 (6H, m), 1.13 (3H, s), 1.16 (3H, s),

1.97 (1H, br s), 2.46 (3H, s), 4.10 (2H, d, J=4.0), 7.24 (2H, d, J=8.0), and 7.74 (2H, d, J=8.0).

To a solution of sodium bromide (2.04 g, 20 mmol) in DMSO (15 ml) was added dropwise a solution of **7** (2.86 g, 10 mmol) in DMSO (7 ml) at 50 °C with stirring. After stirring at 60 °C for 30 min, more sodium bromide (2.5 g, 24 mmol) was added, and the reaction mixture was stirred for a further 2.5 h at 60 °C. The mixture was poured into water and extracted twice with ether. The combined ether extracts were washed twice with water and saturated brine. Evaporation of the ether gave 2.02 g (100%) of 3-bromomethyl-2-methyl-2-pentanol (**8**): bp 60—90 °C/47 Torr; IR (CCl_4) 3400, 1460, 1370, 1230, and 1115 cm^{-1}; NMR δ 0.50—2.30 (6H, m), 1.17 (3H, s), 1.21 (3H, s), 2.20 (1H, br s), and 3.27—3.83 (2H, m). Found: C, 42.96; H, 7.69; Br, 41.58%. Calcd for $C_7H_{15}OBr$: C, 43.09; H, 7.75; Br, 40.96%.

To a solution of **8** (2.5 g) and dihydropyrane (1.7 g) in CH_2Cl_2 (30 ml) was added a catalytic amount of anhydrous *p*-toluenesulfonic acid at 0 °C. After stirring for 30 min at room temperature, pyridine (2 drops) was added, and the mixture washed with saturated brine. The aqueous layer was further extracted with CH_2Cl_2. The combined organic layers were evaporated under reduced pressure and the residue chromatographed on silica gel (50 g) with petroleum ether to give 2.9 g (75%) of the tetrahydropyranyl ether **9**: NMR δ 0.60—2.50 (12H, m), 1.27 (6H, split s), 3.00—4.30 (4H, m), and 4.80 (1H, m).

*5-Ethyl-6,6-dimethyl-3-phenylthiotetrahydropyran-2-one (**12**).* To a slurry of sodium hydride (45% mineral oil dispersion, 2.2 g, washed three times with petroleum ether and once with anhydrous THF) in anhydrous THF (40 ml) was added dropwise a solution of methyl (phenylthio)acetate (5.5 g, 0.03 mol) in anhydrous THF (10 ml) at 0 °C under nitrogen, and the resulting mixture stirred for 1 h at 0 °C. A solution of **9** (14 g, 0.05 mol) in anhydrous THF (10 ml) and then HMPA (25 ml, 0.143 mol) were added dropwise to the above mixture. After stirring overnight at room temperature, the reaction mixture was poured into ice-water and extracted twice with ether. The combined extracts were washed twice with water and saturated brine. Evaporation of the ether left an oil (13.7 g), which was chromatographed on silica gel (150 g) with petroleum ether—petroleum ether–ether (gradient)—ether to give 9.2 g of methyl 4-[1-methyl-1-(tetrahydropyranyloxy)-ethyl]-2-phenylthiohexanoate (**11**): NMR δ 0.50—2.50 (20H, m), 3.00—4.20 (3H, m), 3.60 (3H, s), 4.80 (1H, m), and 7.00—7.70 (5H, m).

A solution of **11** (9.2 g) in dilute THF (80%, 50 ml) containing *p*-toluenesulfonic acid (0.1 g) was heated under reflux for 1 h. The reaction mixture was poured into ice-water and extracted twice with ether. The combined ether extracts were washed with brine and evaporated. The residue (8.53 g) was dissolved in anhydrous benzene (30 ml) containing anhydrous *p*-toluenesulfonic acid (a catalytic amount), and the solution heated under reflux for 40 min using a water separator. The reaction mixture was poured into ice-water, and the water layer extracted twice with ether. The combined organic layers were washed with saturated brine. After removal of the solvent, the residue (6.55 g) was chromatographed on silica gel (70 g) with petroleum ether—1: 2 petroleum ether-ether to give 5.7 g [72% based on methyl (phenylthio)-acetate] of **12**: bp 140 °C/1 Torr; IR (CCl_4) 1725, 1275, and 1125 cm^{-1}; NMR δ 1.03, 1.20, 1.34, and 1.40 (total 6H, each s), 0.50—2.80 (8H, m), 3.50—4.00 (1H, m), and 7.00—8.00 (5H, m). Found: C, 68.16; H, 7.63%. Calcd for $C_{15}H_{20}O_2S$: C, 68.49; H, 7.88%.

*5-Ethyl-5,6-dihydro-6,6-dimethyl-3-phenylthio-2H-pyran-2-one (**14**).* To a solution of **12** (1.27 g, 4.8 mmol) in methanol (30 ml) was added dropwise a solution of $NaIO_4$ (1.23 g, 5.75 mmol) in water (10 ml) at 0 °C, and the reaction mixture stirred for 18 h at room temperature. Inorganic material was removed by filtration, and the filtrate extracted twice with CH_2Cl_2. The combined extracts were washed with saturated brine. Evaporation of the solvent gave 1.34 g (99%) of 5-ethyl-6,6-dimethyl-3-phenylsulfinyltetrahydropyran-2-one (**13**): IR (CCl_4) 1720, 1275, 1135, 1085, and 1050 cm^{-1}; NMR δ 0.30—3.00 (14H, m), 3.40—4.50 (1H, m), and 7.00—8.30 (5H, m).

To a solution of **13** (1.14 g, 4.05 mmol) in CH_2Cl_2 (30 ml) was added dropwise a solution of trifluoroacetic anhydride (1 ml, 7.0 mmol) in CH_2Cl_2 (10 ml) at 0 °C. After stirring for 2 h at room temperature, the solvent was removed under reduced pressure. The residue (1.29 g) was chromatographed on silica gel (20 g) with 5: 1—1: 1 petroleum ether-ether to give 922 mg (86%) of **14**: mp 73—74 °C from petroleum ether-ether; IR ($CHCl_3$) 1710, 1600, 1140, and 1020 cm^{-1}; NMR ($CDCl_3$) δ 0.87 (3H, t, J=7.0), 1.00—1.80 (2H, m), 1.34 (3H, s), 1.45 (3H, s), 2.30 (1H, ddd, J=10.0, 4.0, and 4.0), 6.15 (1H, d, J=4.0), and 7.20—7.60 (5H, m). Found: C, 68.42; H, 6.99%. Calcd for $C_{15}H_{18}O_2S$: C, 68.68; H, 6.92%.

*5-Ethyl-3,6-dihydro-3,6,6-trimethyl-3-phenylthio-2H-pyran-2-one (**24**).* A solution of **14** (493 mg, 1.88 mmol) in anhydrous THF (4 ml) was added dropwise to a solution of potassium *t*-butoxide (260 mg, 2.3 mmol) in anhydrous THF (4 ml) at −60 °C under nitrogen, and the resulting solution was stirred for 1.5 h at −60——40 °C. Methyl iodide (0.5 ml, 8 mmol) and then HMPA (1 ml, 5.6 mmol) were added dropwise *via* syringes to the above solution at −60 °C. After stirring at −60——28 °C for 2 h, the reaction mixture was poured into ice-water, and the resulting aqueous solution extracted twice with ether. The combined extracts were washed with saturated brine and evaporatd. The residue (490 mg) was chromatographed on preparative TLC using silica gel with 1: 1 petroleum ether–ether to give 374 mg (72%) of **24**: bp 100 °C/1 Torr; IR (CCl_4) 1725. 1295, and 1150 cm^{-1}; NMR δ 1.10 (3H, t, J=7.0), 1.13 (3H, s), 1.36 (3H, s), 1.47 (3H, s), 2.01 (2H, q, J=7.0), 5.31 (1H, split s), and 7.17—7.60 (5H, m). Found: C, 69.70; H, 7.58%. Calcd for $C_{16}H_{20}O_2S$: C, 69.54; H, 7.30%.

*5-Ethyl-5,6-dihydro-5-hydroxy-3,6,6-trimethyl-2H-pyran-2-one (**19**).* To a solution of **24** (374 mg, 1.35 mmol) in CH_2Cl_2 (20 ml) was added portionwise *m*-chloroperbenzoic acid (80%, 640 mg, 3 mmol) at 0 °C. After stirring for 30 min at 0 °C, the reaction mixture was poured into a mixture of ice and dilute NaOH solution (3M), and the water layer extracted twice with CH_2Cl_2. The combined extracts were washed with water and saturated brine. Evaporation of the solvent gave 422 mg of 5-ethyl-5,6-dihydro-3,6,6-trimethyl-5-phenylsulfinyloxy-2*H*-pyran-2-one (**27**): IR (CCl_4) 1730 and 1150 cm^{-1}.

A solution of **27** in anhydrous methanol (2 ml) was added dropwise to a solution of sodium methoxide (a catalytic amount) in anhydrous methanol (3 ml) at 0 °C. After stirring at room temperature for 1 h, the mixture was poured into ice-water and extracted twice with ether. The combined extracts were washed with water and saturated brine, and evaporated. The residue (374 mg) was chromatographed on preparative TLC using silica gel with 1: 2 petroleum ether-ether to give 163 mg (66%) of **19**: mp 81—82 °C from petroleum ether-ether; IR ($CHCl_3$) 3570, 3400, 1700, 1120, and 1100 cm^{-1}; NMR ($CDCl_3$) δ 1.00 (3H, t, J=7.0), 1.38 (3H, s), 1.46 (3H, s), 1.60 (2H, q, J=7.0), 1.91 (3H, d, J=1.5), 3.27 (1H, br., OH), and 6.50 (1H, q, J=1.5). Found: C, 65.35; H, 8.42%. Calcd for $C_{10}H_{16}O_3$: C, 65.91; H, 8.75%.

(E)-5-Ethylidene-5,6-dihydro-3,6,6-trimethyl-2H-pyran-2-one (2). A solution of **19** (91 mg) in anhydrous benzene (7 ml) containing a trace of anhydrous *p*-toluenesulfonic acid was heated under reflux for 2 h using a water separator. The reaction mixture was diluted with ether, washed with water and brine, and evaporated. The residual liquid was chromatographed on preparative TLC using silica gel with 1:1 petroleum ether–ether to give 52 mg (63%) of **2**: bp 70 °C/1 Torr; IR (CCl_4) 1720 (sh), 1700, and 1115 cm^{-1}; NMR δ 1.52 (6H, s), 1.85 (3H, d, J=7.0), 1.98 (3H, s), 5.72 (1H, q, J=7.0), and 7.00 (1H, s); mass (70 eV) *m/e* 166 (M^+, 40%), 151 (100%), and 123 (25%). Found: C, 72.27; H, 8.73%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

(Z)-5-Ethylidene-5,6-dihydro-3,6,6-trimethyl-2H-pyran-2-one (3) = the Natural Lactone. A solution of **2** (67 mg) in anhydrous benzene (30 ml) in a Pyrex tube was externally irradiated for 3 h with a 100-W high-pressure mercury lamp under running water cooling and nitrogen. After removal of the solvent under reduced pressure, the residue was chromatographed on preparative TLC using silica gel with 1:1 petroleum ether–ether to give 18 mg (27%) of the recovered **2** and 51 mg (73%) of **3**: mp 63.5—64.5 °C from petroleum ether. Found: C, 72.60; H, 8.54%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

A New Catalyst for the Low Temperature Oxo Process with the Characteristic of Easy Separation[1)]

Akio MATSUDA,* Shigemitsu SHIN, Jun-ichi NAKAYAMA
Ken-ichiro BANDO, and Kazuhisa MURATA
National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153
(Received March 6, 1978)

A new type of catalyst, a cobalt carbonyl-complex has been found for homogeneous hydroformylation. The complex has been prepared from $Co_2(CO)_8$ and the ethylene glycol diester of 3-(2-pyridyl)propionic acid as a ligand. The catalyst is active even at the low temperature of 50 °C and very low carbon monoxide pressure range of less than 1 kg/cm². On subsequent cooling it separates from the reaction product. The ligand was prepared by the hydroesterification of 2-vinylpyridine with carbon monoxide and methanol (or ethanol), followed by the transesterification with ethylene glycol. The effect of the partial pressures of carbon monoxide and hydrogen on the product composition and on the recovery of the catalyst was examined. The catalytic activity of the new complex is considerably higher than that of $Co_2(CO)_8$ at a lower temperature. The selectivity to linear aldehyde in the presence of new complex is significantly higher than in the presence of $Co_2(CO)_8$ when the hydrogen to carbon monoxide ratio (H_2/CO) in gas phase is high, but this difference in selectivity is small when the above gas ratio is normal. The new complex can be applied as catalyst for removal of carbon monoxide in hydrogen by means of oxo process.

Catalyst recovery and recycling in the homogeneously catalyzed oxo process are very important from an industrial point of view, and many reports have been published concerning the separation of the catalyst from the reaction product. In the cobalt catalyzed process, for example, Moffat has developed a catalyst recovery and recycling system consisting of a tetracarbonylhydridocobalt-poly(2-vinylpyridine) complex.[2,3)] In the case of the rhodium catalyzed oxo process, even more efforts have been devoted to catalyst recovery. Haag *et al.* have attempted to insolubilize the rhodium-oxo catalyst by complex formation with phosphin- or amine-polymer ligands;[4)] Bayer *et al.* have prepared a homogeneous rhodium-oxo catalyst attached to a soluble phosphine-polymer,[5)] a catalyst which is easily separated from the reaction product by filtration, *etc.*

Previously, it has been reported that a cobalt carbonyl-pyridine complex catalyst for the homogeneous hydroesterification spontaneously separates from the reaction product.[6)] The separated catalyst phase consisted of an ionic complex: $H_2Co_3(CO)_9(py)_5$, where py represents pyridine. This complex proved to be of an ion-pair structure: $\{Co(H^+)_2(py)_5(CO)\}\{Co(CO)_4^-\}_2$; it is insoluble in hydrocarbons and ether, but soluble in alcohols, ketones, aldehydes and pyridine. Although the complex can also be used for hydroformylation, it does not separate from the hydroformylation product, since it is soluble in aldehydes.

The present paper deals with a new oxo catalyst which is derived from $Co_2(CO)_8$ and ethylene bis-(3-(2-pyridyl)propionate) (hereafter abbreviated as EBP), and soluble under the reaction conditions, but which spontaneously separates from the reaction product on cooling to room temperature. Also an interesting feature of the new catalyst is that it is active in the low temperature range of 50 to 70 °C. As a result, the hydroformylation can be carried out under a very low carbon monoxide partial pressure, so that, it can be used as a catalyst for the removal of carbon monoxide in hydrogen by means of the oxo process. For example, when hydrogen containing 4 to 6% of carbon monoxide was allowed to react with excess olefin in the presence of the catalyst in a suitable solvent at 50 to 60 °C, carbon monoxide was almost completely consumed by the hydroformylation, reasonably pure hydrogen containing less than 0.1% of carbon monoxide being left in the gas phase as a result.

Experimental

Preparation of Ligand. EBP was prepared by the transesterification of methyl (or ethyl) 3-(2-pyridyl)propionate with ethylene glycol.

Hydroesterification of 2-Vinylpyridine with Carbon Monoxide and Methanol(or Ethanol): Hydroesterification was carried out in a 300 ml stainless steel autoclave equipped with a vertical agitator. After charging with 2-vinylpyridine, an alcohol, solvent, and $Co_2(CO)_8$, the autoclave was flushed and pressurized with carbon monoxide, and heated to the reaction temperature. The pressure was kept constant during the reaction by supplying carbon monoxide from a pressure storage vessel through a pressure regulator, while the temperature was kept constant by a temperature controller. After the solvent and alcohol were distilled off under normal pressure, unchanged 2-vinylpyridine and methyl (or ethyl) 3-(2-pyridyl)propionate were distilled under reduced pressure.

Methyl 3-(2-pyridyl)propionate: bp 118 °C/10 mmHg, IR spectrum 1730 cm^{-1} (ester).

Ethyl 3-(2-pyridyl)propionate: bp 122 °C/10 mmHg, IR spectrum 1730 cm^{-1} (ester).

Some typical results of the hydroesterification experiments are listed in Table 1.

Transesterification with Ethylene Glycol: Transesterification was carried out with ethlene glycol (0.1 mol) in the presence of excess methyl(or ethyl) 3-(2-pyridyl)propionate (0.22—0.4 mol) at 200 °C, the liberated methanol (or ethanol) being continuously distilled off. The reaction time necessary to attain 64 to 87% yield of diester based on ethylene glycol was 20 to 40 h in the absence of a catalyst, but decreased to 2 to 5 h in the presence of sodium methoxide (0.2—0.4 mmol).

Hydroformylation of 1-Decene. Reactions were carried out in the same apparatus by essentially the same procedure as in the hydroesterification experiments except that reactions in a lower pressure range (10—50 kg/cm²) were carried out

Table 1. Hydroesterification of 2-vinylpyridine

Exp. No.	Temp (°C)	Press. (kg/cm²)	Time (h)	Alcohol (mol)	Conv.[a] (%)	Yield[b] (%)	Bottom[c] (%)
1	150	100	5	CH_3OH (0.25)	80.0	49.0	31
2	170	100	5	CH_3OH (0.25)	96.2	58.0	38
3	170	70	5	CH_3OH (0.25)	71.4	45.2	26
4	120	40	2	C_2H_5OH (1)	76.0	33.6	42
5	140	50	2	C_2H_5OH (1)	86.3	64.8	21
6	170	70	2	C_2H_5OH (1)	94.7	66.4	28
7[d]	170	70	2	C_2H_5OH (2.7)	95.4	70.4	25

2-Vinylpyridine 0.25 mol, $Co_2(CO)_8$ 1 g, benzene (solvent) 100 ml. a) Conversion of 2-vinylpyridine. b) Yield of methyl (or ethyl) 3-(2-pyridyl)propionate (mol %) from 2-vinylpyridine. c) Yield (wt %) of resinous distillation bottom based on the amount of 2-vinylpyridine used. d) Experiment No. 7 was carried out in the absence of benzene.

in a 400 ml autoclave fitted with windows for observation during the reaction.

Aldehydes were obtained by distilling the reaction product under reduced pressure. The crude aldehyde obtained was separated into four fractions by distillation with a rectifying column of a spining band type, and each fraction identified by IR and ^{13}C-NMR spectra.

Fraction 1 (undecanal): bp 62 °C/2 mmHg.

Fraction 2 (2-methyldecanal): bp 57.5 °C/2 mmHg.

Fraction 3 (2-ethylnonanal): bp 53.2—53.5 °C/2 mmHg.

Fraction 4 (mixture of 2-propyl octanal and 2-butyl heptanal): bp 52 °C/2 mmHg. IR spectra of these fractions showed an absorption attributable to formyl group at 1735 cm^{-1}.

Identification by Means of ^{13}C-NMR Spectra. Spectra were measured with Varian XL 100.

Isomerized decenes and decane formed by the isomerization and the hydrogenation of 1-decene were determined by gas chromatography (squalane, 0.25ϕ, 90 m, 90 °C). Dissolved cobalt in the reaction product was analyzed by heating an aliquot with 1.5M-sulfuric acid, followed by the chelate titration method.

Results

Effect of Recycling the Catalyst. Results of the hydroformylation of 1-decene carried out by recycling the initial catalyst are listed in Table 2.

TABLE 2. HYDROFORMYLATION OF 1-DECENE

Initial catalyst (run No. 1) was prepared *in situ* from 8 mmol of $Co_2(CO)_8$ and 20 mmol of EBP. $H_2/CO=1$, 1-decene 0.2 mol, liquid paraffin (solvent) 30 g.

Run No.		1	2	3	4

Conv.; Conversion of 1-decene into aldehydes. Select.; Selectivity to each aldehyde determined by gas chromatography. A_1; undecanal. A_2; 2-methyl decanal. A_3; 2-ethylnonanal. A_4; 2-propyloctanal plus 2-butylheptanal. Dissolved Co; cobalt which remained dissolved in the reaction product. Co recovery; per cent of cobalt recovered and recycled.

It was observed through the windows of the reaction vessel that the catalyst complex was soluble during the reaction, but, on cooling to room temperature, separated as a dark red viscous liquid from the upper phase consisting of a solvent and reaction products. The remaining gas was discharged and the upper phase drained off; then 1-decene, the solvent, and the gas were charged again and the reaction repeated. The activity of the catalyst increased on repeated use as evident from a comparison of the results of the initial and the fourth runs.

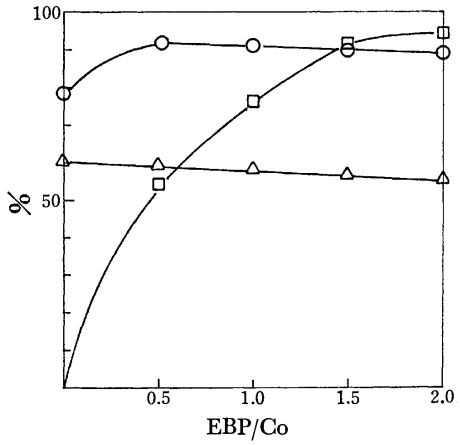

Fig. 1. Results plotted against the EBP/Co ratio.
1-Decene 0.2 mol, benzene 30 g, $Co_2(CO)_8$ 2 mmol, $H_2/CO=1$, 100 °C, 50 kg/cm², 1 h.
-○-: Conversion of decene (%), -△-: selectivity to linear aldehyde (%), -□-: Co recovery (%).

The Effect of the EBP to $Co_2(CO)_8$ Ratio. Results are plotted against the EBP/Co ratio in Fig. 1, where the amount of $Co_2(CO)_8$ was kept constant at 2 mmol.

The degree of conversion of decene increased by the addition of EBP, and reached a maximum when the ratio was 0.5, but slightly decreased as the ratio increased from 0.5 to 2.0. The selectivity to linear undecanal slightly decreased as the above ratio was increased. The catalyst did not separate at all from the reaction products in the absence of EBP, but began to separate as the ratio of EBP to $Co_2(CO)_8$ increased; Cobalt recovery reached near a maximum as the ratio increased to 1.5 and remained unchanged thereafter.

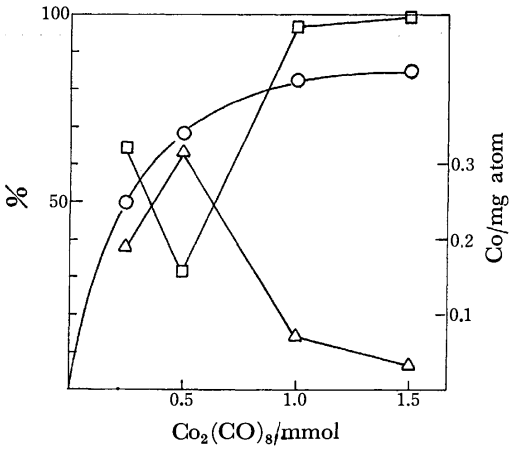

Fig. 2. Effect of catalyst concentration.
1-Decene 0.2 mol, liquid paraffin 30 g, $H_2/Co=1$, 100 °C, 50 kg/cm², 1 h, EBP: Co=4: 3.
-○-: Conversion of decene (%), -△-: dissolved Co (mg atom), -□-; Co recovery (%).

The Effect of Catalyst Concentration. In Fig. 2, the results are plotted against the amount of $Co_2(CO)_8$, where the EBP to $Co_2(CO)_8$ ratio was kept constant at 2.67, the ratio which corresponds to EBP 4: Co 3. The conversion of 1-decene after a definite reaction time increased as a natural result of increasing the amount of catalyst. Figure 2 shows, however, an unusual trend, *i.e.* a contrast between the amount of catalyst used and that of the cobalt remaining dissolved after the reaction. Thus, the larger the amount of catalyst employed, the better the separation of catalyst after the reaction.

The Effect of Pressure. The reactions were carried out under various partial pressures of hydrogen and carbon monoxide by recycling the initial catalyst, the results of which are summarized in Table 3.

The dissolved cobalt in the cooled reaction product decreased by increasing the ratio of hydrogen partial pressure(P_{H_2}) to that of carbon monoxide(P_{CO}); it decreased in the order: run No. 2 ($P_{H_2}/P_{CO}=0.25$)> No. 1($P_{H_2}/P_{CO}=1$)>No.4 ($P_{H_2}/P_{CO}=2$)>No.3($P_{H_2}/P_{CO}=4$)>No. 5($P_{H_2}/P_{CO}=9$). The selectivity to the linear aldehyde increased with the increase in partial pressure of hydrogen(No. 4<No. 3) and also increased with that of carbon monoxide(No. 7<No. 2). Nitrogen pressure did not affect the selectivity(No. 8). The rate constant

TABLE 3. HYDROFORMYLATION OF 1-DECENE UNDER VARIOUS HYDROGEN AND CARBON MONOXIDE PRESSURE

Initial catalyst was prepared *in situ* from 8 mmol of $Co_2(CO)_8$ and 16 mmol of EBP. Synthesis gas($H_2/CO=1$) was supplied during the reaction. 1-Decene 0.2 mol, diethyl ether (solvent) 30 g.

P; Total pressure, which is equal to $P_{H_2}+P_{CO}$, except in run No. 8, where nitrogen pressure ($P_{N_2}=30$) is employed. Conv.; Conversion of decene. k; Rate constant: $k=1/t$ ln $(100/100-x)$, where x is conv. at time t. Decane; Yield (%) of decane. Isomer; Total yield (%) of internal decenes. Other abbreviations: See footnote of Table 2.

increased with increasing partial pressure of hydrogen-(No. 7<No. 4<No. 3), but significantly decreased with that of carbon monoxide(No. 7>No. 2). The extent of isomerization of 1-decene into internal decenes increased as the carbon monoxide partial pressure decreased. Hydrogenation of decene to decane was also favored by lower carbon monoxide pressure.

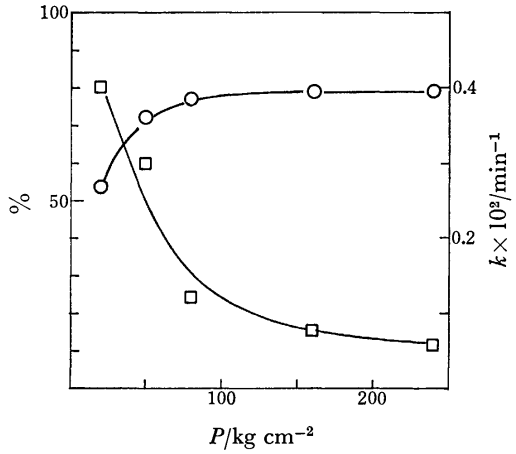

Fig. 3. Results plotted against total pressure.

-○-; Selectivity to linear aldehyde (%), -□-; rate constant k (min^{-1}).

Figure 3 illustrates the effect of the total pressure ($P_{H_2}+P_{CO}$) on the product composition and reaction rate. the selectivity to the linear aldehyde increased with increasing total pressure in the lower pressure range of 20 to 50 kg/cm², but leveled off thereafter. The rate constant decreased with increase in total pressure; this retarding effect of total pressure on the reaction rate was more pronounced in the lower pressure range.

Removal of Carbon Monoxide in Hydrogen by Means of the Oxo Process. Reactions were carried out by recycling the initial catalyst formed *in situ* from 4 mmol of $Co_2(CO)_8$ and 10.67 mmol of EBP. The autoclave was pressurized with hydrogen containing 4 to 6% of carbon monoxide to 100 kg/cm² (20 °C), then it was heated to 50 °C, and the reaction allowed to proceed, agitating at this temperature without supplying the synthesis gas. The results of consecutive experiments are listed in Table 4, the result of a control experiment carried out with 4 mmol of $Co_2(CO)_8$ but in the absence of EBP also being listed.

The activity of a catalyst formed *in situ* from $Co_2(CO)_8$ and EBP is initially very low, and the conversion of carbon monoxide into aldehyde is not complete even after 22 h reaction. The catalyst complex, however, gains in activity on recycling, attaining its highest activity when it has been recycled twice (after more than 40 h). Then, the carbon monoxide initially contained in the hydrogen is almost completely consumed by the hydroformylation in a few hours, and corresponding amount of aldehydes are formed in the liquid phase. The selectivity to the linear aldehyde in the presence of the recycled complex was 62%, which is significantly higher than that of the control experiment (53%) carried out with $Co_2(CO)_8$ in the absence of EBP. The separation of the catalyst after the reaction was in the range of 96 to 99%.

The conversion of carbon monoxide which was determined by analyzing the gas samples withdrawn at regular intervals in runs No. 4, No. 5, and No. 6 are

plotted against the reaction time in Fig. 4. Catalytic activities of the recycled complex in runs No. 4 and No. 5, according to Fig. 4, are markedly higher than that of $Co_2(CO)_8$ at the low temperature of 50 °C.

Infrared Spectrum of the New Complex. The complex, prepared from $Co_2(CO)_8$ (8 mmol) and EBP (21.3 mmol), and recycled several times as hydroformylation catalyst, was washed twice by agitating in petane (100 ml) at 100 °C, 40 kg/cm² ($H_2/CO=1$). A separated viscous phase was taken out of the autoclave after cooling and its IR spectrum together with that of a pyridine complex is shown in Fig. 5. The spectrum of the new complex shows the same absorptions at 2010 and 1890 cm⁻¹ as that of the pyridine complex, indicating the structural analogy of the new complex to $H_2Co_3(CO)_9(py)_5$.

Discussion

The complex, $H_2Co_3(CO)_9(py)_5$, is selectively produced by the reaction of $Co_2(CO)_8$ and pyridine in the molar ratio of one to four at 100 °C, 50 kg/cm² ($H_2/CO=1$), followed by cooling to room temperature.[7] A complex of an analogous structure should also be formed under similar conditions from $Co_2(CO)_8$ and EBP which has two pyridyl groups in the molecule, shown by a comparison of the IR spectra (Fig. 5). The catalyst structure and the mechanism of the catalyst separation can be understood by the model illustrated in Fig. 6, where EBP is represented by a mark N–N (N stands for nitrogen of the pyridyl group).

The higher the concentration of the unit complex during the reaction, the higher the possibility that the unit complex can be linked by N–N bridges with neighboring complexes after being cooled to room temperature, thereby becoming insoluble. This explains the unusual experimental results shown in Fig. 2, that the catalyst separation after cooling is improved by employing larger amounts of $Co_2(CO)_8$ and EBP in a fixed ratio of 3/2: 4, a ratio which corresponds to the

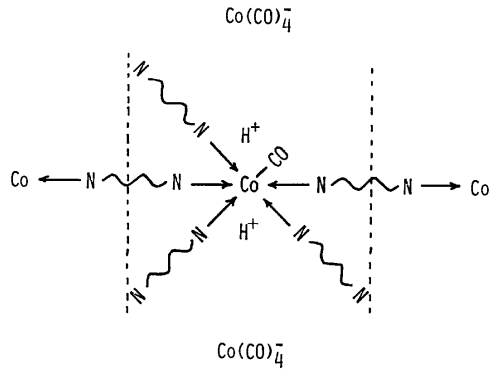

Fig. 6. Structural model of new complex, $H_2Co_3(CO)_9(EBP)_n$, when n is 4.

formula: $H_2Co_3(CO)_9(EBP)_4$. When the temperature is raised, on the other hand, the linking between unit complexes by N–N bridge will dissociate, at least partially, and the solubility of the complex will increase as a result. This explains the change in solubility of the complex with temperature observed through the windows of the reaction vessel.

As the ionic complex, $H_2Co_3(CO)_9(py)_5$, has been found to be in equilibrium with such non-ionic species as $Co_2(CO)_8$ at elevated temperatures,[6] there should also be an equilibrium relation as Eq. 1, in the case of the new complex.

$$H_2Co_3(CO)_9(EBP)_n + 3CO = H_2 + 3/2Co_2(CO)_8 + nEBP \quad (1)$$

The number n in Eq. 1 can be 4 or 3, since the separation takes place satisfactorily when the EBP to Co ratio is 4: 3 (Fig. 2) or 3: 3 (Table 3). The separation occurs only partially when the EBP/Co ratio is less than 1 (Fig. 1).

This complex, $H_2Co_3(CO)_9(EBP)_n$, is probably an active catalyst for hydroformylation under mild conditions, since the analogous pyridine complex, $H_2Co_3(CO)_9(py)_5$, has been found to react with an olefin even at room temperature.[7] The concentration of $H_2Co_3(CO)_9(EBP)_n$, according to Eq. 1, should increase as the hydrogen partial pressure is increased, but decrease as the carbon monoxide partial pressure is increased. This explains the accelerating effect of hydrogen, and the retarding effect of carbon monoxide, on the reaction rate (Table 3). The reaction rate decreases with increasing total pressure (Fig. 3), probably because its decrease due to an increase in P_{CO} is larger than its increase due to an increase in P_{H_2}. The retarding effect of nitrogen pressure on the reaction rate, however, remains unexplained. The fact that the catalyst separation is improved by employing a mixed gas with a higher ratio of hydrogen to carbon monoxide can be explained, since such non-ionic species as $Co_2(CO)_8$ which remain dissolved in the cooled reaction product, will decrease with increasing hydrogen pressure and decreasing carbon monoxide pressure, according to Eq. 1.

The foregoing argument, however, does not exclude the presence of other active species such as $HCo(CO)_4$ and $HCo(CO)_3$ which can also be in equilibrium with $Co_2(CO)_8$ under these reaction conditions. In this connection, it should be noted that the selectivity to the linear aldehyde under extreme conditions of very high P_{H_2}/P_{CO} ratios was remarkably higher in the presence of $H_2Co_3(CO)_9(EBP)_n$ than in the presence of $Co_2(CO)_8$ (Table 4). This strongly suggests that the active catalyst, at least under the extreme conditions of high P_{H_2}/P_{CO} ratios, is different from $HCo(CO)_4$ or $HCo(CO)_3$, and that the active catalyst in this case must be the complex, $H_2Co_3(CO)_9(EBP)_n$, the formation of which is favored by the high P_{H_2}/P_{CO} ratio.

The selectivity to the linear aldehyde under the normal gas ratio ($P_{H_2}/P_{CO}=1$) was, on the contrary, a little lower in the presence of the new complex than in the presence of $Co_2(CO)_8$ (Fig. 1). Therefore, still unidentified catalyst species different from $H_2Co_3(CO)_9(EBP)_n$, $HCo(CO)_4$, and $HCo(CO)_3$, must be taking part in this case.

The reasons for the selectivity to linear aldehyde increasing with increasing carbon monoxide pressure and increasing hydrogen pressure cannot be explained, because there are still unknown factors affecting the selectivity as discussed above. However, the effect of the total pressure on the selectivity to linear aldehyde is, evidently, a result of the co-effects of the respective partial pressures of carbon monoxide and hydrogen, since the increase in total pressure due to such inert gas as nitrogen does not affect the selectivity (Table 3).

The authors wish to express their thanks to Messrs. Toshiyuki Murakami and Ryuji Yamazaki for their assistance in the experimental work.

Metal-catalyzed Organic Photoreactions. The Photooxidation of Olefins in the Presence of Uranyl Acetate[1)]

Eigoro MURAYAMA and Tadashi SATO*

Department of Applied Chemistry, Waseda University, Ookubo 3, Shinjuku-ku, Tokyo 160

(Received March 15, 1978)

The photooxidation of olefins in pyridine in the presence of uranyl acetate afforded β-hydroxy hydroperoxides. It was confirmed by spectroscopic studies and isotope-incorporation experiments that (1) the stereochemistry of the hydroxyl and hydroperoxyl groups in the β-hydroxy hydroperoxides was *trans*, (2) the hydroxyl group was added to the less substituted carbon of the double bond, and (3) the oxygen atom in the hydroxyl group originated mainly from the water molecule, while the oxygen atoms in the hydroperoxyl group originated mainly from molecular oxygen. From these results, we proposed a reaction scheme of: (i) the formation of the hydroxyl radical from water by uranyl acetate-catalyzed photolysis, (ii) the addition of the hydroxyl radical to the double bond, (iii) the combination of the resulted radical with molecular oxygen, and (iv) the hydrogen abstraction of the peroxyl radical to give the product. The scheme was further supported by the photoreaction of 2-methyl-2-butene with bromotrichloromethane in the presence of uranyl acetate, which afforded 3-bromo-3-methyl-2-butanol as the major product.

The dye-sensitized photooxidation and the autoxidation are two major types of the photooxidation of olefins, and they have been interpreted as involving the reaction of singlet oxygen and the initiation by a radical respectively.[2)] Recently several papers on photooxidation through novel types of mechanism have been published. Photooxidations sensitized by dicyanoanthracene,[3)] α-diketones,[4)] or Lewis acids[5)] are some examples.

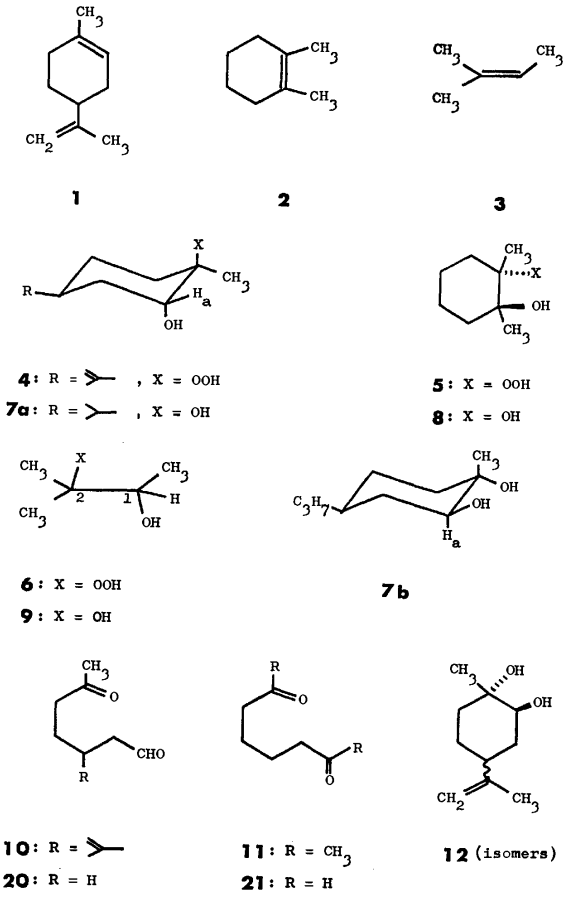
In the course of our study of the metal-catalyzed organic photoreactions,[6)] we found that the photooxidation of olefins in pyridine in the presence of uranyl acetate proceeded in a way quite different from the oxidation processes known so far.

Results and Discussion

Solutions of limonene (**1**), 1,2-dimethylcyclohexene (**2**), or 2-methyl-2-butene (**3**) in pyridine, all containing an equivalent amount of uranyl acetate (dihydrate), were irradiated with Pyrex-filtered light while oxygen was bubbled through, and the products were separated on preparative TLC (silica gel). β-Hydroxy hydroperoxides, **4**, **5**, and **6**, were isolated in a fairly pure state in 14, 8, and 12% yields respectively. The yields of these products, as determined by NMR analyses of the crude reaction mixtures, amounted to 32, 11, and 18% respectively. The compounds **4** and **6** were further purified by vacuum distillation. The structures **4**, **5**, and **6** were assigned on the basis of the spectroscopic and elemental analyses[7)] and the following chemical processes.

Upon the hydrogenation on palladium–charcoal, the β-hydroxy hydroperoxides, **4**, **5**, and **6**, gave 1,2-diols, **7a**, **8**, and **9** respectively, while they afforded C–C bond cleavage products (**10** from **4**, **11** from **5**, and acetone and acetaldehyde from **6**) upon thermolysis or decomposition on silica gel. With a view to elucidating the stereochemistry of **7a**, we hydrogenated a stereoisomeric mixture of *trans*-diol **12**,[8)] and then isolated **7a** and **7b** on a preparative VPC. We assigned the stereochemistry of these isomers as indicated in view of the W_H=6 Hz value of H_a in **7a**, in contrast with the J values of 12 and 4 Hz (doublet of a doublet) for the corresponding proton in **7b**. The reduction product from **4** was identical with **7a**, thus establishing the stereochemistry of **4** to be as shown. The diols, **8** and **9**, were identical with authentic samples prepared by known methods.[9)]

The positional assignments of the substituents in **6** were deduced from the carbon-NMR analyses. While the chemical shifts of the secondary carbons (C_1) in compounds **6** and **9** were fairly close to each other (δ 70.5 for **6** and δ 74.2 for **9**), the signal of the tertiary carbon (C_2) in **6** appeared at a lower field (δ 85.1) than that of the corresponding carbon in **9** (δ 73.4). These observations would definitely support the tertiary



hydroperoxide structure for **6**, and the same regiochemistry was also postulated with compound **4**. Subramanyam *et al.* prepared several β-hydroxy hydroperoxides including **6**, which indicated spectroscopic data very close to ours.[10]

In order to gain an insight into the genuine character of the present reaction, the irradiated materials from **1** and **2** were directly treated with silica gel (to decompose β-hydroxy hydroperoxides) and the products were analyzed by a preparative VPC. A keto aldehyde, **10**, and a ketone, **13**, probable decomposition products of the β-hydroxy hydroperoxides from **1** at the 1,2- and 8,9-positions, were obtained from **1** in 26 and 2% yields respectively, along with three by-products, **12**, **14**, and **15** in 1, 1, and 3% yields respectively. Similarly, **11** was obtained in a 48% isolated yield from **2**, along with several by-products (**16**, **17**, and others; see Reference 2; total yield, 9%). In view of our previous observations,[2] it is evident that these by-products from **1** and **2** are formed through the radical-initiated oxidation. We have also reported that the allyl hydroperoxides, such as **18** and **19** are characteristic products of the singlet-oxygen oxidations of **1** and **2**, but these products were negligible in the present reactions. No observable amounts of any other products were isolated, but we have not examined whether the remainder becomes unextractable polymeric substances or remains intact as the original starting materials. The starting materials, even if they remained at the end of the reaction, could not be detected because they escaped during the work-up procedure of removing the pyridine solvent.

The possibility that the present oxidation might proceed through the uranyl acetate-catalyzed oxidation by singlet oxygen was ruled out in the following way. When solutions of **1** and **2** in *t*-butyl alcohol–water (1 : 1) or in pyridine, containing rose bengal as a sensitizer, were irradiated with a tungsten lamp, oxidation products were obtained with a product distribution typical of singlet-oxygen oxidation.[2] Under these conditions, however, no catalytic effect of uranyl acetate was observed. It was also shown by the experiment with **2** that the present oxidation is not affected by a radical scavenger (tri-*t*-butylphenol).

The same type of reaction seems to proceed with 1-methylcyclohexene and cyclohexene, because these olefins, under the same conditions of irradiation and succeeding decomposition on silica gel, afforded a keto aldehyde, **20**, and a dialdehyde, **21**, in 20 and 6% yields respectively. The yield of **21** was low because of the apparent polymerization during the work-up procedure.

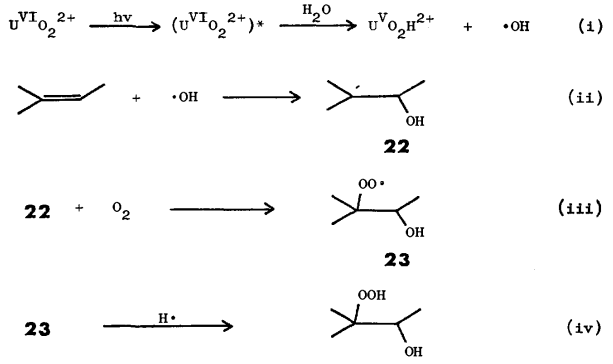
Uranyl chloride in *t*-butyl alcohol–water (1 : 1) also catalyzed the present reaction, although the competitive radical-initiated oxidation process became appreciable under these conditions. However, no appreciable amounts of any products were observed when either of the metal compounds, light, or oxygen was lacking.

With a view to clarifying the reaction mechanism, the sources of the oxygen atoms in the product, **6**, were determined in the following way. The product, **6**, obtained by using oxygen-18 labelled water or molecular oxygen, was directly injected into a gas chromatograph-mass spectrometer, after which the isotope contents

Table 1. Incorporation of oxygen-18 into acetone and acetaldehyde

Condition	^{18}O in acetone (atom % excess)	^{18}O in acetaldehyde (atom % excess)
$^{18}O_2$ (30 atom % excess)–$UO_2(OAc)_2 \cdot 2H_2O$	27	7
O_2–$UO_2(OAc)_2 \cdot H_2{}^{18}O$ (30 atom % excess)	5	20

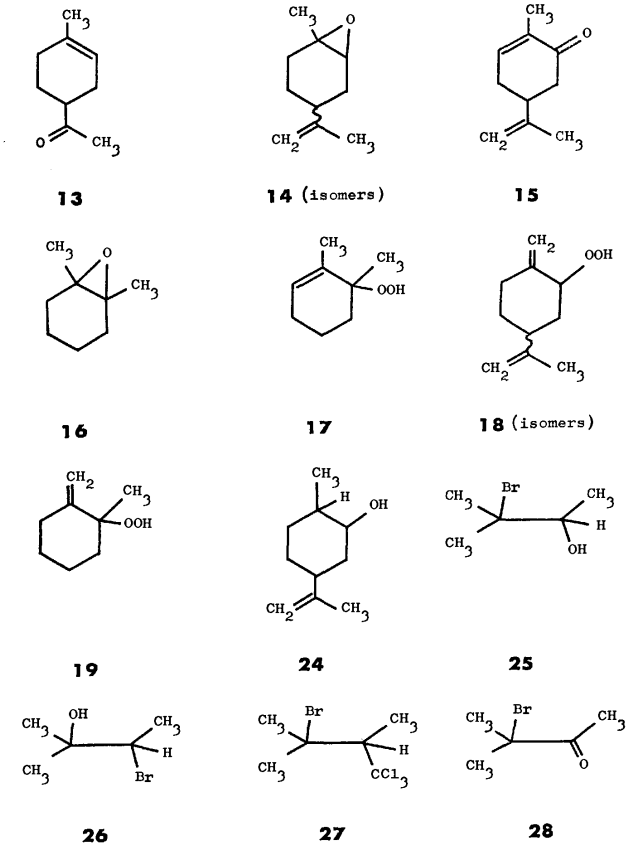
incorporated into acetone and acetaldehyde, the thermolyzed products from **6** in the gas chromatograph, were determined mass-spectrometrically. The results are shown in Table 1. Assuming that no oxygen migration occurs during the thermolysis step of **6**, as has been proposed for the fragmentation of α-hydroperoxy acid,[11] it was concluded that the oxygen atoms in the hydroperoxyl group originated mainly (90%) from molecular oxygen, while the oxygen atom in the hydroxyl group originated, in major part (67%), from the water molecule. We could scheme the major course of the reaction as: (i) the formation of the hydroxyl radical from water by uranyl acetate-catalyzed photolysis; (ii) the addition of the hydroxyl radical to the olefin so as to afford the more stable intermediate; (iii) the combination of the preceeding radical, **22**, with molecular oxygen, and (iv) the hydrogen abstraction of **23** to give the product (Scheme 1).



Scheme 1.

Although the stereo- and regio-chemistry of the present reaction are consistent with the scheme, the fact that the reaction under a lack of oxygen gives no observable products needs further consideration, because some products from the radical **22** (for instance, an alcohol, **24**, through the hydrogen abstraction) should be produced in view of the proposed scheme. The problem could be interpreted in the following way. First, we can assume that Step i is reversible and that, in the absence of oxygen, the back reaction is too fast to allow the hydroxyl radical to be involved in the further reaction. In the presence of oxygen, however, the back reaction might be inhibited due to the oxidation by oxygen of the low-valent uranium compound, and the hydroxyl radical could well survive to be involved in the next step. The reaction shown in Step i has been suggested by Burrows and Kemp[12] in

the uranyl compound-catalyzed photolyses of water, although they failed to detect the hydroxyl radical, supposedly because of the fast back reaction. Alternatively, we can assume that the hydroxyl radical produced in Step i could reversibly add to the olefin, but in the absence of any appropriate substance to trap the radical **22** effectively, the whole reaction does not proceed because of the back reaction in Step i. Presumably the second interpretation is preferable because we observed that the hydroxyl radical could be brought into the reaction, even in the absence of oxygen, as long as a suitable substance to trap the radical **22** is present. We found that bromotrichloromethane serves for this purpose. When a solution of **3** in pyridine containing uranyl acetate and bromotrichloromethane was irradiated with Pyrex-filtered light, two bromohydrins, **25** and **26**, were obtained as a 3: 1 mixture in a 18% yield, along with the addition product, **27**, in a 12% yield. When the irradiation was carried out in the absence of uranyl acetate, **27** was the sole product.[13] The structure of **25** was assigned on the basis of elemental and spectroscopic analyses, and by oxidizing the bromohydrin to α-bromoketone, **28**. The structures **26**[14] and **27**[13] were confirmed by comparing the compounds with authentic samples prepared by known procedures. We found that the ratios of **26**/**25** were independent (≈0.3) of the wavelength of the working light, the amounts of bromotrichloromethane and water, and the presence or absence of some additives, while the ratios of **27**/(**25**+**26**) changed from 0 to 1.2 depending upon the reaction conditions. Although the detailed results will be reported elsewhere, it can be suggested from these observations that **25** and **26** are formed *via* a common intermediate (probably a uranyl-substrate complex). A normal type of the addition of HOBr to the olefin, **3**, is known to occur so as to give **26** selectively;[14] therefore, the abnormal way of addition in the present reaction would be another support for the proposed scheme. Recently we found a photooxidation of olefins in the presence of iron(III) chloride to give chlorinated ketones. These reactions have been speculated[15] as proceeding in a way similar to that shown in the scheme proposed in this paper.



Experimental

General Procedures. The instrumentation was the same as has been described previously.[16] The carbon NMR spectra were determined in a $CDCl_3$ solution on a JEOL JNM-FX 100 spectrometer; the chemical shifts are represented in δ values relative to the internal TMS standard. The isotope incorporations were determined on a Hitachi RMU-6M mass spectrometer equipped with a gas chromatograph.

Unless otherwise stated, a pyridine solution (2—6 mmol, 0.02 M) of olefin containing an equivalent amount of uranyl acetate (dihydrate) was irradiated in Pyrex-glass test tubes with a high-pressure mercury vapor lamp (Ushio UM 452 (450 W)) for 10—90 min while oxygen was bubbled through. After the irradiation, the pyridine was removed *in vacuo* and the reaction products were extracted from the residue with carbon tetrachloride. The extract was filtered, and the solvent was removed *in vacuo*. The residual substance was treated as has been indicated below.

Materials. *a) Unhydrous Uranyl Acetate*: Commercially available uranyl acetate dihydrate (500 mg) was heated at 140 °C under reduced pressure for 30 min, and the resulting yellow powder (459 mg) was used directly for the reactions. *b) Oxygen-18 Labelled Water*: Commercially available $H_2{}^{18}O$ (96.5 atom% excess, Merck Sharp and Dohme Canada, Ltd., Lot No. B-863) was diluted with ordinary water to a concentration of 30 atom % excess of ^{18}O. *c) Oxygen-18 Labelled Molecular Oxygen*: Commercially available $^{18}O_2$ (70 atom % excess, B.O.C. Ltd.) was diluted with ordinary oxygen to a concentration of 30 atom % excess of ^{18}O.

Photooxidation of 1. When the crude oil from 272 mg of **1** was purified by preparative TLC (silica gel, chloroform), **4** was isolated (52 mg, 14%); this was then further purified by vacuum distillation. Bp 45—55 °C (≈10^{-5} mmHg). IR (neat), 3350, 3080, 2930, 1642, 1450, 1378, 1035, 890, and 840 cm^{-1}. NMR (CCl_4), δ 1.22 (3H, s), 1.70 (3H, s), 3.88 (1H, bs), 4.64 (2H, bs), and 4.6—5.9 (2H, bs, shifts upon dilution). Found:[7] C, 64.75; H, 9.11%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%.

When the crude oil was dissolved in chloroform and passed through a silica-gel column (10 cm), an oil was obtained from which five products, **10**, **12**, **13**, **14**, and **15**, were subsequently isolated by preparative VPC. The IR and NMR spectra of **10**[17] and **13**[18] were identical with those of the authentic samples obtained by the known methods. The IR and NMR spectra of **14** and **15** corresponded to those previously reported.[2] The IR and NMR spectra of **12** were identical with those of the samples described below.

Photooxidation of 2. The crude oil from 330 mg of **2** was dissolved in 20 ml water and then washed with hexane. After copper(II) sulfate (3.5 g) had been added to the aqueous layer, the solution was shaken with chloroform. The extract (Extract A) was dried (Na_2SO_4), and the solvent was removed

in vacuo. When the residual substance was purified by preparative TLC (silica gel, chloroform), **5** was isolated (38 mg, 8%). The NMR analysis indicated that the compound contained a small amount of **11**. **5**: in a state containing a small amount of **11**, IR (neat), 3380, 2935, 1372, 1120, and 1060 cm^{-1}. NMR (CCl_4), δ 1.21 (3H, s), 1.27 (3H, s), and 1.2—1.6 (m).

The Extract A obtained from 220 mg of **2** was applied on a silica-gel column (5 cm) and then eluted with chloroform. Upon removing the solvent *in vacuo* from the eluate, crystals of **11** were isolated in a pure state (137 mg, 48%). Mp 24—26 °C (lit,[19] mp 41—42.5 °C). NMR (CCl_4), δ 1.42 (4H, m), 2.03 (6H, s), and 2.33 (4H, dist. t). The IR spectrum was identical with that previously reported.[20]

From the hexane layer, the by-products[2] (40 mg) were obtained (9% total yield).

The same result was obtained (46% yield of **11**) when the reaction was carried out in the presence of tri-*t*-butylphenol (262 mg).

Photooxidation of 3. When the crude oil from 420 mg of **3** was distilled under reduced pressure, **6** was isolated in a pure state (59 mg, 12%). Bp 47—48 °C ($\approx 10^{-5}$ mmHg). IR (neat), 3320, 2980, 1387, 1110, and 835 cm^{-1}. NMR (CCl_4), δ 1.04 (3H, s), 1.07 (3H, d, J=6.4 Hz), 1.16 (3H, s), 3.92 (1H, q, J=6.4 Hz), and 4.8—7.7 (2H, bs, shifts upon dilution). Carbon-NMR ($CDCl_3$), δ 17.3 (q, J=126 Hz), 17.6 (q, J=127 Hz), 21.6 (q, J=126 Hz), 70.5 (d, J=145 Hz), and 85.1 (s). Found:[7] C, 51.20; H, 10.23%. Calcd for $C_5H_{12}O_3$: C, 49.98; H, 10.07%.

Isotope-incorporation experiments were carried out in the following way. A solution of **3** (14 mg) in unhydrous pyridine (10 ml), containing unhydrous uranyl acetate (68 mg) and $H_2{}^{18}O$ (30 atom% excess, 372 mg), was irradiated for 30 min while ordinary oxygen was bubbled through. The crude oil, obtained by means of the work-up described above, was directly injected into the gas chromatograph-mass spectrometer.

Hydrogenation of 4. A solution of **4** (15 mg) in ethanol (5 ml), containing 10% palladium–charcoal (10 mg), was stirred under an hydrogen atmosphere (1 atm) for two days. The oil which remained after the catalyst and solvent had been removed was almost pure **7a**. Preparative VPC gave a pure sample of **7a** which showed spectroscopic data identical with those of the sample described below.

Hydrogenation of 5. A solution of **5** (22 mg) in ethanol (2 ml) was stirred under a hydrogen atmosphere (1 atm) for 20 h in the presence of 10% palladium–charcoal (5 mg). An NMR analysis indicated that the oil remaining after the work-up was a mixture of **8** and **11** (1: 1). The separation was accomplished on a preparative VPC. The IR and NMR spectra of **8** were identical with those of an authentic sample.[9]

Hydrogenation of 6. The hydrogenation in the way described above gave a pure sample of **9**. The IR and NMR data were identical with those of an authentic sample.[9] Carbon-NMR ($CDCl_3$), δ 17.7 (q, J=125 Hz), 22.6 (q, J=125 Hz), 26.5 (q, J=125 Hz), 73.4 (s), and 74.2 (d, J=142 Hz).

Preparation of 7a. A solution of a stereoisomeric mixture of **14**[21] (200 mg) in *t*-butyl alcohol–water (1: 1 by volume, 20 ml), also containing 0.5 M-sulfuric acid (0.2 ml), was stirred at room temperature for 16 h. The reaction mixture was then poured into a saturated aqueous solution of sodium bicarbonate (40 ml) and shaken with chloroform. The extract was dried (Na_2SO_4), and the solvent was removed *in vacuo*. The residual substance was distilled to give a stereoisomeric mixture of **12** (141 mg).[8,22] Bp 95—97 °C (10 mmHg). A solution of the diol **12** obtained above (82 mg) in ethanol (5 ml), containing 10% palladium-charcoal (10 mg), was stirred under a hydrogen atmosphere (1 atm) for 17 h. Preparative VPC after the distillation (94—96 °C (4 mmHg)) gave two stereoisomers, **7a** and **7b**, in a pure state. **7a**: IR (CCl_4), 3650 cm^{-1}. NMR (CCl_4), δ 0.91 (6H, d, J=6 Hz), 1.19 (3H, s), and 3.57 (1H, bs, W_H=6 Hz). **7b**: IR (CCl_4), 3420 cm^{-1}. NMR (CCl_4), δ 0.91 (6H, d, J=6 Hz), 1.11 (3H, s), and 3.52 (1H, dd, J=12 and 4 Hz).

Thermolysis of 4. A solution of **4** (40 mg) in benzene (1 ml) was refluxed for 30 min, and then the solvent was removed *in vacuo*. From the IR, NMR, and VPC analyses, the major part of the residual oil was found to be **10**.,

Thermolysis of 5. A solution of **5** (16 mg) in benzene (2 ml) was refluxed for 1 h, and then the solvent was removed *in vacuo*. From the NMR analysis, the residual oil was found to be **11**.

Thermolysis of 6. A small amount of **6** was injected into a gas chromatograph-mass spectrometer (temperature of the injection port: 260 °C), and the decomposition products were directly analyzed on the mass spectrometer. The two products detected were identified as acetone and acetaldehyde from the mass spectra and the retention times on the VPC.

Photooxidation of 1-Methylcyclohexene. The crude oil from 288 mg of 1-methylcyclohexene was chromatographed on a silica-gel column (chloroform), and **20** (77 mg, 20%) was isolated. The IR and NMR spectra of **20** were identical with those of an authentic sample.[23]

Photooxidation of Cyclohexene. The crude oil from 246 mg of cyclohexene was treated in the way described above; the product thus obtained, **21** (39 mg, 6%), was accompanied by a small amount of a polymerization product of **21**. IR (neat), 2830, 2720, and 1720 cm^{-1}. NMR (CCl_4), δ 1.4—1.8 (4H, m), 2.2—2.8 (4H, m), and 9.57 (2H, t, J=1.5 Hz).

Photoreaction of 3 with Bromotrichloromethane. A solution of **3** (0.5 g) in pyridine (360 ml), containing uranyl acetate (3.1 g) and bromotrichloromethane (2.9 g), was irradiated with Pyrex-filtered light from a high-pressure mercury vapor lamp (Ushio UM 1000 (1 kW)) for 1 h. After the irradiation, the pyridine was removed *in vacuo*. The reaction products were extracted from the residue with chloroform, and the extract was passed through a Florisil column (6 cm) in a chloroform solution. The eluate was washed with a saturated aqueous solution of copper(II) sulfate, and dried over Na_2SO_4, and the solvent was removed *in vacuo*. The residual substance was dissolved in hexane, and the solution was shaken with a cold 2% aqueous solution of sodium bicarbonate. The aqueous layer was shaken with cold chloroform, the chloroform solution was dried (Na_2SO_4), and the solvent was removed *in vacuo* to give a yellow oil (220 mg). From NMR analysis, the oil was found to be a mixture of **25** and **26** (3: 1). The vacuum distillation (bp 40—41 °C (9 mmHg)) did not accomplish the complete separation of the two isomers, and so spectroscopic and elemental analyses were carried out on the mixture. Subtracting the spectra of **26**, which was prepared in a pure state according to the reported method,[14] the spectra of **25** were as follows: IR (neat), 3400, 2975, 1455, 1373, 1112, 942, and 702 cm^{-1}. NMR (CCl_4), δ 1.21 (3H, d, J=6 Hz), 1.68 (3H, s), 1.72 (3H, s), 3.04 (1H, bs), and 3.55 (1H, q, J=6 Hz). Found:[24] C, 36.63; H, 6.58%. Calcd for $C_5H_{11}OBr$: C, 35.95; H, 6.64%.

The hexane layer was dried over Na_2SO_4, and the hexane was removed *in vacuo*. The brown oil was mainly **27** identical with an authentic sample.[13] The yield of **27** was 12%, as determined by NMR analysis, using 1,1,2,2-tetrachloroethane as an internal reference.

Oxidation of 25. The oxidation of the mixture of **25** and **26** obtained above (40 mg) with a Jones reagent was

carried out according to the reported procedure.[14a] α-Bromoketone **28** was obtained, accompanied by unchanged **26**; the spectra of **28** were obtained by subtracting those of **26**. IR[25] (neat), 2975, 1710, 1372, 1360, 1138, and 1104 cm^{-1}. NMR[26] (CCl_4), δ 1.81 (6H, s) and 2.36 (3H, s).

Fluorescence Spectra of 2-Pyridylbenzimidazoles. A Specific Interation of 2-(2-Pyridyl)benzimidazole with Ethanol

Michio KONDO

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140

(Received March 17, 1978)

The fluorescence spectra of 2-(2-pyridyl)- (**1a**), 2-(3-hydroxy-2-pyridyl)- (**1b**), 1-methyl-2-(2-pyridyl)-, 2-(3-pyridyl)-, and 2-(4-pyridyl)-benzimidazole have been studied, and it has been found that their intensities are very strong, except for an ethanolic solution of **1a**. It is likely, therefore, that a specific interaction, probably a bridge-type complexation of **1a** with an ethanol molecule where imidazolic proton is explicitly involved, is responsible for the observed reduction in the fluorescence intensity for ethanol solutions. The fluorescence emission with a large Stokes' shift of **1b** is very strong, in ethanol as well as in other organic solvents tested, indicating a faster intramolecular proton transfer in the excited singlet state than intermolecular deactivation relaxation with ethanol molecules.

The fluorescence and phosphorescence intensities of an aromatic molecule are dependent on the relative alignment of the energy levels of its singlet and triplet states. Therefore, the fluorescence intensity of an aromatic molecule may differ much from those of the isomers. The emission nature of pyrazine, for example, is quite different from those of pyridazine and pyrimidine.[1]

It has been proved in some cases that intramolecular interactions, especially intermolecular hydrogen bonding, between a solvent and a solute molecule in the ground or excited state play an important role in fluorescence emission.[2] This type of interaction seems to be very important in the cases of heteroaromatic compounds, such as acridine, which have been proved to show a remarkable solvent dependence on the emission nature.[3,4]

Recently, it has been reported that pyrrolo[2,3-*b*]-pyridine shows two emission bands in a rather concentrated solution in non-polar solvents as well as in a dilute ethanol solution, and that the emission band at longer wavelengths can be attributed to the isomeric species produced *via* intermolecular proton transposition.[5]

This paper will be concerned with the fluorescence spectra of several 2-pyridylbenzimidazoles in various solvents.

Experimental

Materials. Four compounds, 2-(2-pyridyl)- (**1a**), 2-(3-hydroxy-2-pyridyl)- (**1b**), 2-(3-pyridyl)- (**2**), and 2-(4-pyridyl)-benzimidazole (**3**), were prepared by the condensation of *o*-phenylenediamine with an appropriate pyridinecarboxylic acid at elevated temperatures, according to the literature method.[6]

*1-Methyl-2-(2-pyridyl)benzimidazole (**1c**).* To a dried dimethyl sulfoxide solution (20 ml) containing sodium hydride (1/50 mol) was added **1a** (1/200 mol) under nitrogen purging. The solution was slowly heated up to 85 °C and, then kept for 30 min to yield a dark brown solution. To this solution, cooled in an ice-water bath, methyl iodide (1/50 mol) was added in portions, with care taken not to raise the solution temperature above 30 °C. The reaction mixture was then poured into water (500 ml), resulting in an oil-suspended aqueous solution. The oil was extracted with ethyl acetate. The subsequent evaporation of the solvent yielded a pale yellow oil which crystallized with treated with a glass rod. The pale yellow fine solids were charged on an alumina column and eluted with benzene. The evaporation of the solvent gave fine colorless crystals (**1c**): mp 64—65 °C; Found; C, 68.75; H, 5.30; N, 18.39%. Calcd for $C_{13}H_{11}N_3 \cdot H_2O$: C, 68.72; H, 5.72; N, 18.50%.

Spectral Measurements. The absorption and fluorescence spectra were recorded on a Hitachi spectrophotometer, Model 356, and a Hitachi fluorescence spectrophotometer, Model MPF-2, respectively, both at room temperature. Cyclohexane and 1,2-dichloroethane of a spectral grade and diethyl ether, benzene, and ethanol of a guaranteed grade were used without further purification.

TABLE 1. ABSORPTION AND FLUORESCENCE SPECTRAL DATA OF THREE 2-PYRIDYLBENZIMIDAZOLES (**1a**, **2**, AND **3**) IN VARIOUS SOLVENTS

Compd	Solvent[a]	Absorption		Fluorescence[b]	
		λ_{max}(nm)[c]	ε	λ_F (max)	I_{rel}[d]
1a	CH	311.5	25400	349.0	15
	Benzene	312.0	23100	357.0	11
	DCE	310.5	22600	359.0	10
	EE	310.0	23300	352.0	19
	Ethanol	309.0	20500	358.0	1
2	CH	314.5	20500	355.0	22
	Benzene	311.0	19700	352.5	15
	DCE	310.0	20000	354.5	17
	EE	309.0	21500	347.5	26
	Ethanol	312.0	20100	360.0	16
3	CH	310.0	20900	358.0	11
	Benzene	309.0	20900	357.0	9
	DCE	306.5	20900	363.0	13
	EE	306.0	23200	352.0	12
	Ethanol	306.5	20700	372.5	14

a) CH, DCE, and EE stand for cyclohexane, 1,2-dichloroethane, and ethyl ether respectively. b) The concentrations were 4.23×10^{-6}, 4.20×10^{-6}, and 4.22×10^{-6} M for **1a**, **2**, and **3** respectively. The excitation wavelength of 310 nm was selected. c) The vibrational structures in the absorption and emission spectra were observed for cyclohexane solutions, but not for most of the other solutions. Therefore, the $0 \rightarrow 1'$ and $0' \rightarrow 1$ transition components are recorded here as the band peak for the sake of easy comparison. d) The relative intensity was given as the ratio of the peak height to that for an ethanol solution of **1a**.

Results and Discussion

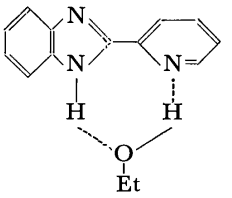
Fluorescence Spectra of Three 2-Pyridylbenzimidazoles, 1a, 2, and 3. Table 1 summarizes the results of the absorption and emission spectral measurements of **1a**, **2**, and **3** in various organic solvents.

The observed red shifts and the enhancement of the molar extinction coefficients for the first absorption bands of these compounds, as compared with those for benzimidazole,[7] indicate the complete conjugation of the pyridyl substituent with the benzimidazole moiety.

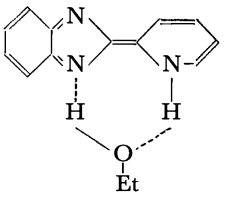
It is possible to say that the fluorescence bands of these compounds are not separated much from, and take mirror images with, the absorption band, indicating that the molecular conjugations in the excited singlet states differ little from those in the ground states. The fluorescence spectra were found to be independent of the excitation wavelengths and of the concentration.

The fluorescence intensities of these compounds are very strong and of the same order of magnitude, except for the case of **1a** in ethanol. It is noteworthy that benzene did not quench the fluorescence emission of these compounds, taking into account the quenching interactions between benzene and indole,[8] where the NH group has been suggested as being essential. The absence of any quenching effect of benzene in the present case is probably to be ascribed to: (i) the presence of a rather bulky pyridyl group, which is believed to prohibit the benzene molecule from interacting with the NH group and (ii) a stronger interaction of the NH group with the pyridine-N atom internally (**1a**) or intermolecularly (**2** and **3**) than with the benzene solvent molecules.

It is of interest that the fluorescence intensity of **1a** in an ethanol solution is much weaker than in cyclohexane. Figure 1 shows the quenching effect of ethanol on the fluorescence spectrum of **1a** in the binary solvent system of cyclohexane and ethanol. From the figure it is clear that ethanol molecules effectively quench the fluorescence emission of **1a**. By plotting the fluorescence intensities *versus* the quencher concentration, a value of 0.05 mol/l was obtained for the quencher efficiency of ethanol. This value is comparable with that reported for the chloroform–indole in cyclohexane.[8] On the other hand, ethanol molecules did not quench the emission of **2** and **3**. From these observations it is possible to assume that the fluorescence quenching by ethanol does not originate from a simple intermolecular hydrogen bonding, but from a specific bridge-type intermolecular hydrogen bonding, which is possible only for a combination of ethanol and **1a** which has two nitrogen atoms in a proper proximity. The specific bridge-type intermolecular hydrogen bonding is shown schematically in **A**. As can readily be expected from the figure, this type of intermolecular hydrogen bonding is impossible between an ethanol molecule and **2** or **3**.



A



A'

A similar quenching effect, of course, is commonly observed for some alcoholic solutions of **1a**. The fluorescence intensity of **1a** in some alcoholic solutions is in this order: MeOH<EtOH<*n*-PrOH<*n*-BuOH (Table 2). This order is inversely proportional to the proton exchange activity of the hydroxyl group.

TABLE 2. SPECTRAL PARAMETERS OF **1a** IN VARIOUS ALCOHOLS AT ROOM TEMPERATURE (21±1 °C)[a]

Solvent	Absorption		Emission		
	λ_{max}	ε	λ_{ex}	λ_F(max)	I[b]
Methanol	308	21100	300	362	1.0
Ethanol	309	20500	300	358	1.4
Propanol	310	21100	300	356	1.7
Butanol	311	20800	300	354	2.1

a) Solutions were prepared by diluting a cyclohexane solution of **1a** with an appropriate alcohol, the resultant concentration being 1.48×10^{-5} M. b) The relative intensities of the emission bands were estimated from the ratio of the peak height to that of the methanol solution. The small difference in the molar extinction coefficients was neglected.

Molecular Mechanism of Fluorescence Quenching by Ethanol. Compound **1c** is similar to **1a** except for the replacement of the imidazolic proton by the methyl group. Consequently, it is unable to form a hydrogen-bonded complex like **A** with an ethanol molecule; thus it can serve as a convenient control for the experiments with **1a**. As would be expected, the absorption and fluorescence spectra of **1c** are very similar to those of **1a** (an ethanol solution; λ_{max}=304 nm, ε=20300, λ_F(max)=361 nm).

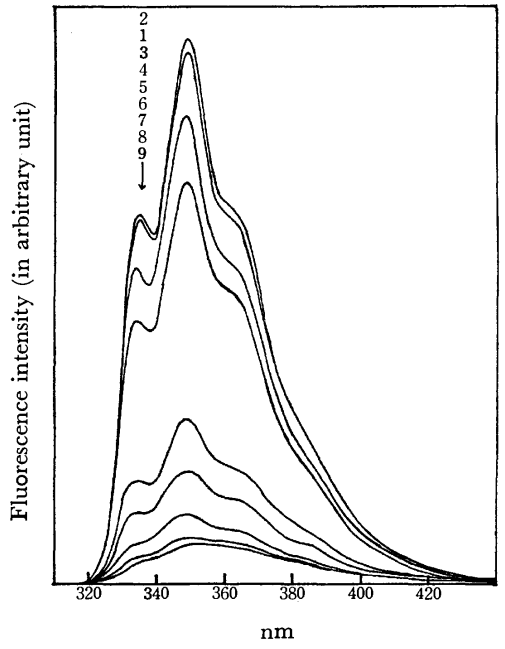


Fig. 1. Fluorescence spectrum of 2-(2-pyridyl)benzimidazole in cyclohexane–ethanol binary solvents (1.6×10^{-5} M, excitation at 310 nm). Ethanol contents are: 1, 0; 2, 0.01; 3, 0.05; 4, 0.1; 5, 0.5; 6, 1.0; 7, 2.0; 8, 5.0; and 9, 10.0.

This means that the molecular configuration of **1c** is very similar to that of **1a** in both the ground and the excited singlet states, except for the inability to form a specific bridge-type complex with an ethanol molecule. As expected, therefore, no serious fluorescence quenching by ethanol molecules was observed for **1c**, when solvents were changed from cyclohexane to ethanol.

It is clear, therefore, that the NH group in the imidazole moiety is explicitly involved in quenching the fluorescence of **1a** by ethanol.

A molecular complex like **A** has been proposed for pyrrolo[2,3-*b*]pyridine in ethanol. In that system, the second fluorescence band was observed at a longer wavelength and was ascribed to the isomeric species which was produced by proton transposition *via* the ethanol molecule being intermolecularly hydrogen bonded.[5] In the present case, however, it is not clear whether or not a similar isomerization occurs through intramolecular proton transposition like that, because no second fluorescence band was observed at any longer wavelength.

As a tentative explanation of the molecular mechanism in the fluorescence quenching of **1a** by ethanol, the present author proposes a proton exchange in the excited singlet state between the solute and solvent molecules in the bridge-type complex, **A**. In the case of ethanol solutions of **2** and **3**, an ethanol molecule can not form a bridge-type complex like **A**. Therefore, it is reasonable that no fluorescence quenching was observed for ethanol solutions of **2** and **3**.

Table 3. Relative fluorescence intensities (R) of **1a**, **2**, and **3** in phosphate buffers at pH 6.8

Compound	Concentration	Excitation	R[a]
1a	2.82×10^{-5} M	320 nm	0.73
2	2.05	300	0.44
3	2.21	320	0.90

a) The R value for an ethanol solution of **1a** at the same concentration was assumed to be 1. The difference in light intensities at 300 and 320 nm was taken into consideration in calculating R.

In the case of aqueous solutions of **1a**, **2**, and **3**, the fluorescence intensities are as weak as that of **1a** in ethanol (Table 3). This implies that a proton transposition-isomerization like that proposed for pyrrolo[2,3-*b*]-pyridine is not responsible for the fluorescence quenching in question, because such a proton-transposed isomer (like **A'**) can not be written for **2**. In aqueous solutions of **2** and **3**, the concerted operation of water molecules makes it possible to exchange protons through polymeric aggregates of water molecules.

Recently Kikuchi *et al.*[9] proposed a transient proton transfer as an internal conversion mechanism for the system of naphthol and pyridine.

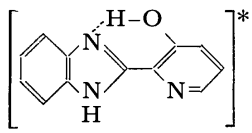
Rapid Proton Transfer in the Excited Singlet State of ***1b***. The first absorption band and the fluorescence band of **1b** in various solvents are listed in Table **4**. The absorption band of **1b** is located at a longer wavelength than that of **1a** in any solvent, primarily because of the effect of the OH-group introduction, but also partly because of its intramolecular hydrogen bond between the

Table 4. Absorption and fluorescence spectral data of **1b** in various solvents

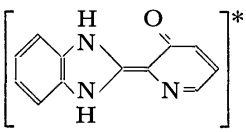
Solvent	Absorption[a]		Fluorescence[b]	
	$\lambda(0\rightarrow0')$	ε	λ_F(max)	I_{rel}
CH	344.5	30000	457	1.0
Benzene	342.5	28300	452	1.0
DCE	343.0	25300	448	1.3
EE	345.9	26700	450	1.4
Ethanol	342.0	25500	442	1.4

a) The concentration was 2.26×10^{-5} M. b) The concentration was 4.53×10^{-6} M.

phenolic hydroxyl and the N-3 atom. The observed large Stokes' shift (*ca.* 9000 cm^{-1}) of the emission band can be attributed to an isomeric species, **K**, which is formed by the intramolecular proton transfer shown schematically below:



E



K

From the table it is clear that the fluorescence intensity of **1b** in ethanol is as strong as in the other solvents examined. This indicates that no serious quenching by ethanol operates and that the intramolecular proton transfer in the excited singlet state occurs in a very short period, within which hardly no quenching by ethanol occurs. In this connection, the rate of the intramolecular proton transfer has been reported to be 1.1×10^{10} s^{-1} for 2,4-bis(dimethylamino)-6-(2-hydroxy-5-methylphenyl)-1,3,5-triazine.[10] If the same proton-transfer rate is assumed in the present case, the ethanol-quenching rate can be roughly estimated as 1×10^{9} s^{-1} or less, because no quenching effect of ethanol was observed.

The Binding and Catalytic Properties of a Positively Charged Cyclodextrin

Yoshihisa MATSUI* and Akihiko OKIMOTO

Department of Agricultural Chemistry, Shimane University, Nishikawazu, Matsue 690

(Received March 20, 1978)

In order to learn the significance of electrostatic interactions between charged groups in an enzymatic process, a positively charged cyclodextrin, mono-(6-trimethylammonio-6-deoxy)-β-cyclodextrin hydrogencarbonate (βCDtma), was prepared as a simple enzyme model, and its binding and catalytic properties were examined. The dissociation constant for an inclusion complex of βCDtma with an azo dye, sodium 4-(4-hydroxy-1-naphthylazo)-1-naphthalenesulfonate (**1**), was found to be 5.4×10^{-5} mol/dm^3 in an alkaline solution (pH 10.5, $I_c=0.0$ mol/dm^3) at 25 °C, the value being smaller than that for an inclusion complex of the parent β-cyclodextrin (βCD) with **1** by a factor of *ca.* 4. The catalytic effect of βCDtma on the alkaline hydrolyses of *o*-, *m*-, and *p*-acetoxybenzoic acids was significantly different from that of βCD. These observations were explained in terms of electrostatic and hydrophobic interactions between βCDtma and a guest molecule.

Cyclodextrin (CD) is a cyclic oligomer composed of six (αCD), seven (βCD), or more α-D-glucopyranose units linked 1→4 as in amylose. The interior cavity of the doughnut-shaped molecule provides a relatively hydrophobic environment into which an apolar molecule can be trapped.[1,2] Since the rate and stereochemistry of a reaction for an organic substrate are significantly changed by the formation of a CD–substrate adduct, CD has been utilized as a simple model for an enzymatic process.[2-4] However, an enzyme is a macromolecular electrolyte, whereas CD contains no charged group in the molecule. Electrostatic interactions between charged groups play an important role in an enzymatic system.[5-7] For example, they contribute not only to strengthening the binding of a specific substrate to an enzyme, but also to orienting the substrate properly in the active site of the enzyme.[8]

In the present work, a positively charged CD, mono-(6-trimethylammonio-6-deoxy)-β-cyclodextrin hydrogencarbonate (βCDtma), was prepared as a simple model of an enzyme containing a positively charged group in the vicinity of the active site. This molecule bears two binding sites, one being the hydrophobic cavity of the βCD ring, and the other, the cationic part of the ammonium ion. Focusing our attention on the cooperative action of the two binding sites, we examined the binding and catalytic properties of the modified CD in an aqueous solution. In this connection, Tabushi *et al.*[9] have recently reported that a CD flexibly capped with a metal ion can effectively bind a hydrophobic anion in such a manner as to facilitate cooperative double recognition.

Experimental

Materials. The βCD of a reagent grade was recrystallized from water and dried overnight *in vacuo* at 110 °C. Pyridine of a reagent grade was dried over calcium hydride and was distilled in the presence of fresh calcium hydride just before use. *p*-Toluenesulfonyl chloride of a reagent grade was used without further purification. *N,N*-Dimethylformamide (DMF) of a reagent grade was dried over K_2CO_3 and distilled in the presence of calcium hydride *in vacuo*. A solution of trimethylamine in DMF was prepared by introducing the gaseous trimethylamine to DMF. The concentration of trimethylamine in DMF was determined by titration with 0.1 mol/dm^3 oxalic acid. An azo dye, sodium 4-(4-hydroxy-1-naphthylazo)-1-naphthalenesulfonate (**1**), was prepared and purified as has been described previously.[10] *o*-Acetoxybenzoic acid (**2o**) of a reagent grade was used without purification. The *m*- and *p*-acetoxybenzoic acids (**2m** and **2p** respectively) were prepared by the reactions of the corresponding hydroxybenzoic acids with acetic anhydride in dry pyridine and were recrystallized from chloroform.

Thin-layer chromatography (TLC) was performed on silica gel G (Merck) with a mixed solvent of acetic acid–chloroform–water (80: 10: 10 (v/v)). A solution of diphenylamine (0.1 g), aniline (0.1 ml), and 85% phosphoric acid (1 ml) in acetone (10 ml) was used as a spray reagent to detect the parent and the modified βCD.

Apparatus. The absorption and NMR spectra were recorded using a Hitachi Model 124 spectrophotometer and a JEOL Model JNM-MH-100 NMR spectrometer respectively. The pH of each aqueous solution was measured by means of an Orion Model 801A digital pH/mV meter.

Preparation of βCDtma. A solution of *p*-toluenesulfonyl chloride (3.65 g, 19.1 mmol) in dry pyridine (30 ml) was added to a solution of βCD (29.60 g, 26.1 mmol) in dry pyridine (300 ml) cooled below 5 °C. After stirring overnight at room temperature, the mixture was evaporated *in vacuo* at 40 °C to dryness. Diethyl ether (700 ml) was added to the residue. The precipitate was collected and recrystallized three times from water to afford 10.37 g (8.0 mmol; yield, 31% based on βCD) of mono-(6-*O*-*p*-tolylsulfonyl)-β-cyclodextrin (βCDots). The TLC of the product gave a spot with R_f 0.38 (*cf.* R_f 0.26 for βCD). The monosubstitution of βCD was confirmed by the PMR spectra of the product in DMSO-d_6.[11] The βCDots (10.27 g, 7.9 mmol) was dissolved in 300 ml of DMF containing 3.2 mol/dm^3 trimethylamine. After being heated overnight at 90—100 °C in sealed tube, the mixture was evaporated *in vacuo* to dryness. The residue was dissolved in 10 ml of water and then chromatographed on a 4.5×43 cm carboxymethylcellulose column, with 0.05 mol/dm^3 ammonium hydrogencarbonate buffer as the eluant. One hundred and sixty fractions were taken, each being 10 ml. The fractions were assayed for carbohydrate by TLC. Fractions which gave only one spot with R_f 0.15 (the fractions from No. 75 to No. 150) were combined and evaporated to dryness at 40 °C *in vacuo* to afford 4.07 g (3.3 mmol; yield, 42% based on βCDots) of the product, βCDtma, as a white powder. The NMR spectra of the product in D_2O showed absorptions at $\delta=3.05$ due to the trimethyl hydrogens and at $\delta=4.97$ due to the anomeric hydrogens of the glucopyranose rings. The relative areas of these peaks were about 9: 7, indicating the monosubstitution of βCD.

An apparent dissociation constant (K_d) for a βCDtma-**1**

inclusion complex and an apparent acid-dissociation constant (K_a) for **1** in both the absence and presence of βCDtma were spectrophotometrically determined as has been described previously.[10] The aqueous buffer solutions used were citric acid–Na_2HPO_4 (pH 3—7), KH_2PO_4–$Na_2B_4O_7$ (pH 6—9), and $Na_2B_4O_7$–NaOH (pH 9—12).

Kinetics. The rates of the alkaline hydrolysis of acetoxybenzoic acids (**2**) were measured by following the appearance of the absorptions of the corresponding phenoxide anions at 300, 310, and 280 nm for **2o**, **2m**, and **2p** respectively in alkaline aqueous solutions. The ionic strength (I_c) of the solution was maintained at 0.65 mol/dm³ with Na_2SO_4. In a typical run, 2.00 ml of a base solution was pipetted into a pair of 1.00-cm quartz cells, one of which was used as the reference cell, and the other, as the sample cell, in a spectrophotometer. After thermal equilibrium at 25.0±0.1 °C had been reached, 5 to 8 μl of a 0.06 to 0.14 mmol/dm³ ester solution in ethanol was added to the sample cell and the change in absorbance was followed. The results for various reaction times were treated according to the ordinary first-order rate equation. The rate constants were graphically determined. All the reactions examined obeyed good first-order kinetics with respect to substrates in both the absence and presence of βCDtma.

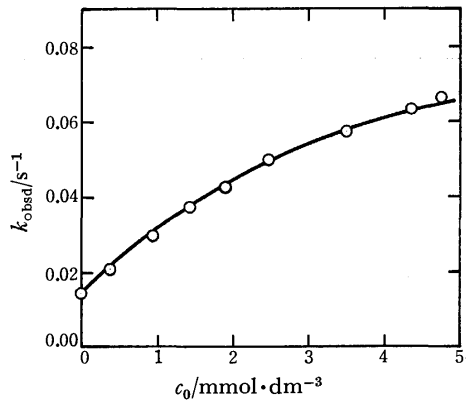

Fig. 1. The plot of k_{obsd} *vs.* c_0 for a βCDtma–**2m** system in 0.0105 mol/dm³ NaOH at 25 °C and I_c=0.65 mol/dm³.

Kinetic Determination of the Dissociation Constants and Rate Constants of βCDtma–2 Complexes. As is shown in Fig. 1 as an example, the observed first-order rate constant (k_{obsd}) for each substrate examined approached a maximum value as the βCDtma concentration (c_0) increased. This saturation behavior suggests that the rate process involves the prior formation of an inclusion complex of βCDtma with each substrate. Upon the assumption of the formation of a 1:1 βCDtma–**2** complex, k_{obsd} is represented by the following equation if c_0 is much higher than that of a substrate (s_0):

$$k_{obsd} = -\frac{K_d(k_{obsd}-k_{un})}{c_0} + k_c. \quad (1)$$

In this equation, k_d is the dissociation constant of an inclusion complex, and k_{un} and k_c, the rate constants for free and complexed substrates respectively. The plot of k_{obsd} *vs.* $(k_{obsd}-k_{un})/c_0$ was virtually linear for each βCDtma–**2** system; the values of K_d and k_c were calculated from the slope and intercept respectively of the line obtained by the use of the least-squares method.

Results and Discussion

Apparent Dissociation Constants for βCDtma–Azo Dye Inclusion Complexes. In order to learn the role of a positively charged group in the binding properties of βCDtma, the apparent dissociation constants (K_d) were determined for the βCDtma– and βCD–azo dye systems. Sodium 4-(4-hydroxy-1-naphthylazo)-1-naphthalenesulfonate (**1**) was used as an azo dye, since the dye shows a large spectral change upon being included within the βCD cavity.[10] In fact, the addition of βCDtma to an aqueous solution of **1** caused a large spectral change, one which is quite similar to that caused by the addition of the parent βCD. An isosbestic point was observed at 438 nm for a solution at pH 4.0 or at 445 nm for a solution at pH 10.5. These observations suggest that **1** forms a 1:1 inclusion complex with βCDtma in a manner similar to that with βCD in an aqueous solution. Table 1 shows the K_d values for the βCDtma– and βCD–**1** systems at the pH values of 4.0 and 10.5. The pK_a value of **1** is *ca.* 7.5 (see Table 2), so the acidic hydroxyl group of **1** is mostly undissociated at pH 4.0, while it is mostly dissociated at pH 10.5. The K_d value for a βCDtma–**1** system is larger than that for a βCD–**1** system at pH 4.0, whereas the former is smaller than the latter at pH 10.5.

Table 1. The K_d values for βCDtma– and βCD–**1** systems at 25 °C and I_c=0.03 mol/dm³

pH	K_d/(mmol/dm³)		K_d(βCD)/K_d(βCDtma)
	βCDtma	βCD	
4.0[a]	0.767	0.508	0.66
10.5[b]	0.096	0.195	2.03

a) Citric acid–Na_2HPO_4 buffer. b) $Na_2B_4O_7$–NaOH buffer.

The modification of βCD to the positively charged form resulted in a decrease in the stability of an inclusion complex with the undissociated form of **1**. A decrease in the hydrophobicity of the interior cavity of the CD ring, as well as a change in the geometry of the inclusion complex, with the modification of βCD may be the cause of the decrease in the stability of the inclusion complex. In this connection, we previously suggested[10] that the 4-hydroxy-1-naphthylazo moiety of **1**, rather than the 4-sulfonato-1-naphthylazo moiety, is bound to the βCD cavity, mainly through hydrophobic interactions. If βCDtma also includes the 4-hydroxy-1-naphthylazo moiety of **1**, a decrease in the hydrophobicity of the CD cavity, accompanied by the close location of a positive charge, may be responsible for the decrease in stability. In such a mode of binding, the negatively charged sulfonate group is too remote in position from the positive charge of βCDtma to enhance effectively the association of **1** with the host by means of the electrostatic force of attraction. It is also possible that the 4-sulfonato-1-naphthylazo moiety of **1**, instead of the 4-hydroxy-1-naphthylazo moiety, is included in the cavity of βCDtma. In this case, electrostatic interactions may contribute considerably to the association, while

the contribution of hydrophobic interactions to the association may significantly decrease. In either event, electrostatic interactions can scarcely cooperate with hydrophobic interactions in the present host-guest system.

On the other hand, the dissociated form of **1** is bound to the βCDtma *ca.* two times more strongly than the parent βCD. This fact suggests that electrostatic interactions between the positive charge of βCDtma and the negative charge of the naphthyloxide anion of **1** cooperate with hydrophobic interactions between the βCD cavity and the naphthylazo moiety in this case. A similar extent of binding enhancement due to electrostatic interactions has recently been reported in differently modified CD-substrate systems.[9]

Effect of the Ionic Strength on the K_d Values for the βCDtma- and βCD-1 Systems. In order to determine which electrostatic or hydrophobic interactions contribute more to the association of the modified βCD with **1**, the effect of the ionic strength (I_c) on the K_d values was examined for inclusion complexes at the pH values of 4.0 and 10.5. An increase in I_c generally weakens ion-ion and ion-dipole interactions,[12] while it strengthens hydrophobic interactions (salting-out effect).[13] Figures 2 and 3 show the plots of log K_d *vs.* $I_c^{1/2}$ for complexes of βCDtma and the parent βCD with **1** at pH 4.0 and at pH 10.5 respectively. Each plot is virtually linear. The K_d values increase with an increase in I_c for the βCDtma–**1** systems, whereas they decrease with an increase in I_c for the parent βCD–**1** systems at both pH's. These observations suggest that electrostatic, rather than hydrophobic, interactions play a dominant role in the association of βCDtma with **1**, while the reverse is true for the βCD–**1** systems. The extrapolation of the linear log K_d *vs.* $I_c^{1/2}$ plot to the intercept gives the K_d value (K_d°) at $I_c=0$ mol/dm³. The K_d° values for the βCDtma- and βCD–**1** systems at pH 10.5 were equal to 5.4×10^{-5} and 2.2×10^{-4} mol/dm³ respectively, indicating that the βCDtma binds the anionic **1** four times more strongly than the parent βCD does at $I_c=0$ mol/dm³.

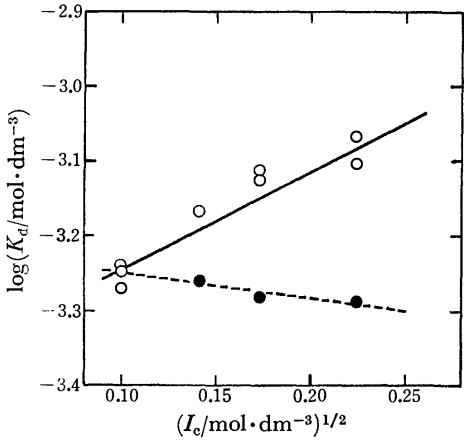

Fig. 2. The effect of I_c on the K_d value for βCDtma–**1** (○) and βCD–**1** (●) systems at pH 4.0 and 25 °C.

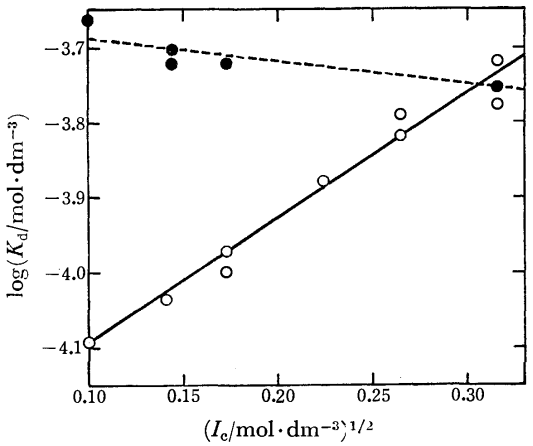

Fig. 3. The effect of I_c on the K_d value for βCDtma–**1** (○) and βCD–**1** (●) systems at pH 10.5 and 25 °C.

TABLE 2. THE EFFECT OF βCDtma ON THE pK_a VALUE OF **1** AT 25 °C AND I_c=0.04 mol/dm³

[βCDtma] / mmol/dm³	pK_a
0.00	7.50
0.48	7.00
0.95	6.87

Effect of βCDtma on the Apparent pK_a *Values of* **1**. In a protein–[14] or micellar–[15] dye system, it has frequently been shown that charged groups around a binding site significantly affect the pK_a value of a bound dye. The apparent pK_a values for **1** in the absence and in the presence of βCDtma were spectrophotometrically measured at I_c=0.04 mol/dm³ (Table 2). The observed pK_a values decrease with an increase in the βCDtma concentration. A similar decrease in pK_a has been observed in a βCD–**1** system at I_c=0.05 mol/dm³.[10] However, the extent of the decrease in pK_a is greater in a βCDtma–**1** system than in a βCD–**1** system. For example, the addition of only 0.95 mmol/dm³ βCDtma lowered the pK_a from 7.50 to 6.87, while the addition of 2.02 mmol/dm³ βCD decreased the pK_a only to 7.02. The pK_a value for an inclusion complex between βCDtma and **1** was calculated, by the use of Eq. 7 in Ref. 10, to be 6.60 at I_c=0.04 mol/dm³ (*cf.* pK_a=6.97 for a βCD–**1** complex at I_c=0.05 mol/dm³ [10]). It is apparent that the acid dissociation of **1** is facilitated to a greater extent by the formation of an inclusion complex with βCDtma than by the formation of a complex with the parent βCD. This fact may also be related to the electrostatic action of a positive charge in βCDtma.

Effect of βCDtma on the Alkaline Hydrolysis of **2**. In order to learn the effect of a positive charge on the catalytic properties of βCDtma, kinetic parameters were determined for the alkaline hydrolysis of **2** in the absence and in the presence of βCDtma. The substrates bear a carboxylate anion in alkaline solutions, so that it can be anticipated that the catalytic action of the positively charged βCDtma is significantly different from that of the parent βCD. The parameters for βCDtma and βCD systems are compared with each other in Table 3.

Table 3. Kinetic and equilibrium parameters for βCDtma- and βCD-acetoxybenzoic acid systems in alkaline solutions at 25 °C and I_c=0.65 mol/dm³

Substrate	Catalyst	$10^3 k_{un}$ / s^{-1}	$10^3 k_c$ / s^{-1}	k_c/k_{un}	K_d / mmol/dm³
2o[a]	βCDtma	1.89	4.25	2.25	2.29
2o	βCD	1.89	14.5	7.67	12.4
2m[b]	βCDtma	14.4	136	9.44	6.39
2m	βCD	14.4	58.1	4.03	4.40
2p[c]	βCDtma	1.51	1.99	1.32	0.528
2p	βCD	1.51	1.93	1.28	2.08

a) 0.0098 mol/dm³ NaOH. b) 0.0105 mol/dm³ NaOH. c) pH 10.84 ($Na_2B_4O_7$–NaOH buffer).

The effects of the modification of βCD on the kinetic and equilibrium parameters for the alkaline hydrolyses of **2o**, **2m**, and **2p** are markedly different from one another. The K_d values for the βCDtma–**2o** and –**2p** systems are smaller than those for the parent βCD–**2o** and –**2p** systems respectively, while the K_d value for a βCDtma–**2m** system is larger than that for the corresponding βCD system. An increase in the electrostatic attraction force does not always result in an increase in the stability of a host-guest complex. It seems that the K_d value depends on the geometry of the inclusion complex, in which electrostatic interactions contribute either favorably or unfavorably to the stabilization of the complex.

The k_c value for a βCDtma–**2o** system is smaller than that for a parent βCD–**2o** system, while that for a βCDtma–**2m** system is larger than that for the corresponding βCD system. The k_c values for βCDtma- and βCD–**2p** systems are virtually equal to each other. The value of k_c/k_{un} is a measure of the proximity between the catalytic and the reaction sites of an inclusion complex.[16] The catalytic site of the complex is an alkoxide ion derived by the acid dissociation of a secondary hydroxyl group of βCD. The reaction site is an ester carbonyl carbon. The significant change in the k_c/k_{un} ratio of the **2o** and **2m** systems with the modification of βCD indicates that the geometries of the βCDtma–**2o** and –**2m** complexes are considerably different from those of the parent βCD–**2o** and –**2m** complexes respectively. The geometry of a βCDtma–**2p** complex may be virtually the same as that of a βCD–**2p** complex. In this connection, the geometries of the βCD–**2o**, –**2m**, and –**2p** inclusion complexes, as well as the changes in the geometries accompanied by the modification of βCD to βCDtma, were presumed to be as is shown in Figs. 4, 5, and 6 respectively; these results

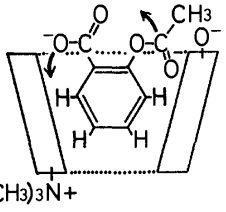

Fig. 4. The geometry of **2o** in the βCD cavity, suggested by the CPK molecular models.

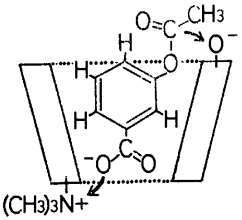

Fig. 5. The geometry of **2m** in the βCD cavity, suggested by the CPK molecular models.

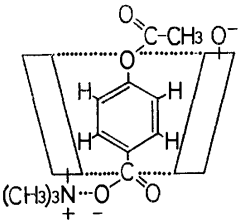

Fig. 6. The geometry of **2p** in the βCD cavity, suggested by the CPK molecular models.

were obtained by the use of the Corey-Pauling-Koltum molecular models. The acetyl groups of **2o** and **2m** may be located in the vicinity of the catalytically active alkoxide ion in their βCD complexes (the k_c/k_{un} values for these complexes are fairly large). In βCDtem–**2o** and –**2m** complexes, the carboxylate anions of the substrates may be electrostatically attracted to the cationic group of βCDtma, as is shown by the arrows in Figs. 4 and 5 respectively. At the same time, the acetyl group of **2o** may go far off from the alkoxide ion on the βCD ring, while that of **2m** may be brought closer to the alkoxide ion. In a βCD–**2p** system, the carboxylate anion of the substrate may lie close to the primary hydroxyl groups of βCD. The modification of one of the hydroxyl groups to the trimethylammonium group may cause little change in the geometry of the substrate in the βCD cavity. However, the electrostatic interaction between the ammonium cation and the carboxylate anion may serve to stabilize a complex of **2p** with βCDtma, compared with that of **2p** with βCD. Therefore, the above observations indicate that electrostatic interactions between a positive charge of βCDtma and a negative charge of a substrate affect not only the stability of the host-guest complex, but also the orientation of the guest in the host molecule. Although the detailed geometry of inclusion complexes remains to be determined, the present host-guest systems are interesting as simple model systems of an enzymatic process.

Stereospecific Synthesis of the C-9—C-16 Segment of Carbonolide B, the Aglycon of Carbomycin B†

Kuniaki TATSUTA,* Toyoaki YAMAUCHI, and Mitsuhiro KINOSHITA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received March 24, 1978)

Stereospecific synthetic routes to methyl (*R*)-7-hydroxy-(2*E*,4*E*)-octadienoate (**9**) and its (2*E*,4*Z*)-isomer (**16**), the former which can be a useful chemical precursor to the 16-membered-ring aglycon of carbomycin B (carbonolide B), are discussed. Compound **9**, corresponding to its C-9—C-16 segment, was synthesized starting with methyl 2-deoxy-α-D-*arabino*-hexopyranoside (**2**). The deoxysugar **2** was converted to the masked 2,4,6-trideoxy-D-*threo*-hexopyranose (**6**) *via* the 4,6-dichloro-2,4,6-trideoxy-α-D-*lyxo*-hexopyranoside derivative. Treatment of **6** with *p*-toluenesulfonyl chloride and triethylamine afforded 3-*O*-acetyl-1,5-anhydro-2,4,6-trideoxy-D-*threo*-hex-1-enitol, which by reaction with mercury(II) acetate was converted to (*R*)-5-hydroxy-(2*E*)-hexenal (**8**). Reaction of **8** with Wittig reagent gave the (2*E*,4*E*)-isomer **9**. Compound **16** was prepared by the Wittig reaction with the 2,3-unsaturated deoxysugar, 2,3,4,6-tetradeoxy-D-*glycero*-hex-2-enopyranose, which was derived from methyl 2,3-anhydro-4,6-dideoxy-α-D-*lyxo*-hexopyranoside by treatment with potassium selenocyanate followed by acid hydrolysis.

In the course of studies directed toward the total synthesis of 16-membered macrolide antibiotics, the regio- and stereoselective introduction of an aminodisaccharide onto the 16-membered aglycon has been reported.[1] Carbomycin B[2] is a representative antibiotic of the 16-membered-ring macrolides, and the structure of the aglycon, carbonolide B (**1a**), can be divided into two segments of C-1—C-8 and C-9—C-16. The latter is stereochemically related to methyl (*R*)-7-hydroxy-(2*E*,4*E*)-octadienoate (**9**), where the C-1 and C-8 carbon atoms correspond to the C-9 and C-16 of carbonolide B. This paper reports the stereospecific synthesis of **9** as an intermediate in the synthesis of carbonolide B using carbohydrates. Recently, a variety of carbohydrates have been used as chiral intermediate in the total synthesis[3,4] of and/or in the synthetic approach[5] to natural products.

The key process was the conversion of 3-*O*-acetyl-1,5-anhydro-2,4,6-trideoxy-D-*threo*-hex-1-enitol (**7**) by mercury(II) acetate to (*R*)-5-hydroxy-(2*E*)-hexenal (**8**), which reacted with Wittig reagent to give **9**. Methyl (*R*)-7-hydroxy-(2*E*,4*Z*)-octadienoate (**16**) was prepared by the Wittig reaction with 2,3,4,6-tetradeoxy-D-*glycero*-hex-2-enopyranose (**15**) in order to provide a reference for **9**.

Results and Discussion

The starting methyl 2-deoxy-α-D-*arabino*-hexopyranoside[6] (**2**) was treated with sulfuryl chloride in pyridine followed by treatment with sodium iodide in aqueous methanol, to give methyl 4,6-dichloro-2,4,6-trideoxy-α-D-*lyxo*-hexopyranoside (**3**). The corresponding 3-*O*-chlorosulfate, which could not be isolated, was considered to be an intermediate.[7] Acetylation of **3** gave a syrupy product **4**, which was dechlorinated with tributylstannane and successively hydrolyzed with dilute hydrochloric acid to give 3-*O*-acetyl-2,4,6-trideoxy-D-*threo*-hexopyranose (**6**). The intermediate methyl 3-*O*-acetyl-2,4,6-trideoxy-α-D-*threo*-hexopyranoside (**5**) was intractable because of its volatility. Conversion of the 2-deoxysugars to the corresponding glycals was achieved by treatment with *p*-toluenesulfonyl chloride in the presence of triethylamine.[1,8] The method was effectively applied to the preparation of 3-*O*-acetyl-1,5-anhydro-2,4,6-trideoxy-D-*threo*-hex-1-enitol (**7**) from **6**. Attempts were unsuccessful to prepare **7** from 2,3-di-*O*-acetyl-4,6-dideoxy-α-D-*xylo*-hexopyranosyl bromide by the usual manner.[9] As **7** was too labile to be purified, it was, without isolation, treated with mercury(II) acetate. This was followed by the addition of dilute sulfuric acid, which gave the syrupy (*R*)-5-hydroxy-(2*E*)-hexenal (**8**)

† Presented at the 37th National Meeting of the Chemical Society of Japan, Yokohama, April 2, 1978.

in a moderate overall-yield. The structure was supported by the characteristic, intense IR absorption at 1695 cm^{-1} and a weak absorption (shoulder) at 1650 cm^{-1}, complemented by a maximum at 223 nm in the UV spectrum. The NMR spectrum provided independent evidence for the open-chain structure of **8**, namely, the doublet at extremely low field (δ 9.62) for H-1, the well-resolved multiplets (δ 6.19 and 6.93) for H-2 and H-3, and the presence of a hydroxyl group (signal at δ 1.80, that disappeared upon addition of D_2O); the large value for $J_{2,3}$ (15.5 Hz) indicated the *trans* position of the olefinic protons. This transformation agrees with expectations based on the reaction of 3,4,6-tri-*O*-acetyl-D-glucal with acidic mercury(II) sulfate.[10] The Wittig reaction of **8** with methoxycarbonylmethylenetriphenylphosphorane provided an 80% yield of the dienoate **9**. The UV and NMR spectra of **9** were very similar to those of ethyl (2*E*,4*E*)-hexadienoate,[11] showing that **9** was a desired (2*E*,4*E*)-isomer implying not only the stereospecific synthesis of the C-9—C-16 segment of carbonolide B but also the utility of the key intermediate, the *trans*-unsaturated aldehyde **8**.

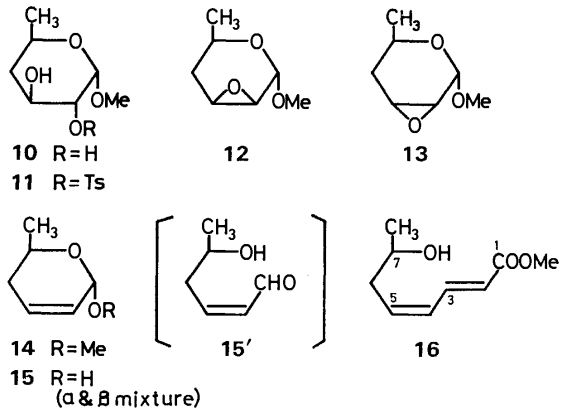

Chart 3.

The (2*E*,4*Z*)-isomer **16** was directly synthesized from the reducing sugar **15** by the Wittig reaction. Selective tosylation of the starting methyl 4,6-dideoxy-α-D-*xylo*-hexopyranoside[12] (**10**) gave predominantly the corresponding 2-*O*-*p*-toluenesulfonate **11** in 72% yield. Treatment of the crude *p*-toluenesulfonate **11**, containing a small amount of the 3-*O*-*p*-toluenesulfonate, with sodium methoxide gave a *ca.* 30: 1 mixture of methyl 2,3-anhydro-4,6-dideoxy-α-D-*lyxo*- and *ribo*-hexopyranosides (**12** and **13**), suggesting that the 3-*O*-*p*-toluenesulfonate was a very minor component. The product **12** could configurationally be a precursor of the C-11—C-16 segment of carbonolide A (**1b**), an aglycon of carbomycin A.[13] Compound **12**, which was isolated as needles, was treated with a boiling solution of potassium selenocyanate[14] in aqueous 2-methoxyethanol for twenty minutes to give methyl 2,3,4,6-tetradeoxy-α-D-*glycero*-hex-2-enopyranoside (**14**). The syrupy product **13**, however, required two hours for the complete reaction to give **14** in the same conditions as described above. Acid hydrolysis of **14** gave a syrupy compound **15**, which was subsequently treated with the Wittig reagent to give the (2*E*,4*Z*)-isomer **16** in 77% overall yield. The structure of **16** was confirmed by UV and NMR spectra in comparison with those of **9** and ethyl (2*E*,4*Z*)-hexadienoate.[11] It appears reasonable on the basis of the above results to suppose that, during the Wittig reaction, the *trans* and *cis* unsaturated aldehydo-forms **8** and **15′**, the latter of which is considered to take part in the reaction of **15** as an intermediate, do not suffer the *trans-cis* and *cis-trans* isomerizations, and the newly produced olefin groups possess the *trans* configuration in both cases.

The utility of the deoxy unsaturated carbohydrates **8** and **15** is thus demonstrated for stereospecific synthesis of α,β: γ,δ-unsaturated esters.

Experimental

Melting points were determined on a micro hot-stage Yanaco MP-S3 and are uncorrected. Specific rotations were measured (0.2-dm tube) with a Carl Zeiss Photoelectric Precision Polarimeter. The NMR spectra were determined with Varian A60, EM-390 or XL100 spectrometers. Unless otherwise stated, chloroform-*d* was used as a solvent and internal tetramethylsilane as a standard. Coupling constants were obtained by measuring spacings of spectra judged to be first-order. TLC and column chromatography were performed on silica gel Wakogel B-5 and Wakogel C-300, respectively. In general, concentration was carried out under reduced pressure below 30 °C.

The starting materials, methyl 2-deoxy-α-D-*arabino*-hexopyranoside[6] [**2**; which was recrystallized from ethyl acetate to give cubics; mp 94—95 °C; $[\alpha]_D^{16}+160°$ (*c* 1.0, CH_3OH)] and methyl 4,6-dideoxy-α-D-*xylo*-hexopyranoside[12] [**10**; which was purified by sublimation at 47 °C at 1 Torr††; mp 108—109 °C, $[\alpha]_D^{24}+179°$ (*c* 1.0, CH_3OH)] were prepared according to the published procedures.

1) Methyl 4,6-Dichloro-2,4,6-trideoxy-α-D-lyxo-hexopyranoside (3). To a stirred solution of **2** (8.91 g) in a dry mixture of pyridine (33 ml) and chloroform (82 ml), cooled in a Dry Ice–acetone bath, was added sulfuryl chloride (21.3 ml) drop by drop over 30 min. Cooling was continued for a further 2 h, after which the reaction mixture was allowed to stand at room temperature overnight. The resulting precipitate, possibly of pyridine salts, was filtered from the chloroform solution. The filtrate was washed successively with 10% sulfuric acid, saturated $NaHCO_3$ solution and water, dried (Na_2SO_4), and evaporated to give an oil. To a methanolic solution (200 ml) of the oil was added a solution of sodium iodide (6.60 g) in 50% aq methanol (16 ml). The mixture was vigorously stirred for 2 h at room temperature and then neutralized with $NaHCO_3$ (11.7 g). The resulting precipitate was removed by filtration, the filtrate evaporated, and the residue chromatographed on a column of silica gel (500 g) with benzene–ethyl acetate (3: 1). The eluate containing the major product (R_f 0.40 by TLC with the same solvent system) was evaporated to give a solid that was further purified by recrystallization from hexane, followed by sublimation at 67 °C under reduced pressure (12 Torr), to give crystals of **3** (4.4 g, 41%): mp 114—115 °C; $[\alpha]_D^{17}+175°$ (*c* 1.0, CH_3OH); NMR δ=1.6—2.6 (3H, m, CH_2-2 and OH-3), 3.39 (3H, s, OCH_3), 3.67 (2H, m, CH_2-5), 3.9—4.3 (2H, m, H-3 and 5), 4.45 (1H, m, H-4) and 4.85 (1H, t, $J_{1,2a}=J_{1,2e}\approx 2.5$ Hz, H-1).

Found: C, 39.15; H, 5.44; Cl, 32.72%. Calcd for C_7H_{12}-

†† Throughout this paper 1 Torr≈133.322 Pa.

O_3Cl_2: C, 39.09; H, 5.62; Cl, 32.97%.

2) Methyl 3-O-Acetyl-4,6-dichloro-2,4,6-trideoxy-α-D-lyxo-hexopyranoside (4). A solution of **3** (121 mg) in a mixture of acetic anhydride (0.11 ml) and pyridine (0.61 ml) was kept overnight at room temperature and, after addition of ethanol (0.11 ml), was concentrated *in vacuo* to give a residue that was chromatographed on a column of silica gel (10 g) with hexane–ethyl acetate (6: 1) to give an oil of **4** (143 mg, 93%). Micro-distillation of **4** at 35 °C at 1 Torr gave an analytically pure oil: $[\alpha]_D^{17}+153°$ (*c* 2.0, CH_3OH); NMR $\delta=1.6$—2.6 (2H, m, CH_2-2), 2.08 (3H, s, OAc), 3.37 (3H, s, OCH_3), 3.64 (2H, d, $J_{5,CH_2}=7$ Hz, CH_2-5), 4.15 (1H, dt, $J_{4,5}=1$ Hz, H-5), 4.59 (1H, m, H-4), 4.87 (1H, dd, $J=1$ and 3 Hz, H-1) and 5.30 (1H, m, H-3).

Found: C, 42.34; H, 5.41; Cl, 27.27%. Calcd for $C_9H_{14}O_4Cl_2$: C, 42.04; H, 5.49; Cl, 27.58%.

3) 3-O-Acetyl-2,4,6-trideoxy-D-threo-hexopyranose (6). To a solution of **4** (318 mg) in dry toluene (3.2 ml) under an argon atmosphere was added tributylstannane (792 mg) and α,α′-azobisisobutyronitrile (20 mg). The solution was stirred overnight at 100 °C and then concentrated to afford a residue, which was chromatographed on a column of silica gel with benzene–ethyl acetate (7: 1). The eluate containing the product (R_f 0.42 on TLC with the same solvent system) was carefully concentrated with an aspirator to give an oil **5**, which contained a little solvent: NMR $\delta=0.7$—2.4 (4H, m, CH_2-2 and 4), 1.23 (3H, d, $J=6.5$ Hz, CH_3-5), 2.02 (3H, s, OAc), 3.34 (3H, s, OCH_3), ≈3.9 (1H, m, H-5), 4.86 (1H, dd, $J=1$ and 3 Hz, H-1) and ≈5.1 (1H, m, H-3). The oil was kept in a desiccator under reduced pressure, where it was distilled away to disappear. Then, a solution of the oil in 10% aq acetic acid (5 ml) containing 1 M hydrochloric acid (1.7 ml) was kept at 40 °C for 3 h, after which TLC (hexane–ethyl acetate=1: 1) indicated that hydrolysis of the glycoside was complete. The solution was neutralized by addition of solid $NaHCO_3$ and extracted with ethyl acetate (10 ml×2). The extracts were combined, washed with saturated NaCl solution, dried ($MgSO_4$), and evaporated. The residue was chromatographed on a column of silica gel (10 g) with the same solvent system described above to give a solid of **6** (181 mg, 84%): mp 49—51 °C; $[\alpha]_D^{20}+13.8°\rightarrow+50.1°$ (*c* 1.0, CH_3OH, 26 h); NMR ($CDCl_3+D_2O$) $\delta=1.19$ and 1.29 (3H in total, each d, $J=7$ Hz, CH_3-5), 2.06 and 2.08 (3H in total, each s, OAc).

Found: C, 55.22; H, 8.02%. Calcd for $C_8H_{14}O_4$: C, 55.16; H, 8.10%.

4) (R)-5-Hydroxy-(2E)-hexenal (8). *p*-Toluenesulfonyl chloride (100 mg) was added to an ice-cold, stirred solution of **6** (60 mg) in dry acetonitrile (0.6 ml) containing triethylamine (0.15 ml). The mixture was allowed to stand at room temperature for 6 h and, after addition of a few drops of water, was poured into water (5 ml). The product was extracted with dichloromethane (2 ml×3). The combined extracts were washed with saturated NaCl solution, dried (Na_2SO_4), and evaporated to give an oil containing **7**. TLC with hexane–ethyl acetate (5: 1) clearly established the R_f of 0.60. Attempts to isolate pure **7** were unsuccessful. To a stirred solution of the oil in 50% aq acetone (2.4 ml) was added mercury(II) acetate (112 mg). After stirring at room temperature for 1 h, the mixture (pH 4) was acidified to pH 1 with dilute sufuric acid and again stirred overnight. The resulting solution, on TLC with hexane–ethyl acetate (1: 2), showed a major product at R_f 0.48. The solution was adjusted to pH 4 with barium carbonate and the suspension filtered and the filtrate extracted with dichloromethane (2.0 ml×5). The combined extracts were dried (Na_2SO_4) and evaporated to a residue, which was passed through a short column of Sephadex LH-20 with hexane–ethyl acetate (1: 2) to give a crude product of **8**. The crude product was further chromatographed on a column of silica gel (1g) to give an analytically pure oil of **8** (20 mg, 51%): $[\alpha]_D^{18}-23°$ (*c* 1.0, $CHCl_3$); IR (CCl_4) 3450 (OH), 1695 and 1650 cm^{-1} (C=C-CHO); UV_{max} (CH_3OH) 223 nm (ε 11,100); NMR $\delta=1.30$ (3H, d, $J=6.5$ Hz, CH_3-5), 1.80 (1H, OH-5), 2.52 (2H, t with a little long-range coupling, $J=7$ Hz, CH_2-4), ≈4.1 (1H, m, H-5), 6.19 (1H, dd, $J_{1,2}=7.5$ Hz, $J_{2,3}=15.5$ Hz, H-2), 6.93 (1H, dt, $J_{3,4}=7$ Hz, H-3) and 9.62 (1H, d, CHO-1).

Found: C, 62.92; H, 8.74%. Calcd for $C_6H_{10}O_2$: C, 63.13; H, 8.83%.

5) Methyl (R)-7-Hydroxy-(2E, 4E)-octadienoate (9). To a solution of **8** (16 mg) in dry benzene (1 ml) was added methoxycarbonylmethylenetriphenylphosphorane (52 mg), and the mixture refluxed for 1 h and then evaporated *in vacuo*. The residue was chromatographed on a column of alumina (Woelm neutral, 3.5 g) with chloroform–acetone (5: 1), followed by chromatography on a column of silica gel (2 g) with hexane–ethyl acetate (1: 1) to give an oil of **9** (20 mg, 83%): TLC (hexane–ethyl acetate 1: 1) R_f 0.50; $[\alpha]_D^{20}-17°$ (*c* 2.0, $CHCl_3$); IR ($CHCl_3$) 3460 (OH), 1720, 1705 (C=O), 1645, 1620 cm^{-1} (C=C-C=C); UV_{max} (CH_3OH) 260 nm (ε 27,800); NMR $\delta=1.23$ (3H, d, $J=6.5$ Hz, CH_3-7), 1.97 (1H, broad s, OH-7), 2.34 (2H, m, CH_2-6), 3.74 (3H, s, $COOCH_3$), 3.91 (1H, m, H-7), 5.83 (1H, d, $J_{2,3}=15$ Hz, H-2), 6.0—6.4 (2H, m, H-4 and 5) and 7.27 (1H, m, H-3).

Found: C, 63.46; H, 8.17%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%.

6) Methyl 4,6-Dideoxy-2-O-p-tolylsulfonyl-α-D-xylo-hexopyranoside (11). To an ice-cold, stirred solution of **10** (2.46 g) in pyridine (24 ml) was added *p*-toluenesulfonyl chloride (3.76 g), and the mixture allowed to stand at room temperature for 1 day. The mixture was then poured into agitated ice-water (70 ml), and the product extracted with chloroform (80 ml×2). The extracts were combined, washed successively with an ice-cold, saturated $KHSO_4$ solution, saturated $NaHCO_3$ solution and water, dried (Na_2SO_4), and evaporated. The residue was chromatographed on a column of silica gel (200 mg) with benzene–ethyl acetate (3: 1) to give an oil of **11** (3.46 g, 72%): $[\alpha]_D^{20}+99°$ (*c* 2.0, CH_3OH); NMR $\delta=1.18$ (3H, d, $J=6.5$ Hz, CH_3-5), 1.3—2.5 (3H, m, CH_2-4 and OH-3), 2.46 (3H, s, Ts-CH_3), 3.28 (3H, s, OCH_3), 3.5—4.3 (2H, m, H-3 and 5), 4.21 (1H, dd, $J_{1,2}=3$ Hz and $J_{2,3}=1.5$ Hz, H-2), 4.67 (1H, d, H-1), 7.37 and 7.87 (each 2H, AB quartet, $J=8.5$ Hz, Ts).

Found: C, 52.91; H, 6.38%. Calcd for $C_{14}H_{20}O_6S$: C, 53.15; H, 6.37%.

7) Methyl 2,3-Anhydro-4,6-dideoxy-α-D-lyxo- and ribo-Hexopyranosides (12 and 13). To a methanolic solution (2.8 ml) of a crude sample of **11** (817 mg) was added a 28% methanolic sodium methoxide solution (0.70 ml), and the solution refluxed for 1 h. After cooling, the solution was poured into ice-water (30 ml) and the product extracted with dichloromethane (35 ml×3). The combined extracts were washed with water, dried (Na_2SO_4), and evaporated. The residue was chromatographed on a column of silica gel (40 g) with benzene–ethyl acetate (7: 1) to give **12** (286 mg) and **13** (8 mg), which on TLC with the same solvent system gave R_f 0.48 and 0.31 respectively, in 79% total yield. Micro-distillation of **12** at 45—80 °C at 16 Torr gave analytically pure needles: mp 28—30 °C; $[\alpha]_D^{20}+70°$ (*c* 1.0, CH_3OH); NMR $\delta=1.15$ (3H, d, $J=6.5$ Hz, CH_3-5), 1.5—2.1 (2H, m, CH_2-4), 2.98 (1H, d, $J_{2,3}=4$ Hz, H-2), 3.40 (1H, m, H-3), 3.48 (3H, s, OCH_3), 3.88 (1H, m, H-5) and 4.91 (1H, s, H-1).

Found: C, 58.35; H, 8.31%. Calcd for $C_7H_{12}O_3$: C, 58.31; H, 8.39%. Compound **13** was an oil: NMR $\delta=1.15$ (3H, d, $J=6.5$ Hz, CH_3-5), 1.4—2.3 (2H, m, CH_2-4), 3.2—3.5 (2H, m, H-2 and 3), 3.46 (3H, s, OCH_3), 3.85 (1H, m, H-5) and 4.92 (1H, d, $J_{1,2}=3$ Hz, H-1).

8) Methyl 2,3,4,6-Tetradeoxy-α-D-glycero-hex-2-enopyranoside (14). To a solution of **12** (57 mg) in 90% aq 2-methoxyethanol (1.1 ml) was added 80% potassium selenocyanate (150 mg), and the mixture refluxed for 20 min. After cooling, the mixture was poured into water (5 ml) and the product extracted with dichloromethane (6 ml×3). The combined extracts were washed with water, dried ($MgSO_4$), and evaporated. The residue was chromatographed on a column of silica gel (3 g) with dichloromethane–chloroform (4: 1) to give an oil of **14** (21 mg, 42%): $[\alpha]_D^{16}-48°$ (*c* 2.0, $CHCl_3$); NMR $\delta=1.25$ (3H, d, $J=6.5$ Hz, CH_3-5), 1.7—2.2 (2H, m, CH_2-4), 3.45 (3H, s, OCH_3), 4.00 (1H, m, H-5), 4.87 (1H, dd, $J=1$ and 3 Hz, H-1), 5.74 (1H, m, H-2) and 6.01 (1H, dt, $J_{2,3}=10$ Hz, $J_{3,4}=4$ Hz, H-3).

Found: C, 65.42; H, 9.25%. Calcd for $C_7H_{12}O_2$: C, 65.59; H, 9.44%. Compound **13** was treated with potassium selenocyanate in a similar manner as above, except for a 2-h reaction time, to give **14** in 23% yield.

9) Methyl (R)-7-Hydroxy-(2E, 4Z)-octadienoate (16). A suspension of **14** (69 mg) in a mixture of 1 M hydrochloric acid (0.38 ml) and 50% aq acetone (3.4 ml) was stirred at room temperature for 2 min. The resulting solution was then neutralized with $NaHCO_3$ (90 mg) and extracted with dichloromethane (2 ml×6). The combined extracts were dried (Na_2SO_4) and evaporated to give a crude oil of **15** (56 mg), which on TLC with chloroform–acetone (9: 1) gave an R_f of 0.54: NMR $\delta=1.23$ and 1.24 (3H in total, d, $J=6.5$ Hz, CH_3-5), 1.58 (1H, sharp m, OH), 1.6—2.3 (2H, m, CH_2-4), 3.7—4.3 (1H, m, H-5), ≈5.4 (1H, m, H-1) and 5.5—6.2 (2H, m, H-2 and 3).

To a solution of the oil (56 mg) in benzene (1.0 mg) was added methoxycarbonylmethylenetriphenylphosphorane (180 mg), and the mixture was refluxed for 3 h, after which time TLC (chloroform–acetone=9: 1) indicated that the Wittig reaction was complete to give a single product (R_f 0.46). The solvent was evaporated, and the residue extracted with pentane (5 ml) under reflux for 30 min. After cooling, the pentane solution was decanted and evaporated. The residue was chromatographed on a column of silica gel (5 g) with chloroform–acetone (9: 1), followed by chromatography on a column of alumina (Woelm neutral, 10 g) with chloroform, to give an oil of **16** (71 mg, 77%): $[\alpha]_D^{15}+5.2°$ (*c* 2.0, $CHCl_3$); IR ($CHCl_3$) 3420 (OH), 1720, 1710 (C=O), 1640, 1605 cm^{-1} (C=C–C=C); UV_{max} (CH_3OH) 265 nm (ε 20,600); NMR $\delta=$ 1.24 (3H, d, $J=6.5$ Hz, CH_3-7), 1.84 (1H, s, OH), 2.50 (2H, t with a little long-range coupling, $J=6.5$ Hz, CH_2-6), 3.79 (3H, s, $COOCH_3$), 3.95 (1H, sextet, H-7), 5.7—6.2 (1H, m, H-5), 5.95 (1H, d, $J_{2,3}=15$ Hz, H-2), 6.32 (1H, t, $J_{3,4}=J_{4,5}=10.5$ Hz, H-4) and 7.65 (1H, dd, H-3).

Found: C, 63.39; H, 8.10%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%.

The authors are grateful to Emeritus Professor Sumio Umezawa for his helpful discussions and Mr. Saburo Nakada for the elemental analyses. This investigation was assisted in part financially by the Naito Research Grant for 1977.

Studies of Reactions of Amines with Sulfur Trioxide. V.[1] Transsulfonation of Amine Salts of Some *N*-Substituted Amidosulfuric Acids

Fujio KANETANI* and Hachiro YAMAGUCHI

Department of Applied Chemistry, Hiroshima University, Senda-machi, Hiroshima 730

(Received March 27, 1978)

4-Methylanilinium butylamidosulfate, butylammonium (4-methylphenyl)amidosulfate, and 4-methylanilinium (4-methylphenyl)amidosulfate were heated separately under reduced pressure at different temperatures ranging from 80 to 180 °C. Butylammonium butylamidosulfate was heated with 4-methylaniline under atmospheric and reduced pressure. The product compositions were determined as functions of reaction time and temperature, and the components were separated and identified. At lower temperatures (4-methylphenyl)amidosulfate and 4-methylaniline-*N*,2-disulfonate were the major products, while at higher temperatures 4-methylaniline-2-sulfonate and 2,6-disulfonate were the major products. The ease of N–S bond cleavage of the amidosulfate salts ($RNHSO_3^-R'NH_3^+$) (**1**) depends largely on the basicity of both the parent amine (RNH_2) (**2**) and the salt-forming base ($R'NH_2$) (**3**). The results suggest that the initial step of the transsulfonation involves the dissociation of **1** into **3** and the free acid followed by an equilibration between $RNHSO_3H$ and $RNH_2^+SO_3^-$ (**4**). It is considered that **4** may be the sulfonating species and the free amines, **2** and **3**, should be the receptors of a sulfonate group. In contrast to the widely accepted scheme (transsulfonation and subsequent intramolecular rearrangement), our results show that both the transsulfonation and the rearrangement process occur concurrently and the same type of mechanism (a bimolecular displacement, *viz.*, $B^+: SO_3^- + B':\rightleftarrows B^+: + B^+: SO_3^-$) may be operative.

Paal and his co-workers first studied the reaction of amidosulfuric acid with a variety of amines.[2a-d] This reaction was later reinvestigated in detail by Quilico.[3] He found that amidosulfuric acid reacts at a water-bath temperature with an aromatic amine such as aniline, 4-methylaniline, or 1-naphthylamine, producing the corresponding ammonium arylamidosulfate, which in turn rearranges to the ring sulfonate at higher temperature (>150 °C). Recently, it has also been reported that the reaction of butyl- and cyclohexylamidosulfuric acids and their salts with a large excess of aniline, *N,N*-dimethylaniline, or anisole gave the corresponding *p*-sulfonic acids in high yields.[4] On the other hand, Saito, Dehara, and Manabe[5] demonstrated that the reaction between amidosulfuric acid and aniline gave a mixture of aniline-2- and 4-sulfonic acids along with a small amount of aniline-2,4- and 2,6-disulfonic acids whose composition depended on the reaction conditions.

Although it is well documented that arylamidosulfates rearrange to the corresponding ring sulfonates,[6,7] the mechanism of the rearrangement has been unsettled.[8-10] Furthermore, the intermediacy of phenylamidosulfuric acid in the sulfonation of aniline with concentrated sulfuric acid or by "baking" has been discussed for many years by many workers,[8-10] but so far phenylamidosulfuric acid has neither been isolated from such reactions nor been synthesized as such.[11]

We, therefore, undertook the thermal reaction of butylammonium and 4-methylanilinium salts of both butylamidosulfuric acid and (4-methylphenyl)amidosulfuric acid in order to gain an insight into the nature of the transsulfonation of *N*-substituted amidosulfates.

Results and Discussion

Isolation and Identification of the Reaction Products. 4-Methylanilinium butylamidosulfate (**5**), butylammonium (4-methylphenyl)amidosulfate (**9**), and 4-methylanilinium (4-methylphenyl)amidosulfate (**11**) were heated separately under reduced pressure at temperatures ranging from 80 to 180 °C. Butylammonium butylamidosulfate (**1**) was, in addition, heated with 4-methylaniline. The product composition depended on both the reaction time and temperature. Namely, (4-methylphenyl)amidosulfate (**9**) and 4-methylaniline-*N*,2-disulfonate (**13**)[12] were the major products at lower reaction temperatures, whereas 4-methylaniline-2-sulfonate (**12**) and 4-methylaniline-2,6-disulfonate (**15**) were the major products at higher temperatures. In no run was any chromatographic evidence obtained for the formation of 4-methylaniline-3-sulfonic acid and the 2,5-disulfonic acid. Each component was separated (as the sodium salts) by preparative liquid chromatography (cellulose Whatman CF-11, dioxane–H_2O 4: 1 and 5: 1 v/v as the developing solvent). **9** and **13** were then converted to the corresponding tetraphenylphosphonium salts and identified by elemental analysis, melting points (mixed mp), and comparison of their IR spectra with those of authentic samples. **12** and **15** were converted to the corresponding hexylammonium salts and identified similarly.

Product Analysis. Quantitative analysis of the reaction products was achieved by the combination of ion-exchange chromatography and chemical analysis (see the Experimental section). Use of quarternary ammonium-type resin-Amberlite CG 400 (Cl^- form) gave unsatisfactory results because this resin had excessively large distribution coefficients.

Thin-layer chromatography (TLC) was used in each run for qualitative analysis. The best resolution was obtained on cellulose with a dioxane–water (3: 1—4: 1 v/v) solvent system. The R_f values for isomeric 4-methylanilinemonosulfonic and disulfonic acids (spotted as their sodium salts) are listed in the Table.

Tetraphenylphosphonium Salts. The tetraphenylphosphonium salts of (4-methylphenyl)amidosulfuric

TABLE. R_f VALUES AND SPECTRAL DATA OF 4-METHYLANILINESULFONIC ACIDS

Compound	R_f[a)]	Color of spot	IR spectra (cm^{-1})
$4\text{-}MeC_6H_4NHSO_3Na$	0.63	orange	3260, 1512, 1198, 1061, 910, 810
