The reaction path of radical-radical recombination and disproportionation has been studied by means of a perturbational method with a clear orbital interaction concept, and the mechanism of these reactions has been elucidated theoretically. It has been confirmed that these termination reactions do not have a common transition state. The recombination is found to take the path which gives the maximum interaction between the singly occupied molecular orbitals (SOMO's) of two radical species, whereas the disproportionation is shown to take the route which gives the significant charge transfer interaction from the particular doubly occupied (DO) MO of one radical to the SOMO of the other radical. The DOMO localized at the C–H bond donates electrons to the SOMO to cause the hydrogen abstraction. In the process of disproportionation, one radical which abstracts a hydrogen atom acts as an electron-acceptor and the other radical with the hydrogen atom to be abstracted as an electron-donor. The difference between the mechanism of the recombination and that of the disproportionation is clarified in terms of the mode of the orbital interaction.

When organic free radicals are generated in a reaction, the unpaired-electron species eventually undergo a termination reaction, yielding stable molecules with closed-shell electronic structures through two reaction pathways. One of them is the recombination in Eq. 1 and the other is the disproportionation with the abstraction of a hydrogen atom β to the radical center in Eq. 2.[1]

$$\left.\begin{array}{l} RCH_2CH_2\cdot \\ + \\ R'CH_2CH_2\cdot \end{array}\right\} \begin{array}{l} \xrightarrow{k_c} RCH_2CH_2CH_2CH_2R' \quad (1) \\ \xrightarrow{k_d} RCH_2CH_3 + R'CH{=}CH_2 \quad (2) \end{array}$$

The knowledge of termination modes together with their relative rates is very important in predicting and interpreting the radical chain reactions and their products. For example, a change from recombination to disproportionation can effect a twofold variation in polymer length.

Early pictures of radical-radical reactions assumed a common transition state for the two processes of Eqs. 1 and 2, involving the excited dimer which could either be rearranged to give the disproportionation products or be quenched to give the recombination product.[2] This, however, is ruled out experimentally by a number of observations.[3] Bradley and Rabinovitch suggested an alternative interpretation of the mechanisms of the recombination and disproportionation of alkyl radicals.[4] They rejected the description of the activated complex for the disproportionation as an excited dimer and suggested that different configurations of the composite system may take part involving couplings of the radical species through three-centered hydrogen atom bonds already suggested for the recombination.[5] Consequently, the terms, "head-to-head" and "head-to-tail", used to describe the configuration of the activated complexes are discarded in the Bradley-Rabinovitch model.

$$2CH_3CH_2\cdot \longrightarrow \begin{array}{l} CH_2\cdots H \\ \| \quad \vdots \\ CH_2\cdots CH_2CH_3 \end{array} \begin{array}{l} \longrightarrow CH_3CH_2CH_2CH_3 \\ \longrightarrow CH_3CH_3 + CH_2{=}CH_2 \end{array}$$

Scheme 1.

Benson put forward the argument that both reactions, though quite different from each other, involve loose transition states with a significant ionic character.[3a]

$$2CH_3\cdot \longrightarrow \overset{-}{C}H_3 : \overset{+}{C}H_3 \quad \text{or} \quad \overset{+1/2}{C}H_2\text{-}H\cdots\overset{-1/2}{C}H_3$$
$$\longrightarrow CH_3CH_3$$

Scheme 2a.

$$2CH_3CH_2\cdot \longrightarrow CH_3\overset{-}{C}H_2 : H\text{-}CH_2\overset{+}{C}H_2$$
$$\text{or} \quad CH_3\overset{+}{C}H_2 : \overset{-}{H}\text{-}CH_2CH_2$$
$$\longrightarrow CH_3CH_3 + CH_2{=}CH_2$$

Scheme 2b.

Although it is accepted that the transition states of two radical-radical termination reactions differ, there are two incompatible ways of speculation for these processes as shown in Schemes 1, 2a, and 2b. Since the reaction paths of the recombination and disproportionation are still undetermined, it seems useful to study radical destruction processes theoretically.

Recently, the ΔW method which deals with the radical-radical reacting system in terms of the molecular interaction was developed by the present authors and was applied to the recombination of two methyl radicals.[6] As the result of calculation, the interaction between both the singly occupied molecular orbitals (SOMO's) and the deformation of the methyl radical were found to be of importance for progress of the reaction. The result also demonstrates the applicability of the ΔW method further to larger reacting systems. In the present work, we have made a comparative study on the recombination and disproportionation by the use of the ΔW method. The purpose of this work is to shed light on the disputing point of the mechanism of two reaction pathways. Furthermore, the general aspect of radical-radical reaction is explained conveniently in terms of the shape of MO's of several isolated radical species, since the value of the interaction energy, ΔW, is completely dependent on the overlap of MO's and gap of orbital-energy levels.

Method of Calculation

A system composed of an ethyl radical (ER) and a methyl radical (MR) is selected as a reaction model in the ΔW method. In this reaction system the recombination gives propane and the disproportionation produces methane and ethylene.

In the ΔW method, the wave function (Ψ) of a chemically-interacting system between ER and MR is represented in the configuration interaction (CI) procedure:

$$\Psi = C_0\Psi_0 + \sum_{i=1}^{6}\sum_{l=5}^{7} C_{i\to l}\Psi_{i\to l} + \sum_{k=1}^{3}\sum_{j=8}^{13} C_{k\to j}\Psi_{k\to j} + \sum_{i=1}^{6} C_{i\to o'}\Psi_{i\to o'} + \sum_{k=1}^{3} C_{k\to o}\Psi_{k\to o} + \sum_{l=5}^{7} C_{o\to l}\Psi_{o\to l} + \sum_{j=8}^{13} C_{o'\to j}\Psi_{o'\to j} + C_{o\to o'}\Psi_{o\to o'} + C_{o'\to o}\Psi_{o'\to o}. \quad (3)$$

In order to describe MO's of ER and MR in their isolated states, a semiempirical all-valence-electron SCF-UHF method including overlap integrals is employed.[7] The way of estimating semiempirical parameters to evaluated MO integrals is the same as that used in a previous paper.[8] Without the lowest occupied ls-like MO, ER has six doubly occupied (DO) MO's and MR has three DOMO's. In Eq. 3, Ψ_0 denotes the adiabatically-interacting configuration in which neither electron transfer nor electron excitation takes place as is shown in Fig. 1. The letters "i" and "j" indicate a DOMO and an unoccupied MO, respectively, of ER, and "k" and "l" a DOMO and an unoccuppied MO, respectively, of MR. "o" is the SOMO of the former radical, and "o'" that of the latter. $\Psi_{i\to l}$ denotes a configuration of one-electron shift from the i-th DOMO to the l-th unoccuppied MO. C_0, $C_{i\to l}$, $C_{k\to j}$, $\cdots$, are the CI coefficients obtained by solving the usual CI secular equation. Our attention is focused on the reacting system with the singlet spin state, because in the system with the triplet spin state a radical-radical reaction is far from occurring. In this calculation, no configurations with intramolecular excitations are taken into account in Eq. 3, since it requires much more CPU time to compute the molecular integrals appearing in the CI matrix elements of the above configurations. Also, two reactants are neutral and consequently the excited configurations do not contribute as much as the charge-transferred ones to the stabilization of the reacting systems.[6]

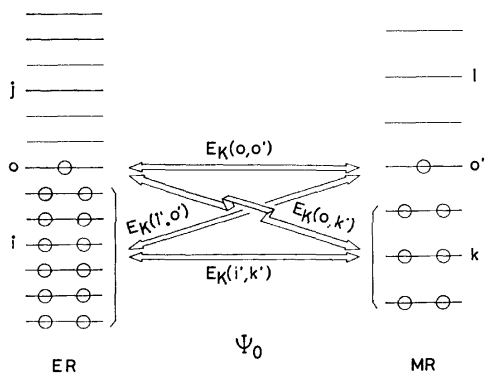

Fig. 1. The adiabatically-interacting configuration (Ψ_0) and the schematic representation of four types of exchange interaction between ethyl (ER) and methyl (MR) radicals. The lowest DOMO of two radicals, *i.e.*, the 1s-type one is omitted in this figure.

When the CI secular equation is expanded perturbationally, the total stabilization energy (ΔW) due to the CI mentioned above can be partitioned into the following three terms, Coulomb (E_Q), exchange (E_K), and delocalization (D).

$$\Delta W = E_Q + E_K - D. \quad (4)$$

E_Q is the classical electronic interaction energy between ER and MR. In both the singlet spin state and the triplet spin state, E_K is found to be the repulsive term (>0) in the system of two radicals of the usual organic-chemical size. E_K can be partitioned approximately into four terms.[6]

$$E_K = E_K(i',k') + E_K(i',o') + E_K(o,k') + E_K(o,o'). \quad (5)$$

In Fig. 1, four components of E_K are shown schematically. D is the stabilization energy due to the mixing-in of the charge transferred configurations with the adiabatically-interacting configuration. D can be represented by the sum of eight components.[6]

$$D = D(i\to l) + D(k\to j) + D(i\to o') + D(k\to o) + D(o\to l) + D(o'\to j) + D(o\to o') + D(o'\to o). \quad (6)$$

In order to visualize the change of electron density along the reaction progress, a contour map of the difference electron density is given. The difference density, $\Delta\rho(1|1)_{E_K}$, of the exchange interaction is partitioned into four terms, each of which corresponds to that of the energy decomposition in Eq. 5.

$$\Delta\rho(1|1)_{E_K} = \Delta\rho(1|1)_{E_K(i',k')} + \Delta\rho(1|1)_{E_K(i',o')} + \Delta\rho(1|1)_{E_K(o,k')} + \Delta\rho(1|1)_{E_K(o,o')}. \quad (7)$$

$\Delta\rho(1|1)_{E_K(i',k')}$, for instance, indicates the difference electron density caused by the exchange interaction between both DOMO's. The difference electron density including the exchange and charge transfer (CT) interactions, $\Delta\rho(1|1)$, is also given.

Figure 2 illustrates the geometry of assumed reaction models. The geometry of the isolated ER comes from Pople's *ab initio* calculation,[9] and that of the isolated MR is referred to Herzberg's book.[10] The length of all C–H bonds and the C_1–C_2 bond of two isolated systems is kept frozen throughout the calculation. Three reaction models (I, II, and III) are shown in Fig. 2. They are distinguished by the position of MR. Models I and II represent a recombination in which MR attacks the radical center (C_2) of ER, MR approaching ER in the *cis*-conformation in I and in the *trans*-conformation in II. Model III represents a disproportionation in which MR attacks a hydrogen atom (H_3) of ER. In this calculation seven geometrical parameters are introduced to indicate various reaction processes. β is the angle between the methylene plane (H–C_2–H) and C_1–C_2 bond axis of ER in Models I, II, and III. R denotes the distance between C_M of MR and C_2 of ER, and α is the angle between $C_M\cdots C_2$ line and the C–H bond of MR in I and II. θ and θ'

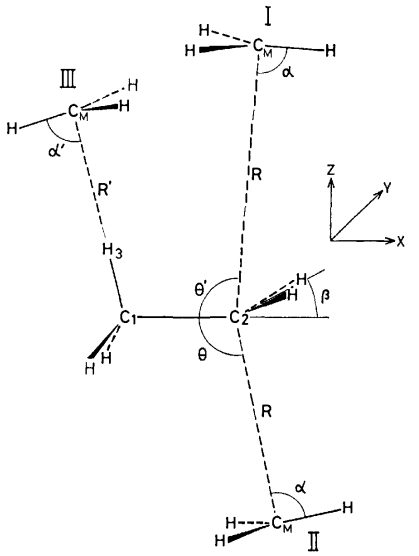

Fig. 2. Three assumed reaction models employed for the calculation of the interaction energy.

stand for the angle between $C_M \cdots C_2$ line and C_1–C_2 bond axis in Models I and II. R' denotes the distance between C_M of MR and H_3 of ER, and α' the angle between $C_M \cdots H_3$ line and the C–H bond of MR in Model III.

Results of Calculation

The interaction energy (ΔW) of Models I and II is given in Table 1. The ΔW of Model I (R=2.7 Å, θ'=100°) is compared with that of Model II (R=2.7 Å, θ=100°). We see that Model II is more favorable for the recombination. The superiority or inferiority of the recombination path is attributable to the two terms of exchange energy, $E_K(i', k')$ and $E_K(i', o')$, (see Fig. 1) and the components originating from o-o' interaction, $E_K(o, o')$, $D(o \rightarrow o')$, and $D(o' \rightarrow o)$. Let us examine the possibility of the three-centered bond exhibited in Scheme 1. If the termination reaction proceeds along Scheme 1, the approach of MR to the C_1–H_3 bond is expected to reduce the ΔW value. In order to see the effect of this geometrical change on each energy, the angle θ' is varied tentatively from 100 to 90° in Model I. This is found to bring about a larger ΔW value, *i.e.*, destabilization of the system (Table 1). In view of the two ΔW's (θ'=100, 90°) of Model I, it is realized that this destabilization comes primarily from the increase of the exchange energy, E_K, and slightly from the decrease of the delocalization energy, D. The analysis of four components of E_K shows that its enlargement is due to the increase of both $E_K(i', k')$ and $E_K(i', o')$ and the decrease of the stabilizing term, $E_K(o, o')$. $D(o \rightarrow o')$ and $D(o' \rightarrow o)$ which are the stabilization energies are reduced by that variation of the geometry. The increase of $E_K(i', k')$ and $E_K(i', o')$ is due to the approach of the electronic cloud of MR to that of the C_1–H_3 bond of ER, whereas the decrease of three stabilizing terms, $E_K(o, o')$, $D(o \rightarrow o')$, and $D(o' \rightarrow o)$ is explained as follows. The SOMO of ER has a node between C_1 and C_2. As MR approaches the C_1–H_3 bond of ER, the out-of-phase overlapping of the SOMO of MR with the lobe of the SOMO of ER localized at C_1 and H_3 becomes larger. The overlap between both the SOMO's becomes small and the stabilization due to $E_K(o, o')$, $D(o \rightarrow o')$, and $D(o' \rightarrow o)$ is reduced by θ'=100→90°.

Table 1. Calculated interaction energies for the recombination and disproportionation of ethyl and methyl radicals

Geometrical parameters, R, R', α, α', β, θ, and θ' are those shown in Fig. 2.

	Model I		Model II		Model III	
R or R' [Å]	2.7	2.7	2.7	2.4	2.4	2.0

the SOMO of ER

The results show that the process of the radical destruction is not described by Scheme 1 and the recombination takes the route in which MR approaches the radical center, C_2, of ER in the *trans*-conformation to the C_1–H_3 bond of a methyl group of ER.

In Model II (R=2.4 Å, θ=105°), the structural deformation of two radicals is taken into account, *i.e.*, α=90→105° and β=0→43.2°. This deformation operates to reduce the E_K and to increase the absolute value of the stabilization terms, $E_K(o, o')$, $D(o\rightarrow o')$, and $D(o'\rightarrow o)$, making the ΔW negative (Table 1). Thus, the need of the structural deformation of the radical species to promote the reaction is explicable in this MO scheme. The deformation associates the change of the extent of the hybridization ($sp^2\rightarrow sp^3$) of two radical centers, resulting in the growth of the o-o' MO interaction which contributes overwhelmingly to the stabilization of the system. As for Model II (R=2.4 Å), the CI coefficients of Eq. 3 are obtained.

$$\Psi = 0.918\Psi_0 - 0.123\Psi_{o\rightarrow o'} - 0.116\Psi_{o'\rightarrow o} + \cdots. \quad (8)$$

This equation is an alternative expression of the importance of $D(o\rightarrow o')$ and $D(o'\rightarrow o)$ to promote the reaction. From the equation the transition state of the recombination hardly seems to have ionic character due to the almost equal weight of two competing ($o\rightarrow o'$ and $o'\rightarrow o$) CT interactions.

The difference density in the reaction process was investigated with respect to Model II (R=2.4 Å, θ=105°). The density map helps us to visualize the movement of electronic cloud through some types of interactions between ER and MR. Figure 3-a shows the electron redistribution by $\Delta\rho(1|1)_{E_K(i',k')}$ caused by mutual overlap between both the DOMO's. The electron redistribution gives negative contour lines amid the $C_2\cdots C_M$ region, corresponding to the repulsive $E_K(i',k')$. The electron density maps of $\Delta\rho(1|1)_{E_K(i',o')}$ and $\Delta\rho(1|1)_{E_K(o,k')}$ are shown in Figs. 3-b and 3-c. Two terms of the exchange interaction, (i', o') and (o, k'), are seen to reduce the electron density along the $C_2\cdots C_M$ line, reflecting the repulsive character of $E_K(i', o')$ and $E_K(o, k')$. The last component of $\Delta\rho(1|1)_{E_K}$, $\Delta\rho(1|1)_{E_K(o,o')}$, is shown in Fig. 3-d. Since the $E_K(o, o')$ is a considerable stabilization energy (Table 1), $\Delta\rho(1|1)_{E_K(o,o')}$ is expected to give the large bonding density in the middle region between ER and MR. The expectation is confirmed by the central huge build-up of the electron density in this figure. The change of the electron distribution, $\Delta\rho(1|1)$, due to the exchange and CT interactions is shown in Fig. 3-e. It is seen that the addition of CT interaction to the exchange interaction accumulates the electron density significantly in the $C_2\cdots C_M$ region. The electron transfer from ER to MR and the compensating one from MR to ER take place equivalently, the transition state having no ionic character. This result is in line with that pointed out in Eq. 8. The trend of these electron redistributions is similar to that of the recombination of two methyl radicals.[6] From Eq. 8 and Fig. 3, the overlap of two SOMO's, the common origin of $E_K(o, o')$, $D(o\rightarrow o')$, and $D(o'\rightarrow o)$, is shown to contribute remarkably to the new bond formation.

Calculation of the ΔW was carried out with respect to Model III. The results are also given in Table 1. It should be noted that the stabilization components, $E_K(o, o')$, $D(o\rightarrow o')$, and $D(o'\rightarrow o)$, are much smaller (absolute value) in this model than in the two recombination models I and II. The difference is attributable to the fact that the SOMO of ER is localized to a greater extent at the C_2 atom, and the overlap between both two SOMO's in Model III is small. Of the many components of ΔW in Model III, it is $D(i\rightarrow o')$ that gives the greatest stabilization energy to the disproportionation path. Comparing the two geometries of R'=2.4 Å and R'=2.0 Å of Model III, we find that D of R'=2.0 Å is larger than that of R'=2.4 Å, which is mainly due to the increase of its one component, $D(i'\rightarrow o)$, along the decrease of R'. The result shows that the $i\rightarrow o'$ type CT interaction becomes more important with the progress of reaction. In spite of the increase of D, ΔW of R'=2.0 Å is larger that that of R'=2.4 Å (Table 1). The global destabilization of Model III (R'=2.0 Å) is attributable to the increase of the repulsive term, E_K. In this calculation, the extension of the C_1–H_3 bond of ER in the course of disproportionation is not taken into account. In the realistic reaction model with the elongated C_1–H_3 bond, however, E_K would become small because of the separation of MR from ethylene fragment of ER and accordingly its ΔW would be much smaller than the ΔW of Model III which has the constant C_1–H_3 bond length regardless of R'.

In order to find the charge-transferred configuration which contributes most to the stabilization of the reacting system, the CI coefficients are obtained with respect to Model III (R'=2.0 Å).

$$\Psi = 0.955\Psi_0 - 0.120\Psi_{i_4\rightarrow o'} + 0.054\Psi_{o\rightarrow o'} + 0.035\Psi_{i_5\rightarrow o'} + 0.034\Psi_{i_2\rightarrow o'} + 0.024\Psi_{o'\rightarrow o} + \cdots. \quad (9)$$

Terms, i_2, i_4, and i_5, denote the DOMO's of ER and suffix attached to "i" stands for the numbering order counted from the lowest DOMO (see Fig. 1). Equation 9 shows that the CT interaction from i_4 (a') to o' (a_1) is the most important.[11] a' denotes the MO of ER within the X-Z plane belonging to the C_s point group and a_1 the MO of MR along the $C_M\cdots H_3$ line belonging to the C_{3v} point group. The i_4 is localized substantially at the C_1–H_3 bond and is the highest occupied (HO) MO of the C–H bond cleaved by disproportionation.

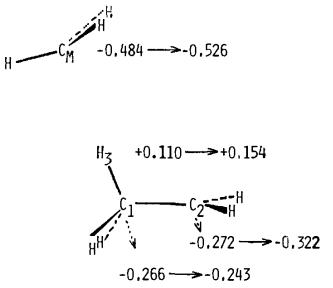
the i_4 MO of ER

The MO of this type is hereafter called the "C–H HOMO." In Model III representing disproportionation, this particular CT interaction plays an important role to weaken the C_1–H_3 bond through the loss of electron density of the i_4, forming a new $C_M \cdots H_3$ bond. From Eq. 9, MR is found to be an electron acceptor and ER to be an electron donor during the course of reaction. This donor-acceptor relation was also observed in a previous work dealing with the hydrogen abstraction reaction of a methane by a methyl radical.[12]

The electron redistribution in disproportionation is evaluated in the same way as in the recombination. Four components of $\Delta\rho(1|1)_{E_K}$ in Eq. 7 are shown separately in Fig. 4. They exhibit the same trend of electron movement as is observed in Fig. 3 of the recombination. $\Delta\rho(1|1)_{E_K(i',k')}$ (Fig. 4-a) show the large amount of the decreased density in the $C_M \cdots H_3$ region. The electron density, running away from this region, is piled up around C_M and the C_1–H_3 bond. The electron density around C_M resembles that of the recombination (Fig. 3-a). The density redistribution, $\Delta\rho(1|1)_{E_K(i',o')}$ (Fig. 4-b) is found to give the decreased density in the $C_M \cdots H_3$ line. Since the overlap between the SOMO of ER and any DOMO of MR is small, the change of the electron arrangement brought about by $\Delta\rho(1|1)_{E_K(o,k')}$ is expected to be minor (Fig. 4-c). The three difference densities, $\Delta\rho(1|1)_{E_K(i',k')}$, $\Delta\rho(1|1)_{E_K(i',o')}$, and $\rho\Delta(1|1)_{E_K(o,k')}$, corresponding to three repulsive energy terms of E_K in Eq. 4 do not contribute to the formation of a new C_M–H_3 bond. The contour map of the electron density of $\Delta\rho(1|1)_{E_K(o,o')}$ is shown in Fig. 4-d. Since the overlap between both SOMO's is smaller in Model III than that in Model II, the density redistribution through $\Delta\rho(1|1)_{E_K(o,o')}$ is not so noticeable in the former model. Figure 4-e shows $\Delta\rho(1|1)$, representing the electron redistribution due to the exchange and CT interactions. The considerable accumulation of the electron density around C_M of MR and C_2 of ER is observed. The diminution of the electron density appears at the C_1–H_3 bond of ER. The electron redistribution shows that the exchange and CT interactions, especially the $i_4 \rightarrow o'$ CT interaction, make electrons of ER flow into MR and that the C_1–H_3 bond is weakened by the loss of bonding electrons. The accumulated electron density around C_M operates to pull the H_3 atom, resulting in the formation of the new C_M–H_3 bond.

The change of atomic charges in Model III ($R'=$ 2.0 Å) is shown in Table 2. We see that the exchange and CT interactions make the charge on the C_M atom of MR more negative and that on the H_3 atom of ER more positive. This indicates that the C_M atom of MR has a negative charge and the H_3 atom of ER has a positive charge at the transition state of disproportionation. The tendency is almost similar to that suggested in the case of the disproportionation of alkoxy radicals. The result showing that the transition state of disproportionation has the ionic character is in agreement with Benson's scheme (Scheme 2b), while that of the recombination has no ionic character as shown with respect to Model II.

Table 2. Change of net charges by the exchange and CT interactions in Model III
A more negative value indicates a larger electron population.



No formation of the π bond between C_1 and C_2 of ER is observed in Fig. 4-e. The absence of the bonding component which is the origin of the π bond in ethylene is attributable to the neglect of the excited configurations in the wave function Ψ of Eq. 3. The process of the π bond formation can be predicted qualitatively, even if the polarization effect is not taken into account explicitly. The orbitals which contribute to the π bond formation are considered to be the i_4 and o, since all residual MO's of ER have no large p_z atomic orbital (AO) component, that is, a π bond character. A schematic representation of the π bond formation by the orbital mixing of i_4 with o through o' is illustrated in Fig. 5.[13] The interaction of o' with o and i_4 gives the ψ_1, ψ_2, and ψ_3 MO's. In a DOMO, ψ_2, o, and o' overlap in phase, whereas i_4 and o' overlap

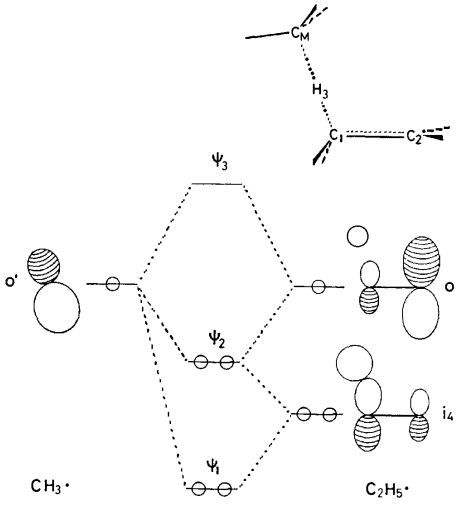


Fig. 5. The schematic representation of the π bond formation of ethyl radical by the orbital mixing of the i_4 and o through the o'. The signs of two MO's (i_4 and o) are chosen so that both of them may have positive overlap integrals with the o'. $\psi_2 = o - i_4 + o'$.

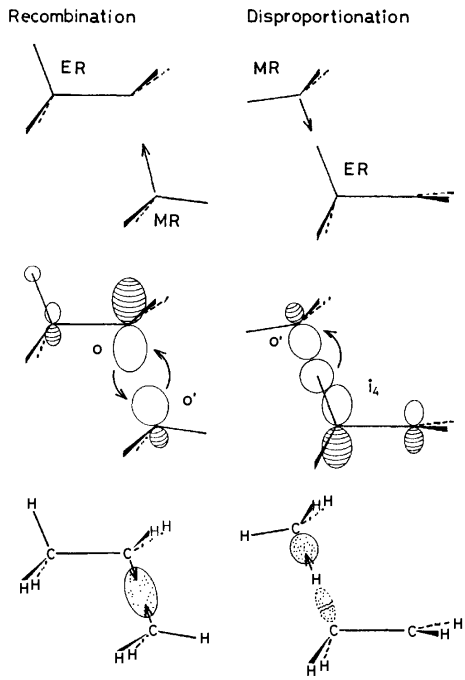

Fig. 6. Schematic representation of the reaction paths of recombination and disproportionation.

out of phase. Consequently in the ϕ_2 orbital the interaction between the lobe at the C_1 atom of i_4 and the lobe at the C_2 atom of o contributes to the π bond formation. Thus, the π bond formation of ER is explained by the orbital mixing of i_4 with o through o'.

Let us summarize our results obtained so far. The reaction pathway of recombination differs a great deal from that of disproportionation, the reactions having no common transition state. This is illustrated schematically in Fig. 6. The SOMO-SOMO interaction is of importance for the progress of the reaction in recombination, whereas the CT interaction from the C–H HOMO (i_4) to the SOMO of one radical directed toward the hydrogen atom of the other is of importance in disproportionation. In the disproportionation, one of radical species which abstracts a hydrogen atom is an electron acceptor and the other radical species which has a hydrogen atom to be abstracted is an electron donor. Consequently the transition state of the disproportionation is expected to have an ionic character. In the recombination, however, this tendency is not observed.

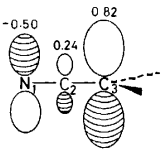
Comparison with Experimental Data

Since the interaction energy, ΔW, is entirely controlled by the extent of the overlap of MO's obtained independently in two radical species, its value can be estimated roughly by analyzing the shape of these MO's. Instead of actual calculation of ΔW, the reactivity of several radical species is conveniently discussed in terms of the shape of some particular MO's. In this section, the theoretical prediction given by such a simple analysis is compared with available experimental data as regards recombination and disproportionation.

Recombination. The simplest way in which odd-electron species are transformed into stable compounds is through the chemical bonding between the radical centers of two such species. However, in a few cases, the recombination takes an unusual path. The dimerization of cyanomethyl radical leads to a ketenimine as well as to the "normal" head-to-head dimer.[14] The former product is an unstable intermediate which rearranges quantitatively to the latter.

$$2R_2\dot{C}\text{—}CN \longrightarrow R_2C\text{—}N{=}C{=}CR_2 + R_2C\text{——}CR_2$$
$$\qquad\qquad\qquad\quad | \qquad\qquad\qquad\qquad\quad | \quad\ |$$
$$\qquad\qquad\qquad\quad CN \qquad\qquad\qquad\qquad CN \quad CN$$

In order to study the reactivity of this radical, the SOMO of cyanomethyl radical is obtained by the extended Hückel (EH) MO method.[15] The shape of the SOMO is as follows.



The numbers attached to each lobe denote the coefficients of the AO's of the SOMO. Judging from the shape of the SOMO of cyanomethyl radical, two recombination paths are possible. The first is the formation of the C_3–C_3 bond, giving the latter stable product, the C_3 atom having the largest lobe of the SOMO. The second is the linkage of the N_1 of one radical with the C_3 of the other, giving an abnormal product (ketenimine). The second mode of recombination is probably due to the following. Since N_1 is charged more negatively than C_3, reflecting the difference of electronegativity, the Coulomb long-range force represented by E_Q of Eq. 4 becomes largely attractive by the approach of the $C_3\cdots N_1$. Thus, the second path of recombination is more favorable than the first in the initial stage of reaction. The abnormal recombination product is formed when the carbon radical center of one radical attacks the nitrogen atom of the other.

Disproportionation. Isotopic Effect: The isotopic effect is expected in the disproportionation path shown in Fig. 6. The substitution from H to D on the carbon atom adjacent to the radical center reduces the disproportionation rate constant, k_d, whereas in the recombination path k_c does not seem to be affected so much by this substitution. In Eq. 11, isotopic substitution on the carbon atom adjacent to the radical center has a large effect on the disproportionation, but a small effect on the recombination in Eq. 10 and the disproportionation in Eq. 12. Consequently, the isotopic substitution is expected to reduce k_d/k_c. It is experimentally evident that in the gas, liquid, and solid phases there is a significant kinetic isotopic effect by which the substitution from H to D reduces k_d/k_c.[18] Gibian and Corley measured the k_d/k_c value of $C_6H_5\dot{C}HCH_3$ and $C_6H_5\dot{C}HCD_3$ in the benzene solution, and found the $[k_d/k_c(H)]/[k_d/k_c(D)]$ value to be 1.87.[16] Boddy and Steacie[17] found the k_d/k_c value of $C_2D_5\cdot$ to be 0.0985 in the gase phase, and that of $C_2H_5\cdot$ 0.13,

leading to the ratio $[k_d/k_c(H)]/[k_d/k_c(D)]=1.32$. The data support the reaction paths of recombination and disproportionation assumed throughout the present work.

Substitution Effect: The CT interaction from the C–H HOMO of one radical to the SOMO of the other radical is found to be of importance to cause disproportionation. In our calculation of ΔW, the former radical is ER and the latter MR. The result together with $\Delta\rho(1|1)$ of Fig. 4-e leads to the prediction that the disproportionation occurs more easily when the radical receiving an abstracted hydrogen (R) has an electron-accepting group or the radical releasing a hydrogen (R′) has an electron-donating group. Let us examine this substitution effect in more detail. For the sake of convenience, the ratio of the rate constants, k_d/k_c, is denoted by Δ(R, R′). The number of the β-hydrogens of R′ is defined as βH. The large value of Δ(R, R′)/βH indicates the ease of the occurrence of disproportionation.

Table 3 gives the Δ(R, R′) of some small alkyl radical reactions.[1a] The orbital energies of the C–H HOMO of R′ are calculated by the EHMO method. The elevation of the level of the C–H HOMO corresponds to the higher reactivity of the electron-donating radical. The C–H HOMO level of the ethyl radical is found to be raised by the electron donating group. In the disproportionation between the methyl radical and the substituted ethyl radical, the Δ(R, R′)/βH increases as the level of the C–H HOMO of the latter radical rises. This tendency is also observed when the ethyl radical reacts with the substituted ethyl radical (Table 3). This is also understandable from the C–H HOMO level. The inclusion of the electron acceptor group, Cl, to the R′ makes the $\Delta(CCl_3, C_2H_4Cl)/\beta H$ smaller than the $\Delta(CCl_3, C_2H_5)/\beta H$. Although the recombination is assumed to be uninfluenced by the substitution effect, the trend of the above data suggests that the disproportionation rate constant is affected by the energy gap between the SOMO of the radical receiving the hydrogen atom and the C–H HOMO of the radical releasing the hydrogen atom when the height of the SOMO is kept frozen.

Table 3. Ratio of rate constants with the substitution effect

R	R′	Δ(R, R′)	Δ(R, R′)/βH	HOMO level[a] (eV)

Solvent Effect: The density map, $\Delta\rho(1|1)$, (Fig. 4-e) shows that the transition state of the disproportionation is polarized in spite of the reaction of two neutral radicals, but not that of recombination. This leads to the expectation that the disproportionation is accelerated in polar solvents, but not recombination. Stefani measured the ratio of the rate constants, k_d/k_c, for the termination reaction of ethyl radicals in various sol-

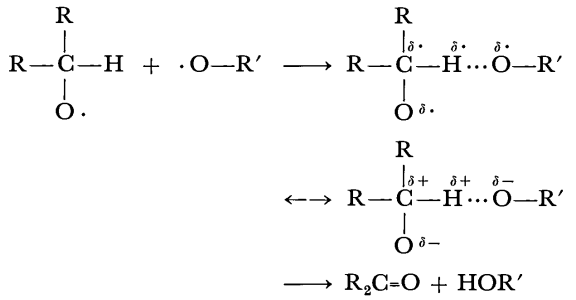
vents.[18] He found that $\log(k_d/k_c)$ is a linear function of $\sqrt{\delta}$ where δ is the Hildebrand solubility parameter, expressing the internal pressure of the solvent.[19] Herbrandson and Neufeld proposed[20] that δ correlated with various polarity parameters such as Y,[21] Ω,[22] Z,[23] and E_T.[24] The values of k_d/k_c, δ, and these four polarity parameters are given in Table 4. The larger the values of the parameters, the larger the solvent polarity. The transition state of disproportionation is expected to have a polar character to be stabilized by the solvent. This is in line with our proposal of the different ionic characters of recombination and disproportionation.

Alkoxy radicals are known to give very high fractions of disproportionation in comparison with alkyl radicals.[1a] It is suggested that this phenomenon is attributable to the increased polar conditions by an electronegative oxygen atom at the transition state.[25]



The suggestion that the transition state of the disproportionation of alkoxy radicals has an ionic character supports our view of the transition state of the disproportionation of alkyl radicals.

Conclusion

Recombination, one of two termination reactions, takes a reaction path differing from that of the other termination reaction, disproportionation. These two reactions are shown to have no common transition state. The recombination path is the route by which two radicals approach in such a direction that the overlap between both SOMO's may become maximum. It is suggested that the transition state of recombination is not much polarized. The disproportionation path is the route by which one radical receiving a hydrogen atom attacks the β hydrogen atom of the other radical. The CT interaction from the C–H HOMO of one radical to the SOMO of the other abstracting a hydrogen atom plays an important role to cause disproportionation. The radical receiving a hydrogen atom is found to be an electron acceptor and the radical with the C–H bond broken in the disproportionation an electron donor. The transition state of disproportionation is shown to have a polar character.

We would like to express our gratitude to the staff of the Data Processing Center, Kyoto University, for permission to use the FACOM 230-75 computer. The MO calculation was carried out with financial support of the Ministry of Education (Grant-in-Aid 139012).

The Electronic Structure and Homolytic Dissociation of Dibenzoyl Peroxide

Osamu KIKUCHI, Akihisa HIYAMA, Hiroshi YOSHIDA, and Keizo SUZUKI

Institute of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 300-31

(Received May 12, 1977)

The conformations and electronic structures of dibenzoyl peroxide (BPO) and the benzoyloxyl radical (PhCOO) were elucidated by means of closed-shell and restricted open-shell SCF MINDO/3 calculations. The dihedral angle of BPO between the two PhCOO planes was predicted to be 115°, and the barrier to the *trans* form of BPO was estimated to be very small. The ground state of the PhCOO radical was predicted to be of the Σ-type. The non-planar conformation of PhCOO was more stable (2 kcal/mol) than the planar one. The variation in the radical-pair property of the lowest state of acetyl peroxide during the homolytic dissociation process was estimated by the analysis of the two-configuration wavefunctions. The substituent effect on the rate of the homolytic dissociation of BPO was discussed in terms of the electronic structures of substituted BPO.

Dibenzoyl peroxide (BPO) undergoes a variety of reactions because of its weak peroxy O–O bond. A typical process is the simple homolytic cleavage of the O–O bond to form benzoyloxyl radicals:

$$C_6H_5\text{-}\overset{\overset{O}{\|}}{C}\text{-}O\text{-}O\text{-}\overset{\overset{O}{\|}}{C}\text{-}C_6H_5 \longrightarrow 2C_6H_5\text{-}\overset{\overset{O}{\|}}{C}\text{-}O\cdot \qquad (1)$$

Numerous investigations[1] have been experimentally performed on the mechanism of (1) and of the successive reactions. The substituent effect[2] on Reaction (1) has been observed; the rate constant correlates with the Hammet σ constant with $\rho=-0.38$. This substituent effect was explained in terms of the electrostatic repulsion between the two peroxy oxygen atoms[2] or that between the two carbonyl oxygen atoms.[3] These explanations are qualitative ones, and no MO-theoretical studies have been reported on the electronic structures of BPO and the benzoyloxyl radical[4] in connection with the dissociation process of BPO. The purposes of this paper are (i) to examine the electronic structures of BPO, substituted BPO, and the benzoyloxyl radical; (ii) to explain the substituent effect on the rate of the O–O cleavage in terms of the electronic structure of BPO, and (iii) to consider the variation in the electronic structure of BPO during its homolytic dissociation process. The results obtained here will be useful for the understanding of a variety of reactions involving BPO and the benzoyloxyl radical.

Method

The MINDO/3 method[5] was employed to determine the most favorable conformation of BPO. Since a large number of geometrical parameters are involved in BPO, the geometry of diacetyl peroxide (APO) was first optimized; the parameters obtained for the COO groups in APO were then employed in the calculations of BPO. The bond lengths and bond angles of the phenyl groups (CC=1.397 Å, CH=1.087 Å, CCC=CCH=120°)[6] were not optimized. Only two parameters, the peroxy O–O bond length and the dihedral angle between the two PhCOO planes, were optimized. The total energy of BPO was partitioned into atomic energies and atom-atom energies in order to elucidate the electronic factors affecting the conformation of BPO. According to Fischer and Kollmar,[7] the total energy of a molecule can be partitioned into one-center and two-center terms:

$$E_{\text{total}} = \sum_{A} E_A + \sum_{A>B} E_{A,B}, \qquad (2)$$

where the two-center energy between the A and B atoms can be written in the form:[7]

$$E_{A,B} = E^{R}_{A,B} + E^{K}_{A,B} + (E^{J}_{A,B} + E^{V}_{A,B} + E^{N}_{A,B}). \qquad (3)$$

$E^{R}_{A,B}$ is the contribution of the resonance integrals to $E_{A,B}$, $E^{K}_{A,B}$ is the corresponding term of the electronic exchange interaction, and the third term in parentheses is the electrostatic interaction energy between the A and B atoms.

The conformation and electronic structure of the benzoyloxyl radical (PhCOO) were discussed on the basis of the interactions between the MO's of the phenyl radical and those of the bent COO fragment. These discussions were supported by the restricted open-shell SCF calculations with the MINDO/3 approximation. The open-shell SCF method employed was the approximate one proposed by Longuet-Higgins and Pople.[8] The general SCF theory,[9] which gives correct variational solutions for the open-shell problems, was also used to confirm the results obtained by the approximate open-shell SCF calculations.

The small configuration interation (CI) calculations, in which only two configurations related to the σ and σ^* MO's of the peroxy O–O bond were taken into account, were carried out to obtain the qualitative potential curves during the dissociation process (1). As may be seen from Fig. 1, the energy difference between the σ and σ^* orbitals of the peroxy O–O bond becomes small when the O–O distance, R_{OO}, increases.

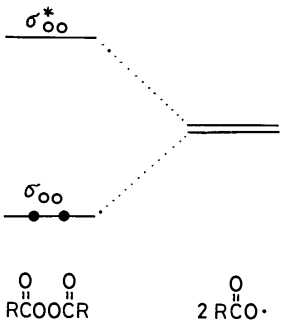

Fig. 1. The correlation diagram for the peroxy O–O σ orbitals along the dissociation process.

Therefore, reliable potential curves of acyl peroxide along the O–O bond cleavage cannot be obtained by the single-configuration wavefunction:[10]

$$\Psi_g = |\cdots\sigma^2\sigma^{*0}|, \quad (4)$$

$$\sigma = \frac{1}{\sqrt{2}}(\chi_a + \chi_b), \quad (5)$$

$$\sigma^* = \frac{1}{\sqrt{2}}(\chi_a - \chi_b), \quad (6)$$

where χ_a and χ_b are the AO's of the two peroxy oxygen atoms, whose directions are parallel to the O–O bond. Near the equilibrium O–O distance, the ground state of acyl peroxide can well be described by Ψ_g, and the mixing of Ψ_g with the excited configuration:

$$\Psi'' = |\cdots\sigma^0\sigma^{*2}|, \quad (7)$$

is very small. When R_{OO} increases, the mixing between Ψ_g and Ψ'' becomes very large and a linear combination of them must be used for the wavefunction of the lowest state. The potential curves were thus calculated by the CI calculations in which Ψ_g and Ψ'' were included. The two-configuration wavefunctions were then analyzed, and the radical-pair property of the RCOO–OOCR system was estimated during the dissociation process of (1).

Results and Discussion

Conformation of BPO. The most stable conformation of BPO predicted by MINDO/3 is shown in Fig. 2. The predicted O–O distance, 1.41 Å, is smaller than the observed value[11] by 0.05 Å, and the dihedral angle, 115°, is slightly larger than the observed value ($\simeq$90°)[11] of BPO. It is interesting that these values are identical with those predicted for APO, despite the large difference in the substituents of BPO and APO. Figure 3 shows the energy variations of BPO and APO with respect to the rotation angle about the peroxy O–O bond. The barrier to a *cis* form was very large($\approx$40 kcal/mol), while that to a *trans* form was very small (1 kcal/mol).

Three factors may be important in analyzing the favorable conformation of BPO: (i) Electron delocalization over both the COO groups through the peroxy O–O bond; (ii) electro-static repulsion between the two carbonyl oxygen atoms, which makes the dihedral angle large, and (iii) the interaction between the lone-pair electrons of the peroxy O–O atoms, which is sensitive to the dihedral angle. These factors were examined on the basis of the partitioned energies. The large dependence upon the dihedral angle, θ, was recognized in the two-center energies between two peroxy oxygen atoms and in those between two carbonyl groups. In Fig. 4, the two-center energy between the two peroxy oxygen atoms, $E_{1,5}$, and that between two carbonyl oxygens, $E_{3,7}$, are plotted. The electrostatic repulsion between two peroxy oxygens, $E^J_{1,5}+E^V_{1,5}+E^N_{1,5}$, was almost constant at any value of θ, because the atomic electron densities of the peroxy oxygen atoms were almost constant to the rotation angle. The lowering of $E_{1,5}$ in the region of θ=60—90° comes from the stabilization of the O–O bond due to the resonance energy:

$$E^R_{1,5} = 2\sum_{r,s} P_{rs}H^{core}_{rs}, \quad (8)$$

a) The geometry of unsubstituted BPO predicted in this paper was employed in the calculations.

b) 
c) The axes, x, y, and z, are shown in Fig. 1. The positive values correspond to the bonding character.

where P_{rs} and H_{rs}^{core} have the usual meanings. The resonance energy between peroxy oxygens decreases (becomes more stable) as a result of the mixing of the lone-pair electrons with the π-electrons of the adjacent carbonyl group.

The electrostatic repulsion energy between two carbonyl oxygens decreases rapidly with increase in θ, because the distance between two carbonyl oxygens increases with θ. This electrostatic energy is dominant in $E_{3,7}$. The angular dependence of $E_{1,5}+E_{3,7}$ shown in Fig. 4 resembles that of the total energy of BPO shown in Fig. 3 The dihedral angle of BPO can thus be interpreted in terms of two factors, the electrostatic repulsion energy between two carbonyl oxygens and the resonance energy between two peroxy oxygens.

Electron Distribution in BPO. Since the rate of the dissociation of BPO depends on the substituents introduced in the phenyl group,[2)] it is worthwhile examining the electronic structures of substituted BPO. Nine substituted BPO were calculated using the conformation of unsubstituted BPO shown in Fig. 2. The electron densities on the carbonyl and peroxy groups and the bond orders between the peroxy oxygen atoms are listed in Table 1. The electron densities appear to reflect gently the characters of the substituents; the electron-withdrawing group, for example, reduces the electron densities on both the peroxy and carbonyl oxygen atoms. The bond order between AO's whose directions are perpendicular to the O–O bond also reflects the characters of the substituents. The effect of CH_3 groups on the electron distribution is very small, perhaps because the $(COO)_2$ group itself has an electron-donating character.

Electronic Structure of the Benzoyloxyl Radical. The energy levels and qualitative pictures of the MO's of the C_∞ CO_2 molecule and those of the bent C_{2v} COO fragment are shown in Fig. 5. A reduction of the symmetry property of CO_2 from C_∞ to C_{2v} causes (i) a rise in the orbital energies of π° and $\bar{\pi}^\circ$ orbitals because of the anti-bonding interaction between the terminal p orbitals, and (ii) a lowering of the 5σ orbital due to the strong mixing of this orbital with the $\bar{\pi}^*$ orbital. Since the instabilization of the $\bar{\pi}^\circ$ orbital is larger than that of the π° orbital, an inversion of the MO levels of $4a_1$ and $3b_2$ is expected for the small OCO angle ($<120°$).

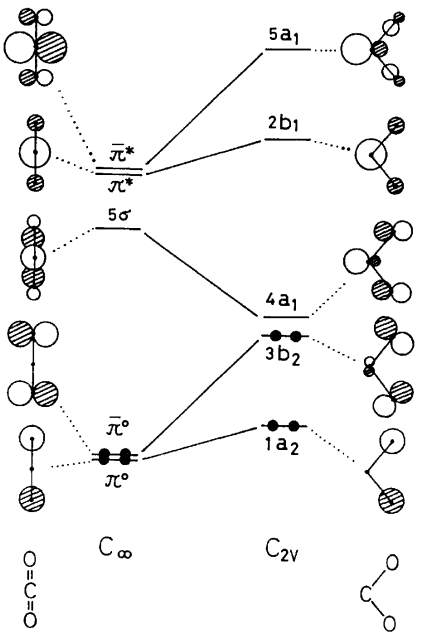

Fig. 5. Energy levels and qualitative pictures of some higher-occupied and lower-unoccupied MO's of the C_∞ CO_2 molecule and the bent CO_2 fragment.

The stability of the PhCOO radical can be elucidated by the interaction between the bent COO fragment and the phenyl radical. The half-occupied MO of the phenyl radical interacts with the unoccupied $4a_1$ MO of COO to form the Ph–COO bond. Since only one electron occupies the newly formed PhCOO bond, the $^2A_1$ state of PhCOO can be expected to break its Ph–COO bond easily to produce the phenyl radical

and CO_2. One-electron migration from the doubly-occupied $3b_2$ orbital to the half-occupied $4a_1$ orbital of the PhCOO radical makes the Ph–COO bond strong. Thus, the stable $^2B_2$ state of the PhCOO radical is expected for the small OCO angle. Since a larger energy is required for the electron migration from la_2 (π) to $4a_1$, the $^2A_2$ state (π-radical) of PhCOO can be expected to be more unstable than the $^2B_2$ state.

The above qualitative discussions were supported by open-shell SCF calculations. Calculations were performed by restricting the COO geometry of PhCOO to C_{2v}. When the OCO angle is 100—120°, the lowest state of PhCOO was predicted to be the $^2B_2$ state (the σ-radical whose unpaired electron occupies the $3b_2$ orbital shown in Fig. 5). When the OCO angle is larger than 130°, the lowest state was $^2A_1$ (σ-radical) and the Ph–COO bond length becomes long. This indicates that the lowest state for OCO>130° is the intermediate stage in the decarboxylation process of PhCOO. The π-state was higher than the σ-state for the entire range of OCO angles. Recently, the σ-ground state of the acyloxyl radical was predicted by semi-empirical NDDO calculations of HCOO and CH_3-COO[12] and by *ab initio* STO-3G calculations of H-COO.[13] However, the σ-ground state predicted in these studies is a distorted one (C_s symmetry), in which the two C–O bond lengths differ from one another. In the present MINDO/3 calculations, the energy lowering caused by the distortion of the OCO geometry was not observed even if the general SCF theory was employed.

The energy dependence of the lowest $^2B_2$ state of PhCOO upon the dihedral angle between the phenyl and COO planes was calculated. The non-planar conformations were more stable than the planar one. When the two planes were perpendicular to each other, the PhCOO radical was the most stable. However, the barrier to the rotation about the Ph–COO bond was very small (2 kcal/mol). The spin delocalization from the COO group into the phenyl group was very small (less than 0.5%) for both the planar and non-planar PhCOO radicals.

Potential Curves and Radical-pair Property during the Homolytic Dissociation. Variations in the electronic properties of APO during the homolytic dissociation process were examined by two-configuration CI calculations in which Ψ_g and Ψ'' were included. The potential curves obtained are shown in Fig. 6, while the wavefunctions of the lowest state are listed in Table 2. It may be seen from Table 2 that the lowest wavefunction at $R_{OO}=\infty$ is

$$\Phi_\infty = \frac{1}{\sqrt{2}}\{\Psi_g - \Psi''\}. \quad (9)$$

This state can be analyzed by expressing the wavefunction in terms of the orbitals of two separate fragments:[14]

$$\Phi_\infty = |\cdots\chi_a^1| \times |\cdots\chi_b^1|, \quad (10)$$

using Eqs. 4—7. It is clear that this wavefunction corresponds to the two-radical, or the radical-pair, state, and that the ground state of acyl peroxide correlates with a pair of acyloxyl radicals at $R_{OO}=\infty$.

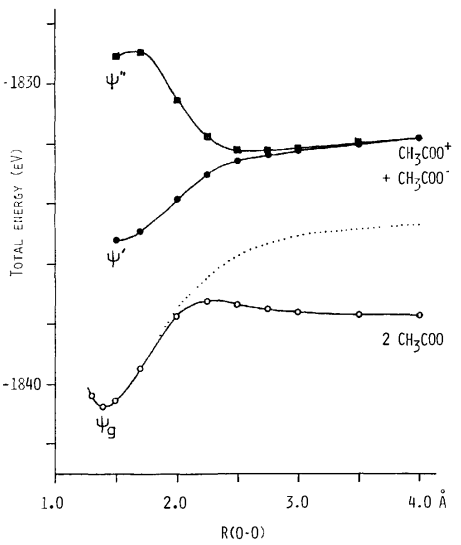

Fig. 6. Potential curves for APO obtained by 2-configuration CI calculations. The dotted line indicates the energy of the single-configuration wavefunction. The Ψ' line corresponds to the electron configuration of $(\cdots\sigma^1\sigma^{*1})$.

TABLE 2. VARIATION IN THE LOWEST WAVEFUNCTION OF APO DURING THE DISSOCIATION OF THE PEROXY O-O BOND

R_{OO} (Å)	Total energy (eV)	Coeffeicients of Ψ_g	Coeffeicients of Ψ''	Radical-pair property (%)
1.30	−1840.378	0.9997	−0.0239	2.5
1.41	−1840.739	0.9996	−0.0285	2.9
1.50	−1840.551	0.9994	−0.0357	3.7
1.70	−1839.469	0.9978	−0.0671	7.2
2.00	−1837.761	0.9857	−0.1685	19.5
2.25	−1837.253	0.9239	−0.3827	50.0
2.50	−1837.342	0.8339	−0.5520	76.5
2.75	−1837.513	0.7723	−0.6353	89.4
3.00	−1837.625	0.7403	−0.6723	95.0
4.00	−1837.750	0.7105	−0.7037	99.5

Similar treatment is possible for the degcnerate states at $R_{OO}=\infty$. They correspond to the ionic states: $RCOO^+$ plus $RCOO^-$ and $RCOO^-$ plus $RCOO^+$.

Since the wavefunction of APO at $R_{OO}=\infty$, $(\Psi_g-\Psi'')/\sqrt{2}$, represents the pure radical-pair, the contribution of this term to the lowest state may be a measure of the radical-pair property of the RCOO–OOCR system. In this sense, the radical-pair property involved in the lowest state of APO was analyzed during the dissociation process. The wavefunction at an arbitrary R_{OO} is expressed by:

$$\Phi \equiv c\Psi_g - d\Psi'' = (c-d)\Psi_g + \sqrt{2}d\left\{\frac{1}{\sqrt{2}}(\Psi_g-\Psi'')\right\}, \quad (11)$$

with $c^2+d^2=1$. The radical-pair property of Φ is thus expressed by:

$$(\sqrt{2}d)^2\left\langle \frac{1}{\sqrt{2}}(\Psi_g-\Psi'')\middle|\frac{1}{\sqrt{2}}(\Psi_g-\Psi'')\right\rangle + (c-d)\sqrt{2}d\left\langle \Psi_g\middle|\frac{1}{\sqrt{2}}(\Psi_g-\Psi'')\right\rangle = d^2+cd, \quad (12)$$

and the covalent-bond property is similarily expressed by c^2-cd. The calculated radical-pair properties of APO during the homolytic dissociation process are listed in Table 2. When $R_{OO}>2.25$ Å, the RCOO–OOCR system can be considered to be a weakly interacting radical pair, while for $R_{OO}<2.25$ Å the covalent-bond property of RCOO–OOCR increases rapidly.

The dissociation energy and the activation energy calculated for the O–O bond cleavage of APO is considerably larger than the observed value ($\simeq$30 kcal/mol).[1,2] In Fig. 6, a large activation energy is predicted for the recombination process of the active acetyloxyl radical. These results may come from the method of calculation employed here where (i) only small configurations were taken into account; (ii) the geometrical parameters involved were not optimized during the dissociation process, and (iii) the inaccuracy inherently involved in the MINDO/3 approximation was not estimated. Thus, any quantitative discussion about the reaction energies may be risky.

Substituent Effect on the Dissociation of BPO. Swain *et al.*[2a] studied the dissociation process of many substituted BPO and found that the electron-withdrawing substituents reduced the rate of the dissociation, while the electron-donating substituents increased the rate. This effect was explained[2a] in terms of the electrostatic repulsion between the two peroxy oxygen atoms, which is reduced by the electron-withdrawing group and which is increased by the electron-donating group. The calculated results (Table 1) reflect the substituent effect pointed out by Swain *et al.* However, the effect is very small. The importance of the electrostatic repulsion between the carbonyl oxygen atoms was pointed out by Imoto.[3] The calculated results show that the electron-donating group increases the repulsion energy between carbonyl oxygens. However, as may be seen from Fig. 3, the barrier to the *trans* form of BPO is expected to be very small, and the increased repulsion between carbonyl oxygens is compensated for by increasing of the dihedral angle, θ.

The bond order between peroxy oxygen atoms, $P_{1y,5y}$, shown in Table 1 is almost constant and fails to explain the substituent effect on the dissociation rate.

Another explanation is more reasonable. When the electron-donating group is introduced to the phenyl group, the electron densities on the carbonyl oxygen atoms increase (Table 1) and the electrostatic repulsion between the oxygen atoms increases. This makes the dihedral angle, θ, large without any appreciable loss of energy, since the barrier to the *trans* form is very small (Fig. 3). The resonance energy between the O–O atoms increases (becomes more unstable) with the increase in the dihedral angle (Fig. 4). As a result, the introduction of the electron-donating group into the phenyl group makes the peroxy bond weak and makes the dissociation of the O–O bond easy.

The radical-pair property defined here may be a measure of the weakness of the O–O bond of BPO. A substituted BPO, in which a large radical-pair property is inherently involved, can be expected to have a low activation energy. The calculated radical-pair properties of *p,p'*-dinitro-BPO (1.5%), unsubstituted BPO (2.1%), *p,p'*-dimethoxy-BPO (2.2%), and APO (2.9%) agreed with the trend of the experimental rates of the dissociation.

One of the authors, O. K., wishes to express his thanks to Professor Katsumi Tokumaru and to Dr. Ken Fujimori for their useful suggestions.

MINDO/3 Study of 7-Norbornyl, 7-Norbornenyl, and 7-Norbornadienyl Cations

Akio FURUSAKI and Takeshi MATSUMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Kita-ku, Sapporo 060

(Received June 9, 1977)

The geometries, charge distributions, and heats of formation for 7-norbornyl, 7-norbornenyl, and 7-norbornadienyl cations have been calculated by the use of the semi-empirical MINDO/3 SCF MO method. Each of these cations is symmetrical with respect to the plane which contains the C(7)–H(7) bond and bisects the C(1)–C(7)–C(4) angle. Both the 7-norbornenyl and the 7-norbornadienyl cations take the nonclassical bridge-structure: the C(2)–C(3) and C(2)–C(7) distances are about 1.43 and 1.67 Å respectively, and the C(2)–C(1)–C(4)–C(7) dihedral angle is about 75°. The classical 7-norbornyl cation also is quite unsymmetrical with regard to the C(1)–C(7)–C(4) plane: the C(2)–C(1)–C(4)–C(7) and C(7)–C(1)–C(4)–C(5) dihedral angles are 94° and 144°, respectively. The calculated barriers to the bridge flipping in the 7-norbornyl and 7-norbornadienyl cations are 3.2 and 33.0 kcal/mol respectively. Although the latter is much higher than its observed value of 19.6 kcal/mol, it seems possible that solvation considerably lowers the barrier height. The present article also touches upon the solvolyses of derivatives of these carbocations.

The chemical behavior of the 7-norbornenyl and 7-norbornadienyl cations, known as unusually stable nonclassical ions, has been closely examined through kinetic, stereochemical, and spectroscopic experiments.[1-4] On the other hand, the theoretical studies which have hitherto been made on these carbonium ions do not necessarily afford enough information to explain their chemical properties.[5-7] For example, the geometries of the cations have not yet been calculated without any assumptions. In order to obtain detailed information about these interesting carbonium ions, we have begun to study them by the MINDO/3 self-consistent-field molecular-orbital method.[8] The present paper will give the calculated geometries, charge distributions, and heats of formation for 7-norbornyl (**1**), 7-norbornenyl (**2**), and 7-norbornadienyl (**3**) cations, and will discuss the stability of these carbocations and the solvent effect on it.

Method of Calculation

The calculations reported here were performed using the MINDO/3 parameters listed in Ref. 8, on a FACOM 230-75 computer at the Computing Center of Hokkaido University. Geometries of carbocations were obtained by minimizing their total energies with respect to all atomic coordinates, using a program written by the present authors. For any cation or molecule, the optimization procedure was repeated until a change in its total energy became less than 0.001 kcal/mol. Transition states were distinguished from other stationary points by two conditions: (a) they have only one negative eigenvalue of the force constant matrix and (b) their transition vector corresponds to the vibration which transforms the reactants into the products.[9]

A difference in solvation energy of two carbocations was estimated by the use of the following equation:

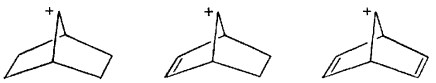
$$\Delta E_s = \Delta[-(1-1/D)(\sum_i q_i^2/2r_i + \sum_{i<j} q_iq_j/r_{ij})], \qquad (1)$$

where D denotes the dielectric constant of the solvent, q_i and q_j represent the net charges of the i-th and j-th atoms in each cation respectively, r_i designates the ionic radius of the i-th atom, and r_{ij} stands for the distance between the i-th and j-th atoms.[10] In this study, the ionic radii of carbon and hydrogen atoms were approximated by their usual van der Waals radii, 1.70* and 1.20 Å, respectively. In applying Eq. 1 to carbocations, we made the following modification: when the interatomic distance, d_{ij}, was less than the sum of the ionic radii, r_i+r_j, the latter was used as r_{ij}; otherwise, as usual, d_{ij} was adopted as r_{ij}. This means that it was assumed that the solvent neither assisted nor prevented the approach of the i-th and j-th atoms from their van der Waals distance to their bond distance. The following example shows that using bond distances as r_{ij}'s may lead to serious errors in the calculation of solvation energies for carbocations.

Let us consider a monoatomic system, A, with an ionic radius of R and a net charge of q and a diatomic system, B, where two atoms with ionic radii of R and net charges of $q/2$ are separated by a bond distance of d. From Eq. 1, the solvation energy for B, relative to that for A, is given by $\Delta E_s=-(1-1/D)(1/d-1/R)q^2/4$, which is negative because usually d is less than R. On the other hand, since B can be well approximated by a monoatomic system with a radius of R' (greater than R) and a net charge of q, the magnitude of the solvation energy for B should be smaller than that for A by $-(1-1/D)(1/R'-1/R)q^2/2$, *i.e.*, ΔE_s should be positive. Such a conflict probably comes mainly from overestimation of solvent effects in the process of forming the covalent bond. For this reason, we made the above-mentioned modification in Eq. 1 as a first approximation. However, it must be kept in mind that, in any way, ΔE_s gives only a rough estimate of a difference in solvation energy.

Results and Discussion

Geometries. Figure 1 shows the calculated geometries for the carbocations **1**, **2**, and **3**. Though no assumption was made about their symmetries, each of these cations has, within the limits of the computational errors, a plane of symmetry which contains the C(7)-H(7) bond and bisects the C(1)–C(7)–C(4) angle. The



1 **2** **3**

* One-half the thickness of benzene rings in crystals.

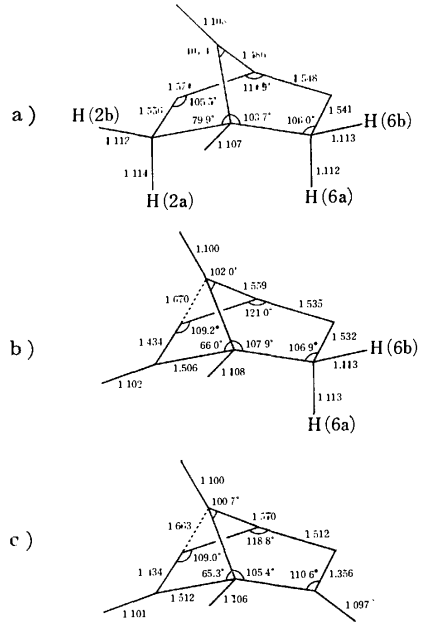


Fig. 1. The calculated geometries (bond lengths in Å) for (a) **1**, (b) **2**, and (c) **3**.

conformations of **1**, **2**, and **3** viewed along the C(1)–C(4) directions are given in Fig. 2. It should be noted here that not only the nonclassical ions **2** and **3**, but also the classical ion **1** is unsymmetrical with respect to the C(1)–C(7)–C(4) plane. As will be shown by an appreciable lengthening of the C(1)–C(2) and C(3)–C(4) bonds, this deformation probably occurs so as to help delocalization of the C(1)–C(2) and C(3)–C(4) σ-bonding electrons into the vacant C(7) 2p-orbital.

The degree of unsymmetry of **2** and **3** is much greater than that of **1**. Both the remarkable lengthening of the C(2)–C(3), C(1)–C(7), and C(4)–C(7) bonds and the close approach of the C(7) atom to the C(2) and C(3) atoms clearly indicate that the vacant C(7) 2p-orbital

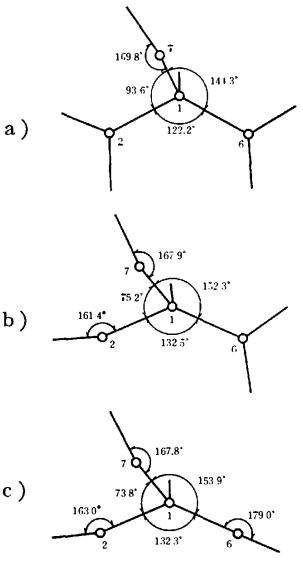

Fig. 2. The conformations viewed along the C(1)-C(4) directions: (a) **1**, (b) **2**, and (c) **3**.

and the C(2)–C(3) π-bonding orbital interact strongly with each other to form a kind of bridged ion. It may be useful for an understanding of this orbital interaction to examine how the two overlapping orbitals in **2** and **3** differ from isolated 2p- and π-orbitals. First, it is found that the C(7)–H(7) bond deviates from the C(1)–C(7)–C(4) plane onto the side opposite to the C(2)–C(3) bond. This will make the C(7) 2p-orbital expand toward the C(2)–C(3) π-bonding orbital, resulting in an increase in the overlapping. On the other hand, both C(2)–H(2) and C(3)–H(3) bonds deviate from the C(1)–C(2)–C(3)–C(4) plane onto the same side as the C(7) atom. Considered simply from the viewpoint of expansion of the π-bonding orbital, such deviations of the two C–H bonds would be unfavorable to the p-π overlapping under consideration, but nevertheless they appear to strengthen this overlapping by directing the C(2) and C(3) 2p atomic orbitals, of which the C(2)–C(3) π-bonding orbital consists, more effectively toward the C(7) 2p-orbital (see Fig. 3).

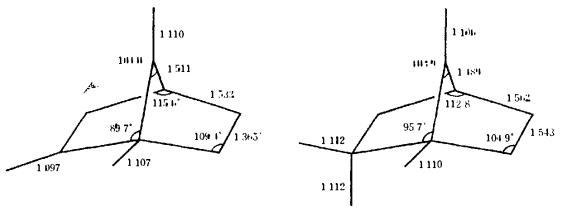
a), b) The transition states for the bridge flipping in **1** and **3** respectively.

Distributions of Net Charges. The distributions of net charges, which are listed in Table 1, show that the C(2)–C(3) π-bonding electrons in **2** and **3** are so remarkably delocalized that the C(2) and C(3) atoms carry greater net charges than the C(7) atom. This result is consistent with the experimental observation that, in the ^{13}C NMR spectra of **2** and **3**, the absorption of the C(2) and C(3) atoms occurs at lower fields than that of the C(7) atom.[4] Although, in both **2** and **3**, the C(2) and C(3) atoms bear the greatest net charge of $+0.106e$, even this does not reach one-third of the net charge ($+0.352e$) on the cationic center in **1**. Thus,

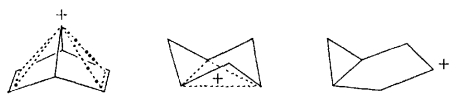


(a) (b)

Fig. 4. The calculated transition state geometries for the bridge flipping in (a) **3** and (b) **1**.

the positive charge of **2** and **3** can be regarded as being spread over almost the whole cation. It is interesting that, in spite of such a pronounced dispersal of the positive charge, the C(5) and C(6) atoms in **3** still bear slight negative net charges ($-0.013e$).**

Bridge Flipping. Figure 4(a) shows the calculated geometry of **3** in the transition state for the bridge flipping. This geometry was calculated on the assumption of C_{2v} symmetry, which was later verified by testing whether the geometry obtained satisfied the two conditions of transition states or not (see the section on Method of Calculation). In the case of the neutral norbornadiene molecule, MINDO/3 optimization affords a length of 1.356 Å to the C(2)–C(3) bond and a value of 121.8° to the C(2)–C(1)–C(4)–C(7) dihedral angle, while the corresponding values of **3** in the transition state are 1.365 Å and 116.2° respectively. This structural variation, caused by extraction of a hydride ion, seems to support the presence of such an interaction between the vacant C(7) 2p-orbital and the C(2)–C(3) or C(5)–C(6) π-bonding orbital, as is shown in **4**. The distribution of net charges, given in the last column of Table 1, also indicates that an appreciable amount of the π-bonding electrons flows into the C(7) 2p-orbital; the C(2), C(3), C(5), and C(6) atoms carry slight positive net charges ($+0.004e$).



4 **5** **6**

The barrier to the bridge flipping in **3** was estimated to be 33.0 kcal/mol by our MINDO/3 calculation. Since its observed value at 45 °C is 19.6 kcal/mol or more,[11] the calculated barrier seems to be somewhat too high. The difference may be ascribed in part to the MINDO/3 approximation and in part to the solvent effects. As will be seen in Table 1, the C(7) atom bears much more net charge in the transition state than in the stable form. Hence, **3** can acquire more stabilization energy due to solvation in the former. This difference in solvation energy was estimated at 5.7 kcal/mol for $D=\infty$ by using Eq. 1. Jorgensen has recently shown that the presence of one molecule of hydrogen chloride can reduce the difference in energy between the more stable cation, **5**, and the less stable one, **6**, by more than 9 kcal/mol.[12,13] This suggests that solvation may facilitate the bridge flipping in **3** to a considerable extent.***

The calculated barrier to the bridge flipping in **1** was only 3.2 kcal/mol. Moreover, the calculation of solvation energy showed that this barrier might be lowered in solvents with $D=\infty$ by 2.0 kcal/mol. Therefore, it seems difficult to observe the bridge flipping of **1** in solution. The calculated geometry and distribution of net charges of **1** in the transition state for the bridge flipping are given in Fig. 4(b) and in the third column of Table 1 respectively. The C(7) atom of **1** in the transition state carries more net charge than that of **3** in the transition state, which is probably due to the absence of π-bonding electrons to delocalize directly into the ionizing center.

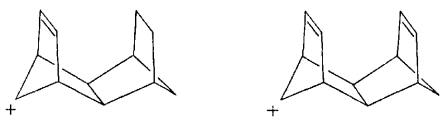
a), b) The calculated relative enthalpies of the gas reactions $RH \rightarrow R^+ + H^-$ and $RCl \rightarrow R^+ + Cl^-$, respectively. c) The relative activation energies estimated from the observed rate constants for the solvolyses of RX. See Refs. 15—19.

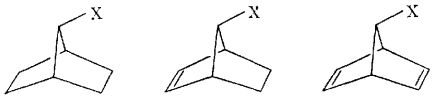
Heats of Formation. The calculated heats of formation of **1**—**3** and **7**—**13** are summarized in Table 2. Since MINDO/3 is known to overestimate the heats of formation of **9** and **11** with X=H by about 21 and 25 kcal/mol respectively,[14] the other heats of formation also should be taken as being overestimated to approximately the same extent as those of the two hydrocarbons. Table 2 further contains the calculated enthalpies of the gas reactions,

$$R\text{-}X \longrightarrow R^+ + X^-. \qquad (2)$$

These enthalpy changes seem not to include such large



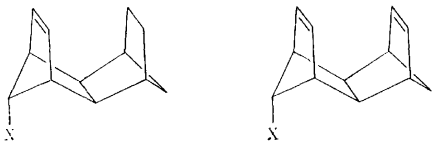
7 **8**



9 **10** **11**

** MINDO/3 gives net charges of $-0.040e$ to the C(5) and C(6) atoms in norbornadiene.

*** The effect of the entropy term on this bridge flipping seems not to be very important, since it is estimated at 2—3 kcal/mol(25 °C) from the entropies of activation for the acetolyses of **9** and **10**.



12 **13**

errors as the heats of formation themselves, because the errors of the latter are probably to a marked degree canceled out in deriving the former from the latter. In fact, it has been shown that MINDO/3 brings about an error of only 4 kcal/mol with respect to the heat of hydrogenation of norbornadiene into norbornane.[14] Since, as will be seen in Table 2, the relative enthalpy of Reaction 2 does not change substantially according to whether the reactant is a hydrocarbon or an alkyl chloride, the results with the chlorides will hereinafter be discussed.

The relative activation energies observed for solvolyses of the compounds of interest are given in the last column of Table 2.[15-19] The calculated enthalpies of the **11**→**3** and **13**→**8** reactions are in good agreement with their corresponding activation energies. This suggests that the formation of **3** and **8** should receive nearly as great solvent-assistance as that of **2**. It has recently been found that the relative energies of nonresonant, isomeric secondary and tertiary carbocations are similar in the gas phase and in solution.[20-22] The cationic portion of **8**, not to mention that of **3**, is quite analogous in charge distribution to that of **2**, as will be seen in Table 3. Accordingly, although these three carbocations are neither nonresonant nor isomeric, it is possible that solvent effects on them may be similar.

As to the **9**→**1** reaction, the case is considerably different. The difference between the enthalpies of the **9**→**1** and **10**→**2** gas reactions was estimated at 33.1 kcal/mol by our MINDO/3 calculation, while the solvolysis experiments have shown that the activation energy for **9** is higher than that for **10** by 15.2 kcal/mol.

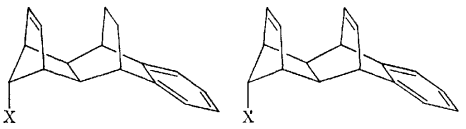
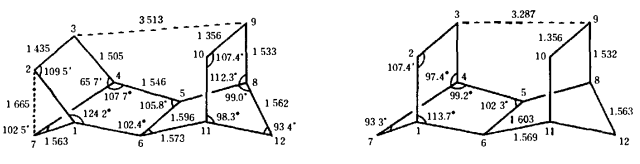
The difference between these calculated and observed values, 17.9 kcal/mol, seems too large to be regarded as due merely to the usual electrostatic effects of the solvent; for example, from Eq. 1, it was shown that **1** might be only 4.8 kcal/mol more stabilized by solvents with $D=\infty$ than **2**. In order to explain this remarkable discrepancy between the gas reactions and the solvolyses, it is necessary to consider different mechanisms for the solvolyses of **9** and **10**. Although **10** presumably solvolyzes through the free, stable carbonium ion, **2**, the solvolysis of **9** may involve rate-determining formation of solvent-separated ion-pairs, as has been found for the 2-adamantyl derivative.[23] The change of **9** into the solvent-separated ion-pair will not require as much energy as the ionization of **9** into the free carbonium ion, **1**. Consequently, the activation energy for the solvolysis of **9** may actually be much lower than could be expected from the mechanism which involves the free cation, **1**.



14 **15**

It is known experimentally that **13** solvolyzes about 10^3 times as fast as **10**.[24] Fukui *et al.* have recently tried to explain this additional acceleration by applying their three-system interaction theory to the carbonium ion, **8**.[25] On the other hand, it has been found that the solvolysis rate for **15** is slightly lower than that for **14**.[19] Our calculations with **12** and **13** also show that, if both of their solvolyses proceed through free carbonium ions, **13** will solvolyze somewhat more slowly than **12**. These results suggest that the solvolytic rate enhancement of **13** and **15** may not necessarily be ascribed to additional stabilization of the intermediate carbonium ions, *i.e.*, anchimeric assistance by the double bond more distant from the cationic center, because **12** and **14** without such anchimeric assistance are more reactive than **13** and **15**. The calculated geometries of **8** and **13** are shown in Fig. 5. The two double bonds in **8** appear too remote from each other to have an effective orbital interaction; the distance between the C(2) and C(10) atoms was estimated at 3.51 Å. Further, no weakening of the C(9)–C(10) double bond in **8** can be detected in Fig. 5. The comparison between the charge distributions for **8** and **13** is given in Table 3, which also shows clearly the absence of detectable flow of the C(9)–C(10) π-electrons into the C(2)–C(3) π-orbital. Thus, it may be said that **8** is not appreciably stabilized



(a) (b)

Fig. 5. The calculated geometries for (a) **8** and (b) **13** (X=H).

by the presence of the C(9)–C(10) double bond. It should thus be concluded that the additional acceleration of the solvolyses of **13** and **15** is due mainly to the relief of steric repulsion between the two adjacent double bonds in the reactants.

Selective Dimerization of Ethylene Catalyzed by Halogenotris-(triphenylphosphine)cobalt(I) Complex-Lewis Acid

Kiyoshi KAWAKAMI, Tsutomu MIZOROKI, and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received June 16, 1977)

Dimerization of ethylene is highly selectively catalyzed by $CoX(PPh_3)_3$ (X=Cl, Br, and I) in the presence of Lewis acid in halobenzene under mild conditions. The catalytic activity is significantly affected by the solvent, bromobenzene being the most effective. The role of $BF_3 \cdot OEt_2$ seems to be formation of a one-to-one complex of Co(I) and BF_3, since the rate of ethylene dimerization attains a plateau on addition of equimolar amount of $BF_3 \cdot OEt_2$. The isomerization of 1-pentene is enhanced by addition of molecular hydrogen or ethylene to the catalyst system. The isotopic scrambling between C_2H_4 and C_2D_4 takes place faster than dimerization. The results are in line with hydridocobalt intermediate formed by the oxidative addition of ethylene to Co(I) complex.

Many papers have appeared on the ethylene dimerization catalyzed by nickel catalysts,[1] but fewer examples are known of cobalt catalysts for the same reaction: *i.e.*, cobalt oxide–charcoal[2] as a heterogeneous catalyst, homogeneously soluble hydridodinitrogentris(triphenylphosphine)cobalt(I) complex,[3] and cobalt(II) compounds[4] activated with alkylaluminium compounds as the reducing agent.

During a study of the role of Lewis acid in the activation of olefin with cobalt complexes, it was found that halogenotris(triphenylphosphine)cobalt(I) is also fairly active and selective in giving ethylene dimer in the presence of Lewis acid such as $BF_3 \cdot OEt_2$ or $AlCl_3$ in halobenzene at ambient temperature and pressure,[5] but it has no activity at all for propylene dimerization, a unique feature of this catalyst system.

This paper reports the properties of this catalyst system in detail.

Experimental

Materials. Halogenotris(triphenylphosphine)cobalt(I) complexes and bromotris(diphenylmethylphosphine)cobalt(I) complex were synthesized according to the method of Sacco.[6] The complexes were also obtained by another method. $AlEt_2(OEt)$ (16 ml) was added to the ether solution (200 ml) of $Co(acac)_2$ (39 mmol) and PPh_3 (156 mmol) under nitrogen atmosphere at 0 °C, followed by addition of halobenzene. A green precipitate was formed in a few minutes. The precipitate dried in a vacuum was identified to be halogenotris-(triphenylphosphine)cobalt(I) complex by elemental analysis, IR, magenetic susceptibility, and several chemical reactions. The result of elemental analysis of cobalt(I) complex is shown in Table 1.

Trace amounts of water and air in ethylene gas were excluded by vacuum distillation. Solvents were dried by P_2O_5 (halobenzene) or metallic sodium(benzene and ether), and distilled under nitrogen atmosphere. $BF_3 \cdot OEt_2$ was also purified by distillation. $AlCl_3$ was purified by sublimation at 200 °C in nitrogen atmosphere. Other commercial Lewis acids, such as $AlBr_3$, $SnCl_2$, $SnCl_4$, and $TiCl_4$ were used, without purification. Hydrogen gas was deoxidized by passing through a $Pd–Al_2O_3$ pellet at 90 °C and dried with a liquid nitrogen trap.

Procedure. To one of the cobalt(I) complexes placed in a two necked flask(50 ml), were added solvent and $BF_3 \cdot OEt_2$ with stirring under nitrogen atomosphere. The nitrogen gas in the flask was evacuated at liquid nitrogen temperature, before ethylene was introduced. The rate of ethylene absorption was measured at constant temperature and pressure by means of a gas burette. The reaction was terminated by addition of an aqueous solution of NaOH, the products being analyzed by GLC.

Isotopic exchange of $C_2H_4–C_2D_4$, dimerization of C_2D_4, and isomerization of 1-alkene were performed by analogous procedures. Isotopic mixtures of butenes and ethylene were analyzed by mass spectrometry with an ionization potential of 10 eV.

Results and Discussions

Effect of Solvent on Catalytic Activity. The catalytic activity of $CoX(PPh_3)_3–BF_3 \cdot OEt_2$ for ethylene dimerization was determined in various solvents (Table 2). Ethylene was absorbed readily in halobenzene solvents, whereas no absorption was observed in other solvents including benzene, anisole, tetrahydrofran, benzonitrile, ethyl bromide, propyl bromide, benzyl bromide, and dichloromethane. Bromobenzene was the most effective solvent among halobenzenes and the rate of ethylene absorption decreased in the order, bromobenzene > iodobenzene > *o*-dichlorobenzene > chlorobenzene > *o*-chlorotoluene. The color of halobenzene solutions of bromotris(triphenylphosphine)cobalt(I) turned

from pale green to deep green on addition of $BF_3 \cdot OEt_2$. In benzene or anisole, however, the color of the solution turned gradually to greenish blue with a black precipitate. The following disproportionation seems to take place readily in benzene or anisole.

$$2CoBr(PPh_3)_3 \longrightarrow CoBr_2(PPh_3)_2 + 4PPh_3 + Co$$

On the other hand, $CoBr(PPh_3)_3$ reacts with alkyl halides to give Co(II) complex and quaternary phosphonium salts. Accordingly the $CoX(PPh_3)_3$ activated with $BF_3 \cdot OEt_2$ could act as a catalyst only in halobenzene for the ethylene dimerization.

When ethylene gas was introduced immediately after the addition of $BF_3 \cdot OEt_2$, a high rate of ethylene dimerization was attained. However, when the $CoBr(PPh_3)_3$–$BF_3 \cdot OEt_2$ mixture was left standing for 40 min without introducing ethylene, a trace amount of black precipitate was formed, resulting in complete deactivation of the catalyst for ethylene dimerization. It seems likely that the activated form of the catalyst is stabilized by the presence of ethylene as well as halobenzene.

Effects of Lewis Acid and Cobalt(I) Complex Concentration. As shown in Fig. 1, the rate increases linearly with increase in $BF_3 \cdot OEt_2$ concentration up to $BF_3 \cdot OEt_2/CoBr(PPh_3)_3 = 1$, where it attains a plateau value, while in the case of σ-arylNiBr$(PPh_3)_2$ the rate increases until the ratio $BF_3 \cdot OEt_2/\sigma$-arylNiBr$(PPh_3)_2$ exceeds unity.[7] The result suggests that there is a strong one-to-one interaction between $CoBr(PPh_3)_3$ and $BF_3 \cdot OEt_2$ such as $CoBr(PPh_3)_3 + BF_3 \cdot OEt_2 \rightarrow [Co(PPh_3)_3]^+[BF_3Br]^-$.

The rate of ethylene dimerization is proportional to the $CoBr(PPh_3)_3$ concentration with a constant ratio of $BF_3 \cdot OEt_2$ to $CoBr(PPh_3)_3$ as shown in Fig. 2. When $AlCl_3$ was used as a Lewis acid, an induction time

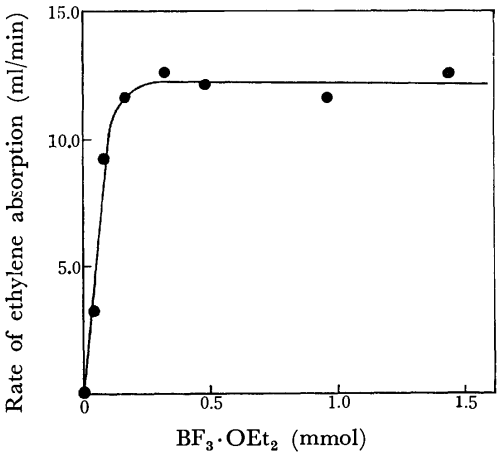

Fig. 1. Rate of ethylene absorption *vs.* the amount of $BF_3 \cdot OEt_2$ added.

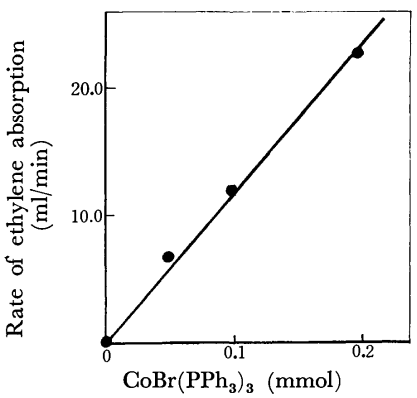

Fig. 2. Rate of ethylene absorption *vs.* the amount of catalyst.
$CoBr(PPh_3)_3/BF_3 \cdot OEt_2$ 1/4.8 (mole ratio), PhBr 10 ml, $P_{C_2'}$ 734 mmHg and 0 °C.

(about 30 min) was observed, which disappeared by pretreatment of $CoBr(PPh_3)_3$ with $AlCl_3$ for 40 min at 0 °C. Since the solubility of $AlCl_3$ is considerably lower than that of $BF_3 \cdot OEt_2$, the induction time can be regarded as the time necessary to activate the Co(I)-complex with $AlCl_3$. No ethylene dimerization was found with the use of other Lewis acids such as $SnCl_2$, $SnCl_4$ and $TiCl_4$.

The addition of PPh_3(PPh_3/$CoBr(PPh_3)_3$=3) to a $CoBr(PPh_3)_3$–$BF_3 \cdot OEt_2$ (1 : 4.8) catalyst system was found to stop the dimerization almost completely. Water was also found to be a strong inhibitor to cause complete deactivation by addition of equimolar amount of water. $CoBr_2(PPh_3)_2$, $ZnBr_2$, or metallic zinc, which might be a contaminant of $CoBr(PPh_3)_3$ in a trace amount, had no effect on the ethylene dimerization.

Isomerization and Isotopic Scrambling of Olefins. Isomerization of 1-alkene was investigated to elucidate why the present catalyst system is highly specific for ethylene dimerization. As shown in Table 3, neither 1-butene, nor 1-pentene is isomerized. The isomerization of 1-pentene, however, is enhanced in the presence of molecular hydrogen or ethylene. The addition of $BF_3 \cdot OEt_2$ is also essential for the isomerization. The rate of 1-pentene isomerization increases with increase in the amount of ethylene. It seems likely that the active species of the catalyst is a hydridocobalt complex to which the hydrogen is supplied from ethylene or molecular hydrogen, but scarcely from the other olefins. It is evident that ethylene is specifically activated by the present catalyst system.

The formation of hydridocobalt species during the course of ethylene dimerization is in line with the result for isotopic scrambling in C_2H_4 and C_2D_4 (Table 4). Since the deuterium distribution in the unreacted ethylene attains a value very close to the equilibrium within 13 min, during which the conversion of ethylene to butenes is only 12%, the hydrogen exchange should proceed much faster than ethylene dimerization. The result for the dimerization of C_2D_4, in which the atomic fraction of hydrogen (f_H) is 0.006, indicates that no hydrogen is supplied from any substance other than ethylene, since no appreciable increase in f_H is observed for the unreacted ethylene as well as for the butenes formed (Table 4). The H–D exchange run between C_2D_4 and C_3H_6 shows that the f_H of propylene considerably decrease, while those of produced butenes and unreacted ethylene decrease, indicating that propylene can react with the hydridocobalt species, while it can not be dimerised.

Possible Processes of Formation of Hydridocobalt Species. Olefin dimerization with transition metal complex catalysts is mostly interpreted in terms of transient hydro- and alkyl-complexes. The isomerization of 1-alkene catalyzed by the present catalyst system in the presence of ethylene or hydrogen (Table 3) and isotopic scrambling in ethylene molecules (Table 4) are also explained by hydridocobalt species, for which the hydrogen is supplied from ethylene.

Since the dimerization proceeds specifically in halobenzene solvents, it may be supposed that halobenzene is oxidatively added to the cobalt(I) complex to give a σ-phenylcobalt(III) complex. Ethylene may, then, be inserted into the σ-phenylcobalt(III) complex, followed by elimination of the β-hydrogen to give H–Co(III) species and styrene. This process, however, seems to be unlikely, since neither styrene, its codimer with ethylene, nor benzene was detected. A more likely process is an oxidative addition of ethylene to give H–Co–CH=CH_2. Oxidative addition of vinyl compounds such as alkyl methacrylate is verified with ruthenium complex.[8] No increase in f_H of butenes and the residual ethylene in the dimerization using deuterioethylene (Table 4) supports this process for the formation of hydridocobalt species, although we have

Raman Studies of Complex Ions in $ThCl_4$–KCl Melt Using Raman Bands Shifts

Susumu YOSHIDA, Ryozo OYAMADA,* and Kazutaka KAWAMURA

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

**Faculty of Education, Nagasaki University, Bunkyo-cho, Nagasaki 852*

(Received August 5, 1976)

Raman spectra of solid and molten $ThCl_4$–KCl system were observed and the structure change of $ThCl_4$ on melting from the octa-coordinate body-centered tetragonal type, D_{4h}, to the tetra-coordinate tetrahedron type, T_d, was studied. The decrease in frequency of the symmetric stretching vibration ν_1 with decrasing $ThCl_4$ concentration for molten $ThCl_4$–KCl is interpreted as due to the presence of $ThCl_4$, $ThCl_5^-$, and $ThCl_7^{3-}$ complexes in the molten $ThCl_4$–KCl mixture. Such a compositional dependence for ν_1 appears to support the idea that, for a decrease in the $ThCl_4$ concentration in molten $ThCl_4$–KCl mixtures, the bond strength between the thorium and chloride ions decreases and the number of chloride ions around the thorium ion increases from 4 to 7.

Various physical properties, such as electromotive force,[1] density,[2] equivalent conductivity,[2] and viscosity[3] for the $ThCl_4$– KCl system, have been measured as fundamentally important data for the electrolytic preparation of thorium metal. In the variation of these physical isothermal properties with $ThCl_4$ concentration, deviations from the additivity line have been attributed to the existence of a complex ion, since the concentration giving the maximum deviation corresponds to that of a congruently melting compound.

In this paper, the formation and structure of complex ions in the $ThCl_4$–KCl system are discussed on the basis of the variation of the Raman bands of solid and molten $ThCl_4$–KCl systems with concentration.

Experimental

Samples. *Thorium Tetrachloride*: As described in a previous report,[4] thorium(IV) chloride was refined by vacuum fractional distillation.

Potassium Chloride: Potassium chloride of special reagent grade was melted, bubbled with dry hydrogen chloride, and the retained HCl was purged by purified argon. The melt was evacuated using a rotary pump for one hour to remove the argon.

Samples: Weighed amounts of thorium and potassium chlorides were melted and mixed in a quartz cell in an HCl atmosphere, and then the mixture was poured into the measuring cell *in vacuo*. The thorium concentration of these samples was corrected by chemical analysis after measuring the spectra.

Apparatus. Raman spectra were recorded with a Spex Model 1401 Ramalog 4 spectrometer. A Coherent Radiation Model 52 488-nm argon-ion laser was used. The furnace temperature for the molten salts was controlled to within ±0.5 °C.

Results and Discussion

Raman Spectra of Pure Thorium Chloride. The Raman spectra of rapidly quenched solid and molten thorium chloride were recorded from 50 to 2000 cm^{-1} at room temperature and at 800 °C, respectively. The Raman bands of solid thorium chloride were found at 296, 182, and 259 cm^{-1} and those of molten thorium chloride at 334, 132, and 270 cm^{-1}, as listed in Table 1.

The crystal structure of thorium(IV) chloride has been reported to be a body-centered tetragonal structure (D_{4h}) as shown in Fig. 1.[5] The number of chloride ion around the thorium(IV) ion is eight. The four Cl^- ions are close to the Th^{4+} ion (2.718 Å) and form a square planar configuration. The remaining four Cl^- ions are far from the Th^{4+} ion (2.903 Å) and form a distorted tetrahedron. Each Th^{4+} ion is dodecahedrally coordinated in a crystal lattice. In the quenched state, pure thorium chloride does not have a stable crystalline form, but is a tetrahedron with a slightly deformed body-centered tetragonal framework resulting from the strong mutual interaction between the four Cl^- ions and the near Th^{4+} ion.[6] Thus, the structure of pure $ThCl_4$ may change from an octa-coordinate body-centered tetragonal structure, D_{4h}, to a tetra-coordinate tetrahedron structure, T_d, upon melting. The Raman band at 334 cm^{-1} for pure molten $ThCl_4$ can be assigned to a symmetric stretching vibration of T_d symmetry, and the other bands at 132 and 270 cm^{-1} to bending vibrations of

T_d symmetry.[7] The assignments of bands for pure solid $ThCl_4$ listed in Table 1 are in analogy to the assignments for molten $ThCl_4$.

Table 1 shows the band shifts to higher frequencies upon melting. These shifts can be explained if four Cl^- ions far from Th^{4+} ion become free, and the four Cl^- ions near Th^{4+} ion are strongly attracted to the Th^{4+} ion by the strong polarization force. In other words, the strong interaction between the Th^{4+} and Cl^- ions resulting from a decrease in the interionic distance can explain the shifts of the Raman bands toward higher frequencies upon melting.

The Raman bands for ThO_2 which have been reported at 460 cm^{-1} [8] were not observed. No evidence for the existence of $ThOCl_2$ in pure solid $ThCl_4$ was obtained. These facts are also supported by failure to detect any ThO_2 or $ThOCl_2$ upon chemical analysis.

Raman Spectra of the Solid $ThCl_4$–KCl System. Raman spectra of the solid $ThCl_4$–KCl system were obtained over the range from 50—2000 cm^{-1} at room temperature (Fig. 2 and Table 2).

The frequencies for the solid $ThCl_4$–KCl system with 1.0—0.10 molar fractions of thorium chloride remain almost constant. The Raman bands at 250 cm^{-1} and near 280 cm^{-1}, which are obtained for $ThCl_4$ molar fractions of 0.34—0.62, are also observed in the solid form containing $ThCl_4$ molar fractions above 0.62 and below 0.34, respectively. Moreover, the discontinuous variation of Raman bands near 300 cm^{-1} with $ThCl_4$ concentration is illustrated in the phase diagram for $ThCl_4$ and KCl, as shown in Fig. 3. This spectral variation with concentration appears to support the presence of a $ThCl_4$ compound with a molar fraction from 1.0—0.62, of a congruently melting compound $KThCl_5$ with a molar fraction of 0.62—0.34, and K_3ThCl_7 with a molar fraction of 0.34—0.10 of $ThCl_4$. Aside from the existence of K^+ ions, it may be assumed by analogy with $KThF_5$[9] and K_3UF_7,[10] that the $ThCl_5^-$ and $ThCl_7^{3-}$ species have trigonal bipyramidal and pentagonal bipyramidal structures, respectively. The symmetric stretching vibration, ν_1, are easily assigned for the $ThCl_4$, $ThCl_5^-$, and $ThCl_7^{3-}$ species, but the assignments of other modes of vibration are quite difficult due to the structural complexities of the above species. Table 2 shows that the frequency of the ν_1 vibration decreases with the $ThCl_4$ concentration from 1.0 to 0.1 molar fraction, suggesting the presence of two congruently melting compounds.

Raman Spectra of the Molten $ThCl_4$–KCl System. Raman spectra of the molten $ThCl_4$–KCl system were observed over the range 50—2000 cm^{-1} at 800 °C. The spectra for melts containing 1.00—0.25 molar fractions of $ThCl_4$ are shown in Fig. 4 and Table 3. The second column in Table 3 lists also the polarization of each band. While the bands for a 0.5 molar

	—	depol	$\nu_9(E_2')$
	219	depol	$\nu_{10}(E_1'')$

fraction of $ThCl_4$ are observed at 293, 219, 187, and 113 cm^{-1}, the bands for a 0.25 molar fraction are observed at 285, 219, and 98 cm^{-1}. As shown in Fig. 3, these compositions of 0.5 and 0.25 molar fractions correspond to those of congruently melting compounds. It should be noted that the wave numbers of Raman bands for a certain concentration range (0.1—0.3 molar frac.) near each congruently melting compound remain almost constant. The above fact suggests the presence of $ThCl_5^-$ and $ThCl_7^{3-}$ complex ions for the melts containing 0.5 and 0.25 molar fractions of $ThCl_4$, respectively. Since the complex ions $ThCl_5^-$ and $ThCl_7^{3-}$ are assumed to have trigonal bipyramidal and pentagonal bipyramidal structures, respectively, the

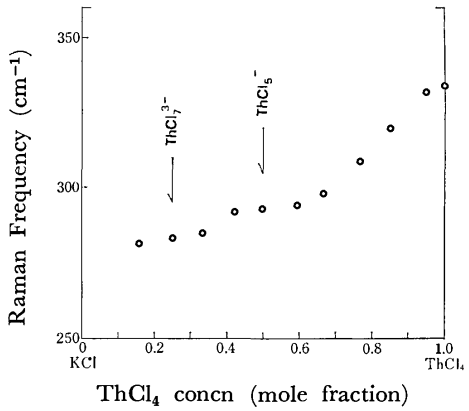

Fig. 5. Frequency shifts of ν_1 band with $ThCl_4$ concentration change in a molten $ThCl_4$–KCl system.

assignments based on these structures are listed in Table 3. From the compositional dependence of the stretching vibration, ν_1, shown in Fig. 5, it is indicated that ν_1 decreases with $ThCl_4$ concentration. Such a compositional dependence of ν_1 appears to support the idea that for decreasing $ThCl_4$ concentration the bond strength between the thorium(IV) ion and chloride ion decreases and the coordination state for thorium-(IV) varies from four, to five and seven coordinations. In these binary mixtures with a common anion, the variations of bond strength and thorium coordination number can be ascribed to a change in the polarization force.

A Finite Element Approach to the Two-dimensional Vibrational Schrödinger Equation and Its Application to the Hydrogen Bond

Isao KANESAKA, Hideyuki ARAI,* and Kiyoyasu KAWAI
Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930
(Received November 8, 1976)

The finite element method was examined in relation to the two-dimensional vibrational Schrödinger equation. Some boundary conditions were used because of the symmetry of the potential, resulting in a higher precision in the case of the symmetrical potential, where the harmonic oscillators and the symmetrical hydrogen bond without anharmonicity were examined satisfactorily. An application was made to the symmetrical hydrogen bond with anharmonicity, where the precision was less for the higher levels. By a comparison of the calculated with the observed infrared spectra, the anharmonic potential constants for the assumed potential function were estimated.

A finite element approach has been successfully applied to a one-dimensional vibrational Schrödinger equation[1] with a harmonic or Lennard-Jones potential. Our purpose in this study is to examine the adaptability of the method to a two-dimensional vibrational Schrödinger equation, which is given by:

$$\frac{\hbar^2}{2m}\frac{\partial^2\Psi}{\partial S_1^2}+\frac{\hbar^2}{2M}\frac{\partial^2\Psi}{\partial S_2^2}+(E-V)\Psi=0, \tag{1}$$

where S_1 and S_2 are the symmetry coordinates of the vibrations with the effective masses of m and M respectively; Ψ, a wave function; E, an energy, and V, a potential with a potential surface expressed by a rectangular coordinate system due to S_1 and S_2, as is shown in Figs. 1—3.

In the harmonic oscillators, V is given by:

$$V=\frac{1}{2}kS_1^2+\frac{1}{2}KS_2^2, \tag{2}$$

where k or K is a force constant. In the symmetric hydrogen bond, which is of interest to us, V is assumed to be:[2,3]

$$V=\frac{1}{2}(FS_1^4-fS_1^2)+\frac{1}{2}KS_2^2+V', \tag{3}$$

where V' is assumed to be:

$$V'=\frac{1}{2}(F'S_1^4-f'S_1^2)S_2. \tag{4}$$

The potential constants in Eqs. 3 and 4 may be estimated reliably for the system of the $[X\text{–}H\text{–}X]^+$ ion, where X is a pyridine derivative.

Finite Element Formulation and Boundary Conditions

The functional of Eq. 1 is found to be:

$$\chi=\frac{1}{2}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\left\{\frac{\hbar^2}{2m}\left(\frac{\partial\Psi}{\partial S_1}\right)^2+\frac{\hbar^2}{2M}\left(\frac{\partial\Psi}{\partial S_2}\right)^2-(E-V)\Psi^2\right\}dS_1dS_2, \tag{5}$$

where the integration is limited in a numerical calculation over the region considered. A trial function is assumed to be:

$$\Psi=\alpha_1+\alpha_2S_1+\alpha_3S_2+\alpha_4S_1^2+\alpha_5S_1S_2+\alpha_6S_2^2=\boldsymbol{N\alpha}. \tag{6}$$

That is, six nodes are used for a triangular element; they are shown in Figs. 1—3. By using the same nota-

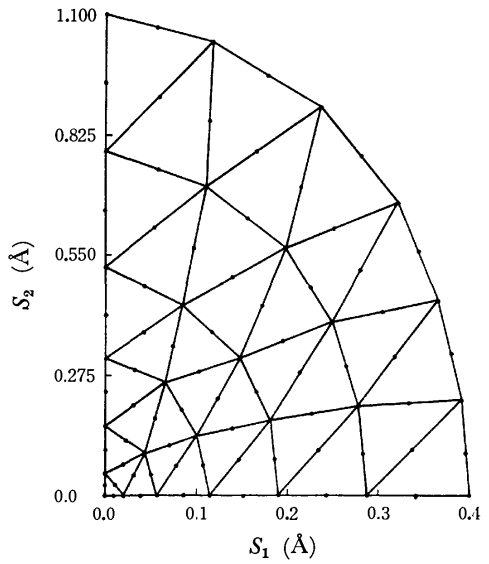

Fig. 1. The triangular elements and the nodes (·) used for harmonic oscillators.

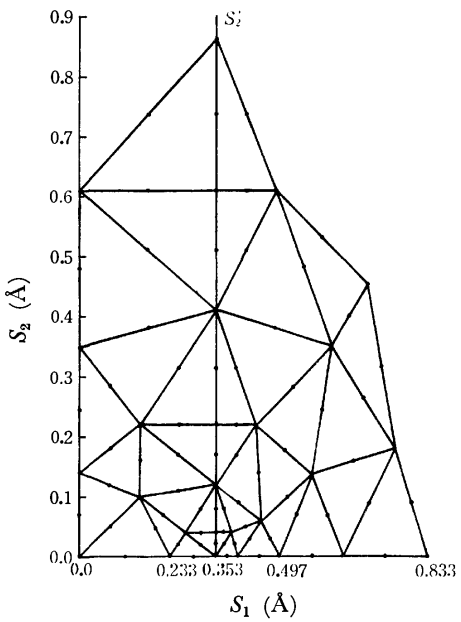

Fig. 2. The triangular elements and the nodes (·) used for the hydrogen bond with $V'=0$.

* *Faculty of Engineering, Toyama University, Nakagawa, Takaoka 933.*

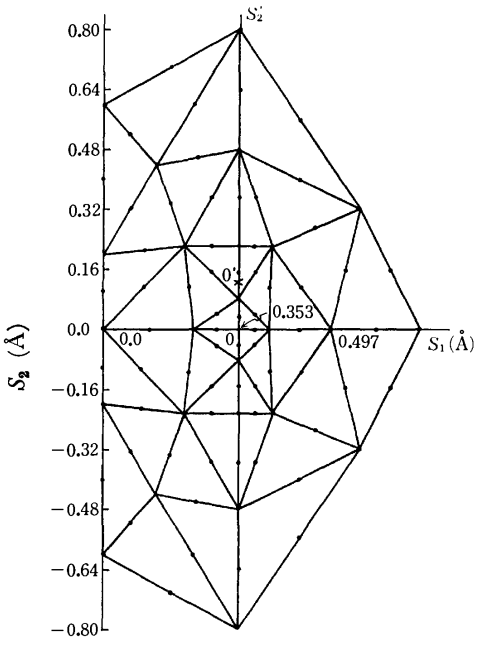

Fig. 3. The triangular elements and the nodes (·) used for the hydrogen bond (H) with $V' \neq 0$. This figure is symmetrical.

as the previous paper,[1] the functional for an element is expressed by:

$$\chi^{(e)} = \frac{1}{2}\boldsymbol{\Psi}^{(e)\mathrm{T}}(\boldsymbol{C}^{(e)-1})^{\mathrm{T}}(\boldsymbol{P}^{(e)} - \boldsymbol{E}\boldsymbol{R}^{(e)})\boldsymbol{C}^{(e)-1}\boldsymbol{\Psi}^{(e)}, \tag{7}$$

where $\boldsymbol{E}$ is the eigenvalue diagonal matrix and where

$$\boldsymbol{P}^{(e)} = \frac{\hbar^2}{2m}\iint \frac{\partial \boldsymbol{N}^{\mathrm{T}}}{\partial S_1}\frac{\partial \boldsymbol{N}}{\partial S_1}\mathrm{d}S_1\mathrm{d}S_2 + \frac{\hbar^2}{2M}\iint \frac{\partial \boldsymbol{N}^{\mathrm{T}}}{\partial S_2}\frac{\partial \boldsymbol{N}}{\partial S_2}\mathrm{d}S_1\mathrm{d}S_2 + \iint V\boldsymbol{N}^{\mathrm{T}}\boldsymbol{N}\mathrm{d}S_1\mathrm{d}S_2, \tag{8}$$

$$\boldsymbol{R}^{(e)} = \iint \boldsymbol{N}^{\mathrm{T}}\boldsymbol{N}\mathrm{d}S_1\mathrm{d}S_2, \tag{9}$$

where the integration is taken over the element. From the procedure given in Appendix I, we obtain:

$$\frac{\mathrm{d}\chi^{(e)}}{\mathrm{d}\boldsymbol{\Psi}^{(e)}} = (\boldsymbol{C}^{(e)-1})^{\mathrm{T}}\boldsymbol{P}^{(e)}\boldsymbol{C}^{(e)-1}\boldsymbol{\Psi}^{(e)} - \boldsymbol{E}(\boldsymbol{C}^{(e)-1})\boldsymbol{R}^{\mathrm{T}(e)}\boldsymbol{C}^{(e)-1}\boldsymbol{\Psi}^{(e)} = 0 \tag{10}$$

The eigenvalues and the eigenfunctions are calculated by interconnecting Eq. 10 over all the elements.

The boundary condition[4] additional to the normal one, which is omitted here, is applied because of the symmetry property of the potential function. In the harmonic oscillators, where the vibrational quantum number for S_1 or S_2 is denoted by v or v' respectively, there are four cases orthogonal to each other;

v, v': even	Non-boundary condition
v: even; v': odd	Zero on the S_1 axis
v: odd; v': even	Zero on the S_2 axis
v, v': odd	Zero on the S_1 and S_2 axes.

They are calculated separately under the boundary conditions, which reduce the matrix of the eigenvalue problem, by using a quarter of the whole region, as is shown in Figs. 1 and 2. If the potential function is symmetric for only one axis, a half of the whole region is necessary, as is shown in Fig. 3. It is clear from Eq. 5 that these treatments give precision to the numerical calculation.

Symmetrical Potential

Harmonic Oscillators. A computational precision of the finite element approach will be examined here by a comparison of the eigenvalues calculated by this method with those obtained analytically.

Since the area of an element greatly affects the calculated eigenvalues, one has to set the elements out carefully in the region considered. We set out the 36 elements with 91 nodes in the elliptical region required by the normal boundary condition, as is shown in Fig. 1. This condition is equal to setting out 144 elements with 337 nodes in the whole region. The i-th element from the origin has the length of id along the coordinate axis, where d is the size of the first element, as has been

established previously for the one-dimensional problem.[1)]

As we will treat later a problem involving two modes separated extremely in the ir frequencies, ν_1 and ν_2, the higher one is set at 3000 cm^{-1}, and the lower one, at 300 cm^{-1}. Under the conditions shown in Fig. 1, the calculated eigenvalues for small numbers of v and v' are given in Table 1; they are compared with the values obtained analytically.

As is shown in Table 1, the agreement between the calculated and the analytical values is regarded to be satisfactory as an approach made computationally. The manners of variation of the eigenvectors are the same as expected.

Hydrogen Bond with $V'=0$. In the case of a double-minimum potential, it is not easy to divide the region into the elements. By means of a trial-and-error method we set out the elements and nodes as is shown in Fig. 2, where the axis of S_2' is drawn through a bottom of the potential minimas. The S_1 coordinate is defined here by the displacement coordinate of the H atom from the center of the X···X bond as the one-dimensional expression.[5)] The potential constants for the vibration of S_1 are set as $F=9.5$[6)] (mdyn/Å^3) and $f=2.37$[6)] (mdyn/Å); they give the potential minimum of -3721 cm^{-1} at ± 0.353 Å. The value of m of H(D) is assumed to be 0.984 (1.938) amu. The normal frequency of the S_2 mode, which is the X···X stretching vibration, is assumed to be 157 cm^{-1}.

The calculated eigenvalues for the small numbers of v and v' under the conditions shown in Fig. 2 are given in Table 1, along with those obtained *analytically* by the method shown in Appendix II. The agreement between the calculated and the *analytical* values may be satisfactory by making allowance for the fact that there is a certain limit in the way of dividing the region into the elements, as is shown in Fig. 2.

From Table 1 we can find the difference between the precisions for the H and the D systems. The result for the D system is less satisfactory than that for the H system, but may be improved by the adjustment of the nodal values, as will be shown later.

Application

In most hydrogen-bond systems, the anharmonicity is particularly large; thus, it is hard to use an ordinary method of vibrational analysis. The finite element method described here is, then, useful in examining the vibration of those systems. We make an application of this method to a problem for the symmetrical hydrogen bond. In this sort of system, however, it is inevitable that, because the boundary condition for one axis can not be used, the precision of calculation is more or less lowered, and so is the convergence of the eigenvectors.

The elements and nodes are set out in the symmetrical potential with $V'=0$, as is shown in Fig. 3. The calculated eigenvalues for the H system under these conditions are given in Table 2 ($F'=0.0$). The calculated eigenvalues for the D system under these conditions are less satisfactory than those for the H system, but they can be improved by adjusting the area of elements to make it somewhat smaller. The

3—2	−500.8	−520.2	(−486.9)	−533.6

results for the D system are given in Table 3 ($F'=0.0$). The agreement between the calculated values given in Table 2 or 3 with the analytical ones for the H or the D system in Table 1 is, as the whole, less than that between them in Table 1. However, the results given in Tables 2 and 3 can be useful in the estimation of the anharmonic potential constants or in the assignment of the observed spectra.

The intensity is calculated by means of this expression:[7)]

$$I_{ij} = \nu_{ij}[\exp\{-(\nu_i-\nu_0)/kT\} - \exp\{-(\nu_j-\nu_0)/kT\}]M_{ij}^2, \quad (11)$$

where ν_{ij} is the transition frequency from the i to the j level; ν_i, ν_j, and ν_0 are the eigenvalues of the i, j, and ground levels respectively, k and T have their usual meanings, and M_{ij} is given by:

$$M_{ij} = \iint \Psi_i S_1 \Psi_j \mathrm{d}S_1 \mathrm{d}S_2, \quad (12)$$

where the integration is carried out in the region considered[3)] by using the normalized function.

The relative intensities, I_{ij}, calculated under the conditions described above for the H and the D systems are shown schematically in Fig. 4-a, in which the observed spectra[8,9)] for the pyridine–H(D)–pyridine system are also given to make a comparison. As is shown in Fig. 4-a, the ν_{ij} values calculated for the H system are

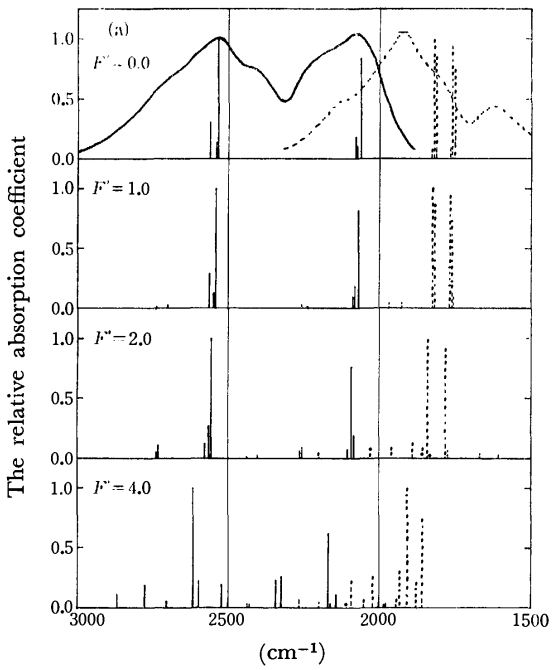

Fig. 4. Variation of the spectra with F'.

in accordance with the observed ones, but those for the D system are not. This disagreement may be attributed mainly to the inadaptability of the potential function assumed for those systems. An other type of potential function, such as the Lippincott-Schroeder potential,[5,10] may be appropriate, though others were not examined here.

In the case with $V' \neq 0$, the force constant, f', in Eq. 4 is assumed to be:

$$f' = 2F'S_e^2, \tag{13}$$

where S_e is the distance between the origin and the potential minimum with $V'=0$ on the S_1 axis. Under the assumption of Eq. 13, the potential minimum is displaced to the point, 0', on the S_2' axis in Fig. 3; the potential is now asymmetric with respect to the abscissa through 0'. Since the more the elements are put on the vicinity of the potential well, the more the result is refined, all elements are transferred parallel with the S_2' axis by a distance between two points, 0 and 0'. Further, the elements above the abscissa are so adjusted that their areas are smaller than those taken under the condition with $V'=0$. On the other hand, the elements below the abscissa remain as they were taken in a good condition with $V'=0$.

The variation in the eigenvalues with F', whose value is set as 1.0, 2.0, or 4.0 (mdyn/Å^3), is given in Tables 2 and 3 for the H and D systems respectively. One notices from those tables that the eigenvalues with a lower quantum number, v, are lowered greatly with an increase in the value of F', while those with a higher v number are lowered only slightly. The eigenvalues in brackets are abnormal and are regarded as being perturbed by a Fermi resonance, since other levels, which are not assigned and which are omitted from the discussion here, appear near those eigenvalues.

The variation in the spectra with the F' is shown schematically in Fig. 4. The spectral feature observed for the H system can be interpreted approximately by I_{ij} calculated with $F'=4.0$; that is, some of the shoulders observed can be assigned satisfactorily to the combination bands. Two places where the observed intensity is higher than the calculated one are seen at about 2100 cm^{-1} in the H system and 1650 cm^{-1} in the D system. This may result from the overlap with the other bands, which may be assigned to a combination band not considered here. When $F=9.0$ and $F'=4.0$ (mdyn/Å^3), the I_{ij} calculated for the H system accords quite well with the observed spectra, but the values, ν_{ij}, calculated for the D system are dislocated much as may be seen in Fig. 4-a.

In the H system, the overtone of the S_1 mode has been observed at 5218 cm^{-1} [8] with a shoulder at 5050 cm^{-1}; it is evaluated *analytically* to be 5211.6 cm^{-1}. When $F'=4.0$ (mdyne/Å^3), it is given as 5178.8 cm^{-1} with the intensity of 0.23 of the maximum given in Fig. 4; this intensity seems to be a little higher than that expected, taking into account the fact that the eigenvectors of the 5-0 level do not converge completely. The transition to the 4-0 level is omitted because of the less convergence of the eigenvectors. On the other hand, in the D system, the eigenvectors of these levels with $F'=4.0$ (mdyn/Å^3) converge well and the calculated intensities are quite weak, in good accordance with the observation.

A very weak band has been observed near 140 cm^{-1} in both systems; it has been assigned to an overlap of such transitions as 0-0→1-1.[3] The calculated intensities in both systems are about 1/1000 of the maximum given in Fig. 4 and nearly half of the observed values.[3,8] This shows that the quadratic term of the transition moment may be quite important, as has been discussed by Singh and Wood.[3] The region near 550 cm^{-1} could not be examined here because of the less convergence of the eigenvectors of the higher v' levels.

Conclusion

The finite element method was examined for the two-dimensional vibrational Schrödinger equation with a high precision in the case of the symmetrical potentials. Thus, even further precision might be obtained if this method were applied to such a symmetrical system as a three-fold potential. On the other hand, though the method is obviously useful for a system with anharmonicity, it would only be adaptable for a system with a large anharmonicity, such as has been examined here, if the eigenvalues of the higher levels are necessary.

The numerical calculation was carried out by using the computer, FACOM 230-45S, of Toyama University.

Appendix

I. Stationary Value in Eq. 5 and the Finite Element Method. We will justify here Eq. 10 by a procedure employing a calculus of variation.[11-13] First, we assume a functional as follows:

$$\chi = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} f(\Psi, p, q, S_1, S_2)\mathrm{d}S_1\mathrm{d}S_2, \tag{A-1}$$

where $p=\partial\Psi/\partial S_1$ and $q=\partial\Psi/\partial S_2$. According to Euler's condition, a characteristic equation is as follows:

$$\frac{\partial}{\partial S_1}\left(\frac{\partial f}{\partial p}\right)+\frac{\partial}{\partial S_2}\left(\frac{\partial f}{\partial q}\right)-\frac{\partial f}{\partial \Psi}=0. \tag{A-2}$$

If we take f as follows:

$$f=\frac{1}{2}\left\{\frac{\hbar^2}{2m}\left(\frac{\partial \Psi}{\partial S_1}\right)^2+\frac{\hbar^2}{2M}\left(\frac{\partial \Psi}{\partial S_2}\right)^2-(E-V)\Psi^2\right\}, \tag{A-3}$$

we find that Eq. A-2 is equal to Eq. 1. Thus, χ, which is called the associated variational functional with Eq. 1, has a stationary value.

Second, we resolve Eq. 5 directly by using a Rayleigh-Ritz approximation, where Ψ is assumed by:

$$\Psi=\sum_i \alpha_i S_1^{m_i} S_2^{n_i}=\boldsymbol{N\alpha}, \tag{A-4}$$

where the summation should be done generally for a very large number of terms. On the other hand, in a finite element method, Eq. A-4 is assumed for an element. To justify this assumption, we introduce a square matrix, $\underline{\boldsymbol{C}}^{(e)}$, which is defined by:

$$\boldsymbol{\Psi}^{(e)}=\underline{\boldsymbol{C}}^{(e)}\boldsymbol{\alpha}, \tag{A-5}$$

and which is determined by the coordinate values. From Eqs. A-4 and A-5, we obtain:

$$\Psi^{(e)}=\boldsymbol{N}\boldsymbol{C}^{(e)-1}\boldsymbol{\Psi}^{(e)}, \tag{A-6}$$

where it should be noticed that $\Psi^{(e)}$ is defined at any point in the element through the matrix $\boldsymbol{N}$ and $\boldsymbol{\Psi}^{(e)}$ for six nodal points.

Finally, since χ in Eq. A-1 is expressed by the integration of the whole region, this is expressed by the summation of the integration of each element:

$$\chi=\sum_i^{\text{all}} \chi_i^{(e)}, \tag{A-7}$$

where $\chi_i^{(e)}$ is obtained by using Eq. A-6 and is given by Eq. 7. Now, χ is expressed by the nodal value Ψ_k. From the first condition, we obtain:

$$\frac{d\chi}{d\Psi_k}=0 \qquad (k=1, 2, \cdots \text{ all nodes}), \tag{A-8a}$$

or:

$$\frac{d\chi^{(e)}}{d\Psi_i^{(e)}}=0 \qquad (i=1, 2, \cdots \text{ all elements}), \tag{A-8b}$$

or:

$$\frac{d\chi}{d\boldsymbol{\Psi}}=0, \tag{A-8c}$$

where $\boldsymbol{\Psi}$ is a column vector consisting of all nodal values. The resultant total equation has a form:

$$(\boldsymbol{A}-\boldsymbol{EB})\boldsymbol{\Psi}=0. \tag{A-9}$$

The eigenvalues and the eigenvectors are calculated from Eq. A-9.

II. Eigenvalues for a One-dimensional Hydrogen Bond.

There is no analytical method to obtain the eigenvalues for the double-minimum potential. Thus, to estimate them we used a finite element method previously reported,[1] because it is clear that the one-dimensional approach is more precise than the two-dimensional one, as may be found from Eq. 5. If the second term in Eq. 1 is neglected and m is replaced by μ, Eq. 1 is equal to Eq. 1 in Ref. 1. The eigenvalues are calculated by using the same potential as used here. The *analytical* values in Table 1 are obtained by the sum of these values and the eigenvalues of the S_2 mode.

Radiation Chemical Reactions in Carbon Dioxide–Propane System. II. Reoxidation of Carbon Monoxide at Low Propane Concentration

Yasumasa IKEZOE and Shoichi SATO

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11

(Received April 18, 1977)

In the γ-radiolysis of carbon dioxide, the back reaction or reoxidation of carbon monoxide, proceeds at a moderate rate with propane concentration less than 0.5%, reducing the apparent G(CO) value. Concerning the total pressure and dose rate dependence of the G(CO) value with such small propane addition, it was found that the back reaction was accelerated by raising the total pressure and by lowering the dose rate. The following reactions of clustered negative ions are considered to explain the pressure and dose rate effects:

$$X^- + CO \rightarrow CO_2 + Y^- + Z_1,$$
$$X^- + C_3H_8 \rightarrow Y^- + Z_2,$$
$$X^- + X^+ \rightarrow mCO_2 + Z_3,$$

where X^- stands for a clustered negative ion.

Radiolysis of carbon dioxide has been studied extensively,[1-3] since Harteck and Dondes[4] irradiated the gas with radon α-rays and reactor radiations in 1955 and 1957. Apparent stability towards ionizing radiation at moderate dose rates ($\approx 10^{16}$ eV/g s) was attributed to a rapid reoxidation reaction, by which carbon monoxide formed is reoxidized to carbon dioxide. However, the detailed mechanism of the reoxidation, or back reaction still remains unclarified. The oxidizing species has not yet been identified, in spite of many species, such as O, O_3, O^+, O_2^+, O^-, O_2^-, CO_3^-, and CO_4^- being proposed. Recently, Parkes[5] suggested that highly clustered ions might be involved in the back reaction.

In this study, we attempted to clarifiy the nature of the back reaction when a small amount of propane is added to carbon dioxide. A controlled amount of propane was added to make the back reaction proceed at a moderate rate, under such conditions, the relation between the apparent G(CO) value and the rate of the back reaction being expected to be connected.

Experimental

Carbon dioxide (Takachiho Chemical, pure gas, stated 99.99% up) and propane (Takachiho Chemical, research grade, stated 99.7% up) were used after removing uncondensable gas with a liquid nitrogen trap. Pyrex glass ampoules (64 ml and 160 ml) were thoroughly washed with distilled water and evacuated to a vacuum of 1×10^{-4} Torr while being heated with a gas burner. The reactant gases were then, introduced into the ampoules, their pressures being measured by a stainless steel Bourdon gage. The total pressure was in the range 0.5—3.2 atm.

The ampoules were irradiated by ^{60}Co γ-rays in the exposure rates in the range 0.32—4.2 MR/h. The absorbed dose was determined by the decomposition of ethylene ($G(H_2) \equiv 1.3$) in the same ampoules as those used for sample irradiation, with a correction for the stopping power ratios of the gases to the secondary electrons.

The uncondensable products (CO, H_2, CH_4) were measured volumetrically by using a Toepler pump. The composition of the products was determined by mass spectrometry and confirmed by gas chromatography. Details were the same as described previously.[3]

Results

Propane Addition and the Back Reaction. In the preceding paper,[3] 1% propane was found sufficient to suppress the back reaction. In this study the propane concentration at which maximum G(CO) value could be obtained was first surveyed. Reactions were carried out at slightly smaller propane concentration, when the back reaction might be expected to proceed at a moderate rate.

The G(CO) value is shown in Fig. 1 as a function of the initial propane concentration. G(CO) values were determined at a constant dose (6.7 Mrad). After irradiation the propane added was consumed to some extent, *e.g.*, 0.55 to 0.39% and 0.27 to 0.18%. The maximum 4.5 was obtained at 0.55% propane concentration. This maximum is greater than the one previously obtained (3.6) by γ and $(n+\gamma)$ rays, but smaller than the one (6.7) by fission fragments.[3]

The gradual decrease in G(CO) with propane concentration higher than 0.55% is the same as our previous results.[3] The effect could be related to the suppression of the formation of carbon monoxide from cationic species by propane.

The gradual decrease in G(CO) with the less than 0.55% decrease in propane concentration is attributable

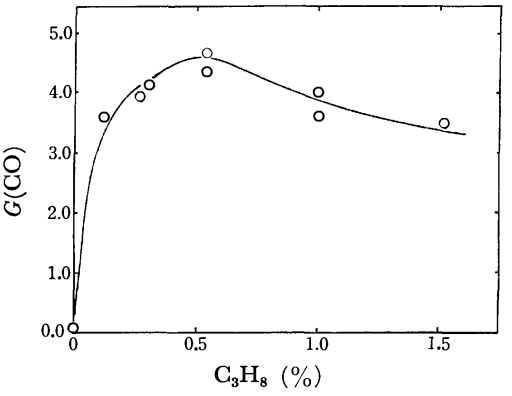

Fig. 1. Effect of propane addition on G(CO). 160-ml glass ampoule, CO_2; 1 atm, γ-rays; 0.95 MR/h, absorbed dose; 6.7 Mrad.

to the back reaction. The lower the concentration of propane, the more pronounced will be the effect of the back reaction. However, when the initial concentration of propane is extremely low (less than 0.1%), the total amount of reaction products, mainly, butane, isobutane, ethane, 2-propanol, and acetone, becomes greater than that of propane at a very small dose.

The radiolysis was carried out mainly at a propane concentration of 0.27%, the middle point between 0.55 % (at which the back reaction became apparent) and 0% (at which the complete back reaction took place). At this propane concentration, dynamic balance was expected between the back reaction and its suppression, no significant interference from the reaction products taking place with the reaction course at the absorbed dose employed. Under these conditions, the quantity of carbon monoxide formed was found to be the same order of magnitude as that of propane present in the reaction system during most of the radiolysis.

Pressure Effect. The pressure dependence of G(CO) at propane concentration less than 0.5% is of special interest, since it may be related to the mechanism of the back reaction.

The pressure dependence of G(CO) at propane concentrations of 0.27, 1.1, and 1.6% is shown in Fig. 2. The pressure dependence of G(CO) at 0.27% clearly differs from that at 1.1 and at 1.6%. The G(CO) value at 0.27% propane decreases from 4.1 to 3.6 with a total pressure rise from 0.4 to 3.2 atm, while the other G(CO) values remain constant (4.0 and 3.6).

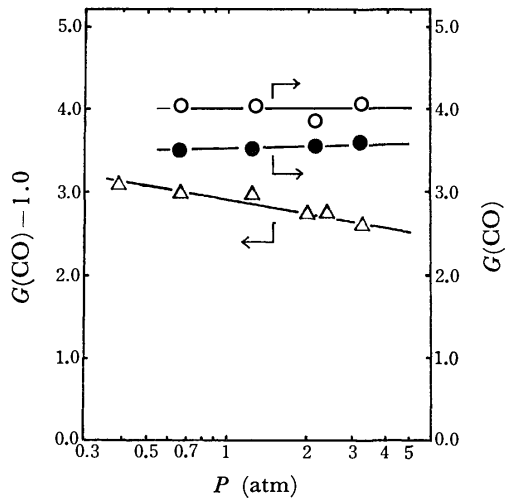

Fig. 2. Pressure dependence of G(CO). 64- and 160-ml glass ampoule, γ-rays; 0.95 MR/h, 6.7 Mrad. ●; C_3H_8 1.6%, ○; C_3H_8 1.1%, △; C_3H_8 0.27%.

This result indicates that higher pressure is favorable for the back reaction. This pressure dependence of the back reaction does not necessarily contradict the result by Yoshimura *et al.*[2] who found that the back reaction is suppressed at much higher density (0.5 g/ml), since there is a large difference between our density of the reaction system (1.8×10^{-3} g/ml) and theirs and a quite different mechanism can be considered as regards the back reaction.

Dose Rate Effect. The dose rate dependence of

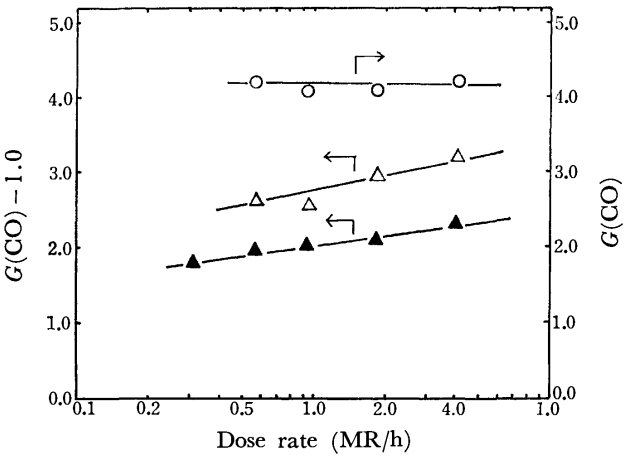

Fig. 3. Dose rate dependence of G(CO). 64-ml glass ampoule, 3.2 atm, 6.7 Mrad. ○; C_3H_8 0.82%, △; C_3H_8 0.27%, ▲; C_3H_8 0.06%.

G(CO) is shown in Fig. 3 at the low propane concentration. At 0.82% propane, where the back reaction can be assumed to be quenched, the G(CO) value is independent of the dose rate. On the other hand, the G(CO) value at 0.27% propane increases from 3.6 to 4.2 with the dose rate increase from 0.57 to 4.2×10^6 R/h. The G(CO) at 0.06% propane shows a similar dependence on the dose rate. The dose rate dependence of G(CO) obtained here is in agreement with that by Anderson and Best.[7] They found that the G(CO) value increased with the dose rate when 0.05% SF_6 was added to carbon dioxide, but remained constant when 1% SF_6 was added.

With respect to the dose rate dependence of the radiolysis of carbon dioxide, it was further found that the steady state concentration of carbon monoxide is proportional to the square root of the dose rate,[8] and that at extremely high dose rate (2×10^{27} eV/g s) carbon dioxide is decomposed with a high G(CO) value (7.8).[9]

All these effects of dose rate indicate that the back reaction becomes less effective at high dose rate.

Discussion

Oxidizing Species. Three kinds of active species, *i.e.*, neutral atomic oxygen, positive and negative ions containing an oxygen atom or molecule,[5] are conceivable as the oxidizing species responsible for the back reaction in the radiolysis of carbon dioxide. Since propane added can scavenge all of them,[2,10] the fact that the back reaction is suppressed by propane affords no information on the nature of the oxidizing species. However, the finding that the back reaction and its suppression is balanced even at 0.27% propane (Fig. 1) indicates that the oxidizing species responsible should have a reactivity of the same order of magnitude for reactions with propane and with carbon monoxide as well.

Of the three kinds of oxidizing species, atomic oxygen is much more reactive with propane than with carbon monoxide.[1] Positive ions containing an oxygen atom or molecule are also more reactive with propane than with carbon monoxide, because the ionization potential

of an oxygen atom (13.6 eV) or of oxygen (12.1 eV) is higher than that of propane (11.1 eV) and lower than that of carbon monoxide (14.0 eV). If two species were the oxidizing species, the balancing between the back reaction and its suppression should have taken place at much lower propane concentration.

On the other hand, negative ions seem to have a similar reactivity both with propane and with carbon monoxide.[11] Negative ions are known to be clustered in carbon dioxide at atmospheric pressure and ambient temperature.[12] Thus, the clustered negative ion containing an oxygen atom or molecule is presumed to be the most probable species responsible for the reoxidation of carbon monoxide in this system.

Parkes[5] has suggested that the following reactions of clustered ions may be responsible for the reoxidation of carbon monoxide.

$$O_2^{\pm}(CO_2)_n + CO \rightarrow O^{\pm}(CO_2)_n + CO_2, \quad (1)$$

$$O^{\pm}(CO_2)_n + CO \rightarrow (CO_2)_n^{\pm} + CO_2. \quad (2)$$

Simple negative ions,[7,8] such as O^-, O_2^-, CO_3^-, and CO_4^-, were found not to be responsible for the rapid back reaction.

Mechanism of the Back Reaction. From the results (Figs. 2 and 3), it is obvious that the back reaction is accelerated by raising the pressure and by lowering the dose rate. The following reactions seem plausible to account for the experimental results:

$$X^- + CO \xrightarrow{k_3} CO_2 + Y^- + Z_1, \quad (3)$$

$$X^- + C_3H_8 \xrightarrow{k_4} Y^- + Z_2, \quad (4)$$

$$X^- + X^+ \xrightarrow{k_5} mCO_2 + Z_3, \quad (5)$$

$$Y^- + X^+ \xrightarrow{k_5} nCO_2 + Z_4. \quad (5')$$

In these reactions, X^- denotes a clustered negative ion containing an oxygen atom or molecule, Y^- an electron or a negative ion other than X^-, X^+ any possible positive ion, and Z neutral reaction products. Reaction 3 is the back reaction, Reaction 4 the scavenging of X^- by propane, and Reaction 5 and 5′ the neutralization of ionic species.

The ratio, R, of the rate of Reaction 3 to that of all reactions of X^-, becomes

$$R = \frac{k_3[CO]}{k_3[CO]+k_4[C_3H_8]+k_5[X^+]} = \frac{1}{1+K_1[C_3H_8]/[CO]+K_2[X^+]/[CO]}, \quad (6)$$

where $K_1=k_4/k_3$ and $K_2=k_5/k_3$.

The concentrations of propane and carbon monoxide are proportional to the total pressure at a constant dose. The concentration of X^+ is proportional to the square root of pressure and dose rate, since it is determined by the balance between the ionization of carbon dioxide by radiations and the neutralization of ionic species.[13] Accordingly, the dependence of R on dose rate and pressure is

$$R = \frac{1}{A+B\cdot I^{1/2}\cdot P^{-1/2}}, \quad (7)$$

where I is the dose rate, P the total pressure, and A and B are constants. R increases with the rise of pressure and with the lowering of dose rate, in qualitative agreement with the dependence of the back reaction on dose rate and pressure.

Pressure and Dose Rate. R can be approximated by the ratio between the reduction in $G(CO)$ due to the back reaction and the ideal $G(CO)$ value, G_0, which would be obtained when no back reaction occurred.

$$R = \frac{G_0-G(CO)}{G_0}. \quad (8)$$

From Eqs. 7 and 8, we have

$$\frac{G_0}{G_0-G(CO)} = A + B\cdot I^{1/2}\cdot P^{-1/2}. \quad (9)$$

The ratio, $G_0/(G_0-G(CO))$, should be linearly dependent on $(I^{1/2}P^{-1/2})$, from the mechanism of the back reaction proposed.

The values of $G_0/(G_0-G(CO))$ are plotted as a function of $(I^{1/2}P^{-1/2})$ in Fig. 4, where $G(CO)$ is taken from the experimental values at 0.27% propane addition (Figs. 2 and 3), and G_0 is estimated to be 5.6 from the primary yields of carbon monoxide obtained by Willis and Boyd.[15,16] It seems possible to draw a straight line in Fig. 4, despite a little scatter at low pressure and high dose rate.

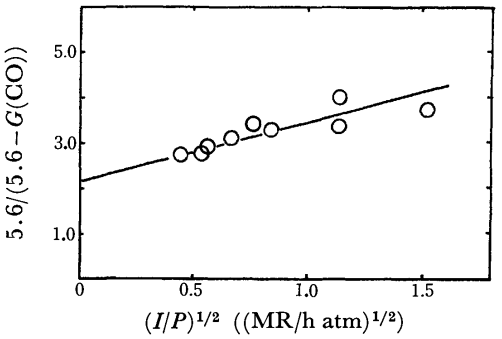

Fig. 4. $G_0/(G_0-G(CO))$ *vs.* $(I/P)^{1/2}$.

From the intercept and the slope of the straight line in Fig. 4, the ratios of the rate constants can be estimated to be $k_4/k_3=1/3$, $k_5/k_3=6.2\times10^7$, using the experimentally determined concentrations of carbon monoxide and propane. k_3 and k_4 become 1.6×10^{-13} and 0.5×10^{-13} $cm^3\,molecule^{-1}\,s^{-1}$, respectively, if we adopt 10×10^{-6} $cm^3\,molecule^{-1}\,s^{-1}$ for the value of k_5.[15] Because of the scatter in Fig. 4 and the approximation included in the above discussion, no accuracy is claimed in these values, though their orders of magnitude seem reasonable when we compare them with those of analogous reactions of a simple negative ion.[17] Clustered ions will have somewhat lower reactivity to the same reactant than ions not clustered.

Determination of Absolute Configuration of Epishamixanthone, a Metabolite of *Aspergillus rugulosus*, by Anomalous Scattering of Light Atoms

Keiichi FUKUYAMA, Kensaku HAMADA, Tomitake TSUKIHARA, and Yukiteru KATSUBE
Faculty of Engineering, Tottori University, Koyama, Tottori 680

(Received April 30, 1977)

The absolute configuration of epishamixanthone has been determined from the Bijvoet differences by anomalous scattering of light atoms for Cu $K\alpha$ radiation. To verify the determination, the absolute configuration of sterigmatocystin which was already determined has been examined by the same procedure. The reliability of the Bijvoet differences calculated from the structure has been estimated by means of the probability method. The errors in the measured values of the Bijvoet differences have been analysed by the normal probability plot. The accuracy of the measurement may be affected considerably by the habit of crystal. The present analysis has established that the configurations of two asymmetric carbon atoms in epishamixanthone are both *R*.

Many natural products are isolated as optically active substances, and the determinations of their structures, including the absolute configurations, are of interest in connection with the study of stereospecificity in biological systems. Although the X-ray method for the determination of the absolute configuration seems to be more direct and more reliable than the spectroscopic[1] and chemical methods,[2] until recently the application of the X-ray method was confined to a crystal containing heavy atoms. The developments of the isolation technique of minor products and the direct method of the X-ray structure analysis have enhanced the need for a reliable method for the determination of the absolute configuration without further chemical modification. Recently, some authors described the determinations of the absolute configurations by using anomalous scattering of light atoms.[3,4] In the present investigation, the absolute configuration of epishamixanthone **1**, a metabolite of *Aspergillus rugulosus*, has been determined by the method described by Engel.[4] In addition, the reliability of this method has been examined by using sterigmatocystin **2**, whose absolute configuration had already been known from its bromo derivative.[5]

Structure Determination

The isolation technique, spectral data, and relative structure of epishamixanthone have been published previously.[6]

Crystallographic Measurement of Epishamixanthone. The crystals of epishamixanthone were grown as greenish-yellow needles elongated along the b axis. The cell constants were obtained by least-squares fits of the θ values for 49 reflections measured by a four-circle diffractometer. Two sets of intensity data were collected to analyze the errors in the calculated Bijvoet differences: the first data-set was collected by the stationary-crystal stationary-counter method and the second set was by the θ-2θ scan method. The experimental conditions for each set are summarized in Table 1(a) together with the crystal data. The intensities were corrected only for the Lorentz and polarization factors.

Structure Determination of Epishamixanthone. The initial structure was determined by using the first data-set. The orientation and location of the xanthone skeleton were determined by application of vector-search method.[7] The location of the remaining non-hydrogen atoms were successively determined by Fourier syntheses. The coordinates and temperature factors were initially refined by the block-diagonal least-squares method by using the carbon scattering factor. The atomic species were determined by inspection of the temperature factors as well as chemical information. The positions of hydrogen atoms were assigned from a difference Fourier synthesis. Including the hydrogen atoms, the refinement reduced the *R* value to 0.081 for 1452 reflections, where the following weighting scheme was adopted: $w=0.63$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq 10$, and $w=1.0/(1.0+0.71(F_o-10))$ for $10<F_o$.

Further refinement was made using the second data-set and the block-diagonal least-squares method. The four strongest reflections, 001, 210, −201, and −311, were rejected from the subsequent calculations. The methyl hydrogen atoms attached to the C(25) atom could not be located; this is probably due to a large thermal motion of the group. Some of the hydrogen atoms obtained from the first set were found to be mislocated. A weighting scheme, $w=0.25$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq 8$, and $w=1.0/(1.0+0.5(F_o-8))$ for $8<F_o$, was used in the final calculation. The final *R* value was 0.058 for 1719 reflections ($R=0.055$ for non-zero reflections). The final atomic parameters refined by the second set are given in Tables 2(a) and 3(a).

Structure Refinement of Sterigmatocystin. The intensity measurement and structure analysis of sterigmatocystin have been described.[8] In order to estimate the effect of error in the atomic parameters on B_{th}*,

TABLE 1. CRYSTAL DATA AND EXPERIMENTAL CONDITIONS

$\beta=105.14(4)°$, $V=1052.1$ Å^3
$D_o=1.28$ g/cm^3
$D_x=1.28$ g/cm^3 (for $Z=2$)
μ(for Cu $K\alpha$) $=7.3$ cm^{-1}
$N_o/N_e=0.20$
(ii) First intensity data-set
Ni-filtered Cu $K\alpha$ radiation
Toshiba four-circle diffractometer
stationary-crystal stationary-counter
peak counting time: 30 s
background: function of 2θ
$\sin\theta/\lambda<0.53$
independent reflections: 1452
(iii) Second intensity data-set
Ni-filtered Cu $K\alpha$ radiation
Rigaku four-circle diffractometer
θ-2θ scan mode
scan range: $\Delta\theta=1.2°+0.15°\tan\theta$
scan speed: 2°/min(θ)
background counting time: 8 s
$\sin\theta/\lambda<0.562$
independent reflections: 1723
(b) Sterigmatocystin
(i) Crystal data
$C_{18}H_{12}O_6$, $M=324.3$
monoclinic, space group $P2_1$
$a=16.056(4)$, $b=4.324(2)$, $c=11.218(3)$ Å
$\beta=113.13(5)°$, $V=716.2$ Å^3
$N_o/N_e=0.33$
(ii) Second intensity data-set
Ni-filtered Cu $K\alpha$ radiation
Rigaku four-circle diffractometer
θ-2θ scan mode
scan range: $\Delta\theta=1.0°+0.15°\tan\theta$
scan speed: 2°/min(θ)
background counting time: 8 s
$\sin\theta/\lambda<0.562$
independent reflections: 1227

intensities were remeasured in different conditions. (The intensity data collected in the condition described in the previous paper is noted as the first set.) The cell constants were remeasured before data collection. The experimental condition for the second set is summarized in Table 1(b) together with refined cell constants. The intensities were corrected only for the Lorentz and polarization factors.

The structure was refined by the block-diagonal least-squares method with the second set. The five strongest reflections, -111, -201, -211, 201, and -312, were omitted from the calculations. The weighting scheme used in the final cycle of the refinement was: $w=0.2$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq14$, and $w=1.0/(1.0+0.6(F_o-14))$ for $14<F_o$. The final R value was 0.039 for 1222 reflections ($R=0.036$ for non-zero reflections). Since the final atomic parameters obtained from the second set seem to be more accurate than those from the first set, they are documented in Tables 2(b) and 3(b). A list of the observed and calculated structure factors is deposited at the office of the Chemical Society of Japan (Document No. 7802).

Determination of Absolute Configuration

Measurement of Bijvoet Differences. The sets of Bijvoet and reference reflections with large BA_{th}* and with relatively large intensity were chosen by hand. Unless otherwise stated, the calculations of the structure factors were executed with $\Delta f_o''=0.02$ and $\Delta f_c''=\Delta f_H''=0.0$. The Bijvoet differences of both compounds were measured under the same experimental condition. A crystal was mounted with its b axis parallel to the ϕ axis of a Rigaku off-line four-circle diffractometer. The θ-2θ scan technique was adopted using Ni-filtered Cu $K\alpha$ radiation with a scan speed of 0.5°/min (θ) and a scan width of 0.8° (θ). Backgrounds were counted for 26 s at both sides of the scan range. In this experimental condition, the intensities of the Bijvoet pair (h_1 k_1 l_1 and h_1 $\bar{k}_1$ l_1) and its reference pair (h_2 k_2 l_2 and h_2 $\bar{k}_2$ l_2) were measured alternately 10 times. To diagnose the error of measurement, the intensities of equivalent reflections ($\bar{h}_1$ k_1 $\bar{l}_1$, $\bar{h}_1$ $\bar{k}_1$ $\bar{l}_1$, $\bar{h}_2$ k_2 $\bar{l}_2$, and $\bar{h}_2$ $\bar{k}_2$ $\bar{l}_2$) were also measured in the same way. The results of the measurements for each compound are summarized in Table 4. The standard deviation of mean value calculated from 10 individual BA's, $\sigma(BA_e)$, is not significantly large compared with that expected from counting statistics, $\sigma(BA_c)$. The signs of DELA for sterigmatocystin are minus through all reflections, while for epishamixanthone a few exceptions are found.

Effect of Error in Atomic Parameters on B_{th}. The magnitude of B_{th} for the enantiomer-sensitive reflection in a light atom structure is fairly small. It is inferred, however, that this fact does not mean that very accurate atomic parameters are necessary to evaluate the B_{th}. The effect of the error in atomic parameters has been quantitatively estimated as listed in Table 5, which shows that each of the $\sigma(B_{th})$ is small enough to hold the sign of the B_{th} invariable. Further, the estimation of the $\sigma(B_{th})$ has been assessed by means of a half-normal probability plot[9] (Fig. 1). These plots show that the $\sigma(B_{th})$'s have been correctly estimated. It should be noted that B_{th} is insensitive to overall thermal parameters; even though the overall thermal parameters obtained from the second data-set for sterigmatocystin are significantly smaller than those from the first set, the slope for sterigmatocystin is approximately 1.0. For the enantiomer-sensitive reflections, all of the signs of the B_{th} calculated at the

* The notations are same as those in Engel's paper.[4] DEL$=B_{ex}/B_{th}$, $B=(Q_{H1}-1)/(1/2)(Q_{H1}+1)$, DELA$=BA_{ex}/BA_{th}$, $BA=(Q_{H1}/Q_{H2}-1)/(1/2)(Q_{H1}/Q_{H2}+1)$, $Q_{Hi}=F_{Hi}/F_{\bar{H}i}$; H1: Bijvoet reflection; H2: reference reflection.

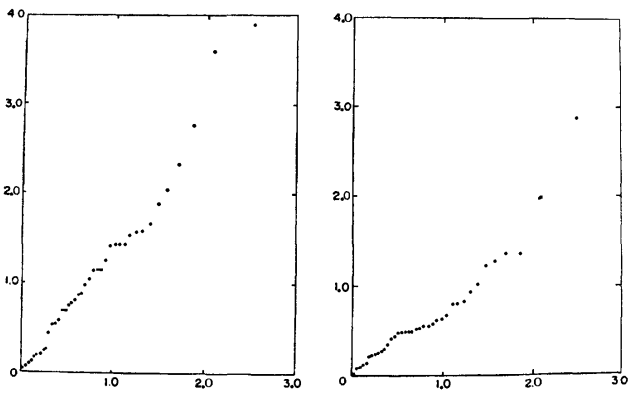
early stage of the refinement were equal to those at the final stage. Therefore, it is not necessary to refine the structure extremely for application of the method described by Engel,[4] if the structure is correctly solved. The other reflections with smaller Bijvoet differences may have a larger value of $\sigma(B_{\rm th})/|B_{\rm th}|$. Average $\sigma(\Delta|F_{\rm c}|)$ value was discussed by Parthasarathy.[10]

Two kinds of $B_{\rm th}$ were calculated: $B_{\rm th}(1)$ with $\Delta f_{\rm o}''=0.032$, $\Delta f_{\rm c}''=0.009$, and $\Delta f_{\rm H}''=0.0$,[11] and $B_{\rm th}(2)$ with $\Delta f_{\rm o}''=0.018$ and $\Delta f_{\rm c}''=\Delta f_{\rm H}''=0.0$. In the $B_{\rm th}(2)$, the $\Delta f_{\rm o}''$ corresponds to the effective anomalous scattering factor of oxygen atom defined by Engel,[4] and the contribution of hydrogen atoms is neglected. For the reflections in Table 5, the values given by $\Sigma|B_{\rm th}(1)-B_{\rm th}(2)|/\Sigma(1/2)(|B_{\rm th}(1)|+|B_{\rm th}(2)|)$ are

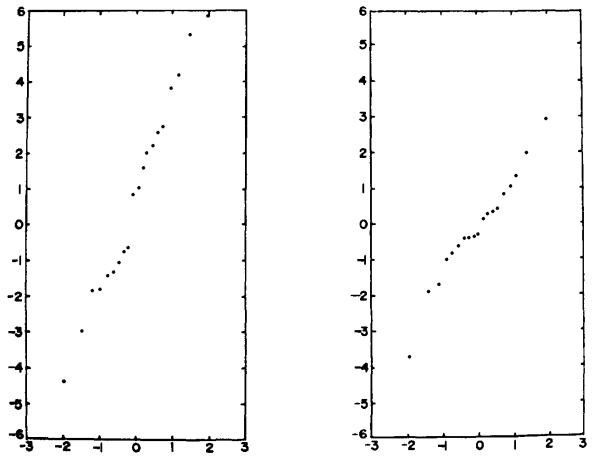


(a) Epishamixanthone (b) Sterigmatocystin

Fig. 1. Half-normal probability plot: the vertical axis is statistic $\delta p_{\rm l}$; the horizontal axis is the expected $\delta p_{\rm l}$.
$\delta p_{\rm l}=||B_{\rm th}(1)_{\rm l}|-|B_{\rm th}(2)_{\rm l}||/\{\sigma^2(B_{\rm th}(1))_{\rm l}+\sigma^2(B_{\rm th}(2))_{\rm l}\}^{1/2}$,
where $B_{\rm th}(1)_{\rm l}$, $B_{\rm th}(2)_{\rm l}$, $\sigma(B_{\rm th}(1))_{\rm l}$, and $\sigma(B_{\rm th}(2))_{\rm l}$ are calculated from two sets of atomic parameters and their estimated standard deviations obtained from independent structure refinement.

0.105 and 0.051 for epishamixanthone and sterigmatocystin respectively.

Error in Intensity Measurement. Various kinds of experimental errors in the detection of the small intensity difference of Bijvoet pair have been eliminated appreciably by the use of the reference reflection; for epishamixanthone mean DEL and DELA are −1.04 ±0.22 and −1.14±0.15 respectively, and for sterigmatocystin the corresponding values are −1.26±0.12 and −0.98±0.07. However, the standard deviation of mean DELA for each compound calculated from individual DELA's is still larger than the corresponding value expected from $\sigma(BA_{\rm c})$'s or $\sigma(BA_{\rm o})$'s. This fact is visualized in the normal probability plot[9] (Fig. 2),



(a) Epishamixanthone (b) Sterigmatocystin

Fig. 2. Normal probability plot: the vertical axis is statistic $\delta m_{\rm l}$; the horizontal axis is the expected $\delta m_{\rm l}$.
$\delta m_{\rm l}=\{(\mathrm{DELA}_{hkl})_{\rm l}-(\mathrm{DELA}_{\bar{h}\bar{k}\bar{l}})_{\rm l}\}/\{\sigma^2(\mathrm{DELA}_{hkl})_{\rm l}+\sigma^2(\mathrm{DELA}_{\bar{h}\bar{k}\bar{l}})_{\rm l}\}^{1/2}$,
where the $\sigma(\mathrm{DELA}_{hkl})_{\rm l}$ and $\sigma(\mathrm{DELA}_{\bar{h}\bar{k}\bar{l}})_{\rm l}$ are calculated from 10 individual DELA's. The plot is independent of $BA_{\rm th}$.

TABLE 4. RESULTS OF THE BIJVOET MEASUREMENTS

BA_{ex} is the mean values of 10 individual BA's. $\sigma(BA_c)$ and $\sigma(BA_e)$ are standard deviations of the mean expected from counting statistics and that calculated from 10 individual BA's respectively. BA_{th}, BA_{ex}, $\sigma(BA_c)$, and $\sigma(BA_e)$ are given in %.

a) $\sigma(B_{th})$ is given in parentheses with respect to the least significant digit. $\sigma(B_{th})$ has been calculated by the formula: $\sigma^2(B_{th})=\sum_i\{\partial B_{th}/\partial P_i\}^2(\sigma P_i)^2$, where P_i and σP_i are the i-th parameter and estimated standard deviation, respectively, obtained from a block-diagonal least-squares calculation. The parameters and estimated standard deviations in the most refined stage (Tables 2 and 3) have been used in this calculation.

although the number of samples is small. The slopes, especially for epishamixanthone, are larger than 1.0. This indicates the existence of some errors due to geomery of the instrument and/or habit of crystal which were not fully eliminated by the method. This is partly explained by the fact that the width of the peak-profile of epishamixanthone changes more drastically, as the direction of the X-ray beam changes, than that of sterigmatocystin.

The errors exist to a great extent in experimental measurements of Bijvoet difference. Since the method described by Engel is insensitive to experimental errors such as the instability and geometrical error of an instrument, the method may generally give a more significant enantiomer-indication than the R method. Various sources of error were discussed by Engel.[4]

The absolute configuration of epishamixanthone is correctly represented by the parameters in Tables 2(a) and 3(a), if the left-handed coordinate system is adopted. The absolute configuration of sterigmatocystin determined by the present analysis agrees with that determined by its bromo derivative.[5] For each of the present compounds, the probability that the selected absolute configuration is wrong is estimated to be far less than 0.01%, assuming a t-distribution of DELA values.

Crystal and Molecular Structure

The crystal and molecular structure of epishamixanthone is shown in Fig. 3, together with the numbering scheme of atoms used in this paper. The figure is drawn with correct absolute configuration. The bond

lengths and angles for non-hydrogen atoms are shown in Table 6. The configurations of the C(16) and C(20) atoms are both *R*. The absolute configuration of shamixanthone has been assigned by Chexal *et al.* by application of the Horeau asymmetric synthesis.[12] Thus the configuration of C(20) in epishamixanthone is the same as that of the corresponding atom in shamixanthone, while that of C(16) is opposite. From the biosynthetic study,[13,14] it was shown that both the carbon atoms are incorporated from the methyl carbon of acetate, and was suggested that the dihydropyran ring is formed by cyclization between 3-methyl-2-butenyloxy and aldehyde groups in the precursor. Chexal *et al.*[14] discussed the mechanism of the formation of substituted dihydropyran rings. Although epishamixanthone is one of epimers of shamixanthone, it is unlikely, from the absolute configurations of these metabolites, that the metabolites arise through ene-reaction with transition states differing to each other only in the conformation of aldehyde group in the precursor.

The equations of the least-squares planes and the deviations of atoms from each plane are given in Table 7. The ring composed of C(1), C(2), C(20), C(16), C(15), and O(5) forms a half-chair conformation. The torsion angles of C(15)–C(16)–C(17)–C(19) and

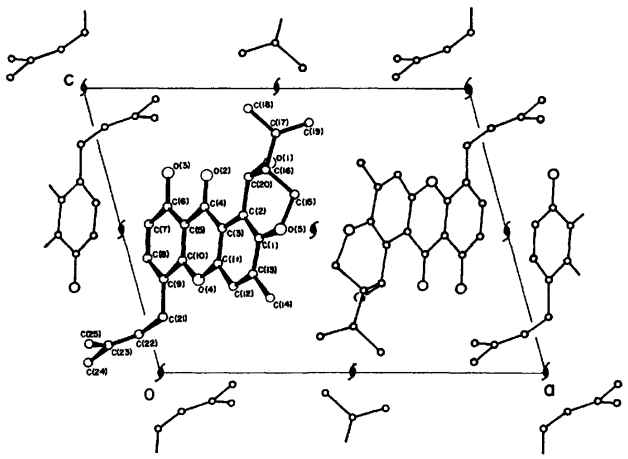

Fig. 3. The crystal and molecular structure of epishamixanthone viewed along the b-axis.

TABLE 7. DEVIATIONS (Å) OF ATOMS FROM LEAST-SQUARES PLANES

In the equations of the plane, X, Y, and Z are $ax+cz\cos\beta$, by, and $cz\sin\beta$ respectively.

Plane: C(1)—C(13), O(2), O(4)

Plane: C(21)—C(25)

$0.380X+0.262Y-0.887Z=-2.308$

[C(21) 0.002, C(22) −0.005, C(23) 0.004, C(24) 0.001, C(25) −0.002]

C(10)-C(9)-C(21)-C(22) are −11.8 and −172.5° respectively. There are two intramolecular hydrogen bonds, O(1)-H(O1)···O(2) and O(3)-H(O3)···O(2). The distances of O(2)···H(O1) and O(2)···H(O3) are 1.89 and 1.76 Å respectively. The angles of O(1)-H(O1)···O(2), O(3)-H(O3)···O(2), H(O1)···O(2)-C(4), and H(O3)···O(2)-C(4) are 157, 144, 108, and 102° respectively. The interplanar distance of xanthone skeletons stacking along the b axis is about 3.65 Å. The intermolecular distances less than 3.8 Å are listed in Table 8. There are neither intermolecular hydrogen bonds nor abnormally short contacts: the crystal is composed of molecules held by van der Waals forces.

The atomic scattering factors were taken from International Tables for X-ray Crystallography.[15] Most of calculations were performed on a TOSBAC-3400 computer at the Tottori University Computing Center by the use of programs written by the authors. The block-diagonal least-squares refinement and the vector-search calculation were executed on a NEAC-2200 N700 computer at the Computation Center of Osaka University using programs written by T. Ashida and I. Tanaka respectively.

TABLE 8. INTERMOLECULAR CONTACTS LESS THAN 3.8 Å EXCLUDING HYDROGEN ATOMS

The superscripts refer to the following equivalent positions: I x, $1+y$, z; II $-x$, $1/2+y$, $1-z$; III $1-x$, $1/2+y$, $1-z$.

C (1)···C (5^{I})	3.763	C (20)···O (3^{I})	3.671

Effect of the Trap Density on Switching in Naphthacene Thin Films

Yoshihiko SADAOKA and Yoshiro SAKAI

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received May 19, 1977)

Switching phenomena were observed in Au(+)–naphthacene (crystalline-state)–Al(−). The threshold voltage was found to be expressable as $V_{th} \propto (\text{thickness})^2$; in amorphous films no reproducible switching phenomena were observed within the same region of the field strength. The differences between them were discussed in terms of the trap density, which is closely related to the crystallinity of the evaporated films.

Szymanski *et al.*[1] reported bistable switching in naphthacene thin films with Au and Al electrodes, but the conditions required were not reproducible, while reproducible switching in aromatic hydrocarbon films was observed by Kevorkian *et al.*[2] when a mobile electrode material was used. Although some authors have proposed the *turn-on* to be due to either metallic filament formation, or the formation of carbonized materials,[3] Kasica *et al.*[4] have proposed that the reproducibility of the switching curves is strongly affected by the surrounding conditions and that the switching is interpretable in terms of the double injection mechanism.

This paper deals with the influence of the trap density on the bulk-limited switching characteristics in naphthacene films, because the state of the naphthacene film can be easily controlled by varying the substrate temperature during the evaporation and the bulk-type high field conduction is expected in Au–naphthacene–Al cell. Also, since the heat of sublimation is larger and the melting point of this material is much higher than that of anthracene, the reproducibility of switching should be much better in naphthacene than in anthracene.

Experimental

The geometry of the cell was of the sandwich type, where naphthacene was deposited over a glass substrate on which thirty strips of gold electrodes of 1 mm in width and 1 mm in separation had been evaporated through an etched stainless steel mask. The upper electrodes(Al) were deposited by the same method. The temperature of the substrate was controlled in the range of −120 to 110 °C. The film thickness of naphthacene was measured with the aid of an interferometer. D.c. conductivities and/or switching curves were measured by means of the circuit described in the previous paper.[5] The load(protective) resistor in the circuit can be varied in the range of 10^3—10^8 Ω to control the current which flows in the high conductivity state. All the electrical measurements were carried out in vacuum.

The state of the films was examined using a scanning electron microscope and a polarizing microscope. Polycrystalline structure was observed for the film prepared by the deposition onto the glass substrate kept at a high temperature (≈100 °C). However, an amorphous film was obtained when the glass substrate was kept at a low temperature(≤−100 °C) during evaporation. The scanning electron microscopic views of the films are shown in Fig.1. In addition, the absorption spectra of the film deposited on the quartz substrate also indicated that a crystalline state was obtained when a substrate was held at a high temperature and an amorphous state when a substrate was held at a low temperature(≤−100 °C) at the time of evaporation. These results are consistent with that reported by Maruyama and Iwasaki.[6] In some cases the substrates were kept at room temperature during evaporation. These films were found to be partly crystallized.

Results and Discussion

A typical current-voltage characteristic in the low-conductivity state is shown in Fig. 2 for an Au–naphthacene–Al cell. This curve is typical for a rectifying contact, *i.e.*, the current increases non-linearly with applied voltage. Similar asymmetry in its characteristic has been reported by Ghosh and Feng.[7] Under the forward-bias condition, the V^n dependence of current on voltage due to an exponential trap distribution was found for all samples prepared in various conditions. Rectification ratios as high as 10^4 was observed in the high-field region.

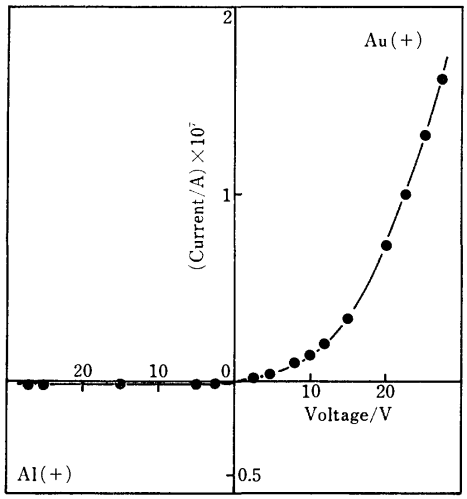

Fig. 2. A typical *I-V* characteristic in the Au–naphthacene–Al cell.

More than 600 films were used for the electrical measurements under the forward-bias conditions in order to clarify the influence of the trap-density on the threshold voltage for the bulk type switching phenomena. Although no switching phenomena were observed in the low-temperature-evaporated films, the switching without any structural changes were observed in the high-temperature-evaporated crystalline-state films in most of the samples. The observed switching characteristics are shown in Fig. 3. When the applied voltage exceeded a critical value (V_{th}) which is poorly dependent on the value of the load resistor R_L, the current abruptly increased, and simultaneously the field dropped (negative resistance region), so that a new high-conductivity state was formed. Since the conductance of this new state is strongly influenced by the value of the load resistor and this dependence on the load resistor cannot be explained by the usual non-linear-conduction mechanisms, this state should be formed in a filamentary way *i.e.* the effective area of this state increases upon decreasing the value of the load resistor.

In addition, the holding voltage (*turn-off* voltage) was observed in the switching characteristics when the load resister R_L was $10^8\ \Omega$, while the memory effect was observed when R_L was $10^5\ \Omega$. After the applied voltage had been taken off, the state with its memory effect quenched off in *ca.* 3 h or more and the initial low-conductivity state was recovered. Such a high-conductivity state with a memory effect may be related to the density of deep trapping levels, and not be caused by any structural changes.

In the low-conductivity state for the crystalline films the current increased rapidly in proportion to V^n with $n \approx 4$. This characteristic is interpretable in terms of the space-charge-limited current (SCLC). According to Mark and Helfrich[8] the SCLC for exponential distribution of traps with energy should follow the equation

$$J = N_0 \mu e^{1-l} \left\{ \frac{\varepsilon \varepsilon_0 l}{H(l+1)} \right\}^l \left(\frac{2l+1}{l+1} \right)^{l+1} \frac{V^{l+1}}{d^{2l+1}}, \quad (1)$$

where N_0 is the effective density of states in the valence band, μ is the hole mobility, ε is the dielectric constant, ε_0 is the vacuum permittivity, e is the electron charge, H is the total hole trap density, d is the film thickness, and $l = T_c/T$. The parameter T_c characterizes the trap distribution. Furthermore, one can obtain an expression for the position dependence of the quasi-Fermi level for holes. It is

$$E_F = kT_c \ln \left[\frac{(l+1)^2}{l(2l+1)} \frac{eHd^2}{\varepsilon \varepsilon_0 V} \left(\frac{x}{d} \right)^{1/l+1} \right], \quad (2)$$

where x is the distance from the injecting electrode (anode). The measurement of the temperature dependence of SCLC yields the value of $E_F(x=d)$, while the density of free carriers, which is proportional to the current, is given by the relation $n \propto \exp(-E_F/kT)$. In Fig. 4, the relation between the activation energy and the value of $\log(d^2/V)$ is shown. From the results in Fig. 4 the total hole trap density was estimated to be $1—2 \times 10^{16}\ \mathrm{cm^{-3}}$ for thicker films(line I) and $1—2 \times$

(△) high-temperature-evaporated crystalline film,
film thickness: 1.0×10^{-4} cm.

10^{17} cm^{-3} for thinner films(line II), respectively, by substituting $\varepsilon=3.8$ and, $x=d$. The values of l obtained from the slope of the lines in Fig. 4 are consistent with those obtained from the current-voltage curves. The values of H for the crystalline films are reasonable ones, although they are somewhat higher than that for single crystals grown by sublimation in nitrogen ($H=3\times10^{15}$ cm^{-3}).[9] The fact that the value of H for a thinner film is somewhat larger than that for a thicker film suggests that the traps caused by residual gas molecules and/or defects are located in the surface regions close to the electrode. In addition, in the case of the amorphous films prepared by low-temperature deposition, similar current-voltage characteristics ($l\approx8$) caused by SCLC for an exponential distribution of traps with energy was obtained and a linear relation (line III) between E_F and $\log(d^2/V)$ was also found. The total hole trap density was estimated to be 4×10^{18} cm^{-3}. Since it is well known that lowering the substrate temperature increases structural disorder, the structural irregularity must be the cause of such trapping-levels rather than the chemical impurities because the low- and high-temperature-evaporated films were deposited from the same evaporation source.

On the other hand, the measurement of the thickness dependence of the threshold voltage(V_{th}) was carried out for the high-temperature-evaporated crystalline films in order to determine whether the *turn-on* is based on the thermal effect or the electronic effect, since such a measurement is a very powerful method[10] to distinguish one from the other. As shown in Fig. 5, the threshold voltage is proportional to the square of the thickness (line I), though other line II different from line I was obtained from the films thinner than *ca.* 3×10^{-5} cm. This relation indicates that the *turn-on* is caused by an electronic mechanism such as the space charge overlap model[11] or the one carrier SCLC model[12] in which the concentration of the injected carriers is sufficient to exceed the critical concentration (N_{th}). And this interpretation is confirmed by the fact that the *turn-on* does not occur in the amorphous films at the conditions under which the *turn-on* occurs in the crystalline films. In the space charge overlap model, it is expected that the current-voltage characteristic in the *pre*-switching state is caused by the double injection and the *turn-on* is achieved by the formation of the space charge overlap region. However, in the one carrier SCLC model the *turn-on* may be expected when the space charge density caused by injected holes in the *pre*-switching state reaches a critical value and the injection of electrons begins.[4,12] Since in the *pre*-switching state the current-voltage curve in Au(+)–naphthacene–Al(−) is similar to that in Au–naphthacene–Au, the electric conduction in the *pre*-switching state is most likely due to one carrier SCLC with traps. This current in the high resistivity state may entirely consist of the holes injected from the Au electrode into naphthacene, as was suggested by Ghosh and Feng.[7] Consequently, the *turn-on* is interpretable in terms of the one carrier SCLC model rather than the space charge overlap model based on the double injection in the *pre*-switching state.

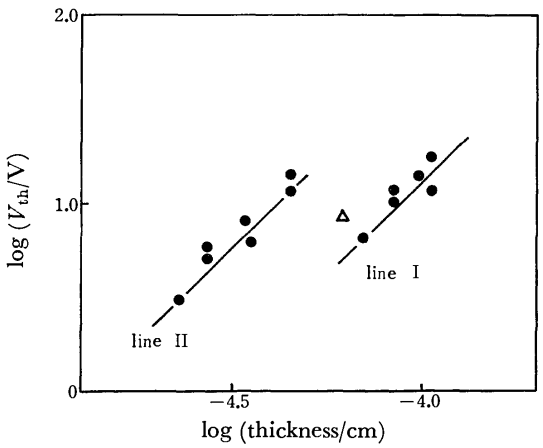

Fig. 5. Thickness dependence of V_{th}.
(●) Observed values, (△) result reported by Szymanski *et al.*[1]

If Q_{th} represents the space charge density formed by the injected holes, the potential distribution in the bulk can be expressed as Eq. 3:

$$V(x)=\frac{Q_{th}}{2\varepsilon\varepsilon_0}x^2. \tag{3}$$

Consequently, the threshold voltage may be introduced as Eq. 4 by substituting $x=d$:

$$V_{th}=\frac{Q_{th}\cdot d^2}{2\varepsilon\varepsilon_0}. \tag{4}$$

The corresponding values of N_{th} and Q_{th} were estimated to be 6×10^{15} cm^{-3} and 9.7×10^{-4} C/cm^{-3} for line I and 2×10^{16} cm^{-3} and 3×10^{-3} C/cm^{-3} for line II, respectively. Since no switching phenomena were observed in the amorphous films and the values of N_{th} obtained by using Eq. 5 for the crystalline films are roughly in agreement with the values of total hole trap density, the *turn-on* can occur when the traps are filled by the injected holes and under such conditions the Al electrode will become an electron-injecting contact. In this case Eq. 4 can be replaced by Eq. 5:

$$V_{th}=\frac{eHd^2}{2\varepsilon\varepsilon_0}. \tag{5}$$

The same relation between the threshold voltage and the trap density was reported in the previous works for poly(*N*-vinylcarbazole)[5] and anthracene.[13]

From the results thus obtained it is concluded that the lack of switching phenomena for the amorphous film is caused by the fact that the number of the trap density is much larger than that in the crystalline films; in these circumstances, the thermal breakdown caused by Joule-heating may occur before the trap-filled state is achieved, since the threshold voltage for the amorphous film of 5×10^{-5} cm in thickness is estimated to be *ca.* 2×10^3 V and the value of l is much larger than that for the crystalline films ($l=4$).

One of us (Y. Sadaoka) thanks the Sakkokai Foundation for a grant.

Ion-Molecule Reactions in the Binary Mixture of Acetaldehyde and Trioxane. I. Hydrogen Atom and Proton Transfer Reactions

Minoru KUMAKURA, Kazuo ARAKAWA, and Toshio SUGIURA*

Takasaki Radiation Chemistry Research Establishment, Japan Atomic Energy Research Institute, Takasaki, Gunma 370-12

** Japan Atomic Energy Research Institute, Shinbashi, Minato-ku, Tokyo 105*

(Received May 19, 1977)

The formation reactions of protonated molecular ions in acetaldehyde–trioxane mixtures have been studied with a modified time-of-flight mass spectrometer. From the analysis of the fine structure of the ionization efficiency curves of fragment and product ions obtained by means of the retarding potential differential technique using acetaldehyde-d_4, the precursors of the product ions were determined. Protonated acetaldehyde is formed by the hydrogen atom transfer reaction of acetaldehyde molecular ion with trioxane, and protonated trioxane by the proton transfer reaction of CHO^+ generated from acetaldehyde with trioxane. The rate constants of the formation reactions of the product ions in acetaldehyde (or acetaldehyde-d_4)–trioxane mixtures were determined and isotope effect was observed. The CHO^+ generated from acetaldehyde participated predominantly in the proton transfer reaction as compared with that generated from trioxane. From the proton transfer reaction involving thermal ion CHO^+ generated from acetaldehyde it was found that the proton affinity of trioxane is smaller than that of acetaldehyde.

In studies on the ion-molecule reactions in the binary mixture of ethylene oxide and trioxane (1,3,5-trioxane) it was found that protonated ethylene oxide and trioxane are formed by cross-reaction.[1] In the ion-molecule reactions of ethylene oxide[2] and acetaldehyde,[3] the CHO^+ plays an important role in the formation of protonated molecular ions. The ion-molecule reactions in acetaldehyde have been studied by several workers.[4-8] However, the ion-molecule reaction of acetaldehyde in the mixture involving cyclic ether molecule of a large member ring such as trioxane does not seem to have been reported. In the present work, the ion-molecule reactions in the binary mixture of acetaldehyde and trioxane were studied in order to clarify the formation mechanism of protonated molecular ions. Highly strained three member ring molecule such as ethylene oxide could be isomerized under appropriate conditions into more stable isomer (acetaldehyde). A relative abundance pattern of the fragment ions from acetaldehyde in electron impact fragmentation resembles that from ethylene oxide.[3] Some oxygen-containing fragment ions of a similar structure were also produced from acetaldehyde, ethylene oxide, and trioxane. A study of the ion-molecule reactions involving the structural isomer ions in acetaldehyde–trioxane mixtures is important in connection with elementary process in radiation and ion chemistry.

Experimental

A Bendix Model 12-101 time-of-flight mass spectrometer modified with a closed ionization chamber was used.[2] Substituted ion source permitted operation under elevated pressures at long delay times. The pulse electronic circuits of the apparatus were also modified. The variable delay time circuit permitted a variation of time between the end of the ionizing pulse and the onset of the ion withdrawal pulse.[1] During the delay time the entire ionization chamber is field-free, ion-molecule reactions occurring during the time interval thus being under purely thermal conditions. The retarding potential differential technique (RPD)[9] was adopted for appearance potential and ionization efficiency curve measurement. Measurement of the ionization efficiency curves of two ions (reactant and product ion) was simultaneously performed by the two-channel ion detection technique. The gas-sample inlet-system consisting of a dual-leak and dual-reservoir was used. Two kinds of samples were introduced separately into the ionization chamber through two separate leaks from separate reservoirs. The partial pressure of the two samples was indirectly measured with an MKS Baratron 90-X RP-2 capacitance manometer, the pressure being calibrated by known rate constant (1.11×10^{-9} cm^3 molecule^{-1} s^{-1}) of CH_5^+ in the ion-molecule reaction of methane.[2]

The following reagents were used: trioxane (Celanese Chemical), acetaldehyde, and acetaldehyde-d_4 (Merck Sharp and Dohme of Canada). The samples were used after vacuum distillation several times.

Results and Discussion

Delay Time Dependence. The delay time dependence of major fragment ions in a 1 : 1 mixture of acetaldehyde and trioxane at pressure of 1.67×10^{13} molecules cm^{-3} and electron energy of 70 eV is shown in Fig. 1. The *m/e* 44 (CH_3CHO^+), 43 (CH_3CO^+), 29 (CHO^+) are fragment ions from acetaldehyde, while *m/e* 89 ($C_3H_5O_3^+$), 61 ($C_2H_5O_2^+$), 31 (CH_3O^+), and a part of *m/e* 29 are those from trioxane. The molecular ion from trioxane was relatively less abundant, its ion intensity being comparable with the ion intensity of ^{13}C atom of *m/e* 89.[9] The variation of ion intensity of the fragment ions with delay time was investigated. The ion intensity of the fragment ions of low mass numbers decreased markedly with increasing delay time as compared with that of high mass numbers. The decrease was mainly due to a mass discrimination effect though a part of the ions was lost by ion-molecule reactions. It is presumed that the CHO^+ ions play an important role in proton transfer reactions.

The delay time dependence of product ions is shown in Fig. 2. The formation of protonated acetaldehyde (CH_3CHOH^+) is remarkable as compared with that of protonated trioxane ($C_3H_6O_3H^+$). The ion intensity ratio of protonated acetaldehyde to protonated trioxane is *ca.* 7 at delay time 1.0 μs. Protonated molecular ions are formed in acetaldehyde as well as in trioxane,[2,10] but further formation of these ions was observed in the mixture. This suggests that the protonat-

ed molecular ions are formed by cross-reactions. Studies in the mixture using deuterated acetaldehyde were carried out to elucidate the formation mechanism of the protonated molecular ions under the same conditions as unlabeled acetaldehyde mixture. The delay time dependence of major fragment and product ions in acetaldehyde-d_4–trioxane mixtures is shown in Figs. 3 and 4. The CHO^+ ions from both molecule were separated into CHO^+ and CDO^+. The isotopic distribution of product ions is given in Fig. 4. The *m/e* 49 (CD_3CDOH^+) and 50 (CD_3CDOD^+) are protonated and deuteronated acetaldehyde-d_4, and *m/e* 91 ($C_3H_6O_3H^+$) and 92 ($C_3H_6O_3D^+$) protonated and deuteronated trioxane, respectively. The CD_3CDOH^+ and $C_3H_6O_3D^+$ are cross-reaction product ions in acetaldehyde-d_4–trioxane mixtures. The ion intensity ratio of CD_3CDOH^+ to CD_3CDOD^+ and $C_3H_6O_3D^+$ to $C_3H_6O_3H^+$ were *ca.* 2 and 0.1 at delay time of 1.0 μs. It is suggested that the cross-reaction of proton or hydrogen atom transfer occurs in the mixture. These observations give important information on the reactivity of ionic and neutral reactants in the mixture.

Pressure Dependence. The ion intensity variation of the product ions with pressure in each molecule was

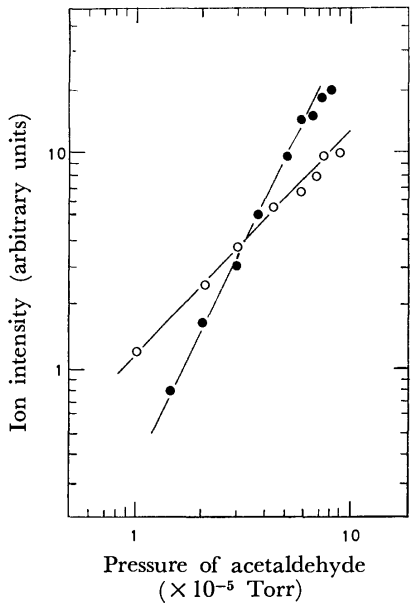

Fig. 5. Dependence of protonated molecular ions on pressure of acetaldehyde.
●: CH_3CHOH^+, ○: $C_3H_6O_3H^+$.

examined in order to clarify the contribution of acetaldehyde and trioxane. The pressure dependence of the protonated molecular ions on acetaldehyde (Fig. 5) was obtained by pressure variation of acetaldehyde using the dual leak at a fixed pressure (8.2×10^{12} molecules cm^{-3}) of trioxane and delay time of 1.0 μs. Protonated acetaldehyde shows a dependence of second order on the pressure of acetaldehyde, protonated trioxane showing one of first order. This suggests that the formation of protonated trioxane is correlated with acetaldehyde. The pressure dependence of protonated molecular ions on trioxane at a fixed pressure (8.2×10^{12} molecules cm^{-3}) of acetaldehyde is shown in Fig. 6. Protonated trioxane and acetaldehyde show

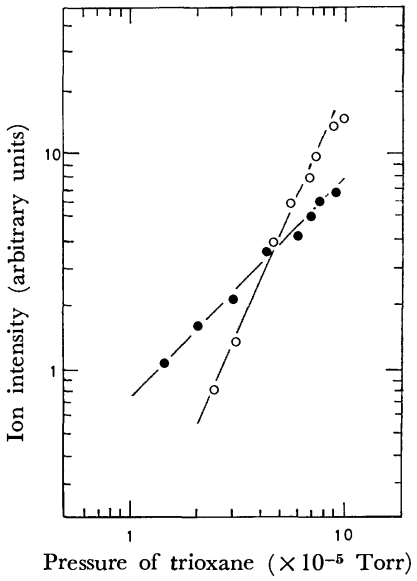

Fig. 6. Dependence of protonated molecular ions on pressure of trioxane.
●: CH_3CHOH^+, ○: $C_3H_6O_3H^+$.

a dependence of second and first order, respectively, on trioxane pressure.

Ionization Efficiency Curves. The ionization efficiency curves of major fragment and product ions in acetaldehyde-d_4–trioxane mixtures were obtained in order to determine the precursors of the product ions at delay time of 1.0 μs. The ionization efficiency curves of CD_3CDOH^+, CD_3CDO^+, and $C_3H_5O_3^+$ are shown in Fig. 7 and those of $C_3H_6O_3D^+$, CD_3CO^+, CDO^+, and CD_3^+ in Fig. 8. The ionization potential of acetaldehyde and the appearance potential of $C_3H_5O_3^+$ from trioxane are 10.32±0.05 and 10.59±0.05 eV, respectively.[9]

The onset and fine structures of the ionization efficiency curves of both CD_3CDOH^+ and CD_3CDO^+ agree. The onset of the ionization efficiency curve of CD_3CDOH^+ approaches that of $C_3H_5O_3^+$, no agreement being observed in the fine structures of the curves of both ions. In fact, the second appearance potentials of CD_3CDOH^+ and $C_3H_5O_3^+$ did not agree, the second and third appearance potential of CD_3CDOH^+ showing a good agreement with those of CD_3CDO^+ in Fig. 7. The appearance potentials (*m/e* 61: 10.79±0.05, 31: 11.49±0.05, and 29: 13.59±0.05 eV) of other fragment ions (*m/e* 61, 31, and 29) from trioxane were higher than that of CD_3CDOH^+, the break points of

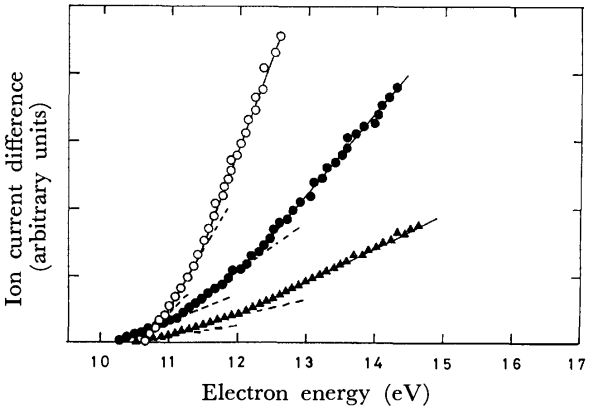

Fig. 7. Ionization efficiency curves of CD_3CDO^+ (●), CD_3CDOH^+ (▲), and $C_3H_5O_3^+$ (○) in acetaldehyde-d_4–trioxane mixtures.

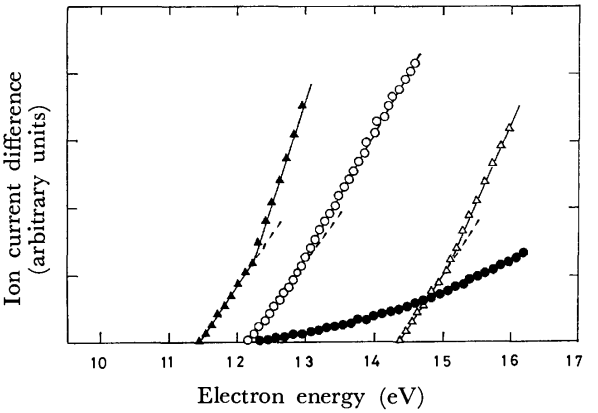

Fig. 8. Ionization efficiency curves of CD_3^+ (△), CDO^+ (○), CD_3CO^+ (▲), and $C_3H_6O_3D^+$ (●) in acetaldehyde-d_4–trioxane mixtures.

the ionization efficiency curve of CD_3CDOH^+ and these fragment ions not agreeing. Thus, it was concluded that CD_3CDO^+ is the sole precursor of CD_3CDOH^+. The onset of the ionization efficiency curve of $C_3H_6O_3D^+$ agreed with that of CDO^+. The appearance potentials of CD_3CO^+ and CD_3^+ which are abundant fragment ions from acetaldehyde-d_4 were 11.42±0.05 and 14.32±0.05 eV, respectively, deviating considerably from the onset of the ionization efficiency curve of $C_3H_6O_3D^+$. The onset of the ionization efficiency curves of both $C_3H_6O_3D^+$ and CD_3CDO^+ did not agree either. It was thus found that the precursor of $C_3H_6O_3D^+$ is CDO^+ from acetaldehyde-d_4.

Reaction Mechanism. The product ions resulting from the reactions in pure acetaldehyde were observed also in acetaldehyde (or acetaldehyde-d_4)–trioxane mixtures.

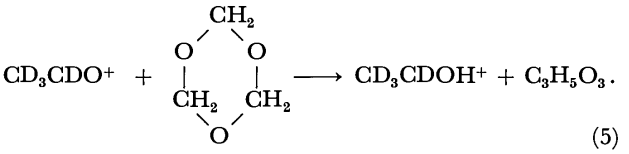
$$CH_3CHO^+ + CH_3CHO \longrightarrow CH_3CHOH^+ + CH_3CO, \quad (1)$$

$$CHO^+ + CH_3CHO \longrightarrow CH_3CHOH^+ + CO, \quad (2)$$

$$CD_3CDO^+ + CD_3CDO \longrightarrow CD_3CDOD^+ + CD_3CO, \quad (3)$$

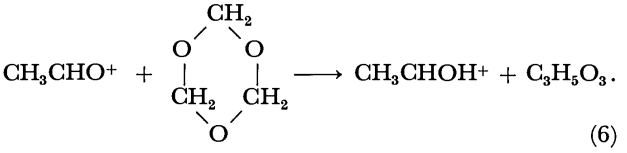
$$CDO^+ + CD_3CDO \longrightarrow CD_3CDOD^+ + CO. \quad (4)$$

It is evident from the ionization efficiency curve measurements that CD_3CDOH^+ in acetaldehyde-d_4–trioxane mixtures is formed by hydrogen atom transfer reaction as follows:



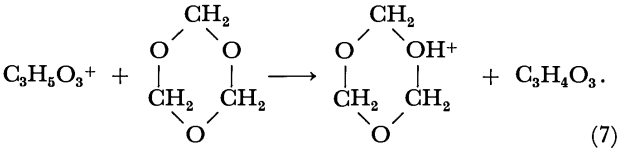
$$CD_3CDO^+ + \text{trioxane} \longrightarrow CD_3CDOH^+ + C_3H_5O_3. \quad (5)$$

Similarly, CH_3CHOH^+ in acetaldehyde–trioxane mixtures is mainly formed by the following reaction:



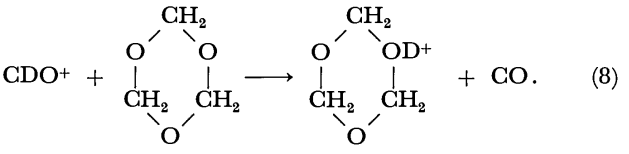
$$CH_3CHO^+ + \text{trioxane} \longrightarrow CH_3CHOH^+ + C_3H_5O_3. \quad (6)$$

On the other hand, protonated trioxane shows a dependence of the second order on the pressure of trioxane. Thus the formation of protonated trioxane occurs in the mixture as follows.



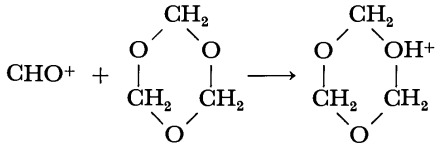
$$C_3H_5O_3^+ + \text{trioxane} \longrightarrow \text{protonated trioxane} + C_3H_4O_3. \quad (7)$$

A slight increase in the ion intensity of $C_3H_6O_3D^+$ with delay time was observed (Fig. 4). The results in the ionization efficiency curve measurements confirm the view that $C_3H_6O_3D^+$ in acetaldehyde-d_4–trioxane mixtures is formed by deuteron transfer from CDO^+ to trioxane.



$$CDO^+ + \text{trioxane} \longrightarrow \text{protonated trioxane} + CO. \quad (8)$$

The contribution of other fragment ions from acetaldehyde for the formation of $C_3H_6O_3D^+$ is negligible since the onset and the fine structures of the ionization efficiency curves of these ions and $C_3H_6O_3D^+$ did not agree with each other. Since the ion intensity of trioxane molecular ion is very low, this ion could not be considered as the main precursor. Protonated trioxane in acetaldehyde–trioxane mixtures results mainly from the following reaction:



$$CHO^+ + \text{trioxane} \longrightarrow \text{protonated trioxane} + CO. \quad (9)$$

Rate Constants and Reactivity. Protonated acetaldehyde in acetaldehyde–trioxane mixtures was formed by Reactions 1, 2, and 6. Thus the rate constant of Reaction 6 is obtained by subtracting the contribution of Reactions 1 and 2. The rate constant of Reaction 9 is obtained in the same way as for k_6. The rate constants of Reactions 3 and 4 which are concurrent are obtained with a ratio plot technique.[2,3] The rate constants obtained are summarized in Table 1. The rate constant ratio k_4/k_3 is 1.68 which is nearly equal to that of k_2/k_1. The ratios k_1/k_3, k_2/k_4, and k_9/k_8 are 1.23, 1.24, and 1.14, respectively. Thus appreciable isotope effect was observed. The striking feature in the mixture is a predominant hydrogen atom transfer reaction (Reactions 5 and 6). The rate constant of Reaction 6 is smaller than that in ethylene oxide–trioxane mixtures by a factor of 1.2, suggesting that ability of hydrogen atom abstraction of acetaldehyde is lower than one of ethylene oxide. The rate constant of hydrogen atom transfer depends on the proton affinity and/or the hydrogen affinity of neutral molecule. Here, the proton affinity of acetaldehyde is 183±2[11] and 182[12] kcal mol^{-1}, and that of ethylene oxide 183 kcal mol^{-1},[11,13] the proton affinity of both molecules thus being almost equal. It is suggested that the hydrogen affinity of acetaldehyde is smaller than that of ethylene oxide.

9	0.137	8	0.120

a) Ref. 3.

The rate constant of Reaction 2 is considerably larger than that of Reaction 9, indicating that the proton affinity of trioxane is smaller than that of acetaldehyde. CHO^+ belongs to proton donor ion among oxygen-containing ions. However, CHO^+ from trioxane did not contribute to the formation reaction of protonated molecular ions as major reactant ion in

acetaldehyde–trioxane mixtures. The effect of the translational and internal energy of reactant ions on ion-molecule reactions is important. In the measurement of translational energies of oxygen-containing ions, it was demonstrated that the energy of CHO^+ from trioxane is considerably higher than that of acetaldehyde.[14] Futrell *et al.*[15] report that the internal energy of CHO^+ depends on the source molecule and that CHO^+ from acetaldehyde has lowest internal energy among the CHO^+ ions from various oxygen-containing molecules. The difference in reactivity of the CHO^+ ions from acetaldehyde and trioxane observed in this work could be explained by an energy effect of reactant ion for proton transfer reaction.

The authors express cordial thanks to Dr. I. Kuriyama for helpful advice and encouragement during the course of the work.

(Received May 23, 1977)

The ion-molecule reactions in the binary mixture of ethylene oxide and trioxane have been studied with use of a modified time-of-flight mass spectrometer. As cross-reaction product ions, $C_3H_5O_2^+$, $C_3H_6O_2^+$, and $C_3H_7O_2^+$ were observed under the conditions of long delay times and elevated pressure. It was found that these ions are formed by the dissociation of unstable intermediate-complex resulting from the reaction of ethylene oxide molecular ion with trioxane. It was proposed that the complex is of cyclic structure in which positive charge is delocalized. From the consideration of isotopic distribution of the prodoct ions in ethylene-d_4 oxide–trioxane mixtures, the skeletal structures of the product ions were investigated. The rate constants of the formation reactions of $C_3H_5O_2^+$, $C_3H_6O_2^+$, and $C_3H_7O_2^+$ in ethylene oxide–trioxane mixtures were found to be 2.20×10^{-10}, 2.61×10^{-10}, and 1.74×10^{-10} cm^3 molecule^{-1} s^{-1}, respectively.

As part of our program dealing with radiation and ion chemistry of oxygen-containing molecules, studies were carried out on the ion-molecule reactions in ethylene oxide, trioxane (1,3,5-trioxane), and acetaldehyde.[1-3] The consecutive association reactions leading to the formation of the cluster ions were observed in trioxane and a study of the kinetics of the reactions was made. The ion-molecule reactions in oxygen-containing organic compounds are sensitive to the nature of the functional groups and the molecular structure of the ionic and neutral reactions.[1,4,5] The reaction pathway of oxygenated ions with cyclic oxygen-containing molecules seems to be of interest. So far the ion-molecule reaction in the mixture system of cyclic oxygen-containing molecules involving large member rings has not been studied, although a number of studies in the pure system of cyclic hydrocarbons have been made.[6-10] Since the formation mechanism of only protonated molecular ions by cross-reactions in the binary mixture of ethylene oxide and trioxane has been studied,[11] the present work deals with the formation of other product ions in the binary mixture under long delay times and elevated pressures. Various product ions were formed by the reaction of ethylene oxide molecular ion with trioxane. The present work was carried out in order to obtain mechanistic information on the ion-molecule reactions involving cyclic ion and neutral molecules.

Experimental

A Bendix Model 12-101 time-of-flight mass spectrometer was used. The ion source of the spectrometer was modified in order to permit operation under elevated pressures.[2] Some pulse electronic circuits of the apparatus were also modified.[11] A variable delay time circuit permitted a variation of time between the end of the ionizing pulse and the onset of the ion withdrawal pulse. During the delay time, the entire ionization chamber is field-free, so that ion-molecule reactions occurring during the time interval are under thermal conditions. The retarding potential differential technique (RPD)[12] was adopted for appearance potential and ionization efficiency curve measurement. Measurement of the ionization efficiency curves of two ions was simultaneously performed by a two-channel ion detection method. The gas-sample inlet-system consisting of dual-leak and dual-reservoir was used. Two kinds of samples are introduced individually into the ionization chamber through two separate leaks from separate reservoirs. The partial pressure of the two samples was indirectly measured with an MKS Baratron 90-X RP-2 capacitance manometer, the pressure being calibrated by the rate constant (1.11×10^{-9} cm^3 molecule^{-1} s^{-1}) of CH_5^+ in the ion-molecule reaction of methane.[13]

The following reagents were used: trioxane (Celanese Chemical), ethylene oxide (Nisso Yuka Industry Co., Ltd.), and ethylene-d_4 oxide (Merck Sharp and Dohme of Canada, deuterium atom purity, 98%). The samples were used after being subjected to vacuum distillation several times.

Results and Discussion

Delay Time Dependence. The delay time dependence of fragment and product ions in a 1 : 1 mixture of ethylene oxide and trioxane at 2.61×10^{13} molecules cm^3 is shown in Figs. 1 and 2. In Fig. 1, *m/e* 44 ($C_2H_4O^+$), 43 ($C_2H_3O^+$), and 29 (CHO^+) are

major fragment ions from ethylene oxide, and *m/e* 89 ($C_3H_5O_3^+$), 61 ($C_2H_5O_2^+$), and a part of *m/e* 29 (CHO^+) are those from trioxane. Trioxane molecular ion is relatively less abundant, its ion intensity being comparable with the ion intensity of ^{13}C isotope of *m/e* 89.[12] The *m/e* 73, 74, and 75 were observed as new product ions in the mixture system as shown in Fig. 2. The plots of these ions are not shown, since the behavior of the protonated molecular ions and product ions formed in individual system has been described.[1,2,11] In order to elucidate the formation mechanism of the product ions in the mixture system, the ion-molecule reactions in ethylene-d_4 oxide–trioxane mixtures were studied under the same conditions as for ethylene oxide–trioxane mixtures. The delay time dependence of product ions is shown in Fig. 3. The isotopic product ions (*m/e* 73—79) correspond to the product ions (*m/e* 73—75) formed in ethylene oxide–trioxane mixtures.

The pressure dependence of the product ions on each molecule was examined in order to determine the contribution of ethylene oxide and trioxane at delay time of 1.0 μs. The pressure dependence of the product ions in ethylene oxide–trioxane mixtures is shown in Figs. 4 and 5. The product ions show a dependence of the first order on the pressure of ethylene oxide and trioxane. The results indicate that the product ions are formed by cross-reactions.

Ionization Efficiency Curves and Reaction Mechanism. In order to identify the reactions with each of the prod-

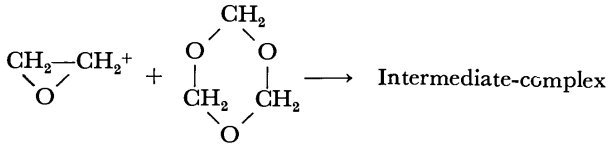
uct ions, we measured the appearance potentials and the ionization efficiency curves of the product ions for comparison with those of the possible reactionts. The fragment ion whose appearance potential lies closest to that of product ion is taken to be the reactant ion (precursor), provided the reaction is energetically possible. If more than one fragment ion is responsible for the formation of a given product ion, a change in the slope of the ionization efficiency curve will often denote the onset of the reaction involving a different reactant ion.

The ionization efficiency curves of major fragment and product ions in ethylene oxide–trioxane mixtures are shown in Fig. 6. All the ionization efficiency curves of the product ions coincide in onset as well as shape. This suggests that the product ions are formed through a common precursor. The onset of the ionization efficiency curves of the product ions agrees with the ionization potential (10.64±0.1 eV) of ethylene oxide. The onset and fine structures in the ionization efficiency curves of the product ions do not agree with those of *m/e* 89 (trioxane). Furthermore, the appearance potentials, *m/e* 61 (10.79±0.05), 31 (11.49±0.05), 43 (12.06 ±0.1 eV),[2,12] of other abundant fragment ions (*m/e* 61, 31, and 43) from both trioxane and ethylene oxide are higher than those of the product ions. An agreement of the break points in the ionization efficiency curves between the product and the fragment ions was not observed. From the results of the ionization efficiency curve measurements of the fragment and the product ions, it is concluded that ethylene oxide molecular ion is the precursor of the product ions. Thus, it is suggested that the product ions result from the dissociation of unstable intermediate-complex.



$$\longrightarrow \text{Product ions} + \text{Neutral fragments.} \quad (1)$$

The intermediate-complex resulting from the association reaction of ethylene oxide molecular ion with trioxane is very unstable. The ring opening of ethylene oxide and trioxane molecule would occur after the association of ethylene oxide molecular ion with trioxane. The ring strain energy of ethylene oxide is large (13 kcal mol^{-1}).[14] Furthermore, it is known that the bond dissociation energy of the C–O bond is lower than that of the C–C bond in ethylene oxide.[15]

Rate Constants and Ion Structures. Since the product ions in the mixture system are formed by a complex reaction mechanism, their rate constants are obtained by steady state treatment. The product ions are formed *via* certain dissociation channels of the intermediate-complex as in the following:

$$P_i^+ + M \xrightarrow{k_{1i}} P_iM^{+*}$$

$$P_iM^{+*} \xrightarrow{k_{2ij}} S_{ij}^+ + N_{ij},$$

where M, P^+, S^+, and P_iM^{+*} denote the concentration of neutral molecule and reactant, secondary product ion, and intermediate-complex, respectively. (P_iM^{+*}) and (P_i^+) are expressed by

$$(P_iM^{+*}) = \frac{k_{1i}(P_i^+)(M)}{\sum_j k_{2ij}}, \quad (2)$$

$$(P_i^+) = (P_i^+)_0 \exp[-k_{1i}(M)t], \quad (3)$$

where t is delay time and $(P_i^+)_0$ is the concentration of (P_i^+) at $t=0$. (S_{ij}^+) is determined by the equation

$$\frac{d(S_{ij}^+)}{dt} = k_{2ij}(P_iM^{+*}). \quad (4)$$

Integrating (4) and applying the condition $(S_{ij}^+)=0$ at $t=0$, we get

$$(S_{ij}^+) = \frac{k_{2ij}(P_i^+)_0}{\sum_j k_{2ij}}\{1-\exp[-k_{1i}(M)t]\}. \quad (5)$$

Assuming that the collection efficiencies are the same for both reactant and product ions, and expanding the exponential term, we have

$$\frac{I_{(S_{ij}^+)}}{I_{(P_i^+)_0}} = \frac{k_{2ij}k_{1i}(M)t}{\sum_j k_{2ij}}. \quad (6)$$

$I_{(P_i^+)_0}$ can be written as

$$I_{(P_i^+)_0} = I_{(P_i^+)} + \sum_i I_{(S_{ij}^+)} + I_{(P_iM^{+*})}. \quad (7)$$

Since $I_{(P_iM^{+*})} \approx 0$, Eq. 6 is simplified to

$$\frac{I_{(S_{ij}^+)}}{I_{(P_i^+)} + \sum_j I_{(S_{ij}^+)}} = \frac{k_{1i}k_{2ij}(M)t}{\sum_j k_{2ij}}. \quad (8)$$

Thus $k_{1i}k_{2ij}/\sum_j k_{2ij}$ is readily obtained by using Eq. 8.

The rate constants obtained in ethylene oxide–trioxane and ethylene-d_4 oxide–trioxane mixtures are summarized in Table 1. The sum of the rate constants for the product ions (*m/e* 73—77) in ethylene-d_4 oxide–trioxane mixtures is nearly equal to that of the product ion (*m/e* 73) in ethylene oxide–trioxane mixtures. Similarly, the rate constants for *m/e* 78 and 79 in ethylene-d_4 oxide–trioxane mixtures are respectively comparable with those for *m/e* 74 and 75 in ethylene oxide–trioxane mixtures. The structures of the product ions proposed from the stoichiometric consideration for the product ions in both mixture systems are shown in Table 2.

Table 1. Rate constants

Ethylene oxide-Trioxane		Ethylene-d_4 oxide-Trioxane

		73	0.052
		74	0.195
73	2.20	75	0.260
		76	1.13
		77	0.364
74	0.261	73	0.294
75	1.74	79	1.43

Table 2. Possible structures of products ions

Product ion[a] m/e	Structure	Product ion[b] m/e
73	CH_2-O-CH_2-O-CH$^+$	
74	CX-O-CH_2-O-CH_2^+	
75	CX_2-O-CH_2-O-CH$^+$	73
76	CX-CX_2-O-CH_2-O$^+$	
77	CX_2-CX_2-O-CH-O$^+$	
78	CX_2-CX_2-O-CH_2-O$^+$	74
79	CX_2-CX_2-O-CH_2-OH$^+$	75

a) Etylene-d_4 oxide-trioxane mixtures. b) Ethylene oxide-trioxane mixtures. X denotes H or D atom.

The skeletal structures of the product ions (m/e 74—79) consist of fragment molecules from ethylene oxide and trioxane, while the product ion at m/e 73 consists of fragment molecules derived only from trioxane. This indicates that positive charge is delocalized in the intermediate-complex having cyclic structure as shown in Fig. 7. From the structures of the product ions (Table 2), it is presumed that extensive scrambling in the complex does not occur.

The authors wish to express appreciation to Prof. K. Hayashi, Osaka Univ., and Dr. A. Ito for helpful discussions on the chemical system.

NvT- and *NpT*-ensemble Monte Carlo Simulations of Ionized Matter. I. *NvT*-ensemble Study on Calcium Oxide Near Normal Melting Point

Akio YAMAMOTO and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received May 19, 1977)

With special attention to calcium oxide, values obtained by *NvT*-ensemble Monte Carlo calculations are reported for the internal energy, pressure, heat capacity, thermal pressure coefficient, Grüneisen's γ, and component radial distribution functions of ionized matter in the condensed phases. The calculations cover 14 vT points: seven points lying on one isochore at the X-ray density and eight on one isotherm at the normal melting point. Both thermodynamic quantities and structural properties in the vicinity of the melting point are indicative of the fluid-solid phase change. A brief comparison of the Monte Carlo results with the experimental data is also made.

Since the stimulating work by Metropolis *et al.*,[1] considerable work has been carried out on the application of Monte Carlo (MC) techniques to the calculation of the equilibrium properties of a wide variety of physical systems. The success of the method rests primarily on the fact that a model containing a relatively small number of particles is in general found to be sufficient to simulate the behavior of a macroscopic system. In addition, computer experiments on Coulomb systems[2] have in recent years provided much valuable information on the thermodynamic, structural, and transport properties of molten salts or plasmas. The purpose of the present paper is to describe the preliminary application of the isothermal-isochoric or *NvT* method to the study of neutral systems of classical charged particles before going into a detailed study of some intricate ionized matter; the present results are quite suggestive in exploring the question of whether the melting transition of a simple ionic system can be satisfactorily simulated by the simple interionic potential.

Calcium oxide has the simple rocksalt crystal structure[3] as do most alkali halides; it also has ionic crystals, but with the doubly charged ions. It appears that the computer simulations of the thermodynamic properties of the oxide and a detailed comparison of the results with both experiments and theories would lead to a better understanding of the material and perhaps aid in understanding the physical and chemical properties of the presumably better understood alkali halides.

Pair potentials derived from the cohesive energy of the solid[4] are used in the computations of the thermodynamic and structural properties in the condensed phases. Since the intermolecular potentials are well identified, the term-by-term contributions of the Coulomb and non-Coulomb energies to the total energy can be calculated explicitly. The values obtained by the MC method, such as pressure or Grüneisen's γ, involve no approximation other than that of the MC method:[5] the MC method is ideal for two- or three-digit accuracy, which is far more accurate than the results from approximate theories except in very special circumstances. Consequently, because we know the explicit form of the intermolecular potentials, it is in retrospect possible to select the theories from among the many suggested which successfully reproduce the machine results.

The principle of the method, furthermore, is equally applicable to other ensembles as well. We will describe in the next paper an application to ionic systems in the isothermal-isobaric or *NpT* ensemble.[6] The use of the *NpT*-MC method allows direct comparisons with experimental data, because the relevant experimental measurements have been usually made only at atmospheric pressure.

Monte Carlo Procedure

Of the many realistic potentials which could be chosen, we have picked an inverse power potential of the form

$$\phi_{ij}(r) = z_i z_j/r + R_{ij}/r^9 - A_{ij}/r^6,$$

where z_i is the ionic charge of the i-th kind of atom. The values of the coefficients, A_{ij} and R_{ij}, are calculated from the solid state properties of calcium oxide:[4]

A_{ij}	Ca	O	R_{ij}	Ca	O
Ca	35.5	63.6	Ca	7.55	32.5
O	63.6	135	O	32.5	113.5

in units of 10^{-60} erg·cm^6 and 10^{-82} erg·cm^9 respectively. No orientational dependence of the potential is specified, meaning that rotational and intramolecular vibrational modes of motion of molecules are supposed to be independent of density. Then the total energy, Φ, and the total virial, Ψ, of a configuration can be estimated as the sums of pair contributions.

All the results reported in this paper were obtained with a system of $N=64$ particles. With periodic boundary conditions,[7] an infinite system was set up by replicas of the basic parent cube of side L translated by a positive or negative multiple of L along its edge. Unlike non-ionic systems, the estimation of the potential energy is complicated here by the presence of long-range Coulomb forces. No methodological difficulties are, however, encountered when the Coulomb energy is evaluated by the Ewald method.[8] Since there happen to be ions around $r=0.5L$, short-range interactions between particles separated by a distance less than $r_c=0.6L$ were included explicitly and the remaining interactions were combined into the integrals[7]

$$\Phi_c = 2\pi N/v \int_{r_c}^{\infty} r^2 \Phi \mathrm{d}r$$

and

$$\Psi_c = 2\pi N/v \int_{r_c}^{\infty} r^3 \{\mathrm{d}\Phi/\mathrm{d}r\} \mathrm{d}r,$$

by assuming that the particle density is uniform: here

$v=L^3$ denotes the MC-cell volume.

Configurations are generated by the method of Metropolis,[1,7] and hence they are accepted or rejected according to a criterion which ensures that a given configuration occurs with a probability proportional to the Boltzmann factor for that configuration. The rate of convergence of the overall averages as a function of the displacement parameter has not been studied systematically. In application of the NvT method a rule-of-thumb[7] used empirically by workers in this field is to assign to the parameter a value such that approximately one-half of the MC moves generate successful new configurations: the present data were accumulated by the use of such a rule. The pseudo-random numbers used here were obtained by the multiplicative congruential method:[9] the generator operates "modulo 2^{32}."

The basic MC data include ensemble averages (indicated by angular brackets) of

1. the potential energy $\langle\Phi\rangle$,
2. the virial $\langle\Psi\rangle=\langle\sum_{1}^{N}{}_{(k)}r_k(\mathrm{d}\Phi/\mathrm{d}r_k)\rangle$,
3. the variance and covariance $\langle\Phi^2\rangle-\langle\Phi\rangle^2$ and $\langle\Phi\Psi\rangle-\langle\Phi\rangle\langle\Psi\rangle$,

and 4. the component pair radial distribution functions obtained by compiling pair distance histograms with intervals of 0.05 Å at randomly sampled MC steps.

When a computation for a vT point started from the NaCl-type lattice configuration, the first 30000—50000 steps were rejected on account of large fluctuations. The numbers of configurations used to estimate the ensemble averages were rather small (approximately $M=70000$ for each point), and the procedure adopted to calculate the effects of distant particles has since been found to introduce small but systematic errors.

According to the coarsed-grain statistics,[5] the probable error in the MC data is given by

$$\Delta X = 0.6745[\sum_{1}^{m}{}_{(t)}(\langle X_t\rangle-\langle X\rangle)^2/m(m-1)]^{1/2},$$

where ΔX is the estimated probable error in the overall MC average, $\langle X\rangle$, calculated from m subaverages, $\langle X_t\rangle$, over successive groups of M/m configurations: $M/m=5000$ in this work. Of the subaverages, $\langle X_t\rangle$, those which deviate seriously from the overall average, $\langle X\rangle$, were omitted by the visual inspection of the control charts.

The calculations were performed on a HITAC 8700 electronic computer at the Computing Center of Hiroshima University.

Results

Thermodynamic Quantity. The present calculations cover 14 vT points: seven points lying on one isochore at the X-ray density,[3] $\rho=3.346$ g/cm^3, and eight on one isotherm at the normal melting point, $t_m=2572$ °C.[10] The temperature range extends from the room temperature to just below the normal boiling point, $t_b=2850$ °C, while the volume ratio is in the range between 0.90 and 1.10. The numerical results of the computer experiments described in this paper are summarized in Table 1.

Thermodynamic quantities were calculated from the appropriate ensemble averages; some important relations for the NvT-ensemble are recalled here for the sake of easy reference.

The *total energy*, U, of the system is obtained from the mean potential energy by

$$U/NkT = \langle\Phi\rangle/NkT + 3/2,$$

where N is the number of particles in the MC cell and where k is the Boltzmann constant. In Table 1, the potential energy is further divided into the Coulomb and non-Coulomb contributions, the relative contributions being more dependent on the volume change than on the temperature. The *Madelung constant*, M, of the equilibrium configurations is also given in Table 1.

The mean virial determines the *pressure* according to[7]

$$pv/NkT = 1 - \langle\Psi\rangle/3NkT.$$

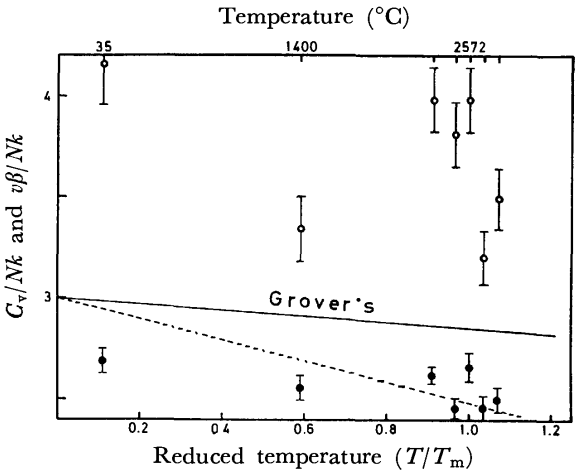

Fig. 2. Isochoric specific heat, C_v/Nk, and thermal pressure coefficient, $v\beta/Nk$, at the X-ray density.
○ $v\beta/Nk$, ● C_v/Nk.
Error bars and T_m represent the probable errors and the normal melting temperature respectively.

The p, v-isotherms at the normal melting point are shown in Fig. 1; no fluctuations indicative of a phase change were observed. The probable errors in the pressure are within 1 kbar. The preliminary data for the liquid branch are also included in Fig. 1. As has been pointed out by Woodcock and Singer,[11] the isotherms obtained from liquid runs are always higher than the solid-branch curve. The molar volume at zero pressure is estimated by interpolation to be approximately 17.4 cm³/mol at the melting point. As is summarized in Table 1, the calculated pressure at constant volume increases roughly linearly with temperature, and at the X-ray density the zero pressure is found to be attained around 1400 °C. The computed change of volume on fusion is 1.0—1.2 cm³/mol at the normal pressure.

The *specific heat* at constant volume, C_v, is determined by fluctuations about the mean as[12]

$$C_v/Nk = 3/2 + N(\langle\Phi^2\rangle - \langle\Phi\rangle^2)/(NkT)^2.$$

As can be seen from Table 1, the specific heat decreases with increasing temperature along isochores and changes little along isotherms. The specific heat on the X-ray density isochores (Fig. 2) shows a tendency to increase near the melting transition.

The *thermal pressure coefficient*, $\beta=(\partial p/\partial T)_v$, can be calculated from the covariance of the potential energy and the virial:[13]

$$v\beta/Nk = 1 + N\langle(\Phi-\langle\Phi\rangle)(\Psi-\langle\Psi\rangle)\rangle/(NkT)^2.$$

Since the coefficient, β, is evaluated as a covariance of two fluctuating quantities, the results are subject to large statistical errors. The calculated values listed in Table 1 show that β decreases with increasing volume along isotherms and that the rate of decrease also decreases in magnitude. The coefficient decreases slowly with increasing temperature along isochores; on fusion β decreases by about 20%. The sudden drop of the coefficient in the vicinity of the normal melting point, both along isotherms and isochores, is certainly indicative of the solid-fluid phase change.

The *Grüneisen's* γ, defined as $\gamma=v(\partial p/\partial T)_v/C_v$, is an extremely useful quantity in high-pressure physics. This parameter, given in the last two columns of Table 1, allows the extraction of a maximum of information from a minimum of data, which is a special virtue for experimental conditions where data are often difficult to obtain.

Radial Distribution Function. The angle-averaged component pair distribution functions, $g_{++}(r)$, $g_{--}(r)$, and $g_{+-}(r)$, are defined by[14]

$$g_{\alpha\beta}(r) = [\Delta n_{\alpha\beta}/\Delta r]/4\pi r^2,$$

where $\Delta n_{\alpha\beta}$ is the number of particles of kind β at a distance between r and $(r+\Delta r)$ from a reference particle of kind α; the mean radial distribution function is given by[15]

$$g_m(r) = [g_{+-}(r)+g_{-+}(r)]/4 + [g_{++}(r)+g_{--}(r)]/4.$$

These functions have been computed as appropriate averages over a total of about 300 randomly-sampled configurations at thermal equilibrium. All the curves are from a 64-particle system, so that beyond $r/L=1/2$ they are directly influenced by the periodicity imposed upon the system; therefore, only the first and second peaks are illustrated in Fig. 3. Furthermore, since the radial distribution functions of like ions are found to be very similar, the averaged function, $g_1(r)=[g_{++}(r)+g_{--}(r)]/2$, is shown in Fig. 3 for the systems on X-ray density isochores. Let us remark that the unambiguous resolution of the component radial distribution functions by X-ray or neutron diffraction is in general difficult, if not impossible. The calculated curves shown in Fig. 3 make it clear that there is some penetration (a few percent) by like ions into the apparent first coordination shell. The appearance of the functions changes gradually with temperature; the well-separated steep peaks at lower temperatures become broad and flat with increasing temperature, and the peaks become connected with each other before 1400 °C. The positions of the first peak also shift slightly from the crystallographic peak position centered at $r=2.405$ Å. In particular, the functions near the melting point exhibit some unexpected features which appear to antici-

$g_l(r)=[g_{++}(r)+g_{--}(r)]/2$, $g_u(r)=[g_{+-}(r)+g_{-+}(r)]/2$, and $g_m(r)=[g_l(r)+g_u(r)]/2$.

pate the change on fusion: those below 2322 °C and above 2472 °C differ strikingly from one another.

Discussion

Possible Error. The number dependence of a finite system can be theoretically studied in certain simple situations,[16] whereas similar studies in the "experimental" situations can only be done empirically by using a system with different sizes. So far, this sort of study[17] has yielded the information that differences between the equation-of-state data of the finite system and the corresponding thermodynamically infinite system are not larger than $1/N$, if the system under observation is in the one phase region. Accordingly, the differences are believed to be within two percent except near the phase-transition region: the discrepancies found were seemingly not larger than would be expected from the following MC fluctuations. Another type of error concerns the statistical errors, which can be derived by using the coarsed-grain techniques. The probable errors, listed in Table 1, display a moderately consistent pattern, amounting to approximately a few percent or less in C_v/Nk and $v\beta/Nk$.

Potential Form. The effects on the thermodynamic and structural properties which result from changes in the intermolecular potentials have been studied by many investigators.[18] From the theoretical considerations, the exponential form of the potentials is known to be a better representation of repulsive interactions between close atoms than is the inverse power form. Nevertheless, because of its mathematical simplicity and its apparent adequacy near the minimum of the interaction curve, the inverse power potential is still the most widely used potential of practical importance. Except in the very high density region, effects of deviations from the inverse power potential and from additivity of pair potentials are seen to be fairly small. For instance, the experimental p, v-isotherms at room temperature[19] suggest that CaO is largely ionic at pressures below 160 kbar, but that, as the interionic distance is reduced, new interactions come into play which are not appropriately considered in the pair potential. From an analysis of a considerable amount of shock data,[13] it is also known that Grüneisen's γ varies more rapidly with compression than that calculated by using the Lennard-Jones potential, and consequently infers that even the inverse-12th-power potential is inappropriate for highly compressed materials. At the highest compression, where only the repulsive forces are important, the value becomes $\gamma=[n/6+1/3]=1.88$: such a compressed condition cannot be attained in the present calculations. We have not yet been able to relate these apparent discrepancies to the parameters used in the pair potential. Moreover, the validity of the approximate theories can be best appreciated by comparing with the MC results rather than with the experimental data, since the potential form of the real systems is not fully specified. At present theoretical data does not exist which would enable us to make such a comparison.

The potential parameters used here were prepared so as to be compatible with the properties of the static lattices.[7] Any refinement of the potential parameters[20] was, however, impracticable on account of the heavy demand of computing time.

Polarizability. The effects of ionic polarization in ionic salts[21] are found to be small and negligible except for the excess properties of liquid mixtures.[22] For typical alkali halides, the net contributions to the total energy are estimated to be small (less than few percent in magnitude);[15] this suggests that the polarization is not a factor which significantly affects the structural and thermodynamic properties. Although the introduction of the polarization effects to the present rigid-ion potential appears to be straightforward,[15,23] we have chosen to leave these factors out entirely, in view of the fact that a satisfactory short-range interaction potential is in itself an incompletely understood quantity for the present material.

Thermodynamic Quantity. A preliminary comparison of the MC results with the experimental data

● Isotherms at the normal melting point.

of the real systems is in order, since the available data for CaO are unfortunately too scanty to permit detailed comparison of calculated with measured quantities over a sufficiently wide vT range. First, the *binding energy*, shown in Fig. 4, can give direct information about the temperature- and volume-dependence of the energy at any temperature of practical importance, while the corresponding energy estimated theoretically is exclusively concerned with the perfect crystal in the limit of 0 K. The binding energy of the static lattice is calculated to be 882.5 kcal/mol, which is the largest of the theoretical values reported so far: the thermochemical binding energy is 842 kcal/mol.[24,25] As is illustrated in Fig. 4, the binding energy at the finite temperature decreases linearly with increasing temperature, suggesting that the crystal lattice is destabilized by the thermal motion. On the other hand, the isothermal energy calculated varies only slowly with volume: the most stable molar volume at the normal melting point is energetically found to be around 16.5 cm³/mol. In the sixth column of Table 1 is given the *Madelung constant*, M,[9] of the equilibrium configurations, which, referred to the nearest-neighbor distance, can be said to present an effective number of nearest neighbors. The values listed are those referred to the lattice parameter, and hence they must be halved to obtain the nearest-neighbor values. The MC results indicate that the constant decreases roughly linearly with increasing temperature at constant volume: this points to an increasing cancellation of the potential as a result of an increase of thermal motion. On the contrary, the isothermal values of M vary gradually with volume: a value greater than that for the solid lattice ($M=3.4951$) shows a less complete cancellation of the negative and positive potential due to ion-pair formation. The presence of these pairs has often been pointed out in the molten salts;[26] the shape of the first peak of the radial distribution illustrates well this situation. The measurement of volume as a function of *pressure* can be accomplished in number of ways;[27] however, the data obtained from X-ray diffraction studies at room temperature are the only ones available at present. The experimental p, v-isotherms are included in Fig. 1, showing that the MC curves are similar in the dependence on the volume to the experimental facts. Next, the observed *specific heat* at constant pressure, C_p, can be modified by using the relation,[28]

$$C_v/Nk = C_p/Nk - \alpha^2 vT/\kappa(Nk),$$

to give the experimental specific heat, C_v: here α, κ, and v are the thermal volume expansivity, the compressibility, and the MC-cell volume respectively. The specific heat, C_v/Nk, at room temperature was thus calculated to be 2.3—2.7:[29-32] the MC results lie within the range of rather widely scattered experimental results. The MC calculations also indicate that the simulation fails entirely to account for the very rapid rise in specific heat that is observed near the critical temperature.[33] In the MC method the small value of N and the periodic boundary conditions are considered to suppress all large fluctuations, and the estimated specific heat is, therefore, very much too low in such a region. Aside from these restrictions, the pronounced maxima (Figs. 2 and 5) in the vicinity of the experimentally known melting point[26,34,35] are indicative of large fluctuations in the molecular arrangement. Despite these increases at near-critical temperatures, the calculated values of C_v/Nk decrease nearly linearly with increasing temperature: the data obey Grover's rule that $C_v/Nk=3(1-\delta\tau)$, where $\delta=0.15$ and τ is the temperature divided by the melting temperature, $T_m=2845$ K. The present value of δ is three times as large as that determined experimentally by Grover[36] for several metals, although the uncertainty in the computer-generated specific heat is quite large. The *Grüneisen parameter*, γ, can be thermodynamically derived from the ratio of the thermal pressure coefficient to the specific heat. As for KCl, the parameter is found to be essentially constant in the temperature range from 0 to 750 °C.[37,38] Figure 6 shows that the isothermal values of γ are substantially constant, while the values on the isochores vary but slowly with tem-

perature. The constant-volume data can only be obtained by means of lattice dynamics: the value of 1.76 was assigned to it by Sirdesmukh and Rao.[39]

As the relevant experimental measurements have been made only at effectively constant pressure, we have found it more convenient to work in an isothermal-isobaric ensemble; furthermore, a strict test of the calculation model would involve a comparison of the results with ideal systems having some well-defined intermolecular potentials. Work along these lines is now in progress, and the detailed interpretation of the results and comparison with both experiments and theories will be discussed in a future publication.

Melting Transition. In systems of finite size, especially the small ones which can be treated on a computer, both the region over which metastable phases can occur, and the time for which they persist can be large. Precisely, these difficulties have complicated the search for the phase transitions in small systems. Even in the largest three dimensional systems investigated so far,[5] the particles are found to be either all in the fluid phase or all in the crystalline phase. Most runs were started from a perfect crystal, obviously unstable at low enough density and at high pressure: they would melt spontaneously. Thus the solid phase was extended from high density where it was at least metastable into the low density where it was seemingly unstable thermodynamically. Due to the irregular nature of a fluid structure it is not easy to invent an unbiased initial condition for a fluid run.[40] We plan a more detailed study of the liquid portion of the phase diagram in the near future, and the comparison of two disconnected branches overlapping in the density of the transition will yield some useful information on phase changes. As to the "computer-generated" solid branch, both large fluctuations of the total energy and the abrupt drop of the thermal pressure coefficient in the close vicinity of the experimentally known solid-fluid transition are certainly suggestive of the existence of the transition; the structural properties also indicate such a transition.

Microwave Spectrum, Structure, and Quadrupole Coupling Constant of *o*-Chlorophenol

Masao ONDA, Yoshitomo OSHIMA, and Ichiro YAMAGUCHI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Tokyo 102

(Received May 20, 1977)

The microwave spectrum of *o*-chlorophenol has been observed in the frequency range 10—34 GHz. The rotational and centrifugal distortion constants were obtained for two isotopic species, $^{35}ClC_6H_4OH$ and $^{37}ClC_6H_4OH$. The analysis of the hyperfine structure gives the following nuclear quadrupole coupling constants for ^{35}Cl species: $\chi_{aa}=-67.6$, $\chi_{bb}=33.3$, and $\chi_{cc}=34.3$ (MHz). The spectrum assigned has been attributed to the *cis*-form (intramolecularly hydrogen bonded between Cl and HO) from a brief consideration of the relative intensity of the a- and b- type transitions. No significant effect of the intramolecular hydrogen bonding on the nuclear quadrupole coupling was observed.

Many studies on the molecular structure of *o*-chlorophenol, mainly by means of infrared spectroscopy, have been reported by a number of authors in the last four decades.[1,2] According to these studies, *o*-chlorophenol exists as a mixture of two isomers, the *cis*- and *trans*-forms, in the gas and liquid phases and in solutions (the *trans*-form is the conformer with the hydroxyl hydrogen pointed away from the chlorine, and the *cis*-form with the hydroxyl hydrogen pointed toward to the chlorine), and the *cis*-form is known to form intramolecular hydrogen bonding between the chlorine atom and the hydroxyl group. Carlson *et al.*[2] estimated the population of the *trans*-form as 6.5% at room temperature from the analysis of the torsional frequencies of the hydroxyl group and concluded that the *cis*-form was more stable than the *trans*-form in the gas phase. Two benzene derivatives which have the intramolecular hydrogen bonding have so far been studied by the microwave spectroscopy: salicylaldehyde[3] and *o*-nitrophenol.[4] It is interesting to study the structure of the *o*-chlorophenol molecule in the gas phase by means of microwave spectroscopy, because this molecule is one of those which have the possibility of forming the intramolecular hydrogen bonding.

Azrak and Wilson[5] studied in detail the influence of the hydrogen bonding on the quadrupole coupling constants for 2-chloroethanol, but they observed no significant effect.

The purposes of the present investigation of *o*-chlorophenol are to find out whether the dominant conformation is *cis*- or *trans*-form in the gas phase and to what extent the nuclear quadrupole coupling constants of chlorine are affected by the intramolecular hydrogen bonding in the *cis*-form.

Experimental

The sample used was obtained commercially and was distilled *in vacuo*. The purity of the sample was checked through its NMR and IR spectra. The microwave spectrum was measured with a conventional spectrometer in the frequency range of 10—34 GHz. A square wave of 100 kHz was used for the Stark modulation. Measurements were made at room temperature with sample pressures of 1.3—5.3 Pa. The absorption lines were displayed on a recorder. Frequency measurements were made with a Hewlett-Packard 5245L electronic counter. The accuracy of the measured frequency was better than 0.2 MHz for most lines and it was better than 0.5 MHz for the broadened lines and for the lines which had a strong line nearby.

Results and Discussion

Analysis of the Spectrum. The observed spectrum consisted of very many lines in the observed region. This complexity of the spectrum comes from the existence of two chlorine isotopic species in the vibra tional ground state as well as in their low frequency vibrational excited states. A molecular model of a planar structure was constructed from the structural parameters of chlorobenzenes[6] and phenols.[8] The model calculation for either *cis*- or *trans*-form, where the Ray's asymmetry parameters for both are $\kappa\approx-0.46$, indicated that the transitions of the a- and b-types will appear in the observed frequency region. The initial step of the assignment was for both a- and b-type R-branch transitions. Clear quartets were observed for $J=9\leftarrow8$, $10\leftarrow9$, and $11\leftarrow10$ transitions with $K_{-1}=0$ and 1, and the separations between the two inner lines of the quartets were 12, 5, and 2 MHz, respectively. The assignments were confirmed by comparing the observed hyperfine structures with the predicted ones for the b-type Q-branch transitions with high-J values. The prediction was made using the nuclear quadrupole coupling constants of chlorobenzene[6] and with the planar molecular models of the *cis*- and *trans*- forms.

Many transitions were observed as doublets with separations of a few MHz due to the nuclear quadrupole coupling of chlorine. The center of the doublet was taken as the unperturbed frequency and was used for the least-squares fitting to obtain the rotational and centrifugal distortion constants. The assigned transitions are given in Tables 1 and 2 for both $^{35}ClC_6H_4OH$ and $^{37}ClC_6H_4OH$ species. The spectrum of $^{35}ClC_6H_4OH$ was fitted by the following seven variables: the three rotational and the four centrifugal distortion constants. For the $^{37}ClC_6H_4OH$ species, only six parameters (three rotational and three centrifugal distortion constants) were obtained because only a small number of high-J transitions were observed and the *hfs* were not well resolved. Table 3 gives the parameters thus obtained. The errors attached are the standard deviations obtained from the least-squares fits. The magnitudes of the centrifugal distortion constants τ obtained were small, as expected from several aromatic molecules.[7]

a) $\Delta\nu=\nu_{obsd}-\nu_{calcd}$.

This spectrum is assigned to the *cis*-form as described in the later sections. A search for lines arising from the *trans*-form has failed, probably because their intensities are weaker than those of the vibrational excited states of the *cis*-form.

Molecular Structure. A small value of the inertia defect, as given in Table 3, is a strong indication of the planar configuration of this molecule. The positive inertia defect indicates that the effect of the out-of-plane vibrational motion, probably the hydroxyl group torsion, is not dominant. This is in contrast to the small negative value for phenol (−0.03 amu Å^2).[8] The value for *o*-chlorophenol is comparable to that for chlorobenzene and therefore the vibrational amplitude of the OH-torsion is considered to be smaller than for phenol. This reflects that the OH group in

o-chlorophenol is more restricted in the molecular plane than in phenol, suggesting that the molecule is of the *cis*-form, having an intramolecular hydrogen bond between the hydroxyl group and the chlorine atom.

Kraitchman's equation was used to calculate the chlorine atom coordinates in the planar structure. The values obtained using the rotational constants A and B for both species are given in Table 4. The error limits given came from the errors in the moment of inertia. The predicted coordinates of the chlorine atom, with the regular hexagonal benzene ring, are included in Table 4. Comparing these results with the coordinates in the model structures, one cannot decide whether the set of coordinates determined corresponds to the *cis* or *trans* conformation.

To solve the problem of the conformation the relative intensity of the a- and b-type transitions was considered. Each of the lines of a quartet, consisting of the transitions $9_{0,9}\leftarrow 8_{1,8}$, $9_{1,9}\leftarrow 8_{1,8}$, $9_{0,9}\leftarrow 8_{0,8}$, and $9_{1,9}\leftarrow 8_{0,8}$, was observed with comparable intensities. The predicted line strengths of these a- and b-type transitions are almost the same for both of the conformations because they have almost the same asymmetric parameter, $\kappa\approx -0.46$. From the vector sum of the values for chlorobenzene[6] and phenol[8] the components of the electric dipole moment were predicted as given in Table 5. The ambiguity of the calculated intensity comes solely from the model structure and the interaction between two group moments, μ_{C-Cl} and μ_{OH}, but the distinction between *cis*- and *trans*-forms is clear. For the *cis*-form the intensities for the a- and b-type transitions should be almost the same, while for the *trans*-form the intensity for the a-type transitions should be larger than for the b-type transitions. Other similar sets of transitions: $J_{0,J}\leftarrow J-1_{1,J-1}$, $J_{1,J}\leftarrow J-1_{1,J-1}$, $J_{0,J}\leftarrow J-1_{0,J-1}$, and $J_{1,J}\leftarrow J-1_{0,J-1}$, with $J=10$ and 11 for ^{35}Cl and ^{37}Cl species, were also observed with comparable intensities. These results imply that the assigned spectrum came from the molecule which has a dipole moment with comparable magnitudes of the a- and b-components: the *cis* form.

Table 5. Predicted dipole moments (debye)[a]

	cis form	*trans* form
μ_a[b]	1.2	2.3
μ_b	1.2	1.2

a) Calculated from the following values: $\mu_a=1.782$ for chlorobenzene[6] and $\mu_a=0.13$ and $\mu_b=1.27$ for phenol.[8] b) a- and b-axes refer to model structure.

Assuming the rigid planar structure, only two moments of inertia are independent. From the results for the two isotopic species, four structural parameters can therefore be determined, while other parameters are assumed. The parameters derived for the *cis*-form were the bond lengths C–Cl and C–O and the angles ∠C(2)–O–H and ∠C(1)–C(2)–O. Assumptions for the other parameters were as follows: the benzene skeleton is regular hexagonal and the C–C bond length is 1.399 Å; all the C–H bonds and the C–Cl bond are located on the ∠C–C–C bisectors; the C–H bond length is 1.084 Å and the O–H bond length is 1.040 Å. A plausible set of parameters obtained on these assumptions is shown in Table 6. The calculated moments of inertia using these parameters coincide with the observed values within 0.1 amu Å^2. For the distorted benzene skeleton, which is the same as for chlorobenzene,[9] the parameters given in Table 6 were obtained. From two different assumptions about the skeleton structure, the same magnitudes of the C–Cl bond length as in chlorobenzene, and the same angle ∠C–C–O, extended by 2° from 120°, have been obtained.

Quadrupole Coupling Constants. The apparent splitting in the doublet was measured for high-J b-type Q-branch transitions as listed in Table 7. The hyperfine patterns were analyzed based on the first-order quadrupole correction computation using the

o-$C_6H_4Cl_2$[e]	−63.3	32.4	30.9	0.02
m-$C_6H_4Cl_2$[f]	−70.2	37.4	32.8	0.06

a) z-Axis is along the C-Cl bond and y-axis is in the molecular plane. b) $\eta=(\chi_{xx}-\chi_{yy})/\chi_{zz}$. c) This work. d) Ref. 6. e) Ref. 10. f) Ref. 11.

uncertainties in Table 8 were calculated from the estimated error in the frequency measurements of the unresolved *F* components. Assuming that the principal z-axis of the χ-tensor lies on the C–Cl bond, the values of χ_{zz} and χ_{yy} are obtained for the *cis*-form, as given in Table 8. The value of χ_{xx}, the component perpendicular to the molecular plane, is the same as χ_{cc}.

The principal values for several substituted chlorobenzenes are listed in Table 9. The value of χ_{zz} in *o*-chlorophenol is apparently smaller than in monochlorobenzene and *m*-dichlorobenzene. The χ_{zz} values, however, depend on the uncertainty of the transformation angle θ_{za}, ±1° as estimated from the ambiguity in the structure model, so that the differences in the values among these compounds are not very significant. The value around −70 MHz for χ_{zz} is considered to be normal for a chlorine atom which has hydrogen atoms nearby at the ortho position.[11] It seems that the hydrogen-halogen interaction does not have a significant effect on the electronic charge distribution about the chlorine nucleus in this molecule. The same conclusion had been obtained for 2-chloroethanol[5] through its microwave spectrum, where the conformation (*gauche-gauche* form) is favorable for the intramolecular hydrogen bond formation. Although the non-bonded distance between chlorine and hydrogen (2.609 Å for 2-chloroethanol and 2.53 Å for *o*-chlorophenol) is shorter than the sum of the van der Waals radii of chlorine and hydrogen (3.0 Å),

no significant effect on the quadrupole coupling constants of chlorine nucleus was observed for o-chlorophenol or for 2-chloroethanol.

The authors wish to express their thanks to Dr. O. Ohashi for his valuable discussions.

The Crystal Structure of the A-super Form of Lauric Acid

Midori GOTO and Eiichi ASADA

National Chemical Laboratory for Industry, Hon-cho, Shibuya-ku, Tokyo 151

(Received June 4, 1977)

The crystal structure of the A-super form of lauric acid has been determined. The structural parameters were refined by the block-diagonal least-squares method, and the final R value was 0.094. Two types of molecular conformations of a lauric acid exist in the crystal; one is the ordinary type, as seen in the C-form or the A_1-form of the lauric acid, while the other is that rotating the carboxyl group about the C1–C2 bond. This unusual structure was explained by the oxygen-oxygen distance of the adjacent molecule.

Even-numbered fatty acids are known by powder X-ray diffractions to exist in three crystalline forms, named A, B, and C.[1] In the case of lauric acid, the crystal structure of the C-form has been determined by Vand, Morley and Lomer.[2] This has an orthorhombic subcell of the hydrocarbon chain. Another crystal form, belonging to A, was studied by von Sydow[3] in only one projection. He showed that it has the triclinic subcell of the hydrocarbon chains. He named it the A-super form, because it could be regarded as a sixfold superstructure from the chain packing. Later, another crystal form, A_1, belonging to the A form, has been completely determined by Lomer.[4]

Three-dimensional results are required in order to discuss thoroughly the relations among polymorphic forms. We could obtain a single crystal of the A-super form of a sufficient size and studied its structure from a three-dimensional approach.

Experimental

Lauric acid was purified according to the procedure described by Tsuchiya.[5] At first it crystallized in the C-form in an isooctane solution. After it had stood in the solution for about two weeks at room temperature, the C-form was gradually transformed into the A-super form with colorless, triclinic needle-like crystals elongated along the a-axis. The crystal data are listed in Table 1. The intensity data were collected by means of a Rigaku-Denki four-circle diffractometer by using graphite monochromated Cu $K\alpha$ radiation. Reflections with 2θ values up to 60° were collected. The total number of observed reflections was 679.

Structure Determination

The y and z co-ordinates of the atoms were assumed to be those given by von Sydow, and the approximate x co-ordinates were obtained by taking into account three-dimensional Patterson maps and the packing of the molecules.

The hydrogen atoms were placed at the calculated positions assuming the C–H length of 1.10 Å and a tetrahedral arrangement about the carbon atom. The hydrogen atoms of the end were assumed to be at the *gauche* position. The hydrogen atom of the carboxyl group was neglected. Refinements were carried out by the block-diagonal least-squares method using HBLS program (Ashida),[6] with anisotropic temperature factors for non-hydrogen atoms. The parameters of the hydrogen atoms were not refined. The R value was reduced to 0.094.

The final atomic parameters are listed in Table 2.* The y and z co-ordinates did not differ significantly from those given by von Sydow.[3]

Table 1. Crystal data

Lauric acid A-super form	
Molecular weight	200.3
Melting point	44.0 °C
The unit cell was chosen as that of von Sydow.	
Triclinic; $A\bar{1}$	
$Z=12$	
$a=5.415(2)$Å	$\alpha=69.82°(4)$
$b=25.964(11)$Å	$\beta=113.14°(4)$
$c=35.183(13)$Å	$\gamma=121.15°(3)$
$U=3829.9$ Å^3	
$D_x=1.04$ g/cm^3	

Results and Discussion

The bond lengths, bond angles, and internal rotation angles are listed in Table 3. The arrangement of the molecules in the crystal is shown in Fig. 1. The chains are packed in a triclinic subcell with dimensions of $a=4.33$ Å, $b=5.42$ Å, $c=2.52$ Å, $\alpha=75.9°$, $\beta=108.9°$. $\gamma=122.1°$. Both carboxyl and methyl end groups appear in the same molecular layer.

An ORTEP (Johnson)[7] drawing of the three crystallographically independent molecules (I, II, and III) is shown in Fig. 2. The conformation of Molecule (III) is roughly equivalent to that of (II). There are two types of molecular conformations of lauric acid in an asymmetric unit; one type is (I), and the other, (II) and (III).

The carbon atoms in each molecule are nearly coplanar, as is shown in Table 4. The dihedral angle between the plane of the carboxyl group and that of the carbon chain is 83° in Molecule (I), 10° in (II) and 25° in (III) respectively. The plane of the carboxyl group in Molecule (I) is almost perpendicular to the carbon chain, while in (II) and (III) the two planes are roughly parallel, as is found in the A_1 form of lauric acid. The conformation as found in Molecule (I) was also reported in the structure of *dl*-2-hydroxytetradecanoic acid,[8] which has a large substituent near the carboxyl group.

It is rare for two types of molecular conformation

* The table of the observed and calculated structure factors has been submitted and is kept by the Office of the Chemical Society of Japan, 1-5, Kanda-Surugadai, Chiyoda-ku, Tokyo 101 (Document No 7804).

to appear in a crystal of the simple fatty acid. The larger thermal parameters of the atoms in the carboxyl group, listed in Table 2, might be due to this unusual arrangement of molecules.

The arrangement of the end groups is shown in Fig. 3. As is commonly found in fatty acids, the molecules are bound together to form dimers through hydrogen bonds between the carboxyl groups. The hydrogen-bond lengths are 2.60 Å between O3–O4$^{(i)}$, 2.70 Å between O2$^{(iii)}$–O1$^{(ii)}$, and 2.75 Å between O6$^{(iii)}$–O5$^{(ii)}$.

If Molecule (I) took the same conformation as (II), the O4–O2$^{(i)}$ distance would be 2.34 Å, too close to form a hydrogen bond between the molecules. This short contact is relieved by rotating the carboxyl group about the C1–C2 bond, resulting in a particular conformation of Molecule (I).

In the C-form of lauric acid, carboxyl groups appear in the same layer, but in the A-form, both the A-super form and the A_1-form, they do not. In the A_1-form the carboxyl group is adjacent to the methyl group of the neighboring molecule, and the short contact mentioned above is relieved.

The structure in which the carboxyl groups of the same conformation appear in the same layer, as is seen in the C-form, might be unfavorable in the A-form of lauric acid.

We wish to thank Professor Y. Iitaka of The University of Tokyo for his encouragement and helpful discussions.

Measurements of the Solubility Coefficients of Gases and Vapors in Natural Rubber by Gas Chromatographic Technique

Mitsuyasu KAWAKAMI and Shuichi KAGAWA

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received June 8, 1977)

The solubility coefficients of hydrocarbons in unvulcanized natural rubber at 25 °C were determined by gas-liquid chromatography. Natural rubber was used as a stationary liquid and nine kinds of lower olefins and paraffins as solutes. The retention volume for all the solutes did not vary with sample size. It was found that the correction for gas phase imperfection is negligible. Thus the solubility coefficient was readily obtained from the specific retention volume without any correction. The values obtained were in fairly good agreement with those determined by the volumetric method given in other works. Modified equations expressing the relationships between the solubility coefficient and the boiling temperature, the critical temperature, and the Lenard-Jones force constant, which might be applicable to a more extensive range of gaseous compounds, were presented.

Recently gas-liquid chromatography (GLC) has attracted attention as a means for determining thermodynamic properties of a solution consisting of stationary liquid and solute gas. Many investigations have been made since Porter *et al.*[1] measured the partition coefficient and the heat of solution by GLC in 1956. The method is especially effective for a system of polymer and organic compounds. For example, the volatility of solvents in polymer coatings was measured by Newman and Prausnitz,[2] and the solubility parameter of polyethylene glycol by Takamiya *et al.*[3] and by Kawakami *et al.*[4] In the present work GLC was employed to determine the solubility coefficients of some lower olefins and paraffins in unvulcanized natural rubber at 25 °C. The values obtained were in fairly good agreement with those determined by van Amerongen[5] and Michaels and Bixler[6] by means of the volumetric method. Modified empirical formulas were proposed on the relation between the solubility coefficient and other physicochemical properties of gases.

Theoretical

When the Henry law holds between stationary liquid and solute gas and the gas phase imperfection can be neglected, the net retention volume V_N is related to the partition coefficient K by[7]

$$V_N = KV_L. \tag{1}$$

Here K is defined by

$$K = \frac{n_L/V_L}{n_G/V_G}, \tag{2}$$

where n_L and n_G are the numbers of moles of solute in the liquid phase and the gas phase with volumes of V_L and V_G, respectively.

The solubility coefficient S, on the other hand, is defined by

$$c = Sp, \tag{3}$$

where c is the concentration expressed in m^3(STP) of solute gas dissolved per m^3 of solvent and p is the equilibrium partial pressure of solute gas. Using the ideal gas equation, the concentrations in the liquid phase and the gas phase are respectively given by $n_L/V_L = cp^\circ/RT^\circ$ (p°=1 atm=101325 Pa, T°=273.2 K) and $n_G/V_G = p/RT$ where T is the column temperature. Thus the partition coefficient is expressed by

$$K = \frac{T}{T^\circ}\frac{p^\circ}{p}c = \frac{T}{T^\circ}p^\circ S, \tag{4}$$

and

$$S = \frac{T^\circ}{T}\frac{1}{p^\circ}\frac{V_N}{V_L}. \tag{5}$$

The simplified expression is obtained by using the specific retention volume V_g which denotes the net retention volume per unit weight of stationary liquid converted into 0 °C. We thus have

$$V_g = \frac{V_N}{w_L}\frac{T^\circ}{T}, \tag{6}$$

where w_L is the weight of stationary liquid. Substitution of Eq. 6 into Eq. 5 gives

$$S = \frac{1}{p^\circ}\rho_L V_g, \tag{7}$$

where ρ_L is the density of stationary liquid. The solubility coefficient can thus be calculated from the specific retention volume. The value of V_g can be obtained experimentally by the equation

$$V_g = \frac{t_R F}{w_L}\frac{T^\circ}{T_r}J_2^3, \tag{8}$$

where t_R is the peak maximum retention time, F is the flow rate of carrier gas at room temperature T_r.

$$J_n^m = \frac{n}{m}\left\{\frac{(p/p_o)^m - 1}{(p_i/p_o)^n - 1}\right\}, \tag{9}$$

where p_i and p_o are the column inlet and outlet pressures, respectively.

Correction is necessary when gas phase imperfection is not negligible.[8] It was first proposed by Everett and Stoddart,[9] and improved by Cruickshank *et al.*[10] According to the latter, the net retention volume is related to the partition coefficient at zero total pressure K_0 by

$$V_N = K_0 V_L \exp(\beta p_o J_3^4). \tag{10}$$

Here

$$\beta = \frac{2B_m - v^\infty}{RT}, \tag{11}$$

where B_m is the second mixed virial coefficient between solute gas and carrier gas, and v^∞ the partial molar volume of solute at infinite dilution. The solubility coefficient at zero pressure S_0 is related to K_0 by Eq. 4. Thus

$$S_0 = \frac{1}{p^\circ}\rho_L V_g \exp(-\beta p_o J_3^4), \quad (12)$$

S_0 can be obtained when the values of B_m and v^∞ are known.

Experimental

Preparation of Column. A certain volume of 1 wt% benzene solution of the stationary liquid, unvulcanized natural rubber (smoked sheet) was added with stirring to a weighed amount of solid support, Uniport B (Gasukuro Kogyo Co.), and then air-dried. For each impregnation operation, the amount of benzene solution equal to the pore volume of solid support was used. The operation was repeated five times to reach the desired coverage ratio of the stationary liquid and finally dried in a vacuum. The coverage ratio measured with a Soxhlet extractor was 8.2 wt%. Since particles adhered to each other with increase in coverage ratio, it was impossible to increase it further. The coated support was packed into a copper tube of 3 mm i.d. and 3 m in length. The density of natural rubber was measured by the floatation method and found to be 910 kg/m^3.

Solute. Nine kinds of commercial lower olefins and paraffins were used.

Apparatus and Procedure. A KOR-70 gas chromatograph (Gasukuro Kogyo Co.) was used. The mercury manometer was attached to the inlet of the column. Helium was used as a carrier gas, the flow rate of which being kept at 10^{-5} m^3/min. The column temperature differed with sample gases in the range -10—25 °C. A solute gas was injected with a micrometer syringe in the range $(2—5)\times10^{-9}$ m^3 as a vapor.

Usually a gas hold-up can be determined from the retention volume of an inert gas. Nitrogen was used as the inert gas. The retention volume of nitrogen, however, has to be corrected, because of its slight solubility in natural rubber. The solubility coefficient of nitrogen determined by Michaels and Bixler[6] was used for the correction.

When the separation of solute gas and air brought within the sample is not sufficient due to lower solubility of the solute gas, the column temperature falls. In such a case the retention volume at 25 °C was estimated by interpolation using a linear relationship between log V_g and $1/T$.

Results and Discussion

Effect of Sample Size on Retention Volume. The retention volume did not vary with sample size. Thus the partition isotherms of all solute gases examined can be regarded as rectilinear under the experimetal conditions.

Correction for Gas Phase Imperfection. The magnitude of the correction term for gas phase imperfection was examined. v^∞ was taken to be equal to the molar volume of pure liquid v°. A negligible error will result from this approximation. The values of B_m, v° and the correction term at 25 °C are given in Table 1. The second mixed virial coefficient was estimated from the McGlashan-Porter reduced equation[11] using Hudson-McCoubrey's combining rule.[12] The molar volume of pure liquid was estimated from the density using the expansion factor proposed by Watson.[13] It is clear from Table 1 that the contribution of the term of $\exp(-\beta p_o J_3^4)$ to the specific retention volume is insignificant. A considerable error may be incurred by the estimation of physical properties such as B_m and v°. Thus it is more reasonable to ignore this term than to make an uncertain correction.

Comparison with Other Works.[14] The results obtained by neglecting gas phase imperfection are given in Table 1. It can be seen that the solubility coefficient of propane is in good agreement with those obtained independently by van Amerongen[5] and Michaels and Bixler,[6] by means of the volumetric method. For propylene, on the other hand, the value obtained seems to differ somewhat from that presented by Michaels and Bixler. Although it is not clear which is accurate, both values do not differ too greatly from the correlations between the solubility coefficient and the physicochemical properties of gases, as described below.

From the assumption that the dissolution process involves condensation and mixing process, the solubility coefficient can be written as[15]

$$2.303\log S = \frac{L_b}{RT_b}\left(\frac{T_b}{T}-1\right)+2.303 \times \log\frac{22.4\times10^{-3}}{v^\circ} - 1 - \chi,$$

where L_b is the molar latent heat of condensation at boiling temperature T_b, and χ is the interaction parameter. When χ can be taken as constant, a linear relationship is valid between log S and T_b. Moreover,

a) Obtained by neglecting gas phase imperfection. b) A. S. Michaels and H. J. Bixler.[6] c) G. J. van Amerongen.[5]

by applying the Guldberg rule, $T_b/T_c \approx 2/3$, a similar relationship between log S and critical temperature T_c can be derived. For solubility coefficients of gases in vulcanized natural rubber Barrer and Skirrow[16] proposed

$$\log S = -7.0 + 0.007\, T_c \text{ (at 50 °C)};$$

van Amerongen[5] proposed

$$\log S = -7.1 + 0.0074\, T_c \text{ (at 25 °C)}$$

and

$$\log S = -7.1 + 0.0123 T_b \text{ (at 25° C)}.$$

The results obtained are shown in Figs. 1 and 2 together with those by van Amerongen and Michaels and Bixler, the relation of van Amerongen being shown by broken lines. Although there exists a fairly good correlation between log S and T_c or T_b, a slight deviation from the broken lines is found when T_c ot T_b becomes higher. Therefore the relationships may be expressed better by the equations

$$\log S = -7.0 + 0.0030\, T_c^{1.15}$$

and

$$\log S = -7.0 + 0.0071\, T_b^{1.10},$$

which were calculated by least-squares treatment with all data in the figures, where the correlation coefficients are 0.994 and 0.992, respectively. These relations are shown in Figs. 1 and 2 by solid lines.

Michaels and Bixler,[6] on the other hand, proposed the use of the Lenard-Jones force constant ε/k instead of T_c or T_b. The plot is shown in Fig. 3. In this study ε/k determined from viscosity[17] was used.[18] The straight line was calculated by least-squares treatment with all data in the figure:

$$\log S = -7.05 + 0.0105\ (\varepsilon/k),$$

where the correlation coefficient is 0.970.

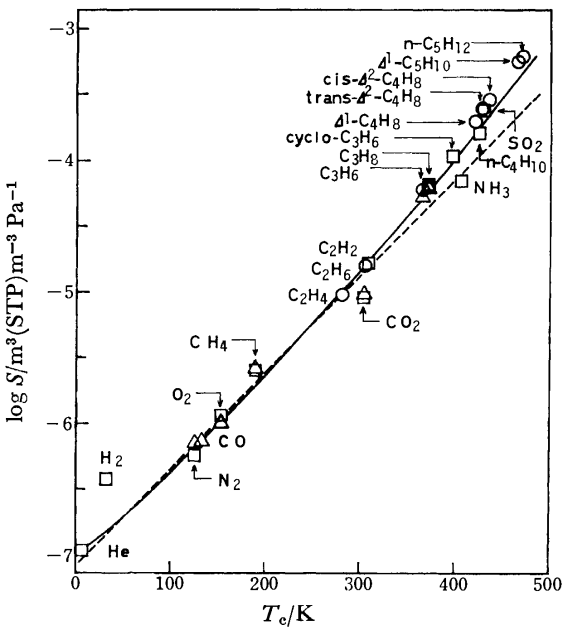

Fig. 1. The relationship between solubility coefficients and critical temperatures.
○: This work, □: Van Amerongen, △: Michaels and Bixler.

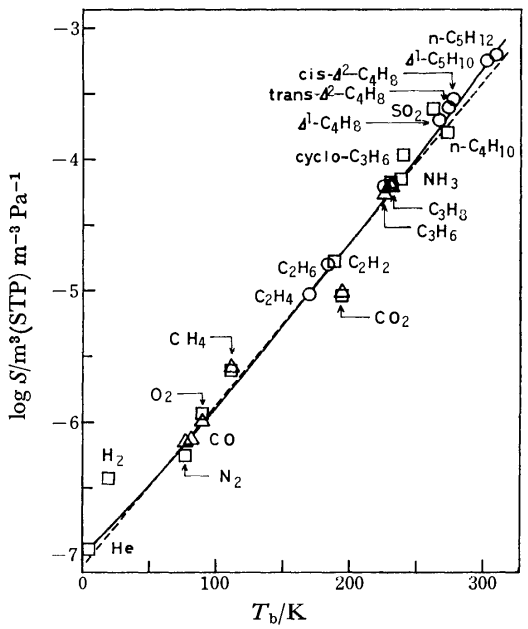

Fig. 2. The relationship between solubility coefficients and boiling temperatures.
○: This work, □: Van Amerongen, △: Michaels and Bixler.

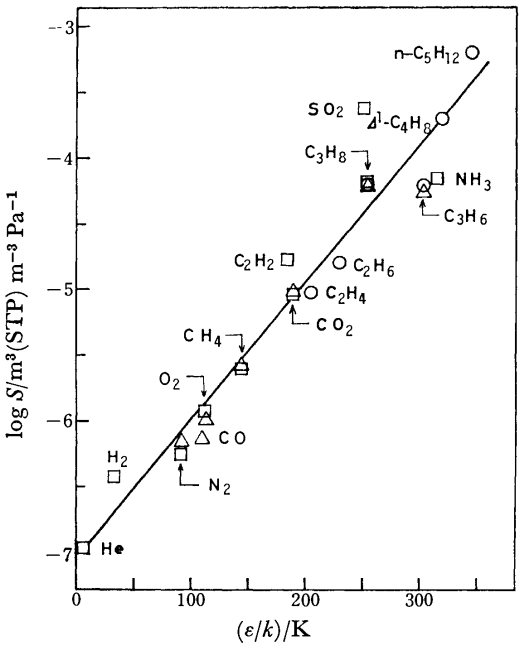

Fig. 3. The relationship between solubility coefficients and Lenard-Jones force constants.
○: This work, □: Van Amerongen, △: Michaels and Bixler.

Thus the values obtained here seem to be reasonable and the relationships are confirmed between log S and T_c, T_b or ε/k.

The solubility coefficients have been measured by the volumetric or gravimetric method. The gas chromatographic technique could be an alternative method, simpler and taking less time than the conventional ones.

Emission Spectra of the Vinyl Polymers with Pendant Benzocarbazolyl Groups

Akira ITAYA, Ken-ichi OKAMOTO, and Shigekazu KUSABAYASHI

Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

(Received June 13, 1977)

The emission spectra of poly(*N*-vinyl-5*H*-benzo[*b*]carbazole) (PV5BCz) and poly(*N*-vinyl-7*H*-benzo[*c*]-carbazole) (PV7BCz), which are prepared by radical and cationic polymerization, and their monomeric model compounds were investigated in solutions. In the case of PV7BCz, the fluorescence spectra were composed of a second excimer fluorescence at the shorter wavelength and a sandwich-like excimer fluorescence at the longer wavelength. The difference in the spectra between the radical and cationic polymers was quite similar to that of the poly(*N*-vinylcarbazole) (PVCz) system. The intensity of the sandwich-like excimer fluorescence was independent of the polymerization methods, but the intensity of the second excimer fluorescence increased with an increase in the content of the syndiotactic sequence. In the case of PV5BCz, the behavior of the fluorescence spectra of the radical polymers was similar to that of the PVCz and PV7BCz systems. On the other hand, the fluorescence spectra of the cationic polymers differed markedly from those of the above-mentioned polymers. The cationic polymers did not show the second excimer fluorescence, but a monomer-like structured fluorescence, at the shorter wavelength, although it did show the sandwich-like excimer fluorescence at the longer wavelength. This significant difference in the fluorescence spectra between the radical and cationic polymers is attributable to the difference between their tacticities. On the basis of these results, the characteristics of the second excimer site were further clarified.

In recent years there has been a growing interest in the emission spectra of aromatic vinyl polymers. It is known that aromatic vinyl polymers show excimer fluorescence in dilute solutions. Considerable data on the emission properties of poly(*N*-vinylcarbazole) (PVCz) have been accumulated because of an interest in high photoconductive polymers.[1-8] The monomeric model compound, *N*-ethylcarbazole (ECz), shows no excimer fluorescence in either a concentrated solution or a solid state.[5] The PVCz, both in solution and in film, shows one broad fluorescence, which is composed of not only one component, but of two components. The broad emission at the longer wavelength (ν_{max}; *ca.* 23900 cm^{-1}) is assigned to the sandwich-like excimer fluorescence. On the other hand, the assignment of the broad emission in the shorter-wavelength region (ν_{max}; *ca.* 27000 cm^{-1}) is controversial because of both the absence of the structure and the large Stokes-shift. David *et al.*[3] and Yokoyama *et al.*[5] have assigned this shorter-wavelength band to the monomer fluorescence for PVCz in solution. P. C. Johnson and Offen,[2] and Powell and Venikouas[6] have assigned it to the emission from a dimer trap site for PVCz films. On the other hand G. E. Johnson[4] has recently assigned it to the second excimer fluorescence for PVCz in solution. Klöpffer and Bauser[8] have also assigned it to the second, more weakly bound excimer fluorescence for PVCz films.

We have reported, on the basis of the NMR spectra and glass transition temperature of PVCz, that the samples prepared by the radical polymerization have higher syndiotacticities than the samples prepared by the cationic one.[9] We have also reported that this difference in tacticity between the radical and cationic polymers is reflected in the fluorescence spectra both in solution and in film, and that the broad emission at the shorter wavelength should be assigned to the second excimer fluorescence,[7] as has been proposed by Johnson and Klöpffer.[4,8] It has also been suggested that the second excimer site, where only one benzene ring in each of the neighboring carbazolyl chromophores overlaps with another, is formed only in the syndiotactic sequence.[7]

Spectroscopic studies of vinyl polymers with aromatic chromophores, which are more bulky than a carbazolyl chromophore, make the above-mentioned suggestion clearer. We have synthesized poly(*N*-vinyl-5*H*-benzo-[*b*]carbazole) (PV5BCz), poly(*N*-vinyl-7*H*-benzo[*c*]-carbazole) (PV7BCz). From the NMR spectra, the glass transition temperatures, and the solubility of the polymers, it has already been found that the stereoregularity of these polymers depends on the polymerization method, as is the case in PVCz.[9]

Concerning the vinyl polymers with small aromatic chromophores, the relation between the tacticity of the polymer chain and the fluorescence spectrum has been reported on in several investigations. For polystyrene (PS),[10-12] poly(α-methylstyrene),[13] and poly(*p*-methylstyrene),[14] it has been reported that the ratio of the sandwich-like excimer to the monomer fluorescence intensity, I_E/I_M, for the isotactic polymer is larger than that for the atactic polymer, although an opposite experimental result for PS has also been reported.[10] Y.-C. Wang and H. Morawetz have found, from the NMR and fluorescence spectra of polyacenaphthylene, that the polymers prepared by cationic and radical polymerizations have different configurations, and that this is reflected in the ease with which they form excimers.[15] However, to the knowledge of the present authors, such a relation has never hitherto been studied for the vinyl polymers with large and bulky aromatic chromophores such as benzocarbazole.

In the present investigation, we have investigated the spectroscopic behavior of PV5BCz, PV7BCz, and their monomeric model compounds (*N*-ethyl-5*H*-benzo[*b*]-carbazole(E5BCz) and *N*-ethyl-7*H*-benzo[*c*]carbazole (E7BCz)) and discussed the relation between the tacticity of the polymer chain and the emission spectra.

Experimental

The vinyl polymers (PV5BCz and PV7BCz) were prepared by the methods described previously.[9] The model compounds

(E5BCz and E7BCz) were obtained by the alkylation of benzocarbazole with diethyl sulfate. The E5BCz was recrystallized twice from ethanol and subsequently sublimed *in vacuo* (mp; 149—150 °C). The E7BCz was isolated by column chromatography (silica gel, benzene : hexane=1 : 2) and was recrystallized twice from methanol (78.5—80.0 °C). All of the solvents used were purified by the usual methods.

The solutions were completely degassed by freeze-pump-thaw cycles if necessary.

The emission spectra and fluorescence-decay times were measured with the apparatus described in a previous paper.[7]

Results and Discussion

The materials used for the present investigation are listed in Table 1. The $I_{H/L}$ value in Table 1 is a measure of the amount of the isotactic sequence relative to the syndiotactic one of the polymer, as is described in Ref. 9. The PV7BCz(c)-III has the largest isotactic sequence, and the free-radical polymer, the smallest.

TABLE 1. CHARACTERIZATION OF MATERIALS USED

Sample	Polymerization[a] temp/°C	Degree of polymerization[b]	$I_{H/L}$[c]
E7BCz	—	—	—
PV7BCz(r)	+75	58	0.32
PV7BCz(c)-I	−78	103	0.51
PV7BCz(c)-II	−40	82	0.68
PV7BCz(c)-III	+10	36	0.92
E5BCz	—	—	—
PV5BCz(r)-I	+100	49	—
PV5BCz(r)-II	+80	13	—
PV5BCz(c)	−78	8	—

a) Initiator; (r): AIBN, (c): BF_3OEt_2. Solvent; none for PV5BCz(r)-I, and toluene for the others. b) The polymer molecular weights were determined by means of a vapor-pressure osmometer. c) The $I_{H/L}$ value is the intensity ratio of the higher-field peak to the lower-field one for the methine proton in the NMR spectra. This value for PV5BCz cannot be obtained because of the highly unresolved NMR spectra.

Absorption Spectra. The absorption spectra in 1,2-dichloroethane solutions are shown in Fig. 1. The absorption bands of the polymers are shifted to frequencies higher by *ca.* 200 cm^{-1} as compared with those of the model compounds. This higher-frequency shift is characteristic for polymers of *N*-vinyl compounds with large π-electronic chromophores. Both the decrease in the intensity (or hypochromism) and the spectral change in the ^1B_b and ^1B_a bands of the polymers, as compared with the spectra of the corresponding monomeric model compounds, are similar to what has been observed for PVCz.[16] The degree of the hypochromism is in the order of PV5BCz(r)-I≈PVCz >PV7BCz(r)>PV5BCz(c).

Fluorescence Spectra of E7BCz and PV7BCz. The fluorescence spectra of E7BCz and PV7BCz are shown in Fig. 2. The E7BCz shows no excimer fluorescence even in concentrated solutions up to 0.1 M, as is the case of ECz. The polymers show one broad fluorescence

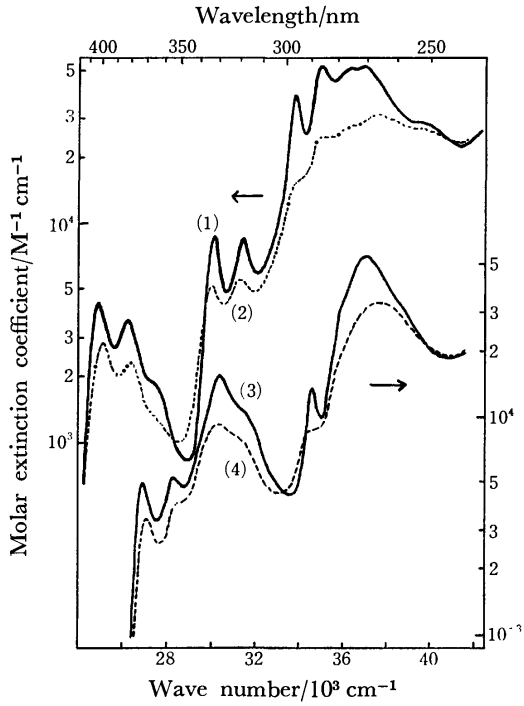

Fig. 1. Absorption spectra of (1) E5BCz, (2) PV5BCz-(r)-I, (3) E7BCz, and (4) PV7BCz(r) in 1,2-dichroloethane solutions at room temperature.

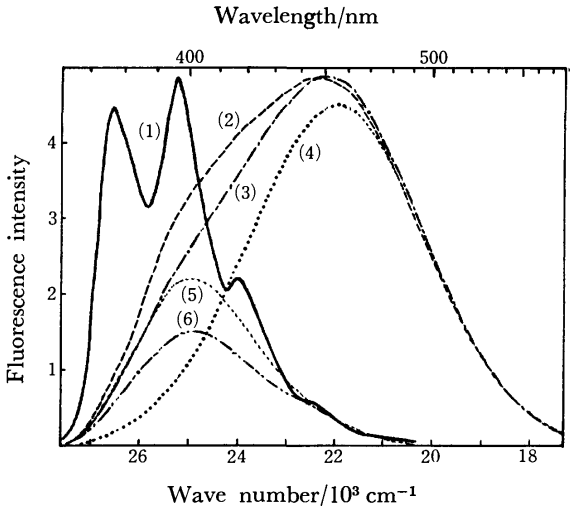

Fig. 2. Fluorescence spectra and their resolution spectra of E7BCz, PV7BCz(r), and PV7BCz(c)-I in MTHF-THF degassed solutions at room temperature. Optical densities of both the polymers at excitation wavelength (350 nm) are 0.249. Fluorescence spectra: (1)——: E7BCz, (2)——, PV7BCz(r), and (3)———: PV7BCz-(c)-I. Resolution spectra: (4)……: the component of the sandwich-like excimer fluorescence of PV7BCz(r) and PV7BCz(c)-I. (5)----, and (6)———: the component of the second excimer fluorescence of PV7BCz-(r) and PV7BCz(c)-I, respectively.

which is composed of two components, as in the case of PVCz. That is, the spectra were successfully resolved into two broad spectral bands with peaks of 21950 and 24900 cm^{-1} on the assumption that the location of the longer-wavelength band in solution was the same as that in film. The energy differences be-

tween the peaks of these two bands and the 0-0 fluorescence band (26560 cm^{-1}) of the E7BCz are 4610 and 1660 cm^{-1}. These are almost the same as the corresponding energy differences between PVCz and ECz (4630 and 1630 cm^{-1}). The fluorescence excitation spectra of the polymers, obtained by monitoring at several wavelengths (390—500 nm), duplicate the absorption spectra of these solutions exactly. By analogy with the fluorescence spectrum of PVCz, the fluorescence bands at the longer wavelength and at the shorter one can be assigned to the sandwich-like excimer fluorescence and the second excimer one respectively. Figure 2 shows that the concentrations of the sandwich-like excimer site are nearly equal between the radical and cationic polymers, and that the concentration of the second excimer site is larger for the radical polymer than for the cationic polymer by a fac tor of about 1.4. That is, the difference in the fluorescence spectra between these two polymers seems to be attributable to the difference in the concentration of the second excimer site.

The $I_{H/L}$ and $\overline{DP}$ of the cationic polymers vary remarkably with the polymerization temperature (Table 1).[9] This result is different from that for PVCz.[9] Thus, the fluorescence spectra of PV7BCz samples in aerated solutions (5.9×10^{-5} M) at room temperature were compared with one another in Fig. 3. The second excimer fluorescence intensities are in the order of (r)> (c)-I>(c)-II>(c)-III. This order is not correlated to the molecular weight of the polymers, but to the decrease in the $I_{H/L}$ value. That is, the concentration of the second excimer site increases with an increase in the syndiotactic sequence.

The sandwich-like excimer fluorescence of each PV7BCz sample has a constant intensity at temperatures from *ca.* −110 to 20 °C, as is shown in Fig. 4. At temperatures above *ca.* 20 °C, the intensity of the sandwich-like excimer fluorescence decreases and the intensity of the second excimer fluorescence increases with

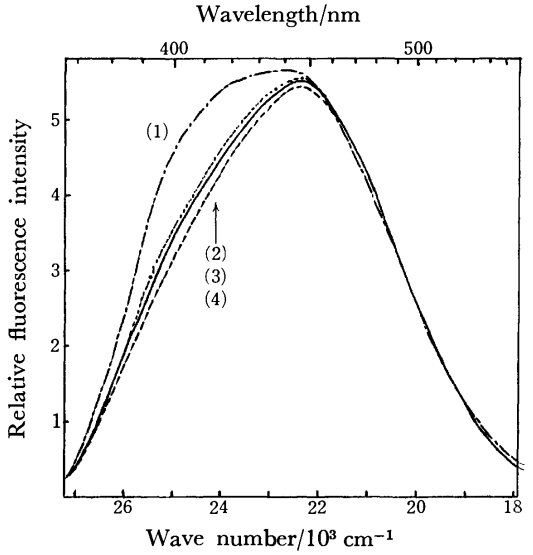

Fig. 3. Fluorescence spectra of (1) PV7BCz(r), (2) PV7-BCz(c)-I, (3) PV7BCz(c)-II, and (4) PV7BCz(c)-III in MTHF-THF aerated solutions at room temperature. Excitation wavelength; 350 nm.

an increase in the temperature. This phenomenon is also observed for PVCz.[4] This behavior and the presence of the long-lived component decay at the shorter wavelength (*vide infra*) indicate the presence of sandwich-like excimer dissociation to give back the second excimer.

The above-mentioned results with regard to the concentrations of the sandwich-like excimer site and the second excimer one may be qualitatively explained as follows. If we consider only a part of the syndiotactic sequence in the polymer chain, both the concentration of the second excimer site and that of the sandwich-like excimer site are larger for the radical polymers than for the cationic polymers, because a photodynamic equilibrium between the second excimer and the sandwich-like excimer is established. However, the concentration of the sandwich-like excimer site formed in the isotactic sequence, which cannot form the second excimer site, is larger for the cationic polymers than for the radical polymers. Therefore, a clear difference in the concentrations of the second excimer sites between the radical and cationic polymers is observed, although no clear difference in the concentrations of the sandwich-like excimer sites is observed.

The presence of two kinds of emitting species in the fluorescence was also clarified by measuring the fluorescence-decay times of the polymers. The fluorescence-decay curves of the polymers at room temperature are multi-component in the shorter-wavelength region (36±2 ns and initial fast decay), while they are one-component (36±2 ns) in the longer-wavelength region. The long-lived component corresponds to the sandwich-like excimer fluorescence.

The spectral band of the polymers in rigid glass solutions at 77 K is shifted to a lower frequency and broadened as compared with that of E7BCz, as is shown in Fig. 5. This deviation from the monomer-like fluorescence band shape seems to be attributable to a large contribution of the second excimer fluorescence. In the case of the PVCz samples,[7] the cationic

polymer shows a monomer-like structured fluorescence, while the radical polymers shows mainly the second excimer fluorescence. The fluorescence decay times of both the PVCz samples (λ_{obsd}=355—390 nm) are approximately the same as that measured for *N*-isopropylcarbazole (17±2 ns), although a slight departure from a strict first-order decay is observed (Table 2). This fact indicates that the lifetime of the second excimer fluorescence seems to be nearly equal to that of the monomer-like fluorescence. In the case of the PV7BCz samples, the fluorescence decay times of both the polymers at 380 nm are *ca.* 18 ns, while those at the longer wavelength (λ>400 nm) are 25±2 ns. The decay curves are roughly single-exponential. This lifetime (25 ns) is not in agreement with those of the monomeric fluorescence of the model compound (13 ns) and the sandwich-like excimer fluorescence (36 ns). When (at 77 K) the formation of the sandwich-like excimer site from the second excimer site is impossible, this lifetime may correspond to that of the second excimer fluorescence. The decay time (18 ns) at 380 nm seems to be an apparent value due to an overlap of the monomer-like fluorescence and the second excimer one.

Fluorescence Spectra of E5BCz and PV5BCz. The fluorescence spectra of E5BCz and PV5BCz are shown in Fig. 6. The E5BCz shows no excimer fluorescence even in concentrated solutions up to 0.1 M, as is also the case with ECz and E7BCz. The radical polymers show one broad fluorescence, the spectra of which were successfully resolved into two broad bands, with peaks of 20350 and 22550 cm^{-1}, in a manner similar to that in PV7BCz. The energy differences between the peaks of these two bands and the 0-0 fluorescence band (24330 cm^{-1}) of E5BCz are 3980 and 1780 cm^{-1} respectively. The fluorescence excitation spectra of the polymers duplicate exactly the absorption of these solutions. Therefore, the fluorescence bands at the longer and shorter wavelengths can be assigned to the sandwich-like excimer fluorescence and the second excimer one respectively.

The temperature dependence of the fluorescence spectrum of the PV5BCz(r)-II sample is shown in Fig. 7. As may be seen, there is no evidence for the formation of an isoemissive point. The sandwich-like excimer fluorescence has a constant intensity over the temperature range from *ca.* —70 to 40 °C, as is shown in Fig. 4. These phenomena observed for the radical polymers are quite similar to those observed for the PVCz and PV7BCz.

On the other hand, the fluorescence spectrum of the cationic polymer differes markedly from those of the

above-mentioned polymers: (1) The monomer-like structured fluorescence (0-0; 23800 cm^{-1}) in the shorter-wavelength region is observed clearly even at room temperature, while the second excimer fluorescence is not observed, as is shown in Fig. 6. (2) An isoemissive point is clearly observed, as is shown in Fig. 8. (3) The intensity of the sandwich-like excimer fluorescence in the longer-wavelength region increases with an increase in the temperature up to *ca.* 20 °C, as is also shown in Fig. 4.

A dilute fluid solution of a *N*-vinylcarbazole oligomer ($\overline{DP}=10$) at room temperature does not show any structured fluorescence at the shorter wavelength, but a broad fluorescence which is composed of two excimer fluorescences. Therefore, these three significant differences in the fluorescence spectra between the radical and cationic polymers seem not to be attributable to any difference in the molecular weight, but to the difference in their tacticities. This explanation seems also to be supported by the polymerization results: the cationic polymer is considered to be composed of only an isotactic sequence, judging from the fact that only low-molecular-weight polymers are obtained almost quantitatively in high yields. The radical polymers are composed of stereoblock arrangements of the isotactic and syndiotactic helixes.[9] Therefore, the above-mentioned discussion supports the idea that the second excimer site is not formed within the isotactic sequence, but only within the syndiotactic sequence.

The fluorescence-decay curves of both the radical and cationic polymers at room temperature are multicomponent in the shorter-wavelength region (57±3 ns and an initial fast decay), while there is only one component with a long lifetime (57±3 ns) in the longer-wavelength region. The long-lived component corresponds to the sandwich-like excimer fluorescence.

Figure 9 shows the fluorescence spectra of PV5BCz and E5BCz in rigid glass solutions at 77 K. The fluorescence spectra of the cationic polymer is mainly composed of a monomer-like fluorescence, the lifetime of which at 420 nm was 23±2 ns. This is the same value as the decay time of E5BCz. On the other hand, the fluorescence spectra of the radical polymers are markedly broadened as compared with that of the cationic polymer. This fluorescence is mainly emitted from the excited monomer state and the second excimer site, although the fluorescence from the sandwich-like excimer site is slightly involved. The fluorescence lifetime at 410 nm, a wavelength where the fluorescence was mainly emitted from the excited monomer state,

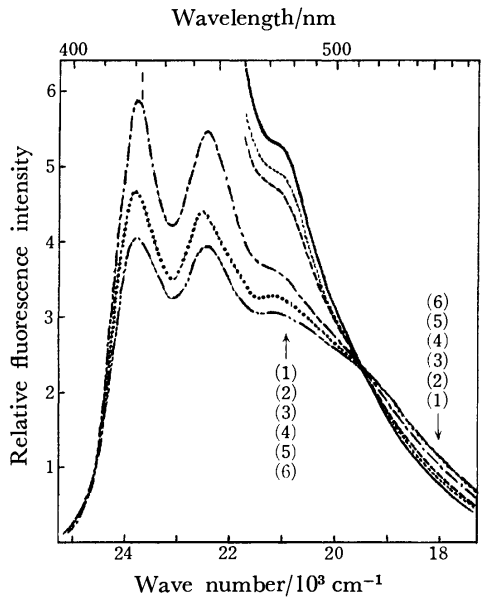

Fig. 8. Temperature dependence of the fluorescence spectra of PV5BCz(c) in MTHF-THF degassed solution. Excitation wavelength; 350 nm. (1) 183.5 K, (2) 202.5 K, (3) 221 K, (4) 262.5 K, (5) 282 K, and (6) 304 K.

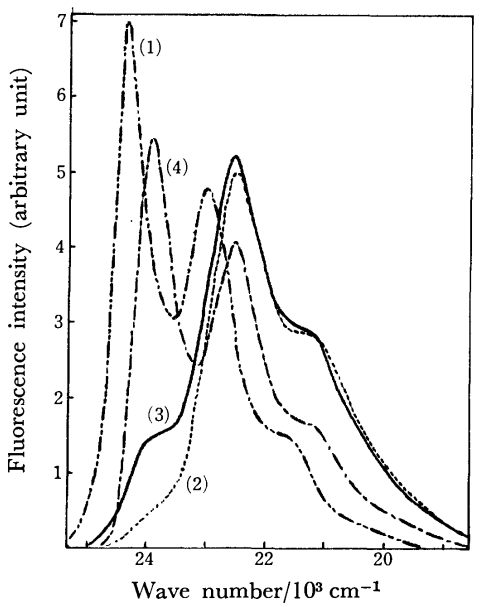

Fig. 9. Fluorescence spectra of (1) E5BCz, (2) PV5BCz-(r)-I, (3) PV5BCz(r)-II, and (4) PV5BCz(c) in MTHF-THF rigid glasses at 77 K. Excitation wavelength; 350 nm.

is *ca.* 26 ns, which is nearly equal to that of E5BCz. The fluorescence decay curves show a departure from the strict exponential decay, with an initial fast component followed by a long tail whose decay constant was 65—75 ns. The ratio of the short-lived component to the long-lived one in the shorter-wavelength region is larger than that in the longer-wavelength region. Therefore, this long-lived component decay may correspond to the lifetime of the second excimer fluorescence of PV5BCz (Table 2).

When we compare the fluorescence spectrum of the PV5BCz(r)-II sample in a polycrystalline 1,2-dichloroethane (fp: −36 °C) matrix at 77 K with the spectrum in a MTHF–THF fluid solution at −29 °C, the concentration of the second excimer site in the matrix turns out to be larger than that in the fluid solution, as is shown in Fig. 10. This is attributable to be impossibility of rotational motion from the second excimer site to the sandwich-like excimer site in the polycrystalline matrix. On the other hand, the cationic sample does not form the second excimer site even under such favorable conditions as the polycrystalline 1,2-dichloroethane matrix. Thus, it may be suggested that the second excimer site is not formed within the isotactic sequence, even under favorable conditions.

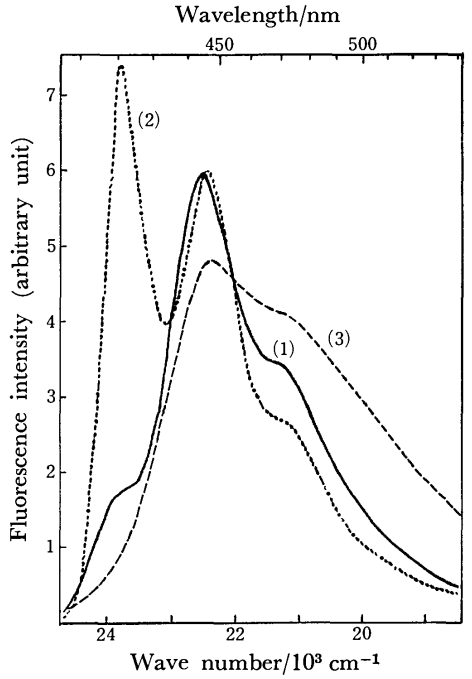

Fig. 10. Fluorescence spectra of (1) PV5BCz(r)-II and (2) PV5BCz(c) in polycrystalline 1,2-dichloroethane matrixes at 77 K. The fluorescence spectra of (3) PV5BCz(r)-II in MTHF-THF fluid solution at −29 °C was also given for comparison.

From the above-mentioned results and discussion, it has further been clarified that the second excimer site is formed only within the syndiotactic sequence. That is, the second excimer site is formed in the conformational state with the lowest energy and the shortest distance between neighboring chromophores in the syndiotactic sequence. Its structure seems to be the overlap of only one benzene ring between the neighboring chromophores, as has been suggested for PVCz.[7]

Analysis of Thermal Desorption Curves for Heterogeneous Surfaces. I. A Linear Variation of the Activation Energy of Desorption

Yasuo Tokoro, Makoto Misono, Toshio Uchijima, and Yukio Yoneda

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 17, 1977)

This paper deals with the analysis of the desorption curves for heterogeneous surfaces, where the activation energy of desorption, E_d, linearly depends on surface coverage, θ, *i.e.*, $E_d = E_d^0 + \alpha(1-\theta)$. Computer simulation resulted in a characteristic change of curve shapes corresponding to the variation of desorption rate parameters, E_d^0, A, and α. By means of empirical parameters characterizing the peak shapes such as peak temperature, half width and symmetry factor, we were able to obtain a set convenient and valid equations for estimating the rate parameters. The curve fitting method was also investigated and found to be more precise, the equations obtained being very useful for giving an initial set of values for this method. The two methods were applied to the thermal desorption curves of CO_2 on TiO_2, and found to be useful and reliable.

The thermal desorption technique, employing a continuous rise of temperature, has been widely used for studies of chemisorbed states on metal surfaces. Thermal desorption curves have been discussed in terms of the reaction order and the activation energy of desorption from the different surface sites or crystal planes.

The technique has been getting familiar in the field of catalysis on oxides and others. The variations of temperature, area and number of the thermal desorption peaks before and after certain treatments and/or chemical reactions were studied, and discussed qualitatively in relation to the nature of reaction sites and the reaction mechanism. Halpern and Germain[1] have reported interesting results in which the values of activation energy obtained from the thermal desorption curves of oxygen on transition metal oxides are correlated to the catalytic activities for oxidation on the oxides. Although their method for analysis is not so reliable, this kind of application is of interest from the viewpoint of characterization of catalysts.

The thermal desorption curves usually show some multiple peaks and complicated shapes, which is supposed to be due to surface heterogeneity, induced or intrinsic. The surface heterogeneity is expected to play an important role in catalysis. It is desirable to express the desorption energy as a function of surface coverage by quantitative analysis of the thermal desorption curves.

The analyses for homogeneous surface have been reported by Redhead,[2] Cvetanović, and Amenomiya[3] and Lord and Kittelberger.[4] An accurate method, discussed in detail by Cvetanović, is to compare the shifts of the peak maximum temperatures, T_m, of the thermal desorption curves with widely differing heating rates, β, where the slope of $\ln(T_m^2/\beta)$ against T_m gives the activation energy of desorption E_d for the first order desorption.

There are a few reports on the analysis of thermal desorption curves for heterogeneous surface. Hobert and Knappe[5] simulated the desorption curves in the case where E_d changes linearly with coverage. Dawson and Peng[6] assumed the same kind of heterogeneity for the λ state nitrogen on tungsten surface, and determined the rate parameters by the curve fitting method, but there remains a problem about the uniqueness of their solution.

We have investigated how the shapes of the desorption curves change by varying the rate parameters widely and systematically in the heterogeneous case where E_d decreases linearly with coverage. The variation of rate parameters leads to the characteristic change of the curve shapes. In turn, the empirical curve parameters can be correlated well with the rate parameters. The relation gives convenient equations to estimate the rate parameters from experimental desorption curves. The curve fitting method was also examined to determine the rate parameters on the heterogeneous surface with the linear variation of the activation energy of desorption. The analyses were verified to be useful and reliable by applying them to the thermal desorption curves of carbon dioxide on titanium dioxide.

Calculations

In the case where a single adsorbed state exists and no readsorption occurs, the desorption rate is expressed by

$$-d\theta/dT = (A(\theta)/\beta)\cdot\theta^n\cdot\exp(-E_d(\theta)/RT), \quad (1)$$

where β is the heating rate ($T = T_0 + \beta t$), θ the surface coverage, *i.e.*, the fraction of the adsorbed species remaining on the surface, n the order of desorption, $A(\theta)$ the frequency factor and $E_d(\theta)$ the activation energy of desorption. In a flow system for thermal desorption, the left side term of Eq. 1 is equivalent to the partial pressure or concentration of desorbed molecules normalized by the experimental constants such as the saturated amount of adsorption, the catalyst volume and the carrier gas flow rate.[3]

In the present paper, we deal with the simple case in which desorption follows the first order kinetics and surface heterogeneity is reflected only in the activation energy of desorption, *i.e.*, $A(\theta)$ is independent of θ, and $E_d(\theta)$ changes with θ as follows:

$$E_d = E_d^0 + \alpha(1-\theta). \quad (2)$$

This indicates that the activation energy of desorption has a value of E_d^0 at saturation coverage and increases with desorption in proportion to $(1-\theta)$. Equation 1, in which $E_d(\theta)$ is given by Eq. 2, is an ordinary differential equation, which can be solved numerically for different sets of values of A/β, E_d^0 and α. Though β is an experimental parameter independent of A, the reciprocal of β makes an essentially equivalent contribu-

tion in Eq. 1. Thus A/β is treated as an independent parameter. Calculations were carried out to simulate the thermal desorption curve with A/β from 10^8 to 10^{16} K^{-1} at 10^2 K^{-1} intervals, E_d^0 from 10 to 45 kcal*/mol in increments of 5 kcal/mol and α from 0 to 20 kcal/mol in increments of 5 kcal/mol. The starting values of T and θ in the calculation were usually 100 K and 1.0, respectively. The value of A is expected to be close to $h/kT \approx 10^{13}$ s^{-1} according to the simple rate theory, but it was changed in the wide range above, the reported values of A for desorption being scattered in the range 10^4—10^{16} s^{-1}.[3] Calculations were made on a HITAC 8700/8800 computer. The simulated curves, $-d\theta/dT$ *vs.* T, will be shown in the later section.

Experimental

The thermal desorption curves were obtained by linear temperature increase of the sample using a thermal conductivity cell as a detector. The sample was titanium dioxide (Junsei Kagaku Co.), which had been calcined for 5 h at 500 °C in the air. The pre-adsorption was carried out by letting low pressure carbon dioxide in He flow through the sample bed at room temperature. The gases desorbed from the sample into the carrier gas stream were confirmed to consist of only carbon dioxide with a quadrupole mass spectrometer.

Results and Discussion

Estimation of Rate Parameters. Some simulated curves with a wide range of values of A/β, E_d^0, and α are shown in Fig. 1. The effect of A/β on the curves when E_d^0 and α remain constant is given in Fig. 1(a); as the value of A/β decreases, peak temperature shifts to a higher one, and peak width becomes broader. As the value of E_d^0 increases when A/β and α are constant, the peak shifts to higher temperature, and its width becomes slightly broader (Fig. 1(b)). The effect of α on the curves when A/β and E_d^0 are kept constant is given in Fig. 1(c). With increase in the value of α, the peak temperature does not change so much but its shape changes remarkably into a broad and flat one. The behavior is in accord with the results of Hobert and Knappe.[5]

The temperature and shape of the peak are characteristic of a set of values of A/β, E_d^0 and α. This, in turn, affords the possibility that the rate parameters A/β, E_d^0, and α can be determined from the experimental desorption curves, if we choose adequate empirical parameters which characterize their peak shapes.

The peak maximum temperature T_m, the half width D and the symmetry factor γ were chosen as the parameters. The parameter γ is defined as the ratio of the area after and before the peak maximum, and is equivalent to $\theta_m/(1-\theta_m)$, where θ_m is the surface coverage at the peak maximum temperature.

Thermal desorption curves can take almost the same value of T_m with multiple sets of different values of A/β, E_d^0 and α as shown in Table 1. The rate parameters A/β, E_d^0, and α can not be analytically determined by only one empirical parameter, *e.g.* T_m. The effect of the rate parameters on the curves leads to the following results.

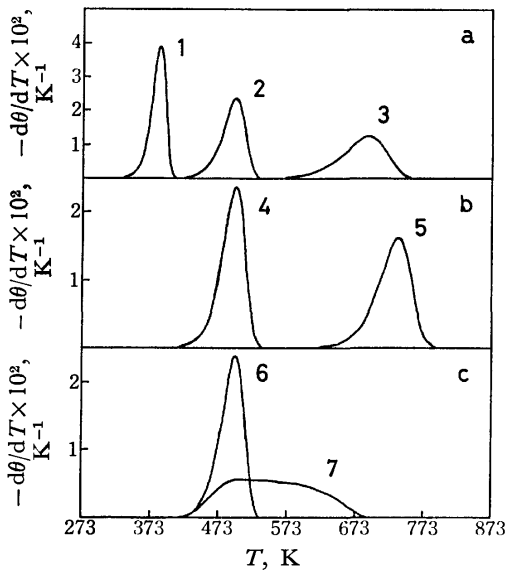

Fig. 1. Simulated thermal desorption curves with various rate parameters. Desorption was treated with the first order kinetics. Numbers in the figures correspond to the rate parameters listed below.

Table 1. Comparison of calculated peak maximum temperatures with different sets of rate parameters

T_m[a]	E_d^0[b]	α[c]	$\log(A/\beta)$[d]
601	40.0	20.0	14.0
601	31.1	5.0	9.9
601	25.0	10.0	8.1
600	35.1	15.1	12.1

a) K. b) kcal/mol. c) kcal/mol. d) A/β, K^{-1}.

T_m changes approximately in proportion to the value of E_d^0 and in inverse proportion to that of $\log(A/\beta)$. The plot, T_m *vs.* $E_d^0/\log(A/\beta)$ gives a roughly linear relation. In the same way, D can be related proportionally to $\alpha/\log(A/\beta)$, and γ to $\alpha\log(A/\beta)/E_d^0$.

These relations hold only roughly with a wide range of values of the rate parameters, and should be refined by introducing other rate parameters and constants. For this, we take the following equations:

$$T_m = (a_1E_d^0 + a_2\alpha + a_3)/\log(A/\beta) + a_4, \quad (3)$$

$$D' = (D/T_m^{0.1})^{1.2} = (b_1E_d^0 + b_2\alpha + b_3)/\log(A/\beta) + b_4, \quad (4)$$

$$\gamma = (c_1\alpha\log(A/\beta) + c_2\alpha + c_3)/E_d^0 + c_4. \quad (5)$$

* 1 cal_{th}=4.184J.

Equation 3 and 4 have the same from, but the coefficients of E_d^0 and α differ a great deal from each other. D' in Eq. 4 is used instead of D for correcting the regular deviation from the linear relation in the range of higher T_m. The coefficients of these equations were determined by the least square method. Their values are given in Table 2.

T_m, D', and γ are plotted in Figs. 2, 3, and 4, respectively, against the right side terms of Eqs. 3, 4, and 5 calculated by use of the coefficients in Table 2. The figures show satisfactory straight lines in the range of the given values of the rate parameters. This indicates that the equations are a good approximation to connect the rate parameters with the empirical ones of the desorption curves.

Table 2. Coefficients in Eqs. 3, 4, and 5

Coefficients in Eq. 3	a_1 191.2	a_2 10.8	a_3 −811.9	a_4 92.2
Coefficients in Eq. 4	b_1 2.2	b_2 308.5	b_3 −85.4	b_4 3.6
Coefficients in Eq. 5	c_1 0.2405	c_2 1.4666	c_3 −1.7301	c_4 0.6524

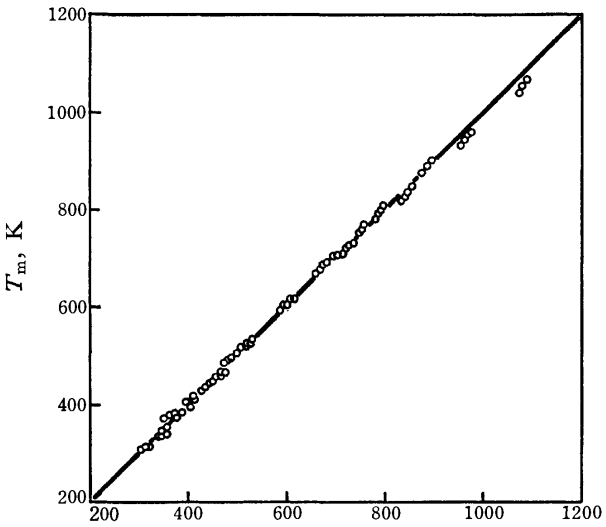

Fig. 2. Correlation of T_m with the right side terms of Eq. 3.

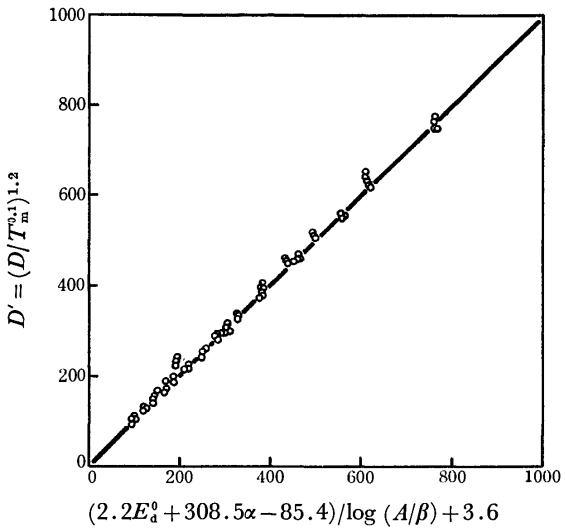

Fig. 3. Correlation of D' with the right side terms of Eq. 4.

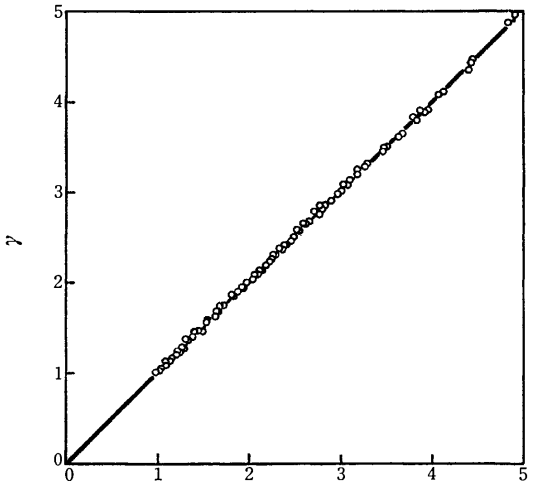

Fig. 4. Correlation of γ with the right side terms of Eq. 5.

The rate parameters should be explicilty expressed by solving these equations. Equations 3, 4, and 5 lead to the relation

$$[\log(A/\beta)]^2 + d_1\log(A/\beta) + d_2 = 0, \quad (6)$$

where d_1 and d_2 are given by Eqs. 7 and 8, respectively,

$$d_1 = (308.5\gamma' T_m' - 10.8\gamma' D'' + 3.2T_m' - 280.4D'' - 3502.8)/(0.522T_m' - 45.98D''), \quad (7)$$

$$d_2 = (249500\gamma' - 80640)/(0.522T_m' - 45.98D''). \quad (8)$$

The terms γ', T_m', and D'' are defined as $\gamma'=\gamma-0.652$, $T_m'=T_m-92.2$, and $D''=D'-3.6$. In the range of values of the rate parameters used for the simulations, the following relations hold. $300<T_m<1100$, $100<D'<800$, $1<\gamma<6$, $d_1>0$, and $d_2<0$. Consequently, the rate parameters can be estimated by Eqs. 9—11 using the empirical parameters T_m, D', and γ.

$$\log(A/\beta) = (-d_1+\sqrt{d_1^2-4d_2})/2 \quad (9)$$

$$E_d^0 = (5.232\times10^{-3}T_m'+1.84\times10^{-4}D'')\log(A/\beta) + 3.97, \quad (10)$$

$$\alpha = (-3.68\times10^{-5}T_m'+3.243\times10^{-3}D'')\log(A/\beta) + 0.25. \quad (11)$$

The values of the rate parameters thus estimated are compared with the true ones used for the simulations. Some examples are given in Table 3. The deviations of the estimated values from the true ones are less than 10%. Thus, Eqs. 9—11 afford a convenient and reliable method for the estimation of the rate parameters from a single desorption curve.

Two restrictions should be pointed out concerning the applicability of the equations. (1) The equations were derived on the basis of first order desorption of a

single adsorbed state from the heterogeneous surface with the linear variation of the activation energy of desorption. (2) The values of the rate parameters were examined in such range as $10<E_d^0<45$ kcal/mol, $5<\alpha<20$ kcal/mol and $10^8<A/\beta<10^{16}$ K^{-1}.

When the thermal desorption curve has multiple peaks, high resolution between peaks is required for the application of this analysis. It is possible to resolve peaks to a certain extent by large increase of β, although some practical difficulties are encountered.

The desorption order can be determined by the symmetry of the peak in the case of a homogeneous surface, but there are no such means in the case of a heterogeneous one. It is necessary to confirm the desorption order by other measurements.

Curve Fitting Method. The curve fitting method was also investigated for obtaining a more accurate solution. We used the Powell method in order to solve a number of simultaneous equations derived after integration of the differential Eq. 1, the convergence being judged by the summation of squares of differences between the observed and calculated curves.

Even if the summation reaches a minimum in such a nonlinear least square method, it does not always mean the global minimum. In order to get the real solution, a global minimum should be found by widely changing the initial values of the rate parameters. This is the case for thermal desorption, since nearly the same curve could be sometimes reproduced with multiple sets of different values of the rate parameters.

The estimated values would be useful as the initial input values for the application of the curve fitting method, since they are very close to the true values. The curve fitting method was applied to several simulated curves with the result that the values of the rate parameters obtained agreed satisfactorily with the true ones. When the estimated values were used as initial inputs, the calculated result converged more easily to the global minimum. This demonstrates that Eqs. 9—11 are effective not only as a simple method for estimation but also as a method giving good initial input values for the curve fitting calculation.

Application to the Desorption of Carbon Dioxide on Titanium Dioxide. The thermal desorption curve of carbon dioxide from titanium dioxide is shown in Fig. 5. Desorption of carbon dioxide should follow first order kinetics since its dissociative adsorption is very unlikely. The first order thermal desorption from a homogeneous surface is known to give an unsymmetrically shaped curve, but the observed curve has a nearly symmetrical shape. This indicates that the desorption should be treated as one from the heterogeneous surface. The above two methods were applied to this case. The values of the rate parameters obtained by the analysis are compared in Table 4. The two methods give almost the same results, and the calculated curves using the above values reproduce the observed one as shown in Fig. 5.

As a result, the two methods were verified to be effective for getting reliable values of the rate parameters by analyzing a single desorption curve.

There are many complicated cases which can not be treated as such simple heterogeneity. The methods should be extended to analyze a more general heterogeneous surface.

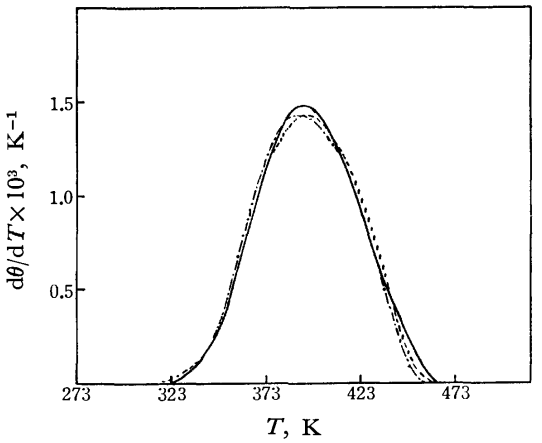

Fig. 5. Observed and calculated thermal desorption curves of carbon dioxide on titanium dioxide: (——) observed; (—·—) calculated using estimated values; (---) calculated by curve fitting method.

Isomorphism in the High-temperature Forms of the Pyrene Complexes with Five Polynitro Aromatic Compounds

Nobuaki INOUE* and Yoshio MATSUNAGA**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 28, 1977)

Crystalline pyrene complexes with 2,4-dinitrofluorobenzene, 2,4-dinitrochlorobenzene, 2,4-dinitrotoluene, 2,4-dinitrophenol, and picryl chloride exhibit polymorphic transitions. Their temperatures and associated enthalpies are presented. The high-temperature forms show essentially identical X-ray diffraction patterns, losing the special natures of the substituents on the acceptor molecules. Isomorphism is supported by the formation of complete solid solutions demonstrated for combinations of these forms. The enthalpy and entropy of melting of the present complexes are characterized by rather small values, 4—6 kcal mol^{-1} and 12—14 cal deg^{-1} mol^{-1} respectively, indicative of anomalously high thermal motion or disorder in the high-temperature forms. Marked changes in the spectral and electrical properties by the transitions are noted in some cases.

The discovery of polymorphic forms has been reported for a number of electron-donor-acceptor complexes; however, little attention has been paid to their structure or to the properties expected to vary with the transitions.[1-12] In order to understand the significance of polymorphism, systematic studies of this phenomenon and of the change in physical properties by the transitions seemed to be highly desirable. For such studies, polymorphism should be observed with complexes consisting of component compounds structurally related to each other. Our preliminary survey indicated that pyrene complexes with polynitro aromatic compounds suit this purpose well. Especially, the five complexes studied here were found to be of considerable interest because of the isomorphism observed with the high-temperature forms.

Experimental

Materials. The pyrene, Eastman yellow label, was boiled with a large excess of maleic anhydride in xylene to remove the tetracene and other reactive impurities.[13] Then, the hydrocarbon was purified by chromatography on a column of activated alumina and finally zone-refined. The acceptors employed were 2,4-dinitrofluorobenzene (hereafter abbreviated as DNF), 2,4-dinitrochlorobenzene (DNC), 2,4-dinitrotoluene (DNT), 2,4-dinitrophenol (DNP), and picryl chloride (2,4,6-trinitrochlorobenzene) (TNC). They were obtained from commercial sources. The complexes were crystallized from benzene or chloroform solutions containing equimolar amounts of the component compounds. The melting points, listed in Table 1, are in fair agreement with the values reported by Shinomiya when available.[14]

Measurements. Calorimetric curves up to the melting points were recorded on a Rigaku Denki differential scanning calorimeter, Model 8001 SL/C, at a heating rate of 3 °C min^{-1}. The enthalpies of transition and of melting were estimated by comparing the peak areas with the enthalpy of the melting of naphthalene, 4.536 kcal mol^{-1},[15] and also with the enthalpy of transition in hexamethylbenzene, 0.422 kcal mol^{-1}.[16] X-Ray measurements on powdered samples were made with a Toshiba recording diffractometer, Model ADG 301, using filtered copper radiation. The sample was mounted on a aluminum plate with a 20-W heater attached to the other side. The temperature of this plate was monitored by means of a copper-constantan thermocouple and was kept constant with the aid of a Chino temperature-indicating controller, Type E 500.

For spectroscopic measurements, the complexes were melted between two quartz plates. Thin polycrystalline films were obtained by the repeated rubbing of two plates over one another, yielding an optical density of less than 1.0 throughout the visible region. The spectra were recorded on a Beckman DK 2A spectrophotometer at various temperatures between 20 and 80 °C with the aid of a temperature-regulated cell holder. Electrical resistivity measurements were performed on pressed pellets by the two-probe method, as has been described in a paper by Koizumi and Matsunaga.[8]

Results and Discussion

The transition temperature, enthalpy, and entropy are collected in Table 1. Fortunately, the transitions in these complexes occur at reasonably low temperatures and are well separated from the melting points. These conditions make our studies of the high-temperature forms considerably easy. The enthalpy of transition is about 3 kcal mol^{-1} or more in all the complexes but that with DNC. When the high-temperature forms of the DNF, DNT, and DNP complexes are quickly cooled, the metastable phases may be obtained, as evidenced by new transitions appearing at 53, 33, and 39 °C respectively.

The X-ray diffraction patterns observed at room temperature are complicated and distinctly different from each other, reflecting the special natures of the substituents. However, the patterns are drastically simplified upon the transition and become almost identical in all five. As is schematically illustrated in Fig. 1, only four diffraction lines can be seen in the range examined: a strong one appearing between 11 and 12°, two weak ones near 20 and 23°, and a strong one between 26 and 27°. If these high-temperature forms really have the same space group and number of molecules per unit cell, a combination of any two should give a continuous solid solution.[17] Moreover, the combinations examined so far consist of molecular complexes sharing the same acceptor compound.[8,18-20] On the other hand, all the present complexes share the same donor compound, pyrene. Consequently, we decided to look into phase diagrams for several selected pairs by means of differential scanning calorimetry. In addition, the phase boundaries at

a) 92.5 °C by Shinomiya (Ref. 14). b) 146.3 °C (Ref. 14). c) 81 °C by Bando and Matsunaga (Ref. 12). d) 154 °C (Ref. 14).

room temperature were checked by the examination of the X-ray diffraction patterns. For example, the diagrams for the following three systems are presented in Fig. 2: pyrene–(DNP,DNC), pyrene–(DNC,DNT), and pyrene–(DNT,DNP). The composition is quoted

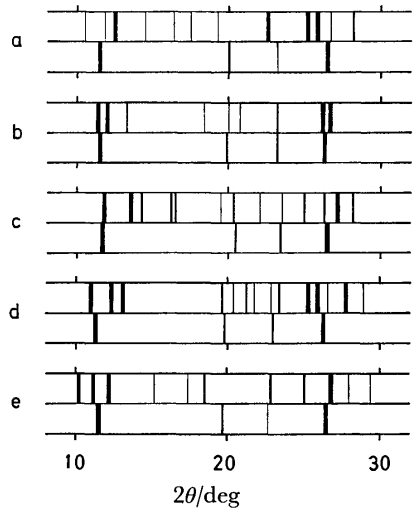

Fig. 1. X-Ray diffraction patterns of the pyrene complexes with a) DNF, b) DNC, c) DNT, d) DNP, and e) TNC. The upper pattern for each complex was recorded at room temperature, and the lower one above the transition temperature.

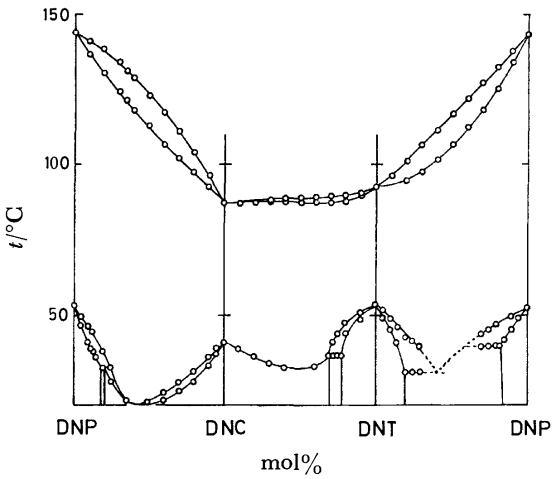

Figs. 2. Phase diagrams for the pyrene–(DNP, DNC), pyrene–(DNC, DNT), and pyrene–(DNT, DNP) systems.

in the mole percentage of the acceptor. The solid-liquid equilibria are of the I type in the Roozeboom classification and clearly indicate the formation of a continuous solid solution within the temperature limits of the diagrams.[21] Similar equilibria have also been noted in pyrene–(DNC,DNF), pyrene–(DNF,DNT), and pyrene–(DNT,TNC). Thus, isomorphism in the high-temperature forms of the five complexes is firmly established.

The solubility characteristics of the low-temperature forms in pyrene–(DNP,DNC) and pyrene–(DNC, DNT) bear a similarity to each other. They are all peritectoid systems. The formation of substitutional solid solutions based on the parent complex lattices occurs over a wide range of stoichiometry. Both the transition temperatures are appreciably lowered by the formation of solid solutions. It is interesting to note that the solubility of the DNP complex into the DNC complex lattice is as much as 80 mol%. Therefore, a miscibility gap with a width as narrow as 2 mol% appears in this system. Similarly, the DNC complex can dissolve the DNT complex to an extent of 70 mol%. The width of the miscibility gap in pyrene–(DNC, DNT) is about 8 mol%.

The diagram for pyrene–(DNT,DNP) could be only partially determined because samples in the range from 30 to 70 mol% of DNP were found not in equilibrium even after standing over two years at room temperature. Nevertheless, the presence of two singular points may be easily noted. As is shown in Fig. 2, one of them may be a eutectoid at about 40 mol% and at 31 °C, while the other may be a peritectoid at about 60 mol% and at 40 °C. If this assignment is correct, and if the equilibrium is achieved, the appearance of a ternary complex dissolving adjacent phases to some extent, and hence of a variable composition, may be expected. This phase may cover a range as wide as 20 mol% of DNP. The formation of two ternary complexes has been known in the (phenanthrene, anthracene)–picric acid system studied by us.[8] They may be supposed to be deposited from mixtures containing liquid phases. In the case of pyrene–(DNT, DNP), the ternary complex must be formed from a solid solution. In other words, an extensive rearrangement of the component molecules must occur in the solid state for the appearance of the new phase. Such a process undoubtedly takes a long time to be accomplished. The other, but less likely, possibility is that the above-mentioned singular points are both eutec-

toids. If so, the miscibility gap for the high-temperature forms is closed at these points, while that for the low-temperature forms covers the whole range from 20 to 84 mol% of DNP.

Although our knowledge of the structural relationship among various molecular complexes is still scanty, several isomorphous pairs are already known. For example, the trinitrobenzene and picric acid complexes of naphthalene, fluoranthene, and pyrene have each been shown to be strictly isomorphous by Herbstein and Kaftory.[9] This relationship has been established for the crystals stable at room temperature. Our results strongly suggest that, if high-temperature forms are examined, isomorphism in molecular complexes may be observed more commonly than has been supposed.

When the interaction between the hydrocarbon molecule and the substituent on the acceptor molecule is specific or localized, the lattice may be rather rigid. The disappearance of this specific interaction above the transition temperature may be due to the onset of an anomalously great thermal motion of the component molecules. This motion appears so great that the interaction is dynamically averaged and becomes nonspecific. Such a thermal motion is expected to contribute significantly to the melting mechanism of the complexes. This speculation is supported by our observation that the enthalpy and entropy of melting of the present complexes are only 4—6 kcal mol^{-1} and 12—14 cal deg^{-1} mol^{-1} respectively (see Table 1). These values are definitely small if compared with the data for the eleven polycyclic aromatic hydrocarbon-trinitrobenzene complexes given by Casellato *et al.*[11] The enthalpy ranges from 6.5 kcal mol^{-1} for the phenanthrene complex to 14.5 kcal mol^{-1} for the dibenzoanthracene complex. The corresponding entropies are 14.9 and 28.5 cal deg^{-1} mol^{-1} respectively. The former complex is known to exhibit a polymorphic transition at 148 °C with an enthalpy value of about 3 kcal mol^{-1}. Apart from this, only the pyrene complex has an entropy value below 20 cal deg^{-1} mol^{-1}. The observed entropies can probably be divided unevenly among the donor and acceptor lattices. On the basis of the wide-line NMR measurements, the reorientation of the donor species in a number of molecular complexes has been suggested by Fyfe and others. It may be added that pyrene and its complexes are notable of this examples.[22-24] The present complexes are now being examined by this technique in our laboratory. The second moments are reduced to 1—2 G^2 at the transition temperatures in all the complexes.

Not only the mode of interaction between the donor and acceptor molecules, but also that between like molecules in a complex may be modified by the structural change upon the polymorphic transition. The charge-transfer absorption has a direct bearing upon the former interaction, and the electrical resistivity, upon the latter. Their temperature dependences may each show anomalies at the transition temperature; however, the magnitudes may be quite different. Consequently, studies of these two properties in parallel may be fruitful. As the only discernible change in the charge-transfer absorption was the intensification

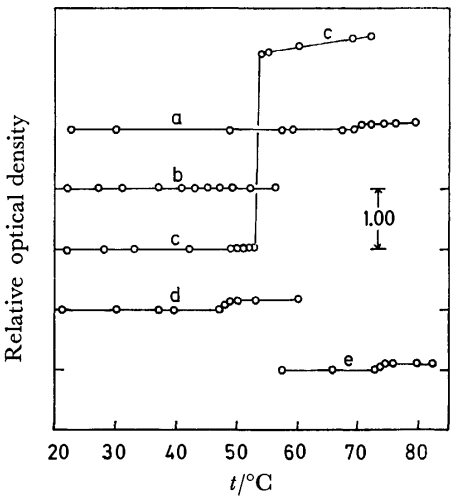

Fig. 3. Temperature dependence of the relative optical density of charge-transfer absorption in the pyrene complexes with a) DNF (at 390 nm), b) DNC (at 400 nm), c) DNT (at 413 nm), d) DNP (at 440 nm), and e) TNC (at 425 nm).

upon the transition, the optical density at the absorption maximum is plotted against the temperature in Fig. 3. The value of the low-temperature form was arbitrarily taken as 1.00 in this figure. The most pronounced change is found with the DNT complex. The optical density at 413 nm after the transition is as much as 4.25 times that before. After the transition, the optical density increases linearly with the temperature, the value at 74 °C being 4.80. The other extreme is observed with the DNC complex, which is known to show the smallest enthalpy of transition. The optical density remains constant throughout the transition. Although the other three complexes show large enthalpy changes upon the polymorphic transition, the increase in the optical density is only about 10% or less.

In Fig. 4, the variation in the electrical resistivity recorded at ascending temperatures is presented. The magnitude of resistivity varies greatly among the members of the series. Thus, the DNF complex is more conducting than TNC complex by a factor of 10^3. All the complexes exhibit abrupt decreases in the resistivities at the transition temperatures. Here again, the change observed with the DNT complex is the largest. Therefore, one may postulate that the donor-donor and/or acceptor-acceptor overlaps are considerably improved by the structural change, as is the overlap between the hydrocarbon and DNT molecules. The DNP complex shows a decrease in the resistivity by almost the same factor. In this case, like molecules presumably gain better overlaps by the transition, without any appreciable effect on the donor-acceptor interaction. It is interesting to point out that, in spite of having the largest enthalpy of transition, the DNF complex exhibits a decrease by merely a factor of five, and that this factor can be well compared with that observed with the DNC complex. The latter is the one with the smallest enthalpy of transition among the complexes studied here. However, we must be aware of a large difference in the magnitude of resis-

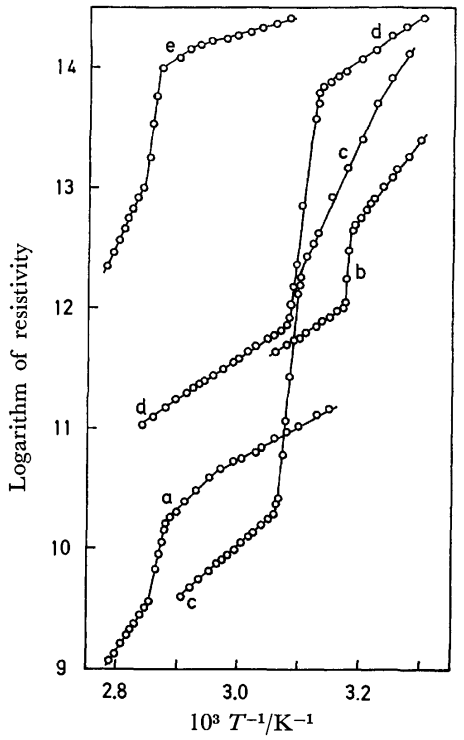

Fig. 4. Electrical resistivities of the pyrene complexes with a) DNF, b) DNC, c) DNT, d) DNP, and e) TNC.

tivity between these two. Since the DNF complex has a relatively low resistivity, the improvement of the overlap between like molecules in this complex cannot be compared with that of the DNC complex by such a factor. If one refers to the magnitude, it is certain that the resistivity change is particularly large for the DNF complex. The acceptor, TNC, is undoubtedly the strongest employed here; nevertheless, its pyrene complex is the least conducting one. The crowded substituents on this acceptor molecule seem to prevent good overlaps between like molecules in this complex. At descending temperatures, large hystereses were observed in all the cases because of a considerable delay in the transition in the reverse direction.

The authors wish to express their thanks to Professor Toshio Yokokawa for letting them use the X-ray diffractometer.

(Received May 30, 1977)

The vertical transition energies of both the Rydberg and valence-shell type transitions of CH_4 were calculated by the use of the *ab initio* SC-LCAO-MO method. We used Slater-type AO's as the basis AO's and added the extra-valence AO's (3s, 3p, 4s, and 4p) of a carbon atom to the minimal-basis set in order to express the Rydberg MO's. From the limited CI calculations, the mixing expressed in terms of the orthogonalized AO's between the Rydberg and valence-shell transitions was shown to be little. The lowest two absorption bands near 9.7 and 11.7 eV were identified as a 3s-like Rydberg transition with a 3p-like one and a 4s-like Rydberg transition with a 4p-like one respectively. The total energy and Mulliken population analysis were also calculated and compared with the results of the minimal-basis calculations.

The studies of the molecular Rydberg states, though not many, have been done continuously for a long time from both experimental and theoretical points of view.[1-15] Recently the Rydberg states of the methane molecule, as well as of water[5,9,15,16] and ethylene[12,16,17] molecules, have been studied in detail because of its simple molecular form. Methane has a diffuse but entirely structureless band system, with a maximum at 9.7 eV in its far ultra-violet absorption spectra.[8] Mulliken[1] identified this band as a $1t_2 \rightarrow 3s$ (Rydberg orbital) transition, using the united atom model. However, another assignment of the valence-shell transition, $1t_2 \rightarrow 2t_2$, is possible. Katagiri and Sandorfy,[18] in fact, carried out P-P-P-type semi-empirical calculations and obtained reasonable values of the transition energies for several *n*-alkanes. Ohmichi *et al.*[19] made modified CNDO calculations of several saturated compounds. They identified the absorption spectra of methane as being due to the valence-shell transitions, in agreement with the Katagiri and Sandorfy results. In 1971 Salahub and Sandorfy[13] carried out CNDO-type calculations with an extended-basis set (RCNDO), in which they used these extra-valence atomic orbitals: 3s and 3p AO's, for a carbon atom and 2s and 2p AO's for a hydrogen atom. The results show that the contribution of the Rydberg orbital to the first excited state of CH_4 is very low. From these semi-empirical calculations, it seems likely that the first band of CH_4 can be explained as the valence-shell transition. Pauzat *et al.*,[20] on the other hand, carried out non-empirical GTO-basis calculations of the ionization and transition energies of this molecule. They used a diffuse molecular orbital (Rydberg MO), as Salahub and Sandorfy did in their RCNDO calculations. The result for the first excited state gave features different from those of Salahub and Sandorfy in its Rydberg character. Williams and Poppinger also carried out non-empirical calculations of CH_4 and H_2O by means of the Equations of Motion and the configuration interaction (CI) method; they obtained a good agreement with the Pauzat *et al.* calculations.

From the experiments on the electron-impact spectra, Harshbager *et al.*[23] assigned the first band to the $1t_2 \rightarrow 3a_1$ (carbon 3s-like MO) Rydberg transition, which is split by Jahn-Teller distortion into two peaks, 9.7 eV and 10.3 eV. Furtheremore, they discussed the band near 11.7 eV and assigned it to the Rydberg transition from $1t_2$ to the carbon 4s-like MO. In our work we used, in order to clarify the nature of the excited states of CH_4, the extra-valence AO's, 3s, 3p, 4s, and 4p AO's of a carbon atom in addition to the minimal-basis set. The Slater-type AO's were used for these AO's. All the following orbital exponents of the STO's except the hydrogen 1s AO's are obtained from Slater's rules: $\delta_{1s}=5.7$, $\delta_{2s}=\delta_{2p}=1.625$, $\delta_{3s}=\delta_{3p}=0.4833$, and $\delta_{4s}=\delta_{4p}=0.3625$ for the carbon atom, and $\delta_{1s}=1.2$ for the hydrogen atom. The symmetry of the molecule is assumed to be T_d, and the nuclear distance is fixed as $R(\text{C–H})=2.05$ a.u.

Calculation and Discussion

The ordinary SC-LCAO-MO calculations are performed for the ground state by the use of the extended-basis set (minimal-basis set plus the extra-valence 3s, 3p, 4s, and 4p AO's of a carbon atom). All the molecular integrals are calculated by using the library program of the University of Tokyo Computer Centre (Y4/TC/ADO5), where the molecular integrals are calculated over the composite GTO's, so we expanded all s-type STO's by 8-terms of the GTO's and the 2p, 3p, and 4p STO's by 6, 6, and 4-terms of GTO's respectively.[27]

The orbital exponents of used AO's are not optimized; *i.e.*, they are fixed as Slater's values. Hosoya[25] calculated the orbital exponents of the carbon Rydberg AO's, *i.e.*, 3s, 3p, and 3d, by optimizing the one-electron energy. He expanded the Rydberg orbitals in terms of several STO's and thus obtained the values of 0.55 and 0.465 for 3s and 3p STO's respectively, which contribute mainly to the optimized Rydberg orbitals. These values are not very different from Slater's values. This shows that, for the orbital exponents of the extra-valence AO's we may use the values obtained from Slater's rules as the first approximation. The calculated SC-LCAO-MO's, both occupied and unoccupied, are shown in Table 1, along with the orbital and total energies. The predicted total energy of the ground state is lower than that of our previous minimal-basis calculations by only 0.0154 a.u.[21] This shows that the employment of the extended-basis set does not affect the total energy greatly. The resulting virtual MO's, however, turn out to be useful in the calculations of the transition energies, as will be shown below.

The gross atomic and bond populations found by Mulliken population analysis are as follows:

Table 1. The MO's and total energy of CH_4

Orbital energy and MO ε_i (a.u.)	1s	2s	3s	4s	2p	3p	4p	H
$-11.2869\,(1a_1)$	0.9953	0.0277	0.0000	0.0002	0.	0.	0.	−0.0058
$-0.9460\,(2a_1)$	−0.2050	0.6817	−0.0576	0.0355	0.	0.	0.	0.1588
$-0.5547\,(1t_2)$	0.	0.	0.	0.	0.5863	0.0372	−0.0193	0.2841
$0.0095\,(3a_1)$	0.0097	−0.0484	0.0002	0.9997	0.	0.	0.	0.0054
$0.0181\,(2t_2)$	0.	0.	0.	0.	−0.0135	−0.1878	1.1321	0.0022
$0.0608\,(4a_1)$	0.0584	−0.2422	1.5605	−1.1581	0.	0.	0.	−0.0212
$0.1049\,(3t_2)$	0.	0.	0.	0.	−0.2099	1.5695	−1.0389	0.1027
$0.6382\,(4t_2)$	0.	0.	0.	0.	1.1242	0.2167	−0.1202	0.6723
$0.8347\,(5a_1)$	0.1928	−1.7567	−0.5338	0.3168	0.	0.	0.	0.7704
Total energy				−40.1284 a.u.				

$n(\mathrm{C})=6.553$, $n(\mathrm{H})=0.862$, $n(\mathrm{C\text{-}H})=0.784$,

and

$n(\mathrm{H\text{-}H})=-0.042$.

Our previous minimal-basis calculations, on the other hand, gave the following results:

$n(\mathrm{C})=6.539$, $n(\mathrm{H})=0.865$, $n(\mathrm{C\text{-}H})=0.784$,

and

$n(\mathrm{H\text{-}H})=-0.042$.

There is little difference. The extra-valence AO's of the carbon atom seem to have no effect in the C–H binding. If we use the extra-valence AO's of the hydrogen atom also, an increase in the bond population may be expected.

The vertical transition energies are calculated by means of Eq. 1, using the virtual orbital approximation

$$\Delta E^{1,3}(i\rightarrow j) = \varepsilon_j - \varepsilon_i - (J_{ij}-K_{ij}) \pm K_{ij}, \qquad (1)$$

where ε_i, J_{ij} and K_{ij} are the orbital energies and the Coulombic and exchange integrals respectively, and where the plus sign of the last term holds for the singlet, and the minus sign for the triplet. The results are shown in Table 2, along with those of other calculations. In the case of the minimal-basis set, the vertical transition energy of the lowest excited state is calculated to be about twice the experimental value. Moreover, this value is higher than the ionization potential. These are common in other *ab initio* minimal-basis calculations.[20,22] The symmetry of the calculated lowest-excited-state is T_1, which is electronically forbidden. On the other hand, the extended-basis calculations bring in another profile of the predicted transition energies. The lowest value for the singlet state appears at 11.61 and 12.37 eV above the ground state with and without CI respectively; this agrees with the experiments fairly well. The symmetry of this state is T_2, which is an allowed transition. The excited states considered to be due to the valence-shell transitions are found at almost the same positions as in the minimal-basis calculations. The relative ordering of the predicted excited states is not necessarily the same in all types of methods and basis sets, but so long as we use the extended-basis set the lowest excited state can be calculated to be T_2 symmetry.[26] Pauzat *et al.*[20] calculated the vertical transition energies by taking into account the Rydberg orbitals, which were constructed by orthogonalizing them to the inner SCF-MO's by the Schmidt procedure. We have already used the carbon 3s, 3p, 4s, and 4p Rydberg AO's as the starting-basis ones, along with the minimal-basis set, in the calculations of the ground state. Therefore, the Rydberg orbitals are assumed to be the virtual SC-LCAO-MO's, and then they are automatically orthonormalized to the inner MO's. It is interesting that the virtual $3a_1$

a) From Table 5 in Ref. 20. b) Ref. 22. c) The parentheses in this table indicate the transition energies of the triplet states. d) The transitions are classified into three types of transitions; the first five transitions are from $1t_2$ to $3a_1$ or $2t_2$ MO's; the second five ones are from $1t_2$ to $4a_1$ or $3t_2$ MO's, and the remaining transitions are from $1t_2$ to $5a_1$ or $4t_2$ MO's.

MO has a strong resemblance to the 4s′ AO which is orthogonalized to the carbon inner 1s and 2s AO's, while the $4a_1$ MO is also like the 3s′ AO which is orthogonalized to the 4s′ AO as follows:

$$3s' = 1.553(3s) - 1.155(4s) - 0.286(2s) + 0.063(1s)$$

$$4a_1 = 1.561(3s) - 1.158(4s) - 0.242(2s) + 0.058(1s)$$

and

$$4s' = 1.014(4s) - 0.028(2s) + 0.006(1s)$$

$$3a_1 = 1.000(4s) - 0.048(2s) + 0.010(1s)$$

These correspondences hold between the $2t_2$ MO and the 4p′ AO, and the $3t_2$ MO and the 3p′ AO respectively: the 3p′ and 4p′ AO's are the orthonormalized AO's, like the above-mentioned 3s′ and 4s′ AO's. The other two virtual MO's, $4t_2$ and $5a_1$, are mainly constructed from the hydrogen 1s and carbon valence AO's.

The results of the CI calculations shown in Table 2 are obtained by means of a limited single-excitation CI. The lowering of the lowest excitation energy is considerable, and the mixing among the excited states seems to be large. Here let us examine six electronically allowed transitions in detail. Three of them (φ_1, φ_2, and φ_3) are one-electron transitions from the $1t_2$ to the $3a_1$, $4a_1$, and $5a_1$ MO's, while the others (φ_4, φ_5, and φ_6) are the transitions from the $1t_2$ to the $2t_2$, $3t_2$, and $4t_2$ MO's respectively. The CI results exhibit the following configuration mixings and transition energies:

$$^1\Psi_1 = 0.588\varphi_1 + 0.807\varphi_2 + 0.058\varphi_3 \quad \Delta E = 11.61\ \text{eV}$$

$$^1\Psi_2 = 0.809\varphi_1 - 0.586\varphi_2 - 0.043\varphi_3 \quad \Delta E = 13.56\ \text{eV}$$

$$^1\Psi_3 = 0.003\varphi_1 - 0.072\varphi_2 + 0.997\varphi_3 \quad \Delta E = 28.38\ \text{eV}$$

$$^1\Psi_4 = 0.683\varphi_4 + 0.726\varphi_5 - 0.075\varphi_6 \quad \Delta E = 12.57\ \text{eV}$$

$$^1\Psi_5 = 0.730\varphi_4 - 0.679\varphi_5 + 0.104\varphi_6 \quad \Delta E = 13.95\ \text{eV}$$

$$^1\Psi_6 = 0.075\varphi_4 + 0.073\varphi_5 - 0.995\varphi_6 \quad \Delta E = 23.84\ \text{eV}$$

for the singlet excited states. We showed previously that there was a likeness between the virtual MO's and the orthogonalized carbon extra-valence AO's, so we can estimate the Rydberg character of the above excited states in terms of the 3s′, 3p′, 4s′, and 4p′ orthogonalized AO's. The contribution of these AO's to each state is calculated approximately as follows:

$$^1\Psi_1 \approx 0.947(3s') - 0.226(4s')$$

$$^1\Psi_2 \approx 0.237(3s') + 0.965(4s')$$

$$^1\Psi_4 \approx 1.010(3p') + 0.012(4p')$$

$$^1\Psi_5 \approx 0.031(3p') - 1.008(4p')$$

From these coefficients of the orthogonalized AO's, four states, $^1\Psi_1$, $^1\Psi_2$, $^1\Psi_4$, and $^1\Psi_5$, are considered to be mainly constructed by the transitions of a $1t_2$ electron to 3s′, 4s′, 3p′, and 4p′, that is the Rydberg MO's, respectively. The remaining two states, $^1\Psi_3$ and $^1\Psi_6$, may be understood as valence-shell types (2s and 2p). We can say, from the above CI results and discussion, that the configuration mixing between the valence-shell and Rydberg transitions does not occur in these excited states of the methane molecule. For the six triplet states which correspond to the above six singlet excited states, the similar configuration mixings given below are obtained:

$$^3\Psi_1 = 0.547\varphi_1' + 0.832\varphi_2' + 0.093\varphi_3' \quad \Delta E = 11.42\ \text{eV}$$

$$^3\Psi_2 = 0.837\varphi_1' - 0.544\varphi_2' - 0.058\varphi_3' \quad \Delta E = 13.51\ \text{eV}$$

$$^3\Psi_3 = 0.002\varphi_1' + 0.109\varphi_2' - 0.994\varphi_3' \quad \Delta E = 25.99\ \text{eV}$$

$$^3\Psi_4 = 0.624\varphi_4' + 0.775\varphi_5' - 0.097\varphi_6' \quad \Delta E = 12.43\ \text{eV}$$

$$^3\Psi_5 = 0.781\varphi_4' - 0.619\varphi_5' + 0.087\varphi_6' \quad \Delta E = 13.86\ \text{eV}$$

$$^3\Psi_6 = 0.008\varphi_4' - 0.130\varphi_5' - 0.991\varphi_6' \quad \Delta E = 18.80\ \text{eV}$$

where the triplet functions, φ_i', are used instead of φ_i. The nature of each triplet state is almost the same as that of the corresponding singlet excited states.

With respect to these transition energies, it is found that the calculated singlet-triplet separation is very small for the Rydberg transitions, but it is quite large for the valence-shell transitions. The experimental values of the singlet-triplet separation are about 1 eV.[24] In order to explain the experimental values, we may need moderate diffuse orbitals for the triplet excited states.

TABLE 3. COMPARISON WITH EXPERIMENTS (eV)

State	Transition type	Calcd	Exptl[a]
$^1\Psi_1$	$1t_2 \longrightarrow 3s'$	11.61	9.7, 10.3
$^1\Psi_4$	$1t_2 \longrightarrow 3p'$	12.57	
$^1\Psi_2$	$1t_2 \longrightarrow 4s'$	13.56	11.7
$^1\Psi_5$	$1t_2 \longrightarrow 4p'$	13.95	

a) Ref. 23.

The vertical transition energies of the four lowest allowed-transitions are summarized in Table 3, along with the experimental values. We may assign the band at 9.7 eV to the $1t_2 \rightarrow 3s'$ Rydberg transition ($^1\Psi_1$): this conflicts with the semi-empirical calculations, but agrees with other extended basis non-empirical calculations. Similarly the band at 11.7 eV is assigned to the $1t_2 \rightarrow 4s'$ Rydberg transition ($^1\Psi_2$) by a comparison with the experimental and calculated energy separation. Two states, $^1\Psi_4$ and $^1\Psi_5$, will overlap with the above two bands respectively. No discussions of the oscillator strength for each allowed transition and the vibronic interactions of the forbidden transitions is given here, so the above assignments of the absorption bands of CH_4 are somewhat qualitative, but they do confirm Hashbarger and Lassetre electron-impact experiments.[23]

The calculations were carried out on the HITAC 8700/8800 Computer at the University of Tokyo Computer Centre. The authors are very grateful to Professor Hiroshi Taketa for his helpful communications about the use of the program (Y4/TC/ADO5: Molecular Integrals over CGTO).

A Molecular Orbital Study of the Partial Reactivity of the Hydrogen of Aliphatic Compounds in the Hydrogen-abstraction Reaction by the Hydroxyl Radical

Hiroyuki SHINOHARA, Akira IMAMURA*, Takahiro MASUDA, and Masaharu KONDO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158

** Shiga University of Medical Science, Seta, Otsu, Shiga 520-21*

(Received June 13, 1977)

The energy required to stretch a C–H bond of alkanes by 0.5 Å from an equilibrium bond length was calculated by the INDO method, and it was found that this energy has a relation with the delocalizability, D_r^R, of hydrogen atoms in alkanes, and with the activation energy for the hydrogen-abstraction reaction of the methyl radical from alkanes. The reactivities of hydrogen atoms in aliphatic alcohols and carboxylate ions, as defined by this energy were found to correlate with the partial reactivities of hydrogen atoms, just as was proposed by Anbar *et al.*, *i.e.*, the rate constants for the hydrogen-abstraction reaction of aliphatic compounds with hydroxyl radicals can be well explained by a summation of the partial reactivities assigned to primary, secondary, and tertiary hydrogen atoms bound to α- or β- (for γ-CH and δ-CH the same value as for β-CH was used) carbon atoms.

It is well established that a hydroxyl radical abstracts a hydrogen atom from C–H bonds of aliphatic alcohols and carboxylate ions. Furthermore, it is well known that the reactivity of an aliphatic compound toward the hydroxyl radical increases with an increase in the number of C–H bonds in a molecule.

Anbar *et al.*[1] determined the rate constants for the reactions of a large number of aliphatic compounds with hydroxyl radicals, and pointed out that the reactivities of long-chain compounds could be calculated by a summation of the assigned partial reactivities of the hydrogen atoms in the molecule. They proposed the following partial reactivities for the hydrogen atoms of carboxylate ions, by the best fit of simultaneous equations derived from the experimental rate constants: (a) the partial reactivities of the hydrogen atoms in the α-position to the carboxyl group are estimated to be 0.235, 2.94, and 8.90×10^8 l mol^{-1} s^{-1} per H atom for the primary ($CH_3CO_2^-$), the secondary ($RCH_2CO_2^-$), and the tertiary ($R_2CHCO_2^-$) hydrogens respectively; (b) the partial reactivities of the hydrogen atoms in the positions other than α are also estimated to be 0.606, 5.05, and 14.1×10^8 l mol^{-1} s^{-1} per H atom for the primary, secondary, and tertiary hydrogens respectively. The originally reported values are corrected by a factor of 1.68, because the rate constant for the reaction of the hydroxyl radical with ethyl alcohol, which was used as a reference substance in their determination of the rate constants, has recently been revised from 1.1×10^9 to 1.85×10^9 l mol^{-1} s^{-1}.[2]

The rate constants calculated from these partial reactivities have been proved to interpret the experimental values successfully. Therefore, it is helpful to investigate the theoretical basis of the assigned partial reactivities from the viewpoint of the molecular orbital method.

In chemical reactions, the delocalization of electrons between reactant and reagent is recognized as the major factor in determining the reactivity.[3,4] Therefore, a hydroxyl radical as well as a reactant should be included in the calculation of the reactivity of the hydrogen atom in order to take the delocalization of electrons into account. However, the total energy of the system including a hydroxyl radical and a reactant can not always be obtained because of the divergent behavior in SCF calculation. In a previous paper,[5] we showed that the reactivity of the hydrogen atom (ΔE), defined as the energy required to stretch a C–H bond by 0.5 Å from the equilibrium bond length, has a close relation with the energy for the hydrogen-abstraction reaction (ΔE_{OH}), calculated from the system including a hydroxyl radical and an amino acid. Therefore, it can be expected that ΔE gives a measure of the reactivity of the hydrogen atom in alcohols and carboxylate ions toward the hydroxyl radical in the present hydrogen-abstraction reaction.

Actually the present results show that ΔE is related to the natural logarithm of the partial reactivities of the primary, secondary, and tertiary hydrogen atoms bound to the α- and β- carbon atoms which were proposed by Anber *et al.*[1]

Method

The total energies were calculated by the INDO method proposed by Pople *et al.*[6]

Results and Discussion

Methyl alcohol, ethyl alcohol, propyl alcohol, isopropyl alcohol, and isobutyl alcohol were taken as a series of alcohols, and acetate, propionate, butyrate, isobutyrate, and isovalerate ions were taken as a series of carboxylate ions. The geometries of these compounds used for the calculation are indicated in Fig. 1. The reactivity of the hydrogen atom expressed by ΔE is calculated by means of Eq. 1;

$$\Delta E = E(\text{C-H } 1.60) - E(\text{C-H } 1.10) \quad (1)$$

where E(C–H 1.60) is the total energy calculated by stretching the C–H bond by 0.5 Å in its singlet state, and E(C–H 1.10) is that at the equilibrium C–H distance in alcohols and carboxylate ions (assumed to be 1.10 Å). In order to examine the validity of ΔE for expressing the reactivity of the hydrogen atom in the hydrogen-abstraction reaction, we compared the ΔE of hydrogen atoms of alkanes with the activation energy for the hydrogen-abstraction reaction of the methyl radical and alkanes. As is shown in Table 1, the order of reactivity for primary, secondary, and tertiary hydrogen atoms is well explained by ΔE, and Fig. 2 shows

a linear relationship between ΔE and the activation energy.

It is well known that the delocalizability, D_r^R, reprsented by Fukui *et al.*[7,8] has successfully been used to interpret the reactivity of saturated compounds toward several radicals.[7,8] As is shown in Table 1 and Fig. 3 for alkanes, ΔE is found to have a close relation with the D_r^R calculated by Kato *et al.*[8] Although the correlation shown in Table 1 cannot be taken as direct evidence for ΔE as a measure of the reactivity, the present result and the observed correlation between ΔE and ΔE_{OH} calculated for the partial reactivities of hydrogen atoms in amino acids[5] may support the validity of ΔE for the present purposes. The reactivities of hydrogen atoms in alcohols defined by ΔE are shown in Table 2, while Table 3 shows the result for carboxylate ions. It was suggested that hydrogen atoms bound to the identical carbon atom have different reactivities, depending on the orientation in the molecule;[9] a similar tendency is observed in the

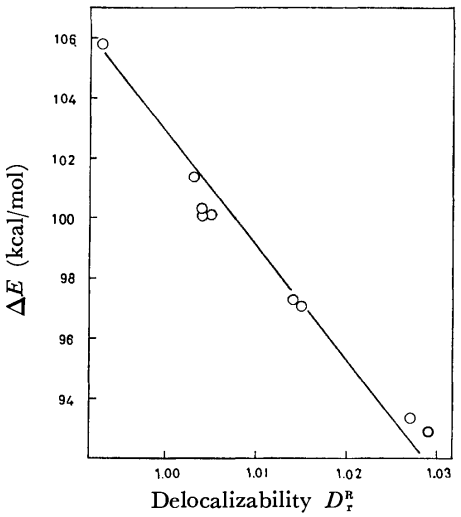

Fig. 3. The linear relationship between ΔE and Delocalizability D_r^R for alkanes.

TABLE 2. THE REACTIVITIES OF HYDROGEN ATOMS OF ALCOHOLS DEFINED BY ΔE

Alcohol	Type of C-H bond		ΔE (au)
CH_3OH	H^4	α-primary	0.1623
	H^5	α-primary	0.1584
C_2H_5OH	H^5	α-secondary	0.1516
	H^7	β-primary	0.1622
	H^8	β-primary	0.1637

	H^6	α-secondary	0.1510
	H^7	β-tertiary	0.1498

cases of both alcohols and carboxylate ions. As the β-primary H^7 and H^8 atoms of ethyl alcohol (also the α-primary H^4 and H^5 atoms of methyl alcohol) have different reactivities, we approximate the reactivity of the β-primary hydrogen atom to the average reactivity of H^7 and H^8 atoms by the assuming Maxwell-Boltzmann distribution in order to compare ΔE with the partial reactivities; Table 4 shows the results. The same approximation was used for carboxylate ions. It is well known that, in hydrogen-abstraction reactions of radicals from alkanes, the reactivities of hydrogen atoms increase in this order; primary<secondary<tertiary, and that a similar tendency is observed for hydrogen atoms in the α-position and β-position of alcohols, as is shown in Table 4. The results for carboxylate ions are shown in Table 5 and Fig. 5. Although

points are scattered, a fairly good correlation was found as a whole.

Asmus *et al.*[10] investigated the reaction site of aliphatic alcohols in the reaction with the hydroxyl radical by means of pulse radiolysis, and found that the main reaction is the abstraction of the hydrogen atom from the α-position, but hydrogen abstraction also occurs at β-, γ-, ··· positions with an increase in the number of carbon atoms. Moreover, they determined the relative probabilities of hydrogen abstraction from the α-positions of various alcohols. For example, 84.3, 53.4, 85.5, and 41.0% are obtained for C_2H_5OH, n-C_3H_5OH, $(CH_3)_2CHOH$, and n-C_4H_9OH respectively. The probabilities can be evaluated from the partial reactivities proposed by Anbar *et al.* to be 90.2, 58.5, 80.3, and 43.4% for the above alcohols respectively.

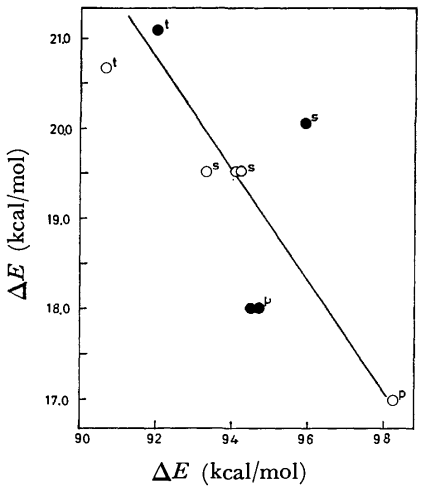

Fig. 5. The relation between ΔE and the partial reactivities of hydrogen atoms in carboxylate ions. ○: α-, ●: β-, p: primary, s: secondary.

This correlation between the observed and the estimated relative probabilities may support the idea that the reactivity of a molecule can be divided into partial reactivities. Furthermore, as is shown in Table 4, the value of ΔE calculated for the α-secondary hydrogen atom of ethyl alcohol is nearly equal to that for the α-secondary hydrogen atom of propyl alcohol or isobutyl alcohol. Similarly, the ΔE for the β-primary hydrogen atom of ethyl alcohol is approximately equal to that for the β-primary hydrogen atom of isopropyl alcohol. For hydrogen atoms in the γ-, δ-, $\cdots$ positions, the same partial reactivities as those for the β-positions are used in the paper of Anber *et al.* The values of ΔE calculated for the β-primary and γ-primary hydrogens may confirm this assignment (Table 4). A similar argument is possible for carboxylate ions (Table 5), although there remains a discrepancy between β-primary and γ-primary hydrogens.

Consequently, the present work, which takes the orientation of hydrogen atoms into consideration, supports the idea that, in hydrogen-abstraction reaction of the hydroxyl radical, the whole reactivity of a molecule can be understood in terms of the partial reactivities assigned to each site of the reaction in the molecule.

The calculations were carried out on the FACOM 230-75 computer of the Computer Center of Kyoto University. The research was supported, in part, by Scientific Grants (139012 and 038012) from the Ministry of Education, Culture and Sciences.

Far Infrared Reflection Spectra and Lattice Vibrations of $CsNiCl_3$ Crystal

Kenji AKIYAMA, Yoshiyuki MORIOKA, and Ichiro NAKAGAWA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received July 7, 1977)

The frequencies of the transverse (TO) and longitudinal (LO) modes of the infrared active vibrations of the crystal $CsNiCl_3$ were obtained from the polarized far infrared reflection spectra. The polarized Raman spectra were also measured. The calculation of the TO and LO frequencies near the center of the Brillouin zone was made on the basis of a rigid ion model which includes effective ionic charges and interionic repulsive force constants. A set of potential constants and effective ionic charges were determined from the observed values of the TO and LO frequencies and Raman frequencies using the least-squares method. The short-range force constant associated with the nickel ion to the chlorine ion indicates that some amount of covalent character is included in this bond.

Cesium nickel trichloride, $CsNiCl_3$, is a so-called ionic crystal which has a hexagonal perovskite-like structure. A large number of double salts of the AMX_3 type (where A is a large univalent cation, M a divalent metal ion and X a halogen ion) are isomorphous to $CsNiCl_3$. The infrared spectra of these crystals reported, however, have been restricted to the transmission spectra of powder samples.[1] McPherson and Chang reported the infrared transmission spectra of powder sample of $CsNiCl_3$.[1] Adams and Smardzewski studied the polarized far infrared transmission spectra of a thin film of $(CH_3)_4NMnCl_3$,[2] the structure of which is closely related to that of $CsNiCl_3$.

Each of the transverse(TO) and the longitudinal (LO) frequencies of the infrared active modes can be determined by the infrared reflection spectra. In the present study we have measured the polarized far infrared reflection spectra and polarized Raman spectra of $CsNiCl_3$. Using the observed frequencies of the normal modes, the short-range potential constants and the effective ionic charges were obtained by means of the normal coordinate analysis for the optically active lattice vibrations.

The crystal structure of $CsNiCl_3$ as shown in Fig. 1 belongs to hexagonal system with the space group D^4_{6h} ($P6_3/mmc$).[3] Bravais unit cell consists of two formula units of $CsNiCl_3$. In this hexagonal structure, the nickel ions are located in the center of octahedra formed by chlorine ions and the chains of slightly compressed $NiCl_3$ octahedra sharing opposite faces run along the c axis of the crystal. The cesium ions are on the planes formed by three chlorine ions. The result of the factor group analysis on the basis of this structure is summarized in Table 1.

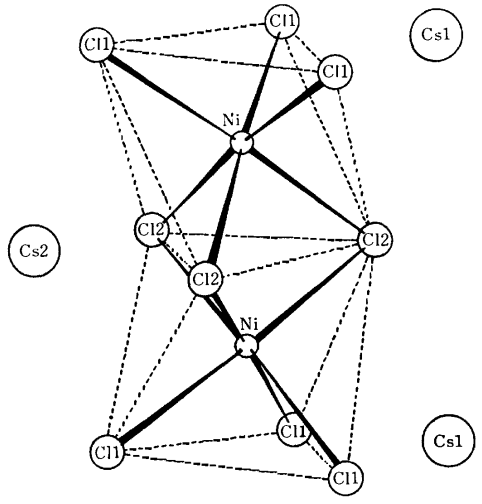

Fig. 1. Crystal structure of $CsNiCl_3$.

Experimental

Sample Preparation. The powder sample of $CsNiCl_3$ was crystallized by evaporation from the hot concentrated aqueous solution of CsCl and $NiCl_2$ in a 1 : 1 mole ratio, and was heated in vacuum for several hours. Completely dehydrated salt was molten in vacuum, filtered through quartz wool and sealed into quartz ampoule. The single crystal was grown from the molten salt by the Bridgman method. Crystal cleaves readily along the (110) plane and this cleavage plane was used for reflection measurement without polishing. For the Raman measurement, the single crystal was polished to a cube, three planes of which were parallel to (100), (001) and (010) planes, respectively.

Spectral Measurement. Polarized far infrared reflection spectra were recorded using a Hitachi 070 far infrared interferometer equipped with a wire-grid polarizer. The reflectivities for the lights polarized perpendicular and parallel to the c axis were measured. The incident angle was fixed at about 20°. The infrared transmission spectrum of the Nujol mull of powder sample was also measured. The polarized Raman spectra of the single crystal were measured by a Narumi double monochromator with a 632.8 nm line

of a He–Ne laser as a source.

Results

Figures 2a and 3a show the observed reflectivities for the lights polarized perpendicular and parallel to the c axis, respectively. The refractive index n, the absorption index k, and the real and imaginary parts of the dielectric constant, ε' and ε'', were obtained from the observed reflectivities using the Kramers-Kronig relation assuming the normal incidence.[4] The obtained results are shown in Figs. 2 and 3 together with the observed reflectivities. The TO frequencies are given by the maxima of the imaginary part of the dielectric constant and the corresponding LO frequencies are given by the frequencies where the real part of the dielectric constant becomes zero in changing from negative to positive values.[5] However, in the frequency region 270—100 cm^{-1} of Fig. 2c the real part of the dielectric constant does not become zero, and the OL frequency 180 cm^{-1} for ν_9(LO) was obtained by the frequency where Im$(-1/\varepsilon)$ has maximum value.[6]

It is clear that the TO and LO frequencies obtained from the reflectivities for the lights polarized perpendicular and parallel to the c axis correspond to the E_{1u} and A_{2u} modes of the factor group D_{6h}, respectively. The all infrared active vibrational modes predicted from the factor group analysis shown in Table 1 have been observed. The assignment of the five observed TO frequencies to the symmetry species is consistent with that of $(CH_3)_4NMnCl_3$ by Adams and Smardzewski, although the structures of $CsNiCl_3$ and $(CH_3)_4N$-

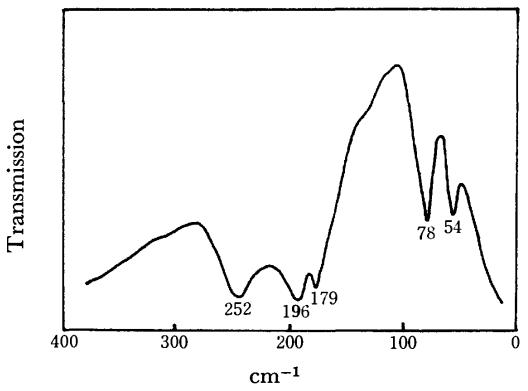

Fig. 4. Transmission spectrum of the powder sample of $CsNiCl_3$.

$MnCl_3$ are not exactly the same.

A short comment should be made on the transmission spectrum of the powder sample. Our result of the powder sample shown in Fig. 4 is in agreement with the spectrum by McPherson and Chang. The maximum absorption frequencies are slightly higher than the TO frequencies determined from the reflection spectra, which may be attributable to the crystal size effect.[7]

Figure 5 shows the observed Raman spectra in which the notations by Damen *et al.*[8] are indicated. On the basis of the Raman tensors of D_{6h} symmetry shown in Table 1 the bands at 264 and 140 cm^{-1} are assigned to the A_{1g} and E_{1g} modes, respectivery, and the bands at 190 and 52 cm^{-1} are assigned to the E_{2g} modes. Observed frequencies and vibrational

assignments are summarized in Table 2.

Normal Coordinate Analysis

Optically active vibrational frequencies are calculated according to the method of Shimanouchi, Tsuboi and Miyazawa.[9] Equations of motion for a rigid ion model are written in terms of the Cartesian displacement coordinates of component ions of a whole crystal;

$$4\pi^2\nu^2\boldsymbol{MX} = (\boldsymbol{F}_x^R + \boldsymbol{F}_x^C)\boldsymbol{X}, \quad (1)$$

$$\boldsymbol{F}_x^C = \boldsymbol{ZCZ}, \quad (2)$$

where $\boldsymbol{X}$ is column matrix corresponding to the Cartesian displacement coordinates and $\boldsymbol{M}$ and $\boldsymbol{Z}$ are the diagonal matrices specifying the masses and ionic charges. $\boldsymbol{F}_x^R$ and $\boldsymbol{F}_x^C$ (or $\boldsymbol{C}$) denote the short-range repulsive potential and the long-range Coulomb potential, respectively. The secular equation

$$|\boldsymbol{M}^{-1}(\boldsymbol{F}_x^R + \boldsymbol{F}_x^C) - \boldsymbol{E}\lambda| = 0 \quad (\lambda = 4\pi^2\nu^2), \quad (3)$$

is set up and the TO and LO frequencies of crystal are calculated.

Since the TO-LO splittings for the infrared active modes arise from the macroscopic electric field, the effective ionic charges are estimated by using the TO-LO splitting. The relation between the effective ionic charges and the TO-LO splittings is derived as[10]

$$8\pi\left(\frac{e_{Ni}^2}{m_{Ni}} + \frac{e_{Cs}^2}{m_{Cs}} + \frac{3e_{Cl}^2}{m_{Cl}}\right)\Big/ v_a = \sum_i \lambda_i^2(\mathrm{LO}) - \sum_i \lambda_i^2(\mathrm{TO}), \quad (4)$$

where m_{Ni}, m_{Cs}, and m_{Cl} are atomic masses, e_{Ni}, e_{Cs}, and e_{Cl} are effective ionic charges, v_a is the volume of the Bravais unit cell and λ_i is the frequency parameter ($\lambda_i = 4\pi^2\nu_i^2$) of the i-th vibration. For a condition of the electrical neutrality of a crystal as a whole, the effective ionic charges must satisfy the relation

$$Z_{Cs} + Z_{Ni} + 3Z_{Cl} = 0, \quad (5)$$

where $Z_i e = e_i$ (i=Ni, Cs, and Cl). From Eqs. 4 and 5, the relation among Z_{Ni}, Z_{Cs}, and Z_{Cl} is determined and therefore only one Z_i of the three becomes independent.

The long-range Coulomb part $\boldsymbol{F}_x^C$ is calculated from the effective ionic charges and the $\boldsymbol{C}$ matrix, which is obtained using Ewald's transformation according to the method derived by Kellerman.[11]

As for the short-range part $\boldsymbol{F}_x^R$, two different model force fields have been applied.

Case I; The central force type potential was assumed for all the interionic interactions.

Case II; The valence force type potential for the $NiCl_6$ structure and the central force type potential for the ion pairs, for which the nonbonded repulsions or the ionic interactions are expected to be appreciable, were assumed.

In case I, the potential energy of the crystal is given as

$$V = \frac{1}{2}\sum_{lk}\sum_{l'k'}{}' \varphi_{kk'}(r(lk:l'k')), \quad (6)$$

where $\varphi_{kk'}$ is the interaction potential between the k-th and k'-th ions and $r(lk:l'k')$ is the instantaneous distance between the k-th ion in the l-th unit cell and the k'-th ion in the l'-th unit cell. The short-range potential $\varphi_{kk'}$ is a function of only the distance between the two ions. The matrix elements of the short range part $\boldsymbol{F}_x^R$ are given as;

$$F_x^R(k\alpha,k'\beta) = -\sum_{l'}\left\{\frac{x_\alpha x_\beta}{r^2}\left[\varphi''_{kk'}(r) - \frac{1}{r}\varphi'_{kk'}(r)\right] + \frac{\delta_{\alpha\beta}}{r}\varphi'_{kk'}(r)\right\}\Big|_{r=r_0(lk:l'k')}$$

$$F_x^R(k\alpha,k\beta) = \sum_{k'(\neq k)}{}' F_x^R(k\alpha,k'\beta), \quad (7)$$

where $r_0(lk:l'k')$ denotes $r(lk:l'k')$ in the equilibrium arrangement and x_α is the α-Cartesian component

(α=x, y, and z) of $r_0(lk:l'k')$.

The ion pairs within a distance of 4.0 Å were taken into account, since the short-range repulsive force may become significant in this interionic distance. The following ten potential constants were taken;

$$K_1 = [\varphi''(\text{Ni-Cl})(r)]_{r=r_0(\text{Ni-Cl})},$$

$$k_1 = \left[\frac{1}{r}\varphi'(\text{Ni-Cl})(r)\right]_{r=r_0(\text{Ni-Cl})},$$

$$K_3 = [\varphi''(\text{Cs-Cl})_{\text{II}}(r)]_{r=r_0(\text{Cs-Cl})_{\text{II}}},$$

$$k_3 = \left[\frac{1}{r}\varphi'(\text{Cs-Cl})_{\text{II}}(r)\right]_{r=r_0(\text{Cs-Cl})_{\text{II}}},$$

$$K_4 = [\varphi''(\text{Cl-Cl})_{\text{I}}(r)]_{r=r_0(\text{Cl-Cl})_{\text{I}}},$$

$$k_4 = \left[\frac{1}{r}\varphi'(\text{Cl-Cl})_{\text{I}}(r)\right]_{r=r_0(\text{Cl-Cl})_{\text{I}}},$$

$$K_5 = [\varphi''(\text{Cl-Cl})_{\text{II}}(r)]_{r=r_0(\text{Cl-Cl})_{\text{II}}},$$

$$k_5 = \left[\frac{1}{r}\varphi'(\text{Cl-Cl})_{\text{II}}(r)\right]_{r=r_0(\text{Cl-Cl})_{\text{II}}},$$

where subscripts I and II denote the inter-layer and intralayer ion pairs, respectively. (According to the numbering of the atoms in Fig. 1, the inter-layer ion-pairs include those of Cs_1–Cl_1, Cs_2–Cl_2, Cl_1–Cl_1, and Cl_2–Cl_2, and the intralayer ion pairs include those of Cs_1–Cl_2, Cs_2–Cl_1, and Cl_1–Cl_2). The interionic distances in the equilibrium arrangement are listed in Table 3.

There are 11 parameters to be determined; ten are the short-range repulsive force constants and one is the effective ionic charge. In the actual procedure, K_4, K_5, k_4, and k_5 were estimated from the nonbonded chlorine-chlorine interaction potential of Lennard-Jones 6—12 type,[12] and k_2 and k_3 were fixed -0.01 mdyn/Å and -0.006 mdyn/Å, respectively, which correspond to the values for -0.1 K_2 and -0.1 K_3*.

The long-range Coulomb part was calculated from various sets of Z_i's and in each case the short-range repulsive force constants were determined by the least squares method using the observed vibrational frequencies. It was found that among the various sets of Z_i's only those for $Z_{\text{Cl}}=-0.6$——-0.7 are physically significant. For the value of Z_{Cl} larger than -0.6 the effective ionic charge of cesium ion becomes negative and for the value smaller than -0.7, no physically significant frequencies are obtained for the low-frequency vibrational modes.

The set of the effective ionic charges shown in Table 3 gives a most satisfactory result. (The sum of the square deviations of the calculated frequencies from the observed ones becomes minimum for this set of Z_i's when Z_{Cl} is varied from -0.6 to -0.7). The calculated frequencies and the obtained short-range repulsive force constants are shown in Tables 2 and 3 as case I, respectively.

In case II, the short-range potential function is given as:

$$V = \frac{1}{2}\sum K_1(\Delta r^i_{\text{Ni-Cl}})^2 + \frac{1}{2}\sum H_1(r^\circ_{\text{Ni-Cl}}\Delta\alpha^i(\text{Cl}_1\text{-Ni-Cl}_1))^2 + \frac{1}{2}\sum H_2(r^\circ_{\text{Ni-Cl}}\Delta\alpha^i(\text{Cl}_1\text{-Ni-Cl}_2))^2 + \frac{1}{2}\sum K_2(\Delta r^i_{(\text{Cs-Cl})_{\text{I}}})^2 + \frac{1}{2}\sum K_3(\Delta r^i_{(\text{Cs-Cl})_{\text{II}}})^2 + \frac{1}{2}\sum K_4(\Delta r^i_{(\text{Cl-Cl})_{\text{I}}})^2 + \frac{1}{2}\sum K_5(\Delta r^i_{(\text{Cl-Cl})_{\text{II}}})^2, \quad (8)$$

where K_1 is the Ni–Cl bond stretching force constant, K_2 and K_3 are those for the interaction between the cesium and chlorine ions, K_4 and K_5 are the repulsive force constants between two chlorine ions and H_1 and H_2 are the Cl_1–Ni–Cl_1 and Cl_1–Ni–Cl_2 bending force constants. The calculated frequencies and the force constants obtained by the least-squares method are shown in Tables 2 and 3 as case II, respectively.

In the procedure of the force constant calculation mentioned above, 4 force constants in case I and 5 force constants in case II were determined by the least-squares method using 14 observed frequencies. The standard deviations are given for these force constants in Table 3.

TABLE 3. DETERMINED SHORT-RANGE FORCE CONSTANTS AND EFFECTIVE IONIC CHARGES

Short range force constants				Corresponding interionic distances (Å)
Case I (mdyn/Å)		Case II (mdyn/Å)		
K_1	0.764(±0.043)	K_1	0.739(±0.048)	2.44
K_2	0.096(±0.022)	K_2	0.085(±0.020)	3.57

Throughout this paper 1Å=0.1 nm, 1 mdyn/Å=10^2N/m.
The values in parentheses denote standard deviations.

Discussion

The spectrum consisting of the five TO vibrations (two A_{2u} and three E_{1u} modes) as shown in Figs. 2, 3, and 4 reveals a typical feature characteristic of the two-layer type of the AMX_3 perovskite structure. The powder transmission spectrum of $CsNiF_3$ which has the same structure is similar to that of $CsNiCl_3$, although the lowest band was not observed for $CsNiF_3$ due to the limitation of the utilized spectrometer.[14]

The observed infrared and Raman frequencies are well explained by the model used in the calculation.

* The values of k_2 and k_3 do not affect the calculated frequencies significantly. Here, the same assumption as in the case of CdX_2 was made.[13]

This model is simple but it includes both the short-range potential and the long-range Coulomb potential in terms of effective ionic charges and explains quantitatively the splittings of the TO and LO frequencies.

In Table 2 the calculated frequencies by the converged set of force constants are not very different in both cases. The short-range potential of the type in case II has been often used for the complex salts such as K_2PtCl_6 and it has been found that this type of the potential is quite satisfactory to interpret the lattice vibrations due to the interaction between the complex ion and the outer ion as well as the intra-ligand vibrations. However, in the case of more ionic crystals like $CsNiCl_3$, the central force type potential may be more adequate for the analysis of the interionic vibrations. In this type of the potential the first derivatives of the interionic potential $\varphi'_{kk'}$ cannot be neglected. In $CsNiCl_3$, k_1, which corresponds to the first derivative of the interaction potential between the Ni and Cl ions, amounts to a significant value as shown in Table 3. A physically significant K_1 value (the second derivative of the Ni–Cl interaction potential) may be obtained, by taking k_1 into consideration. The neglect of the first derivatives in the central force potential cannot explain both Raman and infrared observed frequencies simultaneously, as in the case of CdX_2.[13]

The value of the Ni–Cl stretching force constant K_1 is obtained as 0.764 mdyn/Å in case I and 0.739 mdyn/Å in case II. These values are definitely smaller than the value 1.8 mdyn/Å of the Ni–C stretching force constant in $Ni(CO)_4$[15] but are comparable to the value 0.977 mdyn/Å for the Ni–F stretching force constant in $KNiF_3$,[16] indicating that some amount of covalent character is included in the Ni–Cl bond.

The ionic displacements for each vibration are shown in Fig. 6 on the basis of the eigenvectors L_x for the secular equation (3). The $\nu_5(E_{2g})$, $\nu_7(A_{2u})$, and ν_{10} (E_{1u}) are the translational lattice modes, and the others are the vibrations of the $NiCl_6$-octahedra. The Ni–Cl stretching and Cl–Ni–Cl bending vibrations are not clearly distinguished unlike those for the cubic perovskite fluorides. However, the $\nu_6(A_{2u})$ and $\nu_8(E_{1u})$ modes may have the nature of the Ni–Cl stretching vibration considering the potential energy distribution.

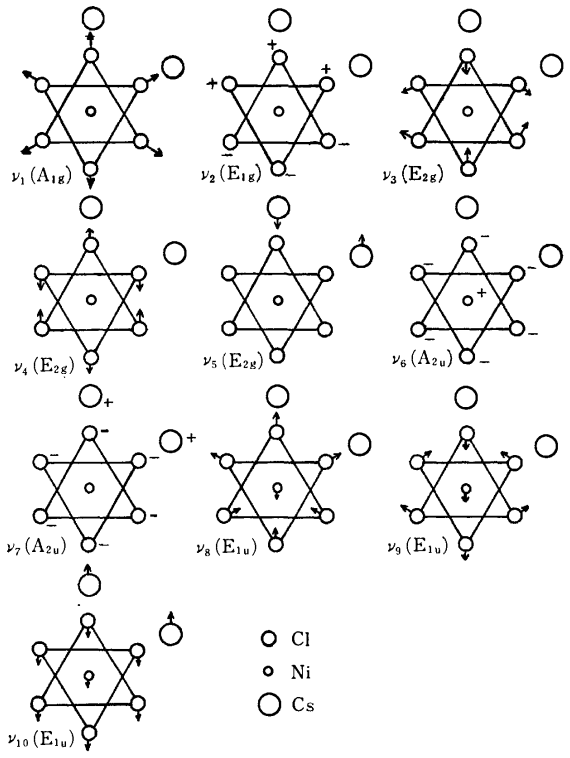

Fig. 6. Displacement of ions for infrared and Raman active vibrations of $CsNiCl_3$ crystal. Projection on the (001) plane.

The authors wish to express their thanks to Professor Mitsuo Ito of Tohoku University for permitting us to use the Raman spectrometer in his laboratory.

(Received August 18, 1977)

Infrared and Raman spectra of hydantoin and its *C*- and *N,N'*-deuterated derivatives in the solid state have been recorded. The fundamental frequencies were assigned by referring to isotopic frequency shifts and vibrational spectra of related compounds. Normal coordinate analysis was carried out by using a planar C_s molecular model. A simple Urey-Bradley force field was used for the stretching and the bending coordinates and a valence force field for the out-of-plane deformation and the torsional coordinates. The force constants were refined by the least squares method to reproduce the observed frequencies

We investigated vibrational spectra and force constants of ethyleneurea, $\boxed{-CH_2CH_2NHCONH-}$, regarding it as a basic compound of ring urea derivatives.[1] Since then we have carried out a detailed vibrational analysis of hydantoin (2,4-imidazolidinedione), $\boxed{-CH_2CONHCONH-}$, which is of biological interest because of its structural analogy to nucleic bases and the anticonvulsive activity of a number of its derivatives.

Infrared and Raman spectra of hydantoin, H-d_0, *C*-deuterated hydantoin, HC-d_2, *N,N'*-deuterated hydantoin, HN-d_2, and perdeuterated hydantoin, H-d_4, were recorded and a normal coordinate analysis based on a modified Urey-Bradley force field was carried out for the four isotopic hydantoins. The force constants fitting the observed frequencies reflect the structural difference between hydantoin and ethyleneurea.

Experimental

Reagent grade H-d_0 (Tokyo Kasei Co.) was recrystallized four times from water. For the preparation of HC-d_2, a mixture of purified H-d_0 (5 g) and 30% D_2SO_4 in D_2O (Merck AG., 10 ml) was warmed at 80 °C in a sealed ampoule for 8 h. The solution was cooled on an ice bath, and the resulting solid was filtered quickly, washed with heavy water and dried under reduced pressure. The procedure was repeated four times until the infrared absorptions due to the CH_2 bending and wagging vibrations became hardly detectable. The yellowish crude product was purified by recrystallization from water: yield 1 g. The *N,N'*-deuteration of H-d_0 and HC-d_2 was carried out by the exchange reaction with heavy water.

The infrared spectra were recorded on a JASCO A-2 and a Hitachi FIS-3 grating spectrophotometers for the samples in Nujol and hexachlorobutadiene mulls. The frequencies were calibrated by the standard absorptions of polystyrene, indene and ammonia. The Raman spectra were recorded on a JEOL S-1 laser Raman spectrophotometer by using the 514.5 nm line of a Coherent 52G Ar^+ laser as the excitation incidence (30 mW at the sample position). The samples were sealed in 1 mm unheparinized haematocrit tubes. The spectra obtained are shown in Figs. 1—3.

Vibrational Assignments

The infrared bands due to the NH stretching modes of H-d_0 and HC-d_2 and the ND stretching modes of HN-d_2 and H-d_4 split into three or four peaks arising certainly from Fermi resonance with the summation tones involving the C=O stretching and the NH (or ND) in plane deformation vibrations. The infrared bands due to the CH_2 and the CD_2 stretching modes are very weak but the corresponding bands in the Raman spectra are observed clearly at 2980 and 2950 cm^{-1} for the *C*-undeuterated compounds H-d_0 and HN-d_2, and at 2240 and 2170 cm^{-1} for the *C*-deuterated compounds HC-d_2 and H-d_4. The *N,N'*-undeuterated compounds, H-d_0 and HC-d_2, show two strong infrared bands near 1775 and 1700 cm^{-1} assignable straightway to the C=O stretching vibrations. The shift of these bands on the *N,N'*-deuteration is much smaller than those reported for methylurea[2] and ethyleneurea.[1]

H-d_0 shows three infrared bands at 1430, 1403, and 1382 cm^{-1} in the region 1500—1350 cm^{-1}. The assignment of the 1430 cm^{-1} band to the CH_2 bending vibration is obvious from its disappearance on *C*-deutera-

a) vs, very strong; s, strong; m, medium; w, weak; vw, very weak; sh, shoulder. b) ν, stretching; β, bending; ω, wagging; t, twisting; ρ, rocking; δ, in-plane deformation; π, out-of-plane deformation; τ, torsion.

tion. The 1403 cm^{-1} and the 1382 cm^{-1} bands are assigned to a skeletal stretching vibration and one of the two NH in-plane deformation vibrations, respectively, since the former persists on both the C- and the N,N'-deuteration without large frequency shifts, while the latter disappears on N,N'-deuteration. According to normal coordinate analysis, the other NH in-plane deformation vibration of H-d_0 seems to contribute to the shoulder band at 1440 cm^{-1} which shifts to 1415 cm^{-1} on C-deuteration.

The infrared absorption bands observed in the region 1350—800 cm^{-1} show complicated isotopic shifts, but are given reasonable assignments by taking account of four skeletal vibrations of all the isotopes, a CH$_2$ wagging vibration of H-d_0 and NH-d_2, two ND in-plane deformation vibrations of HN-d_2 and H-d_4, and a CD$_2$ bending and a CD$_2$ wagging vibrations of HC-d_2 and H-d_4. Some of the infrared bands around 900 cm^{-1} are very weak, but can be recognized as fundamentals by virtue of their strong Raman counterparts.

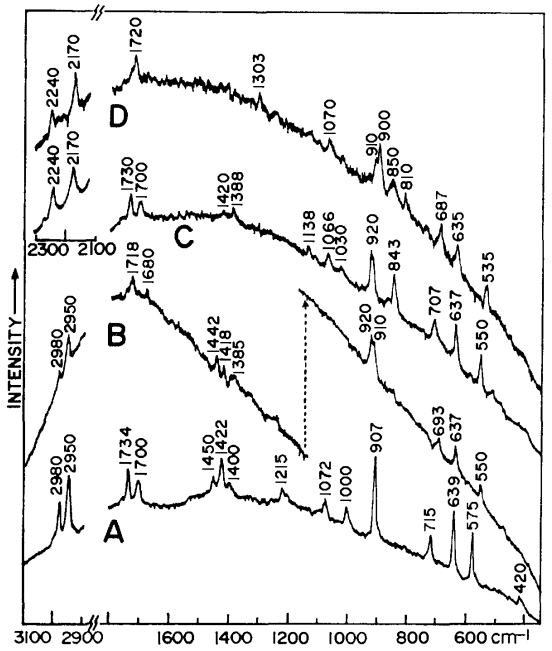

Fig. 3. Raman spectra and the observed frequencies of hydantoin (A), HN-d_2(B), HC-d_2(C), and H-d_4 (D).

As in the case of ethyleneurea,[1] the skeletal in-plane deformation frequencies in the region 800—400 cm^{-1} are easily recognized since they appear strongly in the Raman spectra. The NH and the ND out-of-plane deformation frequencies in the same region were identified from the change of the infrared spectra on *N,N'*-deuteration.

The assigned fundamental frequencies in the a' species of the four isotopic hydantoins were confirmed to be consistent with the product[3] and the sum[4] rules as seen in Table 3. The a" frequencies could not be checked by the isotopic rules because of the lack of data for the CH_2 twisting and the CH_2 and the CD_2 rocking frequencies.

Normal Coordinate Analysis

Taking account of the results of the X-ray analysis of diphenylhydantoin[5] and thiohydantoin,[6] we have assumed a planar C_s conformation of hydantoin. According to this structure, the normal vibrations of hydantoin are classified into 18 a' and 9a" vibrations. On calculating the ***G*** matrices, the C=O bondlength was transferred from diphenylhydantoin[5] and the other structural parameters from thiohydantoin.[6] The out-

a) See footnote a), Table 1. b) See footnote b), Table 1.

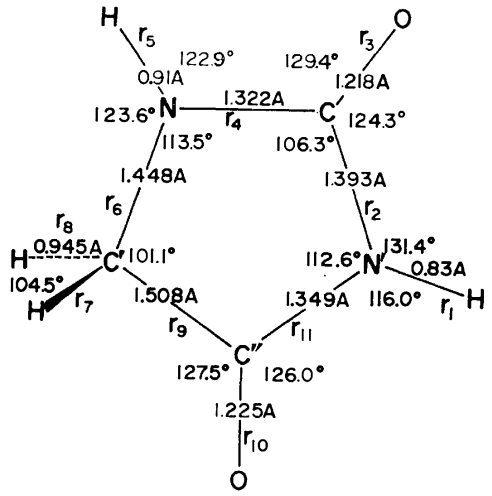

Fig. 4. Structural parameters.

of-plane symmetry coordinates are given in Table 4, where the subscripts for $\Delta\tau$ and $\Delta\pi$ denote the bond indices shown in Fig. 4.

A simple Urey-Bradley force field including 28 force constants was employed for the a′ vibrations. The values of the force constants were transferred initially from ethyleneurea,[1] except that the stretching constants K(C″N′) and K(CN) were taken to be the same as each other on the basis of the similarity in the bond-lengths. After a little adjustment with reference to the $\boldsymbol{J}$ matrix elements, the force constants were refined by the method of least squares to fit the infrared frequencies. The converged set of force constants is given in Table 5. The a″ frequencies were calculated by using a simple Urey-Bradley force field for the CH_2 group and a valence force field for the remaining coordinates. The Urey-Bradley constants were fixed at the final values for the a′ vibrations. The values of the valence type diagonal constants, $f(\pi\text{NH}, \pi\text{NH})$, $f(\tau\text{CN}, \tau\text{CN})$, $f(\pi\text{CO}, \pi\text{CO})$ and $f(\tau\text{C'N}, \tau\text{C'N})$ were taken initially from ethyleneurea,[1] $f(\tau\text{C'C''}, \tau\text{C'C''})$ and $f(\pi\text{C''O}, \pi\text{C''O})$ being estimated by referring to the observed frequencies and the $\boldsymbol{G}$ matrix elements of H-d_0. In order to improve the frequency fit, the off-diagonal constants, $f(\pi\text{NH}, \tau\text{CN})$, $f(\pi\text{CO}, \tau\text{CN})$, $f(\pi\text{CO}, \pi\text{NH})$, and $f(\pi\text{NH}, \tau\text{C'N})$ were added with initial values zero, and the diagonal and the off-diagonal constants were refined alternately by the method of least squares. The final values of the force constants are given in Table 5, and the calculated frequencies in Tables 1 and 2.

Table 3. Product and sum rules for the a′ vibrations

Product rule	H-d_0/HN-d_2	H-d_0/HC-d_2	H-d_0/H-d_4
Obsd	3.741	2.664	10.274
Theor.[a]	3.861	2.731	10.550
Sum rule	$\sum\{\nu^2(\text{H-}d_0)+\nu^2(\text{H-}d_4)\}$		$\sum\{\nu^2(\text{HN-}d_2)+\nu^2(\text{HC-}d_2)\}$
	8.485×10^7 $(\text{cm}^{-1})^2$		8.479×10^7 $(\text{cm}^{-1})^2$

a) Theoretical ratios were obtained from the calculated frequencies.

Table 4. Internal symmetry coordinates for the torsional and out-of-plane deformation vibrations

Coordinate	Description[a]
$S_1=\sum_{i=1,11}\sum_{j=3,4}\Delta\tau_{12j}/4$	τCN′
$S_2=\sum_{i=2,3}\sum_{j=5,6}\Delta\tau_{14j}/4$	τCN
$S_3=\sum_{i=6-8}\sum_{j=10,11}\Delta\tau_{19j}/6$	τC′C″
$S_4=\sum_{i=4,5}\sum_{j=7-9}\Delta\tau_{16j}/6$	τC′N
$S_5=\sum_{i=9,10}\sum_{j=1,2}\Delta\tau_{111j}/4$	τC″N′
$S_6=\Delta\pi_1$[b]	πN′H
$S_7=\Delta\pi_3$[b]	πCO
$S_8=\Delta\pi_5$[b]	πNH
$S_9=\Delta\pi_{10}$[b]	πC″O

a) See footnote b), Table 1. b) The out-of-plane deformation coordinates were defined to be positive when the end atoms (O for S_7 and S_9, and H for S_6 and S_8) move toward the observer from the plane of Fig. 4.

The magnitudes of the three CN stretching constants, K(CN), K(CN′) and K(C′N) in the final set are well correlated with the adopted bondlengths. The CO stretching constant of the –NHCONH– group of hydantoin is much larger than that of ethyleneurea[1] and is comparable with those of diacetamide[7,8] and diketopiperazine.[9] This result may be related to the increase of the CO bond order caused by the decrease of the N–C–N angle on replacement of the CH_2 group of ethyleneurea by a CO group.

We are grateful to Prof. T. Takenaka and Prof. S. Hayashi for use of FIS-3. The calculation was performed on a FACOM 230-60 computer at the Data Processing Center, Kyoto University, and on a NEAC 2200/500 computer at Okayama University Computer Center.

Derivatographic Studies on Transition Metal Complexes. XIX.[1] Thermal Isomerization of *trans*-$[CrCl_2(en)_2](H_5O_2)Cl_2$ and *trans*-$[CrCl_2(pn)_2]Cl \cdot 1.5H_2O$ in Solid Phase[2]

(Received January 17, 1977)

Thermal *trans*-to-*cis* isomerization of $[CrCl_2(en)_2](H_5O_2)Cl_2$ and $[CrCl_2(pn)_2]Cl \cdot 1.5H_2O$ was studied in the solid phase by derivatographic and isothermal measurements. The former complex was found to isomerize in anhydrous state after the complete elimination of hydrogen chloride and water, the latter in the temperature range for dehydration. The activation energies for the isomerization of these two complexes were isothermally estimated to be 202 and 193 kJ mol^{-1}, respectively. The same type of isomerization mechanism is suggested for these complexes, differing from that for the corresponding cobalt(III) complexes in which lattice waters participate.

Few papers have been given on the *cis*↔*trans* isomerization of $[MX_2(a\text{-}a)_2]X$ in solid phase, where M= Co(III) or Cr(III), X=halide ion and a-a=diamine. The *trans*-to-*cis* isomerization is known to take place in *trans*-$[CoCl_2(pn)_2](H_5O_2)Cl_2$[3,4] and *trans*-$[CoBr_2(pn)_2](H_5O_2)Br_2$,[5] but not in *trans*-$[CoCl_2(en)_2](H_5O_2)Cl_2$. The isomerization of the former two always proceeds at the elimination step of hydrogen halide and water, for which "aquation-anation mechanism" has been proposed.[3,4] In contrast, *trans*-$[CrBr_2(pn)_2]Br \cdot H_2O$ isomerizes in the anhydrous state; the presence of lattice waters has no effect on the isomerization.[6] Thus, another mechanism seems to play an important role in the isomerization of the chromium(III) complexes.

The present study was undertaken (1) to investigate derivatographically and isothermally the *trans*-to-*cis* isomerization of $[CrCl_2(en)_2](H_5O_2)Cl_2$ and $[CrCl_2(pn)_2]Cl \cdot 1.5H_2O$, and (2) to find what differences can be produced by changing ethylenediamine with propylenediamine.

Experimental

Preparation of Complexes. *trans*-$[CrCl_2(en)_2](H_5O_2)Cl_2$ (I),[7] *cis*-$[CrCl_2(en)_2]Cl$(II),[8] *trans*-$[CrCl_2(pn)_2]Cl \cdot 1.5H_2O$ (III),[9] and *cis*-$[CrCl_2(pn)_2]Cl$ (IV)[10] were prepared by modification of the usual methods.

The chemical formulas of these complexes were confirmed by elemental analyses, spectrophotometric measurements and Karl Fischer's method of water determination.

Derivatography. The derivatograms for the complexes were obtained with a MOM Typ-OD-102 Derivatograph. The operating conditions are the same as those reported previously.[1]

Isothermal Measurements. The rates of hydrogen chloride elimination and dehydration were measured with a CHYO 100L thermobalance at 92, 105, 119, and 126 °C for complex I and at 160, 172, 178, and 184 °C for complex III. The rates of isomerization were followed by measuring the change in the absorbancies of a 0.1 M $HClO_4$ solution of each sample heated in an Abderhalden apparatus at 249, 260, 269, 279, or 288 °C for complex I, and at 154, 160, 166, or 172 °C for complex III, and by the use of the following simultaneous equations:

$$\left.\begin{aligned} D_{400} &= 32.3X + 71.1Y \\ D_{520} &= 7.6X + 73.1Y \end{aligned}\right\} \quad \text{for complex I}$$

$$\left.\begin{aligned} D_{400} &= 35.8X + 74.6Y \\ D_{530} &= 10.4X + 74.4Y \end{aligned}\right\} \quad \text{for complex III}$$

where X and Y are the molar concentrations of *trans*- and *cis*-isomers, respectively, contained in a 0.1 M $HClO_4$ solution of each sample, the numerical factors are the molar extinction coefficients of pure *trans*- and *cis*-isomers at two wavelengths 400 and 520 or 530 nm for each complex and D is the absorbancy measured. Figure 1 shows the electronic spectra of *trans*- and *cis*-complexes. The isomerization ratios are, therefore, given by $Y/(X+Y)$.

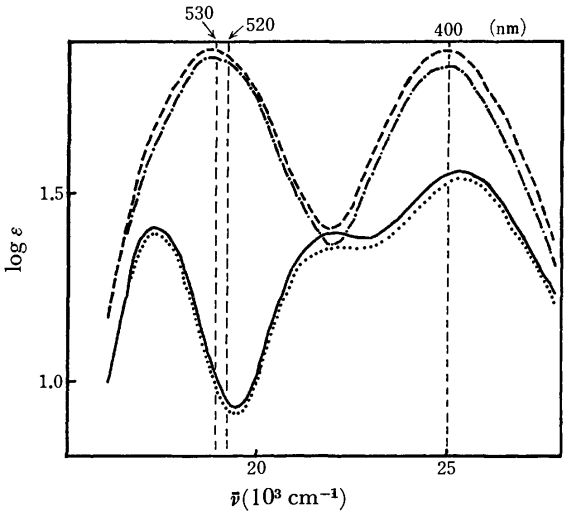

Fig. 1. Electronic spectra of complexes I (·····), II (—·—), III(——) and IV(----).

Results and Discussion

Derivatography. Figure 2 shows the derivatograms of *trans*-$[CrCl_2(en)_2](H_5O_2)Cl_2$ (I) and *trans*-$[CrCl_2(pn)_2]Cl \cdot 1.5H_2O$(III). The TG curve of complex I shows that the complex evolves one mole of hydrogen chloride and two moles of water at 25—120 °C (step I) and then remains unchanged up to 290 °C, above which the decomposition begins. In the DTA curve, an endothermic peak appears at step I and another endothermic peak at 250 °C; a small but clear exothermic peak can be seen just before the second endothermic peak. This is due to the *trans*-to-*cis* isomerization, which was visually confirmed by the color change of the sample from

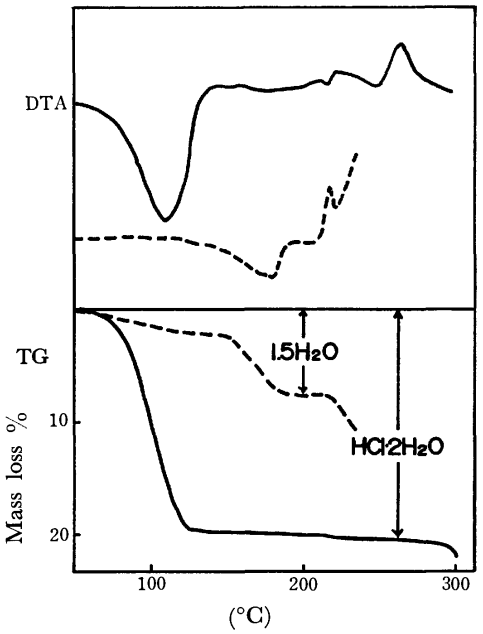

Fig. 2. Derivatograms of complexes I (——) and III (----).

green to violet. The enthalpy change, ΔH, for step I was estimated to be 55 kJ mol^{-1} from analysis of the endothermic curve in the derivatogram.

On the other hand, as seen from the TG curve of complex III, the complex loses 1.5 mol of water at 45—180 °C and decomposes above 215 °C. In the DTA curve, an endothermic peak appears at the dehydration step, and then a clear exothermic peak appears at 210 °C just before the decomposition starts. The complete *trans*-to-*cis* isomerization was also visually confirmed at the end of dehydration.

The isomerization of complex I takes place in an anhydrous state in a manner similar to that of *trans*-$[CrBr_2(pn)_2]Br \cdot H_2O$[6] and *cis*-$[CrCl_2(tn)_2]Cl \cdot 0.5H_2O$.[1] On the other hand, complex III undergoes isomerization with dehydration as mentioned above.

It seems, however, that the presence of lattice water is not always required for the isomerization to occur, if the value of the activation energy obtained by the isothermal measurements is taken into account.

Rate of Step I. The rate of step I was measured with a thermobalance from the weight loss with time. The results for complex I are shown in Fig. 3 in the same way as that reported,[1,6] *viz.*, $\log\{a/(a-x)\}$ is plotted against time, assuming the reaction to proceed in the first order, where a is the initial amount of the starting complex, and x the amount of the hydrated complex which has lost hydrogen chloride or of the anhydrous complex. A curve having a point of inflection was obtained at each temperature. The part below the point of inflection is due to the evolution of hydrogen chloride, and the part above it to dehydration. This was confirmed by chemical analysis of the evolved gas.

The rate constants of step I are given in Table 1 together with those of isomerization. The activation energies for the loss of hydrogen chloride and the dehydration were calculated to be 118 kJ mol^{-1} and 42 kJ mol^{-1}, respectively, from the Arrhenius plots.

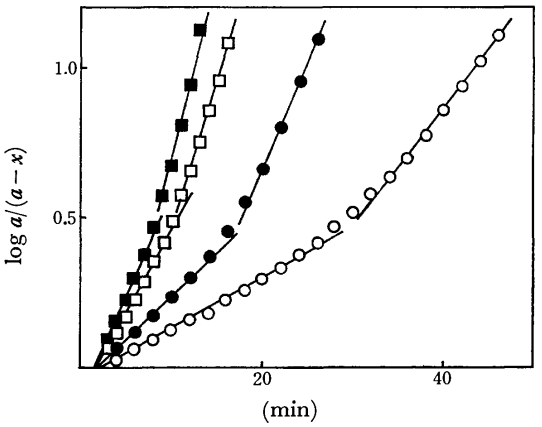

Fig. 3. Plots of $\log\{a/(a-x)\}$ *vs.* time for the hydrogen chloride elimination and dehydration of complex I.

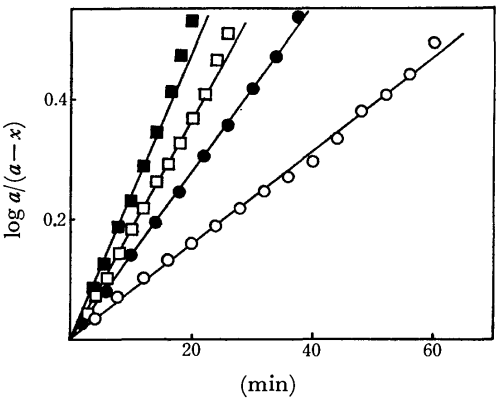

Fig. 4. Plots of $\log\{a/(a-x)\}$ *vs.* time for the dehydration of complex III.
○ 160, ● 172, □ 178, ■ 184 °C.

The relationship of $\log\{a/(a-x)\}$ *vs.* time for the dehydration of complex III is shown in Fig. 4. The rate constants of dehydration are given in Table 2 together with those of isomerization. The activation energy was estimated to be 76 kJ mol^{-1} from the Arrhenius plots of the rate constant.

Rate of Isomerization. The rate of isomerization of complex I measured spectrophotometrically is shown in Fig. 5. It is assumed that the reaction proceeds in

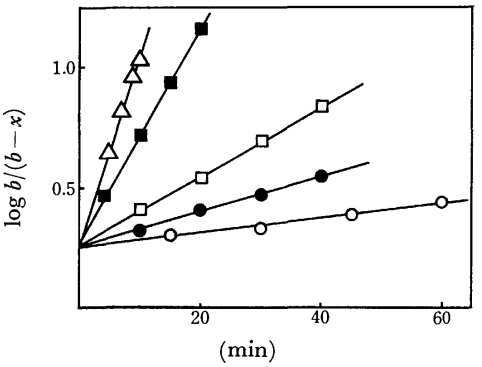

Fig. 5. Plots of $\log\{b/(b-y)\}$ *vs.* time for the isomerization of complex I.

Table 1. Rate constants of hydrogen chloride elimination, dehydration and isomerization of complex I

Temp/°C	92.0	105.0	119.3	125.5	249	260	269	279	288
$k_d(HCl)\times10^{-3}/s^{-1}$	0.642	1.075	2.084	2.572					
$k_d(H_2O)\times10^{-3}/s^{-1}$	1.574	2.764	3.964	4.798					
$k_i\times10^{-4}/s^{-1}$					1.151	2.955	5.245	16.79	29.17

Table 2. Rate constants of dehyration and isomerization of complex III

Temp/°C	154	160	166	172	178	184
$k_d\times10^{-4}/s^{-1}$		3.009		5.322	7.043	9.135
$k_i\times10^{-2}/s^{-1}$	1.490	3.133	6.821	13.083		

the first order. The plots converge to *ca.* 0.26 in the coordinate $\log\{b/(b-y)\}$, where b is the initial amount of the complex I and y that of the *cis*-complex formed during time t. The point to which the plots converge corresponds to 45% isomerization of the complex. Taking the dehydration temperature range under the isothermal heating into account (Fig. 3), the point suggests that 45% of the complex isomerizes very rapidly accompanied by dehydration at least above 249 °C, the residual 55% isomerizing in anhydrous state in the first order.

The rate constants of isomerization for complex I in anhydrous state are summarized in Table 1. From the Arrhenius plots of the rate constants, the activation energy for the isomerization was evaluated to be 202 kJ mol^{-1}.

The rate of isomerization of complex III is shown in Fig. 6 by plotting the isomerization ratio (%) *versus* time. All the plotted lines are linear, indicating that the reaction proceeds in the zeroth order. The rate constants of isomerization for complex III are given in Table 2. The activation energy for the isomerization is calculated to be 193 kJ mol^{-1}.

Complex I isomerizes similarly to *trans*-$[CrBr_2(pn)_2]Br\cdot H_2O$ and *cis*-$[CrCl_2(tn)_2]Cl\cdot 0.5H_2O$, though the last complex undergoes *cis*-to-*trans* isomerization, indicating that the reaction occurs in an anhydrous state with a remarkably large activation energy as compared with cobalt(III) complexes.[4,5] In these complexes, a mechanism differing from "aquation-anation" in the cobalt(III) complexes should be considered.

On the other hand, in complex III, the *trans*-to-*cis* isomerization is completed before dehydration is over. The activation energy is, however, relatively large as compared with the values for the isomerization in cobalt(III) complexes. This suggests that the process of isomerization is independent of the presence of lattice water in these chromium(III) complexes.

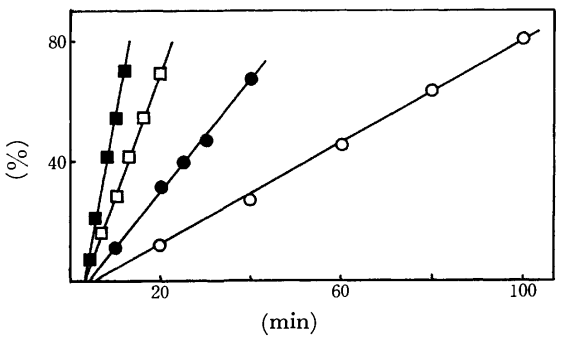

Fig. 6. Plots of isomerization ratio (%) *vs.* time for the isomerization of complex III.
○ 154, ● 160, □ 166, ■ 172 °C.

Thermochemical Reaction Scheme. On the basis of the data presented, the thermochemical reaction schemes for the isomerization of the complexes I and III are illustrated as follows:

In the temperature range 92—126 °C:

trans-$[CrCl_2(en)_2](H_5O_2)Cl_2$

$\downarrow$ $E_d(HCl)=118$ kJ mol^{-1} (28 kcal mol^{-1})
$\downarrow$ $E_d(H_2O)=42$ kJ mol^{-1} (10 kcal mol^{-1})

trans-$[CrCl_2(en)_2]Cl$

At 249—288 °C:

trans-$[CrCl_2(en)_2](H_5O_2)Cl_2$ $\xrightarrow{45\%}$ *cis*-$[CrCl_2(en)_2]Cl$

$\downarrow$ 55%

trans-$[CrCl_2(en)_2]Cl$ $\longrightarrow$ *cis*-$[CrCl_2(en)_2]Cl$

$E_i\simeq 202$ kJ mol^{-1} (48 kcal mol^{-1})

At 154—184 °C:

trans-$[CrCl_2(pn)_2]Cl\cdot 1.5H_2O$: $\xrightarrow[E_i=193\text{ kJ mol}^{-1}\ (46\text{ kcal mol}^{-1})]{}$ *cis*-$[CrCl_2(pn)_2]Cl$

$\downarrow$ $E_d=76$ kJ mol^{-1} (18 kcal mo^{-1})

$[CrCl_2(pn)_2]Cl$

Gel Chromatography of β-Diketones and Their Metal Complexes. IV. The Partition Concept in Gel Chromatography

Koichi SAITOH and Nobuo SUZUKI

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received February 3, 1977)

A new theoretical treatment of the solute distribution in gel chromatography is proposed. Practical gel chromatography can be regarded as one based on a combined function of the molecular sieve effect and the partition effect. Introducing the concept of a regular solution to the column system of gel chromatography, the contribution of the partition effect can be estimated from the data on the physical properties of the solute, the solvent, and the gel matrix. The argument being proposed is supported by the experimental data on the gel chromatography of metal (II, III) chelates with acetylacetone and normal alkanes previously obtained in the systems of a poly(vinyl acetate) gel and various eluting solvents.

In the previous work of this series, the solvent dependence of the gel-chromatographic behavior of some metal (II, III) chelates with acetylacetone (2,4-pentanedione: Hacac) on a cross-linked poly(vinyl acetate) gel (Merckogel OR-2000) was examined.[1] The experimental results showed that the distribution coefficients of a chelate were strongly dependent on the eluting solvent used. The effective molar volume, V_{eff}, for every chelate obtained by the use of the calibration charts prepared on the basis of the elution data for normal alkanes also depended on the solvents; the volmes were different from the expectation derived from the literature values of the molar volume, V_m, for the chelate. On the basis of these facts, it seems reasonable to assume that the solute distribution in a given column system is governed not only by the molecular sieve effect related to the molecular dimensions of the solute, but also by some secondary effects related to interactions among the solute, the solvent, and the gel.

In order to explain the separation mechanism in gel chromatography, various theories, such as steric exclusion,[2] restricted diffusion,[3] and thermodynamic equilibrium,[4] have been proposed. In these theories, the dominant factor governing the solute distribution in a given column system is considered to be the radius of the solute molecule, and the contributions of the secondary effects are not taken into account. Some anomalies were occasionally observed, however, such as the reversal of the predicted elution order of the solutes and the unexpectedly large values of the elution volume.[5,6] These facts could not be explained simply in term of the molecular sieve effect. The importance of the secondary effect was stressed in such a case, therefore. It has thus far been generally agreed that the secondary effect is due to the solute-gel matrix adsorption,[7,8] but this adsorption has not been argued quantitatively in terms of the physical properties inherent in the solute, solvent, and gel materials.

In the course of our previous study, we felt it necessary to understand fully the essence of the secondary effect and the solvent effect in gel chromatography. The present paper thus deals with this problem theoretically. The theoretical investigation of the solute distribution in a column system is developed by assuming that gel chromatography is essentially based on the combined function of the molecular sieve effect and the partition effect. This investigation has been undertaken to explain the gel-chromatographic behavior of metal chelates with Hacac previously observed.

Theoretical

Overall Distribution Coefficient. When a substance is chromatographed in a column system consisting of a liquid phase with the volume of V_o (void volume) and a gel phase with the volume of V_x, the elution volume, V_e, of the substance is expressed by the following general equation:

$$V_e = V_o + K_{av}V_x, \tag{1}$$

where K_{av} is the distribution coefficient characterizing the solute distribution in the column system. When the solute distribution is governed not only by the molecular sieve effect, but also by some other effects, K_{av} is essentially a combined function of all the effects.

When the concept of the theoretical plate is applied to the gel-chromatographic-column system, the solute distribution in a theoretical plate is as will be discussed below.

The column system in the theoretical plate consists essentially of a solvent phase (hereafter abbreviated as the O phase) with the volume of v_o and a gel phase (hereafter abbreviated as the X phase) with the volume of v_x. The former and the latter phases correspond to the moving and the stationary phases in this chromatographic system respectively. A solute material, S, introduced in this system equilibrates between these two phases. Only a certain fraction, K_{size}, of the latter phase is, however, available for S, because of the molecular sieve effect. This leads to the following relation:

$$v_p = K_{size}v_x, \tag{2}$$

where v_p is the volume of the available part (hereafter designated as the P phase) for S. According to the theories proposed by Ogston[9] and Laurent and Killander[10], K_{size} is expressed by the equation:

$$K_{size} = \exp\left[-\pi L(r_r + r_s)^2\right], \tag{3}$$

where r_s is the radius of the solute molecule, r_r is the radius of the polymer chain of the gel matrix, and L is the concentration of the polymer chains in the gel phase. Both L and r_r are constant in a combination of the gel matrix and a solvent. The v_p value in a given column system, therefore, varies according only to the size of the solute molecule.

Considering that S is distributed strictly between the O phase and the P phase, and also that these two phases are not always equilivalent with respect to the interaction with S, it is reasonable to assume that, in general, the concentration of S in P phase, C_p, is different from that in the O phase, C_o. When the P phase can be assumed to be such a medium as a mixture of a solvent and a polymer of gel matrix, into which S can be incorporated, the O and P phases can be regarded as constituting a system of partition chromatography. Thus, the K_{part} given by Eq. 4 corresponds with the partition coefficient of S in this system:

$$K_{part} = C_p/C_o \tag{4}$$

The effective plate volume, v_e, in this partition chromatographic system is expressed by this equation:

$$\begin{aligned} v_e &= v_o + K_{part}v_p \\ &= v_o + K_{part}K_{size}v_x \end{aligned} \tag{5}$$

When the number of the theoretical plates in the total column system, N, is sufficiently larger than unity, Eq. 6 can be derived:

$$V_e = Nv_e = V_o + K_{part}K_{size}V_x \tag{6}$$

From Eqs. 1 and 6, one arrives at:

$$K_{av} = K_{part}K_{size} \tag{7}$$

According to Eq. 6, gel chromatography can be regarded as a special case of partition chromatography, in which the volume of the stationary phase varies with the molecular size of the solute substance introduced. It is reasonable to term K_{av} the overall distribution coefficient.

Partition Concept and the Physical Properties of the Solute, the Solvent, and the Gel. When the partition constant of the solute, S, $K^x_{part,s}$, is given by Eq. 8, the overall distribution coefficient, K_{av}, can be expressed by Eq. 9, provided both C_o and C_p are small:

$$K^x_{part,s} = X_{s,p}/X_{s,o} \tag{8}$$

where $X_{s,p}$ and $X_{s,o}$ are the mole fractions of S in the P phase and the O phase respectively.

$$K_{av} = K^x_{part,s}(\overline{V}_{m,o}/\overline{V}_{m,p})K_{size} \tag{9}$$

where $\overline{V}_{m,o}$ and $\overline{V}_{m,p}$ are the average molar volume of the O phase and the P phase respectively.

According to the regular solution theory,[11] the activity of Component 2, a_2, in a binary mixture of Components 1 and 2 is expressed as a function of the mole fraction, X; the molar volume, V_m; the volume fraction, ϕ, and the solubility parameter, δ, by means of the following equation:

$$\ln a_2 = \ln X_2 + V_{m,2}\phi_1^2(\delta_1-\delta_2)^2/RT \tag{10}$$

where R and T are the gas constant and the temperature respectively, and where the subscripts 1 and 2 distinguish the components of the mixture. When the number of moles of a component is denoted by the symbol n, X_2 and ϕ_1 are, respectively, given by these two equations: $X_2=n_2/(n_1+n_2)$ and $\phi_1=n_1V_{m,1}/(n_1V_{m,1}+n_2V_{m,2})$. The solubility parameter is defined as the square root of the cohesive energy density, *e.g.*, of the energy of vaporization, ΔE^v, per unit of volume ($\delta=(\Delta E^v/V_m)^{1/2}$). The regular solution theory can be successfully applied to discussing the solute distribution in solvent extraction.[12-14]

It is expected that the concept of a regular solution can be applied to discussing the solute distribution between the O phase and the P phase when the following two assumptions are accepted: i) the P phase can be regarded as a homogeneous mixture of a solvent and a gel matrix polymer, and ii) specific interactions among the solute, the solvent, and the polymer, such as hydrogen bonding, are absent in the system. In our earlier work, the solvent dependence of gel swelling could be successfully explained quantitatively by introducing the concept of regular solution into the solvent-gel matrix binary system.[15]

The activities of the solute, S, in the O phase, $a_{s,o}$, and in the P phase, $a_{s,p}$, are expressed by Eqs. 11 and 12:

$$\ln a_{s,o} = \ln X_{s,o} + V_{m,s}\phi_o^2(\delta_o-\delta_s)^2/RT \tag{11}$$

$$\ln a_{s,p} = \ln X_{s,p} + V_{m,s}\phi_p^2(\delta_p-\delta_s)^2/RT \tag{12}$$

The subscripts s, o, and p distinguish the components in these systems. When the partition equilibrium of S is achieved between these two phases ($a_{s,o}=a_{s,p}$), the following relation is derived:

$$\ln K^x_{part,s} = V_{m,s}[(\delta_o-\delta_s)^2-(\delta_p-\delta_s)^2]/RT, \tag{13}$$

provided that the concentration of S is so small that both ϕ_o and ϕ_p can be equated with unity. The solubility parameter, δ_p, is approximately expressed by Eq. 14:

$$\delta_p = \phi_g\delta_g + (1-\phi_g)\delta_o, \tag{14}$$

where ϕ_g is the volume fraction of the gel-matrix polymer in the P phase, δ_g is the solubility parameter of the polymer, and δ_o is, of course, the solubility parameter of the solvent. Then, Eq. 13 is modified to:

$$\ln K^x_{part,s} = V_{m,s}[2(\delta_s-\delta_o)(\delta_g-\delta_o)\phi_g-(\delta_g-\delta_o)^2\phi_g^2]/RT \tag{15}$$

This equation reveals the quantitative relationship between the partition effect in gel chromatography and the physical properties of the solute, the eluting solvent, and the packing material (gel). It is quite an important and interesting suggestion that ($\ln K^x_{part,s}$) is equal to zero under such a condition as $\delta_o=\delta_g$.

It is well known that the molar volume can be used as an effective size parameter for low-molecular-weight compounds in gel chromatography.[16-18] We assume here, for the sake of simplification, that various compounds with a equal molar volume have K_{size} values identical to each other in a given column system. When two different substances, S and S′, are chromatographed in a column system, the K_{av} values of these substances are expected by the $K_{av,s}=K^x_{part,s}K_{size,s}$ and $K_{av,s'}=K^x_{part,s'}K_{size,s'}$ equations. When the V_m values of S and S′ are equal to each other, $K_{size,s}=K_{size,s'}$. Then the following equation can be written:

$$R_{s/s'} = K_{av,s}/K_{av,s'} = K_{part,s}/K_{part,s'} \tag{16}$$

According to Eq. 15, the above equation is modified to give:

$$\ln R_{s/s'} = 2V_{m,s}(\delta_s-\delta_{s'})(\delta_g-\delta_o)\phi_g/RT \tag{17}$$

This equation predicts that the $R_{s/s'}$ value is always constant at unity under the condition $\delta_o=\delta_g$. In usual

column systems, $K_{av,s}$ are not always equal to $K_{av,s'}$, even if $V_{m,s}=V_{m,s'}$. It is stressed that the choice of eluting solvent is quite important in gel chromatography. Ideal gel-chromatographic separation based only on the molecular sieve effect is carried out by the use of an eluting solvent in which the solubility parameter of the solvent is equal to that of the gel matrix; then one can estimate the size of a solute molecule by the use of a calibration chart prepared on the basis of the elution data for other compounds.

Discussion

In order to examine the validity of the above arguments, the theory is then applied to the experimental data already obtained. The elution data for normal alkanes,[19] bis(acetylacetonato) beryllium(II) and tris-(acetylacetonato)chromium(III) (hereafter abbreviated as $Be(acac)_2$ and $Cr(acac)_3$ respectively),[1,20] in column systems consisting of Merckogel OR-2000 and various organic solvents are taken. The data on gel swelling[15] are also available.

Equation 15 shows that the solvent dependence of the partition effect can be discussed quantitatively in terms of the solubility parameters of the solvents. However, it is not easy to evaluate K^x_{part} experimentally. Only K_{av} values can be obtained by means of usual chromatographic techniques. When the K_{av} values of two different compounds with equal V_m values are available, the validity of Eq. 15 must be examined indirectly by discussing Eq. 17.

We suppose here two hypothetical normal alkanes: one (hereafter designated by r(Be)) whose V_m value is equal to that of $Be(acac)_2$, and the other (hereafter designated by r(Cr)) whose V_m value is equal to that of $Cr(acac)_3$. An equation analogous to Eq. 17 can be written for the solute pair of $Be(acac)_2$ and r(Be):

$$\ln R_{Be/r(Be)} = \ln (K_{av,Be}/K_{av,r(Be)}) = 2V_{m,Be}(\delta_{Be}-\delta_{r(Be)})(\delta_g-\delta_o)\phi_g/RT, \quad (18)$$

where the subscript Be denotes $Be(acac)_2$. Introducing the degree of swelling for gel, Q, defined as $Q=1/\phi_g$, into the above equation, one can write Eq. 19:

$$Q \ln R_{Be/r(Be)} = [-2V_{m,Be}(\delta_{Be}-\delta_{r(Be)})/RT](\delta_o-\delta_g) \quad (19)$$

It is expected that $(Q \ln R_{Be/r(Be)})$ shows a linear relationship to δ_o with a slope of $[-2V_{m,Be}(\delta_{Be}-\delta_{r(Be)})/RT]$. The $V_{m,Be}$ value was estimated to be 184 $cm^3\,mol^{-1}$.[1] The $K_{av,r(Be)}$ values in the column systems of Merckogel OR-2000 and various eluting solvents can be estimated by introducing the $V_{m,Be}$ value into the K_{av} *versus* V_m relationship for normal alkanes observed in the column systems (see Fig. 2 in Ref. 1). The δ_{Be} value has not been reported. Considering that the solubility parameters of metal chelates with the same ligand are approximately independent of the metals,[14] we estimate δ_{Be} to be at 9.7 $cal^{1/2}\,cm^{-3/2}$. This value is equal to the reportd value of δ_{Cr}.[21] The $\delta_{r(Be)}$ value is estimated to be 7.7 $cal^{1/2}\,cm^{-3/2}$ from the δ *versus* V_m relationship for normal alkanes shown in Fig. 1. According to these values, it can be predicted that the slope of the $(Q \ln R_{Be/r(Be)})$ *versus* δ_o plot is about -1.2 at 25 °C. The relation of $(Q \ln R_{Be/r(Be)})$ plotted against δ_o, prepared based on the data summarized in Table 1, is shown in Fig. 2. All the plots, except for chloroform (1), fall approximately on a line. According to the regression analysis, the slope of this line is $(-0.92\pm$

a) In $cal^{1/2}\,cm^{-3/2}$. b) Calculated from the value of the heat of vaporization (7.65 kcal/mol).[27]

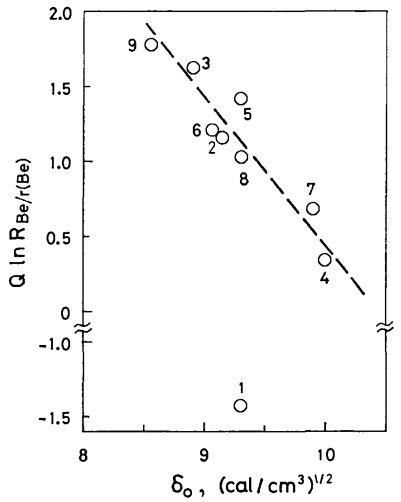

Fig. 2. The $Q \ln R_{Be/r(Be)}$ *versus* δ_0 relationship in the systems of Merckogel OR-2000 and various eluting solvents at 25 °C. Figures 1—9 denote solvents as in Table 1. Dashed line shows the regression line.

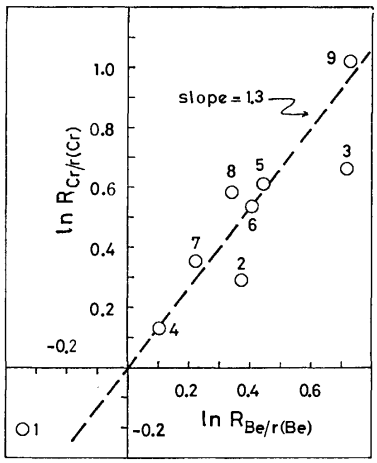

Fig. 3. Correlation between $\ln R_{Cr/r(Cr)}$ and $\ln R_{Be/r(Be)}$. Figures 1—9 denote solvents as in Table 1.

0.12) at a level of significance of 5%. This value is close to the expected one ($=-1.2$). The δ_0-axis intercept of the line, which corresponds with the δ_g value of Merckogel OR-2000, is observed to be (10.4±0.2). This value is near to the δ_g value estimated from the gel-swelling data ($\delta_g=9.7$).[15]

It is shown in Fig. 2 that the relationship expressed by Eq. 17 can be approximately accepted in practice, even in various types of solvents, including both polar and nonpolar ones. Some deviation of the plots from the linearity can still be found. It has not been clarified whether the deviation results from the uncertainty of the original data or from the disregard for the specific interactions among solute, solvent, and gel. Considering that many metal chelates with Hacac form the solvated species in chloroform.[22,23] the remarkable deviation of the plot for chloroform found in Fig. 2 may be referred to the solvation. The concept of the regular solution can be accepted on the assumption that the specific interaction between the solute and the solvent is absent.[11]

One can modify Eq. 17 to give the relation between $Cr(acac)_3$ (designated by the subscript Cr) and r(Cr). Thus,

$$\ln R_{Cr/r(Cr)} = \ln (K_{av,Cr}/K_{av,r(Cr)}) = 2V_{m,Cr}(\delta_{Cr}-\delta_{r(Cr)})(\delta_g-\delta_0)\phi_g/RT \quad (20)$$

From Eqs. 18 and 20, the following equation is derived:

$$\ln R_{Cr/r(Cr)}/\ln R_{Be/r(Be)} = (V_{m,Cr}/V_{m,Be})(\delta_{Cr}-\delta_{r(Cr)})/(\delta_{Be}-\delta_{r(Be)}) \quad (21)$$

It can be expected that ($\ln R_{Cr/r(Cr)}$) is in direct proportion to ($\ln R_{Be/r(Be)}$). The proportional coefficient should be independent of the solvent used, and we should be able to predict it from the physical properties of the solutes. Taking the value of $V_{m,Cr}$ as 267 $cm^3\ mol^{-1}$,[21] $\delta_{r(Cr)}$ is estimated to be 7.9 $cal^{1/2}\ cm^{-3/2}$ from Fig. 1. The δ_{Cr} value has been reported to be *ca.* 9.7 $cal^{1/2}\ cm^{-3/2}$.[21] Then, the proportional coefficient can be predicted to be 1.3.

The values of $K_{av,r(Cr)}$ and $R_{Cr/r(Cr)}$ are estimated in a manner analogous to that used in the case of the $Be(acac)_2$-r(Be) pair and are exhibited in Table 1. When these values are taken, the relationship of ($\ln R_{Cr/r(Cr)}$) plotted against ($\ln R_{Be/r(Be)}$) is as shown in Fig. 3. The dashed line in the figure shows the slope 1.3. It is quite interesting that the plots for many solvents lie close to the prediction. However, benzene (2) and toluene (3) give plots somewhat deviating from the expected line. We have, to data, no clear-cut evidence to explain this deviation.

The facts shown graphically in Figs. 2 and 3 lend some support to the theoretical treatment of the solute distribution in gel chromatography proposed in this paper. The solvent dependence of the gel-chromatographic behavior of metal chelates with Hacac previously observed can be appreciablly explained in terms of the partition effect. The contribution of the partition effect to the overall solute distribution in gel chromatography may be predicted quantitatively in terms of the molar volumes and the solubility parameters of the solute and the solvent. Equation 15 predicts that the partition effect in gel chromatography is not remarkable, provided that the δ value of the eluting solvent is close to that of the gel matrix.

In view of the above arguments, the most reasonable conclusion to be drawn from the available data is that 1,4-dioxane is the nearest to the ideal eluting solvent for the column system including Merckogel OR-2000 as a column packing material, while butyl acetate is farthest from the ideal.

The introduction of the partition concept may give a powerful approach to elucidate the so-called secondary effect in gel chromatography.

The Thermal Decomposition Process of Calcium Sulfite

Ryoko MATSUZAKI, Hagio MASUMIZU, Nagisa MURAKAMI, and Yuzo SAEKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received April 27, 1977)

The thermal decomposition of calcium sulfite at temperatures below 880 °C in an argon stream was examined. Also, the reaction between calcium sulfate and calcium sulfide, which were formed during the decomposition process of calcium sulfite, was examined. The thermal decomposition process of calcium sulfite can be represented as follows: on heating calcium sulfite, the reaction, $CaSO_3 \rightarrow CaO + SO_2$, occurs above about 600 °C. Above about 680 °C, the reaction, $4CaSO_3 \rightarrow 3CaSO_4 + CaS$, occurs besides the above reaction. Furthermore, the reaction between calcium sulfate and calcium sulfide which are formed during the decomposition process of calcium sulfite, $3CaSO_4 + CaS \rightarrow 4CaO + 4SO_2$, occurs above about 780 °C.

As regards the thermal decomposition process of calcium sulfite, Foerster and Kubel[1] have reported that the reaction, $4CaSO_3 \rightarrow 3CaSO_4 + CaS$, occurs above about 600 °C, and that the reaction, $CaSO_3 \rightarrow CaO + SO_2$, occurs besides the above reaction above about 650 °C in a nitrogen stream. Zawadzki[2] has briefly reported that the reaction, $4CaSO_3 \rightarrow 3CaSO_4 + CaS$, occurs above about 600 °C, and that the reaction, $3CaSO_4 + CaS \rightarrow 4CaO + 4SO_2$, occurs above about 800 °C. On the other hand, Ketov and Nichkovskii[3] have reported that the reactions, $CaSO_3 \rightarrow CaO + SO_2$, $4CaSO_3 + 2SO_2 \rightarrow 4CaSO_4 + S_2$, and $4CaO + 3S_2 \rightarrow 4CaS + 2SO_2$, take place successively over the temperature range of 600—800 °C in a nitrogen atmosphere.

In this report, the thermal decomposition process of calcium sulfite at temperatures below 880 °C will be described.

Experimental

A sample of $CaSO_3$ was prepared by dehydrating $CaSO_3 \cdot 1/2H_2O$ at 330 °C in an argon stream. The $CaSO_3 \cdot 1/2H_2O$ was prepared from a guaranteed reagent, $CaCO_3$, by the method based on the report of Kelly and Moore.[4]

The results of the chemical analysis of the $CaSO_3$ obtained were Ca 33.3$_8$, SO_3 66.4% (Calcd for $CaSO_3$: Ca 33.36, SO_3 66.64%). The Ca content in the $CaSO_3$ was determined by complexometric titration[5] after the $CaSO_3$ had been dissolved in dilute hydrochloric acid. The SO_3 content in the $CaSO_3$ was determined by decomposing the $CaSO_3$ with hydrochloric acid to convert the SO_3 to SO_2 gas in an argon atmosphere. The amount of SO_2 gas evolved was determined by volumetric iodometry.[6]

The X-ray analysis of the sample was performed with an X-ray powder diffractometer, equipped with a proportional counter, using Ni filtered Cu radiation. The X-ray diffraction data of the $CaSO_3$ are shown in Table 1. The data reported by Matthews and McIntosh,[7] which are cited in the ASTM X-ray diffraction data file, are also shown in Table 1.

The thermogravimetry(TG) and differential thermal analysis (DTA) were performed in an argon stream. A heating rate of 2.5 °C/min was employed. The sensitivity of the quartz helix used for TG was about 0.14 mg/0.01 mm. α-Al_2O_3 was used as a reference for DTA.

Results and Discussion

The TG and DTA curves of $CaSO_3$ on heating are shown in Fig. 1. It was observed that the weight loss on heating $CaSO_3$ was accompanied by the evolution of SO_2 gas. The results of the X-ray analysis[8] of the samples heated up to Points A(800 °C) and B(1000 °C) are also shown in Fig. 1.

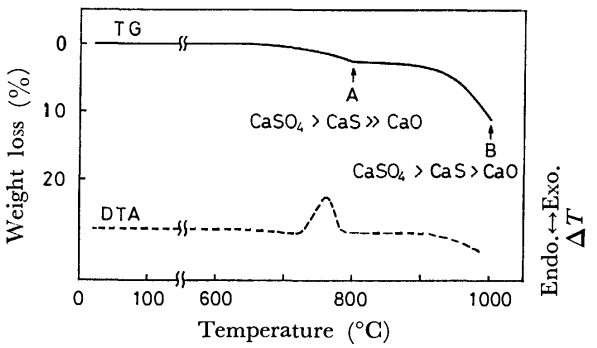

Fig. 1. TG and DTA curves of $CaSO_3$ on heating in an argon stream.

From the facts that CaO was observed in the sample heated up to Point A, and that SO_2 gas was evolved during the weight loss, it was considered that the reaction, $CaSO_3 \rightarrow CaO + SO_2$,[1,3] occurred. Also, an exothermic peak was observed at about 760 °C in the DTA curve, and the formations of $CaSO_4$ and CaS were observed in the sample heated up to Point A. From these facts, it was considered that the reaction, $4CaSO_3 \rightarrow 3CaSO_4 + CaS$,[1,2,9] occurred besides the above reaction.

Furthermore, from the facts that the X-ray diffraction intensity of CaO in the sample heated up to Point B was stronger than that in the sample heated up to Point A, and that the evolution of SO_2 gas was observed during the weight loss from Point A to Point B, it was considered that the reaction, $3CaSO_4+CaS \rightarrow 4CaO+4SO_2$,[2] occurred.

To clarify the thermal decomposition process of $CaSO_3$ in more detail, 1 g of $CaSO_3$ was placed in a quartz boat of 48 mm length, and decomposed in a straight quartz tube (26 mm i. d. and 300 mm heating length) at an argon flow-rate of 100 ml/min for 3 h under isothermal conditions at temperatures below 880 °C. The product obtained in the boat was examined by X-ray analysis. Also, the amount of SO_2 gas formed by the decomposition of $CaSO_3$ was examined. The results are shown in Table 2.

Table 2. Results of heating experiments on $CaSO_3$

Heating temp (°C)	Amount of SO_2 formed (mg)	Sample in the boat
580	—	$CaSO_3$
600	det.	$CaSO_3$

640	4	$CaSO_3 \gg CaO$
660	10	$CaSO_3 \gg CaO$
680	19	$CaSO_3 > CaSO_4 > CaS \gg CaO$
700	33	$CaSO_4 > CaS \gg CaSO_3 > CaO$
720	31	$CaSO_4 > CaS \gg CaO \fallingdotseq CaSO_3$
740	28	$CaSO_4 > CaS \gg CaO$
760	19	$CaSO_4 > CaS \gg CaO$
780	14	$CaSO_4 > CaS \gg CaO$
800	18	$CaSO_4 > CaS \gg CaO$
840	37	$CaSO_4 > CaS > CaO$
880	83	$CaSO_4 > CaS > CaO$

From the results that the formations of SO_2 gas and CaO were observed at 600—660 °C, it was clarified that the reaction, $CaSO_3 \rightarrow CaO+SO_2$, occurred above about 600 °C. Above 680 °C, the formations of $CaSO_4$ and CaS in addition to CaO were observed; the $CaSO_3$ decreased with the increase in the temperature and was not observed above 740 °C. From these results, it was made clear that the reaction, $4CaSO_3 \rightarrow 3CaSO_4+CaS$, occurred above about 680 °C in addition to the reaction, $CaSO_3 \rightarrow CaO+SO_2$.

Above 800 °C, the amount of SO_2 gas formed was again increased; the X-ray diffraction intensity of the CaO in the product also increased with the increase in the temperature. These facts were considered to indicate a reaction between the $CaSO_4$ and CaS formed during the decomposition process of $CaSO_3$, $3CaSO_4+CaS \rightarrow 4CaO+4SO_2$. Therefore, the reaction between $CaSO_4$ and CaS was examined.

A sample of $CaSO_4$ was prepared by adding an aqueous $CaCl_2$ solution to an aqueous Na_2SO_4 solution.[10] Both the salts used were guaranteed reagents. The resulting precipitate was washed with water and dehydrated at 800 °C. A sample of CaS was prepared by heating the CaO formed by the thermal decomposition of a guaranteed reagent, $CaCO_3$, in a stream of H_2S gas at 1000 °C.[11]

One g of a mixture of $CaSO_4$ and CaS (in a molar ratio of $CaSO_4$: CaS=3 : 1) was heated at a specified temperature below 880 °C for 3 h in an argon stream. The product obtained in the boat and the amount of SO_2 gas formed were examined. The results are shown in Table 3.

Table 3. Results of heating experiments on $(3CaSO_4+CaS)$

Heating temp (°C)	Amount of SO_2 formed (mg)	Sample in the boat
760	—	$CaSO_4 > CaS$
780	3	$CaSO_4 > CaS \gg CaO$
800	9	$CaSO_4 > CaS \gg CaO$
840	21	$CaSO_4 > CaS \gg CaO$
880	71	$CaSO_4 > CaS > CaO$

The formations of SO_2 gas and CaO were observed above 780 °C, and the amount of SO_2 gas formed increased appreciably with the increase in the temperature. Also, the X-ray diffraction intensity of CaO in the product increased with the temperature. These results made it clear that the reaction, $3CaSO_4+CaS \rightarrow 4CaO+4SO_2$, occurred above about 780 °C.

From the above-mentioned experimental results, the thermal decomposition process of calcium sulfite can be represented as follows: on the heating of calcium sulfite, the reaction, $CaSO_3 \rightarrow CaO+SO_2$, occurs above about 600 °C. Above about 680 °C, the reaction, $4CaSO_3 \rightarrow 3CaSO_4+CaS$, also occurs. Furthermore, the reaction between calcium sulfate and calcium sulfide which are formed during the decomposition process of calcium sulfite, $3CaSO_4+CaS \rightarrow 4CaO+4SO_2$, occurs above about 780 °C. The thermal decomposition process of calcium sulfite revealed in this work differs from the previously reported processes mentioned above.[1-3]

(Received May 30, 1977)

Cobalt(III) corroles exist predominantly as polymeric species in a concentration range above 5×10^{-3} M in chloroform at room temperature as confirmed by NMR measurements. The coordination behavior of pyridine bases at the axial sites of cobalt(III) corroles, in a concentration range where they are present exclusively in the monomeric species, has been investigated by measuring electronic spectra in acetone at 25.0±0.1 °C. Penta- and hexa-coordination processes were found to take place, and the stepwise formation constants were interpreted by means of the equations $\log K_i = a\cdot pK_a + b$ and $\log K_i/K_i^0 = \rho\sigma$. When the cobalt corrole was reduced at the nuclear cobalt from trivalent to bivalent state, only one pyridine molecule was coordinated at its axial sites, hexa-coordination being no longer possible as confirmed by ESR measurements. The axial ligation behavior of cobalt corroles is quite analogous in nature to that of cobalt corrinoid.

Axial-ligation equilibria for the corrinoid complexes have been studied rather extensively[1] in order to clarify the metabolic functions of vitamin B_{12} systems. It is important, however, to characterize the corrinoid skeleton by referring to the axial ligation behavior of the cobalt complexes of analogous macrocyclic tetrapyrroles involving different numbers of π-electrons in their skeletons, in view of the increasing interest in the chemistry of vitamin B_{12}. The interaction of various organic bases with 8,12-diethyl-1,2,3,7,13,17,18,19-octamethyltetradehydrocorrinatocobalt(II) perchlorate (Co(II)–TDHC) has been investigated.[2] The cobalt(II) complex of 1,19-disubstituted tetradehydrocorrin was found to take up one amine base in its axial position, but unable to yield the corresponding hexa-coordinated complex in which both axial positions were occupied by amines.

We have shown in this work that the axial coordination sites of cobalt(III) corroles are entirely occupied stepwise by amine bases. The equatorial ligand effect, exerted by the corrole skeleton on the axial coordination behavior, is effectively discussed in the light of vitamin B_{12} chemistry.

Experimental

Electronic spectra were taken on a Union Giken SM-401 high sensitive spectrophotometer. Acetone as a solvent for spectroscopic measurements was prepared by fractional distillation after being refluxed with potassium carbonate and kept over a molecular sieve (3A, 1/16; Ishizu Pharmaceutical Co., Ltd.). A Bruker WH-90 FT spectrometer was used to obtain NMR spectra in chloroform-*d* (>99.5%; E, Merck, Darmstadt) at room temperature. Chemical shifts are given in ppm from internal TMS and calibrated with a chloroform signal as the secondary external reference. ESR spectra were recorded on a JEOL JES-ME-3 X-band spectrometer equipped with a 100 kHz field modulation unit. The anionic cobalt(II) complex was prepared by reduction of the corresponding cobalt(III) corrole with sodium tetrahydroborate in *N,N*-dimethylformamide, and measured in the same solvent at 77 K, concentrations being maintained in the 10^{-2}—10^{-3} M range. The manganese ion diffused thermally into magnesium oxide was used to obtain the standard reference signals for measurements.

Commercial liquid amines (pyridine, 2-methyl-, 3-methyl-, 4-methyl-, and 3-acetylpyridine) were refluxed with potassium hydroxide and fractionally distilled. Commercial 4-cyanopyridine was recrystallized from aqueous ethanol. 4-Aminopyridine was prepared by ammonolysis of (4-pyridinio)-pyridinium dichloride[3] and recrystallized twice from benzene. 3-Hydroxypyridine was obtained from ammonium pyridine-3-sulfonate by treatment with potassium hydroxide at elevated temperature,[4] and purified by sublimation *in vacuo*.

2-Acetoxymethyl-3,4-diethyl-5-ethoxycarbonylpyrrole. Into a solution of 2-methyl-3,4-diethyl-5-ethoxycarbonylpyrrole[5-7] (2.5 g) in dry acetic acid (60 ml) was added lead tetraacetate (5.3 g) in small portions at 15-min intervals with stirring at room temperature. The reaction mixture was further stirred at room temperature for 3 h, evaporated *in vacuo*, and the residue was poured into cold water (120 ml). The resulting orange precipitates were recovered by filtration and washed thoroughly with water. Recrystallization from acetone–water gave colorless plates; yield 2.5 g (78%), mp 88.2—89.0 °C. IR (Nujol mull): 3314 (N–H str.), 1741 (acetoxy C=O str.), and 1668 cm^{-1} (ester C=O str.). NMR (CCl_4, TMS): δ 1.19 (9H, overlapping t J=7.0 Hz, 3- and 4-$CH_2\underline{CH_3}$, and 5-$CO_2CH_2\underline{CH_3}$), 1.99 (3H, s, 2-$CH_2OCO\underline{CH_3}$), 2.54 (4H, overlapping q J=7.0 Hz, 3- and 4-$\underline{CH_2}CH_3$), 4.25 (2H, q J=7.0 Hz, 5-$CO_2\underline{CH_2}CH_3$), 4.96 (2H, s, 2-$\underline{CH_2}OCOCH_3$), and 9.80 (1H, broad s, NH).

3,3',4,4'-Tetraethyl-5,5'-diethoxycarbonyldipyrromethane. A solution of 2-acetoxymethyl-3,4-diethyl-5-ethoxycarbonylpyrrole (3.5 g) in ethanol (70 ml) containing hydrochloric acid (37%, 2.6 ml) was refluxed for 5 h with stirring. The solution was concentrated gradually *in vacuo* until a small amount of crystalline precipitates started to appear. After being allowed to stand overnight in a refrigerator, the crystalline solid was recovered by filtration to give colorless prisms; yield 2.5 g (94%), mp 93.0—96.1 °C. IR (Nujol mull): 3320 (N–H str.), 1696 (free ester C=O str.), and 1657 cm^{-1} (bound ester C=O str.). NMR (CCl_4, TMS): δ 1.09 (18H, overlapping t J=7.0 Hz, 3,3'-$CH_2\underline{CH_3}$, 4,4'-$CH_2\underline{CH_3}$, and 5,5'-$CO_2CH_2\underline{CH_3}$), 2.51 (8H, overlapping q J=7.0 Hz, 3,3'-$\underline{CH_2}CH_3$ and 4,4'-$\underline{CH_2}CH_3$), 3.87 (2H, s, bridging CH_2), 4.16 (4H, q J=7.0 Hz, 5,5'-$CO_2\underline{CH_2}CH_3$), and 10.04 (2H, broad s, NH).

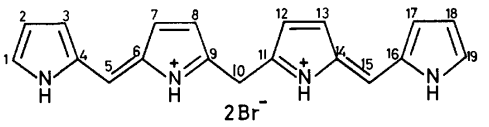
3,3',4,4'-Tetraethyldipyrromethane-5,5'-dicarboxylic Acid. A mixture of 3,3',4,4'-tetraethyl-5,5'-diethoxycarbonyldipyrromethane (2.0 g) and ethanol (35 ml) was refluxed with stirring for a short period. After addition of sodium hydroxide (1.0 g) dissolved in water (10 ml), the reaction mixture was refluxed for 2 h with stirring. A large portion of ethanol was removed *in vacuo* from the mixture, and water (50 ml) was then added to it. Acetic acid was added to adjust the pH of the solution to 4—5. White precipitates were recovered by filtration, washed thoroughly with water, and dried *in vacuo* to give white powder; yield 1.8 g (100%), mp 135—145 °C (dec). On being left to stand the color of the product gradually turned violet particularly when slightly wet. IR (Nujol mull): 3300 (N–H str.), 3210 (O–H str.), and 1661 cm^{-1} (C=O str.).

1,19-Dideoxy-2,3,7,8,12,13,17,18-octaethylbiladiene-ac Dihydrobromide (1). A mixture of 3,3',4,4'-tetraethyldipyrromethane-5,5'-dicarboxylic acid (2.7 g), 2-formyl-3,4-diethylpyrrole[7,8] (2.3 g), and ethanol (80 ml) was heated at 60 °C with occasional shaking. Vigorous reaction took place upon addition of 47% aqueous hydrobromic acid (16 ml) at one time to the hot reaction mixture. The mixture was refluxed for 3 min and allowed to stand overnight in a refrigerator. The glittering red crystals were recovered by filtration, washed with ethyl ether, and recrystallized from chloroform–methanol to give reddish brown prisms; yield 4.0 g (79%). λ_{max} ($CHCl_3$): 374, 433, 460, and 526 nm. IR (KBr disk): 1605 cm^{-1} (biladiene skeletal str.). NMR (CF_3CO_2H, TMS): δ 1.26 (24H, overlapping t J=7.0 Hz, $CH_2\underline{CH_3}$), 2.74 (16H, overlapping q J=7.0 Hz, $\underline{CH_2}CH_3$), 4.60 (2H, s, bridging $-CH_2-$), 7.55 (2H, s, bridging –CH=), and 7.77 (2H, d J= 3.5 Hz, 1,19-H). Found: C, 61.13; H, 7.28; N, 7.90%. Calcd for $C_{35}H_{50}Br_2N_4$: C, 61.21; H, 7.35; N, 8.16%.

1,19-Dideoxy-2,3,17,18-tetramethyl-7,8,12,13-tetraethylbiladiene-ac Dihydrobromide (2). This was prepared from 3,3',4,4'-tetraethyldipyrromethane-5,5'-dicarboxylic acid (1.7 g) and 2-formyl-3,4-dimethylpyrrole[9] (1.05 g) in methanol (50 ml) and aqueous hydrobromic acid (47%, 9 ml) in the same manner as described above; reddish brown prisms, yield 2.4 g (73%). IR (KBr disk): 1608 cm^{-1} (biladiene skeletal str.).

2,3,7,8,12,13,17,18-Octaethylcorrolatocobalt(III) (3). To a mixture of biladiene-ac dihydrobromide **1** (200 mg) and *N,N*-dimethylformamide (25 ml) was added cobalt(II) acetate tetrahydrate (160 mg) dissolved in *N,N*-dimethylformamide (5 ml) with stirring. The reaction mixture was heated at 50 °C for 30 min with stirring and subsequently allowed to cool at 0 °C for 1 h. Recovered crystalline solid was recrystallized from chloroform–methanol as dark brown prisms; yield 90 mg (53%). The osmometric determination of molecular weight in carbon tetrachloride: 1125—1300 in the concentration range 2—4$\times 10^{-3}$ M; calcd mol wt for $C_{35}H_{43}CoN_4$ (monomer) 578.68. This result indicates the existence of monomer-polymer equilibrium in concentrated solutions. Found: C, 72.67; H, 7.46; N, 9.69%. Calcd for $C_{35}H_{43}CoN_4$: C, 72.63; H, 7.50; N, 9.68%.

Pyridine(2,3,17,18-tetramethyl-7,8,12,13-tetraethylcorrolato)cobalt(III) (4). A mixture of cobalt(II) acetate tetrahydrate (800 mg) and pyridine (20 ml) was heated on an oil bath until it turned into a clear solution. Biladiene-ac dihydrobromide **2** (1.0 g) was added to the reaction mixture, which was subsequently heated at 70—75 °C for 20 min with stirring. After addition of hot methanol (70 ml), the mixture was allowed to stand in a refrigerator for 2 h. The crystalline solid was recovered by filtration, and recrystallized from chloroform–methanol–pyridine (3 : 1 : 1) to give glittering purple prisms; yield 720 mg (76%). IR (Nujol mull): 1602 cm^{-1} (pyridine skeletal str.). Found: C, 72.07; H, 6.56; N, 12.48 %. Calcd for $C_{36}H_{40}CoN_5$: C, 71.85; H, 6.71; N, 11.64%.



1: $R_2=R_3=R_7=R_8=R_{12}=R_{13}=R_{17}=R_{18}=C_2H_5$
2: $R_2=R_3=R_{17}=R_{18}=CH_3$; $R_7=R_8=R_{12}=R_{13}=C_2H_5$

Results

NMR Behavior of Cobalt(III) Corrole. The NMR spectra of cobalt(III) corrole **3** were measured for the 10^{-2}—10^{-4} M concentration range in chloroform-*d* at room temperature. The intensity of proton signals appearing in the −5—+3 ppm region highly depends on concentration of the cobalt chelate as shown in Fig. 1. Particular attention should be paid to proton signals due to methylenes of the ethyl groups placed at the peripheral positions. The intensity of the meth-

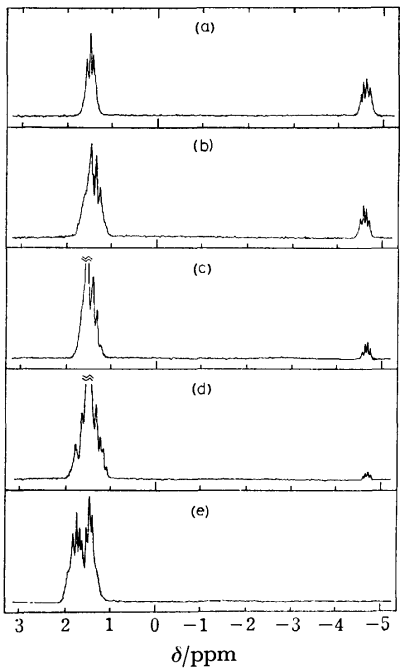

Fig. 1. NMR spectra of cobalt corrole **3** for the −5—+3 ppm range in chloroform-*d* at room temperature at various concentrations: (a), 3.04$\times 10^{-2}$ M; (b), 8.64$\times 10^{-3}$ M; (c), 2.94$\times 10^{-3}$ M; (d), 8.64$\times 10^{-4}$ M; (e), 8.64$\times 10^{-3}$ M (pyridine was added, 1.40$\times 10^{-2}$M).

ylene-proton signal observed at −4.6 ppm in a relatively high concentration range (Fig. 1 (a)) diminishes with decrease in the concentration of the complex. The intensity decrease is counterbalanced with the intensity increase for signals appearing in the 1.5—2.0 ppm range. The high-field signal (−4.6 ppm) disappeared completely, and the new signals were observed in the 1.5—2.0 ppm range upon addition of a 1.5-fold amount of pyridine to the cobalt corrole in 8.64×10^{-3} M (Fig. 1 (e)). The spectral change indicates that the cobalt corrole which exists in polymeric species (D and P in Scheme 2) in a relatively high concentration range dissociates into the monomer form upon coordination of pyridine at the axial sites.

The NMR behavior of the cobalt corrole is in line with the osmometric data which indicate the presence of monomer–dimer–polymer equilibria in a relatively high concentration range. From these measurements, cobalt(III) corrole **3** can exist predominantly in a monomeric species in a concentration range below 10^{-4} M. Since some minor impurity involved in chloroform-*d* showed a proton signal at 1.5 ppm, we were not able to evaluate the equilibrium constant for dimer formation.

Interaction between Cobalt(III) Corrole and Pyridine Bases. The electronic spectra for cobalt corrole **3** were measured by changing the concentration of pyridine bases in a wider range (0.5—10^4-fold amounts relative to **3**), while the concentration of **3** was maintained constant ($\approx7\times10^{-6}$ M). The spectral changes upon addition of pyridine are shown in Fig. 2, where isosbestic points are observed at 373, 400, 450, and 520 nm for the lower pyridine concentrations, and at 393, 460, and 532 nm for the higher concentrations (10^{-3}—10^{-1} M), while no distinct isosbestic points are present for the intermediate concentration range (10^{-4}—10^{-3} M). For the concentration range 10^{-1}—1 M, the electronic spectrum remains practically unchanged. This indicates that the axial sites of **3** are entirely occupied by

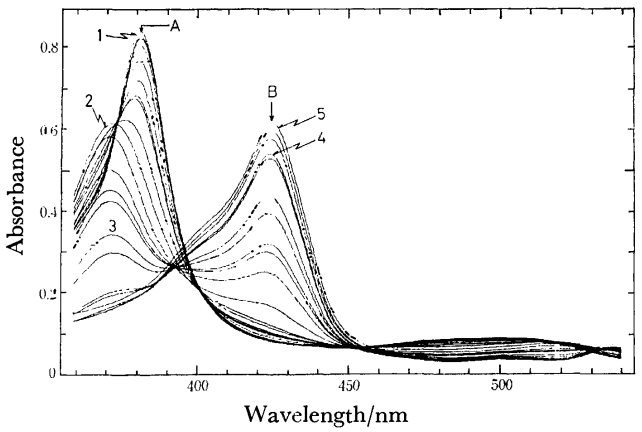

Fig. 2. Electronic spectra of cobalt corrole **3** (7.19×10^{-6} M) in acetone at 25.0±0.1 °C in the presence of pyridine at various concentrations (0—3.47 M): the absorption intensity in A-range decreases as pyridine concentration increases from 0 to higher, while that in B-range increases as pyridine concentration is raised. Pyridine concentrations: 1, 0 M; 2, 4.94×10^{-4} M; 3, 4.94×10^{-2} M; 4, 2.47×10^{-1} M; 5, 3.47 M.

pyridine molecules in this base-concentration range. As the pyridine concentration rises still higher, the spectral curves do not pass the isosbestic points most plausibly due to some solvent effect.

The spectral behavior is in line with the following equilibria.

Penta-coordination: $\mathrm{CoL} + \mathrm{B} \rightleftharpoons \mathrm{CoLB}$

$$K_1 = \frac{[\mathrm{CoLB}]}{[\mathrm{CoL}][\mathrm{B}]} \quad (1)$$

Hexa-coordination: $\mathrm{CoLB} + \mathrm{B} \rightleftharpoons \mathrm{CoLB_2}$

$$K_2 = \frac{[\mathrm{CoLB_2}]}{[\mathrm{CoLB}][\mathrm{B}]} \quad (2)$$

where CoL and B stand for cobalt corrole **3** and a pyridine base, respectively. At relatively low levels of the base concentration where the first set of isosbestic points are observed, the following stoichiometric relations hold.

$$[\mathrm{CoL}]_\mathrm{T} = [\mathrm{CoL}] + [\mathrm{CoLB}] + [\mathrm{CoLB_2}] \quad (3)$$

$$[\mathrm{B}]_\mathrm{T} = [\mathrm{B}] + [\mathrm{CoLB}] + 2[\mathrm{CoLB_2}] \quad (4)$$

where $[\mathrm{CoL}]_\mathrm{T}$ and $[\mathrm{B}]_\mathrm{T}$ represent total concentrations of cobalt corrole **3** and a pyridine base, respectively. Since no hexa-coordinated complex exists in any significant concentration, the last term of each equation can be neglected. The equilibrium constant (K_1) for the first axial coordination is given by

$$K_1 = \frac{[\mathrm{CoLB}]}{([\mathrm{CoL}]_\mathrm{T}-[\mathrm{CoLB}])([\mathrm{B}]_\mathrm{T}-[\mathrm{CoLB}])} \quad (5)$$

We employ here notations ε_i and A_i to represent molar extinction coefficient and optical density, respectively, for a cobalt corrole complex of coordination number i (i=4, 5, and 6), and A_obsd for observed optical density at various base concentrations while the concentration of cobalt complex was maintained constant. The following equation is derived for the first equilibrium step:

$$A_4 - A_\mathrm{obsd} = (\varepsilon_4-\varepsilon_5)[\mathrm{CoLB}]l = \Delta\varepsilon_\mathrm{I}[\mathrm{CoLB}]l \quad (6)$$

where l represents the length of light path.

For the higher base-concentration range where the second set of isosbestic points are observed, Eqs. 3 and 4 can be simplified as follows:

$$[\mathrm{CoL}]_\mathrm{T} = [\mathrm{CoLB}] + [\mathrm{CoLB_2}] \quad (7)$$

$$[\mathrm{B}]_\mathrm{T} = [\mathrm{B}] \quad (8)$$

Since a pyridine base was present in a large excess relative to the cobalt complex, the contribution of [CoLB] and $[\mathrm{CoLB_2}]$ to $[\mathrm{B}]_\mathrm{T}$ can be neglected. The corresponding equilibrium constant (K_2) is

$$K_2 = \frac{[\mathrm{CoLB_2}]}{([\mathrm{CoL}]_\mathrm{T}-[\mathrm{CoLB_2}])[\mathrm{B}]} \quad (9)$$

and

$$A_\mathrm{obsd} - A_6 = (\varepsilon_5-\varepsilon_6)[\mathrm{CoLB}]l = \Delta\varepsilon_\mathrm{II}[\mathrm{CoLB}]l \quad (10)$$

Combination of Eqs. 7 through 10 gives

$$A_\mathrm{obsd} = \frac{\Delta\varepsilon_\mathrm{II}[\mathrm{CoL}]_\mathrm{T}}{1+K_2[\mathrm{B}]_\mathrm{T}}l + A_6 \quad (11)$$

or

$$\frac{[\mathrm{CoL}]_\mathrm{T}l}{A_\mathrm{obsd}-A_6} = \frac{1}{\Delta\varepsilon_\mathrm{II}} + \frac{K_2}{\Delta\varepsilon_\mathrm{II}}[\mathrm{B}]_\mathrm{T} \quad (12)$$

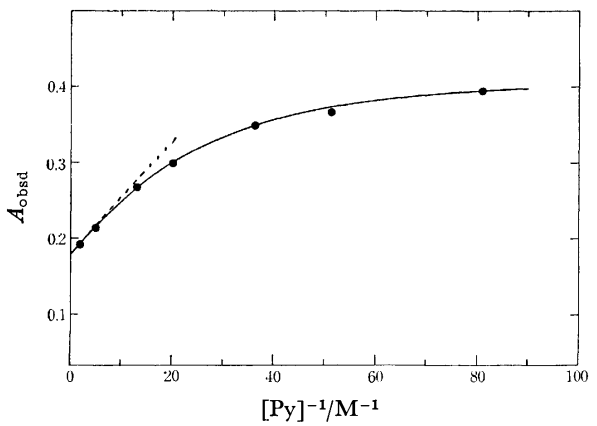

Fig. 3. Correlation of absorbance (at 380 nm) wtih pyridine concentration ([Py]) for the cobalt corrole (**3**)-pyridine system: $[\mathbf{3}]=7.19\times10^{-6}$ M in acetone at 25.0±0.1 °C.

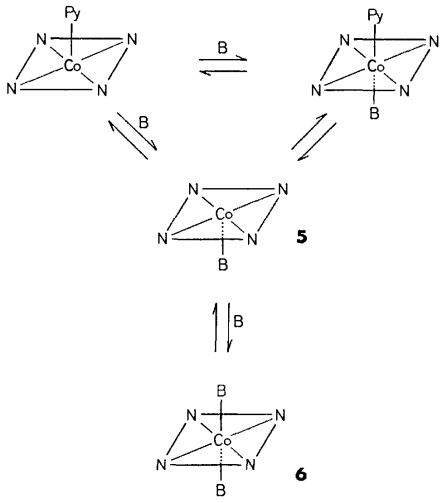

Scheme 1.

The subsequent mathematical treatments were performed by referring to the absorption intensities observed at 380 nm. The A_6-values were evaluated by extrapolation of the A_{obsd}—[Pyridine base]$^{-1}$ correlation curve to [Pyridine base]$^{-1}\rightarrow0$ on the basis of Eq. 11, as exemplified for the **3**–pyridine system in Fig. 3. Since all the cobalt species exist in the hexa-coordinated form at the pyridine-base concentrations of 0.1—1 M as judged from the corresponding spectral behavior (refer to Fig. 2), A_6-values can be evaluated directly from the corresponding spectra. The agreement between graphically and directly determined A_6-values was quite satisfactory; *e.g.*, 0.182 and 0.179, respectively, with pyridine at 7.19×10^{-6} M of **3**. The graphically determined A_6-values were used, however, for further computations for the sake of reliability. K_2 and $\Delta\varepsilon_{II}$ values were obtained by means of Eq. 12, as exemplified for the **3**–pyridine system in Fig. 4. From the analysis of spectral data for the second equilibrium step, ε_5 and ε_6 values were evaluated, which can be used for the analysis of the first equilibrium step by means of Eqs. 5 and 6.

The axial coordination behavior of penta-coordinated cobalt corrole **4** was also investigated in the presence of large excess of pyridine bases and the corresponding K_2-values were evaluated in the same way as described above. The equilibrium step for the **4**–pyridine base systems under investigation can be referred to process **5**⇌**6** shown in Scheme 1. We confirmed this by preparing the penta-coordinated 4-aminopyridine and 4-methylpyridine adducts of (tetramethyltetraethylcorrolato)cobalt(III) independently. In the presence of the same pyridine bases as used for the formation of these base adducts, the corresponding equilibrium constants were evaluated by means of Eq. 12. The values are in good agreement with those evaluated for the **4**–pyridine base systems within an experimental error. All the formation constants obtained in this work are listed in Table 1.

Interaction between Cobalt(II) Corrole Anion and Pyridine. The ESR spectra for the anionic cobalt(II)–corrole complex were not observed at room temperature probably due to short spin-lattice relaxation time. The (2,3,17,18-tetramethyl-7,8,12,13-tetraethylcorrolato)-cobaltate(II) ion shows an ESR spectrum at 77 K with three g-values (g_1, g_2, and g_3) as shown in Fig. 5. Eight hyperfine splitting lines through interaction with ^{59}Co

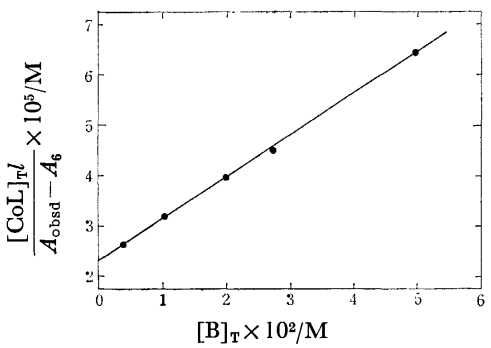

Fig. 4. Determination of K_2 and $\Delta\varepsilon_{II}$ values for the cobalt corrole (**3**)-pyridine (B) system on the basis of Eq. 12: $[\mathbf{3}]=7.19\times10^{-6}$ M in acetone at 25.0± 0.1 °C.

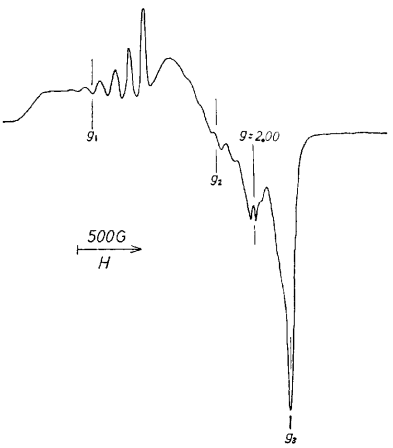

Fig. 5. ESR spectrum of the (2,3,17,18-teramethyl-7,8,12,13-tetraethylcorrolato)cobaltate(II) ion in *N*,*N*-dimethylformamide at 77 K. Thecobalt(III) corrole (**4**) was reduced with $NaBH_4$ in *N*,*N*-dimethylformamide.

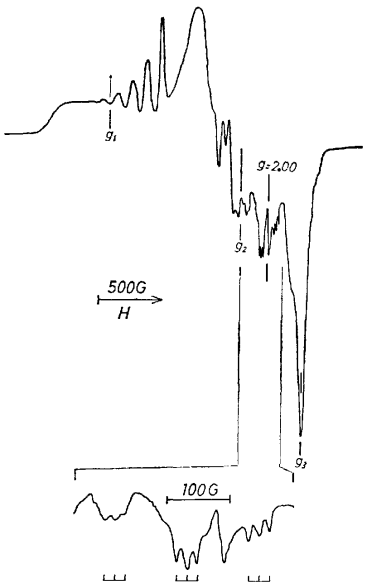

Fig. 6. ESR spectrum of the (2,3,17,18-tetramethyl-7,8,-12,13-tetraethylcorrolato)cobaltate(II) ion in *N,N*-dimethylformamide-pyridine (3 : 1 by volume) at 77 K. The g_2 component is expanded as shown in the lower part; triplet superhyperfine structure is observed.

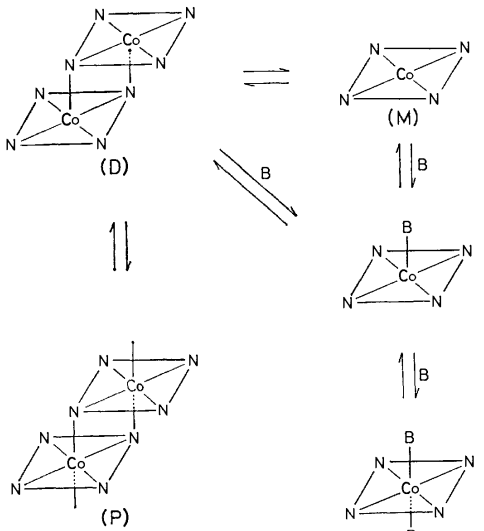

Scheme 2.

nucleus (I=7/2) are also observed in the g_1 and g_2 ranges, indicating that the central cobalt is in a low spin state (S=1/2). Upon addition of pyridine, a triplet superhyperfine structure can be seen on the hyperfine lines of the g_2 component as shown in Fig. 6. This may be caused by the interaction between nitrogen nucleus of the axially coordinated pyridine molecule and electron occupying the d_{z^2} obrital of the nuclear cobalt. Further spectral change was not observed by increasing the pyridine content. Consequently, only one pyridine molecule can be coordinated to the anionic cobalt(II)-corrole complex.

Discussion

The solution equilibria for the cobalt(III) corrole in the presence of amine bases can be illustrated by Scheme 2. The cobalt(III) corrole forms polymeric species in an organic solvent most plausibly through metal–nitrogen bonding in a manner as suggested for the copper(II) complex of phthalocyanine.[10)] The presence of such polymeric species is significant in a concentration range above 5×10^{-3} M as detected by the accumulative NMR measurements. The first equilibrium constants (K_1) for the formation of pyridine adducts of **3** are larger by one order of magnitude than those for the cobalt(II) complex of 1,19-disubstituted tetradehydrocorrin.[2)] This is attributed to the greater electrophilicity of nuclear cobalt in trivalent state. The second equilibrium constants (K_2) are much smaller than the K_1-values by an order of 10^2—10^3 due to the so-called *trans effect* in a manner as observed for the axial ligation of pyridine to tetrakis(4-*N*-methylpyridyl)porphincobalt(III).[11)] The equilibrium constant (K_i, $i=1$ or 2) can be correlated with the basicity of pyridine bases (pK_a) by Eq. 13 for the axial coordination of pyridine bases to the cobalt corroles except for 2-methyl- and 3-acetylpyridine, as shown in Fig. 7.

$$\log K_i = a\cdot pK_a + b \qquad (13)$$

The *a*- and *b*-parameters thus evaluated are listed in

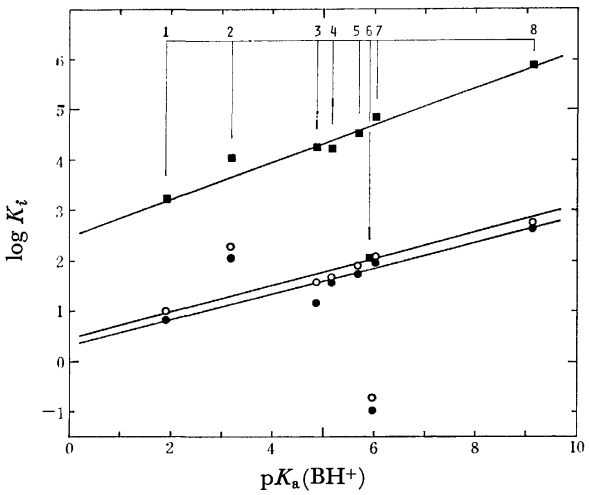

Fig. 7. Correlations between formation constant (K_i) and amine basicity: ■, K_1 for the **3**-amine system; ●, K_2 for the **3**-amine system; ○, K_2 for the **4**-amine system. Amines: 1, 4-CNPy; 2, 3-AcPy; 3, 3-HOPy; 4, Py; 5, 3-CH_3Py; 6, 2-CH_3Py; 7, 4-CH_3Py; 8, 4-NH_2Py (see Table 1 for abbreviations).

Table 2. Lower coordination ability of 2-methylpyridine with respect to the correlation line given by Eq. 13 is attributed to the steric hindrance effect due to the interaction between the corrole skeleton and the 2-methyl group of the pyridine base. The free energy loss by the steric effect is estimated to be 3.5 kcal/mol (25 °C) for the penta-coordination step, while 3.8 kcal/mol (25 °C) for the hexa-coordination process. That the free energy loss for the latter coordination process is comparable to that for the former is quite reasonable because no extra steric effect would be expected for the latter. On the other hand, 3-acetylpyridine shows a greater formation constant for its pK_a-value. The $d\pi$-$p\pi$ interaction betweeen the nuclear cobalt and the pyridine nitrogen, which is facilitated by the 3-acetyl group, would be responsible for such apparent increase in formation constant.

The equilibrium data for the present set of pyridine bases can be referred to the Hammett equation for which the coordination equilibrium with pyridine (K_i^0) is taken as a reference and suffix i stands for either 1 or 2.

$$\log K_i/K_i^0 = \rho\sigma . \quad (14)$$

The evaluated ρ values are listed in Table 2 along with other reference data of relevant cobalt(II) complexes.

It must be noted that both a and $-\rho$ values for the present cobalt(III)–corrole systems are considerably larger than the corresponding values for cobalt(II) complexes of protoporphyrin[12] and tetrakis(*p*-methoxyphenyl)porphyrin.[13] The values for the first coordination step of **3** is even larger than those for Co(II)–TDHC in spite of the fact that TDHC and corrole are anionic ligands with charges of −1 and −3, respectively. The a and ρ values suggest that the nuclear cobalt in cobalt(III) corrole is more electronegative than those in cobalt(II) complexes listed in Table 2, even though the total electric charges at the coordination site of corrole and porphyrin complexes are neutral and that of TDHC complex is positive (+1). It should be pointed out, however, that the a and $-\rho$ values for cobalt(III) corroles in the second coordination process are more or less comparable to those for Co(II)–TDHC. This seems to indicate that the extent of σ- and π-bonding characters of the coordinate bond formed in the final coordination step of cobalt(III) corroles is nearly the same as that of Co(II)–TDHC, since the former complexes secure the trans effect of the initially coordinated pyridine bases.

When the cobalt corrole is reduced at the nuclear cobalt from trivalent to bivalent state, only one pyridine molecule can be coordinated at its axial sites and hexacoordination is no longer possible as confirmed by ESR measurements. Cobalt(III) corrinoid forms the hexacoordinated complexes with amine bases at its axial positions but cobalt(II) corrinoid yields the bis(pyridine) complex only at a very high pyridine concentration, whereas bis(dimethylglyoximato)cobalt(II) takes on two pyridine ligands readily.[14] In this respect, the present tetrapyrrolic ligand gives out an equatorial ligand effect on the nuclear cobalt in a manner analogous to that observed for corrinoid. In other words, the axial ligation behavior of cobalt corrinoid is more or less analogous to that of cobalt corrole and differs a great deal from that of cobaloxime.

Synergistic Effect of Pyridine and Ammonia in the Extraction of Copper(II) Fixed on the Ion Exchange Resin with 2-Thenoyltrifluoroacetone

Kunio OHZEKI, Katsunori NOZAWA, and Tomihito KAMBARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 31, 1977)

The composition of hydrated copper(II), copper-pyridine, and -ammine species fixed on the cation exchange resin was determined by chemical and thermogravimetric analyses. Provided that all the water and bases were coordinated to copper(II) ion, the species on the resin were estimated to be $[Cu(H_2O)_5]^{2+}$, $[Cu(py)(H_2O)_3]^{2+}$, and $[Cu(NH_3)_3(H_2O)_3]^{2+}$, respectively. The removal of copper(II) ion from the resin with 2-thenoyltrifluoroacetone (Htta) was studied in various organic solvents. The rate of reaction was accelerated with the replacement of water molecules coordinated to the metal ion with pyridine or ammonia.

The reaction of metal ion fixed on the ion exchange resin with β-diketone in the organic phase has been investigated.[1-3] The quantitative removal of copper(II) ion fixed on Amberlyst 15 by acetylacetone was first achieved by the addition of a small amount of pyridine.[2] The effect of pyridine in the above system is considered to be similar to that observed in the solvent extraction system, *i.e.*, the rate-promoting synergistic effect.[4,5] Akaiwa *et al.* investigated the kinetics of synergistic extraction with nickel(II)– and cobalt(II)–Htta–pyridine base systems, and reported that the formation of the mono(tta) complex is accelerated by the pyridine base, which seemingly facilitates the release of a water molecule bound to metal ion.[5]

In the present work, it is shown that the reaction of copper(II) ion fixed on the resin with Htta is increased by replacement of some of the coordinated water molecules by unidentate neutral ligands, such as pyridine and ammonia.

Experimental

Apparatus and Reagents. Thermogravimetric curves were recorded with a Shimadzu thermal micro-balance TGA-20 with 5 mg sample at a heating rate 5 °C min^{-1} in the air. A Hitachi 508 atomic absorption spectrometer was used for the determination of copper and for the flame photometric determination of sodium. Visible absorption spectra were measured with a Hitachi 356 two-wavelength double beam spectrophotometer. 2-Thenoyltrifluoroacetone (Wako Pure Chemicals, Inc.) was used without further purification. Chloroform was purified by distillation after washing. Copper(II) sulfate and the other materials used were of guaranteed grade.

Preparation of Copper(II) Form Resin. Macroreticular resin Amberlyst 15 (Rohm and Haas Co.) was used. The dry resin was sized into the 60—80 mesh range, washed with ethanol, cleaned and recycled several times between hydrogen and sodium forms, ending in the latter. It was converted, in a column, into the copper-ammine form with 1.0 M (M=mol dm^{-3}) aqueous ammonia solution containing a total copper(II) concentration of 1.0×10^{-2} M, and washed with a dilute ammonia solution until the effluent became colorless. The copper-py form resin was also prepared using the copper(II) solution containing a large excess of pyridine. The copper(II)-aqua form resin was prepared as usual. The resins were air- and oven-dried at 105 °C for 3 h to purge free base and moisture, and then stored in a desiccator over silica gel for six months. The resin has a characteristic color; namely, Cu-ammine form light blue, Cu-py form grayish green, and Cu-aq form grey, respectively.

Chemical Analysis of the Species on the Resin. The column packed with a known amount of each form of resin was prepared, and the metal ion on the resin was eluted with 2 M hydrochloric acid, and then the column was washed free from the acid with water. The content of hydrogen ion in the resulting resin was determined by titration and the exchange capacity of the resin was evaluated. The analysis of the eluate was carried out as follows. The copper(II) content was determined by EDTA titration. Sodium was determined by flame photometry and the ion exchange sites which have not been displaced by copper(II) were found. Ammonia was determined by back titration; namely, after masking the copper(II) ion with EDTA, a known excess of a standard sodium tetraphenylborate was added to the sample solution, the resulting precipitate was filtered, and then the unreacted precipitant was determined with a standard solution of zephiramine (benzyldimethyltetradecylammonium chloride). The pyridine content was successfully determined spectrophotometrically with potassium thiocyanate-1-phenyl-3-methyl-5-pyrazolone.[6] It was found from the preliminary experiments carried out with synthetic samples that the interference by copper(II) ion could easily avoided with EDTA.

Results and Discussion

Chemical Analysis. The analytical data are given in Table 1. Provided that all the bases found on the resin were coordinated to copper(II), the mole ratio of copper to ammine and that of copper to py in the complexes are 1 : 3 and 1 : 1, respectively. The proportion of the ion exchange sites occupied by the copper(II) species to the exchange capacity was found to be as follows: Cu-aq form resin 100%, Cu-ammine 86%, and Cu-py 66%. The total amounts of copper(II) and sodium ions were less than the exchange capacity in the case of Cu-ammine and Cu-py form resins. Remaining sites on the resins may be occupied by hydrogen ions as a result of the probable decomposition of formerly adsorbed ammonium or pyridinium ions during the course of oven drying.

Thermogravimetric Analysis. It was found from preliminary experiments that a considerable amount of water had been adsorbed on the resin during six months' storage over silica gel in a desiccator. The thermogravimetric analysis was applied to the determination of water content in the resin. The resin matrix begins to decompose at around 300 °C as shown in Fig. 1. Upon further heating, it decomposes rapidly leaving a black residue. Only one step was found on the thermogravimetric curve of the Cu-aq form resin

Table 1. Results of analysis the species on the resin

Complex on the resin	Weight of resin taken (mg)	Cu found (μmol)	Base found (μmol)	Na found (μmol)	H^+ found after conversion to H-form (μmol)	Water found [a] (μmol)

a) Results of thermogravimetric analysis.

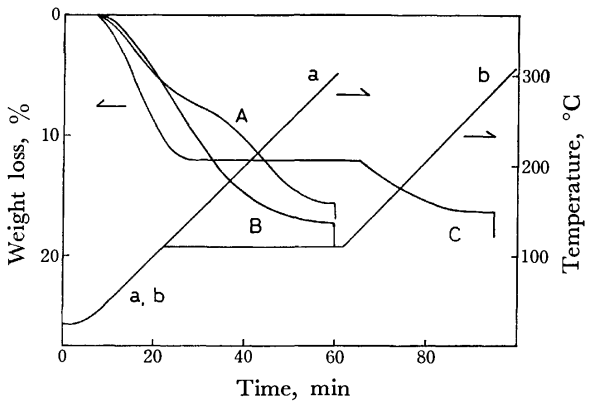

Fig. 1. Thermogravimetric curves of (A) copper-py, (B) copper-ammine, and (C) copper-aq form resin. The curves a and b indicate the heating rate.

at the constant heating rate of 5 °C min^{-1}. The mole ratio of water to copper content on the resin was found to be 5 : 1. On keeping the temperature at 110 °C, the Cu-aq form resin was found to show a constant weight after losing 4 molecules of water (curve C, Fig. 1). Thus, the copper species on the resin at 110 °C was expected to be $[Cu(H_2O)]^{2+}$, which agrees with the result of previous investigation.[2] The copper-py form resin gave two steps before 300 °C. The first step in the temperature range 40—110 °C was assumed to be due to the loss of water, and the second in the range 110—300 °C due to the loss of pyridine. The ratio of pyridine to copper content was found to be 1 : 1, which is consistent with the result of chemical analysis (Table 1), the ratio of water to copper content being 3 : 1. On keeping the temperature at 110 °C, the weight loss reached a constant and definite value, the resulting copper species being found to be $[Cu(py)]^{2+}$. The copper-ammine form resin decomposed in one step before decomposition of the resin matrix. The water content was calculated from the weight loss and analytical data of resin, the weight loss being assumed to be caused by the loss of water and ammonia. The ratio of water to copper content on the resin was found to be 3 : 1.

Copper Species on the Resin. Provided that all the water and base molecules determined by chemical and thermogravimetric analysis are bound to copper(II), the composition of copper species on the resin was found to be $[Cu(H_2O)_5]^{2+}$, $[Cu(py)(H_2O)_3]^{2+}$, and $[Cu(NH_3)_3(H_2O)_3]^{2+}$.

Reaction of Copper Species on the Resin with Htta. A weighed portion of the resin containing 2 mg of copper(II) was taken into an eggplant type flask and a 10-ml portion of 0.1 M Htta solution was added. After mechanical shaking for a certain time at room temperature, the resin was separated by filtration, washed with a small amount of ethanol, and then with water. Copper(II) ions remaining on the resin were eluted with 2 M hydrochloric acid solution and determined by atomic absorption spectrometry. The feasibility of extraction of copper(II) from the resin into Htta-benzene and Htta-chloroform solution increased in the order: Cu-aq, Cu-py, and Cu-ammine (Figs. 2 and 3).

More than 99% of copper(II) was removed from Cu-ammine form resin after a 15-min shaking, while *ca.* 50% of copper(II) was extracted from Cu-aq form resin. The mole ratio of copper to Htta in the complex was confirmed to be 1 : 2. However, the formation of an adduct, such as $[Cu(tta)_2py]$, was not found spectrophotometrically. In carbon tetrachloride

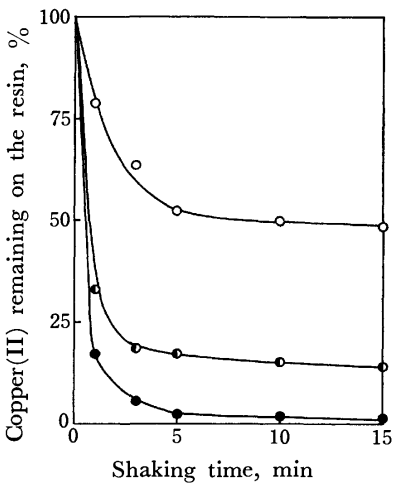

Fig. 2. Effect of shaking time on the removal of copper(II) from the resin into 0.1 M Htta solution in benzene. ○: Copper-aq, ◐: copper-py, ●: copper-ammine form resin.

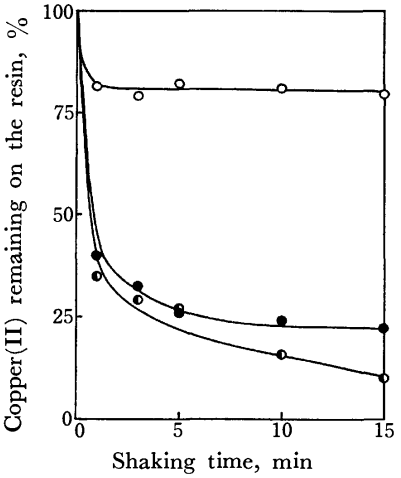

Fig. 4. Effect of shaking time on the removal of copper-(II) from the resin into 0.1 M Htta solution in carbon tetrachloride. The symbols on each curve are the same as in Fig. 2.

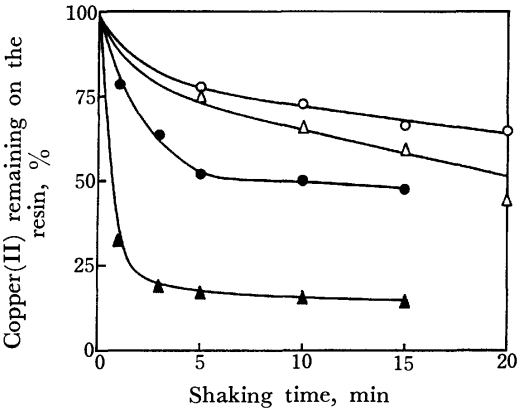

Fig. 6. Effect of water contents on the removal of copper-(II) into 0.1 M Htta solution in benzene. Air-dried resin; ●: copper-aq, ▲; copper-py form. Oven-dried resin; ○: copper-aq, △: copper-py form.

solution, Cu-py species was most easily expelled by Htta, whereas Cu-aq species persistently remained on the resin (Fig. 4). In ethanol solution, the rate of conversion of Cu-aq species on the resin into the tta complex was highly increased in comparison with the other solvent systems (Fig. 5). The color of the resulting solution was light green. The absorption maximum at 670 nm suggests the adduct formation between $[Cu(tta)_2]$ and ethanol. Since the phenomenon was characteristic to the aquacopper(II) ion, the first step of the reaction might be assumed to be the displacement of water molecules associated to copper(II) on the resin with ethanol.

Effect of Water. The Cu-aq and Cu-py form resins were dried at 110 °C and cooled for 3 h over silica gel in a desiccator. The copper species on the resin were estimated to be $[Cu(H_2O)]^{2+}$ and $[Cu(py)]^{2+}$, respectively. Evidence for the binding of pyridine to copper(II) was revealed by the light blue color of the resin phase. The results of the removal of copper(II) by Htta in benzene are given in Fig. 6. For the sake of comparison, the results of $[Cu(H_2O)_5]^{2+}$ and $[Cu(py)(H_2O)_3]^{2+}$ in the Htta-benzene system are also illustrated. The reactivity decreases with the removal of some or all water molecules around copper(II).

It can be assumed that the reaction of copper(II) with Htta is accelerated when the coordination sites around the copper(II) ion on the resin are simultaneously occupied by both water and pyridine. The pyridine probably facilitates the release of a water molecule bound to the copper(II) ion when Htta attacks the metal ion to form the mono(tta) complex, and with the progress of complexation the adsorption sites of the resin are competitively occupied by pyridinium and hydrogen ions. The synergistic effect might also hold in the case of the reaction of the copper–ammine complex with Htta and that of aquacopper(II) species with Htta in ethanol.

The Formation of Manganese and Cobalt Ferrites by the Air Oxidation of Aqueous Suspensions and Their Properties

Masao KIYAMA

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received June 3, 1977)

Manganese and cobalt ferrites were prepared by the air oxidation of aqueous suspension of $Fe(OH)_2$ and either $Mn(OH)_2$ or $Co(OH)_2$ at 50—80 °C. In alkaline suspensions, all the metal ions are transformed into spinel ferrites, $M_xFe_{3-x}O_4$ (M=Mn or Co), by a suitable combination of the oxidation temperature and the concentration of the excess NaOH. Both manganese and cobalt ferrites consist of ferromagnetic particles (ferrite(A)) when x is smaller than 1.3, nonferromagnetic particles (ferrite(B)) when x is larger than 2, and mixtures of the two in the intervening range. The contents of Mn or Co, both in a solid solution of hydroxides, $M_{x/3}Fe_{1-x/3}(OH)_2$, and in ferrite, increase with the progress of the formation of the ferrite(A) caused by oxidation. The formation of the ferrite(B) begins when x in the solid solution reaches 2. Each particle in the ferrite(A) is less homogeneous in comparison with that in the ferrite prepared by a solid-state reaction, although with the same composition. The difference in the homogeneity causes the essential difference in magnetic properties.

Spinel ferrites with the general formula of $M_xFe_{3-x}O_4$(M being a bivalent metal ion, such as Mn^{2+}, Co^{2+}, Ni^{2+}, or Mg^{2+}), polycrystalline compounds prepared by a solid-state reaction between the constituent oxides, MO and Fe_2O_3, have been thoroughly investigated as regards their properties[1-3] and the conditions needed for their formation.[4] An alternative method of formation, precipitating spinel ferrites from aqueous suspensions containing $M(OH)_2$ and $Fe(OH)_3$ at the boiling point, was worked out by Schuele and Deetscreek.[5] The precipitates thus prepared consist of superparamagnetic particles of MFe_2O_4.

The appropriate conditions of oxidation have been found for the preparation of Fe_3O_4 from a $Fe(OH)_2$ suspension.[6] Since all the spinel ferrites have the same crystal structure as that of Fe_3O_4, it seemed to the present author that it would be possible to prepare the spinel ferrites under conditions similar to those used for the formation of Fe_3O_4, provided that $Fe(OH)_2$ and $M(OH)_2$ coexist in the starting suspension. The formation of a few kinds of spinel ferrites has been achieved from suspensions.[7-9] It was found that the composition of manganese and cobalt ferrites can be optionally varied in the $0 \leq x \leq 3$ range by selecting appropriate oxidation conditions.

This paper will give an account of the conditions and mechanisms for the formation of $Co_xFe_{3-x}O_4$ and $Mn_xFe_{3-x}O_4$ as well as of their properties.

Experimental

The starting suspension containing $Fe(OH)_2$ and either $Mn(OH)_2$ or $Co(OH)_2$ was prepared as follows. The required amounts of $FeSO_4 \cdot 7H_2O$, $MnSO_4 \cdot 5H_2O$ or $CoSO_4 \cdot 7H_2O$ (analytical grade) were dissolved in 1 l water, the resulting solution being acidic. To this NaOH was then added in the required amounts. Each suspension was diluted with water to 3 l. A number of suspensions were thus prepared, varying in the mole ratio of $2OH^-/SO_4^{2-}$ ($=R$) and in the metal concentration. The oxidation of the suspensions was carried out by bubbling air into them at a constant rate of 300 l/h for a period of 20 h. The details of the procedure of oxidation were previously reported.[6] A series of suspensions were prepared by adding excess aqueous ammonia to the solution. Air containing NH_3, bubbled through 0.5 M aqueous ammonia in a separate vessel, was used for oxidation.

The oxidation products were separated from each solution by filtration, washed with water, treated with acetone, and then dried at 50 °C under reduced pressure. The products, found by X-ray analysis to consist of only ferrites, were subjected to electronmicroscopic observation, and BET surface area and magnetic measurements. The mean particle size, $r(\mu m)$, of each product was estimated from the BET surface area by assuming that each particle was cubic.

The contents of Fe, Mn, and Co ions in the products were determined by the usual chemical analysis, combined with either X-ray-fluorescence or atomic-absorption spectrometry. The results agreed to within 0.01 in x; that is, $M_{1.00}Fe_{2.00}O_4$ has $x=1.00(\pm 0.01)$.

The excess oxygen content, δ, in a powdery sample of $MnFe_2O_{4+\delta}$ was determined by means of a reaction between the sample and the Fe^{2+} ion in an acidic solution. After the sample had been dissolved in a mixture of 0.05 M $FeSO_4$ and a dilute solution of H_2SO_4 and H_3PO_4 by heating in a nitrogen atmosphere, the amount of the Fe^{2+} ion remaining in the mixture was titrated with $KMnO_4$.

Results and Discussion

Conditions for the Formation of Ferrites. When a solution of NaOH was added to an acidic solution containing 0.72M $FeSO_4$ and either 0.36M $MnSO_4$ or 0.36M $CoSO_4$, a whitish precipitate was formed. When NaOH was added to the acidic solution in the $0.1<R<1$ range, a whitish precipitate appeared in a neutral or slightly alkaline suspension. The precipitate was found to be amorphous by X-ray analysis. When $R>1$, X-ray analysis showed that the precipitate had a CdI_2-type crystal structure. Through oxidation, the ferromagnetic precipitate was formed indirectly via a dark green intermediate oxidation product, or directly from a whitish precipitate, provided that a suitable oxidation temperature was chosen.

When $R<1$, a dark green precipitate(which is nonferromagnetic at room temperature) appeared upon oxidation. During oxidation, the concentration of the dissolved metal ions in the suspension medium decreased. The dark green precipitate was found by microscopic and X-ray diffraction examinations to consist of hexagonal, plate-like particles with the same crystal structure (a_0 3.17 and c_0 10.7 Å) as that of green rust II.[10] In view of the composition of green rust II, the precipitate is inferred to be a basic sulfate, one-half containing bivalent, and the other half, trivalent

metal ions. The dark green precipitate was gradually transformed into a brownish black and ferromagnetic precipitate during oxidation, provided that the temperature of suspension was kept higher than that at which a yellowish brown precipitate, which is non-ferromagnetic at room temperature, would occur. The intermediate oxidation product was eventually transformed into the brownish black and ferromagnetic precipitate by oxidation, with an abrupt drop of the pH value to 6 or a little lower, and with the cessation of the occurrence of the ferromagnetic precipitate. At the same time, the concentration of the Mn^{2+} or Co^{2+} ion increased to the concentration in the starting suspension medium. Further oxidation merely caused a very slight dissolution of the Mn^{2+} or Co^{2+} ion contained in the ferromagnetic particles.

When $1<R\leq3$, the metal ions were precipitated almost entirely as hydroxides of Fe^{2+} and Mn^{2+} or Co^{2+} in the form of a solid solution of $M_{x/3}Fe_{1-x/3}(OH)_2$ (M=Mn or Co). With a decrease in the amount of the solid solution during oxidation, the amount of the black ferromagnetic precipitate increased in the suspension when a suitable oxidation temperature was selected.

Microscopic and X-ray diffraction examinations showed that the ferromagnetic products consist of cubic or spherical particles of the cubic spinel ferrite, whereas the yellowish brown products consist of needle-like particles with the same crystal structure as that of α-FeO(OH).[11] It was found from these experiments that the temperature at which ferrites were formed was lowered with a decrease in the concentration of excess NaOH or a metal sulfate and that the R range suitable for ferrite formation became wider with an increase in the oxidation temperature beyond 50 °C. The composition of the products obtained at 70 °C by varying the R is given in Table 1, together with the change in pH before and after oxidation. The x value of the $Co_xFe_{3-x}O_4$ samples prepared in the presence of aqueous ammonia is 1.00 or less, depending on the concentration of aqueous ammonia present, as a result of the formation of ammine complexes of Co^{2+} in the suspension medium. When $0.6<R<3$, the needlelike particles besides the ferrite particles were formed at 70 °C.

The sample of ferrite prepared at 70 °C from a suspension containing an excess of aqueous ammonia

a) Excess aqueous ammonia used as a precipitant.

or no excess NaOH ($R<1$) consisted of a mixture of very fine particles(size, 0.01 μm) and spherical particles(size, 0.1—0.2 μm), their mean particle size, r, being less than 0.1 μm. The r value increased as the concentration of excess NaOH in the alkaline suspension was increased.

Properties of Manganese Ferrites. $MnFe_2O_{4+\delta}$ samples were prepared at 50—80 °C from each of the alkaline suspensions with $R=1.1$—3.0 containing 0.36 mol/l of $Mn_{1/3}Fe_{2/3}(OH)_2$. Table 2 demonstrates that an increasing T and/or R increases r and slightly decreases the lattice constant, a_0, and the excess oxygen content, δ. A Mn NMR spectral pattern of the $MnFe_2O_4$ precipitate prepared from a suspension exhibits two peaks, at 551 and 524 MHz, at room temperature, with the higher peak corresponding to the Mn ions at the A sites in the spinel-crystal structure.[8] The patterns of the samples obtained showed that the higher peak becomes higher and steeper with an increasing R and T, but the ratio of peak heights remains almost constant, the Curie temperatures estimated from the patterns all being 500 °C.

Samples of $Mn_xFe_{3-x}O_4$ were prepared by subjecting suspensions containing 0.36 mol/l of $Mn_{x/3}Fe_{1-x/3}(OH)_2$ with various x and one of 0.072, 0.72 or 1.44 M excess NaOH(=1.1, 2.0, and 3.0 in R, respectively) to oxidation at 70 °C. The samples with $0\leq x\leq1.3$ were found to consist only of the cubic spinel ferrite. In the $1.4\leq x\leq1.8$ range, a small amount of tetragonally deformed spinel ferrite coexisted with the cubic spinel

Table 2. Properties of $MnFe_2O_{4+\delta}$ formed at various oxidation temperatures, T, and R values

R	T(°C)	r(μm)	a_0(Å)	δ
1.1	70	0.17	8.464	0.025

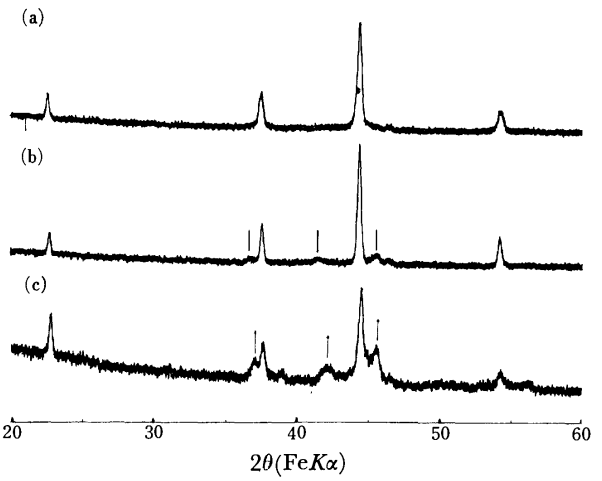

Fig. 1. X-Ray diffraction patterns of $Mn_xFe_{3-x}O_4$ precipitates, (a) $x=1.5$, $R=1.1$, (b) $x=1.5$, $R=2.0$, and (c) $x=2.0$, $R=1.1$. Arrows indicate the peaks caused by the presence of a tetragonal ferrite.

ferrite. As the concentration of excess NaOH increases, the content of the tetragonal ferrite in the mixture slightly increases for a given value of x((a) and (b) in Fig. 1). The content began to increase remarkably at $x=2$ (c) and reached 100% for $x\geq 2.6$. The shape and size of both kinds of ferrite particles with $x\leq 1.3$ and $x\geq 2.6$, prepared at given concentrations of excess NaOH, were found by microscopic examination to be similar. When $x<1$, the a_0 of the cubic spinel ferrites increases with x, regardless of the concentration of excess NaOH(Fig. 2). It approaches 8.5 Å with a further increase in x, depending on the concentrations of excess NaOH. The Mn NMR spectral patterns of these cubic spinel ferrites showed that an increase in x shifts the higher peak to the lower frequency side as a result of lowering the Curie temperature(447 °C for $x=1.3$). Heating the samples of $Mn_xFe_{3-x}O_4$ *in vacuo* at 450 °C decreased the Curie temperature and increased a_0(to the value of the dotted curve shown in Fig. 2), both the values approaching those of a manganese ferrite with the same composition prepared by a solid-state reaction. It was found by electron-microscopic examination that the particle shape and size in each sample with $x\leq 1.3$ remain almost unchanged in spite of heat treatment at 450 °C.

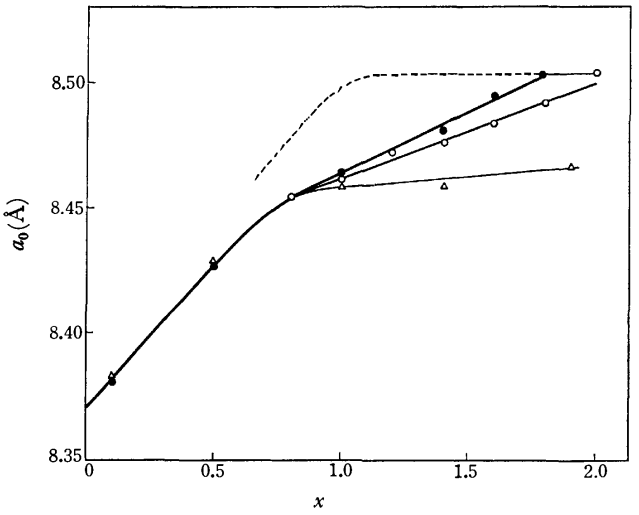

Fig. 2. Lattice constant a_0 of cubic spinel ferrite as a function of x in $Mn_xFe_{3-x}O_4$ preicpitates prepared from the suspensions with $R=1.1$(●), 2.0(○), and 3.0(△) by oxidation at 70 °C.

Properties of Cobalt Ferrites. Samples of $Co_xFe_{3-x}O_4$ were prepared by oxidizing at 70 °C suspensions containing 0.36 mol/l of $Co_{x/3}Fe_{1-x/3}(OH)_2$ with various x and 0.075 M excess NaOH. Figures 3 and 4 show, respectively, electron-micrographs and X-ray diffraction patterns of some typical samples. The black and ferromagnetic samples with $0\leq x\leq 1.3$ consisted of cubic particles (for $0\leq x\leq 0.6$), or spherical particles (for $0.9\leq x\leq 1.3$), and had lattice constants which were nearly constant at 8.38 Å. When $x\geq 1.4$, very fine particles of another kind of ferrite with a_0 8.34—8.31 Å coexist with the spherical particles((a) and (b) in Figs. 3 and 4).

Increasing the x caused a retardation of the rate of transformation of the solid solution of hydroxides, $Co_{x/3}Fe_{1-x/3}(OH)_2$, into ferrites. In the $2\leq x\leq 3$ range, the solid solution was not completely transformed into ferrites in 20 h(Fig. 4(c)), so that the oxidation was carried out for 50 h. The resulting sample with $x=2.4$ was nonferromagnetic because of its Curie temperature, lower than room temperature,[12] consisting of very fine particles (Fig. 3(c)). Incidentally, the nonferromagnetic samples with $2.7\leq x\leq 3.0$ had the same crystal structure as that of $CoHO_2$(=CoO(OH)).[13]

Similar experiments were conducted with $Co_xFe_{3-x}O_4$ by varying the excess NaOH concentration in the 0.1—1.5 M range. The results indicated that increasing the concentration of excess NaOH accelerates the particle growth of $Co_xFe_{3-x}O_4$ with $0\leq x\leq 1.3$ and causes a slight decrease in the content of the nonferromagnetic ferrite for a given value of x(the inset in Fig. 4(b)). In the absence of excess NaOH($0.9\leq R\leq 0.95$), the oxidation products obtained at 70 °C, corresponding to $Co_xFe_{3-x}O_4$ with $2.2\leq x\leq 3.0$, were nonferromagnetic

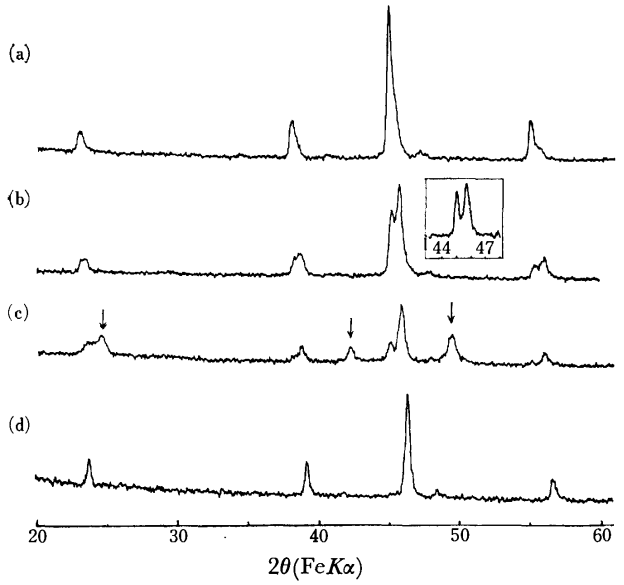

Fig. 4. X-Ray diffraction patterns of $Co_xFe_{3-x}O_4$ precipitates with $x=1.4$(a), 1.7(b), 2.0(c), and 2.4(d) prepared at $R=1.1$. The inset denotes a pattern of a ferrite with $x=1.7$ prepared from the suspension with $R=2.0$. Arrows in (c) indicate the peaks caused by the presence of a solid solution of hydroxides.

at room temperature. The nonferromanetic products with $2.2\leq x\leq 2.5$ were amorphous, and the products with $x\geq 2.6$ had the same crystal structure as that of Co_3O_4.[14]

$Co_xFe_{3-x}O_4$ samples with 0.1—0.2 μm in r were chosen from the products prepared from the alkaline suspensions, and their demagnetization curves at room temperature were obtained after their saturation magnetization, σ_s, had been measured as has been described previously.[15] The increase in x from 0 to 0.8 caused a slight decrease in σ_s. A further increase in x from 1.4 caused a remarkable decrease in σ_s. The coercive force, ${}_iH_c$, increases with x and reaches 1.3 kOe for

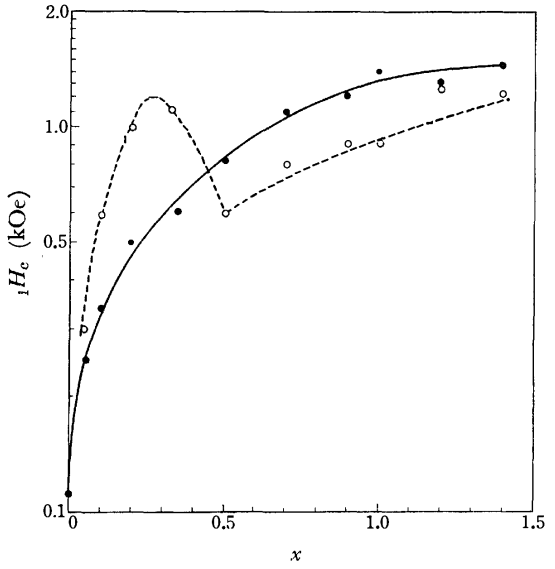

Fig. 5. Coercive force ${}_iH_c$ plotted against x in $Co_xFe_{3-x}O_4$ precipitates before (●) and after(○) heat treatment at 350 °C *in vacuo*.

$x\geq 1.2$(Fig. 5). The magnetic properties of each sample which had been subjected to heating *in vacuo* at 350 °C for 5 h were measured. The shape and size of particles in the sample were found by microscopic examination to remain almost unchanged in spite of the heat treatment. The difference in the magnetic properties before and after the heat treatment is dependent on x (Fig. 5). The change in the magnetic properties by heat treatment must be caused by the diffusion of the metal ions within each particle in the $Co_xFe_{3-x}O_4$ samples as well as in the $Mn_xFe_{3-x}O_4$ samples.

Mechanism of Ferrite Formation. As has been mentioned above, the solid solution, $M_{x/3}Fe_{1-x/3}(OH)_2$ (M=Mn or Co), with $1.4\leq x\leq 2.4$ in the starting suspension was transformed into a mixture of two kinds of ferrites, the content of each in the final oxidation product for a given value of x depending on the excess NaOH concentration. After the ferromagnetic ferrite(A), corresponding to $x\leq 1.3$, had been formed, the transformation of the remaining solid solution, $M_{x/3}Fe_{1-x/3}(OH)_2$(M=Mn or Co), into the other ferrite(B) took place and proceeded gradually. It can be deduced from this finding that the content of the Mn or Co ion in the remaining solid solution increases with the progress of the formation of ferrite(A) caused by oxidation.

As has been generally known, the dissolution rate of ferrite into an acidic solution is extremely small as compared with that of the solid solution of hydroxides. By making use of this fact, the changes in the composition of ferrite and the solid solution with the time lapse of oxidation were studied. Several suspensions, each containing 0.36 mol/l of $M_{x/3}Fe_{1-x/3}(OH)_2$(M=Mn or Co) and either 0.11 or 0.95 M excess NaOH($R=1.1$ or 2.3), were subjected to oxidation at 70 °C for 20 h. In the course of oxidation, 200-ml samples of each suspension were taken out after 2, 5, 8, and 20 h. The particle size of ferrite(A) was found by microscopic examination to become greater with the progress of the formation of ferrite(A) by oxidation. The precipitate in each 200-ml suspension, separated from the alkaline solution by filtration, was added to acetic acid (10 wt%). The alkaline filtrate was found to contain a trace of the metal ions. The acidic suspension with pH=4 containing acetic acid was left standing at room temperature for 10—30 min with occasional stirring. The remaining precipitate was separated from the acidic solution with pH=4 by filtration. The precipitate treated with acetic acid was found by X-ray analysis to consist of ferrites with no hydroxides.

The contents of Mn or Co in the remaining solid solution and in the ferrite formed were estimated from the amounts of the metal ions in the acidic filtrate and in the precipitate obtained by treatment with acetic acid respectively. These results are given in Table 3. The Mn or Co content, both in the solid solution and in ferrite (A), becomes greater as the formation of ferrite (A) proceeds by oxidation, and the formation of ferrite (B) begins when x in the solid solution becomes greater than 2. An increase in the concentration of excess NaOH accelerates the particle growth of ferrite (A) and retards the rate of increase in x in both the

TABLE 3. RELATIVE CHANGE IN THE COMPOSITION(x) OF THE REMAINING SOLID SOLUTION, $M_{x/3}Fe_{1-x/3}(OH)_2$ (M=Mn or Co), AND OF THE FERRITE, $M_xFe_{3-x}O_4$, IN THE COURSE OF OXIDATION AT 70 °C

a) Consisting of a mixture of ferrites (A) and (B).

solid solution and ferrite (A) in the course of oxidation.

The change in the size and shape of the particles before and after the transformation into ferrites suggests that the transformation takes place in the suspension medium by the same mechanism as that described for the formation of Fe_3O_4.[6] The suspension medium is saturated with respect to the solid solution of $M_{x/3}Fe_{1-x/3}(OH)_2$(M=Mn or Co). When the suspension is subjected to oxidation with air, the bivalent metal ions (probably hydroxo complexes) in the suspension medium react with the dissolved oxygen. The relative redox potential of each metal ion between bivalent and trivalent states in the suspension medium has been known to decrease in the order of Co>Mn>Fe.[16] This probably causes the predominant formation of an iron(III) hydroxo complex(probably polynuclear). It is considered that the polynuclear complex reacts with the hydroxo complexes of bivalent metal ions of Fe^{2+} and Mn^{2+} or Co^{2+} to form the nuclei of ferrite (A). The hydroxo complexes consumed by the ferrite formation may be incessantly replenished by the dissolution of the particles of the solid solution into the suspension medium.

The nuclei of ferrite(A) might, therefore, grow on epitaxially by the slow coprecipitation of the hydroxo complexes of bivalent metal ions with the polynuclear complex formed by oxidation. As the growth of the particles of ferrite(A) proceeds, x in the remaining solid solution becomes greater and x in each particle of ferrite(A) increases until the epitaxial reaction of its surface with the complexes has been stopped. Thus, the rate of the increase in x of each particle of ferrite(A) during the growth period, which is influenced by the oxidation conditions, will determine the inhomogeneity in the composition of each particle in the samples with $x \leq 1.3$.

Table 2 indicates that, in spite of the decrease in cation vacancies, the a_0 of the samples of manganese ferrite decreases only slightly with an increase in the r. It can be inferred from these results that the Mn concentration increases continuously from the central to the sub-surface portion of each particle, and that both the difference in the concentration between the two portions and the concentration gradient within the particle depend on the r of the sample with a given value of x. The inhomogeneity in the composition of the individual Mn ferrite particles described above will hold true of the particles in the samples of $Co_xFe_{3-x}O_4$ with $x \leq 1.3$.

In conclusion, the anomalous magnetic behavior of the ferrite(A) prepared from the suspension by oxidation must inevitably be associated with its unique structural properties, differing from those of ferrite with the same composition prepared by the solid-state reaction.

The author is indebted to Professors T. Takada and N. Bando, and to Dr. T. Shinjo (of this Institute) for their valuable advice, and Dr. H. Yasuoka (the University of Tokyo) for his NMR measurements and helpful comments. He also wishes to thank Messrs T. Akita, T. Akiyama, and I. Sugano for their assistance in the experiments and the Sumitomo Special Metal Co., Ltd., for the magnetic measurements with cobalt ferrites.

Magnetic and Spectral Properties of Copper(II) Chloride Complexes of Tridentate Salicylideneamines with ONN Set of Donors

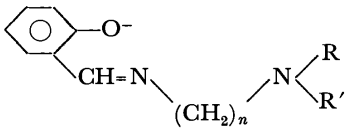
Yoneichiro MUTO and Tadashi TOKII

Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received June 20, 1977)

Four complexes with the general formula of Cu[sal·$(CH_2)_n$·N(R)R′]Cl (sal= ·$\overset{2}{O}$·C_6H_4·$\overset{1}{C}$H=N·; n=2 and 3; R=H and CH_3; R′=CH_3) were characterized by elemental analyses, IR and visible reflectance spectra, ESR spectra, and magnetic susceptibilities. The complexes where n=2, Cu[sal·$(CH_2)_2$·$NHCH_3$]Cl and Cu[sal·$(CH_2)_2$·$N(CH_3)_2$]Cl, showed normal paramagnetic behavior. The Cu[sal·$(CH_2)_3$·$N(CH_3)_2$]Cl complex was obtained in two forms, one red-violet and the other green. The red-violet form showed the usual magnetic behavior expected for a mononuclear copper(II) complex, whereas the green one exhibited the antiferromagnetic behavior typical of binuclear copper(II) complexes. The magnetic properties of these complexes are discussed in terms of structural considerations. The characterization of the Cu[sal·$(CH_2)_3$·$N(CH_3)_2$]Br complex is also reported.

The results of synthetic and characterization studies on copper(II) chloride complexes of *N*-(hydroxyalkyl)-salicylideneamines with ONO set of donors were reported in previous papers.[1,2] In the course of our studies, we found that the antiferromagnetic interaction in dimeric copper(II) chloride complex with *N*-(2-hydroxyethyl)salicylideneamine, $[Cu(sal\cdot en\cdot OH)Cl]_2$, is much weaker than that in the corresponding *N*-(3-hydroxypropyl) complex, $[Cu(sal\cdot pr\cdot OH)Cl]_2$. This observation prompted us to investigate the analogous complexes with ONN tridentate salicylideneaminato ligands of the general formula



abbreviation

sal·en·N(H)Me; n=2, R=H, R′=CH_3
sal·en·NMe_2; n=2, R=R′=CH_3
sal·pr·NMe_2; n=3, R=R′=CH_3

The complexes Cu[sal·en·N(H)Me]Cl, **1**, and Cu(sal·en·NMe_2)Cl, **2**, were originally synthesized and investigated by Sacconi *et al.*[3] The complex Cu(sal·pr·NMe_2)Cl has been obtained in two forms, one red-violet, **3**, and the other green, **4**; the corresponding bromide complex Cu(sal·pr·NMe_2)Br, **5**, only in a green form. In addition, the interconversion between **3** and **4** has been observed as follows: **3** is converted to **4** by recrystallizing **3** from methanol or chloroform while the reverse conversion is carried out by heating **4** in ethanol. One object of the present work is to elucidate the structure difference between **3** and **4**.

We report here the results of magnetic and spectral studies on these complexes **1**—**5** and discuss their magnetic properties in terms of structural considerations.

Experimental

Syntheses. Compounds **1** and **2** were prepared by methods which were slightly modified from those of Sacconi *et al.*,[3] as follows: *Compound* ***1****, Cu[sal·en·N(H)Me]Cl*: A solution of copper(II) chloride (10 mmol) in ethanol (50 ml) was added to a mixture of bis(salicylaldehydato)copper(II) (10 mmol) and *N*-methylethylenediamine (20 mmol) in ethanol (30 ml). The solution was stirred at *ca.* 70 °C for 1/2 h and then concentrated to one-fourth of its volume. After the solution had been allowed to stand overnight at *ca.* 5 °C in a freezer, the separated green crystals were collected and recrystallized from chloroform. Found: Cu, 23.02%. Calcd for $C_{10}H_{13}N_2OClCu$: Cu, 23.00%. *Compound* ***2****, Cu(sal·en·NMe_2)Cl*: A mixture of Cu(sal·en·NMe_2)$_2$ (10 mmol) and copper(II) chloride (10 mmol) in ethanol (30 ml) was stirred on a hot plate for 1/2 h. The green crystals thus precipitated were collected and recrystallized from chloroform. Found: Cu, 21.64%. Calcd for $C_{11}H_{15}N_2OClCu$: Cu, 21.89%.

Compound ***3****, the Red-violet Form of Cu(sal·pr·NMe_2)Cl*: This was prepared by the reaction of Cu(sal·pr·NMe_2)$_2$ and copper(II) chloride according to the procedure described above (Compound **2**). The purification was made by recrystallization from ethanol. This was also obtained by heating Compound **4** in ethanol. Found: C, 47.29; H, 5.67; N, 9.19; Cu, 20.80%. Calcd for $C_{12}H_{17}N_2OClCu$: C, 47.37; H, 5.63; N, 9.21; Cu, 20.88%.

Compound ***4****, the Green Form of Cu(sal·pr·NMe_2)Cl*: A solution of copper(II) chloride (10 mmol) in methanol (30 ml) was added to a solution of Cu(sal·pr·NMe_2)$_2$ (10 mmol) in methanol (20 ml). The mixture was stirred at *ca.* 40 °C for 1/2 h. The green crystals which precipitated were collected and washed with methanol and dried. This was also obtained by recrystallizing Compound **3** from methanol or chloroform. Found: C, 47.14; H, 5.65; N, 9.10; Cu, 21.05%. Calcd for $C_{12}H_{17}N_2OClCu$: C, 47.37; H, 5.63; N, 9.21; Cu, 20.88%.

Compound ***5****, Cu(sal·pr·NMe_2)Br*: The synthetic procedure is similar to that for Compound **3** except for the use of copper(II) bromide instead of copper(II) chloride. The green crystals collected were recrystallized from ethanol. Found: C, 41.26; H, 4.89; N, 7.99; Cu, 18.10%. Calcd for $C_{12}H_{17}N_2OBrCu$: C, 41.33; H, 4.92; N, 8.03; Cu, 18.22%.

Physical Measurements. The magnetic susceptibilities were determined by the Gouy method in the range from the temperature of liquid nitrogen to room temperature. The effective magnetic moments per copper ion at room temperature were calculated from the equation:

$$\mu_{eff} = 2.83\sqrt{(\chi_A - N\alpha)\cdot T} \quad (1)$$

where χ_A is the molar magnetic susceptibility corrected for the diamagnetism of the constituted atoms using Pascal's constant[4] and $N\alpha$ is the temperature-independent paramagnetism per gram-ion of copper(II). The $N\alpha$ was assumed to be 60×10^{-6} cgs emu.[5] The results are given in Table 1. The ESR (X-band) spectra of polycrystalline samples were recorded with a JEOL ESR-apparatus, model JES-ME-1X, at room temperature. The IR spectral measurements were made with a Hitachi EPI-G2 IR spectrophotometer in the 400—4000 cm^{-1} region on Nujol mulls. The reflectance

3.	Cu(sal·pr·NMe_2)Cl (red-violet form)	1.80 (293)	0		
4.	Cu(sal·pr·NMe_2)Cl (green form)	1.44 (298)		248	2.10 (2.10)
5.	Cu(sal·pr·NMe_2)Br	1.42 (295)		260	2.10 (2.09)

a) The data in parentheses were determined by ESR measurements on the polycrystalline samples.

spectra were recorded with a Hitachi EPS-3T recording spectrophotometer.

Results and Discussion

Magnetic Data. The results of the magnetic susceptibility measurements are shown in Fig. 1.

The susceptibility data of Compounds **1** and **2** follow the Curie law down to liquid nitrogen temperature, indicating that they are magnetically diluted in crystals. Hence they are considered to be mononuclear. The red-violet complex **3** also showed the usual magnetic behavior expected for a mononuclear copper(II) complex; a plot of $(\chi_A - N\alpha)^{-1}$ as a function of temperature gives a Weiss constant θ of almost 0 K (Fig. 1). Their X-band ESR spectra provide further evidence for their monomeric nature: the spectra show a strong signal at *ca.* 3100 G due to a copper(II) ion with $S=1/2$. In contrast to **3**, the green complex **4** and the analogous bromide complex **5** show subnormal magnetic moments at room temperature (*cf.* Table 1), and their magnetic susceptibility data fit the Bleaney-Bowers equation[6]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1} + N\alpha \qquad (2)$$

where each symbol has the general meaning. The J and g values listed in Table 1 were evaluated from the best fit of the cryomagnetic data to Eq. 2, assuming $N\alpha = 60\times10^{-6}$ cgs emu.[5] The negative values of J indicate the presence of antiferromagnetic interaction in these complexes, and the g values are in good agreement with the average g values obtained from ESR measurements (*cf.* Table 1). The close agreement between the experimental and theoretical $\chi_A - T$ curves is a powerful argument for a binuclear structure in these complexes.

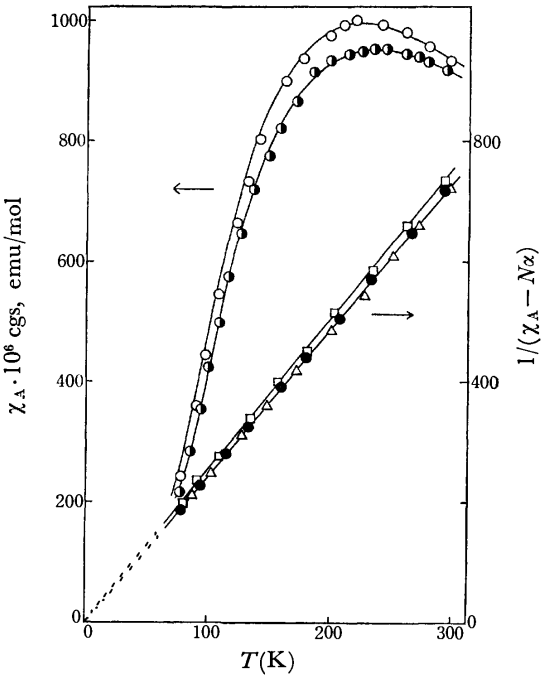

Fig. 1. Variation of magnetic susceptibilities with temperature. (△) Cu[sal·en·N(H)Me]Cl, (●) Cu(sal·en·NMe_2)Cl, (□) Cu(sal·pr·NMe_2)Cl (red-violet form), (○) Cu(sal·pr·NMe_2)Cl (green form), (◑) Cu(sal·pr·NMe_2)Br.

These magnetic data clearly indicate that the two forms of Cu(sal·pr·NMe_2)Cl, red-violet and green in color, are monomer-dimer type isomers of each other.

IR Spectra. The wave number of the intense band near 1540 cm^{-1} observed for the present complexes **1**—**5** and the parent bis-complexes, Cu(sal·en·NMe_2)$_2$ and Cu(sal·pr·NMe_2)$_2$, are listed in Table 2. The IR spectra of mononuclear complexes of salicylaldehyde Schiff bases display a sharp band at *ca.* 1530 cm^{-1}, whereas the band in the spectra of polynuclear salicylideneamine complexes with phenolic oxygen-bridges between metal ions appears in the range 1545—1550 cm^{-1}.[7] This band shift toward higher frequencies is now taken as an umambiguous criterion for the formation of a phenolic oxygen-bridging in polymeric salicylideneamine complexes.[1,2,7-11]

As is shown in Table 2, the band shift was observed for Compounds **4** and **5**. This indicates the presence

5.	Cu(sal·pr·NMe_2)Br	1549	12.5, 11.1 sh
	Cu(sal·pr·NMe_2)$_2$	1534	16.7 sh, 14.1

a) sh = shoulder.

of phenolic oxygen-bridges between copper(II) ions in these complexes. On the other hand, no significant band shift was observed for Compounds **2** and **3**, indicating that, in these complexes, no phenolic oxygen-bridge exists. The strong band at 1531 cm^{-1} for Compound **1** indicates the non-existence of any bridging phenolic oxygen in this complex.

Diffuse Reflectance Spectra. The present complexes give rise to several bands in the 5000—25000 cm^{-1} region in the diffuse reflectance spectra. The wave numbers of the band maxima are collected in Table 2 and their spectral curves are shown in Fig. 2.

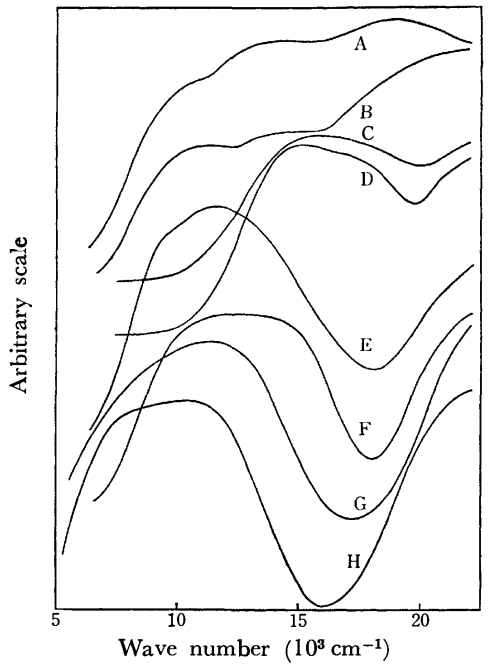

Fig. 2. Reflectance spectra of Cu(sal·pr·NMe_2)Cl (red-violet form) (A), [Cu(sal·*i*-C_3H_7)Cl]$_2$ (B), Cu[sal·en·N(H)Me]Cl (C), Cu(sal·en·NMe_2)Cl (D), Cu(sal·pr·NMe_2)Cl (green form) (E), Cu(sal·pr·NMe_2)Br (F), [$CuCl_2$(pyo)$_2$]$_2$ (G), and [$CuBr_2$(pyo)$_2$]$_2$ (H).

The spectral feature of Compounds **1** and **2** is apparently of a square planar type (Fig. 2), as pointed out by Sacconi *et al.*[3] Compound **3** gave rise to three ligand-field bands in the 5000—25000 cm^{-1} range. This spectral feature indicates a pseudo-tetrahedral geometry around the metal ion.[8,12] For comparison the reflectance spectral curve of [Cu(sal·*i*-C_3H_7)Cl]$_2$ complex with a pseudo-tetrahedral copper(II) geometry[13] is given in Fig. 2. The spectral features of Compounds **4** and **5** apparently indicate that these have a five-coordinated copper(II) geometry, square-pyramid or trigonal-bipyramid. However, unambiguous structural assignments for these complexes could not be drawn from their spectra, since the differences in spectra among a square-pyramidal, a distorted square-pyramidal, a distorted trigonal-bipyramidal, and a trigonal-bipyramidal structure are not always clear. In Fig. 2, for comparison, are given the reflectance spectral curves of the dimeric 1 : 2 complex of copper(II) chloride with pyridine *N*-oxide, [$CuCl_2$(pyo)$_2$]$_2$, in which the geometry around the copper(II) ion is a tetragonal-pyramid,[14] and the analogous bromide complex, [$CuBr_2$(pyo)$_2$]$_2$, which has a distorted trigonal-bipyramidal copper(II) geometry.[15]

Structure and Magnetic Property. The monomeric four-coordinated planar structure shown schematically in Fig. 3A had been proposed for both Compounds **1** and **2** by Sacconi *et al.*[3] on the basis of their electronic reflectance spectra. Our magnetic and spectral data for these complexes have substantiated their structural assignment.

The structure should be compared with that of Cu(sal·en·OH)Cl, which displays a dimer type of antiferromagnetism.[1,2] In previous papers we assigned a chloride-bridging binuclear structure shown in Fig. 3B for Cu(sal·en·OH)Cl on the basis of its magnetic and spectral properties.[1,2] This assignment is further supported by the fact that the J value of -60 cm^{-1} determined for the complex[1] is practically identical with those of -50——-70 cm^{-1} reported for dimeric copper(II) chloride complexes with dithiocarbamates in which a pair of copper(II) ions is bridged by two chloride ions in a similar manner to that shown in Fig. 3B.[16] Since an alcohol group has usually a poorer coordinating ability than does an amine group, it is concluded that the absence of coordination of the OH group in Cu(sal·en·OH)Cl (Fig. 3B) leads to the formation of the chloride-bridged dimer, whereas the coordination of the terminal amine group in Compound **1** or **2** (Fig. 3A) hinders the dimer formation.

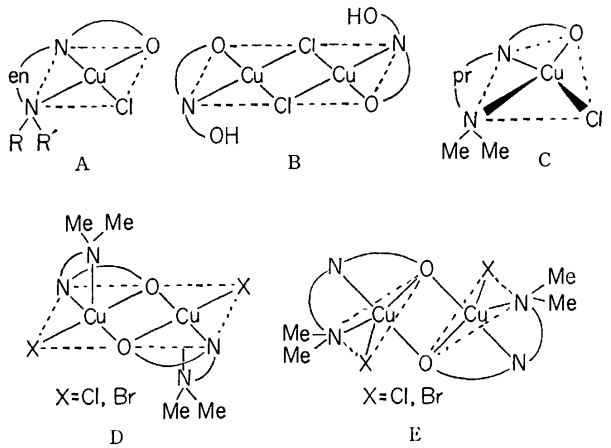

Fig. 3. Schematic representations of possible structure. (A)Cu[sal·en·N(H)Me]Cl and Cu(sal·en·NMe_2)Cl, (B) Cu(sal·en·OH)Cl, (C) Cu(sal·pr·NMe_2)Cl (red-violet form), (D) and (E) Cu(sal·pr·NMe_2)Cl (green form) and Cu(sal·pr·NMe_2)Br.

The monomeric pseudo-tetrahedral structure of the C type shown in Fig. 3 should be assigned to Compound **3** on the basis of its magnetic and spectral data. The magnetic and spectral data for Compounds **4** and **5** showed that these complexes have a phenolic oxygen-bridged binuclear structure with a five-coordinated copper(II) geometry. Molecular models show that two types of five-coordinated metal dimers, one with square-pyramidal and the other trigonal-bipyramidal coordination (Fig. 3D and E), can be produced from sal·pr·NMe_2. This is apparently due to the greater

flexibility of the diamine part in sal·pr·NMe_2 as compared with that in sal·en·NMe_2. Thus, in a similar manner to the case of binuclear four-coordinated copper(II) complexes of the type $[Cu(sal\cdot R)X]_2$, where R=alkyl or aryl and X=Cl, [7,8] Br[9] or NO_3,[10,11] the antiferromagnetism observed in these complexes may be interpreted in terms of superexchange interaction through the bridging phenolic oxygen atoms. It has been well established that the strength of antiferromagnetic interaction in $[Cu(sal\cdot R)X]_2$ complexes decreases as the distortion of copper(II) geometry from planar toward tetrahedral increases.[8,13,17,18] With five-coordinated copper(II) complexes, two metal geometries, trigonal-bipyramid and tetragonal-pyramid, are usually encountered, and a continuous structural variation may take place, through structural deformation, between the two regular geometries depending upon the environments of metal coordination. At present, for five-coordinated copper(II) dimers, the correlation of the structure with the detected degree of antiferromagnetic interaction is not apparent.[8] However, comparison of the J values of Compounds **4** and **5** with those of five-coordinated copper(II) dimers found in the literature seems to suggest a conclusion about the metal geometry of these complexes: The $|J|$ values of Compounds **4** and **5** are about one-half of $[Cu(sal\cdot pr\cdot OH)Cl]_2$ ($J=-252$ cm^{-1},[1] distorted trigonal-bipyramidal)[19] and of $[Cu(sal\cdot R)X\cdot DMF]_2$ ($J=-200$ —-250 cm^{-1},[8,20] DMF=*N*,*N*-dimethylformamide) to which a square-pyramidal copper(II) geometry was previously assigned.[8,20] The J value of $[CuBr_2(pyo)_2]_2$ (distorted trigonal-bipyramidal) is -121 cm^{-1} [21] and this is approximately one-fourth of that of the corresponding chloride complex, $[CuCl_2(pyo)_2]_2$ ($J=-440$ cm^{-1},[21] tetragonal-pyramidal). The J value of $[Cu(sal\cdot t\text{-}C_4H_9)(hfa)]_2$ (hfa=hexafluoroacetylacetonato, slightly distorted trigonal-bipyramidal)[22], -105 cm^{-1},[23] is small and comparable with those of Compounds **4** and **5**. Thus, copper(II) dimers with trigonal-bipyramidal metal coordination happened to give rise to a large $|J|$ value in $[Cu(sal\cdot pr\cdot OH)Cl]_2$, but in the other cases they have shown small values for the exchange integral. On the other hand, the $|J|$ values of copper(II) dimers with tetragonal-pyramidal metal geometry have appeared to be fairly large for the cases so far investigated.[20,21] These facts strongly suggest that the present complexes **4** and **5** take essentially a trigonal-bipyramidal metal coordination. For five-coordinated copper(II) dimers with the same type of ligands, the $|J|$ value is considered to be lowered progressively according as the copper(II) geometry is distorted from regular tetragonal-pyramid toward trigonal-bipyramid; we are now attempting to prepare more copper(II) dimers of the required types in order to clarify this point.

Ground States of the Square Planar Low-Spin Cobalt(II) Complexes[1)]

Yuzo NISHIDA and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka, 812

(Received June 30, 1977)

In order to investigate the ground state configuration of some square planar cobalt(II) complexes such as Schiff base complexes of the *cis*-[CoN_2O_2] type, whose ESR spectra are quite different from those of cobalt(II) phthalocyanine and porphyrins, the spin-orbit matrix based on the four zero-order wave functions, $(yz)^1$, $(xz)^1$,$(z^2)^1$, and $(xy)^{1,2)}$ were diagonalized on assuming reasonable values for necessary parameters. The result has clearly shown that an unpaired electron is localized in d_{yz} orbital in the ground state for these complexes. ESR spectra of a series of cobalt(II) complexes with N_4-macrocyclic ligands were measured and interpreted in terms of the conclusion obtained here.

In recent years the electronic states of low-spin cobalt(II) complexes have attracted attention because of their close relation to Vitamin B_{12} and biological oxygen carriers. As the consequence of studies on ESR and magnetism, it was established that the electronic configuration of the ground state is $(d_{xy})^2(d_{xz})^2(d_{yz})^2(d_{z^2})^1$, (denoted by $(z^2)^{1,2)}$) for cobalt(II) phthalocyanine[3,4)] and porphyrins,[5)] where x, y, and z axes were adopted as shown in Fig. 1-a. This is referred to as Type I. On the other hand, there is another type(Type II) of low-spin cobalt(II) complexes whose ESR spectra show a quite different pattern from that of the former group, as shown in Table 1. They include Schiff base complexes such as [Co(salen)] and [Co(acen)], where H_2salen and H_2acen denote *N,N'*-disalicylideneethylenediamine and *N,N'*-bis(1-acetonylethylidene)ethylenediamine, respectively. Their ESR spectra differ a great deal from those of the Type I group in (1) the large separation between g_x and g_y (whereas the porphyrin group shows axial symmetry of *g*-tensors) and (2) the very small $|A_z|$ and $|A_y|$ values as compared with those of the Type I group. For the ground state configuration of the Type II compounds, three possibilities which have given rise to much argument can be considered.[6—13)] Recently the correct values of *g*- and *A*-tensors for [Co(acen)][11)] and [Co(amben)][13)] were determined in the single crystals of the corresponding nickel(II) complexes, where H_2amben denotes *N,N'*-bis(*o*-aminobenzylidene)ethylenediamine. In their attempt to interpret the result by use of perturbation calculation, Cariati *et al.*[11)] could not give an unambiguous assignment of the ground state configuration. They suggested the mixing of the two configurations for the ground state. However, their conclusion is unsatisfactory, since 1) they employed a positive value (0.28) for the Fermi hyperfine coulpling constant to fit A_1[14)] values with the experimental ones in the case of the $(z^2)^1$ configuration, which is not compatible with the generally accepted view that the Fermi hyperfine coulpling constant assumes a negative value in the case of the $(z^2)^1$ configuration as the consequence of the coupling with the $(4s)^{1,2)}$ configuration, and 2) in order to fit g_1[14)] values with the experimental ones, the energy separation between d_{xz} and d_{yz} orbitals was assumed to be $6—7\times10^3$ cm^{-1} in the case of both $(z^2)^1$ and $(yz)^1$ electronic configuration. Similar results have also been reported.[13,15,16)] However, there appears no reasonable evidence to assume such a large separation between d_{xz} and d_{yz} orbitals for the complexes of the planar *cis*-[CoN_2O_2] and [CoN_4] types.

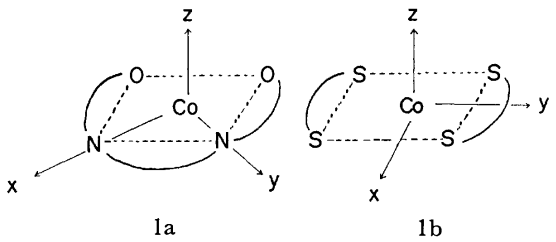

Fig. 1. x, y, and z axis in the square planer complexes.

This unsatisfactory result seems to be due to the inadequate application of the perturbation theory to the present system. Calculation of *g*- and *A*-values for these systems have so far been carried out by use of the well-known formula of the first order perturbation theory for a nondegenerate ground state.[17)]

$$|\psi_g> = N\left[|\psi_g^0> - \sum \frac{\langle\psi_e^0|\lambda\hat{l}\cdot\hat{S}|\psi_g^0\rangle}{\Delta_e}|\psi_e^0\rangle\right] \quad (1)$$

However, application of equation (1) is valid only when $\Delta_e \gg \lambda$. In our system there is a sufficient probability for some of d_{xy}, d_{xz}, d_{yz}, and d_{z^2} orbitals to be

TABLE 1. ESR PARAMETERS OF SQUARE PLANAR COBALT(II) COMPLEXES

a) H_2pc: phthalocyanine, H_2tpp: $\alpha,\beta,\gamma,\delta$-tetraphenylporphyrin, H_2acen: *N,N'*-bis(1-acetonylethylidene)ethylenediamine, H_2salen: *N,N'*-bis(salicylidene)ethylenediamine, Hsac: dithioacetylacetone.

energetically close to each other. Thus, in diagonalizing the 4×4 spin-orbit matrix based on the $(xy)^1$,$(xz)^1$, $(yz)^1$ and $(z^2)^1$ states,[18] we have calculated g_i- and A_i-values as the function of various parameters and compared the results with the experimental values in order to elucidate the ground state of the Type II complexes. In order to examine the conclusion thus reached, we have measured the ESR spectra of a series of cobalt(II) complexes with N_4-macrocyclic ligands.

Calculation

In performing the perturbation calculation for the spin-orbit interaction, we have adopted the eight zero-order wave functions, $(\chi)^{+\text{or}-}$, where $(\chi)^+$ denotes an antisymmetrized determinatal function, $|(\overset{+}{d_{x^2-y^2}})(\overset{-}{d_{x^2-y^2}})(\overset{+}{\chi})|$ ($\chi=d_{xz}$, d_{yz}, d_{xy}, and d_{z^2}) based on the three electron hole formalism. Hence the wave functions for the system were formulated according to the Kramers theorem[19] as follows.

$$\Psi^+ = c_1\overset{+}{(yz)^1} + ic_2\overset{+}{(xz)^1} - ic_3\overset{-}{(z^2)^1} + c_4\overset{-}{(xy)^1} \quad (2)$$

$$\Psi^- = c_1\overset{-}{(yz)^1} - ic_2\overset{-}{(xz)^1} - ic_3\overset{+}{(z^2)^1} - c_4\overset{+}{(xy)^1} \quad (3)$$

The coefficients c_1, c_2, c_3, and c_4 were determined by diagonalizing the following 4×4 matrix,

$\overset{+}{(yz)^1}$	$\overset{+}{(xz)^1}$	$\overset{-}{(z^2)^1}$	$\overset{-}{(xy)^1}$
Δ_4	$i\frac{\lambda}{2}$	$-i\frac{\sqrt{3}}{2}\lambda$	$-\frac{\lambda}{2}$
$-\frac{i}{2}\lambda$	Δ_1	$\frac{\sqrt{3}}{2}\lambda$	$\frac{i}{2}\lambda$
$i\frac{\sqrt{3}}{2}\lambda$	$\frac{\sqrt{3}}{2}\lambda$	Δ_2	0
$-\frac{\lambda}{2}$	$-i\frac{\lambda}{2}$	0	Δ_3

where λ denotes the spin-orbit coupling constant for the system, $\lambda=-k\zeta_{3d}$, ζ_{3d} being the free ion value for Co^{2+}(-515 cm^{-1}), and k is the orbital reduction factor evaluated at 1.0, 0.9, 0.8 and 0.7. The diagonal elements, Δ_1, Δ_2, Δ_3, and Δ_4 are functions of ligand field and interelectronic repulsion.

Based on Eqs. 2 and 3, g_i- and A_i-values can be expressed in terms of k, c_1, c_2, c_3, and c_4 (and κ in the case of A_i/P), where P and κ denote $2g_N\beta_e\beta_N\langle r^{-3}\rangle_{3d}$[20] and Fermi hyperfine coupling energy in units of P, respectively.

$$g_z = 2[c_1^2+c_2^2-c_3^2-c_4^2-2kc_1c_2] \quad (4)$$

$$g_x = 2[c_1^2-c_2^2+c_3^2-c_4^2-2\sqrt{3}kc_1c_3-2kc_2c_4] \quad (5)$$

$$g_y = 2[c_1^2-c_2^2-c_3^2+c_4^2+2\sqrt{3}kc_2c_3-2kc_1c_4] \quad (6)$$

$$A_z/P = 2[-2c_1c_2-\frac{\kappa}{2}(c_1^2+c_2^2-c_3^2-c_4^2) + \frac{1}{7}(c_1^2+c_2^2-2c_3^2+2c_4^2+3c_1c_4 - \sqrt{3}c_1c_3-3c_2c_4-\sqrt{3}c_2c_3)] \quad (7)$$

$$A_x/P = 2[-2\sqrt{3}c_1c_3-2c_2c_4-\frac{\kappa}{2}(c_1^2-c_2^2+c_3^2-c_4^2) + \frac{1}{7}(-2c_1^2+c_2^2-c_3^2-c_4^2-3c_1c_2-3c_1c_4 - \sqrt{3}c_2c_3-2\sqrt{3}c_3c_4)] \quad (8)$$

$$A_y/P = 2[2\sqrt{3}c_2c_3-2c_1c_4-\frac{\kappa}{2}(c_1^2-c_2^2-c_3^2+c_4^2) + \frac{1}{7}(c_1^2+2c_2^2+c_3^2+c_4^2+3c_1c_2 + \sqrt{3}c_1c_3-3c_2c_4-2\sqrt{3}c_3c_4)] \quad (9)$$

Throughout the calculation $P=0.020$ cm^{-1} was adopted (free ion value for P is 0.025 cm^{-1},[21]).

Results and Discussion

After several preliminary calculations we have become convinced that the small $|A_z|$ and $|A_y|$ values of Type II complexes can not be accounted for on the basis of $(z^2)^1$ ground state, where a negative value is to be assigned to the Fermi hyperfine coupling constant, κ.[4,22,23] The $(xy)^1$ ground state is also improbable, because 1) the d_{xy} orbital is practically nonbonding in the Schiff base complexes, and 2) the interelectronic repulsion in the $(xy)^1$ state is higher (at least 6000 cm^{-1}) than that in both the $(z^2)^1$ and $(yz)^1$ states.[24] Recently McGarvey[12] investigated the contributions from the spin-quartet states and the mixing of d_{z^2} and d_{xy}[25] orbitals to the ESR parameters of low-spin cobalt(II) complexes. He showed that the contributions from the spin-quartet states are very important for 5- and 6-coordinated complexes, but can be neglected for 4-coordinated planar complexes. This can be explained as follows. The energy separation between d_{z^2} and $d_{x^2-y^2}$ orbitals in the square planar complexes is larger than that in 5- and 6-coordinated complexes, so that the energy gap between the ground doublet state, $|(\overset{+}{d_{x^2-y^2}})(\overset{-}{d_{x^2-y^2}})(\overset{+}{d_{z^2}})|$ and the excited quartet states such as $|(\overset{+}{d_{x^2-y^2}})(\overset{+}{d_{z^2}})(\overset{+}{d_{yz}})|$ *etc.* is larger than in the former complexes.

McGarvey also took a sizeable mixing of d_{z^2} and d_{xy}[25] into consideration in order to explain the ESR parameters of $[Co(sac)_2]$ and $[Co(mnt)_2]^{2-}$ on the basis of $(z^2)^1$ ground state, these complexes being classified as Type II complexes in this paper. However, his interpretation appears to be imcompatible with our experimental results. Accordingly, we considered here only the $(yz)^1$ configuration for the ground state of the Type II compounds throughout the calculation, assuming the contribution from the spin-quartet states to be negligibly small. This means that we have set Δ_4 to be zero in the 4×4 matrix, therefore Δ_1, Δ_2, and Δ_3 are the energy separation from the ground $(yz)^1$ state for $(xz)^1$, $(z^2)^1$, and $(xy)^1$, respectively.

It has been known that a sharp absorption band is always observed around 8000 cm^{-1} in the complexes with quadridentate Schiff bases of the *cis*-$[CoN_2O_2]$ type.[26] Judging from its intensity ($\log\varepsilon\approx1.5$), this is undoubtedly a spin-allowed d-d transition. This band is most probably assigned to the $(yz)^1\rightarrow(xy)^1$ transition, since the interelectronic repulsion energy in $(xy)^1$ state is much larger than that in $(yz)^1$ and $(z^2)^1$ states, and there seems to be no particular reason to separate

the $(xz)^1$ and $(z^2)^1$ states from the $(yz)^1$ state in such a high energy as 8000 cm^{-1}. Furthermore, it has been revealed in the course of calculation that the large g_x values, 3.2—3.9 (Table 1), can be accounted for in terms of the orbital contribution from the $(xy)^1$ and $(z^2)^1$ states, only when these states are separated from the ground state by less than 3000 cm^{-1}. Thus, Δ_3 was fixed at 8000 cm^{-1} throughout the calculation.

In Figs. 2—9, g_i and A_i values are plotted as functions of Δ_1 and Δ_2. The g_z, g_x, and g_y values vary sensitively with Δ_1 and Δ_2, as seen in Figs. 4, 5 and 6. respectively. It should be noted that g_z(Fig. 4) can be fitted to the

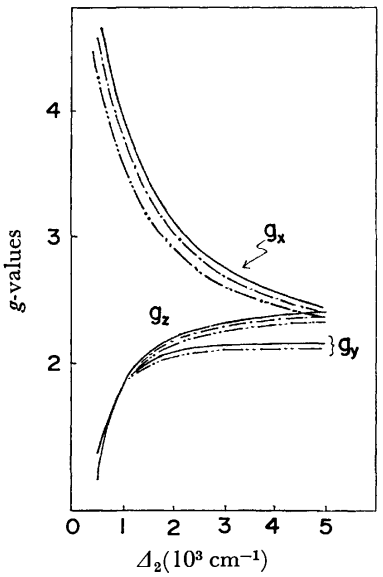

Fig. 2. The variation of g_i-values(i=x, y, z,) *versus* Δ_2, with $k=1.0$(——), $k=0.9$(—·—) and $k=0.8$(—··—). Other parameters, Δ_1 and λ are fixed to be 2000 and -450 cm^{-1}, respectively.

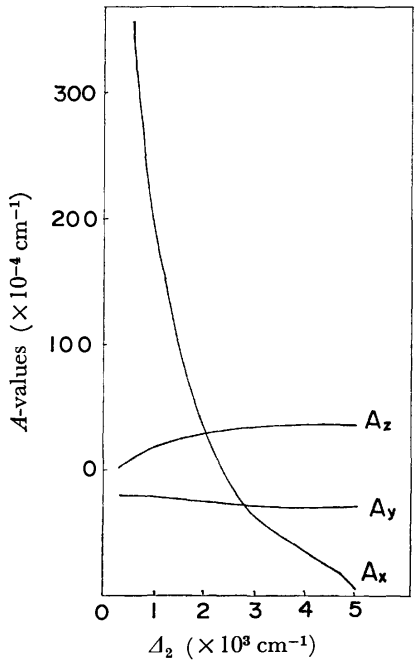

Fig. 3. The variation of A_i-values(i=x, y, z) *versus* Δ_2 with $\Delta_1=2000$ cm^{-1}, $\lambda=-450$ cm^{-1} and $\kappa=0.5$.

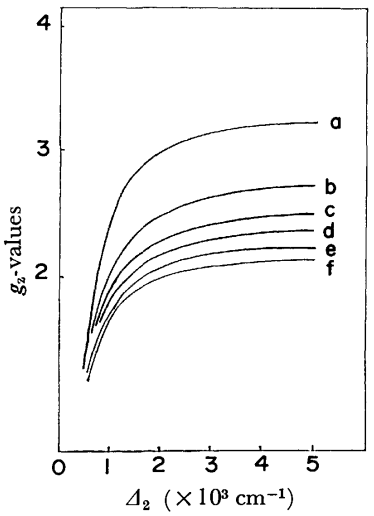

Fig. 4. The variation of g_z as a function of Δ_2. Δ_1 are (a) 500 cm^{-1}, (b) 1000 cm^{-1}, (c) 1500 cm^{-1}, (d) 2000 cm^{-1}, (e) 3000 cm^{-1} and (f) 5000 cm^{-1}. In all cases, k and λ are fixed to be 1.0 and -450 cm^{-1}, respectively.

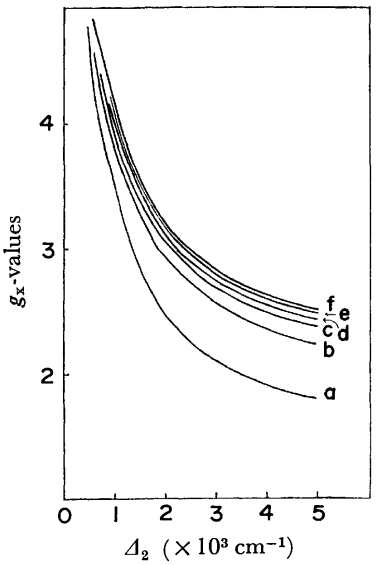

Fig. 5. The variation of g_x as a function of Δ_2. Δ_1 are (a) 500 cm^{-1}, (b) 1000 cm^{-1}, (c) 1500 cm^{-1}, (d) 2000 cm^{-1} (e) 3000 cm^{-1}, and (f) 5000 cm^{-1}. Other parameters, k and λ are fixed to be 1.0 and -450 cm^{-1}, respectively.

experimental value (*e.g.*, 2.00 for [Co(acen)]) by assuming a reasonable d_{xz}-d_{yz} separation, *i.e.*, 0—3000 cm^{-1}, whereas in the case of the calculation based on Eq. 1, an unreasonably large separation ($\geq$5000 cm^{-1}) has to be assumed in order to fit the calculated g_z value to the experimental one.[13,15,16]

The g_x value(Fig. 5) sharply increases with the decrease of Δ_2, the effect of Δ_1 being minor compared with that of Δ_2. Accordingly, Δ_2 can be estimated as 900—1500 cm^{-1} for [Co(acen)] from Fig. 5 and experimental g_x value (3.26).[11] The A_x value (Fig. 8) highly dependent on Δ_2, and suffers little effect from the variation of Δ_1, thereby enabling us to estimate the Δ_2 value for [Co(acen)] at 1300—1600 cm^{-1} from the

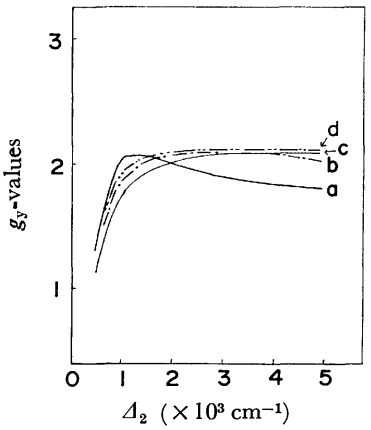

Fig. 6. The variation of g_y as a function of Δ_2. Δ_1 are (a) 500 cm^{-1}, (b) 1000 cm^{-1}, (c) 1500 cm^{-1}, and (d) 5000 cm^{-1}. In all cases, k and λ are fixed to be 1.0 and -450 cm^{-1}, respectively.

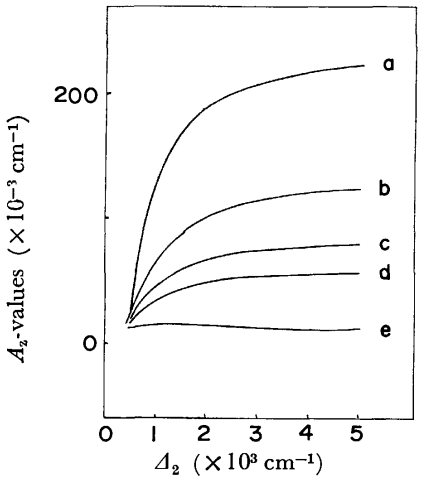

Fig. 7. The variation of A_z as a function of Δ_2. Δ_1 are (a) 500 cm^{-1}, (b) 1000 cm^{-1}, (c) 1500 cm^{-1}, (d) 2000 cm^{-1}, (e) 5000 cm^{-1}. Other parameters, κ and λ are fixed to be 0.4 and -450 cm^{-1}, respedtively.

experimental value of $|A_x|$ (115.8×10^{-4} cm^{-1}).[11] This is compatible with the value, 900—1500 cm^{-1}, estimated from g_x according to the diagram in Fig. 5.

On the basis of the above discussion, assuming reasonable values for the necessary parameters, we obtained satisfactory agreement between calculated and experimental g_1 and A_1 values in the case of the two examples of Type II complexes, as shown in Table 2, where both ESR spectra were measured on single crystals. From the c_1, c_2, c_3 and c_4 values listed in Table 2, it can be concluded that an unpaired electron is localized in the d_{yz} orbital, *i.e.*, mixing of the $(z^2)^1$ is very small.

It is well known that the ESR spectrum of [Co(mnt)$_2$]$^{2-}$, (where H_2mnt denotes 2,3-dimercaptomaleonitrile) shows[20] a pattern similar to that of both [Co(acen)] and [Co(salen)], undoubtedly belonging to Type II. However, analysis of the ESR spectra on single crystals revealed that the directions of principal axes of g-tensors are, as depicted in Fig. 1-b,[20] different from those of [Co(acen)]. Thus, on the basis of the

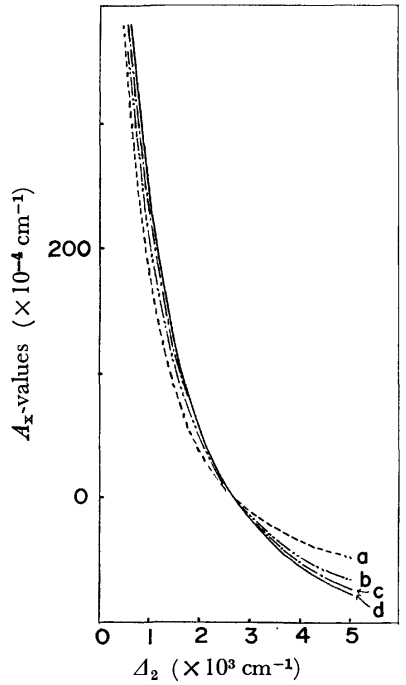

Fig. 8. The variation of A_x as a function of Δ_2. Δ_1 are (a) 500 cm^{-1}, (b) 1000 cm^{-1}, (c) 1500 cm^{-1}, and (d) 3000 cm^{-1}. Other parameters, κ and λ are fixed to be 0.4 and -450 cm^{-1}, respectively.

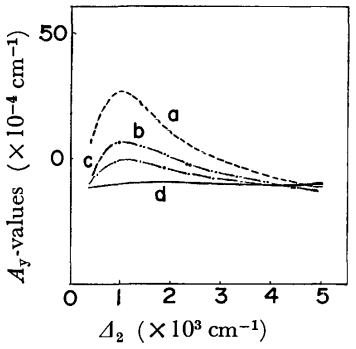

Fig. 9. The variation of A_y as a function of Δ_2. Δ_1 are (a) 500 cm^{-1}, (b) 1000 cm^{-1}, (c) 1500 cm^{-1}, and (d) 3000 cm^{-1}. Other parameters, κ and λ are fixed to be 0.4 and -450 cm^{-1}, respectively.

new x, y, and z axes we formulated equations similar to Eqs. 2—9 according to the same principle. The results was very similar to that obtained in the case of the coordinated system in Fig. 1-a. For example, a similarity of results of the calculation based on the different coordinate systems can be seen, if we compare Figs. 10, 11 and Table 3 (based on the coordinate system in Fig. 1-b) with Figs. 2,3 and Table 2 (based on the coordinate system in Fig. 1-a), respectively. It was confirmed by repeated examination that the choice of the x and y axes does not bring about any significant effect on the calculated values.

From the above discussion, we can conclude that in Type II complexes an unpaired electron is localized in the d_{yz} orbital in the ground state. It should be emphasized that in this approach we could interpret the ESR parameters of the compounds on the assump-

Table 2. Calculated values of g_i, A_i(i=x, y, z) and c_j(j=1, 2, 3, 4) for the coordinate system of Fig. 1-a Experimentally obtained values are given in parentheses.

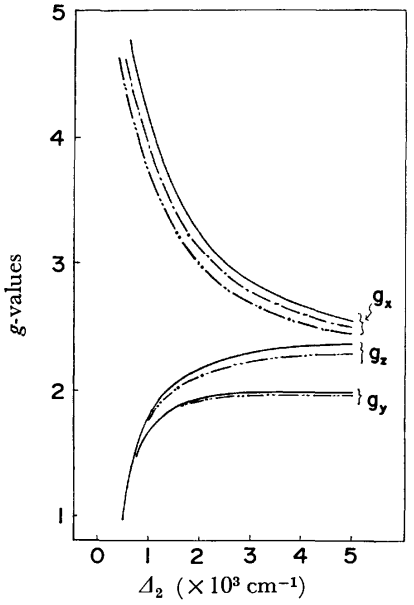

Fig. 10. The variation of g_i-values (i=x, y, z) *versus* Δ_2 in the case of the coordinate system of Fig. 1-b, with k=1.0 (——), k=0.9 (—·—), and k=0.8 (—··—). Other parameters Δ_1, λ, and Δ_3 (in this case, this means the energy separation between $(yz)^1$ and $(x^2-y^2)^1$) are fixed to be 2000, −450, and 8000 cm^{-1}, respectively.

tion of reasonably small energy separation for the d_{xz} and d_{yz} orbitals, for which in the previous calculations[13,15,16] a large separation had to be assumed in order to fit the calculated values to the experimental ones. The present result has enabled us to analyze the ground state configuration of low-spin square planar cobalt(II) complexes from their ESR spectra (even spectra of powder samples), where the magnitude of hyperfine coupling energy of the peaks around the g=2.0 is most characteristic (*cf.* Table 1).

The presently obtained experimental results support the above conclusion. The powder ESR spectra of diluted cobalt(II) complexes with the N_4-macrocyclic ligands, **L-a**, **L-b**, and **L-c** (Fig. 13) are shown in Fig.

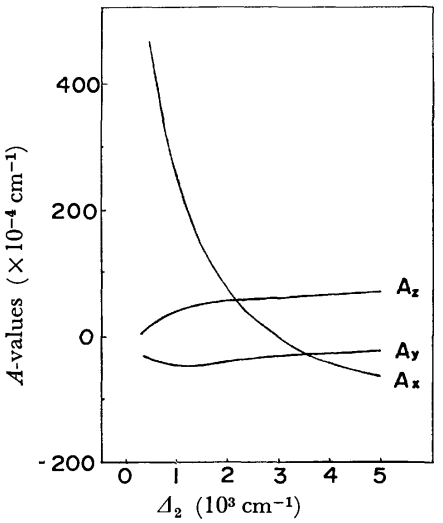

Fig. 11. The variation of A_i-values (i=x, y, z) *versus* Δ_2 in the case of the coordinate system of Fig. 1-b. Other parameters, Δ_1, λ, Δ_3, and κ are fixed to be 2000, −450, 8000 cm^{-1} and 0.4, respectively.

c_4	−0.0294	−0.0279

a) Assumed values: Δ_1=2000 cm^{-1}, Δ_2=1500 cm^{-1}, Δ_3=8000 cm^{-1}, λ=−450 cm^{-1}, k=0.9, and κ=0.45. b) Assumed values: Δ_1=2000 cm^{-1}, Δ_2=1000 cm^{-1}, Δ_3=8000 cm^{-1}, λ=−450 cm^{-1}, k=0.9, and κ=0.5.

12. It is evident that the ESR pattern of [Co(**L-a**)]$^{2+}$ entirely differs from that of both [Co(**L-b**)] and [Co(**L-c**)]. According to our criterion, [Co(**L-a**)]$^{2+}$ belongs to Type I complexes because of the hyperfine splitting ($|A_3|=138\times10^{-4}$ cm^{-1}) of the highest field absorption (g_3=2.00). On the other hand, two absotptions (g_2, g_3) were observed around g=2.0 for [Co(**L-b**)] and [Co(**L-c**)], their hyperfine splittings being very small ($|A_2|$, $|A_3|<50\times10^{-4}$ cm^{-1}). The features of [Co(**L-b**)] and [Co(**L-c**)] are very similar to those of [Co(amben)] and [Co(acen)], respectively. It should be noted that the hyperfine splitting at the lowest fields aborption of [Co(**L-c**)], (g_1=3.153, $|A_1|=126\times10^{-4}$ cm^{-1}), is much larger than that of [Co(**L-b**)], (g_1=2.636, $|A_1|\cong0$). This can be readily elucidated in terms of our calculated results based on the $(yz)^1$ ground state configuration. One absorption band is observed in the range 10000—12000 cm^{-1} for [Co(amben)][29] and [Co(**L-b**)]. For these cases, we have calculated g_i and A_i

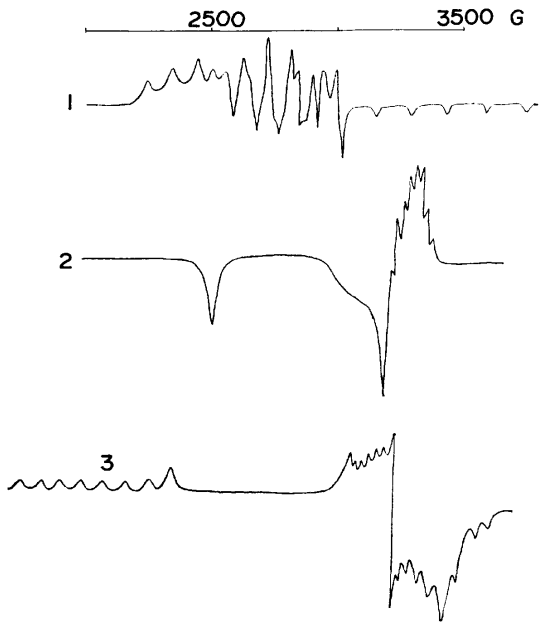

Fig. 12. ESR spectra of some square planar cobalt(II) complexes (obtained at 77 K, and $G=10^{-4}$ T). 1; [Co(**L-a**)]$^{2+}$ 2; [Co(**L-b**)] 3; [Co(**L-c**)].

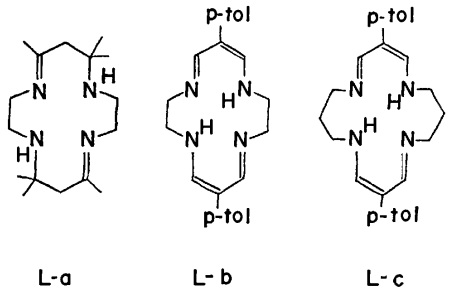

Fig. 13. Some N_4-macrocyclic ligands used in this paper, where *p*-tol represents *p*-tolyl.

values, assuming Δ_3 to be 10000—12000 cm^{-1}. As a result, it was found that the variation of Δ_3 in the range 8000—12000 cm^{-1} brings about no significant effect on the calculated values, shown in Figs. 2—9. As shown in Figs. 8 and 3, A_x is very sensitive to the energy separation between $(yz)^1$ and $(z^2)^1$. As this energy separation increases from 1400 to 2500 cm^{-1}, g_x varies from 3.2, to 2.7, and A_x, from 140×10^{-4} cm^{-1} to zero. Thus, we can elucidate the ESR parameters of [Co(amben)], [Co(**L-b**)] and [Co(**L-c**)] in tersm of our calculated results based on the $(yz)^1$ ground state configuration.

McGarvey took a sizeable mixing of d_{z^2} and d_{xy} orbitals into consideration in order to explain the ESR parameters of $[Co(sac)_2]$ and $[Co(mnt)_2]^{2-}$. According to his discussion, there should be a large difference in the mixing of d_{z^2} and d_{xy} orbitals in [Co(**L-a**)]$^{2+}$, [Co(**L-b**)] and [Co(**L-c**)]. However, this is naturally unrealistic since all these complexes have effective D_{2h} symmetry and such a large difference can not be expected.

Experimental

Preparation. The perchlorate of 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacycotetradeca-1,7-diene, **L-a**, and the tetraphenylborate of [Ni(**L-a**)]$^{2+}$ were prepared according to the methods of Curtis.[30] The ligands, **L-b** and **L-c**, 6,13-di-*p*-tolyl-1,4,8,11-tetraazacyclotetradeca-4,6,11,13-tetraene, and 3,11-di-*p*-tolyl-1,5,9,13-tetraazacyclohexadeca-1,3,9,11-tetraene, were obtained from the reaction mixtures of 4-*p*-tolyl-1,2-dithiolium hydrogensulfate and ethylenediamine or 1,3-propanediamine, according to methods similar to those described by Tang *et al.*[31] Low-spin square planar nickel(II) and cobalt(II) complexes with **L-b** and **L-c** were also prepared according to the methods of Tang *et al.*[31]

Measurements. For the ESR measurements, all the cobalt(II) complexes were diluted in the corresponding nickel(II) complexes. ESR spectra were obtained with a JEOL ESR apparatus model JES-3X-ME using an X-band. DPPH was used as a standard marker.

The calculations were performed on the Facom 230–75 computer at the Computer Center of Kyushu University. Secular determinants were solved by program HERMTS.

The Study of Thermochemical Hydrogen Preparation. VI.[1] A Hydrogen-evolving Step through the H_2S–CO Cycle

Masayuki DOKIYA, Kenzo FUKUDA, Harumi YOKOKAWA, and Tetsuya KAMEYAMA

National Chemical Laboratory for Industry, 2-19-19 Mita, Meguro-ku, Tokyo 153

(Received August 5, 1977)

A two-step decomposition process of hydrogen sulfide was studied. The process is constituted from a hydrogen-evolution step ($CO+H_2S \xrightarrow{ca.\,200\,^\circ C} H_2+COS$) and a carbonyl sulfide-decomposition step ($COS \xrightarrow{ca.\,830\,^\circ C} CO+1/x\cdot S_x$). Almost an equilibrium amount of hydrogen could be produced in the first reaction (*ca.* 40%, 200 °C, 1 atm, $CO/H_2S=2.2$) with a cobalt sulfide or nickel sulfide catalyst. In the second reaction, an almost equilibrium amount of carbonyl sulfide (45%) could also be decomposed into carbon monoxide and elementary sulfur at 830 °C under 1 atm with a sufficient reaction rate and selectivity without using any catalysts. Carbon dioxide was formed as a by-product in the second reaction: however, its yield was only 5% of the carbon monoxide produced. From these results, it may be concluded that this two-step decomposition process of hydrogen sulfide can produce more hydrogen than that produced by the direct decomposition of hydrogen sulfide. In the second reaction, however, the recombination of carbon monoxide with elementary sulfur can not be neglected. Thus, a rapid separation of sulfur from carbon monoxide is required.

The recovery of hydrogen form hydrogen sulfide is of industrial importance in relation to the thermochemical splitting of water[2] and to the desulfurization of oil and coal.[3] It has been found by the present authors that molybdenum(IV) sulfide and tungsten(IV) sulfide effectively decompose hydrogen sulfide into hydrogen and elementary sulfur at 500—800 °C:[4]

$$H_2S \longrightarrow H_2 + 1/x\cdot S_x. \quad (1)$$

The yield of hydrogen was, however, thermochemically limited, and only 5.5% of hydrogen could be produced even at 1000 K under 1 atm.

There have been many investigations undertaken in an attempt to overcome such a thermochemical disadvantage by using the external energies—for example, by α-ray,[5] by γ-ray,[5] by electron beam,[6] by UV irradiation,[7] by electric discharge,[8] or by electrolysis.[9] Besides these methods, it has been proved that the hydrogen can be separated selectively from hydrogen sulfide in the reaction zone by using a micro porous Vycor-type glass as an effusion barrier.[10] Such a process makes possible the production of more hydrogen than the equilibrium amount of Reaction 1.

Besides these single-step methods, several two-step cycles[11] and multi-step open cycles[12] have been proposed.

The present authors have previously reported a method for the production of hydrogen and carbonyl sulfide from hydrogen sulfide and carbon monoxide according to Reaction 2.[13] A closed cycle could be set up for the production of hydrogen and elementary sulfur from hydrogen sulfide if carbonyl sulfide could be decomposed selectively into carbon monoxide and sulfur:

$$H_2S + CO \longrightarrow H_2 + COS, \quad (2)$$

$$COS \longrightarrow CO + 1/x\cdot S_x, \quad (3)$$

$$H_2S \longrightarrow H_2 + 1/x\cdot S_x. \quad (1)$$

In this study, experiments were performed on Reaction 2, 3, and 4 in order to examine the possibility of this cycle:

$$CO + S \longrightarrow COS \quad (4)$$

Experimental

Reaction 2. The apparatus employed in this study was made of Pyrex glass and was a flow reactor under atmospheric pressure, as is shown in Fig. 1. The catalyst was placed in the reactor, A. A mixture of hydrogen sulfide and carbon monoxide ($CO/H_2S=2.2$) was introduced into the reactor, A, at two different constant rates (Table 1). The reactor was then kept at certain given temperatures between 170—380 °C (Table 1). The effluent gas from the reactor was cooled at the trap, E, where the produced sulfur was condensed out; then it was introduced into the two-stage gas chromatograph in order to determine the composition of the reaction mixture. The first stage of the gas chromatograph was equipped with a Deactigel column (Applied Science Co.) in order to separate the mixture of hydrogen and carbon monoxide from the carbonyl sulfide and hydrogen sulfide, while a molecular-sieve column was used in the second stage for the separation of the hydrogen from the carbon monoxide.

Catalyst. The catalysts employed in Reaction 2 were as same as those employed in a previous work.[13]

Reaction 3. This reaction was a non-catalytic thermal decomposition reaction. The apparatus shown in Fig. 1 was used again except that the A reactor was changed to a quartz reactor, B. The carbonyl sulfide gas was introduced

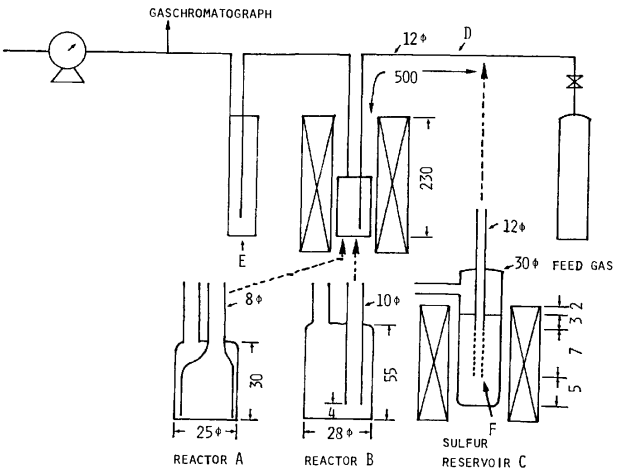

Fig. 1. Apparatus.

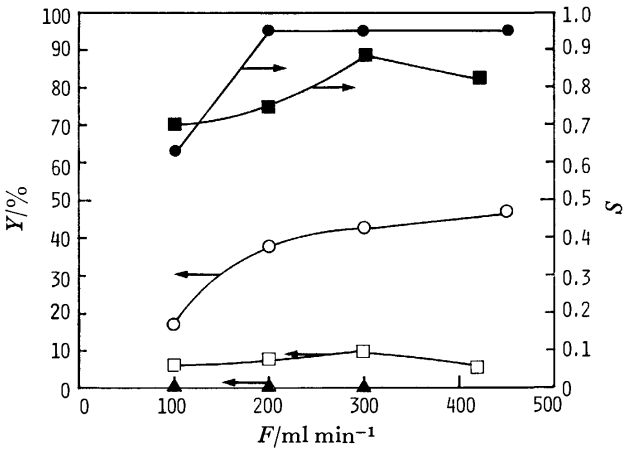

Fig. 3. Yields and selectivity against flow rate in Reaction 3. F: Flow rate, S: selectivity=(CO)/(CO $+2CO_2$), Y: yield=(CO)/(COS). ●, ○: 830 °C, ■, □: 630 °C, ▲: 430 °C.

at the given flow rates (Fig. 3). The reactor, B, was kept at 630, 730, and 830 °C. The composition of the each reaction mixture was determined by the same two-stage gas chromatograph.

Reaction 4. Reaction 4 was also performed in the same apparatus as Reaction 3, but now a sulfur reservoir, C, was attached to the apparatus shown in Fig. 1. The glass pipe, D, between the reactor, B, and the sulfur reservoir, C, was kept at 250 °C to prevent the condensation of the sulfur. The sulfur reservoir and the reactor were kept at the given temperatures (Figs. 4 and 5). In some cases, the inner pipe, F, of the sulfur reservoir was elongated (broken line in Fig. 1) in order to check the effect of the sulfur reservoir on Reaction 4. The carbon monoxide was introduced into the apparatus at certain given flow rates (Figs. 4 and 5). The carbon monoxide was made to react with sulfur in the sulfur reservoir, C, in the pipe, D, and in the reactor, B. The composition of the reaction mixture was determined by the two-state gas chromatograph.

Reagents. The purities of hydrogen sulfide, carbon monoxide, carbonyl sulfide, and sulfur were 99.99, 99.9, 99.9, and 99.5% respectively.

Results and Discussion

Table 1 represents the data for the various metal sulfide catalysts of Reaction 2 obtained at the reaction temperature of 170—380 °C and with the CO/H_2S ratio of 2.2 in the mixture of reactants. The results for Cu_2S, ZnS, and MnS were excluded from the table because the reactions on these catalysts did not proceed with a measurable velocity at 170—380 °C. As can be seen from Table 1, hydrogen and carbonyl sulfide can generally be obtained from hydrogen sulfide and carbon monoxide by using transition metal sulfides as catalysts at 170—380 °C. In the case of cobalt sulfide,

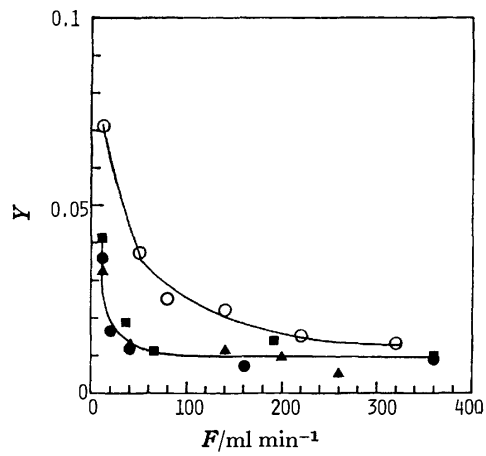

Fig. 4. Yield of Reaction 4 against flow rate (1). F: Flow rate, Y: yield=(COS)/(CO). Temperature of reactor: ○ 500 °C, ■ 450 °C, ● 400 °C, ▲ 300 °C. Temperature of sulfur reservoir: 200 °C.

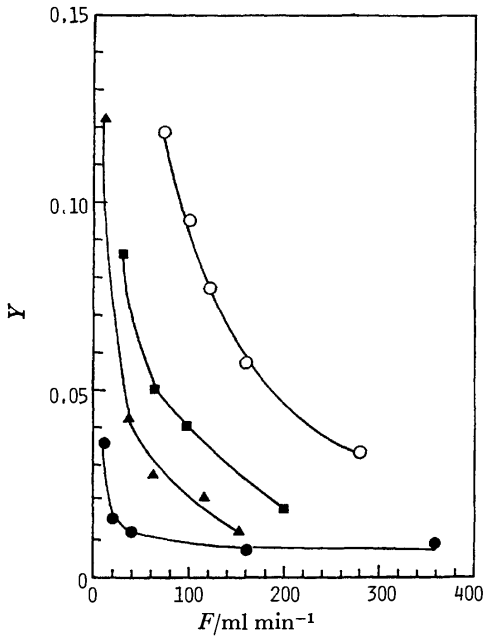

Fig. 5. Yield of Reaction 4 against flow rate (2). F: Flow rate, Y: yield=(COS)/(CO). Temperature of reactor: 400 °C. Temperature of sulfur reservoir: ○ 400 °C, ■ 300 °C, ▲ 200 °C, ● 200 °C.

hydrogen can be obtained in an amount as much as the equilibrated amount even at 220 °C. It should be noted that, in spite of the small surface area of the nickel sulfide catalyst, the conversion of hydrogen sulfide significantly high; thus, the reaction can proceed nearly to the equilibrium below 200 °C if a sufficient amount of a catalyst is employed.

Assuming that it is possible to separate each constituent from the produced gas mixture and that the selective decomposition of carbonyl sulfide into carbon monoxide and elementary sulfur can be performed, a two-step closed cycle for the decomposition of hydrogen sulfide can be constructed by the combination of Reactions 2 and 3.

Figure 2 represents the temperature dependence of the free energy changes of Reactions 1, 2, 3, and 5, which were calculated from the published thermochemical data.[14]

Figure 2 shows that the equilibrium conversions of Reactions 2 and 3 are much higher than that of Reaction 1. If Reaction 1 can be divided into Reactions 2 and 3, the additional yield of the two reactions can exceed that of Reaction 1. This is the most important reason to make up a multi-step cycle for the decomposition of hydrogen sulfide.

Unfortunately, carbonyl sulfide undergoes thermal decomposition by two reaction paths; one is the cracking reaction into carbon monoxide and elementary sulfur, as is expressed by Reaction 3, and the other is the disproportionation reaction to form carbon dioxide and carbon disulfide, as is expressed by Reaction 5.[15] Thus, the selectivity of the decomposition of carbonyl sulfide between Reaction 3 and Reaction 5 becomes a serious problem.

$$2COS \longrightarrow CO_2 + CS_2 \qquad (5)$$

Figure 3 shows the results obtained for the thermal decomposition of carbonyl sulfide. As can be seen in Fig. 3, the selectivity of carbon monoxide formation, which is represented by $CO/(CO+2CO_2)$, was as high as 95%, while that of carbon dioxide was as low as 5% at 830 °C when the flow rate of carbonyl sulfide was 420 ml min^{-1}. This selectivity seems to be sufficient to constitute a two-step closed cycle. Moreover, it must be emphasized that the yield and the selectivity of the carbon monoxide formation depended on the flow rate of the reactant carbonyl sulfide at 830 °C. The more carbon monoxide was produced, the faster the flow rate of the carbonyl sulfide. It was possible to obtain an almost equilibrated amount of carbon monoxide (*ca.* 45%) at 830 °C with the flow rate of 420 ml min^{-1}, without using any catalyst. On the other hand, the yield and selectivity of carbon monoxide were low at 630 and 430 °C over a wide range of flow rates.

When the flow rate was 100 ml min^{-1} at 830 °C, the yield and the selectivity of carbon monoxide formation were as low as that at 630 °C. From this fact, it may be concluded that Reaction 3 is very fast in both forward and reverse directions; thus, when the flow rate is slow, the reverse reaction occurs at the cooler part of the reactor, thus reducing the yield of carbon monoxide. The quenching of the gas mixture produced is, therefore, required in order to prevent the reverse reaction (Reaction 4).

In order to elucidate this reverse reaction more precisely, Reaction 4 was studied. In Fig. 4, the yields (COS/CO) of Reaction 4 are plotted against the fow rates of carbon monoxide at various temperatures of the reactor, B (300, 400, 450, and 500 °C). Below 450 °C, the yields were found to be as small as 1% at flow rates higher than 40 ml min^{-1}. At 500 °C, some increase in the yield was observed; however, the yield could be reduced to be less than 2% by raising the flow rate. Thus, Reaction 4 may be made negligible by increasing the flow rate. These results were obtained when the sulfur reservoir was kept at 200 °C and when the inner pipe, F, was dipped into the liquid

sulfur to a depth of *ca.* 3 cm. Then, in order to estimate the effect of the sulfur reservoir more precisely, the inner pipe, F, was elongated to *ca.* 7 cm and the temperature of the reservoir was raised from 200 to 400 °C, while the temperature of the reactor, B, was kept at 400 °C. The results are shown in Fig. 4. The solid circles in Fig. 5 are the same data as those in Fig. 4. The results in Fig. 5 show that the yield of carbonyl sulfide increased when the carbon monoxide was mixed well with the liquid sulfur in the sulfur reservoir and when the temperature of the reservoir was elevated. The yield of carbonyl sulfide, however, depended greatly on the flow rate of the carbon monoxide. Thus, these results show that the recombination of carbon monoxide and liquid sulfur can be eliminated as negligible if the reaction mixture of Reaction 3 can be cooled promptly and if the separation of carbon monoxide from liquid can be carried out rapidly.

This work was done as part of the Sunshine Project of the Ministry of International Trade and Industry of Japan.

Studies on the Chemical Shifts of Auger Electron Energies for Magnesium and Zinc in Their Compounds

Shunichi NISHIKIDA and Shigero IKEDA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 13, 1977)

The energy shifts of X-ray excited Auger electrons and photoelectrons for zinc and magnesium in their metals, oxides, halides, and chelate compounds are analyzed in terms of the relaxation effect. Zn $2p_{3/2}$, 3d photoelectron, Zn $L_3M_{45}M_{45}{}^1G$ Auger electron, Mg ls, 2p photoelectron and Mg $KL_{23}L_{23}{}^1D$ Auger electron peaks were provided for the investigation. The quantitative estimation of the extra-atomic relaxation energies for core electron emission was performed by combining atomic spectral data, XPS and AES data of the compounds. For zinc compounds, extra-atomic relaxation energies increase in the order of $ZnF_2 < ZnCl_2 < ZnBr_2 \approx ZnO < ZnI_2 \approx ZnS < Zn(acac)_2$, whilst the values are not fairly systematic for magnesium compounds. The nearest neighbored atom is found to be the important function for the extra-atomic relaxation energies.

Few investigations on the XPS for inner shell electrons of magnesium or zinc atoms in their compounds have been undertaken[1-3] because of the small chemical shifts in these binding energies. For zinc halides, shifts of zinc 3d bands have been discussed in terms of the ionic character of the zinc–halogen bonds[4] measured in vapor phase in UPS. For zinc, Auger spectra were measured for atom,[5,6] zinc metal, oxide, and fluoride.[7] Kowalczyk[7] *et al.* have given a theoretical interpretation of Auger energies and discussed the shifts of extra-atomic relaxation energies for zinc in metal, oxide, and fluoride. Hoogewijs *et al.*[8,9] have given a similar but improved results for the analysis of Auger electron energies of zinc atom and metal. No data have been explored about the Auger emission of magnesium compounds other than that of magnesium atom,[10] metal, and oxide.[11]

In this paper, we report on the chemical shifts of the core level electron binding energies and Auger electron energies for zinc and magnesium in their metals and compounds. Atomic spectral data for these elements are applied here to elucidate the extra-atomic relaxation energies in Auger electron emission. For oxides, sulfides and halides, extra-atomic relaxation energies were corelated with polarizabilities of ligands. In both elements, common ligands give the same extent of contributions to the extra-atomic relaxation energy shifts of host atoms.

Experimental

Spectra of photoelectrons and Auger electrons were recorded by AEI ES 200 type spectrometer with the Al $K\alpha_{1,2}$ X-ray source. The pressure in the sample chamber was maintained at about 5×10^{-8} Torr (1 Torr = 133.322 Pa) during the measurements.

Magnesium and zinc metal films were provided for the investigation by evaporating them onto the sample holder.

Testing samples for zinc chloride, bromide, and iodide were deposited onto a stainless holder plate by using a platinum filament. The XPS spectra of these halides were free from the background O ls and C ls photoelectron peaks. Original magnesium chloride and magnesium bromide were obtained by pyrolysis of their double salts with ammonium chloride and ammonium bromide. The dehydration of magnesium iodide was carried out with heating in vacuum.

8-Quinolinolate complexes for zinc and magnesium were prepared by the ordinary method[12] and dehydrated by heating at 150 °C for a few hours.

All the other samples were obtained from commercial sources without further purification.

Solid samples other than halides and metals were powdered and pressed onto the cellophane tape placed on the metal holder to provide for the X-ray exposure.

The energy scale of the spectra was calibrated with reference to the photoelectron energies of the following levels of standard materials: Pd $4d_{5/2}$, Au $4f_{7/2}$, Pd $3d_{5/2}$, Ag $3d_{5/2}$, and Ag $3p_{3/2}$ of highly pure metallic palladium, gold, and silver. From a knowledge of the spectrometer constant thus obtained,[13] the measured values of kinetic energies for various levels in samples were corrected. The binding energies of $4f_{7/2}$ photoelectron peak of gold (83.8 eV) deposited onto each sample were measured and used to evaluate the extent of charging of the respective solid.

Results

The binding energies of 1s and 2p photoelectrons and $KL_{23}L_{23}$ Auger electron energies for all of the measured magnesium compounds are summarized in Table 1.

For zinc compounds, the binding energies of $2p_{3/2}$, 3d and $L_3M_{45}M_{45}$ Auger peaks are summarized in Table 2. Each value for the shifts of these energies referred to those of the respective fluorides is also listed in the tables.

In the photoelectron and the Auger electron spectra for magnesium metal film, peaks due to the partially oxidized magnesium are observed, but no such oxidized peaks were observed for zinc metal in both photoelectron and Auger electron spectra. A satellite peak due to the plasmon loss is observed at the 10.8 eV lower kinetic energy side of the main peak in both photoelectron and Auger electron spectra for magnesium metal. The absence of the O 1s peak in zinc halides gives the evidence of the complete dehydration of these samples by the evaporation method.

In spite of the careful preparations, O 1s photoelectron peak was slightly observed in magnesium chloride, bromide and iodide spectra. For a zinc 8-quinolinolate compound, O 1s peak with rather high intensity was observed compared with the intensity of N 1s peak, despite of the heating at 150 °C for a few hours. On the other hand, the spectrum for magnesium 8-quinilinolate showed appropriate intensity of O 1s photoelectron peak to the predicted stoichiometric value for its structure.

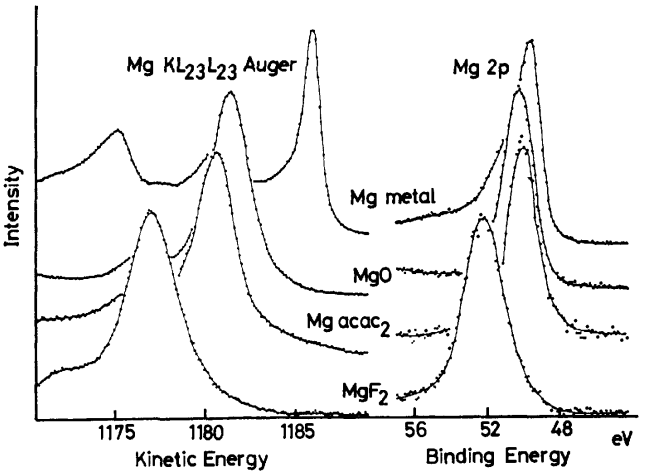

Fig. 1. Magnesium 2p photoelectron and $KL_{23}L_{23}$ Auger electron spectra for various magnesium compounds.

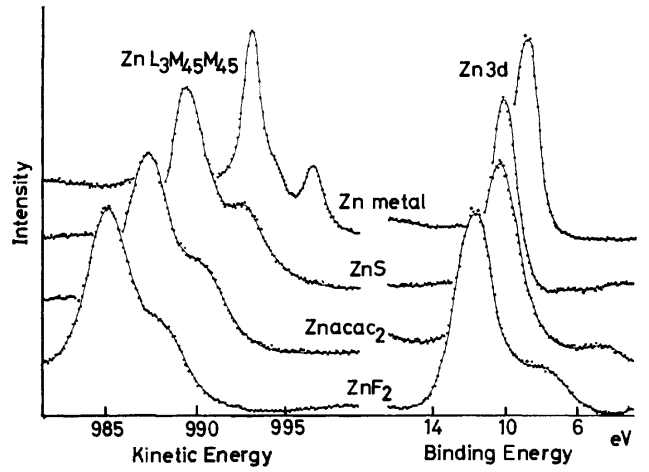

Fig. 2. Zinc 3d photoelectron and $L_3M_{45}M_{45}$ Auger electron spectra for various zinc compounds.

For the other chelate compounds of magnesium and zinc, the intensity ratios in each photoelectron peak give good agreements with the predicted ratios from their structures.

In Fig. 1 the spectra of Mg $KL_{23}L_{23}$ Auger electron and 2p photoelectron for magnesium metal, magnesium oxide, magnesium acetylacetonate, and magnesium fluoride are shown. Also those of Zn $L_3M_{45}M_{45}$ Auger electron and 3d photoelectron for zinc compounds are shown in Fig. 2.

The chemical shifts of Auger lines are larger than those of photoelectrons for both elements in all the compounds.

The magnitudes of the shifts of these lines for each metal referred to their fluorides are the largest of the compounds investigated for both elements. The energy separations of the binding energies between magnesium 1s and 2p photoelectrons are as constant as those between zinc 2p and 3d orbital electrons in all the compounds.

Discussion

As shown in Tables 1 and 2, chemical shifts of Auger electrons are larger than those of photoelectrons. This

Table 1. Chemical shifts of photoelectron binding energies (ΔE_b), Auger electron energies (ΔE_{Auger}) and extra-atomic relaxation energies (R^{ea}) for magnesium compounds

Sample	Mg 2p		Mg $KL_{23}L_{23}(^1D)$		R^{ea}

[Mg(oxine)[a]$_2$]	49.2	3.0	1182.0	5.0	10.8
[M(acac)[b]$_2$]	50.0	2.2	1180.6	3.6	10.2
Na_2[Mg(edta)]	50.2	2.0	1180.6	3.6	10.4

a) oxine=8-quinolinolate ion. b) acac=acetylacetonate ion=2,4-pentanedionate ion. c) edta=ethylenediaminetetraacetate(4−) ion.

can be interpreted in terms of the larger relaxation energy due to the final state after two-electron ejection in Auger process, as described in the following equation.[7,14–16]

$$E_{Auger}(KLL) = E(K) - 2E(L) + R - F, \quad (1)$$

where $E(K)$ and $E(L)$ are the photoelectron binding energies of 1s and 2p orbitals, respectively, and F is a two-electron interaction term, for which Asaad and Burhop[17] have made a theoretical analysis by taking into account the effect of intermediate coupling in the two-hole final state for KLL Auger transitions. R is a so-called static relaxation energy according to the definition after Shirley.[7] It may be separated into two parts, atomic and extra-atomic static relaxation energies. Static atomic relaxation energy should be twice the dynamic relaxation energy, E_R,[18] accompanied with photoelectron emission. Extra-atomic static relaxation energy, R^{ea}, is the relaxation energy due to surrounding atoms in the electron emission process. Then, Eq. 1 is expressed as follows.

$$E_{Auger}(KLL) = E(K) - 2E(L) + 2E_R + R^{ea} - F. \quad (2)$$

For a free atom, R^{ea} value in Fig. 2 is zero and the following equation will be established.

$$E^A_{Auger}(KLL) = E^A(K) - 2E^A(L) + 2E^A_R - F, \quad (3)$$

where E^A means the energy term for a free atom. The photoelectron binding energy for a free atom is referred to the vacuum level, and the kinetic energy of an Auger electron is independent of the excitation energy. When a measurement is carried out using characteristic X-ray with the energy of $h\nu$, Eq. 3 is expressed as follows.

$$2E_R - F = (E_b(K) - E_b(L)) + (E_{kin}(L) - E_{Auger}(KLL)) - h\nu, \quad (4)$$

where $E_b(K) - E_b(L)$ is equivalent to the value $E_{kin}(L) - E_{kin}(K)$. Then, $2E_R - F$ can be obtained directly from the observed kinetic energies for each peak. Here, the energy level for an Auger electron could be defined with just the same reference as that for photoelectron binding energy.

TABLE 2. CHEMICAL SHIFTS OF PHOTOELECTRON BINDING ENERGIES (ΔE_b), AUGER ELECTRON ENERGIES (ΔE_{Auger}) AND EXTRA-ATOMIC RELAXATION ENERGIES (R^{ea}) FOR ZINC COMPOUNDS

Sample	Zn $2p_{1/2}$		Zn 3d		Zn $L_3M_{45}M_{46}(^1G)$		R^{ea}
	E_b	ΔE_b	E_b	ΔE_b	E_{Auger}	ΔE_{Auger}

[Zn(pc)][c]	1021.8	1.6	10.1	1.6	988.6	3.5	11.4

a) acac: acetylacetonate ion (2,4-pentanedionate ion). b) oxine: 8-quinolinolate(2−) ion. c) pc: phthalocyanine.

In a similar fashion for a solid sample, both photoelectron binding energy and Auger electron kinetic energy must be referred to the same level.

Then, the electron energy values can be scaled from the reference level, that is, electrons at the reference level are to be photoejected with the kinetic energy of $h\nu$. In this paper, both photoelectron and Auger electron energies are referred to the Fermi level.

Using Eq. 3 the numerical values of $2E_R^A - F$ term can be estimated for magnesium atom on the basis of the following data; the energy value, 1167.3eV for Mg KL_{23}-$L_{23}{}^1D$ in magnesium atom measured by Breuckmann and Schmidt,[10] the binding energy of 2p orbital electron, 57.64 eV, estimated from the atomic spectral data[19] and 1s orbital binding energy, a sum of the binding energy of 2p orbital and magnesium $K\alpha$ X-ray energy 1256.6 eV[20] being equal to 1311.24 eV. Then the value for $2E_R^A - F$ term is calculated to be −28.66 eV. The result is graphically shown in Fig. 3.

For magnesium, the sum of $2E_R - F$ in Eq. 2 is considered to be equal for all the compounds and then the extra-atomic relaxation energy, R^{ea}, a parameter for the characterization of molecular environment surrounded by a host atom, could be estimated with the following method. As magnesium in its compounds under investigation exists as cation with oxidation number +II, no 3s orbital electrons are assumed to contribute to the atomic relaxation effect. Then, the atomic relaxation of magnesium ion, $2E_R$, was calculated by subtracting the relaxation energy due to 3s orbital electrons and we obtained the value of 3.9 eV by using Slater's orbitals and equivalent core model.[21,22]

$$-F + 2E'_R = -33.02\,\text{eV}$$

where E'_R is dymanic relaxation energy ignoring 3s electrons.

On the other hand, as shown in Fig. 4, the value of $2E_R - F$ can be directly estimated from atomic data[19] for magnesium ion with a similar fashion for magnesium atom. That is, the value can be obtained as a difference between ionization potentials of the spectroscopic MgIII(Mg^{2+}) and MgIV(Mg^{3+}) states, −29.17 eV. As the lowest energy state of $MgV(2s)^2(2p)^4$ is $^3P_2$ in optical term, $-F+2E_R'$ value corresponding to ^1D state can be obtained from a energy difference between $^3P_2$ and ^1D states, 3.8 eV, as follows:

$$-F + 2E'_R = -32.97\,\text{eV}$$

The value is in good agreement with the former results. Utilizing this value with the observed Mg $KL_{23}L_{23}{}^1D$ Auger electron energy, and 1s and 2p photoelectron binding energies, extra-atomic relaxation energy, R^{ea}

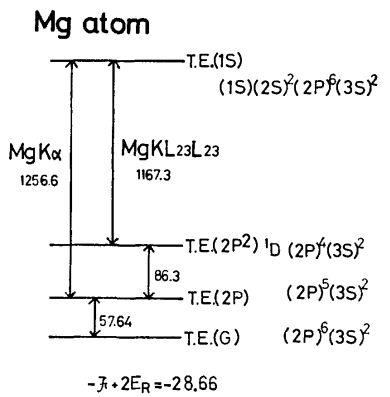

Fig. 3. Total energy (T.E.) level diagram of a free magnesium atom for various core-ionized electron configurations (eV).

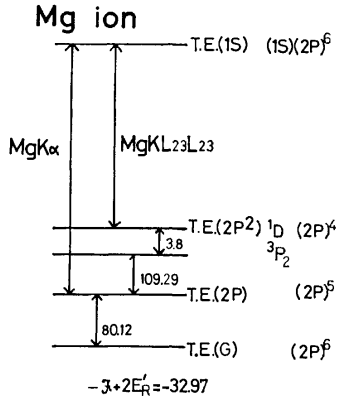

Fig. 4. Total energy (T.E.) level diagram of magnesium ion (+2) for various core-ionized electron configurations (eV).

could be calculated for various magnesium compounds.

For zinc Auger electrons, $L_3M_{45}M_{45}{}^1G$ electron with the highest intensity is adopted to calculate the extra-atomic relaxation. For the fourth ionization potential of zinc atom, the value obtained by Lotz[23] was used and the energy separation between ^1G and $^3F_4$, the lowest energy state of $Zn(Zn^{4+})$ ion ($3d^84s^0$), has the measured value of 3.75 eV for the free zinc atom.[5] The result obtained from these data is graphically shown in Fig. 5.

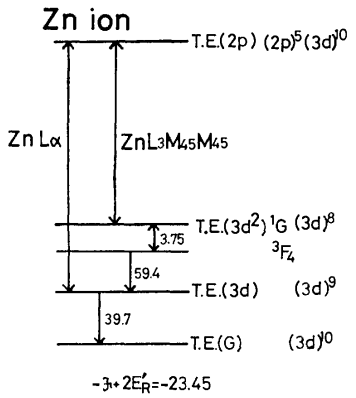

Fig. 5. Total energy (T.E.) level diagram of zinc ion (+2) for various core-ionized electron configuration.

In Tables 1 and 2, the extra-atomic relaxation energies obtained by the above mentioned method (Eq. 2) for various magnesium and zinc compounds are shown, respectively.

The distance between Auger electron and photoelectron peaks is independent of the reference level. The ambiguity of reference level or charging effect can be canceled out. Wagner[24] has also noted this energy difference and defined a parameter for Auger chemical shift. He found out that the shifts of this parameter qualitatively obey the trend of Pearson's concept of soft-hard acid and base character of bonding atoms to host atom. The shift of Auger parameter can be identified with the change of the magnitudes R^{ea}, assuming $E(K)-E(L)$ and $-F+2E_R$ to be constant for all the compounds.

For zinc halides, the electron binding energies of Zn $2p_{3/2}$ are nearly the same for all the compounds but fluoride, whereas the shifts in R^{ea} are clearly progressive and the order of the magnitudes of R^{ea} is quite coordinated with polarizabilities of halide ions. Although the Zn $2p_{3/2}$ binding energies in zinc oxide are the same with that of zinc iodide, R^{ea} in zinc iodide is larger than that in zinc oxide. This corresponds to the fact of the larger polarizability of iodide ion than that of oxygen ion. Sulfide ion with a large polarizability shows a large relaxation energy in zinc sulfide. For three zinc chelate complexes, the order of magnitudes in extra-atomic relaxation energies obeys the donicity of the coordinated atoms, that is, is in the order of O–O, O–N, and N–N.

A plot of the measured relaxation energy *vs.* the product of polarizability[25,26] for a neighbored surrounding atom and the inverse of the nearest neighbor distance[27] for various zinc compounds is shown in Fig. 6. It is seen that the extra-atomic relaxation energies are linearly related to the polarization energies due to nearest neighbored surrounding atoms. A value obtained by extrapolating the line, the intercept of the line with the ordinate, 8.8 eV, means the residual relaxation energies which are commonly contributed to all the compounds. A part of this residual relaxation energies may be due to contributions from all the atoms in crystal except the host and nearest neighbored atoms. The second important contribution may be the participation of 4s orbital electrons. In order to calculate the extra-atomic relaxation energies for zinc compounds, the assumption has been made for 4s orbital electrons to be absent from the host atom, leaving it ideally in Zn^{2+} ion state. Thus, the relaxation energies due to the charge density on zinc atom may be considered as the sum of those localized to the host atom, the values dependent on the bonding character being proportional to the polarizability of surrounding atoms.

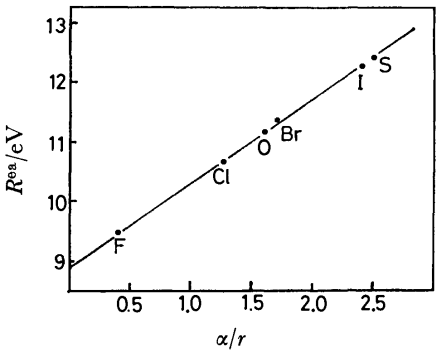

Fig. 6. Corelation between extra-atomic relaxation energies and polarizabilities of neighbor atoms divided by nearest neighbor distance for zinc compounds.

For magnesium halides except for fluorides, the extra-atomic relaxation energies are nearly the same and the order of the magnitude does not correspond to that in zinc halides. Ambiguity exists on the electron emission data sources because of the hydroscopic character of these compounds. For three magnesium chelate compounds investigated, magnesium bonding with nitrogen and oxygen in 8-quinolinol shows the largest relaxation energy. This means that the contribution of nitrogen to relaxation energy may be larger than that of oxygen, like the case of zinc chelate complexes.

The extra-atomic relaxation energies due to the same ligand in both magnesium and zinc compounds are in good agreement with each other except for the bromide and iodide, as shown in Tables 1 and 2.

(Received May 9, 1977)

Two types of copper(II) complexes, $Cu(c\text{-chxn})_2X_2\cdot nH_2O$ and $Cu(t\text{-chxn})_2X_2\cdot nH_2O$ ($X=Cl^-$, Br^-, NO_3^-, and ClO_4^-, $n=0$—2), and three types of nickel(II) complexes, $[Ni(c\text{-chxn})_2]X_2$, $[Ni(c\text{-chxn})_3]X_2\cdot nH_2O$ ($X=Cl^-$, Br^-, NO_3^-, and ClO_4^-, $n=0.5$—1.5) and $[Ni(t\text{-chxn})_2(H_2O)_2]X_2$ ($X=Br^-$ and ClO_4^-), were synthesized. Here, *c*-chxn and *t*-chxn stand for *cis*- and *trans*-1,2-cyclohexanediamine respectively. Based upon the analyses of the electronic spectra and magnetic moments, the structures of the copper(II) complexes synthesized were found to be distorted octahedrons. The influence of the steric configurations of the diamine isomers on the structures of the copper(II) complexes is small. The three types of nickel(II) complexes were found to have square planar, octahedral, and distorted octahedral structures respectively. The steric influence of the ligands on the properties of the nickel(II) complexes was also considered.

Although the properties of various metal complexes of *trans*-1,2-cyclohexanediamine (abbreviated as *t*-chxn), but not the 1 : 2 complexes of copper(II) and nickel(II), have been studied so far,[2] no investigation of the metal complexes of *cis*-1,2-cyclohexanediamine (*c*-chxn) has been reported. These ligands may be regarded as C,C′-disubstituted ethylenediamine derivatives, but their steric properties due to the cyclohexane ring are quite different from one another. In the *c*-chxn complexes, the two amino groups are bound to the cyclohexane ring with axial and equatorial orientations simultaneously, so that the cyclohexane ring exists much closer to the chelate ring than in the *t*-chxn complexes. The present authors have prepared copper(II) and nickel(II) complexes of *c*-chxn and *t*-chxn and studied their properties by means of the electronic and infrared spectra, as well as the magnetic moments.

Experimental

Materials. From the Tokyo Kasei Co., Ltd., we purchased 1,2-cyclohexanediamine, which was then separated into *cis*- and *trans*-isomers according to the procedure described in previous paper.[3] The copper(II) and nickel(II) perchlorates were prepared from the corresponding metal basic carbonates and perchloric acid. The other metal salts used were of the highest grade available.

Preparation of Complexes. *$Cu(c\text{-chxn})_2X_2\cdot nH_2O$ and $Cu(t\text{-chxn})_2X_2\cdot nH_2O$ ($X=Cl^-$, Br^-, NO_3^-, and ClO_4^-, $n=0-2$)*: These complexes were synthesized by the reaction of 2 mmol of copper(II) salt and 4 mmol of *c*- or *t*-chxn in methanol. The violet product obtained was recrystallized from methanol–water.

$[Ni(c\text{-chxn})_2]X_2$ ($X=Cl^-$, Br^-, NO_3^-, and ClO_4^-): The syntheses of these complexes were carried out much like those employed for the copper(II) complexes. The yellow crystals obtained were recrystallized from water. In the process of the recrystallization of $[Ni(c\text{-chxn})_2](NO_3)_2$ and $[Ni(c\text{-chxn})_2](ClO_4)_2$, a small amount of the yellow crystals occasionally turned violet. The violet complexes were completely transformed back to the yellow crystals, though, when they were kept in desiccated atmosphere.

$[Ni(t\text{-chxn})_2(H_2O)_2]X_2$ ($X=Br^-$ and ClO_4^-): The bromide complex was obtained by adding 15 ml of a 0.75 M ligand solution in methanol to 15 ml of a 0.5 M aqueous nickel(II) bromide solution. A blue violet precipitate was recrystallized from methanol–water. The perchlorate complex was prepared according to the following procedure. Six mmol of *t*-chxn in 6 ml of methanol were added to a solution of 4 mmol nickel(II) perchlorate in 8 ml of methanol. After removing a small amount of the tris-complex, the solution was heated on a water bath and concentrated until a small amount of product was deposited. The mixture was then allowed to stand at room temperature to give blue violet complex.

$[Ni(c\text{-chxn})_3]X_2\cdot nH_2O$ ($X=Cl^-$, Br^-, NO_3^-, and ClO^-_4, $n=0.5$—1.5): To 3 mmol of *c*-chxn in 2 ml of ethanol we added 1 mmol of nickel(II) halide in 1 ml of water. The violet crystals thus obtained were recrystallized from ethanol–water to give $[Ni(c\text{-chxn})_3]Cl_2\cdot 1.5H_2O\cdot 0.5C_2H_5OH$ and $[Ni(c\text{-chxn})_3]Br_2\cdot H_2O\cdot 0.5C_2H_5OH$. The ethanol was removed by heating at 100 °C in the air for a few hours. $[Ni(c\text{-chxn})_3](NO_3)_2\cdot 0.5H_2O$ and $[Ni(c\text{-chxn})_3](ClO_4)_2\cdot H_2O$ were readily obtained by mixing 3 mmol of the ligand in methanol with 1 mmol of nickel(II) salt in water.

$[Ni(t\text{-chxn})_2(H_2O)_2]X_2$ ($X=Cl^-$ and NO_3^-): These complexes were synthesized according to the methods described in the literature.[4]

Measurements. The magnetic moments were measured with a Shimadzu MB-2 magnetic balance at room temperature. Measurements of the electronic spectra of the copper(II) complexes in solution and the temperature dependence on the ε of the diamagnetic nickel(II) complexes were carried out using a Hitachi 124 spectrophotometer. The absorption and reflectance spectra of the nickel(II) complexes were measured with a Hitachi EPS-3T spectrophotometer. The infrared spectra in the range of 600—4000 cm^{-1} were recorded with a JASCO IRA-2 spectrophotometer by means of the KBr disc method. The far-infrared spectra in the range of 200—600 cm^{-1} were recorded on a JASCO DS-710G spectrophotometer in Nujol mulls.

Results and Discussion

Properties of the Complexes. The results of the elemental analyses, the magnetic moments, and the colors of the complexes newly synthesized in the present study are listed in Table 1. The copper(II) complexes with Cl^- and Br^- have 1—2 moles of water, while those with NO_3^- and ClO_4^- are anhydrous. From the values of the magnetic moments, the copper(II) complexes may be considered to be mononuclear.

The facility of the nickel(II) complex formation depends on the geometrical structure of the ligand, as well

as on the counter anion concerned. The diamagnetic nickel(II) complexes of *c*-chxn were preferentially synthesized by the reaction of a 1:2 molar ratio of nickel(II) salt and ligand in a methanol solution. Tsuchida[4] reported the preparation of two types of bis complexes, $[Nichxn_2]X_2$ ($X=Cl^-$, Br^-, and ClO_4^-) and $[Nichxn_2(H_2O)_2]X_2$ ($X=Cl^-$ and NO_3^-), and described the chxn as *t*-chxn. The synthetic method and the electronic and magnetic properties of $[Ni(c\text{-chxn})_2]X_2$ obtained here are almost the same as those of Tsuchida' s$[Nichxn_2]X_2$. Therefore, the $[Nichxn_2]X_2$ obtained by Tsuchida seems to consist of the *c*-chxn complexes formed with a small amount of the *cis* isomer contained in chxn.[3] On the other hand, the *t*-chxn ligand afforded paramagnetic dihydrated bis-complexes. The isolation of $[Ni(t\text{-chxn})_2(H_2O)_2]X_2$ ($X=Br^-$ and ClO_4^-) was a little more difficult than that of the same type of the complexes with Cl^- and NO_3^-, because less soluble $[Ni(t\text{-chxn})_3]X_2\cdot nH_2O$ substances were precipitated during the syntheses of the bis-complexes. The $[Ni(t\text{-chxn})_2(H_2O)_2](ClO_4)_2$ shows a tendency to change to the orange yellow form in the dried atmosphere, losing almost 2 mol of coordinated water, which were, on the contrary, taken up by the complex when it was kept in the air. The $[Ni(c\text{-chxn})_3]Cl_2\cdot 1.5H_2O$ and $[Ni(c\text{-chxn})_3]Br_2\cdot H_2O$ are a little less stable than the corresponding tris-complexes of *t*-chxn and tend to change to yellow complexes when refluxed in methanol. The magnetic moments of all the nickel(II) complexes except for the yellow complexes of the *c*-chxn are around 3.1 B. M., and they indicate octahedral structures.

Electronic Spectra. The electronic spectra of the complexes were studied either in solution or in the solid state. Some typical spectra are shown in Figs. 1—2, and the numerical results, in Tables 2—3. The absorption spectra of the *c*-chxn and *t*-chxn complexes with

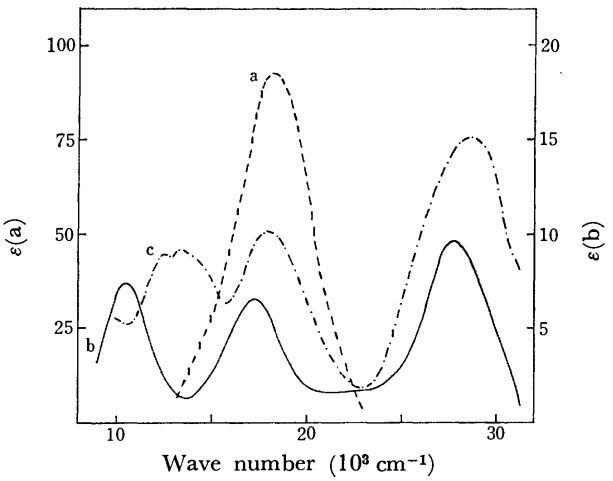

Fig. 1. Electronic spectra of (a) $Cu(t\text{-chxn})_2(ClO_4)_2$ (MeOH soln), (b) $[Ni(t\text{-chxn})_2(H_2O)_2](ClO_4)_2$ (MeOH soln), and (c) $[Ni(t\text{-chxn})_2(H_2O)_2](ClO_4)_2$ (Solid).

copper(II) halides show a d-d transition band at around 17700 cm^{-1}. The corresponding bands of the nitrate and perchlorate complexes appear in a somewhat shorter-wavelength region than those of the halide complexes. The reflectance spectra of the copper(II) complexes show a band in the region of 17900—19400 cm^{-1}. It is generally recognized that the electronic spectra of the copper(II) complexes of ethylenediamine derivatives exhibit a broad d-d band in the region of 14000—22000 cm^{-1}.[5] The structures of the copper(II) complexes obtained are considered to be tetragonally distorted octahedrons, with diamine ligands to form a square planar structure. The degrees of the tetragonal distortion in the structures of the complexes with NO_3^- and ClO_4^- seem to be larger than those of Cl^-

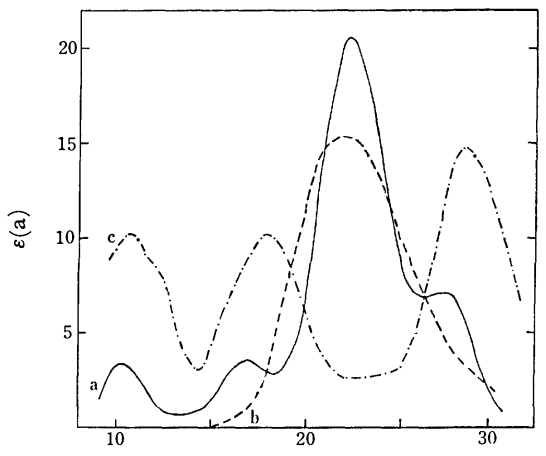

Fig. 2. Electronic spectra of (a) $[Ni(c\text{-chxn})_2](ClO_4)_2$ (H_2O soln), (b) $[Ni(c\text{-chxn})_2](ClO_4)_2$ (Solid), and (c) $[Ni(c\text{-chxn})_3](ClO_4)_2 \cdot H_2O$ (Solid).

and Br^-. The former two polyatomic anions were assumed to coordinate very weakly toward the copper(II) ion, because no appreciable distortion of the free ion was found in their infrared spectra. For the structures of the copper(II) complexes containing both X^- and H_2O, it was difficult to know which ligand, X^- or H_2O, coordinates in the tetragonal positions. The spectral properties suggest, however, that the steric configurations of the ligands have little effect on the coordination tendencies toward copper(II) ions. These results agree with the stability constants of the copper(II) complexes of the chxn isomers, whose values are nearly equal to each other.[6]

The electronic spectra of $[Ni(c\text{-chxn})_2]X_2$ ($X=Cl^-$, Br^-, NO_3^-, and ClO_4^-) in the solid state show a relatively strong band at around 22000 cm^{-1} which is characteristic of a square planar structure. In aqueous solutions of these complexes, three additional bands (Bands I, III, and IV) corresponding to the octahedral structure are observed. These results indicate that $[Ni(c\text{-chxn})_2]^{2+}$ and $[Ni(c\text{-chxn})_2(H_2O)_2]^{2+}$ coexist in water. The $[Ni(c\text{-chxn})_2(H_2O)_2]^{2+}$ cation can be assigned to the *cis* configuration because its spectral features are very similar to those of the $[Ni(en)_2(H_2O)_2]^{2+}$ cation which exists as the *cis* form in solution.[7] Thermochromism is found in aqueous solutions of four $[Ni(c\text{-chxn})_2]X_2$ complexes. As is shown in Fig.3, the intensity of Band V increases with an increase in the temperature. This reveals that the equilibrium between square planar and octahedral structures proceeds toward a dehydration reaction with a rise in the temperature. Similar behavior has been reported for ethylenediamine–nickel(II) complexes.[8]

The structures of the $[Ni(t\text{-chxn})_2(H_2O)_2]X_2$ ($X=Br^-$ and ClO_4^-) complexes in the solid state are regarded as tetragonally distorted octahedrons, with water molecules coordinating in the axial positions, since these spectra show a splitting of Band I, although the peak at the lower wave number has not been measured in the present study, and since the spectra resemble those of $[Ni(en)_2(H_2O)_2]X_2$ ($X=NO_3^-$ and ClO_4^-) and of *t*-chxn complexes of the same type previously

reported.[4,7] In a methanol solution, they are transformed to the *cis* form as well as $[Ni(c\text{-chxn})_2(H_2O)_2]^{2+}$.

The spectra of a series of tris-complexes of *c*-chxn have three main peaks typical of octahedrally coordinated nickel(II). Although these structures are analogous to those of the *t*-chxn and ethylenediamine complexes, the tris-complexes of *c*-chxn are thermodynamically less stable and the successive stability constant, k_3, has not been measured.[6] The instability of the tris-complexes of the *c*-chxn may be ascribable to the configuration of the ligand. The structures of the tris-complexes of *c*-chxn are more puckered due to the axial amino groups than those of the *t*-chxn. Similarly, the fact that hardly no paramagnetic bis-complexes of the *c*-chxn were obtained may also be explained by their unfavorable *cis* form in solution.

Infrared Spectra. All the nickel(II) complexes with the NO_3^- group show a broad strong absorption near 1350 cm^{-1} in their infrared spectra and seem to contain free nitrate ions.[9] Similarly, the $[Ni(c\text{-chxn})_2](ClO_4)_2$, $[Ni(t\text{-chxn})_2(H_2O)_2](ClO_4)_2$, and $[Ni(c\text{-chxn})_3](ClO_4)_2\cdot H_2O$ complexes were assumed to have ionic perchlorate ions on the basis of the ν_{Cl-O} band at around 1080 cm^{-1}.[10] Therefore, in octahedral $[Ni(t\text{-chxn})_2(H_2O)_2](ClO_4)_2$, water molecules were regarded as coordinating to the nickel(II) ion. The ν_{O-H} bands, overlapping the two ν_{N-H} bands, were observed in a lower frequency region than that of water of crystallization. In the spectra of the copper(II) complexes containing NO_3^- and ClO_4^-, hardly any splitting of ν_{N-O} and ν_{Cl-O} was observed.

Table 4 summarizes the infrared frequencies of these complexes. The ν_{N-H} frequencies are found to shift toward higher frequencies in the order of $Cl^- \leqq Br^- < NO_3^- < ClO_4^-$. This shift is considered to arise mainly from the hydrogen bond between the amino group and the anion. The δ_{NH_2} of the bromide complexes shifted to frequencies lower by 2—11 cm^{-1} than those of the corresponding chloride complexes. The deformation frequency may be affected by the strength of the M–N bond and the structural difference of the complexes, in addition to the extent of the hydrogen bond; hence, a systematic trend of band shifts has not been deduced for all the complexes prepared. The rocking modes of the NH_2 groups, which were assigned by means of the deuteration of the representative complexes, are distinctly metal-sensitive as has been described in the literature.[10] Figure 4 illustrates some typical far-infrared spectra of the 1:2 copper(II) and nickel(II) complexes. The assignment of the metal nitrogen stretching bands has been subject to great confusion; however, two bands located at 370—420 and 240—280 cm^{-1} have been found to be fairly metal-sensitive. These bands are illustrated as (A) and (B) in Fig. 4 and are summarized in the last two columns in Table 4. Lever and Mantovani[11] studied the far-infrared spectra of metal complexes of ethylenediamine

Table 4. The main infrared bands of the bis-complexes (cm^{-1})

sh = shoulder. a) These bands seem to be overlapped with the neighboring ν_{O-H} bands. b) 1—2 bands were observed assignable to ρ_{rNH_2} or ρ_{rH_2O} in the 650—750 cm^{-1} region.

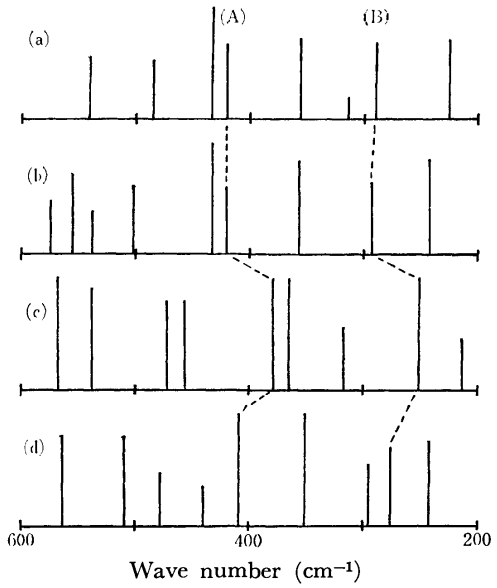

Fig. 4. Observed bands in the infrared spectra in the region between 200 and 600 cm^{-1}. (a): $Cu(c\text{-chxn})_2(NO_3)_2$, (b): $Cu(t\text{-chxn})_2(NO_3)_2$, (c): $[Ni(c\text{-chxn})_2]Br_2$, (d): $[Ni(t\text{-chxn})_2(H_2O)_2]Br_2$.

and its derivatives extensively and assigned the peaks in the regions of 403—421 and 309—331 cm^{-1} to ν_{Cu-N}, while the peaks in the region of 275—395 cm^{-1} were assigned to ν_{Ni-N}. Omura *et al.*[12] assigned the two bands at 412 and 472 cm^{-1} to the ν_{Cu-N} of $[Cu(en)_2]^{2+}$. Therefore, the bands observed around 370—420 cm^{-1} may be regarded one consisting dominantly of the ν_{M-N} band. The other lower metal-sensitive bands are supposed to be characteristic of the δ_{NMN} vibration, considering the values of the same type of complex. It is of interest that the frequency order of the metal-sensitive bands is $Cu(t\text{-chxn})_2X_2 > Cu(c\text{-chxn})_2X_2 > [Ni(t\text{-chxn})_2(H_2O)_2]X_2 > [Ni(c\text{-chxn})_2]X_2$, which is consistent with the order of the stability constants.

The authors would like to thank Dr. Noboru Nakayama of the Goverment Industrial Institute, Nagoya, for the use of a Shimadzu MB-2 magnetic balance, and Dr. Kenji Yoshimoto of the Aichi Environmental Research Center, for the use of a JASCO DS-710G infrared spectrophotometer. Thanks are also due to Misses Masae Ishiguro and Shizuko Iwauchi of the Analytical Center of the Nagoya City University for their elemental analyses.

(Received June 2, 1977)

An accurate method has been proposed for the determination of pentathionate in mixtures with thiosulfate and sulfite. The method is based on the formation of thiosulfate equivalent to the pentathionate, and the spectrophotometric determination of excess iodine for the reaction with the thiosulfate formed. The conditions for pentathionate to be quantitatively converted into thiosulfate were established by varying pH, reaction time, and amounts of sulfite. The method can be successfully applied to the determination of pentathionate, thiosulfate, and sulfite when they are mixed in various ratios, giving a relative standard deviation of 0.82% at the 0.5 μmol level of pentathionate in a 10.0 cm^3 sample solution in the presence of 0.5 μmol of thiosulfate and 0.25 μmol of sulfite.

When polythionates are formed in nature like hot springs, or in Wackenroder's solution obtained when hydrogen sulfide is passed into a solution of sulfite, various sulfur species, such as sulfite, thiosulfate, sulfide, sulfate, and free sulfur, can be simultaneously present with polythionates.[1] Renewed interest has arisen in the procedure for determination of micro amounts of polythionates in mixtures with other sulfur compounds, for the clarification of the chemical behavior of sulfur compounds in hot springs or in Wackenroder's solutions. Chapman and Beard have proposed a procedure[2] for the separation and determination of the polythionates in Wackenroder's solution by high-speed liquid chromatography, and Blasius and Münch a coulometric method[3] for polythionates. The reactions of polythionates (tri-, tetra-, penta-, and hexathionate) with cyanide, sulfite, sulfide, and hydroxide should be studied in detail for determining a specific polythionate in the presence of other polythionates.[4]

In regard to the cyanolysis of polythionates, various investigations have been made, the methods for the determination of trithionate,[5-8] tetrathionate,[7-12] pentathionate,[12,13] and hexathionate,[12,14] based on the formation of thiocyanate, being proposed. As a result of these investigations, a method[15] for the determination of polythionates in mixtures with each other was developed, based on the photometric determination of different amounts of thiocyanate formed by the cyanolysis of polythionate in the presence or in the absence of copper(II) ions. A method for determining total amounts of polythionates in mixtures,[16] based on the spectrophotometric measurement of excess iodine for thiosulfate formed by the cyanolysis of polythionates, was also devised.

With respect to the sulfitolysis of polythionates, methods have been described for the determination of tetrathionate[17] and hexathionate,[4] based on the consumption of iodine by the thiosulfate formed. However, no consideration has been given to the spectrophotometric determination of pentathionate by means of its sulfitolysis. The reaction

$$S_5O_6^{2-} + 2SO_3^{2-} = 2S_2O_3^{2-} + S_3O_6^{2-} \quad (1)$$

was investigated in detail and the conditions under which pentathionate is completely converted into thiosulfate were established. Simultaneous sulfitolysis of both pentathionate and hexathionate could be quantitative only under strict conditions. The present method is based on the formation of thiosulfate equivalent to pentathionate, and on the spectrophotometric measurement of excess iodine for the thiosulfate. A procedure for the analysis of mixtures of pentathionate, thiosulfate and sulfite is also described.

Experimental

Apparatus. Spectrophotometric measurements were carried out with a Shimadzu Model QV-50 spectrophotometer with 10-mm quartz cells. pH Measurements were made with a Hitachi-Horiba Model M-7 pH meter.

Reagents. All chemicals except for pentathionate, were of analytical grade and used without further purification.

Potassium Pentathionate was prepared as described by Goehring and Feldmann.[18] The pentathionate obtained was recrystallized twice in an acid medium of 0.5 M (M=mol/dm^3) hydrochloric acid, and then dried at room temperature before storage at -10 ± 2 °C. The water content was estimated by Karl Fischer method to be 10.48% including the water of crystallization. The pentathionate was confirmed to be pure enough for the present purpose; its purity was estimated by determining the total potassium and sulfur contents.[13]

Standard Pentathionate Solution of 1.0×10^{-3} M was prepared by dissolving 186.8 mg of the potassium pentathionate (water content 10.48%) in redistilled water, and then diluting it to 500 cm^3. The standard pentathionate solution was stored at 5 ± 2 °C.

Standard Sulfite Solution was prepared by dissolving sodium hydrogensulfite in freshly boiled and cooled redistilled water, and standardized by iodimetry. Working standards were obtained by appropriate dilution. The sulfite solution (0.15 M), which was not standardized, proved useful for the sulfitolysis of pentathionate 2 weeks after its preparation.

Standard Thiosulfate Solution was prepared by dissolving sodium thiosulfate pentahydrate in freshly boiled and cooled redistilled water containing a small amount of sodium carbonate as a stabilizer, and standardized by iodimetry a week after preparation. Working solutions were prepared by suitable dilution. These standards were used to confirm stoichiometry and completion of the reaction of pentathionate with sulfite.

Standard Iodate-Iodide Solution was prepared by adding 50.0 cm^3 of 1.67×10^{-3} M standard iodate to a solution containing 0.2 g of sodium carbonate and 72.2 g of potassium iodide,

and diluted to 500 cm³ to give 1.67×10^{-4} M iodate in a 0.87 M iodide solution.

Iodide Solution of 0.87 M was prepared by dissolving 72.2 g of potassium iodide in redistilled water containing 0.2 g of sodium carbonate, and then diluting it to 500 cm³.

Buffer Solution series are as follows: acetic acid (0.1, 0.5, or 1 M) and sodium acetate (0.1, 0.5, or 1 M), sodium dihydrogenphosphate (0.2 M) and sodium hydroxide (0.2 M), sodium hydrogencarbonate (0.1, 0.3, or 0.5 M) and sodium carbonate (0.05, 0.3, or 0.5 M), and sodium monohydrogenphosphate (0.5 M) and sodium hydroxide (0.5 M). The buffer solutions (pH 9.9 and 3.5) used in Procedures A and B were prepared by mixing 50 cm³ of 0.3 M sodium carbonate with 50 cm³ of 0.3 M sodium hydrogencarbonate, and by mixing 80 cm³ of 0.5 M acetic acid with 5 cm³ of 0.5 M sodium acetate, respectively.

Acetic Acid Solution was prepared by diluting glacial acetic acid as required.

Formaldehyde Solution was prepared by suitable dilution of formalin.

Procedure A for the Amount of Pentathionate Alone. 1.8 cm³ of a carbonate buffer solution (pH 9.9), 2.0 cm³ of 0.15 M sulfite, and 10.0 cm³ of a sample solution containing pentathionate were placed in a 25-cm³ volumetric flask, the pH of the solution becoming 8.0. The mixture was allowed to stand at room temperature for 10 min, to convert pentathionate completely into thiosulfate, Then, 1.5 cm³ of an acetate buffer solution (pH 3.5) and 2.0 cm³ of 0.5 M formaldehyde were added to the reaction mixture. The pH of the solution was kept at 5.8. The mixture was then allowed to stand for 5 min to mask excess sulfite with formaldehyde completely. To this mixture were added 2.0 cm³ of 15 M acetic acid and 2.4 cm³ of 1.67×10^{-4} M standard iodate in a 0.87 M iodide solution, and the flask was filled to the mark with redistilled water. The contents were mixed well, and the absorbance of the solution of iodine-iodide complex was measured against distilled water at 350 nm within 10 min after the addition of the standard iodate-iodide solution.

An iodate-free reagent blank was prepared by addition of 2.4 cm³ of 0.87 M iodide in place of 2.4 cm³ of 1.67×10^{-4} M standard iodate in a 0.87 M iodide solution and by the same treatment as in the above procedure. The absorbance of this blank was subtracted from all the absorbances obtained.

Procedure B for Mixtures of Pentathionate, Thiosulfate, and Sulfite. Three reaction mixtures were prepared in 25-cm³ volumetric flasks as follows.

Procedure B-I for Total Amount of Pentathionate and Thiosulfate in the Mixtures: A 10.0-cm³ aliquot of the sample solution containing pentathionate, thiosulfate, and sulfite was treated as in Procedure A, in order to convert the pentathionate completely into thiosulfate. 1.5 cm³ of an acetate buffer solution (pH 3.5) and 2.0 cm³ of 0.5 M formaldehyde were then added to the reaction mixture, which was allowed to stand for 5 min to mask the sulfite completely.

Procedure B-II for the Amount of Thiosulfate in the Mixtures: 1.8 cm³ of a carbonate buffer solution (pH 9.9), a 10.0-cm³ aliquot of the sample solution, 1.5 cm³ of an acetate buffer solution (pH 3.5), and 2.0 cm³ of 0.5 M formaldehyde were placed in a 25-cm³ volumetric flask, and the resulting mixture was allowed to stand for 5 min.

Procedure B-III for Total Amount of Thiosulfate and Sulfite in the Mixtures: A 10.0-cm³ aliquot of the sample solution and 1.5 cm³ of an acetate buffer solution (pH 3.5) were placed in a 25-cm³ volumetric flask.

Finally, 2.0 cm³ of 15 M acetic acid and 2.4 cm³ of 1.67×10^{-4} M standard iodate in a 0.87 M iodide solution were added to each mixture. The three flasks were then filled to the mark with redistilled water. The contents were mixed thoroughly and the absorbance of the solution of iodine-iodide complex was measured against distilled water at 350 nm.

Results and Discussion

Calibration Plots. A series of standard solutions of pentathionate and thiosulfate were treated as in Procedure A. The resulting graphs are shown in Fig. 1. According to Eq. 1, when 1 mol of pentathionate undergoes sulfitolysis, 2 mol of thiosulfate are formed. Thus, if pentathionate is completely converted into thiosulfate stoichiometrically, the calibration plot of pentathionate should coincide with that of thiosulfate when the molar concentration scale for thiosulfate is drawn to one second of the scale for pentathionate concentration. Figure 1 shows that pentathionate is quantitatively converted into thiosulfate according to Eq. 1.

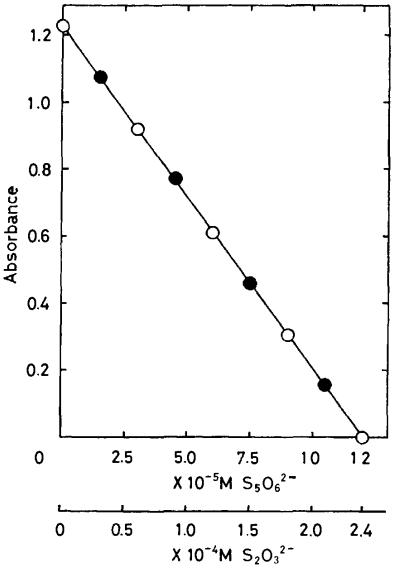

Fig. 1. Calibration plots for pentathionate and thiosulfate.
○: $S_5O_6^{2-}$; ●: $S_2O_3^{2-}$.

Rate of Sulfitolysis of Pentathionate. The rate was studied at both 5 °C and room temperature. The results are given in Tables 1 and 2. At pH 6.5, 8.0, and 8.2, the absorbance which was in complete agreement with the expected value was reached in 20 min at both 5 °C and room temperature, in 4 min at 5 °C and in 3 min at room temperature, and in 3 min at both 5 °C and room temperature, respectively, and then remained constant over different intervals of time. Higher absorbances then ensued as a result of the reaction of thiosulfate formed with the excess sulfite as shown in Eq. 2:

$$S_2O_3^{2-} + 4SO_3^{2-} + 6H^+ = 2S_3O_6^{2-} + 3H_2O \quad (2)$$

deviating from the expected value. The rate of sulfitolysis of pentathionate was little affected by temperature. Thus, pentathionate was allowed to react with sulfite at room temperature.

Effect of pH. In measuring the effect of pH on the sulfitolysis of pentathionate, the reaction was carried out for 10 min at various pH values. Figure 2 shows that pentathionate was quantitatively converted into thiosulfate in the pH range 6.9—8.2. A decrease in absorbance at higher pH levels was thought to be caused by the alkaline decomposition of pentathionate,[19] in addition to its sulfitolysis, as follows.

$$2S_5O_6^{2-} + 6OH^- = 5S_2O_3^{2-} + 3H_2O \quad (3)$$

The optimal pH range could be extended to a lower pH value by lengthening the sulfitolysis time; for instance, it was in the pH range 6.5—8.2 when sulfitolyzed for 20 min. However, the sulfitolysis time cannot be made any longer at the lower pH value, since the

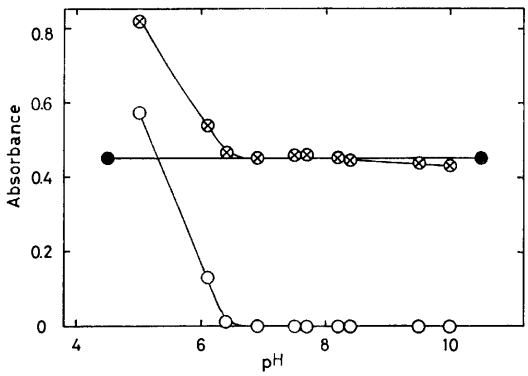

Fig. 2. Effect of pH on the sulfitolysis of pentathionate.

lower the pH of the solution, the faster the reaction rate of thiosulfate formed with the sulfite.

The conditions under which sulfitolysis of polythionates goes to stoichiometric completion must be established to determine specific polythionate in mixtures of the polythionates. An optimal pH for the sulfitolysis of hexathionate was found to be in the range 7.5—9.5[4] when sulfitolyzed for 10 min. Therefore, in so far as the pH of the reaction solution is kept in the range 7.5—8.2, the sulfitolysis of both penta- and hexathionate will be quantitative. In fact, the calibration plots for penta- and hexathionate were, respectively, in exact accordance with that for thiosulfate when plotted in terms of equivalent concentrations, demonstrating the fact that sulfitolysis of both the polythionates attained stoichiometric completion.

Effect of Amount of Sulfite. The extent of sulfitolysis of pentathionate can be affected by the concentra-

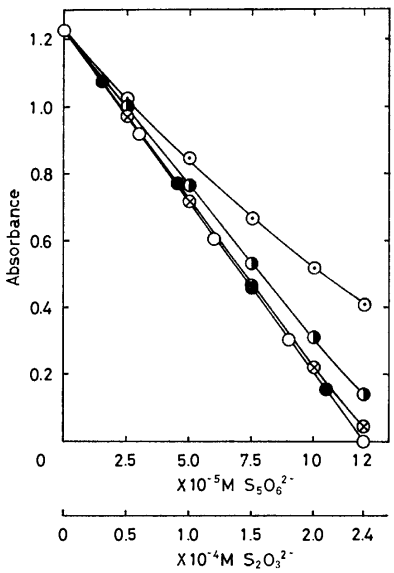

Fig. 3. Effect of amount of sulfite on the sulfitolysis of pentathionate.
⊙: $S_5O_6^{2-}$ with 2.0 cm³ of 0.01 M SO_3^{2-}; ◑: $S_5O_6^{2-}$ with 2.0 cm³ of 0.02 M SO_3^{2-}; ⊗: $S_5O_6^{2-}$ with 2.0 cm³ of 0.03 M SO_3^{2-}; ○: $S_5O_6^{2-}$ with 2.0 cm³ of 0.07, 0.1, or 0.15 M SO_3^{2-}; ●: $S_2O_3^{2-}$ with 2.0 cm³ of 0.15 M SO_3^{2-}.

tion of sulfite. In measuring the effect of the amount of sulfite on the conversion of pentathionate into thiosulfate, 2.0 cm^3 of 0.01, 0.02, 0.03, 0.07, 0.1, and 0.15 M sodium hydrogensulfite were employed, respectively. In all cases, the solutions were kept at pH 6.9—8.2, which is the optimal range for the sulfitolysis of pentathionate when sulfitolyzed for 10 min. As can be seen in Fig. 3, the sulfitolysis of pentathionate was incomplete with 2.0 cm^3 of 0.01, 0.02, or 0.3 M sulfite, because of an insufficient amount of sulfite. However, when 2.0 cm^3 of 0.07, 0.1, or 0.15 M was used, the calibration graph of pentathionate was linear and coincided exactly with that of standard thiosulfate. 2.0 cm^3 of 0.15 M sulfite was therefore used.

The sulfite used for the sulfitolysis consumed iodine completely, as a result of its reaction with iodine. However, it was confirmed that the excess sulfite was completely masked in the pH range 4.0—9.1, when 2.0 cm^3 of 0.5 M formaldehyde was added and the mixture solution was allowed to stand for 5 min. It is desirable to carry out spectrophotometric measurements within at least 10 min after the addition of standard iodate–iodide solution, because the reaction of iodine–iodide complex with the adduct formed ensued slowly.[4]

Analysis of Mixtures of Pentathionate, Thiosulfate, and Sulfite. The three sulfur compounds in mixtures give the following equivalents in three procedures:

Procedure B-I $\triangleq 2S_5O_6^{2-} + S_2O_3^{2-}$

Procedure B-II $\triangleq S_2O_3^{2-}$

Procedure B-III $\triangleq S_2O_3^{2-} + 2SO_3^{2-}$

The absorbance obtained by Procedure B-I corresponds to the sum of twice the pentathionate (see Eq. 1) and the thiosulfate in the mixtures, because sulfite is masked by the formaldehyde added for the removal of excess sulfite. The absorbance obtained by Procedure B-II, in which no sulfitolysis of pentathionate was carried out, corresponds to only the amount of thiosulfate in the mixtures. The absorbance obtained by Procedure B-III corresponds to the sum of the thiosulfate and twice the sulfite in the mixture solution.

Moreover, the calibration graphs for pentathionate, thiosulfate, and sulfite were in full agreement with one another when plotted in terms of equivalent concentrations. Thus, the following equations can be obtained: $(S_5O_6^{2-})=(I-II)/2$, $(S_2O_3^{2-})=II$, and $(SO_3^{2-})=(III-II)/2$, where I, II, and III denote the molar concentration which was determined from the calibration graph for thiosulfate in Fig. 1 using the absorbance obtained by Procedures B-I, B-II, and B-III, respectively. Table 3 shows that the above technique can be successfully applied to the determination of a mixture of pentathionate, thiosulfate, and sulfite at various ratios.

The precision was estimated from six results for three 10.0-cm^3 aliquots of sample solutions containing 0.5 μmol of pentathionate, 0.5 μmol of thiosulfate, and 0.25 μmol of sulfite. The method gave a mean value of 0.498 μmol with a standard deviation of 0.0041, and a ralative standard deviation of 0.82% for pentathionate, 0.503 μmol with 0.0052 and 1.0% for thiosulfate, and 0.257 μmol with 0.0052 and 2.0% for sulfite.

Effect of Diverse Ions. The interference of various ions was checked under the conditions of Procedure A, both in the presence of pentathionate (6.0×10^{-5} M) and in its absence. The results are given in Table 4.

The present method is based on the spectrophotometric measurement of excess iodine such as triiodide for the thiosulfate formed by the sulfitolysis of pentathionate. Therefore, iron(III), copper(II), nitrite, or sulfide which can oxidize iodide or reduce iodine, interferes seriously with the determination of pentathionate. In the case of both lead(II) and iron(II), the positive error in absorbance may be attributed to the formation of lead–iodide complex which exhibits its absorption at 350 nm, and to the oxidation of iodide by the iron(III) ion produced by the air-oxidation of iron(II). Approximately 1000 ppm of almost all the other ions listed in Table 4 is allowable.

Synthesis of Ylide Complexes of Cobalt and the Crystal Structure of [Benzoyl(1-pyridinio)methanide]chlorobis(dimethylglyoximato)cobalt(III) Toluene Solvate

Taro SAITO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 4, 1977)

Bis(dimethylglyoximato)halogenocobalt(III) complexes of benzoyl(1-pyridinio)methanide were synthesized by a new kind of oxidative addition reaction of *N*-phenacylpyridinium halides to diaquabis(dimethylglyoximato)cobalt-(II) in air. The crystal structure of the [benzoyl(1-pyridinio)methanide]chlorobis(dimethylglyoximato)cobalt(III) toluene solvate was solved by single-crystal X-ray diffraction techniques. The crystals are monoclinic (space group $P2_1/c$), with cell dimensions of $a=11.41(1)$, $b=10.28(1)$, $c=27.50(3)$ Å, $\beta=116.3(1)°$, and $Z=4$. The final R was 0.068. The ylide ligand coordinates to cobalt through the ylide carbon, with a Co–C distance of 2.07(1) Å, and the chlorine atom is bonded to cobalt with a Co–Cl distance of 2.285(4) Å and with a C(ylide)–Co–Cl bond angle of 175.5(3)°. The dimethylglyoxime ligands and cobalt atom are co-planar to within 0.04 Å.

We have long been interested in the nature of ylide as ligands,[1] and we reported recently the synthesis of chelating ylide ligands and their palladium and platinum complexes.[2] Ylides are formally similar to such neutral ligands as amines or phosphines, but in another respect the ylide carbon-metal bonding formed upon coordination resembles the metal-carbon bond of metal alkyls. Because of this dual function, it seemed intriguing to synthesize ylide complexes of cobaloxime, which is known to form a wide variety of ER_3 (E=N or P) as well as alkyl (E=C) complexes,[3] and to gain insight into the nature of the ylide carbon-metal bonding. Thus, we have succeeded in the preparation of benzoyl-(1-pyridinio)methanide complexes of cobaloxime by a new type of oxidative addition reaction starting from the corresponding *N*-phenacylpyridinium halides; the structures were inferred from the infrared and ^1H NMR spectra.[4] In the present study, the crystal structure of the [benzoyl(1-pyridinio)methanide]chlorobis(dimethylglyoximato)cobalt(III) toluene solvate was determined by X-ray diffraction techniques, and the bonding of the ylide carbon to cobalt was confirmed.

Experimental

Synthesis. $[Co(dmgH)_2(H_2O)_2]$ (dmgH=dimethylglyoxime mono anion)[5] (6.5 g) and *N*-phenacylpyridinium chloride (4.2 g) were suspended in 99% ethanol (50 ml), and air was bubbled into the suspension for 30 min at 10 °C. The mixture became homogeneous, and then a brown solid was precipitated. The product was filtered, washed with ethanol (30 ml) and diethyl ether (30 ml), and dried *in vacuo*, (4.5 g). The infrared spectrum of the crude product indicated that it contained about 20% of $[pyCH_2COC_6H_5]^+[CoCl_2(dmgH)_2]^-$ (ν(CO) 1690 cm^{-1}) (py=pyridine). The product was dissolved in CH_2Cl_2 (250 ml), and diethyl ether (100 ml) was added very slowly to produce very fine crystals of $[CoCl(dmgH)_2(pyCHCOC_6H_5)]$, (2.5 g). $[CoBr(dmgH)_2(pyCHCOC_6H_5)]$ and $[CoI(dmgH)_2(pyCHCOC_6H_5)]$ were prepared in a similar fashion. The properties of these complexes are given in Table 1.

Preparation of the Crystal. $[CoCl(dmgH)_2(pyCHCOC_6H_5)]$ (0.5 g) was dissolved in warm CH_2Cl_2 (50 ml), and then toluene (30 ml) was slowly added and then filtered out. The solution was kept overnight at 5 °C, and the black crystals thus precipitated were filtered, washed with diethyl ether (10 ml), and dried. The ^1H NMR spectrum indicated that the crystals contained one mole toluene per mole of the complex.

Found: C, 54.7; H, 5.6; N, 11.4; Cl, 6.2%. Calcd for $C_{28}H_{33}ClCoN_5O_5$: C, 54.8; H, 5.4, N, 11.4; Cl, 5.8%.

Crystal Data. A single crystal with dimensions of *ca.* $0.45\times0.25\times0.15$ mm was used for the measurements of the diffraction intensities and unit-cell dimensions on a Rigaku automated four-circle diffractometer, by the use of graphite-monochromatized Mo $K\alpha$ radiation. The unit-cell constants were obtained by a least-squares refinement of the angular measurements of 25 reflections, but the results were not always satisfactory because of the weak intensities of the high-angle reflections.

$C_{21}H_{25}ClCoN_5O_5\cdot C_7H_8$, M=613.7, monoclinic, space group $P2_1/c$ from systematic absences: $h0l$, $l=2n+1$, $0k0$, $k=2n+1$. $a=11.14(1)$, $b=10.28(1)$, $c=27.50(3)$ Å, $\beta=116.3(1)°$, $V=2825$ Å^3, $Z=4$, $D_m=1.44$ g cm^{-3}, $D_x=1.44$ g cm^{-3}, $\mu=7.74$ cm^{-1} (Mo $K\alpha$), Mo $K\alpha$ radiation $\lambda=0.7107$ Å.

Data Collection. The intensity data were recorded by the ω-2θ scan technique, with a scan speed of 2° min^{-1}; background counts over 10 s were taken at each end of the scan. The intensities of 3 standard reflections measured every 50 reflections during the data collection did not vary by more than 4%. The intensities were measured up to 2θ 60°, and 1997 independent reflections with $F_o>3\sigma$ were used for the structure analysis. The data were corrected for Lorentz and polarization effects, but not for absorption.

Solution and Refinement of the Structure. The structure

Table 1. Elemental analysis, infrared, and ^1H NMR spectral properties of $[CoX(dmgH)_2(pyCHCOC_6H_5)]$

X	Elemental analysis Found (Calcd)%				IR(KBr) ν(CO) cm^{-1}	^1H NMR(CH_3CN) δ(CH) ppm
	C	H	N	X		
Cl	48.5(48.3)	4.9(4.8)	13.3(13.4)	6.6(6.8)	1654	5.62
Br	44.3(44.5)	4.4(4.5)	12.4(12.4)	14.9(14.1)	1641	5.55
I	40.5(41.1)	4.4(4.1)	11.5(11.4)		1640	5.60

was solved by the usual heavy-atom method. The position of the cobalt atom was determined from a Patterson synthesis, and all the non-hydrogen atoms were located by the subsequent Fourier syntheses. The positions of the atoms were refined by the block-diagonal least-squares method with anisotropic temperature factors. A difference-Fourier synthesis at the stage of $R=0.083$ revealed the positions of the ylide methine hydrogen, 13 aromatic hydrogens, and one hydrogen for each of the methyl groups of the dimethylglyoxime ligands, but no hydrogen atom was located for the methyl group of the toluene molecule or for the oxime groups. Further refinements including the calculated positions (l(C–H) 1.08 Å, $B=3$ Å^2) of the remaining aromatic hydrogen atoms and the methyl hydrogen atoms of the dimethylglyoxime ligands, using isotropic temperature factors for the hydrogen and anisotropic temperature factors for non-hydrogen atoms, reduced the final R factor to 0.068. The H–C–H and C–C–H bond angles were normal within the estimated standard deviations.

Atomic scattering factors were taken from Ref. 6, those of cobalt and chlorine being corrected for the real and imaginary parts of anomalous dispersion, using values from Ref. 7. A weighting scheme with $w=1$ for $|F_o|\geq 21.80$ on an absolute scale and $w=0.5$ in other cases was employed.

The calculations were performed on the HITAC 8700/8800 computer at the Computer Center of the University of Tokyo, using a local version of the UNICS programs.[8]

Results and Discussion

The present ylide complexes of cobaloxime are formed in the presence of air by the replacement of the two H_2O ligands in $[Co^{II}(dmgH)_2(H_2O)_2]$ with halogen and benzoyl(1-pyridinio)methanide. The reaciton seems to proceed according to the following scheme, although the reaction mechanism is not clear:

$$[Co^{II}(dmgH)_2(H_2O)_2] + [pyCH_2COC_6H_5]^+X^- + 1/4O_2 \longrightarrow [Co^{III}X(dmgH)_2(pyCHCOC_6H_5)] + 5/2H_2O.$$

The addition of halogen and the ylide ligands, which is accompanied by the oxidation of Co(II) to Co(III), may be described as a kind of oxidative addition reaction. This reaction, however, is somewhat different from the ordinary oxidative addition of X–Y molecules to Co(II), which results in the formation of two Co(III) species, such that [Co(II)]+X–Y→[Co(III)X]+[Co(III)Y].[9] The synthesis of ylide complexes directly from onium salts is advantageous because these salts are generally much more stable than the corresponding free ylides, and some palladium ylide complexes from phosphonium salts have been reported.[10] The present synthesis provides another example of the *in situ* synthesis of ylide complexes starting from onium salts.

The infrared spectra of the ylide complexes show ν(CO) at lower wave numbers than the corresponding *N*-phenacylpyridinium halides (*cf.* $[pyCH_2COC_6H_5]^+X^-$: 1693 cm^{-1} (X=Cl), 1695 cm^{-1} (X=Br), 1698 cm^{-1} (X=I), KBr disk); the lowering of ν(CO) is considered to indicate the bonding of the ylide carbon to the metal in keto-stabilized ylide complexes.[2] It has been reported that a platinum pyridinium propylide complex, $[PtCl_2(py)(pyCHCH_2CH_3)]$[11] shows an ylide methine proton signal at δ 5.67 in $CDCl_3$, which is near the positions of the signals of the present cobalt complexes. The methyl-proton signals of the dimethylglyoxime ligands at δ 1.9 are split into two absorptions in an intensity ratio of 1 : 1. This splitting may presumably be ascribed to the different magnetic environments of the methyl groups due to the presence of the asymmetric ylide carbon.[10]

Molecular and Crystal Structure. The numbering scheme employed in this paper is shown in Fig. 1. Figure 2 is a stereoview of the unit cell drawn by ORTEP. The final atomic parameters and their standard deviations are listed in Tables 2 and 3. Table 4 gives the bond distances, and Table 5, the bond angles within the molecule. The least-squares planes, dihedral angles, and vector-plane angles are given in Table 6.*

The results of the structure determination of the [benzoyl(1-pyridinio)methanide]chlorobis(dimethylgly-

oximato)cobalt(III) toluene solvate have proved that the complex is an ylide complex in which the ylide carbon coordinates to cobalt. The Co–C(1) bond length, 2.07 (1) Å, is close to the bond length of Co–C, 2.04 Å, in carbomethoxymethylbis(dimethylglyoximato)(pyridine)-cobalt(III),[12] one of the few alkyl cobaloxime complexes whose crystal structures have been described in the literature.[13] The alkyl moiety, CH_2COOCH_3, is comparable to benzoyl(1-pyridinio)methanide in that both have a carbonyl group adjacent to the carbon which is bonded to cobalt.

The ylide carbon C(1) is bonded to the N(1) of pyridine, the C(10) of the carbonyl group, and H(1) as well as cobalt, and the bond angles, Co–C(1)–N(1) 114.6(8)°, Co–C(1)–C(10) 112.7(7)° and N(1)–C(1)–C(10) 114.4(8)°, are a little larger than the normal tetrahedral angle of 109°28′; the deviation of C(1) from the plane (4) formed by N(1), C(10), and Co is 0.41 Å. The ylide methine hydrogen atom H(1) is clearly evident in the difference-Fourier map.

The cobalt atom and the four nitrogen atoms of the dimethylglyoxime ligands are planar to within 0.04 Å, The Co–N bond distances range from 1.86(1) to 1.92(1) Å, but we are not certain whether the difference of 0.06 Å, about six times the standard deviation, actually reflects the non-equivalence of the Co–N bonds. The Co–Cl bond distance is 2.285(4) Å, and the Cl···Co vector is almost perpendicular (89.2°) to the plane(1)

of the dimethylglyoxime ligands. The C(1)···Co vector is a little out of the perpendicular (85.6°), making the C(1)–Co–Cl bond angle 175.5(3)°. There is no indication that the carbonyl oxygen O(1) forms any significant hydrogen bonding with an oxime hydrogen atom of the dimethylglyoxime ligand, which in [CoCH-$(CH_3)COCH_3(dmgH)_2(py)$] was suspected to account for the lowering of the ν(CO) of the infrared spectra.[14] The C(10)–O(1) bond distance of 1.26 Å indicates an essentially double bond, but the lowering of the ν(CO) of 39 cm^{-1} in the ylide complex compared with that

of the N-phenacylpyridinium chloride may be associated with the small reduction of the CO bond order in the ylide complex.[15)]

The stereoview of a unit-cell (Fig. 2) shows a crystal packing of the complex with toluene molecules filling the voids enclosed by the molecules of the complex. The toluene molecules probably make a minor contribution to the lattice forces, since the crystals used in the present X-ray analysis were very brittle.

The author is most grateful to Dr. Akiko Kobayashi for her assistance and helpful discussions during the X-ray study.

Aluminum Chloride Catalyzed Friedel-Crafts Reaction of Anisole with Epoxide Accompanying Isomerization[1)]

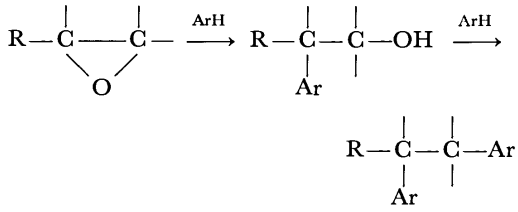
Masashi INOUE, Toshio SUGITA, and Katsuhiko ICHIKAWA*

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received February 24, 1977)

The reaction of anisole with propylene oxide by aluminum chloride has been studied in various kinds of solvents. While the normal Friedel-Crafts reaction yielded 2-(methoxyphenyl)-1-propanols, 1,1-bis(methoxyphenyl)-propanes were also formed in this reaction; these were not obtained by the subsequent reaction of mono(methoxyphenyl) products with another anisole. The yields of 1,1-bis(methoxyphenyl)propanes increased by increasing the basicity of solvents. The mechanism of the formation of 1,1-bis(methoxyphenyl)propanes can be explained by the isomerization of epoxide to aldehyde and the subsequent condensation with anisole. Various kinds of epoxides also gave 1,1-bis(methoxyphenyl)alkanes in nitromethane.

It is generally believed that Friedel-Crafts reactions of aromatic substrates with epoxides produce β-hydroxyarylalkanes which react further with aromatics to give 1,2-diarylalkanes.[2)]



During the course of the study of solvent effects on the ring-opening reaction of epoxide with aluminum chloride,[3)] we found, however, that the reaction of propylene oxide with anisole by aluminum chloride yielded 1,1-bis(methoxyphenyl)propanes (**1**) without any contamination of the 1,2-isomers (**2**). In order to clarify the mechanism, the reaction of various epoxides with anisole has been studied in various solvents.

The reaction of propylene oxide and anisole without solvent at 0—2 °C gave a complex mixture containing at least eight compounds: 2-chloro-1-propanol (**3**, 24 %), 1-chloro-2-propanol (**4**, 8%), 2-(*o*- and *p*-methoxyphenyl)-1-propanols (**5**, 17%), 1-phenoxy-2-propanol (**6**, 4%), and three isomers (*o,o*-, *o,p*-, and *p,p*-) of 1,1-bis(methoxyphenyl)propanes (**1**, 24%). The first two are the ring-opening products of the epoxide; their isomer distribution and stereochemistry have been discussed previously.[3)] The mechanism of the formation of **5**, a normal Friedel-Crafts reaction product of propylene oxide, is considered to be of the S_N2 type analogous to the reported case of benzene.[4)] In this paper, however, we are concerned mainly with the formation of **1**.

Table 1 shows the results of the reaction of propylene oxide with anisole in various solvents. For experimental convenience, the yields of the products which did not include methoxyphenyl moiety were not determined. The other products were chloropropanols, oligomers of the epoxide, and high boiling tarry matter. The characteristic features of the results are as follows. When 1,2-dichloroethane was used as a solvent, changes in the reaction conditions resulted in only minor changes in the product distributions. The formation of **2** was not observed in any experiments except one at a higher temperature (32—34 °C). The yield of **1** increased in the following order of the solvents: hexane<chloroform<1,2-dichloroethane<anisole<nitromethane.

Table 1. Effects of the solvent on the reaction of propylene oxide with anisole[a)]

CH_3NO_2	0.0	25.8	0.7	12.3	87.0

a) Unless otherwise mentioned, 40 ml of solvent, 20 mmol of epoxide, 40 mmol of anisole, and 20 mmol of aluminum chloride were used. Reaction temperature and time were 0—2 °C and 3.5 h, respectively. b) Reaction time, 1.0 h. c) Reaction time, 6 h. d) Anisole, 20 mmol. e) Anisole, 200 mmol. f) Aluminum chloride, 10 mmol. g) Aluminum chloride, 40 mmol. h) Aluminum chloride, 60 mmol. i) Reaction temperature, 32—34 °C.

In nitromethane, **1** was obtained in a good yield but no mono(methoxyphenyl) products were detected. This result forms a striking contrast to the fact that benzene does not react with propylene oxide in this solvent.[4)] Therefore, the reaction of various epoxides with anisole was examined. Results are summarized in Table 2.

One of the possible routes to **1** is the successive reaction of **5** with another anisole. The literature contains a number of papers on the Friedel-Crafts type alkylation of aromatics with 1,2-difunctional propanes including propylene oxide which gave 1,2-diarylpropanes,[5)] while a few papers have reported the formation of 1,1-diarylpropanes as by-products.[6)] Masuda *et al.* explained the formation of 1,1-diphenylpropane (minor product) in the reaction of 1-phenyl-2-chloropropane and 2-phenyl-1-chloropropane with benzene in terms of an isomerization from a phenonium ion type inter-

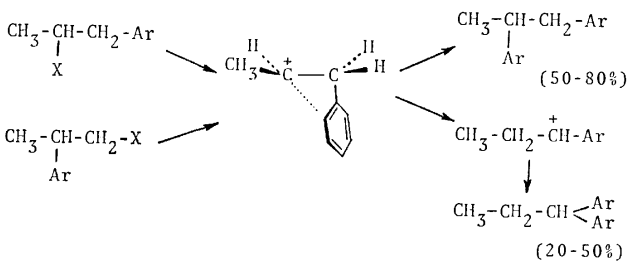
a) Reactions were conducted with anisole (100 mmol) and $AlCl_3$ (40 mmol) in nitromethane (40 ml), and the epoxide (20 mmol) in nitromethane (20 ml) at 0—2 °C, the mixtures were homogeneous. Isolated yields given in parentheses were calculated on the basis of the epoxides used. b) Calcd from GLPC. c) The possibility of contamination of 1,2-bis(methoxyphenyl)-1,2-diphenylethane cannot be excluded. d) bp 117—118 °C (lit,[15a)] bp 116—119 °C). e) bp 98—100 °C/33 mmHg (lit,[15b)] bp 71 °C/10 mmHg). f) bp 105—106 °C (lit,[15c)] bp 105—107 °C). g) mp 68—69 °C (lit,[15d)] mp 68.5—69 °C). h) bp 72—74 °C/105 mmHg (lit,[15e)] bp 137—138 °C).



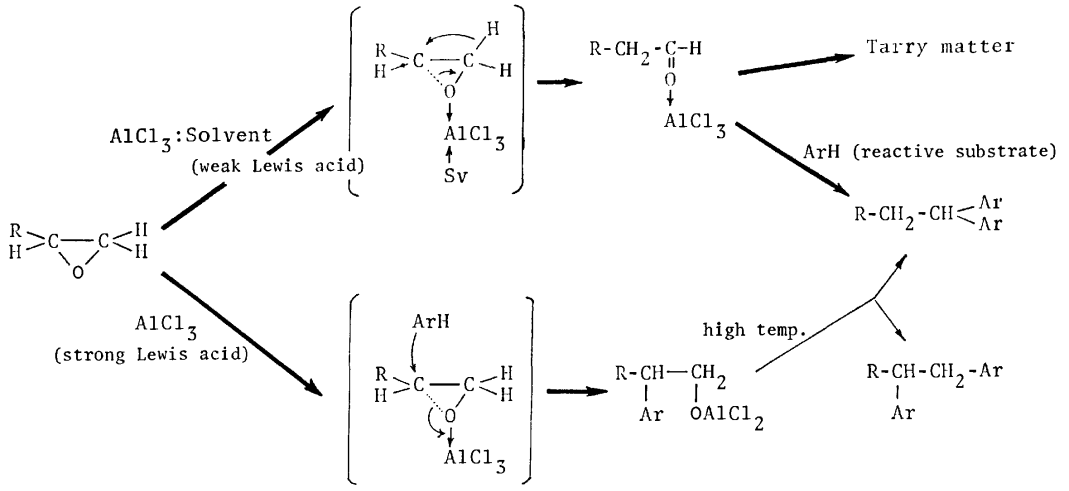
Scheme 1.

mediate to 1-phenyl-1-propyl cation on the basis of stereochemical results.[7,8)]

To examine this reaction sequence, **5** was subjected to react with excess anisole in the presence of aluminum chloride at 0—2 °C. The predominant product was **2** (80%), and **1** was only a minor one (20%). Although the data may not reflect exactly the path of the reaction of propylene oxide with anisole, since hydrogen chloride is produced in the reaction of **5** with aluminum chloride to form the assumed precursor, dichloroaluminum 2-(methoxyphenyl)propoxide, it can be concluded that the main route to **1** is different from this reaction sequence, since the hydride shift from the phenonium type ion to 1-aryl-1-propyl cation is not affected by the leaving groups of the precursors of the carbonium ion.[8)]

Possible routes for the formation of **1** are shown in Scheme 2, in which R is methyl and Ar is methoxyphenyl or phenyl. Isomerization from epoxide to aldehyde, followed by condensation with anisole, leads to **1**. The isomerization competes with the normal Friedel-Crafts reaction and the aldehyde condensation with anisole competes with the formation of tarry matter *via* aldol condensation, Tischenko reaction, and so on.

It is well known that epoxide forms aldehyde under the catalysis of magnesium bromide, zinc chloride, and boron trifluoride–ether complex.[10)] These catalysts are weak Lewis acid as compared with aluminum chloride. The acidity of aluminum chloride dissolved in nitromethane is lower than those in the other usual solvents for Friedel-Crafts reactions, since nitromethane is a



Scheme 2.

stronger base than the other solvents. The activity of the catalyst becomes low, and benzene does not react with propylene oxide in this solvent. When more reactive anisole was used as a substrate, the isomerized aldehyde condenses with anisole to form **1**. As the basicity of the solvents increases in the order mentioned above, the solvent effects on the formation of **1** can be explained along the same line.

Although the condensation of aldehyde with aromatics is well known,[11] no detailed study of the reaction with aluminum chloride catalyst has appeared to our knowledge. The reaction of propionaldehyde with anisole in 1,2-dichloroethane at 0—2 °C in the presence of aluminum chloride gave **1** as a main product (59%), accompanied with 1,1-bis(methoxyphenyl)propenes (**7**, 13%) and 1-methoxyphenylpropanes (**8**, 20%). The formation of the latter two products shows that hydrogen transfer took place, this will be discussed in a separate paper.

The results shown in Table 2 are also well consistent with the mechanistic paths mentioned in Scheme 2. The products in runs 8, 9, and 10 indicate that phenyl and alkyl migrations took place instead of hydrogen migration. The products which are not expected from the reaction sequence mentioned above are suggestive for the study of the nature of aluminum chloride catalysis. The formations of **15** and **16** appear to indicate that the splitting of the phenyl or methoxyphenyl group, isomerization, and a hydride attack to an intermediate carbonium ion occurred. The compound **18** is an isomerization product of **17**.

In a Grignard reaction and a metal hydride (weak nucleophile, *e. g.*, AlH_3 and AlH_2Cl) reduction of epoxides, it is well known that rearrangement to a carbonyl intermediate followed by nucleophilic addition competes with direct nucleophilic ring-opening of epoxide.[12,13] The result presented in this paper is the first example of a Friedel-Crafts type reaction in which the rearrangement to aldehyde followed by condensation has been shown to be the main reaction path.

Experimental

NMR and IR spectra were recorded on a JEOL PMX-60 or a Varian HR-220, and a Hitachi EPI-G2 spectrometers, respectively.

Propylene oxide, 1,2-epoxybutane, and styrene oxide were dried over sodium carbonate and distilled before use. Commercial cyclohexene oxide was used without further purification. Other epoxides were prepared by *m*-chloroperbenzoic acid oxidation of the corresponding olefins. Commercial aluminum chloride (GR grade) was used without further purification. Anisole and nitromethane were dried over sodium hydroxide and phosphorous pentoxide respectively, and distilled before use.

Reaction of Propylene Oxide with Excess Anisole in 1,2-Dichloroethane in the Presence of Aluminum Chloride. To a stirred and cooled (ice bath) solution of 108 g (1.0 mol) of anisole and 14 g (0.11 mol) of aluminum chloride in 200 ml of 1,2-dichloroethane, a mixture of propylene oxide (5.8 g, 0.1 mol) and anisole (54 g, 0.5 mol) was added dropwise during the course of 1.5 h. After 2.0 h, reaction was quenched with 300 ml of water and the organic layer was washed with 100

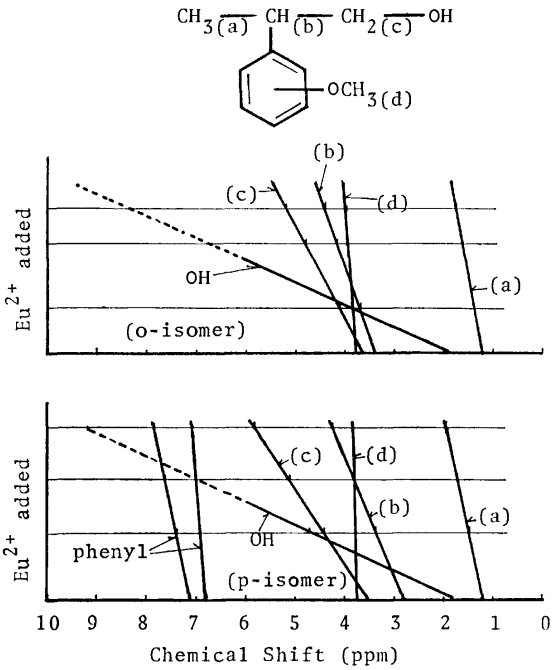


Fig. 1. Paramagnetic shift experiment.

ml of water three times. The combined water layers were extracted with 200 ml of ether three times. The combined organic layers were dried over magnesium sulfate. After removal of the solvents, the product was distilled under reduced pressure: 1st fraction, 70—82 °C/15 mmHg, **3**, **4**, and recovered anisole; 2nd fraction, 0.2 g, 42 °C/5.7 mmHg, phenol; 3rd fraction, 0.7 g, 98 °C/5.0 mmHg, **6**; 4th fraction, 107—111 °C/4.8 mmHg, **5**; 5th fraction, 6.0 g, 140—169 °C/3.2 mmHg, **1**. GLPC analysis showed that the 4th fraction contained 57% and 43% of *o*- and *p*-isomers of **5** respectively together with small amounts of **1** and **6**. To confirm the structure of **5**, a paramagnetic shift experiment in the NMR spectra was carried out using tris(2,2-dimethyl-6,6,7,7,8,8,8-pentafluoro-3,5-octanedionato)europium(III). Results are shown in Fig. 1.

Reaction of Methoxyphenylpropanols with Anisole in the Presence of Aluminum Chloride. In an ice bath, **5** (10 mmol, 70% of *o*-isomer and 30% of *p*-isomer) was treated with anisole (11 g) in the presence of aluminum chloride (20 mmol) for 2 h. After the usual treatments, the reaction mixture was distilled. The yield of a mixture of **1** and **2** (146—172 °C/3.3 mmHg) was 53%. NMR analysis showed that the product contained 20% of **1** and 80% of **2**.

Reaction of Propionaldehyde with Anisole in the Presence of Aluminum Chloride. Propionaldehyde (0.1 mol) was added to anisole (0.2 mol) in 1,2-dichloroethane (300 ml) in the presence of aluminum chloride (0.1 mol) at room temperature for 3.5 h. After the usual work up, 31.7 g of a residual product was obtained. GLPC analysis showed that **1** was formed as a main product, along with many others. Products were separated by column chromatography on silica gel using 30% benzene–hexane.

Reaction of Propylene Oxide with Anisole in the Presence of Aluminum Chloride—Effects of Reaction Conditions. The following example shows a typical experimental procedure. To a solution of anisole (4.33 g) and aluminum chloride (2.7 g) in 1,2-dichloroethane (40 ml) was added 1.33 g of propylene oxide over a period of 2 h at ice-bath temperature. The reaction mixture was stirred at that temperature for an additional 1.5 h. Then the reaction was quenched with a mixture of ice water (50 ml) and concd hydrochloric acid (5 ml). The organic layer was washed with 20 ml of water. The combined water layers were extracted twice with 50 ml of ether and twice with 30 ml. The combined organic layers were dried over magnesium sulfate and distilled to remove the solvent. GLPC analysis of the residual products using dibutyl phthalate as an internal standard showed 785 mg of **1** was formed in this reaction.

Reaction of 1,2-Epoxybutane with Anisole in the Presence of Aluminum Chloride in Nitromethane Solvent. To a mixture of anisole (100 mmol), aluminum chloride (40 mmol), and nitromethane (40 ml) was added a mixture of 1,2-epoxybutane (20 mmol) and nitromethane (20 ml) during the course of 45 min in an ice bath. After an additional 2.5 h, the reaction was quenched as mentioned above. After removal of the solvents, the residual product was purified by chromatography with silica gel, using benzene as an elutant. Distillation of the crude product by a ball-oven apparatus yielded 1.79 g (33.0%) of **9**, bp 169—172 °C/2.5 mmHg. Isomers of the products could be separated by further chromatography using

Reactions of 4*H*-Pyran-4-thiones with Ammonia, Hydrazine, and Guanidine

Hiromichi Besso,* Kimiaki Imafuku,† and Hisashi Matsumura

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

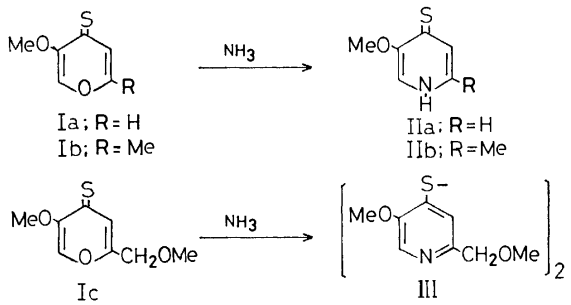
(Received March 22, 1977)

The reaction of 4*H*-pyran-4-thiones with ammonia gave 4(1*H*)-pyridinethiones or bis(4-pyridyl) disulfide, while that of 3-methoxy-2-methyl-4*H*-pyran-4-thione with guanidine gave the 1,3-thiazine derivative. 4*H*-Pyran-4-thiones reacted with hydrazine to afford pyridazines, pyrazoles, and 1-amino-4(1*H*)-pyridinethiones. 4*H*-Pyran-4-thiones having the hydroxyl group in the β-position gave the pyridazine derivatives.

Elkaschef and Nosseir[1] obtained 4(1*H*)-pyridinethiones by the reaction of 4*H*-pyran-4-thiones with ammonia. Ainsworth and Jones[2] reported that the reaction of 4-pyrones with hydrazine gives the pyrazole derivatives. Kotani and Tatsumi[3] obtained the 1,4-dihydropyridazine derivative and the pyrazole derivatives by the reaction of kojic acid with hydrazine. However, little is known about the reaction of 4*H*-pyran-4-thiones with hydrazine.[4] We wish to report the reactions of several 4*H*-pyran-4-thiones with ammonia, hydrazine, and guanidine.

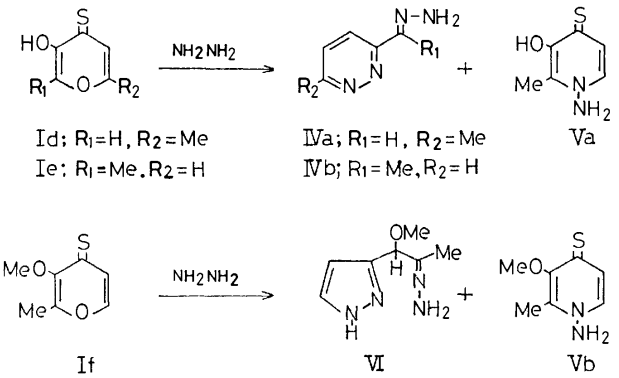
Results and Discussion

Reaction of 4H-Pyran-4-thiones with Ammonia. The reaction of 3-methoxy-4*H*-pyran-4-thione (Ia) and 5-methoxy-2-methyl-4*H*-pyran-4-thione (Ib) with ammonia gave respectively 3-methoxy-4(1*H*)-pyridinethione (IIa) and 5-methoxy-2-methyl-4(1*H*)-pyridinethione (IIb), while that of 5-methoxy-2-methoxymethyl-4*H*-pyran-4-thione (Ic) with ammonia gave bis(5-methoxy-2-methoxymethyl-4-pyridyl) disulfide (III) but no 4(1*H*)-pyridinethione. It is thought that the disulfide is produced by further oxidation of 5-methoxy-2-methoxymethyl-4(1*H*)-pyridinethione which might be obtained by the mechanism proposed by Elkaschef and Nosseir.[1] The presence of sulfur in the three products (IIa, IIb, and III) was confirmed by Sugiyama's method.[5]



Scheme 1.

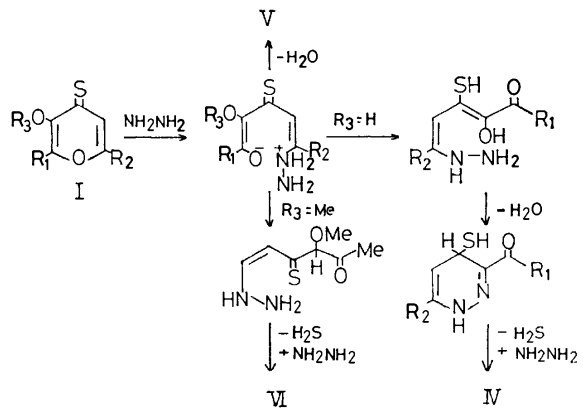
Reaction of 4H-Pyran-4-thiones with Hydrazine. The reaction of 5-hydroxy-2-methyl-4*H*-pyran-4-thione (Id) with hydrazine hydrate gave 6-methyl-3-pyridazinecarbaldehyde hydrazone (IVa), and that of 3-hydroxy-2-methyl-4*H*-pyran-4-thione (Ie) with hydrazine hydrate gave 3-acetylpyridazine hydrazone (IVb) and 1-amino-3-hydroxy-2-methyl-4(1*H*)-pyridinethione (Va), respectively.



Scheme 2.

Ichimoto[6,7] reported that the attack of hydrazine occurs on the 2- and 6-positions of 3-hydroxy-2-methyl 4-pyrone. It seems that hydrazine attacks on the 6-position of 3-hydroxy-2-methyl-4*H*-pyran-4-thione (Ie) and the 2-position of 5-hydroxy-2-methyl-4*H*-pyran-4-thione (Id), the adducts formed giving the pyridazine derivatives (IVa) and (IVb) according to Scheme 3. The elimination of hydrogen sulfide was confirmed by its conversion into copper(II) sulfide.

The reaction of 3-methoxy-2-methyl-4*H*-pyran-4-thione (If) with hydrazine hydrate is of some interest because of lack of hydroxyl group in the β-position. Actually, the reaction gave the pyrazole derivative but no pyridazine derivative. The products were α-(3-pyrazolyl)-α-methoxyacetone hydrazone (Vb) and 1-amino-3-methoxy-2-methyl-4(1*H*)-pyridinethione (Vb). It was impossible to obtain the 6-membered ring as pyridazines because of the methoxyl group in the β-position, as shown in Scheme 3.



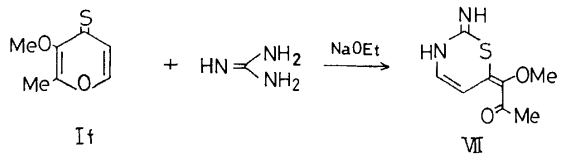
Scheme 3.

* Present address: Wakunage Pharmaceutical Co., Ltd., Koda-machi, Takata-gun, Hiroshima 729-64.

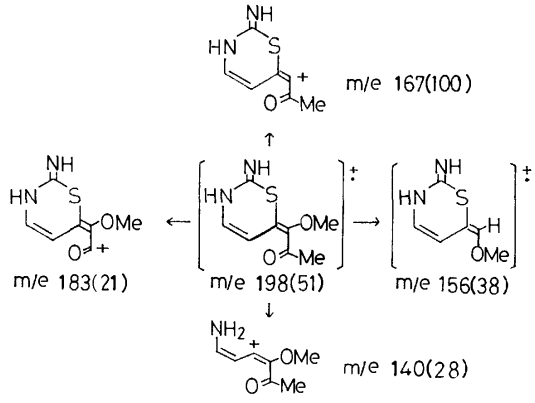
† To whom correspondence should be addressed.

It was found that hydrazine attacks on the 2-position of 5-hydroxy-2-methyl-4*H*-pyran-4-thione (Id) and on the 6-position of 3-hydroxy-2-methyl-4*H*-pyran-4-thione (Ie), and pyridazine (IVa) and (IVb), respectively, are produced by the elimination of water and hydrogen sulfide. However, 4*H*-pyran-4-thiones having no hydroxyl group in the β-position gave the pyrazole derivatives by the elimination of hydrogen sulfide.[4]

Reaction of 3-Methoxy-2-methyl-4H-pyran-4-thione (If) with Guanidine. When 3-methoxy-2-methyl-4*H*-pyran-4-thione (If) was treated with guanidine, the 1,3-thiazine derivative (VII) was obtained in 8.2% yield. The structure was confirmed by the spectral and analytical data. The NMR spectrum in CF_3COOH shows peaks at 2.41 for C–CH_3, 3.84 for O–CH_3, 8.8—8.3 for NH, and 7.01 and 9.65 for -CH=CH-. The IR spectrum shows bands at 3200, 1690, and 1610 cm^{-1}. The mass spectrum shows peak at *m/e* 198 for parent. The fragmentation of VII is shown in Scheme 5. The presence of sulfur was also confirmed as mentioned above.

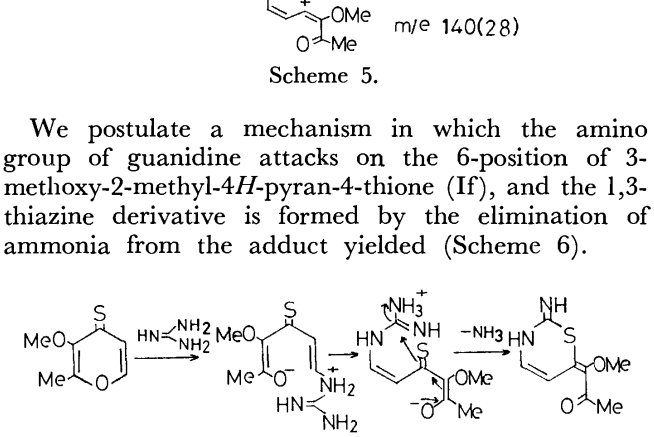


Scheme 4.



Scheme 5.

We postulate a mechanism in which the amino group of guanidine attacks on the 6-position of 3-methoxy-2-methyl-4*H*-pyran-4-thione (If), and the 1,3-thiazine derivative is formed by the elimination of ammonia from the adduct yielded (Scheme 6).



Scheme 6.

Experimental

The melting points were determined with a Yanagimoto micro-melting point apparatus and are uncorrected. All the ^1H NMR spectra were recorded with a Hitachi-Perkin-Elmer R-24 spectrometer (60 MHz), with tetramethylsilane as an internal reference. The IR spectra were taken on a JASCO IRA-1 spectrophotometer, and the UV spectra on a Hitachi EPS-3T spectrophotometer. The mass spectra were taken on a JMS-01 SG-2 mass spectrometer.

Materials. All the 4*H*-pyran-4-thiones were prepared by the reaction of the corresponding 4-pyrones with phosphorus pentasulfide in dry benzene: 5-hydroxy-2-methyl-4*H*-pyran-4-thione (Id); mp 99.5—100.5 °C (lit,[6] 100—101 °C). 3-Hydroxy-2-methyl-4*H*-pyran-4-thione (Ie): mp 78—79 °C (lit,[8] 81—82 °C). 3-Methoxy-4*H*-pyran-4-thione (Ia); mp 110—114 °C (from carbon tetrachloride); Yield, 36%; IR(KBr) 1604 cm^{-1}; NMR($CDCl_3$) δ: 7.45(d, 1H, J=4.7 Hz), 7.45(s, 1H), 7.26(d, 1H, J=4.7 Hz), 3.83(s, 3H). Found: C, 50.49; H, 4.26%. Calcd for $C_6H_6O_2S$: C, 50.71; H, 4.26%. 5-Methoxy-2-methyl-4*H*-pyran-4-thione (Ib); mp 98.5—100 °C (from carbon tetrachloride); Yield, 40%; IR(KBr) 1615 cm^{-1}; NMR($CDCl_3$) δ: 7.43(s, 1H), 7.22(s, 1H), 3.82(s, 3H), 2.24(s, 3H). Found: C, 53.55; H, 5.06%. Calcd for $C_7H_8O_2S$: C, 53.84; H, 5.16%. 5-Methoxy-2-methoxymethyl-4*H*-pyran-4-thione (Ic); mp 56—56.5 °C (from benzene-petroleum ether); Yield, 37%; IR(KBr) 1635 cm^{-1}; NMR($CDCl_3$) δ: 7.47(s, 1H), 7.36(s, 1H), 4.24(s, 2H), 3.86(s, 3H), 3.46(s, 3H). Found: C, 51.48; H, 5.33%. Calcd for $C_8H_{10}O_3S$: C, 51.59; H, 5.42%. 3-Methoxy-2-methyl-4*H*-pyran-4-thione (If); mp 61—63 °C (from petroleum ether); Yield, 47%; IR(KBr) 1625 cm^{-1}; NMR ($CDCl_3$) δ: 7.39 (d, 1H, J=5.0 Hz), 7.16(d, 1H, J=5.0 Hz), 3.85(s, 3H), 2.36(s, 3H). Reaction of 4H-Pyran-4-thiones with Ammonia. *a) 3-Methoxy-4(1H)-pyridinethione (IIa)*: A mixture of 3-methoxy-4*H*-pyran-4-thione (Ia) (104 mg) and 28% aqueous ammonia solution (0.8 ml) was heated in a sealed tube at 60 °C for 5 min. Ammomia and water were evaporated off, and the residue was recrystallized from methanol to afford IIa, yellow-ochre prisms. Yield 46 mg (44%); mp 149—152 °C; IR (KBr) 3160, 2800, 1602 cm^{-1}; NMR(CF_3COOH) δ: 8.3—7.7(m, 3H), 4.20(s, 3H). Found: C, 50.80; H, 5.02; N, 9.94%. Calcd for C_6H_7NOS: C, 51.06; H, 5.02; N, 9.95%.

b) 5-Methoxy-2-methyl-4(1H)-pyridinethione (IIb): A mixture of 5-methoxy-2-methyl-4*H*-pyran-4-thione (Ib) (187 mg) and 28% aqueous ammonia solution (1.5 ml) was heated in a sealed tube at 60 °C for 10 min. Ammonia and water were evaporated off, and the residue was recrystallized from ethyl acetate to afford IIb, yellow micro-crystals. Yield 123 mg (66%); mp 156—158 °C; IR(KBr) 3245, 2800, 1615 cm^{-1}; NMR(CF_3COOH) δ: 7.9—7.5(m, 2H), 4.15(s, 3H), 2.69(s, 3H). Found: C, 54.04; H, 5.78; N, 8.90%. Calcd for C_7H_9NOS: C, 54.19; H, 5.81; N, 9.03%.

c) Bis(5-methoxy-2-methoxymethyl-4-pyridyl) Disulfide (III): A mixture of 5-methoxy-2-methoxymethyl-4*H*-pyran-4-thione (Ic) (164 mg) and 28% aqueous ammonia solution (0.4 ml) was heated in a sealed tube at 60 °C for 10 min. Ammonia and water were evaporated off, and the residue was recrystallized from methanol to afford III, pale yellow needles. Yield, 46 mg (28%); mp 123—123.5 °C; IR (KBr) 1565 cm^{-1}; NMR($CDCl_3$) δ: 8.07(s, 1H), 7.45(s, 1H), 4.44 (s, 2H), 4.00(s, 3H), 3.29(s, 3H); *m/e* 368 (parent). Found: C, 52.03; H, 5.47; N, 7.64%. Calcd for $C_{10}H_{20}N_2O_4S_2$: C, 52.13; H, 5.47; N, 7.60%.

Reaction of 5-Hydroxy-2-methyl-4H-pyran-4-thione (Id) with Hydrazine Hydrate: A mixture of 5-hydroxy-2-methyl-4*H*-pyran-4-thione (Id) (203 mg, 1.4 mmol) and 80% hydrazine hydrate (280 mg, 3 mmol) in methanol (10 ml) was refluxed for 30 min. After methanol had been evaporated off, the residue was recrystallized from benzene to give 6-methyl-3-

pyridazinecarbaldehyde hydrazone (IVa), yellow plates. Yield, 85 mg (44%); mp 180—182 °C; IR(KBr) 3350, 3200, 1635, 1585 cm^{-1}; NMR($CDCl_3$) δ: 9.03(dd, 1H, J=4.5 and 1.5 Hz), 8.06(s, 1H), 7.95(dd, 1H, J=1.5 and 8.0 Hz), 7.41 (dd, 1H, J=4.5 and 8.0 Hz), 6.5—5.5(br, 2H), 2.67(s, 3H); UV λ_{max}(MeOH) nm(log ε) 230(3.74), 291(4.28). Found: C, 52.85; H, 5.91; N, 41.28%. Calcd for $C_6H_8H_4$: C, 52.92; H, 5.92; N, 41.15%.

*Reaction of 3-Hydroxy-2-methyl-4*H*-pyran-4-thione (Ie) with Hydrazine Hydrate.* A mixture of 3-hydroxy-2-methyl-4*H*-pyran-4-thione (Ie) (434 mg, 3 mmol) and 80% hydrazine hydrate (550 mg, 6 mmol) in methanol (10 ml) was refluxed for 1.5 h. After methanol had been evaporated off, the residue was filtered and recrystallized from methanol to give 1-amino-3-hydroxy-2-methyl-4(1*H*)-pyridinethione (Va), yellow needles. Yield, 91 mg (19%); mp 165 °C (dec); IR(KBr) 3250, 1615 cm^{-1}; NMR(CF_3COOH) δ: 8.09(d, 1H, J=8.0 Hz), 7.50(d, 1H, J=8.0 Hz), 2.81(s, 3H); UV λ_{max}(MeOH) nm(log ε) 254(3.98), 275(3.36), 348(4.27). Found: C, 45.36; H, 5.03; N, 17.71%. Calcd for $C_6H_8N_2OS$: C, 46.15; H, 5.16; N, 17.94%. The filtrate was evaporated off to dryness, and the residue was recrystallized from carbon tetrachloride to give 3-acetylpyridazine hydrazone (IVb), yellow micro-crystals. Yield, 145 mg (35%); mp 67—69 °C; IR(KBr) 3350, 3210, 1645, 1570 cm^{-1}; NMR($CDCl_3$) δ: 9.03(dd, 1H, J=1.5 and 4.5 Hz), 8.06(dd, 1H, J=1.5 and 8.0 Hz), 7.34(dd, 1H, J=4.5 and 8.0 Hz), 6.2—5.4(br, 2H), 2.37(s, 3H); UV λ_{max}(MeOH) nm(log ε) 224(3.69), 288 (4.06); *m/e* 136 (parent). Found: C, 52.72; H, 5.89; N, 41.18%. Calcd for $C_6H_8N_4$: C, 52.92; H, 5.92; N, 41.15%.

*Reaction of 3-Methoxy-2-methyl-4*H*-pyran-4-thione (If) with Hydrazine Hydrate.* A mixture of 3-methoxy-2-methyl-4*H*-pyran-4-thione (If) (404 mg, 2.5 mmol) and 80% hydrazine hydrate (510 mg, 5.5 mmol) in methanol (10 ml) was allowed to stand at roon temperature for 1 h. After methanol had been evaporated off, the residue was filtered and recrystallized from methanol to afford 1-amino-3-methoxy-2-methyl-4(1*H*)-pyridinethione (Vb), yellow plates. Yield, 116 mg (27%); mp 150—152 °C(dec); IR(KBr) 3200, 3150, 1620, 1590 cm^{-1}; NMR(CF_3COOH): 8.25(d, 1H, J= 7.9 Hz), 7.64(d, 1H, J=7.9 Hz), 4.00(s, 3H), 2.85(s, 3H); UV λ_{max}(MeOH) nm(log ε) 252(3.89), 285(3.21), 349(4.33). Found: C, 49.29; H, 5.86; N, 16.40%. Calcd for $C_7H_{10}N_2OS$: C, 49.40; H, 5.92; N, 16.46%. The solvent was evaporated off from the filtrate, and the residue was extracted with chloroform. After chloroform had been evaporated off, an oily product was obtained and confirmed to be α-(3-pyrazolyl)-α-methoxyacetone hydrazone (VI). Yield, 255 mg (58%); IR($CHCl_3$) 3200, 1620 cm^{-1}; NMR($CDCl_3$) δ: 7.53(d, 1H. J=2.2 Hz), 6.24(d, 1H, J=2.2 Hz), 4.94(s, 1H), 3.35(s, 3H), 1.72(s, 3H). This hydrazone decomposed within one day, not forming picrate.

*Reaction of 3-Methoxy-2-methyl-4*H*-pyran-4-thione (If) with Guanidine.* To a sodium ethoxide solution, prepared from sodium (180 mg, 8 mmol) and absolute ethanol (8 ml), were added guanidine hydrochloride (700 mg, 8 mmol) and 3-methoxy-2-methyl-4*H*-pyran-4-thione (If) (244 mg, 1.5 mmol) and the mixture was stirred at room temperature for 5 min. The reaction mixture was poured into water and extracted with chloroform. Chloroform was evaporated off, and the residue was recrystallized from ethyl acetate to give 1,3-thiazine derivative (VII), yellow plates. Yield, 25 mg (8.2%); mp 212 °C (dec); IR (KBr) 3200, 1690, 1610 cm^{-1}; NMR(CF_3COOH) δ: 9.65(d, 1H, J=2.0 Hz), 8.8—8.3(br, 2H), 7.01(d, 1H, J=2.0 Hz), 3.84(s, 3H), 2.41(s, 3H); *m/e* 198(parent). Found: C, 48.43; H, 5.14; N, 14.04%. Calcd for $C_8H_{10}N_2O_2S$: C, 48.48; H, 5.09; N, 14.14%.

The authors wish to thank Dr. Kazu Kurosawa of Kumamoto University for valuable discussions and Mr. Shuichi Ueda of Taiho Pharmaceutical Co., Ltd. for the measurement of mass spectra.

The Hydrolysis of Carbohydrates in the Presence of a Reversed Micelle. II. The Hydrolysis of Sucrose in Benzene

Kenichiro Arai and Yoshitaka Ogiwara

Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received March 28, 1977)

The formation of a reversed micelle by dodecylbenzenesulfonic acid in benzene containing a certain amount of water was examined by means of the absorption spectra of the Methylene Blue added to the system. The hydrolysis of the sucrose secondary-solubilized in the system was then investigated. The maximum rate enhancement of 400-fold was obtained in the presence of the micelle on the basis of the reaction in an aqueous solution in the presence of hydrochloric acid, whereas the addition of ethanesulfonic acid to the system showed only a little effect on the reaction rate. The reaction rates were found to show behavior similar to that of the stability of the micelle with respect to changes in the substrate concentration and in the amount of solubilized water. From these results, the greater part of the rate enhancement obtained in the present system might be concluded to result from some effects due to the formation of the reversed micelle.

Numerous studies have been made of new catalysis systems in the presence of a polymer catalyst[1] or a micelle[2] showing interactions with the substrate. However, there is only a little information on the system for the hydrolysis of such carbohydrates as cellulose, starch, and their low-molecular-weight analogues. Although some attempts have been made to employ a polymeric acid[3-9] or a reversed micelle[10] as catalysts for the hydrolysis, the rate enhancements thus obtained were small.

In a previous paper,[10] the hydrolysis of sucrose in the presence of a dodecylbenzenesulfonic acid (DBSH)-reversed micelle in dioxane–water mixed solvents was investigated; rate enhancements up to 21-fold were observed on the basis of the reaction in an aqueous solution. The rate enhancement, however, had been inferred to result from the solvent effect of dioxane, related to the structuredness of water (*ca.* 10-fold), which was also effective in the catalysis in the presence of sulfuric acid, and from the substrate-binding effect by the reversed micelle (*ca.* 2.1-fold).

In the present experiment, the formation of a reversed micelle by DBSH in benzene containing a certain amount of water is examined, and then the hydrolysis of sucrose secondary-solubilized in the system is investigated.

Experimental

Materials. Reagent-grade sucrose, benzene, ethanesulfonic acid, and hydrochloric acid were used. De-ionized and distilled water was used. Commercially available sodium dodecylbenzenesulfonate (Tokyo Chemical Co., Tokyo) was passed through a cation-exchange column in order to obtain a free acidic surfactant.

UV Spectrum. The UV spectra were obtained with a Hitachi Spectrophotometer 124 (Hitachi Seisakusho Co., Tokyo) at various concentrations of DBSH in benzene containing a certain amount of water and a very small amount of Methylene Blue (cationic dye); the shifts of an absorbance peak in the range of 660—690 nm were measured.

Maximum Amount of Solubilized Water. Water was added, drop by drop with a bulet into the DBSH benzene solution, and the amount of water just before turbidity appeared was estimated as the maximum amount of solubilized water.

Measurement of the Reaction Rate. DBSH was dissolved in benzene, and a sucrose aqueous solution was added. The resulting reaction mixture was then quickly poured into a cell and the optical rotatory powers were measured at intervals at 20 °C by means of a polarimeter (Polax, Atago Kogaku Co., Tokyo). The logarithm of the difference in the optical rotatory powers between that at a reaction time t (m_t) and that at infinity (m_∞) (practically, the optical rotatory power of the corresponding 1:1 mixture of glucose and fructose, because the precise value of m_∞ cannot be obtain in an organic solvent) was plotted against the reaction time, and the pseudo-first-order rate constant was estimated from the slope of the straight line thus obtained.

Results and Discussion

The absorption spectra of Methylene Blue added to a DBSH benzene solution containing a certain amount of water were investigated at various concentrations of DBSH, water, and sucrose. Figure 1 shows typical changes in the spectrum with the concentration of DBSH. Two absorbance peaks are observed in the figure, and one of them, on the left-hand side, is found to shift to a longer wave length with an increase in the concentration of DBSH. This sort of red shift is well known as methachromasis and may suggest the forma-

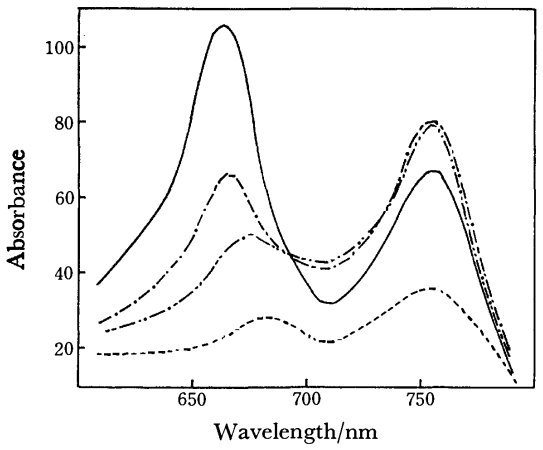

Fig. 1. Typical changes in absorption spectrum of Methylene Blue added to DBSH benzene solution with changing concentration of DBSH. Solubility water, 5 vol%. DBSH concn, N: ——; 0.03, ——; 0.45, ——; 0.50, ----; 0.70.

tion of a micelle. In general, the micelle formed in an apolar solvent such as benzene is known to be a reversed micelle,[11] so the micelle formed in the present system is inferred also to be a reversed one. Figure 2 shows typical changes in the wavelength corresponding to the peak in the spectrum with the concentration of DBSH. A sigmoidal curve is obtained, and the inflection point of the curve is presumed to be a critical micelle concentration of DBSH (CMC).

The maximum amounts of solubilized water in the DBSH benzene solution were measured at various concentrations of DBSH. Figure 3 shows the plots of the maximum amount of water against the concentration of DBSH; the amount of water is found to increase proportionally with the increase in the concentration of DBSH. The slope of the straight line obtained corresponding to 9.3 mol of water/mol of DBSH, which is comparable to the water-solubilizability of Aerosol OT.[12]

The hydrolysis of sucrose secondary-solubilized in the reversed micelle system containing a certain amount of water was investigated at various concentrations of acid, water, and sucrose. Figure 4 shows some typical

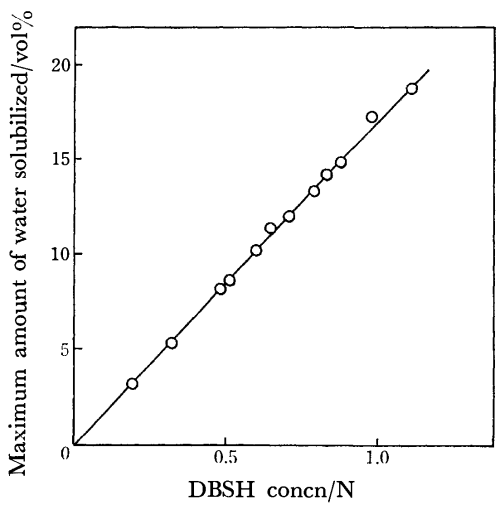

Fig. 3. Plot of maximum amount of water solubilized in DBSH benzene solution against concentration of DBSH.

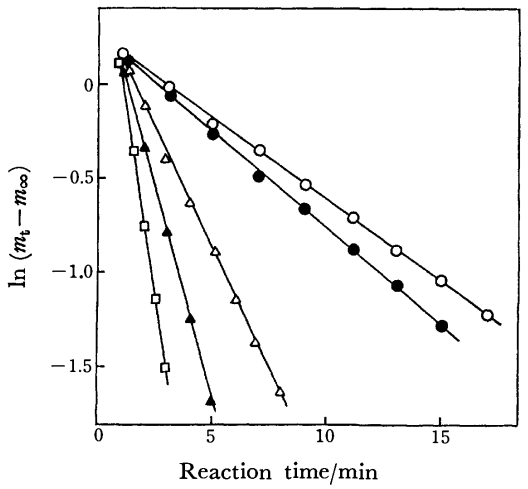

Fig. 4. Typical first-order plots of the changes in the optical rotatory power of sucrose at 20 °C. m_t and m_∞ are the optical rotatory powers at a reaction time t and infinity. Sucrose concn, 32 mM. DBSH concn, N: ○; 0.55, ●; 0.61, △; 0.68, ▲; 0.77, □; 0.86. Solubilized water, 7.5 vol%.

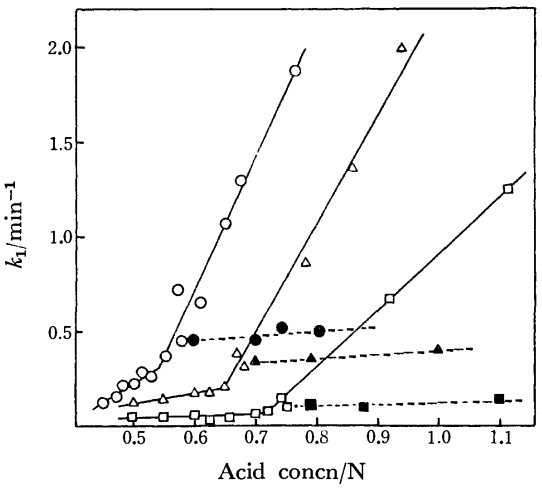

Fig. 5. Plots of pseudo-first-order rate constant, k_1, of sucrose hydrolysis against acid concentration. Sucrose concn, 32 mM. Solubilized water, vol%: ○, ●; 5.0, △, ▲; 7.5, □, ■; 10.0. Acid: ——; DBSH only, ----; ethanesulfonic acid added to DBSH.

first-order plots of the changes in the optical rotatory power of sucrose at 20 °C. A fairly good straight line is obtained for each plot. A pseudo-first-order rate constant, k_1, was estimated from the slope of the straight line. Figure 5 shows the plots of the k_1 against the concentration of acid. the total concentration of DBSH and ethanesulfonic acid. The plots shown with a solid line are those of the k_1 in the presence of DBSH alone; a straight line is obtained for each plot in the concentration range of DBSH higher than a certain concentration, which is nearly in accord with the corresponding CMC presumed from the changes in the absorption spectrum. The slope of the straight line gives an apparent second-order rate constant, k_{2obsd}, when the amount of solubilized water is not considered. The k_{2obsd}'s are far larger than that of the reaction in water

in the presence of hydrochloric acid (the plot is omitted in the figure to avoid complexity, and the second-order rate constant, k_{2HCl}, is 0.016 $l\,mol^{-1}\,min^{-1}$) and is found to decrease with an increase in the amount of solubilized water. The plots shown with dotted line are those of the k_1 in the presence of the ethanesulfonic acid added to the system after DBSH formed the micelle. Ethanesulfonic acid is presumed not to form any micelle, and in fact, CMC was not influenced by the addition of ethanesulfonic acid to the system. In the figure the slopes of the dotted straight lines are found to be far smaller than those in the presence of DBSH alone in a higher concentration range at the same acid concentration.

Figure 6 shows the plots of CMC presumed from the absorption spectrum and of the ratio of the sucrose hydrolysis rates with the DBSH micelle to those with hydrochloric acid, k_{2obsd}/k_{2HCl}, against the concentration of sucrose. Again, for each reaction with different concentrations of sucrose, the DBSH concentration at the break point of the plots of k_1 against the DBSH concentration were nearly in accord with the corresponding CMC. It can be seen in Fig. 6 that CMC decreases with an increase in the concentration of sucrose and that k_{2obsd}/k_{2HCl} also increases in the concentration range higher than 40 mM. It may be explained qualitatively that the more stable the micelle is, the larger k_{2obsd}/k_{2HCl} is given, although the larger values of k_{2obsd}/k_{2HCl} in a concentration range lower than 40 mM cannot be explained at the present time. Figure 7 shows the plots of the CMC and k_{2obsd}/k_{2HCl} against the amount of solubilized water. It is found that the CMC increases proportionally with the amount of solubilized water and that the k_{2obsd}/k_{2HCl} decreases. Again, from these plots it may be possible to explain qualitatively that the more stable the micelle is, the larger k_{2obsd}/k_{2HCl} is given.

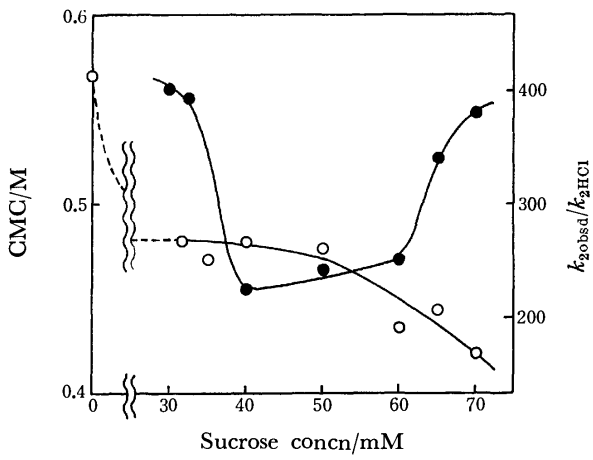

Fig. 6. Plots of CMC (○) and the ratio of sucrose hydrolysis rates with the DBSH micelle to those with hydrochloric acid, k_{2obsd}/k_{2HCl} (●), against sucrose concentration. Solubilized water, 5 vol%.

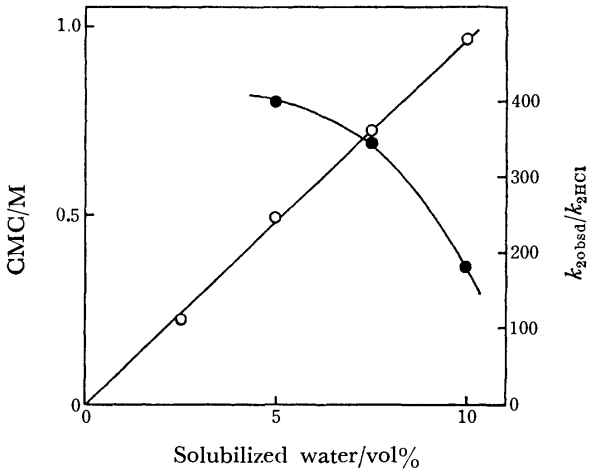

Fig. 7. Plots of CMC (○) and the ratio of sucrose hydrolysis rates with the DBSH micelle to with hydrochloric acid, k_{2obsd}/k_{2HCl} (●), against the amount of solubilized water. Sucrose concn, 32 mM.

Conclusion

The hydrolysis of sucrose secondary-solubilized in a DBSH benzene solution containing a certain amount of water was investigated, and rate enhancements up to 400-fold were obtained on the basis of the reaction in an aqueous solution in the presence of hydrochloric acid. Some facts observed in the present investigation, which show the existence of a close relationship between the changes in the reaction rate and the micelle formation, suggest that the greater part of the rate enhancement is related to the formation of the reversed micelle; in contrast to the corresponding reaction in a dioxane–water mixed solvent,[10] the micelle effect may be far larger than the solvent effect. The micelle effects obtained in the present system are supposed to arise from a substrate-binding effect into the micelle, from the increase in the activities of the water molecules and hydronium ions, from a more suitable conformation of transition state for the reaction, and from other factors. At the present time, however, the details are not apparent.

Sensitized Photooxygenation of 9-Vinylphenanthrenes

Masakatsu MATSUMOTO, Satoshi DOBASHI, and Kiyosi KONDO

Sagami Chemical Reserch Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received April 20, 1977)

The sensitized photooxygenation of several 9-vinylphenanthrenes in carbon tetrachloride was investigated. In the cases of 9-vinyl- and 9-(β-substituted vinyl)phenanthrenes, the 1,4-cycloaddition of singlet oxygen to a conjugated system composed of the side chain and 9,10-double bond of the ring surpassed other oxidation modes, *i.e.*, the "ene" reaction and 1,2-cycloaddition of singlet oxygen, to give the 1,2-dioxatriphenylene-type peroxides. On the other hand, the sensitized photooxygenation of 9-isopropenylphenanthrene gave a hydroperoxide due to the "ene" reaction.

Anthracenes are known to easily undergo photooxygenation to give 9,10-epidioxides, while phenanthrenes have scarcely been reported to react with singlet oxygen.[1] Recently, an aromatic double bond in conjugation with extranuclear unsaturation has observed to produce an active diene system capable of undergoing the 1,4-cycloaddition of singlet oxygen for certain 1,1-diphenylethylenes,[2] cyclic styrene derivatives,[3] vinylnaphthalenes,[4] and some vinyl-substituted heteroaromatics.[5] These facts promted us to investigate the sensitized photooxygenation of 9-vinylphenanthrenes. 9-Vinyl- and 9-(β-substituted vinyl)phenanthrenes, **1a**—**d**, underwent the 1,4-cycloaddition of singlet oxygen to give 1,2-dioxatriphenylene-type peroxides, **2a**—**d**, while 9-(α-substituted vinyl-) such as 9-isopropenylphenanthrene (**1e**) did not, although the "ene" reaction did occur.

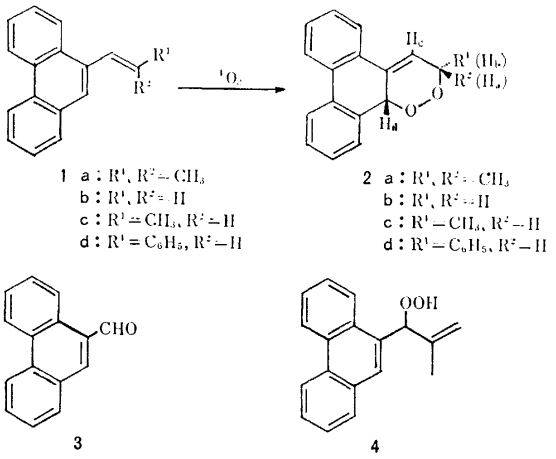

Fig. 1.

Results and Discussion

Preparation of 9-Vinylphenanthrenes. Phenanthrenes having 9-vinyl- (**1b**), 9-isopropenyl- (**1e**), and *trans*-9-styryl- (**1d**) substituents were prepared from 9-formylphenanthrene or 9-acetylphenanthrene using a Wittig reaction. The other phenanthrene, 9-(2-methyl-1-propenyl)- (**1a**) and *trans*-9-(1-propenyl)-phenanthrene (**1c**) were synthesized by dehydration of the corresponding alcohols prepared by a Grignard reaction of 9-bromophenanthrene. The preparations of these vinylphenanthrenes are described in detail in the experimental section.

Photooxygenation of 9-Vinylphenanthrene. First the sensitized photooxygenation of 9-(2-methyl-1-propenyl)-phenanthrene (**1a**) was examined, since **1a** is expected to be most favorable for the 1,4-cycloaddition of singlet oxygen of the phenanthrene **1a**—**e** in accord with the results of the sensitized photooxygenation of 1-vinylnaphthalenes.[5] A solution of **1a** and tetraphenylporphine (TPP) as a sensitizer in carbon tetrachloride was irradiated externally with eight low-pressure sodium vapor lamps in an oxygen atmosphere at 5 °C. When the photolysate was chromatographed on silica gel, a peroxide, **2a**, was obtained in an 80% yield. The structure of **2a** was assigned on the basis of spectral evidence and combustion analysis. In this run, both 9-formylphenanthrene (**3**) and 9-(1-hydroperoxy-2-methyl-2-propenyl)phenanthrene (**4**) were scarcely detected. The former would be formed through the 1,2-addition of singlet oxygen to the side chain of **1a**, and the latter through "ene" reaction of **1a**. Similarly, irradiation of **1b** gave the corresponding endo peroxide, **2b** in a 40% yield. In this case, during the irradiation, a considerable amount of **1b** appeared to be polymerized.

Similar irradiation of *trans*-9-(1-propenyl)phenanthrene (**1c**) gave the corresponding endo peroxides, **2c**, in a 94% yield. The peroxide, **2c**, was one of two obtainable stereoisomers and its configuration was assigned by comparing the NMR spectra of **2a** and **2c** with those of the endo peroxides, **5**, derived from 1-(2-methyl-1-propenyl)-, *trans*-(1-propenyl)-, and *cis*-(1-propenyl)naphthalene.[5] In the NMR spectra of peroxide **2**, the peak of the methyl attached to the carbon atom adjacent to the oxygen atom are situated at 1.29 and 1.42 ppm for **2a**, and at 1.39 ppm for **2c**, as shown in Table 1. On the other hand, in the cases of **5**, the corresponding quasi-axial and quasi-equatorial methyl peaks are located at 1.21—1.25 and 1.51 ppm, respectively.[5] From these facts, **2c** was assigned to have the quasi-equatorial methyl. The sensitized photooxygenation of *trans*-9-styrylphenanthrene (**1d**) gave one of two possible isomeric 1,4-endo peroxides, **2d**, in a 63% yield. The structure of **2d** was also assigned by comparing its NMR spectrum with that

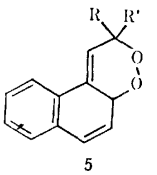

Fig. 2.

TABLE 1. NMR SPECTRAL DATA OF ENDO PEROXIDES **2**[a]

of the endo peroxide of *trans*-1-styrylnaphthalene.[5] Thus, the 1,4-cycloaddition of singlet oxygen to 9-vinylphenanthrenes **1** was confirmed to be stereospecific and the attack of singlet oxygen on the diene system may occur suprafacially. All the endo peroxides **2** obtained in this work were thermally stable and exhibited complex NMR spectra, which were analyzed using the spin-decoupling technique, as shown in Table 1.

For the sensitized photooxygenation of 1-vinylnaphthalenes, the α-substituent on the side chain was found to inhibit the 1,4-cycloaddition of singlet oxygen to the aromatic-extranuclear unsaturation system. This tendency was observed in the reaction of 9-vinylphenanthrene; when 9-isopropenylphenanthrene (**1e**) was oxygenated in a manner similar to that described above, no corresponding endo peroxide, **2**, but instead 9-(3-hydroperoxy-1-propen-2-yl)phenanthrene, (**6**), was formed. This result is in contradiction to the Diels-Alder reaction of maleic anhydride with **2e** in boiling xylene.[6] One of the reasons for this phenomenon may be the steric repulsion between the α-methyl and a hydrogen atom at the 8-position of the aromatic ring, which may be overcome at high temperature.

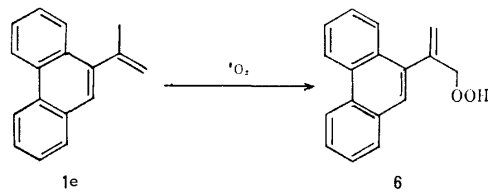

Fig. 3.

In conclusion, it was clarified that, for 9-vinylphenanthrenes excepting aromatics having α-substituted vinyl, such as **2e**, the 9,10-double bond, which is only slightly active itself to singlet oxygen, produces, in conjugation with a 9-ethylenic substituent, an active diene system capable of undergoing the 1,4-cycloaddition of singlet oxygen.

Experimental

All melting points are uncorrected. NMR spectra were recorded on a Varian HA-100 spectrometer with TMS as an internal standard. Mass spectra were obtained with a Hitachi RMU-6E spectrometer. The light source consisted of eight 60-W low-pressure sodium vapor lamps (National SOI-60). The yields are based on reacted starting materials.

*Preparation of 9-(2-Methyl-1-propenyl)phenanthrene (**1a**).* To a solution of 9-phenanthrylmagnesium bromide (prepared from 0.023 mol of 9-bromophenanthrene and 0.023 mol of magnesium) in 50 ml of tetrahydrofuran (THF) a THF solution (10 ml) of isobutylaldehyde (0.024 mol) was added at room temperature. After the usual work-up, crude 1-(9-phenanthryl)-2-methyl-1-propanol was dehydrated with phosphorous pentaoxide in hot benzene (80 ml) for 3 h. A benzene solution containing the crude product was washed with a $NaHCO_3$ aqueous solution and dried over $MgSO_4$. The benzene was evaporated and the residual solid was crystallized from ethanol. Thus, **1a** was obtained as colorless granules, mp 66—67 °C, in 57% yield (3.03 g); IR (KBr): 3050, 2920, 1450, 895, 762, 748, 723 cm^{-1}; NMR ($CDCl_3$): δ 1.73 (s, 3H), 2.00 (s, 3H), 6.58 (m, 1H), 7.4—8.7 (m, 9H) ppm; MS *m/e*: 232 (M^+, 41), 217 (48), 116 (31), 108 (93), 101 (100).

*Preparation of 9-Vinylphenanthrene (**1b**).* To a solution of methylenetriphenylphosphorane (prepared from 0.009 mol of methyltriphenylphosphonium bromide and an equimolar amount of butyllithium) in THF (50 ml) was added 9-formylphenanthrene (0.009 mol) at ambient temperature. After 2 h, the reaction mixture was poured into water and extracted with hexane. The hexane solution was dried over $MgSO_4$ and condensed. The residue was chromatographed on silica gel (Wakogel C-200) and eluted with hexane. Thus, **1b** was obtained as a colorless viscous oil in a 60% yield; IR (liquid film): 3070, 1493, 1450, 990, 771, 751, 730 cm^{-1}; NMR (CCl_4): δ 5.47 (d with fine coupling, J=5.5 Hz, 1H), 5.70 (d with fine coupling, J=16 Hz, 1H), 7.2—8.6 (m, 10H).

Preparation of trans-*9-(1-Propenyl)phenanthrene (**1c**).* The olefin, **1c**, was prepared from 9-bromophenanthrene and allyl bromide according to a procedure in the literature.[6] **1c** was obtained as colorless needles, mp 99—99.5 °C, from hexane (55%) (lit,[6] bp 157 °C/1.25 Torr); NMR (CCl_4): δ 1.95 (d, J=7.0 and 2.0 Hz, 3H), 6.12 (d of q, J=16.0 and 7.0 Hz, 1H), 6.96 (d with fine couping, J=16.0 Hz, 1H), 7.3—8.6 (m, 9H); MS *m/e* :218 (M^+, 80), 217 (37), 203 (100).

Preparation of trans-*9-Styrylphenanthrene (**1d**).* To a solution of benzylidenetriphenylphosphorane (prepared from 0.0049 mol of benzyltriphenylphosphonium bromide and an equimolar amount of butyllithium) in THF (30 ml) was added 0.0049 mol of 9-formylphenanthrene with stirring for 30 min at room temperature. The reaction mixture was treated as in the case of **1b**. Recrystallization of crude **1d** from ethanol gave colorless granules, mp 118 °C (lit,[6] 118 °C) (69%); IR (KBr): 3045, 1597, 1495, 960, 746, 740, 692 cm^{-1}; NMR (CCl_4): δ 6.7—8.7 (m, 16H); MS *m/e*: 280 (M^+, 100), 202 (16), 138 (11).

*Preparation of 9-Isopropenylphenanthrene (**1e**).* To a solution of methylenetriphenylphosphorane (prepared from 0.0086 mol of methyltriphenylphosphonium bromide and an equimolar amount of butyllithium) in 50 ml of THF was added 9-acetylphenanthrene (0.0086 mol). Treatment of the crude product similar to the case of **1b** gave colorless crystals, mp 51 °C (lit,[6] 51 °C) in a 63% yield; IR (KBr): 3060, 1450, 892 cm^{-1}; NMR (CCl_4): δ 2.22 (broad s, 3H), 5.10 (m, 1H), 5.35 (m, 1H), 7.2—8.7 (m, 9H).

*Photooxygenation of 9-(2-Methyl-1-propenyl)phenanthrene (**1a**).* A solution of 0.53 g of **1a** and 5 mg of TPP in 70 ml of CCl_4 was irradiated in an oxygen atmosphere at 5 °C. After 2 h, 53 ml of oxygen was consumed. The photolysate was condensed at room temperature *in vacuo* and the residue was

subjected to chromatography on silica gel. Elution with a hexane–CH_2Cl_2 (3 : 1) mixture gave 0.48 g of peroxide **2a** as colorless granules (mp 94—95 °C, from methanol) (80% yield): IR (KBr): 3050, 2975, 1480, 1445, 1060, 1048, 757, 750, 730 cm^{-1}; MS *m/e* :264 (M^+, 24), 246 (49), 232 (59), 221 (41), 205 (42), 202 (42), 178 (93), 176 (49), 165 (68), 43 (100).

Found: C, 81.15; H, 6.08%. Calcd for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10%.

*Photooxygenation of 9-Vinylphenanthrene (**1b**).* A solution of 1.15 g of **1b** and 5 mg of TPP in 70 ml of CCl_4 was irradiated in an oxygen atmosphere at 5 °C for 5.5 h. The CCl_4 solution was condensed and subjected to chromatography on silica gel. Elution with a hexane-CH_2Cl_2 (3 : 1) mixture gave unreacted **1b** (200 mg) and successively 440 mg of peroxide **2b** (oil): IR (liquid film): 3050, 1450, 1072, 1045, 787, 760, 750 cm^{-1}; MS *m/e*: 237 (M^++1, 33), 205 (100), 179 (47).

Photooxygenation of trans-*9-(1-Propenyl)phenanthrene (**1c**).* Olefin **1c** (0.50 g) and TPP (5 mg) was irradiated in an oxygen atmosphere in 70 ml of CCl_4 for 40 min (O_2 uptake= 54 ml). The CCl_4 was removed from the photolysate under reduced pressure and the residue was purified by chromatography on silica gel in a hexane–CH_2Cl_2 (3 : 1) mixture. Thus, peroxide **2c** (0.54 g) was obtained as colorless granules (from methanol), mp 85—87 °C, in a 94% yield; IR (KBr): 3065, 2975, 1600, 1498, 1450, 1090, 1070, 765, 760, 752, 740 cm^{-1}; MS *m/e*: 250 (M^+, 18), 232 (100), 207 (38), 202 (31), 179 (36), 101 (18).

Found: C, 81.64; H, 5.64%. Calcd for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%.

Photooxygenation of trans-*9-Stryylphenanthrene (**1d**).* A solution of 0.95 g of **1d** and TPP (5 mg) in CCl_4 (70 ml) was irradiated for 2 h. After the removal of the CCl_4, the crude product was subjected to chromatography on silica gel and eluted with a hexane-CH_2Cl_2 (3 : 1) mixture. As the first fraction, unreacted **1d** (0.43 g) was recovered and successively peroxide **2d** (0.37 g) was obtained as colorless granules, mp 126—127 °C (from hexane); IR (KBr): 3030, 1450, 1085, 1042, 762, 752, 742, 702 cm^{-1}; MS *m/e*: 312 (M^+, 20), 294 (62), 280 (100), 178 (32).

Found: C, 84.09; H, 5.07%. Calcd for $C_{22}H_{16}O_2$: C, 84.59; H, 5.16%.

*Photooxygenation of 9-Isopropenylphenanthrene (**1e**).* A solution of 0.44 g of **1e** and TPP (5 mg) in CCl_4 (50 ml) was irradiated in an oxygen atomosphere at 5 °C, until the sensitizer faded (6 h, O_2 uptake=21 ml). The photolysate was filtered and condensed *in vacuo* at room temperature. The NMR spectrum (in CCl_4) of the crude photolysate showed the existence of 9-(3-hydroperoxy-1-propen-2-yl)phenanthrene (**6**) [δ 4.70 (m, 2H, $-CH_2OO-$), 5.39 (m, 1H, olefinic) ppm] together with unreacted **1e**. No formation of other compounds, such as endo peroxide **2** and 9-formylphenanthrene, was observed. The chromatographic purification of hydroperoxide **6** on silica gel or alumina was unsuccessful. A KI test (for peroxide) of the crude photolysate was positive.

Autoxidation Reactions of Hydrocarbons Catalyzed by Co(II) Tetra(*p*-tolyl)porphyrin

Yasukazu OHKATSU and Teiji TSURUTA

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received April 25, 1977)

Autoxidation reactions of saturated and unsaturated hydrocarbons were carried out using Co(II) tetra(*p*-tolyl)porphyrin as the catalyst in ethyl acetate at 30 °C. The Co(II) complex activated the oxygen molecule to the superoxide ion, which abstracted a hydrogen atom from a saturated hydrocarbon or added to the double bond of an unsaturated hydrocarbon, to initiate autoxidation. The reactivity of the activated oxygen molecule was found at the site of the free radical rather than that of the anion thereof. The reactivities were compared with those of superoxide ions derived from other origins.

The superoxide ion is known to be formed by several different methods: the electroreduction of molecular oxygen,[1,2] the activation of molecular oxygen on some organometallic complexes.[3] and the complexation of the potassium cation of KO_2 with crown ethers.[4]

The superoxide ion is considered to have dual characteristics as a free radical and also as an anion. For example, the electrogenerated free superoxide ion is known[1] to oxidize organic substrates according to the two mechanisms mentioned above. The superoxide ion originating from KO_2, on the other hand, behaves as an anion, as may be seen in the nucleophilic oxidation of alkyl halide to form dialkyl peroxide.[5] Little information, however, has been available on the nature of the molecular oxygen which is activated on a metal complex, especially on a metal porphyrin, though the metal complex is known to catalyze the autoxidation reaction of aldehydes.[6,7]

The purpose of this paper is to elucidate the reactivity of molecular oxygen activated on Co(II) tetra(*p*-tolyl)porphyrin in autoxidation reactions of several hydrocarbons, and to compare the reactivity with that of superoxide ions resulting from other sources.

Experimental

Materials. Co(II) tetra(*p*-tolyl)porphyrin (reffered to as CoTPP) was prepared, according to the method described by Rothemund *et al.*,[8] from pyrrole, *p*-tolualdehyde, and cobalt(II) acetate.

The hydrocarbons, such as tetralin, cumene, 2-norbornene, *dl*-limonene, cyclopentene, cyclohexene, 1-methylcyclohexene, 4-methylcyclohexene, 1,3-dihydrohexadiene, cycloheptene, cyclooctene, and cyclodecene, were purified by conventional methods using activated alumina. The furan, 2,5-dihydrofuran, and 2,3-dihydropyran were used after simple distillations.

The ethyl acetate used as a solvent and the 1,1′-azobiscyclohexanecarbonitrile used as an initiator were purified by usual methods.

Procedure. The autoxidation of a hydrocarbon was carreid out as has been described in a previous paper.[6] The $k_p/(2k_t)^{1/2}$ value was determined with 1,1′-azo-biscyclohexanecarbonitrile under the irradiation of a high-voltage mercury lamp. The rates of chain initiation were determined by the usual induction-period method, using 2,6-di-*t*-butyl-4-methylphenol as the inhibitor. The oxidation products for the two hydrocarbons were analyzed by means of GLC method (column: Silicone SE-1, column temperature: 100 °C) using authentic samples.

Results and Discussion

Autoxidation of Hydrocarbons. It is widely accepted that the autoxidation reactions of organic compounds proceed through the following steps:

$$\mathrm{RH} \longrightarrow \mathrm{R}\cdot \text{ (or } \dot{\mathrm{R}}\mathrm{H}\text{) rate: } R_i, \quad (1)$$

$$\mathrm{R}\cdot + \mathrm{O_2} \longrightarrow \mathrm{RO_2}\cdot \text{ (or } \dot{\mathrm{R}}\mathrm{H} + \mathrm{O_2} \longrightarrow \mathrm{HROO}\cdot), \quad (2)$$

$$\mathrm{RH} + \mathrm{RO_2}\cdot \xrightarrow{k_p} \mathrm{RO_2H} + \mathrm{R}\cdot$$

$$\text{(or } \mathrm{RH} + \mathrm{HROO}\cdot \xrightarrow{k_p} \mathrm{HROO}\dot{\mathrm{R}}\mathrm{H}\text{)}, \quad (3)$$

$$2(\text{peroxyl radical}) \xrightarrow{k_t} \text{inert compounds}, \quad (4)$$

provided that the chain length is sufficiently long and the partial pressure of oxygen is high. The rate of oxidation is expressed[9] as

$$R = -\frac{\mathrm{d}[\mathrm{O_2}]}{\mathrm{d}t} = \{k_p/(2k_t)^{1/2}\}[\mathrm{RH}]R_i^{1/2}. \quad (5)$$

Cobalt(II) tetra(*p*-tolyl)porphyrin was recently shown[6] to behave as a catalyst which initiates the autoxidation of acetaldehyde by activating molecular oxygen into the superoxide type; the rate of initiation reaction was expressed as

$$R_i = k_i[\mathrm{CH_3CHO}][\mathrm{CoTPP}][\mathrm{O_2}]. \quad (6)$$

The present study has revealed that hydrocarbons also undergo the autoxidation reaction with the aid of Co(II) tetra(*p*-tolyl)porphyrin as a catalyst. Tables 1 and 2 show the results of the autoxidation reactions of the two representatitave hydrocarbons, cyclohexene, and 2,3-dihydrofuran respectively. The data in Tables 1 and 2 can satisfactorily be expressed by

$$-\mathrm{d}[\mathrm{O_2}]/\mathrm{d}t = \mathrm{const}[\mathrm{RH}]^{3/2}[\mathrm{CoTPP}]^{1/2}[\mathrm{O}]_2^{1/2}. \quad (7)*$$

By comparing Eq. 7 with Eq. 5, it may be seen that the rate of initiation possesses the formula,

$$R_i = (2k_t)\left(\frac{\mathrm{const}}{k_t}\right)^2[\mathrm{RH}][\mathrm{CoTPP}][\mathrm{O_2}]. \quad (8)$$

Eq. 8 is exactly the same type as that found in the autoxidation of acetaldehyde catalyzed by the same catalyst.[6] The kinetic results are compatible with the concept that the autoxidations of cyclohexene and

* The term "const" in Eq. 7 means $k_p\left\{\frac{2k_t}{k_iK_1}\right\}^{1/2}$, which corresponds to a terms calculated from Eqs. 7, 8, and 11.

2,5-dihydrofuran are initiated by molecular oxygen activated on Co(II) tetra(*p*-tolyl)porphyrin (superoxide ion) in a way similar to the autoxidation of acetaldehyde.[6,7]

$$\text{Co(II)TPP} + O_2 \overset{K_1}{\rightleftharpoons} \text{Co(II)TPP-}O_2, \quad (9)$$

$$\text{Co(III)TPP-}O_2 + \text{RH} \xrightarrow{k_1} \text{Co(III)TPP-}O_2\text{H} + \text{R}\cdot, \quad (10)$$

$$\text{or Co(III)TPP-}O_2\dot{\text{R}}\text{H}. \quad (11)$$

Table 3 shows the rates of oxygen absorbed for several hydrocarbons (1 M), using Co(II) tetra(*p*-tolyl)porphyrin (5×10^{-3} M) in ethyl acetate at 30 °C. Significant differences in the rates were observable in response to the kind of hydrocarbons. It is, however, a general trend that Co(II) tetra(*p*-tolyl)porphyrin exhibits a higher reactivity toward hydrocarbons which can undergo both oxidation reactions *via* hydrogen abstraction and addition to double bonds.

Among the cyclic compounds with double bonds, monoenes were generally oxidized more easily than dienes, as exemplified by the comparison of cyclohexene with 1,3-cyclohexadiene, and by that of dihydrofuran with furan.

The oxidation products of both cyclohexene and 2,5-dihydrofuran were representatively analyzed. The former substrate gave cyclohexen-2-one (80%), cyclohexan-2-ol (6%), and cyclohexene oxide (13%); this result forms a contrast with the result[10] obtained by the use of a similar catalyst, Ni(II) phthalocyanine, where 17, 6, and 4% of the above-cited products were obtained respectively. The latter substrate, 2,5-dihydrofuran, on the other hand, formed 2-hydrofuran-5-

Table 3, Oxidation of hydrocarbons with Co(II) tetra(*p*-tolyl)porphyrin

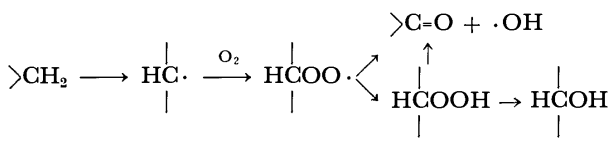
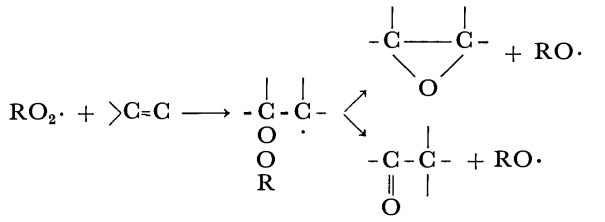
one and 2-hydrofuran-5-ol (79%) and 2,3,5-trihydrofuran-4-one (15%).

The products mentioned above, as is well known,[9] are presumably derived from a hydrogen abstraction reaction



and an addition to double bonds



The distribution of these products may suggest the reactivities of the oxygen molecules activated on Co(II) tetra(*p*-tolyl)porphyrin toward hydrocarbons in terms of reaction routes *via* hydrogen abstraction and/or addition to double bonds. This suggestion, however, is apt to be somewhat obscure, because we can observe only overlapped spectra for the distribution of the products which should be derived from peroxyl radicals as well as Co(III)TPP–O_2^-.

*Reactivity of the Oxygen Molecule Activated on Co(II) Tetra(*p*-tolyl)porphyrin.* As shown in Table 3, the modes of the oxidation reactions of hydrocarbons can be classified into those *via* hydrogen abstractions and those *via* additions to double bonds.[11]

The ease of hydrogen abstraction from hydrocarbons is known to be related with the bond dissociation energy between the carbon and hydrogen of the relevant hydrocarbons.[12] Therefore, the hydrogen-abstracting ability of the molecular oxygen, activated on Co(II) tetra(*p*-tolyl)porphyrin, as a free radical can be evaluated by means of the bond-dissociation energy of hydrocarbon, which enters the autoxidation reaction after its initiation by hydrogen abstraction in the presence of the cobalt porphyrin.

The chemical behavior of three types of superoxide ions was compared in terms of the reactivities toward hydrocarbons, which undergo oxidation reactions only *via* hydrogen abstractions. Co(II) tetra(*p*-tolyl)porphyrin and π-allyl $Fe(CO)_3Br$[13] were found to form less reactive superoxide ion than the electrogenerated one. The latter superoxide ion could catalyze, for instance, the autoxidation reactions at 30 °C of 9,10-dihydroanthracene (71 kcal/mol), cumene (79 kcal/mol), tetralin (82 kcal/mol), and cyclohexene (95 kcal/mol), where the numerals in parentheses are the respective C–H bond dissociation energies (D_{C-H}). The former two metal complexes failed to catalyze at 30 °C the autoxidation reaction of cumene and tetralin, which have D_{C-H} values above 79 kcal/mol.

In considering the reactivity of Co(II) tetra(*p*-tolyl)-porphyrin toward the cyclic olefins listed in Table 3, it may necessary first to solve the question of which reaction mode, double-bond addition or hydrogen abstraction, is predominant in the autoxidation reaction. In order to determine such a mode of reaction by the molecular oxygen activated on the cobalt–porpyrin catalyst, the rates of initiation for several cyclohexene derivatives were measured.

The rate of initiation, R_i, was determined by measuring the induction period in autoxidation reactions of cyclohexenes with Co(II) tetra(*p*-tolyl)porphyrin in the presence of 2,6-di-*t*-butyl-4-methylphenol at 30 °C. The values for the rate constant were calculated using

$$R_i = k_i K_1[RH][CoTPP][O_2], \quad (12)$$

which can be derived by assuming Reactions 9—11. Table 4 shows the observed values for the rate of initiation, together with the calculated rate constant, k_iK_1, of Reaction 12 at 30 °C.

The calculated rate constants of the initiation reactions were found to have a good correlation with the $\nu_{C=C}$ of cyclohexenes as is shown in Fig. 1. It should be noted that the oxygen molecule activated on Co(II) tetra(*p*-tolyl)porphyrin cannot abstract the hydrogen atom from 1-methylcyclohexene, 4-methylcyclohexene, and cyclohexene, because the D_{C-H} values of the cyclic olefins are estimated to be about 82 kcal/mol.[10] 1,3-Cyclohexadiene is also considered to enter the autoxi-

Table 4. Determination of rate constants (k_i) of the initiation reaction in the autoxidation of cyclohexene derivatives with Co(II) tetra(*p*-tolyl)porphyrin

Substrates	Temp (°C)	$k_p/(2k_t)^{1/2}$ $M^{-1/2}s^{-1/2}$	R $M\,s^{-1}$	R_i $M\,s^{-1}$	k_iK_i $M^{-2}s^{-1}$
1-Methylcyclohexene	15[a]	1.56×10^{-3}	4.9×10^{-6}	1.58×10^{-6}	1.4×10^{-1}
	30[b]	3.90×10^{-3}			
	40[a]	5.93×10^{-3}			
4-Methylcyclohexene	15[a]	2.78×10^{-3}	8.3×10^{-7}	4.65×10^{-8}	3.97×10^{-3}
	30[b]	3.85×10^{-3}			
Cyclohexene	15[a]	0.6×10^{-3}	6.2×10^{-7}	8.97×10^{-8}	7.67×10^{-3}
	30[b]	2.07×10^{-3}			
	40[a]	2.93×10^{-3}			
1,3-Cyclohexadiene	30[a]	1.0×10^{-9}	2.2×10^{-7}	4.8×10^{-12}	4.14×10^{-5}

a) From Ref. 9. b) This work. Reaction conditions: [cyclohexene derivative]: 1 M, [Co(II) tetra(*p*-tolyl)porphyrin]: 5×10^{-3} M, [O_2]: 2.34×10^{-3} M, in ethyl acetate at 30 °C.

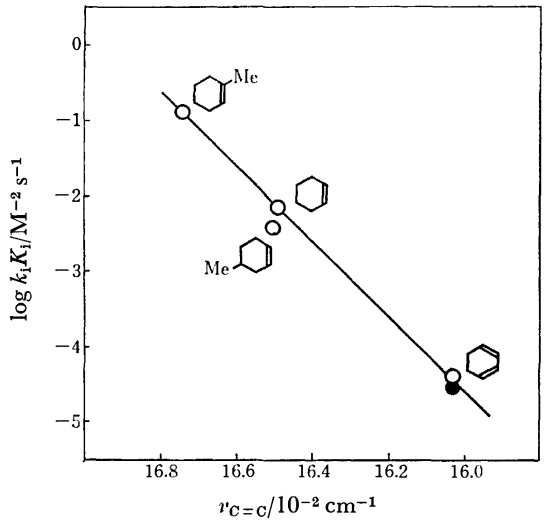


Fig. 1. Correlation of rate constants (k_i) of initiation reaction with $\nu_{C=C}$ of cyclohexene derivatives in autoxidations of the derivatives (1 M) with Co(II) tetra(*p*-tolyl)porphyrin (5×10^{-3} M) under one atom of oxygen at 30 °C.
●: The value calculated by assuming that 73% of 1,3-cyclohexadiene is oxidized through addition reaction.[14]

dation reaction under the initiation through the addition to the double bond, in light of the previous report[14] that about 73% of the autoxidation reaction proceeded through the addition reaction, though the D_{C-H} of 1,3-cyclohexadiene is only 71 kcal/mol.[10]

Therefore, the oxygen molecule activated on Co(II) (*p*-tolyl)porphyrin can be said to react with the double bonds according to an electrophilic addition mechanism, since the value of $\nu_{C=C}$ is regarded as a measure of the electron density of double bonds. From these results and discussion, the reactivity of the activated oxygen molecules can be presumed to be based on the site of the radical.

According to ESR measurement,** the *g*-value of the oxygen molecule activated on Co(II) tetra(*p*-tolyl)-porphyrin was 2.012,[6] which is rather close to that of a peroxy radical (g=2.015),[15] in contrast with the *g*-value of the electrogenerated superoxide ion (2.006).[6] These results suggest the following structure for the activated oxygen molecule:†

$$\text{Co(II)TPP} + O_2 \rightleftharpoons \text{Co(III)TPP}^{-}\text{-OO}\cdot \qquad (13)$$

The Co(III)TPP^{-}-OO· structure can explain the results shown in Fig. 1 in terms of its radical character. The electrophilic reactivity of the oxygen molecule activated on Co(II) tetra(*p*-tolyl)porphyrin should be noticed as a counterpart to the nucleophilic reactivity of other superoxide ions, which are originated, for example, from KO_2.

** The *g*-values for Co(II)TPP-O_2^- and the electrogenerated superoxide ion were measured at −196 °C in the absence of any substrates to be oxidized.[6]

† The transfer of the spin density from Co(II) to O_2 on complex formation is reported to be about 90% for Co(II)(acacen) and 100% for Co(II)(Schiff base)(base). Such oxygen complexes are formally described as Co(III)-O_2^-. The formal description can be also applied to the cobalt(II) protoporphyrin IX dimethyl ester (see Ref. 16).

A-Substituted 5β-Steroids. VIII. Synthesis and Bromination of 3-Alkyl-5β-cholestan-2-one

J. Yasuo SATOH, C. Akira HORIUCHI, and Akira HAGITANI

Department of Chemistry, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received April 26, 1977)

3α-Alkyl-5β-cholestan-2-one (R=CH_3, C_2H_5, and $CH_3CH_2CH_2$) was prepared by the direct alkylation of 5β-cholestan-2-one with alkyl iodide and potassium *t*-butoxide in a reflux of *t*-butyl alcohol-benzene. The 3α-benzyl ketone was prepared from 5β-cholestan-2-one by aldol condensation with benzaldehyde in the presence of potassium hydroxide, followed by hydrogenation of the condensation product. The bromination of these 3α-alkyl ketones gave 3β-bromo-3α-alkyl-5β-cholestan-2-ones.

The alkylation of the steroids which have an oxo group in ring A has been investigated.[1-4] In addition, the preparation and use of hydroxymethylene derivatives of 5β-stigmast-22-en-3-one[5] and pregn-4-ene-3,20-dione[6] have been described.

Recently, as a part of our studies on the A-substituted 5β-steroids, we reported the halogenation[7] of 5β-cholestan-2-one and some reactions[7] of their halo ketones. In the present paper, the direct alkylation of 5β-cholestan-2-one with alkyl iodide (RI; R=CH_3, C_2H_5, or $CH_3CH_2CH_2$) and potassium *t*-butoxide is described, together with the synthesis of α-benzyl ketone of 5β-cholestan-2-one. The bromination of these alkyl derivatives is also described.

Results and Discussion

The reaction of 5β-cholestan-2-one (**1**) with alkyl iodide (RI; R=CH_3, C_2H_5, and $CH_3CH_2CH_2$) and potassium *t*-butoxide yielded the corresponding alkylated ketones (**2a**, **2b**, and **2c**). Each alkylated ketone showed a weak negative Cotton effect in the CD spectrum compared with that of 5β-cholestan-2-one (**1**). Compound **2a** was identical with the hydrogenation product of a hydroxymethylene derivative (**4**), which was obtained by the condensation of 5β-cholestan-2-one with ethyl formate. To determine the position of the hydroxymethylene group in compound **4**, it was brominated with NBS and sodium acetate to yield 3β-bromo-5β-cholestan-2-one.[7] Thus compound **4** was confirmed to be 3-hydroxymethylene-5β-cholestan-2-one.

In order to determine the configuration of **2a** and **2b**, the synthesis of their epimers was attempted. Spencer *et al.*[8] reported that the methylation of the α-bromo ketone with zinc powder–methyl iodide in benzene–dimethyl sulfoxide (10 : 1) in a nitrogen atmosphere gave the α-methyl ketone which retained the configuration at the original site of the bromine. The reaction of 3β-bromo-5β-cholestan-2-one (**5**) with methyl iodide and with ethyl iodide in the presence of zinc powder according to the procedures described above by Spencer *et al.*[8] yielded compounds **6a** and **6b**, respectively. These products (**6a** and **6b**) were isomerized by treatment with concd sulfuric acid in ethanol to give the stable compounds **2a** and **2b**. The structures of the two compounds were confirmed to be 3β-methyl- (**6a**) and 3β-ethyl-5β-cholestan-2-one (**6b**). This was also supported by the CD spectra.

The reaction of 5β-cholestan-2-one (**1**) with benzaldehyde in the presence of base yielded benzylidene ketone (**11**). Hydrogenation of **11** gave a benzyl ketone (**2d**). By comparison with the CD spectra of 3α-alkyl ketones (**2a**, **2b**, and **2c**), the structure of the benzyl ketone (**2d**) was presumed to be 3α-benzyl-5β-cholestan-2-one (**2d**).

The bromination of the alkylated ketones (**2a**, **2b**, **2c**, and **2d**) gave the bromo derivative (**3a**, **3b**, **3c**, or **3d**).

On the basis of the CD, ORD, IR, and NMR spectral data for **3a**, **3b**, **3c**, and **3d**, the structures of these bromo derivatives were determined to be 3α-bromo-3α-alkyl-5β-cholestan-2-ones. This received support from the following evidence. The bromo derivatives (**3a**, **3b**, and **3d**) were reduced with sodium borohydride to give the bromohydrins (**7a**, **7b**, and **7d**), which were converted to the bromohydrin acetates (**8a**, **8b**, and **8d**). The NMR spectra of these bromohydrin acetates showed a quartet at δ 4.24 ppm (J=4.5 and 11.5 Hz) assignable to the 2α-H of an axial character. Therefore, **8a**, **8b**, and **8d** were presumed to be 2β-acetoxy-3β-bromo-3α-alkyl-5β-cholestane. By treating these bromohydrins with potassium hydroxide, the corresponding 3α-alkyl ketone (**2a**, **2b**, or **2d**) was obtained. From these results, a hydroxyl group and a bromine atom of the bromohydrins (**7a**, **7b**, and **7d**) were shown to be *cis*; this led to a 3β-bromo-3α-alkyl-2β-hydroxy-5β-cholestane structure for these bromohydrins.

It was found that the enolisation of the alkylated ketones (**2a** and **2b**) with 60% perchloric acid–acetic anhydride occurred in the direction of a carbon atom possessing an alkyl group, as shown by the NMR spectra. The bromination of the enolisation product (**10a**) of one (**2a**) of the alkylated ketones yielded the 3β-bromo-3α-methyl ketone (**3a**).

From these results, it is suggested that the enolisation of the alkylated ketone occurs at the C_2–C_3 position. The bromination of the 3α-alkyl ketone occurs at a carbon atom having an alkyl group, namely, the C_3β-bond, as has been reported for the bromination of the alkylated ketone.[2]

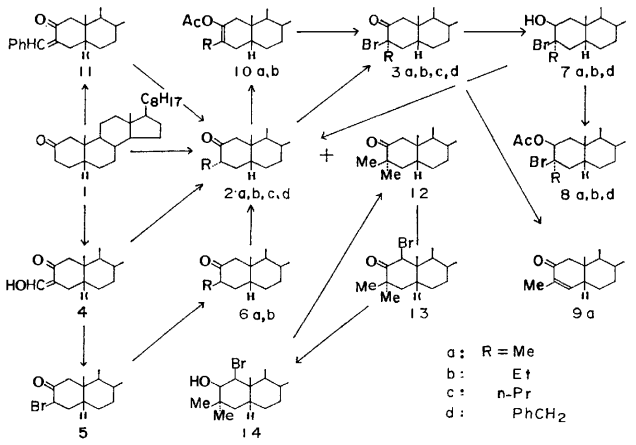
The reaction of 3β-bromo-3α-methyl ketone (**3a**) with lithium chloride gave the α,β-unsaturated ketone (**9a**), which showed absorptions at 1670 and 1632 cm^{-1} in its IR spectrum. It was determined to be 3-methyl-5β-cholest-3-en-2-one (**9a**) by means of its NMR spectrum, which showed a signal at δ 1.72 ppm due to the olefinic methyl proton. Hydrogenation of **9a** in the presence of 10% palladium charcoal gave the 3α-methyl ketone (**2a**). These facts indicate that the direct alkylation of 5β-cholestan-2-one occurs at the C_3 position.

The reaction of 5β-cholestan-2-one (**1**) with excess methyl iodide yielded the dimethylated ketone (**12**) and 3α-methyl ketone (**2a**).

The bromination product of the dimethylated ketone (**12**) was presumed to be 1β-bromo-3,3-dimethyl ketone (**13**) from the sign of the Cotton effect, the Δ[A]-, and the $\Delta\lambda_1$-values [+141 (+11,200) and +24 nm, as compared with the corresponding values for the dimethylated ketone (**12**)] in the ORD (CD) spectrum, the shift of the C=O stretching band (1703 cm^{-1}) in the IR spectrum, and from the signal (δ 4.29 ppm, singlet) due to the C_1HBr in the NMR spectrum. From these spectral data, it can be considered that the conformation in the A ring of **13** is a distorted form due to the 1 : 3-interaction between the C_1β–Br bond and the C_3β–Me bond.

The bromo ketone (**13**) was then converted to the dimethylated bromohydrin (**14**) by reduction with sodium borohydride, as described above. By treatment of **14** with potassium hydroxide in 2-propanol under reflexing conditions, the dimethylated ketone (**12**) was obtained. From these results, the dimethylated bromohydrin (**14**) was identified as 1β-bromo-2β-hydroxy-3,3-dimethyl-5β-cholestane.

Thus, on the basis of all of the foregoing results, it was concluded that the α-alkylation and the aldol condensation of 5β-cholestan-2-one (**1**) occur at the C_3 position, in contrast with the case of the enolisation and the halogenation of 5β-cholestan-2-one (**1**). It was further concluded that the enolisation of the alkylated ketone occurs in the direction of C_3, and that the bromination of these alkylated ketones forms the 3β-bromo-3α-alkyl ketones.



Experimental

All the melting points are uncorrected. The IR, ORD, and CD spectra were measured using a Hitachi model 215 grating infrared spectrophotometer and a model J-20 spectropolarimeter. The NMR spectra were measured in carbon tetrachloride, with TMS as the internal standard, using a nuclear magnetic resonance spectrometer, Hitachi-Perkin Elmer R-20A.

*3α-Methyl-5β-cholestan-2-one (**2a**)* A mixture of **1** (500 mg), methyl iodide (1.0 ml), and potassium *t*-butoxide (200 mg) in *t*-butyl alcohol-dry benzene (1 : 1) (10 ml) was refluxed under stirring in a nitrogen atmosphere for 2 h. The reaction was then removed under reduced pressure; the residue was poured into water and extracted with ether. The ethereal solution was washed with water, dried, and evaporated under reduced pressure. The resultant oil (510 mg) was chromatographed on silica gel (20 g). Elution with benzene–petroleum ether (1:5) (540 ml) gave plates of **2a** (55 mg), from methanol–acetone, mp 102.5—105.5 °C, IR (KBr): 1706 cm^{-1}; ORD (*c*, 0.980, Di) at 27 °C: $[\alpha]_D$ +36.7°, $[\alpha]_{400}$ +78.1°, $[\alpha]_{324}$ 0°, $[\alpha]_{316}$ −99.3° (trough), $[\alpha]_{311}$ 0°, $[\alpha]_{306}$ +49.0° (shoulder), $[\alpha]_{283}$ +410.7° (peak); CD (*c*, 0.980, Di) at 27 °C: $[\theta]_{311}$ −850° (shoulder), $[\theta]_{302}$ −1218° (trough), and $[\theta]_{294}$ −1019° (shoulder).

Found: C, 84.11; H, 11.84%. Calcd for $C_{28}H_{48}O$: C, 83.93; H, 12.08%.

The next fraction, eluted by the same solvent (360 ml) on crystallization from ethanol, gave plates of **1** (95 mg), mp 82—84.5 °C.

*3α-Ethyl-5β-cholestan-2-one (**2b**).* A mixture of **1** (3.0 g), potassium *t*-butoxide (3.02 g), and ethyl iodide (4.0 ml) in *t*-butyl alcohol-benzene was treated according to the procedure described for the methylation of **1**. After the usual work-up, the resultant oil was chromatographed on silica gel (100 g). Elution with hexane (800 ml) and hexane–benzene (10 : 1) (500 ml) gave plates of **2b** (601 mg) from ethanol, mp 92—93 °C, IR (KBr): 1706 cm^{-1}; ORD (*c*, 0.066, Di) at 20 °C: $[\alpha]_D$ +24.2°, $[\alpha]_{400}$ +54.5°, $[\alpha]_{335}$ +60.6°, $[\alpha]_{320}$ +24.2° (trough), and $[\alpha]_{292}$ +29.4° (peak); CD (*c*, 0.567, Di) at 19 °C: $[\theta]_{312}$ −453.6°, $[\theta]_{309}$ −434.3° (shoulder), $[\theta]_{304}$ −499.4° (trough), and $[\theta]_{275}$ +168.9° (peak).

Found: C, 84.14; H, 12.32%. Calcd for $C_{29}H_{50}O$: C, 83.99; H, 12.15%.

*3α-Propyl-5β-cholestan-2-one (**2c**).* A mixture of **1** (4.0 g), potassium *t*-butoxide (4.0 g), and propyl iodide (6.0 ml) in *t*-butyl alcohol-benzene (1 : 1) was treated according to the procedure described for the methylation of **1**. After the usual work-up, the resultant oil (4.1 g) was chromatographed on silica gel (100 g). Elution with hexane (1200 ml) gave plates of **2c** (282 mg) from ethanol–acetone, mp 74—74.5 °C, IR (KBr): 1706 cm^{-1}; ORD (*c*, 0.171, Di) at 21 °C: $[\alpha]_D$ +35.2°, $[\alpha]_{400}$ +117.3°, $[\alpha]_{328}$ +105.6° (trough), and $[\alpha]_{292}$ +263.9° (peak); CD (*c*, 0.572, Di) at 19 °C: $[\theta]_{310}$ −341.5°, $[\theta]_{303}$ −353.9° (trough), and $[\theta]_{273}$ +163.3° (peak).

Found: C, 84.34; H, 12.41%. Calcd for $C_{30}H_{52}O$: C, 84.04; H, 12.23%.

The next fraction was eluted with benzene (800 ml) and on crystallization from ethanol gave 5β-cholestan-2-one (**1**) (1.472 g), mp 86—88 °C.

*3-Hydroxymethylene-5β-cholestan-2-one (**4**).* The ketone (**1**) (753 mg) in dry benzene (10 ml) was treated with ethyl formate (763 mg) and sodium methoxide (131 mg) in a nitrogen atmosphere for 4 h at room temperature. The reaction mixture was then taken up in ether, and the ether extracts were washed with dilute hydrogen chloride and water, dried, and evaporated. The crystallization of the residue from methanol–ether gave plates of **4** (531 mg), mp 128—130 °C, IR (KBr): 1646 and 1593 cm^{-1}; UV (EtOH) λ_{max} 281 nm: (log 4.13).

Found: C, 80.88; H, 11.54%. Calcd for $C_{28}H_{46}O_2$: C, 81.10; H, 11.18%.

*3β-Methyl-5β-cholestan-2-one (**6a**).* The bromo ketone (**5**) (200 mg) in benzene–dimethyl sulfoxide (10 : 1) (11 ml) was stirred with zinc powder (500 mg) and methyl iodide (2.5 ml) in a nitrogen atmosphere at 40—45 °C for 4 h. After the usual work-up, the resultant oil (144 mg) was chromatographed on silica gel (30 g). Elution with hexane (100 ml) gave needles of **6a** (19 mg) from ethanol, mp 120—121 °C, IR (KBr): 1708 cm^{-1}; ORD (*c*, 0.6815, Di) at 22 °C: $[\alpha]_D$ −1.47°, $[\alpha]_{400}$ −5.87°, $[\alpha]_{320}$ −89.5° (trough), $[\alpha]_{312}$ −55.8°

(peak), $[\alpha]_{310}$ −60.2° (trough), and $[\alpha]_{274}$ +105.6° (peak); CD (*c*, 0.6815, Di) at 22 °C: $[\theta]_{316}$ −346.9° (shoulder), $[\theta]_{305}$ −570.3° (trough), $[\theta]_{301}$ −517.4° (peak), and $[\theta]_{296}$ −558.6° (trough).

Found: *m/e* 400.3718. Calcd for $C_{28}H_{48}O$: M, 400.6866.

The next fraction was eluted with hexane-benzene (1 : 1) (150 ml) and on crystallization from ethanol gave 5β-cholestan-2-one (**1**) (52 mg), mp 85—88 °C.

*3β-Ethyl-5β-cholestan-2-one (**6b**).* A mixture of **5** (320 mg), zinc powder (800 mg), and ethyl iodide (4.0 ml) in benzene-dimethyl sulfoxide (10 : 1) (17.6 ml) was treated according to the procedure described for the methylation of **5**. After the usual work-up, the resultant oil (295 mg) was chromatographed on silica gel (20 g). Elution with hexane-benzene (1 : 1) (250 ml) gave needles of **6b** (5 mg) from ethanol, mp 107—108 °C, IR (KBr): 1700 cm^{-1}; ORD (*c*, 0.336, Di) at 24 °C; $[\alpha]_D$ +68.4°, $[\alpha]_{400}$ +181.3°, $[\alpha]_{319}$ +633.2° (peak), $[\alpha]_{314}$ +591.6° (trough), $[\alpha]_{308}$ +633.2° (peak), $[\alpha]_{299}$ +401.3° (shoulder), and $[\alpha]_{273}$ +11.89° (trough); CD (*c*, 0.336, Di) at 24 °C: $[\theta]_{315}$ +1158.9° (shoulder), $[\theta]_{304}$ +2305.4° (peak), $[\theta]_{300}$ +2256.1° (trough), $[\theta]_{294}$ +2551.9° (peak), and $[\theta]_{287}$ +2157° (shoulder).

Found: *m/e* 414.3850. Calcd for $C_{29}H_{50}O$: M, 414.7134.

The next fraction was eluted with the same solvent (150 ml) and on crystallization from ethanol gave 5β-cholestan-2-one (**1**) (119 mg), mp 83—86 °C.

*Isomerization of 3β-Methyl- (**6a**) and 3β-Ethyl-5β-cholestan-2-one (**6b**).* 3β-Methyl (**6a**) and 3β-ethyl ketone (**6b**) (12 mg) in ethanol (10 ml) was treated with a few drops of concd sulfuric acid under refluxing for 2 h. After the usual work-up, crystallization from ethanol afforded plates of **2a** (7 mg) (mp 101—105 °C) and **2b** (5 mg) (mp 89—92 °C), respectively.

*Hydrogenation of 3-Hydroxymethylene-5β-cholestan-2-one (**4**).* The hydroxymethylene ketone (**4**) (200 mg) was hydrogenated in the usual method over 10% palladium charcoal in ethanol-ether (4 : 1) (25 ml). After the usual work-up, crystallization from ethanol afforded plates of **2a** (97 mg), mp 101—103 °C.

*3β-Bromo-5β-cholestan-2-one (**5**).* A mixture of **4** (100 mg), sodium acetate (132 mg) in acetic acid (0.12 ml), and *N*-bromosuccinimide (44.6 mg) in dioxane-water (10 : 1) (11 ml) was stirred overnight at room temperature. After the usual work-up, crystallization of the residue from ethanol gave plates of **5** (67 mg), mp 139—142 °C.

*3β-Bromo-3α-methyl-5β-cholestan-2-one (**3a**).* The methylated ketone (**2a**) (500 mg) in acetic acid (20 ml) was treated with bromine (219 mg) in acetic acid (1.5 ml) containing a few drops of 48% hydrobromic acid at room temperature for 15 min. The reaction mixture was taken up in ether, and the ethereal extracts were washed with a sodium hydrogencarbonate solution and water, dried, and evaporated. The crystallization of the residue from ethanol gave needles of **3a** (364 mg), mp 126—128 °C, IR (KBr): 1712 cm^{-1}; ORD (*c*, 0.794, Di) at 24 °C: $[\alpha]_D$ −94.4°, $[\alpha]_{400}$ −582.4°, $[\alpha]_{337}$ +3085° (trough), and $[\alpha]_{290}$ +3728° (peak); CD (*c*, 0.794, Di) at 24 °C: $[\theta]_{314}$ −25710° (trough).

Found: C, 69.47; H, 9.56%. Calcd for $C_{28}H_{47}OBr$: C, 70.11; H, 9.88%.

*3β-Bromo-3α-ethyl-5β-cholestan-2-one (**3b**).* The bromination of **2b** (50 mg) was carried out using the technique described for the synthesis of 3β-bromo-3α-methyl-5β-cholestan-2-one. After the usual work-up, the resultant oil, on crystallization from methanol, gave needles of **3b** (25 mg), mp 85—86 °C, IR (KBr): 1709 cm^{-1}; ORD (*c*, 0.220, Di) at 22 °C: $[\alpha]_D$ −43.1°, $[\alpha]_{400}$ −272.3°, $[\alpha]_{339}$ −1234° (trough), and $[\alpha]_{290}$ +1688° (peak); CD (*c*, 0.220, Di) at 22 °C: $[\theta]_{318}$ −11469° (trough) and $[\theta]_{290}$ +1688° (peak).

Found: C, 70.12; H, 10.33%. Calcd for $C_{29}H_{49}OBr$: C, 70.57; H, 10.01%.

*3β-Bromo-3α-propyl-5β-cholestan-2-one (**3c**).* The bromination of **2c** (290 mg) was carried out using the technique described for the synthesis of 3β-bromo-3α-methyl-5β-cholestan-2-one. After the usual work-up, the resultant oil, on crystallization from methanol-acetone, gave needles of **3c** (136 mg), mp 83—84 °C, IR (KBr): 1709 cm^{-1}; ORD (*c*, 0.287, Di) at 23 °C: $[\alpha]_D$ −65.4°, $[\alpha]_{400}$ −505.8°, $[\alpha]_{338}$ −2591.6° (trough), $[\alpha]_{318}$ 0°, and $[\alpha]_{289}$ +3261° (peak); CD (*c*, 0.287, Di) at 23 °C: $[\theta]_{318}$ −22753° (trough).

Found: C, 71.06; H, 10.21%. Calcd for $C_{30}H_{51}OBr$: C, 70.98; H, 10.13%.

*3-Benzylidene-5β-cholestan-2-one (**11**).* The ketone (**1**) (256 mg) in methanol (50 ml) was refluxed under stirring with benzaldehyde (7.8 ml) and sodium hydroxide (1.4 g) for 2.5 h. The reaction mixture was then removed under reduced pressure; the residue was poured into water, and extracted with ether. The ethereal solution was washed with sodium bisulfite solution and water, dried, and evaporated. The crystallization of the residue from methanol gave plates of **11** (270 mg), mp 140—141 °C, IR (KBr): 1675, 1587, and 1569 cm^{-1}.

Found: C, 86.04; H, 10.90%, Calcd for $C_{34}H_{50}O$: C, 86.02; H, 10.61%.

*3α-Benzyl-5β-cholestan-2-one (**2d**).* The benzylidene ketone (**11**) (2.10 g) was hydrogenated in the usual way over 10% palladium charcoal in ethanol-ether (10 : 1) (150 ml). After 4 h, the filtrate from catalyst was evaporated under reduced pressure. The crystallization of the residue from ethanol gave needles of **2d** (1.751 g), mp 134—135 °C, IR (KBr): 1709 and 1600 cm^{-1}; ORD (*c*, 0.381, Di) at 22 °C: $[\alpha]_D$ +99.7°, $[\alpha]_{400}$ +251.9°, $[\alpha]_{316}$ +426.4° (trough), and $[\alpha]_{284}$ +911.8° (peak); CD (*c*, 0.238, Di) at 21 °C: $[\theta]_{312}$ −800.7° (trough), $[\theta]_{308}$ −688.1° (peak), and $[\theta]_{303}$ −738.1° (trough).

Found: C, 85.96; H, 11.12%. Calcd for $C_{34}H_{52}O$: C, 85.65; H, 10.99%.

*3β-Bromo-3α-benzyl-5β-cholestan-2-one (**3d**).* A mixture of **2d** (959 mg), bromine (354 mg) in acetic acid (3.1 ml) containing a few drops of 48% hydrobromic acid, and acetic acid (40 ml) was allowed to react according to the procedure described for the synthesis of the 3β-bromo-3α-methyl ketone. After the usual work-up, the resultant oil, on crystallization from ethanol, gave needles of **3d** (604 mg), mp 109—111 °C, IR (KBr): 1712 cm^{-1}; ORD (*c*, 0.333, Di) at 22 °C: $[\alpha]_D$ +21.0°, $[\alpha]_{460}$ 0°, $[\alpha]_{400}$ −24.0°, $[\alpha]_{238}$ −1005.7° (trough), $[\alpha]_{321}$ 0°, and $[\alpha]_{290}$ +2176.5° (peak); CD (*c*, 0.333, Di) at 22 °C: $[\theta]_{318}$ −13212° (trough).

Found: C, 73.61; H, 9.30%. Calcd for $C_{34}H_{51}OBr$: C, 73.49; H, 9.25%.

*3-Methyl-5β-cholest-3-en-2-one (**9a**).* A mixture of **3a** (115 mg), lithium chloride (250 mg), and *N*,*N*-dimethylformamide (10 ml) was refluxed under stirring for 40 min. The reaction mixture was then taken up in ether, and the ether extracts were washed with dilute hydrochloric acid and water, dried, and evaporated. The crystallization of the residue from methanol-ether gave plates of **9a** (55 mg), mp 114—115.5 °C, IR (KBr): 1670 cm^{-1}; NMR (CCl_4) δ=6.18 (1H, m) and 1.72 (3H, m); ORD (*c*, 0.346, Di) at 30 °C: $[\alpha]_D$ −15.9°, $[\alpha]_{400}$ −216.8°, $[\alpha]_{373}$ −439.4° (trough), $[\alpha]_{367}$ −427.9° (peak), $[\alpha]_{358}$ −508.8° (trough), $[\alpha]_{346}$ −263.1° (peak), $[\alpha]_{343}$ −268.9° (trough), $[\alpha]_{335}$ 0°, $[\alpha]_{331}$ +57.8° (peak), $[\alpha]_{329}$ +52.0° (trough), $[\alpha]_{320}$ +196.6° (peak), $[\alpha]_{315}$ +161.9° (trough), $[\alpha]_{311}$ +170.6° (peak), $[\alpha]_{296}$ 0°, $[\alpha]_{255}$ −2205.9° (trough), $[\alpha]_{242}$ 0°, and $[\alpha]_{222}$ +5392.2° (peak); CD (*c*, 0.346,

Di) at 30 °C: $[\theta]_{347}$ −2091° (trough), $[\theta]_{342}$ −2054° (peak), $[\theta]_{335}$ −2529° (trough), $[\theta]_{328}$ −2054° (shoulder), $[\theta]_{280}$ −209.2° (peak), $[\theta]_{241}$ −14182° (trough), $[\theta]_{224}$ 0°, and $[\theta]_{214}$ +60168° (peak).

Found: C, 84.18; H, 11.86%. Calcd for $C_{28}H_{46}O$: C, 84.35; H, 11.63%.

*Hydrogenation of 3-Methyl-5β-cholest-3-en-2-one (**9a**).* A mixture of **9a** (50 mg), 10% palladium charcoal, and hydrogen in ethanol was treated according to the procedure described for the hydrogenation of **4**. After the usual work-up, the resultant oil, on crystallization from ethanol, gave plates of **2a** (19 mg), mp 101—103 °C.

*3,3-Dimethyl-5β-cholestan-2-one (**12**).* The ketone (**1**) (1.0 g) in *t*-butyl alcohol-dry benzene (1 : 1) (25 ml) was treated with methyl iodide (11.0 ml) and potassium *t*-butoxide (3.0 g) under refluxing in a nitrogen atmosphere for 6 h. After the usual work-up, the resultant oil (1.065 g) was chromatographed on silica gel (100 g). Elution with benzene-petroleum ether (1 : 5) (720 ml) gave plates of **12** (365 mg) from acetone, mp 100—101.5 °C, IR (KBr): 1706 cm^{-1}, ORD (*c*, 1.132, Di) at 22 °C: $[\alpha]_D$ +1.77°, $[\alpha]_{400}$ −53.5°, $[\alpha]_{319}$ −954.4° (trough), $[\alpha]_{311}$ −600.9° (peak), $[\alpha]_{309}$ −636.3° (trough), $[\alpha]_{303}$ 0°, and $[\alpha]_{275}$ +1113.4° (peak); CD (*c*, 1.132, Di) at 22 °C: $[\theta]_{313}$ −3870° (shoulder), $[\theta]_{303}$ −6289° (trough), $[\theta]_{298}$ −6047° (peak), and $[\theta]_{294}$ −6168° (trough).

Found: C, 84.53; H, 12.17%. Calcd for $C_{29}H_{50}O$: C, 83.99; H, 12.15%.

The next fraction, eluted with the same solvent (570 ml), on crystallization from methanol-acetone gave 3α-methyl-5β-cholestan-2-one (**2a**) (147 mg), mp 97—104 °C.

*1β-Bromo-3,3-dimethyl-5β-cholestan-2-one (**13**).* The bromination of **12** (300 mg) was carried out using the technique described for the synthesis of **3a**. After the usual work-up, the resultant oil, on crystallization from acetone, gave needles of **13** (200 mg), mp 138—141 °C, IR (KBr): 1703 cm^{-1}; NMR (CCl_4) δ=4.29 (1H, s); ORD (*c*, 0.365, Di) at 30 °C: $[\alpha]_D$ +30.1°, $[\alpha]_{400}$ +123.2°, $[\alpha]_{343}$ +533.8° (peak), $[\alpha]_{320}$ 0°, and $[\alpha]_{280}$ −588.5° (trough); CD (*c*, 0.365, Di) at 30 °C: $[\theta]_{321}$ +4906° (peak), $[\theta]_{317}$ +3746° (trough), $[\theta]_{312}$ +3836° (peak), and $[\theta]_{230}$ −3479° (trough).

Found: C, 70.38; H, 10.27%. Calcd for $C_{29}H_{49}OBr$: C, 70.57; H, 10.01%.

*The Enolisation of 3α-Methyl-5β-cholestan-2-one (**2a**).* This enolisation was treated according to the method of the enolisation described for 5β-cholestan-2-one.[7] The reaction product gave plates of 2-acetoxy-3-methyl-5β-cholest-2-ene (**10a**) from ethanol, mp 78—79 °C, IR (KBr): 1750 and 1739 cm^{-1}; NMR ($CDCl_3$) δ=2.11 (3H, s). A mixture of **10a** (20 mg), bromine (7.9 mg) in tetrachloromethane, and tetrachloromethane (10 ml) containing a few drops of epichlorohydrin was carried out according to the directions of Djerassi *et al.* described for 2-acetoxy-5α-cholest-2-ene.[9] After the usual work-up, the resultant oil, on crystallization from ethanol, gave needles of **3a** (15 mg), mp 126—128 °C.

*Confirmation of the Configuration of 3β-Bromo-3α-methyl-5β-cholestan-2-one (**3a**) by Using Chemical Reactions.* The bromo derivative (**3a**) (60 mg) in methanol-ether (1 : 2) (15 ml) was treated with sodium borohydride (20 mg) at room temperature. After 45 min, water was added and the mixture was extracted with ether. The ethereal solution was washed with water, dried, and evaporated under reduced pressure. Attempts to crystallize the resultant oil (**7a**) were unsuccessful, and the product was used for the next step without purification [IR (NaCl): 3444 cm^{-1}]. A mixture of the methyl bromohydrin (**7a**) (15 mg), acetic anhydride (3 ml), and pyridine (3 ml) was allowed to stand at room temperature overnight. After the usual work-up, attempts to crystallize the resultant oil (**8a**) were unsuccessful. The methylated bromohydrin (**7a**) (35 mg) in 2-propanol (5 ml) was treated with a solution of potassium hydroxide (20 mg) in the same solvent (3 ml), and the mixture was refluxed for 30 min. 2-Propanol was then removed under reduced pressure; the residue was diluted with water, and extracted with ether. The ethereal solution was washed with water, dried, and evaporated under reduced pressure. Crystallization of the residue from methanol gave plates of **2a** (13 mg), mp 101—104 °C.

*Confirmation of the Configuration of 1β-Bromo-3,3-dimethyl-5β-cholestan-2-one (**13**) by Using Chemical Reactions.* The dimethylated bromo ketone (**13**) (150 mg) in methanol-ether (1 : 2) (30 ml) was treated with sodium borohydride (50 mg) at room temperature. After the usual work-up, the resultant oil, on crystallization from ethanol-ether, gave needles of dimethylated bromohydrin (**14**) (97 mg), mp 118—119 °C, IR (KBr): 3575 cm^{-1}; NMR (CCl_4) δ=4.75 (1H, d, J=3.6 Hz). A mixture of **14** (57 mg) and potassium hydroxide (46 mg) in 2-propanol (10 ml) was allowed to react according to the procedure described for the synthesis of 3α-methyl ketone (**2a**) from 3-methyl bromohydrin (**7a**). After the usual work-up, the resultant oil, on crystallization from acetone, gave plates of **12** (17 mg), mp 100—101.5 °C.

The authors are indebted to Mr. Takashi Takakuwa, Applied Research Laboratory of the Japan Spectroscopic Co., Ltd., for the measurement of ORD and CD spectra, and to Mr. Isao Yoshino for collaboration in the experimental work. This research was supported in part by a Matsunaga Research Grant from the Matsunaga Science Foundation.

(Received May 4, 1977)

Appearance of *p*-dinitrobenzene anion radical has been demonstrated by visible and ESR spectroscopy in the replacement of the one nitro group of *p*-dinitrobenzene by hydroxide ion in aqueous dimethyl sulfoxide. The formation of the anion radical seems to be due to the direct electron transfer from hydroxide ion to *p*-dinitrobenzene. The results of kinetic studies suggest that the anion radical is a precursor in the substitution reaction.

It has been strongly postulated that an *o*-dinitrobenzene anion radical is a precursor in the substitution reaction of the one nitro group of *o*-dinitrobenzene (*o*-DNB) by hydroxide ion in aqueous dimethyl sulfoxide (DMSO).[1] The anion-radical precursor mechanism[2] essentially differs from the widely-accepted conventional one, in which the nucleophilic aromatic substitution should proceed only *via* the Meisenheimer-type intermediate.

In order to pursue the anion-radical precursor mechanism, the following investigations have been made on a similar substitution reaction of *p*-dinitrobenzene (*p*-DNB).[3] (1) Demonstration of the appearance of *p*-DNB$^{\cdot-}$ (the *p*-dinitrobenzene anion radical) by visible and ESR spectroscopy. (2) Discussion on the possibility of the direct electron-transfer from the nucleophilic reagent to *p*-DNB. (3) Kinetic studies for confirmation of the view that the anion radical is the precursor in the replacement of the one nitro group of *p*-DNB by hydroxide ion in aqueous DMSO. Comparison of the results with those for *o*-DNB is made.

Experimental

Commerical *p*-DNB was purified by recrystallization from benzene. DMSO was kept in contact with barium oxide for a week and fractionated twice under reduced pressure.

Unless otherwise stated, the mixing of degassed DMSO solutions of *p*-DNB with degassed DMSO solutions of sodium hydroxide was carried out in sealed cells for the measurements of electronic and ESR spectra. Before degassing, the cells in which the DMSO solutions had been placed were sealed by flame after blowing dry argon through the cells, since DMSO considerably takes up carbon dioxide. Unless argon is blown, the hydroxide ion in the DMSO solution placed in the cell is considerably consumed. Path lengths of 0.1—3 cm were available for the measurements of electronic spectra. Electronic-spectral changes were recorded with a Cary 14 recording spectrophotometer equipped with a thermostated cell compartment. ESR spectra were recorded with a Varian E-4 EPR spectrometer.

Results and Discussion

When a DMSO solution of *p*-DNB was mixed with an aqueous DMSO solution of sodium hydroxide, the resulting reaction system showed absorption spectral changes shown in Figs. 1 and 2. All the absorption curves in Fig. 1 are corrected for the absorption of DMSO, since DMSO absorbs above 700 nm.[1] The reaction system shows characteristic bands in the region

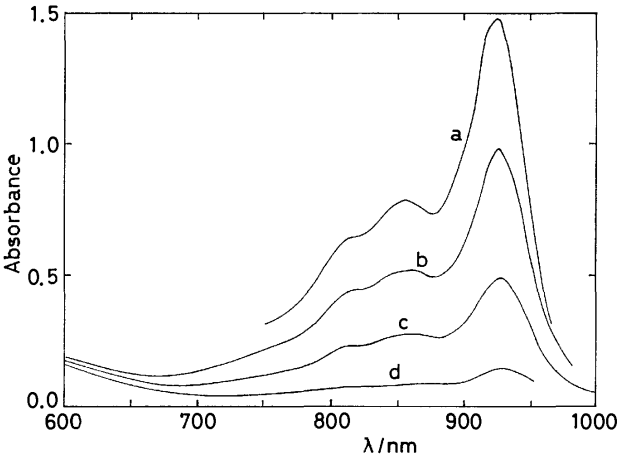

Fig. 1. Spectral change of the DMSO solution containing *p*-dinitrobenzene (3.34×10^{-4} M), sodium hydroxide (1.00×10^{-2} M), and 4%(v/v) water (25 °C). Starting time of scanning at 2.5 nm/s from longer wavelengths after mixing: a, 0.6 min; b, 2.4 min; c, 6 min; d, 11.4 min. Path length was 3.06 cm. All the curves are corrected for the absorption of DMSO.

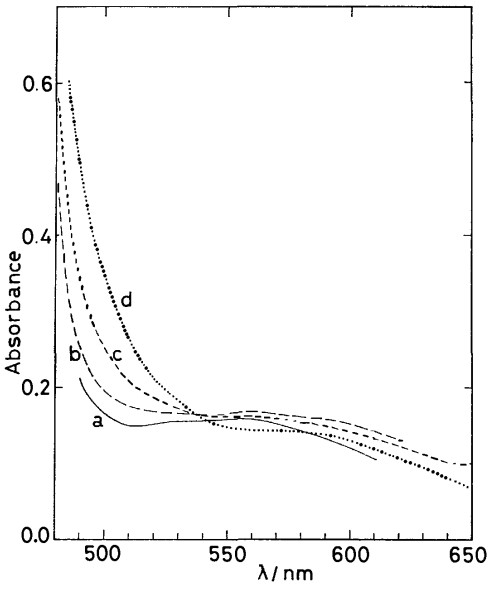

Fig. 2. Spectral change of the DMSO solution containing *p*-dinitrobenzene (3.42×10^{-4} M), sodium hydroxide (9.5×10^{-3} M), and 4%(v/v) water (25 °C). Starting time of scanning at 2.5 nm/s from longer wavelengths after mixing: a, 0.3 min; b, 1.3 min; c, 7.2 min; d, 60 min. Path length was 2.93 cm.

800—1000 nm and a weak band around 555 nm. The weak absorption shoulder is observed at *ca.* 580 nm in the final spectrum (curve d, Fig. 2). The shoulder is probably due to a small amount of a by-product. The bands in the region 800—1000 nm are similar to those of *p*-$DNB^{\cdot-}$ in a rigid solution in 2-methyltetrahydrofuran at 77 K,[4] and are assigned to *p*-$DNB^{\cdot-}$. The weak band around 555 nm is assumed to be the weak 475 nm band of *p*-$DNB^{\cdot-}$ in the rigid solution.[4] This was justified by calculating the absorption coefficient change at 560 nm. According to Shida and Iwata,[4] *p*-$DNB^{\cdot-}$ shows an intense band with vibrational structure in the range 380—430 nm. We were unsuccessful in scanning the spectral change in the range 400—500 nm when the reaction system was degassed, since an intense band rapidly developed at 430 nm. In the case of a similar reaction system open to the air, the initial band with a vibrational structure was observed at *ca.* 440 nm at 32 ms after mixing with a Hitachi rapid scan spectrophotometer RSP-2.[3] The time dependence of absorption-coefficient at 930, 560, and 430 nm is shown in Figs. 3 and 4. Curve b in Fig. 3 indicates that the entire absorption at 430 nm is not due to one species, since the increase in the coefficient slows down at *ca.* 1 min after mixing. We thus infer that the band assigned to *p*-$DNB^{\cdot-}$ initially appears in the range 400—500 nm.

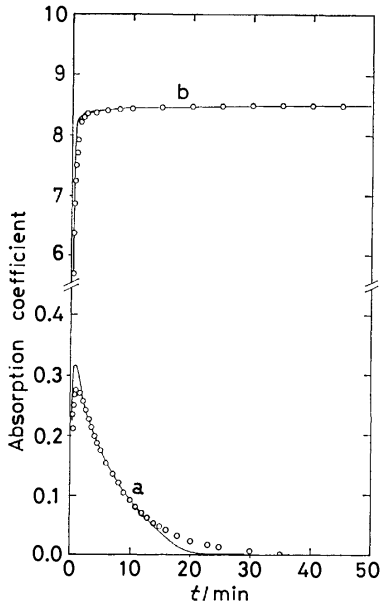

Fig. 3. Time courses (full lines) of absorption coefficient of the same solution as in Fig. 1 (25.0 °C). a, 930 nm; b, 430 nm. Circles show the values calculated according to Eqs. 1—4.

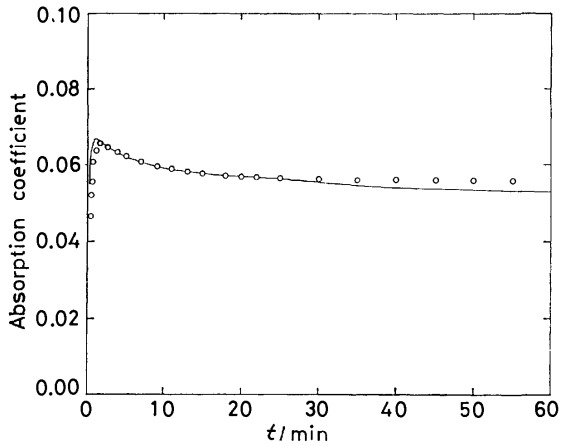

Fig. 4. Time course (full line) of 560-nm absorption coefficient of the same solution as in Fig. 1 (25.0 °C). Circles show the values calculated according to Eqs. 2 and 4.

The reaction system finally showed the 430 nm band identical with that of a similar solution of *p*-nitrophenol in the peak position and shape. A yellow substance was obtained by evaporating the solvent from the final reaction system under reduced pressure at *ca.* 60 °C. Treatment of the substance with aqueous hydrochloric acid gave *p*-nitrophenol. Thus, the final species showing the 430 nm band was identified as *p*-nitrophenoxide ion. The formation of *p*-nitrophenoxide ion in the reaction of *p*-DNB with hydroxide ion in aqueous DMSO open to the air has also been identified spectroscopically by Bowden and Cook.[5] The yield of *p*-nitrophenoxide ion based on spectroscopic estimation was over 90%. Thin-layer chromatography also showed *p*-nitrophenol as the major product. The production of nitrite ion was confirmed by the brown ring test.

The formation of the labile *p*-$DNB^{\cdot-}$ in the reaction system was confirmed by ESR spectroscopy. The generation of *p*-$DNB^{\cdot-}$ in a similar reaction system has been reported by Bilkis and Shein.[6] The reaction system under study showed a strong ESR signal. The hyperfine structure of the ESR spectrum (Fig. 5) is in line with that of the *p*-$DNB^{\cdot-}$ having two equivalent nitrogen atoms. The splitting constants, $a_N = 1.68$ and $a_H = 1.12$ G, agree with the reference values.[7] The time dependence of relative ESR-signal intensity of *p*-$DNB^{\cdot-}$ in the reaction system at *ca.* 24 °C resembles that of the absorption coefficient change at 930 nm in Fig. 3. No other radical species was found in the ESR spectrum of the reaction system. The result eliminates all the schemes in which other free radicals produced reversibly should live together for a length of time with *p*-$DNB^{\cdot-}$, and which do not give the pseudo-first order decomposition of *p*-$DNB^{\cdot-}$, because the decomposition of *p*-$DNB^{\cdot-}$ obeys the pseudo-first order kinetics.[1] Thus *p*-$DNB^{\cdot-}$ is not produced from a Meisenheimer-type complex.

The formation of *p*-$DNB^{\cdot-}$ in DMSO is not due to the electron transfer from methylsulfinylmethanide[8]

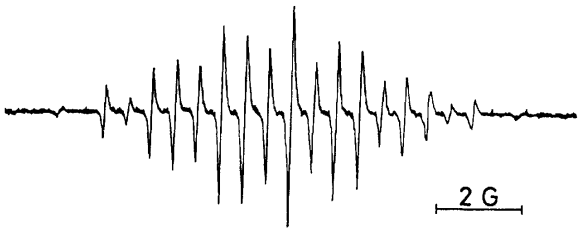

Fig. 5. ESR Spectrum of the same solution as in Fig. 1 (*ca.* 24 °C).

to *p*-DNB, since the mixture obtained by mixing an aqueous solution of sodium hydroxide with an *N,N*-dimethylformamide solution of *p*-DNB showed the same characteristic bands in the region 800—1000 nm as in Fig. 1.

The DMSO solution containing *p*-DNB (5.89×10^{-4} M), *p*-nitrophenol (2.56×10^{-3} M), sodium *p*-nitrophenoxide (1.25×10^{-3} M), and 4%(v/v) water showed no characteristic band in the region above 600 nm. The formation of *p*-$DNB^{\cdot-}$ is, therefore, not ascribed to electron transfer to *p*-DNB from the *p*-nitrophenol or *p*-nitrophenoxide ion produced by the conventional mechanism.

In a similar reaction system of *p*-DNB and hydroxide ion in aqueous DMSO solution, the production of the short-lived hydroxyl radical has been confirmed by Bilkis and Shein by means of spin-trapping with 2-nitroso-2-methylpropane.[6]

Thus, the formation of *p*-$DNB^{\cdot-}$ is probably due to the direct electron transfer from hydroxide ion to *p*-DNB. According to the electron transfer theory proposed by Nagakura and Tanaka,[9,10] nucleophilic aromatic substitution should proceed *via* the anion radical resulting from the one-electron transfer from the highest occupied orbital of a nucleophilic reagent to the lowest vacant orbital of an aromatic molecule. The energy level of the highest occupied orbital should be higher than that of the lowest vacant orbital. The lowest-vacant energy level of *p*-DNB can be estimated to be −6.14 eV from the values[11] of the lowest π-π^* transition energy (4.22 eV) and ionization potential (10.36 eV) of *p*-DNB. The energy level is sufficiently lower by 4.04 eV than the occupied energy level of OH^- (−2.1 eV[9]). The energy level difference of 4.04 eV would not be small in the DMSO solution owing to the poor solubility of OH^- in DMSO.[12] *p*-$DNB^{\cdot-}$ can be formed as a result of the direct electron transfer from hydroxide ion to *p*-DNB.

The plot of logarithmic absorption coefficient ($\log a$) at 930 nm *vs.* time *t* is shown in Fig. 6. We see that the decomposition of *p*-$DNB^{\cdot-}$ obeys the pseudo-first order kinetics from 2.5 min. The absorption coefficient

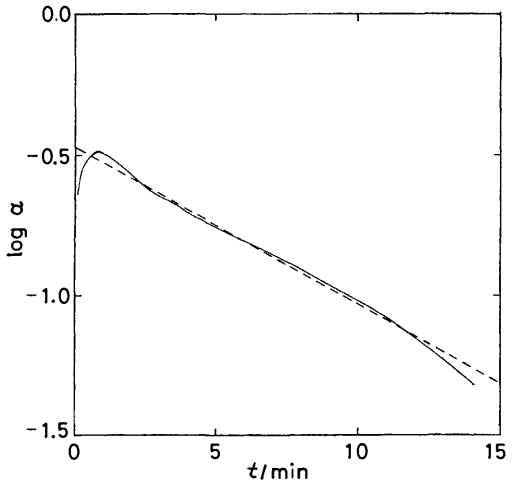

Fig. 6. Plot of logarithmic 930-nm absorption coefficient *vs.* time for curve a in Fig. 3.

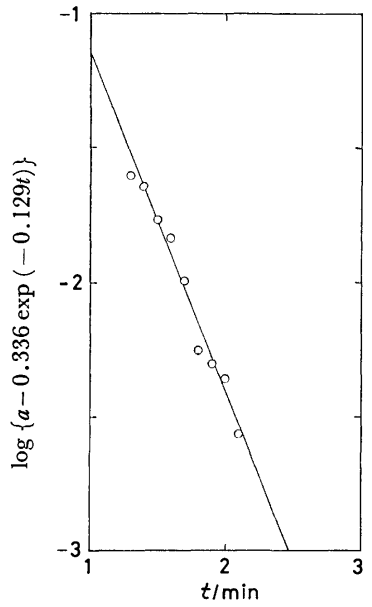

Fig. 7. Plot of $\log\{a-0.336\times\exp(-0.129t)\}$ *vs.* time. Here the values of *a* are those of curve a in Fig. 3.

is expressed by $0.336\times\exp(-0.129t)$ from 2.5 min. From 0.5 min to 2.5 min the $\log a$ values lie over a straight line, though all the $\log a$ values lie on or below the corresponding line in the case of *o*-DNB.[1] This indicates that at the initial stage the decomposition of *p*-$DNB^{\cdot-}$ consists of two kinds of parallel reactions. One of the reactions is probably the same as that where *o*-$DNB^{\cdot-}$ decomposes through the whole reaction course.[1] The degree of the overlying of $\log a$ (Fig. 6) varies to some extent in each measurement. Thus the other reaction, apparently observed at the initial stage, is very sensitive to the experimental conditions. As shown in Fig. 7, the plot of $\log\{a-0.336\times\exp(-0.129t)\}$ *vs.* *t* is linear. This indicates that the reaction of *p*-$DNB^{\cdot-}$ is of the pseudo-first order. The other may therefore be the rapid reaction of *p*-$DNB^{\cdot-}$ with a slight amount of the unknown intermediate appearing in a steady state at the initial stage.

We denote the initial concentrations of *p*-DNB and sodium hydroxide by $[p\text{-DNB}]_0$ and $[NaOH]_0$, respectively. Figure 8 shows that the decomposition of *p*-$DNB^{\cdot-}$ is relatively fast and of the first order in the case of $[NaOH]_0/[p\text{-DNB}]_0\geq3$, and that the decomposition is extremely slow in the case of $[NaOH]_0/[p\text{-DNB}]_0<3$. The slow decomposition is not due to the irradiation of the 930 nm light, since the decomposition proceeded in the absence of the light. It is indicated that the fast decomposition of *p*-$DNB^{\cdot-}$ requires hydroxide ion, and that the conditions of $[NaOH]_0\geq3[p\text{-DNB}]_0$ are necessary for the production of *p*-nitrophenoxide ion. Thus, the present reaction does not proceed by the $S_{RN}1$ mechanism,[13,14] which is characterized by the unimolecular decomposition of the anion radical. The hydroxide ion equivalent to $[p\text{-DNB}]_0$ will be consumed for ionizing *p*-nitrophenol, because *p*-nitrophenol scarcely dissociates in the DMSO solution containing 4%(v/v) water in the absence of sodium hydroxide. Thus, in analogy with the case of *o*-DNB,[1] the two

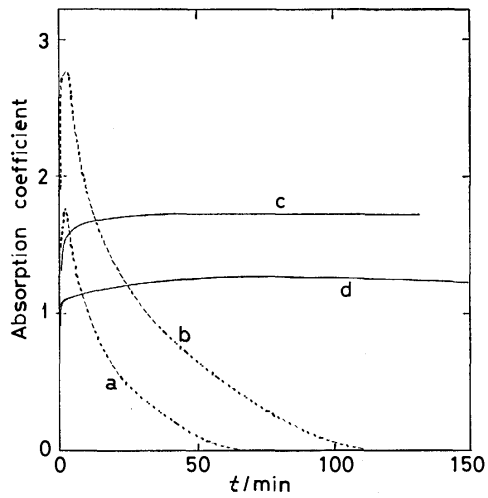

Fig. 8. Time courses of 930-nm absorption coefficient of the following DMSO solution containing 4% (v/v) water (25.0 °C).

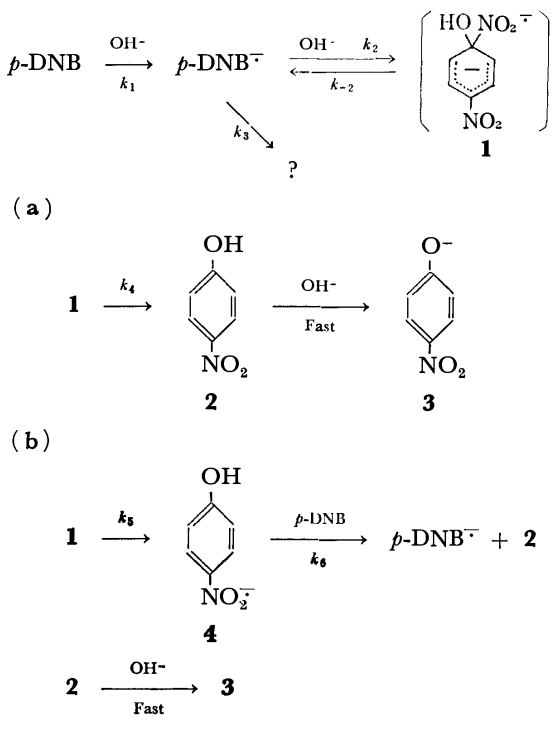
	[*p*-DNB]$_0$ $\times 10^3$, M	[NaOH]$_0$ $\times 10^2$, M	[NaOH]$_0$/[*p*-DNB]$_0$
a	2.47	1.00	4.05
b	3.34	1.00	2.99
c	3.36	0.69	2.1
d	3.34	0.33	1.0

possible schemes for the present reaction may be written as shown in Scheme 1 where k_i denotes the rate constant for the ith step, and both k_1 and k_2 contain [NaOH]$_0$. Of course, k_3 is of the pseudo-first order and is negligible after 2.5 min. Since no band of intermediates other than that of *p*-DNB$^{\cdot-}$ is found in Figs. 1 and 2, we make the steady state treatment for the concentrations of **1** and **4**.

According to Scheme 1(a), the absorption coefficient



Scheme 1.

changes at 930 and 430 nm with time are expressed below under the conditions of [*p*-DNB]$_0 \ll$ [NaOH]$_0$.

$t<2.5$ min:

$$a(930\text{ nm}) = \frac{k_1\varepsilon_R[p\text{-DNB}]_0}{k_1-k_2'-k_3} \times [\exp\{-(k_2'+k_3)t\} - \exp(-k_1t)] \quad (1)$$

$$a(430\text{ nm}) = \frac{k_2'\varepsilon_3[p\text{-DNB}]_0}{k_2'+k_3} - \frac{k_1[p\text{-DNB}]_0}{k_1-k_2'-k_3} \times \left(\frac{k_2'\varepsilon_3}{k_2'+k_3}-\varepsilon_R'\right)\exp\{-(k_2'+k_3)t\} - \frac{[p\text{-DNB}]_0}{k_1-k_2'-k_3} \times (k_1\varepsilon_R'-k_2'\varepsilon_3) \times \exp(-k_1t) \quad (2)$$

$t\geq 2.5$ min:

$$a(930\text{ nm}) = \frac{k_1\varepsilon_R[p\text{-DNB}]_0}{k_1-k_2'} \times \exp(-k_2't) \quad (3)$$

$$a(430\text{ nm}) = \varepsilon_3[p\text{-DNB}]_0 - \frac{k_1[p\text{-DNB}]_0}{k_1-k_2'} \times (\varepsilon_3-\varepsilon_R') \times \exp(-k_2't) \quad (4)$$

Here $k_2'=k_2k_4/(k_{-2}+k_4)$, and ε_R and ε_3 are molar absorption coefficients of *p*-DNB$^{\cdot-}$ and **3**, respectively. Equations 3 and 4 are similar to the corresponding equations for the case of *o*-DNB,[1] in which the terms including $\exp(-k_1t)$ are neglected. The values calculated according to Eqs. 1—4 are plotted in Fig. 3 by assuming the following values; $k_1=2.88$ min^{-1}, $k_2'=0.129$ min^{-1}, $k_3=0.002$ min^{-1}, $\varepsilon_R(930\text{ nm})=9.61\times10^2$, $\varepsilon_R'(430\text{ nm})=2.49\times10^4$, and $\varepsilon_3(430\text{ nm})=2.54\times10^4$. As compared with the corresponding rate constants of $k_1=0.638$ min^{-1} and $k_2'=0.0519$ min^{-1} for the case of *o*-DNB,[1] *p*-DNB$^{\cdot-}$ has formation and decomposition rates greater than those of *o*-DNB$^{\cdot-}$.

Equations 2 and 4 can be applied to the absorption coefficient change at 560 nm. The result obtained by assuming $\varepsilon_R''(560\text{ nm})=205$ and $\varepsilon_3'(560\text{ nm})=168$ is shown in Fig. 4. Figures 3 and 4 show that the calculated values of absorption coefficients at 930, 560, and 430 nm fairly agree with those observed. The value of $\varepsilon_R'(430\text{ nm})$ is considerably larger than that (*ca.* 1.6×10^4) of the 420 nm band of *p*-DNB$^{\cdot-}$ in the rigid solution at 77 K.[4] The value of $\varepsilon_3(430\text{ nm})$ is smaller than that of 3.17×10^4 for *p*-nitrophenoxide ion in a similar solution. This difference seems to be due mainly to the initial rapid reaction of *p*-DNB$^{\cdot-}$. The value of 3.34×10^{-4} M is calculated for the maximum concentration of *p*-DNB$^{\cdot-}$ by dividing the observed maximum absorption coefficient (0.321) at 930 nm (Fig. 3) by $\varepsilon_R(930\text{ nm})=9.61\times10^2$. The calculation shows that *p*-DNB was almost converted into *p*-DNB$^{\cdot-}$ within 0.7 min. The anion radical is, therefore, probably formed in the main reaction path.

The relation of $k_1=22.3\ k_2'$ and $k_2'=64.5\ k_3$ is obtained from the values assumed above for the case of Scheme 1(a). Under the conditions $k_1\gg k_2'\gg k_3$, Scheme 1(b) gives approximate expressions similar to those to which Eqs. 1—4 can be reduced. Accordingly, Scheme 1(b) is also possible in addition to Scheme 1(a). The mechanisms including the reaction to re-

produce *p*-DNB instead of the reaction step denoted by k_3 in Scheme 1 are also considered. Under the conditions $k_1 \gg k_2' \gg k_3$, however, the mechanisms give approximate expressions which cannot explain the appearance of the initial overlying of $\log a$ and are probably impossible. In conclusion, the kinetic results strongly suggest that *p*-$DNB^{\cdot-}$ is the precursor in the reaction, though we do not know which to select, Scheme 1 (a) or (b).

From the studies on the photosubstitution of 3,5-dinitroanisole[15,16] and on the reaction between DMSO and hydroxyl radical[17] the generation of *p*-$DNB^{\cdot-}$ may be accounted for by the following mechanism as in the case of *o*-$DNB^{\cdot-}$:[1]

$$p\text{-DNB} + OH^- \rightleftharpoons \underset{\mathbf{5}}{[p\text{-}DNB^{\cdot-}\cdots\dot{O}H]}$$

$$\mathbf{5} + CH_3SOCH_3 \longrightarrow p\text{-}DNB^{\cdot-} + \dot{C}H_3 + CH_3S(=O)\text{-}OH$$

The reaction between **5** and DMSO may be extremely rapid, because the rate constant for the reaction of hydroxyl radical with DMSO in aqueous solution is 5×10^9 $M^{-1}\,s^{-1}$ at 25 °C.[17] The methyl radical would undergo a rapid reaction. Thus, only *p*-$DNB^{\cdot-}$ may survive in the present reaction system. The production of short-lived hydroxyl radical[6] supports the formation of **5**.

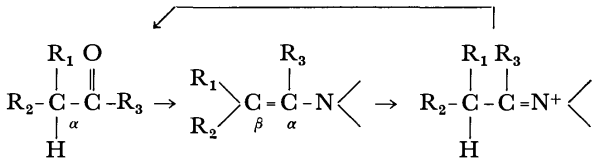
(Received May 6, 1977)

Optical activation of 2-phenylpropionaldehyde (PPA) *via* enamines using L-proline derivatives as amine components was studied. *S*(+)-PPA was obtained when *R*(−)-2-methylpyrrolidine and *S*(−)-2-ethoxycarbonylpyrrolidine were used, while *R*(−)-PPA was obtained when *S*(−)-prolinamide, *N*-(L-prolyl)pyrrolidine, *N*-(L-prolyl)piperidine, *S*(+)-2-(1-pyrrolidinylmethyl)pyrrolidine, and *S*(+)-2-(piperidinomethyl)pyrrolidine were used. This suggests that there are two mechanisms for optical activation.

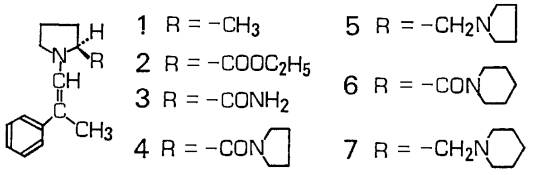
The syntheses of optically active carbonyl compounds have been studied by many workers.[1] The optical activation *via* enamines has been studied in our laboratories.[2-4] Formation of an enamine causes deprotonation from the α-carbon of a racemic α-substituted carbonyl compound, the transformation of the enamine into the iminium salt causing protonation at the carbon. In an asymmetrical circumstance, it is possible that stereospecific protonation to the enamine takes place in the formation of the salt.



Carbonyl compound Enamine Iminium salt

In the case of optical activation of 2-methylcyclohexanone *via* optically active 2-methylpiperidine enamine, the chirality of the ketone obtained is determined by the stability of the iminium salt. The stability was affected by an interaction between the substituent in amine component and the residue of the enamine.

We have extended the study to the optical activation of PPA *via* enamine using amines derived from L-proline without inversion at the asymmetric carbon, and found that the chirality of the PPA obtained *via* enamines, **3**—**7** is *R*, and that *via* enamines, **1** and **2**, is *S*. This suggests that two reactions may participate in the induction of optical activity.



Experimental

Optical rotations were determined with a JASCO Digital Automatic Polarimeter Model DIP 181. Gas chromatographic analyses were carried out using a 2 m column of 20% Carbowax 20 M on Chromosorb W and of 20% SE-30 on Chromosorb W with a Hitachi Gas Chromatograph Model K53. Nuclear magnetic resonance spectra were measured with a JNM-PS-100 Spectrometer using tetramethylsilane or sodium 2,2-dimethyl-2-silapentane-5-sulfonate as an internal standard. Chemical shifts are given in δ values. Infrared spectra were obtained with a JASCO Model IR-G and mass spectra with a Hitachi GC-MS RM-50 (column: 10% SE-30 on Chromosorb W, 3 mm × 1 m).

Preparation of Amines. *S(−)-2-Ethoxycarbonylpyrrolidine*: Esterification of L-proline was carried out in the usual way.

S(−)-Prolinamide: A solution of *N*-benzyloxycarbonyl-L-proline (37.7 g, 0.15 mol) and triethylamine (15.3 g, 0.15 mol) in chloroform was cooled in an ice bath. Ethyl chloroformate (16.4 g, 0.15 mol) was added to the solution at 5—10 °C during a period of 10 min with stirring, the reaction being continued at 5—10 °C for 30 min. Aqueous ammonia (28 %, 40 ml) was then added dropwise to the reaction mixture with vigorous stirring under cooling. The pasty reaction mixture was stirred at 5—10 °C for 1 h. After removal of the aqueous layer, the chloroform layer was washed with an aqueous $NaHCO_3$ solution (5%) and water, and dried over Na_2SO_4. Chloroform was removed *in vacuo*, the residual oil (37.2 g) being crystallized from ethyl acetate. Recrystallization from ethyl acetate gave 29.4 g (78.4%) of *N*-benzyloxycarbonyl-L-prolinamide as mp 91—93.5 °C. IR (Nujol) 3180, 3370, 1670 cm^{-1}; NMR ($CDCl_3$) δ=7.36 (5H, s), 5.9—6.3 (2H, broad), 5.18 (2H, s) 4.2—4.44 (1H, broad), 3.4—3.7 (2H, broad), 1.7—2.4 (4H, m); $[\alpha]_D^{23}$ −34.0° (*c*=2.2, EtOH).

Hydrogenolysis of *N*-benzyloxycarbonyl-L-prolinamide (29.4 g) in ethanol was carried out with 5% Pd-C (1.8 g) in an atmosphere of hydrogen, L-prolinamide (5.7 g, 42.2%) being obtained as very fine white needles. Mp 104.0 °C; IR (Nujol) 3390, 3200, 1645 cm^{-1}; NMR (D_2O) δ=3.8 (1H, t), 3.0 (2H, t), 1.6—2.4 (4H, m); MS 114 (M^+), 70 (base), 43, 44; $[\alpha]_D^{23}$ −106.9° (*c*=0.90, EtOH).

N-(L-Prolyl)pyrrolidine: This was prepared according to the method reported by Otani and Yamada.[5]

S(+)-2-(1-Pyrrolidinylmethyl)pyrrolidine: This was prepared according to the method reported by Sone *et al.*[6]

N-(L-Prolyl)piperidine: The method employed was virtually identical with that for *N*-(L-prolyl)pyrrolidine except that pyrrolidine was replaced by piperidine. *N*-benzyloxycarbonyl-L-proline (43.8 g) gave *N*-(benzyloxycarbonyl-L-prolyl)-piperidine (19.0 g) as white needles from ether-ethyl acetate (4 : 1). Yield 34.3%; mp 93.5—94.5 °C; IR (Nujol) 1635 cm^{-1}; NMR ($CDCl_3$) δ=7.20 (5H), 4.75 (1H, t), 3.2—3.8 (6H, broad), 1.2—2.4 (10H, broad); $[\alpha]_D^{23}$ −14.5° (*c*=1.0, benzene).

Hydrogenolysis of *N*-(benzyloxycarbonyl-L-prolyl)piperi-

dine (18.8 g) in ethanol was carried out with 5% Pd-C (1.0 g) in an atmosphere of hydrogen, *N*-(L-prolyl)piperidine (8.0 g, 74%) being obtained. Bp 128 °C (2 mmHg); IR 3450, 1635 cm^{-1}; NMR ($CDCl_3$) δ=3.9 (1H, t), 3.4—3.7 (4H, broad), 3.06 (1H, s), 2.7—3.3 (2H, m), 1.3—2.4 (10H, broad); $[\alpha]_D^{23}$ −65.1° (c=2.0, benzene).

S(+)-2-(Piperidinomethyl)pyrrolidine: The method used here was virtually identical with that described for *S*(+)-2-(1-pyrrolidinylmethyl)pyrrolidine except that pyrrolidine was replaced by piperidine. Bp 72.0 °C (1.5 mmHg); IR 3300 cm^{-1}; NMR ($CDCl_3$) δ=1.2—2.0 (10H, broad), 2.2—2.7 (7H, broad), 2.7—3.2 (2H, m), 3.4 (1H, s); $[\alpha]_D^{23}$ +1.58° (c=2.2, benzene).

R*(−)-2-Methylpiperidine*: *dl*-2-Methylpiperidine (99 g) was treated with *d*-10-camphorsulfonic acid (125 g) in benzene. Recrystallization of the resulting salt was repeated seven times. The free base was isolated from the salt by the general method. Yield 4.1 g; bp 116—120 °C; $[\alpha]_D^{23}$ −16.4° (c=1.1, hexane).

Preparation of Enamines. Enamines were prepared by the usual azeotropic procedure using benzene as the solvent.

2: IR 1665 cm^{-1} ($\nu_{C=C}$); NMR ($CDCl_3$) mixture of two geometrical isomers in a 22 : 5 ratio at room temperature; major isomer δ=2.09 (C=C–CH_3, s), 6.30 (N–CH=C, s), minor isomer δ=1.96 (C=C–CH_3, s), 6.00 (N–CH=C, s); $[\alpha]_D^{23}$ +0.34° (c=33, benzene).

3: This could not be distilled because of its high boiling point and viscosity. Analysis was carried out using GC-MS. *m/e* 186, 125 (base), 117, 105, 97, 77, 70; $[\alpha]_D^{23}$ +24° (calculated for 100% yield).

4: Bp 175 °C (1.5 mmHg); IR 1638 cm^{-1} ($\nu_{C=C}$); NMR ($CDCl_3$) mixture of two geometrical isomers in a 25 : 7 ratio at room temperature; major isomer δ=2.15 (C=C–CH_3, s), 6.42 (N–CH=C, s), minor isomer δ=2.01 (C=C–CH_3, s), 6.13 (N–CH=C, s).

5: Bp 154 °C (3 mmHg); IR 1630 cm^{-1} ($\nu_{C=C}$); NMR ($CDCl_3$) mixture of two geometrical isomers in a 4 : 1 ratio at room temperature; major isomer δ=2.13 (C=C–CH_3, s), 6.55 (N–CH=C, s), minor isomer δ=2.05 (C=C–CH_3, s), 6.21 (N–CH=C, s); $[\alpha]_D^{23}$ +326.4° (c=1.0, benzene).

6: Bp 189 °C (2 mmHg); IR 1640 cm^{-1} ($\nu_{C=C}$); NMR ($CDCl_3$) mixture of two geometrical isomers in a 16 : 7 ratio at room temperature; major isomer δ=2.12 (C=C–CH_3, s), 6.34 (N–CH=C, s), minor isomer δ=2.00 (C=C–CH_3, s), 6.05 (N–CH=C, s); $[\alpha]_D^{23}$ −2.3° (c=9.0, benzene)

7: Bp 139 °C (1.5 mmHg); IR 1630 cm^{-1} ($\nu_{C=C}$); NMR ($CDCl_3$) mixture of two geometrical isomers in a 39 : 7 ratio at room temperature; major isomer δ=2.12 (C=C–CH_3, s), 6.54 (N–CH=C, s), minor isomer δ=2.03 (C=C–CH_3, s), 6.18 (N–CH=C, s); $[\alpha]_D^{23}$ +265.2° (c=1.7, benzene).

8: Physical data except for specific rotation were reported.[3] $[\alpha]_D^{23}$ −400° (neat).

Hydrolysis of Enamines. *Procedure A*: An equivalent aqueous HCl was added to a benzene solution of enamine in an ice bath with vigorous stirring for 30 min. The aqueous layer was removed and the benzene layer was washed with water several times, dried over Na_2SO_4 and the optical rotation was measured. The concentration of the solution was determined gas-chromatographically.

Procedure B: Dry HCl gas was bubbled into the anhydrous benzene solution of enamines to give the salts. The solution was heated up to 50 °C immediately and the temperature was maintained at 50—60 °C for 30 min. Water was added to the solution with vigorous stirring at 0 °C. Subsequent procedure was identical to that described above.

Oxidation of PPA. *R*(+)-2-Methylpiperidine enamine[3] of PPA (14.6 g) was hydrolyzed by procedure A, optically active PPA (7.06 g, 77.6%) being obtained. $[\alpha]_D^{23}$ +8.58° (c=8.8, benzene). The aldehyde was suspended in water (10 ml), and aqueous $KMnO_4$ (4.5 g in 100 ml) was added dropwise to the suspension.

The precipitated MnO_2 was filtered off, and the aqueous solution was made basic with NaOH pellets. After being washed with ether to remove PPA, the aqueous layer was acidified with HCl, and extracted with $CHCl_3$. The chloroform layer was dried over Na_2SO_4, and concentrated.

The residual oil was distilled to yield 4.1 g (52%). $[\alpha]_D^{23}$ +1.97° (c=6.3, benzene). This was identified as 2-phenylpropionic acid by IR and NMR.

Results and Discussion

Determination of the Absolute Configuration of PPA. In order to elucidate the optical activation mechanism, it is necessary to know the relationship between the direction of optical rotation and the absolute configuration of PPA. The problem was solved by oxidation of (+)-PPA into (+)-2-phenylpropionic acid which is known to have *S*-configuration.

Optical Activation of PPA via *Chiral Enamines.* Enamines were hydrolyzed according to procedure A. The results of the optical activation of PPA *via* enamines of L-proline derivatives and of *R*(−)-2-methylpiperidine are given in Table 1. The direction of optical rotation of PPA obtained is seen to be dependent on the amine components of enamines. Enamines, **1**, **2**, and **8**,[3] gave *S*(+)-PPA. On the other hand, enamines **3**—**7** gave *R*(−)-PPA. The substituents of the amine components in **4**—**7** are bulkier than those of **1**, **2**, and **8**. However, the bulkiness does not seem to determine the chirality of PPA obtained, since the bulkiness of the substituent of the amine component in enamine **3** which gave the same *R*(−)-PPA as **4**—**7** is not so large as that of **2**. The electronic effect of CH_2–N< and CO–N< in the substituents of amine components probably controls the mechanism of the optical activation as well as their steric effect.

It was difficult to isolate the enamines **2**, **3**, and **6**, because their boiling points and viscosities are high and they are unstable at a high temperature. The result of the optical activation *via* **4** suggests that a certain racemization of the enamines takes place during the course of distillation. The extent of racemization was not estimated, so the data in Table 1 cannot be compared except for the directions of the optical rotation.

Mechanism of Optical Activation. Since all the amine components except for *R*(−)-2-methylpiperidine were derived from L-proline, enamines **1**—**7** and their salts seem to have the same stereochemical configuration as regards their asymmetric carbon adjacent to nitrogen atom. With respect to the stereochemistry, **8** and its salts are also identical with **1** and its salts. However, the direction of the optical rotation of PPA obtained from **1**, **2**, and **8** differs from that from **3**—**7**. This suggests that there are two optical activation mechanisms. In a previous paper,[4] the optical activation mechanism of 2-methylcyclohexanone *via* its optically active 2-methylpiperidine enamine was accounted for by the thermodynamical stability of the correspond-

Table 1. Optical activation of PPA *via* enamines

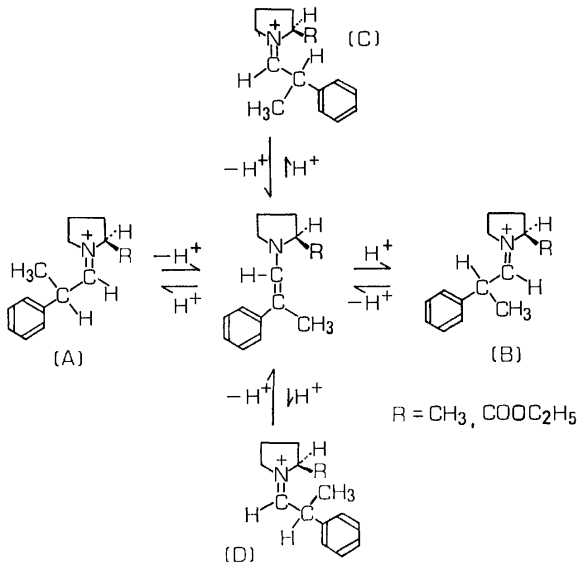
a) Enamines hydrolyzed according to procedure A. b) No enamine isolated.

ing iminium salt. The mechanism seems to apply to the optical activation of PPA *via* enamines, **1**, **2**, and **8**. As shown in Scheme 1, the iminium salts would exist as an equilibrium mixture of diastereomeric isomers. The enamine can be considered to be an intermediate of these isomers in the solution. Displacement of the balance in the interconversion reaction in favor of one diastereomeric isomer results in the optically active aldehyde. The thermodynamical stability of the iminium salt determines the direction of the optical rotation of the aldehyde. The existence of the isomers (C) and (D) in the solution seems to be inappreciable in consideration of the steric interaction between substituent *R* and the substituents attached to β-carbon atom using Stuart and Dreiding models.[3] The structure shown in Fig. 1 is considered to be the most stable iminium salt. In this case, *S*(+)-PPA can be obtained from the hydrolyzate of this salt.

On the other hand, the reaction which gave *R*(−)-



Scheme 1.

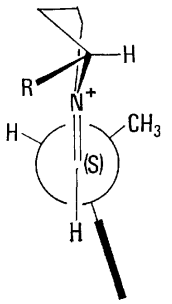


Fig. 1. The most stable structure of the iminium salt.

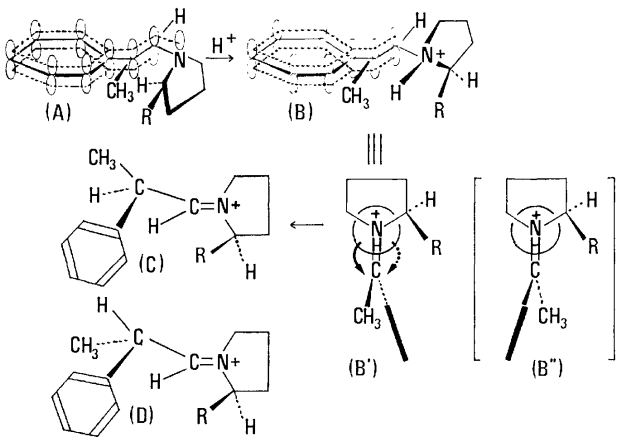

Fig. 2.

PPA is likely to proceed by a different mechanism from that mentioned above. This can be accounted for kinetically in the step of rearrangement from enammonium salt to iminium salt. It is known that protonation of enamines takes place on nitrogen and is followed by transfer of the proton to the β-carbon atom.[7] The electrostereochemical structures of the enamine and its salts are shown in Fig. 2. The enamine is characterized by the overlap of the nitrogen lone pair with the electrons of the double bond and the benzene ring

(Fig. 2(A)). The conversion from enamine into the corresponding enammonium salt implies the disappearance of the lone pair. Consequently, the amine moiety twists out of the coplanality of the olefinic group and the benzene ring (Fig. 2(B)). The geometrical isomer, structure (B″), would not exist because of the steric interaction between pyrrolidine ring moiety and C_β–CH_3. Thus, the predominant conformation of the enammonium salt would be structure (B′) in Fig. 2.

Rearrangement of the enammonium salt to the iminium salt implies the migration of the proton on the nitrogen atom to the β-carbon atom. The migration should take place following the path shown by the arrow(←) in Fig. 2-(B′) because the substituent **R** interferes in the migration in the opposite direction (←···). If hydrolysis of this iminium salt is rapid enough to neglect the contribution of the thermodynamical interconversion between C and D, it would predominantly give *R*(−)-PPA.

In the case of the methyl or ethoxycarbonyl group as a substituent of amine component, the thermodynamical equilibrium between the iminium salts is key step of the optical activation which gives *S*(+)-PPA.

On the other hand, when amine components have groups CH_2–N< or CO–N< as 2-substituents, the rearrangement from enammonium salt to iminium salt seems to be the key step of activation. The substituents probably stabilize the enammonium structure by the hydrogen bond between nitrogen or oxygen lone pair of these substituents and the *N*-coordinated hydrogen atom.

The isolation of the enammonium salt and its easy rearrangement to the corresponding iminium salt by heating were reported.[8] Enamines **3** and **6** which gave *R*(−)-PPA by the hydrolysis procedure A, were hydrolyzed according to procedure B. Application of heat before the addition of water promotes the rearrangement, and the thermodynamical equilibrium of the resulting iminium salts is reached. The results are shown in Table 2. *S*(+)-PPA was obtained according to procedure B, which supports the optical activation mechanism mentioned above.

TABLE 2. OPTICAL ACTIVATION OF PPA *via* ENAMINES
(Hydrolysis by procedure B)

Amine component	Enamine	Obtained PPA($[\alpha]_D^{23}$)
 R=-$CONH_2$	**3**	+26.24 (c=0.2)
-CON<	**6**	+34.07 (c=3.1)
	**8**	+71.5 (c=20.8)

There are two optical activation mechanisms of PPA *via* enamines which can be applied to the optical activation of other α-substituted carbonyl compounds. It is necessary to control these two mechanisms in order to obtain the higher or desirable optically active compounds.

Regeneration to the Native Form of Hen Egg-White Lysozyme from Its Protected Derivatives

Saburo AIMOTO and Yasutsugu SHIMONISHI

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received May 11, 1977)

The following derivatives of hen egg-white lysozyme were prepared from native hen egg-white lysozyme, 2-chlorobenzyloxycarbonyl-lysozyme, *S*-(4-methylbenzyl)-reduced-lysozyme, and 2-chlorobenzyloxycarbonyl-*S*-(4-methylbenzyl)-reduced-lysozyme. Treatment of these derivatives with anhydrous liquid hydrogen fluoride for 90 min at 0 °C yielded fully active lysozyme with recoveries, in order, of 23, 12, and 7.4%. The properties of the lysozyme recovered were identical with those of native hen egg-white lysozyme, and crystals of this material were indistinguishable from those of native enzyme.

Previously we[1,2] reported the effect of treatment of hen egg-white lysozyme (HEL) with anhydrous liquid hydrogen fluoride (HF) under the usual conditions for peptide synthesis. We recovered fully active enzyme in a crystalline state from HF-solutions of the native and reduced forms of HEL. As a further step in our studies on the chemical synthesis of HEL, this paper describes the preparation of various protected derivatives of HEL from native HEL and the regeneration of active enzyme from them. The protected derivatives synthesized were similar to protected polypeptides covering the entire sequence of HEL, that must be synthesized to obtain the complete lysozyme molecule. Studies were made on the introduction of protecting groups into HEL using the reagents *t*-butoxycarbonyl azide (Boc-N_3), benzyl 2,5-dioxo-1-pyrrolidinyl carbonate (Z-ONSu) and its derivatives with the aromatic ring chlorinated for the amino groups of native HEL, and the reagents 4-methoxybenzyl and 4-methylbenzyl chlorides for the mercapto groups of reduced HEL. These reactions were performed to find suitable protected derivatives of HEL that could be regenerated to the original enzyme by treatment with HF under appropriate conditions for peptide synthesis. The results showed that 2-chlorobenzyloxycarbonyl and 4-methylbenzyl substituents are extremely suitable for protecting amino and mercapto groups, respectively, and that fully active enzyme can be regenerated from derivatives of HEL that are blocked with these protecting groups.

Materials and Methods

Hen egg-white lysozyme (6 × crystallized Lot. E5201 and spray-dried cells of *Micrococcus lysodeikticus* (Lot. No. 21-88-778) were purchased from Seikagaku Fine Biochemicals (Tokyo). Sephadex was purchased from Pharmacia Co. (Uppsala). Hydrogen fluoride was a product of Daikin Industrial Co. (Osaka). Urea of reagent grade was recrystallized from ethanol before use. Chlorinated benzoic acids of extra pure reagent grade were purchased from Nakarai Chemicals Ltd. (Kyoto). All other chemicals used were of analytical grade. Melting points were measured by the capillary method and are given as uncorrected values. HEL derivatives were hydrolyzed in 6 M hydrochloric acid with phenol in sealed tubes for 48 h at 105 °C, and amino acids in the hydrolysates were examined in a Hitachi KLA-5 analyzer by the method of Moore *et al.*[3] The abbreviations used in this text are those recommended by IUPAC-IUB: *J. Biol. Chem.*, **247**, 977 (1972).

Synthesis of Benzyl 2,5-Dioxo-1-pyrrolidinyl Carbonate(Z-ONSu). Benzyloxycarbonyl chloride (17.1 g, 100 mmol) and *N*-hydroxysuccinimide (11.5 g, 100 mmol) were dissolved in dioxane (200 ml). Pyridine (9.5 g, 120 mmol) was added dropwise to the solution at 8—10 °C with stirring, and then the mixture was stirred at room temperature for an hour. The mixture was concentrated *in vacuo*, and the residue was dissolved in ethyl acetate. The solution was washed with water and dried over anhydrous sodium sulfate. The dried solution was concentrated to a crystalline residue *in vacuo*, and the material was recrystallized from ethyl acetate and hexane; wt 16.0 g (64.3%); mp 79.5—81.5 °C.

Found: C, 57.74; H, 4.55; N, 5.80%. Calcd for $C_{12}H_{11}O_5N$: C, 57.83; H, 4.45; N, 5.62%.

Synthesis of Benzyl 2,5-Dioxo-1-pyrrolidinyl Carbonate with the Aromatic Ring Chlorinated. 2-Chlorobenzoic acid was reduced with $LiAlH_4$ in dried ether to give the corresponding alcohol, 2-chlorobenzyl alcohol, in about 90% yield. This 2-chlorobenzyl alcohol (10.0 g, 70 mmol) was added to an ethereal solution (200 ml) of phosgene (25 g). The solution was kept for 20 h at room temperature in a closed vessel. The excess phosgene was removed by passing a stream of dry nitrogen gas through the solution, and the solvent was evaporated off under reduced pressure. The residual oil (2-chlorobenzyloxycarbonyl chloride) was dissolved in dioxane (160 ml) with *N*-hydroxysuccinimide (9.2 g, 80 mmol) and pyridine (7.19 g, 100 mmol) at 8—10 °C. The solution was treated in the similar way to that of the benzyl derivative. 2-Chlorobenzyl 2,5-dioxo-1-pyrrolidinyl carbonate [Z(2-Cl)-ONSu] was obtained in 62% yield; mp 103 °C.

Found: C, 50.63; H, 3.51; N, 4.99; Cl, 12.59%. Calcd for $C_{12}H_{10}O_5NCl$: C, 50.81; H, 3.55; N, 4.94; Cl, 12.50%.

The following derivatives were prepared in a similar way.

3-Chlorobenzyl 2,5-Dioxo-1-pyrrolidinyl Carbonate [Z(3-Cl)-ONSu]: Mp 129.5—130.5 °C. Found: C, 50.74; H, 3.51; N, 5.04; Cl, 12.52%. Calcd for $C_{12}H_{10}O_5NCl$: C, 50.81; H, 3.55; N, 4.94; Cl, 12.50%.

4-Chlorobenzyl 2,5-Dioxo-1-pyrrolidinyl Carbonate [Z(4-Cl)-ONSu]: Mp 125 °C. Found: C, 50.64; H, 3.52; N, 5.05; Cl, 12.58%. Calcd for $C_{12}H_{10}O_5NCl$: C, 50.81; H, 3.55; N, 4.94; Cl, 12.50%.

2,4-Dichlorobenzyl 2,5-Dioxo-1-pyrrolidinyl Carbonate [Z(2,4-Cl_2)-ONSu]: Mp 92—93 °C. Found: C, 45.15; H, 2.82; N, 4.52; Cl, 22.30%. Calcd for $C_{12}H_9O_5NCl_2$: C, 45.31; H, 2.85; N, 4.40; Cl, 22.29%.

3,4-Dichlorobenzyl 2,5-Dioxo-1-pyrrolidinyl Carbonate [Z(3,4-Cl_2)-ONSu]: Mp 118—119 °C. Found: C, 45.08; H, 2.79; N, 4.54; Cl, 22.34%. Calcd for $C_{12}H_9O_5NCl_2$: C, 45.31; H, 2.85; N, 4.40; Cl, 22.29%.

2,6-Dichlorobenzyl 2,5-Dioxo-1-pyrrolidinyl Carbonate [Z(2,6-Cl_2)-ONSu]: Mp 127—128 °C. Found: C, 45.29; H, 2.84; N, 4.54; Cl, 22.03%. Calcd for $C_{12}H_9O_5NCl_2$: C, 45.31; H, 2.85; N, 4.40; Cl, 22.29%.

Reaction of Native HEL with t-Butoxycarbonyl Azide. A solution of native HEL (100 mg) in distilled water (1.4 ml) was mixed with pyridine (0.6 ml) and then *t*-butoxycarbonyl azide (Boc-N_3) (0.428 g, *ca.* 3 mmol) in dimethyl sulfoxide (4 ml). The mixture was gently stirred until it became homogeneous, and then kept for 48 h at 38 °C without stirring. It was concentrated under reduced pressure and the residue was mixed with a large volume of ethyl acetate. The precipitate formed was collected by centrifugation, dissolved in dimethyl sulfoxide and reprecipitated by adding ethyl acetate. The precipitate was again collected by centrifugation and reprecipitated in the same way several times. Finally, the precipitate was dissolved in dimethyl sulfoxide and dialyzed against dilute aqueous acetic acid and then distilled water. The dialyzed solution was lyophilized and the powder was dried over diphosphorus pentaoxide *in vacuo*. This material is denoted as Boc-HEL.

Reaction of Native HEL with Benzyl 2,5-Dioxo-1-pyrrolidinyl Carbonate and Its Derivatives. Native HEL was allowed to react with benzyl 2,5-dioxo-1-pyrrolidinyl carbonate (Z-ONSu) or its derivatives [Z(X)-ONSu] under the same conditions as those used with Boc-N_3. These materials are denoted as Z-HEL and Z(X)-HELs.

Determination of Free Amino Groups in Proteins. The free amino groups in proteins were measured by a modification of the method of Moore and Stein[4] using ninhydrin solution. The reagent was prepared in the following way: tin(II) chloride (0.8 g) was dissolved in 0.2 M citrate buffer (500 ml) at pH 5.0. The solution was mixed with a solution of ninhydrin (20 g) in methyl cellosolve (500 ml), and the mixture was saturated with nitrogen gas and kept in a closed vessel in a refrigerator. Protein was dissolved in 3% aqueous sodium dodecyl sulfate and the solution was mixed with the above stocked solution (1 ml), heated for 20 min in a vigorously boiling water bath, cooled rapidly to room temperature and mixed with 50% aqueous 2-propanol (5 ml). Then within 15 min, the absorbance of the solution at 570 nm was measured. Protein contents of 3% aqueous sodium dodecyl sulfate solutions were determined by measuring the absorbance at 290 nm. The percentage of free amino groups (F%) in a protein was calculated as a ratio to free amino groups of native HEL using the following equation:

$$F = \frac{\dfrac{A_{570}\ \text{sample}}{A_{290}\ \text{sample}}}{\dfrac{A_{570}\ \text{native}}{A_{290}\ \text{native}}} \times 100$$

where A_{570} sample and A_{570} native mean the absorbances at 570 nm of the sample protein and native HEL solutions after treatment with ninhydrin solution, and A_{290} sample and A_{290} native mean the absorbances at 290 nm of solutions of sample protein and native HEL in 3% aqueous sodium dodecyl sulfate.

Treatment of Boc-HEL with Formic Acid. Lyophilized powder (*ca.* 30 mg) of Boc-HEL was dissolved in 99% formic acid (10 ml). The solution was stood for 24 h at 15 °C and then lyophilized. The resulting powder was dissolved in buffer solution (7.9 ml), consisting of 0.2 M tris (3 ml) at pH 8.6, 5% EDTA·2Na (0.3 ml), urea (3.61 g) and 2-mercaptoethanol (0.5 ml), under a nitrogen atmosphere, and stirred overnight at room temperature. Then the solution was acidified to below pH 4 with glacial acetic acid and charged on a column of Sephadex G-10 (3×60 cm). The eluate containing the protein was added to 0.08 M tris buffer solution at pH 8 (1 liter) containing 5.4×10^{-3} M L-cysteine and 4.8×10^{-4} M L-cystine.[5] The pH of the solution was adjusted to 8.0 with glacial acetic acid or concentrated ammonia. Then, the solution was kept for over 5 h at 37 °C, and the pH of the solution was adjusted to 4.5—5 with glacial acetic acid. The solution was applied to a CM-cellulose column (2×30 cm, carboxylic acid cycle). The adsorbed protein was eluted with 0.3 M sodium phosphate buffer at pH 8.0. The eluate containing the protein was acidified with glacial acetic acid and lypohilized. The lyophilized material was desalted by passage through a column of Sephadex G-10 (3.2×60 cm) in 1 M acetic acid and fractions containing the protein were collected and lyophilized.

Treatment of Native HEL and Derivatives of HEL with HF. Lyophilized powder (*ca.* 30 mg) of native HEL or its derivatives was weighed with 1,4-butanedithiol (0.5 ml) and anisole (1.0 ml) in the Daiflon cylinder of an HF-reaction apparatus.[6] The cylinder containing the protein was cooled to −78 °C in a Dry Ice-methanol bath and HF (10 ml) was distilled into it. The reaction was started by transferring the sample from the bath at −78 °C to a bath at 0 °C. The resulting solution was stirred at 0 °C for a certain period and then the HF was rapidly evaporated off as completely as possible from the reaction mixture under reduced pressure. The residue was washed repeatedly with hexane and the amorphous powder obtained was treated in the way used for Boc-HEL.

Reductive Alkylations of Native HEL with Benzyl, 4-Methoxybenzyl and 4-Methylbenzyl Groups in Liquid Ammonia. Native HEL was reduced with dithiothreitol in liquid ammonia at its boiling temperature for 3 h by the method of Meienhofer *et al.*[7] Then an alkylating reagent was added and the solution was refluxed for 3 h. The ammonia was evaporated off from the reaction mixture through a water aspirator.

When benzyl chloride was used as an alkylating reagent, the residue was kept overnight over concentrated sulfuric acid *in vacuo*, and then washed successively with ether, ethyl acetate and methanol. The crude material obtained was dissolved in a buffer containing 1 M acetic acid and 5 M urea, and chromatographed on Sephadex G-75 (3×60 cm) in the same buffer. The fractions containing protein were collected, dialyzed against distilled water and lyophilized. The material obtained is denoted as HEL(*S*-Bzl).

When 4-methoxybenzyl and 4-methylbenzyl chlorides were used as alkylating reagents, the residues were dissolved in dimethyl sulfoxide, and ethyl acetate was added to the solutions. The insoluble material formed was collected by centrifugation, washed repeatedly with ethyl acetate, and then dissolved in dimethyl sulfoxide. The resulting solutions were dialyzed against aqueous acetic acid and then distilled water. The dialyzed solutions were lyophilized and these materials are denoted as HEL(*S*-Bzl(OMe)) and HEL(*S*-Bzl(Me)), respectively.

Reductive Alkylations of Z(2-Cl)-HEL with 4-Methoxybenzyl and 4-Methylbenzyl Groups in Liquid Ammonia. Z(2-Cl)-HEL was reduced with dithiothreitol in liquid ammonia and allowed to react with 4-methoxybenzyl or 4-methylbenzyl chloride under similar conditions to those used with native HEL. The crude products were purified by a similar procedure to that used in the preparations of HEL(*S*-Bzl(OMe)) and HEL(*S*-Bzl(Me)). The purified products are denoted as Z(2-Cl)-HEL(*S*-Bzl(OMe)) and Z(2-Cl)-HEL(*S*-Bzl(Me)), respectively.

Determination of Remaining Thiols in Proteins. The amount of thiols in HEL(*S*-Bzl) that remained to be alkylated was calculated from the amount of *S*-benzylcysteine in the acid hydrolysate of the protein, determined by amino acid analysis. On the other hand, the amounts of thiols that remained to be alkylated in HEL(*S*-Bzl(OMe)), HEL(*S*-Bzl(Me)), Z(2-Cl)-HEL(*S*-Bzl(OMe)) and Z(2-Cl)-HEL(*S*-Bzl(Me)) were calculated from the amount of *S*-(carboxy-

methyl)cysteine measured as follows: Lyophilized powder (*ca.* 15 mg) of the proteins was dissolved in buffer solution consisting of 0.2 M tris (1.2 ml) at pH 8.6, 5% EDTA·2Na (0.12 ml) and guanidine hydrochloride (2.87 g). The solution was diluted with 0.2 M tris (1.5 ml) at pH 8.6 and 5% EDTA·2Na (0.15 ml), mixed with dithiothreitol (24.6 mg) and stirred overnight at room temperature under a nitrogen atmosphere. Then iodoacetic acid (270 mg) in 1 M NaOH (1 ml) was added. The mixture was stirred for 15 min in a dark room, acidified with formic acid and dialyzed against distilled water, and the dialyzed solution was lyophilized. The resulting powder was hydrolyzed with 6 M hydrochloric acid, and the ratios of the amount of *S*-(carboxymethyl)cysteine to the average amounts of glycine and alanine in the hydrolysate were determined by amino acid analysis.

Treatments of the Reduced and Alkylated Derivatives of HEL with HF. Reductively alkylated derivatives of HEL were treated with HF as described above.

Gel-filtration and Ion-exchange Chromatography. Gel-filtration and ion-exchange chromatography were used to isolate fully active HEL from the derivatives of HEL treated with HF, as described in the preceding paper.[1] Materials were detected by measuring the absorption of the eluate at 280 nm.

Enzyme Assays. The specific activity of HEL was determined by measuring the initial rate of lysis of *Micrococcus lysodeikticus* cell walls spectrophotometrically at 540 nm by the method described in the preceding paper,[1] with native HEL as a standard.

Ultraviolet Absorption Spectra. UV-absorption spectra were measured using a Hitachi spectrophotometer type-124, equipped with a recording attachment.

Crystallization of HEL. Crystallization was carried out by the method of Berthou and Jolles[8] with the modification described in the preceding paper.[1]

Results

Reaction of Native HEL with Boc-N_3. When native HEL was treated with Boc-N_3 in the presence of pyridine in a mixture of dimethyl sulfoxide and water, only 76% of its amino groups were acylated with Boc groups, as estimated by the ninhydrin reaction. However, when the partially acylated native HEL was treated with Boc-N_3 repeatedly under the same conditions, but without water, 98% of its amino groups could be acylated.

Reactions of Native HEL with Z-ONSu and Z(X)-ONSu. Native HEL was treated with Z-ONSu in ratios of 1.3 to 65 equivalents of the reagent to one amino group of native HEL, then the product was isolated and its acylated amino groups were estimated by the ninhydrin color reaction. The relation between the ratio of Z-ONSu to amino group of native HEL and the percentage of amino groups acylated with Z groups is summarized in Table 1. Native HEL was also treated with the derivatives of Z-ONSu [Z(X)-ONSu] using a ratio of 6.5 equivalents of the reagents to one amino group of native HEL. Measurements with ninhydrin showed that these derivatives cause almost complete acylation of the amino groups with Z(X) groups, as seen in Table 2.

Table 1. Effect of the ratio of equivalents of Z-ONSu to amino groups of native HEL on the percentage of amino groups acylated

	A	B	C	D	E	F
Z-ONSu (equivalents)	1.3	2.6	6.5	13.0	26.0	65.0
Acylated amino groups (%)	95.5	96.6	98.0	99.0	98.4	98.3

Table 2. Percentages of acylated amino groups in Z(X)-HELs

X in Z(X)-ONSu	Acylated amino groups (%)
2-Cl	98.0
3-Cl	98.0
4-Cl	98.0
2,4-Cl_2	97.0
3,4-Cl_2	97.0
2,6-Cl_2	97.0

Removal of Z Groups from Z-HEL by Treatment with HF. Z-HEL was treated with HF at 0 °C for periods of 0 to 120 min, and then the reaction was stopped by evaporating the HF off completely. The residue was dissolved in 3% aqueous sodium dodecyl sulfate. The protein concentration in the solution was determined by measuring the optical density at 290 nm and free amino groups in the protein regenerated by HF-treatment were determined by the ninhydrin method. The recovery of regenerated amino groups was calculated from the equation given in the methods, and the results are shown in Fig. 1.

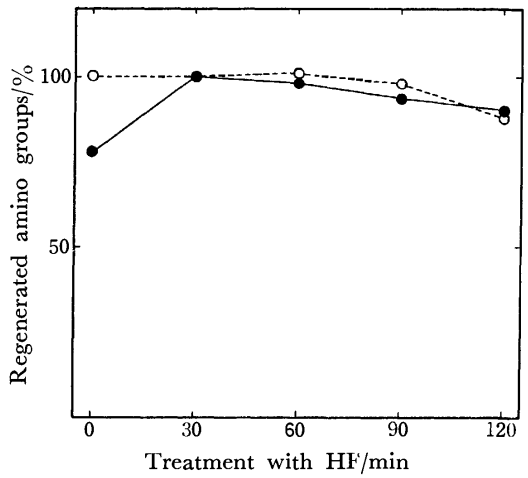

Fig. 1. Removal of Z groups from Z-HEL by HF-treatment.
—●—: Z-HEL, —○—: native HEL.

Table 3. Percentages of free amino groups recovered from Z(X)-HELs by HF-treatment

Z(X)-HEL	HF-treatment at 0 °C (min)				
	0	30	60	90	120
2-Cl	21	96	98	94	83
3-Cl	18	62	97	89	92
4-Cl	74	94	92	90	75
2,4-Cl_2	18	94	95	83	82
3,4-Cl_2	13	58	99	92	75
2,6-Cl_2	18	60	93	90	92

Removal of Z(X) Groups from Z(X)-HELs by Treatment with HF. Z(X)-HELs were treated with HF at 0 °C for periods of 0 to 120 min, and the free amino groups of the proteins recovered were estimated. The results are shown in Table 3.

Regeneration to Native HEL from Boc-HEL. Treatment of Boc-HEL with formic acid for 24 h at 15 °C or with HF for 90 min at 0 °C gave fully active HEL in yields of 46 and 25%, respectively. After treatment of native HEL under the same conditions as Boc-HEL, fully active HEL was recovered in yields of 72 and 50%, respectively.

Regeneration to Native HEL from Z-HEL. Z-HEL, prepared under conditions C in Table 1, was treated with HF at 0 °C for periods of 30 to 90 min. Then the residues of HF-treated Z-HEL were reduced and reoxidized, as described in the methods and the resultant protein fraction was chromatographed on Sephadex G-50 using buffer solution containing 1 M acetic acid and 5 M urea. The fraction eluted in the same position as native HEL was fully active. After treatment of Z-HEL with HF for 30 min at 0 °C the recovery of this fraction was 41%. The recovery of fully active HEL decreased with increase in the period of HF-treatment and after periods of 60 and 90 min the yields of fully active HEL were 28 and 23%, respectively When the Z-HELs prepared under the various conditions described in Table 1 were treated with HF for 30 min at 0 °C, the recoveries of fully active HEL varied depending on the conditions used for preparation of the Z-HELs. The relation between the recoveries of fully active HELs and the conditions used for preparation of Z-HEL are shown in Fig. 2.

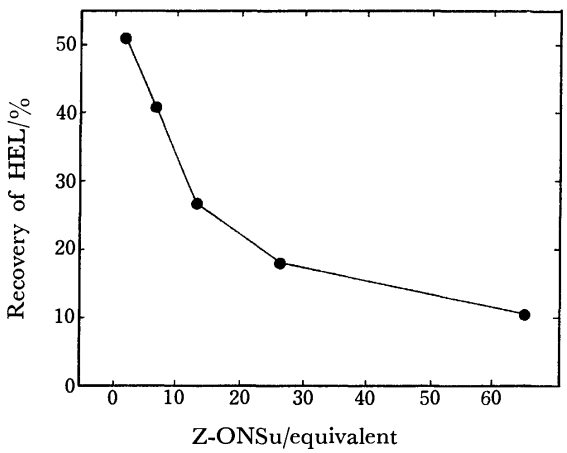

Fig. 2. Effect of the ratio of equivalent of Z-ONSu to amino groups of native HEL used in the synthesis of Z-HEL on the recovery of fully active HEL from Z-HEL by HF-treatment.

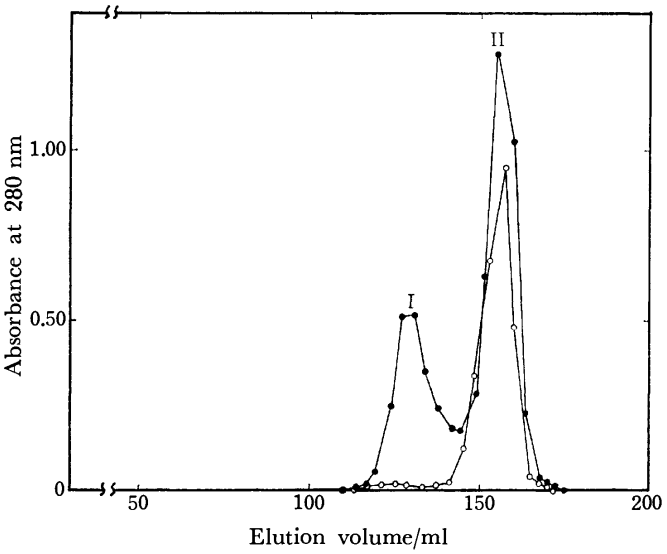

Fig. 3. Gel-filtration of Z(2-Cl)-HEL treated with HF for 60 min at 0 °C (—●—) and native HEL (—○—) on Sephadex G-50 (2×95 cm) using buffer containing 1 M acetic acid and 5 M urea.

Regeneration to Native HEL from Z(X)-HELs. Z(X)-HEL was treated with HF for 60 and 90 min at 0 °C. Then the HF-treated Z(X)-HEL was reduced, reoxidized and chromatographed on Sephadex G-50, as described in the methods. Two fractions (I and II) were eluted from the column: the first (I) had less enzymatic activity than native HEL, whereas the second (II), eluted in the same position as standard native HEL, had full enzymatic activity. A chromatogram of the protein fraction recovered after HF-treatment of Z(2-Cl)-HEL for 60 min at 0 °C is shown in Fig. 3. The recoveries of fraction II's from Z(X)-HELs are summarized in Table 4.

Purification and Crystallization of Fully Active HEL Regenerated from Z(2-Cl)-HEL. Fraction II in Fig. 3 was desalted by passage through Sephadex G-10, and the eluate containing protein was lyophilized. Then the powder was subjected to chromatography on Bio-rex 70 in 0.2 M sodium phosphate buffer solution, pH 7.18, as shown in Fig. 4. In this way four fractions (IIa, IIb, IIc, and IId) were separated. Fraction IId was eluted in the same position as the main fraction of native HEL. The lytic activities of the four fractions, IIa, IIb, IIc, and IId, were 65, 96, 101, and 101%, respectively, of that of native HEL in M/15 sodium phosphate buffer solution containing 0.1% sodium chloride, and 18, 29, 48, and 100%, respectively, of that of native HEL in the same buffer solution containing 1% sodium chloride. The UV absorption spectrum of fraction IId is shown in Fig. 5. Fraction

Table 4. Recoveries of fully active HEL from Z(X)-HELs by HF-treatment

Conditions for HF-treatment	Native HEL	Z-HEL	Z(X)-HEL					
			2-Cl	3-Cl	4-Cl	2,4-Cl_2	3,4-Cl_2	2,6-Cl_2
0 °C, 60 min	59	28	22	10	20	16	7.3	16

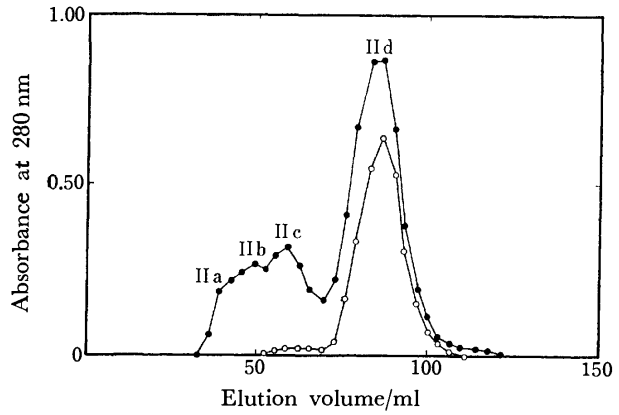

Fig. 4. Ion-exchange chromatogram of fractionII of Fig. 3 (—●—) and native HEL(—○—) on Bio-rex 70 (1.5×33 cm) in 0.2 M sodium phosphate buffer solution (pH 7.18).

IId was desalted by passage through Sephadex G-10, and the eluate containing protein was collected and lyophilized. When the lyophilized material was stood under conditions inducing crystallization, it formed crystals identical with those of native HEL.

Reductive Alkylations of Native HEL with Benzyl, 4-Methoxybenzyl, and 4-Methylbenzyl Groups in Liquid Ammomia. Native HEL was reduced and alkylated under the conditions described for Table 5. The degree of alkylation with benzyl groups was estimated from the ratio of the amounts of *S*-benzylcysteine to the average amounts of glycine and alanine, determined by amino acid analysis of the acid hydrolysate of the alkylated product, as shown in Table 5. It was difficult to estimate the degrees of alkylation with 4-methoxybenzyl and 4-methylbenzyl groups by measuring *S*-(4-methoxybenzyl)cysteine and *S*-(4-methylbenzyl)cysteine in acid hydrolysates of the alkylated products by amino acid analysis, because these *S*-(4-methoxybenzyl)- and *S*-(4-methylbenzyl)cysteine residues are destroyed during acid hydrolysis. Therefore, they were estimated by analysis of the amount of thiols in the protein that remained unalkylated; namely the reduced and alkylated derivatives of HEL were carboxymethylated, and the amounts of *S*-(carboxymethyl)cysteine residues in the carboxymethylated proteins were determined by measuring the amounts of amino acids in their acid hydrolysates with an amino acid analyzer. The results are summarized in Table 5.

Treatment of HEL(S-Bzl) with HF. HEL(*S*-Bzl) was treated with HF under various conditions, the resultant material was hydrolyzed with 6 M hydrochloric acid, and *S*-benzylcysteine in the acid hydrolysate was measured by amino acid analysis. Table 6 shows the percentages of *S*-benzyl groups cleaved by treatment of HEL(*S*-Bzl) with HF under various conditions. The products of the reactions were treated under similar conditions to those used to isolate enzymatically active HEL from the products of Z-HEL. However, no enzymatically active material was recovered under any of the conditions examined.

Treatments of S-(4-Methoxybenzyl) and S-(4-Methylbenzyl) Derivatives of Native HEL and Z(2-Cl)-HEL with HF. The derivatives of HEL were treated with HF at 0 °C for 60 and 90 min, and the materials isolated from their HF-solutions were treated under similar conditions to those described above. The percentages of fully active HEL recovered from them are shown in Table 7.

Purification and Crystallization of Fully Active HEL Regenerated from Z(2-Cl)-HEL(S-Bzl(Me)). The material obtained from Z(2-Cl)-HEL(*S*-Bzl(Me)) by HF-treatment for 60 min at 0 °C was reduced, and reoxidized under similar conditions to those used for Z(2-Cl)-HEL. The reoxidized material was chromatographed on Sephadex G-50 using buffer containing 1 M acetic acid and 5 M urea, as shown in Fig. 6. Fraction II, eluted in the same position as native HEL, was fully active. The yield of fraction II was 8.3% on the basis of the protein content of the Z(2-Cl)-HEL(*S*-Bzl(Me)) preparation used, as shown in Table 7. Lyophilized material was obtained from fraction II by desalting and chromatographed on a Bio-rex 70 column using 0.2 M sodium phosphate buffer solution at pH 7.18. Fraction II was separated into four fractions

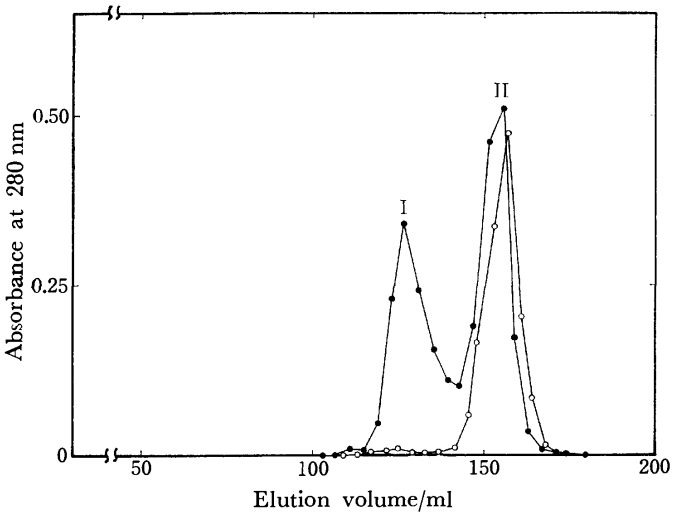

Fig. 6. Gel-filtration of Z(2-Cl)-HEL(*S*-Bzl(Me)) treated with HF for 60 min at 0 °C (—●—) and native HEL (—○—) on Sephadex G-50 (2×95 cm) in buffer containing 1 M acetic acid and 5 M urea.

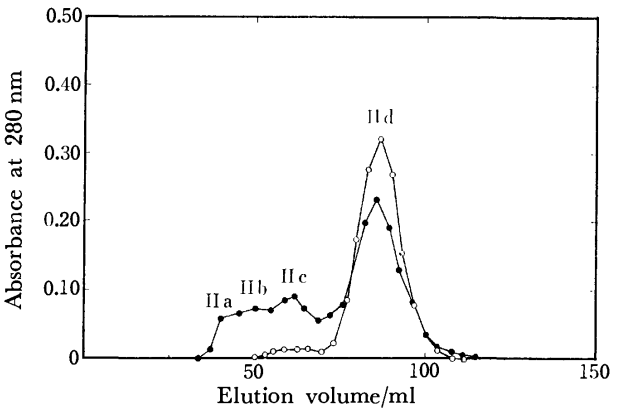

Fig. 7. Ion-exchange chromatogram of fraction II of Fig. 6 (—●—) and native HEL (—○—) on Bio-rex 70 (1.5×33 cm) in 0.2 M sodium phosphate buffer solution (pH 7.18).

(IIa, IIb, IIc, and IId), as shown in Fig. 7. Fraction IId was eluted in the same position as the main fraction of native HEL. These four fractions, IIa, IIb, IIc, and IId, had 79, 99, 101, and 102%, respectively, of the lytic activity of native HEL in buffer containing 0.1% sodium chloride, and 13, 30, 39, and 102% of the latter in buffer containing 1% sodium chloride. The UV absorption spectrum of fraction IId is shown in Fig. 8. When the lyophilized powder obtained from fraction IId (Fig. 7) after desalting was stood under conditions inducing crystallization, it yielded similar crystals to those of native HEL, as shown in Fig. 9.

Discussion

In this work we first prepared derivatives of native HEL in which the amino groups were combined with *t*-butoxycarbonyl (Boc) or benzyloxycarbonyl (Z) groups or derivatives of the latter, [Z(X)]. These derivatives were prepared by treating the enzyme with Boc-N_3 or Z-ONSu or derivatives of the latter [Z(X)-ONSu]. The first reagent was not very reactive so that repeated treatment was required to achieve complete acylation of the amino groups of native HEL. Then, we tested Z-ONSu, which can easily be prepared by the reaction of benzyloxycarbonyl chloride (Z-Cl) with *N*-hydroxysuccinimide (HONSu), and found that Z groups could be introduced almost quantitatively onto the amino groups of native HEL in a single reaction. We also found that the reaction was complete using a ratio of at least 6.5 equivalents of the reagent to one amino group of native HEL, as shown in Table 1; derivatives of the Z group in which the aromatic ring was chlorinated could be introduced onto the amino groups of native HEL almost completely using 6.5 equivalents of the reagents to one amino group of native HEL.

Next, we examined to regenerate enzymatically active HEL from the derivatives of HEL. Treatments of Boc-HEL with formic acid for 24 h at 15 °C and with HF for 90 min at 0 °C gave fully active HEL in yields of 46 and 25%, respectively, and treatment of native HEL with formic acid and HF under the same conditions gave recoveries of 72 and 50%, respectively, of the active enzyme. Namely, the recovery of fully active HEL from Boc-HEL was about one half of that from native HEL. These results suggest that some side-reactions occur during the treatment of Boc-HEL with formic acid or HF, or that some side-reactions occur during introduction of the Boc group onto native HEL using Boc-N_3 and are not reversed by formic acid- or HF-treatment, whereas these reactions were not examined in this work. However, these results show that enzymatically active material can be recovered in fair yields from Boc-HEL under the conditions described above. We next tested to regenerate enzymatically active HEL from Z-HEL and Z(X)-HELs. We first determined free amino groups regenerated by the treatment of Z-HEL and Z(X)-HELs, in which the amino groups are completely protected, with HF under various conditions. When Z-HEL was treated with HF at 0 °C for 0 and 30 min, the regenerated free amino groups were estimated as 78 and 100% of those of native HEL, respectively. These results indicate that Z groups could be removed from Z-HEL as easily as from oligopeptides by HF-treatment. Then, HELs, substituted with monochloro- or dichloro-Z group, were treated with HF. The free amino groups of the original enzyme could be regenerated almost quantitatively with HF, by 30 min-treatment of Z(2-Cl)-, Z(4-Cl)- and Z(2,4-Cl_2)-HELs and by 60 min-treatment of Z(3-Cl)-, Z(3,4-Cl_2)- and Z(2,6-Cl_2)-HELs. Thus the relative stabilities of these groups on HF-treatment are proportional to their relative stabilities on acidolysis in 50% trifluoracetic acid, in methylene chloride reported by Merrifield *et al.*[9] The results show that the free amino groups of HEL can be regenerated quantitatively from all the derivatives of HEL examined by HF-treatment for up to 60 min at 0 °C. Then, we tried to isolate fully active HEL from the products obtained by HF-treatment of derivatives of HEL. We found that on HF-treatment for 30 min at 0 °C fully active HEL could be recovered in 41% yield from Z-HEL, in which the amino groups had been acylated almost completely under conditions C in Table 1. However, the recovery decreased on increasing the period of HF-treatment. These findings are in accordance with results on HF-treatment of native HEL, described in the preceding paper[1]. When Z-HELs prepared by the reaction of native HEL with Z-ONSu under conditions D, E, and F in Table 1 were treated with HF for 30 min at 0 °C, the recoveries of fully active HELs decreased in order; namely with increase in the ratio of equivalents of the reagent, Z-ONSu, to amino groups of native HEL, the recovery of fully active HEL decreased. Since fully active HEL could be recovered in 69% yield from native HEL on HF-treatment under the same conditions, the results suggest that the acylation of native HEL with Z-ONSu did not cause an irreversible change in the molecule of native HEL, but caused some side-reactions of the molecule or that HF-treatment of Z-HEL caused some modification of the HEL molecule. Therefore, it is essential to use only the minimal amount of the reagent necessary to achieve complete acylation of the amino groups of native HEL. In studies on the recovery of HEL from Z(X)-HELs by HF-treatments at 0 °C for 60 and 90 min, fully active HEL was recovered from Z(2-Cl)- and Z(4-Cl)-HELs in approximately the same yield as from Z-HEL. It has been described[9] that use of Z(2-Cl) group for ε-amino protection of lysine reduces branching at the amino acid residue in peptide synthesis, whereas Z and Z(4-Cl) groups are sufficiently labile in acidic conditions that peptide chains undergo branching at the side chain of lysine residue during peptide synthesis if either group is used for ε-amino protection. This and our results suggest the usefulness of Z(2-Cl) group for ε-amino protection of lysine residue in our studies on the chemical synthesis of HEL. Therefore, HEL substituted with Z(2-Cl) groups was examined further in detail. On the other hand, the recoveries of HEL from other Z(X)-HELs were lowered, as shown in Table 4. These results seem inconsistent with the

fact that all the Z(X) groups could be completely removed from Z(X)-HELs under the same conditions, as described already, because if this is so fully active HEL should be recovered in the same yield from all the derivatives of HEL examined. This inconsistency remains to be explained. It may be due to various extents of side-reactions during preparation of Z(X)-HELs and their treatments with HF.

We also investigated the reductive alkylations of native HEL and Z(2-Cl)-HEL and the regeneration of enzymatically active HEL from reduced and alkylated enzymes by HF-treatment. Meienhofer *et al.*[7] reported that native HEL can be reduced by dithiothreitol in liquid ammonia, and that the resulting mercapto groups can be almost completely alkylated by benzyl chloride. Accordingly native HEL and Z(2-Cl)-HEL were reduced and alkylated by benzyl, 4-methoxybenzyl and 4-methylbenzyl chlorides by their method. Amino acid analyses of acid hydrolysates of the products showed that native HEL and Z(2-Cl)-HEL were reduced and alkylated almost completely by benzyl groups, but partially by 4-methoxybenzyl and 4-methylbenzyl groups, as seen in Table 5. When these derivatives of HEL were treated with HF to regenerate enzymatically active HEL, it was found that the *S*-benzyl substituents were too stable to be cleaved from HEL(*S*-Bzl) under the mild conditions used for peptide synthesis, as presented in Table 6. Moreover, HEL would be destroyed under the stronger conditions necessary for complete cleavage of the *S*-benzyl group from HEL(*S*-Bzl), as described in the preceding paper.[1] Thus, fully active HEL could not be recovered from the HEL(*S*-Bzl) by HF-treatment. It seemed probable that the *S*-4-methoxybenzyl substituent should be removed from HEL(*S*-Bzl(OMe)) and Z(2-Cl)-HEL(*S*-Bzl(OMe)) under appropriate conditions for HF-treatment, because it is known that the *S*-4-methoxybenzyl group can be almost completely removed from oligopeptides containing the *S*-(4-methoxybenzyl)cysteine residue(s) by HF-treatment for 60 min at 0 °C, and completely removed by treatment for 90 min at 0 °C. However, only traces of fully active HEL could be recovered from either HEL(*S*-Bzl(OMe)) or Z(2-Cl)-HEL(*S*-Bzl(OMe)) by HF-treatment for 90 min at 0 °C, and no fully active enzyme could be recovered by treatment for 60 min at 0 °C. These low recoveries of fully active enzyme seemed to be due to use of unsuitable reaction conditions for preparing HEL(*S*-Bzl(OMe)) and Z(2-Cl)-HEL(*S*-Bzl(OMe)), because these derivatives of HEL were always obtained as pale yellow materials. Next, HEL(*S*-Bzl(Me)) and Z(2-Cl)-HEL (*S*-Bzl(Me)) were treated with HF. Erickson and Merrifield[10] reported that *S*-4-methylbenzyl group can be completely removed from *S*-(4-methylbenzyl)cysteine by HF-treatment at 0 °C for 60 min. However, we observed that trace amounts of the group remain in *S*-(4-methylbenzyl)cysteine after treatment with HF under the same conditions, whereas the group is completely removed by HF-treatment for 90 min at 0 °C. Therefore, we treated the above materials with HF at 0 °C for 60 and 90 min. Fully active HEL was recovered in 19 and 12% yield from HEL(*S*-Bzl(Me)) by HF-treatment at 0 °C for 60 and 90 min, respectively. Table 5 shows that about 89% of the mercapto groups were alkylated in the HEL(*S*-Bzl(Me)) preparation; namely, about 11% of the mercapto groups remained unalkylated. Assuming that 11% of the mercapto groups were exclusively constituted by the reduced form of HEL, and that no active enzyme could be recovered from completely alkylated HEL(*S*-Bzl(Me)), we can deduce that fully active HEL could be recovered in only 3—5% yield from the HEL(*S*-Bzl(Me)) preparation by HF-treatment for 60 min at 0 °C, from simple calculation ($0.11 \times 0.33 \times 100\% = 3.63\%$), since the reduced form of HEL gave fully active HEL with 33% yield under the same conditions.[2] Therefore, the 19% yield of fully active HEL was probably mainly derived from *S*-4-methylbenzylated HEL. Next, Z(2-Cl)-HEL (*S*-Bzl(Me)) was treated with HF at 0 °C; fully active enzyme was recovered in yields of 8.3 and 7.4% after treatment with HF for 60 and 90 min, respectively. On the other hand, fully active HEL could be recovered in 20% yield from the reduced form of Z(2-Cl)-HEL, in which not all the mercapto groups were alkylated, by HF-treatment for 60 min at 0 °C. These findings indicate that fully active enzyme was mainly obtained by cleavage of Z(2-Cl) and Bzl(Me) groups from Z(2-Cl)-HEL(*S*-Bzl(Me)) with HF, although 8% of the mercapto groups remained to be alkylated in the Z(2-Cl)-HEL(*S*-Bzl(Me)) preparation.

The fully active HELs recovered by HF-treatment of Z(2-Cl)-HEL and Z(2-Cl)-HEL(*S*-Bzl(Me)) were purified by chromatography on a Bio-rex 70 column. The main fraction, eluted in the position of native HEL, had the same activity on *Micrococcus lysodeikticus* cells as native HEL also purified on Bio-rex 70. The fractions eluted before the main fraction had similar activity to native HEL in buffer containing 0.1% sodium chloride, but had very low enzymatic activity in buffer containing 1% sodium chloride. They may represent deaminated derivatives of HEL formed during the chemical treatments. The main fraction eluted from the Bio-rex 70 column had the same UV-spectra as native HEL, as shown in Figs. 5 and 8. Furthermore, when the protein in this fraction was treated under appropriate conditions, it gave crystals that were identical with those of native HEL, as shown in Fig. 9.

As a further step in the chemical synthesis of hen egg-white lysozyme we prepared Z(2-Cl)-HEL(*S*-Bzl-(Me)) as a model, since it closely resembles the protected polypeptide covering the whole sequence of the lysozyme molecule required to synthesize the whole molecule. The present work showing that fully active HEL can be regenerated in fair yield and in a crystalline state from Z(2-Cl)-HEL(*S*-Bzl(Me)) by treatment with HF is an encouraging indication that chemical synthesis of this enzyme should be possible.

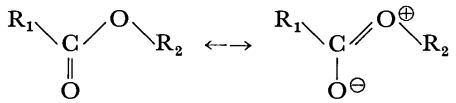
Nuclear Magnetic Resonance Study of Exchanging Systems. X.[1] Rotational Barriers to *trans-cis* Isomerization in Esters

Hiroshi NAKANISHI, Hitoshi FUJITA, and Osamu YAMAMOTO
National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151
(Received May 11, 1977)

The ^{13}C NMR spectra of *t*-butyl formate (**1**), 1,1-diethylpropyl formate (**2**), and 2,6-dimethylphenyl formate (**3**) were measured at various temperatures. It was found that the signals of the *trans* and *cis* isomers in **1** and **2** are separated at very low temperatures, and that the signal of **3** only shows a slight line broadening. The complete line shape analyses of these temperature-dependent spectra were performed. The activation energies $E_a(t\text{-}c)$ of the isomerization from the *trans* isomer to the *cis* were determined to be 10.9 kcal/mol for **1** and 7.2 kcal/mol for **2**.

It is well known from a number of dynamic NMR spectroscopic studies[2] that the rotation about the amide C–N bond is sufficiently slow at room temperature, for the C–N bond has a partial double-bond character. In secondary amides, therefore, there is a possibility for two isomers (*trans* and *cis*) to exist. Indeed, in monosubstituted formamides, both *trans* and *cis* isomers exist in the solution state,[3] and the isomerization barrier between the two isomers in formanilide has been reported to be 20 kcal/mol.[4]

In contrast with the case of amides, however, the conformation of the ester, which is a compound structurally analogous to the amide, is reported to be *s-trans* only from the dipole moment and from NMR, IR, and microwave spectroscopic studies,[5] although it is also known[6] that the ester C–O bond has a partial double bond character due to the delocalization of electrons, as is shown below:



It has also been reported from ultrasonic absorption studies concerning various esters that the population of the *cis* isomer is small.[7-14]

However, in *t*-butyl formate (**1**) and other formates with a very bulky alcohol part, we previously found[15] from the results of studies using the dipole moment and the NMR, UV, and IR methods, that the *cis* isomer exists to a considerable extent. Similarly, the existence of the *cis* isomer was proved in several ester analogues (carbamates,[16] carbonates,[17] thiocarbonates,[18] and chloroformates[19]). Rotational barriers to the isomerization between the *trans* and the *cis* isomers have hardly been investigated at all except for the ultrasonic relaxation and IR investigation. The ΔH^* of the isomerization of methyl formate has been reported to be 7.8 kcal/mol from the ultrasonic relaxation analyses,[11,14,20] while Miyazawa supposed its potential barrier to be 13 kcal/mol in his analysis of the C–O out-of-plane vibrations of its infrared spectrum.[21] The discrepancy between these data is rather large, and so it is necessary to study in more detail the thermodynamic and kinetic parameters of the isomerization between the *trans* and *cis* conformers of the esters in other methods. In this connection, an NMR line-shape analysis is the most appropriate method.

In this paper, we will present the accurate isomerization parameters of formates, including both *trans* and *cis* isomers, on the basis of the complete line-shape analyses of their ^{13}C NMR spectra. In addition, we will discuss the influence of the bulkiness of the alkyl and aryl groups on the rotational barriers in the formates.

Experimental

Materials. *t*-Butyl formate (**1**), 1,1-diethylpropyl formate (**2**), and 2,6-dimethylphenyl formate (**3**) were prepared from the mixed anhydride of formic and acetic acids and the corresponding alcohols and phenol according to Stevens' method.[22] Methyl formate (**4**), ethyl formate (**5**), and isopropyl formate (**6**) were prepared from formic acid and the corresponding alcohols in the presence of a trace of sulfuric acid.

NMR Measurements. The ^{13}C NMR spectra of the esters were recorded on NEVA NV-14 (15.087 MHz) and Varian XL-100-15 (25.16 MHz) spectrometers. The pulsed FT method was made by a Varian 620/L computer (16k). Acetone-d_6 was used for the deuterium lock. The solvents and sample concentrations were as follows: 80 vol% in acetone and acetone-d_6 (5 vol%) for **1**, 30 vol% in dimethyl ether and acetone-d_6 (5 vol%) for **2**, and 10 vol% in dimethyl ether, carbon disulfide (25 vol%), acetone-d_6 (5 vol%) for **3**. The temperature was read by means of a calibrated copper-constantan thermocouple.

Spectral Calculations. The calculations of the theoretical spectra in the computer simulation were made by means of a FACOM 270/30 computer.

Results and Discussion

Previously we found[15] in an ^1H NMR spectral study of *t*-butyl formate (**1**) in DMF, that the line width of the formyl proton signal, which is only a singlet at room temperature, becomes broader as the temperature is lowered, and finally two separate peaks, which were assigned to the *cis* and *trans* isomers, appear at −94.0 °C. It was also found that the two signals of the *trans* and *cis* formyl protons show very complex line shapes at such a conformationally frozen temperature as −99 °C. This occurs because they couple with the methyl protons of the *t*-butyl group through five chemical bonds, and the line shapes show that the long-range spin-spin coupling constant in the *trans* isomer ($^5J_{trans}$) is different from that in the *cis* isomer ($^5J_{cis}$). A complete line-shape analysis of these very complex ^1H NMR spectra of $AX_9 \rightleftarrows A'X'_9$ spin system must be made using the density matrix method.[23,24] The calculation for this multi-spin system is quite hard. Moreover, the population change in the isomers at different tempera-

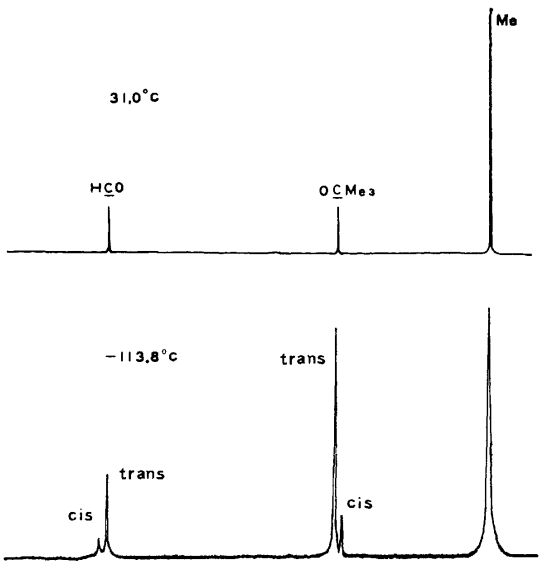


Fig. 1. ^{13}C NMR spectra of **1** at 31.0 and −113.8 °C.

tures makes the line-shape analysis very complex and difficult. Drakenberg *et al.* analyzed the ^{1}H NMR spectra of **1** using a rather approximate method.[25]

On the other hand, it is known that an ^{1}H-decoupled ^{13}C NMR spectral pattern is much simper than that of the ^{1}H NMR spectrum. Therefore, the line-shape analysis can be made much easily in the ^{13}C NMR spectra.[26-28]

Temperature-dependent ^{13}C NMR Line Shape. The ^{13}C NMR spectrum of **1** at an ambient temperature (Fig. 1) shows that the signals of the formyl, alkoxy ($OC(CH_3)_3$), and methyl carbons are sharp singlets. This means that the rate of the isomerization between the *trans* and *cis* isomers is very rapid at that temperature. As the temperature is lowered, the line widths become broader. The signals of the formyl and alkoxy carbons begin to separate into two peaks at about −96 °C (see Fig. 2); the minor peaks were assigned to the *cis* isomer of the ester, because other spectroscopic data show that the population of the *cis* isomer is smaller than that of the *trans* in **1**.[15] In contrast with this, the signal of the methyl groups is not divided into two peaks, even at temperature as low as −113.8 °C, although the line width becomes larger to some extent with the temperature decrease.* This may mean that the difference between the chemical shifts of the methyl

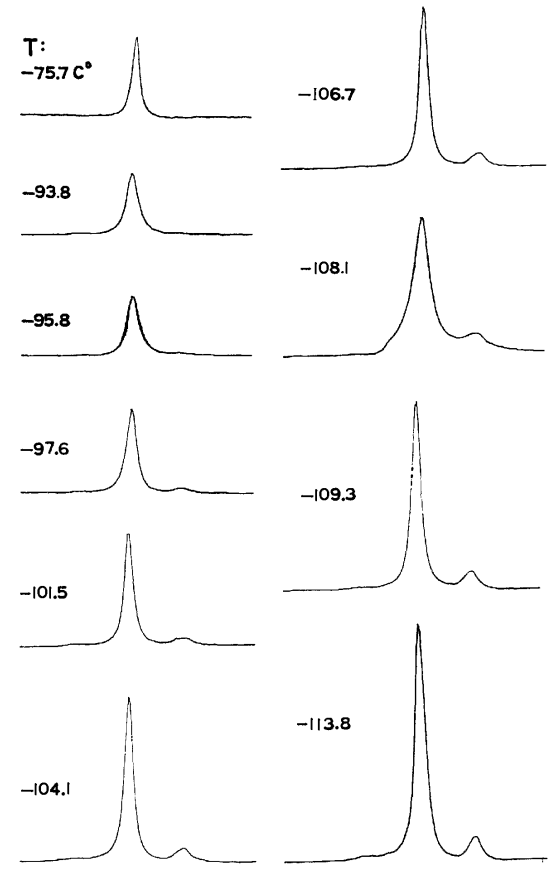

Fig. 2. The temperature-dependent ^{13}C NMR spectra of ethereal carbons in the *trans* and *cis* isomers of **1**.

groups in the two isomers is considerably smaller than those of the formyl and alkoxy carbon signals.

In a previous paper concerning the conformations of esters,[15] it has been discussed that the steric bulkiness of the R group (HCO_2R) severely affects the stabilization of the *trans* and *cis* isomers. This reasonably leads us to consider that the barrier to the rotation about the ester C–O bond must also be influenced by the bulkiness of the R group. Thus, the ester **2** and **3**, whose R groups are bulkier than the *t*-butyl group, were prepared and their ^{13}C NMR spectra were measured at low temperatures. The change in the line shape of **2** with the temperature decrease was almost the same as that of **1**, although the temperature had to be lowered to about −130 °C in order to freeze the isomerization reaction in **2**. In the case of **3**, however, no peak sepa-

3: R=

* At temperatures below −110 °C, the broad line shape of the methyl carbon becomes unsymmetrical and a small shoulder signal appears at the lower field of the main peak, although it does not separate into peaks even at −120.3 °C.

TABLE 1. ^{13}C CHEMICAL SHIFTS AND CHEMICAL-SHIFT DIFFERENCES OF THE *cis* AND *trans* ISOMERS IN **1**—**3** (ppm from TMS)

Signal	Isomer	**1**	**2**	**3**
HCO	*cis*	169.4	168.2	162.6
	trans	166.7	165.8

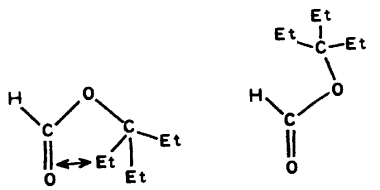
a) Probably δ of the signal of the *trans* isomer.

rations in the formyl, aryloxy, and methyl carbon signals were found even at temperatures as low as −133 °C, although the line-shape broadening in the formyl carbon signal is quite large.

*^{13}C NMR Chemical Shifts of **1**—**3**.* The chemical shifts and chemical-shift differences of the two isomers in **1**—**3** are given in Table 1. It is worthwhile pointing out that in the carbonyl region of **1** and **2**, the chemical shift of the *cis* isomer is at a lower field than that of the *trans*, while in the alkoxy carbon region, the reverse is the case. This interesting chemical-shift tendency in the carbonyl and alkoxy carbon regions of the *trans* and *cis* isomers in these esters was also found in a structually analogous compound, *N*-*t*-butylformamide (HCONH-^{t}Bu) (**7**).[29] Table 1 shows that the chemical-shift difference ($\Delta\delta$) of the carbonyl carbon signals of the two isomers in **1** is almost the same as that in **2**, while in the alkoxy-carbon region the difference, $\Delta\delta$, in **2** is considerably larger than that in **1**. This result may be explained by considering that there is a very severe steric compression between the carbonyl and the 1,1-diethylpropyl groups in the *trans* isomer of **2**, and that the chemical shift moves to a lower field due to the steric compression effect,[30] while in the *cis* isomer the compression can be expected to be greatly reduced because the counter group for the repulsion is the smallest formyl hydrogen atom.



Populations of the Two Isomers. The populations of the *trans* and *cis* isomers change as the temperature is lowered. The determination of the populations was made using a computer simulation by the trial-and-error method in the conformationally frozen temperature range. This method was considered to be the most accurate for determining the populations, making it possible to dispense with the troublesome determination of the base line of the signals. This determination was made independently for the carbonyl and alkoxy carbon signals. The populations obtained in these two regions are in good agreement with each other. The population of the *cis* isomer in **1** is 9% at −113.8 °C, and that in **2** is 7% at −130.1 °C. The thermodynamic static parameters of the ester isomerization ($\Delta G°$, $\Delta H°$, and $\Delta S°$) were determined from these populations at different temperatures and their Arrhenius plots. The results are shown in Table 2.

Isomerization Barriers. The computer simulation of the temperature-dependent spectra of **1** and **2** was performed using the modified Bloch equation method in order to obtain the activation parameters of the isomerization. The computer program is EXNMR1.** The simulation in the line-shape analyses was made by

** A modified version of EXNMR0.[31]

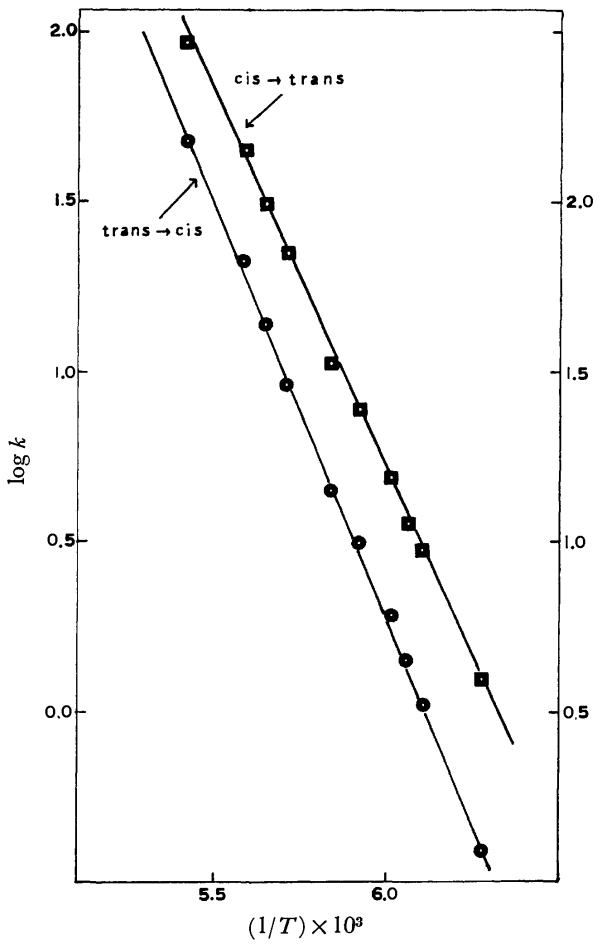

Fig. 3. The Arrhenius plots of log k *versus* $1/T$ in the two isomerization processes of **1**. The square dots □ are for the isomerization process from the *cis* to the *trans*, and the circular dots ○ are for that from the *trans* to the *cis*. The scale in the right hand is for the former process, and that the left hand is for the latter.

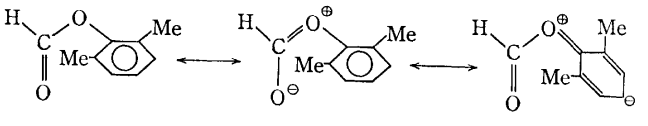
independently changing two parameters, the isomerization rate k_1 and the populations p_1, at each temperature. The line-shape analyses were performed in the two regions. The activation parameters of the ester isomerization were obtained from the Arrhenius plots of the k's and from Eyring's equation (Fig. 3). The results are shown in Table 2.*** The activation energy of the isomerization in **1** is considerably larger than in **2**. This may be accounted for by the destabilization of the energy level of the *trans* isomer in **2** at the ground state in comparison with the case of **1** because of the severe steric repulsion between the carbonyl and 1,1-diethylpropyl groups. This steric interaction in the *trans* isomer of **2** is revealed in the steric-compression lower-field shift of the alkoxy carbon signal described before. The activation entropy (ΔS^*) of **2** is much smaller than that of **1**. The reason for the smaller Δ^*S of **2** is not clear at the present time, but it is certain that it causes the activation free energy (ΔG^*) of **2** to increase. Thus, the ΔG^* of **2** is quite near to the ΔG^* of **1** ($\Delta\Delta G^*=0.9$—1.0 kcal/mol), although the difference between the activation energies (E_a) of **1** and **2** is remarkably large ($\Delta E_a=3.7$—4.4 kcal/mol).

In the case of **3**, the line broadening at low temperatures show the coexistence of the *trans* and *cis* isomers, which was also proved by the IR spectroscopic data.[15] However, we cannot determine the activation parameters of the isomerization in **3** because the signal of **3** does not separate into two peaks even at temperatures as low as −133 °C; therefore, we cannot know the chemical shifts and the populations of the two isomers. Assuming the chemical shift difference in the formyl carbon signals of the *trans* and *cis* isomers in **3** similar to those in **1** and **2**, however, it may be supposed that the activation energy in **3** is considerably smaller than those in **1** and **2**. The lower rotational barrier about the ester C–O bond in **3** may be explained by two factors: the destabilization of the *trans* isomer by the repulsion between the carbonyl and aryl groups, and the effect of the resonance between the ester and aryl groups. The latter effect may have a considerable influence, because, if the former factor is predominant, the activation energy in **3** must be larger than that in **2**, for the steric compression between the 2,6-xylyl and carbonyl groups in **3** is smaller than that between the 1,1-diethylpropyl and carbonyl groups in **2**. Concerning the latter factor, a full discussion cannot be made, but it is worthwhile pointing out that, if the resonance form, for example, **3c**, contributes to some extent, the single-bond character in the ester C–O bond may increase and the rotational barrier may be reduced.



3a **3b** **3c**

Therefore, as it was made clear that the steric bulkiness of the R group in HCO_2R strongly influences the rotational barrier about the ester C–O bond, we measured the ^{13}C spectra of methyl formate (**4**), ethyl formate (**5**), and isopropyl formate (**6**). However, they show little line broadening†, even at the temperatures below −100 °C. This result indicates two possibilities concerning the rotational barriers of these esters. The rotational barriers of these esters are so low that we cannot obtain information about them on the NMR time scale, even at these low temperatures. The second possibility is that, although the barriers of **4**—**6** are higher than those of **1** and **2**, the chemical-shift differences between the two isomers are so small, and/or the population of the *cis* (less stable) isomer is so small, that the line shapes hardly change with the temperature decrease. Since it has been reported[8] that the popu-

*** The activation parameters obtained in this study are somewhat different from those obtained in an ^1H NMR investigation by Drakenberg *et al.*[25] For example, ΔH_{t-c} in **1** at −90 °C is reported to be 9.5 kcal/mol. This small discrepancy may be explained partly by the solvent or concentration effect on the activation parameters and partly by the systematic errors of their approximate method.

† The very slight line broadening is probably caused by the high viscosity effect at low temperature.

lation of the *cis* isomer in **5** is only a few percent at room temperature, it may be negligibly small for the NMR detection at such a low temperature as −100 °C. Thus, at present, unfortunately we cannot conclude which is the true case. Since the rotational barriers of **4** obtained from the ultrasonic relaxation and IR studies are considerably different from each other, as has been described before, more detailed investigation using other techniques should be made in the future.

Neighboring Group Participation in Solvolysis. VII. Trifluoroacetolysis of ω-Phenylalkyl 6-Methyl-2-naphthalenesulfonates*

Takashi Ando, Junko Yamawaki, and Yoshimasa Saito

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received May 12, 1977)

The title compounds, $Ph(CH_2)_nOMns$ (n=2—6), were solvolyzed in buffered trifluoroacetic acid in order to elucidate the effect of a phenyl group at a remote position on the reactivity and the course of the reaction. The reactivities varied remarkably with the length of the alkyl chain(n); $2 \gg 3 \ll 4 > 5 > 6$. The rate enhancement was attributed to anchimeric assistance by a remote phenyl group, and the rate depression to the electron-withdrawing inductive effect of a phenyl group. Studies on reaction products revealed that in trifluoroacetolysis of 4-phenylbutyl menasylate (n=4) the only pathway to take place is the one with δ-phenyl participation, and that even for 5-phenylpentyl menasylate (n=5) 12% of the reaction proceeds *via* ε-phenyl participation.

Participation of remote aryl groups in solvolysis has been investigated by Winstein and collaborators with ω-arylalkyl *p*-bromobenzenesulfonates in acetic acid and formic acid.[1] Rate enhancements and formation of cyclic products, however, are not remarkable except when the aryl groups are activated with suitable substituents. Formolysis of 4-phenylbutyl *p*-bromobenzenesulfonate, *e.g.*, proceeded with a comparable rate as that of butyl *p*-bromobenzenesulfonate, and gave only a 17% yield of 1,2,3,4-tetrahydronaphthalene (tetralin). On the other hand, solvents with low-nucleophilicity and high-ionizing power such as trifluoroacetic acid are known to enhance the solvolysis with anchimeric assistance.[2] Recently, Mason reported that a considerable rate enhancement by δ-phenyl participation was detected in trifluoroacetolysis of a series of 1-methyl-ω-phenylalkyl tosylates.[3] He observed a 93% yield of 1-methyltetralin in trifluoroacetolysis of 1-methyl-4-phenylbutyl tosylate. In the case of the secondary tosylates, however, a quantitative discussion is difficult because it can not be denied that the methyltetralin may be produced from the first-formed ion or ion-pair. The present investigation on trifluoroacetolysis of ω-phenylalkyl 6-methyl-2-naphthalenesulfonates was undertaken in order to elucidate quantitatively the effect of a remote phenyl group on the reactivity and the course of the reaction. In this case of the primary esters in the low-nucleophilic solvent, anchimeric assistance must be pronounced and a rate-product correlation must be valid.

Results

By use of a newly-developed leaving group, 6-methyl-2-naphthalenesulfonate (menasylate; Mns), trifluoroacetolysis can be followed easily and accurately by the spectrophotometric method.[4] At the standard substrate concentration (0.05 M) in the presence of 0.125 M of sodium trifluoroacetate, the reaction rates of butyl (**1**) and ω-phenylalkyl menasylates (**2**—**6**) were determined by following decrease in absorption at 326 nm.

$CH_3(CH_2)_3OMns$	$C_6H_5(CH_2)_nOMns$
1	**2** (n=2), **3** (3), **4** (4), **5** (5), and **6** (6)

The observed rate constants together with the corresponding activation parameters are given in Table 1. Each reported rate constant is the average value of duplicate or triplicate runs. The individual runs have correlation coefficients greater than 0.9995 over two half-lives for all compounds except 3-phenylpropyl menasylate (**3**). In the case of **3**, discoloration of the solution was observed as the reaction proceeded. The rate constants were thus calculated from absorbances observed at the earlier stage of the reaction (up to 50—65%) and those at infinity estimated therefrom.

Reaction products were analyzed by gas chromatography after more than seven half-lives under the same conditions as those for the kinetic runs. Reaction solutions containing dodecane or hexadecane as internal standards were injected directly into a gas chromatograph. The yields of the products corrected with their respective sensitivities are summarized in Table 2. All the products were separated by preparative gas chromatography and identified by comparison with authentic samples or by spectroscopic methods. Control experiments showed that primary trifluoroacetates (**7**, **10**, **12**, and **15**) and hydrocarbons (**9**, **11**, and **14**) were stable under the reaction conditions but a secondary trifluoroacetate (**8**) was unstable under the present reaction conditions.

Discussion

It is evident from Table 1 that the chain length has a decisive influence on the trifluoroacetolysis rates of ω-phenylalkyl menasylates. The phenomenon is more clearly demonstrated in Fig. 1, in which logarithms of the relative rate constants (k_{rel}) of ω-phenylalkyl menasylates to the reference compound, butyl menasylate (**1**), are plotted against the number of the alkyl chain. Similar plots for acetolysis and formolysis of ω-phenylalkyl brosylates are also shown in Fig. 1 for comparison.[1]

Large rate enhancements for **2** and **4**, and a distinct rate depression for **3** both in trifluoroacetolysis are apparent in Fig. 1. With respect to the solvent effect, the order of rate increase observed for **2** is exactly the same order of rate decrease for **3**, *i.e.*, $CF_3CO_2H > HCO_2H > CH_3CO_2H$. Thus a solvent of low-nucleophilicity and high-ionizing power is effective for both the rate enhancement and the rate depression. The rate enhancement must be the result of anchimeric

* A preliminary report of this work was presented at the 32nd National Meeting of the Chemical Society of Japan, Tokyo, April 1975.

Table 1. Trifluoroacetolysis rates of ω-phenylalkyl menasylates

Substrate	t/°C	$k_t \times 10^5$/s^{-1}	k_{rel}[a]	ΔH^*/kcal mol^{-1} [b]	ΔS^*/e. u.[c]

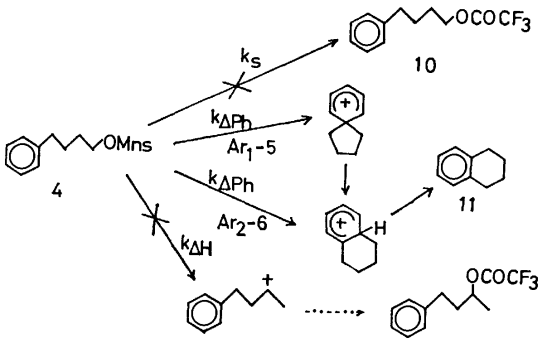
assistance by a phenyl group, and the rate depression is attributable to the electron-withdrawing inductive effect of a phenyl group.

There have been many kinds of evidence that solvolysis of phenethyl esters is accelerated by anchimeric assistance of the neighboring phenyl group.[5] The fact that anchimeric assistance is usually pronounced in trifluoroacetic acid is also well-known.[2] On the other hand, evidence for anchimeric assistance by a phenyl group at delta to the reaction center has been very limited.[1,3,6-8] A rate enhancement with a factor of 26.2 indicates clearly the existance of such assistance. Another evidence was obtained from the study on the reaction products. In trifluoroacetolysis of **4**, the yield of tetralin (**11**) was quantitative and no other product was detected. As 4-phenylbutyl trifluoroacetate (**10**), a possible product of the solvent-assisted (k_s) pathway from **4**, was stable under the reaction conditions and did not give **11**, trifluoroacetolysis of **4** proceeds exclusively *via* the phenyl-assisted (k_Δ) pathway.

It is interesting to compare the rate enhancement factor of the δ-phenyl participation in the primary menasylates with that in the secondary tosylates. However, it is difficult to calculate the latter one because the reference tosylate was not solvolyzed under the same

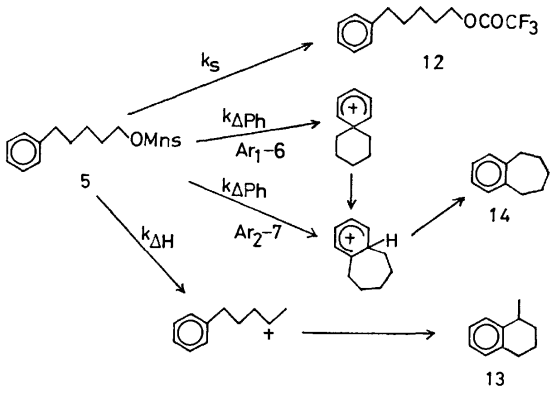
conditions. A rate ratio of 1-methyl-4-phenylbutyl tosylate to 1-methyl-5-phenylpentyl tosylate (6.6) is a good estimation for the enhancement. A corresponding ratio in the primary esters, **4** to **5**, is 22.1. A ratio of **4** to **6**, 25.2, may be a better estimation because the trifluoroacetolysis rate of **5** can not be considered as a standard (*vide infra*). The larger rate enhancement factor for the primary esters is quite reasonable as the electron demand in the form of anchimeric assistance is more pronounced in the primary solvolysis with a less stabilized reaction center than in the secondary solvolysis. The mechanism of trifluoroacetolysis of **4** is summarized in Scheme 1.



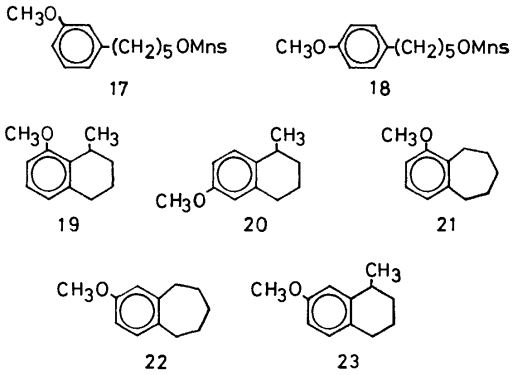
Scheme 1.

No new information was obtained from this study concerning the relative importance of the two possible modes of δ-phenyl participation, Ar_1-5 and Ar_2-6, proposed by Winstein.[1] It will be discussed in detail in a forthcoming paper.[9]

A small rate enhancement (18%) was also observed in trifluoroacetolysis of **5**. Inspection of the reaction products revealed that a 12.0% yield of 6,7,8,9-tetrahydro-5*H*-benzocycloheptene (**14**) was produced in the solvolysis. This is the first case of the production of a seven-membered ring compound through the k_Δ pathway by a carbon atom. By analogy to δ-phenyl participation, two modes of the reaction are possible in ε-phenyl participation; Ar_1-6 and Ar_2-7 (Scheme 2). In order to obtain information on the mechanism of this participation, 5-(*m*- and *p*-methoxyphenyl)pentyl menasylates (**17** and **18**) as well as **5** were solvolyzed under the same conditions. The rate constants and the reaction products were compared with each other (Table 3).



Scheme 2.



Since a methoxyl group is considered to activate its ortho and para positions and deactivate its meta positions, it was anticipated that introduction of a methoxyl group should have differentiated the two modes of participation. Unfortunately, however, introduction of a methoxyl group also caused the reactants and/or the products unstable under the reaction conditions. Because of faint discoloration of the reaction solutions at "infinity," the rate constants obtained involve much uncertainties. The yield of solvolysis products were also low especially in the case of the *m*-isomer (**17**). Nevertheless, a higher yield (16.8%) of 2-methoxy-6,7,8,9-tetrahydro-5*H*-benzocycloheptene (**22**) from **18** than that of **14** (12.0%) from **5** indicates that activation of the ipso position by the *p*-methoxyl group contributes to an increase of the fraction of the k_Δ pathway. The result clearly verifies the importance of the Ar_1-6 pathway in ε-phenyl participation. Although no definite conclusion can be drawn concerning the Ar_2-7 pathway from a comparable yield (12.5%) of 1- and 2-methoxy-6,7,8,9-tetrahydro-5*H*-benzocycloheptene (**21** and **22**) from **17**, we feel that the Ar_2-7 pathway also operates because deactivation of the ipso position by the *m*-methoxyl group does not decrease the fraction of the k_Δ pathway. A contribution from the Ar_2-7 pathway may compensate the ipso deactivation.

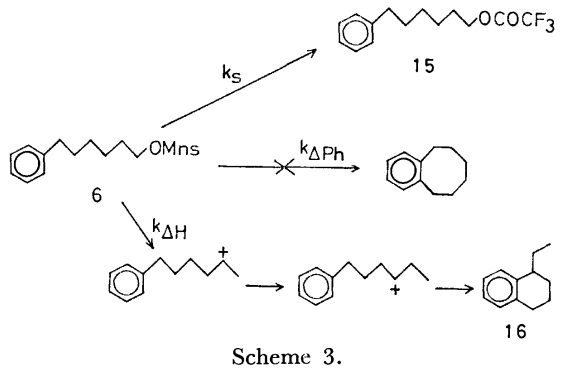
Table 3. Trifluoroacetolysis rates and products of 5-arylpentyl menasylates at 110 °C

Aryl	Rate $k_t \times 10^4/s^{-1}$	Product yield (%)		
		Prim. trifluoroacetate	1-Methyltetralin	Benzocycloheptene
C_6H_5 (**5**)	1.04±0.03	12.3	65.2	12.0
m-$CH_3OC_6H_4$ (**17**)	0.95[a]	12.6	28.2[b]	12.5[c]
p-$CH_3OC_6H_4$ (**18**)	0.99±0.06	14.0	50.4[d]	16.8[e]

a) The rate constant of a single run. b) The sum of yields of **19** (8.9%) and **20** (19.3%). c) The sum of yields of **21** (5.9%) and **22** (6.6%). d) A yield of **23**. e) A yield of **22**.

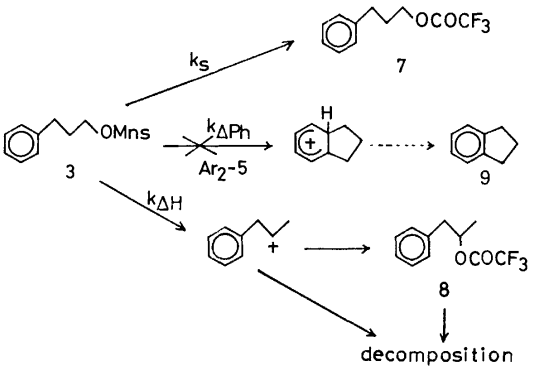
Formation of a large amount of 1-methyltetralin without a trace of a secondary trifluoroacetate from **5** is noteworthy. As it is well known that even a hydrogen next to the reaction center can participate in the solvolysis in trifluoroacetic acid, **5** must give 1-methyl-4-phenylbutyl cation or ion-pair at first.[10] The rate constant of this pathway should be designated as $k_{\Delta H}$ in contrast to that of the competitive pathway of phenyl participation as $k_{\Delta Ph}$. The cation must cyclize easily to give a 6-membered ring. A secondary trifluoroacetate (**6**) was found to be unstable in trifluoroacetic acid at a high temperature, although it was said stable at 29 °C.[3] Absence of secondary trifluoroacetates in the products from **3**, **5**, and **6** is attributed to their instability.

A phenyl ring at a more remote position than ε seems not to participate to the reaction center. The menasylate **6** was solvolyzed at a comparable rate with **1**. A small quantity (1.2%) of an unknown compound was detected by gas chromatography but its structure could not be identified as 5,6,7,8,9,10-hexahydrobenzocyclooctene. Hydrogen participation followed by hydrogen migration and cyclization is a possible route to 1-ethyltetralin (Scheme 3).



Scheme 3.

Inductive effects are considered to be transmitted to a more remote position in trifluoroacetic acid than in usual solvolysis solvents.[11] A distinct rate depression in **3** (k_{rel}=0.26) is clearly attributable to the electron-withdrawing inductive effect of a remote phenyl group. Indan, a possible product of the phenyl-assisted pathway, was not detected in the reaction mixture. In order to enhance the possibility of the Ar_2-5 pathway, the nucleophilicity of the ortho positions to the alkyl chain was increased by introduction of a methoxyl group at the meta position. Trifluoroacetolysis of 3-(*m*-methoxyphenyl)propyl menasylate (**24**), however, did not give methoxyindan at all. The rate constant for **24** was measured at 110 °C and similar to that of **3**. Accurate rate data could not be obtained because of discoloration of the reaction solutions. Reaction products from both of **3** and **24** were determined at the several stages of the reactions. About 1 : 1 mixtures of the primary and secondary trifluoroacetates were detected at the early stages of the reactions, but the latters decreased gradually and disappeared finally. Thus, the reaction of **3** is summarized in Scheme 4. The disadvantage of the Ar_2-5 pathway appears to be curious since indan is a stable and strain-free compound.



Scheme 4.

In the transition state of the phenyl-assisted pathway, however, the phenyl ring must approach to the reaction center from its perpendicular direction in order to ensure the p-σ overlap. The geometry is apparently a very unfavorable one for the Ar_2-5 pathway.[12]

Although the quantitative discussion on the activated parameters is difficult when the reaction includes composite pathways, useful information on the reaction is sometimes obtained from these parameters as they vary with the composition of the reaction. Relatively high entropies of activation have been considered a good criterion for anchimeric assistance besides rate enhancements and stereochemistry of reaction products.[13] In contrast to $\Delta S^{\ddagger}$ of *ca.* −17——18 e. u. (1 e. u.=4.184 J K^{-1} mol^{-1}) for the solvent-assisted (k_s) solvolysis, $\Delta S^{\ddagger}$ of *ca.* −7 e. u. for Ar_1-3 and *ca.* −10 e. u. for Ar_1-5 have been reported in ethanol, acetic acid, and formic acid.[1,13] Less negative $\Delta S^{\ddagger}$ for the anchimerically assisted (k_Δ) solvolysis can be attributed to a consequence of unimportance of nucleophilic involvement of the solvent in the transition state of the reaction. On the contrary, fairly constant and low $\Delta S^{\ddagger}$ were observed in trifluoroacetolysis throughout the series of ω-phenylalkyl menasylates; −15——16 e.u. for solvolysis with β and δ phenyl participation and −17——19 e.u. for others. As described above, most of the reactions in trifluoroacetic acid proceed *via* the k_Δ pathway in a sense; $k_{\Delta Ph}$ or $k_{\Delta H}$. Relatively constant $\Delta S^{\ddagger}$ can reasonably be expected in these cases. The low values of $\Delta S^{\ddagger}$ for the k_Δ pathway observed in this series are not anomalous in trifluoroacetic acid. $\Delta S^{\ddagger}$ for trifluoroacetolysis of ethyl tosylate, the pure k_s pathway, was −27 e.u. and much more negative than those in other solvents, *ca.* −17 e.u.[10] The differences of *ca.* 10 e.u. between $\Delta S^{\ddagger}$ in trifluoroacetic acid and those in other solvents observed in both of the k_Δ and k_s pathways suggest that electrophilic rather than nucleophilic solvation is important in trifluoroacetic acid and becomes a driving force of the reaction.

The effect of the concentration of sodium trifluoroacetate on the rates and the products was not studied in this series of solvolysis. It should be mentioned, however, that in trifluoroacetolysis of 4-phenylbutyl-1,1-d_2 menasylate (**4**-d_2) in the presence or absence of sodium trifluoroacetate, no deuterium scrambling was detected in the recovered menasylate. The cyclic intermediates of Ar_1-5 and/or Ar_2-6 pathways must afford tetralin without ion-pair return.

Experimental

General. All melting points were measured on a hot stage and not corrected. NMR spectra were recorded with Hitachi R-20 and R-24 spectrometers with tetramethylsilane as an internal standard.

Starting Alcohols. 1-Butanol and 3-phenyl-1-propanol were commercially available and used after purification. Other alcohols were prepared as follows.

4-Phenyl-1-butanol: This alcohol was prepared in a quantitative yield by lithium aluminum hydride reduction of 4-phenylbutanoic acid: bp 99—110 °C/4 Torr (lit,[14] 140 °C/14 Torr).

5-Phenyl-1-pentanol: This material was prepared by the Friedel-Crafts reaction of benzene with glutaric anhydride and aluminum chloride,[15] followed by the Wolff-Kishner reduction, esterification, and lithium aluminum hydride reduction, successively: bp 127 °C/5.5 Torr (lit,[14] 155 °C/20 Torr).

6-Phenyl-1-hexanol: This material was prepared by the Friedel-Crafts reaction of benzene with adipic anhydride polymer and aluminum chloride,[16] followed by the Wolff-Kishner reduction, esterification, and lithium aluminum hydride reduction, successively: bp 124 °C/3.5 Torr (lit,[14] 160—161 °C/13 Torr).

3-(m-Methoxyphenyl)-1-propanol: This alcohol was prepared by the Knoevenagel reaction of *m*-methoxybenzaldehyde with malonic acid,[17] followed by esterification and lithium aluminum hydride reduction: bp 137—138 °C/5.5 Torr (lit,[1] 135—140 °C/3.5 Torr).

5-(m-Methoxyphenyl)-1-pentanol: 3-(*m*-Methoxyphenyl)-1-propanol was converted to the chloride,[18] cyanide,[19] acid, ethyl ester, and 4-(*m*-methoxyphenyl)-1-butanol, successively. Application of the same series of reactions to the butanol gave the pentanol: bp 144—146 °C/3.5 Torr.

5-(p-Methoxyphenyl)-1-pentanol: This alcohol was prepared from 4-(*p*-methoxyphenyl)-1-butanol by the same sequence of reactions as described in the meta series: bp 147—148 °C/3 Torr (lit,[20] 144—145 °C/2 Torr).

4-Phenyl-1-butan-1,1-d_2-ol: This alcohol was prepared from ethyl 4-phenylbutanoate by reduction with lithium aluminum deuteride: bp 119.5 °C/6.5 Torr; deuterium content better than 99% (by ^{1}H NMR). Found: C, 78.91; H(D), 9.48% Calcd for $C_{10}H_{12}D_2O$: C, 78.90; H, 7.95; D, 1.32%.

Preparation of Menasylates. Menasylates were prepared by standard procedures from menasyl chloride and alcohols at 0°C in pyridine as a solvent.[4]

*Butyl Menasylate (**1**)*: Bp 177 °C/0.4 Torr, mp 33.7—34.7 °C. Found: C, 64.66; H, 6.48; S, 16.80%. Calcd for $C_{15}H_{18}O_3S$: C, 64.72; H, 6.52: S, 17.24%.

*Phenethyl Menasylate (**2**)*: Mp 104.3—105.0 °C (lit,[4] 101.9—102.5 °C).

*3-Phenylpropyl Menasylate (**3**)*: Mp 75.0—75.5 °C (from petroleum ether-ether). Found: C, 70.71; H, 5.75; S, 9.20%. Calcd for $C_{20}H_{20}O_3S$: C, 70.56; H, 5.92; S, 9.42%.

*4-Phenylbutyl Menasylate (**4**)*: Mp 104.9—105.0 °C (from hexane-benzene). Found: C, 71.36; H, 6.11; S, 9.17%. Calcd for $C_{21}H_{22}O_3S$: C, 71.16; H, 6.26; S, 9.06%.

*5-Phenylpentyl Menasylate (**5**)*: Mp 63.0—63.4°C (from cyclohexane). Found: C, 71.53; H, 6.27; S, 8.61%. Calcd for $C_{22}H_{24}O_3S$: C, 71.71; H, 6.57; S, 8.70%.

*6-Phenylhexyl Menasylate (**6**)*: Mp 52.0—52.8 °C (from petroleum ether-ether). Found: C, 72.08; H, 6.72; S, 8.33%. Calcd for $C_{23}H_{26}O_3S$: C, 72.22; H, 6.85; S, 8.38%.

*5-(m-Methoxyphenyl)pentyl Menasylate (**17**)*: This menasylate was obtained as an oil at a room-temperature and purified by recrystallization at a low temperature from petroleum ether-ether. Found: C, 69.21; H, 6.45; S, 8.15%. Calcd for $C_{23}H_{26}O_4S$: C, 69.32; H, 6.58; S, 8.05%.

*5-(p-Methoxyphenyl)pentyl Menasylate (**18**)*: Mp 57.7—58.3 °C (from petroleum ether-ether). Found: C, 69.11; H, 6.55; S, 8.15%. Calcd for $C_{23}H_{26}O_4S$: C, 69.32; H, 6.58; S, 8.05%.

*3-(m-Methoxyphenyl)propyl Menasylate (**24**)*: Mp 46.0—47.0 °C (from petroleum ether-ether). Found: C, 67.81; H, 5.71; S, 8.70%. Calcd for $C_{21}H_{22}O_4S$: C, 68.08; H, 5.99; S, 8.65%.

*4-Phenylbutyl-1,1-d_2 Menasylate (**4**-d_2)*: Mp 104.5—105.0 °C (from ligroin); deuterium content better than 99% (by ^{1}H NMR). Found: C, 70.69; H(D), 6.13; S, 9.12%. Calcd for $C_{21}H_{20}D_2O_3S$: C, 70.76; H, 5.66; D, 0.56; S, 8.99%.

Preparation of Trifluoroacetates and Other Solvolysis Products. Authentic samples of trifluoroacetates were prepared from alcohols and three molar equivalents of trifluoroacetic anhydride at 0 °C. Excess of the anhydride was removed under reduced pressure and the residual esters were distilled. Indan (**9**) and tetralin (**11**) were purchased and purified.

*3-Phenylpropyl Trifluoroacetate (**7**)*: Bp 83—90 °C/5.5 Torr. Found: C, 56.98; H, 4.97; F, 24.21%. Calcd for $C_{11}H_{11}F_3O_2$: C, 56.90; H, 4.78; F, 24.55%.

*1-Methyl-2-phenylethyl Trifluoroacetate (**8**)*: Bp 67 °C/6 Torr (lit,[2a] 70—71 °C/5 Torr).

*4-Phenylbutyl Trifluoroacetate (**10**)*: Bp 91.1—92.0 °C/4 Torr. Found: C, 57.75; H, 5.32; F, 23.97%. Calcd for $C_{12}H_{13}F_3O_2$: C, 57.83; H, 5.26; F, 24.07%.

*5-Phenylpentyl Trifluoroacetate (**12**)*: Bp 77—78 °C/2 Torr. Found: C, 59.80; H, 5.95; F, 21.60%. Calcd for $C_{13}H_{15}F_3O_2$: C, 60.00; H, 5.81: F, 21.90%.

*6-Phenylhexyl Trifluoroacetate (**15**)*: Bp 96 °C/6 Torr. Found: C, 61.25; H, 6.44%. Calcd for $C_{14}H_{17}F_3O_2$: C, 61.31; H, 6.25%.

*6,7,8,9-Tetrahydro-5H-benzocycloheptene (**14**)*: This material was prepared by the Wolff-Kishner reduction of 6,7,8,9-tetrahydro-5*H*-benzocyclohepten-5-one: bp 96.5-97.0 °C/13 Torr (lit,[21] 108—109 °C/22 Torr).

Trifluoroacetolysis Media. Trifluoroacetic acid containing 1 wt% of trifluoroacetic anhydride and 0.125 M of sodium trifluoroacetate was prepared according to the procedure described before.[4]

Kinetic Procedures. The usaul ampoule technique described before was employed.[4] Absorbances after more than ten half-lives were used as those at "infinity" except in the cases of **3**, **17**, and **18**. In these cases absorbances at infinity (A_∞) were calculated so as to make plots of $\log(A-A_\infty)$ *vs.* time linear. Absorbances were measured with a Hitachi Perkin-Elmer 139 UV-visible spectrophotometer.

Product Analyses. Reaction solutions containing 0.01 M of dodecane after more than seven half-lives were directly injected into a Varian Aerograph Model 2850-30 gas chromatograph with a flame ionization detector and a Hewlett-Packard 3370B digital integrator. A column packed with Silicon DC550 on Celite 545 was used. For the product analysis of **17**, PEG 20M on Celite 545 as a packing of a column and hexadecane as a standard were used. Sensitivities were determined using authentic samples for primary trifluoroacetates (**7**, **12**, and **15**), a secondary trifluoroacetate (**8**), tetralin (**11**), and 6,7,8,9-tetrahydro-5*H*-benzocycloheptene (**14**). For other compounds sensitivities were calculated by the method described by Sternberg *et al.*[22] Accuracy of calculated sensitivities were established for related compounds.

Identification of Solvolysis Products. All the reaction

products were separated by preparative gas chromatography and identified by comparison with authentic samples when available. Identification of following compounds were performed by spectroscopic analysis. NMR data in carbon tetrachloride are summarized below.

*1-Methyltetralin (**13**)*: δ=1.28 (3H, d, J=7.5 Hz, CH_3), 1.80 (4H, m), 2.80 (3H, m), and 7.07 (4H, m, Ar).

*1-Ethyltetralin (**16**)*: δ=0.95 (3H, t, J=7.5 Hz, CH_3), 1.80 (6H, m) 2.70 (3H, m), and 6.95 (4H, m, Ar).

*1-Methyl-8-methoxytetralin (**19**)*: δ=1.15 (3H, d, J=6.0 Hz, CH_3), 1.75 (4H, m), 2.73 (2H, m), 3.17 (1H, m), 3.77 (3H, s, OCH_3), and 6.42—7.00 (3H, m, Ar).

*1-Methyl-6-methoxytetralin (**20**)*: δ=1.18 (3H, d, J=8.0 Hz, CH_3), 1.67 (4H, m), 2.67 (3H, m), 3.59 (3H, s, OCH_3), and 6.40—7.05 (3H, m, Ar).

*1-Methoxy-6,7,8,9-tetrahydro-5H-benzocycloheptene (**21**)*: δ= 1.68 (6H, m), 2.72 (4H, m), 3.63 (3H, s, OCH_3), and 6.35 —6.92 (3H, m).

*2-Methoxy-6,7,8,9-tetrahydro-5H-benzocycloheptene (**22**)*: δ= 1.71 (6H, m), 2.70 (4H, m), 3.69 (3H, s, OCH_3), and 6.33— 6.92 (3H, m).

*1-Methyl-7-methoxytetralin (**23**)*: δ=1.22 (3H, d, J=7.5 Hz, CH_3), 1.75 (4H, m), 2.65 (3H, m), 3.60 (3H, s, OCH_3), and 6.30—6.85 (3H, m, Ar).

*Trifluoroacetolysis of 4-Phenylbutyl-1,1-d_2 Menasylate (**4**-d_2)*. A reaction solution of 0.05 M of **4**-d_2 in the same media as that for kinetic runs was allowed to react one half-life at 70.0 °C. The solvent was removed under reduced pressure and the residue was poured into ice-water. Precipitates were recovered by filtration and purified by recrystallization. No scrambling of the deuterium in the recovered **4**-d_2 was indicated by the absence of any signal at δ 4.06 (t, CH_2OMns).

A similar experiment in the absence of sodium trifluoroacetate also showed no scrambling of the deuterium in the recovered menasylate.

We thank Dr. Yasuhide Yukawa, Professor Emeritus of Osaka University, for his helpful discussion. The present work was partially supported by a Grant-in-Aid (No. 964097) for Scientific Research from Minitstry of Education.

Branched-chain Sugars. II. Synthesis of Methyl 5-Deoxy-3-*C*-hydroxymethyl-2,3-*O*-isopropylidene-β-DL-*lyxo*-furanoside (Dihydrostreptose) and Ribofuranoside Derivatives

Takamasa KINOSHITA and Toshio MIWA

Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

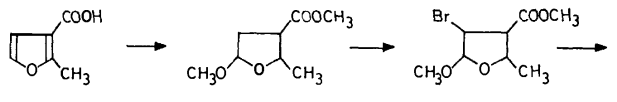
(Received May 14, 1977)

The title compounds, methyl 5-deoxy-3-*C*-hydroxymethyl-2,3-*O*-isopropylidene-β-DL-*lyxo*-furanoside, and ribofuranoside derivatives were conveniently synthesized *via* the Birch reduction of 2-methyl-3-furoic acid, and the latter was identified with the sample prepared from D-xylose.

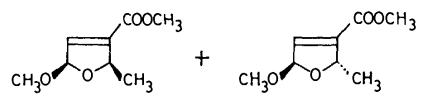
In a previous paper,[1] we reported the synthesis of DL-apiose from 2-methoxy-4-(methoxycarbonyl)tetrahydrofuran which had been prepared *via* the Birch reduction of 3-furoic acid.[2] This paper will describe the synthesis of 5-deoxy-3-*C*-branched-DL-*lyxo*- and ribofuranoses of Type A[3] as an application of the method to the total synthesis of 3-*C*-branched-chain sugars from substituted 3-furoic acids.

Results and Discussion

The Birch reduction of 2-methyl-3-furoic acid (**1**) gave 2-methyl-2,3-dihydro-3-furoic acid, which, after esterification with diazomethane, followed by the acid-catalyzed addition of methanol, was isolated as a methoxy methyl ester (**2**) in a 95% yield. This compound was shown by gas chromatography (GLC) to be a mixture of four diastereoisomers with respect to each functional group, but the constituents could not be separated. The bromination of **2** by pyridinium tribromide in tetrahydrofuran at room temperature afforded a bromo compound (**3**) in a 75% yield. On the treatment of the isomeric mixture **3** with DBU (1,8-diazabicyclo[5.4.0]undec-7-ene) in benzene at room temperature for one minute, 5-methyl-2-methoxy-4-(methoxycarbonyl)-2,5-dihydrofuran (**4**), a mixture of (**4a**) and (**4b**) with the expected spectroscopic data, was obtained in a 75% yield. The oxidation of **4** with osmium tetraoxide–sodium chlorate[4] in aqueous tetrahydrofuran yielded diol in a 95% yield; it was subsequently isolated as an isomeric mixture of isopropylidene compounds, (**5a**), (**5b**), and (**5c**). These were separated by GLC in a ratio of 1.0: 1.5 : 1.7.

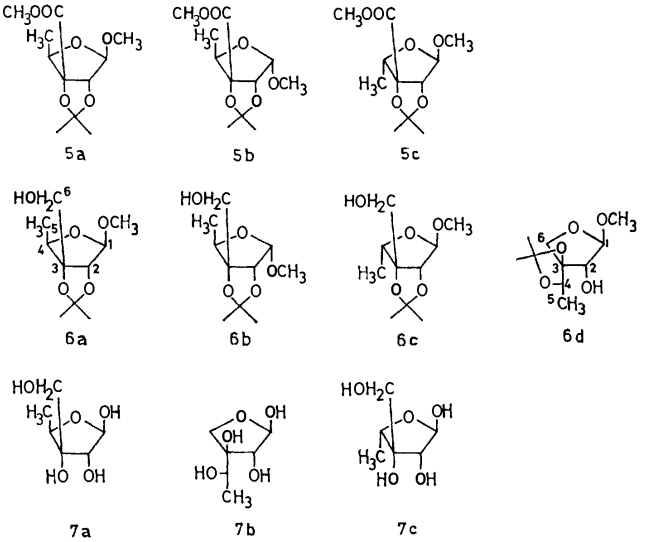


1 2 3



4a 4b

The structures of the compounds were assigned on the basis of the PMR spectrum. No coupling was observed between H-1 and H-2 in **5a** and **5c**, indicating that the methoxyl group is *trans*-disposed[5] to the 2,3-*O*-isopropylidene group. On the other hand, the doublets ($J_{1,2}$=4.6 Hz) for H-1 and H-2 in **5b** indicate these protons to be *cis* on the furanoid ring.[1] Although the exact orientation of the methyl group on carbon-4 was assigned by independent synthesis (see below), the signals of the methyl group in **5c** and that of the anomeric methoxyl group in **5b** appeared at the lowest field as a result of deshielding by the dioxolan ring. At this point, some comments may be added regarding the hydroxylation of **4**. In the oxidation of **4** with osmium tetraoxide, *cis*-**4a** gave exclusively **5a**, while *trans*-**4b** gave **5b** and **5c** in approximately equal quantities; this means that the steric bulkiness towards hydroxylation is almost the same in the methyl and methoxyl group.



5a 5b 5c

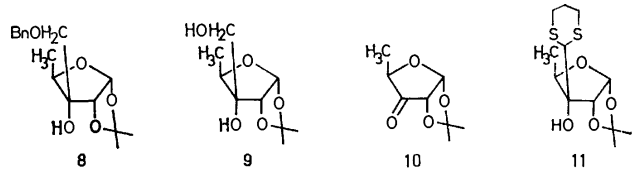
6a 6b 6c 6d

7a 7b 7c

The acid-catalyzed hydrolysis of **5a**, followed by reglycosidation in methanol and acetonation , yielded **5a** and **5b** in a ratio of 2 : 7 (by GLC). This fact shows that **5b**, being an α-anomer, is more stable than **5a**. The methyl esters, **5a**—**c**, were reduced quantitatively to the corresponding alcohols (**6a**—**c**). The assignment of the configuration of (**6**) was based on its PMR spectral data and on the individual conversion of **5** to **6**. The chemical shifts and coupling constants were assigned as is shown in the Table. The fact that the methyl signal in **6a** appeared at the lowest may be explained by the deshielding effect being by the hydroxymethyl group rather than by the dioxolan ring.

A mixture of **6a** and **6b** was converted to a 1,2-*O*-isopropylidene derivative (**8**) *via* the following sequence of reactions: benzylation[6] in DMSO (37%), acid-catalyzed hydrolysis (85%), and acetonation (15%).[7]

Hydrogenation on Pd–charcoal of **8** gave a crystalline 5-deoxy-3-*C*-hydroxymethyl-1,2-*O*-isopropylidene-α-DL-ribofuranose (**9**) (mp 128—129 °C[8]) in a 90% yield. Compound **9** was synthesized in three steps from 5-deoxy-1,2-*O*-isopropylidene-α-D-*erythro*-pentofuranos-3-ulose (**10**),[9] which had been prepared from D-xylose. The reaction of **10** with 2-lithio-1,3-dithiane gave the branched-chain sugar, 5-deoxy-3-*C*-formyl-1,2-*O*-isopropylidene-α-D-ribofuranose trimethylene dithioacetal (**11**). Mercury(II) oxide and boron trifluoride etherate hydrolyzed **11** to 5-deoxy-3-*C*-formyl-1,2-*O*-isopropylidene-α-D-ribofuranose, which was then reduced with sodium borohydride to give **9**. The resulting compound was identified by comparing its PMR and mass spectra with those of the sample derived from 2-methyl-3-furoic acid.



8 9 10 11

The acid-catalyzed hydrolysis of the alcohol **6c** with hydrochloric acid gave dihydrostreptose (**7c**), while that of **6a** or **6b** gave (**7a**). The hydrolysis of **6b**, followed by reglycosidation in methanol and acetonation, gave (**6d**) and **6a** in a ratio of 1 : 5. These substances were separated by GLC. **6a** was identified by comparing its GLC, MS, and PMR. The structure of **6d** was established by spin-decoupling studies. In the PMR spectrum of **6d**, the irradiation of C-5 methyl protons (δ, 1.28) collapsed the H-4 methin proton (δ, 4.20, quartet) to a singlet. The irradiation of H-2 (δ, 3.76) changed the H-1 (δ, 4.78, doublet) and the hydroxyl signals (δ, 2.60, doublet) both into singlets. A small H-1, H-2 coupling constant (1.2 Hz) could be taken as an indication of the *trans* arrangement of the protons. From the above data, **6d** was concluded to be a methyl 3-*C*-(1-hydroxyethyl)-3,3′-*O*-isopropylidene-β-DL-*threo*-furanoside.

Accordingly, in the production of **6d** it may be assumed that **7a** comprised an isomer (**7b**). In the PMR spectrum of **7c**, the methyl signals (doublet, J=6.5) appeared at δ 1.24 (75%, β-anomer) and δ 1.29 (25%, α-anomer), as had been reported by Dyer.[10] The predominance of the β-anomer, contrasted with methyl glycoside, is apparently due to the hydrogen bonding with the 3-*C*-hydroxymethyl group. Although the PMR spectrum of **7a** could not be assigned because of the concomitance of isomeric **7b**, the same situation was observed with the 4-epimer **7a**, which showed the methyl signals at δ 1.20 (25%, α-anomer) and δ 1.24 (75%, β-anomer) in a lower field than those of **7c**.

Experimental

Melting points were determined on a micro hot stage and are uncorrected. GLC was performed on a Varian Aerograph Model 90-P instrument equipped with a 4 mm × 1 mm column of Poly(ethylene glycol) (20% on Chromosorb W-AW, DMCS). The column temperature was 180 °C, and the flow rate was 60 ml of helium/min. IR spectra were taken on a JASCO Model IR-E. PMR spectra were recorded in chloroform-*d* solution at 100 MHz with a JEOLCO PS-100 spectrometer. Mass spectra were recorded with a HITACHI M-52 mass spectrometer at 70 eV. Elemental analyses were carried out on a Perkin Elmer Model 240 elemental analyzer.

*2-Methyl-3-furoic Acid (**1**)* (mp 102 °C) was prepared from ethyl 2-methyl-3-furoate; bp 87—95 °C/25 mmHg (lit,[11] bp 81—84 °C/18 mmHg).

The Birch Reduction of 2-Methyl-3-furoic Acid. To a mixture of 2-methyl-3-furoic acid (5.68 g) and anhydrous methanol (20 ml) in liquid ammonia (150 ml) was added sodium metal (5.2 g) little by little with constant stirring under reflux. The mixture was then stirred for an additional hour and ammonium chloride (11 g) was added. After evaporation of the liquid ammonia at room temperature, the residue was dissolved in water (100 ml). The aqueous solution was acidified with hydrochloric acid to pH 2 and extracted continuously with ether for 15 h. The ether extract was esterified with diazomethane, and, after the evaporation of the solvent, the residue was distilled to give **2**; 7.38 g (95%); bp 99—101 °C/20 mmHg; IR cm^{-1} 2830 (OCH_3), 1735 (C=O) Found: C, 55.09; H, 8.22%. Calcd for **2** ($C_8H_{14}O_4$): C, 55.16; H, 8.10%.

Bromination of 2. To a stirred solution of **2** (1.74 g)

in dry THF (20 ml) was added pyridinium tribromide (3.1 g). The reddish solution was stirred at room temperature. After 12 h, a white precipitate appeared and the color disappeared. The precipitate was filtered off and the filtrate was concentrated to a light-brown oil, which was then purified by chromatography on silica gel (80 g) with benzene to give a colorless liquid (**3**) (1.92 g, 75%); IR cm^{-1} 2830 (OCH_3), 1735(C=O). MS *m/e* (%) 254 (1) (M^+), 252(1) (M^+), 223 (50), 221(49), 191(25), 189 (22), 141 (78), 130 (75), 113(100), 83 (70).

*Dehydrobromination of **3** with DBU.* To a vigorously stirred solution of **3** (1.2 g) in dry benzene (25 ml) was added DBU (1.52 g) at room temperature. There immediately appeared a white precipitate of DBU-hydrobromide. Water (20 ml) was added to the reaction mixture and the organic layer was separated, washed with water, dried over sodium sulfate, and evaporated to give a 2,5-dihydrofuran derivative (**4**) as a colorless liquid (650 mg, 75%); IR cm^{-1} 3080, 2830, 1723, 1645; PMR δ1.47 (3H, d, J=6, CH_3), 3.40 (3H, s, OCH_3), 3.75 (3H, s, $COOCH_3$), 5.10—4.85 (1H, m, H-5), 5.70 (1H, s, H-2), 6.58 (1H, s, H-3).

*Methyl 5-Deoxy-3-*C*-methoxycarbonyl-2,3-*O*-isopropylidene-β- and α-*DL*-Ribofuranoside, **5a** and **5b**,* and *Methyl 5-Deoxy-3-*C*-methoxycarbonyl-2,3-*O*-isopropylidene-β-*DL*-lyxo-furanoside, **5c**.* To a stirred solution of the dihydro compound **4** (4.71 g) and osmium tetraoxide (80 mg) in THF (25 ml) was added a solution of sodium chlorate (3.82 g) in water (25 ml) at room temperature. After stirring for 24 h, the light-yellow solution was decomposed by passing hydrogen sulfide gas through it. Black precipitates were removed by filtration through Celite, and the colorless solution was concentrated to a volume of about 20 ml. The aqueous solution was extracted continuously with ether for 15 h to give a diol as a syrup; crude yield, 4.86 g (91%). IR cm^{-1} 3450, 2830, 1730.

The diol (2.06 g) was acetonated by treatment with dry acetone (150 ml), anhydrous copper(II) sulfate (15 g), and a catalytic amount of sulfuric acid at room temperature for 24 h to afford an oil, a mixture of **5a**, **5b**, and **5c**, after purification by column chromatography on silica gel; yield, 2.24 g (91%). The mixture was separated by GLC in a ratio of 1.0 : 1.5 : 1.7. The retention times: **5a**, 9.5 min; **5b**, 12.0 min; **5c**, 7.2 min. Found for **5a**: C, 53.51; H, 7.33%. Found for **5b**: C, 53.53; H, 7.44%. Found for **5c**: C, 53.50; H, 7.34%. Calcd for ($C_{11}H_{18}O_6$): C, 53.65; H, 7.37%.

*Chemical Conversion of **5a** to **5b**.* Compound **5a** (50 mg) in water-methanol (5 ml; 4 : 1) was hydrolyzed in the presence of a catalytic amount of *p*-toluenesulfonic acid at reflux for 2 h. After the disappearance of the anomeric methoxyl and isopropylidene groups has been ascertained by an estimation of the PMR spectrum in deuterium oxide, the syrup was boiled in dry methanol-dry acetone (20 ml; 10 ml) in the presence of *p*-toluenesulfornic acid for 6 h. The resulting compound (35 mg) was identified by comparing its GLC (**5a** : **5b**=2 : 7) with those of the sample.

*Methyl 5-Deoxy-3-*C*-hydroxymethyl-2,3-*O*-isopropylidene-β- and α-*DL*-Ribofuranoside, **6a** and **6b**, and Methyl 5-Deoxy-3-*C*-hydroxymethyl-2,3-*O*-isopropylidene-β-*DL*-lyxo-furanoside, **6c**.* Those substances were obtained quantitatively by the lithium aluminium hydride reduction in boiling ether for 3 h of **5a**, **5b**, and **5c** respectively. MS *m/e* (%) for **6a**: M^+ (absent), 203(12), 187(16), 171(9), 143(52), 119(20), 100(48), 85(96), 82(88), 73(100), 71(60). **6b**: M^+(absent), 203(4), 187(12), 171(9), 143(32), 119(16), 100(20). 85(35), 82(55), 73(100), 71(80). **6c**: M^+(absent), 203(3), 187(10), 171(5), 143(25), 119(15), 100(25), 85(40), 82(55), 73(100), 71(75). *p*-Nitrobenzoate of **6a**: syrup; **6b**, mp 109—110 °C; **6c**, mp 130—130.5 °C. Found for **6b**: C, 55.86; H, 5.80; N, 3.87%. Found for **6c**: C, 55.54; H, 5.80; N, 3.77%. Calcd for *p*-nitrobenzoate ($C_{17}H_{21}O_8N$): C, 55.58; H, 5.76; N, 3.81%.

*Chemical Conversion of **6b** to **6a** and **6d**.* Compound (**6b**) (70 mg) in water (5 ml) was hydrolyzed in the presence of two drops of concentrated hydrochloric acid at reflux for 10 min. After the evaporation of the solvent, the syrup was boiled in dry methanol-dry acetone (20 ml; 10 ml) in the presence of ion-exchange resin (Dowex 50X8, 500 mg) for 20 h to afford an oil (crude; 85 mg) as a mixture of the two compounds. The mixture was separated by GLC (at 200 °C) in the ratio of 1 : 5. The retention times: 6.2 min (**6d**); 7.5 min (**6a**).

*α,β-DL-Dihydrostreptose, **7c**, and Its 4-Epimer, **7a**.* Compound (**6c**) (300 mg) in water (5 ml) was hydrolyzed in the presence of a catalytic amount of concentrated hydrochloric acid at room temperature for 15 h. The evaporation of the solvent under diminished pressure below 40 °C gave a syrup of **7c** (220 mg, 95%). The PMR spectrum in deuterium oxide showed the absorptions of two isomers. The β-anomer comprised 75% of the mixture and showed absorptions at δ1.24 (3H, d, J=6.5, CH_3–), 3.60 (2H, s, H-6), 4.09 (1H, d, J=4.0, H-2), 4.35 (1H, q, J=6.5, H-4), 5.26 (1H, d, J=4.0, H-1). The α-anomer: δ1.29 (3H, d, J=6.5), 3.60 (2H, s), 4.10 (1H, q, J=6.5), 4.17 (1H, d, J=5.0), 5.23 (1H, d, J=5.0).

By the same procedure, **7a** was also obtained from **6a** or **6b**. δ1.20 (3H, d, J=6.5); α-anomer, 25%. δ1.24 (3H, d, J=6.5); β-anomer, 75%.

*5-Deoxy-3-*C*-hydroxymethyl-1,2-*O*-isopropylidene-α-*DL*-ribofuranose, **9**.* The benzylation of a mixture of **6a** and **6b** (1.0 g) was performed in accordance with Iwashige's method[6] to afford the benzyl ether in a 37% yield. The ether (200 mg) dissolved in dioxane-water (10 ml) was hydrolyzed at reflux for 2 h in the presence of concentrated hydrochloric acid to give a syrup (140 mg), which was then acetonated by the procedure described above to give 1,2-*O*-isopropylidene benzyl ether, **8**; 25 mg (15%); PMR δ5.60 (1H, d, $J_{1,2}$=4, H-1), 4.48 (1H, d, H-2), 3.91 (1H, q, $J_{4,5}$=6, H-4), 3.42(2H, q, $J_{6,6'}$=10, H-6), 2.66 (OH), 1.55 (3H, s), 1.35 (3H, s), 1.17 (3H, d, H-5), 4.52 (2H, q, J=12, benzyl), 7.27 (5H, s, arom.).

The hydrogenation of the benzyl ether **8** (25 mg) over 10% Pd-C in methanol for 5 h afforded a crystalline **9** (15 mg, 90%): mp 128—129 °C; PMR δ5.75 (1H, d, $J_{1,2}$=4, H-1), 4.55 (1H, d, H-2), 3.92 (1H, q, $J_{4,5}$=6.2, H-4), 3.75 (2H, d, $J_{6,6'}$=12, H-6), 2.73 (OH), 3.36 (OH), 1.56 (3H, s), 1.37 (3H, s), 1.18 (3H, d, CH_3–). MS *m/e* (%) M^+ (absent), 189 (14), 129(40), 99(36), 88(25), 71(89), 59(100). Found: C, 52.60; H, 7.86%. Calcd for **9** ($C_9H_{16}O_5$): C, 52.93; H, 7.92%.

*5-Deoxy-3-*C*-formyl-1,2-*O*-isopropylidene-α-*D*-ribofuranose Trimethylene Dithioacetal, **11**.* To a stirred solution of 1,3-dithiane (200 mg) in dry THF (4 ml) was added butyllithium (1.5 ml, 1.2 M in hexane) at −78 °C under a nitrogen atmosphere. After stirring at that temperature for 2 h, the ulose, **10** (170 mg) in dry THF (2 ml) was added and the reaction mixture was stirred for 3 h at room temperature. Water (10 ml) was then added and subsequently extracted with dichloromethane (20 ml×3). After an usual work-up and preparative thin-layer chromatography (0.75 mm silica gel on plate) (benzene-ether, 8 : 2), dithioacetal, **11** (270 mg, 92%), was obtained; mp 123—124 °C; $[\alpha]_D^{26}$ +5° (c=1, in acetone). PMR δ5.86 (1H, d, $J_{1,2}$=4, H-1), 4.74 (1H, d, H-2), 4.43 (1H, s, S–CH–S), 4.02 (1H, q, $J_{4,5}$=7, H-4), 3.00 (1H, s, OH), 2.80—3.00 (4H, m, $-CH_2-S-$), 2.05 (2H, bs, $-CH_2-$), 1.57 (3H, s,), 1.39 (3H, s), 1.45 (3H, d, H-5). MS *m/e* (%) 292 (6) (M^+), 277(1), 217(2), 190(1), 175(5), 146(3), 127(2), 119(100). Found C, 49.31; H, 6.89%. Calcd for

$C_{12}H_{20}O_4S_2$: C, 49.31; H, 6.90%.

5-Deoxy-3-C-hydroxymethyl-1,2-O-isopropylidene-α-D-ribofuranose **9**. To a suspension of red mercury(II) oxide (650 mg) and boron trifluoride etherate (365 mg) in 5 ml of 80% aqueous acetone was added, drop by drop, dithioacetal **11** (250 mg) in THF (2 ml) under a nitrogen atmosphere. After the mixture had been stirred overnight, the color disappeared. Water (2 ml) and acetone (6 ml) were then added, and the mixture was neutralized with a sodium hydroxide solution. The precipitate was filtered off, and the filtrate was concentrated to dryness under diminished pressure below 40 °C, extracted with chloroform, washed with water, and dried over sodium sulfate. The resulting syrup was reduced with sodium borohydride in 70% aqueous methanol (15 ml) to give an oil (120 mg). The residue was chromatographed on silica gel (5 g) (CH_2Cl_2–ether, 10 : 1); fractions were collected every 15 ml. Fraction 4—6 (30 mg) **9**, mp 112—113 °C. The PMR and mass spectra were identified with DL-**9**.

The authors are greately indebted to Dr. Kozo Shibata for the recording and analyses of the mass spectra and to Mr. Junichi Gōda for the elemental analyses. The authors also wish to thank Dr. Yoichi Kawashima for his skillful technical assistance.

Azafulvenes 8.[1] Cycloaddition Reaction of 8-Azaheptafulvene to Sulfene

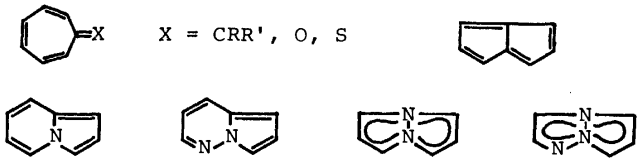
Takahiko IWASAKI, Shoji KAJIGAESHI, and Shuji KANEMASA

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

(Received May 19, 1977)

Peri- and stereoselective cycloadducts were obtained from the reactions of 8-aryl-8-azaheptafulvenes with some sulfenes. 8-Aryl-8-azaheptafulvenes reacted with phenylsulfene to give *cis* [8+2] cycloadducts as the sole products which would have resulted either from the endo approach or *via* the endo intermediate of the two reagents. On the other hand, with benzoylsulfene *trans* [8+2] cycloadducts were isolated. The formation of the latter products was rationalized by considering epimerization of the initially formed *cis* adducts. The *cis* [8+2] cycloadducts to vinylsulfene did not give the *trans* isomers but the hydrogen migrated derivatives under the influence of bases. The mechanism of the above reactions is also discussed.

Thermal [8+2] cycloaddition reaction is, as well known, allowed to proceed in a concerted manner.[2] Nevertheless, this type of reaction concerned with a straight polyene has not been reported hitherto because a [4+2] cycloaddition reaction, which is also thermally allowed and known as the Diels-Alder reaction, would compete with an [8+2] cycloaddition reaction and defeat it. Not a [4+2] but an [8+2] cycloaddition, however, is possible to go on well when both the ends of a conjugate system with eight electrons are sterically fixed at the place where a convenient formation of new bonds is possible to occur. A cross-conjugated or peripherally conjugated 8 pi electrons system serves such an example. Thus, heptafulvene,[3] tropone,[4] tropothione,[5] and pentalene[6] have afforded the corresponding [8+2] cycloadducts. In addition, and 8 pi conjugate system along the perimeter (except for one pair of n-electrons on the condensed nitrogen atom) of indolizine[7] and mesoionic polyazapentalene[8] has combined with electron-deficient olefins and acetylenes to give the tricyclic [8+2] cycloadducts.



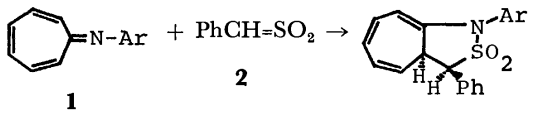
The reactions of 8-azaheptafulvene[9] with isocyanate, isothiocyanate, and ketone showed not only the high reactivity but also the excellent periselectivity of 8-azaheptafulvene toward these heterocumulenes.[10,11] In all of above reactions, 8-azaheptafulvane exclusively behaved only as an 8 pi addend to give the corresponding [8+2] cycloadducts in high yields.

Now, we would like to describe the cycloaddition reaction of 8-aryl-8-azaheptafulvene to some sulfenes. As for tropone, Ciabatonni and his coworker[12] have communicated the reactions with methanesulfonyl or mesylmethanesulfonyl chloride in the presence of triethylamine, both of which yielded the same product that was identified to be the [8+2] cycloadduct of tropone to mesylsulfene. They postulated a stepwise mechanism *via* dipolar intermediate for its formation. Stereoselective [8+2] cycloaddition reactions of tropone to asymmetrically substituted sulfenes have also been reported by Truce and Lin.[13]

Results and Discussion

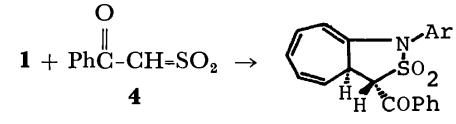
The reaction of 8-(*p*-methoxyphenyl)-8-azaheptafulvene (**1a**) with phenylsulfene (**2**), generated *in situ* from the corresponding azaheptafulvenium salt and sulfonyl chloride, respectively, afforded the 1 : 1 adduct **3a**. The similarity in the PMR spectrum of **3a** to that of the [8+2] cycloadducts of 8-azaheptafulvenes to some heterocumulenes,[10,11] particularly in spectral patterns for the protons on the seven-membered ring, indicates **3a** to be the [8+2] cycloadduct of **1a** to **2**. Double resonance experiments provided the confirmable assignment for each proton and evidence for the structure of **3a**. The coupling constant between the two methine hydrogens at the 3- and 3a-position was measured to be 8.4 Hz. No difference in the PMR spectra before and after purification shows that the product **3a** is not the mixture of *cis* and *trans* isomer but either of them.

Similarly 8-(*p*-methylphenyl)- (**1b**) and 8-(*p*-chlorophenyl)-8-azaheptafulvene (**1c**) gave the corresponding [8+2] cycloadducts **3b** and **3c** with the same stereochemistry as **3a**.



1 **2** **3**

a: Ar=*p*-$CH_3OC_6H_4$
b: Ar=*p*-$CH_3C_6H_4$
c: Ar=*p*-ClC_6H_4



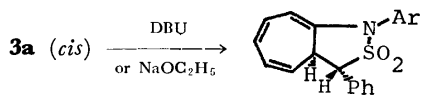
4 **5**

a: Ar=*p*-$CH_3OC_6H_4$
c: Ar=*p*-ClC_6H_4

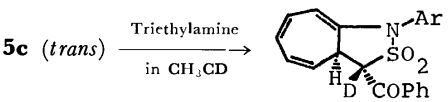
The reactions of benzoylsulfene (**4**) with **1a** and **1c** gave the 1 : 1 adducts **5a** and **5c**, respectively. In these reactions it had been expected that the [8+4] cycloadducts would be formed besides the [8+2] cycloadducts.[10] Contrary to our expectation, the former products could not be even detected by spectroscopy. The IR spectrum of **5a** revealed the carbonyl stretching vibrations at 1685 cm^{-1} and the absorption bands at

1330 and 1160 cm^{-1} characteristic of sulfonyl group. The coupling constant of 4.2 Hz between the two methine hydrogens at the 3- and 3a-position in **5c** indicates that the structure of **5c** may differ from that of **3** in stereochemistry. It is very difficult to estimate the stereochemistry of the cyclic compound which involves sulfonyl group as one member only on the basis of the coupling constant between the two vicinal hydrogens. Therefore the epimerization reactions of both cycloadducts **3** and **5** were investigated using some bases in order to confirm the above anticipation.

The compound **3a** was recovered unchanged on being refluxed in benzene with triethylamine. But **3a** was converted into the isomer **6** when refluxed either with a catalytic amount of sodium ethoxide in ethanol or 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) in benzene. The spectral data of **6** are very similar to those of the starting **3a**. The methine proton at the 3-position was observed as doublet with a coupling constant of 7.6 Hz. The above results show that the sole product **3a** from **1a** with **2** was a thermodynamically less stable *cis* isomer which underwent the epimerization into a more stable *trans* isomer **6** *via* the carboanionic intermediate.



6 (*trans*)



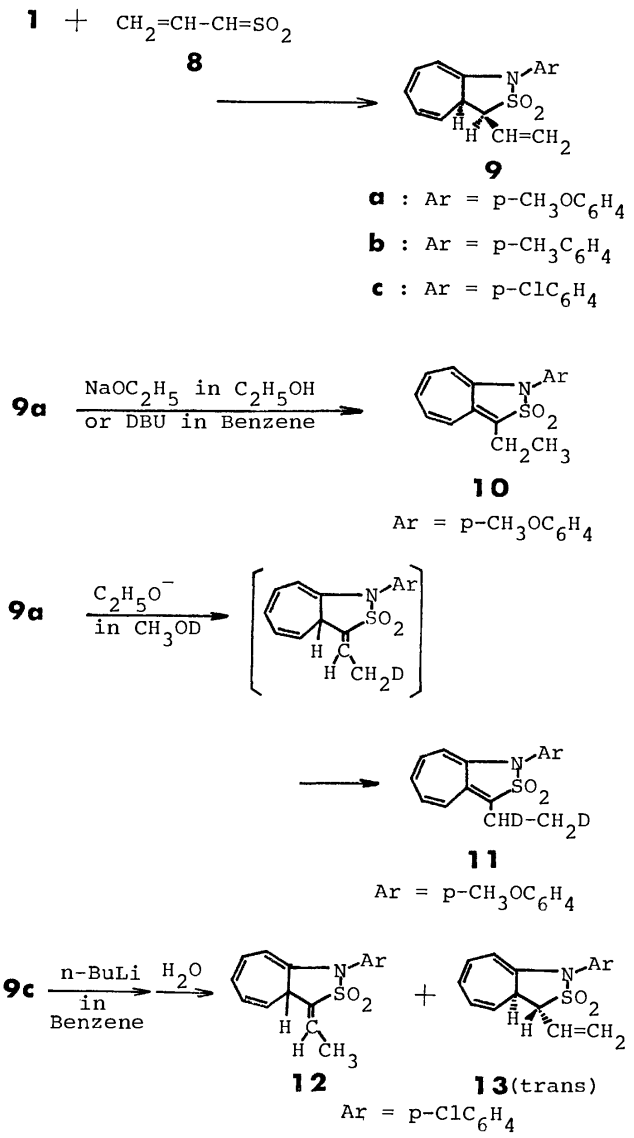
7 (*trans*)

Ar = *p*-ClC_6H_4

On the other hand, the [8+2] cycloadduct **5c** to **4** did not change its stereochemistry even if it was treated with DBU in benzene. An inversion should take place more easily at the 3-position in **5c** than the corresponding position in **3a** because the former contains a more acidic hydrogen atom at 3-position and possibly forms itself into an enolic form. Unchangeableness of **5c** on the treatment with DBU indicates that **5c** is a thermodynamically stable *trans* isomer.

The formation of monodeuterio derivative **7**, which was also a *trans* isomer, from the reaction of **5c** with triethylamine in methanol-*d* at room temperature led us to presume that the reaction of 8-aryl-8-azaheptafulvene (**1**) with **4** would have given the *cis* [8+2] cycloadduct as an initial product and been followed by the epimerization into the isolated *trans* product **5**. The reaction in which the diluted solution of triethylamine in dichloromethane was slowly added to the mixture of **1c** and benzoylmethanesulfonyl chloride in the same solvent at −50 °C, or in which **1c** was trated with the previously generated **4** in dichloromethane at −50 °C failed to form the *cis* [8+2] cycloadduct.

Vinylsulfene (**8**) reacted with **1** affording the 1 : 1 adduct **9** which was also found to be the [8+2] cycloadduct on the basis of the spectral data as well as the chemical conversion. The IR spectrum of **9a** showed the out of plane bending vibration bands at 960 cm^{-1}. The existence of a vinyl group was also confirmed from the PMR spectrum which exhibited the two terminal protons of vinyl group at 5.71 and 5.74 ppm (J_{cis}= 10.0 and J_{trans}=17.8 Hz), and whose spectral patterns were very similar to those of **3** and **5**. The coupling constant between the 3- and 3a-H (8.6 Hz) could not determine whether **9** was the *cis* or *trans* [8+2] cycloadduct.



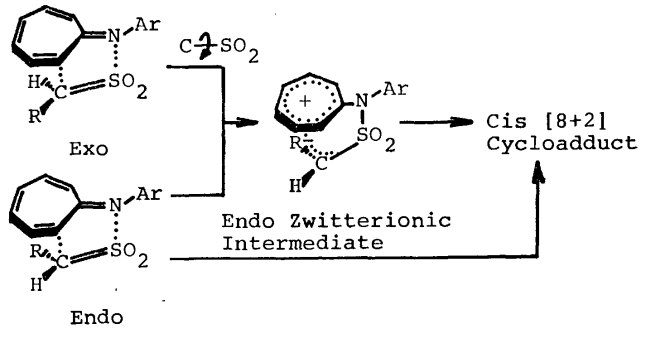
The compound **9a** was recovered unchanged when refluxed with triethylamine in benzene, whereas its treatment with sodium ethoxide in ethanol gave the isomeric **10**. By means of PMR spectroscopy, this product **10** was assigned to the isomer which was derived not from the inversion at carbon atom of the 3-position in **9a** but through the migration of vinyl double bond to a position of conjugation with the seven-membered ring. The mechanism for the double bond migration was confirmed by use of methanol-*d* in the above reaction.

The formation of **10** seemed to be caused by the fact that the allyl anionic intermediate from **9a** by deprotonation readily incorporated a proton from the solvent. Therefore, **9a** was reacted with DBU in dry benzene

at room temperature, but unexpectedly gave the same product **10**. These above results could not determine the stereochemistry of the [8+2] cycloadducts of **1** to **8**.

On the other hand, the reaction of **9c** with butyllithium in dry benzene under nitrogen gave an unseparable mixture of two products **12** and **13** whose structures were decided on the basis of the PMR spectrum of the mixture. The PMR spectrum showed the doublet (1.90, $C\underline{H}_3CH$=), quartet (6.82, $CH_3C\underline{H}$=), and multiplet (3.30 ppm, 3a-H) for the major product **12**, and the complex signals (5.45—5.87, $C\underline{H}_2$=CH– and 4-H), triplet (4.14, 3-H, $J_{3\text{-}3a}$=3.0 Hz), and multiplet (2.89 ppm, 3a-H) for the minor one **13**. The former corresponds to an intermediate involved in the course of isomerization of **9a** to **11**. The latter was assigned to be a thermodynamically stable *trans* [8+2] cycloadduct, whose formation indicated that the reaction of **1** with **8** had afforded the *cis* [8+2] cycloadduct as a sole product. The assignment of stereochemistry of **9** is compatible with the fact that although the treatment with DBU and butyllithium allowed the isomerization into **10**, **12**, and **13**, triethylamine did not change the stereochemistry of **9**.

As mentioned above, the reactions of **1** with **2**, **4**, and **8** gave the corresponding *cis* [8+2] cycloadducts as the isolated and initially formed products. Two mechanisms are possible for these reactions as depicted below: a concerted mechanism and stepwise one. The *cis* [8+2] cycloadduct would have been formed *via* endo approach between the two reagents in a concerted manner or *via* endo zwitterionic intermediate in a stepwise manner. As for the latter mechanism, it has been reported[13] that the reactions of tropone with some sulfenes might proceed stepwise *via* endo zwitterionic intermediates in which Coulombic attractions between the tropylium cation and the negatively charged group would facilitate the formation of thermodynamically unstable *cis* [8+2] cycloadducts.



The similar stepwise reactions of **1** with isocyanates and isothiocyanates have given the [8+2] cycloadducts in general cases but the [8+4] cycloadducts in some cases.[10] Furthermore only the *trans* [8+2] cycloadducts have been obtained from the reactions of **1** with phenylketene.[11]

The [8+4] cycloadducts to benzoyl- or vinylsulfene and the *trans* [8+2] cycloadduct to phenylsulfene should be formed when the reaction of **1** with sulfene proceeds in a stepwise mechanism. The above reactions will have taken place, but not conclusively, in a concerted manner *via* the endo approach between 8-azaheptafulvenes and sulfenes. Further investigation has to be made for the clarification of the reaction mechanism.

Experimental

General. Melting and boiling points are all uncorrected. IR spectra were taken in KBr disks with a Japan Spectroscopic Co. IRA-1 spectrometer. PMR spectra were obtained at 100 MHz using a JEOL JNM-MH-100 spectrometer with tetramethylsilane as an internal standard. Mass spectra were determined with a JEOL JMS-D 100 mass spectrometer equipped with a direct inlet and at an ionization energy of 70 eV.

Materials. (8-*p*-Methoxy-, 8-*p*-methyl-, and 8-*p*-chlorophenyl)-8-azaheptafulvenium fluoroborate were prepared from tropylium fluoroborate and the corresponding anilines according to the method mentioned in the literature.[9] Phenylmethane-: mp 92—93 °C (lit,[14] mp 92—93 °C), benzoylmethane-: mp 87—88 °C (lit,[15] mp 87.5—88.2 °C) and 2-propenesulfonyl chloride: bp 76 °C/15 mmHg (lit,[16] bp 74—75 °C/15 mmHg) were synthesized from the reactions between the corresponding sodium sulfonates and phosphorus pentachloride. Triethylamine and dichloromethane were purified by simple distillation and dried with potassium hydroxide and calcium chloride, respectively.

*1-p-Methoxyphenyl-3-phenyl-3,3a-dihydro-1H-cyclohept[c]isothiazole 2,2-Dioxide (**3a**).* To a solution of 8-*p*-methoxyphenyl-8-azaheptafulvenium fluoroborate (0.30 g) and phenylmethanesulfonyl chloride (0.20 g) in dry dichloromethane (10 ml) was added dropwise a solution of triethyl amine (0.25 g) in dry dichloromethane (3 ml) at −50 °C. The reaction mixture was strired at the same temperature for 1 h and at room temperature overnight, and then evaporated *in vacuo* to dryness. The residue was extracted with hot benzene and the extract was evaporated again to give an oily product. The crude, but almost pure, product was filtered through a short column packed with alumina using benzene as eluent, giving pale yellow prisms of **3a** (0.37 g, 99%) which were purified by recrystallization from methanol; mp 123—124 °C. IR(KBr, cm^{-1}): 1615 (C=C), 1325 and 1140 (SO_2); PMR ($CDCl_3$, δ ppm): 3.34 (m, 1H, 3a-H), 3.77 (s, 3H, OCH_3), 4.97 (d, 1H, $J_{3\text{-}3a}$=8.4 Hz, 3-H), 5.11(dd, 1H, $J_{4\text{-}3a}$=4.5 and $J_{4\text{-}5}$=9.0 Hz, 4-H), 5.29 (br. d, 1H, $J_{8\text{-}7}$= 6.5 Hz, 8-H), 6.02—6.54 (m, 3H, 5-, 6-, and 7-H) and 6.86—7.58 (m, 9H, aromatic protons); MS (*m/e*, relative intensity) : 365 (M^+ 94), 301 (M^+-SO_2, 46), 300 (301^+-H, base peak), and 211 (M^+−phenylsulfene, 89).

Found: C, 68.78; H, 5.10; N, 3.64%. Calcd for $C_{21}H_{19}NO_3S$: C, 69.02; H, 5.24; N, 3.83 %.

*1-p-Methylphenyl-3-phenyl-3,3a-dihydro-1H-cyclohept[c]isothiazole 2,2-Dioxide (**3b**).* The reaction of 8-*p*-methylphenyl-8-azaheptafulvenium fluoroborate (0.57 g), phenylmethanesulfonyl chloride (0.40 g) and triethylamine (0.50 g), in a similar way described above, gave colorless prisms of **3b** (0.56 g, 80 %) which were purified by recrystallization from methanol; mp 136—138 °C. IR (KBr, cm^{-1}): 1620 (C=C), 1330 and 1145 (SO_2); PMR ($CDCl_3$, δ ppm): 2.34 (s, 3H, CH_3), 3.33 (m, 1H, 3a-H), 4.96 (d, 1H, $J_{3\text{-}3a}$=8.4 Hz, 3-H), 5.05 (dd, 1H, $J_{4\text{-}3a}$=5.0 and $J_{4\text{-}5}$=9.0 Hz, 4-H), 5.29 (br. d, 1H, $J_{8\text{-}7}$=5.5 Hz, 8-H), 6.01—6.50 (m, 3H, 5-, 6-, and 7-H) and 7.12—7.60 (m, 9H, aromatic protons); MS (*m/e*, relative intensity): 349 (M^+, 57), 285 (M^+-SO_2, 63), 284 (285^+-H, base peak) and 195 (M^+−phenylsulfene, 75).

Found: C, 71.73; H, 5.37; N, 3.84%. Calcd for $C_{21}H_{19}NO_2S$: C, 72.18; H, 5.48; N, 4.01%.

1-p-Chlorophenyl-3-phenyl-3,3a-dihydro-1H-cyclohept[c]*isothiazole 2,2-Dioxide (**3c**).* In a similar way as that of **3a**, the reaction of 8-*p*-chlorophenyl-8-azaheptafulvenium fluoroborate (0.61 g), phenylmethanesulfonyl chloride (0.40 g) and triethylamine (0.50 g) gave colorless prisms of **3c** (0.50 g, 69%) which were purified by recrystallization from methanol; mp 135.5—137 °C. IR (KBr, cm^{-1}): 1615 (C=C), 1330 and 1140 (SO_2); PMR ($CDCl_3$, δ ppm): 3.35 (m, 1H, 3a-H), 5.00 (d, 1H, J_{3-3a}=8.4 Hz, 3-H), 5.08 (dd, 1H, J_{4-3a}=5.0 and J_{4-5}=9.5 Hz, 4-H), 5.31 (br. d, 1H, J_{8-7}=5.5 Hz, 8-H), 6.08—6.60 (m, 3H, 5-, 6-, and 7-H) and 7.19—7.67 (m, 9H, aromatic protons); MS (*m/e*, relative intensity): 369, 371 (M^+, 43, 15), 305, 307 (M^+-SO_2, 73, 24), 304, 306 (305^+-H, base peak, 307^+-H, 32) and 215, 217 (M^+-phenylsulfene, 71, 24).

Found: C, 65.03; H, 4.32; N, 3.79%. Calcd for $C_{20}H_{16}NO_2SCl$: C, 64.95; H, 4.36; N, 3.79%.

3-Benzoyl-1-p-methoxyphenyl-3,3a-dihydro-1H-cyclohept[c]*isothiazole 2,2-Dioxide (**5a**).* To a solution of 8-*p*-methoxyphenyl-8-azaheptafulvenium fluoroborate (0.30 g) and benzoylemthanesulfonyl chloride (0.22 g) in dry dichloromethane (10 ml) was added drowpise a solution of triethylamine (0.20 g) in dry dichloromethane (3 ml) at −50 °C. The reaction mixture was stirred at the same temperature for 1 h and at room temperature overnight, and then evaporated *in vacuo* to dryness. The residue was extracted with hot benzene and the benzene solution was evaporated to give pale yellow prisms of **5a** (0.35 g, 89 %) which were purified by recrystallization from 2-propanol using charcoal; mp 171—173 °C. IR (KBr, cm^{-1}): 1685 (C=O), 1620 (C=C), 1330 and 1160 (SO_2); PMR ($CDCl_3$, δ ppm): 3.66 (m, 1H, 3a-H), 3.77 (s, 3H, OCH_3), 5.16 (dd, 1H, 4-H), 5.21 (br. d, 1H, J_{8-7}=5.5 Hz, 8-H), 5.39 (d, 1H, J_{3-3a}=4.2 Hz, 3-H), 6.06—6.60 (m, 3H, 5-, 6- and 7-H), 6.87, 7.22 (each d, 4H, *p*-methoxyphenyl protons) and 7.52, 8.09 (m, 5H, benzoyl protons); Mass (*m/e*, relative intensity): 393 (M^+, 4), 208 ($M^+-CH_3OPhNSO_2$, 45) and 207 (208^+-H, base peak).

Found: C, 67.25; H, 4.89; N, 3.77%. Calcd for $C_{22}H_{19}NO_4S$: C, 67.16; H, 4.87; N, 3.56 %.

3-Benzoyl-1-p-chlorophenyl-3,3a-dihydro-1H-cyclohept[c]*isothiazole 2,2-Dioxide (**5c**).* In a similar way described above, the reaction of 8-*p*-chlorophenyl-8-azaheptafulvenium fluoroborate (0.30 g), benzoylmethanesulfonyl chloride (0.22 g) and triethylamine (0.20 g) gave colorless needles of **5c** (0.30 g, 78 %) which were purified by recrystallization from methanol; mp 161—162 °C. IR (KBr, cm^{-1}): 1685 (C=O), 1625 (C=C), 1330 and 1160 (SO_2); PMR ($CDCl_3$, δ ppm): 3.68 (m, 1H, 3a-H), 5.20 (dd, 1H, 4-H), 5.32 (br d, 1H, J_{8-7}=5.5 Hz, 8-H), 5.46 (d, 1H, J_{3-3a}=4.2 Hz, 3-H), 6.18—6.66(m, 3H, 5-, 6-, and 7-H), 7.23—7.66 (m, 7H, aromatic protons) and 8.13 (br d, 2H, *o*-protons of benzoyl); MS (*m/e*, relative intensity): 397, 399 (M^+, 2), 208 ($M^+-ClPhNSO_2$, 48) and 207 (208^+-H, base peak).

Found: C, 63.46; H, 4.02; N, 3.80%. Calcd for $C_{21}H_{16}NO_3SCl$: C, 63.39; H, 4.05; N, 3.52%.

*Epimerization of **3a**.* One drop of 1,5-diazabicyclo-[5.4.0]undec-5-ene (DBU) was added to a solution of **3a** (0.10 g) in dry benzene (5 ml) and the mixture was refluxed for 1 h. Evaporation of benzene *in vacuo* gave pale yellow prisms of **5** (0.08 g, 80 %) which were purified by recrystallization from methanol mp 162—163 °C. IR (KBr, cm^{-1}): 1610 (C=C), 1320 and 1130 (SO_2); PMR ($CDCl_3$, δ ppm): 3.33 (m, 1H, 3a-H), 3.84 (s, 3H, OCH_3), 4.77 (d, 1H, J_{3-3a}= 7.6 Hz, 3-H), 5.25 (dd, 1H, 4-H), 5.35 (br. d, 1H, J_{8-7}=6.0 Hz, 8-H), 6.18—6.49 (m, 3H, 5-, 6-, and 7-H) and 6.89—7.61 (m, 9H, aromatic protons); Mass (*m/e*, relative intensity): 365 (M^+, 43), 301 (M^+-SO_2), 300 (301^+-H, 81) and 211 (M^+-phenyl sulfene, base peak).

The *trans* isomer **5** was also obtained from the following reaction: a solution of **3a** (0.32 g) and sodium ethoxide (0.01 g) in 10 ml of ethanol was refluxed for 1 h and evaporated *in vacuo* to dryness. The residue was dissolved in water and extracted with benzene. The extract was dried over magnesium sulfate and evaporated *in vacuo* to give **5** (0.18 g, 56 %).

*Deuteration of **5c**.* A mixture of **5c** (0.10 g), triethylamine (2 drops), and methanol-*d* (CH_3OD, 98 %, 0.5 g) in benzene (2 ml) was stirred at room temperature overnight and then evaporated *in vacuo* to give colorless crystals of **7** (0.098 g, 98 %) which were purified by recrystallization from methanol. In the PMR spectrum ($CDCl_3$) of **7**, the doublet of 3-H in **5c** which had been observed at 4.97 ppm completely disappeared.

1-p-Methoxyphenyl-3-vinyl-3,3a-dihydro-1H-cyclohept[c]*isothiazole 2,2-Dioxide (**9a**).* To a solution of 8-methoxyphenyl-8-azaheptafulvenium fluoroborate (0.60 g) and 2-propenesulfonyl chloride (0.30 g) in dry dichloromethane (10 ml) was added drowpise a solution of triethylamine (0.50 g) at −50 °C. The reaction mixture was stirred at room temperature overnight and evaporated *in vacuo* to dryness. The residue was extracted with hot benzene and the extract was evaporated again to give an oily product. The crude, but almost pure, product was filtered through a short column packed with alumina using benzene as eluent, giving pale yellow needles of **9a** (0.63 g, 100 %) which were purified by recrystallization from 2-propanol; mp 113.5—115 °C. IR (KBr, cm^{-1}): 1620 (C=C), 1320, 1140 (SO_2) and 960 (CH=CH_2); PMR ($CDCl_3$, δ ppm): 2.92 (m, 1H, 3a-H), 3.83 (s, 3H, OCH_3), 4.40 (t, 1H, $J_{3-3a}=J_{3-4}$=8.6 Hz, 3-H), 5.20 (br. d, 1H, J_{8-7}=5.5 Hz, 8-H), 5.47 (dd, 1H, J_{4-3a}=5.2 and J_{4-5}=8.5 Hz, 4-H), 5.71 (br. d, 1H, J_{trans}=17.8 Hz, =CH_2), 5.74 (br. d, 1H, J_{cis}=10.0 Hz, =CH_2), 6.10—6.55 (m, 4H, 5-, 6-, 7-H and -CH=) and 6.97, 7.30 (each d, 4H, aromatic protons); MS (*m/e*, relative intensity): 315 (M^+, 81), 251 (M^+-SO_2, 42), 250 (251^+-H, 76) and 211 (M^+-vinylsulfene, base peak).

Found: C, 64.65; H, 5.35; N, 4.24%. Calcd for $C_{17}H_{17}NO_3S$: C, 64.74; H, 5.43; N, 4.44%.

1-p-Methylphenyl-3-vinyl-3,3a-dihydro-1H-cyclohept[c]*isothiazole 2,2-Dioxide (**9b**).* The reaction of 8-*p*-methylphenyl-8-azaheptafulvenium fluoroborate (0.57 g), 2-propenesulfony chloride (0.35 g) and triethylamine (0.50 g), in a similar way described above, gave pale yellow plates of **9b** (0.35 g, 58 %) which were purified by recrystallization from cyclohexane; mp 97.5—100 °C. IR (KBr, cm^{-1}): 1620 (C=C), 1325, 1150 (SO_2) and 940 (CH=CH_2); PMR ($CDCl_3$, δ ppm): 2.34 (s, 3H, CH_3), 2.93 (m, 1H, 3a-H), 4.33 (t, 1H, $J_{3-3a}=J_{3-4}$=8.6 Hz, 3-H), 5.14 (br. d, 1H, J_{8-7}=5.5 Hz, 8-H), 5.38 (dd, 1H, J_{4-3a}=5.0 and J_{4-5}= 9.0 Hz, 4-H), 5.58 (br. d, 1H, J_{trans}=16.0 Hz, =CH_2) 5.61 (br d, 1H, J_{cis}=10.0 Hz, =CH_2), 5.95—6.38 (m, 4H, 5-, 6-, 7-H, and -CH=) and 7.13 (s, 5H, aromatic protons); MS (*m/e*, relative intensity): 299 (M^+, 57), 235 (M^+-SO_2, 44), 234 (235^+-H, 71) and 195 (M^+-vinylsulfene, base peak).

Found: C, 68.22; H, 5.63; N, 4.55%. Calcd for $C_{17}H_{17}NO_2S$: C, 68.20; H, 5.72; N, 4.68%.

1-p-Chlorophenyl-3-vinyl-3,3a-dihydro-1H-cyclohept[c]*isothiazole 2,2-Dioxide (**9c**).* In a similar way as that of **9a**, the reaction of 8-*p*-chlorophenyl-8-azaheptafulvenium fluorobotate (0.61 g), 2-propenesulfonyl chloride (0.28 g) and triethylamine (0.40 g) afforded colorless prisms of **9c** (0.41 g, 64 %) which were purified by recrystallization from 2-propanol; mp 112.5—113 °C. IR (KBr, cm^{-1}): 1620 (C=C), 1330, 1140 (SO_2) and 960 (CH=CH_2); PMR ($CDCl_3$, δ

ppm): 2.93 (m, 1H, 3a-H), 4.46 (t, 1H, $J_{3-3a}=J_{3-4}=8.6$ Hz, 3-H), 5.31 (br. d, 1H, $J_{8-7}=5.0$ Hz, 8-H), 5.51 (dd, 1H, $J_{4-3a}=5.5$ and $J_{4-5}=9.5$ Hz, 4-H), 5.72 (br. d, 1H, $J_{trans}=17.0$ Hz, $=CH_2$), 5.77 (br. d, 1H, $J_{cis}=10.0$ Hz, $=CH_2$), 6.06—6.64 (m, 4H, 5-, 6-, 7-H, and $-CH=$) and 7.34, 7.48 (each d, 4H, aromatic protons); MS (*m/e*, relative intensity): 319, 321 (M^+, 52, 18), 355, 357 (M^+-SO_2, 36, 13), 354, 356 (355^+-H, 83, 357^+-H, 29) and 215, 217 (M^+-vinylsulfene, base peak, 30).

Found: C, 60.01; H, 4.57; N, 4.29%. Calcd for $C_{16}H_{14}NO_2SCl$: C, 60.09; H, 4.41; N, 4.38%.

*3-Ethyl-1-*p*-methoxypehenyl-1*H*-cyclohept*[c]*isothiazol 2,2-Dioxide (**10**).* A solution of **9a** (0.20 g) and sodium ethoxide (0.04 g) in dry ethanol (10 ml) was refluxed for 1 h. The residue obtained by evaporation of the soluvent *in vacuo* was dissolved in water and the aquious solution was extracted with benzene. The extract was dried over magnesium sulfate and evaporated to give orange prisms of **10** (0.18 g, 90 %) which were recrystallized from 2-propanol; mp 152—153 °C. IR (KBr, cm^{-1}): 1590 (C=C), 1290 and 1150 (SO_2); PMR ($CDCl_3$, δ ppm): 1.38 (t, 3H, $C\underline{H}_3CH_2$), 2.80 (q, 2H, $CH_3-C\underline{H}_2$), 3.93 (s, 3H, OCH_3), 5.78 (br. d, 1H, $J_{4-5}=8.0$ Hz, 4-H), 6.30—6.84 (m, 4H, 5-, 6-, 7-, and 8-H) and 7.10, 7.48 (each d, 4H, aromatic protons): MS (*m/e*, relative intesity): 315 (M^+, base peak).

Found: C, 64.48; H, 5.26; N, 4.42%. Calcd for $C_{17}H_{17}NO_3S$: C, 64.74; H, 5.43; N, 4.44%.

This compound **10** was also obtained by the following procedure: a mixture of **9a** (0.11 g) and DBU (1 drop) in dry benzene (5 ml) was refluxed for 1 h and the solvent was evaporated *in vacuo* to give **10** (0.083 g, 75%).

3-(Ethyl-1,2-d_2*)-1-*p*-methoxyphenyl-1*H*-cyclohept*[c]*isothioazole 2,2-Dioxide (**11**).* A solution of **9a** (0.20 g) and sodium ethoxide (0.04 g) in emthanol-*d* (CH_3OD, 98%, 1.0 g) and dry benzene (1 ml) was refluxed for 1 h. The same work-up as described above gave orange prisms of **11** (0.10 g, 50%) which were recrystallized from 2-propanol; mp 151—152 °C. PMR ($CDCl_3$, δ ppm): 1.39 (m, 2H, $C\underline{H}_2DCHD$), 2.83 (m, 1H, $CH_2DC\underline{H}D$) and the other signals which were at the same positions as those of **10**; MS (*m/e*, relative intensity): 317 (M^+, base peak).

*The Reaction of **9c** with Butyllithium.* To a solution of **9c** (0.10 g) in dry benzene (10 ml) was added butyllithium (15% in hexane, 1.0 ml) at 0 °C under nitrogen. The solution was stirred for 15 min at the same temperature and poured into water. The organic compound was collected with benzene, dried over magnesium sulfate, and then the solution was evaporated *in vacuo*. The residue was filtered through a short column packed with alumina using benzene as eluent to give an yellow oil (**12** and **13**).

12,13-Epoxy-*C*-nor-*D*-homosteroids. I.[1] The Synthesis and Stereochemistry of 17α-Acetyl-12,13-epoxyetiojervanes

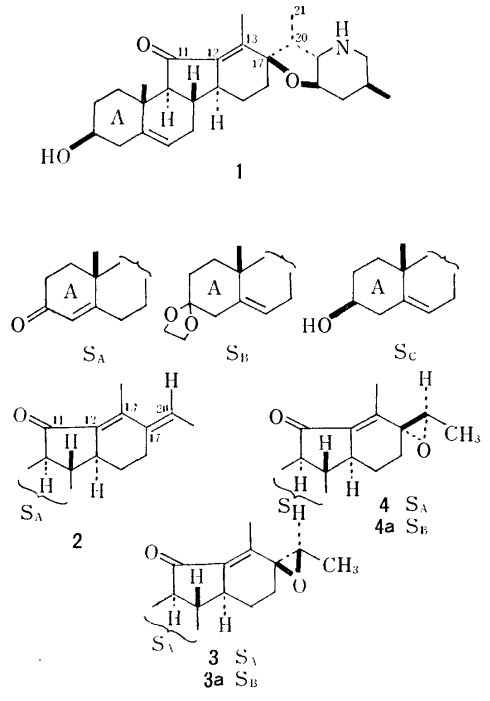
Akio Murai, Hiroshi Sasamori, and Tadashi Masamune
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received May 30, 1977)

Several 11-substituted 17α-acetyl-12,13-epoxyetiojervanes were prepared from jervine. Jervine was degraded by a known process into (17*E*)-17-ethyletiojerva-4,12,17(20)-triene-3,11-dione, which on epoxidation followed by acid treatment gave 17α-ethyletiojerva-4,12-diene-3,11,20-trione as the main product. Acetalization of the carbonyl groups, at C_3 and C_{20} of the triketone and subsequent hydride reduction produced two 11-epimeric alcohols, which on hydrolysis afforded 17α-ethyl-11α-hydroxyetiojerva-4,12-diene-3,20-dione and its 11β-hydroxy epimer. These alcohols and their acetates were oxidized with perbenzoic acid and/or *t*-butyl hydroperoxide to give the epoxides. The structure and configuration of these epoxides and the synthetic intermediates were determined on the basis of the chemical and spectral evidence.

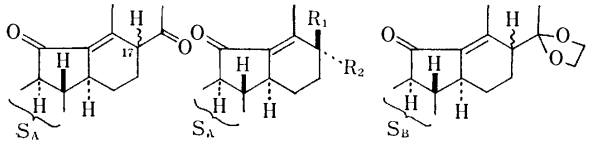
A number of papers have appeared on the cleavage of an epoxy ring accompanied by the ring skeletal rearrangement in the field of steroid and other closely related compounds.[2] However, only one example[3] seems to be known for the skeletal transformation of a *C*-nor-*D*-homosteroid (etiojervane), *via* the 12,13-epoxy ring opening, into a normal steroid, although the reverse rearrangement (normal to *C*-nor-*D*-homo) has been investigated extensively.[4] In a series of studies aimed at the preparation of biologically active steroids from jervine and other available alkaloids, we have been working on the synthesis and reaction of 12,13-epoxyetiojervanes. In this paper we describe the synthesis and stereochemistry of 17α-acetyl-12,13-epoxyetiojervanes.

Jervine (**1**) was degraded by a known three-step process [*N*-methylation, boron trifluoride etherate (BF_3) treatment and the Oppenauer oxidation][5] into (17*E*)-17-ethyletiojerva-4,12,17(20)-triene-3,11-dione[6] (**2**) in a 70% yield. Compound **2** was then oxidized with perbenzoic acid to give its 17β,20*S*- (**3**) and 17α, 20*R*-epoxy derivatives (**4**), mp 190—192 °C and 176—178 °C, in 73 and 0.4% yields, respectively. The configurations of these compounds were assigned as shown by formulas **3** and **4** mainly by comparison of the NMR spectra with those of the corresponding Δ^5-3-oxo 3-ethylene acetals (**3a**, 17β, 20*S* and **4a**, 17α, 20*R*):[7] δ for 18-C$\underline{H}_3$, $\underline{H}$ at C_{20}, and 21-C$\underline{H}_3$; **3**, 1.98, 3.36, and 1.38; **3a**, 1.96, 3.35, and 1.37; **4**, 1.95, 3.21, and 1.38; **4a**, 1.93, 3.19, and 1.36. The predominant formation[7] of 17β,20*S*-epoxide **3** is understood to be the result of preferential axial attack of the peracid to the 17,20-double bond.[8]

Treatment of 17β,20*R*-epoxide **3** with a large excess of the Lewis acid (BF_3) produced a 5 : 1 (estimated by NMR) mixture of 17βH- and 17αH-methyl ketones (**5**) and (**6**) and 17β-aldehyde (**7**), mp 145—147 °C, in 60 and 7.5% yields, respectively. The mixture of methyl ketones was further separated by fractional recrystallization to yield **5**, mp 151.5—153.5 °C, and **6**, mp 195—197 °C, in pure state. The same treatment of 17α,20*R*-epoxide (**4**) afforded 17α-aldehyde (**8**), mp 148—150 °C, epimeric at C_{17} for **7**, in a 60% yield along with a 30% yield of a 1 : 1 mixture of **5** and **6**. The planar structures of these compounds (**5**—**8**) were completely consistent with the spectral data (see, Experimental). While the configurations at C_{17} of aldehydes **7** and **8** were assigned only by mechanistic consideration, those of methyl ketones **5** and **6** were deduced from the NMR spectra [17βH (pseudo-axial) in **5**, δ 3.33 (br W_H=20 Hz), and 17αH (pseudo-equatorial) in **6**, δ 3.38 (br W_H=11 Hz)], as well as from the relative amplitude in the ORD curves (**5**, a=+40°, and **6**, a=−20°).[9] In accordance with this assignment, the latter (**6**) with a pseudo-axial 17β-side chain was isomerized to the former (**5**) with *p*-toluenesulfonic acid (*p*-TsOH) in benzene under reflux to give a 2 : 1 equilibrium mixture of **5** and **6**. Each of these methyl ketones (**5**) and (**6**) would be formed by initial cleavage of the 17C–O bond with concomitant hydride shift from C_{20} and/or with subsequent deprotonation at C_{20}. The hydride shift would give only 17αH-methyl ketone (**6**) from 17β-epoxide (**3**) and only 17βH-methyl ketone (**5**) from 17α-epoxide (**4**), while the deprotonation would produce (an) enol intermediate(s), which would then be protonated at C_{17} mainly from the β-side with continued overlap between the p-orbitals of 17-, 13-, and 12-carbon atoms and of the labile donor proton (axial approach), giving 17βH-methyl ketone (**5**) as a major product. The result is explained by assuming



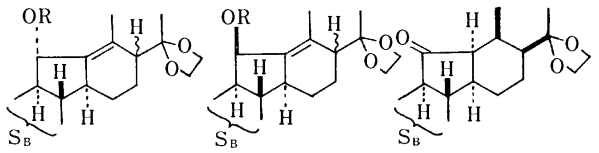
that the β-oriented 17C–O bond (pseudo-axial) in **3** would be cleaved more readily and followed mainly by deprotonation, whereas the corresponding α-bond (pseudo-equatorial) in **4** would require the hydride (and also methanide) shift owing to relatively difficult cleavage of the bond. On the other hand, 17-aldehydes (**7**) and (**8**) would result from the 17C–O bond cleavage accompanied by concurrent methyl migration, most probably from the opposite side against the epoxy group. On this premise, the configurations of 17-aldehydes were assigned as shown in formulas **7** and **8**.



5 17β**H** **7** R_1=CHO, R_2=CH_3 **9** 17β**H**
6 17α**H** **8** R_1=CH_3, R_2=CHO **10** 17α**H**

The 5 : 1 mixture of methyl ketones (**5**) and (**6**) was refluxed with ethylene glycol and acid (*p*-TsOH) in benzene for 6 h to give a mixture of the respective 3,20-di(ethylene acetal)s, from which 17β**H**-3,20-diacetal (**9**), mp 181—183 °C, and 17α**H**-3,20-diacetal (**10**), mp 143.5-144.5 °C, were isolated in 50 and 10% yields, respectively, by fractional recrystallization. The latter (**10**) was epimerized quantitatively to the former (**9**) by the prolonged acid treatment (28 h).

Reduction of 17β**H**-3,20-diacetal (**9**) with aluminium trihydride followed by chromatographic purification gave 11α-alcohol (**11**), mp 135—137 °C, and 11β-alcohol (**12**), mp 163—164 °C, in 80 and 15% yields, respectively. A similar result was obtained by treatment with lithium aluminium hydride (LAH); alcohols **11** and **12** were produced in 73 and 17% yields, respectively. The configuration at C_{11} of each alcohol was assigned as shown in formulas **11** and **12** on the basis of the following evidence. (i) The 19-methyl protons of **12** were observed as a singlet at a lower field (δ 1.24) than those of **11** (δ 1.06), indicating the 1,3-diaxial-like disposition of the hydroxyl and 19-methyl groups in **12**.[10] (ii) Treatment of 11α-alcohol (**11**) with acetic anhydride at room temperature readily produced the corresponding acetate (**11a**), mp 194—196 °C, in a 95% yield, whereas the same treatment of 11β-alcohol (**12**) led to recovery of the starting alcohol; the corresponding acetate (**12a**), mp 143—145 °C, was obtained in a 94% yield by heating with acetic anhydride at 100 °C. The hydride (LAH) reduction of 17α**H**-3,20-diacetal (**10**) afforded a mixture of three compounds, from which 11α-alcohol (**13**), mp 194—196 °C, 11β-alcohol (**14**), mp 139—141 °C, and 12α**H**-11-ketone (**15**), mp 156—157 °C, were isolated in 15, 40, and 22% yields, respectively. The hydroxyl groups at C_{11} of **13** and **14** were assigned α- and β-configurations, respectively, in essentially the same manner as the reduction products of the 17β**H**-epimer (**9**); 19-methyl protons, δ 1.05 for **13**, and δ 1.24 for **14**. Saturated 11-ketone (**15**) was assigned α-hydrogen configuration at C_{12} and C_{13} on the ORD (a negative Cotton effect, a= −86°)[11] and NMR spectral data [19- and 18-methyl protons, δ 1.12 (δ_{calcd} 1.10) and δ 0.88].[10]



11 17β**H**, R=H **12** 17β**H**, R=H **15**

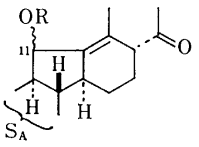
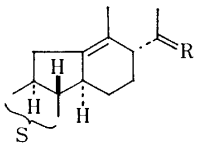
13 17α**H**, R=H **14** 17α**H**, R=H

The reduction results for diacetals **9** and **10** deserve the following comments. (i) The hydride reduction of 17α**H**-3,20-diacetal (**10**) yielded 11β-alcohol (**14**) mainly while that of the 17β**H**-epimer (**9**) gave 11α-alcohol (**11**) as a major product irrespective of the reagents.[12] The latter result is remarkable as being the first example of the predominant formation of 11α-alcohol by the hydride reduction of 11-oxoetiojervanes. Compound **9** would take a twist-boat form with the pseudo-axial 17α-side chain rather than a half-chair with the pseudo-equatorial bulky substituent. The conformational change in passing from the ketone (**5**) to the acetal (**9**) would result in decrease of steric interaction between the 18-methyl group and the 17-substituent,[13] leading to more facile attack of the reagent from the less-hindered β-side to the carbonyl carbon at C_{11}, contrary to the approach from the α-side as has been illustrated in many 11-oxoetiojervanes. (ii) While no saturated 11-ketone was isolated from the reduction products of **9**, a considerable amount (22%) of saturated 12α**H**-11-ketone (**15**) was obtained in the reduction of **10**. In view of the slight but definite difference in the absorption maxima [λ_{max} 257 nm (ε 10000) for **9**, and 259 nm (ε 13000) for **10**], it seems that the 12,13-double bond of **9** is conjugated with the carbonyl group at C_{11} to a less extent as compared with that of **10**, suggesting a greater probability of the reduction of the double bond in question in the latter case. It should be emphasized that the 11-ketone (**15**) is the first example of 11-oxo-12α-etiojervanes (13α**H**) formed by the hydride reduction of 11-oxoetiojerv-12-enes. This is rationalized by assuming the preferential attack of the reagent from the less-hindered α-side to the 13-carbon atom and subsequent axial approach of the donor proton from the less-hindered α-side to the 12-carbon atom of the resulting Δ^{11}-11-olate or Δ^{11}-11-ol, since these intermediates would adopt a twist-boat conformation with both the 18-methyl group and the 17-side chain pseudo-equatorial.[11] As expected for 11-oxo-12α-etiojervanes with a bulky 17-substituent,[10] the 11-ketone (**15**) with C/D *cis*-linkage was recovered unchanged by treatment with base under the usual epimerization conditions (see, Experimental), its 12β-epimer (C/D *trans*) being not detected on TLC.

Treatment of 11α-hydroxy 3,20-diacetal (**11**) and its 11-acetate (**11a**) with acid (*p*-TsOH) in aqueous acetone afforded the corresponding 3,20-diketones (**16**) and (**16a**), mp 178—180 °C and 143—145 °C, in 83 and 99% yields, respectively. Likewise, 11β-hydroxy 3,20-diacetal (**12**) and its acetate (**12a**) were converted into the respective 3,20-diketones (**17**) and (**17a**), mp 158—160 °C and 187—190 °C, in 85 and 99% yields. Naturally the two alcohols (**16**) and (**17**) were acetylated

to form the respective acetates (**16a**) and (**17a**) in quantitative yields. It is to be noted that the 12,13-double bond remained unshifted at the original position during the deacetalization, as shown by the UV spectra [λ_{max} 236—238 nm (ε 10,000—11,000) for ketones **16**—**17a**]. 11α-Acetoxy 3,20-diacetal (**11a**) was then submitted to the Birch reduction in ethylamine to give 11-deacetoxy 3,20-diacetal (**18**), mp 139—140 °C in a 90% yield, which was also obtained by the same treatment of 11β-hydroxy 3,20-diacetal (**12**). The diacetal (**18**) underwent deacetalization with acid to give 3,20-diketone (**19**), mp 131—133 °C, in an 80% yield along with a small amount (15%) of 20-oxo 3-acetal (**20**), mp 140—142 °C. The main product (**19**) was also derived in a 70% yield by the Oppenauer oxidation of 3β-hydroxy-17α-ethyletiojerva-5,12-dien-20-one[14] (**21**), a known compound with established configurations. The transformation to correlate compound **11a** with **21** has confirmed the configurations of 17-side chains of a series of the related compounds.

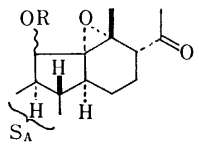


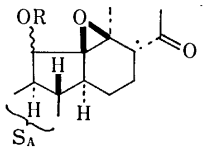


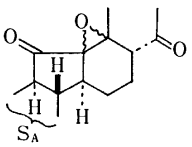
16 11α-OH
16a 11α-OAc
17 11β-OH
17a 11β-OAc

18 R=OCH_2CH_2O-, S=S_B
19 R=O, S=S_A
20 R=O, S=S_B
21 R=O, S=S_C

Epoxidation of 11-alcohols and 11-acetates (**16**—**17a**) with perbenzoic acid proceeded smoothly to give the respective 12,13-epoxides. In general, peracid epoxidation of olefins takes place by an electrophilic attack mainly from a less-hindered side.[8] Hence, the epoxidation of these etiojerv-12-enes is expected to proceed from the rear (α) side of the molecules and result in predominant formation of 12α,13α-epoxides. The oxidation of 11α-alcohol (**16**) gave a single product (**22**), mp 206—208 °C, in a quantitative yield, which was assigned 12α, 13α-epoxy configuration on the basis of the above presumption. Compound **22** on acetylation and the Jones oxidation formed the corresponding 11α-acetate (**22a**), mp 200—203 °C, and 11-ketone (**23**), mp 176.5—178 °C, in good yields. On the other hand, the same treatment of 11β-alcohol (**17**) produced two 12,13-epoxides, one (**24**), mp 204—207 °C, in a 60% yield, and the other (**25**), mp 159.5—160.5 °C, in a 36% yield. These 11β-alcohols (**24**) and (**25**) were converted with acetic anhydride at 100 °C into the respective 11β-acetates (**24a**) and (**25a**), mp 209—211 °C and 165—167 °C, in good yields. Oxidation of the major epoxide (**24**) with the Jones reagent gave the 11-ketone (**23**) in an 80% yield, while that of the minor (**25**) afforded a new 11-ketone (**26**), mp 157—159 °C, in an 87% yield. This indicates that the major epoxide (**24**) is 11β-hydroxy 12α,13α-epoxide with the same epoxy configuration as that of epoxide **22**, and the minor (**25**) 11β-hydroxy 12β,13β-epoxide. Likewise, 11α-acetate (**16a**) was oxidized under almost the same conditions as 11α-alcohol (**16**) to give two epimeric epoxides in 45 and 22% yields along with the recovered 11α-acetate (30%). The main epoxide was identified as 11α-acetoxy 12α,13α-epoxide (**22a**), and the minor (**27**), mp 140—142 °C, as the 12β,13β-epoxy epimer. The same epoxidation of 11β-acetate (**17a**) afforded 11β-acetoxy 12α,13α-epoxide (**24a**) as the only isolable 12,13-oxide in a 27% yield, leaving 41% of the starting 11β-acetate (**17a**) unreacted. The formation of 12β, 13β-epoxide (**27**) on the oxidation of 11α-acetate (**16a**) would result from steric hindrance due to the α-acetoxyl group at C_{11}. Finally, compound **19** having no substituent at C_{11} was oxidized with the peracid. The epoxidation proceeded very rapidly, as compared with that of 11-alcohols and 11-acetates (**16**—**17a**), and one major (**28**), mp 161—163 °C, and two minor products (**29** and **30**), mp 175—177 °C and 202—205 °C, were isolated in 65, 24, and 3.5% yields, respectively. In view of the fact that the major compound was the sole isolable 12,13-epoxide, it was assigned formula **28** with a 12α,13α-epoxy group. Moreover, structures **29** and **30** were assigned tentatively to the minor products on the basis of spectral data (see, Experimental).







22 11α-OH
22a 11α-OAc

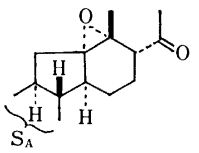
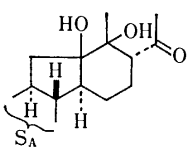
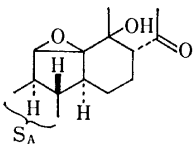
26 12β,13β-O-







28 **29** **30**

As mentioned in the preceding section, the configurational assignment of compounds **22**—**28** to the 12,13-epoxy groups was deduced from the same ground, the preferential attack of the peracid from the less-hindered rear (α) side. However, the stereoselectivity of epoxidation is also influenced by nearby polar substituents,[15] as has been illustrated by many allyl alcohols,[16] especially in the presence of transition metal catalysts.[17] In good accord with the prediction, 11β-alcohol (**17**) was oxidized with *t*-butyl hydroperoxide in refluxing benzene containing bis(acetylacetonato)oxovanadium(IV) to give 11β-hydroxy 12β,13β-epoxide (**25**) almost quantitatively. Naturally, 11α-alcohol (**16**) yielded the corresponding 12α,13α-epoxide (**22**) quantitatively by the same treatment. The results are in line with the assigned configurations to the 12,13-epoxy groups, supported also by comparison of the chemical shifts of protons at C_{18} and C_{17}: 18-methyl protons, **22** (11α-OH and 13β-CH_3) δ 1.36: **24** (11β-OH and 13β-CH_3) δ 1.47; **25** (11β-OH and 13α-CH_3) δ 1.33: proton at C_{17}, **25**, **25a**, **26**, and **27** (each 12α,13α-epoxy) 3.14 (br W_H=16 Hz), 3.06 (16), 3.16 (16), and 3.04 (16); **22**, **22a**, **23**, **24**, **24a**, and **28** (each 12α,13α-epoxy),

not observed below δ 3.00 as a separated peak.[18]

In a previous paper[10] on the NMR spectra of a number of 12β- and 12α-etiojervanes, it was reported that the effects of many different substituents on the chemical shifts of 19-methyl protons are additive.

Table 1. Contribution ($\Delta\delta$) of functional groups to the chemical shift of the 19-methyl protons of etiojervanes

Groups	A-T[a]	B-T[a]
Reference shifts	0.74[a]	0.79[a]
Functional groups	$\Delta\delta$[b]	$\Delta\delta$[b]
11β-OH, Δ^{12}	0.28	—
11β-OAc, Δ^{12}	0.03	—
11α-OH, Δ^{12}	0.08	—
11α-OAc, Δ^{12}	0.12	—
11β-OH, 12β,13β-O-[c]	0.28	—
11β-OH, 12α,13α-O-[c]	—	0.28

a) "Δ, α-O and β-O" denote "double bond, 12α,13α-epoxy, and 12β,13β-epoxy groups," respectively. b) Abbreviations "d and br" denote "doublet and broad."

However, the results for 11-hydroxy, 11-acetoxy and/or 11-oxoetiojervanes with a 12,13-double bond or an 12,13-epoxy group were not given. We now give the contribution of new functional groups (Table 1) in addition to that given previously.[10] The chemical shift and spectral pattern of a proton at C_{11} in these allyl or β,γ-epoxy alcohol and acetate systems are also summarized in Table 2. These data would be valuable for the confirmation of certain stereochemical conclusions as well as the improvement of the structure determination of new derivatives. The summarized results (Tables 1 and 2) are noteworthy in the following points. (i) Each of the 11-hydroxyl and 11-acetoxyl groups with a 12,13-double bond provides the same deshielding effect as the corresponding group with a 12,13-epoxy group, irrespective of the configuration of the epoxy groups (Table 1). (ii) The 11β-protons of etiojerv-12-en-11-ols and their acetates were observed clearly as a doublet with a large coupling constant of *ca.* 8 Hz, while the 11α-protons appeared as broad peaks with small half-width of *ca.* 12 Hz or doublets with a small coupling constant of *ca.* 4 Hz (Table 2). On the other hand, these protons of 12,13-epoxyetiojervan-11-ols and the acetates were observed as doublets with different coupling constants, depending on the configuration of the epoxy groups.

Experimental

All the melting points were uncorrected. The homogeneity of each compound was always checked by TLC on silica gel (Wakogel B-5) with various solvent systems, the spots being developed with cerium(IV) sulfate in dil. sulfuric acid and/or iodine. The optical rotations, ORD curves, UV and IR spectra were measured in chloroform, dioxane, methanol and chloroform, respectively, unless otherwise stated. The NMR spectra were obtained in chloroform-*d* at 60 and/or 100 MHz, and the chemical shifts were given in δ-values, TMS being used as an internal reference. Abbreviations "s, d, q, br, and do" in the NMR spectra denote "singlet, doublet, quartet, broad, and double", respectively.

*(20S)-17,20-Epoxy-17α-ethyletiojerva-4,12-diene-3,11-dione (**3**) and Its 17-Epimer (**4**).* To a solution of (17*E*)-17-ethyletiojerva-4,12,17(20)-triene-4,11-dione[6] (**2**, 20 g) in chloroform (1.2 l) cooled with ice was added perbenzoic acid (10 g, purity, 97.3%) in chloroform (100 ml) under stirring for 10 min. The resulting solution was allowed to stand at room temp for 3 h, and treated with 5% aq sodium thiosulfate to decompose excess of the perbenzoic acid. The chloroform layer was separated, washed with 5% aq sodium hydrogencarbonate and water, dried over anhydrous sodium sulfate, and evaporated to leave an oily residue (21.5 g), which crystallized on trituration with acetone–diisopropyl ether (5 : 1) and was recrystallized from the same solvent mixture to give **3** (14.6 g), mp 190—192 °C; $[\alpha]_D$ +57.0°; MS, *m/e* 326 (M^+); UV, λ_{max} 253 nm (ε 17000) and λ_{max} (dioxane) 254 nm (ε 15000); IR, ν_{max} (Nujol) 1705, 1677, and 1625 cm^{-1}; NMR, δ 1.25 (3H, s, 19-C$\underline{H}_3$), 1.38 (3H, d J=6 Hz, 21-C$\underline{H}_3$), 1.98 (3H, s, 18-C$\underline{H}_3$), 3.36 (1H, q J=6 Hz, $\underline{H}$ at C_{20}), and 5.81 (1H, s, $\underline{H}$ at C_4). Found: C, 77.23; H, 8.03%. Calcd for $C_{21}H_{26}O_3$: C, 77.27; H, 8.03%.

The mother liquors obtained on crystallization of crude **3** were evaporated to give a resinous material, which was crystallized and recrystallized from ethyl acetate–hexane (5 : 1) to yield **4** (80 mg), mp 176—178 °C; $[\alpha]_D$ +203.5 °C; MS,

m/e 326 (M^+), UV, λ_{max} 253 nm (ε 17000) and λ_{max} (dioxane) 257 nm (ε 16000); IR, ν_{max} (Nujol) 1714, 1664, and 1628 cm^{-1}; NMR, δ 1.25 (3H, s, 19-C$\underline{H}_3$), 1.38 (3H, d J=6 Hz, 21-C$\underline{H}_3$), 1.95 (3H, s, 18-C$\underline{H}_3$), 3.21 (1H, q J=6 Hz, $\underline{H}$ at C_{20}), and 5.78 (1H, s, $\underline{H}$ at C_4). Found: C, 77.41; H, 8.04%. Calcd for $C_{21}H_{26}O_3$: C, 77.27; H, 8.03%.

*17α-Ethyletiojerva-4,12-diene-3,11,20-trione (**5**), Its 17β-Epimer (**6**), and 17β-Formyl-17α-methyletiojerva-4,12-diene-3,11-dione (**7**), and Its 17-Epimer (**8**).* (i) A solution of **3** (1.0 g) in benzene (50 ml), dried over sodium and then LAH, was stirred with BF_3 (2.0 ml), freshly distilled over calcium hydride, at room temp for 60 s. The benzene solution was mixed with ether, washed with 5% aq sodium hydrogencarbonate and water, dried and evaporated to leave a resinous substance (1.0 g), which was purified by chromatography over silica gel (Merck, 70—230 mesh, 50 g) with benzene and ether. Eluates with benzene-ether (5 : 1) crystallized on trituration with ether. Recrystallization from ether gave **7** (75 mg), mp 145-147 °C; $[\alpha]_D$ +17°; ORD, $[\Phi]_{338}^{trough}$ −352°, $[\Phi]_{280}^{peak}$ +2280°, a=−26°; MS, *m/e* 326 and 297 (M^+ −CHO); UV, λ_{max} (dioxane) 250 nm (ε 18000); IR, ν_{max} 1717, 1703, and 1658 cm^{-1}; NMR, δ 1.24, 1.30, and 2.12 (each 3H, s, 19-, 17-, and 18- C$\underline{H}_3$), 5.76 and 9.44 (each 1H, s, $\underline{H}$ at C_4 and C$\underline{H}$O).

Eluates with a 3 : 1 mixture of benzene and ether afforded a mixture (600 mg) of **5** and **6**. A part of the mixture was separated by fractional recrystallization to give the respective compounds in pure state. Compound **5**, mp 151.5—153.5 °C (from ether-acetone); $[\alpha]_D$ +95°; ORD, $[\Phi]_{312}^{peak}$ +2710°, $[\Phi]_{298}^{trough}$ −1320°, a=+40°; MS, *m/e* 326 (M^+) and 284 (base); UV, λ_{max} (dioxane) 249 nm (ε 15,000); IR, ν_{max} 1718, 1708, and 1670 cm^{-1}; NMR, δ 1.24, 2.11, and 2.17 (each 3H, s, 19-, 18-, and 21-C$\underline{H}_3$), 3.33 (1H, br W_H=20 Hz, $\underline{H}$ at C_{17}), and 5.76 (1H, s, $\underline{H}$ at C_4). Found: C, 76.95; H, 8.04%. Calcd for $C_{21}H_{26}O_3$: C, 77.27; H, 8.03%. Compound **6**, mp 195—197 °C (from acetone-diisopropyl ether); $[\alpha]_D$ +25°; ORD, $[\Phi]_{314}^{trough}$ −960°, $[\Phi]_{294}^{peak}$ +1080°, a=−20°; MS, *m/e* 326 (M^+) and 284; UV, λ_{max} (dioxane) 251 nm (ε 16000); IR, ν_{max} 1714, 1699, and 1674 cm^{-1}; NMR, δ 1.30, 2.13, and 2.32 (each 3H, s, 19-, 18-, and 21-C$\underline{H}_3$), 3.38 (1H, br W_H=11 Hz, $\underline{H}$ at C_{17}), and 5.08 (1H, s, $\underline{H}$ at C_4). Found: C, 77.24; H, 7.97%. Calcd for $C_{21}H_{26}O_3$: C, 77.27; H, 8.03%.

(ii) 17α,20*R*-Epoxide (**4**, 1.0 g) in dry benzene (50 ml) was treated with dry BF_3 (2.0 ml) at room temp for 60 s and then worked up in the same manner as **3** to give a resinous substance (1.0 g), which was separated by chromatography (silica gel, 50 g). Fractions eluted with benzene-ether (5 : 1) crystallized on trituration with ether and were recrystallized from ether to yield **8** (600 mg), mp 148—150 °C; $[\alpha]_D$ +204°; ORD, $[\Phi]_{328}^{peak}$ +2140°, $[\Phi]_{272}^{trough}$ −3970°; a=+61°; MS, *m/e* 326 (M^+) and 297 (M^+−CHO); UV, λ_{max} (dioxane) 250 nm (ε 18,000); IR, ν_{max} 1725, 1706, and 1668 cm^{-1}; NMR, δ 1.25, 1.32, and 2.08 (each 3H, s, 19-, 17-, and 18-C$\underline{H}_3$), 5.78 and 9.30 (each 1H, s, $\underline{H}$ at C_4 and C$\underline{H}$O). Found; C, 77.24; H, 7.97%. Calcd for $C_{21}H_{26}O_3$: C, 77.27; H, 8.03%. Fractions eluted with a 3 : 1 mixture of benzene and ether afforded a 1 : 1 mixture (300 mg) of **5** and **6** which were isolated by fractional recrystallization as described in part (i).

(iii) A solution of **6** (22 mg) in benzene (4 ml) was stirred with *p*-TsOH (25 mg) under reflux for 2 h. The solution was worked up as mentioned above to leave a crystalline residue, showing a single spot on TLC, which was identified as a 1 : 2 mixture of **6** and **5** on the basis of the NMR spectrum. When compound **5** was submitted to the same treatment, almost the same equilibrium mixture was obtained. However, none of these ketones (**5** and **6**) was isomerized under the conditions (BF_3, room temp, 60 s) as described in parts (i) and (ii).

*17α-Ethyletiojerva-5,12-diene-3,11,20-trione 3,20-Di(ethylene Acetal) (**9**) and Its 17-Epimer (**10**).* The afore-mentioned 5 : 1 mixture (6.0 g) of **5** and **6** was refluxed with ethylene glycol (60 ml) and *p*-TsOH (0.6 g) in benzene (600 ml) for 6 h, water being removed with a Dean-Stark apparatus. After being cooled, the solution was worked up as usual to leave crystalline acetals (7.5 g), which on recrystallization from ether gave **9** (3.3 g), mp 181—183 °C; $[\alpha]_D$ −77°; MS, *m/e* 414 (M^+), 399, 99, and 87; UV, λ_{max} 257 nm (ε 10000); IR, ν_{max} 1710 and 1623 cm^{-1}; NMR, δ 1.09, 1.23, and 2.30 (each 3H, s, 19-, 21-, and 18-C$\underline{H}_3$), 3.97 (8H, s, 2OC$\underline{H}_2$-C$\underline{H}_2$O), and 5.39 (1H, br W_H=10Hz, $\underline{H}$ at C_6). Found: C, 72.04; H, 8.45%. Calcd for $C_{25}H_{34}O_5$: C, 72.43; H, 8.27%.

The mother liquors on recrystallization from ether were evaporated and purified by chromatography over silica gel (80 g). Eluates with benzene gave crystals (1.3 g), which on recrystallization from ether yielded **10** (0.75 g), mp 143.5—144.5 °C; $[\alpha]_D$ −128°; MS, *m/e* 414 (M^+), 399, 99, and 87; UV, λ_{max} 259 nm (ε 13000); IR, ν_{max} 1708 and 1623 cm^{-1}; NMR, δ 1.08, 1.28, and 2.32 (each 3H, s, 19-, 21-, and 18-C$\underline{H}_3$), 3.96 (8H, s, 2OC$\underline{H}_2$C$\underline{H}_2$O), and 5.39 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 72.03; H, 8.04%. Calcd for $C_{25}H_{34}O_5$: C, 72.43; H, 8.27%. Eluates with benzene-ether (10 : : 1) afforded an additional sample of **9** (1.0 g).

17αH-Di(ethylene acetal) (**10**, 30 mg) was treated with ethylene glycol (1 ml) and *p*-TsOH (10 ml) in benzene (10 ml) under reflux for 28 h. The reaction mixture was worked up as usual to leave a crystalline residue (28 mg), showing essentially the same NMR spectrum and TLC spot as those of **9**.

*17α-Ethyl-11α-hydroxyetiojerva-5,12-diene-3,20-dione 3,20-Di(ethylene Acetal) (**11**), Its 11-Acetate (**11a**), and Their 11β-Epimers (**12** and **12a**).* (i) To a solution of **9** (5.2 g) in dry tetrahydrofuran (THF, 260 ml) was added dropwise aluminium trihydride (0.57 g) in dry THF (29 ml) under cooling with ice and stirring in a stream of nitrogen during 20 min, the whole mixture being stirred at room temp for 3 h. After addition of methanol to decompose excess hydride, the mixture was mixed with 6M aq ammonia and then filtered. The filtrate was dried and evaporated to leave an amorphous residue (5.9 g), which was separated by chromatography over silica gel (150 g). Eluates with benzene-ether (3 : 1) were crystallized and recrystallized from ether to give **12** (0.8 g), mp 163—164 °C; $[\alpha]_D$ +32°; MS, *m/e* 416 (M^+); IR, ν_{max} 3580 and 3440 cm^{-1}; NMR, δ 1.18, 1.24, and 1.90 (each 3H, s, 21-, 19-, and 18-C$\underline{H}_3$), 3.88 (8H, s, 2OC$\underline{H}_2$C$\underline{H}_2$O), 4.86 (1H, br W_H=12 Hz, $\underline{H}$ at C_{11}), and 5.24 (1H, br W_H=8 Hz, $\underline{H}$ at C_6). Found: C, 71.77; H, 8.75%. Calcd for $C_{25}H_{36}O_5$: C, 72.08; H, 8.71%.

Eluates with benzene-ether (1 : 2), crystallized on trituration with acetone-diisopropyl ether, were recrystallized from the same solvent mixture to yield **11** (4.2 g), mp 135—137 °C; $[\alpha]_D$ +10°; MS, *m/e* 416 (M^+); IR, ν_{max} 3580 and 3440 cm^{-1}; NMR, δ 1.06, 1.18 and 1.82 (each 3H, s, 19-, 21-, and 18-C$\underline{H}_3$), 3.90 (8H, s, 2OC$\underline{H}_2$C$\underline{H}_2$O), 4.60 (1H, d J=8 Hz, $\underline{H}$ at C_{11}), and 5.36 (1H, br W_H=8 Hz, $\underline{H}$ at C_6). Found: C, 72.00; H, 8.70%. Calcd for $C_{25}H_{36}O_5$: C, 72.08; H, 8.71%.

(ii) 11α-Alcohol (**11**, 200 mg) was stirred with acetic anhydride (Ac_2O, 0.55 ml) in pyridine (Py, 5 ml) at room temp for 24 h. The mixture was worked up as usual to give an amorphous residue, which was crystallized and recrystallized from diisopropyl ether-acetone to give **11a** (210 mg), mp 194—196 °C; $[\alpha]_D$ −6.5°; MS, *m/e* 443 (M^+−CH_3), 398 (M^+ −AcOH), 383, 99, and 87; IR, ν_{max} 1725 cm^{-1}; NMR,

δ 1.11. 1.15, 1.62, and 1.94 (each 3H, s, 19-, 21-, 18-CH$_3$, and OCOCH$_3$), 3.90 (8H, s, 2OCH$_2$CH$_2$O), 5.38 (1H, br W_H=8 Hz, H at C$_6$), and 5.99 (1H, br W_H=12 Hz, H at C$_{11}$). Found: C, 70.62; H, 8.32%. Calcd for $C_{27}H_{38}O_6$: C, 70.71; H, 8.35%.

11β-Alcohol (**12**, 630 mg) was heated with Ac_2O (1.7 ml) in Py (16 ml) at 100 °C for 11h. The mixture, after being worked up as usual, was purified by chlomatography over silica gel (6 g) to give benzene-ether (1 : 1) eluates (650 mg), which crystallized from ether to give **12a**, mp 143—145 °C; $[\alpha]_D$ −6.0°; MS, 443 ($M^+ - CH_3$) and 398 (M^+ −AcOH); IR, ν_{max} 1720 cm^{-1}; NMR, δ 0.98, 1.16, 1.62, and 1.96 (each 3H, s, 19-, 21-, 18-CH$_3$, and OCOCH$_3$), 3.88 (8H, s, 2OCH$_2$-CH$_2$O), 5.28 (1H, br W_H=8 Hz, H at C$_6$), and 6.18 (1H, d J=4 Hz, H at C$_{11}$). Found: C, 70.67; H, 8.30%. Calcd for $C_{27}H_{38}O_6$: C, 70.71; H, 8.35%.

*17β-Ethyl-11α-hydroxyetiojerva-5,12-diene-3,20-dione 3,20-Di(ethylene Acetal) (**13**), Its 11β-Epimer (**14**), and 17β-Ethyl-12α-etiojerv-5-ene-3,11,20-trione 3,20-Di(ethylene Acetal) (**15**).*

(i) A solution of **10** (3.2 g) in THF (162 ml) was treated with aluminium trihydride (0.35 g) in THF (18 ml) at room temp for 5 h in the same manner as **9**. After addition of methanol, the mixture was treated with 6 M aq ammonia and then filtered. The filtrate was dried, evaporated and shaken with water and chloroform repeatedly. The chloroform solutions were combined and worked up as usual to give a resinous material (3.3 g), which was separated by chromatography over silica gel (100 g). Eluates with benzene-ether (8 : 1) gave a crystalline substance, which was recrystallized from diisopropyl ether to yield **15** (690 mg), mp 156—157 °C; $[\alpha]_D$ −56°; ORD, $[\Phi]_{334}^{trough}$ −5200°, $[\Phi]_{300}^{peak}$ +3370°, a=−86°; MS, *m/e* 416 (M^+), 401, 99, and 87; IR, ν_{max} 1730 cm^{-1}; NMR, δ 0.88 (3H, d J=7 Hz, 18-CH$_3$), 1.12 and 1.26 (each 3H, s, 19- and 21-CH$_3$), 3.94 (8H, s, 2OCH$_2$CH$_2$O), and 5.35 (1H, br W_H=8 Hz, H at C$_6$). Found: C, 71.76; H, 8.64%. Calcd for $C_{25}H_{36}O_5$: C, 72.08; H, 8.71%.

Eluates with benzene-ether (5 : 1) gave **14** (1.3 g), mp 139—141 °C (from ether); $[\alpha]_D$ −57°; MS, *m/e* 416 (M^+), 401, and 383; IR, ν_{max} 3608 and 3480 cm^{-1}; MNR, δ 1.24, 1.28, and 1.92 (each 3H, s, 19-, 21-, and 18-CH$_3$), 3.95 (8H, s, 2OCH$_2$-CH$_2$O), 4.84 (1H, br W_H=12 Hz, H at C$_{11}$), 5.24 (1H, br W_H=8 Hz, H at C$_6$). Found: C, 71.80; H, 8.68%. Calcd for $C_{25}H_{36}O_5$: C, 72.08: H, 8.71%.

Eluates with benzene-ether (3 : 1) afforded **13** (0.5 g), mp 194—196 °C (from diisopropyl ether-acetone); $[\alpha]_D$ −53°; MS, *m/e* 416 (M^+), 401, and 383; IR, ν_{max} 3606 and 3480 cm^{-1}; NMR, δ 1.05, 1.22, and 1.91 (each 3H, s, 19-, 21-, and 18-CH$_3$), 3.94 (8H, s, 2OCH$_2$CH$_2$O), 4.60 (1H, d J=8 Hz, H at C$_{11}$), and 5.33 (1H, br W_H=8 Hz, H at C$_6$). Found: C, 71.89; H, 8.70%. Calcd for $C_{25}H_{36}O_5$: C, 72.08; H, 8.71%.

(ii) 11-Ketone (**15**, 100 mg) was refluxed with 5% aq potassium hydroxide in methanol (20 ml) for 7 h under nitrogen. The solution was cooled, neutralized with acetic acid, evaporated, and shaken with water and chloroform. The chloroform solution, after being worked up as usual, gave a crystalline residue (104 mg), showing a single spot on TLC, which displayed the same NMR spectrum as that of the starting ketone and had mp 158—159°C on recrystallization from diisopropyl ether.

*17α-Ethyl-11α-hydroxyetiojerva-4,12-diene-3,20-dione (**16**) and Its 11-Acetate (**16a**).* (i) A solution of **11** (5.1 g) in acetone (1.4 l) and water (220 ml) was refluxed with *p*-TsOH (1.0 g) for 3 h. After being cooled, the solution was evaporated and shaken with water and chloroform, and the chloroform solution was washed with 5% aq sodium hydrogencarbonate and water, dried and evaporated to leave a crystalline residue. The residue was recrystallized from ether to give **16** (3.4 g), mp 178—180 °C; $[\alpha]_D$ +198°; MS *m/e* 328 (M^+); UV, λ_{max} 238 nm (ε 11000); IR, ν_{max} 3447, 1705, and 1660 cm^{-1}; NMR, δ 1.22, 1.71, and 2.14 (each 3H, s, 19-, 18-, and 21-CH$_3$), 3.16 (1H, br W_H=22 Hz, H at C$_{17}$), 4.54 (1H, d J=8 Hz, H at C$_{11}$), and 5.79 (1H, s, H at C$_4$). Found: C, 76.57; H, 8.67%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%.

(ii) 11α-Acetate (**11a**, 0.5 g) was treated with *p*-TsOH (105 mg) in acetone (140 ml) and water (21 ml) under reflux for 9 h. The reaction mixture was worked up as usual to give a crystalline residue, which was recrystallized from ether to give **16a** (390 mg), mp 143—145 °C; $[\alpha]_D$ +203°; MS, *m/e* 310 (M^+ −AcOH), 295 (310−CH$_3$), and 267 (310 −COCH$_3$); UV, λ_{max} 236 nm (ε 10000); IR, ν_{max} 1724, 1710, and 1660 cm^{-1}; NMR, δ 1.24, 1.50, 2.04, and 1.97 (each 3H, 19-, 18-, 21-CH$_3$, and OCOCH$_3$), 3.10 (1H, br W_H=20 Hz, H at C$_{17}$), and 5.75 (1H, s, H at C$_4$), 5.88 (1H, d J=8 Hz, H at C$_{11}$). Found: C, 74.28; H, 8.02%. Calcd for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16%.

*17α-Ethyl-11β-hydroxyetiojerva-4,12-diene-3,20-dione (**17**) and Its 11-Acetate (**17a**).* (i) 3,20-Di(ethylene acetal) (**12**, 207 mg) was refluxed with *p*-TsOH (60 mg) in acetone (60 ml) and water (9 ml) for 2.5 h. The mixture on the usual work-up gave a crystalline substance, which was recrystallized from ether-acetone to yield **17** (139 mg), mp 158—160 °C; $[\alpha]_D$ +256°; MS, *m/e* 328 (M^+); UV, λ_{max} 238 nm (ε 11000); IR, ν_{max} 3444, 1700, and 1675 cm^{-1}; NMR, δ 1.44, 1.75, and 2.12 (each 3H, s, 19-, 18-, and 21-CH$_3$), 3.20 (1H, br W_H=22 Hz, H at C$_{17}$), 4.89 (1H, d J=4.5 Hz, H at C$_{11}$), and 5.73 (1H, s H at C$_4$). Found: C, 76.57; H, 8.67%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%.

(ii) 11β-Acetate (**12a**, 0.3 g) was deacetalized in the same manner [*p*-TsOH (63 mg), acetone (84 ml), water (13 ml), reflux, 9 h] as **12** and gave **17a** (230 mg) on recrystallization from ether, mp 187—190 °C; $[\alpha]_D$ +204°; MS, *m/e* 310 (M^+ −AcOH), 295 (310−CH$_3$), and 267 (310−COCH$_3$); UV, λ_{max} 237 nm (ε 10000); IR, ν_{max} 1724, 1710, and 1660 cm^{-1}; NMR, δ 1.20, 1.48, 2.07, and 2.01 (each 3H, s, 19-, 18-, 21-CH$_3$, and OCOCH$_3$), 3.18 (1H, br W_H=20 Hz, H at C$_{17}$), 5.75 (1H, s, H at C$_4$), and 6.18 (1H, d J=4 Hz, H at C$_{11}$). Found: C, 74.28; H, 8.02%. Calcd for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16%.

*17α-Ethyletiojerva-5,12-diene-3,20-dione 3,20-Di(ethylene Acetal) (**18**).* (i) To ethylamine (5 ml), dried over potassium hydroxide, containing lithium lump (20 mg) was added **11a** (100 mg) in THF (4 ml), and the blue-colored mixture was refluxed for 50 min. On addition of ammonium chloride (1 g), the mixture became colorless. It was then evaporated, mixed with water and extracted with chloroform repeatedly. The chloroform solution, after being worked up as usual, left a crystalline residue, which was recrystallized from acetone-diisopropyl ether to yield **18** (78 mg), mp 139—140 °C; $[\alpha]_D$ −12°; MS, *m/e* 400 (M^+), 385, 99, and 87; IR, no absorption maximum near 1700 cm^{-1}; NMR, δ 1.00, 1.22, and 1.71 (each 3H, s, 19-, 21-, and 18-CH$_3$), 4.00 (8H, s, 2OCH$_2$-CH$_2$O), and 5.42 (1H, br W_H=10 Hz, H at C$_6$). Found: C, 74.73; H, 9.02%. Calcd for $C_{25}H_{36}O_4$: C, 74.96; H, 9.06%.

(ii) 11β-Alcohol (**12**, 90 mg) was submitted to the Birch reduction under almost the same conditions [ethylamine (5 ml), lithium (30 mg), THF (4 ml), reflux, 60 min] as **11a**. The mixture was worked up as mentioned above to leave an amorphous residue (92 mg), showing two spots on TLC. The residue was separated by chromatography over silica gel (5 g) into two fractions, one (53 mg) being eluted with benzene-ether (10 : 1) and the other (39 mg) with benzene-

ether (3 : 1). The former with mp 138—140 °C (from acetone–diisopropyl ether) was identified as **18** (TLC, IR and NMR), and the latter with mp 164—166 °C (from acetone–diisopropyl ether) proved to be the starting material (**12**).

*17α-Ethyletiojerva-4,12-diene-3,20-dione (**19**) and 17α-Ethyletiojerva-5,12-diene-3,20-dione 3-Ethylene Acetal (**20**).* (i) 3,20-Di(ethylene acetal) (**18**, 1.95 g) was refluxed with *p*-TsOH (600 mg) in acetone (600 ml) and water (90 ml) for 2 h. The solution, after being worked up as usual, afforded an amorphous substance (1.90 g), which was separated by chromatography over silica gel (40 g). Eluates with benzene–ether (5 : 1) gave **20** (270 mg), mp 140—142 °C (from diisopropyl ether); MS, *m/e* 356 (M^+) and 313 (M^+-COCH_3); IR, ν_{max} 1705 cm^{-1}; NMR, δ 1.01, 1.56, and 2.12 (each 3H, s, 19-, 18-, and 21-C$\underline{H}_3$), 3.10 (1H, br W_H=20 Hz, $\underline{H}$ at C_{17}), 3.98 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), and 5.41 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 77.20; H, 9.18%. Calcd for $C_{23}H_{32}O_3$: C, 77.49; H, 9.05%. Eluates with benzene–ether (3 : 1) afforded **19** (1.17 g), mp 131—133 °C (from diisopropyl ether–acetone); $[\alpha]_D$ +198°; MS, *m/e* 312 (M^+) and 269 (M^+-COCH_3); UV, λ_{max} 238 nm (ε 12000); IR, ν_{max} 1700, 1655, and 1603 cm^{-1}; NMR, δ 1.18, 1.57, and 2.13 (each 3H, s, 19-, 18-, and 21-C$\underline{H}_3$), 3.10 (1H, br W_H=20 Hz, $\underline{H}$ at C_{17}), and 5.08 (1H, s, $\underline{H}$ at C_4). Found: C, 80.90; H, 9.15%. Calcd for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03%.

(ii) A solution of 3β-hydroxy-17α-ethyletiojerva-5,12-diene-20-one[14] (**21**, 34 mg) in toluene (20 ml) and dry cyclohexanone (0.5 ml) was heated to distil *ca.* 12 ml of toluene to dry the system by azeotropization. To the stirred solution was added aluminium isopropoxide (34 mg), and the suspended mixture was again heated to distil *ca.* 6 ml of toluene and then refluxed for 2.5 h. After being cooled, the mixture was submitted to distillation with steam, until most of the solvents were removed, and the residue was treated with water and chloroform. The chloroform solution was worked up as usual to leave an amorphous substance, which was purified by preparative TLC to give an α,β-unsaturated ketone (14 mg), mp 126—128 °C (from diisopropyl ether). This was found to be identical with **19** (TLC, IR, NMR, and mixed mp).

*12α,13α-Epoxy-17α-ethyl-11α-hydroxyetiojerv-4-ene-3,20-dione (**22**) and Its 11-Acetate (**22a**).* (i) To a chloroform solution (4 ml) of **16** (25 mg) was added perbenzoic acid (15 mg, purity, 84%) in chloroform (1.2 ml), and the whole solution was allowed to stand at room temp for 24 h. After addition of 5% aq sodium thiosulfate (5 ml) to decompose excess peracid, the solution was washed with 5% aq sodium hydrogencarbonate and water, dried, and evaporated to leave a crystalline residue. The residue was recrystallized from diisopropyl ether–acetone to yield **22** (24 mg), mp 206—208 °C; $[\alpha]_D$ +192°; MS, *m/e* 344; UV, λ_{max} 239 nm (ε 11000); IR, ν_{max} 3400, 1708, and 1663 cm^{-1}; NMR δ 1.28, 1.36, 2.24 (each 3H, s, 19-, 18-, and 21-C$\underline{H}_3$), 3.85 (1H, d J=9 Hz, $\underline{H}$ at C_{11}), and 5.78 (1H, s, $\underline{H}$ at C_4). Found: C, 73.44; H, 8.38%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

(ii) Compound **22** (460 mg) was treated Ac_2O (4.6 ml) and Py (9.2 ml) at room temp for 25 h under stirring. The mixture was worked up as usual to give an amorphous residue (530 mg), which was separated by chromatography over silica gel (11 g). Eluates with benzene–ether (3 : 1) afforded **22a** (430 mg), mp 200—203 °C (from ether); $[\alpha]_D$ +189°; MS, *m/e* 386 (M^+); UV, λ_{max} (EtOH) 238 nm (ε 10,000); IR, ν_{max} 1734, 1706, and 1674 cm^{-1}; NMR, δ 1.24, 1.29, 2.20, and 2.07 (19-, 18-, 21-C$\underline{H}_3$, and COC$\underline{H}_3$), 5.32 (1H, d J=8 Hz, $\underline{H}$ at C_{11}), and 5.78 (1H, s, $\underline{H}$ at C_4). Found: C, 71.10; H, 7.84%. Calcd for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82%. Eluates with ether gave the starting alcohol (**22**, 50 mg), mp 204—206 °C.

(iii) To a refluxing greenish solution of **16** (100 mg) in dry benzene (3 ml) containing bis(acetylacetonato)oxovanadium (IV) [$VO(acac)_2$] (1.35 mg) was added rapidly *t*-butyl hydroperoxide (0.06 ml), when the solution became red-colored. The solution was further refluxed for 30 min and cooled. The resulting yellow mixture was washed with 5% aq sodium thiosulfate, 5% aq sodium hydrogencarbonate, water, dried and evaporated to give a crystalline residue, which on recrystallization from diisopropyl ether–acetone to give **22** (94 mg), mp 204—206 °C, identical with the sample (**22**) in part (i).

*12α,13α-Epoxy-17α-ethyl-11β-hydroxyetiojerv-4-ene-3,20-dione (**24**), Its 12β,13β-Epoxy Epimer (**25**), and Their 11-Acetates (**24a** and **25a**).* (i) A chloroform solution (29.5 ml) of **17** (118 mg) was treated with perbenzoic acid (65 mg, purity, 84%) at room temp for 21 h. The solution was worked up as usual to give an amorphous residue (138 mg), which was separated by chromatography over silica gel (3.5 g). Eluates with benzene–ether (5 : 1) gave **25** (44 mg), mp 159.5—160.5 °C (from ether); $[\alpha]_D$ +118°; MS, *m/e* 344 (M^+); UV, λ_{max} 238 nm (ε 8000); IR, ν_{max} 3500, 1718, and 1673 cm^{-1}; NMR, δ 1.33, 1.44, and 2.22 (18-, 19-, and 21-C$\underline{H}_3$), 3.14 (1H, br W_H=16 Hz, $\underline{H}$ at C_{17}), and 4.33 (1H, d J=7.5 Hz, $\underline{H}$ at C_{11}), and 5.70 (1H, s, $\underline{H}$ at C_4). Found: C, 73.28; H, 8.24%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

Eluates with benzene–ether (2 : 1) gave **24** (74 mg), mp 204—207 °C (from ether–acetone); $[\alpha]_D$ +174°; MS, *m/e* 344 (M^+); IR, ν_{max} 3470, 1695, and 1675 cm^{-1}; NMR, δ 1.45 and 1.47 (each 3H, s, 19- and 18-C$\underline{H}_3$ or *vice versa*), 2.20 (3H, s, 21-C$\underline{H}_3$), 4.25 (1H, d J=4 Hz, $\underline{H}$ at C_{11}), and 5.75 (1H, s, $\underline{H}$ at C_4). Found: C, 73.24; H, 8.10%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

(ii) Compound **24** (33 mg) was heated with Ac_2O and Py at 100 °C for 4 h. The reaction mixture was worked up as usual to yield an amorphous residue, which was purified by preparative TLC followed by recrystallization from ether to give **24a** (18 mg), mp 209—211 °C; $[\alpha]_D$ +140°; MS, *m/e* 386 (M^+) and 326 (M^+-AcOH); UV, λ_{max} (EtOH) 237 nm (ε 14500); IR, ν_{max} 1733, 1713, 1673, and 1613 cm^{-1}; NMR, δ 1.22 (6H, s, 19- and 18-C$\underline{H}_3$), 2.07 and 2.00 (each 3H, s, OCOC$\underline{H}_3$ and 21-C$\underline{H}_3$), 5.46 (1H, d J=4 Hz, $\underline{H}$ at C_{11}). Found: C, 71.10; H, 7.84%. Calcd for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82%. The starting alcohol (**24**, 7 mg) was also recovered unchanged by preparative TLC.

Compound **25** (50 mg) was acetylated under the same conditions as **24** to give an amorphous residue (48 mg), showing a single spot, which was crystallized and recrystallized from ether to yield **25a** (22 mg), mp 165—167 °C; $[\alpha]_D$ +131°; MS, *m/e* 386 (M^+), 344, and 326; UV, λ_{max} (EtOH) 237 nm (ε 12000); IR, ν_{max} 1737, 1715, 1667, 1616, and 1242 cm^{-1}; NMR, δ 1.32, 1.36, 2.20, and 2.10 (each 3H, s, 19-, 18-, 21-C$\underline{H}_3$, and OCOC$\underline{H}_3$), 3.06 (1H, br W_H=16 Hz, $\underline{H}$ at C_{17}), 5.68 (1H, d J=7 Hz, $\underline{H}$ at C_{11}), and 5.72 (1H, s, $\underline{H}$ at C_4).

(iii) A benzene solution (3 ml) of **17** (100 mg) was refluxed with *t*-butyl hydroperoxide (0.06 ml) in the presence of $VO(acac)_2$ (1.35 mg) for 30 min. The reaction mixture was worked up in the same manner as that of **16** to give a crystalline residue (110 mg) showing a single spot, which on recrystallization from ether gave **25** (83 mg), mp 162—164 °C, identical with **25** obtained in part (i).

*12α,13α-Epoxy-17α-ethyletiojerv-4-ene-3,11,20-trione (**23**) and Its 12β,13β-Epimer (**26**).* (i) A solution of **22** (30 mg) in dry acetone (5 ml) was stirred with a few drops of the Jones reagent under cooling with ice for 1 h. After addition of

ethanol to decompose the reagent, the mixture was evaporated and shaken with water and chloroform. The chloroform solution was worked up as usual to leave an amorphous residue (29 mg), which was separated into two fractions by preparative TLC (Wakogel B-5F), ether being used as a solvent. A more mobile fraction gave **23** (10 mg), mp 176.5—178 °C (from diisopropyl ether-acetone); $[\alpha]_D$ +200°; ORD, $[\Phi]_{351}^{trough}$ −1900°; $[\Phi]_{310}^{peak}$ +16100°; $a=-180°$; MS, *m/e* 342 (M^+) and 299 (M^+-COCH_3); UV, λ_{max} (EtOH) 234 nm (ε 13000); IR, ν_{max} 1750, 1710, 1665, and 1618 cm^{-1}; NMR, δ 1.22, 1.55, and 2.21 (each 3H, s, 19-, 18-, and 21-$C\underline{H}_3$), and 5.80 (1H, s, $\underline{H}$ at C_4). Found: C, 73.57; H, 7.65%. Calcd for $C_{21}H_{26}O_4$: C, 73.66; H, 7.66%. A less mobile fraction afforded the starting alcohol (**22**, 12 mg).

Compound **24** (28 mg) was oxidized with the Jones reagent in the same manner as **22** and gave epoxy ketone (22 mg), mp 178—180 °C (from ether), which was identical with the sample (**23**) described above.

(ii) Compound **25** (8 mg) in dry acetone (1 ml) was stirred with one drop of the Jones reagent under ice-cooling for 1 h. The reaction mixture, after addition of ethanol, was worked up as usual to leave a crystalline residue, which was recrystallized from ether to give **26** (7 mg), mp 157—159 °C; $[\alpha]_D$ −25°; ORD, $[\Phi]_{345}^{trough}$ −6900°; $[\Phi]_{305}^{peak}$ +9600°; $a=-165°$; MS, *m/e* 342 (M^+) and 299 (M^+-COCH_3); UV, λ_{max} (EtOH) 233 nm (ε 7000); IR, ν_{max} 1750, 1718, 1665, and 1615 cm^{-1}; NMR, δ 1.26, 1.55, and 2.24 (each 3H, s, 19-, 18-, and 21- $C\underline{H}_3$), 3.16 (1H, br $W_H=16$ Hz, $\underline{H}$ at C_{17}), and 5.82 (1H, s, $\underline{H}$ at C_4). Found: C, 73.31; H, 7.53%. Calcd for $C_{21}H_{26}O_4$: C, 73.66; H, 7.66%.

*Epoxidation of 11α-Acetate (**16a**).* A chloroform solution (30 ml) of **16a** (150 mg) was stirred with perbenzoic acid (75 mg) at room temp for 26 h. The chloroform solution was washed with 5% aq sodium thiosulfate, 5% aq sodium hydrocarbonate and water, dried and evaporated to leave a resinous residue (183 mg), which was separated into three fractions by preparative TLC (Wakogel B-5), a 2 : 1 mixture of benzene and ether being used as solvent. The most mobile fraction (51 mg) was found to be the unchanged starting acetate (**16a**, 51 mg), mp 141—143 °C. A middle fraction was crystallized and recrystallized from ether to yield 12β,13β-epoxy-17α-ethyl-11α-hydroxyetiojerv-4-ene-3,20-dione 11-acetate (**27**, 27 mg), mp 140—142 °C; $[\alpha]_D$ +102°; MS, *m/e* 386 (M^+), 344, and 326; UV, λ_{max} (EtOH) 237 nm (ε 10000); IR, ν_{max} 1734, 1714, 1664, 1612, and 1244 cm^{-1}; NMR, δ 1.24, 1.26, 2.22, and 2.05 (19-, 18-, 21-$C\underline{H}_3$, and $OCOC\underline{H}_3$), 3.04 (1H, br $W_H=16$ Hz, $\underline{H}$ at C_{17}), 5.34 (1H, d $J=8$ Hz, $\underline{H}$ at C_{11}), and 5.76 (1H, s, $\underline{H}$ at C_4). Found: C, 71.74; H, 7.89%. Calcd for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82%.

The least mobile fraction gave crystalline epoxide (71 mg), mp 200—202 °C (from ether), which was identical with the sample (**22a**), obtained by acetylation of **22**.

*Epoxidation of 11β-Acetate (**17a**).* A chloroform solution (20 ml) of **17a** (100 mg) was treated with perbenzoic acid (50 mg) at room temp for 26 h under stirring. The chloroform solution, after being worked up as usual, gave an amorphous residue (122 mg), which was separated into two fractions by preparative TLC (Wakogel B-5), a 2 : 1 mixture of benzene and ether being used as solvent. The starting acetate (**17a**, 41 mg), mp 190—192 °C (from ether) was recovered unchanged from a more mobile fraction. A less mobile fraction yielded epoxy acetate (28 mg), mp 205—207 °C (from ether), which was identified as **24a** described above by comparison of the spectral data.

*Epoxidation of 17α-Ethyletiojerva-4,12-diene-3,20-dione (**19**).* A chloroform solution (192 ml) of **19** (1.04 g) was treated with perbenzoic acid (536 mg) at room temp under stirring. The reaction proceeded rapidly as compared with those of other etiojerv-12-enes and the starting material (**19**) disappeared on TLC after 3 h. The chloroform solution, after being worked up as usual, left a resinous residue (1.15 g), which was separated by chromatography over silica gel (30 g). Eluates with benzene-ether (5 : 1) afforded crystalline epoxide, which on recrystallization from acetone-diisopropyl ether gave **28** (700 mg), mp 161—163 °C; $[\alpha]_D$ +176°; MS, *m/e* 328 (M^+) and 285 (M^+-COCH_3); UV, λ_{max} (EtOH) 237 nm (ε 12000); IR, ν_{max} 1702 and 1663 cm^{-1}; NMR, δ 1.18, 1.28, and 2.21 (each 3H, s, 19-, 18-, and 21-$C\underline{H}_3$), and 5.78 (1H, s, $\underline{H}$ at C_4). Found: C, 76.57; H, 8.59%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%.

Eluates with benzene-ether (3 : 1) afforded a crystalline substance, which on recrystallization from ether gave **30** (39 mg), mp 202—205 °C; $[\alpha]_D$ +57°; MS, *m/e* 344 (M^+), 326 (M^+-H_2O), 311 ($326-CH_3$), 301 (M^+-COCH_3), and 283 ($326-COCH_3$); UV, λ_{max} 238 nm (ε 15000); IR, ν_{max} (Nujol) 3405, 1705, 1658, and 1611 cm^{-1}; NMR, δ 1.24, 1.33, and 2.32 (each 3H, s, 19-, 18-, 21-$C\underline{H}_3$), 2.66 (1H, s, O$\underline{H}$), 3.68 (1H, br s, $\underline{H}$ at C_{11}), and 5.80 (1H, s, $\underline{H}$ at C_4). Found: C, 73.00; H, 8.25%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

Eluates with benzene-ether (1 : 1) gave a crystalline substance, which was recrystallized from acetone-diisopropyl ether to yield **29** (318 mg), mp 175—177 °C; $[\alpha]_D$ +61°; MS, 346 (M^+), 328 (M^+-H_2O), 310 ($328-H_2O$), 303 (M^+-COCH_3), and 285 ($328-COCH_3$); UV, λ_{max} 239 nm (ε 10000); IR, ν_{max} (Nujol) 3385, 3285, 1693, 1675, and 1612 cm^{-1}; NMR, δ 1.16, 1.26, and 2.33 (each 3H, s, 19-, 18-, and 21- $C\underline{H}_3$), 2.16 and 5.06 (each 1H, s, 2O$\underline{H}$), 3.14 (1H, br $W_H=18$ Hz, $\underline{H}$ at C_{17}), 5.77 (1H, s, $\underline{H}$ at C_4). Found: C, 72.71; H, 8.71%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%.

The Configuration of 17-Ethyl-3β-hydroxyetiojerva-5,12,17(20)-trien-11-one and Related Compounds[1]

Akio MURAI, Hiroshi SASAMORI, and Tadashi MASAMUNE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 30, 1977)

The title compound, one of the most important starting materials for the synthesis of *C*-nor-*D*-homosteroid and normal steroid hormones, was determined to possess (*E*)-configuration at the 17,20-double bond on the basis of chemical and spectral evidence.

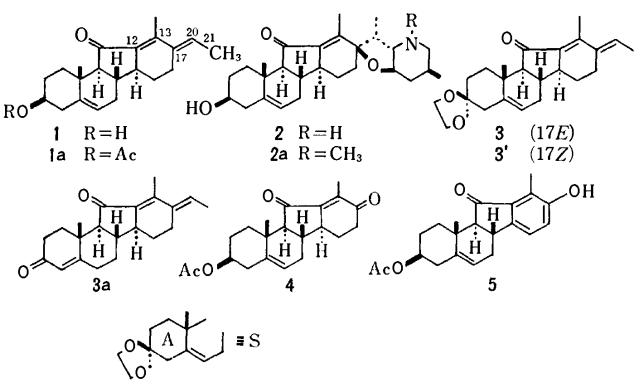
The title compound (**1**), a simple fragmentation product of jervine (**2**), was first obtained by Fried, Wintersteiner and coworkers[2] as a key substance for the structure elucidation of the jerveratrum alkaloids. The compound and its simple derivatives have since been used extensively as one of the most important starting materials for the synthesis of a number of etiojervanes including *C*-nor-*D*-homosteroid hormones[3] and of normal steroid hormones.[4] However, the configuration of the 17,20-double bond in **1** has not been determined yet, and compounds derived therefrom have often been left undecided stereochemically. In this paper, we present evidence indicating that the double bond in question should be assigned the (*E*)-configuration.[5]

Compound (**1**), prepared in good yields by degradation of *N*-methyljervine (**2a**) with boron trifluoride etherate,[6] forms its 3-acetate[2] (**1a**), and is readily converted into 17-ethyletiojerva-5,12,17(20)-triene-3,11-dione 3-ethylene acetal[7] (**3**) *via* the corresponding Δ^4-3-ketone (**3a**). All these compounds (**1**, **1a**, **3**, and **3a**), which are correlated with each other and exhibit the same NMR signals due to the 20-methine, 18- and 21-methyl protons [δ 6.12—6.14 (1H, q J=6 Hz), 2.29—2.31 (3H, s), and 1.79—1.81 (3H, d J=6 Hz)], have been defined completely with respect to the configurations of all asymmetric carbon atoms. In order to decide the configuration of the 17,20-double bond, we first attempted to prepare its geometrical isomer (**3'**) concerning the double bond by the Wittig reaction of a known 17-ketone, 3β-hydroxyetiojerva-5,12-diene-11, 17-dione 3-acetate[7] (**4**) with triphenylethylidenephosphorane. However, no trienones could be obtained, only a known phenol[2b] (**5**), mp 245—247 °C, being isolated in a 50% yield. Preparation of 20- and/or 17-epimeric 20-alcohols, which might undergo dehydration to yield the desired isomer (**3'**), was then undertaken.

Oxidation of the $\Delta^{5,12,17(20)}$-11-ketone (**3**) with *m*-chloroperbenzoic acid produced a 5:1 (estimated by NMR) mixture of 17,20-monoepoxides in a 50% yield (**3** recovered, 16%), from which major and minor epoxides (**6**) and (**7**), mp 187—189 °C and 160—162 °C, could be separated in pure state by fractional recrystallization. The epoxy groups of **6** and **7** were tentatively assigned β- and α-configurations, respectively, at C_{17} by analogy of the UV spectra [λ_{max} 251 nm (ε 14000) for **6** and 261 nm (ε 11000) for **7**] with those of 17-epimeric 17-hydroxyetiojervanes [λ_{max} 252 nm (ε 14000) for the 17β-hydroxy compound and 261 nm (ε 10300) for the 17α-epimer].[8] The Birch reduction of the mixture of epoxides **6** and **7** followed by chromatography afforded two 20-alcohols (**8**) and (**9**), mp 152—154 °C and 160—162 °C, in 42 and 8% yields, which were naturally obtained from **6** and **7**, respectively, under the same Birch conditions. The 12αH configuration in each of these compounds was deduced from the ORD curves; a=+282° for **8** and a=+300° for **9**.[9] Treatment of **8** with potassium carbonate under mild conditions effected only migration of the 13,17-double bond to give two α,β-unsaturated ketones (**10**) and (**11**), mp 185—187 °C and 175—177 °C, in 66 and 18% yields, respectively. Likewise, compound **9**, when treated under almost the same conditions, was converted into a new α,β-unsaturated ketone (**12**) as an isolable main product (40%). A modification of the Collins oxidation[10] of the 20-alcohols (**10**) and (**11**) gave the corresponding 20-ketones (**13**) and (**14**), mp 160—162 °C and 176—178 °C, in quantitative yields, which were assigned 17αH and 17βH configurations, respectively, on the basis of the ORD and NMR data: **13**, a=−225°,[11] δ 3.33 (1H, br W_H=11 Hz, H at C_{17}); **14**, a=+370°,[11] δ 3.35 (1H, br W_H=20 Hz, H at C_{17}). It is to be noted that the latter (**14**, 17βH) on reduction with lithium aluminium tri-*t*-butoxide hydride formed 20-alcohol **12** as the sole isolable product in a 23% yield (**14** recovered, 61%).

Having available 20- and/or 17-epimeric 20-alcohols (**8**—**11**), we again attempted to prepare the geometrical isomer (**3'**) of **3**. However, 20-epimeric $\Delta^{13(17)}$-20-alcohols (**8**) and (**9**), when treated with tosyl chloride in pyridine (room temp, 22 h), gave rise to only the known trienone (**3**) in good yields. Likewise, 20-alcohol **10** was converted readily into **3** by treatment under the same conditions or with phosphoryl chloride in benzene (room temp, 19 h). Only 20-alcohol **11** formed its tosylate (**11a**), mp 158—160 °C, but attempted base treatment (5% KOH in CH_3OH, reflux, 70 min) of the tosylate led to formation of only **3**, no isomer (**3'**) being detected in the product.

The 20-epimeric Δ^{12}-11-ketones (**11**) and (**12**) were



again submitted to the Birch reduction to give the corresponding saturated 11-ketones (**15**) and (**16**), mp 194—196 °C and 182—184 °C, in 76 and 68% yields, respectively. In accordance with the assigned configurations (12βH and 13αH), each of the ketones exhibited the following spectra: **15**, ORD, $a=-145°$,[9] NMR, δ 1.04 (3H, s, 19-C$\underline{H}_3$);[12] **16**, ORD, $a=-145°$,[9] NMR, δ 1.02 (3H, s, 19-C$\underline{H}_3$).[12] Oxidation of **15** under the afore-mentioned conditions[10] produced the corresponding 20-ketone (**17**), mp 184—186 °C, in a quantitative yield, whose ORD curve with a negative Cotton effect ($a=-86°$) confirmed the 17βH configuration; $a_{calcd}=-72°$ for 17βH and $-227°$ for 17αH.[11] The 11,20-diketone (**17**) was also obtained readily by the same oxidation of **16**. All the results indicate that two pairs of the 20-alcohols (**11**, **12**), and (**15**, **16**) possess the same configuration at C_{17} (17βH). They are diastereoisomers differing only at the configuration at C_{20}.

Recently Yamaguchi and co-workers[13] reported a procedure for the determination of the absolute configurations of epimeric secondary alcohols, which involves measurement of the relative magnitude of the lanthanoid induced shift (LIS) by the shift reagent Eu(fod)$_3$ for the NMR signals for the methoxy protons of diastereoisomeric (*R*)-α-methyl-α-trifluoromethyl-α-phenylacetate (MTPA ester) of the epimeric alcohols. The 20-alcohols (**15** and **16**) were then converted by treatment with (*S*)-(+)-α-methoxy-α-trifluoromethyl-α-phenylacetyl chloride[14] (MTPA-Cl) in pyridine into the respective MTPA esters (**15a**) and (**16a**), mp 176—178 °C and 138—140 °C, respectively, in good yields, showing the methoxy protons at δ 3.56 and 3.45 in the respective NMR spectra in chloroform-*d* solutions. Addition of the shift reagent Eu(fod)$_3$ to the solutions caused down-field shift of the relevant protons, and the LIS values for the protons were found to be larger for ester **16a** than for **15a** (Fig. 1 and Table 1). The result indicates that **15** with smaller LIS values has an (*S*)-configuration at C_{20} and its epimer (**16**) with larger LIS values an (*R*)-configuration.[13] This assignment not only confirms the tentatively assigned configurations for epoxides **6** and **7**, but also indicates that all

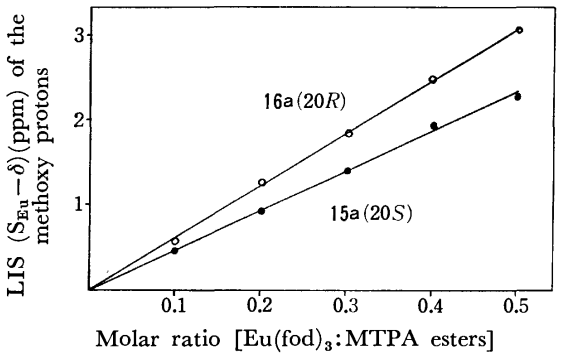


Fig. 1. LIS values of the methoxyprotons of MTPA esters **15a** and **16a**.

the other compounds (**8**—**17**) are represented correctly by the respective formulas. On the other hand, hydroboration of the relevant $\Delta^{5,12,17(20)}$-11-ketone (**3**) followed by oxidation resulted in hydration at the 17,20-double bond to give the (20*S*)-alcohol (**11**) as the only isolable product (25%) (**3** recovered, 48%). Since hydroboration usually proceeds in a *cis*-addition manner,[15] the present result leads to the conclusion that the 17,20-double bond in question in **3** and hence in related compounds (**1**, **1a**, and **3a**) should be assigned the (*E*)-configuration. It should be emphasized that the epoxidation and hydroboration of the 17,20-double bond take place preferentially at the β-side (axial approach), suggesting that the hydroxylation with osmium tetraoxide[7] would also lead to formation of (20*R*)-17α,20-glycol (equatorial attack).[16]

Experimental

All the melting points were uncorrected. The homogeneity of each compound was checked by TLC on silica gel (Wakogel B-5) with various solvent systems, the spots being developed with cerium(IV) sulfate in dil sulfuric acid and/or iodine. The optical rotations, ORD curves, UV, IR, and NMR (100 MHz) spectra were measured in chloroform, dioxane, methanol, chloroform, and chloroform-*d*, respectively. Abbreviations "s, d, q, qui, br, and do" in the NMR spectra denote "singlet, doublet, quartet, quintet, broad, and double," respectively.

The Witting Reaction of ***4***. A solution of dry dimethyl sulfoxide (DMSO, 2 ml) containing sodium hydride (157 mg) was heated at 72—80 °C (bath temp) for 20 min and then cooled. To the solution was added ethyltriphenylphosphonium bromide (1.07 g, 2.88 mmol) in dry DMSO (5 ml) and compound **4**[7] (240 mg, 0.71 mmol) in dry tetrahydrofuran (THF, 3 ml) at room temp under stirring. The mixture was stirred at room temp for 20 min and then at 50—56 °C for 15 h. After being cooled, the mixture was poured into ice-water (100 ml) and extracted with dichloromethane. The dichloromethane solution was washed with water, dried over sodium sulfate, and evaporated to leave an amorphous residue (300 mg), which was separated by chromatography over silica gel (Merck, 70—230 mesh, 26 g) with benzene and ether (3 : 1) to give 3β,17-dihydroxyetiojerva-5,12,14,16-tetraen-11-one 3-acetate[2b] (**5**, 120 mg), mp 245—247 °C (from ether) (lit,[2b] 245—247 °C): MS, *m/e* 280 (M^+-AcOH), 265, and 247; NMR, δ 1.22, 2.52, and 2.07 (each 3H, s, 19- and 18-C$\underline{H}_3$, and OCOC$\underline{H}_3$), 4.64 and 5.51 (each 1H, br W_H=22 and 10 Hz, 2$\underline{H}$ at C_3 and C_6), 5.84 (1H, s, O$\underline{H}$), 7.08 and 7.27 (each 1H, ABq J=8 Hz, 2$\underline{H}$ at C_{15} and C_{16}).

*(20S)-17,20-Epoxy-17α-ethyletiojerva-5,12-diene-3,11-dione 3-Ethylene Acetal (****6****) and Its 17,20-Epimer (****7****).* A solution of **3**[7] (14 g) in chloroform (680 ml) was mixed with *m*-chloroperbenzoic acid (9.7 g, 1.2 mol equiv) in chloroform (140 ml) under cooling with stirring, the whole solution being stirred for 20 min under cooling with ice. After addition of 5% aq sodium thiosulfate to decompose excess of the peracid, the chloroform solution was washed with 5% aq sodium hydrogencarbonate and water, dried and evaporated to leave a resinous material (16.5 g), which was separated by chromatography over silica gel (500 g). Eluates with benzene and ether (10 : 1) yielded **3** (2.3 g), mp 130—132 °C, (from diisopropyl ether). Eluates with benzene and ether (5 : 1) afforded a 5 : 1 (estimated by NMR) mixture of **6** and **7**, which on crystallization from diisopropyl ether gave **6** (3.8 g), mp 187—189 °C. The mother liquors were evaporated, crystallized on trituration with acetone to give **7** (340 mg), mp 160—162 °C (from acetone). **6**, $[\alpha]_D$ −154°; MS, *m/e* 370 (M^+); UV, λ_{max} 251 nm (ε 14000); IR, ν_{max} 1708 and 1625 cm^{-1}; NMR, δ 1.09 and 1.95 (each 3H, s, 19- and 18-C$\underline{H}_3$), 1.37 (3H, d J=6 Hz, 21-C$\underline{H}_3$), 3.35 (1H, q J=6 Hz, $\underline{H}$ at C_{20}), 3.97 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), and 5.40 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 74.63; H, 8.14%. Calcd for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16%. **7**, $[\alpha]_D$ −28°; MS, *m/e* 370 (M^+); UV, λ_{max} 261 nm (ε 11000); IR, ν_{max} 1707 and 1623 cm^{-1}; NMR, δ 1.08 and 1.93 (each 3H, s, 19- and 18-C$\underline{H}_3$), 1.36 (3H, d J=6 Hz, 21-C$\underline{H}_3$), 3.19 (1H, q J=6 Hz, $\underline{H}$ at C_{20}), 3.95 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), and 5.40 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 74.85; H, 8.20%. Calcd for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16%.

*(20S)-17-Ethyl-20-hydroxy-12α-etiojerva-5,13(17)-diene-3,11-dione 3-Ethylene Acetal (****8****), and Its 20-Epimer (****9****).* (i) To liquid ammonia (350 ml), distilled over sodium, containing lithium (880 mg) was added the afore-mentioned mixture (880 mg) of **6** and **7** in dry THF (20 ml), and the mixture was stirred at −70 °C for 15 min. After addition of ammonium chloride (8.8 g), the reaction mixture was stirred for 5 min and evaporated to leave an amorphous material, which was mixed with water (400 ml) and extracted with chloroform repeatedly. The chloroform solution was worked up as usual to give an amorphous residue (925 mg), which was purified by chromatography over silica gel (30 g). Eluates with benzene-ether (3 : 1) gave etiojerva-5,12-diene-3,11-dione 3-ethylene acetal (**18**, 70 mg), mp 177—179 °C (from diisopropyl ether); MS, *m/e* 328 (M^+); NMR, δ 1.08 and 2.15 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.96 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), and 5.42 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Eluates with benzene-ether (1 : 1) afforded **8** (365 mg), mp 152—154 °C (from diisopropyl ether) and then **9** (65 mg), mp 160—162 °C (from diisopropyl ether). **8**, $[\alpha]_D$ −8.5°; ORD, $[\Phi]_{340}^{peak}$ +11700°, $[\Phi]_{289}^{trough}$ −16500°, a=+282°; MS, *m/e* 372 (M^+) and 354; IR, ν_{max} 3630, 3370, and 1735 cm^{-1}; NMR, δ 1.00 and 1.78 (each 3H, s, 19- and 18-C$\underline{H}_3$), 1.21 (3H, d J=6 Hz, 21-C$\underline{H}_3$), 2.82 (1H, br W_H=10 Hz, $\underline{H}$ at C_{12}), 3.94 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 4.81 (1H, q J=6 Hz, $\underline{H}$ at C_{20}), and 5.38 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 73.99; H, 8.68%. Calcd for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66%. **9**, $[\alpha]_D$ +38°; ORD, $[\Phi]_{340}^{peak}$ +13000°, $[\Phi]_{289}^{trough}$ −17000°, a=+300°; IR, ν_{max} 3630, 3370, and 1735 cm^{-1}; NMR, δ 0.94 and 1.85 (each 3H, s, 19- and 18-C$\underline{H}_3$), 1.17 (3H, d J=6 Hz, 21-C$\underline{H}_3$), 2.83 (1H, br W_H=10 Hz, $\underline{H}$ at C_{12}), 3.95 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 4.87 (1H, q J=6 Hz, $\underline{H}$ at C_{20}), and 5.41 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 73.86; H, 8.42%. Calcd for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66%.

(ii) Compound **6** (300 mg) was reduced under the same Birch conditions as mentioned above to give **8** (125 mg) and **18** (30 mg). Likewise, the same treatment of **7** (300 mg) afforded **8** (113 mg) and **18** (20 mg).

*(20S)-17β-Ethyl-20-hydroxyetiojerva-5,12-diene-3,11-dione 3-Ethylene Acetal (****10****) and Its 17-Epimer (****11****).* A solution of **8** (185 mg) in methanol (48 ml) and water (18 ml), containing potassium carbonate (1.85 g), was stirred at room temp for 30 min under nitrogen. The solution was worked up as usual to give an amorphous residue (195 mg), showing four spots on TLC, which was separated in the order of decreasing R_f value into four fractions by preparative TLC over silica gel (Wakogel B-5F, 20×20 cm^2, 0.75 mm, 10 plates), with benzene and ether (1 : 1), a UV lamp being used as a detector. Compounds **3** (13 mg), mp 128—130 °C, (from acetone-diisopropyl ether), and **18** (11 mg), mp 178—180 °C (from diisopropyl ether), were obtained from the first two fractions. The third fraction (123 mg) was crystallized and recrystallized from diisopropyl ether to yield **10** (77 mg),

mp 185—187 °C; $[\alpha]_D$ −109°; MS, *m/e* 372 (M^+); UV, λ_{max} 258 nm (ε 10000); IR, ν_{max} 3626, 3406, 1706, and 1626 cm^{-1}; NMR, δ 1.10 and 2.27 (each 3H, s, 19- and 18-CH_3), 1.32 (3H, d J=6 Hz, 21-CH_3), 3.97 (4H, s, OCH_2CH_2O), 4.36 (1H, q J=6 Hz, H at C_{20}), and 5.40 (1H, br W_H=10 Hz, H at C_6). Found: C, 74.29; H, 8.51%. Calcd for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66%. The least mobile fraction (34 mg) was recrystallized from diisopropyl ether to give **11** (25 mg), mp 175—177 °C; $[\alpha]_D$ −130°; MS, *m/e* 372 (M^+); UV, λ_{max} 255 nm (ε 16000); IR, ν_{max} 3626, 3406, 1706, and 1626 cm^{-1}; NMR, δ 1.08 and 2,14 (each 3H, s, 19-, and 18-CH_3), 1.04 (3H, d J=6 Hz, 21-CH_3), 3.95 (4H, s, OCH_2CH_2O), 4.39 (1H, q J=6 Hz, H at C_{20}), and 5.38 (1H, br W_H=10 Hz, H at C_6). Found: C, 73.73; H, 8.71%. Calcd for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66%.

(20R)-17α-Ethyl-20-hydroxyetiojerva-5,12-diene-3,11-dione 3-Ethylene Acetal (12). Compound **9** (172 mg) was stirred with potassium carbonate (1.72 g) in methanol (45 ml) and water (35 ml) at room temp for 1.5 h under nitrogen. The solution was worked up as usual to leave an amorphous residue (185 mg), showing two main spots, which was separated into two fractions by preparative TLC over silica gel (10 plates) with benzene and ether (1 : 1). A more polar fraction (68 mg) gave a crystalline substance (68 mg), which was recrystallized from diisopropyl ether to yield **12** (50 mg), mp 148—150 °C; $[\alpha]_D$ −124°; MS, *m/e* 372 (M^+); UV, λ_{max} 255 nm (ε 14000); IR, ν_{max} 3626, 3445, 1705, and 1629 cm^{-1}; NMR, δ 1.10 and 2.24 (each 3H, s, 19- and 18-CH_3), 1.26 (3H, d J=6 Hz, 21-CH_3), 3.94 (4H, s, OCH_2CH_2O), 4.36 (1H, q J=6 Hz, H at C_{20}), and 5.40 (1H, br W_H=10 Hz, H at C_6). Found: C, 74.41; H, 8.60%. Calcd for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66%. A more mobile fraction was found to be a 1 : 1 (estimated by NMR) mixture of a new 17β-ethyl epimer and **9**, but was not further purified.

17β-Ethyletiojerva-5,12-diene-3,11,20-trione 3-Ethylene Acetal (13) and Its 17-Epimer (14). (i) To a stirred suspension of chromium (VI) oxide (33 mg) in dichloromethane (0.81 ml), distilled over phosphorus pentaoxide, and pyridine (0.051 ml), distilled over calcium hydride, was added a solution of **10** (20 mg) in dichloromethane (1 ml). The mixture was stirred at room temp for 15 min and filtered. The resulting ppt was washed with ether. The filtrate and ether washings were combined, washed with 5% aq sodium hydroxide and saturated aq sodium chloride, dried and evaporated to leave a crystalline substance (19 mg), which was recrystallized from diisopropyl ether to yield **13** (15 mg), mp 160—162 °C; $[\alpha]_D$ −198 °; ORD, $[\Phi]_{316}^{trough}$ −6100°, $[\Phi]_{284}^{peak}$ +16400°, a=−225°; MS, *m/e* 370 (M^+); UV, λ_{max} 254 nm (ε 13000); IR, ν_{max} 1714 and 1629 cm^{-1}; NMR, δ 1.10, 2.07, and 2.23 (each 3H, s, 19-, 18-, and 21-CH_3), 3.33 (1H, br W_H=11 Hz, H at C_{17}), and 3.94 (4H, s, OCH_2CH_2O).

(ii) Compound **11** (20 mg) was oxidized in the same way as above to give **14** (17 mg), mp 176—178 °C (from diisopropyl ether); $[\alpha]_D$ −12°; ORD, $[\Phi]_{312}^{peak}$ +14700°, $[\Phi]_{286}^{trough}$ −22300°, a=+370°; MS, *m/e* 370 (M^+); UV, λ_{max} 253 nm (ε 13000); IR, ν_{max} 1713 and 1629 cm^{-1}; NMR, δ 1.12, 2.14, and 2.19 (each 3H, s, 19-, 18-, and 21-CH_3), 3.35 (1H, br W_H=20 Hz, H at C_{17}), and 4.00 (4H, s, OCH_2CH_2O).

Hydride Reduction of 14 to 12. To a stirred solution of **14** (26 mg) in dry THF (6 ml) was added dropwise a suspension of lithium alminium tri-*t*-butoxide hydride (35 mg) in dry THF (5 ml) under cooling with ice. The mixture was stirred at room temp. for 23 h under nitrogen and filtered, after addition of aq ammonium sulfate. The filtrate was evaporated and shaken with water and chloroform. The chloroform extracts were washed with water, dried and evaporated to leave an amorphous residue (25 mg), showing two spots, which was separated into two fractions by preparative TLC over silica gel (one plate) with benzene and ether (1 : 1). While a less polar fraction (16 mg) gave **14**, mp 176—178 °C (from diisopropyl ether), a more polar fraction (8 mg) was crystallized and recrystallized from diisopropyl ether to yield **12** (4 mg), mp 148—150 °C, which was identical with the afore-mentioned sample (MS, IR, NMR, and TLC).

Dehydration of Alcohols 8, 9, 10, and 11. (i) A solution of **8** (20 mg) in pyridine (0.2 ml), distilled over potassium hydroxide, was stirred with tosyl chloride (*p*-TsCl, 25 mg) at room temp for 22 h. The mixture was worked up as usual to leave an amorphous material (18 mg), which was purified by preparative TLC over silica gel (one plate) with benzene and ether (5 : 1) to give **3** (9 mg), mp 130—132 °C.

The same treatment of **9** (20 mg) gave **3** (8 mg), mp 131—133 °C, and that of **10** (20 mg) afforded **3** (8 mg), mp 128—130 °C, and **10** (4 mg), mp 183—186 °C.

(ii) To a stirred and ice-cooled solution of **10** (20 mg) in benzene was added phosphoryl chloride (0.02 ml). The mixture was stirred at room temp. for 19 h, poured into ice-water, and extracted with chloroform. The extracts were washed with 5% aq sodium hydrogencarbonate and water, dried and evaporated to leave a tarry residue (19 mg), which was purified in the same manner as described above to yield **3** (4 mg), mp 130—132 °C, as a sole detectable product.

(iii) Compound **11** (15 mg) was treated with *p*-TsCl (18 mg) in pyridine (0.15 ml) at room temp for 22 h under stirring. The reaction mixture was worked up as usual to yield its tosylate (**11a**, 7 mg), mp 158—160 °C (from diisopropyl ether); $[\alpha]_D$ −102°; MS, *m/e* 354 ($M^+-CH_3C_6H_4SO_3H$); UV, λ_{max} 252 nm (ε 12000) and 228 (13,500); IR, ν_{max} 1708, 1630, 1352, 1170, 1095, 912, and 893 cm^{-1}; NMR, δ 1.05 and 2.03 (each 3H, s, 19- and 18-CH_3), 1.08 (3H, d J=6 Hz, 21-CH_3), 2.46 (3H, s, $CH_3C_6H_4SO_2$), 3.96 (4H, s, OCH_2CH_2O), 5.06 (1H, qui J=6 Hz, H at C_{20}), 5.38 (1H, br W_H=10 Hz, H at C_6), 7.34 and 7.81 (each 2H, ABq J=8 Hz, $CH_3C_6H_4SO_2$). The starting material (**11**; 3 mg), mp 176—178 °C, was recovered.

Compound **11a** (10 mg) was refluxed with 5% potassium hydroxide in methanol (2 ml) for 70 min under nitrogen. The solution was neutralized with 10% acetic acid, evaporated, mixed with water and extracted with chloroform. The chloroform extracts, after being worked up as usual, gave an amorphous residue (8 mg), which was purified by preparative TLC over silica gel (one plate) with benzene and ether (5 : 1) to give **3** (4 mg), mp 131—133 °C, as the sole isolable product.

(20S)-17α-Ethyl-20-hydroxy-12β-etiojerv-5-ene-3,11-dione 3-Ethylene Acetal (15), Its 20-Epimer (16), and Their MTPA Esters (15a and 16a). (i) To liquid ammonia (20 ml), cooled with dry ice-acetone, containing lithium (70 mg), was added **11** (50 mg) in dry THF (1 ml). The mixture was stirred at −78 °C (bath temp) for 30 min, and then worked up as described before to give an amorphous residue (57 mg), which was purified by chromatography over silica gel (5 g) with benzene-ether (1 : 1) to yield **15** (38 mg), mp 194—196 °C (from diisopropyl ether); $[\alpha]_D$ −106°; ORD, $[\Phi]_{334}^{trough}$ −7900°, $[\Phi]_{290}^{peak}$ +6600°, a=−145°; MS, *m/e* 374 (M^+); IR, ν_{max} 3630, 3444, and 1734 cm^{-1}; NMR, δ 1.04 (3H, s, 19-CH_3), 1.06 and 1.26 (each 3H, d J=4 and 6 Hz, 21- and 18-CH_3), 3.94 (4H, s, OCH_2CH_2O), 4.22 (1H, q J=6 Hz, H at C_{20}), and 5.40 (1H, br W_H=8 Hz, H at C_6).

(ii) Compound **12** (50 mg) was reduced under the same Birch conditions as described above to give **16** (34 mg), mp 182—184 °C (from diisopropyl ether); $[\alpha]_D$ −102°; ORD, $[\Phi]_{334}^{trough}$ −7900°, $[\Phi]_{290}^{peak}$ +6600°, a=−145°; MS, *m/e* 374 (M^+); IR, ν_{max} 3630, 3440, and 1734 cm^{-1}; NMR, δ 1.02

(3H, s, 19-C$\underline{H}_3$), 1.16 and 1.28 (each 3H, d J=6 Hz, 21- and 18-C$\underline{H}_3$), 3.91 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 4.18 (1H, q J=6 Hz, $\underline{H}$ at C_{20}), and 5.37 (1H, br W_H=8 Hz, $\underline{H}$ at C_6).

(iii) A solution of **15** (15 mg, 0.04 mmol) in dry pyridine (0.12 ml) and carbon tetrachloride (0.12 ml) was stirred with MTPA-Cl[14] (10.4 μl, 0.056 mmol) at room temp for 6 h.[13] After addition of *N,N*-dimethyl-1,3-propanediamine (9.6 μl), the mixture was allowed to stand for 5 min, diluted with ether, washed with dil hydrochloric acid, saturated aq sodium carbonate and saturated aq sodium chloride, dried and evaporated to leave an amorphous residue, which was passed through a small column packed with silica gel (Merck, 70—230 mesh, 2g) with benzene to yield its crude MTPA ester (22 mg). This was recrystallized from hexane to give **15a** (18 mg), mp 176—178 °C; $[\alpha]_D$ −67°; MS, *m/e* 590 (M^+); IR, ν_{max} 1740, 1170, 710, and 690 cm^{-1}; NMR, δ 1.05 (3H, s, 19-C$\underline{H}_3$), 1.21 (3H, d J=6 Hz, 21-C$\underline{H}_3$), 1.37 (3H, br W_H=6 Hz, 18-C$\underline{H}_3$), 3.56 (3H, s, OC$\underline{H}_3$), 3.96 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 5.38 (1H, br W_H=10 Hz, $\underline{H}$ at C_6), and 5.53 (1H, q J=6 Hz, $\underline{H}$ at C_{20}). Found: C, 67.36; H, 7.17%. Calcd for $C_{33}H_{41}O_6F_3$: C, 67.12; H, 6.95%.

Compound **16** (15 mg) was converted in the same manner as **15** into its MTPA ester (**16a**, 17 mg), mp 138—140 °C (from aq methanol); $[\alpha]_D$ −87°; MS, *m/e* 590 (M^+); IR, ν_{max} 1738, 1175, 710, and 694 cm^{-1}; NMR, δ 1.03 (3H, s, 19-C$\underline{H}_3$), 1.23 and 1.29 (each 3H, d J=6 Hz, 21- and 18-C$\underline{H}_3$), 3.45 (3H, s, OC$\underline{H}_3$), 3.94 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 5.36 (1H, br W_H=10 Hz, $\underline{H}$ at C_6), and 5.42 (1H, q J=6 Hz, $\underline{H}$ at C_{20}). Found: C, 67.38; H, 7.25%. Calcd for $C_{33}H_{41}O_6F_3$: C, 67.12; H, 6.95%.

17α-Ethyl-12β-etiojerv-5-ene-3,11,20-trione 3-Ethylene Acetal (17). To a stirred suspension of chromium(VI) oxide (17 mg) in dry dichloromethane (0.41 ml) and dry pyridine (0.026 ml) was added **15** (11 mg) in dry dichloromethane (0.1 ml). The mixture was stirred at room temp for 15 min and filtered, when ppts formed were washed with ether. The filtrate and ether washings were combined, washed with 5% aq sodium hydroxide and saturated aq sodium chloride, dried and evaporated to leave an amorphous residue, showing a single spot, which crystallized on trituration with diisopropyl ether and was recrystallized from the same solvent to yield **17** (10 mg), mp 184—186 °C; $[\alpha]_D$ −108°; ORD, $[\Phi]_{334}^{trough}$ −3000°, $[\Phi]_{302}^{peak}$ +5600°, a=−86°; MS, *m/e* 372 (M^+); IR, ν_{max} 1735 and 1713 cm^{-1}; NMR, δ 1.07 and 2.17 (each 3H, s, 19- and 21-C$\underline{H}_3$), 1.20 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 3.97 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), and 5.41 (1H, br W_H=10 Hz, $\underline{H}$ at C_6).

Compound **16** (14 mg) was oxidized in the same manner as described above to give **17** (13 mg), mp 183—185 °C.

Hydroboration of 3 Followed by Oxidation. To a stirred solution of **3** (2.0 g, 6 mmol) in THF (90 ml) was added diborane in THF (3.6 ml, 2.2 M) under cooling with ice. The solution was stirred at the temp for 50 min under nitrogen. After dropwise addition of water (14.4 ml) to decompose excess of the diborane, the reaction mixture was stirred with 1 M aq sodium hydroxide (43 ml) and 30% aq hydrogen peroxide (29 ml) at room temp for 1 h and then treated with 5% aq sodium thiosulfate (60 ml) under cooling to decompose excess hydrogen peroxide. The THF layer was separated and the aqueous layer was extracted with THF. All the THF solutions were combined, washed with water, dried and evaporated to leave a resinous material (2.4 g), which was separated by chromatography over silica gel (70 g). Eluates with benzene and ether (5 : 1) afforded the starting compound (**3**, 950 mg), mp 130—132 °C. Eluates with benzene and ether (1 : 1) gave a crystalline substance (0.5 g), which on recrystallization from diisopropyl ether afforded **11** (0.44 g), mp 174—176 °C, identical with a sample obtained from **8** (TLC, IR, and NMR).

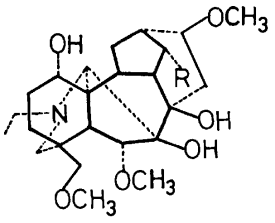
Some Derivatives of Anhydrodiacetyldelcosine (Anhydrodiacetyllucaconine)*[1,2]

Takashi AMIYA, Yoshio KANAIWA, Naomi NAKANO, and Takeo SHIMA**
Hokkaido Institute of Pharmaceutial Sciences, Otaru 047

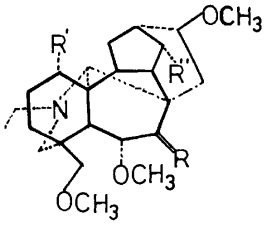
(Received May 31, 1977)

On the basis of the structure of delcosine (lucaconine), a diterpene alkaloid, the structures of anhydrodiacetyldelcosine and dihydroanhydrodiacetyldelcosine have previously been established. Some reactions of these compounds and their derivatives are described, and the reaction products are shown.

Delcosine (lucaconine) (**1**) ($C_{24}H_{39}O_7N$)[2] is an alkaloid isolated from species of Aconitum and Delphinium.[3] The structure of anhydrodiacetyldelcosine (anhydrodiacetyllucaconine) (**2**) ($C_{28}H_{41}O_8N$) has previously been proposed on the basis of the reactions as it undergoes[3] and the structure of delcosine.[4] The treatment of Compound **1** with acetyl chloride gave Compound **2** by the esterification of the two secondary hydroxyl groups, followed by the loss of one molecule of water between the two vicinal tertiary hydroxyl groups.

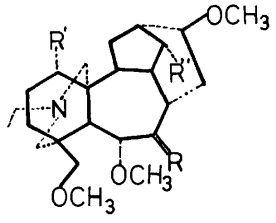


1 R=OH
7 R=H



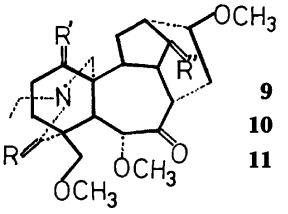
2 R=O R′=R″=OAc
4 R=OH, H R′=R″=OH

Compound **2** absorbs one molecule of hydrogen, giving dihydroanhydrodiacetyldelcosine (anhydrodihydrodiacetyllucaconine) (**3**) ($C_{28}H_{43}O_8N$). The structure and the mechanism of formation of **3** have previously been reported.[3,4]



3 R=O, R′=R″=OAc
5 R=O, R′=R″=OH
6 R=OAc, H, R′=R″=OAc
8 R=O, R′=OAc, R″=H

The present paper will deal mainly with some derivatives of Compounds **2** and **3**. The reduction of Compound **2** with lithium aluminium hydride yielded anhydrodelcosinol (anhydrolucaconinol) (**4**) ($C_{24}H_{39}O_6N$). Although the infrared spectrum of Compound **2** showed bands at 1733 and 1721cm^{-1} characteristic of an ester and carbonyl function respectively, Compound **4** showed no carbonyl band. This shows that the carbonyl group in Compound **2** was reduced in Compound **4**. The hydrolysis of Compound **3** gave dihydroanhydrodelcosine (anhydrodihydrolucaconine) (**5**) ($C_{24}H_{39}O_6N$), which showed a band due to a seven-membered cyclic ketone at 1689 cm^{-1} in the infrared spectrum. The reduction of Compound **5** by lithium aluminium hydride, followed by acetylation with acetic anhydride in pyridine, gave dihydroanhydrotriacetyldelcosinol (anhydrodihydrotriacetyllucaconinol) (**6**) ($C_{30}H_{47}O_9N$). This compound showed no carbonyl band near 1689 cm^{-1}, but did show bands due to ester functions in the infrared spectrum. These observations support the reduction of the carbonyl group in Compound **5**. The treatment of deoxy-14-dehydrodelcosine (deoxylucaconinone-I) (**7**) ($C_{24}H_{39}O_6N$)[5] with acetyl chloride, followed by hydrogenation over platinum in acetic acid, gave 1-monoacetyldihydroanhydrodeoxy-14-dehydrodelcosine (anhydrodihydromonoacetyldeoxylucaconine-I) (**8**) ($C_{26}H_{41}O_6N$). Compound **8** showed a seven-membered cyclic carbonyl band at 1686 cm^{-1} and a band due to an ester function at 1730 cm^{-1}. These observations suggest that Compound **8** resulted from **7** by an initial dehydration of **7** to give a cyclic ketone, which was subsequently hydrogenated, just as Compound **3** resulted from Compound **1** *via* **2** in analogous reactions.[3] The oxidation of Compound **3** with the chromium trioxide–pyridine complex, followed by hydrolysis, yielded dihydroanhydrooxodelcosine (**9**) ($C_{24}H_{37}O_7N$).



9 R=O, R′=R″=α-OH,H
10 R=R′=R″=O
11 R=H_2, R′=α-OH,H, R″=O

Compound **9** is a monoketo lactam and showed absorption bands at 1689 and 1621 cm^{-1} characteristic of a seven-membered ring ketone and of a lactam respectively. Its ultraviolet absorption spectrum showed a maximum (λ_{max} 307 nm, log ε 1.94) due to a carbonyl group. The oxidation of Compound **5** with the chromium trioxide–pyridine complex gave a neutral product, dihydroanhydro-1,14-didehydrooxodelcosine (**10**) ($C_{24}H_{33}O_7N$), and a base, dihydroanhydro-14-dehydrodelcosine (**11**) ($C_{24}H_{37}O_6N$). Compound **10** is a triketo lactam and showed absorption bands at 1754, 1712, 1681, and 1647 cm^{-1} characteristic of a five-membered ring ketone, a six-membered ring ketone, a seven-membered ring ketone, and a lactam respectively. Its ultraviolet absorption spectrum showed a maximum (λ_{max} 300 nm, log ε 2.11) due to carbonyl groups. Compound **11** is a diketo base.

* A part of this study was carried out in the Department of Chemistry, Faculty of Science, Hokkaido University.

** Central Research Institute, Teijin, Limited, Asahigaoka, Hino-shi, Tokyo 191.

It showed bands at 1751 and 1686 cm^{-1} in the infrared absorption spectrum due to the presence of a five-membered ring ketone and a seven-membered ring ketone respectively.

Experimental

Anhydrodelcosinol (Anhydrolucaconinol) (4). Anhydrodiacetyldelcosine(**2**) (0.5 g) was dissolved in dioxane (10 ml). Lithium aluminium hydride (0.2 g) dissolved in 10 ml ether was then added, and the temperature was raised until the ether evaporated. The mixture was thereafter refluxed for 30 min. Upon cooling, the excess reagent was destroyed by the addition of water, and the aluminium hydroxide formed was removed; the solution was then evaporated *in vacuo*. After the addition of 1 ml of aqueous 10% sodium hydroxide, the residue was extracted with chloroform. The evaporation of the chloroform left a residue (30 mg). The aluminium hydroxide was dissolved in 20 ml of a 10% sodium hydroxide solution and extracted with chloroform five times. A residue (200 mg) was obtained upon the removal of the chloroform. These residues were combined and neutralized with about 5% perchloric acid, and the mixture was allowed to stand to crystallize anhydrodelcosinol perchlorate. The recrystallization of the salt from water gave crystals (150 mg); mp 230 °C. This salt (150 mg) was dissolved in 1 ml of 10% aqueous sodium hydroxide and extracted with chloroform. The removal of the chloroform gave a residue was crystallized from ether. Recrystallization from ethanol gave crystals; mp 185—190 °C. Yield, 0.1 g. The ultraviolet absorption spectrum of this compound in methanol showed an end-absorption and no maximum. The infrared absorption spectrum (in Nujol) showed a hydroxyl absorption (3472 cm^{-1}), but did not show any bands attributable to the presence of an ester or carbonyl group near 1700 cm^{-1}.

Found: C, 66.22; H, 8.47; OCH_3, 20.31%. Calcd for $C_{24}H_{39}O_6N$: C, 65.87; H, 8.98; OCH_3, 21.27%.

Dihydroanhydrodelcosine (Anhydrodihydrolucaconine) (5). Dihydroanhydrodiacetyldelcosine (**3**) (1.5 g) was hydrolyzed under a stream of nitrogen for 1 h by boiling it in methanolic potassium hydroxide. Upon the removal of the methanol, a residue was obtained. Water was added to the residue, and it was extracted with chloroform three times. The residue obtained after the evaporation of the chloroform was crystallized from ethanol. Recrystallization from ethanol afforded crystals; mp 205—210 °C; $[\alpha]_D$ +43.4° (chloroform); pK_a 7.0. The ultraviolet absorption spectrum of this compound in methanol showed an end-absorption and no maximum. The infrared absorption spectrum (in Nujol) showed the presence of hydroxyl groups (3484, 3425, 3356 cm^{-1}) and a carbonyl group (1689 cm^{-1}).

Found: C, 65.98; H, 9.11%. Calcd for $C_{24}H_{39}O_6N$: C, 65.87; H, 8.98%.

Dihydroanhydrotriacetyldelcosinol (Anhydrodihydrotriacetyllucaccninol) (6). A solution of dihydroanhydrodelcosine (**5**) (0.3 g) and lithium aluminium hydride (0.2 g) in tetrahydrofuran was refluxed for 1.5 h. The reaction mixture was allowed to stand overnight, after which the excess reagent was decomposed by the addition of water; after the removal of the aluminium hydroxide formed, the solution was extracted with chloroform. The removal of the chloroform afforded a residue (0.2 g) which was subsequently dissolved in a mixture of acetic anhydride (1 ml) and pyridine (1 ml). The solution was allowed to stand in a sealed tube at room temperature for 3 days. The reaction mixture was poured into 100 ml of water to precipitate the product. Recrystallization from ethanol gave crystals; mp 130—133 °C. Yield, 40 mg. The infrared absorption spectrum (in Nujol) showed the presence of ester groups (1739 and 1727 cm^{-1}).

Found: C, 64.19; H, 8.62; OCH_3, 19.66; $COCH_3$, 20.18%. Calcd for $C_{30}H_{47}O_9N$: C, 63.69; H, 8.38; OCH_3, 16.46;[6] $COCH_3$, 22.83%.

1-Monoacetyldihydroanhydrodeoxy-14-dehydrodelcosine (Anhydrodihydromonoacetyldeoxylucaconine-I) (8). A mixture of 50 mg of deoxy-14-dehydrodelcosine (**7**) and 1 ml of acetyl chloride was allowed to stand in a sealed tube at room temperature for a week. After the removal of the excess acetyl chloride, the residue was treated with water (3 ml) and then with aqueous ammonia to give a precipitate (40 mg). This precipitate was dissolved in 5 ml of glacical acetic acid and hydrogenated with 20 mg of platinum oxide for 1h. After the subsequent removal of the platinum, the solution was evaporated to dryness *in vacuo*. The treatment of the residue with water and then with aqueous ammonia gave a precipitate. Recrystallization from ethanol gave crystals; mp 84—90 °C. Yield, 20 mg. The infrared absorption spectrum (in Nujol) showed the presence of a carbonyl group (1686 cm^{-1}) and an ester function (1730 cm^{-1}).

Found: C, 67.41; H, 9.26; OCH_3, 21.58; $COCH_3$, 10.63%. Calcd for $C_{26}H_{41}O_6N$: C, 67.36; H, 8.91; OCH_3, 20.08; $COCH_3$, 9.28%.

Dihydroanhydrooxodelcosine (9). A mixture of dihydroanhydrodiacetyldelcosine (**3**) (0.5 g) and chromium trioxide (0.5 g) in pyridine (10 ml) that had been allowed to stand overnight at room temperature was evaporated to dryness *in vacuo*. Water (20 ml) was then added to the residue, and the mixture was reduced with sulfur dioxide to remove the excess reagent. The acid solution thus obtained was extracted with chloroform. The evaporation of the chloroform extract gave a residue (0.3 g) which was then hydrolyzed with boiling ethanolic potassium hydroxide for 1 h. After cooling, the solution was evaporated and the residue was extracted with chloroform following the addition of water (10 ml). After the evaporation of the solvent, the residue was crystallized from acetone. The product was recrystallized twice from ethanol to give crystals; 0.2 g; mp 290 °C. The ultraviolet absorption spectrum of this compound in methanol showed λ_{min} 280 nm, log ε 1.71 and λ_{max} 307 nm, log ε 1.94. The infrared absorption spectrum (in Nujol) showed the presence of hydroxyl groups (3497, 3448 cm^{-1}), a carbonyl group (1890 cm^{-1}), and a lactam group (1621 cm^{-1}).

Found: C, 63.23; H, 8.22; N, 2.97; OCH_3, 18.99; (N)-C_2H_5, 4.70%. Calcd for $C_{24}H_{37}O_7N$: C, 63.83; H, 8.26; N, 3.10; OCH_3, 20.62; (N)-C_2H_5, 6.44%.

Dihydroanhydro-1,14-didehydrooxodelcosine (10). A mixture of dihydroanhydrodelcosine (**5**) (0.5 g) and chromium trioxide (1 g) in pyridine (20 ml) that had been allowed to stand overnight at room temperature was evaporated to dryness *in vacuo*. After the addition of water (20 ml), the residue was treated with sulfur dioxide to reduce the excess reagent. The resulting acid solution was extracted with chloroform. A residue (0.3 g) was obtained upon the evaporation of the chloroform. The further oxidation of the residue with the same reagent (0.3 g of chromium trioxide and 6 ml of pyridine), followed by the subsequent treatment mentioned above, gave 0.2 g of a residue. It was dissolved in chloroform (2 ml) and placed in an alumina column (2 g). The column was eluted with chloroform, and then with chloroform containing 1% methanol. From the chloroform eluate, a residue (0.1 g) was obtained. It was crystallized from ethanol. Repeated recrystallizations from ethanol gave a product which melted at 204—207 °C. The ultraviolet absorption spectrum of this compound in methanol

showed λ_{min} 260 nm, log ε 1.75 and λ_{max} 300 nm, log ε 2.11. The infrared absorption spectrum (in Nujol) showed the presence of carbonyl groups (1754, 1712, 1681 cm^{-1}) and a lactam group (1647 cm^{-1}).

Found: C, 64.79; H, 7.91; N, 3.15; OCH_3, 20.15%. Calcd for $C_{24}H_{33}O_7N$: C, 64.41; H, 7.43; N, 3.13; OCH_3, 20.80%.

*Dihydroanhydro-14-dehydrodelcosine (**11**).* The acid solution obtained after the chloroform extraction of Compound **10** in the oxidation of Compound **5** was made alkaline by aqueous ammonia. The chromic hydroxide formed was removed by filtration, and the filtrate was extracted with chloroform. The evaporation of the chloroform gave a residue which was dissolved in chloroform (4 ml) and placed in an alumina column (1.5 g). The column was eluted with chloroform (15 ml), and then with chloroform containing 1% of methanol (30 ml). From the chloroform-methanol eluate a residue was obtained. It was crystallized from acetone. Further recrystallization from ethanol gave crystals which melted at 155 °C. The ultraviolet absorption spectrum of this compound in methanol showed an end-absorption and no maximum. The infrared absorption spectrum (in Nujol) showed the presence of a hydroxyl group (3448 cm^{-1}) and carbonyl groups (1751 and 1686 cm^{-1}).

Found: C, 66.30; H, 8.39; N, 3.08; OCH_3, 20.62%. Calcd for $C_{24}H_{37}O_6N$: C, 66.18; H, 8.56; N, 3.22; OCH_3, 21.38%.

Synthesis Using Pyridinium *N*-Ylides. I. Synthesis and Some Reactions of Substituted 1-(Acetylimino)pyridinium Ylides

Akikazu KAKEHI, Suketaka ITO, Yoshiaki KONNO, and Toshiaki MAEDA

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received June 2, 1977)

Pyridinium *N*-imines reacted smoothly with diethyl malonate and ethyl cyanoacetate in ethanol at room temperature to give the corresponding 1-(ethoxycarbonylacetylimino)- and 1-(cyanoacetylimino)pyridinium ylides in 59—87% yields. These ylides were converted to 1-(acetylimino)pyridinium ylide derivatives by the treatment with acetic anhydride. The alkaline treatment of the pyridinium salts which were prepared by the alkylation of the *N*-ylides with alkyl halides, gave the corresponding 3-ethoxycarbonyl- and 3-cyano-1,2-dihydropyrazolo-[1,5-*a*]pyridin-2-one derivatives in 8—51% yields.

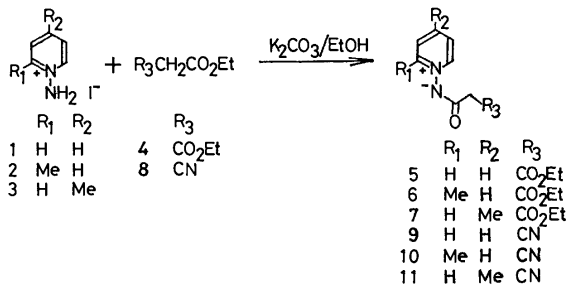
In connection with our work in the chemistry of pyridinium *N*-ylides, we became especially interested in the reactions of pyridinium *N*-imines and *N*-methylides with various unsaturated bonds substituted with a leaving group.[1-4] Recently, we found that a certain ester group reacted smoothly with pyridinium *N*-imines to give the corresponding 1-(acetylimino)pyridinium ylides. Since the use of ester compounds such as diethyl malonate and ethyl cyanoacetate in this reaction can lead to the formation of pyridinium *N*-ylides bearing an active methylene group in the substituent at 1-position, we examined the possibility of a new intramolecular coupling reaction between the cationic center of the pyridinium moiety and the anionic center generated at the methylene group.

Kato and Masuda reported recently the preparation of 1-(acetoacetylimino)pyridinium ylide and its conversion to 1,2-dihydropyrazolo[1,5-*a*]pyridin-2-one.[5] In the pyrazolone formation step, a similar coupling reaction of the cationic center with the carbanion was proposed. In this paper we wish to report the new preparations of some 1-(ethoxycarbonylacetylimino)- and 1-(cyanoacetylimino)pyridinium ylides and their reactions which lead to 1-(acetylimino)pyridinium ylide and 1-alkyl-1,2-dihydropyrazolo[1,5-*a*]pyridin-2-one derivatives.

Results and Discussion

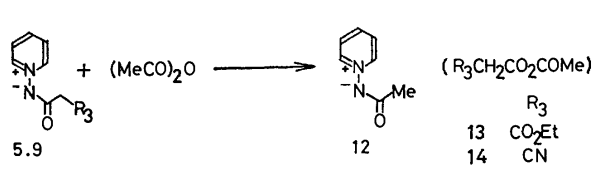
*Preparation of 1-(Ethoxycarbonylacetylimino)- **5**—**7** and 1-(Cyanoacetylimino)pyridinium Ylides **9**—**11**.* Syntheses of pyridinium *N*-ylides possessing an active methylene group were achieved by using nucleophilic reactions of pyridinium *N*-imines onto the ester carbonyl carbon of sufficiently active methylene compounds. When 1-aminopyridinium iodides **1**—**3** were treated with diethyl malonate **4** or ethyl cyanoacetate **8** in ethanol in the presence of potassium carbonate at room temperature for 3 days, the expected 1-(ethoxycarbonylacetylimino)-**5**—**7** or 1-(cyanoacetylimino)pyridinium ylides **9**—**11** were obtained in 59—87% yilds (Scheme 1). These *N*-ylides were very stable, colorless hygroscopic substances which solidified gradually on standing, and were not decomposedeven at the refluxing temperature of xylene.

Structural assignments of *N*-ylides **5**—**7** and **9**—**11** were generally accomplished by comparison of their spectra with those of other 1-(acylimino)pyridinium ylides.[6-9] In particular, the IR spectra exhibited a widely shifted absorption band of the carbonyl group conjugated with the imino nitrogen (near 1600 cm^{-1}), and the NMR chemical shifts and their signal patterns due to protons except the methylene protons (δ=3.3—3.5, singlet) are quite similar to those of 1-(ethoxycarbonylimino)-[6-8] and 1-(acetylimino)pyridinium ylides[9] which have already been reported.



Scheme 1.

Reactions of N-*Ylides **5** and **9** with Acetic Anhydride.* In order to examine the reactivity of the active methylene group of the *N*-ylides prepared above, the reaction with acetic anhydride was first carried out. When *N*-ylide **5** was heated with a large excess of acetic anhydride at ca. 80 °C for 3 h, 1-(acetylimino)pyridinium ylide **12** was obtained in 96% yield as the only isolated product. Similarly, the same *N*-ylide **12** was formed in 65% yield by the reaction of *N*-ylide **9** with acetic anhydride under the same conditions. However, the attempted isolation of the anhydride derivatives **13** and **14** which might be formed in these reactions was unsuccessful. These results are shown in Scheme 2. The structure of *N*-ylide **12** was determined by comparison with the authentic specimen described by Okamoto *et al.*[10]



Scheme 2.

*Alkaline Treatment of Pyridinium Salts **15**—**23** and **33**—**41**.* Since the proceeding of transacylation in the above reactions might suggest that the generation of carbanion at the methylene group is unfavorable, we next attempted the formation of a carbanion

by the alkaline treatments of the corresponding 1-(*N*-alkylated imino)pyridinium salts. When pyridinium salts **15**—**23**, readily obtainable from the reactions of *N*-ylides **5**—**7** with methyl iodide, allyl bromide, and benzyl bromide, were treated with excess potassium carbonate in ethanol at room temperature, crystalline products **24**—**32** were formed in 16—51% yields (calculated from *N*-ylide). Similarly, the salts **33**—**41** obtained from *N*-ylides **9**—**11** and the same alkylating agents gave the corresponding products **42**—**45** and **47**—**51** in 8—40% yields. Furthermore, the reaction of the salt **36** also gave the colorless crystalline product **46** in only 4% yield, together with the compound **45** (21%). In the cases of the reactions of pyridinium salts **16**, **19**, **22**, **34**, **37**, and **40** which have a methyl group at 2-position, the yields of products **25**, **28**, **31**, **43**, **47**, and **50** always diminished. These results are shown in Schemes 3 and 4.

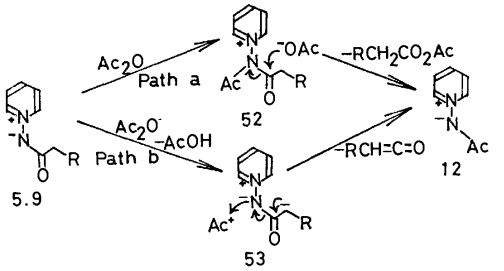
Scheme 4.

These products **24**—**32**, **42**—**45**, and **47**—**51** are colorless or pale yellow crystals which are well characterized by their strong fluorescences, their high melting points, and their comparatively low solubilities in common organic solvents. Each IR spectrum showed a characteristic absorption band at 1621—1676 cm^{-1} due to an amide carbonyl group and at 1694—1729 cm^{-1} due to an ester carbonyl group (**24**—**32**) or at 2215—2225 cm^{-1} due to a cyano group (**42**—**45** and **47**—**51**). The NMR spectrum of compound **24**, for example, showed signals at $\delta=6.89$ (1H, br t, $J=7.5$, 7.0 and 2.0 Hz), 7.45 (1H, br t, $J=9.0$, 7.5 and 1.0 Hz), 7.93 (1H, dd, $J=7.0$ and 1.0 Hz), and 8.08 (1H, dd, $J=9.0$ and 2.0 Hz) due to the protons on the pyridine ring and at $\delta=3.65$ (3H, s) due to the methyl protons, together with proton signals at $\delta=1.37$ (3H, t, $J=7.0$ Hz) and 4.33 (2H, q, $J=7.0$ Hz) attributable to the ethoxycarbonyl group (see Table 4). The chemical shifts of the protons of the pyridine ring are intermediate between those in 1-(vinylimino)pyridinium ylides[11] and those in 3,3a-dihydropyrazolo[1,5-*a*]pyridines[11] and are rather similar to those in 1-alkyl-2-allylidene-1,2-dihydropyridines.[12,13] The methyl signals appeared at $\delta=3.65$ indicated that this methyl group is a substituent on a nitrogen atom rather than an oxygen atom. The other chemical shifts of the *N'*-alkyl group derived from alkylating agents were, of course, in good accord with those of known *N*-alkylated compounds,[12-14] and this fact excluded the possibility of the *O*-alkylated compounds, that is, 2-alkoxypyrazolo[1,5-*a*]pyridines, for these products: **24**—**32**, **45**, **47**, **48**, **50**, and **51**. From the above spectral data and an analogous reaction given by Kato and Masuda,[5] these products were assigned to be 1-alkyl-3-ethoxycarbonyl- **24**—**32** and 1-alkyl-3-cyano-1,2-dihydropyrazolo[1,5-*a*]pyridin-2-one derivatives **42**—**45** and **47**—**51**.

On the other hand, the structure of compound **46** was determined to be a 1 : 1 adduct of 1-allyl-3-cyano-1,2-dihydropyrazolopyridine **45** and ethanol by its microanalysis and its NMR spectral inspection. Furthermore, the IR spectrum exhibited absorption bands at 1668 and 3340 cm^{-1} due to an amide carbonyl and a secondary amino group, respectively, but no cyano absorption band was observed. These results suggested clearly that compound **46** is 1-allyl-3-ethoxycarbonimidoyl-1,2-dihydropyrazolo[1,5-*a*]pyridin-2-one.

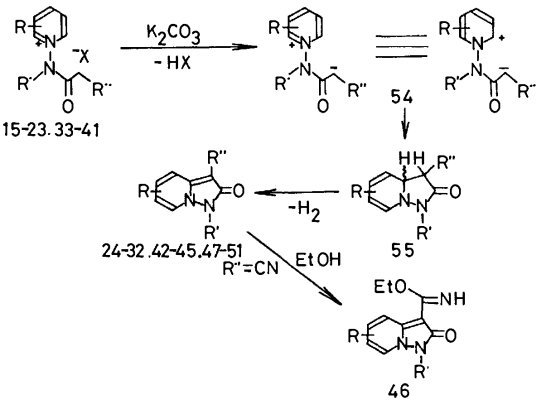
Mechanism. The transacylations of *N*-ylides **5** and **9** with acetic anhydride may proceed via the formation of *N'*-acetylated intermediate **52**, followed by its decomposition to 1-(acetylimino)pyridinium ylide **12** and anhydride **13** or **14** (Path a). An alternate route (Path b) in which the formation of dehydrogenated compound **53** followed by its decomposition to *N*-ylide **12** and ketene takes place is negligible because the collapse of the intermediate such as **53** should lead to the formation of 2-hydoxypyrazolo[1,5-*a*]pyridine derivative rather than *N*-ylide, as suggested in the alkaline treatment[5] of 1-(acetoacetylimino)pyridinium ylide (Scheme 5).



Scheme 5.

On the other hand, the formation of 1,2-dihydropyrazolo[1,5-*a*]pyridin-2-ones **24**—**32**, **42**—**45**, and **47**—**51** seems to proceed via the intramolecular coupling reaction of intermediate **54** formed initially by dehydro-

halogenation of 1-(*N*-alkylated imino)pyridinium salts **15**—**23** and **33**—**41**, followed by the oxidation of the resulting 1,2,3,3a-tetrahydropyrazolopyridine **55** (Scheme 6). This mechanism is the same as that proposed for the alkaline treatment of 1-[*N*-(acetoacetyl)methylamino]pyridinium iodide by Kato and Masuda.[5] Furthermore, imidate **46** must be formed by a base-catalyzed addition of ethanol on the 3-cyano group in 1-allyl-3-cyano-1,2-dihydropyrazolo[1,5-*a*]pyridin-2-one **45**, since the reaction of compound **45** with ethanol did not give the imidate **46** in the absence of alkali even under more drastic conditions, but gave it in the presence of alkali. Similar additions[15] of alcohol to a cyano group have been found often.



Scheme 6.

Experimental

Melting points were measured with a Yanagimoto micro-melting point apparatus and are uncorrected. Microanalyses were carried out on a Perkin-Elmer 240 Elemental Analyzer. The NMR spectra were determined with a JEOL JNM-100 spectrometer in deuteriochloroform with tetramethylsilane as an internal standard, The chemical shifts are expressed in δ values. The IR spectra were taken with a JASCO DS-301 spectrophotometer.

Preparations of Pyridinium N-*Ylides* ***5***—***7*** *and* ***9***—***11***. *General Method*: A solution of 1-aminopyridinium iodide (3 mmol) and diethyl malonate (4 g, 25 mmol) or ethyl cyanoacetate (4 g, 35 mmol) in 50 ml of ethanol was stirred with potassium carbonate (5 g) at room temperature for 3 days. The reaction mixture was then filtered to remove insoluble inorganic substances and the filtrate was concentrated under reduced pressure. The residue was separated by column chromatography (alumina) using ether and then chloroform as eluents. The pyridinium *N*-ylides **5**—**7** and **9**—**11** thus obtained are colorless substances which solidified gradually on standing. Except for *N*-ylide **11**, recrystallizations of the other *N*-ylides, **5**—**7**, **9**, and **10**, were unsuccessful because of their high hygroscopic properties. Some physical and spectral data of *N*-ylides **5**—**7** and **9**—**11** are summarized in Tables 1 and 2.

Reactions of N-*Ylides* ***5*** *and* ***9*** *with Acetic Anhydride*. A solution of *N*-ylide **5** (208 mg, 1 mmol) in 10 ml of acetic anhydride was heated at *ca.* 80 °C in a water bath for 3 h, and then the reaction mixture was concentrated under reduced pressure. The usual work-up of the residual oil gave 1-(acetylimino)pyridinium ylide **12** (130 mg, 96%) as colorless hygroscopic needless, mp (its picrate) 169—170 °C (lit,[10] 168 °C). The same *N*-ylide **12** was also obtained in 65% yield from the reaction of *N*-ylide **9** and acetic anhydride. However, our attempts to isolate the anhydride **13** or **14** were unsuccessful.

Alkaline Treatments of Pyridinium Salts ***15***—***23*** *and* ***33***—***41***. *General Method*: Pyridinium *N*-ylide (2 mmol) was treated with an alkylating agent (5 ml) without solvent at room temperature for 3—7 days, and then the reaction mixture was concentrated to remove the excess alkylating agent under reduced pressure. The ethanolic solution (50 ml) of the crude pyridinium salt was stirred with potassium carbonate (5 g) at room temperature for 3—5 days. The reaction mixture was filtered and the filtrate was concentrated under reduced pressure. The usual separations of the residues using column chromatography (alumina) gave the corresponding 1-alkyl-3-

The Enantioface-differentiating (Asymmetric) Hydrogenation of the C=O Double Bond with Modified Raney Nickel. XXX. The Temperature Dependency of the Optical Yield

Hiroshi OZAKI

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Suita, Osaka 565

(Received June 4, 1977)

The effect of the reaction temperature upon the optical yield was studied in the liquid-phase enantioface-differentiating hydrogenation of methyl acetoacetate with various modified Raney nickel catalysts (MRNi) under an atmospheric pressure of hydrogen. The results obtained are as follows: 1) the enantiomer produced in excess in the reactions with (*S*)-alanine-, (*S*)-2-aminobutyric acid-, and (*S*)-valine-MRNi, changed from (*S*)-(+) to (*R*)-(−) with the elevation in the reaction temperature (The temperature, T_0, at which the direction of the differentiation changed decreased in the order of alanine-, 2-aminobutyric acid-, and valine-MRNi. The origin of T_0 is expected to be steric and polar effects that act in opposite directions for the differentiation of the enantioface.), and 2) the temperature dependence of the optical yield with (*R*,*R*)-tartaric acid- and (*S*)-lactic acid-MRNi differed from that with other catalysts. The OH group of the modifying reagent is expected to play an important role in enantioface-differentiation by making a hydrogen bond with the substrate.

The Raney nickel catalyst modified with an optically active substance (MRNi) is an intensively studied catalyst for the enantioface-differentiating hydrogenation of the β-keto ester. In a preceeding communication, it has been reported that the interaction of a substrate with a modifying reagent on the catalyst surface was the essential step in the enantioface-differentiation.[1)]

To gain an insight into the origin of the inter-molecular forces participating the enantioface-differentiating process, the effect of reaction temperatures on the optical yield was investigated.

Results and Discussion

The enantioface-differentiating hydrogenation of methyl acetoacetate (MAA) to methyl 3-hydroxybutyrate (MHB) over various MRNi was carried out. As is shown in Fig. 1, each modifying reagent had a characteristic temperature, T_0, at which an optical yield of zero was observed.

The temperature dependence of the ratio of enantiomers produced (C_R/C_S) has generally been discussed based on the following relation:

$$\ln (C_R/C_S) = \Delta\Delta S^*/R - \Delta\Delta H^*/RT.$$

The existence of T_0 may be explained by the contribution of the $\Delta\Delta S^*$ term. If the enantioface-differentiation of MRNi were expressed by the above equation, the linear relationship of $\ln(C_R/C_S)$ toward $1/T$ should be expected. However, none of our results gave a linear relationship between $\ln(C_R/C_S)$ and $1/T$, as is shown in Fig. 2. This fact indicates that it is difficult to explain the result by a simple energetic correlation.

As for the (*S*)-monoamino monocarboxylic acid-MRNi in Fig. 1, the optical yields increase in the direction of an excess of (*R*)-(−)-enantiomer as the reaction temperatures increase. The temperatures, T_0, for valine-, 2-aminobutyric acid-, and alanine-MRNi were at 30—40 °C, 40—50 °C, and 50—60 °C respectively.

Figure 3 shows the temperature dependence of the optical yield in the enantioface-differentiating hydrogenation of methyl acetoacetate and butyl acetoacetate

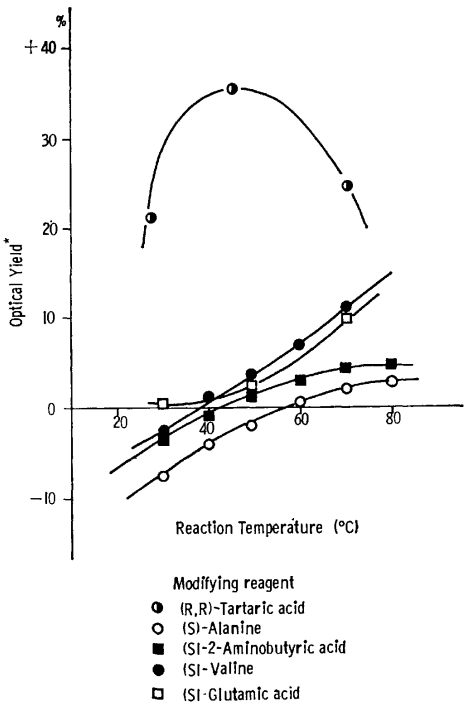

Fig. 1. Effect of modifying reagent on the temperature dependence of optical yield.
*The sign of optical yield is taken as + in the case of an excess of (*R*)-(−)-enantiomer.

with (*S*)-valine-MRNi. T_0 also varies in accordance with the ester moiety of the substrate, and T_0 for methyl acetoacetate is higher than that for butyl acetoacetate. These results show that the temperature, T_0, becomes higher as the chain length of both the alkyl substituent of the modifying reagent and the ester moiety of the substrate decrease.

As the main difference in alkyl substituents is their bulkiness, the above facts may indicate that the steric interaction between a modifying reagent and a substrate is one of the factors in enantioface-differentiation.

As is shown in Fig. 1, the dependence of the optical yield on the reaction temperature for (*R*,*R*)-tartaric acid-MRNi is different from that for amino acid-MRNi.

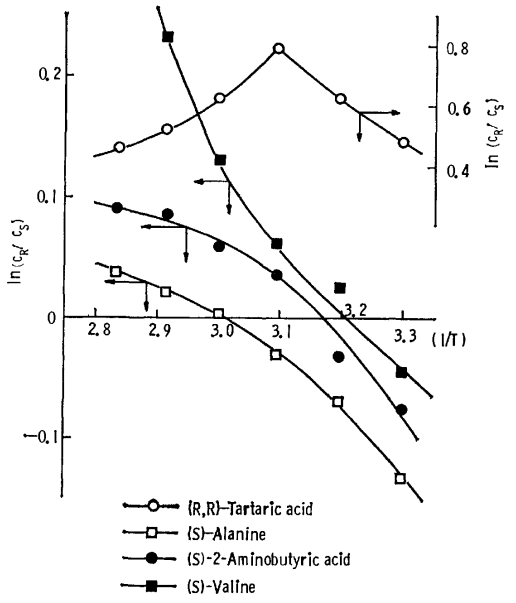

Fig. 2. Plots of $\ln(C_R/C_S)$ against $1/T$.

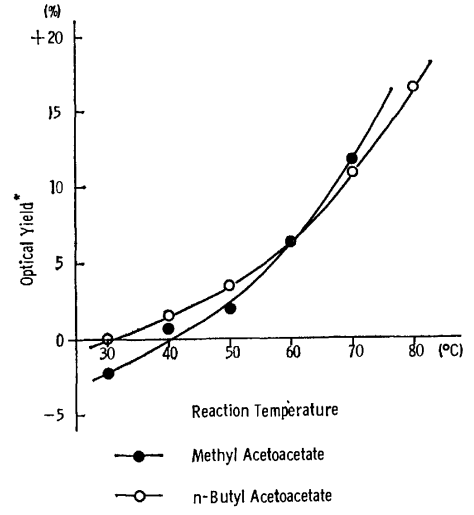

Fig. 3. Effect of ester group in substrate on the temperature dependence of optical yield.
*The sign of optical yield is taken as + in the case of an excess of (*R*)-(−)-enantiomer.

The maximum optical yield is observed at around 50 °C, and the optical yield decreases both above and below this temperature.

Taking into consideration the fact that this temperatue of 50 °C corresponds to the initial temperature of the dissociation of the hydrogen bond, the convex shape of the temperature dependence of the optical yield for (*R*,*R*)-tartaric acid-MRNi can be interpreted by the idea that the OH groups in the modifying reagent participate predominantly in enantioface-differentiation by making a hydrogen bond with the substrate up to the temperature at which the hydrogen bond disappears.

In order to investigate the role of the hydroxy group in α-hydroxy acid-MRNi in enantioface-differentiation, hydrogenations with catalysts modified with α-hydroxy carboxylic acids and their *O*-methyl derivatives were carried out. The results are listed in Table 1. (*S*)-Lactic acid-MRNi tends to afford (*S*)-(+)-enantiomer in excess as the reaction temperature rises.

Table 1. Effect of the modifying reagent on the temperature dependence of the optical yield

Modifying reagent	Reation temperature (°C)	Optical yield[a] (%)
(*S*)-lactic acid	30	0.00
	60	−0.65
	80	−1.08
(*S*)-2-methoxy-propionic acid	60	−0.07
	80	0.33
(*S*)-2-methoxy-3-methylbutyric acid	40	0.00
	60	0.24
	80	1.06

a) The sign of the optical yield is taken as + in the case of an excess of the (*R*)-(−)-enantiomer.

On the other hand, the catalysts modified with (*S*)-α-methoxy carboxylic acids showed the same temperature dependence as (*S*)-α-amino acid-MRNi, in which the amino group has much less capacity of making a hydrogen bond and T_0 decreased with the change in the α-alkyl group from methyl to isopropyl.

These phenomena indicate that the OH group plays an important role in the enantioface-differentiation by its ability of hydrogen bonding and that the function of the OH group in the enantio-differentiation differ from that of the NH_2 or OCH_3 group.

As has been reported, the comparative study of the rate and the optical yield indicates that the role of a modifying reagent can be divided into two independent functions. One is to regulate the rate by occupying a part of the active area of the catalyst, and the other is to differentiate the enantiofaces of the substrate as a reference chiral system.[1]

It is also known that at least two polar groups must attach to a chiral center of a modifying reagent for the stereo-differentiating reaction to take place.[2] When these facts are taken into account, the formation of dipolar interaction or a hydrogen bond between the substrate and modifying reagent could be the essential step in the enantio-differentiating hydrogenation.

Since the mode of the interaction is expected to be determined by the balance of an associative dipolar interaction or hydrogen bond and repulsive steric effect, the origin of T_0 can be explained by the change in the balance of the two effects because of their different temperature dependences.

Thus, T_0 and the feature of the temperature dependence of the optical yield may give a clue to the nature of the stereo-differentiating reaction. In order to understand the origin of T_0 and the temperature dependence of the optical yield in detail, there are still several problems to be solved, such as the temperature effect on the interaction between the modifying reagent and the catalyst and the effect of the minor contaminants of the catalyst, such as the aluminum ion, water, and methanol, on the mode of interaction between the substrate and the modifying reagent.

Further investigation on the origin of T_0 is in progress.

Experimental

The GLC analysis was carried out with a Shimadzu GC-3AH apparatus with a TC detector, using a 300×0.5 cm stainless-steel column packed with PEG 20-M (10%) on Chromosorb W. The optical rotations were measured at the Na-D line with a Perkin-Elmer 241 Polarimeter with a quartz cell (length of light path, 1 dm). All the materials except those listed below were obtained from commercial sources and were used without further purification. Butyl acetoacetate,[3] (*S*)-lactic acid (as Zn salt), $[\alpha]_D$ −7.9 (*c* 2, H_2O),[4] (*S*)-2-methoxy-3-methylbutyric acid,[5] $[\alpha]_D$ −77.6 (neat), and (*S*)-2-methoxypropionic acid,[5] $[\alpha]_D$ +69.1 (neat), were prepared by published procedures.

Preparation of the Catalyst. Into an alkaline solution (52 g of sodium hydroxide in 260 ml of deionized water), which had been cooled to 20 °C on an ice bath, 19.5 g of a well-pulverized Raney alloy (Ni 42%, Al 58%, Kawaken Fine Chemical Co.) was added in portions at such a rate that the temperature of the mixture was maintained at 20± 2 °C with occasional shaking. The resulting suspension of Raney nickel was kept at 75—78 °C for 45 min and then allowed to stand at room temperature for 2 h. After the removal of the alkaline solution by decantation, the Raney nickel was washed four times with 650 ml portions of deionized water. The modification of the catalyst was carried out at 0 °C by a published method.[6] The pH of the modifying solution was adjusted to an isoelectric point for each monoamino monocarboxylic acid and to 5.1 for each hydroxy acid.

Hydrogenation. Into an atmospheric-pressure hydrogenation vessel filled with hydrogen, 0.6 g of a catalyst suspended in 17.5 ml (0.15 mol) of a substrate was introduced. The mixture was then heated at the stated temperature for 3 h under shaking. After the subsequent removal of the catalyst from the reaction mixture by filtration, the filtrate was flash-distilled under reduced pressure. The optical rotation and the concentration of product in the distillate were determined by means of polarimetry at 25 °C and by GLC (90 °C) respectively. The optical purity of the product was determined by means of a calibration chart.

The author wishes to express his thanks to Professor Yoshiharu Izumi, Drs. Akira Tai, and Tadao Harada for their guidance and encouragement.

Reactions of Alkyl Diphenylphosphinates and Related Thio Esters with Some Nucleophiles. S_N2 (S) Reaction and Wittig Type Rearrangement

Koshiro GODA, Renji OKAZAKI, Kin-ya AKIBA, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received June 7, 1977)

Reactions of alkyl diphenylphosphinates $Ph_2P(=X)YCHR^1R^2$ (X, Y=O,S) with organolithiums and Grignard reagents afforded different types of products depending on the combination of X and Y. When Y=O, the reagents (R^3M) mainly attacked the phosphorus atom to give $Ph_2P(=X)R^3$ and $R^1R^2CHO^-$ irrespective of X, while, when X=Y=S, the reaction occurred exclusively at the ester sulfur atom, S_N2(S), to give $R^3SCHR^1R^2$ and $[Ph_2PS]^-$. When the X=O and Y=S, a Wittig type rearrangement of a carbanion $[Ph_2P(=O)SCR^1R^2]^-$ was observed along with attacks on the phosphorus (major) and the sulfur (minor) atoms. Reactions with some other nucleophiles (hydride, amide and alkoxide ions) are also described.

Substitution on the phosphoryl group with Grignard reagents[1] and organolithiums[2] has been used as a synthetic method. However, there seems to be no report on the reaction of alkyl diphenylphosphinates and related thio esters (**1**—**4**) with organolithiums or Grignard reagents.

$Ph_2P(X)-Y-R$ **1**: X=Y=O **3**: X=O, Y=S **2**: X=S, Y=O **4**: X=Y=S

The esters (**1**—**4**) have four reaction centers towards nucleophile, the phosphorus, Y atoms, and the α-carbon and α-hydrogen atoms of the R group. In the course of an investigation on the reactions of the esters (**1**—**4**) with some nucleophiles, we found two types of novel reactions in the case of Y=S (**3** and **4**), *viz.*, Wittig type rearrangement and S_N2 attack on the sulfur atom (S_N2 (S)).[3] This paper gives detailed results of the investigation.

Reactions of **1** *(X=Y=O).* Reactions of diphenylphosphinate esters (**1**) with nucleophiles such as butyl- and phenyllithiums, sodium hydride, and potassium *t*-butoxide were carried out in tetrahydrofuran (THF) under nitrogen. The results are summarized in Table 1.

$$Ph_2P(O)-O-R + R'Li \longrightarrow Ph_2P(O)-R' + ROLi \xrightarrow{H^+} ROH$$

1: **a**: R'=Bu, **b**: R'=Ph → **5**; $\xrightarrow{MeI}$ $ROCH_3$

The formation of (1-methylbutyl)diphenylphosphine oxide (**6**) is attributed to methylation of butyldiphenylphosphine oxide (**5a**) initially formed by methyl iodide in the presence of excess butyllithium.

$$Ph_2P(O)-CH_2CH_2CH_2CH_3 \xrightarrow{BuLi} Ph_2P(O)-\overset{\ominus}{C}HCH_2CH_2CH_3$$

5a

$$\xrightarrow{MeI} Ph_2P(O)-CH(CH_3)CH_2CH_2CH_3$$

6

The formation of bis(diphenylmethyl) ether in the case of diphenylmethyl ester might be due to S_N2 attack on the α-carbon atom by diphenylmethoxide anion produced in the reaction. In the reaction with sodium hydride, benzophenone is considered to be formed in the following ways, $[Ph_2PO]^-$ being isolated as diphenylphosphinic acid because of the easy oxidation during the work-up.

$$Ph_2P(O)-O-CHPh_2 \xrightarrow{B:} Ph_2P(O)-O-\overset{\ominus}{C}Ph_2 \longrightarrow [Ph_2PO]^- + Ph_2CO$$

$$Ph_2P(O)-O-\overset{\ominus}{C}Ph_2 \xrightarrow[\text{rearr.}]{\text{Wittig}} Ph_2P(O)-CPh_2(O^-)$$

The following example of Wittig type rearrangement has been reported.[4]

$$A_2P(O)OCH_2Ph + BuLi \longrightarrow A_2P(O)\overset{\ominus}{O}CHPh \longrightarrow A_2P(O)CHPhO^-$$

A=MeO, EtO, Me_2N

Table 1. Reactions of **1** with nucleophiles (Nu) in THF

R	Nu	Reaction temp (°C)	Reaction time (h)	Product (%)
$PhCH_2$	BuLi[a]	−78	0.5	**6** (60)[b]
Ph_2CH	BuLi[a]	−78	0.5	**6** (59),[b] ROMe (77)[b]
	PhLi	−78	0.5	**5b** (50), ROH (55)
	NaH	r. t.	6.0	$Ph_2P(O)OH$ (51), ROH (trace) Ph_2CO (59)
	t-BuOK[a]	r. t.	0.5	$Ph_2P(O)O$-*t*-Bu (19) ROMe (73),[b] ROR (14)

a) The reaction mixture was treated with methyl iodide. b) Methylated product.

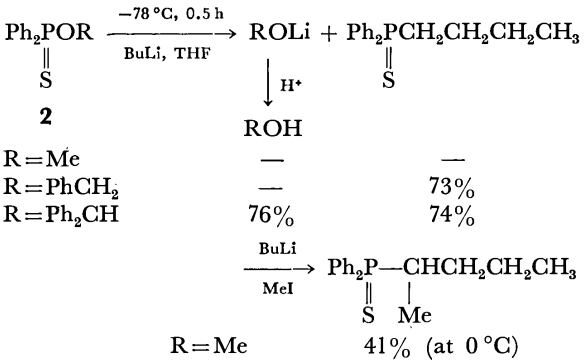
Examples of $S_N2(C)$ reaction has also been reported in the case of phosphate esters with Grignard reagents.[5] However, no reaction of this type was detected in the present system, *i.e.*, diphenylphosphinate esters with organolithiums.

$$(RO)_2P(O)OR + PhMgBr \longrightarrow (RO)_2P(O)O^- + R\text{-}Ph$$

The low yield of *t*-butyl diphenylphosphinates in the reaction with potassium *t*-butoxide is attributed to the easy S_N1 type hydrolysis on silica gel column during the work-up.

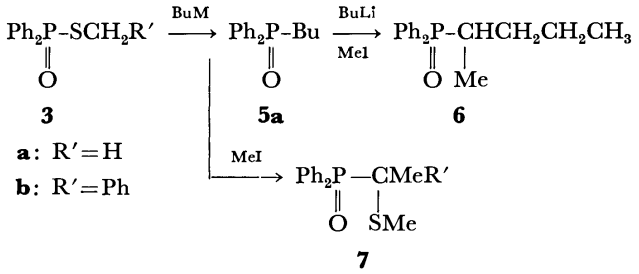
Therefore, the main reaction modes in **1** are S_N2 (P) and S_N2(C) reactions.

Reactions of **2** *(X=S, Y=O).* The results of the reaction of *O*-alkyl diphenylphosphinothioates (**2**) with butyllithium are shown in the following scheme.

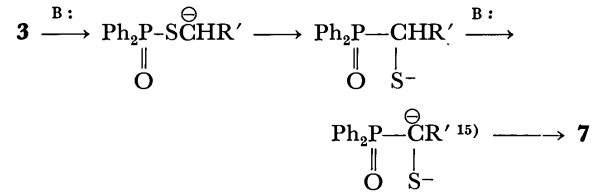


Thus, S_N2(P) pathway occurs mainly.

Reaction of **3** *(X=O, Y=S).* The results are given in Table 2.



Formation of (α-methylthioalkyl)diphenylphosphine oxide (**7**) is the first example of Wittig type rearrangement in **3**.



Formation of benzyl methyl sulfide and methyldiphenylphosphine oxide from **3b** is attributed to methylation of α-toluenethiolate anion and $[Ph_2PO]^-$ produced by S_N2(P) and S_N2(S) pathway, respectively. The latter is of the same type as that in the reactions of **4** described below.

Thus, the main pathway is S_N2(P) accompanied by S_N2(S).

Reactions of **4** *(X=Y=S).* Reactions of diphenylphosphinodithioate esters (**4**) with butyllithium or butylmagnesium chloride were carried out in THF at −78 °C or under reflux. The reaction mixture was

Table 2. Reactions of **3** with nucleophiles (Nu) in THF

R′	Nu	Reaction temp (°C)	Reaction time (h)	Product (%)
H	BuMgCl	refl.	0.1	**5a** (93)[b]
	BuLi	−78	0.5	**5a** (48)
	$LiN(c\text{-}C_6H_{11})_2$	−78	0.5	**7a** (12)
Ph	BuLi[a]	−78	0.5	**6** (57), **7b** (11) $Ph_2P(O)Me$ (14), $PhCH_2SMe$ (54)

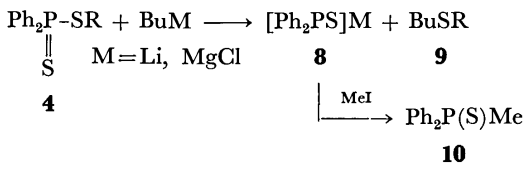
a) The reaction mixture was treated with methyl iodide. b) Mp 93.0—94.5 °C (lit,[14] 95 °C).

Table 3. Reactions of **4** with butyllithium and butylmagnesium chloride followed by methylation (in THE)

R	M	Reaction temp (°C)	Reaction time (h)	Product (%)[a]
Me	Li	−78	0.5	**10** (100)
	MgCl	refl.	0.5	**10** (47)
Ph	Li	−78	0.5	**10** (94), **9** (95)[b]
	MgCl	refl.	0.5	**10** (35)[b], recovered **4** (48)[b]
$PhCH_2$	Li	−78	0.5	**10** (84), **9** (39)[b]
	MgCl	refl.	0.5	**10** (10),[b] recovered **4** (74)[b]
CH_2=$CHCH_2$	Li	−78	0.5	**10** (62)
t-Bu	Li	−78	1/6	**18** (trace), $Ph_2P(S)CHMe\text{-}n\text{-}C_3H_7$ (main), $Ph_2P(S)SMe$ (minor)

a) Determined by GLC unless noted otherwise. b) Isolated by DCC.

then treated with methyl iodide. The results are summarized in Table 3.

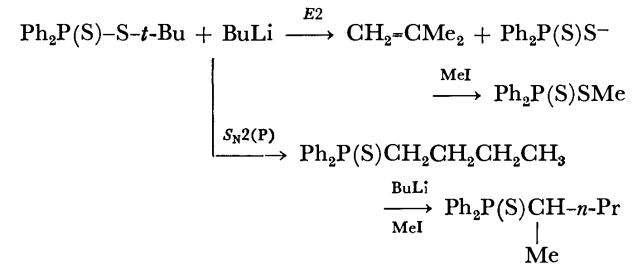


The results show that the reactions of **4** with butyllithium in THF at −78 °C were fast, giving diphenylphosphinothioylide (**8**) and butyl sulfides (**9**) selectively in excellent yields. Thus, the reactions are utilized in preparation of unsymmetrical sulfides.[6]

On the other hand, the reactions with Grignard reagents were very slow. Phenylmagnesium bromide in particular did not react with methyl, phenyl, and benzyl esters to an appreciable extent even in refluxing THF for 3 h.

The reactions are the first example of $S_N2(S)$ reaction in **4**. Since methyl diphenylphosphinodithioate is prepared easily and in a high yield from the Friedel-Crafts reaction of benzene and phosphorus pentasulfide followed by refluxing with methanol,[7] the reaction of methyl diphenylphosphinodithioate with butyllithium is used as a new method for preparation of **8**.

The $S_N2(S)$ reaction did not occur in the case of *t*-butyl ester, because of steric hindrance, the reaction proceeding *via* *E*2 and $S_N2(P)$ pathways as follows:



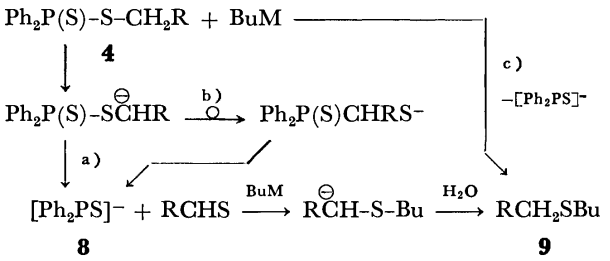
The formation of **8** was also indicated by means of ^{31}P-NMR as shown below.

	δ_P		δ_P	δ_P
R=Me	−64.2	M=Li	−20.7	−20.8
Ph	−64.8	MgCl	−14.3	
$PhCH_2$	−62.9			
Et	−62.4			
CH_2=$CHCH_2$	−62.4			

In each case, the signal was observed at the same position, *i.e.*, at −20.7 or −14.3 ppm depending on M=Li or MgCl, respectively.[8]

In the reaction of allyl ester with butylmagnesium chloride, the signal due to $Ph_2P(S)SMgCl$ at −58.6 ppm was detected, indicating the existence of $S_N2(C)$ pathway.

Evidence for $S_N2(S)$ *Mechanism in* **4**. The following three pathways are possible for the formation of **8** and **9**.

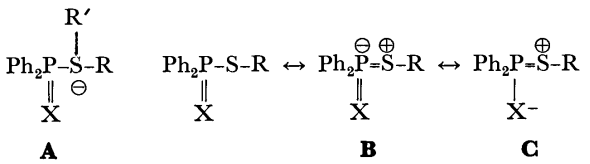


Paths a) and b) involve the formation of the corresponding α-carbanion in the first step, followed by direct elimination of thioaldehyde (path a)) or by the Wittig type rearrangement followed by elimination (path b)). Path c) is a direct attack on the sulfur atom of **4** ($S_N2(S)$ reaction). Paths a) and b) are ruled out in view of the following: 1) the reaction did not require two molar amounts of BuM, the yield of methyldiphenylphosphine sulfide (**10**) being 97 and 100% in the reactions of an equimolar and two molar amounts of butyllithium with methyl ester, respectively, 2) even phenyl ester reacted quantitatively in spite of the absence of α-hydrogen atom, and 3) reaction of benzyl ester with an equimolar amount of butyllithium at −78 °C afforded benzyl butyl sulfide containing no deuterium atom after quenching with D_2O (by MS and NMR).

Thus, it can be concluded that the formation of **8** and **9** takes place through $S_N2(S)$ mechanism (path c)).

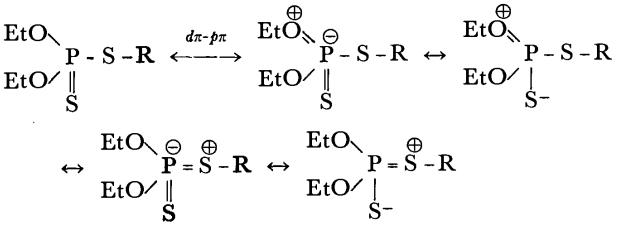
Reason for the Differences in Reaction Modes. In the case of **1** and **2** (Y=O), the main path is $S_N2(P)$ reaction. On the other hand, in the case of **4** (X=Y=S), $S_N2(S)$ reaction occurs selectively, and in the case of **3** (X=O, Y=S), the $S_N2(P)$ pathway occurs along with $S_N2(S)$.

The fact that organometalloids R′M attack Y only when Y=S is explained in terms of the possible involvement of **A** as an intermediate (or transition state), since such a structure is impossible in the case of oxygen, $S_N2(P)$ process being considered to occur irrespective of X when Y=O.



Canonical structures such as **B** and **C** having a positive charge on sulfur may also make some contribution in the ground state of **4**, making the formation of **A** possible.

No $S_N2(S)$ reaction was found to occur in the reaction of butyllithium with *S*-alkyl *O*,*O*-diethyl dithiophosphate, in which the following resonance structures are possible.



Since the contribution of $d\pi$-$p\pi$ interaction in the S–P bond is considered to be smaller than that in O–P bond, $S_N2(S)$ pathway cannot take place, since the ester sulfur atom does not carry such a positive charge as in **4** to accept organometalloids. The following reaction[9] might support the above interpretation.

$$(EtO)_2P(S)\text{-}Et + EtI \longrightarrow EtO\text{-}P(O)(SEt)_2 + EtI$$

It has been shown that the organolithiums possess a larger thiophilicity than the Grignard reagents, as indicated in the reactions with thioketones[10] and with 2-nitrosoimino-2,3-dihydrobenzothiazoles.[11] The results we obtained are in line with these facts.

The observation that **3** (X=O, Y=S) undergoes both $S_N2(P)$ and $S_N2(S)$ in contrast to the exclusive occurrence of $S_N2(S)$ in **4** (X=Y=S) is easily understandable in view of the well-known greater electrophilic reactivity of phosphinyl group than that of a thiophosphinyl group. For example, diphenylphosphinic chloride undergoes hydrolysis more easily than diphenylphosphinothioic chloride. Similarly, *S*-benzyl diphenylphosphinothioate undergoes hydrolysis more easily than benzyl diphenylphosphinodithioate (see Experimental).

Experimental

^{31}P-NMR spectra were measured with a Hitachi R-20B-R-204 PB spectrometer using 85% phosphoric acid as an external standard.

Materials. *S*-Methyl,[8] *S*-benzyl,[12] *O*-methyl,[12] *O*-benzyl diphenylphosphinothioates,[13] and *t*-butyl diphenylphosphinodithioate[7b] were prepared by the reported methods.

Methyl Diphenylphosphinodithioate. A mixture of sodium hydroxide (20 g, 0.5 mol) and diphenylphosphinodithioic acid (105 g, 0.42 mol) in THF (300 ml) was stirred at room temperature for 1 h. Methyl iodide (60 g, 0.42 mol) was added and the mixture was stirred at room temperature for 1 h. The reaction mixture was washed with water and extracted with benzene. After removal of the solvent from the dried extract, the residue was recrystallized from ethanol, mp 86—87 °C (lit,[7] 82—83 °C), yield 98 g (88%).

Diphenylmethyl Diphenylphosphinate. A mixture of diphenylphosphinic chloride (17.3 g, 73 mmol), diphenylmethanol (22.7 g, 123 mmol) and triethylamine (12 ml) in THF (80 ml) was refluxed for 2 h. The reaction mixture was treated similarly. Mp 138—139 °C (from 2-propanol), yield 20.6 g (73%). NMR ($CDCl_3$): δ 6.60 (d, 1H, J_{POCH}=11 Hz, CH), 7.42 (s, 10H, 2Ph), and 7.30–8.10 (m, 10H, 2P-Ph); ^{31}P-NMR (THF): δ_P −29.5 ppm.

Benzyl Diphenylphosphinate. A mixture of diphenylphosphinic chloride (1.86 g, 79 mmol) and benzyl alcohol (20 ml) in THF (80 ml) was stirred for 1 h. The reaction mixture was washed with 10% aqueous sodium hydrogencarbonate and extracted with benzene. After removal of the solvent from the dried extract, the residue was recrystallized from ether, mp 82.5—83.5 °C, yield 17.1 g (71%). NMR ($CDCl_3$): δ 4.95 (d, 2H, J_{POCH}=7 Hz, OCH_2), 7.22 (s, 5H, Ph), and 7.20—8.00 (m, 10H, 2P-Ph).

Found: C, 74.15; H, 5.65%. Calcd for $C_{19}H_{17}O_2P$: C, 74.02; H, 5.56%.

O-Diphenylmethyl Diphenylphosphinothioate. To a mixture of diphenylmethanol (10 g, 54 mmol) and sodium (1 g, 43 mmol) in THF (40 ml) was added diphenylphosphinothioic chloride (11.0 g, 45 mmol) in THF (50 ml), and the reaction mixture was treated in the usual way, mp 97—98 °C (from ethanol), yield 13.9 g (95%). IR (KBr): 980 (P-O) and 640 cm^{-1} (P=S); NMR ($CDCl_3$): δ 6.75 (d, 1H, J_{POCH}=13 Hz, CH), 7.20 (s, 10H, 2Ph), and 7.10—7.95 (m, 10H, 2P-Ph); ^{31}P-NMR (THF): δ_P −82.1 ppm.

Found: C, 75.06; H, 5.25; S, 8.13%. Calcd for $C_{25}H_{21}OPS$: C, 74.98; H, 5.29; S, 8.01%.

Benzyl Diphenylphosphinodithioate. To a mixture of diphenylphosphinodithioic acid (48 g, 0.19 mol) and sodium (4.6 g, 0.2 mol) in THF (200 ml) was added benzyl bromide (34.2 g, 0.2 mol), and the mixture was stirred for 3 h. After the usual work-up, the reaction mixture was subjected to column chromatography with $CHCl_3$ to give colorless viscous oil, yield 56 g (86%), which could not be distilled. NMR ($CDCl_3$): δ 4.05 (d, 2H, J_{PSCH}=13 Hz, CH_2), 7.05 (s, 5H, Ph), and 7.15—8.05 (m, 10H, 2P-Ph); ^{31}P-NMR (THF): δ_P −62.9 ppm.

Found: C, 66.98; H, 5.06; S, 18.81%. Calcd for $C_{19}H_{17}PS_2$: C, 67.03; H, 5.03; S, 18.84%.

Phenyl Diphenylphosphinodithioate. To a mixture of benzenethiol (10 ml) and sodium (2.5 g, 0.11 mol) in THF (30 ml) was added diphenylphosphinothioic chloride (24 g, 0.095 mol), and the reaction mixture was stirred for 3 h. After the usual work-up, the product was distilled *in vacuo*, bp 229 °C/0.1 mmHg, mp 57—59 °C (from ethanol), yield 24 g (77%). ^{31}P-NMR (THF): δ_P −64.8 ppm.

Found: C, 66.14; H, 4.50; S, 19.57%. Calcd for $C_{18}H_{25}PS_2$: C, 66.23; H, 4.63; S, 19.65%.

Ethyl Diphenylphosphinodithioate. To a mixture of diphenylphosphinodithioic acid (50 g, 0.2 mol) and sodium hydroxide (8 g, 0.2 mol) in THF (150 ml) was added ethyl bromide (15 ml) under stirring at room temperature and the mixture was stirred for 1 h. The usual work-up afforded the ester (46 g, 83%), bp 166 °C/0.2 mmHg (lit,[7b] 166—167 °C/0.3 mmHg).

Allyl Diphenylphosphinodithioate. To a mixture of diphenylphosphinodithioic acid (29 g, 0.12 mol) and sodium hydroxide (6 g, 0.15 mol) in THF (100 ml) was added allyl bromide (10 ml), and the mixture was stirred for 3 h at room temperature. The usual work-up gave the ester (27 g, 80%), bp 160 °C/0.04 mmHg. NMR (CCl_4): δ 3.55 (dd, 2H, J_{PSCH}=13 Hz, CH_2), 4.7—6.0 (m, 3H, $CH{=}CH_2$), and 7.2—8.2 (m, 10H, 2P-Ph); ^{31}P-NMR (THF): δ_P −62.4 ppm.

Found: C, 62.32; H, 4.92%. Calcd for $C_{15}H_{15}PS_2$: C, 62.02; H, 5.21%.

*Reactions of **1** with Nucleophiles.* Only some typical examples are described. Reactions were carried out under nitrogen or argon.

Reaction of Benzyl Diphenylphosphinate with Butyllithium. Butyllithium (3 mmol) in hexane (2 ml) was added to the ester (0.795 g, 2.6 mmol) in THF (30 ml) at −78 °C and the mixture was stirred at this temperature for 0.5 h. After addition of methyl iodide (1 ml), the reaction mixture was warmed to room temperature, washed with water, and extracted with chloroform. After removal of the solvent from the dried extract, the residue was subjected to dry column chromatography (DCC) (SiO_2, $MeCO_2Et$) to give **6** (0.419 g, 60%), mp 86—88 °C (from ether). NMR (CCl_4): δ 0.87 (t, 3H, Me), 1.17 (dd, J_{PCCH}=14 Hz, J_{HH}=7 Hz, 3H, Me), 1.27—1.70 (m, 4H, $2CH_2$), 2.05—2.50 (m, 1H, CH), and 7.20—7.90 (m, 10H, 2P-Ph).

Found: C, 75.22; H, 7.61%. Calcd for $C_{17}H_{21}OP$: C, 74.98; H, 7.71%.

Reaction of Diphenylmethyl Diphenylphosphinate with Sodium Hydride. Sodium hydride (0.157 g, 6.5 mmol) was

added to the ester (0.247 g, 0.64 mmol) in THF (15 ml) at room temperature, and the mixture was stirred for 6 h. After addition of methanol (1 ml), the mixture was acidified with dil. hydrochloric acid and extracted with benzene. Removal of benzene from the extract gave 71 mg (51%) of diphenylphosphinic acid and oily material, the latter being separated with DCC (SiO_2, $CHCl_3$; then SiO_2, hexane) to give benzophenone(69 mg, 59%) and diphenylmethanol (trace) which were identified by IR and NMR.

Reaction of O-*Methyl Diphenylphosphinothioate with Butyllithium.* Butyllithium (10.9 mmol) in hexane (7 ml) was added to a solution of the ester (1.467 g, 5.9 mmol) in THF (30 ml) at 0 °C and the mixture was stirred for 1 h. After addition of methyl iodide (1 ml), the mixture was stirred for 3 h. After the usual work-up, recrystallization of the residue from 2-propanol twice gave 0.699 g (41%) of (1-methylbutyl)diphenylphosphine sulfide, mp 114—115 °C. IR (KBr): 1430, 1105 (P-Ph), and 605 cm^{-1} (P=S); NMR ($CDCl_3$): δ 0.85 (t, 3H, $J_{HH}=7$ Hz, Me), 1.15 (dd, 3H, $J_{PCCH}=19$ Hz, $J_{HH}=7$ Hz, Me), 1.35—1.65 (m, 4H, $2CH_2$), 2.50—2.90 (m, 1H, CH), and 7.35—8.10 (m, 10H, 2P-Ph); MS: *m/e* 288 (M^+, 7%), 218 (Ph_2P^+SH, 100), and 185 (Ph_2P^+, 25).

Found: C, 70.84; H, 7.44; S, 11.12%. Calcd for $C_{17}H_{21}SP$: C, 70.80; H, 7.34; S, 11.12%.

Reaction of S-*Methyl Diphenylphosphinothioate with Lithium Dicyclohexylamide.* Butyllithium (12.5 mmol) in hexane (8 ml) was added to dicyclohexylamine (2.28 g, 12.6 mmol) in THF (25 ml) at −78 °C and the mixture was stirred at this temperature for 0.5 h. *S*-Methyl diphenylphosphinothioate (1.74 g, 7.0 mmol) in THF (25 ml) was then added to the mixture and the mixture was stirred at the same temperature for 0.5 h. After addition of methyl iodide (2 ml), the reaction mixture was warmed to room temperature, washed with aqueous citric acid, and extracted with benzene. The extract was dried, evaporated, and subjected to DCC (SiO_2, AcOEt) to give 0.229 g (12%) of **7a**, mp 185—187 °C (from ether). IR (KBr): 1438, 1120(P-Ph), and 1198 cm^{-1} (P=O); NMR ($CDCl_3$): δ 1.54 (dd, 3H, $J_{PCCH}=14$ Hz, $J_{HH}=7$ Hz, Me), 2.73 (s, 3H, SMe), 3.83 (dq, 1H, $J_{PCH}=14$ Hz, $J_{HH}=7$ Hz, CH-P), and 7.40—8.10 (m, 10H, 2P-Ph); MS: *m/e* 276 (M^+, 7%), 230 (M^+-SCH_2, 100), and 202 (Ph_2P^+OH, 78).

Found: C, 64.93; H, 5.66%. Calcd for $C_{15}H_{17}OPS$: C, 65.20; H, 6.20%.

Reaction of S-*Benzyl Diphenylphosphinothioate with Butyllithium.* Butyllithium (2.0 mmol) in hexane (1.3 ml) was added to the ester (0.354 g, 1.1 mmol) in THF (15 ml) at −78 °C and the mixture was stirred at this temperature for 0.5 h. Methyl iodide (0.5 ml) was added to the mixture at −78 °C. The temperature was then raised to room temperature. The reaction mixture was washed with water and extracted with chloroform. DCC (SiO_2, CCl_4) of the dried extract gave benzyl methyl sulfide (81 mg, 54%), methyldiphenylphosphine oxide (32 mg, 14%), **6** (168 mg, 57%) (by IR and NMR), and oily **7b** (42 mg, 11%).

7b: NMR ($CDCl_3$): δ 1.85 (d, 3H, $J_{PCCH}=14$ Hz, Me), 2.03 (s, 3H, SMe), 7.13 (s, 5H, Ph), and 7.22—8.10 (m, 10H, 2P-Ph).

Found: C, 71.48; H, 6.14; S, 9.03%. Calcd for $C_{21}H_{21}OPS$: C, 71.56; H, 6.01; S, 9.10%.

Reaction of Phenyl Diphenylphosphinodithioate with Butyllithium. Butyllithium (4.5 mmol) in hexane (3 ml) was added to a solution of the ester (0.496 g, 1.5 mmol) in THF (10 ml) at −78 °C and the mixture was stirred at this temperature for 0.5 h. After addition of methyl iodide (0.5 ml) at −78 °C, the mixture was stirred at room temperature for 0.5 h and determined by gas chromatography (GLC, at 210 °C, H 523 column). The yield of **10** was 94%. DCC (SiO_2, CCl_4) of the reaction mixture after the usual work-up gave butyi phenyl sulfide (0.240 g, 95%) (by IR and NMR).

Reaction of Benzyl Diphenylphosphinodithioate with Butyllithium Followed by Treatment with D_2O. A mixture of butyllithium (1.5 mmol) in hexane (1 ml) and the ester (1.06 g, 3.1 mmol) in THF (15 ml) was treated in a similar way to that above and the reaction mixture was quenched with D_2O (0.1 ml). DCC (SiO_2, $CHCl_3$) gave 0.25 g (1.4 mmol) of benzyl butyl sulfide. NMR ($CDCl_3$): $C_6\mathbf{H}_5 : C\mathbf{H}_2$–*n*-Pr= 5.3 : 2.0 (as average value of five measurements). MS: *m/e* 180 (M^+): 181 (M^++1): 182 (M^++2)=100 : 15 : 7 (calcd: 100 : 14 : 5).

Alkaline Hydrolysis. *1) Benzyl Diphenylphosphinodithioate*: The ester (1.295 g, 3.8 mmol) was stirred with 10% aqueous sodium hydroxide (30 ml) at 80 °C for 6 h. The reaction mixture was extracted with chloroform to remove unchanged ester. The extract was acidified with hydrochloric acid and extracted with chloroform. Evaporation of the dried extract gave diphenylphosphinothioic acid (11 mg, 1%), which was identified by IR.

2) S-Benzyl Diphenylphosphinothioate: The ester (0.512 g, 1.6 mmol) was treated in a similar way to that above with 10% aqueous sodium hydroxide (20 ml). The reaction products were diphenylphosphinic acid (0.304 g, 89%) and α-toluenethiol (72 mg, 37%) (by IR and NMR).

Synthesis and Absolute Stereochemistry of (+)-7,14-Dihydro-7,14-ethanodibenz[*a*,*h*]anthracene and Its Derivatives

Nobuyuki HARADA, Yuki TAKUMA, and Hisashi UDA

Chemical Research Institute of Nonaqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received June 8, 1977)

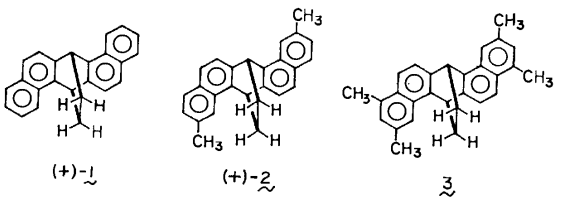
(7*R*,14*R*)-(+)-7,14-Dihydro-7,14-ethanodibenz[*a*,*h*]anthracene (**1**), and the 2,9-dimethyl- (**2**) and 2,4,9,11-tetramethyl- (**3**) derivatives were synthesized from (9*R*,10*R*)-(+)-9,10-dihydro-9,10-ethanoanthracene-1,5-dicarbaldehyde (**4**) of known absolute configuration. The CD spectra of **1**, **2**, and **3** clearly exhibit positive first and negative second Cotton effects due to the coupling of the ^1B_b transitions of two naphthalene chromophores: $\Delta\varepsilon_{237.0}=+326.5$, $\Delta\varepsilon_{224.0}=-180.5$, $A=+507.0$, for **1**; $\Delta\varepsilon_{240.6}=+371.5$, $\Delta\varepsilon_{227.0}=-149.4$, $A=+520.9$, for **2**; $\Delta\varepsilon_{242.0}=+340.3$, $\Delta\varepsilon_{225.0}=-88.0$, $A=+428.3$, for **3**. Since the sign of the A values is positive, positive exciton chirality between the two long axes of the naphthalene moieties is assigned. The (7*R*,14*R*) absolute configuration of **1**, **2**, and **3** is established by both CD exciton chirality and X-ray Bijvoet methods.

The circular dichroic exciton chirality method based on chiral exciton coupling between two or more chromophores enables one to determine the absolute stereochemistry of organic compounds in a nonempirical manner.[1,2] We have reported the synthesis and absolute configuration of (+)-6,15-dihydro-6,15-ethanonaphtho[2,3-*c*]pentaphene determined by the exciton chirality method and chemical correlations, providing definite evidence of the consistency between nonempirical CD and X-ray crystallographic methods.[3,4]

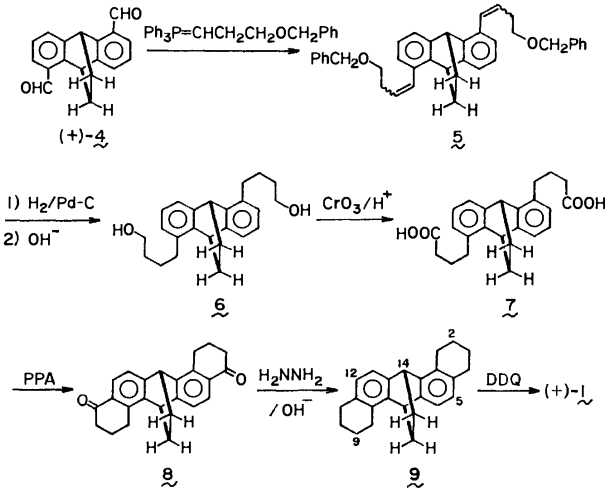
This paper describes the synthesis and absolute stereochemistry of (+)-7,14-dihydro-7,14-ethanodibenz[*a*,*h*]anthracene and its derivatives. The CD spectra of these compounds show typical split Cotton effects due to the chiral exciton coupling between two naphthalene chromophores. The absolute configuration determined by the present CD method is in accord with that obtained by the X-ray Bijvoet method, as in the case of (+)-6,15-dihydro-6,15-ethanonaphtho[2,3-*c*]pentaphene.

Results and Discussion

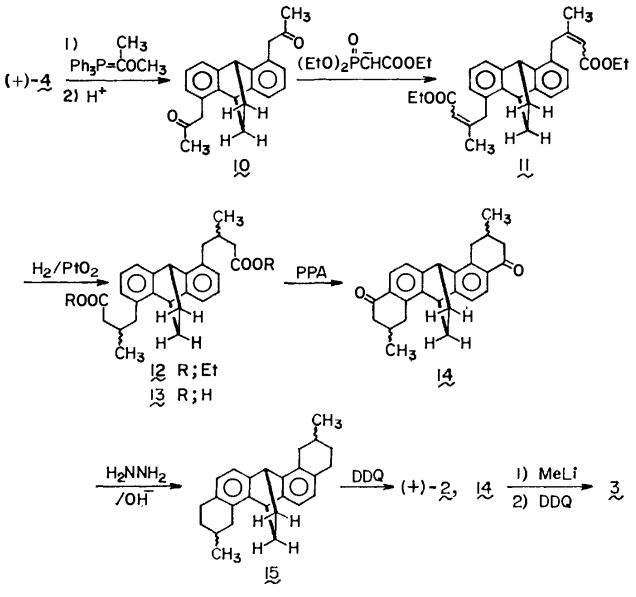
*Synthesis of (7*R*,14*R*)-(+)-7,14-Dihydro-7,14-ethanodibenz*[a,h]*anthracene (**1**) and the 2,9-Dimethyl- (**2**) and 2,4,9,11-Tetramethyl- (**3**) Derivatives.* Compounds **1**, **2**, and **3** were synthesized from (9*R*,10*R*)-(+)-9,10-dihydro-9,10-ethanoanthracene-1,5-dicarbaldehyde (**4**), mp 128.0—129.5 °C, $[\alpha]_D$ +487.3°, the absolute stereochemistry of which has been established by chemical correlations.[3,4]



In order to elongate side chains, dialdehyde **4** was subjected to the Wittig reaction with γ-benzyloxypropylenetriphenylphosphorane to afford an isomeric mixture of bisbenzyl ether **5** in an almost quantitative yield (Scheme 1). Catalytic hydrogenation of **5** over palladium on charcoal in acetic acid containing a catalytic amount of sulfuric acid, and successive hydrolysis of the intermediary acetate formed yielded glycol **6**. Oxidation of glycol **6** with Jones reagent, followed by cyclization of the resulting dicarboxylic acid **7** with polyphosphoric acid gave (+)-diketone **8**, $[\alpha]_D$ +184.6°. The Huang-Minlon reduction of **8** afforded hydrocarbon **9**, which was subsequently oxidized with DDQ to yield



Scheme 1.



Scheme 2.

the desired hydrocarbon (+)-**1**, mp 234.0—235.5 °C, $[\alpha]_D$ +670.0°.

In the cases of hydrocarbons **2** and **3**, dialdehyde **4** was allowed to react with α-methoxyethylenetriphenylphosphorane to give an isomeric mixture of bisvinyl ether, which was hydrolyzed to diketone **10** (Scheme 2). Diketone **10** was subjected to the second Wittig reaction with triethylphosphonoacetate to yield a *cis,trans* isomeric mixture of diester **11**. Catalytic hydrogenation of the unsaturated diester **11** over platinum oxide and the hydrolysis of ester groups afforded dicarboxylic acid **13**, which was cyclized with polyphosphoric acid yielding diketone **14**. Although the NMR signal of the secondary methyl groups of compound **14** appears as one doublet, diketone **14** could be considered to be a mixture of three possible stereoisomers. Diketone **14** was subjected to the Huang-Minlon reduction giving hydrocarbon **15**, which was oxidized with DDQ to yield the dimethyl derivative (+)-**2**. Methylation of **14** with methyl lithium and successive treatment with DDQ afforded the tetramethyl derivative **3**.

Since the absolute configuration of the ethano-bridge remains unchanged throughout all the reactions, the (7*R*,14*R*) absolute stereochemistry of compounds **1**, **2**, and **3** has been established by the present chemical correlations.

Circular Dichroic Spectra and Absolute Stereochemistry. The linear dichroic properties of electronic transitions of naphthalene chromophore are established as follows. The weak ^1L_b transition around 310 nm (ε 200) and the intense ^1B_b transition around 220 nm (ε 100000) are polarized parallel to the long axis of the chromophore, while the ^1L_a transition of medium intensity around 280 nm (ε 5800) has an electric transition moment along the short axis of the chromophore.[5]

Of these transitions, the allowed ^1B_b transition is ideal for chiral exciton coupling because of its large extinction coefficient value. In fact, hydrocarbon (+)-**1** exhibits strong split Cotton effects due to the exciton coupling between the two ^1B_b transitions: the positive first Cotton effect at 237.0 nm (Δε +326.5) and the negative second one at 224.0 nm (Δε −180.5); $A(\Delta\varepsilon_1 - \Delta\varepsilon_2) = +507.0$ (Fig. 1).[6]

Since the sign of the A value is positive, it is established that the hydrocarbon (+)-**1** has positive exciton chirality between the two long axes of the naphthalene moieties (Fig. 1), which corresponds to the (7*R*,14*R*) absolute configuration in line with the chemical correlation results.

Similarly, compounds (+)-**2** and **3** exhibit strong positive first and negative second Cotton effects in the region of the ^1B_b transition (Figs. 2 and 3). As the number of methyl groups increases, the Cotton effects undergo red shift of 4—5 nm corresponding to that of

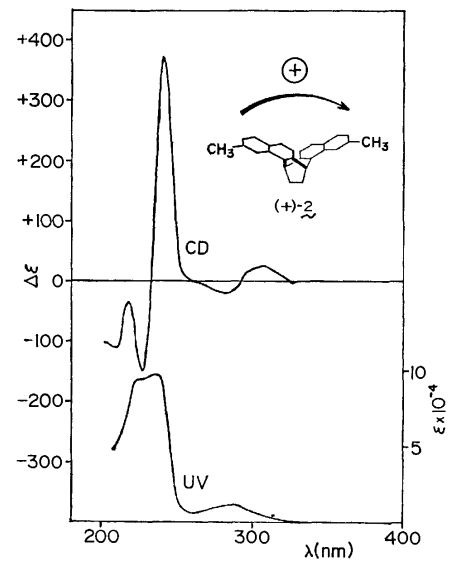


Fig. 2. CD and UV spectra of (7*R*,14*R*)-(+)-7,14-dihydro-2,9-dimethyl-7,14-ethanodibenz[*a*,*h*]anthracene (**2**) (see text for the solvent systems used).

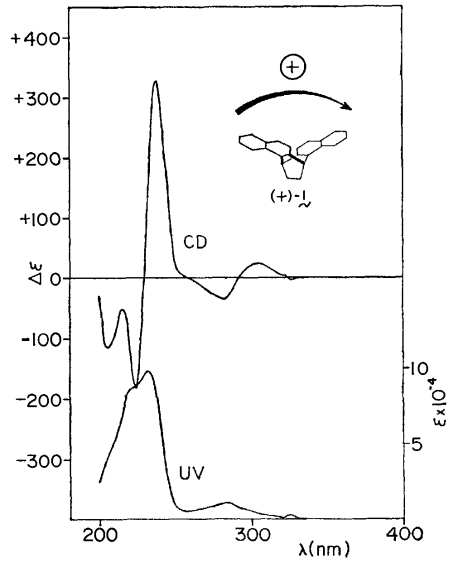

Fig. 1. CD and UV spectra of (7*R*,14*R*)-(+)-7,14-dihydro-7,14-ethanodibenz[*a*,*h*]anthracene (**1**) in ethanol.

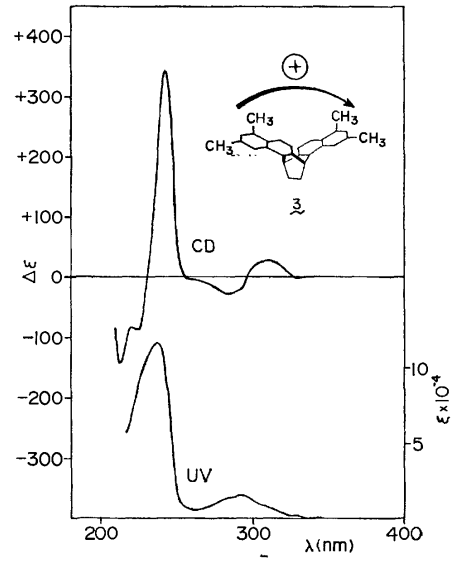

Fig. 3. CD and UV spectra of (7*R*,14*R*)-7,14-dihydro-2,4,9,11-tetramethyl-7,14-ethanodibenz[*a*,*h*]anthracene (**3**) in ethanol.

UV spectrum, the second Cotton effect becoming weaker and the positive first one remaining almost unchanged. On the other hand, the third Cotton effect of negative sign appears around 210 nm, becoming stronger and undergoing red shift as the number of methyl groups increases. In compound **3**, the third and second Cotton effects overlap each other. Although the origin of the third Cotton effect is still unknown, it is obvious that the unsubstituted hydrocarbon **1** is superior to compounds **2** and **3** for observation of exciton split Cotton effects.

In contrast to the case of the intense ^1B_b transition, the Cotton effects due to other weak transitions can not be assigned in a straightforward manner. Compounds **1**, **2**, and **3** show positive first and negative second Cotton effects of medium intensity ($\Delta\varepsilon$ −27) in the region of a ^1L_a transition (around 307 and 283 nm), as if they were based on simple exciton coupling mechanism (Figs. 1, 2, and 3). However, the sequence of the sign of the Cotton effects, *i.e.*, positive and negative from longer wavelength side, is in conflict with the negative exciton chirality predicted by a point dipole approximation method. A similar situation was observed for the weak ^1L_b transition of compound **1** around 325 nm; the sequence of the negative first Cotton effect at 326 nm ($\Delta\varepsilon$ −4.3) and the positive second one at 322 nm ($\Delta\varepsilon$ +5.0) disagrees with the positive exciton chirality between the two long axes of the chromophores. The pattern of the Cotton effects also differs from that of (+)-7,14-dihydro-7,14-ethanodibenz[*a*,*h*]anthracene-15,16-dicarboxylic acid.[7] Thus, the weak ^1L_a and ^1L_b transitions are unsuitable for the exciton chirality method.

The CD spectrum of diketone **8** is of much interest because of its peculiar behavior in the exciton coupling between the two α-tetralone chromophores; the CD spectrum exhibits split Cotton effects of $\Delta\varepsilon_{275.0}=-17.4$ and $\Delta\varepsilon_{252.0}=+24.7$, correospnding to the intramolecular charge transfer transition at 261.0 nm (ε 28300) (Fig. 4).

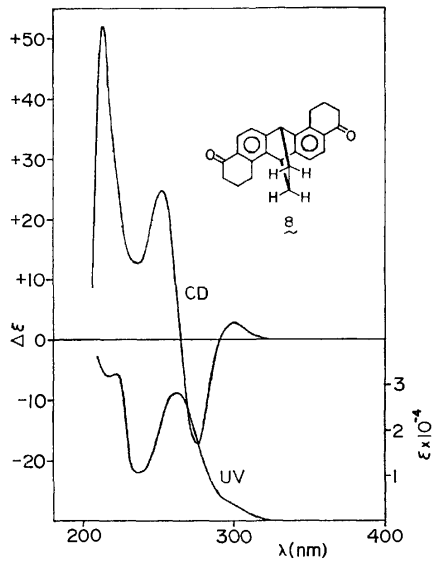

Fig. 4. CD and UV spectra of 1,2,3,7,8,9,10,14-octahydro-7,14-ethanodibenz[*a*,*h*]anthracene-4,11-dione(**8**) in ethanol.

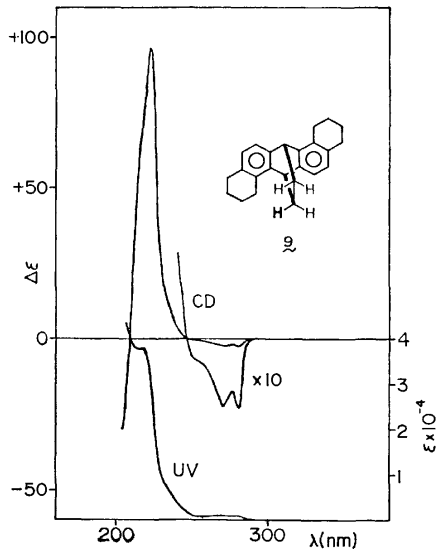

Fig. 5. CD and UV spectra of 1,2,3,4,7,8,9,10,11,14-decahydro-7,14-ethanodibenz[*a*,*h*]anthracene (**9**) in ethanol.

Since the intramolecular charge transfer band has a transition moment along the direction from benzene to carbonyl group,[8] positive exciton chirality is predicted by projection of molecular models. However, the observed sequence of the Cotton effects, *i.e.*, negative and positive, is the reverse of this prediction. A similar case has been reported for (−)-9,10-dihydro-9,10-ethanoanthracene-2,6-diamine.[7] It seems that the homoconjugation effect between the two chromophores makes dominant contribution to the sequence of energy levels.

Hydrocarbon **9** shows a strong positive Cotton effect at 222.5 nm ($\Delta\varepsilon$ +96.4) and a negative one below 209 nm (Fig. 5). Although the extremum of the negative Cotton effect could not be observed, these Cotton effects are presumably due to the exciton coupling of the allowed ^1L_a transition of the benzene chromophores. However, the transition is unsuitable for the exciton chirality method because of the ambiguity of polarization of tetra-alkylated benzene chromophore. Moreover, in the region of a forbidden ^1L_b transition around 280 nm, compound **9** merely exhibits one negative Cotton effect with vibronic structure. It is therefore impossible to determine the absolute configuration of **9** on the basis of these Cotton effects.

For determination of absolute stereochemistries by the circular dichroic method, it is important to chose a suitable electronic transition of suitable chromophores for chiral exciton coupling.

Experimental

General Procedures. Melting points are uncorrected. Spectral data were recorded on the following instruments. NMR: Jeol C-60HL, PMX60, and JNMPS-100 spectrometers; IR: Hitachi EPI-G2 infrared spectrophotometer; MS: Jeol JMS-01 SG-2 mass spectrometer; UV: Hitachi EPS-3T spectrophotometer; CD: Jasco J-20 spectropolarimeter; optical rotations: Jasco DIP-4 spectropolarimeter.

The following CD data are those of the extrema and zero line intersections.

Elemental analyses were carried out in the microanalytical laboratory of our institute.

(3-Benzyloxypropyl)triphenylphosphonium Bromide. To a solution of 2.88 g (11.0 mmol) of triphenylphosphine in 5 ml of dry xylene and 25 ml of ligroine was added 2.29 g (10.0 mmol) of benzyl 3-bromopropyl ether.[9] The reaction mixture was refluxed for 5.5 days under stirring, during which time white crystals deposited. After being cooled to room temp, the crystals were filtered, washed with petroleum ether, and dried *in vacuo*, giving 2.760 g (56%) of the phosphonium salt: IR (KBr) ν_{max} 3025, 2850, 1580, 1480, 1435, 1120, 750, 740, 720, 700 cm^{-1}.

1,5-Bis(4-benzyloxyl-1-butenyl)-9,10-dihydro-9,10-ethanoanthracene (5). To a suspension of 20 g (40.7 mmol) of (3-benzyloxypropyl)triphenylphosphonium bromide in 100 ml of dry THF cooled at −70 °C was added dropwise, over 10 min, 25 ml (1.55 mmol/ml, 38.75 mmol) of a solution of butyl lithium in hexane under nitorgen atmosphere and vigorous stirring. After the dark red reaction mixture had been stirred for 15 min at −70 °C, a solution of 731 mg (2.79 mmol) of (9*R*,10*R*)-(+)-9,10-dihydro-9,10-ethanoanthracene-1,5-dicarbaldehyde (**4**),[4] mp 128.0—129.5 °C, $[\alpha]_D$ +487.3°, in 30 ml of THF was added dropwise. The reaction mixture was stirred overnight, during which time the temperature was allowed to rise to room temp. After addition of water, the mixture was extracted with ethyl acetate and the organic layer was washed with water and brine. Evaporation of the solvent afforded 11.623 g of syrup containing a large amount of triphenylphosphine oxide, which was chromatographed on silica gel giving 1.729 g (*ca.* 100%) of bisbenzyl ether **5**: IR ($CHCl_3$) ν_{max} 3000, 2950, 2850, 1450, 1360, 1100, 700 cm^{-1}; NMR (60 MHz, $CDCl_3$) δ 1.63 (4H, br s, ethane bridge), 2.13—2.80 (4H, m, allylic), 3.33—3.77 (4H, m, α protons of ether), 4.45—4.56 (4H, m, benzylic), 5.43—6.37 (2H, m, bridge head), 6.67—7.46 ppm (20H, m, vinyl and aromatic).

9,10-Dihydro-9,10-ethanoanthracene-1,5-dibutanol (6). A mixture of 1.720 g (3.27 mmol) of bisbenzyl ether **5**, 110 ml of acetic acid, 1.0 ml of concd H_2SO_4, and 1.5 g of 5% palladium on charcoal was magnetically stirred under hydrogen atmosphere at room temp, for 35 h. After removal of the catalyst, the solution was poured into water and extracted with ethyl acetate. The organic layer was washed with water and brine, and evaporated to dryness. To the residue (0.990 g) was added a solution of 2.5 g of KOH in 50 ml of ethanol, and the mixture was gently refluxed for 3 h. After being cooled to room temp, the reaction mixture was poured into water and extracted with ethyl acetate. The organic solution was washed with brine, and evaporated to dryness yielding 0.789 g of syrup, which was subjected to preparative TLC on silica gel ($CHCl_3$–MeOH 20 : 1) giving 315 mg (28%) of glycol **6**: IR ($CHCl_3$) ν_{max} 3600, 3525—3100, 2995, 2920, 2850, 1460, 1425, 1140, 1045 cm^{-1}; NMR (100 MHz, $CDCl_3$) δ 1.68 (14H, m, hydroxyl, ethane bridge, and β and γ protons to hydroxyl group), 2.80 (4H, m, benzylic), 3.68 (4H, m, α protons to hydroxyl group), 4.58 (2H, s, bridge head), 6.82—7.28 ppm (6H, m, aromatic).

9,10-Dihydro-9,10-ethanoanthracene-1,5-dibutyric Acid (7). To a solution of 283 mg (0.807 mmol) of glycol **6** in 35 ml of acetone was added dropwise, under ice-cooling, 2.5 ml (10.03 mmol of oxygen equivalent) of Jones reagent. After being stirred at 0 °C for 3 h, water was added and the mixture was extracted with ethyl acetate. The organic layer was washed with brine, and dried over anhyd Na_2SO_4. Evaporation of the solvent gave 264 mg (86%) of dicarboxylic acid **7** as white solid: IR ($CHCl_3$) ν_{max} 3500—2400, 2930, 1700, 1270, 1140 cm^{-1}; NMR (60 MHz, $CDCl_3$) δ 1.50—2.23 (8H, m, ethane bridge and β protons to carboxyl group), 2.47 (4H, t, J=7.0 Hz, α protons to carboxyl group), 2.83 (4H, t, J=7.0 Hz, benzylic), 4.0 (2H, br s, bridge head), 6.87—7.76 ppm (8H, m, aromatic and carboxyl).

(+)-1,2,3,7,8,9,10,14-Octahydro-7,14-ethanodibenz[a,h]*anthracene-4,11-dione (8).* A mixture of 213 mg (0.563 mmol) of dicarboxylic acid **7** in 3 ml of polyphosphoric acid (prepared by dissolving 10 g of P_2O_5 in 10 ml of 85% H_3PO_4) was heated at 90—100 °C for 3.5 h under stirring. After being cooled to room temp, the reaction mixture was poured into ice-water and extracted with ethyl acetate. The organic layer was washed with brine and dried over anhyd Na_2SO_4. Evaporation of the solvent yielded 178 mg (92%) of diketone **8**: IR ($CHCl_3$) ν_{max} 2950, 1680, 1590, 1330, 1290 cm^{-1}; NMR (100 MHz, $CDCl_3$) δ 1.72 (4H, s, ethane bridge), 2.16 (4H, br quintet, J=7.0 Hz, β protons to carbonyl), 2.62 (4H, dd, J=7.0 and 6.0 Hz, α protons to carbonyl), 3.12 (4H, t, J=6.0 Hz, benzylic), 4.70 (2H, s, bridge head), 7.24 (2H, d, J=7.6 Hz, aromatic meta to carbonyl), 7.88 ppm (2H, d, J=7.6 Hz, aromatic ortho to carbonyl); $[\alpha]_D$ +184.6° (*c* 0.00325, $CHCl_3$); UV (EtOH) λ_{max} 261.0 (ε 28300), λ_{max} 221.5 nm (ε 32700); CD (EtOH) $\Delta\varepsilon_{330.0}$= +0.4, $\Delta\varepsilon_{302.0}$=+2.3 $\Delta\varepsilon_{293.0}$=0.0, $\Delta\varepsilon_{275.0}$=−17.4, $\Delta\varepsilon_{264.5}$= 0.0, $\Delta\varepsilon_{252.0}$=+24.7, $\Delta\varepsilon_{213.5}$=+51.9.

1,2,3,4,7,8,9,10,11,14-Decahydro-7,14-ethanodibenz[a,h]*anthracene (9).* A mixture of 145 mg (0.423 mmol) of diketone **8**, 0.75 ml of hydrazine hydrate, and 5 ml of diethylene glycol was heated at 100 °C for 1 h. Potassium hydroxide (900 mg) was added and the reaction mixture was heated at 200 °C for 2 h, during which time volatile materials were removed by distillation. After being cooled to room temp, the reaction mixture was poured into ice-water, acidified to pH 1 with 2M HCl, and extracted with ethyl acetate. The organic layer was washed with water and brine, and dried over anhyd Na_2SO_4. Evaporation of the solvent afforded 226 mg of syrup, which was chromatographed on silica gel (EtOAc–hexane 1 : 20) giving 35 mg (26%) of hydrocarbon **9**: IR ($CHCl_3$) ν_{max} 2920, 1450, 1430, 1140, 910 cm^{-1}; NMR (60 MHz, $CDCl_3$) δ 1.53—2.03 (12H, m, ethane bridge and methylene), 2.57—3.07 (8H, m, benzylic), 4.51 (2H, s, bridge head), 6.73 and 6.97 ppm (2H each, d, J=7.5 Hz, aromatic): UV (EtOH) λ_{max} 280.0 (ε 900), λ_{max} 270.7 (ε 900), λ_{max} 263.0 (ε 900), λ_{max} 217.5 nm (ε 37900); CD (EtOH) $\Delta\varepsilon_{280.5}$=−2.3, $\Delta\varepsilon_{270.0}$=−2.2, $\Delta\varepsilon_{246.0}$=0.0, $\Delta\varepsilon_{222.5}$= +96.4, $\Delta\varepsilon_{209.0}$=0.0; MS *m/e* 314 ($M^+$).

(+)-7,14-Dihydro-7,14-ethanodibenz[a,h]*anthracene (1).* A solution of 35 mg (0.111 mmol) of hydrocarbon **9** and 300 mg (1.32 mmol) of DDQ in 10 ml of benzene was gently refluxed for 4 h. After being cooled to room temp, excess DDQ and hydroquinone formed were removed by chromatography on silica gel. Evaporation of the solvent gave 29 mg (85%) of compound **1**: mp 234.0—235.5 °C from ethanol; IR (KBr) ν_{max} 3025, 2950, 2850, 1620, 1510 1380, 1170, 1150, 1140, 820, 805, 755, 740, 680, 535, 445 cm^{-1}; NMR (100 MHz, $CDCl_3$) δ 1.82 (4H, s, ethane bridge), 5.34 (2H, s, bridge head), 7.26—7.86 (10 H, m, aromatic), 8.28 ppm (2H, br d, J=8.0 Hz, aromatic); $[\alpha]_D$ +670.0° (*c* 0.02030, $CHCl_3$); UV (EtOH) λ_{max} 325.0 (ε 2500), λ_{max} 283.5 (ε 11100), λ_{max} 232.3 nm (ε 98200); CD (EtOH) $\Delta\varepsilon_{326}$= −4.3, $\Delta\varepsilon_{324}$=0.0, $\Delta\varepsilon_{322}$=+5.0, $\Delta\varepsilon_{304.5}$=+25.5, $\Delta\varepsilon_{291.5}$=0.0, $\Delta\varepsilon_{283.0}$=−35.6, $\Delta\varepsilon_{259.0}$=0.0, $\Delta\varepsilon_{237.0}$=+326.5, $\Delta\varepsilon_{229.5}$=0.0, $\Delta\varepsilon_{224.0}$=−180.5, $\Delta\varepsilon_{205.0}$=−115.0; MS *m/e* (relative intensity) 306 (30, M^+), 278 (100, $M-C_2H_4$).

Found: *m/e* 306.1410. Calcd for $C_{24}H_{18}$: M, 306.1409.

1,1'-(9,10-Dihydro-9,10-ethanoanthracene-1,5-diyl)di-2-propanone (10). To a cooled (−70 °C) suspension of 3.5 g (8.05 mmol) of (1-methoxyethyl)triphenylphosphonium chloride in 30 ml of dry THF was added dropwise, over 10 min,

5.4 ml (1.49 mmol/ml, 8.05 mmol) of a solution of *n*-butyl lithium in hexane under nitrogen with vigorous stirring. After the dark red reaction mixture had been stirred for 20 min at −70 °C, a solution of 175 mg (0.67 mmol) of dialdehyde (+)-**4** in 10 ml of THF was added dropwise. The reaction mixture was stirred for 14 h, during which time the temperature was allowed to rise to room temp. After addition of water, the mixture was extracted with chloroform. The organic layer was washed with water and brine, and evaporated to dryness giving 2.975 g of syrup. The syrup was dissolved in 20 ml of methanol contaning 1 ml of 0.1 M HCl, and the mixture was refluxed for 1 h. After being cooled to room temp, the reaction mixture was poured into water, and extracted with ethyl acetate. The organic layer was washed with water and brine, and evaporated to afford 3.624 g of syrup, which was chromatographed on silica gel in order to remove triphenylphosphine and triphenylphosphine oxide formed. The eluate was evaporated to dryness and the residue was subjected to preparative TLC (EtOAc-hexane, 1 : 4) giving 146 mg (69%) of crystalline diketone **10**: mp 136.5—137.5 °C from ethanol; IR (KBr) ν_{max} 2960, 2950, 1715, 1700, 1360, 1160, 785 cm^{-1}; NMR (100 MHz, $CDCl_3$), δ 1.65 (4H, s, ethane bridge), 2.09 (6H, s, methyl), 3.82 (4H, s, benzylic), 4.49 (2H, s, bridge head), 7.28 (2H, dd, J=7.0 and 2.3 Hz, aromatic), 7.40 (2H, t, J=7.0 Hz, aromatic), 7.55 ppm (2H, dd, J=7.0 and 2.3 Hz, aromatic).

Found: C, 82.99, H, 7.13%. Calcd for $C_{22}H_{22}O_2$: C, 82.98; H, 6.96%.

*Diethyl 9,10-Dihydro-β,β'-dimethyl-9,10-ethanoanthracene-1,5-dicrotonate (**11**).* To a suspension of 331 mg (13.8 mmol) of sodium hydride in dry THF was added dropwise under nitrogen and ice-cooling a solution of 4.65 g (20.7 mmol) of triethylphosphonoacetate in 2 ml of dry THF. After the clear brown reaction mixture had been stirred at room temp for 30 min, a solution of 438 mg (1.38 mmol) of diketone **10** in 1 ml of THF was added dropwise, and the mixture was stirred overnight. After addition of water, the reaction mixture was extracted with ether. The ethereal solution was washed with water and brine, and dried over anhyd Na_2SO_4. Evaporation of the solvent gave 757 mg of syrup, which was chromatographed on silica gel in order to remove excess triethylphosphonoacetate, giving 356 mg (56%) of diester **11** as syrup: IR (neat) ν_{max} 2950, 1733, 1711, 1215, 1145, 1045 cm^{-1}; NMR (60 MHz, $CDCl_3$) δ 1.05—1.45 (6H, m, methyl), 1.50—1.75 (4H, br s, ethane bridge), 1.45—2.30 (6H, m, vinyl methyl), 3.03—3.62 (4H, m, benzylic), 3.90—4.20 (6H, m, bridge head and methylene of ethoxyl group), 5.30—5.85 (1H, m, vinyl), 6.40—7.40 ppm (7H, m, vinyl and aromatic). Thus, the NMR spectrum indicates that diester **11** is a *cis,trans* isomeric mixture.

*Diethyl 9,10-Dihydro-β,β'-dimethyl-9,10-ethanoanthracene-1,5-dibutyrate (**12**).* A mixture of 356 mg (0.778 mmol) of diester **11** and 20 mg of PtO_2 in 20 ml of ethanol was magnetically stirred under hydrogen atmosphere at room temp for 4 h. Removal of the catalyst by filtration, and evaporation of the solvent afforded 348 mg (100%) of an epimeric mixture of diester **12** as syrup: IR (neat) ν_{max} 2950, 1715, 1155, 755 cm^{-1}; NMR (60 MHz, $CDCl_3$) δ 0.70—0.96 (6H, m, methyl), 1.05—1.45 (6H, m, methyl of ethoxy), 1.65 (4H, br s, ethane bridge), 2.10—2.85 (10H, m, methylene and methine) 3.85—4.35 (4H, m, methylene of ethoxy), 4.35—4.70 (2H, br s, bridge head), 6.46—7.28 ppm (6H, m, aromatic).

*9,10-Dihydro-β,β'-dimethyl-9,10-ethanoanthracene-1,5-dibutyric Acid (**13**).* Diester **12** (348 mg, 0.754 mmol) was dissolved in 20 ml of a 5% ethanolic KOH solution and the solution was gently refluxed for 3.5 h. After being cooled to room temp, the reaction mixture was acidified with 2 M HCl under ice-cooling, and extracted with chloroform. The organic layer was washed with water and brine, and dried over anhyd Na_2SO_4. Evaporation of the solvent yielded 314 mg (100%) of dicarboxylic acid **13** as syrup: IR (CCl_4) ν_{max} 3650—2200, 2950, 1705, 1430, 1405, 1290, 1220, 1140, 940 cm^{-1}: NMR (60 MHz, $CDCl_3$) δ 0.60—1.40 (8H, m, methyl and methine), 1.65 (4H, br s, ethane bridge), 1.90—2.95 (8H, m, methylene), 4.55 (2H, br s, bridge head), 6.50—7.30 (6H, m, aromatic), 8.20—8.90 ppm (2H, br s, carboxyl).

1,2,3,7,8,9,10,14-Octahydro-2,9-dimethyl-7,14-ethanodibenz[a,h]*anthracene-4,11-dione (**14**).* A mixture of 275 mg (0.678 mmol) of dicarboxylic acid **13** in 9 ml of polyphosphoric acid (prepared in the same way as described for diketone **8**) was heated at 90 °C for 1 h under stirring. After being cooled to room temp, the reaction mixture was poured into ice-water, and extracted with chloroform. The organic layer was washed with water and brine, and dried over anhyd Na_2SO_4. Evaporation of the solvent gave 281 mg of syrup, which was chromatographed on silica gel to yield 135 mg (50%) of diketone **14** as syrup: IR (CCl_4) ν_{max} 2950, 1685, 1595, 1580, 1285, 1110 cm^{-1}; NMR (100 MHz, $CDCl_3$) δ 1.23 (6H, d, J=6.0 Hz, methyl), 1.72 (4H, s, ethane bridge), 2.19—2.79 (8H, m, methylene and/or methine), 3.12—3.48 (2H, m, methylene or methine), 4.72 (2H, s, bridge head), 7.24 (2H, d, J=7.5 Hz, aromatic meta to carbonyl), 7.85 ppm (2H, d, J=7.5 Hz, aromatic ortho to carbonyl).

1,2,3,4,7,8,9,10,11,14-Decahydro-2,9-dimethyl-7,14-ethanodibenz[a,h]*anthracene (**15**).* A solution of 127 mg (0.342 mmol) of diketone **14** and 5 ml of hydrazine hydrate in 50 ml of diethylene glycol was heated at 100 °C for 30 min. Potassium hydroxide (2.5 g) was added and the reaction mixture was heated at 200 °C for 3 h, during which time volatile substances were distilled. After being cooled to room temp, the reaction mixture was poured into ice-water, acidified with 2 M HCl, and extracted with ether. The ethereal layer was washed with water and brine. Evaporation of the solvent afforded 371 mg of a mixture of yellow crystals and oil, which was recrystallized from methanol giving 68 mg (58%) of hydrocarbon **15**: mp 176.0—177.0 °C; IR (KBr) ν_{max} 2940, 2920, 2360, 1475, 1455, 1435, 825 cm^{-1}; NMR (100 MHz, $CDCl_3$) δ 1.08 (6H, d, J=6.5 Hz, methyl), 1.0—2.0 (6H, m, methylene and methine), 1.62 (4H, s, ethane bridge), 2.31 (2H, dd, J=16.8 and 10.6 Hz, benzylic), 2.73 (4H, m, benzylic), 3.06 (2H, dt, J=16.8 and 4.5 Hz, benzylic), 4.49 (2H, s, bridge head), 6.75 (2H, d, J=7.6 Hz, aromatic), 6.98 ppm (2H, d, J=7.6 Hz, aromatic).

(+)-7,14-Dihydro-2,9-dimethyl-7,14-ethanodibenz[a,h]*anthracene (**2**).* A mixture of 67 mg (0.196 mmol) of hydrocarbon **15** and 426 mg (1.88 mmol) of DDQ in 10 ml of benzene was gently refluxed for 4 h. After being cooled to room temp, excess DDQ and hydroquinone were removed by chromatography on silica gel. The eluate was evaporated and the residue was subjected to preparative TLC (petroleum ether–EtOAc 100 : 3) yielding 47 mg (72%) of hydrocarbon **2**: mp 209.5—211 °C from ethanol; IR (KBr) ν_{max} 3040, 2920, 2850, 1625, 830, 557 cm^{-1}; NMR (100 MHz, $CDCl_3$) δ 1.76 (4H, s, ethane bridge), 2.55 (6H, s, methyl), 5.26 (2H, s, bridge head), 7.15 (2H, dd, J=8.2 and 2.0 Hz, 3-H and 10-H), 7.40 and 7.49 (2H each, d, J=9.0 Hz, 5-H, 6-H, 12-H, and 13-H), 7.64 (2H, d, J=8.2 Hz, 4-H and 11-H), 8.01 ppm (2H, br s, 1-H and 8-H); $[\alpha]_D$ +786° (c 0.01005, 10% dioxane in ethanol); UV (0.18% dioxane in ethanol) λ_{max} 326.3 (ε 1000), λ_{max} 286.5 (ε 11700), λ_{max} 236.8 (ε 98100), λ_{max} 226.0 nm (ε 95300); CD (0.18% dioxane in ethanol) $\Delta\varepsilon_{326.5}=-2.3$, $\Delta\varepsilon_{324.5}=0.0$, $\Delta\varepsilon_{307.0}=+25.1$, $\Delta\varepsilon_{292.0}=0.0$, $\Delta\varepsilon_{281.0}=-18.7$, $\Delta\varepsilon_{261.0}=0.0$, $\Delta\varepsilon_{240.6}=+371.5$, $\Delta\varepsilon_{232.8}=0.0$,

$\Delta\varepsilon_{227.0}=-149.4$, $\Delta\varepsilon_{210.0}=-111.3$; MS *m/e* (relative intensity) 334 (35, M^+), 306 (100, $M-C_2H_4$).

Found: *m/e* 334.1727. Calcd for $C_{26}H_{22}$: M, 334.1720. Found: C, 92.82; H, 6.75%. Calcd for $C_{26}H_{22}$: C, 93.37; H, 6.63%.

7,14-Dihydro-2,4,9,11-tetramethyl-7,14-ethanodibenz[a,h]*anthracene (3).* To a solution of 30 mg (0.0812 mmol) of diketone **14** in 2 ml of dry THF was added dropwise 4 ml of an ethereal solution of methyl lithium (2.0 mmol) under nitrogen and ice-cooling. The reaction mixture was stirred for 2 h. After addition of ice-water, the mixture was extracted with ether. The ethereal layer was washed with water and brine, dried over anhyd Na_2SO_4, and evaporated to dryness giving 24 mg of syrup. The residue was dissolved in 20 ml benzene, to which 82 mg (0.36 mmol) of DDQ was added. The reaction mixture was gently refluxed for 3 h under stirring. After being cooled to room temp, the mixture was poured into water and extracted with ethyl acetate. The organic layer was washed with water, 1% aq KOH, and brine, and dried over anhyd Na_2SO_4. Evaporation of the solvent afforded 39 mg of syrup, which was subjected to preparative TLC on silica gel (EtOAc-hexane 1 : 20) yielding 5.5 mg (19%) of hydrocarbon **3**: mp 124.0—126.0 °C from ethanol; IR (KBr) ν_{max} 2940, 2850, 1620, 1150, 850 cm^{-1}; NMR (100 MHz, $CDCl_3$) δ 1.82 (4H, s, ethane bridge), 2.54 (6H, s, 2-CH_3 and 9-CH_3), 2.61 (6H, s, 4-CH_3 and 11-CH_3), 5.32 (2H, s, bridge head), 7.10 (2H, s, 3-H and 10-H), 7.53 (2H, d, J=8.3 Hz, 6-H and 13-H), 7.73 (2H, d, J=8.3 Hz, 5-H and 12-H), 7.96 ppm (2H, s, 1-H and 8-H); UV (EtOH) λ_{max} 293.0 (ε 16000), λ_{max} 238.0 nm (ε 116200); CD (EtOH) $\Delta\varepsilon_{311.5}=+27.5$, $\Delta\varepsilon_{296.5}=0.0$, $\Delta\varepsilon_{283.0}=-27.1$, $\Delta\varepsilon_{255.5}=0.0$, $\Delta\varepsilon_{242.0}=+340.3$, $\Delta\varepsilon_{230.5}=0.0$, $\Delta\varepsilon_{225.0}=-88.0$, $\Delta\varepsilon_{212.5}=-139.3$.

The authors thank Dr. Hiroshi Hayashi, Asahi Chemicals Industry, Co., for measurements of the mass spectra. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Peptide Syntheses with Proteinases. Fragment Condensation of ZLeuGlnGlyOH or ZGlnGlyOH with HLeuValNH$_2$ Using Metalloproteinases

Yoshikazu Isowa, Tetsuya Ichikawa, and Muneki Ohmori
Sagami Chemical Research Center, Sagamihara, Kanagawa 229
(Received June 16, 1977)

The crude preparations of microbial metalloproteinase from *Bacillus subtilis var. amyloliquefaciens* (Prolisin) catalyzed the condensation of ZLeuGlnGlyOH or ZGlnGlyOH with HLeuValNH$_2$ in the presence of the serine-proteinase inhibitor from potatoes to give the corresponding Z-penta or tetra-peptide amide in good yields in an aqueous buffer solution. Two other metalloproteinases, from *Bacillus thermoproteoliticus* (Thermolysin or Thermoase) and *Streptomyces caespitosus* (Tacynase N), also catalyzed this reaction; however, they gave poorer results than Prolisin. The yields of the coupling products were affected most by the concentration of the substrates, among the several factors investigated. Addition of a small amount of an organic solvent sometimes promoted the yield for this method.

In previous papers[1] we reported that the peptide linkage is catalytically formed by proteinases from two suitably protected amino acids and peptides and that the catalytic specificities of the enzymes are similar to those in the peptide hydrolysis. Since microbial metalloproteinases hydrolyze specifically the peptide linkage with an amino acid residue carrying a hydrophobic side chain at the amino side of the linkage,[2] they are expected to catalyze the condensation between a C-terminal protected peptide which has this amino acid residue as its N-terminal and an N-terminal protected peptide. Moreover, the proteinases do not usually catalyze the hydrolysis of esters or amides of amino acids or peptides,[2] so that appropriate use of them is very effective for the peptide synthesis.

We investigated their catalytic ability in the peptide bond formation in accordance with their characteristics in hydrolysis. In this article we report that three microbial metalloproteinases catalyze the condensation of ZGlnGlyOH or ZLeuGlnGlyOH with HLeuValNH$_2$ to give ZGlnGlyLeuValNH$_2$ (Secretin 24—27) or ZLeuGlnGlyLeuValNH$_2$ (Secretin 23—27) in good yields. The crude crops from the reaction mixture were almost pure without further purification. Furthermore, it is noticeable that even crude preparations of metalloproteinase were effective in the reaction, under the condition of using serineproteinase inhibitor from potatoes.

Materials and Methods

All amino acids used are of the L configuration. The following abbreviations are used: PU=protease unit; EDTA =ethylenediaminetetraacetic acid; Tris=tris(hydroxymethyl)-methanamine; Z=benzyloxycarbonyl; BOC=*t*-butoxycarbonyl; OSu=*N*-hydroxysuccinimide ester; DCCI=dicyclohexylcarbodiimide; DCU=*N,N'*-dicyclohexylurea; HOBt=1-hydroxybenzotriazole. Thin layer chromatography was performed on precoated TLC plates Silica Gel 60 F254 (from Merck) using the following solvent system: *s*-BuOH-3% aqueous ammonia (8 : 3 by vol). See Ref. 1b for other analytical procedures, execpt that here the UV spectra for the assaying of the protease activity of the proteinases were determined on a Hitachi Recording Spectrophotometer 323.

Serineproteinase Inhibitor from Potatoes. The crude inhibitor (115 g) was obtained by the method of Melville and Ryan[3] from potatoes (60 kg) and used without further purification. This inhibitor will be called potato inhibitor here after in this article.

Proteinases. All proteinases were used without further purification. Protease activity was assayed at pH 7.2 using Hammarsten casein (Merck) by the method of Tsuru *et al.*[4] Thermolysin and Thermoase were dissolved in 0.2 M AcONa–0.2 M Ca(OAc)$_2$ aqueous solution (pH 8.1) and the others in 5×10^{-3} M Ca(OAc)$_2$ aqueous solution. Protease activity was also assayed in the presence of 1/500 M EDTA or of potato inhibitor.

Prolisin:[5] Two lots of Prolisin obtained from *Bacillus subtilis var. amyloliquefaciens* were purchased from Ueda Chemical Co. (Neyagawa, Osaka) and characterized as follows. One of the preparations, which was manufactured May 19, 1976 and stated to have a protease activity of 7.7×10^5 PU/g, was demonstrated to contain metalloproteinase, serineproteinase, amylase, and other proteins and showed the protease activity of 1.9×10^6 PU/g according to Tsuru's method. This specimen of the Prolisin will be called Prolisin A hereafter in this article. The protease activity was 1.45×10^6 PU/g in the presence of potato inhibitor in 10 times the weight of the enzyme (Table 1) and was 5.1×10^5 PU/g in the presence of 1/500 M EDTA. Hence the rough ratio between metallo- and serineproteinase was 14 : 5 PU/PU. The other preparation, which was manufactured on February 8,

Table 1. Protease activity of proteinases in the presence of potato inhibitor

	P.I.: Proteinase wt/wt	Activity PU/g
Prolisin A	0	1.90×10^6
	1:1	1.73
	5:1	1.60
	10:1	1.49
	50:1	1.49
Prolisin B	0	7.2×10^5
	1:2	5.6
	1:1	5.4
	3:2	5.4
Tacynase N	0	2.60×10^5
	1:1	2.47
	3:1	2.37
	5:1	2.33
	10:1	2.30
Thermoase	0	4.0×10^6
	1:1	3.7
	3:1	3.2
	5:1	3.1

1975 and stated to have the activity of 3.0×10^5 PU/g, was found to contain metalloproteinase, serineproteinase, a small amount of amylase, other proteins, and starch as an excipient in about 65% of the weight and exhibited a protease activity of 7.2×10^5 PU/g according to Tsuru's method. This specimen of the Prolisin will be called Prolisin B hereafter in this article. The protease activity was 5.4×10^5 PU/g in the presence of potato inhibitor in equal weight of the enzyme (Table 1) and was 1.6×10^5 PU/g in the presence of 1/500 M EDTA. Hence the rough ratio between metallo- and serineproteinase was 27 : 8 PU/PU.

Tacynase N[6] *(with a Stated Protease Activity of* $\geqslant10^5$ *PU/g)*: This enzyme preparation obtained from *Streptomyces caesptitosus* was purchased from Kyowa Hakko Kogyo Co. (Tokyo, Japan) and found to show a protease activity of 2.6×10^5 PU/g according to Tsuru's method. The enzyme was slightly inhibited by potato inhibitor in 10 times the weight of the enzyme (2.3×10^5 PU/g) (Table 1) and almost completely inhibited by 1/500 M EDTA ($<6\times10^3$ PU/g)

Thermolysin[7] *and Thermoase*: Both enzyme preparations obtained from *Bacillus thermoproteoliticus* were purchased from Daiwa Kasei Co. (Osaka, Japan). Thermoase was an unpurified specimen and its protease activity, which was stated to be 1.6×10^6 PU/g, was found to be 4.0×10^6 PU/g according to Tsuru's method and was reduced to 3.1×10^6 PU/g in the presence of potato inhibitor in 5 times the weight of the enzyme (Table 1) and to 8.5×10^5 PU/g in the presence of 1/500 M EDTA. Thermolysin was the enzyme purified from Thermoase; its protease activity, which was stated to be 8.0×10^6 PU/g, was shown to be 1.8×10^7 PU/g according to Tsuru's method.

Detection and Inhibition of Esterase Action of Crude Proteinase Preparations. The esterase action was detected by observing the drop in pH, on addition of proteinase, of a solution of 0.1 M HPheOEt·HCl (10 ml). The pH had been previously adjusted at 7.0 with 1 M NaOH. The esterase action of Prolisin A,B, and Thermoase were repressed almost completely by the potato inhibitor in 3 times, equal, and equal weight of the enzyme (Table 2); however, that of Tacynase N was not completely inhibited by the potato inhibitor even in 5 times the weight of the enzyme (Table 2). Accordingly, the enzymatic syntheses of peptides with Prolisin A, B, and Thermoase were carried out in the presence of the potato inhibitor in 3 times, equal, and equal weight of the enzyme for 3—17 h, while that with Tacynase N in the presence of the inhibitor in equal weight of the enzyme for 3 h. Thermolysin has scarcely any esterase action, so that the condensation with Thermolysin was carried out in the absence of the potato inhibitor.

Table 2. Inhibitory effect of potato inhibitor on the esterase action of proteinases[a]

	P.I.: Enzyme wt/wt	pH		
		0.5 h	3 h	17 h
Prolisin A	0	4.8	4.1	3.9
	3:1	6.9	6.8	6.4
	5:1	7.0	6.9	6.4
		3/4 h	4 h	20 h
Prolisin B	0	4.6	4.1	4.0
	1:2	6.9	6.8	6.8
	1:1	6.9	6.9	6.9
		1 h	2.5 h	8 h
Tacynase N	0	6.6	5.7	4.8
	1:1	6.7	6.2	5.6
	5:1	6.8	6.5	6.0
		1.5 h	3 h	24 h
Thermoase	0	6.2	5.4	4.1
	1:1	6.9	6.7	6.3
	2:1	6.9	6.8	6.5

a) Amounts of each enzyme used: Prolisin A, 0.035 g; Prolisin B, 0.2 g; Tacynase N, 0.2 g; Thermoase, 0.1 g.

The Enzymatic Syntheses of Peptides (General Procedure). Appropriate amounts of an enzyme and, when necessary, of potato inhibitor were dissolved in an adequate volume of buffer (unless otherwise stated 0.2 M Tris–HCl buffer (pH 8, containing 5×10^{-2} M $Ca(OAc)_2$) was used) and the undissolved materials were filtered off if required. The solution was added to a mixture of a carboxyl and an amine component. Then 4 M NaOH of equimolar quantity with the amine component was added. The mixture was stirred at 38—40 °C for a certain period. The product was collected on a filter by suction, washed thoroughly in succession with 1 M aqueous ammonia, 1 M HCl, and water, and dried *in vacuo* over P_2O_5 at room temperature.

Peptide Syntheses According to the Chemical Methods. Ordinary chemical syntheses were used to prepare some peptides for substrates in the enzymatic synthesis and for the purpose of identification of the products by comparison.

HValNH₂·HCl (I): ZValNH$_2$ (50.0 g, 0.2 mol) was hydrogenated over 10% Pd–C (2 g) in MeOH (300 ml) containing 1 M HCl (21 ml). After filtering the catalyst, the filtrate was evaporated to give a white powder, which was recrystallized from MeOH and ether: yield 29.3 g (96%); mp 281—282 °C (dec); $[\alpha]_D^{24}$ +34.1° (*c* 1, MeOH).

Found: C, 39.52; H, 8.77; N, 18.38; Cl, 23.08%. Calcd for $C_5H_{13}N_2OCl$: C, 39.35; H, 8.58; N, 18.36; Cl, 23.23%.

ZLeuValNH₂ (II): To a cooled solution (−10 °C) of ZLeuOH (103.5 g, 0.39 mol) and HValNH$_2$·HCl (59.3 g, 0.39 mol) in DMF (1500 ml) were added *N*-methylmorpholine (41 g, 0.41 mol), HOBt (58.1 g, 0.43 mol), and DCCI (88.6 g, 0.43 mol) dissolved in DMF; the mixture was stirred at 0 °C for 3 h and at room temperature for 17 h. After filtering DCU, the filtrate was concentrated and water was added. The slightly brownish precipitate obtained was washed successively with 1 M aqueous ammonia, 1 M HCl, and water, air dried, and dried *in vacuo* over P_2O_5 at 60 °C to give a white powder: yield 103.3 g (72.9%); mp 238—239.5 °C; $[\alpha]_D^{20}$ −24.2° (*c* 1, AcOH) (lit,[8] mp 231—232 °C; $[\alpha]_D^{20}$ −24.4±0.5° (*c* 1.8, AcOH)).

HLeuValNH₂·HCl (III): ZLeuValNH$_2$ (17 g, 0.0468 mol) was hydrogenated over 10% Pd–C (2 g) in MeOH (200 ml) containing 1 M HCl (50 ml). After the reaction, the catalyst was removed by filtration and the filtrate was evaporated to give a white powder, which was recrystallized from MeOH and ether: yield 10.8 g (86.9%); mp 153—155 °C; $[\alpha]_D^{26}$ +28.2° (*c* 1, AcOH). Found: C, 49.87; H, 9.05; N, 15.89; Cl 13.15%. Calcd for $C_{11}H_{24}N_3O_2Cl$: C, 49.71; H, 9.10; N, 15.81; Cl, 13.34%.

ZGlnGlyOH (IV): This was obtained from ZGlnGlyOEt (18.3 g, 0.05 mol) according to the procedure described by E. Wünsch *et al.*:[8] yield 15.1 g (90%); mp 185—187 °C; $[\alpha]_D^{28}$ −2.8° (*c* 1, DMF) (lit,[8] mp 183 °C; $[\alpha]_D^{20}$ −3.1±0.5° (*c* 2, DMF)).

ZGlnGlyLeuValNH₂ (V): This was obtained from ZGlnGlyOH (20.4 g, 0.06 mol) and HLeuValNH$_2$·HCl (15.9 g, 0.06 mol) according to the procedure described by E. Wünsch *et al.*:[8] yield 25.5 g (77.5%); mp 243.5—246 °C; $[\alpha]_D^{30}$ −26.0° (*c* 1, AcOH); R_f 0.75. (lit,[8] mp 239.5—240.5 °C; $[\alpha]_D^{20}$ −24.6±0.5° (*c* 1.8, AcOH)). Found: C, 56.91; H, 7.39; N, 15.17%. Calcd for $C_{26}H_{40}N_6O_7$: C, 56.92; H, 7.35; N, 15.32%.

ZLeuGlnGlyOEt (VI): This was obtained according to the procedure described by E. Wünsch *et al.*[8] A solution of HGlnGlyOEt·HCl (0.05 mol equivalent) was obtained by the hydrogenation of ZGlnGlyOEt (18.2 g, 0.05 mol) over 10% Pd-C (2 g) in DMF–H_2O (250 : 70 ml) with 1 M HCl (50 ml) added portionwise to keep the solution at pH 4. After the reaction the catalyst was filtered off and to the filtrate was added DMF (100 ml). To the cooled solution (−10 °C) were added Et_3N (5 g, 0.05 mol), pyridine (3.9 g, 0.05 mol), and ZLeuOSu (18.1 g, 0.05 mol) dissolved in DMF. The mixture was stirred at −10 °C for 2 h and at room temperature for 40 h. The suspension was concentrated to give a white powder, which was washed with water thoroughly, air dried, and dried *in vacuo* over P_2O_5 at 60 °C: yield 23.0 g (96%); mp 214 °C; $[\alpha]_D^{25}$ −14.5° (*c* 1, DMF).

Found: C, 57.88; H, 7.16; N, 11.58%. Calcd for $C_{23}H_{34}N_4O_7$: C, 57.72; H, 7.16; N, 11.71%.

ZLeuGlnGlyOH (VII): A solution of ZLeuGlnGlyOEt (19.5 g, 0.04 mol) in DMF (300 ml) at 50 °C, after addition of MeOH–H_2O (100 : 50 ml), was allowed to cool to room temperature. 1 M NaOH (52 ml) was then added portionwise over 1 h, and the solution was stirred at room temperature for 2 h. After the reaction, water (100 ml) was added and undissolved materials were filtered off. The filtrate was acidified by adding Amberlite CG120 (H form, 3.5 mmol/g, 15 g) and stirring for 10 min, then the resin was filtered off. The filtrate was concentrated to syrup, which was triturated with water. The precipitate which formed was collected by suction, washed with water, air dried, and dried *in vacuo* over P_2O_5 at 60 °C: yield 16.3 g (84%); mp 185—186.5 °C; $[\alpha]_D^{20}$ −13.8° (*c* 1, DMF).

Found: C, 56.13; H, 6.89; N, 12.55%. Calcd for $C_{21}H_{30}N_4O_7$: C, 55.99; H, 6.71; N, 12.44%.

ZLeuGlnGlyLeuValNH$_2$ (VIII): *a) HGlnGlyLeuValNH$_2$·HCl (IX).* This was obtained according to the procedure described by E. Wünsch *et al.*[8] except that DMF–H_2O (3 : 1) was used as the solvent of hydrogenation in place of MeOH–H_2O (3 : 1). ZGlnGlyLeuValNH$_2$ (5.5 g, 0.01 mol) was hydrogenated in DMF–H_2O (3 : 1, 200 ml) over 10% Pd-C (0.5 g) with the addition of two 5 ml portions of 1 M HCl. The catalyst was removed and the filtrate was used immediately in the subsequent step.

b). VIII: To the cooled solution (−10 °C) obtained from the above procedure were added Et_3N (1.0 g, 0.01 mol), pyridine (0.8 g, 0.01 mol), and ZLeuOSu (4.3 g, 0.012 mol) dissolved in DMF (30 ml). The mixture was stirred for 4 h at −10 °C and for 36 h at room temperature. The reaction mixture was concentrated to give a gelatinous mass, which was washed with water three times, air dried, then washed with boiling ethyl acetate (100 ml), air dried, and dried *in vacuo* over P_2O_5 at 60 °C: yield 6.2 g (93.7%); mp 273—275 °C; $[\alpha]_D^{28}$ −33.9 ° (*c* 0.5, AcOH); R_f 0.65.

Found: C, 57.99; H, 7.53; N, 14.58%. Calcd for $C_{32}H_{51}N_7O_8$: C, 58.07; H, 7.77; N, 14.82%.

BOCLeuGlnGlyLeuValNH$_2$ (X): It was synthesized by the same procedure as in the case of the compound VIII. The compound IX obtained from the compound V (2.75 g, 0.005 mol) using 10% Pd-C (0.3 g) and 1 M HCl (5 ml) in DMF–H_2O (3 : 1, 100 ml) was allowed to react with BOCLeuOSu (2 g, 0.006 mol) in the presence of Et_3N (0.5 g) and pyridine (0.4 g): yield 2.7 g (87%); mp 237—238 °C (dec); $[\alpha]_D^{25}$ −18.4° (*c* 0.5, DMF) (lit,[8] mp 234—235 °C (dec); $[\alpha]_D^{20}$ −19.4° (*c* 1, DMF)). Found: C, 55.29; H, 8.52; N, 15.84%. Calcd for $C_{29}H_{53}N_7O_8$: C, 55.48; H, 8.51; N, 15.62%.

Results and Discussion

I. The Influence of the Nature of Buffer Solutions upon the Protease Activity of Metalloproteinase. *Bacillus subtilis* metalloproteinase had been reported to be disadvantageously affected by phosphate ions,[9] so the effect of three buffers (**A** McIlvaine, pH 7; **B** Tris–HCl, pH 7; **C** citrate buffer, pH 6.5) on the protease activity of the metalloproteinase in Prolisin was investigated using varying concentrations in the presence of potato inhibitor to suppress serineproteinase action (Table 3). Tris–HCl buffer solution reduced the activity least among the three and kept about 75% of the initial activity even after 23 h. The other two buffers were inadequate as a medium for the enzymatic synthesis of peptides. Moreover, since metalloproteinases are generally most active in the neutral pH region from 6—9.0 and the pH of the medium slightly fell toward the acidic side during the course of the reaction, it is recommended to use a buffer adjusted to the alkaline side, pH 8 being the best, and in a concentration of 0.2—0.4 M to maintain the correct pH.

Table 3. Influence of three buffers on the protease activity of Prolisin B[a]

	Buffer concn (M)		Activity remaining (%)			
			1 h	4 h	6 h	23 h
	Na_2HPO_4	Citric acid				
A	0.4	0.2	71	37	32	0
	0.2	0.1	74	55	48	0
	0.1	0.05	83	66	58	0
B	0.2		94	89	83	72
	0.1		95	91	83	75
	0.05		95	93	84	79
C	0.1		69	38	25	0
	0.05		88	68	59	21

a) A mixture of Prolisin B (0.1 g) and the potato inhibitor (0.1 g) was incubated in each buffer solution containing 2×10^{-3} M $Ca(OAc)_2$ (10 ml) at 40 °C and the protease activity was assayed at intervals.

II. The Effect of Potato Inhibitor on Commercial Crude Metalloproteinases.[10] The esterase action of crude metalloproteinase preparations probably is due to some serineproteinase which was present in the preparations. Since the serineproteinase, in addition to esterase action, shows amidase action, the crude metalloproteinases in such a condition are inadequate for the present study and must be used in the presence of some suitable serineproteinase inhibitor. Among several serineproteinase inhibitors, the potato inhibitor[11] was chosen and used, for it is attractive to use and not toxic. Consequently, the condensation between ZGlnGlyOH and HLeuValNH$_2$ with Prolisin in the presence of potato inhibitor gave the product in 75% or above of the theoretical yield (see below). On the other hand, the above reaction in the absence of the inhibitor gave a product which showed 3 spots on TLC, one of which corresponded to those of the object matter. Furthermore, though the amount of the product gradually

increased with time and reached a maximum after 3 h, it was far less than that from the reaction in the presence of the potato inhibitor.

III. Fragment Condensation of ZGlnGlyOH or ZLeuGlnGlyOH with HLeuValNH$_2$ by the Aid of Prolisin.

The enzymic condensation between ZGlnGlyOH and HLeuValNH$_2$ (Reaction 1) or ZLeuGlnGlyOH and HLeuValNH$_2$ (Reaction 2) was examined in the search for suitable coupling conditions with respect to the substrate concentration, the enzyme concentration, the reaction period, the reaction temperature, the pH of the buffer, the effect of organic solvent, and the nature of amino-protecting groups, Z or BOC.

1) The Influence of the Substrate Concentration on the Yield: When Reaction 1 was carried out at the substrate concentration of 300 mM in the presence of Prolisin A in 0.2 M Tris-HCl buffer (pH 8), the condensation product was obtained in 71 % of the theoretical yield; however, the reaction at the substrate concentration of 73 mM gave a surprisingly low yield of the product under otherwise the same conditions (Fig. 1). Reaction 2 exhibited results similar to those of Reaction 1 (Fig. 1). These findings indicate that the substrates in higher concentrations will gave better results in these reactions, but that too high a substrate concentration interrupts the progress of the reaction owing to rapid caking of the reaction mixtures.

2) The Influence of the Enzyme Concentration on the Yield: Figure 2 shows the results of Reaction 1 with enzyme concentrations increasing from 0.3—19 mg/ml at 167 (a), 235 (b), and 300 mM (c) substrate concentrations under conditions similar to those described under the heading III-1. It can safely be said that the optimal yield is reached at a rather low concentration of enzyme, *i.e.*, 1.6—3.7 mg/ml.

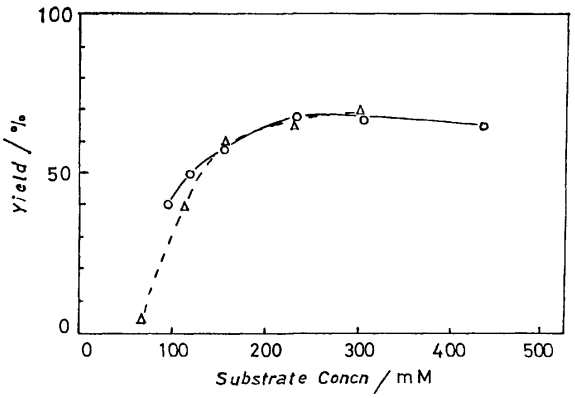

Fig. 1. The influences of substrate concentrations on the syntheses of ZGlnGlyLeuValNH$_2$ with Prolisin A and of ZLeuGlnGlyLeuValNH$_2$ with Prolisin B. Buffer solution used: 0.2 M Tris-HCl (pH 8, containing 5×10^{-2} M Ca(OAc)$_2$). △----△: An equimolar amount of ZGlnGlyOH and HLeuValNH$_2$·HCl (73—300 mM respectively), Prolisin A (4.25 mg/ml), and potato inhibitor (12.5 mg/ml) were used. The reactions were carried out according to the general procedure in the buffer (4 ml) at 40 °C for 3 h. ○——○: An equimolar amount of ZLeuGlnGlyOH and HLeuValNH$_2$·HCl (97.6—444 mM respectively), Prolisin B (24 mg/ml), and potato inhibitor (24 mg/ml) were used. The reactions were carried out according to the general procedure in the buffer at 40 °C for 17 h. Mps and R_f of all products were comparable with those of the products in the investigation III-6 (Table 4 or 5).

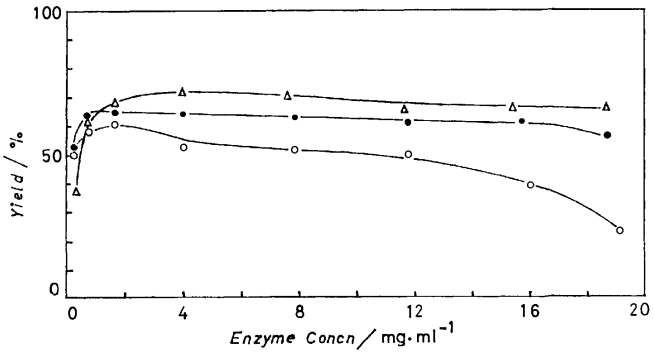

Fig. 2. The effect of enzyme concentration on the yield of ZGlnGlyLeuValNH$_2$. An equimolar amount of ZGlnGlyOH and HLeuValNH$_2$·HCl (167 (○——○), 235 (●——●), and 300 (△——△) mM respectively), Prolisin A (0.3—19 mg/ml), and potato inhibitor(0.9—57 mg/ml, Prolisin A: potato inhibitor=1 : 3 (wt/wt)) were used. The reactions were carried out in 0.2 M Tris-HCl (pH 8, containing 5×10^{-2} M Ca(OAc)$_2$, 4 ml) according to the general procedure at 40 °C for 3 h. Mps and R_f of all products were comparable with those of the products in the investigation III-6 (Table 4).

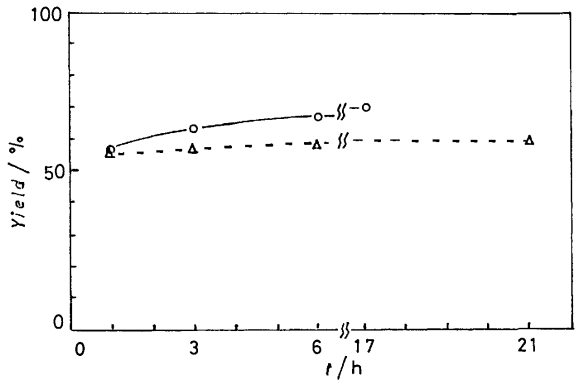

Fig. 3. The influence of the reaction period on the yield of ZGlnGlyLeuValNH$_2$ and ZLeuGlnGlyLeuValNH$_2$ with Prolisin B. The reactions were carried out in 0.2 M Tris-HCl (pH 8, containing 5×10^{-2} M Ca(OAc)$_2$) at 40 °C according to the general procedure. △----△: ZGlnGlyOH and HLeuValNH$_2$·HCl (307 mM respectively), Prolisin B(30.8 mg/ml), potato inhibitor (30.8 mg/ml), and the buffer (3 ml) were used. ○——○: ZLeuGlnGlyOH and HLeuValNH$_2$·HCl (235 mM respectively), Prolisin B (23.5 mg/ml), potato inhibitor (23.5 mg/ml), and the buffer (4 ml) were used. Mps and R_f of all products were comparable with those of the products in the investigation III-6 (Table 4 or 5).

3) The Influence of the Reaction Period on the Yield: Figure 3 illustrates the influence of the reaction period of both condensations (1—21 h) on the yield and the virtual completion of the reactions in 1 or 3 h.

4) The Influence of the Reaction Temperature on the Yield: J. D. McConn *et al.*[9] reported that the activity of *Bacillus subtilis* metalloproteinase has its maximum

at 58 °C in the presence of 5.5×10^{-4} M calcium acetate and was reduced to about 2/3 at 40 °C. However, when Reaction 1 was carried out for 3 h in the presence of Prolisin A under conditions similar to those of III-1 at 20—60 °C, the yield was almost unaffected by variations in temperature.

5) The Influence of the Buffer pH: When Reaction 2 was carried out under conditions similar to those of III-1, the change in the pH of the buffer had no perceptible influence in the range of 6.5—8.5. Therefore, in our examination of other factors influencing the peptide bond formation, the reactions were carried out always in a buffer of pH 8.

6) The Effect of Organic Solvent: Many organic solvents miscible with buffer solutions were examined for their effect on the yield of the product in both condensations under conditions similar to those of III-1 with Prolisin A or B (Tables 4 and 5). The results showed that small amounts (15% of total volume) of dioxane, *n*-BuOH, and MeOH brought about good results in both reactions and acetonitrile in one reaction; however, the addition of more solvent than 32% of the total volume gave unsatisfactory results. It is important to note that these products were generally purer than that from the reaction without organic solvent. It is not understood why better results were brought about by Prolisin A than by Prolisin B in Reaction 2.[12]

7) The Effects of the Amino-protecting Groups: As shown in Table 6, BOC for the amino-protecting group in place of Z brought about unsuccessful results under the same conditions as those of III-1. In this case organic solvents did not give the desired results, in contrast to the former two examples.

IV. Synthesis of ZGlnGlyLeuValNH$_2$ and ZLeuGlnGlyLeuValNH$_2$ with Other Enzymes. Since differences among several microbial metalloproteinases in the rate of hydrolysis of peptide bonds have been reported,[13] the above two reactions were examined further by using Thermolysin (Thermoase) and Tacynase N. The reactions were performed under the conditions most suitable for Prolisin; however, the two enzymes produced poorer results than Prolisin (Table 7). The differences observed with the three enzymes seem to correspond to those in the hydrolysis, though careful examinations will be necessary for each enzyme in view of the fact that the high concentration of Thermolysin brought about good results.

Table 4. The effect of organic solvent on the synthesis of ZGlnGlyLeuValNH$_2$[a]

Substrate (mM)	Prolisin A (mg/ml)	Inhibitor (mg/ml)	Org. solv.	Yield (%)

Conclusions

It was found that ZLeuGlnGlyOH or ZGlnGlyOH is catalytically coupled with HLeuValNH$_2$ by several metalloproteinases to give protected Secretin 23—27 or 24—27 peptide fragments in good yields. Since these reactions are performed in an aqueous solution and the crude products obtained from the reaction mixture are approximately pure in most cases, the after treatments are much easier than with the conventional methods. The lengthening of the peptide chain of a carboxyl component from 2 to 3 seemed to have no influence on the yield. The addition of a small amount of suitable organic solvents usually assisted the enzymatic reaction to give pure products in good yields.

The authors wish to express their deep gratitude to Dr. Yonezo Morino for his constant encouragement throughout the work. Their thanks are also due to Mrs. Tomoko Matsumura and Miss Noriko Shutoh for their technical assistance.

The Ullmann Condensation Reaction of Haloanthraquinone Derivatives with Amines in Aprotic Solvents. III. The Formation and Role of Copper(II) Species in the Condensation with 2-Aminoethanol by Copper(I) Catalyst

Sadao ARAI, Mitsuhiko HIDA, and Takamichi YAMAGISHI

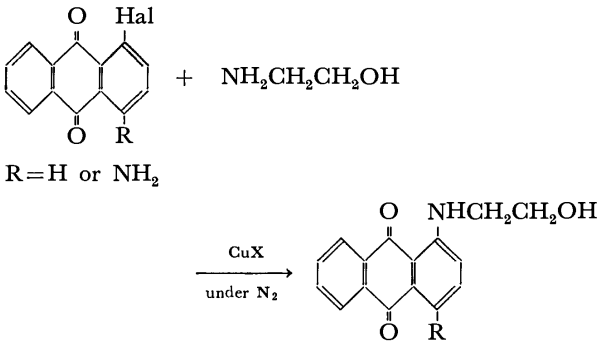
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received June 24, 1977)

The ESR spectra of the Ullmann condensation reaction system of 1-bromoanthraquinone-2-aminoethanol-CuBr showed that copper(II) species and 1-bromoanthraquinone radical anion were formed by an electron transfer from copper(I) species to 1-bromoanthraquinone. Although copper(II) species alone had little catalytic activity, the resulting copper(II) species increased the catalytic activity of the copper(I) species, and a pseudo-first order rate constant could be expressed as follows: $k=k_1[Cu^I]+k_2[Cu^I][Cu^{II}]$. According to the magnitude of k_1 and k_2C_0, where C_0 is the initial concentration of copper(I) catalyst, the reaction of haloanthraquinone with 2-aminoethanol by copper(I) catalyst can be classified into three modes. When $k_1<k_2C_0$, an induction period is present. The possible mechanisms of the cooperation between copper(I) and copper(II) species have been proposed. It has been also found that 1-bromoanthraquinone radical anion was responsible for the debromination.

In our preceding papers,[1,2] we reported that copper(II) species was formed in the Ullmann condensation reaction of haloanthraquinones with amines by using a copper(I) salt as a catalyst in aprotic solvents under a nitrogen atmosphere. The reaction rate did not remarkably decrease in spite of the formation of copper(II) species.[1] An induction period was observed in some reaction systems, such as 1-bromoanthraquinone (AQBr)–2-aminoethanol(AE)–CuBr or AQBr–AE–CuI. These results were explained by suggesting that the formation of the copper(II) species increased the catalytic activity of the copper(I) species, though the copper(II) species alone was found to have little catalytic activity for these reactions.[2] Therefore, the formation and catalytic action of the copper(II) species are considered to be a very interesting problem connected with the Ullmann condensation reaction of haloanthraquinones in aprotic media.

In this paper, the formation and role of copper(II) species will be described in more detail and we will propose the reaction mechanism of haloanthraquinones with 2-aminoethanol by copper(I) catalyst in aprotic media under a nitrogen atmosphere.



Results and Discussion

The Formation of Copper(II) Species. Previously we described that copper(I) species was oxidized to copper(II) species during the progress of the Ullmann condensation reaction of haloanthraquinones with 2-aminoethanol(AE).[1] The ESR spectra showed that

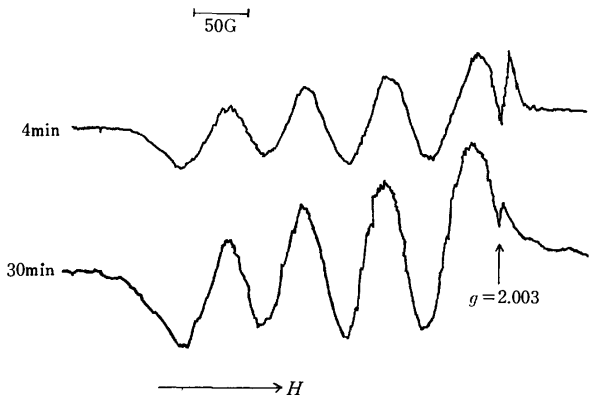


Fig. 1. ESR spectra of the reaction system of 1-bromoanthraquinone–2-aminoethanol–CuBr. $[AQBr]_0=5.00\times10^{-3}$ mol/l, $[AE]_0=0.50$ mol/l, $[CuBr]_0=2.00\times10^{-3}$ mol/l, temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4 : 1.

the formation of the copper(II) species was accompanied by an organic paramagnetic species (g value 2.003) (Fig. 1). The spectra seem to reveal that the copper(II) species is mostly present as copper(II) complex containing 2-aminoethanol in the coordination sphere, because the ESR spectra of the copper(II) species in the reaction system are very similar to that of copper(II) bromide in AE solution.

The copper(II) and organic paramagnetic species are considered to be formed by single electron transfer from copper(I) species to 1-bromoanthraquinone (AQBr) or its condensation product [1-(2-hydroxyethylamino)anthraquinone]. A mixture of the condensation product with CuBr–AE, however, gave scarcely any organic paramagnetic species and copper(II) species. The system of AQBr–CuBr–2-(dimethylamino)ethanol, which did not give any amination product, also gave copper(II) and organic paramagnetic species. These results seem to indicate that the organic paramagnetic species cannot be ascribed to a radical anion of the condensation product. Further, the organic paramagnetic species may be a 2-aminoethanol

radical cation, formed by an electron transfer from AE to the resulting copper(II) species.[3] However, this possibility can be ruled out by the finding that the ESR spectra of the system of AQBr–AE–$CuBr_2$ showed only the copper(II) species. The copper(II) species may be possibly formed by the dismutation of the copper(I) species: $2Cu(I) \rightarrow Cu(II) + Cu(0)$.[4] In the absence of 1-bromoanthraquinone, however, no copper(II) and organic paramagnetic species were observed.

Consequently, all of the experimental results indicate that the copper(II) species is not formed by the dismutation of the copper(I) species, but formed by an electron transfer from the copper(I) species to 1-bromoanthraquinone, and that the organic paramagnetic species is a 1-bromoanthraquinone radical anion ($AQBr^{\cdot-}$): $AQBr + Cu(I) \rightarrow AQBr^{\cdot-} + Cu(II)$. Single electron transfer from copper(I) species to aryl halides has been proposed in the halogen-exchange reaction between aryl halides and copper(I) salts[5] and in the Ullmann coupling reaction of *o*-bromonitrobenzene by copper(I) bromide,[6] even though the radical anions of aryl halides have not been directly detected.

In the reaction system of AQBr–AE–CuBr, anthraquinone was produced, along with the condensation product (Fig. 2). This result also seems to support the formation of $AQBr^{\cdot-}$ in the course of the reaction, since $AQBr^{\cdot-}$ can be considered to be debrominated in a similar manner to the dehalogenation of the radical anions of aryl halides: $AQBr^{\cdot-} \rightarrow AQ\cdot \rightarrow AQH$.[7] It is well known that the Ullmann condensation reaction of haloanthraquinones or aryl halides are accompanied by the dehalogenation reaction.[8-14] Although homolytic, heterolytic, or hydride transfer mechanisms have been proposed,[15] our results suggest that the radical anion, formed by an electron transfer from copper(I) species to AQBr, is mainly responsible for the dehalogenation.

After 120 min the yield of anthraquinone was only about 8%, whereas the yield of the copper(II) species was estimated as about 34% on the basis of the ESR signal height for the $CuBr_2$–AE solution. If the radical anion decays out only by its debromination, the yield of anthraquinone should be the same as that of the copper(II) species. Therefore, the 1-bromoanthraquinone radical anion should be considered to decay out only by the debromination, but by other faster decay processes,[16] such as an electron transfer to copper(II) species[17] and/or some other substance, and the dismutation,[18] although the rate of the debromination of the radical anion has remained unknown.

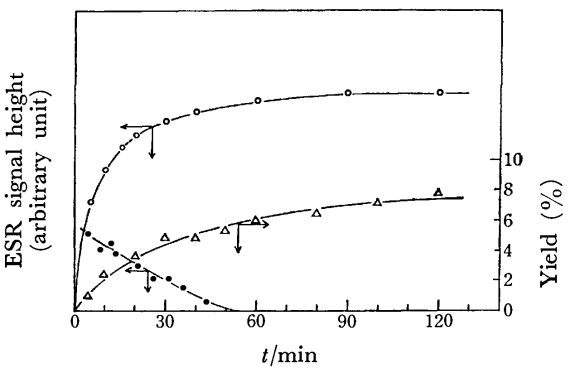

Fig. 2. The time dependence of ESR signal height and the yield of anthraquinone. $[AQBr]_0 = 5.00 \times 10^{-3}$ mol/l, $[AE]_0 = 0.50$ mol/l, $[CuBr]_0 = 2.00 \times 10^{-3}$ mol/l, temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4 : 1. ○: Cu(II) species, ●: $AQBr^{\cdot-}$., △: anthraquinone.

The Role of Copper(II) Spceies. In our preceding paper[2] we reported that the copper(II) species increased the catalytic activity of the copper(I) species, since the addition of copper(II) bromide($CuBr_2$) resulted in the vanishing of an induction period in the reaction system of AQBr–AE–CuBr. As is shown in Fig. 3, with the increase of $CuBr_2$ the pseudo-first order rate constant increases, passes through a maximum, and finally falls, when the total concentration of copper species is kept constant. Thus, the addition of copper(II) bromide increases the catalytic activity of the copper catalyst. From Fig. 3 the pseudo-first order rate constant(k_{app}) may be simply expressed by Eq. 1.

$$k_{app} = k_a(1-\alpha) + k_b\alpha(1-\alpha), \quad (1)$$

where α denotes the mole fraction of the copper(II) bromide. However, if k_a and k_b are assumed to be constant, Eq. 1 cannot reproduce the plot in Fig. 3. Because of the addition of copper(II) bromide as copper(II) species, the bromide ions were present in a larger amount than an equivalent to the copper concentration. Thus, the pseudo-first order rate constant seems likely to be affected by the presence of the excess bromide ions.

If k_a is assumed to be unaffected by the presence of the excess bromide ions, it can be estimated from the intercept of the plot of the pseudo-first order rate constant(k_{app}) against α. Then k_b can be given as a function of the concentration of the excess bromide ions by substituting the value of k_a in Eq.1. The rate constant k_b decreases linearly with increasing of the concen-

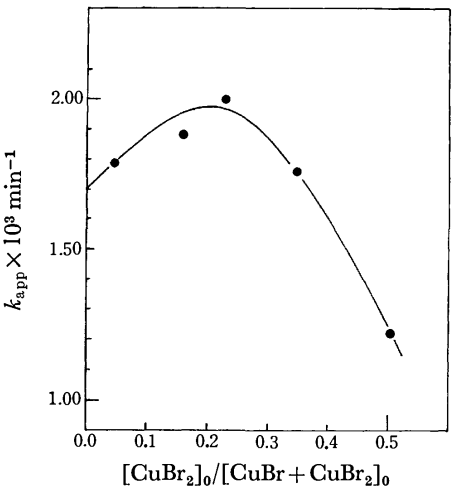

Fig. 3. The effect of the addition of $CuBr_2$ on pseudo-first order rate constant (k_{app}). $[AQBr]_0 = 5.00 \times 10^{-3}$ mol/l, $[AE]_0 = 0.50$ mol/l, $[CuBr + CuBr_2]_0 = 2.00 \times 10^{-3}$ mol/l, temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4 : 1. The full circles represent the experimental values. The solid line represents the curve calculated by Eq. 3.

tration of the excess bromide ions (Eq. 2).

$$k_b = k_{bo}(1-\beta), \quad (2)$$

where β is the excess of bromide ions. By combining Eq. 1 with Eq. 2 the pseudo-first order rate constant (k_{app}) is given by Eq. 3:

$$k_{app} = \{k_a + k_{bo}(1-\beta)\alpha\}(1-\alpha). \quad (3)$$

The solid curve in Fig. 3 represents the result calculated according to Eq. 3 by assuming that k_a and k_b are 1.7×10^{-3} and 3.9×10^{-3} min^{-1}, respectively.

In order to confirm the effect of the excess bromide ions, tetraethylammonium bromide was added to the reaction mixture. As shown in Table 1, k_{app} decreased clearly by the addition of tetraethylammonium bromide. The calculated values of k_{app} by using Eq. 3 were close to the observed ones, though the reason for the effect of the excess bromide ions is not yet clearly understood.

Table 1. Effect of the excess bromide ion on pseudo-first order rate constants(k_{app})[a]

$\frac{[CuBr_2]_0}{[CuBr]_0+[CuBr_2]_0}$	k_{app}(min^{-1}) Controlled	Addition of $(C_2H_5)_4N^+Br^-$ [b] Obsd	Calcd[c]
0.063	1.82×10^{-3}	1.71×10^{-3}	1.71×10^{-3}
0.158	1.88×10^{-3}	1.77×10^{-3}	1.70×10^{-3}

a) $[AQBr]_0=5.00\times10^{-3}$ mol/l; $[AE]_0=0.50$ mol/l; $[CuBr]_0+[CuBr_2]_0=2.00\times10^{-3}$ mol/l; temp 70°C; solvent 1,2-dimethoxyethane-methyl cellosolve 4 : 1. b) The excess of bromide is 1.0×10^{-3} mol/l. c) The values calculated by Eq. 3.

These experimental results tell us that the kinetics of the Ullmann condensation reaction cannot be described in terms of the action of copper(I) catalyst alone. Thus, on the basis of the above considerations, the rate law is assumed to be expressable as follows:

$$-\frac{d[AQBr]}{dt} = k_1[Cu^I][AQBr] + k_2[Cu^I][Cu^{II}][AQBr] + k_3[Cu^{II}][AQBr] + k_0[AQBr]. \quad (4)$$

Since k_3 and k_0 are very small compared to k_1 and k_2, both k_3 and k_0 may be neglected. Therefore, the pseudo-first order rate constant can be expressed by Eqs. 5 and 6.

$$k = k_1[Cu^I] + k_2[Cu^I][Cu^{II}], \quad (5)$$

$$k = k_1C_0 + (k_2C_0-k_1)[Cu^{II}] - k_2[Cu^{II}]^2, \quad (6)$$

where C_0 denotes the concentration of total copper or the initial concentration of copper(I) catalyst. Differentiating Eq. 6 by time t, Eq. 7 is derived.

$$\frac{dk}{dt} = (k_2C_0-k_1-2k_2[Cu^{II}])\frac{d[Cu^{II}]}{dt} \quad (7)$$

Since the rate constant has a maximum value, in such a case an induction period is observed:

$$k_2C_0 - k_1 - 2k_2[Cu^{II}] = 0. \quad (8)$$

Thus,

$$[Cu^{II}]_{max} = (k_2C_0-k_1)/2k_2 \quad (9)$$

where $[Cu^{II}]_{max}$ is the concentration of copper(II) species which gives the maximum rate constant(k_{max}). When $k_1<k_2C_0$,

$$k_{max} = \left(C_0-\frac{k_2C_0-k_1}{2k_2}\right)\left(k_1+\frac{k_2C_0-k_1}{2}\right). \quad (10)$$

Therefore,

$$\sqrt{k_{max}} = \frac{\sqrt{k_2}}{2}C_0 + \frac{k_1}{2\sqrt{k_2}}. \quad (11)$$

Consequently, when $k_1<k_2C_0$, the induction period will be present and the rate constant will have a maximum value. If the above assumption is valid, a linear relationship between $\sqrt{k_{max}}$ and C_0 will be obtained. Figure 4 shows that the relationship indicates a good linearity, when C_0 is larger than k_1/k_2 obtained from the intercept on the abscissa axis. This result suggests that the above assumption is valid. The rate constants (k_1 and k_2) are determined from the slope and intercept of the line, as shown in Table 2. By comparing Eq. 3 with Eq. 6, it is obvious that k_1C_0 and $k_2C_0^2$ correspond to k_a and k_{bo} in Eq. 3, respectively. In the reaction system of AQBr–AE–CuBr, the rate constant $k_a(1.7\times10^{-3})$ is nearly equal to the value k_1C_0 (1.778×10^{-3}), while k_{ob} (3.9×10^{-3}) is approximate to $k_2C_0^2$ (3.088×10^{-3}).

k_2(l^2·mol^{-2}·min^{-1})	772	332	2015	1685

Temp 70°C; solvent 1,2-dimethoxyethane-methyl cellosolve 4 : 1.

The time dependence of the copper(II) species concentration can be well expressed by Eq. 12, if the intensity of ESR signal is proportional to the copper(II) species concentration.

$$[Cu^{II}] = a(1-e^{-\gamma t}) \quad (12)$$

By combining Eq. 6 with Eq. 12 and integrating, Eq. 13 can be derived, if the amount of the debrominated product can be assumed to be negligible.

$$-\ln(1-x) = A(1-e^{-2\gamma t}) + B(1-e^{-\gamma t}) + Ct \quad (13)$$

where x denotes the yield of the aminated product, and where A, B, and C are $-a^2k_2/2\gamma$, $(a/\gamma)\{k_1+k_2\cdot(2a-C_0)\}$, and $(k_1+ak_2)(C_0-a)$, respectively.

At the amine concentration of 0.5 mol·l^{-1} in the reaction system of AQBr–AE–CuBr, k_1, k_2, a, and γ are given as follows: 0.889, 772, 6.8×10^{-4}, and 0.082. Figure 5 shows that the calculated values are in good agreement with the experimental data.

As shown in Table 3, k_1 increases with the increase in the concentration of 2-aminoethanol, but the reverse is found in the value of k_2. When the initial concentration of copper(I) catalyst was kept constant, the induction period was shortened with the increase in the concentration of amine and it was absent at high concentrations of amine, as reported previously.[2] In the reaction system of 1-iodoanthraquinone–AE–copper(I) salt and AQBr–AE–$[Cu(CH_3CN)_4]ClO_4$, the induction period was absent.[2] The presence of the induction period would be ascribed to the catalytic activity of copper(I) species, the reactivities of haloanthraquinones, and the degree of contribution of copper(II) species as a promoter. According to the magnitude of k_1 and k_2C_0, the reaction between haloanthraquinone and 2-aminoethanol by copper(I) catalyst can be classified into three modes, as illustrated in Fig. 6. That is to say, when $k_1<k_2C_0$, an induction period will be present, but when $k_1>k_2C_0$, the reaction rate decreases with the formation of copper(II) species. In the case of the constant concentration of amine, the induction period was shortened with the increase in the concentration of copper(I) catalyst. This result also supports the classification of the reaction mentioned above.

Reaction Mechanism. As described in Table 3, the rate constant k_1 increased with the increase in the concentration of amine. The plot of $1/k_1$ against 1/[AE] gave a good straight line(Fig.7). On the other hand, the rate constant k_2 decreased with the increase in the concentration of amine. The plot of $1/k_2$ against [AE] gave a good straight line (Fig. 8).

All of the results mentioned above can be reasonably explained by assuming the following mechanism.

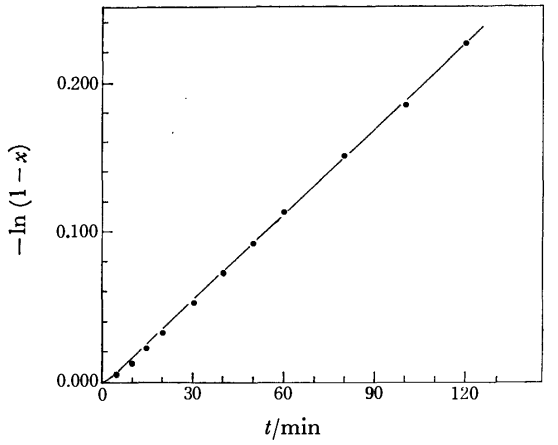

Fig. 5. Pseudo-first order plots for the reaction of 1-bromoanthraquinone with 2-aminoethanol by CuBr catalyst.
$[AQBr]_0=5.00\times10^{-3}$ mol/l, $[AE]_0=0.50$ mol/l, $[CuBr]_0=2.00\times10^{-3}$ mol/l, temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4 : 1. The full circles represent the experimetal values. The solid line represents the curve calculated by Eq. 13.

Thus, copper(I) species is supposed to be in equilibrium among Cu^I, Cu^I(AE), and Cu^I(AQBr). The reaction of Cu^I(AQBr) and AE gives an amination product. On the other hand, the copper(II) species formed in the course of the reaction is in equilibrium between Cu^{II} and Cu^{II}(AE). Cu^I(AQBr) reacts with Cu^{II}(AE) to give the product.

$$\left.\begin{array}{l} Cu^I + AE \overset{K_1}{\rightleftharpoons} Cu^I(AE) \\ Cu^I + AQBr \overset{K_2}{\rightleftharpoons} Cu^I(AQBr) \xrightarrow[k_r]{AE} \text{Product} \\ Cu^{II} + AE \overset{K_1'}{\rightleftharpoons} Cu^{II}(AE) \\ Cu^I(AQBr) + Cu^{II}(AE) \xrightarrow[k_r']{} \text{Product} \end{array}\right\} \quad (14)$$

On the basis of this reaction scheme (Eq. 14) the rate constant k_1 is expressed by Eq. 15, while k_2 is expressed by Eq. 16.

$$k_1 = \frac{k_r K_2[AE]}{1+K_1[AE]+K_2[AQBr]} \quad (15)$$

$$k_2 = \frac{k_r' K_2}{1+K_1[AE]+K_2[AQBr]} \cdot \frac{K_1'[AE]}{1+K_1'[AE]} \quad (16)$$

Previously we reported that the pseudo-first order plots were independent of the initial concentration of haloanthraquinone.[2] Therefore, $K_2[AQBr]$ can be supposed to be much smaller than unity: $K_2[AQBr] \ll 1$. In addition, Fig. 9 shows that k_1/k_2 is proportional to the concentration of 2-aminoethanol. This result indicates that $K_1'[AE]$ is much larger than unity: $K_1'[AE] \gg 1$. Thus, Eqs. 15 and 16 can be rewritten as follows:

$$k_1 = \frac{k_r K_2[AE]}{1+K_1[AE]} \quad (17) \quad \text{or} \quad k_1^{-1} = \frac{1}{k_r K_2}\left(\frac{1}{[AE]} + K_1\right), \quad (18)$$

$$k_2 = \frac{k_r' K_2}{1+K_1[AE]} \quad (19) \quad \text{or} \quad k_2^{-1} = \frac{1}{k_r' K_2}(1+K_1[AE]). \quad (20)$$

Therefore,

$$(k_1/k_2) = (k_r/k_r')[AE] \quad (21)$$

Both $k_r K_2$ and K_1 can be evaluated by the slope and the intercept of the straight line in the plot of $1/k_1$ against $1/[AE]$ (Fig. 7), and $k_r' K_2$ and K_1 from the straight line in the plot of $1/k_2$ against [AE] (Fig. 8). The values of K_1 evaluated independently from Eqs. 18 and 20 are nearly equal (Table 4). Since the equilibrium between Cu^I and AE does not include haloanthraquinone, there should not be any difference in the magnitude of K_1 between haloanthraquinones (1-bromoanthraquinone and 1-amino-4-bromoanthraquinone). Table 4 shows that this is the case.

The value of k_r/k_r' given by the ratio between $k_r K_2$ and $k_r' K_2$ agrees with the slops of the linear plot of k_1/k_2 against the concentration of 2-aminoethanol. This result also supports the above mechanism. Table 4 also tells us that both values of $k_r K_2$ and $k_r' K_2$ of 1-amino-4-bromoanthraquinone are greater than those of 1-bromoanthraquinone. We reported previously that the latter was more reactive toward 2-aminoethanol in

$k_r' K_2$(l^2·mol^{-2}·min^{-1})		0.127×10^4	0.326×10^4
k_r/k_r'	(from Figs. 7 and 8)	2.55×10^{-3}	1.18×10^{-3}
	(from Fig. 9)	2.33×10^{-3}	1.00×10^{-3}

Temp 70 °C; solvent 1,2-dimethoxyethane–methyl cellosolve 4 : 1.

the absence of copper(I) than the former was, while the reverse was found in the presence of the catalyst.[1] This is mainly caused by the fact that 1-amino-4-bromoanthraquinone possesses larger values of $k_r'K_2$ than 1-bromoanthraquinone does.

Another possible mechanism for the cooperation between copper(I) and copper(II) species can be a complex formation between them. Even if this is the case, however, k_1 can be expressed by Eq. 17, and k_2 by Eq. 19 rewritten by replacing k_r' with $k_r'K_c$, where K_c is the formation constant of the assumed complex between copper(I) and copper(II).

Several variations of the mechanism which satisfy the experimental results could be considered. However, it is difficult to decide which of these mechanisms is valid.

Experimental

The 1-bromoanthraquinone, 1-amino-4-bromoanthraquinone, 1-(2-hydroxyethylamino)anthraquinone, and copper(I) halides were prepared by the methods described in the previous paper.[1] The copper(II) bromide, 2-aminoethanol, and tetraethylammonium bromide were purified according to the usual methods. Commercial guaranteed reagent grade 2-(dimethylamino)ethanol was distilled, and stored under a nitrogen atmosphere. Solvents were dried in the usual manner, distilled, and stored under a nitrogen atmosphere.

The kinetic measurements were the same as those given previously.[1] The anthraquinone formed in the course of the reaction was analyzed by the use of a Shimadzu Du Pont LC-1 high speed liquid chromatograph(column: Zorbax ODS; mobile phase: methanol-water 67 : 33) with 1-methylaminoanthraquinone as the internal standard.

The ESR spectra were measured at 70 °C under a nitrogen atmosphere by the use of a JEOL-PE-3X ESR spectrometer, and the g value was calculated by comparison with a Mn^{2+} marker. Field and modulation width were 3360±500 and 6.3 G, respectively.

Studies on the Syntheses of Sesquiterpene Lactones. I. Chemical Transformation of α-Santonin into Vulgarin, C_4-Epivulgarin, and Arglanine*

Masayoshi Ando, Atsushi Akahane, and Kahei Takase

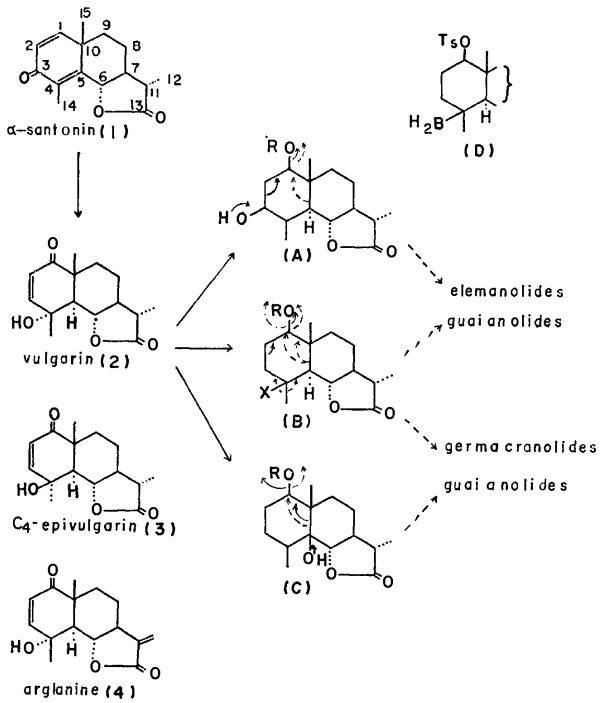
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-aza-Aoba, Sendai 980

(Received July 1, 1977)

Syntheses of vulgarin, C_4-epivulgarin, and arglanine are reported. An efficient conversion of 3-oxo-5αH, 4β,6β, 11βH-eudesm-1-en-6,13-olide into 1-oxo-5αH,4β,6β,11βH-eudesm-2-en-6,13-olide, a key intermediate of these syntheses, was achieved by the Meerwein-Ponndorf reaction and the allylic rearrangement of the resultant 3-hydroxyl derivative followed by the Collins oxidation. Acetalization of 1-oxo-5αH,4β,6β,11βH-eudesm-2-en-6,13-olide and successive isomerization of the double bond gave 1,1-ethylenedioxy-5αH,6β,11βH-eudesm-3-en-6,13-olide regioselectevity. Oxidation of this compound with OsO_4 gave 3α,4α-dihydroxy-1,1-ethylenedioxy-5αH,6β,11βH-eudesman-6,13-olide, 3α,4α-dihydroxy-1-oxo-5αH,6β,11βH-eudesman-6,13-olide and 3β,4β-dihydroxy-1,1-ethylenedioxy-5αH,6β,11βH-eudesman-6,13-olide. Oxidation of 1,1-ethylenedioxy-5αH,6β,11βH-eudesm-3-en-6,13-olide with *m*-chloroperoxybenzoic acid gave 3α,4α-epoxy-1,1-ethylenedioxy-5αH,6β,11βH-eudesm-6,13-olide stereoselectively in a quantitative yield. Treatment of 3α,4α-dihydroxy-1,1-ethylenedioxy-5αH,6β,11βH-eudesman-6,13-olide,3α,4α-dihydroxy-1-oxo-5αH,6β,11βH-eudesman-6,13-olide, and 3α,4α-epoxy-1,1-ethylenedioxy-5αH,6β,11βH-eudesm-6,13-olide with boiling 50% AcOH gave vulgarin. The same treatment of 3β,4β-dihydroxy-1,1-ethylenedioxy-5αH,6β,11βH-eudesman-6,13-olide gave C_4-epivulgarin. Phenylselenenylation of 3α,4α-dihydroxy-1,1-ethylenedioxy-5αH,6β,11βH-eudesman-6,13-olide and successive syn-elimination of the resultant phenylseleno lactone gave 3α,4α-dihydroxy-1,1-ethylenedioxy-5αH,6βH-eudesm-11-en-6,13-olide, which was transformed into arglanine by treatment with boiling 50% AcOH.

The sesquiterpene lactones with α-methylene-γ-lactone moiety fused on various skeletons are a rapidly expanding group of natural products, comprising to date more than 400 varieties.[1] These unsaturated lactones have considerable biological activities as allergenic agents,[2] cytotoxic and antitumor agents,[3] regulators of plant growth and antimitotic activity,[4] and antischistosomal agents.[5] In all these cases, the α-methylene-γ-lactone unit has been assigned a central role in the activity mechanism.

Efficient syntheses of these sesquiterpene lactones are a synthetic challenge which has received much attention during the past few years.[6] For the general syntheses of these sesquiterpene lactones with various skeletons, we envisioned approaches which consisted of the solvolytic rearrangements or the fragmentation reactions of the appropriately functionalized eudesmanolides, such as compounds (**A**), (**B**), and (**C**), as shown in Scheme 1. Solvolytic rearrangements of cis- and trans-decalin derivatives with an equatorial hydroxyl group at C_1 have been applied to the syntheses of guaiane-type sesquiterpenes with rather simple structures, such as bulnesol, bulnesene, and kessane.[7] The fragmentation reaction of alkyl borane derivatives[8] with a partial structure (**D**) is a well-documented reaction and has been applied to the syntheses of hedycaryol. The fragmentation of 1,4a-decalindiol monosulfonates[9] has provided an efficient route to cyclodecenones. But these solvolytic rearrangements or fragmentation reactions have not yet been applied to the syntheses of guaianolides, germacranolides, and elemanolides, probably because of the difficulties of the syntheses of appropriately functionalized eudesmanolides such as **A**, **B**, and **C**. For the syntheses of these compounds, vulgarin



Scheme 1.

(**2**) and the related compounds are considered to be useful materials. Since vulgarin available from a natural source is limited,[10] and no practical synthesis of this compound has so far been reported, we have decided to examine the syntheses of vulgarin and related compounds. In the present paper we wish to report the efficient syntheses of vulgarin (**2**),[11] C_4-epivulgarin (**3**), and arglanine (**4**),[12] from α-santonin (**1**).

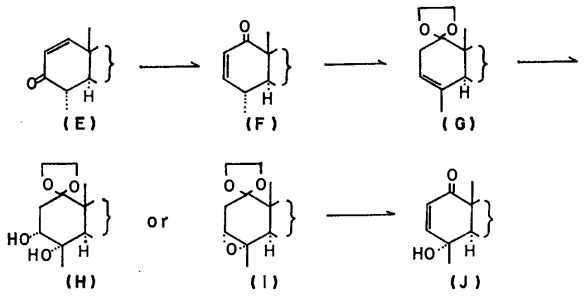
Results and Discussion

Synthesis of Vulgarin and C_4-Epivulgarin. Although one synthesis of vulgarin has been reported,[13] its final

* A preliminary report of this work was presented at the 34th Annual Meeting of the Chemical Sciety of Japan, Tokyo, April, 1976.

stages were carried out without the isolation or purification of intermediates and in very poor yield (0.5% in the last two steps). We wish to report the improved syntheses of vulgarin by two different routes starting from the α,β-unsaturated ketone (**5**) which was prepared from α-santonin by the known procedure.[14]

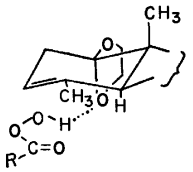
We envisioned an approach which consisted of the transfer of the oxygen function at C_3 of **5** into C_1 (**E**→**F**), protection of the carbonyl group and successive isomerization of the double bond (**F**→**G**), stereoselective oxidation of the double bond (**G**→**H** or **I**), and their transformation into vulgarin by deacetalization and simultaneous dehydration or acid-promoted opening of the epoxide (**H** or **I**→**J**).



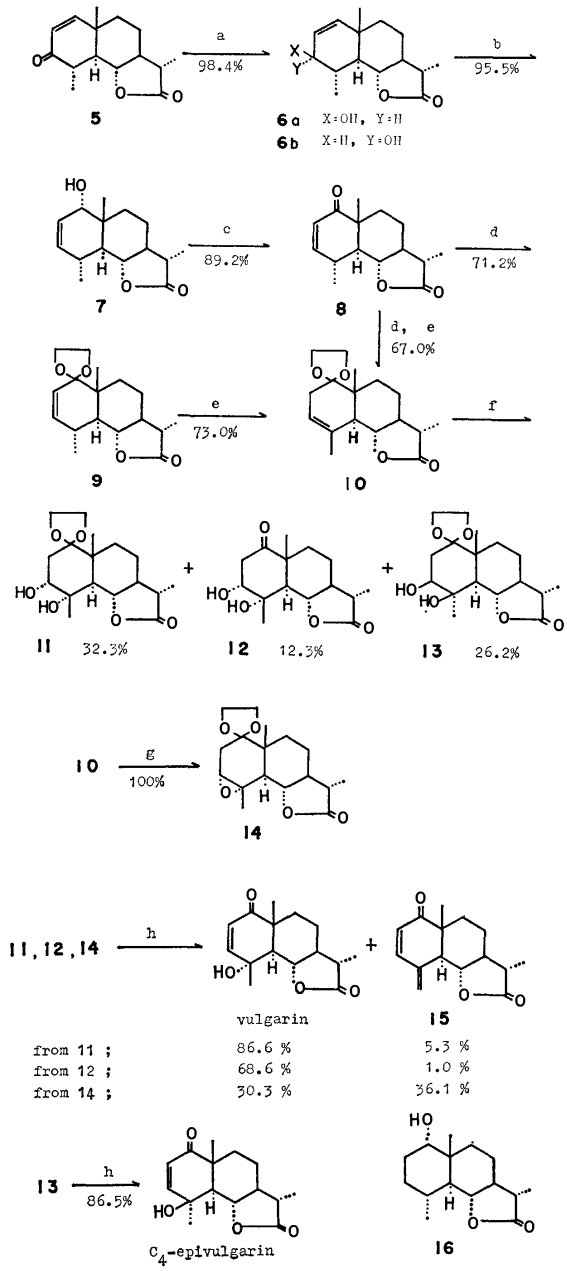
The Wharton rearrangement,[15] which involves the epoxidation of α,β-unsaturated ketone with hydrogen peroxide in alkali solution followed by the reduction of the resultant α,β-epoxy ketone with hydrazine, is a well-known reaction for the purpose of transferring the oxygen function from C_3 into C_1. Application of this method to **5** gave the desired alcohol (**7**) in poor yield (*ca.* 20%) because the γ-lactone moiety was sensitive to the reaction conditions. An efficient conversion of **5** to **7** was achieved by an alternative way. The Meerwein-Ponndorf reaction of **5** gave a 4 : 1 mixture of an allyl alcohol (**6a**) and its C_3-epimer (**6b**) in 98.4% yield.[16] Allylic rearrangement of this mixture by refluxing in THF containing 2 M HCl gave the desired allyl alcohol (**7**) stereoselectively in 78.5% yield, along with the recovery of the starting material (**6**) in 17.8% yield. (The conversion yield of **7** based on the starting material consumed was 95.5%.) The predominant formation of Δ^2-derivative (**7**) in this equilibrium reaction starting from Δ^1-derivative (**6**) is consistent with the fact that in *trans*-decalin series or 5α-steroid series Δ^2-derivatives are thermodynamically more stable than the corresponding Δ^1-derivatives.[17] α(ax)-Configuration of the hydroxyl group at C_1 in **7** was confirmed by the NMR spectrum of its dihydro derivative (**16**), which showed a peak at δ 3.37 (t, J=2.5 Hz, C_1–H) ppm. Oxidation of **7** by the Collins procedure gave an α,β-unsaturated ketone (**8**) in 89.2% yield. In agreement with the structure (**8**) the product exhibited an IR ($CHCl_3$) absorption at 1674 cm^{-1} and the NMR spectrum showed peaks at δ 5.85 (dd, J= 2.5 and 10.0 Hz, C_2–H) and 6.59 (dd, J=2.0 and 10.0 Hz, C_3–H) ppm.

Having completed the conversion of **5** to **8** in a sufficient yield (83.8%), we turned our attention to the problem of the isomerization of the double bond. Acetalization of **8** in a standard condition gave an acetal (**9**) in 71.2% yield.[18] Since it was expected that the acetal (**9**) with disubstituted double bond could be isomerized to the acetal (**10**) with a more stable trisubstituted double bond, the conditions of this isomerization reaction were investigated carefully; the best result was given by the following procedure. The double bond of **9** was isomerized by heating in ethylene glycol in the presence of *p*-toluensulfonic acid at 145 °C for 10 min, yielding **10** in 73.0%. No other double bond isomer of **10** was detected in these conditions.[19] The acetal (**10**) was also prepared in 67.0% overall yield from **8** without isolation of **9**.

Oxidation of the double bond of **10** was carried out by two different procedures and gave different results. Oxidation of **10** with osmium tetraoxide and successive treatment with hydrogen sulfide gave a mixture of an acetal (**11**) (32.3%), a ketone (**12**) (12.3%), and an acetal (**13**) (26.2%). Their stereochemistry was deduced from the coupling constant of C_3–H in their NMR spectra, as well as from the manner of reaction with osmium tetraoxide (cis addition). Since the 1,3-diaxial interaction between the 1α-oxygen of the acetal group and the entering reagent is expected in **10** because of the presence of the acetal group at C_1, the 1 : 1.7 ratio of the β face attack product (**13**) and the α face attack product (**11**+**12**) can be reasonably explained in terms of the competitive steric hindrance of the angular methyl group and the 1α-oxygen of the acetal group to the entering reagent. On the other hand, the epoxidation of **10** with *m*-chloroperoxybenzoic acid in dichloromethane proceeded stereoselectively from the α face to give 3α,4α-epoxide (**14**) in a quantitative yield. The difference of stereoselectivities between the osmylation and the epoxidation of **10** cannot be explained by simple steric factors. Probably the hydrogen-bonding interaction between *m*-chloroperoxybenzoic acid and the 1α-oxygen of the acetal group directs the α face attack of the reagent, as shown below.



Finally, the syntheses of vulgarin and C_4-epivulgarin have been completed by deacetalization and/or selective dehydration of the C_3-hydroxyl group of **11**, **12** and **13** or deacetalization and simultaneous ring opening of the epoxide (**14**). Deacetalization and selective dehydration of the C_3-hydroxyl group of **11** was accomplished by treatment with boiling 50% aqueous acetic acid for 74 h to give vulgarin in 86.6% yield. The same treatment of **12** gave vulgarin in 68.6% yield by dehydration of the C_3-hydroxyl group. The deacetalization and simultaneous opening of the epoxide ring of **14** to the expected direction was also accomplished by treatment with boiling 50% aqueous acetic acid for 65 h to give vulgarin in 30.3% yield, along with a 36.1% yield of dienone (**15**). The synthetic material was identical with the natural product in its melting point and NMR ($CDCl_3$) and IR ($CHCl_3$) spectra.[11,20] On the other hand, treatment of **13** with

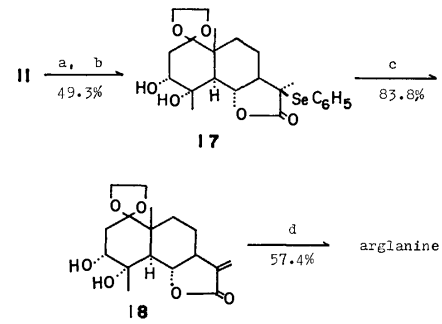


a: $Al(i\text{-}PrO)_3$, *i*-PrOH; b: 2 M HCl, THF; c: $CrO_3 \cdot 2Py$, CH_2Cl_2; d: $HO(CH_2)_2OH$, *p*-TsOH, C_6H_6; e: Δ(145 °C), *p*-TsOH, $HO(CH_2)_2OH$; f: OsO_4, aq Dioxane, H_2S; g: *m*-$ClC_6H_4CO_3H$, CH_2Cl_2; h: 50% aq AcOH.

Scheme 2.

boiling 50% aqueous acetic acid for 72 h gave the C_4-epivulgarin (**3**) in 86.5% yield. The 1,3-diaxial relationship between C_4–OH and C_{10}–Me in this compound was clearly demonstrated in the NMR spectrum, in which the signal of C_{10}–Me appeared at 0.13 ppm lower field than the corresponding signal of vulgarin.[21]

Synthesis of Arglanine. Having completed the synthesis of vulgarin, we turned our attention to the synthesis of arglanine (**4**) with an α-methylene-γ-lactone group. Recently Yamakawa *et al.* reported the chemical transformation of α-santonin into arglanine.[22] We want to report here our independent result of the synthesis of arglanine. The convenient intermediate for this purpose was the compound (**11**) in which the carbonyl group at C_1 was protected as the ethylene acetal. Conversion of α-methyl-γ-lactone group of **11** into α-methylene-γ-lactone group was accomplished by the Grieco's procedure.[23] Thus the phenylselenenylation of **11** with diphenyl diselenide afforded phenylseleno lactone (**17**) in 49.3% yield. Oxidative syn-elimination of **17** with H_2O_2 in THF–HOAc afforded α-methylene-γ-lactone derivative (**18**) in 83.8% yield. Deacetalization and successive dehydration of the C_3-hydroxyl group of **18** was accomplished by treatment with boiling 50% aqueous acetic acid for 71 h to give arglanine in 57.4% yield. The synthetic material was identical with the natural product in IR (KBr) and NMR (60 MHz, $CDCl_3$) spectra.[12]



a: $LiN(i\text{-}Pr)_2$, THF; b: $C_6H_5SeSeC_6H_5$, HMPA; c: 30% H_2O_2, AcOH; d: 50% aq AcOH.

Scheme 3.

As the total synthesis of α-santonin has been accomplished,[24] the syntheses of vulgarin, C_4-epivulgarin, and arglanine reported in this paper are the formal total synthesis of these compounds. The investigation of the chemical transformations of vulgarin and related compounds into eudesmane-type α-methylene-γ-lactones,[25] guaiane-type α-methylene-γ-lactones, germacrane-type α-methylene-γ-lactones, and elemane-type α-methylene-γ-lactones are now in progress and will be reported elsewhere.

Experimental

All the melting points were uncorrected. IR spectra were determined on a Shimadzu IRG-I spectrometer. NMR spectra were recorded on Varian A-60 and HA-100 spectrometers in $CDCl_3$ containing TMS as internal standard. Mass spectra were recorded on a Hitachi RMU-6D spectrometer with a direct inlet system operating at 25 eV.

*3-Hydroxy-5αH,4β,6β,11βH-eudesm-1-en-6,13-olide (**6**).* A solution of 3-oxo-5αH,4β,6β,11βH-eudesm-1-en-6,13-olide (**5**, 1.32 g, 5.32 mmol) and $Al(i\text{-}PrO)_3$ (5.00 g, 23.90 mmol) in dry *i*-PrOH (80 ml) was allowed to boil gently in a 200 ml flask fitted with a Vigreux column. The acetone vapor formed was allowed to escape from the reaction mixture. After 4 h *i*-PrOH was distilled and the reaction mixture was reduced to *ca.* a 10 ml volume. Cold 2 M HCl (75 ml) was added, and the resulting acidic solution was extracted with EtOAc. The combined extracts were washed successively with sat $NaHCO_3$ aq and sat NaCl aq, dried (Na_2SO_4), and concentrated *in vacuo* to give 1.31 g (98.4%) of *ca.* 4 : 1

mixture of 3β-hydroxy-5αH,4β,6β,11βH-eudesm-1-en-6,13-olide (**6a**) and 3α-hydroxy-5αH,4β,6β,11βH-eudesm-1-en-6,13-olide (**6b**) as a mixture of plates and needles; mp 159—165 °C. IR (KBr): 3510 and 1750 cm^{-1}. NMR: δ 5.57 (s, 1.6H, C_1- and C_2-H of **6a**) and 5.71 (m, 0.4H, C_1- and C_2-H of **6b**) ppm. Found: C, 71.49; H, 9.26%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

1α-Hydroxy-5αH,4β,6β,11βH-eudesm-2-en-6,13-olide (7). A solution of **6** (1096 mg, 4.25 mmol) in a mixture of THF (95 ml) and 2 M HCl (63 ml) was refluxed under N_2 for 16 h, cooled, and poured into sat NaCl aq (150 ml). The mixture was extracted with $CHCl_3$ (50 ml×3). The combined extracts were washed successively with sat $NaHCO_3$ aq and sat NaCl aq, dried (Na_2SO_4), and concentrated *in vacuo* to give an oily crude product, which was chromatographed over silica gel (Merck, 70—230 mesh, 60 g) and eluated with CCl_4–$CHCl_3$ (2 : 1). The first running gave 40 mg of 1α-chloro-5αH,4β,6β,11βH-eudesm-2-en-6,13-olide, which was recrystallized from $CHCl_3$-ether (1 : 1) to give 20 mg of colorless needles; mp 218—219 °C. IR (KBr); 1770 and 778 cm^{-1}. NMR (100 MHz): δ 1.06 (3H, s, C_{10}–Me), 1.23 (3H, d, J=6.5 Hz, C_4- or C_{11}–Me), 1.24 (3H, d, J=6.5 Hz, C_4- or C_{11}–Me), 3.83 (1H, t, J=10.0 Hz, C_6–H), 4.07 (1H, broad d, J=5.5 Hz, C_1–H), 5.58 (1H, broad d, J=10.0 Hz, C_3–H), and 5.82 (1H, broad q, J=5.5 and 10.0 Hz, C_2–H) ppm. Found: C, 66.68; H, 7.91%. Calcd for $C_{15}H_{21}O_2Cl$: C, 66.97; H, 7.87%. The second running gave 850 mg (78.5%) of **7** as an amorphous substance: mp 138 °C. IR (KBr): 3600, 3400, 1765, and 742 cm^{-1}. NMR; δ 0.90 (3H, s, C_{10}–Me), 1.22 (6H, d, J=6.5 Hz, C_4- and C_{11}-Me), 3.46 (1H, d, J=5.0 Hz, C_1–H), 3.93 (1H, t, J=10.0 Hz, C_6–H), and 5.5—6.1 (2H, m, C_2- and C_3–H) ppm. Found: C, 71.08; H, 9.00%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

The third running gave 195 mg (17.8%) of recovered starting material, which was recrystallized from ether-$CHCl_3$ to give **6a** as colorless prisms; mp 180—181 °C. IR (KBr) 3530, 1758, and 752 cm^{-1}. NMR: δ 1.08 (3H, s, C_{10}–Me), 1.20 (3H, d, J=6.8 Hz, C_{11}–Me), 1.25 (3H, d, J=6.0 Hz, C_4–Me), 2.46 (1H, s, –OH), 3.82 (1H, d, J=8.0 Hz, C_3–H), 3.93 (1H, m, $W_{h/2}$=17.0 Hz, C_6–H), 5.58 (2H, s, C_1- and C_2–H) ppm.

1-Oxo-5αH,4β,6β,11βH-eudesm-2-en-6,13-olide (8). CrO_3 (5.12 g, 51.2 mmol) was added in small portions into a mixture of dry pyridine (10.5 ml, 103 mmol) and dry CH_2Cl_2 (65 ml) at 0 °C and stirred for 10 min. Then **7** (644 mg, 2.57 mmol) dissolved in CH_2Cl_2 (50 ml) was added, and the mixture was stirred at 0 °C for 6 h and filtered. The filtrate was washed successively with sat $NaHCO_3$ aq (30 ml×3), 2 M HCl (30 ml), and sat NaCl aq, dried (Na_2SO_4), and concentrated *in vacuo* to give 586 mg of crystalline material, which was chromatographed over silica gel (Merck, <230 mesh, 27 g) and eluted with CCl_4–$CHCl_3$ (1 : 1) to give 568 mg (89.2%) of **8**. This material (334 mg) was recrystallized from ether to give 206 mg of colorless prisms; mp 110—111 °C. IR (KBr): 1768, 1668, 812, and 738 cm^{-1}. NMR: δ 1.16 (3H, s, C_{10}-Me), 1.33 (6H, d, J=7.5 Hz, C_4- and C_{11}-Me), 4.01 (1H, t, J=10.0 Hz, C_6-H), 5.85 (1H, dd, J=2.5, 10.0 Hz, C_2–H), 6.59 (1H, dd, J=2.0, 10.0 Hz C_3–H) ppm. Found: C, 72.62; H, 8.33%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

1,1-Ethylenedioxy-5αH,4β,6β,11βH-eudesm-2-en-6,13-olide (9). A mixture of **8** (320 mg, 1.28 mmol), ethylene glycol (5 ml), and *p*-toluenesulfonic acid (38 mg) in dry C_6H_6 (60 ml) was refluxed in a flask equipped with a Dean-Stark column packed with molecular sieves for 24 h under N_2. The mixture was cooled and diluted with a mixture of sat NaCl aq and sat $NaHCO_3$ aq and the benzene layer was drawn off. The aqueous layer was further extracted with EtOAc. The combined extracts were washed with sat NaCl aq, dried (Na_2SO_4), and concentrated to give 408 mg of an oil, which was chromatographed over silica gel (Wakogel C-200, 20 g) and eluted with CCl_4–$CHCl_3$ (1 : 2) to give 268 mg (71.2%) of **9**. This material was recrystallized from ether to give a crystal; mp 148—152 °C. IR (KBr): 1777 and 745 cm^{-1}. NMR: δ 1.06 (3H, s, C_{10}–Me), 1.20 (6H, d, J=6.5 Hz, C_4- and C_{11}–Me), 3.5—4.2 (m, 5H, $\langle{}^{-O}_{-O}\rangle$ and C_6–H), 5.52 (2H, m, $W_{h/2}$=2.5 Hz, C_2- and C_3–H) ppm. Found: C, 69.74; H, 8.28%. Calcd for $C_{17}H_{24}O_4$: C, 69.83; H, 8.27%.

1,1-Ethylenedioxy-5αH,6β,11βH-eudesm-3-en-6,13-olide (10) from 9. A mixture of **9** (140 mg), ethylene glycol (8 ml) and *p*-toluenesulfonic acid (17 mg) in dry C_6H_6 was refluxed in a flask equipped with a Dean-Stark column packed with molecular sieves for 1 h under N_2. C_6H_6 was removed and the residue was heated at 145 °C for 10 min under N_2, cooled, diluted with EtOAc, washed with sat NaCl aq, dried (Na_2SO_4) and concentrated to give a crude product which was chromatographed over silica gel (Merck, <230 mesh, 7 g) to give 102 mg (73%) of **10**.

1,1-Ethylenedioxy-5αH,6β,11βH-eudesm-3-en-6,13-olide (10) from 8. A mixture of **8** (438 mg, 1.77 mmol), ethylene glycol (26 ml) and *p*-toluenesulfonic acid (52 mg) in dry C_6H_6 (100 ml) was refluxed in a flask equipped with a Dean-Stark column packed with molecular sieves for 23 h under N_2. C_6H_6 was removed and the residue was heated at 145 °C for 10 min under N_2, cooled, diluted with EtOAc, washed with sat NaCl aq, dried (Na_2SO_4), and concentrated to give an oily crude product (401 mg), which was chromatographed over silica gel (Merck, <230 mesh, 20 g) and eluted with CCl_4–$CHCl_3$ (1 : 1). The first running gave 345 mg (67.0%) of **10**, which was recrystallized from ether to give colorless prisms; 130—131 °C. IR ($CHCl_3$): 1765, 892, 863, and 852 cm^{-1}; NMR: δ 1.03 (3H, s, C_{10}–Me), 1.22 (3H, d, J=6.5 Hz, C_{11}–Me), 1.85 (3H, broad s, C_4–Me), 3.5—4.2 (m, 5H, $\langle{}^{-O}_{-O}\rangle$ and C_6–H), 5.29 (1H, m, $W_{h/2}$=7.0 Hz, C_3–H) ppm. Found: C, 69.70; H, 8.27%. Calcd for $C_{17}H_{24}O_4$: C, 69.83; H, 8.27%. The second running gave 47 mg of recovered **8**.

*Oxidation of **10** with Osmium Tetraoxide; Formation of 3α,4α-Dihydroxy-1,1-ethylenedioxy-5αH,6β,11βH-eudesman-6,13-olide (11), 3α,4α-Dihydroxy-1-oxo-5αH,6β,11βH-eudesman-6,13-olide (12), and 3β,4β-Dihydroxy-1,1-ethylenedioxy-5αH,6β,11βH-eudesman-6,13-olide (13).* To a solution of **10** (885 mg, 3.0 mmol) in dry dioxane (85 ml) was added OsO_4 (800 mg, 3.15 mmol). The mixture was allowed to stand at room temperature for 72 h, then saturated with hydrogen sulfide, and filtered through a layer of celite. The filtrate was poured into sat NaCl aq (250 ml) and extracted with chloroform (100 ml×3). The combined extracts were washed successively with sat $NaHCO_3$ aq (100 ml) and sat NaCl aq (100 ml), dried (Na_2SO_4), and concentrated to give a crude semisolidal product (903 mg) which showed three spots (R_f 0.45, 0.35, and 0.20) on TLC (silica gel GF_{254}, thichness 0.25 mm, EtOAc) and was purified by preparative TLC. The first band gave 256 mg (26.2%) of **13**, which was recrystallized from $CHCl_3$-ether (1 : 1) to give colorless prisms; mp 199—200 °C. IR ($CHCl_3$): 3560, 3460, and 1768 cm^{-1}. NMR: δ 1.17 (3H, d, J=7.0 Hz, C_{11}–Me), 1.27 (3H, s, C_{10}–Me), 1.46 (3H, s, C_4–Me), 2.61 (2H, m, –OH), 3.50 (1H, q, J=6.5, 10.5 Hz, C_3–H), 3.91 (4H, m, $\langle{}^{-O}_{-O}\rangle$), 4.23 (1H, m, $W_{h/2}$=*ca.* 18 Hz,

C_6–H) ppm. Found: C, 63.00; H, 8.28%. Calcd for $C_{17}H_{26}O_6$: C, 62.56; H, 8.08%. The second band gave 104 mg (12.3%) of **12**, which was recrystallized from $CHCl_3$–ether (1 : 1) to give colorless prisms; mp 223 °C. IR (KBr) 3590, 3555, 1775, and 1718 cm^{-1}; NMR: δ 1.22 (3H, s, C_{10}–Me), 1.23 (3H, d, J=6.5 Hz, C_{11}–Me), 1.56 (3H, s, C_4–Me), 2.83—3.65 (2H, m, –OH), 3.92 (1H, t, J=4.0 Hz, C_3–H), 4.14 (1H, t, J=11.0 Hz, C_6–H). MS *m/e*: 282 (M^+). Found: C, 63.43; H, 7.88%. Calcd for $C_{15}H_{22}O_5$: C, 63.81; H, 7.85%. The third band gave 316 mg (32.3%) of **11**, which was recrystallized from $CHCl_3$–ether (1 : 1) to give colorless plates; mp 226—227 °C. IR ($CHCl_3$): 3480, 1782, and 1772 cm^{-1}: NMR: δ 1.14 (3H, s, C_{10}–Me), 1.20 (3H, d, J=6.5 Hz, C_{11}–Me), 1.34 (3H, s, C_4–Me), 3.62 (1H, m, $W_{h/2}$=6.0 Hz, C_3–H), 3.8—4.3 (5H, m, $\langle{}^{-O}_{-O}$ and C_6–H) ppm. After addition of D_2O, the signal at 3.62 ppm was changed to a triplet (J=3.4 Hz). Found: C, 62.53; H, 8.13%. Calcd for $C_{17}H_{26}O_6$: C, 62.56; H, 8.08%.

Vulgarin (Tauremisin) from ***11***. A solution of **11** (225 mg, 0.69 mmol) in 50% AcOH aq (37 ml) was refluxed for 74 h under N_2, cooled, and poured into sat NaCl aq. The mixture was extracted with $CHCl_3$ (20 ml×3). The combined extracts were washed successively with sat $NaHCO_3$ aq (10 ml×2) and sat NaCl aq, dried (Na_2SO_4), and concentrated to give 181 mg of crude crystalline material, which showed two spots (R_f 0.38, minor; R_f 0.10, major) on TLC [silica gel GF_{254}, thickness 0.25 mm, EtOAc–$CHCl_3$ (1 : 9)]. This material was purified by preparative TLC [silica gel GF_{254}, EtOAc–$CHCl_3$ (1 : 9)]. The first band gave 9 mg of 1-oxo-5αH,6β,11βH-eudesm-2,4(14)-dien-6,13-olide (anhydrovulgarin, **15**) as an crystalline material. IR ($CHCl_3$): 1775, 1670, 927, and 840 cm^{-1}. NMR: δ 1.07 (3H, s, C_{10}–Me), 1.24 (3H, d, J=6.7 Hz, C_{11}–Me), 2.83 (1H, dt, J=10.0 and 1.8 Hz, C_5–H), 4.21 (1H, t, J=10.0 Hz, C_6–H), 5.56 and 5.83 (each, 1H, m, $=\langle{}^{H}_{H}$), 5.87 (1H, broad d, J=10.0 Hz, C_2–H), 7.08 (1H, dd, J=0.8 and 10.0 Hz, C_3–H) ppm. UV (MeOH) max: 268 nm. The second band gave 158 mg (86.6%) of vulgarin (Tauremisin), which was recrystallized from ethanol to give fine needles; mp 174—175 °C (lit, 174—175 °C). This material was identical with natural vulgarin in IR ($CHCl_3$) and NMR (60 MHz, $CDCl_3$).

Vulgarin from ***12***. A solution of **12** (56 mg, 0.199 mmol) in 50% AcOH aq (10 ml) was refluxed for 74 h under N_2, cooled, and poured into sat NaCl aq. The mixture was extracted with $CHCl_3$ (10 ml×3). The combined extracts were washed successively with sat $NaHCO_3$ aq, and sat NaCl aq, dried (Na_2SO_4), and concentrated to give 43 mg of crystalline material, which was purified by the combination of preparative TLC [silica gel GF_{254}, EtOAc–$CHCl_3$ (1 : 9)] and recrystallization from ethanol to give 36 mg (68.6%) of vulgarin and 0.5 mg of **15**.

C_4-Epimer of Vulgarin (4β-Hydroxy-1-oxo-5αH,6β,11βH-eudesm-2-en-6,13-olide, ***3***). A solution of **13** (100 mg, 0.307 mmol) in 50% AcOH aq (16 ml) was refluxed 72 h under N_2, cooled, and poured into sat NaCl aq. The mixture was extracted with chloroform (10 ml×3). The combined extracts were washed successively with sat $NaHCO_3$ aq (10 ml×2) and sat NaCl aq, dried (Na_2SO_4), and concentrated to give 95 mg of crystalline material, which was purified by preparative TLC [silica gel GF_{254}, thickness 0.25 mm, EtOAc–$CHCl_3$ (1 : 9), R_f 0.14] to give 70 mg (86.5%) of C_4 epimer of vulgarin (**3**). This material was recrystallized from EtOH to give colorless cubes; mp 185—186 °C. IR (KBr): 3540, 1773, and 1680 cm^{-1}. NMR: δ 1.23 (3H, d, J=6.5 Hz, C_{11}–Me), 1.34 (3H, s, C_{10}–Me), 1.58 (3H, s, C_4–Me), 2.01 (1H, d, J=10.5 Hz, C_5–H), 2.46 (1H, s, –OH), 4.36 (1H, t, J=10.5 Hz, C_6–H), 5.83 (1H, d, J=10.0 Hz, C_2–H), 6.51 (1H, d, J=10.0 Hz, C_3–H) ppm. MS *m/e*: 264 (M^+). Found: C, 67.67; H, 7.83%. Calcd for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63%.

3α,4α-Epoxy-1,1-ethylenedioxy-5αH,6β,11βH-eudesm-6,13-olide (*)*. A mixture of **10** (103 mg, 0.35 mmol) and *m*-chloroperoxybenzoic acid (64 mg, 0.37 mmol) in CH_2Cl_2 (5 ml) was allowed to stand at room temperature for 100 h. The mixture was poured into KI aq and extracted with $CHCl_3$ (10 ml×3). The combined extracts were washed successively with 0.2 M $Na_2S_2O_3$ aq, sat $NaHCO_3$ aq, and sat NaCl aq, dried (Na_2SO_4), and concentrated to give 109 mg (100%) of spectroscopic pure **14**, which was recrystallized from $CHCl_3$–ether (1 : 1) to give colorless needles, mp 257 °C (dec). NMR: δ 1.12 (3H, s, C_{10}–Me), 1.23 (3H, d, J=6.5 Hz, C_{11}–Me), 1.49 (3H, s, C_4–Me), 2.16 (1H, d, J=3.0 Hz, C_2–H), 2.20 (1H, d, J=1.5 Hz, C_2–H), 2.43 (1H, d, J=12.0 Hz, C_5–H), 3.01 (1H, dd, J=1.5 and 3.0 Hz, C_3–H), 3.6—4.1 (5H, m, $\langle{}^{-O}_{-O}$ and C_6–H). Found: C, 66.26; H, 7.89%. Calcd for $C_{17}H_{24}O_5$: C, 66.21; H, 7.85%.

Vulgarin and Anhydrovulgarin from ***14***. A solution of **14** (50 mg, 0.16 mmol) in 50% AcOH aq (5 ml) was refluxed for 65 h. The mixture was poured into sat NaCl aq and extracted with EtOAc (10 ml×2). The combined extracts were washed successively with sat $NaHCO_3$ aq and sat NaCl aq, dried (Na_2SO_4), and concentrated *in vacuo* to give 37 mg of crude product, which was purified by preparative TLC (silica gel GF_{254}, thickness 0.25 mm, EtOAc). The first band gave 20 mg (36.1%) of **15**. The second band gave 18 mg (30.3%) of vulgarin.

3α,4α-Dihydroxy-1,1-ethylenedioxy-11β-phenylseleno-5αH,6βH-eudesman-6,13-olide (*)*. To a dry THF solution of lithium diisopropylamide [prepared from diisopropylamine (77.4 μl, 0.72 mmol), 1.70 M butyllithium in hexane (0.43 ml, 0.72 mmol), and dry THF (1.8 ml) at −78 °C] was added dropwise over a period of 1h, 65 mg (0.2 mmol) of **11** in 2.0 ml of THF. After the solution was stirred at −78 °C for 40 min, diphenyl diselenide (225 mg, 0.72 mmol) in dry THF (1.2 ml) and HMPA (126 μl) was added dropwise at −78 °C. The reaction mixture was stirred at −78 °C for 40 min, then warmed to −40 °C and kept at that temperature for 1 h. The reaction was quenched by the addition of 0.1 M HCl aq (15 ml). The mixture was extracted with EtOAc (10 ml×2). The combined extracts were washed with sat NaCl aq, dried (Na_2SO_4), and concentrated to give 277 mg of product, which was purified by preparative TLC (silica gel GF_{254}, thickness 0.25 mm, EtOAc). The first band (R_f 0.64) gave 177 mg of diphenyl diselenide. The second band (R_f 0.14) gave 57 mg (49.3%) of **17**. NMR: δ 1.10 (3H, s, C_{10}–Me), 1.25 (3H, s, C_4–Me), 1.55 (3H, s, C_{11}–Me), 3.39 (1H, –OH), 3.66 (1H, m, C_3–H), 3.85 (1H, –OH), 3.97 (5H, m, $\langle{}^{-O}_{-O}$ and C_6–H), 7.2—7.8 (5H, m, $-C_6H_5$) ppm.

3α,4α-Dihydroxy-1,1-ethylenedioxy-5αH,6βH-eudesm-11-en-6,13-olide (**). To a solution of **17** (55 mg, 0.114 mmol) in THF (0.6 ml) containing acetic acid (17 μl) cooled to 0 °C was added 30% hydrogen peroxide (81 μl). The mixture was stirred for 30 min at 0 °C, then poured into cold sat $NaHCO_3$ aq and extracted with chloroform (10 ml×3). The combined extracts were washed with sat NaCl aq, dried (Na_2SO_4), and concentrated to give a crystalline material, which was purified by preparative TLC (silica gel GF_{254}, thickness 0.25 mm, EtOAc) to give 31 mg (83.8%) of **18** (R_f 0.20). NMR: δ 1.14 (3H, s, C_{10}–Me), 1.35 (3H, s,

C_4–Me), 3.45 (1H, –OH), 3.64 (1H, m, C_3–H), *ca.* 4.0 (6H, m, –OH, $\langle{}^{-O}_{-O}\rangle$, and C_6–H), 5.42 and 6.09 (each, 1H, d, J=3.0 Hz) ppm.

Arglanine (4). A solution of **18** (30 mg, 0.093 mmol) in 50% AcOH aq was refluxed for 71 h under N_2, cooled, and poured into sat NaCl aq (20 ml). The mixture was extracted with $CHCl_3$ (10 ml×2). The combined extracts were washed with sat $NaHCO_3$ aq (10 ml) and sat NaCl aq (10 ml), dried (Na_2SO_4), and concentrated to give a semi-solidal crude product. This was purified by preparative TLC (silica gel GF_{254}, EtOAc, thickness 0.25 mm) to give 14.0 mg (57.4%) of arglanine (R_f 0.52), which was recrystallized from EtOH to give colorless prisms, mp 190—192 °C. This material was identical with natural arglanine in IR (KBr) and NMR (60 MHz, $CDCl_3$).

The authors wish to thank Prof. V. Herout, Czechoslovak Academy of Sciences, for the generous gift of the IR spectrum of vulgarin. The authors are also grateful to Prof. S. Matsueda, Hirosaki University, for his kindness in supplying the IR and NMR spectra of arglanine.

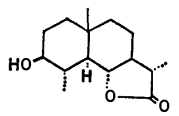
16) The major product (**6a**) was isolated by the combination of column chromatography over silica gel and recrystallization. β(eq)-Configuration of the hydroxyl group at C_3 in **6a** was deduced from its NMR spectrum, which showed a peak at δ 3.82 (broad d, J=8.0 Hz) ppm, and confirmed by the NMR spectrum of its dihydro derivative (**19**), which showed a peak at δ 3.09 (ddd, J=5.0, 9.5, and 9.5 Hz) ppm.



(19)

Although the attempted isolation of the minor product (**6b**) was unsuccessful, **6b** was deduced to be the C_3-epimer of **6a** from the fact that oxidation of the mixture of **6a** and **6b** gave **5** as the sole product.

Reduction by a Model of NAD(P)H. XVI. Effect of Magnesium Ion for the Reduction of Thiopivalophenone

Atsuyoshi OHNO, Shinro YASUI, Kaoru NAKAMURA, and Shinzaburo OKA

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

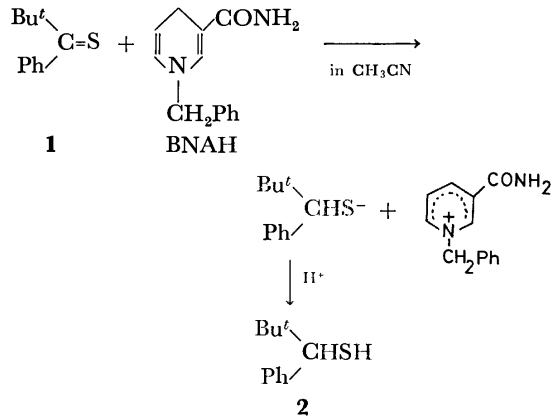
(Received July 11, 1977)

Magnesium ion retards the reduction of thiopivalophenone with 1-benzyl-1,4-dihydronicotinamide (BNAH) in acetonitrile. Kinetics and other investigation have revealed that the retardation is due to the formation of non-reactive complexes, thiopivalophenone·Mg^{2+} and BNAH·Mg^{2+}.

It has been reported that the reduction of certain substrates, namely those that contain a pyridine moiety, with a derivative of 1,4-dihydronicotinamide is accelerated by a divalent metal ion such as magnesium or zinc ion.[1-4] The acceleration has been interpreted in terms of bidentate chelation of a metal ion onto the substrate to polarize the carbonyl group to be reduced. We reported that magnesium or zinc ion also promotes the reduction of α-keto esters, and the chelation of a metal ion onto a 1,4-dihydronicotinamide derivative was attributed to the promotion of reduction.[5] The polarization of the carbonyl group in an α-keto ester takes place only at the transition state of the reduction.[6]

Hexachloroacetone can be appointed for a third type substrate. The reduction of this compound is decelerated by the addition of a metal ion.[7] These authors proposed that the deceleration is caused by the formation of a complex between a 1,4-dihydronicotinamide derivative and a metal ion.[7]

In order to obtain a universal insight into the role of a metal ion, we studied the reduction of thiopivalophenone (**1**), a substrate in the third type, with 1-benzyl-1,4-dihydronicotinamide (BNAH) in the presence or absence of magnesium ion.



Results

The reaction of **1** with an equivalent molar amount of BNAH in dry acetonitrile at a room temperature afforded 1-phenyl-2,2-dimethyl-1-propanethiol (**2**) in quantitative yield. The direct transfer of a hydrogen at the C_4-position of BNAH onto the C_1-position of the product was confirmed by an experiment with BNAH-4,4-d_2.

As a source of magnesium ion, magnesium nitrate was employed for most reactions. It was confirmed that the substitution of the salt for magnesium perchlorate did not affect the kinetics. Magnesium nitrate contains six molecules of water of crystallization. However, that the water of crystallization did not affect the kinetics was tested with a run with more than equivalent amount of water in the absence of magnesium nitrate.

Kinetics was followed vapor-phase-chromatographically by observing the decrease in the amount of **1**, or,

a) $Mg(NO_3)_2 \cdot 6H_2O$ was used unless otherwise indicated. b) Correlation coefficient. c) $Mg(ClO_4)_2$ was used. d) Followed by spectrophotometry.

in part, spectrophotometrically by observing the decrease in the intensity of absorption at 350 nm (from BNAH). Each run gave a good pseudo-first-order correlation ($r>0.999$). From the result listed in Table 1, the second-order rate constant, k_2, at 25 °C was calculated to be 5.80×10^{-3} M^{-1} s^{-1} (see Fig. 1). Table 2 summarizes kinetic result in the presence of magnesium ion.

Discussion

The fact that two different methods gave the same pseudo-first-order rate constant indicates that the decreases of the concentration of BNAH corresponds directly to that of **1**.[8]

In contrast to the reduction of α-keto esters, the reduction of **1** is retarded by the presence of magnesium ion. On the other hand, ammonium perchlorate results in slight increase in the rate, probably due to a salt effect. In the presence of magnesium ion, the second-order rate constants, k_2, tentatively calculated by dividing k_{obsd} by the concentration of BNAH gave neither a constant value nor a simple dependence on the concentration of magnesium ion. In previous papers we reported that magnesium ion forms a complex with BNAH.[6] However, the complex-formation alone does not explain the present result. That is, one cannot expect the change in the concentration of BNAH.

In analogy with a treatment for kinetics of fully and noncompetitively inhibited enzymic reactions,[9] plots were made for $1/k_{obsd}$ against $1/$[BNAH] for each constant concentration of magnesium ion. The result is illustrated in Fig. 2, from which it is obvious that the substrate, **1**, forms a non-reactive (noncompetitive) complex with magnesium ion. Moreover, the plots give curved lines instead of linear relationships. The result can be interpreted with the following reaction scheme:

$$\mathbf{1} + \mathrm{BNAH} \overset{K_1}{\rightleftharpoons} \mathbf{1}\cdot\mathrm{BNAH} \xrightarrow{k_2} \mathrm{Products}$$

$$\mathbf{1} + Mg^{2+} \overset{K_3}{\rightleftharpoons} \mathbf{1}\cdot Mg^{2+}$$

$$\mathrm{BNAH} + Mg^{2+} \overset{K_4}{\rightleftharpoons} \mathrm{BNAH}\cdot Mg^{2+}$$

$$\mathbf{1}\cdot Mg^{2+} + \mathrm{BNAH} \overset{K_5}{\rightleftharpoons} \mathbf{1}\cdot Mg^{2+}\cdot\mathrm{BNAH}$$

$$\mathrm{BNAH}\cdot Mg^{2+} + \mathbf{1} \overset{K_6}{\rightleftharpoons} \mathbf{1}\cdot Mg^{++}\cdot\mathrm{BNAH}$$

$$\mathbf{1}\cdot\mathrm{BNAH} + Mg^{2+} \overset{K_7}{\rightleftharpoons} \mathbf{1}\cdot Mg^{2+}\cdot\mathrm{BNAH}.$$

Based on the above reaction scheme, the concentrations of free **1** and BNAH are expressed by Eqs. 1 and 2, respectively.[10]

$$[\mathbf{1}] = \frac{[\mathbf{1}]_0}{1+[\mathrm{BNAH}]/K_1+[Mg^{2+}]/K_3+[\mathrm{BNAH}][Mg^{2+}]/K_1K_7}, \tag{1}$$

$$[\mathrm{BNAH}] = \frac{[\mathrm{BNAH}]_0}{1+[\mathbf{1}]/K_1+[Mg^{2+}]/K_4+[\mathbf{1}][Mg^{2+}]/K_1K_7}, \tag{2}$$

where the subscript 0 denotes a stoichiometric concentration. Since

$$v = k_2[\mathbf{1}\cdot\mathrm{BNAH}] = k_2[\mathbf{1}][\mathrm{BNAH}]/K_1, \tag{3}$$

when A, B, C, and D are defined by Eqs. 4—7, the rate expression shown in Eq. 8 is obtained.

$$A = K_1K_7(K_3+[Mg^{2+}])(1+[Mg^{2+}]/K_4), \tag{4}$$

$$B = K_3\,(K_7+[Mg^{2+}]), \tag{5}$$

$$C = (K_3+[Mg^{2+}])(K_7+[Mg^{2+}]), \tag{6}$$

$$D = \frac{1}{2C}(\sqrt{\{A+B([\mathrm{BNAH}]_0-[\mathbf{1}]_0)\}^2+4AB[\mathbf{1}]_0} - \{A+B([\mathrm{BNAH}]_0-[\mathbf{1}]_0)\}), \tag{7}$$

$$\frac{1}{v} = \frac{K_1}{k_2[\mathrm{BNAH}]_0}\left\{\frac{1}{K_1}\left(1+\frac{[Mg^{2+}]}{K_7}\right)+\frac{1}{D}\left(1+\frac{[Mg^{2+}]}{K_4}\right)\right\}. \tag{8}$$

The denominator of the right-hand side in Eq. 8 is composed of the second-, three-halves-, and first-order terms of the stoichiometric concentration of BNAH in accord with the observed result. The result leads to a conclusion that both BNAH-magnesium ion and **1**-magnesium ion complexes are non-reactive, which is a marked contrast with the reaction of α-keto esters. It is known that thioketones form complexes with various metal salts[11] as well as with BNAH.[12]

The validity of the proposed reaction scheme can be tested in several ways. In the range of BNAH-concentrations where the curves in Fig. 2 can be approximated by straight lines, slopes of the lines, m, are expressed by Eq. 9.

$$m = \frac{1}{k_2}\left(1+\frac{[Mg^{2+}]}{K_7}\right). \quad (9)$$

A plot of m against the concentration of magnesium ion indeed gave a straight line as shown in Fig. 3. From the intercept and slope the values of k_2 and K_7 were calculated to be 5.81×10^{-3} M^{-1} s^{-1} and 3.77×10^{-3} M, respectively. Thus, calculated rate constant is identical to the observed one.[13]

The dependence of the rate constants in the presence and absence of magnesium ion on the reaction temperature is listed in Table 3, from which the energy of activations in the presence and absence of magnesium ion were calculated to be identical (8.9±0.5 and 8.0±0.3 kcal/mol for reactions with and without magnesium ion, respectively).[14]

The reduction of **1** with optically active *N*-(α-methylbenzyl)-1-propyl-1,4-dihydronicotinamide (**3**) affords optically active **2**. The reductions with *R*-**3** in the presence and absence of magnesium ion resulted in the formation of **2** of $[\alpha]_D=-5.8$ and -6.2, respectively. Although we do not know the degree of rotation for optically pure **2**, there is no doubt that both reactions gave the identical stereochemical result.

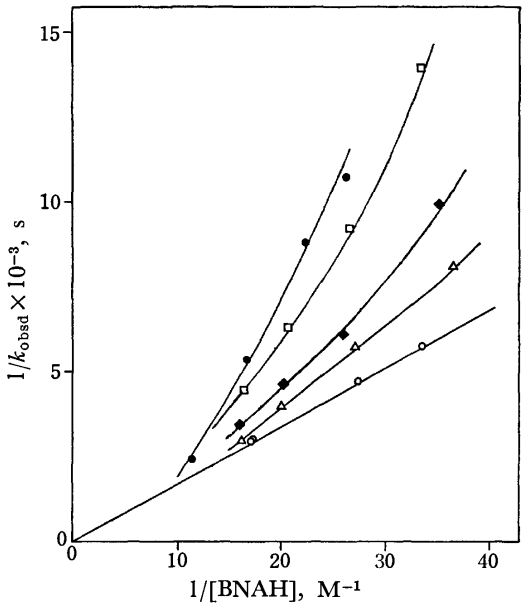

Fig. 2. Correlation of $1/k_{obsd}$ against 1/[BNAH] for constant concentrations of magnesium ion: ○ $[Mg^{2+}]=0$; △ $[Mg^{2+}]=1.2\times10^{-3}$ M; ◆ $[Mg^{2+}]=3.0\times10^{-3}$ M; □ $[Mg^{2+}]=6.0\times10^{-3}$ M; ● $[Mg^{2+}]=8.0\times10^{-3}$ M.

TABLE 3. TEMPERATURE-DEPENDENCE OF RATE CONSTANTS IN PRESENCE AND ABSENCE OF MAGNESIUM ION[a]

$10^3[Mg^{2+}]$, M[b]	Temp, °C[c]	k
6.00	14	0.672[d]
6.00	25	1.09[d]
6.00	30	1.58[d]
0	10	2.83[e]
0	17	3.98[e]
0	25	5.80[e]
0	30	7.12[e]

a) Under the condition of [**1**] $=2.80\times10^{-3}$ M and [BNAH] $=3.72\times10^{-2}$ M. b) $Mg(NO_3)_2\cdot6H_2O$ was used. c) ±0.05 °C. d) 10^4k_{obsd}, s^{-1}. e) 10^3k_2 $(=10^3 k_{obs}/[BNAH])$, M^{-1} s^{-1}.

The final diagnosis was made by kinetic deuterium isotope effect using BNAH-4,4-d_2. The isotope effects, k_H/k_D, for both reactions were found to be identical (5.0±0.2).

All of above results indicate that magnesium ion is not involved in the product-forming process and that the polarization of a substrate does not necessarily result in the acceleration of the reduction. Detailed discussion on the difference in reactivities of **1** and α-keto esters will appear in the following paper.[15]

Partial support in the form of a Scientific Research Grant from the Ministry of Education, Japan, is acknowledged.

Experimental

Materials. Thiopivalophenone[16,17] and 1-benzyl-1,4-dihydronicotinamide[18] were prepared according to literatures. 1-Benzyl-1,4-dihydronicotinamide-4,4-d_2 was prepared from BNA^+Cl^- by three times repetition of D_2O–$Na_2S_2O_4$-reduction—malachite green-oxidation.[18] Magnesium nitrate and perchlorate were commercially available (Wako Chem. Co.) and purified prior to use.[6b] Acetonitrile

was distilled once on phosphorus pentaoxide and kept over molecular sieves 4A.

Procedure. Preparation of solutions for kinetic studies and the method to follow the kinetics by spectrophotometry were described previously.[6] For kinetic observations under the conditions of excess BNAH, 1 ml aliquots were taken out from a 20 ml reaction solution after appropriate time intervals and poured into 5 ml of dilute hydrochloric acid. The organic materials were extracted with 5 ml hexane. The hexane-layer (20 μl) was subjected to VPC (Yanagimoto G-18000, FID, 15% BDS, 1 m, 135 °C). 1,4-Dipropoxybenzene was used as an internal standard. At least 10 points were obtained for a run. The reaction temperatures were kept constant within the accuracy of ±0.05 °C. Least-squares method was employed to evaluate linear relashioships.

Deuterium contents were analyzed on a Varian T-60 NMR Spectrometer and Shimadzu LKB-9000S GC-MS Spectrometer.[19,20] The optical activity of the thiol was measured on a Perkin-Elmer 241 Polarimeter (30 mg/2 ml EtOH).

The method for isolation and identification of 1-phenyl-2,2-dimethyl-1-propanethiol was the same as described previously for the case of 2,2,4,4-tetramethyl-3-pentanethiol.[21]

Reduction by a Model of NAD(P)H. XVII. Isotope Effects and Magnesium Ion Catalysis

Atsuyoshi OHNO, Shinro YASUI, Hiroyuki YAMAMOTO, Shinzaburo OKA, and Yutaka OHNISHI*

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

**Sagami Chemical Research Center, Nishiohnuma, Sagamihara, Kanagawa 229*

(Received July 11, 1977)

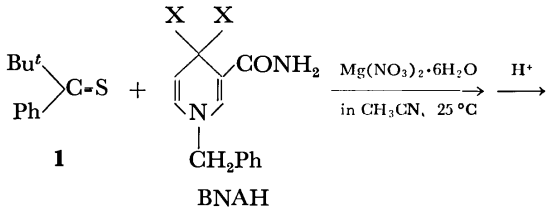
The reduction of thiopivalophenone (**1**) with 1-benzyl-1,4-dihydronicotinamide (BNAH) gives the same value for kinetic deuterium isotope effect (k_H/k_D) and isotopic distribution in the product (Y_H/Y_D) regardless of the presence or absence of magnesium ion. The reduction of methyl benzoylformate (**2**) with a BNAH-analog in the presence of magnesium ion also gives similar values for k_H/k_D and Y_H/Y_D. It has been concluded that magnesium ion stabilizes the transition state in the reduction of **2**, whereas an intermediate is stabilized by magnesium ion in the reduction of **1**.

In the preceeding paper, we reported that magnesium ion decelerates the reduction of thiopivalophenone (**1**) with 1-benzyl-1,4-dihydronicotinamide (BNAH).[1] The deceleration was accounted for by the formation of non-reactive complexes, $\mathbf{1}\cdot Mg^{2+}$ and $BNAH\cdot Mg^{2+}$. On the other hand, the reduction of α-keto esters is accelerated by magnesium ion and the acceleration was ascribed to the formation of the reactive complex, $BNAH\cdot Mg^{2+}$.[2]

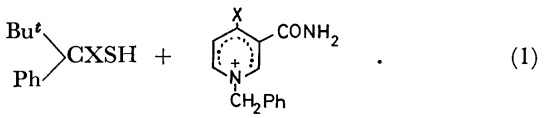
This paper describes, based on the results from the study on isotope effects, that such an apparently contradictory phenomenon as $BNAH\cdot Mg^{2+}$ being non-reactive in one reaction but reactive in another is not a real contradiction.

Results

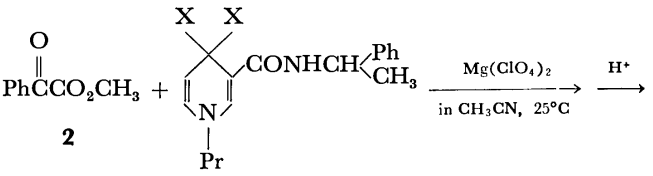
All reactions were carried out in acetonitrile at 25 °C. Pseudo-first-roder kinetics for the reduction of methyl benzoylformate (**2**) with *N*-(α-methylbenzyl)-1-propyl-1,4-dihydronicotinamide (PPNAH) was followed spectrophotometrically by observing the decrease in intensity of absorption maximum at 354 nm.[2b] Kinetics for the reduction of **1** with BNAH was followed vapor-phase-chromatographically by observing the decrease in concentration of **1**.[1] It was confirmed that spectrophotometric and vapor-phase-chromatographic methods gave the identical result.[1] It was also confirmed that magnesium nitrate used for the reduction of **1** behaved similarly to magnesium perchlorate.[1] Since the rate of the reduction of **1** is a complex function of the concentration of magnesium ion,[1] the kinetics was followed under a constant concentration of magnesium ion. The rate of the reduction of **2** followed zero-order in magnesium ion under its existence in large excess.[2b] In Tables 1 and 2 are summarized



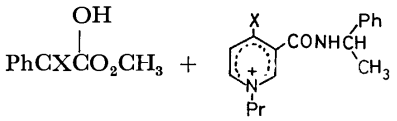
1 BNAH



X=H or D (1)



2 PPNAH



X=H or D (2)

Table 1. Isotope effects in the reduction of thiopivalophenone

Reductant	$10^3[Mg^{2+}]$, M	10^3k_2, $M^{-1}s^{-1}$ a)	k_H/k_D	Y_H/Y_D

a) Under the condition of $[\mathbf{2}]=1.0\times10^{-2}$ M, $[PPNAH\text{-}d_x]=2.0\times10^{-4}$ M, and $[Mg^{2+}]=1.0\times10^{-2}$ M. b) $k_2=k_{obsd}/[\mathbf{2}]$. c) Under the condition of $[\mathbf{2}]=1.0\times10^{-3}$ M, $[PPNAH]=1.0\times10^{-3}$ M, and $[Mg^{2+}]=2.0\times10^{-3}$ M. $Y_H/Y_D=3.1\pm0.3$ was obtained when each 6.8×10^{-2} M of reagent was used.

kinetic results together with isotopic ratio (Y_H/Y_D) in the product, 1-phenyl-2,2-dimethyl-1-propanethiol and methyl mandelate, from the reduction with BNAH-4-*d* and PPNAH-4-*d*, respectively. Kinetic isotope effect (k_H/k_D) was calculated after Steffens and Chipman.[3] The values for k_H/k_D and Y_H/Y_D were corrected for isotopic contents of deuterated BNAH and PPNAH used.

Discussion

Steffens and Chipman suggested elegantly that there is at least one intermediate in the reduction of α,α,α-trifluoroacetophenone with BNAH or its analogs.[3] Their argument based on the fact that kinetic deuterium isotope effect, k_H/k_D, is much smaller than the ratio of the amounts of isotopes incorporated in the product, Y_H/Y_D. Later, Creighton and his coworkers reported similar result in the reduction of 1,10-phenanthroline-2-carbaldehyde.[4] We confirmed that the intermediate proposed by these authors is indeed a charge-transfer-type complex.[5]

The large discrepancy between the values of k_H/k_D and Y_H/Y_D appears only when the free energy of the transition state for k_1-step in Eq. 3 is slightly larger than that for the k_2-step as shown by a solid line in Fig. 1.

$$S+BH \underset{k^{-1}}{\overset{k_1}{\rightleftharpoons}} S\cdot BH \xrightarrow{k_2} SH^- + B^+. \quad (3)$$

The values of k_H/k_D and Y_H/Y_D for the reduction of **1** or hexachloroacetone[6] are equal, respectively, which indicates that the free energy of the transition state for the k_2-step is much larger than that for the k_1-step in this reduction as shown in Fig. 1 by a dotted line. Note that both **1** and hexachloroacetone are substrates that can be reduced without the assistance of metal ion. When metal ion is added to the reaction system, the metal ion may form a stable ternary complex, say, **1**·Mg^{2+}·BNAH.[1] If the free energy of the complex becomes small enough so that the activation energy for the k_2-step becomes larger than that for the k_1-step, the net reduction (more precisely, the transfer of a proton) through the ternary complex becomes difficult to proceed (dashed line in Fig. 1). This argument is partly supported by the following observation:[7] 4,4′-Dichlorobenzil is reduced by BNAH in the presence of magnesium ion in acetonitrile. However, no ESR-signal was detected from the reaction solution. When acetonitrile was substituted by dimethyl sulfoxide, no reduction took place, whereas strong ESR-signal from 4,4′-dichlorobenzil anion radical paired by magnesium ion was recorded. Even in the absence of magnesium ion, weak ESR-signal of the anion radical could be recorded from the mixture in dimethyl sulfoxide. This observation reveals that the charge-transfer intermediate is too unstable in the reacting system to be detected by ESR-spectroscopy. When the solvent is changed to the one which stabilizes the intermediate, the net reduction is prohibited because the k_2-step becomes unfavorable and the intermediate is accumulated. Magnesium ion increases the stability of the intermediate.[8]

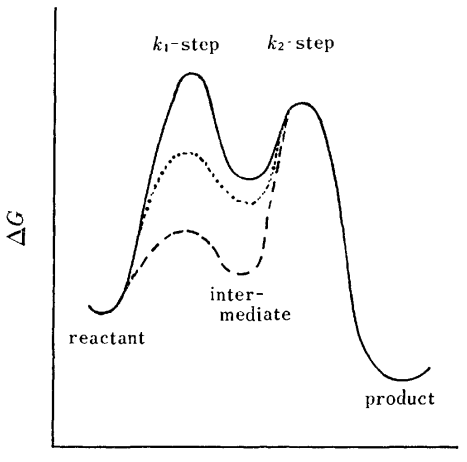

Fig. 1. Schematic energy diagram.

Reduction of **2** in acetonitrile does not take place without magnesium ion. Therefore, there is no doubt that magnesium ion plays a role to reduce the free energy of a transition state for either of k_1- or k_2-step, or both of this reaction. However, it is highly unlikely to expect that the process of electron-transfer is associated with such a large kinetic isotope effect as 4.3, the value which is comparable to that of **1**. This leads to a conclusion that magnesium ion catalyzes the k_1-step, or an electron-transfer process, and the energy diagram for this reaction may be represented by the dotted line in Fig. 1. The similarity in the values of Y_H/Y_D for the reductions of **1** and **2** suggests that the positions of transition states for these reactions may be similar.

It is noteworthy that the ternary complex, **2**·Mg^{2+}·PPNAH, has been proposed to be the transition state,[2] whereas the ternary complex, **1**·Mg^{2+}·BNAH, is in the ground state.[1] The metal ion complex must stabilize the transition state of the reaction in order to assist the reaction effectively, and metal ion complex formation in the ground state depresses the reaction rate. In true catalyses such as enzymic catalysis the strongest coordination must be to the transition state, and not to the reactant or product.[9]

Klinman argued on the transition state of enzymic reductions.[10] Kinetic isotope effects and substituent effects[10,11] reconcile with the energy diagram schematically shown by the dotted line in Fig. 1 provided general-acid catalysis is assumed for the reduction with alcohol dehydrogenases.[12-15] Furthermore, it is interesting to point out that the energy diagrams for the present model reactions with **1** and **2** without magnesium ion correspond fortuitously with those for enzymic reductions of ketones and α-keto esters, respectively. The rate-determining step for the reaction with an alcohol dehydrogenase is the process of a proton-transfer, whereas that with a lactate dehydrogenase is the process that takes place prior to the proton-transfer.[16]

Experimental

Preparation, purification, and identification of materials were described previously.[1,2,17] Procedures for the kinetics

and the analyses of isotopic contents were also described in previous papers.[1,2b]

The deuterium contents in BNAH-4-*d* or PPNAH-4-*d* were 99.0±1%, and those in BNAH-4,4-d_2 or PPNAH-4,4-d_2 were 91.5±1—94.5±1% depending on the runs of preparation. For the calculation of the purity of dideuterated compound, no contamination of undeuterated compound was assumed.

8) The reduction of cationic substrate such as malachite green is also retarded by the presence of magnesium ion (preliminary result from our laboratory). There are two pcssibilities for this retardation: one involves a stable ternary complex as an intermediate. The other is due to the ionic repulsion between charges on the substrate and BNAH·Mg^{2+} complex. We have no datum at present to choice the one over the other.

Studies of Peptide Antibiotics. XXXVII.[1] Synthesis of [1,1',3,3'-L-Alanine]-Gramicidin S

Hideo TAKIGUCHI, Hiroshi NISHIKAWA, Setsuko ANDO, and Nobuo IZUMIYA*

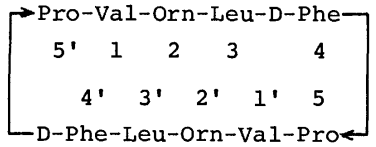
Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Nishi-ku, Fukuoka 814

** Laboratory of Biochemistry, Faculty of Science 33, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812*

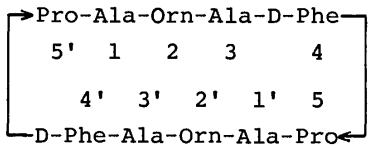
(Received July 29, 1977)

An analog containing alanyl residues in place of valyl and leucyl residues in gramicidin S, namely [1,1',3,3'-L-alanine]-gramicidin S, was synthesized to investigate the influence of the bulky side chains of the amino acid residues for antibacterial activity and conformation. The analog has the small aliphatic side chains of alanyl residues on one side of the ring frame in the gramicidin S-structure. In the experiments of optical rotatory dispersion and circular dichroism, this analog gave curves similar in shape to these of gramicidin S, and thus should have a similar conformation to that of gramicidin S. The analog showed, however, no antibacterial activity. Thus the four methyl side chains of alanyl residues in the analog are not sufficient for the substance to exhibit biological activity.

Various analogs of gramicidin S (GS, Fig. 1) have been studied to investigate the relationship between chemical structure and biological activity. Particularly, some analogs with other amino acid residues in place of either the valyl or leucyl residues have been prepared by Izumiya and his collaborators. Some of them, such as [1,1'-Ala]-[2] and [1,1'-Leu]-GS,[3] exhibited substantial antibacterial activities. On the other hand, very weak or no activity was observed for the other analogs, that is, [1,1'-Gly]-,[2] [3,3'-Gly]-,[4] and [3,3'-Ala]-GS.[4] In Table 1 are listed the antibacterial activities of the 1,1'- or/and 3,3'-position substituted



(a) gramicidin S (GS)



(b) [1,1',3,3'-Ala]-GS

Fig. 1. Structure of GS and [1,1',3,3'-Ala]-GS.

TABLE 1. ANTIBACTERIAL ACTIVITIES OF 1,1'- OR/AND 3,3'-POSITION SUBSTITUTED GS ANALOGS[a]

Substituted residues	*S. aureus*	*B. subtilis*	Reference No.
1,1'-Gly	100	100	2
1,1'-Ala	5	5	2
1,1'-Val (GS)[b]	2—5	2—5	—
1,1'-Leu	5	10	3
3,3'-Gly	>100	>100	4
3,3'-Ala	50	20	4
3,3'-Leu (GS)[b]	2—5	2—5	—
1,1',3,3'-Ala	>100	>100	This work

a) This table shows the minimum inhibitory concentration (μg/ml) with a Bouillon agar medium. b) The natural GS used as the control.

GS analogs. As shown in Table 1, the activity of 3,3'-position substituted GS decreases significantly upon decreasing the bulkiness of the side chains of 3,3'-residues, whereas the bulkiness of the side chains in 1,1'-position substituted GS is not so important for the activity. For the conformation of GS, several models have been proposed. One of them is based on the β-pleated sheet structure shown in Fig. 2, which seems to be the most likely model.[5] In this specific model, the four hydrophobic side chains of valyl and leucyl residues are located on one side of the ring frame consisting of the cyclic peptide chain, while the two hydrophilic side chains of ornithyl residue are placed on the opposite side.

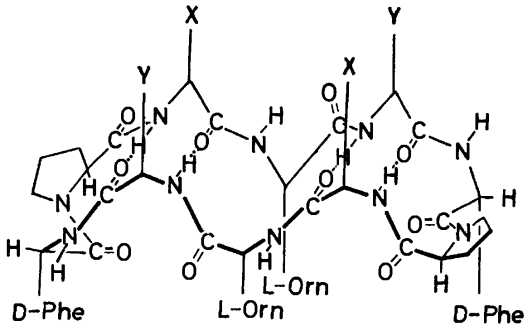


Fig. 2. Possible model of GS (X=Val, Y=Leu) and [1,1',3,3'-Ala]-GS (X, Y=Ala).

For the purpose of investigating the effect of the hydrophobic side chains on the activity, it seemed of interest to synthesize an analog having alanyl residues in place of both the valyl and leucyl residues in GS. The analog has the small aliphatic side chains on one side of the ring frame in the GS-structure. The present paper will describe the synthesis of [1,1',3,3'-L-analine]-gramicidin S ([1,1',3,3'-Ala]-GS) (as shown in Fig. 1), the ORD and CD measurements, and the antibacterial properties.

The synthesis of [1,1',3,3'-Ala]-GS (**10**) is outlined in Fig. 3. Acyldipeptide ester (**1**) was prepared by means of the MA method,[6] and then converted into a hydrazide (**2**). Acyltripeptide ester (**3**) was prepared by stepwise elongation by means of the DCC method as a crystalline solid. It had previously been reported as an oil.[4]

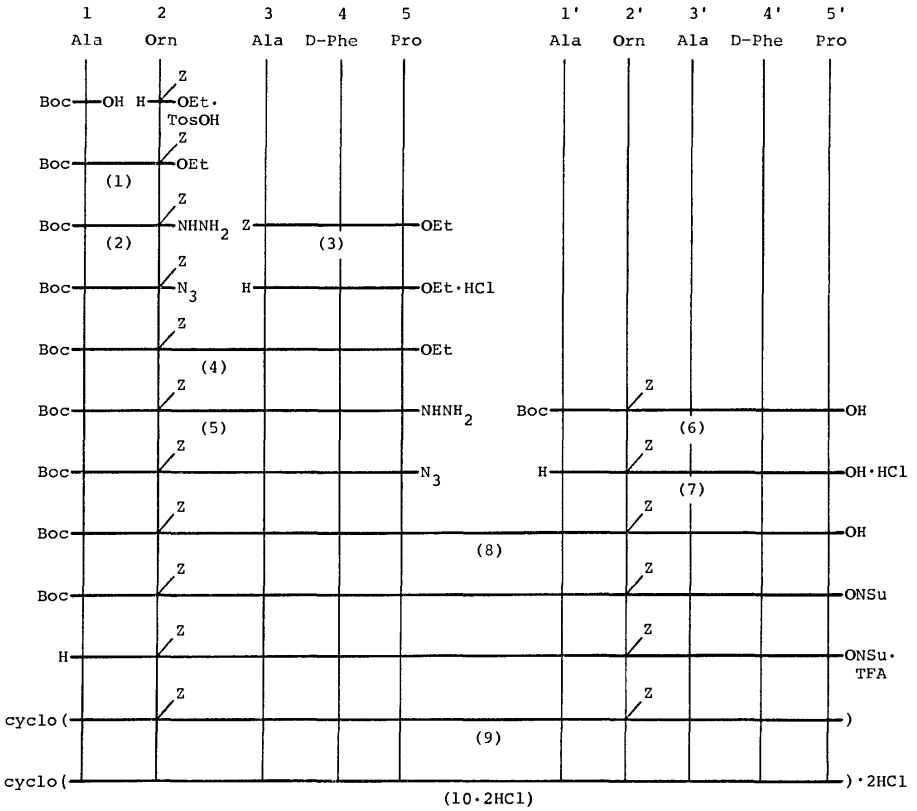

Fig. 3. Synthesis of [1,1',3,3'-Ala]-GS.

Its hydrogenolysis gave a tripeptide ester. Acylpentapeptide ester (**4**) was prepared by condensation of the azide derived from **2** with the tripeptide ester mentioned above. The ester (**4**) was converted into a hydrazide (**5**), while a part of **4** was saponified to afford an acylpentapeptide (**6**). Compound **6** was converted into a pentapeptide (**7**) by treatment with HCl in formic acid. Acyldecapeptide (**8**) was prepared by condensation of the azide derived from **5** with **7**. For its cyclization, the *N*-hydroxysuccinimide ester of **8** was prepared as an active ester, and its Boc-group was removed by the action of TFA at low temperature. The decapeptide active ester was treated with a large amount pyridine, and the resulting Z-substituted cyclic decapeptide (**9**) was purified by passing it through a column of resins. For the synthesis of the final [1,1',3,3'-Ala]-GS, the Z-substituted cyclodecapeptide (**10**) was subjected to hydrogenolysis, and the desired analog was obtained as a crystalline dihydrochloride (**10·2HCl**). The homogeneity of **10** was confirmed by paper and thin-layer chromatography, paper electrophoresis, and elemental analysis.

The ORD curves of the analog (**10**) in ethanol as well as of GS are shown in Fig. 4-a. The analog has a very similar to that which curve with a negative trough at 232 nm, GS possesses. The CD measurements of cyclic and linear peptides relating to GS or its analogs are interesting in connection with the elucidation of antibacterial activities and cyclization reactions. Thus, the CD curves of the analog and GS were measured with methanol as a solvent (Fig. 4-b). The CD curves of both peptides have nearly the same

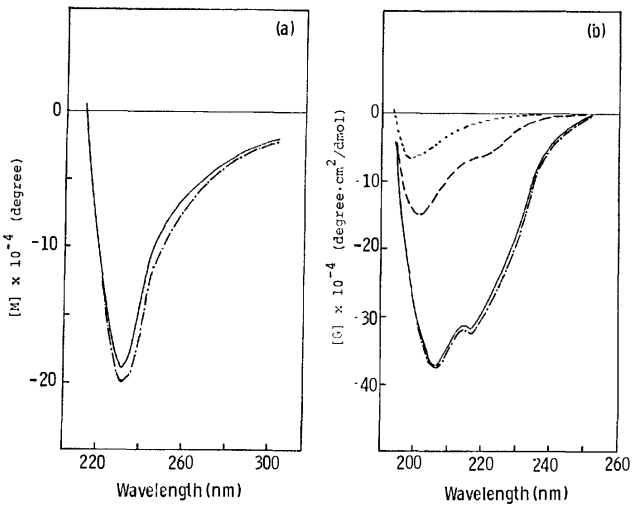

Fig. 4. ORD (a) and CD (b) curves of the cyclic peptides and the Boc-peptides. Solvent: a, ethanol; b, methanol. GS: ——, [1,1',3,3'-Ala]-GS (**10**): ——, Boc-pentapeptide (**6**): ----, Boc-decapeptide (**8**): ———.

pattern, in which the two troughs are at 207 and 217 nm. The CD curves of Boc-peptides (**6** and **8**) were also measured: the trough of the Boc-pentapeptide (**6**) is at 198 nm, whereas that of the Boc-decapeptide (**8**) is at 202 nm. The troughs of the linear peptides (**6** and **8**) are shallower than those of cyclic peptides (GS and **10**).

The results of ORD and CD measurements indicate

that the conformation of the analog (**10**) is similar to that of GS. On the other hand, the CD curve of the Boc-pentapeptide (**6**) shows that **6** has a random structure, and that of the Boc-decapeptide (**8**) indicates that **8** lies in a transition state toward the β-sheet structure such as GS. In a number of experiments, it has been found that a linear decapeptide in the cyclization reaction gives rise to only the cyclic decapeptide, whereas a linear pentapeptide gives a mixture of the cyclic penta- and decapeptides. In the present study, the decapeptide active ester derived from **8** afforded a cyclic monomer in good yield as the sole product; this result can be explained by the suggestion that **8** possesses a spatial conformation resembling that of GS.

At the beginning of this study, we expected that [1,1′3,3′-Ala]-GS (**10**) might possess appreciable antibacterial activity, like [3,3′-Ala]-GS, because [1,1′-Ala]-GS possesses the same strong activity as GS. It seemed that this expectation was supported by the results of the ORD and CD experiments of **10** and GS. Compound **10** showed, however, no activity against any of Gram positive microorganisms even at 100 μg/ml of assay medium. These results indicate that analogs with two methyl side chains in place of either of the two bulky side chains of $Val^{1,1'}$ or $Leu^{3,3'}$ show some activity, but that the analog (**10**) with four methyl side chains loses its activity completely because of its inability to interact with the surface of a Gram positive microorganism.

Experimental

Melting points are uncorrected. TLC was carried out on silica gel G (Merck) with the solvent system: R_f^1, 1-butanol-pyridine-water (4 : 1 : 1 : 2, v/v). Paper chromatography was carried out on Toyo Roshi No. 52 with the above solvent, R_f^3, being used.

*Boc–Ala–Orn(Z)–OEt (**1**).* To a solution of Boc–Ala–OH (3.78 g, 20 mmol) and TEA (2.80 ml, 20 mmol) in THF (40 ml) was added isobutyl chloroformate (2.62 ml, 20 mmol) at −5 °C. After 15 min, a mixture of H–Orn(Z)–OEt TosOH[7] (9.33 g, 20 mmol) and TEA (2.80 ml, 20 mmol) in chloroform (40 ml) was added. The mixture was left to stand overnight at room temperature, evaporated *in vacuo*, and the oily residue was dissolved in ethyl acetate (80 ml). The solution was washed successively with 4% $NaHCO_3$, 10% citric acid, and water, and then dried (Na_2SO_4). The filtrate which separated from the salt was concentrated *in vacuo*. The product which precipitated upon the addition of ether and petroleum ether was collected and washed with the same solvent. It was obtained as very hygroscopic crystals: yield, 5.33 g (57%); mp 49—52 °C; $[\alpha]_D^{29}$ −14.2° (*c* 1, DMF); R_f^1 0.87.

Found: C, 58.81; H, 7.74; N. 8.91%. Calcd for $C_{23}H_{35}O_7N_3 \cdot 1/3H_2O$: C, 58.58; H, 7.62; N, 8.91%.

*Boc–Ala–Orn(Z)–NHNH$_2$ (**2**).* A solution of **1** (5.12 g, 11 mmol) and hydrazine hydrate (10.7 ml, 220 mmol) in DMF (50 ml) was allowed to stand at room temperature for 3 days. The excess hydrazine was evaporated *in vacuo*, and then water (60 ml) was added to the residue. The resulting solid was collected by filtration: yield, 4.18 g (84%); mp 174—175 °C; $[\alpha]_D^{29}$ −27.3° (*c* 1, AcOH).

Found: C, 55.92; H, 7.45; N, 15.48%. Calcd for $C_{21}H_{33}O_6N_5$: C, 55.86; H, 7.37; N, 15.51%.

*Z–Ala–D-Phe–Pro–OEt (**3**).* To a solution of Z–Ala–OH (7.39 g, 33.1 mmol) in chloroform (60 ml) was added DCC (6.83 g, 33.1 mmol) at −5 °C. After several minutes, a solution of H–D-Phe–Pro–OEt·HCl[8] (10.8 g, 33.1 mmol) and TEA (4.63 ml, 33.1 mmol) in chloroform (60 ml) was added to this solution. The mixture was left to stand for 25 h at room temperature, evaporated *in vacuo*, and the oily residue was dissolved in ethyl acetate (150 ml). The solution was washed successively with 4% $NaHCO_3$, 2% HCl, and water, dried (Na_2SO_4), and the filtrate was evaporated. The oily residue solidified upon the addition of ether and petroleum ether. The product was obtained in solid form, though a previous paper[4] had reported it as an oily substance: yield, 10.3 g (63%); mp 93—94 °C; $[\alpha]_D^{20}$ −33° (*c* 1, DMF); R_f^1 0.94.

Found: C, 65.17; H, 6.95; N, 8.44%. Calcd for $C_{27}H_{33}O_6N_3$: C, 65.44; H, 6.71; N, 8.48%.

*Boc–Ala–Orn(Z)–Ala–D-Phe–Pro–OEt (**4**).* A solution of **2** (4.06 g, 9 mmol) dissolved in DMF (50 ml) was cooled to −20 °C. To this solution, 3.70 M HCl in dioxane (4.86 ml) and isopentyl nitrite (1.22 ml, 9 mmol) were added. After 20 min, the solution was neutralized with TEA (2.52 ml, 18 mmol). To this solution was added a chilled solution of H–Ala–D-Phe–Pro–OEt·HCl[4] (3.58 g, 9 mmol) and TEA (1.26 ml, 9 mmol) in DMF (20 ml). The reaction mixture was stirred at 0 °C for 3 days and evaporated. The residual solid was triturated with petroleum ether (30 ml) and water (30 ml), and allowed to stand in a refrigerator. The solid was collected by filtration and washed successively with 4% $NaHCO_3$, 10% citric acid, and water. It was recrystallized from ethanol-ether: yield, 4.92 g (70%); mp 190—192 °C; $[\alpha]_D^{18}$ −27.6° (*c* 1, DMF); R_f^1 0.94.

Found: C, 61.34; H, 7.22; N, 10.89%. Calcd for $C_{40}H_{56}O_{10}N_6$: C, 61.52; H, 7.23; N, 10.76%.

*Boc–Ala–Orn(Z)–Ala–D-Phe–Pro–NHNH$_2$ (**5**).* This hydrazide was obtained from **4** (1.56 g, 2 mmol) as described for the preparation of **2**: yield, 1.44 g (93%); mp 203—206 °C; $[\alpha]_D^{18}$ −75.0° (*c* 1, AcOH).

Found: C, 59.23; H, 7.08; N, 14.21%. Calcd for $C_{38}H_{54}O_9N_8$: C, 59.52; H, 7.10; N, 14.61%.

*Boc–Ala–Orn(Z)–Ala–D-Phe–Pro–OH (**6**).* To a solution of **4** (1.95 g, 2.5 mmol) in a mixture of methanol (10 ml) and DMF (15 ml), 1 M NaOH (3 ml) was added, and the solution was allowed to stand at 5 °C for 1 day. After the addition of 1 M citric acid (5 ml), the solution was evaporated to dryness. The residual oil was dissolved in ethyl acetate and the solution was concentrated *in vacuo*. The product which precipitated upon the addition of ether was collected by filtration: yield, 1.69 g (90%); mp 126—130 °C; $[\alpha]_D^{18}$ −35.6° (*c* 1, DMF); R_f^1 0.74.

Found: C, 60.23; H, 6.92; N, 10.77%. Calcd for $C_{38}H_{52}O_{10}N_6$: C, 60.62; H, 6.96; N, 11.16%.

*H–Ala–Orn(Z)–Ala–D-Phe–Pro–OH·HCl (**7**).* Compound **6** (1.51 g, 2 mmol) was dissolved in 0.164 M HCl in formic acid (15 ml). After being left to stand at room temperature for 20 min, the solution was evaporated to dryness, and the resulting solid was collected by filtration with the aid of ether. The product was a very hygroscopic powder: yield, 1.47 g (107%); mp 131—135 °C; $[\alpha]_D^{18}$ −31.0° (*c* 1, DMF); R_f^1 0.71.

Found: C, 53.27; H, 7.50; N, 11.15%. Calcd for $C_{33}H_{47}O_8N_6Cl \cdot 3H_2O$: C, 53.18; H, 7.17; N, 11.28%.

*Boc–Ala–Orn(Z)–Ala–D-Phe–Pro–Ala–Orn(Z)–Ala–D-Phe–Pro–OH (**8**).* The azide derived from **5** (1.30 g, 1.7 mmol) was coupled with **7** (1.17 g, 1.7 mmol) as described for the preparation of **4**. The product was obtained as a crystalline solid: yield, 2.02 g (93%); mp 134—136 °C;

$[\alpha]_D^{18}$ −39.0° (*c* 1, DMF); R_f^1 0.75.

Found: C, 59.02; H, 6.78; N, 11.30%. Calcd for $C_{71}H_{94}O_{17}N_{12}\cdot 3H_2O$: C, 59.15; H, 6.99; N, 11.66%.

cyclo-[*Ala–Orn(Z)–Ala–*D*-Phe–Pro–*]$_2$ (**9**). To a solution of **8** (770 mg, 0.555 mmol) in ethyl acetate (25 ml), DCC (124 mg, 0.66 mmol) and HONSu (69 mg, 0.66 mmol) were added at 0 °C. After being left to stand at 0 °C for 3 h, the dicyclohexylurea which precipitated was filtered off, and the filtrate was evaporated *in vacuo* at 0 °C. The residual solid was washed with ether by decantation and dried. To this acyldecapeptide *N*-hydroxysuccinimide ester, anisole (0.6 ml) and trifluoroacetic acid (6 ml) were added at −5 °C. After being left to stand for 25 min, the solution was evaporated *in vacuo* at 0 °C, and the residual oil was dissolved in DMF (15 ml). The solution was added dropwise into pyridine (300 ml) at room temperature for 2 h; the stirring was continued for an additional 2 h. After the solvent was removed, the residue was dissolved in a mixture of dioxane, methanol, and water (250 ml, 2 : 1 : 1, v/v). The solution was passed through the columns of Dowex 1 (OH^- form) and 50 (H^+ form). The columns were washed with the same solvent (300 ml), and the effluent was evaporated to dryness. The residual solid was collected by filtration with the aid of water. It was recrystallized from ethanol–dioxane–petroleum ether: yield, 246 mg (35%); mp 288—292 °C (dec); $[\alpha]_D^{24}$ −243° (*c* 0.3, DMF); R_f^1 0.95.

Found: C, 59.63; H, 6.76; N, 12.72%; mol wt 1290.[9] Calcd for $C_{66}H_{84}O_{14}N_{12}\cdot 3H_2O$: C, 59.85; H, 6.85; N, 12.69%; mol wt 1325.

cyclo-*(Ala–Orn–Ala–*D*-Phe–Pro–)*$_2$*·2HCl ([1,1′,3,3′-Ala]-GS·2HCl) (**10·2HCl**).* A solution of **9** (127 mg, 0.1 mmol) in 0.102 M HCl in ethanol (2.35 ml) was hydrogenated in the presence of Pd black. After removal of the catalyst, the filtrate was evaporated, and the resulting crystals were collected by filtration with the aid of ether. It was recrystallized from methanol–ether; yield, 90 mg (84%); mp 246—249 °C (dec); $[\alpha]_D^{24}$ −365° (*c* 0.2, MeOH); R_f^1 0.70, R_f^2 0.87.

Found: C, 52.80; H, 7.14; N, 14.42%. Calcd for $C_{50}H_{74}O_{10}N_{12}Cl_2\cdot 4H_2O$: C, 52.40; H, 7.20; N, 14.66%.

Electrophoresis. Electrophoresis on Toyo Roshi No. 52 paper was carried out with the solvent system: formic acid–acetic acid–methanol–water (1 : 3 : 6 : 10, v/v; pH 1.8) for 3 h at 600 V/30 cm. The mobility of **10** was comparable with that of GS; the ratio of the mobility of **10** *vs.* GS was 1.04.

ORD and CD Measurements. The measurements of ORD and CD were performed with Jasco Models J-20 and J-40, respectively. In Fig. 4-a are shown the ORD curves of **10** and GS, and in Fig. 4-b are shown the CD curves of Boc-pentapeptide (**6**), Boc-decapeptide (**8**), **10**, and GS.

Microbiological Assays. The microorganisms employed were *Escherichia coli*, *Staphylococcus aureus*, *Proteus vulgaris*, and *Bacillus subtilis*. The minimum amount of the compounds necessary for the complete inhibition of growth was determined by a dilution method in nutrient agar medium. GS was examined as a reference compound. Compound **10** exhibited no antibacterial activity against the microorganisms tested even at 100 μg/ml, whereas the minimum concentration of GS for inhibition were 2—5 μg/ml on *S. aureus* and 1—2 μg/ml on *B. subtilis*.

The authors wish to express their thanks to the staff members of Takeda Chemical Industries, Ltd., for the microbiological assays.

Cycloaddition Reactions of Thioacylketene Thioacetals and *N*-Thioacyldithioimidocarbonates

Masaharu O-OKA, Akihide KITAMURA, Renji OKAZAKI, and Naoki INAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
(Received August 10, 1977)

Thioacylketene thioacetals (**7**) and *N*-Thioacyldithioimidocarbonates (**8**) undergo 1,4-cycloaddition reactions with active acetylenes and olefins to give six-membered heterocycles. Tetracyanoethylene behaves in a different way to afford conjugated dienes. In the reactions with diphenylketene and diazo compounds, **7** and **8** undergo different types of reactions; **7** gave products derived from 1,2-cycloaddition to the C=S bond, while **8** afforded 1,4-cycloadducts. Compound **7** was found to be more reactive than **8**. The reactivity difference between **7** and **8** is discussed.

Conjugated dienes and their heteroanalogues (*i.e.*, heterodienes) (**1**) have been thoroughly investigated in organic chemistry.[1-5] However, investigations on heterodienes having a thiocarbonyl group (**1**, W and/or Z=S), are relatively scarce.[6-9]

W=X—Y=Z

1 W, X, Y, Z=C, O, N, S *etc.*

The finding[10] that the photoreactions of 1,2,4-dithiazole-3-thione (**2**) and 1,2-dithiole-3-thione (**3**) with olefins (**4**) provide a facile and efficient route to conjugated thiones such as 2-thioacylimino- (**5**) and 2-thioacylmethylene-1,3-dithiolanes (**6**) has aroused interest in the reactivity of these conjugated heterodienes containing a thiocarbonyl group.

9a—c

The possibility of a 1,2-cycloadducts such as **12** or **13** was excluded for the following reasons: (i) the UV spectra of **9** and **11** show no absorption due to a thiocarbonyl or thioamide group in the visible region, (ii) the NMR signals of four methylene protons in **9b** and **9c** appear as an A_2B_2 multiplet at δ 3.5, while **8b** and **8c**, which have an iminodithiolane ring, show their methylene protons as a singlet at δ 3.5, and (iii) thiete[13] is unstable in contrast to the high thermal stability of **9**—**11** obtained here.

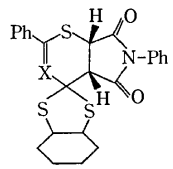
13



14: X=CH
15: X=N

Reactions with Electron-Deficient Olefins. Reactions of **7** and **8** with *N*-phenylmaleimide in refluxing benzene afforded 1,4-cycloadducts **14** and **15** in 67 and 70% yields, respectively. The NMR signals of the two methine protons at 5- and 6-positions appear as an AB quartet (J=10 Hz for **14** and J=9 Hz for **15**) at about δ 4.4. The value of this coupling constant indicates their *cis* configuration.

Reactions of **7**, **8a**, and **8b** with acrylamide in refluxing xylene afforded 1,4-cycloaddition products **16**, **17a**, and **17b**, respectively. In the case of **8a** and **8b**, the cycloadditions were carried out using acrylonitrile, methyl vinyl ketone, methyl and ethyl acrylates, and acrylaldehyde. The yields of the products and the reaction conditions are summarized in Table 1.

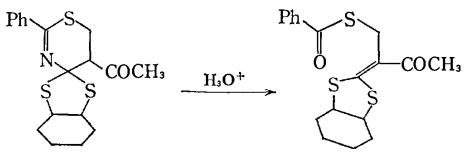
8	Olefin	Solvent	Temp (°C)	Time (h)	Product (%)
8a	$Y=CONH_2$	Xylene	140	24	**17a** (52)
8b	$Y=CONH_2$	Xylene	140	8	**17b** (22)
8a	Y=CN	Xylene[a)]	140	24	**18a** (73)
8a	$Y=COCH_3$	Xylene[a)]	140	24	**19a** (80)
8a	$Y=CO_2CH_3$	Xylene[a)]	140	24	**20a** (40)
8b	Y=CHO	Benzene[a)]	90	9	**21b** (74)
8b	$Y=CO_2C_2H_5$	DMF[a)]	154	12	**22b** (44)

a) In a sealed tube.

a single product and no isomer was obtained, in line with the above argument.

The orientation of addition in these reactions was established by acid-catalyzed hydrolysis of **19a**, affording **23**.



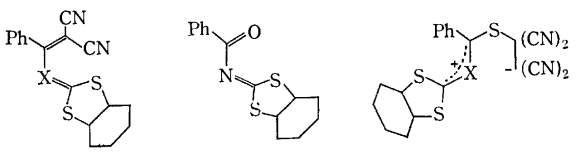
19a **23**

Since the other adducts (**17**—**22**) show similar spectral features to those of **19**, they would have a similar orientation to that in **19**, suggesting that the addition reaction takes place in a regioselective manner.

The reactions of **7** and **8a** with dimethyl fumarate, dimethyl maleate, and crotononitrile were carried out in order to examine the stereospecificity of the 1,4-cycloaddition reactions. However, they did not occur under the same conditions.

Reaction of **7** with tetracyanoethylene (TCNE) in refluxing acetonitrile afforded **24** (57%), while **8a** gave **25** (10%) and **26** (18%).

The formation of **24**—**26** can be explained in terms of the intermediacy of the zwitterion **27**; 1,2-addition followed by the elimination of $(NC)_2C{=}S$[14] would give **24** and **25** and hydrolysis by adventitious water in the solvent would lead to **26**.

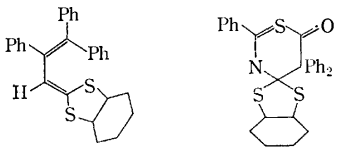


24: X=CH **26** **27**
25: X=N

Reaction with Diphenylketene. Reactions of **7** and **8a** with diphenylketene in *N,N*-dimethylformamide (DMF) at room temperature afforded diene **28** and 1,4-cycloadduct **29** in 88 and 80% yields, respectively. The NMR spectrum of **29** shows two methine protons as multiplets centered at δ 2.60 and 3.25 with equal intensity, suggesting the presence of two isomers (α and β forms). Compound **28** is identical with the compound obtained by desulfurization of episulfide **35** (*vide infra*).

The mass spectrum of **29** shows a weak metastable ion peak corresponding to the loss of COS from the molecular ion, but no molecular ion peak. The IR spectrum shows the presence of a carbonyl group at 1700 cm^{-1}, typical of an ester of alkanethioic *S*-acid.[15]

Formation of vinylketene thioacetal (**28**) is explicable by 1,2-cycloaddition to the thiocarbonyl bond followed by elimination of COS, in contrast to the formation of 1,4-cycloadduct (**29**) from **8a**.

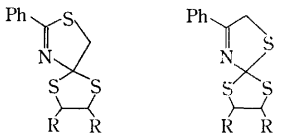


28 **29**

Reactions with Diazo Compounds. Reactions of **8a** and **8b** with diazomethane in ether at room temperature afforded 1,4-adducts **30a** (90%) and **30b** (90%), respectively, while **7** gave no tractable product.

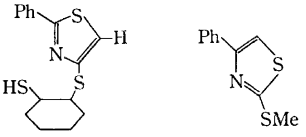
Compound **30a** consists of two stereoisomers (**30a**α and **30a**β), both of which are isolable by chromatography. The fact that the UV spectrum of **30a** has an absorption maximum at 247.5 nm, which is similar to that of the above-mentioned [4+2] adducts with olefins, strongly supports the structure **30** having Ph–C(=N–)S– unit.

A strong peak at *m/e* 121 ($PhCS^+$) in its mass spectrum is compatible with **30**, but not with isomeric structure **31**.



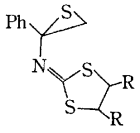
30a: RR=$(CH_2)_4$ **31**
b: R=H

Acid hydrolysis of **30a** yielded **32**. The UV spectrum shows absorption maxima at 254.5 (ε 15700) and 308 nm (7310), which are much higher than those reported[16] for **33** [238 (ε 18000) and 268 nm (12200)], a structure similar to that obtained from **31**.

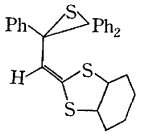


32 **33**

The possibility of episulfide (**34**) as an alternative structure of **30** is excluded by the fact that **30** was not desulfurized by triphenylphosphine. Episulfide **35** underwent desulfurization by triphenylphosphine to give diene **28**.

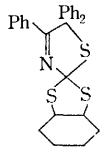


34

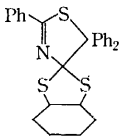


35

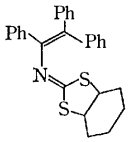
Compound **7** reacted with diphenyldiazomethane in ether at room temperature to give episulfide **35** in 47% yield, whereas **8a** (in benzene) afforded **36** (51%), **37** (16%), and **38** (7%).



36

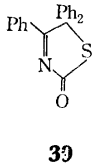


37

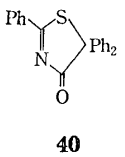


38

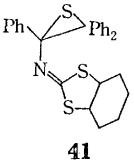
Compound **36** also consists of two chromatographically isolable stereoisomers (**36**α and **36**β). The fragmentation pattern of the mass spectrum of **36** is similar to that of **38**, but not to that of **37**. Compound **36** has strong peaks at *m/e* 427 (M^+—S), 287 ($PhCPh_2CS^+$), and 255 ($PhCCPh_2^+$), whereas these peaks are negligible in the case of **37**. Although both **36** and **37** have an absorption maximum near 253 nm, they differ in pattern, that of **37** being very similar to the pattern of [4+2] adducts obtained from olefins. Further support for the structure **36** comes from conversion (treatment with trimethyloxonium tetrafluoroborate and subsequent hydrolysis) of the thioacetal into the carbonyl group to give **39**, which has a different melting point from that reported for **40**.[17]



39



40

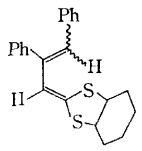


41

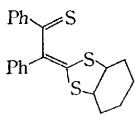
The possibility of episulfide **41** as an alternative to **36** or **37** is excluded also in this case; the compounds (**36** and **37**) undergo no desulfurization by triphenylphosphine.

Reaction of **7** with phenyldiazomethane in ether led to diene **42** (61%) instead of the corresponding episulfide like **35**.

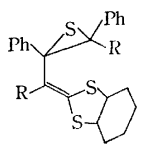
Thione **43** also reacted with diphenyl- or phenyldiazomethane to give **44** (93%), or **45** (7%), and **47** (67%), respectively. Episulfide **44** gave **46** by triphenylphosphine.



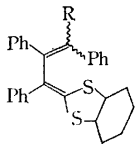
42



43

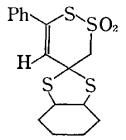


44: R=Ph **45**: R=H



46: R=Ph **47**: R=H

Reaction with Sulfene. Sulfene generated *in situ* from methanesulfonyl chloride and triethylamine at 5 °C in benzene reacted with **7** to afford 1,4-cycloadduct **48** (57%). Under comparable conditions **8a** did not react with sulfene.



48

Comparison of the Reactivities of Thioacylketene Thioacetal (7) and N-Thioacyldithioimidocarbonate (8). A comparison of the reaction conditions of **7** with those of **8** in some reactions is given in Table 2.

Table 2. Comparison of the reactions of **7** and **8**

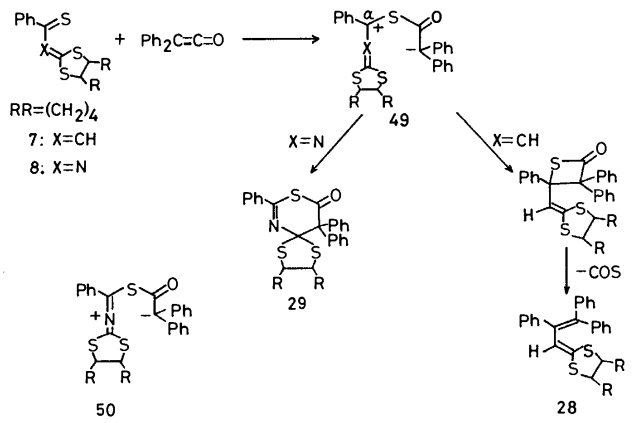
Reagents	**7**	**8**
MeO_2C-C≡C-CO_2Me	in CH_2Cl_2, r.t. 10 h	in benzene, r.t. 7 days
N-Phenylmaleimide	in benzene, reflux, 4 h	in benzene, reflux, 58 h
Acrylamide	in xylene, reflux, 2 h	in xylene, reflux, 24 h
TCNE	in CH_3CN, reflux, 2 h	in CH_3CN, reflux, 28 h
Ph_2CN_2	in ether, r.t. 15 h	in ether, r.t. 3 days
Sulfene[a]	in benzene, 5 °C, 1 h	no reaction

a) Generated from methanesulfonyl chloride and triethylamine.

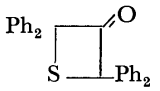
We see that **8** requires severer conditions than **7**, indicating that the reactivity of **8** is lower than that of **7**. This is in line with the known fact[2] that the reactivity of dienes decreases upon replacement of its component carbon by nitrogen, which is due to the lowering of HOMO level of the diene part.

The reactions of **8** with diphenylketene and diazo compounds give rise to 1,4-cycloadducts, while those of **7** afford products *via* 1,2-addition. The preference of 1,4-addition over 1,2-addition in the reactions of **8** presumably reflects an importance of the lone pair electrons of nitrogen in these reactions.

The reaction with diphenylketene most likely proceeds *via* zwitterionic intermediate (**49**). This is strongly supported by the observation that the reaction of **7** with the ketene is greatly accelerated by use of a polar solvent; the reaction requires refluxing for 2 days in benzene whereas in DMF it was complete after 12 h at room temperature.



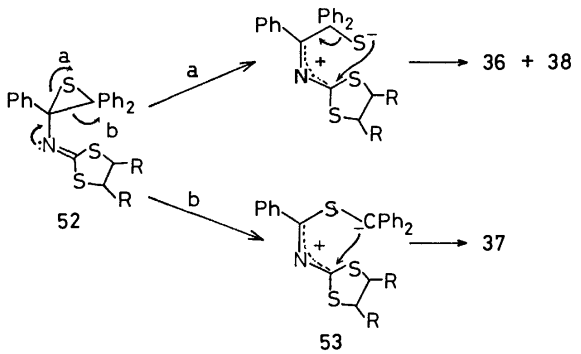
In the case of **8**, the possible contribution of canonical structure (**50**) would reduce reactivity of C_α, thus leading to 1,4-adduct. It is noteworthy that the reaction pattern of **7** and **8** with the ketene differs from that of thiobenzophenone, a typical thioketone, which gives 3-oxothietane (**51**).[18]



51

The fact[19] that the reaction product of a thioketone with diphenyldiazomethane is always an episulfide shows that **35** is the expected product in the reaction of **7** with diphenyldiazomethane.

The instability of **52** as compared with **35** is most probably due to the additional assistance of the heterolytic cleavage by the nitrogen lone pair electrons other than by the N=C double bond as depicted below. The preferable cleavage *via* path *a* over *via* path *b* is presumably due to the higher lability of the C–S bond in heterolytic cleavage and also to the stability of thiolate anion thus formed.



For the formation of **37**, however, the possibility that **53** or its diradical counterpart is formed directly from the two substrates can not be excluded.

Experimental

IR and UV spectra were recorded on Hitachi EPI-G2 and ESP-3 spectrophotometers, respectively. The NMR spectra were obtained in deuteriochloroform solution, unless otherwise noted, at 60 MHz with a Hitachi R-24 spectrometer using tetramethylsilane as an internal standard. The mass spectra were measured with a Hitachi RMU-6 spectrometer (beam energy 70 eV). All the reactions were carried out under nitrogen or argon.

*Preparation of 2-Thiobenzoylimino-1,3-dithiolane (**8b**).* To a solution of 2-benzoylimino-1,3-dithiolane[20] (0.5 g, 2.2 mmol) in benzene (20 ml) was added phosphorus pentasulfide (2 g, 4 mmol) and pyridine (1 ml). The mixture was refluxed for 4.5 h under stirring. The phosphorus pentasulfide was filtered off and the filtrate was washed with water until the aqueous layer became neutral. The benzene layer was dried ($MgSO_4$) and evaporated under reduced pressure. The residue was subjected to dry column chromatography (DCC) (silica gel, ether-hexane (1 : 2)) to give 246 mg (46%) of **8b** as a purple oil. The oil was crystallized from ether at Dry Ice temperature as thin purple crystals, mp 49—50 °C; NMR: δ 3.4 (s, 4H), 7.2—7.6 (m, 3H), and 8.2—8.5 (m, 2H); UV: λ_{max} (CH_2Cl_2) 239 (ε 13400), 327 (25500), 370 sh (10100), and 560 nm (161).

*Preparation of 2-Thioacetylimino-1,3-dithiolane (**8c**).* A mixture of 2-acetylimino-1,3-dithiolane[20] (1 g, 6.2 mmol), phosphorus pentasulfide (3 g, 6 mmol) and pyridine (1 ml) in benzene (40 ml) was heated at 70 °C for 1 h under stirring. After the usual work-up, the residue was subjected to DCC (silica gel, CH_2Cl_2) to give 0.5 g (46%) of **8c** as a red oil, which could not be crystallized. NMR: δ 2.75 (s, 3H) and 3.55 (s, 4H).

*Reaction of **7** with Dimethyl Acetylenedicarboxylate.* A solution of **7**[10] (140 mg, 0.48 mmol) and the ester (91 mg, 0.64 mmol) in dichloromethane (3 ml) was left to stand at room temperature for 10 h. After evaporation of the solvent, the residue was recrystallized from methanol to give **10** (173 mg, 83%); mp 128—129 °C; IR (KBr): 1735 cm^{-1}; NMR: δ 1.3—2.2 (m, 8H), 3.85 (s, 6H), 3.9—4.2 (m, 2H), 6.30 (s, 1H), and 7.30—7.65 (m, 5H).

Found: C, 58.32; H, 5.08; S, 21.87%. Calcd for $C_{21}H_{22}O_4S_3$: C, 58.04; H, 5.10; S, 22.13%.

*Reaction of **8a** with Dibenzoylacetylene.* A solution of **8a**[10] (293 mg, 1 mmol) and the acetylene (281 mg, 1.2 mmol) in benzene (30 ml) was refluxed for 9.5 h. The solvent was evaporated *in vacuo* and the residue was subjected to DCC (silica gel, CH_2Cl_2–CCl_4 (1 : 1)) to give **9a** (320 mg, 61%) as colorless crystals; mp 148—149 °C (dec) (from cyclohexane); IR (KBr): 1660 cm^{-1}; NMR: δ 1.1—2.5 (m, 8H), 3.7—4.0 (m, 2H), and 7.1—8.1 (m, 15H); UV: λ_{max} (CH_2Cl_2) 257 nm (ε 35400); MS: *m/e* 104 (30%) and 103 (100).

Found: C, 68.19; H, 4.65; N, 2.48; S, 18.11%. Calcd for $C_{30}H_{25}NO_2S_3$: C, 68.28; H, 4.77; N, 2.65; S, 18.23%.

*Reaction of **8b** with Dibenzoylacetylene.* A solution of **8b** (102 mg, 0.4 mmol) and the acetylene (100 mg, 0.4 mmol) in benzene (20 ml) was stirred at room temperature for 4 days. A similar treatment to that in the reaction of **8a** gave 168 mg (84%) of **9b**; mp 170—170.5 °C (dec) (from CH_2Cl_2–MeOH); IR (KBr): 1660 and 1590 cm^{-1}; NMR: δ 3.5 (m, 4H) and 7.1—8.1 (m, 15H).

Found: C, 66.01; H, 3.90; N, 3.01; S, 20.33%. Calcd for $C_{26}H_{19}NO_2S_3$: C, 65.93; H, 4.04; N, 2.96; S, 20.31%.

*Reaction of **8b** with Dimethyl Acetylenedicarboxylate.* A mixture of **8b** (156 mg, 0.65 mmol) and the ester (*ca.* 0.3 ml) in benzene (20 ml) was stirred at room temperature for 7 days. The benzene was evaporated and the residue was chromatographed (DCC, silica gel) with CH_2Cl_2 to give 196 mg (79%) of **11**; mp 171—172 °C (from CH_2Cl_2–MeOH); IR (KBr): 1730 cm^{-1}; NMR: δ 3.65 (m, 4H), 3.92 (s, 3H), 3.95 (s, 3H), 7.3—7.6 (m, 3H), and 7.7—8.1 (m, 2H); UV: λ_{max}

(CH_2Cl_2) 254.5 nm (ε 22000); MS: *m/e* 381 (M^+, 9%) and 353 (100).

Found: C, 50.32; H, 3.80; N, 3.72; S, 25.04%. Calcd for $C_{16}H_{15}NO_4S_3$: C, 50.37; H, 3.96; N, 3.67; S, 25.21%.

Reaction of ***8c*** *with Dibenzoylacetylene.* A solution of **8c** (231 mg, 1.4 mmol) and the acetylene (332 mg, 1.4 mmol) in chloroform (10 ml) was stirred at room temperature for 4 days. After removal of chloroform, the residue was chromatographed with CH_2Cl_2–CCl_4 (2 : 1) to give 460 mg (80%) of **9c**; mp 62—63 °C (CH_2Cl_2–MeOH); IR (KBr): 1660 cm^{-1}; NMR: δ 2.4 (s, 3H), 3.4 (m, 4H), and 7.1—8.0 (m, 10H); UV: λ_{max} (CH_2Cl_2) 259.5 nm (ε 29800); MS: *m/e* 411 (M^+, trace) and 47 (100%).

Reaction of ***7*** *with* N-*Phenylmaleimide.* A mixture of **7** (144 mg, 0.50 mmol) and the imide (110 mg, 0.63 mmol) in benzene (4 ml) was refluxed for 4 h. The residue obtained after removal of benzene was recrystallized from ethanol to afford **14** (122 mg, 67%); mp 179.5—181.0 °C; IR (KBr): 1720 cm^{-1}; NMR: δ 1.1—2.2 (m, 8H), 3.6—4.2 (m, 2H), 4.35 (ABq, 2H, J=10 Hz, $\Delta\delta$=0.29), 6.97 (s, 1H), and 7.1—7.7 (m, 10H).

Found: C, 59.30; H, 6.48; N, 3.55; S, 26.00%. Calcd for $C_{25}H_{23}NO_2S_3$: C, 59.14; H, 6.34; N, 3.83; S, 26.31%.

Reaction of ***8a*** *with* N-*Phenylmaleimide.* A solution of **8a** (293 mg, 1 mmol) and the imide (208 mg, 1.2 mmol) in benzene (30 ml) was refluxed for 58 h. The solvent was evaporated and the residue was subjected to preparative TLC (silica gel, CH_2Cl_2–hexane (1 : 1)) to give **15** (326 mg, 70%) as colorless crystals; mp 208—209 °C (from EtOH); IR (KBr): 1720 cm^{-1}; NMR: δ 1.0—2.7 (m, 8H), 3.6—4.1 (m, 2H), 4.1 (d, 1H, J=9 Hz), 4.7 (d, 1H, J=9 Hz), and 7.0—8.2 (m, 10H); UV: λ_{max} (EtOH) 249 (ε 19800) and 309 nm (3690); MS: *m/e* 466 (M^+, 19%), and 104 (100).

Found: C, 61.98; H, 4.76; N, 5.96; S, 20.41%. Calcd for $C_{24}H_{22}N_2O_2S_3$: C, 61.77; H, 4.75; N, 6.00; S, 20.61%.

Reaction of ***7*** *with Acrylamide.* A suspension of **7** (146 mg, 0.50 mmol), acrylamide (351 mg, 5.0 mmol) and a trace of hydroquinone in xylene (4 ml) was refluxed for 2 h. After cooling, excess acrylamide was filtered off and the filtrate was washed thoroughly with water to remove acrylamide. After removal of the solvent, the residue was recrystallized from methylcyclohexane to give **16** (127 mg, 70%); mp 190—191 °C; IR (KBr): 3450 and 1670 cm^{-1}; NMR: δ 0.9—2.3 (m, 8H), 3.32 (bs, 3H), 3.7—4.1 (m, 2H), 6.28 (s, 1H), 6.1—6.6 (m, 2H), and 7.1—7.7 (m, 5H).

Found: C, 59.78; H, 5.90; N, 3.75; S, 26.18%. Calcd for $C_{18}H_{21}NOS_3$: C, 59.47; H, 5.82; N, 3.85; S, 26.46%.

Reaction of ***8a*** *with Acrylamide.* A mixture of **8a** (293 mg, 1 mmol), acrylamide (710 mg, 10 mmol) and a small amount of hydroquinone in xylene (10 ml) was refluxed for 24 h. After similar work-up to that in the reaction of **7**, the reaction mixture was subjected to DCC (silica gel, ether). The column was divided into four fractions. The second fraction was recrystallized from methanol to afford 76 mg (21%) of **17a**α; mp 194—194.5 °C; IR (KBr): 3460, 3420, and 1660 cm^{-1}; NMR: δ 1.0—2.5 (m, 8H), 3.35 (m, 1H), 3.4—3.7 (m, 2H), 3.9—4.4 (m, 2H), 5.8—6.9 (bd, 2H), 7.2—7.6 (m, 3H), and 7.7—8.0 (m, 2H); UV: λ_{max} (EtOH) 246 nm (ε 13400); MS: *m/e* 364 (M^+, trace) and 121 (100%).

Found: C, 56.27; H, 5.56; N, 7.39; S, 26.27%. Calcd for $C_{17}H_{20}N_2OS_3$: C, 56.01; H, 5.53; N, 7.68; S, 26.39%.

The third fraction was also recrystallized from methanol to give 112 mg (31%) of **17a**β; mp 192—192.5 °C; IR (KBr): 3450 and 1665 cm^{-1}; NMR: δ 1.2—2.6 (m, 8H), 3.15 (m, 1H), 3.4—3.7 (m, 2H), 3.7—4.1 (m, 2H), 6.2—7.0 (bd, 2H), 7.25—7.65 (m, 3H), and 7.65—8.0 (m, 2H); UV: λ_{max} (EtOH) 246 nm (ε 13400); MS: *m/e* 364 (M^+, trace) and 121 (100%).

Found: C, 55.99; H, 5.55; N, 7.77; S, 26.10%. Calcd for $C_{17}H_{20}N_2OS_3$: C, 56.01; H, 5.53; N, 7.68; S, 26.39%.

Reaction of ***8b*** *with Acrylamide.* A solution of **8b** (359 mg, 1.5 mmol), acrylamide (727 mg, 10 mmol), and a small amount of hydroquinone in xylene (15 ml) was refluxed for 8 h. After the same treatment as described above, the residue was subjected to preparative TLC on silica gel with chloroform-ethyl acetate (1 : 1) to give 69 mg (22%) of **17b**; mp 179—180 °C (from MeOH); IR (KBr): 3460 and 1685 cm^{-1}; NMR: δ 3.2—3.9 (m, 7H), 6.1—6.9 (bd, 2H), 7.2—7.6 (m, 3H), and 7.6—8.0 (m, 2H).

Found: C, 50.10; H, 4.49; N, 8.98; S, 30.70%. Calcd for $C_{13}H_{14}N_2OS_3$: C, 50.29; H, 4.55; N, 9.02; S, 30.98%.

Reaction of ***8b*** *with Ethyl Acrylate.* A solution of **8b** (239 mg, 1 mmol), the ester (1 g, 10 mmol), and a small amount of hydroquinone in DMF (20 ml) was heated at 154 °C for 14 h in a sealed tube. The DMF solution was poured into water and extracted with CH_2Cl_2. The extracts were washed with water, dried ($MgSO_4$) and evaporated. The residue was subjected to preparative TLC (silica gel, CH_2Cl_2) to give 149 mg (44%) of **22b** as a yellow oil; IR (neat): 1730 cm^{-1}; NMR: δ 1.23 (t, 3H, J=7 Hz), 3.2—3.9 (m, 7H), 4.2 (q, 2H, J=7 Hz), 7.2—7.6 (m, 3H), and 7.6—8.0 (m, 2H).

Reaction of ***8a*** *with Acrylonitrile.* A mixture of **8a** (293 mg, 1 mmol), acrylonitrile (530 mg, 10 mmol) and a small amount of hydroquinone in xylene (1 ml) was heated in a sealed tube at 140 °C for 1 day. After removal of the solvent *in vacuo*, the residue was subjected to DCC (silica gel, CH_2Cl_2) to give 252 mg (73%) of **18a** as colorless crystals; mp 134—135 °C (from MeOH); IR (KBr): 2240 cm^{-1}; NMR: δ 1.0—2.1 (m, 8H), 3.45 (bs, 3H), 3.85—4.3 (m, 2H), 7.2—7.65 (m, 3H), and 7.65—7.9 (m, 2H); UV: λ_{max} (EtOH) 248 nm (ε 18100); MS: *m/e* 346 (M^+, 2%) and 121 (100).

Found: C, 59.19; H, 5.30; N, 7.92; S, 27.47%. Calcd for $C_{17}H_{18}N_2S_3$: C, 58.92, H, 5.24; N, 8.08; S, 27.76%.

Reaction of ***8a*** *with Methyl Vinyl Ketone.* The reaction was carried out in the same scale and under the same conditions as those in the reaction with acrylonitrile. The same work-up gave 291 mg (80%) of **19a**; mp 175—176 °C (from MeOH); IR (KBr): 1710 cm^{-1}; NMR: δ 1.0—2.4 (m, 8H), 2.35 (s, 3H), 3.5 (bs, 3H), 3.7—4.0 (m, 1H), 4.0—4.35 (m, 1H), 7.2—7.6 (m, 3H), and 7.6—8.1 (m, 2H); UV: λ_{max} (EtOH) 247 nm (ε 16900); MS: *m/e* 363 (M^+, trace) and 121 (100%).

Found: C, 59.29; H, 5.75; N, 3.81; S, 26.42%. Calcd for $C_{18}H_{21}NOS_3$: C, 59.47; H, 5.82; N, 3.85; S, 26.46%.

Acid-catalyzed Hydrolysis of ***19a***. A mixture of **19a** (530 mg, 1.46 mmol) and 1 M sulfuric acid (3 ml) in ethanol (10 ml) was refluxed for about 10 h. After removal of ethanol 100 ml of water was added and the solution was extracted with CH_2Cl_2. The dried extract was evaporated and the residue was subjected to DCC (silica gel, CH_2Cl_2) gave 177 mg (33%) of **23**; mp 127—128 °C (from MeOH); IR (KBr): 1650 and 1630 cm^{-1}; NMR: δ 1.05—2.30 (m, 8H), 2.30 (s, 3H), 3.47—3.96 (m, 2H), 4.25 (s, 2H), 7.0—7.46 (m, 3H), and 7.5—8.17 (m, 2H); UV: λ_{max} (EtOH) 238 (ε 12600), 273 (11100), and 330 nm (14700); MS: *m/e* 364 (M^+, 5%) and 227 (100).

Found: C, 59.22; H, 5.42; S, 26.36%. Calcd for $C_{18}H_{20}O_2S_3$: C, 59.31; H, 5.53; S, 26.39%.

Reaction of ***8a*** *with Methyl Acrylate.* The reaction was also carried out in the same way as that in the reaction with acrylonitrile to give **20a** (154 mg, 40%); mp 132.5—133 °C

(from MeOH); IR (KBr): 1740 cm^{-1}; NMR: δ 1.0—2.6 (m, 8H), 3.4—3.75 (m, 3H), 3.72 (s, 3H), 3.75—4.1 (m, 2H), 7.15—7.5 (m, 3H), and 7.6—7.9 (m, 2H); UV: λ_{max} (EtOH) 247 nm (ε 14000); MS: *m/e* 379 (M^+, trace) and 121 (100%).

Found: C, 57.16; H, 5.54; N, 3.65; S, 25.11%. Calcd for $C_{18}H_{21}NO_2S_3$: C, 56.96; H, 5.58; N, 3.69; S, 25.34%.

Reaction of ***8b*** *with Acrylaldehyde.* A solution of **8b** (239 mg, 1 mmol), acrylaldehyde (168 mg, 3 mmol), and a small amount of hydroquinone in benzene (3 ml), was heated at 90 °C for 9 h in a sealed tube. After evaporation of the solvent, the residue was chromatographed with ether-hexane (4 : 1) to give 219 mg (74%) of **21b** as a yellow oil; IR (KBr): 1720 cm^{-1}; NMR: δ 2.8—4.0 (m, 7H), 7.2—7.6 (m, 3H), 7.6—7.9 (m, 2H), and 9.9 (s, 1H).

Reaction of ***7*** *with TCNE.* A solution of TCNE (144 mg, 1.12 mmol) and **7** (290 mg, 1.0 mmol) in acetonitrile (5 ml) was refluxed for 2 h. After the usual work-up, the reaction mixture was subjected to DCC (silica gel, $CHCl_3$) to give yellow crystals **24** (212 mg, 57%); mp 146.5—148 °C (from MeOH); IR (KBr): 2200 (C≡N) and 1495 cm^{-1} (conj. C=C); NMR: δ 1.1—2.0 (m, 8H), 3.6—4.0 (m, 2H), 6.98 (s, 1H), and 7.1—7.6 (m, 5H); MS: *m/e* 324 (M^+, 33%) and 81 (100).

Found: C, 66.75; H, 5.02; N, 8.77; S, 19.55%. Calcd for $C_{18}H_{16}N_2S_2$: C, 66.63; H, 4.97; N, 8.63; S, 19.76%.

Reaction of ***8a*** *with TCNE.* A solution of **8a** (293 mg, 1 mmol) and TCNE (153 mg, 1.2 mmol) in acetonitrile (50 ml) was refluxed for 28 h. Purification by DCC (silica gel, CH_2Cl_2-CCl_4 (2 : 1)) and preparative TLC (silica gel, CH_2Cl_2-hexane (2 : 1)) gave 32 mg (10%) of **25** (a yellow oil); IR (neat): 2220 cm^{-1}; NMR: δ 1.2—2.4 (m, 8H), 3.9—4.4 (m, 2H), and 7.2—7.9 (m, 5H); UV: λ_{max} (CH_2Cl_2) 230 (ε 13500), 277 (17200), 314 (19600), and 324 nm (18400); MS: *m/e* 325 (M^+, 2%) and 81 (100); and 51 mg (18%) of **26** (colorless crystals); mp 110.5—111 °C (from EtOH); IR (KBr): 1625 cm^{-1}; NMR: δ 1.2—2.4 (m, 8H), 3.7—4.2 (m, 2H), 7.25—7.65 (m, 3H), and 8.15—8.45 (m, 2H); MS: *m/e* 277 (M^+, 3%) and 105 (100).

Found: C, 60.85; H, 5.40; N, 4.85; S, 23.09%. Calcd for $C_{14}H_{15}NOS_2$: C, 60.62; H, 5.45; N, 5.05; S, 23.12%. Compound **25** was not purified so as to give an analytically pure specimen.

Reaction of ***7*** *with Diphenylketene.* A DMF solution (10 ml) of **7** (292 mg, 1 mmol) and the ketene[21] (1.0 g, 5.2 mmol) was stirred at room temperature for 10 h. Addition of water, extraction with ether and then DCC (hexane-ether (9 : 1)) afforded **28** (376 mg, 88%) as yellow crystals. A similar reaction in refluxing benzene for 47 h also gave **28** (85%), which was identical with the desulfurization product of **35** by triphenylphosphine (*vide infra*).

Reaction of ***8a*** *with Diphenylketene.* A solution of **8a** (293 mg, 1 mmol) and the ketene (1.07 g, 5.5 mmol) in DMF (10 ml) was stirred at room temperature for 2 days. After similar work-up to that described above, DCC (silica gel, CH_2Cl_2-hexane (2 : 1)) of the residue afforded 389 mg (80%) of **29**. It was thermally unstable, undergoing fragmentation to **8a** upon refluxing in ethanol. Mp 122—125 °C (dec) (from CH_2Cl_2-MeOH). IR (KBr): 1700 cm^{-1}; NMR: δ 0.7—2.5 (m, 8H), 2.4—2.8 (m, 1H), 3.05—3.45 (m, 1H), and 6.9—7.85 (m, 15H); UV: λ_{max} (CH_2Cl_2)229 (ε 17400) and 251 nm (18200); MS: *m/e* 427 (0.3%) and 165 (100).

Found: C, 68.68; H, 5.11; N, 2.86; S, 19.49%. Calcd for $C_{28}H_{25}NOS_3$: C, 68.96; H, 5.17; N, 2.87; S, 19.72%.

Reaction of ***8a*** *with Diazomethane.* A solution of **8a** (293 mg, 1 mmol) and a large excess of diazomethane[22] in ether (150 ml) was stirred for 1 h. The ether was evaporated and the residue was subjected to preparative TLC (silica gel, benzene) to give 129 mg (41%) of **30a**α and 154 mg (50%) of **30a**β. **30a**α: mp 90—91 °C (from EtOH); NMR: δ 1.1—2.7 (m, 8H), 4.07 (s, 2H), 3.8—4.3 (m, 2H), 7.3–7.7 (m, 3H), and 7.8—8.2 (m, 2H); UV: λ_{max} (EtOH) 247.5 (ε 17800) and 285 sh nm (6340); MS: *m/e* 307 (M^+, 12%), 274 (10), 225 (100), and 121 (22).

Found: C, 58.69; H, 5.61; N, 4.63; S, 31.01%. Calcd for $C_{15}H_{17}NS_3$: C, 58.59; H, 5.56; N, 4.56; S, 31.28%.

30aβ: mp 92—93 °C (from EtOH); NMR: δ 1.1—2.7 (m, 8H), 4.07 (s, 2H), 3.9—4.4 (m, 2H), 7.3—7.7 (m, 3H), and 7.8—8.2 (m, 2H); UV: λ_{max} (EtOH) 247.5 (ε 17800) and 285 sh nm (6340); MS: *m/e* 307 (M^+, 5%), 274 (4), 225 (27), 193 (100), and 121 (10).

Found: C, 58.83; H, 5.55; N, 4.80; S, 30.96%. Calcd for $C_{15}H_{17}NS_3$: C, 58.59; H, 5.56; N, 4.56; S, 31.28%.

Acid-Catalyzed Hydrolysis of ***30a***α. An ethanol solution (25 ml) of **30a**α (192 mg, 0.63 mmol) and 3/2M sulfuric acid (2 ml) was refluxed for 15 h. After removal of ethanol, 50 ml of water was added and the solution was extracted with CH_2Cl_2, the extract being dried over $MgSO_4$, and the solvent evaporated. The residue subjected to preparative TLC (silica gel, hexane-ether (4 : 1)) gave 108 mg (56%) of **32** as a colorless oil; IR (neat): 2550 cm^{-1}; NMR: δ 0.8—2.1 (m, 8H), 2.04 (d, 1H, J=6.5 Hz), 3.5 (m, 1H), 3.86 (m, 1H), 7.18 (s, 1H), 7.25—7.6 (m, 3H), and 7.7—8.15 (m, 2H); MS: *m/e* 307 (M^+, 4%) and 193 (100); and 21 mg (11%) of **30a**β.

Reaction of ***8b*** *with Diazomethane.* A solution of **8b** (239 mg, 1 mmol) and a large excess of diazomethane in ether (200 ml) was stirred at room temperature for 1 h. The solvent was evaporated and the residue was chromatographed (DCC, silica gel) with CH_2Cl_2–CCl_4 (1 : 1) to give 228 mg (90%) of **30b**; mp 104—105 °C (from EtOH); NMR: δ 3.52 (m, 4H), 3.95 (s, 2H), 7.2—7.6 (m, 3H), and 7.6—8.0 (m, 2H); MS: *m/e* 253 (M^+, 28%), 193 (100), and 121 (29).

Found: C, 52.26; H, 4.21; N, 5.43; S, 37.86%. Calcd for $C_{11}H_{11}NS_3$: C, 52.14; H, 4.34; N, 5.53; S, 37.96%.

Reaction of ***7*** *with Diphenyldiazomethane.* A mixture of **7** (876 mg, 3.0 mmol) and the diazomethane[23] (873 mg, 4.5 mmol) in ether (70 ml) was stirred at room temperature for 17 h. Colorless precipitates **35** (651 mg, 47%) were collected and recrystallized from benzene-ether; mp 147—148 °C; NMR: δ 0.9—2.0 (m, 8H), 3.5—3.75 (m, 2H), 5.85 (s, 1H), and 6.8—7.7 (m, 15H); MS: *m/e* 458 (M^+, trace), 426 (70%), and 344 (100).

Found: C, 73.41; H, 5.86; S, 20.67%. Calcd for $C_{28}H_{26}S_3$: C, 73.31; H, 5.72; S, 20.97%.

Reaction of ***8a*** *with Diphenyldiazomethane.* A solution of **8a** (879 mg, 3 mmol) and the diazomethane (679 mg, 3.5 mmol) in benzene (30 ml) was stirred for 5 days. The solvent was evaporated *in vacuo* and the residue was subjected to preparative TLC (silica gel, benzene-CCl_4 (1 : 1)) to give 592 mg (43%) of **36**α, 109 mg (8%) of **36**β, 219 mg (16%) of **37**α, and 93 mg (7%) of **38** as pale yellow crystals. **36**α: mp 158.5—159 °C (from CH_2Cl_2–MeOH); NMR: δ 1.0—2.5 (m, 8H), 3.8—4.15 (m, 2H), and 6.9—7.9 (m, 15H); UV: λ_{max} (EtOH) 253 (ε 12900) and 281 nm (9180); MS: *m/e* 459 (M^+, 2%), 427 (100), 345 (56), 313 (42), 287 (39), and 255 (42).

Found: C, 70.32; H, 5.37; N, 3.22; S, 20.93%. Calcd for $C_{27}H_{25}NS_3$: C, 70.55; H, 5.48; N, 3.05; S, 20.92%.

36β: mp 171—172 °C (from CH_2Cl_2–MeOH); NMR: δ 1.0—2.5 (m, 8H), 3.9—4.3 (m, 2H), and 6.8—7.8 (m, 15H); UV: λ_{max} (EtOH) 253 (ε 12900) and 281 nm (9180); MS: *m/e* 459 (M^+, 8%), 427 (87), 345 (35), 313 (45), 287 (26), 255 (38), and 81 (100).

Found: C, 70.49; H, 5.38; N, 3.17; S, 20.99%. Calcd for $C_{27}H_{25}NS_3$: C, 70.55; H, 5.48; N, 3.05; S, 20.92%.

37α: mp 185—186 °C (from CH_2Cl_2–MeOH); NMR: δ 1.0—2.5 (m, 8H), 3.1—3.5 (m, 2H), and 6.9—8.0 (m, 15H); UV: λ_{max} (EtOH) 253 (ε 16100) and 310 nm (3350); MS: *m/e* 459 (M^+, 11%), 427 (3), 345 (8), 313 (54), 261 (41), and 121 (100).

Found: C, 70.82; H, 5.47; N, 3.23; S, 20.84%. Calcd for $C_{27}H_{25}NS_3$: C, 70.55; H, 5.48; N, 3.05; S, 20.92%.

38: mp 92—93 °C (from hexane); NMR: δ 1.0—2.0 (m, 8H), 3.6—4.1 (m, 2H), and 7.0—7.6 (m, 15H); UV: λ_{max} (EtOH) 236 (ε 14200) and 305 nm (8110); MS: *m/e* 427 (M^+, 100%), 345 (38), 313 (13), 287 (30), and 255 (33).

A similar experiment was carried out in ether using 293 mg (1 mmol) of **8a** and 241 mg (1.2 mmol) of diphenyldiazomethane, 144 mg (31%) of **36α**, 62 mg (13%) of **36β**, 57 mg (12%) of **37α**, 73 mg (16%) of **37β** and 101 mg (24%) of **38** being obtained. **37β**: mp 231—232 °C (from CH_2Cl_2–MeOH); NMR: δ 1.0—2.0 (m, 8H), 3.8—4.2 (m, 2H), and 6.9—7.9 (m, 15H); UV: λ_{max} (EtOH) 253 (ε 16100) and 305 nm (3350); MS: *m/e* 459 (M^+, 8%), 427 (4), 345 (24), 313 (49), 261 (36), and 121 (100).

Found: C, 70.54; H, 5.44; N, 3.42; S, 20.40%. Calcd for $C_{27}H_{25}NS_3$: C, 70.55; H, 5.48; N, 3.05; S, 20.92%.

*Conversion of **36α** into **39**.* A solution of **36α** (100 mg, 0.22 mmol) and trimethyloxonium tetrafluoroborate (66 mg, 0.46 mmol) in CH_2Cl_2 (20 ml) was refluxed for 10 h. The reaction mixture was subjected to preparative TLC (silica gel, benzene) to give 27 mg (27%) of unchanged **36α**, 48 mg (48%) of **36β**, and 15 mg (27%) of **39**, mp 166—167 °C; IR (KBr): 1705 cm^{-1}; NMR: δ 7.3—7.8 (m, 13H) and 7.8—8.15 (m, 2H); MS: *m/e* 329 (M^+, 21%) and 198 (100).

*Reaction of **7** with Phenyldiazomethane.* An ethereal solution (40 ml) of **7** (205 mg, 0.7 mmol) and excess phenyldiazomethane[24] was stirred at room temperature for 2 h. TLC purification afforded **42** (176 mg, 61%) as a yellow oil. NMR: δ 1.0—2.1 (m, 8H), 3.5—3.85 (m, 2H), 6.50 (s, 1H), 7.10 (s, 1H), and 6.9—7.5 (m, 10H); MS: *m/e* 350 (M^+, 14%) and 278 (100).

Found: C, 75.16; H, 6.07%. Calcd for $C_{22}H_{22}S_2$: C, 75.37; H, 6.34%.

*Reaction of **43** with Diphenyldiazomethane.* A benzene solution (35 ml) of **43**[10] (368 mg, 1 mmol) and diphenyldiazomethane (388 mg, 2 mmol) was stirred at room temperature for 15 h. After the usual work-up, **44** (447 mg, 93%) was obtained as colorless crystals. No analytically pure sample could be obtained. Mp 157—158.5 °C (dec) (from hexane-ether); NMR: δ 0.8—2.1 (m, 8H), 3.2—3.6 (m, 2H), and 6.8—7.6 (m, 20H); MS: *m/e* 534 (M^+, trace), 502 (trace), and 78 (100%).

*Reaction of **43** with Phenyldiazomethane.* A benzene solution (25 ml) of **43** (204 mg, 0.55 mmol) and excess phenyldiazomethane was stirred at room temperature for 2 h. DCC (SiO_2, hexane-benzene(1 : 1)) gave yellow crystals (201 mg), recrystallization of which from ether gave **45** (18 mg, 7.1%) as colorless crystals, the filtrate affording **47** (157 mg, 67%) as pale yellow crystals. **45**: mp 159—160.2 °C (dec); NMR: δ 0.9—1.55 (m, 8H), 3.2—3.75 (m, 2H), 4.45 (s, 1H), and 6.9—7.6 (m, 15H); MS: *m/e* 458 (M^+, trace), 426 (8%), and 344 (100). **47**: mp 64—65 °C; NMR: δ 0.8—1.9 (m, 8H), 3.3—3.85 (m, 2H), and 6.9—7.6 (m, 16H); MS: *m/e* 426 (M^+, 13%) and 344 (100). No analytically pure sample could be obtained.

*Desulfurization of Episulfides **35** and **44**.* a) A benzene solution (10 ml) of **35** (46 mg, 0.1 mmol) and triphenylphosphine (29 mg, 0.11 mmol) was left to stand at room temperature for 5 days. The usual work-up afforded **28** (43 mg) quantitatively as yellow crystals. Mp 144—145.5 °C (from EtOH); NMR: δ 0.9—1.9 (m, 8H), 3.4—3.7 (m, 2H), 6.25 (s, 1H), and 6.7—7.35 (m, 15H); MS: *m/e* 426 (M^+, 71%) and 344 (100).

Found: C, 78.55; H, 5.88; S, 14.90%. Calcd for $C_{28}H_{26}S_2$: C, 78.82; H, 6.15; S, 15.03%.

Desulfurization was also effected by refluxing benzene solution (24 h) of **35** without triphenylphosphine.

b) A benzene solution (10 ml) of **44** (54 mg, 0.1 mmol) and triphenylphosphine (29 mg, 0.11 mmol) was refluxed for 4 h. TLC purification gave 46 mg (91%) of **46** as yellow crystals; mp 164.5—165.5 °C (from EtOH); NMR: δ 1.0—2.0 (m, 8H), 3.5—3.8 (m, 2H), and 6.9—7.8 (m, 20H); MS: *m/e* 502 (M^+, 52%), 420 (76), and 344 (100).

Found: C, 81.43; H, 6.01; S, 17.55%. Calcd for $C_{34}H_{30}S_2$: C, 81.24; H, 6.02; S, 17.75%.

*Reaction of **7** with Sulfene.* To a benzene solution (5 ml) of **7** (292 mg, 1.0 mmol) and methanesulfonyl chloride (296 mg, 2.58 mmol) was added dropwise triethylamine (290 mg, 2.87 mmol) in benzene at 5 °C. After 1 h, insoluble material was filtered off, the filtrate being washed with water and dried over anhydrous magnesium sulfate. The solvent was evaporated to give brown solid (0.356 g), which was purified by TLC (silica gel, $CHCl_3$: CCl_4 = 1 : 2) to afford **48** (211 mg, 57%); mp 149—150 °C (from MeOH); IR (KBr): 1450 and 1320 cm^{-1} (SO_2); NMR: δ 1.2—2.3 (m, 8H), 4.0—4.4 (m, 2H), 4.51 (s, 2H), 6.02 (s, 1H), and 7.2—7.6 (m, 5H); MS: *m/e* 306 (M^+–SO_2, 16%) and 64 (100).

Found: C, 51.57; H, 4.95; S, 34.28%. Calcd for $C_{16}H_{18}O_2S_4$: C, 51.86; H, 4.90; S, 34.61%.

Reactions of Thioacylketene Thioacetals and *o*-Thioquinone Methides with Enamines

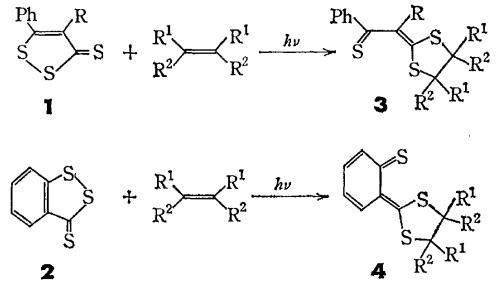
Renji Okazaki, Fumio Ishii, and Naoki Inamoto

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

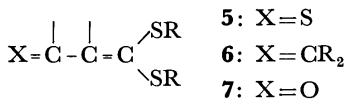
(Received August 10, 1977)

o-Thioquinone methide reacted with enamines to give [4+2] cycloadduct in good yield. In the case of morpholinoenamine, 1 : 2 adduct was obtained. Thiobenzoylketene thioacetals underwent dimerization accompanied by concomitant desulfurization upon reaction with 1-(1-pyrrolidinyl)cyclohexene. The reaction mechanism of these reactions were discussed. Some other reactions of thioacylketene thioacetals with enamines were also described.

1,2-Dithiole-3-thiones (**1**) and (**2**) photochemically react with olefins to give α-thioacylketene thioacetals (**3**) and (**4**) respectively in good yields, the latter thioacylketene thioacetal (**4**) (*i. e.*, *o*-thioquinone methide) existing as an equilibrium mixture with the dimer in solution.[1,2]



We became interested in the reactivities of these conjugated thioacetals because very few reactions have been reported on compounds of this type inspite of recent intensive studies on vinylketene (**6**)[3] and α-keto ketene thioacetals (**7**).[4]

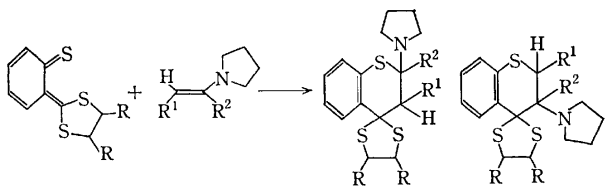


5: X=S
6: X=CR_2
7: X=O

Reactions of **3** and **4** with some electron-deficient olefins and acetylenes have been reported.[2,5] This paper gives a full account of the reactions of **3** and **4** with an electron-rich olefin, enamine.[6]

Results and Discussion

Reactions with o-*Thioquinone Methides.* *o*-Thioquinone methide (**8**) reacted with excess enamines (**9a—c**) in refluxing acetonitrile to give 1:1 adducts (**10**). Of two possible structures for the cycloadduct, **11** was eliminated by the fact that desulfurization of **10c** with Raney-nickel resulted in the formation of 2-methyl-1-phenyl-3-(1-pyrrolidinyl)propane.



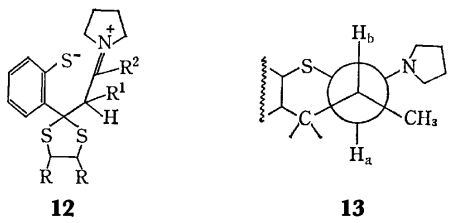
8 **9** **10** **11**

RR=$(CH_2)_4$

10a: $R^1R^2=(CH_2)_3$ 77%
10b: $R^1R^2=(CH_2)_4$ 47%
10c: R^1=Me, R^2=H 62%

It is reasonably assumed that the orientation in the cycloaddition of **9a** and **9b** is the same as that of **9c**; the products from them would thus be **10a** and **10b**, respectively.

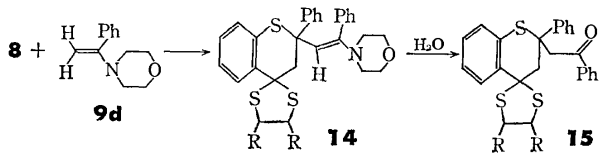
The reaction probably proceeds *via* a zwitterionic intermediate **12** followed by cyclization.



12 **13**

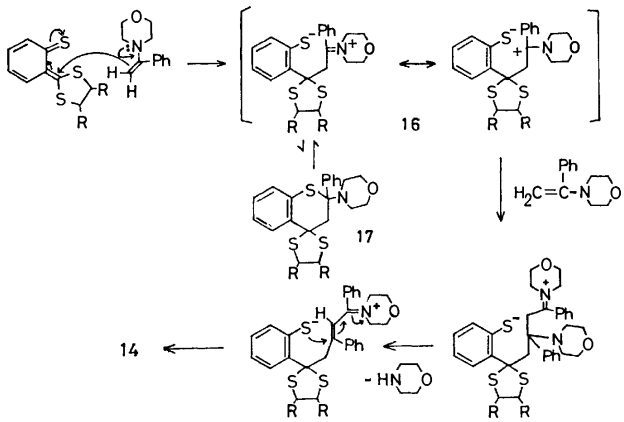
The NMR spectrum of **10c** shows a doublet (J= 10.0 Hz) at δ 4.66 attributable to H_a (see **13**). The large J value is compatible only with the configuration **13**. The formation of **13** can be explained by the cyclization of the intermediate **12** to **10** with the most stable configuration.

Enamine (**9d**) reacted with **8** in a different way from **9a—c** to afford a 1 : 2 adduct(40%), the orientation of which is presumably as shown in **14** by analogy with that of **10**. Enamine (**14**) was hydrolyzed to give ketone (**15**) upon chromatographic purification.



9d **14** **15**

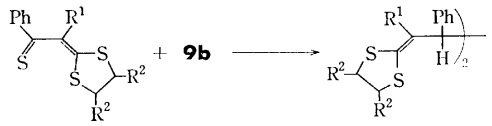
The formation of **14** can be explained as depicted in Scheme 1.



Scheme 1.

The formation of the 1:2 adduct only in the case of **9d** would be due to the enhanced stabilization of the carbocation center of **16** caused by the phenyl group. Since 1:1 adduct **17** could be subjected to cleavage because of the stabilization, **16** could be attacked by another enamine followed by the elimination of morpholine and cyclization to give **14**.

Reactions with Thioacylketene Thioacetals. Thiobenzoylketene thioacetals (**3a—c**) reacted with 1-(1-pyrrolidinyl)cyclohexene (**9b**) to give 2,3-diphenylbutane derivatives (**18**) (in refluxing acetonitrile for 10—20 h).

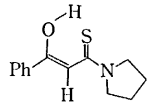


3a: R^1=Ph, R^2R^2=$(CH_2)_4$ **18a**: 48%
3b: R^1=H, R^2R^2=$(CH_2)_4$ **18b**: 24%
3c: R^1=CH_3, R^2=H **18c**: 4%

The structure of **18** was determined by spectral data and elemental analyses. Although mass spectra of the products show a weak or no parent peak, a very strong peak of half the parent peak always appears, suggesting a symmetric structure such as **18**. An intensive peak due to $[PhCH\text{-}C(R)=C=S]^+$ was also observed in each compound. The NMR spectra also support the structure **18**.

In the case of the reaction of **3b** with **9b**, two isomeric products **18b** (18%, mp 160—161 °C) and **18b'** (6%, mp 217—238 °C) were obtained. They show the same fragmentation pattern in the mass spectra, their IR spectra being nearly the same. It was impossible to measure the NMR spectrum of the isomer with a higher melting point because of poor solubility. These observations suggest that they are *meso*- and *dl*-compounds. In view of the fact that the *dl*-isomer has a lower melting point and higher solubility,[7] **18b** with a lower melting point and higher solubility was tentatively assigned to a *dl*-isomer and hence **18b'** with a higher melting point and lower solubility to a *meso*-isomer.

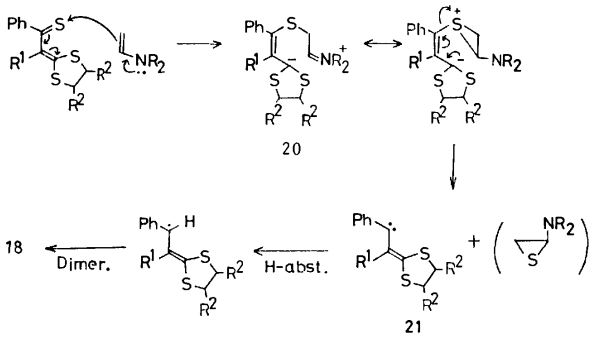
In this reaction thioamide **19** (4%) was also obtained in addition to **18b** and **18b'**. Since **19** was produced from **3b** and pyrrolidine under similar conditions, **19** obtained in the enamine reaction seems to be formed as a by-product from the reaction of **3b** with pyrrolidine derived from enamine.



19

The formation of **18** could be explained by an attack of an enamine on the sulfur atom of thiocarbonyl group (Scheme 2). The zwitterionic intermediate **20** thus formed would undergo fragmentation to form carbene **21** stabilized by the phenyl group which subsequently abstracts a hydrogen atom, dimerizing to give the final product **18**.

The ground state of vinylcarbene is triplet and capable of abstracting hydrogen atom of allylic position,[8] supporting the mechanism in Scheme 2.



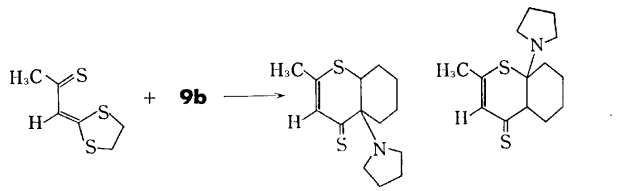
Scheme 2.

This is the first observation that an enamine can attack the sulfur atom of a thiocarbonyl group (*i.e.*, "thiophilic reaction") as in the case of organolithium compounds or Grignard reagents.[9-12] Phenyllithium attacks diphenyl trithiocarbonate to produce bis(phenylthio)carbene.[9,10] Carbene **21** can be regarded as a vinylog of dithiocarbene of type **22**, similarity between these two reactions being noteworthy.

$$(PhS)_2C{=}S + PhLi \longrightarrow (PhS)_3C^-Li^+ \rightleftarrows PhSLi + (PhS)_2C:$$

22

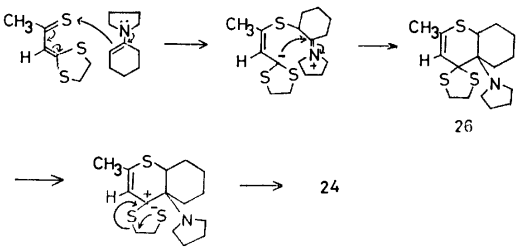
Thioacylketene thioacetal (**23**) reacted with **9b** to give conjugated thione (**24**) in 10% yield. The structure of **24** was established by its NMR and mass



23 **24** **25**

spectra and elemental analysis. The chemical shift (δ 3.20—3.80) of a broad doublet assignable to four α-protons of the pyrrolidine ring is considerably lower than that of **10a** (δ 2.5—2.9), **10b** (δ 2.4—2.9), and **10c** (δ 2.5—3.0). The lower chemical shift of **24** could be explained in terms of magnetic anisotropy of the thiocarbonyl group, suggesting structure **24** rather than **25**. The demonstrated thiophilicity described above of **3a—c** is also evidence for **24**.

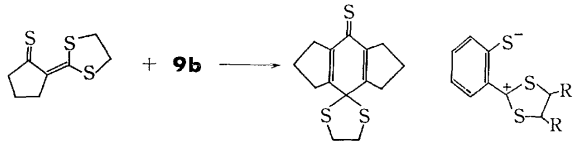
The formation of **24** can be accounted for by Scheme 3. The heterolytic cleavage of the C–S bond in **26**



Scheme 3.

might be supported by such factors as stability of the carbocation formed, participation of α-nitrogen, and high polarity of the solvent.

No reaction of 2-(1,3-dithiolan-2-ylidene)cyclopentanethione (**27**) and enamine **9b** took place in refluxing acetonitrile for 30 h. However, the reaction in *N,N*-dimethylformamide (DMF) at 110—120 °C for 15 h led to the formation of conjugated thione (**28**) (24%).



27 **28** **29**

Elemental analysis and the mass spectrum show that the molecular formula of the product is $C_{14}H_{16}S_3$. The NMR spectrum suggests the symmetric nature of the product and the UV spectrum (225 (log ε 4.23), 329 (4.44), 468 (269), and 526 nm (1.22)) reveals the presence of a conjugated thione system. The mechanism of the formation of **28** has not been clarified as yet.

The difference in reactivity in which the attack of an enamine occurs at the sulfur atom of the thiocarbonyl group in **3** but at the β-carbon of the thiocarbonyl group in *o*-thioquinone methide (**8**), can be explained mainly in terms of a greater contribution of an ionic canonical structure **29** in the case of **8**. It would reduce the thionic nature of **8** and enhance the electrophilicity of the β-carbon.

Experimental

All the reactions were carried out under nitrogen. The IR and UV spectra were measured on Hitachi EPI-G2 and EPS-3 spectrophotometers, respectively. The NMR spectra were recorded as $CDCl_3$ solutions with a Hitachi R-24 or R-20B spectrometer, tetramethylsilane being used as an internal standard. Mass spectra were determined on a Hitachi RMU-6L mass spectrometer operating at 70 eV.

Reactions of o-Thioquinone Methides (8) with Enamine (9). Thione **8**(0.662 g, 2.5 mmol)[2] was suspended in dry acetonitrile (30 ml) and two or three molar excess of **9** was added in a small portion over a period of 5 min. The solution was heated to reflux and maintained at this temperature with agitation for 1—2 h. The solution turned colorless from blue. The reaction was monitored by TLC. When the reaction was complete, acetonitrile was removed *in vacuo*. The residue was recrystallized from methanol or ethanol. All the products **10** were colorless crystals.

4,4-(1,2-Cyclohexylenedithio)-2-(1-pyrrolidinyl)-2,3-trimethylenethiochroman (**10a**): 0.78 g (77%); mp 154—155 °C (EtOH); NMR: δ 1.00—2.40 (m, 18H), 2.50—2.90 (m, 4H), 2.95—3.30 (m, 1H), 3.65—4.00 (m, 2H), 7.03—7.44 (m, 3H), and 8.10—8.26 (m, 1H).

Found: C, 65.28; H, 7.38; N, 3.43; S, 23.79%. Calcd for $C_{22}H_{29}NS_3$: C, 65.46; H, 7.24; N, 3.47; S, 23.83%.

4,4-(1,2-Cyclohexylenedithio)-2-(1-pyrrolidinyl)-2,3-tetramethylenethiochroman (**10b**): 0.45 g (47%); mp 71—72 °C (MeOH); NMR: δ 0.90—2.95 (m, 25H), 3.50—4.14 (m, 2H), 6.94—7.46 (m, 3H), and 8.08—8.37 (m, 1H); MS: *m/e* 226 (12%), 184 (24), 151 (45), 105 (100), and 78 (71).

Found: C, 65.98; H, 7.68; N, 3.54; S, 23.07%. Calcd for $C_{23}H_{31}NS_3$: C, 66.14; H, 7.48; N, 3.35; S, 23.03%.

4,4-(1,2-Cyclohexylenedithio)-2-(1-pyrrolidinyl)-3-methylthiochroman (**10c**): 0.584 g (62%); mp 145—146 °C (PhH:EtOH=1:2); NMR: δ 0.86—2.44 (m, 16H), 2.44—2.98 (m, 4H), 3.43—4.15 (m, 2H), 4.66 (d, J=10.0 Hz, 1H), 6.91—7.54 (m, 3H), and 8.08—8.38 (m, 1H).

Found: C, 63.78; H, 7.23; N, 3.64; S, 25.52%. Calcd for $C_{20}H_{27}NS_3$: C, 63.61; H, 7.21; N, 3.70; S, 25.47%.

Desulfurization of 10c with Raney Nickel. To 2.48 g (6.5 mmol) of **10c** was added Raney nickel[13] prepared from 25 g of Al-Ni alloy in 60 ml of ethanol. The solution was heated under reflux for 1 h. After Raney nickel was separated, the filtrate was concentrated, 10 ml of ether was added and the mixture was extracted with 50 ml of 0.1 M aq HCl. The aqueous solution was neutralized with 0.1 M aq KOH, extracted with ether, and dried over anhydrous magnesium sulfate. The solution was concentrated and the residue (0.646 g, 49%) was purified by gas chromatography (JEOL JGC-750, Versamide 900, 1 m, 125 °C) to give 2-methyl-1-phenyl-3-(1-pyrrolidinyl)propane, the structure of which is supported by the following spectral data: NMR: δ 0.88 (d, J=6.0 Hz, 3H), 1.60—3.10 (m, 13H), and 7.21 (s, 5H); MS: *m/e* 203 (M^+, 0.7%), 91 (8), and 84 (100).

Reaction of 8 with 9d. To 0.709 g (2.7 mmol) of **8** in 30 ml of dry acetonitrile was added 1.90 g (10 mmol) of **9d**. The solution was heated under reflux for 6.5 h. Upon cooling, 4,4-(1,2-cyclohexylenedithio)-2-phenyl-2-(β-morpholinostyryl)thiochroman (**14**) was precipitated as colorless crystals and recrystallized from a mixture of benzene and ethanol (1:2), 0.511 g, 34%. Mp 190—191 °C; NMR: δ 1.00—2.90 (m, 14H), 3.35—3.75 (m, 4H), 3.80—4.30 (m, 2H), 4.68 (s, 1H), and 6.60—8.80 (m, 14H); MS: *m/e* 557 (M^+, 0.1%), 291 (59), and 184 (100).

Found: C, 71.20; H, 5.88; N, 2.58; S, 16.91%. Calcd for $C_{33}H_{35}NOS_3$: C, 71.05; H, 6.32; N, 2.51; S, 17.24%.

The filtrate was concentrated and subjected to dry column chromatography on silica gel with dichloromethane. 4,4-(1,2-Cyclohexylenedithio)-2-phenacyl-2-phenylthiochroman (**15**) was precipitated as colorless crystals, and recrystallized from a mixture of benzene and ethanol (1:2), yield 81 mg (6%). Mp 220—221 °C; NMR: δ 1.00—2.70 (m, 10H), 3.40—4.20 (m, 2H), 4.20—4.70 (m, 2H), and 6.90—8.70 (m, 14H); IR(KBr): 1680 cm^{-1} (C=O); MS 488 (M^+, 0.2%) and 184 (100).

Found: C, 71.11; H, 5.88; S, 19.34%. Calcd for $C_{29}H_{28}OS_3$: C, 71.27; H, 5.77; S, 19.68%.

Reaction of 3 with 9b. a) To **3b**[1] (0.83 g, 3.0 mmol) in refluxing acetonitrile (30 ml) was added 2.57 g (17 mmol) of **9b** in a small portion over a period of 10 min. The solution was stirred at this temperature for 12 h. When the reaction was complete, the color of the solution turned red from deep green. Upon cooling, **18b'** (45 mg, 6%) was precipitated as colorless crystals and recrystallized from THF. The filtrate was subjected to dry column chromatography on silica gel with dichloromethane to give 2,3-diphenyl-1,4-bis(4,5-tetramethylene-1,3-dithiolan-2-ylidene)butane **18b** (0.14 g, 18%) and 3-hydroxy-*N,N*-tetramethylenethiocinnamamide **19** (30 mg, 4%), the latter being identical with an authentic sample.[14]

18b: mp 160—161 °C; NMR: δ 1.10—2.20 (m, 16H), 3.50—4.10 (m, 6H), 5.60—5.80 (dd, J=7.6 Hz, J=1.5 Hz, 2H), and 6.90—7.40 (m, 10H); MS: *m/e* 522 (M^+, 7%), 261 ($M^+/2$, 46), and 147 (100).

Found: C, 69.09; H, 6.62; S, 24.20%. Calcd for $C_{30}H_{34}S_4$: C, 68.92; H, 6.55; S, 24.53%.

18b': mp 237—238 °C; MS: *m/e* 522 (M^+, 0.9%), 261 ($M^+/2$, 36), and 147 (100).

Found: C, 68.79; H, 6.68; S, 24.56%. Calcd for $C_{30}H_{34}S_4$: C, 68.92; H, 6.55; S, 24.53%.

b) Reactions of **3a**[1] (0.280 g, 0.76 mmol) and **3c**[15] (1.89 g, 0.75 mmol) with **8b** (2.00 g, 13.2 mmol for **3a** and 3.00 g, 18.7 mmol for **3c**) were carried out in a similar way to that for **3b**.

1,2,3,4-Tetraphenyl-1,4-bis(4,5-tetramethylene-1,3-dithiolan-2-ylidene)butane (**18a**): 0.124 g, 48%; mp 244—245 °C; NMR: δ 1.10—2.40 (m, 16H), 3.50—4.10 (m, 4H), 4.30—4.60 (m, 2H), and 6.90—7.60 (m, 20H); MS: *m/e* 337 ($M^+/2$, 100%) and 223 (70).

Found: C, 74.81; H, 6.26; S, 18.63%. Calcd for $C_{42}H_{42}S_4$: C, 74.73; H, 6.27; S, 18.99%.

3,4-Diphenyl-2,5-bis(1,3-dithiolan-2-ylidene)hexane (**18c**): 60 mg, 4%; mp 260—261 °C; NMR: δ 1.84 (s, 6H), 3.30 (s, 8H), 4.58 (s, 2H), and 7.00—7.50 (m, 10H); MS: *m/e* 442 (M^+, trace), 221 ($M^+/2$, 100), and 161 (33).

Found: C, 65.41; H, 5.87; S, 28.79%. Calcd for $C_{26}H_{24}S_4$: C, 65.11; H, 5.92; S, 28.97%.

*Reaction of **23** with **9b**.* To 0.870 g (5 mmol) of **23**[15] in 30 ml of dry acetonitrile was added 3.00 g (19 mmol) of **9b** in a small portion. The reaction mixture was refluxed for 2 h. After the solvent had been removed, the residue was dissolved in benzene and chromatographed on alumina. 2-Methyl-5,6-tetramethylene-5-(1-pyrrolidinyl)-5,6-dihydro-4*H*-thiopyran-4-thione (**24**) (0.125 g, 10%) was eluted with a mixture of benzene and ethyl acetate (1:1), which was recrystallized from ethanol as yellow crystals, mp 220—221 °C. NMR: δ 1.10—2.50 (m, 12H), 2.72 (s, 3H), 3.20—3.80 (m, 5H), and 6.46 (s, 1H); MS: *m/e* 267 (M^+, 55%), 234 (39), 223 (32), 190 (47), 152 (20), and 41 (100).

Found: C, 62.70; H, 7.87; N, 5.14; S, 24.00%. Calcd for $C_{14}H_{21}NS_2$: C, 62.87; H, 7.92; N, 5.24; S, 23.97%.

*Reaction of **27** with **9b**.* To a DMF solution (30 ml) of **27**[15] (2.32 g, 11 mmol) was added **9b** (4.50 g, 30 mmol) in a small portion. After being refluxed at 110—120 °C for 15 h, the solution was poured into 50 ml of water and extracted with 100 ml of dichloromethane, the extract being dried over anhydrous magnesium sulfate. After removal of the solvent, the residue was dissolved in benzene and subjected to dry column chromatography on silica gel with dichloromethane. 4,4-(Ethylenedithio)-2,3 : 5,6-bis(trimethylene)-2,5-cyclohexadiene-1-thione (**28**) was precipitated as purple crystals, and recrystallized from a mixture of benzene and hexane (1:1), 0.363 g (24%). Mp 133—134 °C; NMR: δ 1.60—2.10 (m, 4H), 2.40—3.20 (m, 8H), and 3.46 (s, 4H); MS: *m/e* 280 (M^+, 98%), 252 (12), 220 (29), and 176 (100); UV: λ_{max} (EtOH) 225 (log ε 4.23), 329 (4.44), and 468 (2.69); λ_{max} (PhH) 526 nm (1.22).

Found: C, 59.82; H, 5.79; S, 34.60%. Calcd for $C_{14}H_{16}S_2$: C, 59.95; H, 5.75; S, 34.30%.

Environment Effect on the Symmetry of Yang's Biradical

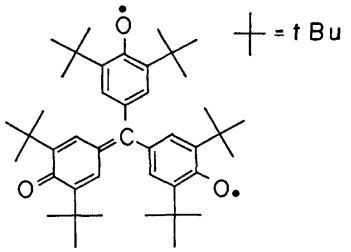
Kazuo MUKAI

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790

(Received June 6, 1977)

Synopsis. The ESR spectrum of Yang's biradical, which has a structural three-fold symmetry and degenerate, partially filled levels, has been measured in several solvents at 77 K. The results of the analyses of the ESR spectra have shown that Yang's biradical must lack a three-fold symmetry in frozen solutions. The notable solvent effects observed for the zero-field splitting parameters (D and E) suggest that the asymmetric environment due to frozen-solvent molecules contributes to the molecular distortion found for Yang's biradical.

Yang and Castro have reported the preparation of a fairly stable phenoxyl biradical, which is known as Yang's biradical (I).[1] Yang's biradical is a ground-state triplet molecule which has a structural three-fold symmetry and degenerate, partially filled levels.[2-4] However, recently, the toluene rigid matrix ESR spectrum of Yang's biradical was reported to be a characteristic spectrum of a non-axially symmetrical triplet, with $D=34.1$ and $E=2.3$ G.[5] This result may be explained by assuming that at least one of the twist angles of the three phenyl rings is different from the other two rings in the low-temperature rigid matrix. It is probable that the Jahn-Teller effect induces such molecular



Yang's Biradical (I)

distortion in Yang's biradical, thus splitting the degenerate, partially filled levels. In addition to the above Jahn-Teller distortion, the asymmetric environment due to frozen solvent molecules may contribute to the molecular distortion found for Yang's biradical in the low-temperature rigid matrix. In fact, recent ENDOR studies[6] of phenylgalvinoxyl and some of its derivatives in fluid solutions and ESR studies[7] of *p*- and *m*-phenylenebis(galvinoxyl) biradicals in frozen solutions have given evidence that solvent molecules may play an important role in fixing the conformation and symmetry of the radical in both fluid and frozen solutions.

On the other hand, the fluid-solution ESR spectrum of Yang's biradical shows seven equally spaced lines, due to the six equivalent protons in the biradical.[5] The results of NMR and ENDOR studies[8,9] in solution also indicate that the six ring protons are magnetically equivalent, giving a hyperfine splitting for the six meta-ring protons. The expected inequivalence of the proton splitting was not observed in these measurements.

In the present work, in order to obtain further information on such molecular distortion, we have measured the ESR spectra of Yang's biradical in five solvents— ethanol, toluene, 2-methyltetrahydrofuran (2-MTHF), diethyl ether, and diglyme, and have studied the effect of solvents on the unpaired spin distribution and symmetry of Yang's biradical.

Experimental

Yang's biradical was prepared by the oxidation of the corresponding bisphenol (mp 276—278 °C) (lit, mp 278—279 °C)[1] with alkaline potassium hexacyanoferrate (III) in diethyl ether under a nitrogen atmosphere, with the temperature kept between 5 and 10 °C, according to the method of Yang and Castro.[1] A deep purple crystalline compound with a metallic luster was isolated from the diethyl ether layer. The ESR spectra were obtained at the X band using a JES-ME-3X spectrometer equipped with a Takeda-Riken microwave frequency counter to measure the klystron frequency. The ESR splittings were determined using $(KSO_3)_2NO$ ($a^N=13.05\pm0.03$ G) as a standard. The g-values were measured relative to the value of Li-TCNQ powder, calibrated with $(KSO_3)_2NO$ ($g=2.0054$).[10]

Results and Discussion

When the solution containing the biradical is frozen into a rigid glass (77 K), one can observe some dipolar splittings. The zero-field parameters (D and E) and g-tensor values have been tentatively estimated from the positions of the three pairs of turning points (ZZ', YY', XX'), as performed in a previous paper.[5] Notable solvent dependences of the zero-field splitting parameters were observed in the frozen-solution spectra of the biradical; the results are summarized in Table 1. The observed D and E values are 34.6 and 1.5 G in ethanol, 34.1 and 1.9 G in toluene, 33.1 and 1.9 G in 2-MTHF, 32.7 and 4.7 G in diethyl ether, and 32.1 and 3.6 G in diglyme, respectively. The g-tensor values also appear to be slightly solvent-dependent, while the observed change in the g_{iso} value of the biradical at 20 °C is negligible, as is shown in Table 1.

Since the axial spectra, *i.e.*, the spectra characterized by only one zero-field splitting parameter, D, could not be observed in any of the solvents used, Yang's biradical must lack a three-fold symmetry in these frozen solutions. In a previous paper,[5] it was suggested that both Jahn-Teller distortion and the asymmetric environment due to the frozen-solvent molecules may contribute to such molecular distortion in Yang's biradical. The notable solvent effect observed for the zero-field param-

Table 1. *D*- and *g*-tensor values of Yang's biradical (I) in several solvents at 77 K

	$\|D\|$[a] (G)	$\|E\|$[a] (G)	g_{zz}[b]	g_{yy}	g_{xx}	g_{av}[c]	g_{iso}[d]
Ethanol	34.6	1.5	2.0025	2.0057	—[e]	—	2.00441
Toluene	34.1	1.9	2.0026	2.0054	2.0054	2.0045	2.00451
2-MTHF	33.1	1.9	2.0025	2.0054	2.0058	2.0046	2.00443
Diethyl ether	32.7	4.7	2.0032	2.0060	—	—	2.00446
Diglyme	32.1	3.6	2.0033	2.0061	—	—	2.00442

a) The $|D|$ and $|E|$ values were calculated from the $ZZ'=2D$ and $YY'=D+3E$ separations, because the turning points, X and X', are not obvious as a result of overlapping with the central monoradical signal. The E value thus calculated is smaller than the true value, considering the overlapping of the inner two pairs of lines.[5] The experimental errors in the values of $|D|$ and $|E|$ are ± 0.3 and 0.5 G respectively. b) The experimental errors in the values of g_{zz}, g_{yy}, g_{xx}, and g_{av} are ± 0.0003. c) The average $g_{av}=1/3(g_{zz}+g_{yy}+g_{xx})$. d) The isotropic g_{iso}-values measured at 20 °C. The experimental errors in the values of g_{iso} are ± 0.00003. e) In ethanol, diethyl ether, and diglyme solvents, the g_{xx} values could not be determined because of overlap with the central monoradical signal.

eters of Yang's biradical indicates that solvent molecules may contribute remarkably to a change in the steric structure of the radical molecule. In addition, it is interesting that this solvent effect on the symmetry of Yang's biradical is larger than the effects due to the asymmetric deuterium[5] and tertiary pentyl[11] substitutions. Yang's biradical may be considered to have a propeller configuration, with a twist angle of about 30°. Due to the delocalization of each unpaired electron, the principal Z axis of the *D*-tensor, corresponding to the maximum $2D$ value (ZZ'), is probably parallel to the $2p_z$ orbital of the center triphenylmethyl carbon atom. Therefore, in Yang's biradical with a non-zero E value, at least one of the twist angles of the three phenyl rings is different from the other two rings in the low-temperature rigid matrices. Upon an increase in these twist angles, the D parameter will decrease and, inversely, the E parameter will increase. In fact, it can be seen from Table 1 that the decrease in the D parameter results in the increase in the E parameter.

On the other hand, the fluid solution ESR spectra of Yang's biradical in the above solvents at 20 °C appear to correspond to hyperfine interaction with the six equivalent meta-ring protons. This result can be explained as follows: (i) the biradical apparently shows an equivalent hyperfine splitting due to the rapid exchange between distorted structures, or (ii) the radical molecule retains a three-fold symmetry in fluid solutions, because the asymmetric environment due to frozen solvent molecules disappears in fluid solutions.

We wish to express our gratitude to Mr. Jun Sakamoto for his kind help in preparing Yang's biradical.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (1), 315—316 (1978)

A Molecular Orbital Study of the Conformation and *g*-Factors of the $HSSH^-$ Radical Anion

Osamu KIKUCHI

Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 300-31

(Received July 22, 1977)

Synopsis. The electronic structure and *g*-factors of the $HSSH^-$ radical anion were calculated by means of a restricted open-shell SCF MO method with the MINDO/3 approximation, and the dependence of the *g*-factors upon the conformation was clarified. The most stable conformation predicted agreed well with the experimentally estimated –S–S– geometry of dialkyl disulfide anions, and its *g*-factors agreed well with the observed values.

Attention has been drawn in recent literature[1,2] to the electronic structures of sulfur-containing radicals and their ESR data. Lin and Lunsford[1] observed the $HSSH^-$ radical anion formed by allowing H_2S to react with trapped electrons on MgO. From the hyperfine splittings and the *g*-factors ($g_\perp=2.015$, $g_{//}=2.003$), they pointed out that the radical earlier identified as H_2S^- by Bennett *et al.*[3] is $HSSH^-$. Since the principal values of the *g*-tensor correlate strongly with the electronic structure of a radical, the theoretical analysis of the *g*-tensor can clarify the electronic structure and conformation of the radical. The purpose of the present note is to investigate the relation between the *g*-factors and the conformation of $HSSH^-$ by means of restricted open-shell SCF calculations.

The MO's of the spin-restricted doublet state were obtained by the approximate SCF version which has been proposed by Longuet-Higgins and Pople[4] for π-radicals and which has since been applied to all-valence-electron systems by the present author.[5] For the evaluation of the electron integrals involved, the MINDO/3 approximation[6] was employed. The geometry of $HSSH^-$ was first optimized with respect to three parameters; the S–S bond length, the HSS angle, ψ, and the dihedral angle, θ, between two planes containing the HSS' or SS'H group. The dependence of the *g*-factors upon ψ and θ was calculated according to Stone's formula,[7] the S–S bond length being fixed at the optimized value, 2.17 Å. A more detailed description of the calculation has been reported elsewhere.[8]

Results and Discussion

The electronic structure and *g*-factors of a typical conformation (shown in Fig. 1) will be discussed first, since the *g*-tensor of this conformation is practically diagonal in terms of the axes, x, y, and z. The ground electron configuration of C_2 symmetry is:

$$\cdots(2a)^2(2b)^2(3a)^2(3b)^2(4a)^2(4b)^1:\ ^2B$$

where 2a and 2b MO's are bonding S–H σ orbitals and where 3a is the bonding S–S $3p\sigma$ orbital directed along the S–S bond. The 3b and 4a orbitals are nearly degenerate and are expressed as $(3p_\alpha(S)+3p_\beta(S'))/\sqrt{2}$ and $(3p_\alpha(S)-3p_\beta(S'))/\sqrt{2}$ respectivley. The half-occupied MO, 4b, is the anti-bonding $3p\sigma^*$ orbital directed along the S–S bond. The contribution of each excited configuration to the principal values of the *g*-tensor is shown in Table 1. The large deviation of g_{xx} from the free-spin value can be understood as resulting from the spin-orbit mixing of the ground state with the 4a→4b excited configuration, and that of g_{zz}, from the mixing with the 3b→4b excited configuration. The contributions of the bonding S–H σ orbitals (2a and 2b) compensate for those of the anti-bonding S–H σ^* orbitals (5a and 5b). The calculated principal values ($g_\perp=2.011$ and $g_{//}=2.002$) are in fair agreement with the observed values.[1]

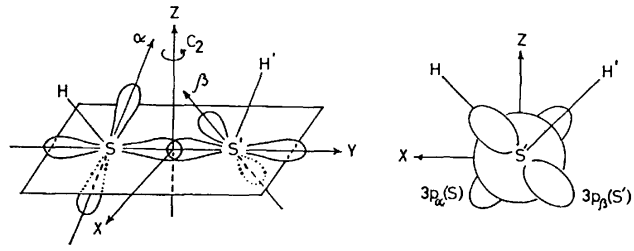

Fig. 1. The coordinate axes and the Newman projection for a typical conformation of $HSSH^-$ viewed in the direction of the S–S bond. The dihedral angle, θ, between two planes containing H–S–S' and S–S'–H' is 90° and the HSS' angle, ψ, is 90°.

TABLE 1. CALCULATED Δg_{ii}[a] VALUES OF THE $HSSH^-$ OF THE C_2 SYMMETRY, WITH $\theta=90°$ AND $\psi=90°$

Excited configuration	ΔE (eV)[b]	Δg_{xx}	Δg_{yy}	Δg_{zz}

a) Deviation from the free-spin value. The value of $\Delta g_{ii}\times10^4$ are listed in each column. b) Energy difference between the ground state and an excited configuration. c) The three principal values calculated from these values are: $g_{xx}=2.0119$, $g_{yy}=2.0023$, and $g_{zz}=2.0119$.

The ground state of the $HSSH^-$ with the C_2 symmetry was calculated to be the ^2B state for any value of ψ or θ. Though the half-occupied MO is always expressed as $3p\sigma^*$, its shape depends considerably upon ψ and θ. This is the reason why the *g*-factors of $HSSH^-$ depend largely on the conformation of $HSSH^-$. The dependence of $g_{av}=1/3(g_1+g_2+g_3)$ upon ψ and θ is shown in Fig. 2. It can be seen from Fig. 2 that there are many conformations for a given value of g_{av}. The three principal values, however, vary largely with the

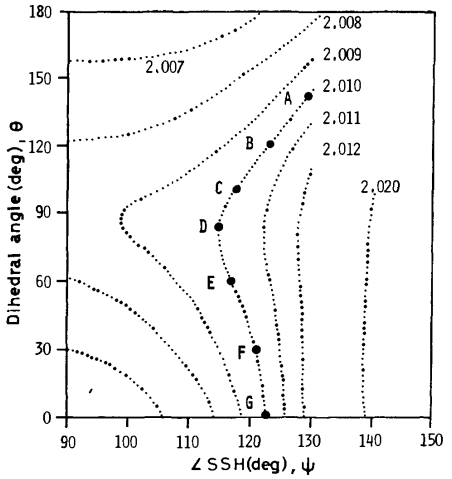

Fig. 2. The conformational dependence of the g_{av} value of $HSSH^-$. The bond lengths shown in Fig. 4 were employed.

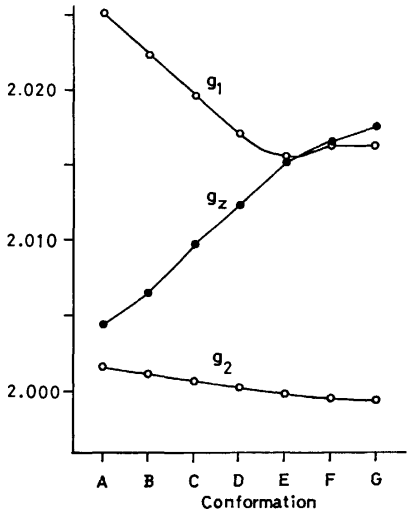

Fig. 3. Variations of three principal values of the g-tensor of $HSSH^-$ along A→G cited in Fig. 2.

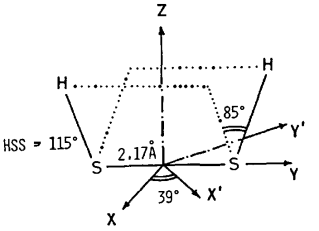

Fig. 4. The most stable conformation of $HSSH^-$ and the principal axes, x', y', and z, of its g-tensor.

conformation of $HSSH^-$. When $g_{av}=2.010$, for example the three principal values of the conformations corresponding to A—G in Fig. 2 vary as is shown in Fig. 3. From a detailed examination of the three principal values, it was found that the conformations whose calculated three principal values agree with the observed ones within ±0.003 have (i) $\theta=90°$ and $90°<\psi<115°$ or (ii) $60°<\theta<90°$ and $105°<\psi<115°$. The g-factors for the D conformation ($\theta=85°$, $\psi=115°$, SS=2.17 Å, SH=1.358 Å (ass.)) cited in Fig. 4 are worth listing, since this conformation is most stable in the present calculations and closely resembles the estimated –S–S– geometry of dialkyl disulfide anions.[9] The g-factors calculated ($g_{x'x'}=2.0172$, $g_{y'y'}=2.0003$, $g_{zz}=2.0124$, $g_{av}=2.0010$) agree well with the observed values.[1]

The radicals which have been attributed to $R_2S_2^-$ are RCH_2–S–S–CH_2R^- ($g_\perp=2.018$, $g_{//}=2.002$),[9] the n-amyl disulfide anion ($g_\perp=2.022$, $g_{//}=2.003$),[10] and the dibenzoyldisulfide anion ($g_1=2.014$, $g_2=2.010$, $g_3=2.004$).[11] In spite of the large substituents in these radicals, their g-factors have the same features as those of $HSSH^-$. This indicates that the dependence of the conformation of $R_2S_2^-$ and of the electronic structure of the –S–S– group upon the substituent is relatively small, and that the present analysis of the g-factors gives information not only about $HSSH^-$, but also about $RSSR^-$.

The spin distribution of $HSSH^-$ is worth discussing since the identification of $HSSH^-$ has thus far rested on the ^1H and ^{33}S hyperfine coupling constants. The small ^1H coupling constants[1] suggest that the primary interaction in ^1H coupling is due to spin polarization by an unpaired electron on the sulfur atom. The spin densities were thus calculated by means of the unrestricted SCF version[12] with the MINDO/3 approximation. The spin density on the 3s(S) AO is almost constant (0.06—0.07) for all the above conformations (i) and (ii). The spin density on the 1s(H) AO depends largely on the HSS angle (−0.050(90°), −0.040(100°), −0.009 (115°), +0.001(120°), with the constant value of $\theta=90°$), while its dependence on θ is small. The calculated spin distribution[13] and observed ^1H coupling constants (6—9 G)[1] predict that the HSS angle will be 105°—115°.

The author wishes to express his thanks to Dr. Tatsuo Numata for his helpful discussions.

The Gas Chromatographic Analysis of Bis(chloromethyl) Ether in Air

Yoshio BABA and Toshiyuki TANAKA

National Research Institute for Pollution & Resources, Kawaguchi, Saitama 332

(Received June 10, 1977)

Synopsis. Bis(chloromethyl) ether was converted into bis(ethylthiomethyl) ether by a reaction with sodium ethanethiolate in a hexane solution; the latter sulfur-containing compound was then analyzed by means of a gas chromatograph equipped with a flame photometric detector.

Bis(chloromethyl) ether (BCME) is known to be one of the impurities present in chloromethyl methyl ether, which is a commercial chloromethylating reagent widely used in the production of anion-exchange resins, membranes, and other aromatic products.

Because of its strong carcinogenicity at the 100 ppb level concentration in air, possible industrial exposure to BCME has been of great concern, and so several analytical techniques for monitoring the ppb level of BCME in air have been developed. These analytical methods include gas chromatography and high-resolution mass spectroscopy.[1-5]

BCME is known to be unstable in humid air, and a recent kinetic study of its hydrolysis in an aqueous solution showed that BCME was hydrolyzed very fast, with a half-life of the order of 10 s;[6] this unstability of BCME has presented difficulty in the process of concentrating the air sample in the preparation of the analytical sample used in the analysis described above.

Collier[5] used an enriching column packed with Porapak Q resin, which retains only the organic material, to concentrate the ppb level of BCME in air, and Solomon[2] used the 2,4,6-trichlorophenyl ether derivative of BCME ($2,4,6\text{-}Cl_3C_6H_2\text{-}OCH_2OCH_2OCH_3$) in the analysis by means of a gas chromatograph equipped with an electron-capture detector.

In this study, BCME was converted into bis(ethylthiomethyl) ether (BETME), and the latter sulfur-containing derivative was detected by means of a flame photometric detector (FPD). FPD's selective and sensitive detectability of the sulfur compounds permits the selective detection of the sulfur-containing derivative of BCME in a contaminated sample obtained by the concentration of an air sample containing foreign compounds other than BCME.

BETME can be prepared simply by the reaction of BCME and sodium ethanethiolate (NaSEt) in a hexane solution; this sulfur compound is not only stable to the hydrolysis, but also the presence of water in the reaction mixture does not interfere with the BETME formation reaction.

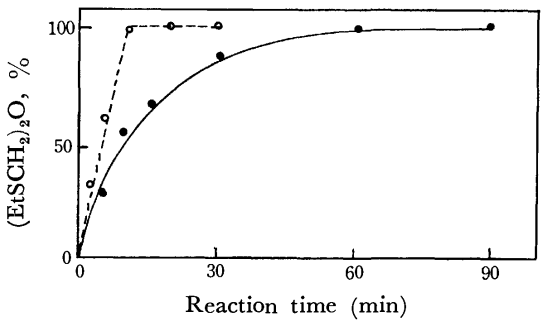

Fig. 1. Reaction rate of the $(EtSCH_2)_2O$ formation reaction.
——: At room temp,
----: at reflux temp of hexane solution.

As is shown in Fig. 1, the reaction of BCME with sodium ethanethiolate proceeds in the course of 1 h at room temperature. The reaction rate can be accelerated with a higher reaction temperature; at the reflux temperature of the hexane solution the reaction can be completed within 10 min. No side reactions have been observed in either reaction. However, the use of freshly prepared sodium ethanethiolate is recommended to keep the reaction rate rapid. The sodium ethanethiolate, even when kept in a desiccator, gradually loses its reactivity in the reaction with BCME, and after one month's storage a large depression of its reactivity was observed.

The presence of water does not change the course of the reaction, as is shown in Table 1, but it decreases the rate of the reaction. In the presence of 960% of water to BCME (mole ratio), 3 h stirring at room temperature was required to complete the reaction. However, no side reaction was observed in this case.

Excellent linearity and reproducibility were observed

Table 1. The effect of water in the BCME/NaSEt reaction

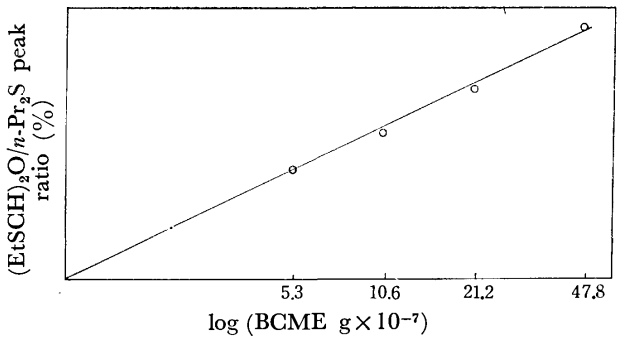

Fig. 2. Calibration curve of bis(ethylthiomethyl) ether.

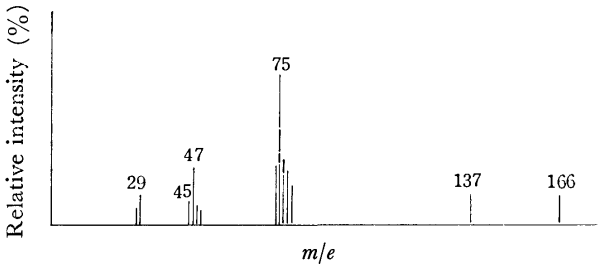

Fig. 3. Mass spectrum of bis(ethylthiomethyl) ether.

in the preparation of the calibration curve (Fig. 2); this fact indicates this analytical method can be applied practically. The mass spectra of the product obtained by the BCME/NaSEt reaction have been shown to be consistent with the assignment of bis(ethylthiomethyl) ether (Fig. 3).

Experimental

Bis(ethylthiomethyl) Ether. A solution of sodium methoxide in methanol (10%) was mixed with a slightly excessive molar amount of ethanethiol. The solution was stirred for 10 min and then evaporated to dryness under a vacuum. The solid residue was pulverized, and a solution of BCME in hexane was added (mole ratio of NaSEt/BCME=2.5). The reaction mixture was stirred for 1 h at room temperature, or refluxed for 10 min.

Gas Chromatography. Micro Tek Instruments Corp. A Model 160 gas chromatograph equipped with a flame photometric detector was used. The analytical column was 1 m× 3 mm i.d. Teflon column packed with 25% 1,2,3-tris(2-cyanoethoxy)propane on Chromosorb W AW(60—80 mesh). The column oven was kept at 150 °C (isothermal). The carrier gas was a chromatographic grade nitrogen at a flow rate of 60 ml/min.

Mass Spectrometry. The mass spectra of bis(ethylthiomethyl) ether were obtained using a JMS-Q 10 Gas Chromatograph-Mass Spectrometer operated at an ionizing potential of 70 eV.

The Esterification of Thujopsene with Bismuth(III) Sulfate in Carboxylic Acids

Kazuo Abe and Masaaki Ito

Chemistry Laboratory, Department of General Education, Higashi Nippon Gakuen University, Onbetsu, Hokkaido 088-01

(Received March 7, 1977)

Synopsis. The catalytic interaction of *cis*-(−)-thujopsene with a series of organic acids from acetic to octanoic in the presence of bismuth(III) sulfate afforded the corresponding esters in 20—34% yields, accompanied by skeletal rearrangement. The follow-up of the reaction, an investigation of the reaction conditions, and the effects of catalysts are described.

In organic acids, the autoxidation of some olefins occurs in the presence of bismuth(III) sulfate.[1] Valkanas[2] has recently found that the interaction of *d*-α-pinene with a series of organic acids from acetic to octanoic, over a wide range of olefin-to-acid ratios, yields esteric and rearrangement products. We have obtained some findings on the esterification of thujopsene **1** with a series of organic acids from acetic to octanoic in the presence of bismuth(III) sulfate. Thus, it may be seen that the esterification proceeds through a skeletal conversion to give a bicyclic ester as the major product, without any autoxidation reaction occurring.

The esterification of thujopsene was carried out using organic acid in a ratio of 20 parts of thujopsene to 0.25 parts of bismuth(III) sulfate at 70 °C for 40 h. The results are summarized in Tables 1 and 2, including the spectral data of the reaction products. The reactions all afforded the same reaction products, regardless of the carboxylic acid used. The amounts of esterification are shown to increase from 20 to 34% between acetic acid and valeric acid, and to decrease from 34 to 29% between valeric acid and octanoic acid. The structures of the esters were confirmed by means of the analytical and spectral data, and also by the fact that the hydrolysis of the esters afforded 2β-hydroxymethyl-2α,8,8,4aβ-tetramethyl-1(8a)-octalin (*cis*-neopentyl-type alcohol)[3] evenly, in disregard of the partial structures from carboxylic acids. The isomeric α-type neopentyl ester has already been reported by us.[4]

The rise-and-fall ratio of intermediates or products in the reaction path was observed by GLC (Fig.1): in a reaction time of 2 min, Peak **a** (thujopsene) is shown to isomerize into the other hydrocarbons of Peaks **b**, **c**, and **d**: in 15 min, Peak **a** decreases strikingly to give a hydrocarbon (Peak **c**) and Peak **e**: in 40 h, Peak **e** reaches a suitable amount and a new peak, **f**, appears. Peaks **c** and **f** were identified, by comparisons of the spectral (IR and NMR) data and the GLC retention times with those of authentic samples, as 1,4,11,11-tetramethylbicyclo[5.4.0]undeca-3,7-diene,[5] **3**, and 2,2,3,7-tetramethyltricyclo[5.2.2.0^{1,6}]undec-3-ene,[5] **4**, respectively.

Then, the suitable conditions of the esterification were determined by experiments using propionic acid. To obtain a high yield of the ester, the reaction must be carried out at the reaction temperature of 70 °C, for a reaction time of 40 h, and using carboxylic acid in a ratio of 20 parts of thujopsene to 0.25 parts of the

Table 1. Analytical data of the esters

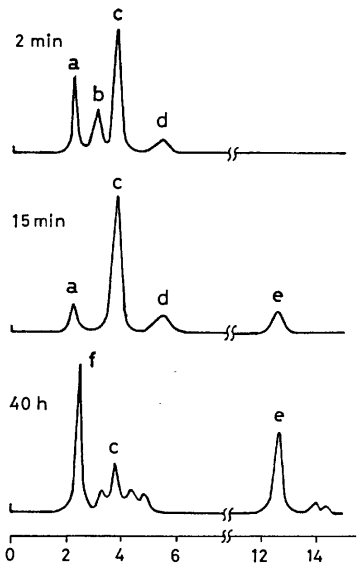

Fig. 1. Follow-up of the reaction path by GLC at the esterification of thujopsene using C_2H_5COOH and $Bi_2(SO_4)_3$.

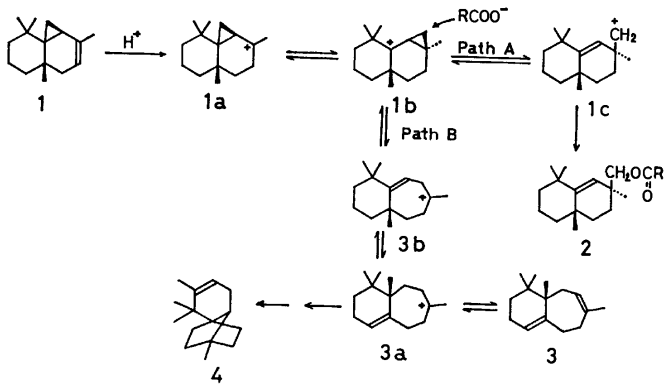
catalyst.

In the presence of bismuth(III) sulfate, this esterification reaction proceeded most readily under mild conditions, accompanied by rearranged products of thujopsene. In this system, however, no ester or rearranged products could be found in a blank reaction at temperatures lower than 70 °C for 40 h or more. Also, tin(II) sulfate and antimony(III) sulfate showed a catalytic effect, affording the same products. In view of these results, and with reference to the reaction mechanisms using other reagents presented by Dauben and Friedrich[5] and by Hochstetler and Kitchens,[6] the esterification to give the β-type bicyclic ester as the major product, accompanied by the tricyclic hydrocarbon, **4**, may be explained as is shown in Scheme 1. By considering the results for the follow-up of the reaction shown in Fig. 1, the protonation of (−)-thujopsene leads to the **1b** cation the subsequent attack of the carboxylate anion as **1b** would lead to the bicyclic ester, **2**, *via* Path A. Path B would afford the tricyclic hydrocarbon, **4**, *via* the **3a** cation by the pathway reported by Dauben and Friedrich.[5]



Scheme 1.

Experimental

The spectra were recorded on a JEOL JNM-PMX 60 NMR spectrometer, using TMS as the internal standard, and a Shimadzu IR-400 IR spectrometer. The elemental analyses were performed by a Hitachi 026 CHN analyzer. The analytical GLC were performed on a Shimadzu GC-4B apparatus with a 1.5 m glass column packed with 15% OV-17, at 10 °C/min 150—250 °C. For the preparative GLC, a JEOL JGC-1100 apparatus was employed with 15% OV-17 at 240 °C.

The thujopsene used was purified by the careful distillation of Cedar H oil (Takasago Perfumery Co., Ltd.) through a concentric column; bp 120 °C/10 mmHg. The inorganic salts used for the catalyst and organic acids were commercial, extra-pure reagents.

Esterification of Thujopsene. A mixture of 3.07 g (15 mmol) of thujopsene, 0.3 mol of organic acid, and 2.65 g (3.75 mmol) of bismuth(III) sulfate was stirred in a thermostated bath at 70 °C for 40 h. After the organic acid had been removed under reduced pressure, the resulting residue was poured into a cold mixture of petroleum ether and 5% aqueous sodium hydroxide while standing. The petroleum layer was further washed with a sodium hydrogencarbonate solution and dried over anhydrous sodium sulfate, and then the solvent was removed. The residue was analyzed by GLC. The analytical sample was chromatographed on a silica gel column and further purified by preparative GLC to yield material of a 97—98% purity. The saponification value was determined using a 2-h boiling in a 90% aqueous ethanolic solution of 0.3 M potassium hydroxide.

Follow-up of the Reaction Path by GLC. A mixture of 1.54 g (7.5 mmol) of thujopsene, 11.1 g (0.15 mol) of propionic acid, and 1.33 g (1.88 mmol) of bismuth(III) sulfate was stirred at 70 °C in the manner described above. The reaction product was analyzed by GLC, using sample aliquots at appropriate time intervals after the reaction mixture had been worked-up as described above.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (1), 321—322 (1978)

The Micellar Acceleration of the Reduction of Nitroblue Tetrazolium by Superoxide Anion Radicals during the Autoxidation of Polyphenols

Teruhiro TAKABE, Masako MIYAKAWA, and Sueki NIKAI

Department of Chemistry, Faculty of Science and Technology, Meijo University, Tenpaku, Nagoya 468

(Received April 25, 1977)

Synopsis. The rates of the reduction of Nitroblue Tetrazolium by O_2^- during the autoxidation of pyrogallol, epinephrine, and catechol were increased 110, 55, and 37-fold respectively in the presence of hexadecyltrimethylammonium bromide. A nonionic micelle of polyoxyethylene dodecyl ether also accelerated these reactions. The microenvironment effects on the electron-transfer from O_2^- to Nitroblue Tetrazolium were discussed.

The superoxide anion radical (O_2^-) is known to be produced by a number of biologically significant oxidations and is probably generated, to some degree, in all oxygen-metabolizing cells.[1] Recently, O_2^- has also been shown to be generated during the autoxidation of some phenols[2,3] and thiols.[4] Many other autoxidizable compounds may be found to generate O_2^- during autoxidation. Therefore, it is useful to develop easy and sensitive methods to detect O_2^-. The detection of O_2^- has been carried out by using direct kinetics techniques, such as EPR, or pulse radiolysis, and using inhibition by superoxide dismutase (SOD).[1] Nitroblue Tetrazolium (NBT) has been used for the detection of small amounts of such reducing agents as O_2^-, S^{2-}, and $S_2O_4^{2-}$.[5] Since it has been reported that the nucleophilic reactivity of the hydroxide ion and thiol are affected by the cationic micellar environment,[6] one may anticipate that the reaction rate between O_2^- and NBT is also accelerated by the micellar systems. In this study, we will report that the rate of electron transfer from O_2^- to NBT is accelerated by the surface-active cation hexadecyltrimethylammonium bromide (CTAB) and by nonionic micelles of polyoxyethylene dodecyl ether (Brij 35), and that NBT in micellar systems may be used in an easy and sensitive method to detect O_2^- during autoxidation.

Experimental

The pyrogallol was purified by sublimation. The epinephrine (Merck A. G.) and catechol (Katayama Chem. Co.) were used without further purification. Sodium dodecyl sulfate (NaLS) and CTAB were recrystallized from methanol and water respectively. Brij 35 (Katayama Chem. Co.), NBT (Sigma Chem. Co.), and bovin Cu–Zn SOD (Sigma Chem. Co.) were used without further purification. The water was deionized and distilled.

The spectroscopic measurements were made with a Shimadzu UV-200S recording spectrometer at 25 °C. The rates of the autoxidation of polyphenols were taken from the increase in the absorbance at 420 nm for pyrogallol[2] and at 480 nm for epinephrine[3] and catechol. The reduction of NBT was measured from the increase in the absorbance at 560 nm due to the accumulation of blue formazan. In all cases, reactions were started by adding an aliquot of an acidic (pH 2.0) stock solution of polyphenol to the buffered reaction mixture.

Results and Discussion

Since it has been shown that the autoxidations of pyrogallol, epinephrine, and catechol all involve O_2^-,[2,3] these polyphenols can transfer electrons to NBT *via* oxygen under aerobic conditions. Therefore, we investigated the reduction of NBT by O_2^- in micellar systems. As the mixing of NaLS and NBT resulted in precipitation, we used CTAB and Brij 35 for the experiment. The initial rates of the aerobic reduction of NBT during the autoxidation of pyrogallol were linear functions of the NBT concentration in either the absence or presence of a detergent, as is shown in Fig. 1. This result indicates that the rates of the reduction of NBT were accelerated by both CTAB and Brij 35. We show in Fig. 2 the effects of the concentrations of CTAB and Brij 35 on the reduction of NBT by O_2^- during the autoxidation of pyrogallol at pH 8.0. The reduction rate of NBT was markedly accelerated above 1×10^{-3} M CTAB (the critical micelle concentration is 0.92×10^{-3} M[6]) and tended to be saturated beyond 7×10^{-3} M CTAB. The rate was also accelerated by Brij 35 and saturated above the detergent concentration of 2×10^{-3} M. 5×10^{-3} M of CTAB and Brij 35 increased the rates by factors of 110 and 13-fold respectively. Similar results were obtained for the autoxidations of epinephrine and catechol, as is shown in Table 1. We can see that 5×10^{-3} M CTAB accelerated the reduction of NBT during the autoxidations of epinephrine and catechol by factors 55 and 37-fold respectively. 5×10^{-3} M Brij 35 also accelerated these reactions by factors of 7 and 5-fold respectively. The drastic acceleration in micellar systems described above raises the question whether these micelles accelerate the rate of autoxidation or electron-transfer from O_2^- to NBT. In order to clarify this point, we examined the micellar effects on the rates of the autoxidation of polyphenols by the methods described in the experimental section. We found that CTAB, Brij 35, and NaLS had almost no effect on the rates of autoxidation of these polyphenols with the

TABLE 1. MICELLAR EFFECT ON THE REDUCTION OF NBT DURING THE AUTOXIDATION OF EPINEPHRINE AND CATECHOL

The reaction mixture contained 2.5×10^{-4} M of polyphenol, 8.3×10^{-5} M of NBT, 5×10^{-3} M of the surfactant, and 1×10^{-4} M of EDTA in 0.1 M Tris-HCl at pH 9.0.

Epinephrine	0.011	0.590	0.079
Catechol	0.007	0.260	0.033

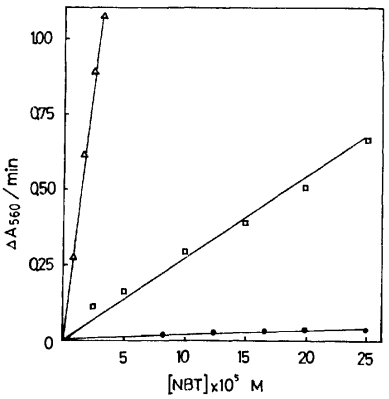

Fig. 1. The initial reduction rate of NBT as a function of NBT concentration. 2.5×10^{-4} M pyrogallol was added to the reaction mixture containing indicated concentration of NBT, 5×10^{-3} M surfactant, 1×10^{-4} M EDTA, and 0.1 M Tris-HCl at pH 8.0. ●; No surfactant, △; CTAB, □; Brij 35.

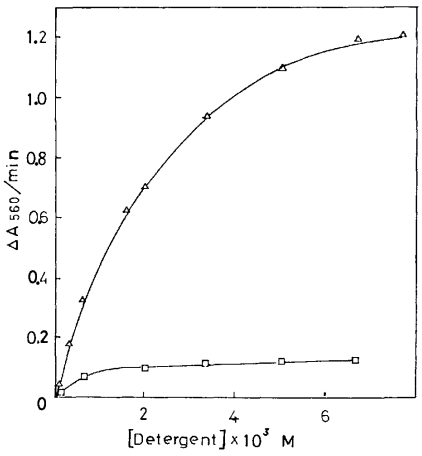

Fig. 2. Plots of the observed pseudo-first-order rate constant against the surfactant concentration for the reduction of NBT during the autoxidation of pyrogallol. Reaction-mixture contained 2.5×10^{-4} M pyrogallol, 3.3×10^{-5} M NBT, 0.1 M Tris-HCl at pH 8.0, and the indicated concentration of CTAB (△) and Brij 35 (□).

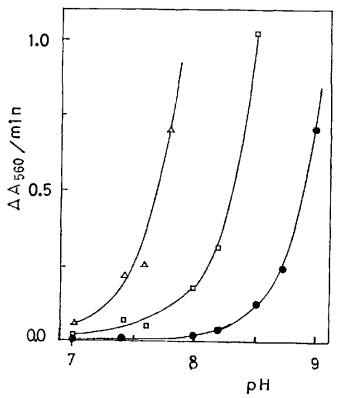

Fig. 3. Effect of pH on the reduction rate of NBT during the autoxidation of pyrogallol. Reaction mixture contanied 2.5×10^{-4} M pyrogallol, 8.3×10^{-5} M NBT, 5×10^{-3} M detergent, and 1×10^{-4} M EDTA in the following buffer systems; pH 7.0 and 7.4, 0.1 M potassium phosphate; other pH, 0.1 M Tris-HCl. ●; No surfactant, △; CTAB, □; Brij 35.

exception of the autoxidation of pyrogallol in the presence of CTAB. 5×10^{-3} M CTAB accelerated the autoxidation of pyrogallol 11-fold. However, its value is quite small in comparison with that for the reduction of NBT (110-fold). Therefore, these results indicate that CTAB and Brij 35 accelerated the rate of electron-transfer from O_2^- to NBT.

Since it has been shown that polyphenols are autoxidized rapidly in an aqueous alkaline solution,[2,3] we investigated the pH effects on the reduction of NBT. As is shown in Fig. 3, the reduction of NBT was accelerated by both CTAB and Brij 35 over the whole pH range of 7.0—9.0. This indicates that even a small amount of O_2^- generated during the autoxidation at a neutral pH is detectable by NBT in the micellar systems. From these result, it seems likely that the catalytic functions of both CTAB and Brij 35 are due to binding organic substrates to the micellar phase, giving more favorable environment for the O_2^- attack on NBT (the orientation effect[6]). Both Fig. 3 and Table 1 indicate that CTAB accelerates the reduction of NBT about 8 times more than does that Brij 35. Therefore, for the rate-enhancement effect by CTAB, besides the orientation effect, electrostatic interactions between the cationic micelle and O_2^- might be important. When KO_2 was directly added to the NBT solution, the rate of the reduction of NBT was accelerated only 30 percent by CTAB and Brij 35 compared with that in the non-micellar system. Therefore, the generation of O_2^- in the micellar phase may be important for the rapid reduction of NBT.

In order to determine whether or not O_2^-, which is generated during the autoxidation of polyphenols, practically reduces NBT in these micellar systems, we examined the effect of SOD on the reduction of NBT. As is shown in Fig. 4, the reduction of NBT during the autoxidation of pyrogallol was inhibited by SOD in either the absence or the presence of a surfactant. The

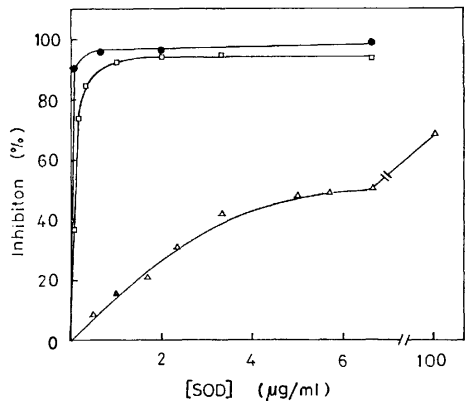

Fig. 4. Inhibition of the reduction of NBT during the autoxidation of pyrogallol by SOD. Cuvets contained 2.5×10^{-5} M NBT, 5×10^{-5} M pyrogallol, 5×10^{-3} M surfactant, 1×10^{-4} M EDTA, and 0.1 M Tris-HCl at pH 8.0. ●; No surfactant, △: CTAB, □; Brij 35.

reductions of NBT during the autoxidation of epinephrine and catechol were also inhibited by SOD in a manner similar to that is the case of pyrogallol. Quite similar micellar effects were also observed in the cases of the autoxidations of anthrone and such thiols as dithiothreitol, 2-mercaptoethanol, glutathione, and *l*-cysteine, all involving O_2^-. Therefore, NBT in the micellar systems might be useful as an easy and sensitive method to detect O_2^- during autoxidation.

Steric Effects on Carbon-13 Chemical Shifts in 3-Aryl-1,2,3-oxathiazolidine 2-Oxides

Tomihiro NISHIYAMA, Takashi MIZUNO, and Fukiko YAMADA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

(Received May 11, 1977)

Synopsis. The carbon-13 NMR spectra of 3-aryl-1,2,3-oxathiazolidine 2-oxides were obtained and discussed. Some of the carbon shifts are greatly influenced by the conformation of the oxathiazolidine ring.

In a previous paper,[1] we reported the conformations of a series of 3-aryl-1,2,3-oxathiazolidine 2-oxides (**1**) as determined by means of their ^{1}H-NMR spectra. In continuation of our studies concerning the steric structure of **1**, this paper will describe the relationships between their carbon-13 NMR spectra and the conformational structures of the oxathiazolidines.[1]

Experimental

Measurements. The ^{13}C-NMR spectra were obtained using a JNM-PS-100/EC-100 spectrometer equipped with a Fourier transform recorder at 25.15 MHz under a complete proton decoupling. The pulse width and repetition time were 10.2 μs and 6 s respectively. The spectral width and data points were 6250 Hz and 8191 respectively. The chemical shifts were reported in ppm downfield from the internal TMS, using deuteriochloroform.

Compounds. The preparations and the physical properties of **1** were reported in a previous paper by the present authors,[2,3]

Results and Discussion

Carbon-13 NMR measurements were made on the above 10 compounds. The carbons in the oxathiazolidine ring are represented by the notations of C-α and C-β respectively, and those in the benzene ring, by C-1—C-6, as is shown in the above diagram. The assignments of the carbons were made on the basis of (1) the relative signal intensity, (2) the off-resonance decoupling technique, and (3) the predicted chemical shifts obtained by the aid of the additivity rule.[4]

As can be seen in Table 1, the C-α signals appeared at around 70 ppm, whereas the C-β appeared at 46—49 ppm. The observed shifts from C-1 to C-6 were in close agreement with the predicted values for the compounds with an *m*- or *p*-substituent except for the case of IIIc. On the other hand, the shifts of C-1, C-2, and C-6 for the compounds with an *o*-substituent deviated from the predicted ones. In IIIa, the C-3 signal is shifted upfield compared with the predicted one (−3.1 ppm). This fact is considered to be a steric shift caused by the preferred conformation of the terminal CH_3 of the OCH_3 group being turned away from the C-1 and being now close to C-3.[5]

Table 2 shows the values obtained by subtracting the substituent parameters (S.P.) from the observed

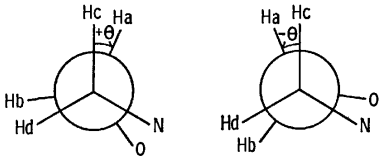
a) These values are taken from Ref. 1.

values. Consequently, these values show mainly the effects of the oxathiazolidine ring on the shifts of the benzene-ring carbons. From the data of I, the substituent parameters of the oxathiazolidine ring can be obtained as follows: +12.2 for C-1, −12.0 for *ortho*, +1.3 for *meta*, and −4.8 for *para* carbons. In the compounds with an *m*- or *p*-substituent, the individual carbon shifts come close to those of I, and the electronic effects of the substituent may contribute greatly to the shifts of benzene carbons. In these cases, there is no steric hindrance between either benzene or oxathiazolidine rings. In IIa, IIIa, and Va, the shifts of C-1, C-2, and C-6 deviate greatly from those of I.

In a previous paper,[1] we reported that the oxathiazolidine rings tend to form twist-envelope conformations, that their torsion angles with both the position and the nature of the ring substituent, and that the distortions of the oxathiazolidine ring of the compounds with *m*- and *p*-substituents are in the direction of the **2** projection, while those with an *o*-substituent cause a distortion toward the **3** projection, as can be seen in the following diagram. The values of the torsion angles are listed in Table 2.



2 **3**

θ: Torsion angle

In order to obtain further information about the conformational influence of the oxathiazolidine ring on the shifts of benzene-ring carbons, an attempt was made to plot the shifts of the ring carbons against their torsion angles.

As can be seen in Fig. 1, all the shifts of C-1 in the cases of the *m*- and *p*-substituents appeared at about 141 ppm, regardless of the torsion angle, while that of IIa appeared upfield about 4.5 ppm, and those of IIIa and Va shifted downfield about 3.4 and 2.1 ppm respectively. In IIa, the preferred comformation of the oxathiazolidine ring may be considered, from the evidence of the upfield shifts for both C-1 and methyl carbon (Table 1), that in which the lone pair of electrons on nitrogen is located close to the *o*-substituted methyl group. In the case of IIIa or Va, the lone pair of nitrogen was turned away from the *o*-substituent. On the other hand, two kinds of good linear correlations are obtained in the cases of C-2 and C-6. The

◐: C-1, ●: C-2, ◐: C-3, C-5, ◑: C-4, ○: C-6.

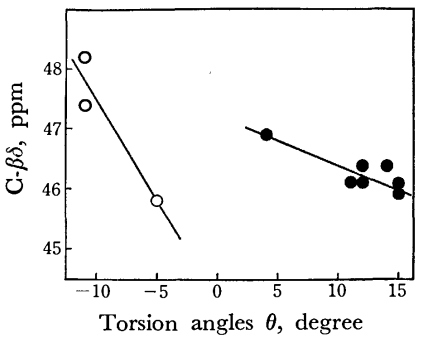

Fig. 2. Plots of the chemical shifts of C-β *vs.* torsion angles.
○: The compound bearing an *o*-substituent,
●: *m*-, or *p*-substituent.

left line is due to the data of the compounds bearing an *o*-substituent (Projection **3**), while the right line is due to those bearing an *m*- or *p*-substituent (Projection **2**). From the slopes of these lines, the effects on the chemical shifts of the *o*-substituent are larger than those of the other conformation.

The correlation of the chemical shifts of C-β *versus* their torsion angles is shown in Fig. 2. The effects on the chemical shifts of the *o*-substituent are shown to be larger than that of the *m*- or *p*-substituent, just as in Fig. 1.

Syntheses of Heliparvifoline and *O*-Demethylpteleine

Tetsuya SEKIBA

Faculty of Chemical Engineering, Toyama Technical College, Hongo, Toyama 930

(Received May 13, 1977)

Synopsis. 2,3-Dihydroheliparvifoline (Va) was obtained from 4-methoxy-3-benzyloxyaniline by condensation with diethyl (2-benzyloxyethyl)-malonate, and by subsequent methylation, debenzylation, and then cyclodehydration. Benzyl ether of Va was dehydrogenated and then treated with hydrochloric acid to give heliparvifoline.

Recently, heliparvifoline was isolated from the leaves and twigs of *Helietta parvifolia* Benth (Rutaceae).[1] Its structure was proposed to be 4,6-dimethoxy-7-hydroxyfuro[2,3-*b*]quinoline (Ia) on the basis of the spectral data. However, the synthesis of Ia has not yet been reported. Although *O*-demethylpteleine (Ib) has not yet been found in any natural source, it is considered valuable to synthesize this substance, because it may be expected to occur in nature and to be an intermediate in medicosmine synthesis.[2] Govindachari and his co-workers attempted to synthesize Ib, but they merely obtained benzyl ether of Ib.[3] In previous papers,[4,5] the present author reported the syntheses of some furoquinoline alkaloids through the corresponding dihydrofuroquinolines as key intermediates.

The present paper will describe convenient syntheses of Ia and Ib from 3-benzyloxy-4-methoxyaniline. The condensation of an aniline derivative and diethyl (2-benzyloxyethyl)-malonate without a solvent gave the 4-hydroxy-2-quinolone derivatives (IIa, b), which were methylated with diazomethane into 4-methoxy compounds (IIIa, b). The catalytic debenzylation of IIIa and IIIb using 5% Pd–C gave 3-(2-hydroxyethyl)-4-methoxy-2-quinolone derivatives (IVa, b). The IR spectra of IVa and IVb indicated the presence of a hydroxyl group (*ca.* 3500 cm^{-1}), and the NMR spectra of IVa and IVb indicated the complate debenzylation and exhibited a signal for one proton of the hydroxyl group which easily disappeared upon deuterium exchange. The cyclodehydration of IVa and IVb with polyphosphate ester yielded 2,3-dihydrofuro[2,3-*b*]quinoline derivatives (Va, b). The structures of Va and Vb were assigned on the basis of their NMR spectra, which showed signals at δ *ca.* 3.42(t) and 4.58(t) ppm attributable to two methylene protons of a dihydrofuran-ring system. Since the dehydrogenation of Va and Vb with DDQ (2,3-dichloro-5,6-dicyanobenzoquinone) was unsuccessful, Va and Vb were treated with benzyl chloride to give benzyl ether (VIa,b), whose IR spectra indicated the absence of the hydroxyl group, and their NMR spectra showed signals characteristic of a benzyl group. VIa and VIb were then treated with DDQ in dry toluene to give the corresponding dehydro compounds (VIIa,b). The structures of VIIa and VIIb were assigned on the basis of their NMR spectra, which showed signals at δ 7.04 (d) and 7.62 (d) ppm attributable to the 2,3-protons of a furan-ring system. The debenzylation of VIIa and VIIb with ethanol-hydrochloric acid gave furo[2,3-*b*]quinoline derivatives (Ia; heliparvifoline and Ib; *O*-demethylpteleine). The synthetic heliparvifoline (Ia) was shown to be identical with a natural specimen by a mixed-melting-point determination and by a comparison of the IR, UV, and NMR spectra.

Experimental*

3-(2-Benzyloxyethyl)-4-hydroxy-2-quinolones (IIa, b). A mixture of 3-benzyloxy-4-methoxyaniline (4.2 g) or 4-benzyloxyaniline (3.5 g) and diethyl (2-benzyloxyethyl)-malonate (6.3 g) was heated under reduced pressure (*ca.* 70 mmHg). The temperature was then raised to 180 °C over a period of 30 min, maintained at that temperature for a further 30 min, and then raised and kept at 250 °C for 30 min. The cooled reaction mixture was subsequently dissolved in chloroform. The chloroform solution was treated in a way similar to that described in previous papers.[4,5] IIa: Mp 185—186 °C (pale yellow plates from EtOH) (yield, 58.0%). Found: C, 72.08; H, 5.99; N, 3.21%. Calcd for $C_{26}H_{25}O_5N$: C, 72.37; H, 5.84; N, 3.25%. IR (cm^{-1}, Nujol): 3200, 1650. NMR ($CDCl_3$): δ 3.14, 3.82 ppm (both 2H, t, J=5.0 Hz, CH_2–CH_2), 3.93 (3H, s, OCH_3), 4.66, 5.20 (both 2H, s, CH_2Ph), 6.85 (1H, s, arom-**H**), 7.2—7.5 (11H, m, arom-**H** and 2×CH_2**Ph**), 9.68 (1H, br, O**H**), 12.04 (1H, br, N**H**). IIb: Mp 190.5—191.5 °C (pale yellow needles from ethyl acetate) (yield, 88.5%). Found: C, 74.73; H, 5.72; N, 3.50%. Calcd for $C_{25}H_{23}O_4N$: C, 74.79; H, 5.78; N, 3.49%. IR (Nujol); 3400, 1650. NMR ($CDCl_3$): δ 3.20, 3.90 (both 2H, t, J=5.3 Hz, CH_2–CH_2), 4.67, 5.15 (both 2H, s, CH_2Ph), 7.28, 7.38 (both 5H, s, CH_2**Ph**) 7.2—7.6 (3H, m, arom-**H**), 9.75 (1H, br, O**H**), 12.00 (1H, br, N**H**).

3-(2-Benzyloxyethyl)-4-methoxy-2-quinolones (IIIa, b). Prepared by the usual diazomethane method: IIIa: Mp 175—176 °C (colorless plates from ethyl acetate) (yield, 81.0%). Found: C, 72.52; H, 6.16; N, 3.08%. Calcd for $C_{27}H_{27}O_5N$: C, 72.79; H, 6.11; N, 3.14%. IR (Nujol): 1660. NMR ($CDCl_3$): δ 3.92, 3.94 (both 3H, OCH_3), 3.06, 3.82 (both 2H, t, J=6.8 Hz, CH_2–CH_2), 4.51, 5.18 (both 2H, s, CH_2Ph), 6.8—7.5 (12H, m, arom-**H** and CH_2**Ph**),

* All the melting points are uncorrected.

12.46 (1H, s, NH). IIIb: Mp 163—165 °C (pale yellow needles from EtOH) (yield, 90.5%). Found: C, 75.08; H, 6.01; N, 3.45%. Calcd for $C_{26}H_{25}O_4N$: C, 75.16; H, 6.07; N, 3.37%. IR (Nujol): 1650. NMR ($CDCl_3$): δ 3.87 (3H, s, OCH_3), 3.07, 3.83 (both 2H, t, J=7.2 Hz, CH_2–CH_2), 4.55, 5.12 (both 2H, s, CH_2Ph), 7.24, 7.40 (both 5H, s, CH_2Ph), 7.0—7.5 (3H, m, arom-H), 12.25 (1H, br, NH).

3-(2-Hydroxyethyl)-4-methoxy-2-quinolones (IVa, b). To a hydrogen-saturated solution of Pd-C (5%, 2.0 g) in abs ethanol 100 ml, IIIa or IIIb (5.0 g) was added; the mixture was then stirred for 3 h at *ca.* 60 °C in an atmosphere of hydrogen. After the catalyst had been filtered off, the residue was recrystallized from ethanol to give 1.7 g (62.7%) of IVa or 1.8 g (63.6%) of IVb. IVa: Mp 217—219 °C. Found: C, 58.80; H, 5.69; N, 5.27%. Calcd for $C_{13}H_{15}O_5N$: C, 58.86; H, 5.70; N, 5.28%. IR (Nujol): 3500, 3200, 1650. NMR (DMSO-d_6): δ 3.87, 3.91 (both 3H, s, OCH_3), 2.77, 3.65 (both 2H, t, J=7.0 Hz, CH_2–CH_2), 6.85, 7.06 (both 1H, s, C_8–H and C_5–H), 8.28, 9.80, 11.40 (each 1H, br, OH and NH). IVb: Mp 227—229 °C (colorless needles from EtOH). Found: C, 61.04; H, 5.65; N, 6.24%. Calcd for $C_{12}H_{13}O_4N$: C, 61.27; H, 5.57; N, 5.96%. IR (Nujol): 3600, 3200, 1655. NMR (DMSO-d_6): δ 3.86 (3H, s, OCH_3), 2.70, 3.57 (both 2H, t, J=6.0 Hz, CH_2–CH_2), 4.66 (1H, t, J=5.25 Hz, CH_2OH), 6.8—7.4 (3H, m, arom-H), 9.38 (1H, s, OH), 11.45 (1H, s, NH).

2,3-Dihydrofuro[2,3-b]quinolines (Va, b). A mixture of IVa or IVb (1.0 g) and polyphosphate ester (15 g) was heated at 120—130 °C for 2.5 h. The cooled mixture was then poured into water, and the insoluble materials were filtered off. The aq. solution was neutralized with ammonia. The precipitate was collected, washed with water, and recrystallized to give Va or Vb. Va: Mp 320 °C (dec, pale green needles from EtOH) (yield, 42.2%). Found: C, 63.30; H, 5.29; N, 5.47%. Calcd for $C_{13}H_{13}O_4N$: C, 63.15; H, 5.30; N, 5.67%. IR (Nujol): 3400, 1630, 1490. NMR (DMSO-d_6): δ 3.60, 4.50 (both 2H, t, J=7.8 Hz, CH_2–CH_2), 3.85, 4.18 (both 3H, s, OCH_3), 6.93, 7.23 (both 1H, s, C_8–H and C_5–H), 9.55 (1H, br, OH). Vb: Mp 288—290 °C (colorless needles from EtOH) (yield, 67.7%). Found: C, 66.46; H, 5.07; N, 6.50%. Calcd for $C_{12}H_{11}O_3N$: C, 66.35; H, 5.10; N, 6.45%. IR (Nujol): 3450, 1630, 1520. NMR (DMSO-d_6): δ 3.60, 4.50 (both 2H, t, J=7.5 Hz, CH_2–CH_2), 4.15 (3H, s, OCH_3), 6.95—7.55 (3H, m, arom-H), 9.45 (1H, s, OH).

Benzyl Ether of 2,3-Dihydrofuro[2,3-b]quinolines (VIa, b). To a sodium ethoxide solution prepared from metallic sodium (140 mg) and abs. ethanol (100 ml), Va (1.0 g) or Vb (0.9 g), and benzyl chloride (0.7 g) were added, after which the mixture was refluxed for 8 h in an atmosphere of nitrogen. After the mixture had then been evaporated under a vacuum, the residue was extracted with chloroform. The chloroform solution was washed with a sodium hydroxide solution and water, and then extracted with a 6M hydrochloric acid solution. The acidic solution was neutralized with ammonia and extracted with chloroform. After the solvent had been evaporated, the residue was recrystallized to give VIa or VIb. VIa: Mp 177—179 °C (colorless plates from EtOH) (yield, 60.2%). Found: C, 71.23; H, 5.61; N, 4.05%. Calcd for $C_{20}H_{19}O_4N$: C, 71.20; H, 5.68; N, 4.15%. NMR ($CDCl_3$): δ 3.90, 4.09 (both 3H, s, OCH_3), 3.51, 4.49 (both 2H, t, J=8.8 Hz, CH_2–CH_2), 4.44 (2H, s, CH_2Ph), 7.14 (7H, m, arom-H and CH_2Ph). VIb: Mp 182—184 °C (colorless plates from EtOH) (yield, 63.5%). Found: C, 74.02; H, 5.52; N, 4.40%. Calcd for $C_{19}H_{17}O_3N$: C, 74.25; H, 5.58; N, 4.56%. NMR ($CDCl_3$): δ 4.10 (3H, s, OCH_3), 3.50, 4.50 (both 2H, t, J=8.0 Hz, CH_2–CH_2), 5.07 (2H, s, CH_2Ph), 7.38 (5H, s, CH_2Ph), 7.0—8.0 (3H, m, arom-H).

Benzyl Ether of Furo[2,3-b]quinolines (VIIa, b). To a solution of VIa or VIb (1.0 g) in dry toluene (150 ml), DDQ (2.0 g) was added; the mixture was then stirred under reflux for 16 h in an atmosphere of nitrogen. The mixture was filtered, and the filtrate was washed with water and extracted with 6M hydrochloric acid. After the acidic solution had been neutralized with ammonia, the resulting precipitate was collected and recrystallized to give VIIa or VIIb. The product was purified by means of chromatography on Wako-gel C-200 (10% $CHCl_3$–C_6H_6). VIIa: Mp 186—187 °C (pale yellow needles from EtOH) (yield, 42.4%). Found: C, 71.43; H, 5.25; N, 4.20%. Calcd for $C_{20}H_{17}O_4N$: C, 71.63; H, 5.11; N, 4.18%. NMR ($CDCl_3$): δ 3.97, 4.35 (both 3H, s, OCH_3), 6.96, 7.50 (both 1H, d, J=2.4 Hz, C_3–H and C_2–H), 5.27 (2H, s, CH_2Ph), 7.44 (7H, m, arom-H and CH_2Ph). VIIb: Mp 193—194.5 °C (colorless needles from EtOH) (yield, 32.6%). Found: C, 74.68; H, 5.20; N, 4.79%. Calcd for $C_{19}H_{15}O_3N$: C, 74.74; H, 4.95; N, 4.59%. NMR ($CDCl_3$): δ 4.40 (3H, s, OCH_3), 7.01, 7.57 (both 1H, d, J=3.0 Hz, C_3–H and C_2–H), 5.16 (2H, s, CH_2Ph), 7.95 (1H, d, J=9.0 Hz, arom-H), 7.2—7.6 (7H, m, arom-H and CH_2Ph).

Heliparvifoline (Ia) and O-Demethylpteleine (Ib). A mixture of VIIa or VIIb (0.5 g) and ethanol-hydrochloric acid (1 : 1, 50 ml) was treated by a method similar to that described in previous papers.[4,5] The precipitate was collected and recrystallized to give 4,6-dimethoxy-7-hydroxyfuro[2,3-*b*]-quinoline (heliparvifoline, Ia) and 6-hydroxy-4-methoxyfuro[2,3-*b*]quinoline (*O*-demethylpteleine, Ib). Ia: Mp 243—245 °C (lit,[1] 245—246 °C; a mixed melting point with natural heliparvifoline was not depressed.) (pale yellow cubic from MeOH) (yield, 76.5%). Found: C, 63.55; H, 4.48; N, 5.65%. Calcd for $C_{13}H_{11}O_4N$: C, 63.67; H, 4.42; N, 5.71%. IR (Nujol): 3500, 1630, 1490. NMR (DMSO-d_6): δ 3.94, 4.38 (both 3H, s, OCH_3), 7.06 (1H, d, J=2.4 Hz, C_3–H), 7.52 (1H, d, J=2.4 Hz, C_2–H), 7.20 (1H, s, C_8–H), 7.40 (1H, s, C_5–H), 7.70 (1H, s, OH, disappeared with D_2O). Ib: mp 216—217 °C (pale yellow prisms from EtOH–C_6H_6) (yield, 51.7%). Found: C, 66.75; H, 4.30; N, 6.44%. Calcd for $C_{12}H_9O_3N$: C, 66.97; H, 4.22; N, 6.51%. NMR (DMSO-d_6): δ 4.41 (3H, s, OCH_3), 7.14 (1H, d, J=2.4 Hz, C_3–H), 7.68 (1H, d, J=8.0 Hz, arom-H), 7.90 (1H, d, J=2.4 Hz, C_2–H), 6.7—7.4 (2H, m, arom-H), 9.60 (1H, br, OH, disappeared with D_2O).

The author wishes to express his deep gratitude to Dr. Mitsuru Nakayama, Hiroshima University, for his encouragement throughout the course of this work, and also to Dr. G.A. Cordell, University of Illinois, Chicago, for his gift of a natural specimen of heliparvifoline.

The Reaction of *N*-(Phenylsulfonyl)benzohydrazonoyl Chloride with Enamines

Suketaka Ito, Yumo Tanaka, Akikazu Kakehi, and Toshiyuki Matsuno

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received May 23, 1977)

Synopsis. 3-(Diethylamino)crotonic acid esters and 1-diethylamino-1-cyclohexene react with *N*-(phenylsulfonyl)-benzohydrazonoyl chloride to give substituted pyrazoles in 87—89% and 1.4% yields, respectively, the corresponding morpholine enamines affording no pyrazoles. The pyrazole formation is interpreted in terms of a step-by-step process involving the nucleophilic attack of the enamines on the hydrazonoyl chloride.

N-Phenylbenzohydrazonoyl chloride reacts with benzamidine to give 1,3,5-triphenyl-1*H*-1,2,4-triazole,[1] and with enamines to afford substituted pyrazoles;[2,3] the 1,3-dipolar cycloaddition mechanism has been suggested for these reactions.[2,4]

On the other hand, the reaction of *N*-(phenylsulfonyl)-benzohydrazonoyl chloride(**1**) with benzamidines and benzimidates proceeds through a two-step path involving the nuclephilic attack of amidines or imidates on the imidoyl carbon of the hydrazonoyl chloride, leading also to the formation of 1,2,4-triazoles.[5]

The present study shows a pyrazole-formation by the reaction of **1** with enamines which proceeds through the two-step path involving the nucleophilic process.

When a mixed solution of **1** and one equivalent of ethyl or allyl 3-(diethylamino)crotonate(**2a** or **2b**) in THF was allowed to stand at room temperature, 4-ethoxycarbonyl- or 4-allyloxycarbonyl-5-methyl-3-phenyl-1-phenylsulfonylpyrazole(**3a** or **3b**) was formed in a good yield. Much the same result was obtained when two equivalents of **2** were used. In the reaction with 1-diethylamino-1-cyclohexene(**2c**), however, the corresponding pyrazole(**3c**) was obtained in a low yield, 3,6-diphenyl-1,4-bis(phenylsulfonyl)-1,4-dihydro-1,2,4,5-tetrazine(**4**) being formed together with a small amount of *N*-(phenylsulfonyl)-*N*-[*N*-(phenylsulfonyl)-benzohydrazonoyl]benzohydrazonoyl chloride(**5**)[5] and 3,5-diphenyl-4-phenylsulfonylamino-4*H*-1,2,4-triazole (**6**)(Scheme 1).

In contrast, the corresponding morpholine enamines (**2'a** and **2'c**) afforded no pyrazoles but **4** and/or **5** and **6**. *N*-Phenylsulfonylmorpholine was also obtained along with N^2-(phenylsulfonyl)benzohydrazide[6] in the reaction with ethyl 3-morpholinocrotonate(**2'a**). The results are summarized in Table 1.

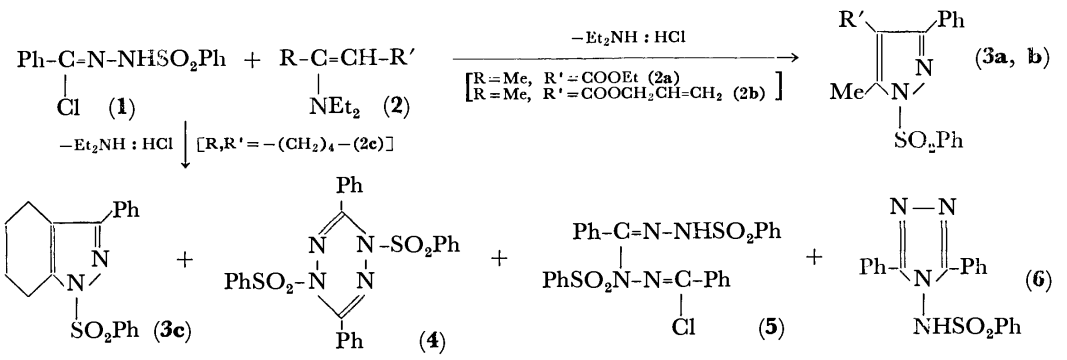
Table 1. Reaction of *N*-(phenylsulfonyl)benzohydrazonoyl chloride with enamines

Enamines[a]	Yield(%) of Products[b]			
	3	**4**	**5**	**6**
2a	89(**3a**)	—	—	—
2b	87(**3b**)	—	—	—
2c	1.4(**3c**)	42	2.7	4.0
2'a[c]	—	trace	14	13
2'c	—	48	—	—

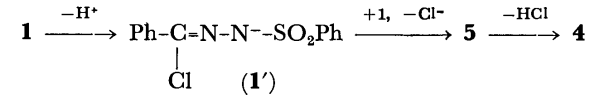
a) **2'a**: Me-C(-N O)=CH-COOEt, **2'c**: O N-C_6H_9. b) Yield(isolated) as mole per cent based on **1**. c) Yield of *N*-phenylsulfonylmorpholine: 18%. Yield of N^2-(phenylsulfonyl)benzohydrazide: 24%.

In the hydrazonoyl chloride **1**, the electron-attractive phenylsulfonyl group may enhance the acidity of the amino group and also the electrophilicity of the imidoyl carbon of **1**. Thus, for the formation of **5** and **4**, the following reaction route can be given: (Scheme 2). Actually, **4** was obtained almost quantitatively by the treament of **5** with a base.

The attempted reactions of **1** with a number of dipolarophiles in the presence of a base were unsuccessful, but resulted in the formation of **4** in all cases:[5] the negative charge of the *N*-(phenylsulfonyl)benzohydrazonoyl chloride *N*-anion (**1'**) may be delocalized by the sulfonyl group, so that the anion becomes stable and will not release chloride anion to form the 1,3-dipolar nitrilimine. Furthermore, the 1,3-dipolar cycloaddition mechanism cannot explain the different reactivity of



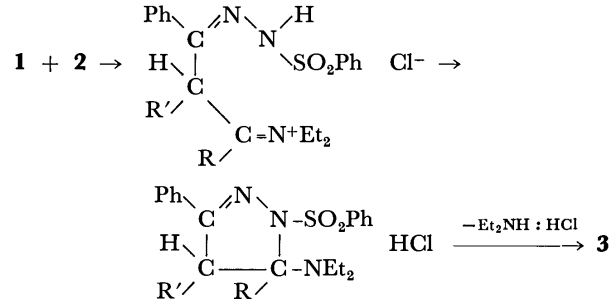
Scheme 1.



Scheme 2.

enamines in the present pyrazole-formation.

Consequently, it is reasonable to consider that the pyrazole formation may proceed via the nucleophilic attack of **2** on the imidoyl carbon of **1** followed by the intramolecular cyclization of the resulting intermediate (Scheme 3).



Scheme 3.

Since enamine **2c** is a stronger base than **2a** and **2b**, the proton abstraction from **1** by **2c** takes place predominantly to lead to the formation of **5** and **4**. Owing to the internal strain which arises in the iminium salt structure of morpholine moiety, it may be difficult for the first step of pyrazole-formation to take place in the reaction with the morpholine enamines. These circumstances and the stronger basicity of morpholine enamines probably account for their different behavior.

Compound **5** may be the precursor of the triazole **6**: efforts have been made to verify this postulation, but no experimental evidence could be obtained.

Experimental

Melting points were determined with a Yanagimoto micro-melting point apparatus Model MP-S3 and are uncorrected. The microanalysis was performed on a Perkin-Elmer elemental analyzer Model 240. The IR and NMR spectra were recorded with a JASCO DS-301 spectrometer and a JEOL JNH-4H-100 spectrometer, respectively.

N-(Phenylsulfonyl)benzohydrazonoyl chloride (**1**) was prepared by the method reported.[7] Ethyl and allyl 3-(diethylamino)crotonate (**2a**: bp 150—152 °C/18 mmHg, **2b**: bp 169—170 °C/20 mmHg), and ethyl 3-morpholinocrotonate (**2'a**: bp 172—174 °C/14 mmHg) were prepared according to the procedure of Décombe.[8] 1-Diethylamino-1-cyclohexene (**2c**: bp 66—67 °C/6 mmHg) and 1-morpholino-1-cyclohexene (**2'c**: bp 133—134 °C/17 mmHg) were obtained according to the method of Blanchard[9] and of Hünig *et al.*,[10] respectively.

The products were identified by their analytical and spectral data.

*Reaction of **1** with Enamines (1 : 1 mole ratio). General Procedure*: A solution of **2** (0.01 mol) in THF (20 ml) was mixed with a solution of **1** (0.01 mol) in THF (20 ml) at room temperature. In a few minutes, precipitates began to separate. The reaction mixture was allowed to stand for one day. The separated precipitates (amine hydrochloride) were filtered and washed with THF. The filtrate was concentrated and chromatographed over silica gel (20 g) using benzene as an eluent to give the products shown in Table 1.

*4-Ethoxycarbonyl-5-methyl-3-phenyl-1-phenylsulfonylpyrazole (**3a**).* Mp 111—112 °C (benzene). IR (KBr, cm^{-1}): 1700 (ν_{CO}); 1575, 1543 (ring $\nu_{C=C}$, $\nu_{C=N}$); 1370, 1184 (ν_{SO_2}), NMR ($CDCl_3$, δ): 1.13 ppm (3H t, J=7.5 Hz, CH_3CH_2–); 2.91 ppm (3H s, 5-CH_3); 4.27 ppm (2H q, J=7.5 Hz, CH_3–CH_2–); 7.40—8.00 ppm (8H m, 3-Ph, *m,m'* and *p*-protons of $PhSO_2$–); 8.16—8.35 ppm (2H m, *o,o'*-protons of $PhSO_2$–). Found: C, 61.49; H, 4.88; N, 7.57%. Calcd for $C_{19}H_{18}N_2O_4S$: C, 61.61; H, 4.90; N, 7.56%.

*4-Allyloxycarbonyl-5-methyl-3-phenyl-1-phenylsulfonylpyrazole (**3b**).* Mp 104—105 °C (CCl_4). IR (KBr, cm^{-1}): 1713 (ν_{CO}); 1575, 1532 (ring $\nu_{C=C}$, $\nu_{C=N}$); 1370, 1184 (ν_{SO_2}), NMR ($CDCl_3$, δ): 2.93 ppm (3H s, 5-CH_3); 4.73 ppm (2H brd, J=5.0 Hz, $-OCH_2-CH=CH_2$); 5.21 ppm (1H brd, J=17.5 Hz, $-OCH_2>C=C<\underline{H}$); 5.24 ppm (1H brd, J=10.0 Hz, $-OCH_2>C=C<\underline{H}$); 5.90 ppm (1H m, $-OCH_2-C\underline{H}=CH_2$); 7.45—7.80 ppm (8H m, 3-Ph, *m,m'* and *p*-protons of $PhSO_2$–); 8.15—8.30 ppm (2H m, *o,o'*-protons of $PhSO_2$–). Found: C, 62.75; H, 4.65; N, 7.24%. Calcd for $C_{20}H_{18}N_2O_4S$: C, 62.81; H, 4.73; N, 7.33%

*3-Phenyl-1-phenylsulfonyl-4,5,6,7-tetrahydrobenzo[c]pyrazole (**3c**).* Mp 243—244 °C (acetone). IR (KBr, cm^{-1}): 1580, 1565 (ring $\nu_{C=C}$, $\nu_{C=N}$); 1372, 1183 (ν_{SO_2}), NMR ($CDCl_3$, δ): 1.50—2.00 ppm (4H m, C^5 and C^6–H); 2.66 ppm (2H m, C^4–H); 3.05 ppm (2H m, C^7–H); 7.45—7.95 ppm (8H m, 3-Ph, *m,m'* and *p*-protons of $PhSO_2$–); 8.10—8.30 ppm (2H m, *o,o'*-protons of $PhSO_2$–). Found: C, 67.56; H, 5.16; N, 8.21%. Calcd for $C_{19}H_{18}N_2O_2S$: C, 67.43; H, 5.36; N, 8.28%.

*3,5-Diphenyl-4-phenylsulfonylamino-4H-1,2,4-triazole (**6**).* Mp 312—315 °C (dec) (acetone). IR (KBr, cm^{-1}): 3171 (ν_{NH}); 1580 ($\nu_{C=N}$); 1353, 1165 (ν_{SO_2}); 1276 (triazole ring). Found: C, 63.51; H, 4.29; N, 14.59%. Calcd for $C_{20}H_{16}N_4O_2S$: C, 63.81; H, 4.28; N, 14.88%.

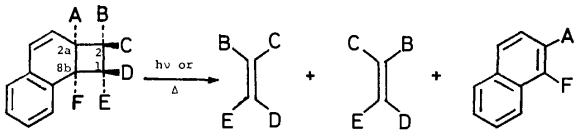
Photochemical Reactions of Aromatic Compounds. XXIX.[1] Photochemical and Thermal Cycloreversions of 1,2,2a,8b-Tetrahydrocyclobuta[*a*]naphthalenes

Chyongjin PAC,* Kazuhiko MIZUNO,** and Hiroshi SAKURAI
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received June 18, 1977)

Synopsis. Photochemical and thermal cycloreversions of 1,2,2a,8b-tetrahydrocyclobuta[*a*]naphthalenes were investigated. The cycloreversion in the excited singlet state was completely stereospecific; a concerted mechanism was assigned. The benzophenone-sensitized and thermal decomposition gave a mixture of *cis*- and *trans*-olefins, but favored stereoretention. The mechanisms are discussed in terms of singlet and triplet 1,4-biradicals.

The [2+2] cycloreversions of cyclobutane compounds have been of theoretical and mechanical interest in relation to the Woodward-Hoffmann rule[2] and 1,4-biradical intermediates.[3] We wish to report here on the stereochemical features of photochemical and thermal cycloreversions of 1,2,2a,8b-tetrahydrocyclobuta[*a*]naphthalenes **1a—d**.



1 2 3 4

	A	B	C	D	E	F
a:	H	H	CH_3	OC_6H_5	H	CN
b:	H	CH_3	H	OC_6H_5	H	CN
c:	CN	H	CH_3	OCH_3	H	H
d:	CN	CH_3	H	OCH_3	H	H

The direct or benzophenone-sensitized photolysis of **1a—d** quantitativlly gave **2a—d**, **3a—d**, and **4**. The results are listed in Table 1. The olefin formation by the direct photolysis of **1a**, **b** occurred with >95% stereospecificities, whereas the cycloreversion in the presence of ferrocene or in neat 1,3-pentadiene was completely stereospecific. Since ferrocene and 1,3-pentadiene are well-known to be good triplet quenchers, the formation of small amounts of **3a**, **b** in the absence of such compounds probably occurs by means of a triplet mechanism. Similarly, the direct photolysis of **1c** or **1d** in the presence of ferrocene gave only **2c** or **2d** each. In the excited singlet state, therefore, the cycloreversions proceed *via* a $_s2_s+_s2_s$ concerted mechanism.

On the other hand, the benzophenone-sensitized decomposition of **1a**, **b** occurred with only a partial stereoretention. In recovered **1a**, **b**, the epimers could not be detected. The results suggest that triplet biradicals, ^{3}**4c** and ^{3}**5t**, undergo the C_1–C_2 bond rotation in competition with the intersystem crossing to singlet biradicals (Scheme 1).[4]

The thermal decomposition of **1a—d** at 300±10 °C gave **2a—d**, **3a—d**, and **4**> in 80% yields, with high stereospecificities. It should be noted that the stereoretention of the *cis* configuration in **1a**, **c**→**2a**, **c** predominanted over that of the *trans* configuration in **1b**, **d**→**2b**,**d**;[6] usually the retention of the *trans* configuration predominates over that of the *cis* configuration in thermolyses of cyclobutane[5a,5c,7] and oxetane[8] compounds. The C_2–C_3 bond cleavage of singlet biradicals is spin-allowed and favored by the aromatization of the dihydronaphthyl residue. Moreover, the sterically crowded nature of ^{1}**4c** reinforces the bond cleavage which overcomes the C_1–C_2 bond rotation, whereas ^{1}**5t** undergoes the bond rotation to a significant extent

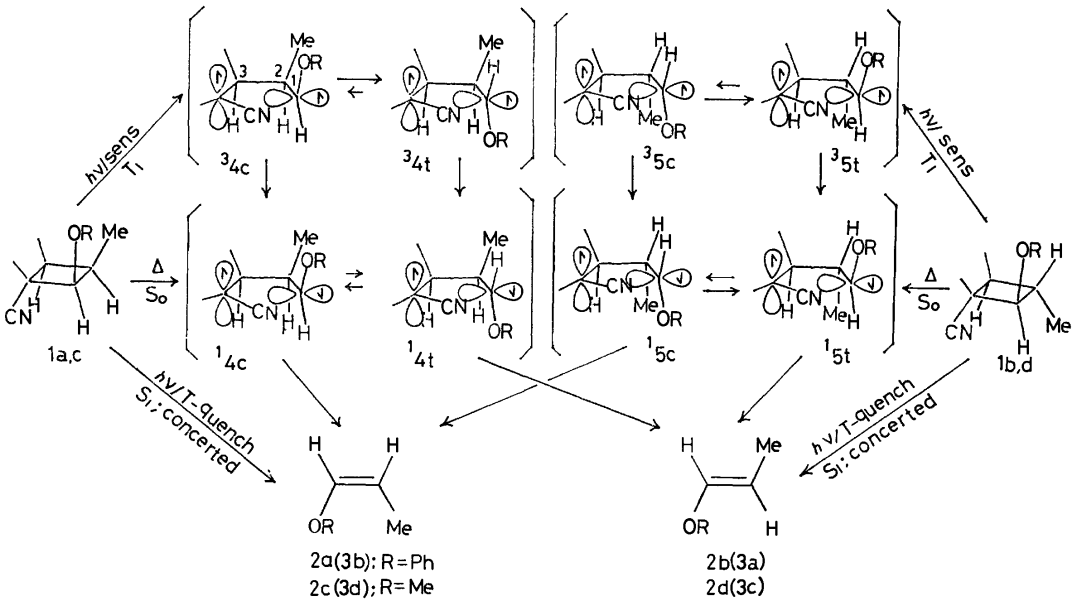

Scheme 1.

because of the smaller steric repulsion. Alternatively, a biradicaloid transition-state mechanism[3b,3f] offers an attractive speculation; a concerted mechanism could contribute more to the cycloreversion of **1a**, **c** than to that of **1b**,**d**.[8b,9]

Experimental

Materials. *cis*- and *trans-endo*-1-Phenoxy-2-methyl-1,2,2a,8b-tetrahydrocyclobuta[*a*]naphthalene-8b-carbonitriles **1a** (mp 138.5—139.5 °C) and **1b** (mp 97.5—98.5 °C) were obtained by the photocycloaddition of *cis*- and *trans*-1-phenoxypropenes to 1-naphthonitrile[10] respectively. Similarly, **1c** (mp 65—66 °C) and **1d** (mp 127.5—129 °C) were prepared according to the method reported previously.[11] These materials, benzophenone, and ferrocene were recrystallized from methanol. The 1,3-pentadiene was distilled from sodium under a nitrogen atmosphere.

Photolyses. Solutions of **1a**—**d** (2 mg/cm³) in cyclohexane, acetonitrile, or 1,3-pentadiene were prepared. Solutions of **1a**—**d** (2 mg/cm³) and ferrocene (2 mg/cm³) or benzophenone (1 mg/cm³) in acetonitrile were also prepared. Each solution (2 cm³) was placed in a Pyrex tube, bubbled with a pure nitrogen stream, and irradiated with a high-pressure mercury arc at 20±2 °C, using a merry-go-round apparatus. In benzophenone-sensitized runs, a hexane solution of naphthalene (13 g/dm³, 1 cm path length) was used as the light filter. During the course of the irradiation, the photolysates were analyzed by VPC at 5-min intervals.

Thermolyses. Pyrex tubes, in which **1a** or **1b** (10—20 mg) was placed, were degassed ($<10^{-3}$ mmHg), sealed, and heated on a metal bath maintained at 300±10 °C for 2—3 h. The decomposition was completed. 1-Naphthonitrile and a mixture of *cis*- and *trans*-1-phenoxypropenes were formed in *ca.* 90 and 80% yields respectively. More conveniently, the thermolyses were carried out by introducing 0.5—1.0 μl portions of acetonitrile solutions of **1a**—**d** into a Shimadzu GC-2C gas chromatograph, the inlet part of which was maintained at a constant temperature (300—480 °C).

The Synthesis of 1,2,3,4-Tetramethyl-5-nitronaphthalene and 1,2,3,4-Tetramethyl-6-nitronaphthalene

Akira Oku and Akira Matsui

Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

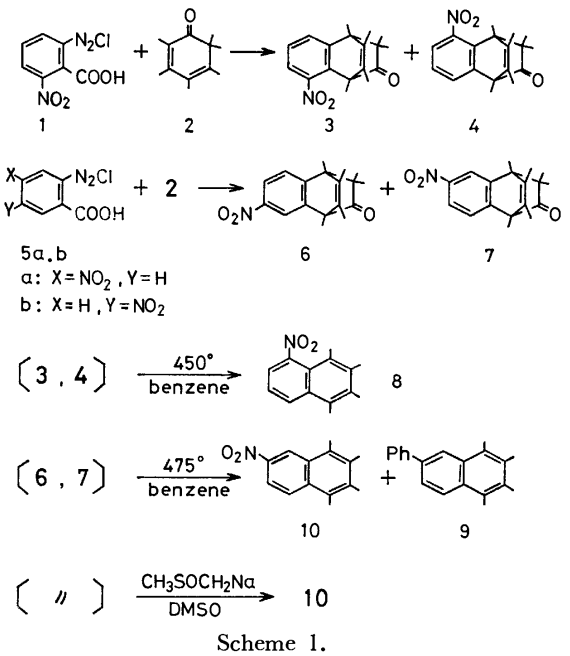
(Received June 27, 1977)

Synopsis. 1,2,3,4-Tetramethyl-5-nitronaphthalene and 1,2,3,4-tetramethyl-6-nitronaphthalene were prepared by the pyrolysis of 5- and 8-nitro-1,2,3,4,10,10-hexamethyl-1,4-dihydro-1,4-ethanonaphthalen-9-ones and their 6- and 7-nitro-isomers respectively.

Polymethyl-substituted nitronaphthalenes, in which one aromatic ring is fully substituted by four methyl groups and the other ring by a certain number of nitro groups, are of particular interest from the point of view of their electronic structures. Their syntheses, however, have not hitherto reported except in the cases of such homologues as dimethylnitronaphthalenes,[1] because a) the substitution on the α-position of naphthalenes by a bulky group, which causes a severe nonbonded peri-interaction, is difficult and b) the electrophilic nitration of polymethylnaphthalenes usually occurs on the methylated ring and often leads to abnormal reactions that take place on alkyl side chains.[2]

In this report, we wish to present the first syntheses of two tetramethylnitronaphthalenes, *i.e.*, 1,2,3,4-tetramethyl-5-nitro-naphthalene (**8**) and 1,2,3,4-tetramethyl-6-nitronaphthalene (**10**), prepared by a method that does not require the direct introduction of a nitro group on the naphthalene ring. This method is based on a modification of the one that has been used successfully to synthesize a number of polymethylnaphthalenes.[3] The synthetic process is outlined in Scheme 1.

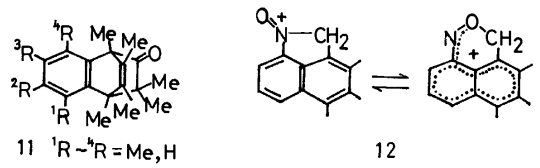
A mixture of Compound **6** and **7**, both of which were obtained from either 4- or 5-nitroanthranilic acid and hexamethyl-2,4-cyclohexadien-1-one (**2**),[4] was used as the precursor of naphthalene **10**, and it was subjected to the following two treatments: A) treatment with the methylsulfinylmethanide anion in dimethyl sulfoxide, and B) pyrolysis. Method A has been known to be an efficient method[3] to prepare a certain number of polymethylnaphthalenes from the methylaryne-adducts of Type **11**. By applying this method to the nitrobenzyne adducts (**6** and **7**) under various conditions, however, only a slight amount of **10** was formed (3%). Thus, Method A was found to be preparatively inadequate. (The same inapplicability was also encountered in the cases of chloro- and dichlorobenzyne-adducts.)



Scheme 1.

On the other hand, Method B proved effective. The pyrolysis of the adduct was carried out by means of a simple pyrolysis apparatus heated at 475±5 °C; it gave naphthalene, **10**, in a 60% yield. This naphthalene is thermally unstable, for the VPC analysis at 250 °C did not give any reliable chromatogram of **10**. Related to this characteristic, when the pyrolysis was carried out at 500 °C and above, 1,2,3,4-tetramethyl-6-phenylnaphthalene (**9**) was formed as the major by-product (>7%). It was apparently formed by the homolysis of **10** in the atmosphere of benzene.[5]

Similarly, nitronaphthalene **8** was obtained (16%) from a mixture of Compounds **3** and **4** by the pyrolysis at 450±5 °C. This nitronaphthalene **8** is also thermally unstable, and its VPC analysis was unsuccessful. Of particular interest is the fact that the mass spectrum of **8** taken while varying the chamber voltage between 80—12 eV showed its major fragment peak at *m/e* 212 (M^+-17). This is fragmentation behavior characteristic of **8**, differentiating it from **10**, and it can be interpreted in terms of the elimination of OH[6] from the peri-position (see **12**), where the 4-methyl and 5-nitro groups are subjected to a severe peri-interaction. This interaction is also illustrated by the ^{1}H-NMR spectra of **8**, in which the 4-methyl proton absorbs at a higher field (δ 2.31) than does the 1-methyl proton (2.61), indicating that the 5-nitro group is twisted perpendicularly to the ring plane.[7]



Experimental

Preparation of Nitrobenzyne-adducts ***3***, ***4***, ***6***, *and* ***7***. These compounds were prepared from the corresponding nitrobenzenediazonium-2-carboxylate hydrochlorides[8,9] by means of the reaction with hexamethyl-2,4-cyclohexadien-1-one (**2**)

according to the procedure previously reported.[4]

Pyrolysis Procedure. A vertically held Pyrex tube (15 mm ID × 300 mm length) packed with glass beads (5.5 mm OD) was heated at 450—500 °C under a gentle stream of nitrogen (15 ml/min). A benzene solution of the adduct mixture (6.0 g, 0.02 mol) in 120 ml of benzene was then dropped into this tube from the dropping funnel placed on the top of the tube. The pyrolyzed products were collected through a condenser that was connected to the bottom-end of the tube, and were chromatographed through a silica gel column (developing solvent: cyclohexane for **9**, cyclohexane/benzene=3 for **8**, and benzene for **10**) to give the nitronaphthalenes.

*1,2,3,4-Tetramethyl-6-nitronaphthalene (**10**).* The best yield of this naphthalene was attained by the pyrolysis performed at 475±5 °C; 60%. Mp 155—156 °C (recrystallized from cyclohexane, yellow needles); MS(*m/e*) 229 (M^+); ^{1}H-NMR(δ, CCl_4) 2.59 (6H, bs, α-Me), 2.42 (6H, bs, β-Me), 7.89—8.02 (2H, m, Ar-H at 7- and 8-positions), 8.74 (H, a pair of d, Ar-H at the 5-position); ^{13}C-NMR (δ, $CDCl_3$) Ar-Me at 15.3 (2Me), 17.4, and 17.7, Ar-C at 117.2, 120.8, 125.4, 129.1, 130.9, 133.7, 135.4, 137.8, and 143.9 (C–NO_2); UV(EtOH) max 222(ε 4.3×10^4), 280(2.9×10^4), and 326(8.7×10^3). Found: C, 73.26; H, 6.63; N, 6.21%. Calcd for $C_{14}H_{15}NO_2$: C, 73.34; H, 6.60; N, 6.11%.

When the pyrolysis was carried out at 500 ± 5 °C, 1,2,3,4-tetramethyl-6-phenylnaphthalene (**9**) was isolated from the chromatograph fraction that eluted faster than **10**. Yield, 8%; mp 135—136 °C(pet. ether); MS(*m/e*) 260 (M^+); ^{1}H-NMR(δ, CCl_4) 2.37 (6H, s, β-Me), 2.57 (3H, s, α-Me), 2.61 (3H, s, α-Me), 7.17—8.17 (8H, m, Ar-H); UV(EtOH) max 218 (ε 2.9×10^4), 260 (5.6×10^4), and 300 nm (8.8×10^3). Found: C, 91.99; H, 7.73%. Calcd for $C_{20}H_{20}$: C, 92.30; H, 7.69%.

*1,2,3,4-Tetramethyl-5-nitronaphthalene (**8**).* This naphthalene **8** was obtained in a 16% yield when the pyrolysis was performed at 450±5 °C. Mp 111—113 °C (recrystallized from cyclohexane, orange-yellow needles); MS(*m/e*) 229(M^+), 212(M^+-17, base peak); ^{1}H-NMR(δ, CCl_4) 2.31 (3H, s, 4-Me), 2.41 (6H, bs, 2- and 3-Me), 2.61 (3H, s, 1-Me), 7.17—7.68 (2H, m, Ar-H at 7- and 6-positions), 8.12 (H, a pair of d, J_1=8.2, J_2=1.6 Hz, Ar-H at 8-position); ^{13}C-NMR(δ, $CDCl_3$) Ar-Me at 15.8, 17.5, 17.7, and 18.1, Ar-C at 122.0, 122.4, 123.7, 127.0, 128.8, 129.3, 133.0, 135.2, 138.1, and 149.1 (C–NO_2); UV(cyclohexane) max 233(ε 4.2×10^4) and 260 nm (1.0×10^4). The Reaction of Dibenzylselenonium Ylides with Various Acids[1)]

Seizo TAMAGAKI, Katsuyuki TAMURA, and Seizi KOZUKA
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received July 4, 1977)

Synopsis. Dibenzylselenonium cyano(methoxycarbonyl)methylide and dibenzylselenonium dicyanomethylide react readily with strong acids at room temperature, giving 1,3-diselena compounds and active methylene compounds.

The reactions of stable alkylsulfonium ylides with electrophilic reagents such as acids,[2)] molecular halogens,[3)] and acyl peroxides[4)] have been intensively studied and the reactions are assumed to proceed by a common mechanism in which sulfonium intermediates are first formed, as follows.

$$R_2S{=}CR'_2 \xrightarrow{XY} \left[R{-}S^{\oplus}(R)(CXCR'_2)\ Y^{\ominus} \right] \begin{cases} \rightarrow RY + RSCXR'_2 \\ \rightarrow R'_2CXY + R_2S \end{cases}$$

However, no report seems to have been presented so far for the decomposition of selenonium ylides by electrophilic reagents. We have examined the reaction of dibenzylselenonium ylides with various acids, and found that the reaction involves an α-carbon attack by the counter anions in the initial stage,[5)] similar to the reactions mentioned above, one of the products, however, eventually giving disproportionation products, *i.e.*, 1,3-diselena compounds and active methylene compounds.

Results and Discussion

Dibenzylselenonium cyano(methoxycarbonyl)methylide (Ia) was allowed to react with dried gaseous hydrogen chloride and the equivalent of trifluoroacetic acid in chloroform or with an equimolar amount of aqueous sulfuric and nitric acids in acetonitrile at room temperature. The reaction with hydrogen chloride was followed by thin-layer chromatography. After completion of the reaction, evaporation of the solvent and the subsequent preparative thin-layer chromatographic separation of the residue gave an oily material, the structure of which was identified by its MS, IR, and NMR spectra and elemental analysis as methyl α,α-bis(benzylseleno)-α-cyanoacetate (IIIa). From another part of the TLC plate, the corresponding methylene compound (IVa) was isolated in a good yield. The products and yields are summarized in Table 1.

$$(PhCH_2)_2Se{=}C(CN)(COOMe) \xrightarrow{HCl} PhCH_2Cl$$

$$+\ (PhCH_2Se)_2C(CN)(COOMe) + CH_2(CN)COOMe$$

(IIIa) (IVa)

The NMR and IR spectra of the reaction mixture show that the appearance of some peaks is due to a substance (IIa) not isolable in the pure state and also to benzyl chloride; the former displays the IR band at 2250 and 1759 cm^{-1} due to its cyano and ester carbonyl groups and NMR peaks at 7.3 (Ph), 4.2 (CH_2), 4.03 (CH), 3.75 (OCH_3) ppm with the intensity ratio of 5 : 2 : 1 : 3, respectively; the methylene protons of the latter lie at 4.53 ppm. A similar phenomenon was observed in the reaction with other acids such as tri-

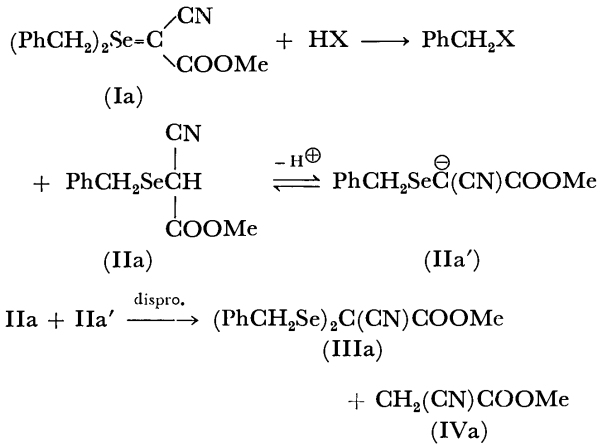
a) $R_2Se{=}C(CN)Y$: $R{=}PhCH_2$. b) All the compounds shown were isolated by thin-layer chromatography. c) In a solution saturated with gaseous HCl. d) Yields were not determined. e) Concentrated acid was used. f) In addition, dibenzyl diselenide was obtained in 5% yield. g) Characterization was performed by NMR. Yields determined by NMR are given in parentheses.

fluoroacetic, sulfuric, and nitric acids.

These observations demonstrate that compound (IIa) initially produced is methyl α-(benzylseleno)-α-cyanoacetate which is very stable under acidic conditions but decomposes readily, on a TLC plate, *via* disproportionation to give isolable products. Thus, the following reaction pathway is the most probable.



As was the case for Ia, dibenzylselenonium dicyanomethylide (Ib), when subjected to reaction with trifluoroacetic acid, gave benzyl trifluoroacetate almost quantitatively together with, the expected selenide, α-(benzylseleno)malononitrile (IIb) as evidenced by the NMR analysis. However, malononitrile and α,α-bis-(benzylseleno)malononitrile (IIIb) were the products isolated.

$PhCH_2SeCH(CN)_2$ (IIb) $(PhCH_2Se)_2C(CN)_2$ (IIIb)

The latter was unstable and spontaneously decomposed, at room temperature within 2 days, into dibenzyl diselenide in a moderate yield. The reaction of the ylide, Ib, with hydrochloric, sulfuric, and nitric acids is complicated.

Experimental

Typical experimental procedures are as follows:

Reaction of Ia with Trifluoroacetic Acid. A mixture of Ia (1 mmol) and trifluoroacetic acid (1 mmol) was stirred in 20 ml of chloroform at room temperature for 3 h. Evaporation of the solvent and subsequent thin layer chromatography of the residue afforded an oily IIIa. The yields are given in Table 1. The NMR data (IIIa in $CDCl_3$, δ) are as follows: 7.25(10H), 4.25(4H), 3.60(3H) ppm; IR (KBr): 2230 and 1740 cm^{-1}; MS: *m/e* 439 (M^+), 342, 269, 262, 171, and 91; Found: C, 49.48; H, 3.84; N, 2.98 %. Calcd for $C_{18}H_{17}O_2NSe_2$: C, 49.72; H, 4.02; N, 3.11%.

The Reaction of Ib with Trifluoroacetic Acid. Ib (1 mmol) was suspended in a chloroform solution of trifluoroacetic acid (3 mmol). After 2 h, the reaction mixture was concentrated *in vacuo*. Preparative TLC (Kieselgel G, chloroform) afforded an oily IIIb (29%). NMR 7.25 (10H), 4.43(4H) ppm; IR(KBr): 2240 cm^{-1}; MS: *m/e* 406(M^+), 342, 262, 171 and 91; Found: C, 50.79; H, 3.71; N, 7.12%. Calcd for $C_{17}H_{14}N_2Se_2$: C, 50.51; H, 3.50; N, 6.93%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (1), 335—336 (1978)

The Acetoxylation of *p*-Substituted Acetophenones and β-Diketones with (Diacetoxyiodo)benzene

Fujio MIZUKAMI, Moriyasu ANDO, Tatsuo TANAKA, and Juichi IMAMURA
National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received July 6, 1977)

Synopsis. The methyl groups of *p*-substituted acetophenones and the methylene groups of β-diketones were acetoxylated with (diacetoxyiodo)benzene. When the substrates were *p*-chloroacetophenone, *p*-nitroacetophenone and 4,4,4-trifluoro-1-phenyl-1,3-butanedione, the corresponding acetoxylated compounds were obtained in high yields.

The oxidations of glycols and alkenes with (diacetoxyiodo)benzene ($PhI(OAc)_2$) are well known to proceed by means of a mechanism[1-3] similar to those with lead tetraacetate, and the acetoxylation of the methylene group adjacent to the carbonyl group with lead tetraacetate has been reported.[4] However, there have been no reports on the acetoxylation of the methyl and methylene groups adjacent to the carbonyl group with $PhI(OAc)_2$. In the present work, we will report that *p*-substituted acetophenones (p-$XC_6H_4COCH_3$) and β-diketones are acetoxylated with $PhI(OAc)_2$.

Results and Discussions

The reactions of p-$XC_6H_4COCH_3$ (X=CH_3O, CH_3, H, Cl, NO_2, CN) and β-diketones with $PhI(OAc)_2$ were carried out at 30 °C in a mixed solvent of acetic acid and acetic anhydride, using sulfulic acid as the catalyst. When X in p-$XC_6H_4COCH_3$ was CH_3, H, Cl, or NO_2, the acetoxylated compounds were obtained; their structures were determined from the spectra (IR and NMR) and elemental analyses, as is shown in Tables 1 and 2. When X in p-$XC_6H_4COCH_3$ was OCH_3, the diaryliodonium salt ($[CH_3O(CH_3CO)$-C_6H_3-I^+-Ph]Br^-) was obtained in a 59.1% yield and the acetoxylated compound occurred in a trace amount. In the reaction of *p*-cyanoacetophenone with $PhI(OAc)_2$, neither the acetoxylated compound nor the diaryliodonium salt could be isolated, although both $PhI(OAc)_2$ and *p*-cyanoacetophenone were easily consumed at 30 °C and a tarry matter was obtained. The yields of the acetoxylated compounds increased in this order: X=Cl>NO_2≫H>CH_3⋙CH_3O. High yields were obtained in the case of the substrates in which the *p*-substituents are electron-attracting, execpt for X=CN.

4,4,4-Trifluoro-1-phenyl-1,3-butanedione (C_6H_5-$COCH_2COCF_3$) was easily acetoxylated with $PhI(OAc)_2$. Acetylacetone and dibenzoylmethane were also confirmed from the NMR spectra to be acetoxylated with $PhI(OAc)_2$, although their acetoxylated compounds gave only an approximate coincidence between found and calculated analytical results. As is shown in Table 1, the acetoxylated compound of $C_6H_5COCH_2COCF_3$ was obtained in a higher yield than those of *p*-substituted acetophenones.

It has been stated that the acetoxylation of the methylene group adjacent to the carbonyl group with lead tetraacetate seems to proceed by means of the following mechanism:[3]

TABLE 1. THE ACETOXYLATION OF *p*-SUBSTITUTED ACETOPHENONES AND β-DIKETONE WITH (DIACETOXYIODO)BENZENE

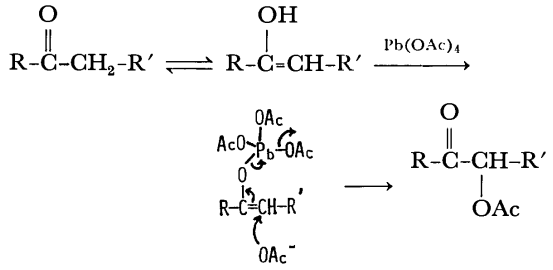
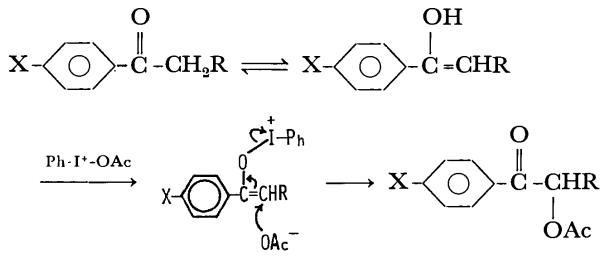
p-$NO_2C_6H_4COCH_2OAc$	1698, 1742	2.25(OAc), 5.37(OCH_2O), 8.0—8.6(C_6H_4)
$C_6H_5COCH(OAc)COCF_3$	1690[c], 1750	2.10(OAc), 6.20, 6.40(keto and enol COCH), 7.4—8.2(C_6H_5)

a) KBr disk. b) In $CDCl_3$. c) Broad band.



Briody[5] has also reported that, in the presence of sulfuric acid, (diacetoxyiodo)benzene in acetic acid seems to dissociate into ions according to the following equilibria: $PhI^+(OAc)+OAc^- \rightleftharpoons PhI(OAc)_2 \overset{H_2SO_4}{\rightleftharpoons} PhI^+(OAc)+HSO_4^-$.

Accordingly, if the oxidation with $PhI(OAc)_2$ in the present work proceeds by means of a mechanism similar to that with lead tetraacetate, the acetoxylation mechanism may be thought to be as follows:



The fact that such substrates *p*-$ClC_6H_4COCH_3$, *p*-NO_2-$C_6H_4COCH_3$, and $C_6H_5COCH_2COCF_3$ produce the acetoxylated compounds in high yields seems to be explained by the above Scheme, because these substrates tend to be converted into enol forms.

Experimental

All the melting points and boiling points are uncorrected. The IR spectra were obtained on Shimadzu 27G and 400 spectrometers. The NMR spectra were obtained on a JEOL C-60-HL spectrometer, using tetramethylsilane as the internal standard. The amount of acetoxylated compound in the reaction mixture was determined by means of a JEOL JGC-1100 chromatograph with a 2 m × 3 mm column packed with Silicone DC550 (20%) coated on Chromosorb AW-DMCS.

Materials. Reagent-grade *p*-substituted acetophenones and *β*-diketones were used without further purification. The (diacetoxyiodo)benzene was synthesized according to the procedure submitted by Sharefkin and Saltzman[6] and was used after recrystallization from 5M acetic acid.

Preparation of Acetoxylated Compounds. The *p*-substituted acetophenone or *β*-diketone (0.06 mol) was dissolved in 55 cm^3 of a mixed solution (AcOH 50 cm^3, Ac_2O 5 cm^3) with stirring at 30 °C. To the vigorously stirred solution, we then added 5 cm^3 of sulfuric acid and then eight 2-g portions of $PhI(OAc)_2$ (total 0.05 mol) at 30-min intervals. The temperature was kept at about 30 °C throughout the additions. The reaction mixture was then stirred at 30 °C for another 6 h.

In the first stage, the reaction mixture was extracted with three 100-cm^3 portions of water and the extract was concentrated. Potassium bromide was then added to the concentrated solution. When diaryliodonium salt was present in the solution, white crystals were deposited.

In the second stage, the above reaction mixture was extracted with three 100-cm^3 portions of chloroform or ether and the extract was concentrated under reduced pressure. When the acetoxylated compound was crystalline, the concentrated solution was cooled to 0 °C. The crystals were filtered off and recrystallized from hexane. When the acetoxylated compound was liquid, the concentrated solution was distilled under reduced pressure.

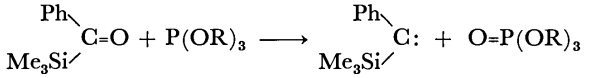
BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (1), 337—338 (1978)

Formation of Dialkyl α-Siloxybenzylphosphonate *via* 1,2-Anionic Rearrangement of a Silyl Group

Akira SEKIGUCHI, Masayuki IKENO, and Wataru ANDO
Department of Chemistry, The University of Tsukuba, Niiharigun, Ibaraki 300-31
(Received July 8, 1977)

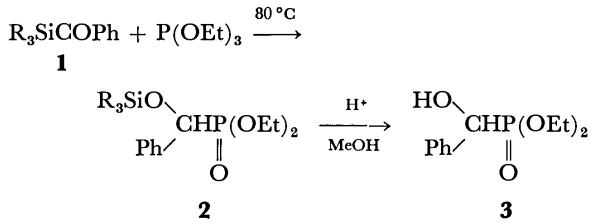
Synopsis. The reactions of silyl phenyl ketones with trialkyl phosphites and dialkyl sodiophosphonates gave dialkyl α-siloxybenzylphosphonates in good yields. The mechanism involves the migration of a silyl group from carbon to anionic oxygen. No deoxygenation of silyl ketone with trialkyl phosphite was observed.

Silylcarbenes have recently been found to be one of the most interesting species for the formation of silicon-carbon double bond. A report was given on the intermolecular and intramolecular reactions of silylcarbenes generated by either photolysis or thermolysis of silyl diazo compounds.[1] On the other hand, trialkyl phosphite is known to deoxygenate or desulfurate to give carbene intermediates.[2] We attempted to generate a silylcarbene by deoxygenation of a silyl phenyl ketone.



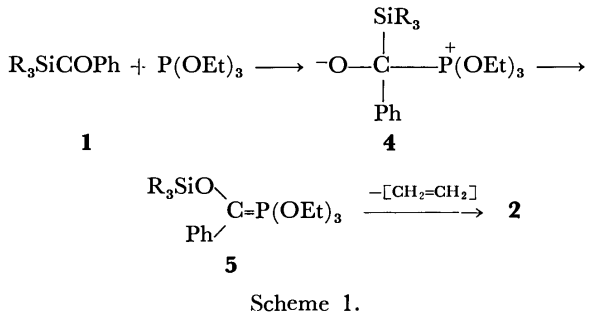
However, we found 1,2-anionic rearrangement of a silyl group in the reaction of silyl phenyl ketone with trialkyl phosphite instead of the formation of silylcarbene.

A mixture of trimethylsilyl phenyl ketone **1a**(5.72 mmol) and triethyl phosphite(60 mmol) was heated at 80 °C with stirring for 12 h. Distillation of the reaction mixture afforded **2a**(1.09 g, 60%, bp 142 °C/2 mmHg), which was found to be diethyl α-trimethylsiloxybenzylphosphonate from analysis of the spectra. The phosphonate **2a** was desilylated by refluxing methanol followed by crystallization from cyclohexane to give diethyl α-hydroxybenzylphosphonate **3** in 86% yield. Phosphonate **3** was also obtained from a variety of other silyl ketones, **1b**, **1c**, and **1d** in 72, 43, and 38% yields, respectively.



a: $R_3=Me_3$, **b**: $R_3=Et_3$,
c: $R_3=PhMe_2$, **d**: $R_3=Ph_3$.

The low yields of product **3** in the case of **1c** and **1d** may be ascribed to the steric hindrance on the silicon having phenyl groups. The formation of the products may be explained as resulting from the addition of triethyl phosphite to the carbonyl group to give betaine **4**, which may rearrange to triethoxymethylenephosphorane **5** by 1,2-anionic rearrangement of the silyl group.[3] However, no Wittig-type products expected from the reaction of the methylenephosphorane with the starting silyl ketone were observed. An attempt to trap the methylenephosphorane with benzaldehyde was unsuccessful. Thus, the reaction of **1a**(5.76 mmol) with triethyl phosphite(60 mmol) in the presence of benzaldehyde(8.07 mmol) also led to the formation of **2a** in 65% yield under the above conditions.

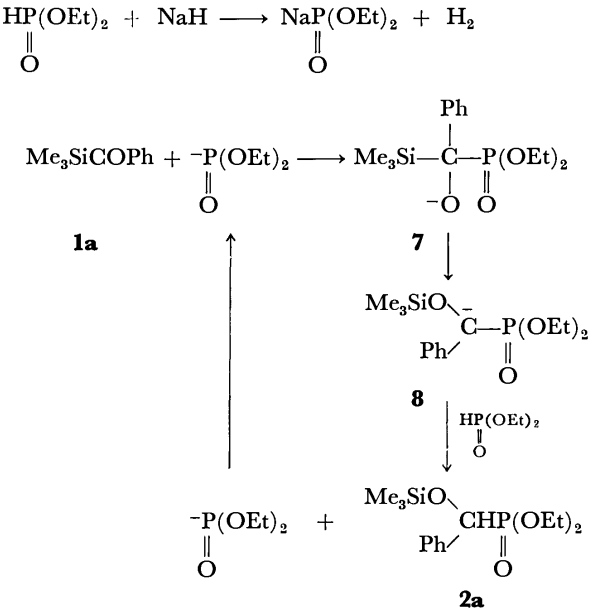


Scheme 1.

Methylenephosphorane **5** also decomposes to phosphonate **2** with cyclic elimination of ethylene under the reaction conditions (Scheme 1). Generation of ethylene was ascertained by trapping with a solution of bromine in 1,2-dibromoethane, but the yield was only 22% based on the silyl ketone **1a**.[4]

Dimethyl α-trimethylsiloxybenzylphosphonate **6** was produced in the reaction of **1a** with an excess trimethyl phosphite under the above conditions, probably with elimination of methylene. However, **1a** did not react with triphenyl phosphite under the same conditions, probably because of the incapability of olefin elimination.

Extended studies on the 1,2-anionic rearrangement of the silyl group were carried out by the reaction of the silyl ketone with dialkyl sodiophosphonate. Diethyl sodiophosphonate reacts with the silyl ketone under mild conditions. Catalytic amount of sodium hydride (1.07 mmol) was added to the mixture of the silyl ketone **1a**(5.91 mmol) and diethyl phosphite(36 mmol) with stirring. An exothermic reaction took place with evolution of hydrogen, phosphonate **2a** being produced in 59% yield. However, **2a** was not formed in the absence of sodium hydride even if a mixture of **1a** and diethyl phosphite was heated at 100 °C for 16 h (Scheme 2). Adduct **7** can be formed initially by the addition of diethyl sodiophosphonate to the silyl ketone **1a** followed by rearrangement to anion **8** which may abstract hydrogen from diethyl phosphite to produce **2a** and diethyl sodiophosphonate. Diethyl sodiophosphonate produced again reacts with the silyl ketone as shown in Scheme 2. The phosphonate **6** was also obtained in 56% yield in the reaction of **1a** with dimethyl phosphite in the presence of catalytic sodium hydride.



Scheme 2.

Experimental

General. NMR data were obtained on a Varian A-60D spectrometer, IR spectra on a Hitachi EP-1-G3 spectrometer and mass spectra on a Nippon Denshi JMF-07 at 20 eV. All silyl ketones were prepared by the hydrolysis of the corresponding dibromides with silver acetate in water-acetone-ethanol system using the method of Brook.[5] Melting points are uncorrected.

Reaction of ***1a*** *with Triethyl Phosphite.* A mixture of **1a** (5.72 mmol) and triethyl phosphite(60 mmol) was heated at 80 °C for 12 h. After removal of excess triethyl phosphite *in vacuo*, **2a**[6] was obtained by vacuum distillation in 60% yield, bp 142 °C/2mmHg; IR(NaCl) 1250, 1070—1020 cm^{-1}; NMR(CCl_4) δ 0.08(s, 9H, SiMe), 1.20(t, J=7Hz, 6H, $OCCH_3$), 3.6—4.2(m, 4H, OCH_2), 4.80(d, J=14Hz, 1H, POCH), and 7.0—7.6(m, 5H, ArH). Phosphonate **2a** was desilylated in refluxing methanol. Crystallization from cyclohexane after removal of the methanol yielded **3** in 86% yield, mp 83 °C; IR(KBr) 3250, 1230, 1205, 1050, and 1030 cm^{-1}; Mass *m/e*: M^+ 244(rel. int. 39), 138(100), 111(56), and 106(28); NMR($CDCl_3$) δ 1.1—1.4(m, 6H, $OCCH_3$), 3.7—4.3(m, 4H, OCH_2), 4.51(br. s, 1H, OH), 5.01(d, J= 12 Hz, 1H, POCH), and 7.2—7.7(m, 5H, ArH); Found: C, 53.93; H, 7.27%. Calcd for $C_{11}H_{17}O_4P$: C, 54.10; H, 7.02%.

Reaction of Other Silyl Ketones, ***1b****,* ***1c****, and* ***1d*** *with Triethyl Phosphite.* The reactions of **1b**(5.70 mmol), **1c**(6.12 mmol), and **1d**(5.22 mmol) with triethyl phosphite(60 mmol) were performed under the same conditions as described above. Desilylation in refluxing methanol containing one drop of hydrochloric acid yielded **3** in 72, 43, and 38% yields, respectively.

Reaction of ***1a*** *with Trimethyl Phosphite.* A mixture of **1a**(7.08 mmol) and trimethyl phosphite(80 mmol) was heated at 80 °C for 12 h. Phosphonate **6** was obtained in 50% yield, bp 128 °C/2 mmHg; IR(NaCl) 1260, 1060—1020 cm^{-1}; NMR(CCl_4) δ 0.08(s, 9H, SiMe), 3.45(d, J= 10Hz, 6H, POMe), 4.75(d, J=14 Hz, 1H, POCH), and 7.2(m, 5H, ArH). Desilylation of **6** in refluxing methanol gave dimethyl α-hydroxybenzylphosphonate, mp 98—99 °C; IR(KBr) 3620, 1205, 1060, and 1020 cm^{-1}; Mass *m/e*: M^+ 216(12), 111(13), 110(100), 107(19), 106(36), 105(35), and 104(25); NMR($CDCl_3$) δ 3.67(d, J=11 Hz, 3H, POMe), 3.75(d, J=11 Hz, 3H, POMe), 5.07(d, J=11 Hz, 1H, POCH), 5.17(br. s, 1H, OH), and 7.2—7.7(m, 5H, ArH); Found: C, 50.49; H, 6.14%. Calcd for $C_9H_{13}O_4P$: C, 50.01; H, 6.06%.

Reaction of ***1a*** *with Diethyl Phosphite in the Presence of Sodium Hydride.* Sodium hydride(1.07 mmol) was added to a mixture of **1a**(5.91 mmol) and diethyl phosphite(36 mmol) with stirring. Exothermic reaction occurred with evolution of hydrogen. After the reaction ceased, the reaction mixture was distilled under reduced pressure to give **2a** in 59% yield.

Reaction of ***1a*** *with Dimethyl Phosphite in the Presence of Sodium Hydride.* Sodium hydride(1.60 mmol) was added to a mixture of **1a**(9.07 mmol) and dimethyl phosphite(45 mmol) with stirring. Phosphonate **6** was obtained in 56% yield.

Electrochemical Reaction of Organoboranes in the Presence of Propenoic Acid Esters. A Convenient Carboxylic Ester Synthesis from Organoboranes

Yuzuru TAKAHASHI, Kazuma YUASA, Masao TOKUDA, the late Mitsuomi ITOH, and Akira SUZUKI*

Faculty of Engineering, Hokkaido University, Sapporo 060

(Received July 28, 1977)

Synopsis. Electrolysis of trialkylboranes using two platinum electrodes in the presence of α,β-unsaturated esters in an acetonitrile solution containing tetraalkylammonium halide as a supporting electrolyte, produces the corresponding alkylated carboxylic acid esters in good yields.

Previously, we have reported that organoborane undergo spontaneous 1,4-addition reactions in the presence of oxygen to numerous α,β-unsaturated carbonyl compounds including methyl vinyl ketone[1] and acetylacetylene,[2] and to α,β-unsaturated oxiranes such as 1,3-butadiene monoxide[3] and 3,4-epoxy-1-butyne,[4] followed by hydrolysis to give corresponding alkylated compounds (Eqs. 1—4). However, it has been shown

$$R_3B + CH_2{=}COCH_3 \xrightarrow{O_2} RCH_2CH{=}C(CH_3)(OBR_2) \xrightarrow{H_2O} RCH_2CH_2{-}COCH_3 \quad (1)$$

$$R_3B + CH{\equiv}C{-}COCH_3 \longrightarrow RCH{=}C{=}C(CH_3)(OBR_2) \longrightarrow RCH{=}CH{-}COCH_3 \quad (2)$$

$$R_3B + CH_2{=}CH{-}\underset{\backslash O /}{CH}{-}CH_2 \longrightarrow RCH_2CH{=}CHCH_2OBR_2 \longrightarrow RCH_2CH{=}CHCH_2OH \quad (3)$$

$$R_3B + CH{\equiv}C{-}\underset{\backslash O /}{CH}{-}CH_2 \longrightarrow RCH{=}C{=}CHCH_2OBR_2 \longrightarrow RCH{=}C{=}CHCH_2OH \quad (4)$$

that neither acrylonitrile nor ethyl acrylate (**1**) reacts with organoboranes under the same conditions. Although we have recently reported that the reaction of acrylonitrile or **1** with copper(I) trialkylmethylborates gives corresponding alkylation products,[5] this procedure has a disadvantage in that there is a difficulty in introducing secondary alkyl groups. On the other hand, the electrochemical reactions of trialkylboranes with compounds containing acidic hydrogens such as acetonitrile,[6] nitromethane,[7] and 1-alkynes[8] have also been reported by us to give the corresponding alkylated products such as cyanoalkanes, nitroalkanes and internal acetylenes, respectively.

In the present paper we wish to report that the electrochemical reaction of trialkylboranes with α,β-unsaturated esters such as **1** or ethyl methacrylate (**2**) in an acetonitrile solution containing tetraalkylammonium halide as a supporting electrolyte produces corresponding saturated carboxylic acid ester in good yields (Eq. 5).

The electrochemical reaction was carried out by means of controlled current electrolysis in an undivided

$$R_3B + CH_2{=}C(R')CO_2Et \xrightarrow[Pt\text{-}Pt,\ CH_3CN]{\text{Electrolysis: } R_4''NX} RCH_2CH(R')CO_2Et \quad (5)$$

1, R′=H; **2**, R′=CH_3 — **3**, R′=H; **4**, R′=CH_3

cell. The results of representative reactions are summarized in Table 1. As shown in the table, in this procedure there appears to be no difficulty in introducing secondary alkyl groups of organoboranes as well as primary alkyl groups. The effect of supporting electrolytes on the yield of **3c** in the reaction of tripropylborane with **1** was as follows: $(C_2H_5)_4NI$, 63; $(C_2H_5)_4NBr$, 17; $(n\text{-}C_4H_9)_4NI$, 77; $(n\text{-}C_4H_9)_4NBr$, 31; $(n\text{-}C_4H_9)_4NClO_4$, 0%. These results indicate that tetraalkylammonium bromide and iodide are effective as the supporting electrolyte in the reaction, whereas electrolysis using tetrabutylammonium perchlorate gives no detectable amount of the corresponding addition product.

Although the detailed reaction mechanism is not clear at present, several points must be noted. (a) The halide ion of a supporting electrolyte seems to play an important role in the reaction. (b) When a mixture of tripentylborane and **1** was electrolyzed in an undivided cell, small amounts of ethyl 2-pentyloctanoate (**6**; R=C_5H_{11}) and ethyl 2-methylheptanoate (**8**; R=C_5H_{11}) were obtained as by-products together with the normal product, ethyl octanoate. (c) When the electrolysis was carried out in a divided cell, the desirable reaction did not occur. By the use of a divided cell, electrolysis of a mixture of trialkylborane and **1** in an acetonitrile solution containing tetraalkylammonium iodide afforded the corresponding alkyl iodide at the anode and the dimer of **1** at the cathode as the main products. (d) Electrolysis of butyl iodide, instead of tributylborane, in the presence of ethyl acrylate under the same conditions described above gave ethyl heptanoate in a 22% yield. (e) The reduction potentials of

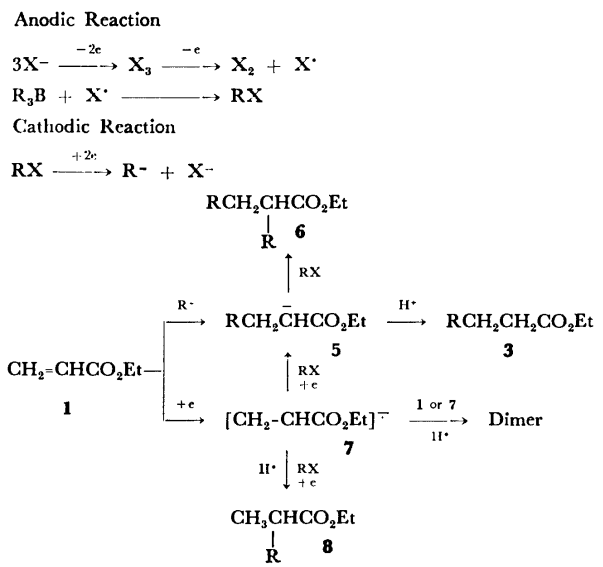

Scheme 1.

1 and **2** were observed at −2.28 and −2.41V *vs.* SCE, respectively, whereas those of alkyl iodide and alkyl bromide were reported to be around −1.63—−2.37V *vs.* SCE.[9,10] From these results the following mechanism involving two independent reaction pathways at the anode and the cathode may be proposed for the reaction of **1** (Scheme 1).

Experimental

Materials. Trialkylboranes were obtained by hydroboration of olefins.[11] Ethyl acrylate (**1**) and ethyl methacrylate (**2**) were distilled before use. Acetonitrile was dried over diphosphorus pentaoxide and distilled.

The IR and NMR spectra were taken on a Hitachi-Perkin-Elmer Model 125 spectrophotometer and a Hitachi R-22 spectrometer at 90 MHz using tetramethylsilane as the internal standard, respectively.

Quantitative analyses were carried out with Hitachi-063 gas chromatograph using a column of 15% Carbowax 20M on Uniport-B. Preparative VPC was done with JEOL JGC-20K gas chromatograph using the same type of column. The electrolyses were carried out with Yanagimoto VE-8.

General Procedure. The following procedure for the preparation of ethyl 2-methylhexanoate (**4c**) is representative. The electrolysis was carried out in the usual undivided cell equipped with two platinum plate electrodes (20×20 mm²), a magnetic stirring bar and a reflux condenser. Tripropylborane (4.9 mmol) and 4.0 ml of **2** are dissolved in 17 ml of acetonitrile containing Bu_4NI (0.5 g, 1.35 mmol). The solution was electrolyzed at a constant current (0.5 A/cm²) for 5 h under nitrogen atmosphere. After the electrolysis, the reaction mixture was oxidized by adding 3N aqueous sodium hydroxide (5.0 ml) and 30% hydrogen peroxide (5.0 ml) for 2 h at room temperature. The products were extracted with ether and dried over sodium sulfate. Distillation of organic layer gave 0.56 g (73%) of ethyl 2-methylhexanoate (**4c**), bp 50—52 °C/16 mmHg.

Identification of the Products. *Ethyl Octanoate (**3a**)*: n_D^{22} 1.4213. Found: C, 69.98; H, 11.88%. Calcd for $C_{10}H_{20}O_2$: C, 69.72; H, 11.70%. MS: *m/e*=172 (M^+). IR (neat): 1730 cm⁻¹. An Additional Discussion of the Micropore-volume Determination of Active Carbon Using Dubinin-Radushkevich Plots

Ryoichi TSUNODA

Industrial Research Institute of Kanagawa Prefecture, Showa-machi, Kanazawa-ku, Yokohama 236

(Received July 20, 1977)

Synopsis. The validity of the recently presented method for determining the micropore volume (V_o) from the distribution curve of the adsorption potential based on the Dubinin-Radushkevich plot is further discussed in terms of the relationship between the V_o and the adsorption volume (V_h) at the beginning of the hysteresis loop on the adsorption isotherm.

In a recent paper,[1] the present author reported that the adsorption volume (V) corresponding to the adsorption potential ($A=RT\ln P_o/P$), at which the plot of $dV/d(-A)$ *vs.* A has its minimum value, is the micropore volume (V_o) when the extrapolation of the Dubinin-Radushkevich plot cannot be applied because of its non-linearity. However, the relationship between the micropore volume (V_o), determined by the new method described above, and the adsorption volume (V_h) at the beginning of the hysteresis loop on the adsorption isotherm was not clarified quantitatively. In this report, this relationship is clarified on the basis of the experimental data on 6 types of active carbons.

The adsorption of methanol on active carbons at 30 °C was measured gravimetrically by means of a conventional quartz spring balance. The active carbons examined were Pittsburgh CAL-, Filtrasorb 100-, SGL-, PCB (5.3% burn-off)-,[1] and PCB (33.3% burn-off)[1]-type activated carbons; for the latter 4 carbons, the experimental data shown in the previous paper[1] were used. The conditions of the experiment were the same as those reported previously.[1]

The effective radius at the beginning of hysteresis is considered to be 15 Å,* and the hysteresis is attributed to the filling of transitional pores by the mechanism of capillary condensation.[2] The point of the beginning of hysteresis is also the boundary point dividing micropores from transitional pores according to the customary classification of pores.[2] Furthermore, this point is the end of the filling of micropores and, at the same time, that of the beginning of the capillary condensation of transitional pores, but monolayers and multilayers exist on the walls of the transitional pores. Moreover, the adsorption volume (V_h) at the hysteresis must be the sum of the micropore volume (V_o) and the volume (V_l) of adsorption layers on the transitional-pore walls.

The surface area (S_{trans}) of the transitional pores can be calculated by means of the equation

$$S_{trans} = \sum 2\Delta V/\bar{r}, \quad (1)$$

from the curve of the pore-volume distrubution,[1] here, $\Delta V=V_i-V_{i-1}$, and $\bar{r}=(r_i+r_{i-1})/2$, and with r_j lying from 15 to 100 Å. (The shapes of the pores are assumed to be cylindrical, and the surface area of the large pores (radii>100 Å) may be neglected compared with that of the small pores (15 Å≦radii≦100 Å).) Moreover, the volume (V_l) of the adsorption layers on the walls of the transitional pores at the beginning of hysteresis is obtained by the multiplication of S_{trans} by the thickness of the adsorption layers, 4.9 Å, corresponding to the radius of 15 Å in the Kelvin equation;[1]

$$V_l = 4.9\times S_{trans}. \quad (2)$$

The values of V_o, V_l, and V_h are shown in Table 1. The sum of the V_o and V_l coincide with V_h. These results show that the adsorption volume at $dV/d(-A)$=minimum on the distribution curve of the adsorption potential corresponds to the micropore volume; the validity of the method for determinimg the micropore volume of active carbon from the adsorption-potential distribution is thus further confirmed.

The Chromium(VI) Oxide Oxidation of Epimeric 1,2,3,4-Tetrahydro-1-naphthols

Kaoru HANAYA, Sachio AWANO, and Hideaki KUDO

Department of Chemistry, Faculty of Science, Yamagata University, Koshirakawa-cho, Yamagata 990

(Received July 7, 1977)

Synopsis. The rates of the chromium(VI) oxide oxidation of 2- and 3-substituted 1-tetralols(1,2,3,4-tetrahydro-1-naphthols) have been determined. In the 3-substituted compounds, the rates of *cis*-isomers(eq'-OH) are markedly larger than those of *trans*-isomers(ax'-OH). On the other hand, in the case of 2-substituted compounds, the rates of the *cis*-isomers(ax'-OH) and *trans*-isomers (eq'-OH) are almost equal.

It is well known[1] that the epimeric axial cyclohexanols are oxidized more rapidly by chromium(VI) oxide than the equatorial ones. However, turning to the allylic alcohols, it has been demonstrated that the quasi-equatorial alcohols are oxidized more rapidly than the quasi-axial ones.[2] Although isolated studies of the oxidation rates of allyl alcohols are on record, few systematic studies have been made.

Recently, Yamaguchi *et al.*[3] have studied the chromium(VI) oxide oxidation of 4-chromanols and discussed the effect of conformational and strain factors. 1-Tetralols are considered to have conformations similar to those of the corresponding 4-chromanols.

In order to learn more about the stereochemistry of the chromium(VI) oxide oxidation of the cyclic benzyl alcohols, we have examined the chromium(VI) oxide oxidation of 2- and 3-substituted 1-tetralols. The results are summarized in Table 1.

These results show the rates of *cis*-3-substituted 1-tetralols (eq'-OH) to be markedly larger than those of *trans*-isomers(ax'-OH). In the case of 2-substituted 1-tetralols, on the other hand, the rates of the *cis*-isomers (ax'-OH) and *trans*-isomers(eq'-OH) are almost equal.

In the 3-substituted compounds, it is considered that the greater reactivity of the *cis*-isomer over the *trans*-isomer should be attributed to the relief of strain from the *peri*-interaction—the $A^{1,2}$ strain between the hydroxyl group and the aromatic methin group at Position 8 —when the above 1-tetralols are converted to the ketones. The *peri*-interaction in the *cis*-isomer involving a quasi-equatorial hydroxyl group may be larger than that is the *trans*-isomer; therefore, the former epimer will undergo oxidation more rapidly than the latter.

In the oxidation of *cis*-2-substituted 1-tetralols, the steric effect due to the *gauche* interaction between the hydroxyl group and the adjacent substituent should also be considered. In this case, the steric effect of the *peri*-interaction in the *trans*-isomer and the *gauche* interaction in the *cis*-isomer appear to be almost equal.

Experimental

Materials. 1-Tetralols were prepared by the reduction of the corresponding α-tetralones according to the literature.[4] The conformations of 1-tetralols were examined by means of their NMR[5] and IR[6] spectra.

Kinetic Determinations. The chromium(VI) oxide oxidations were carried out at 25±0.1 °C and were followed spectrophotometrically by measuring the decrease in the optical density of the Cr^{VI} maximum at 380 nm, as has been described in the literature.[3] The medium was 85% acetic acid; the concentrations of alcohol and CrO_3 were 1.75×10^{-3} M and 2.00×10^{-3} M respectively. A Hitachi ESP-3T spectrophotometer and standard 1.00-cm quartz cells were used.

The Photoreaction of 1-Cycloalkenyl Phenethyl Ketone

Masaru TADA, Hiroshi SAIKI, Hidemi MIZUTANI, and Kyo MIURA

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku, Tokyo 160

(Received July 18, 1977)

Synopsis. The UV irradiation of 1-cyclopentenyl phenethyl ketone in benzene or methanol gave a cyclobutane derivative. The irradiation of 1-cyclohexenyl phenethyl ketone in methanol or in benzene containing either BF_3–Et_2O or CF_3COOH gave a cycloheptanone derivative. The formation of the cycloheptanone derivative requires an acid catalyst.

In an earlier paper[1] we reported that 1-cycloalkenyl benzyl ketones (I and II) undergo photo-cyclization to give tricyclic ketones (III and IV). In this paper we wish to report on the difference in the photo-reactivity between 1-cyclopentenyl phenethyl ketone (V) and 1-cyclohexenyl phenethyl ketone (VI).

The 1-cycloalkenyl phenethyl ketones (V and VI) were synthesized by the Friedel-Crafts-type acylation[2] of cycloalkene with 3-phenylpropionyl chloride, followed by the base-catalyzed elimination of hydrogen chloride. The UV irradiation of 1-cyclopentenyl phenethyl ketone (V) in benzene containing 0.05 M BF_3–Et_2O gave the product VII in poor yield and recovered most of the starting material. The reaction did not proceed extensively due to the deterioration of the reaction mixture, which turned into a non-transparent, dark brown solution. This deterioration must be due to the interaction between the acid catalyst and the ketene formed by the photolysis of VII, as has been reported by Smith and Agosta[3] for a similar system. The photoreactions of ketone V in methanol or benzene without an acid catalyst were clean and gave the product VII in better yields (30 and 80% respectively). The structure of VII was deduced from the spectral data: an IR absorption at 1780 cm^{-1} is characteristic of cyclobutanone, the NMR signals at 3.73—3.36 ppm (δ) have an ABC pattern, and attempted decoupling by resonating the hydrogens at a higher field (cyclopentane moiety) did not change the signal pattern. This fact demonstrates that these signals are due to three hydrogens on the cyclobutanone moiety isolated from the hydrogens on the cyclopentane moiety.

The irradiation of 1-cyclohexenyl phenethyl ketone (VI) in the presence of BF_3–Et_2O under the same conditions as were used for ketone V afforded a product VIII in 67% yield. The photoreaction of VI in methanol or benzene containing 0.05 M CF_3COOH also gave ketone VIII in a 40% yield. The irradiation of ketone VI in benzene containing no acid catalyst, however, did not give any VIII, but instead a small amount of fragmentation products. The structure of VIII was deduced from the spectral data: an IR absorption at 1690 cm^{-1} is typical of a seven-membered ketone, and an absorption at 762 cm^{-1} is due to an ortho-disubstituted benzene. The NMR signals are complex but the integration showed the signal ratio of four hydrogens at 7.20—6.80 ppm, six hydrogens due to methylenes and methines adjacent to the benzene ring and the carbonyl group at 3.20—2.4 ppm.

There is no difference in the reaction pattern between 1-cyclopentenyl benzyl ketone (I) and 1-cyclohexenyl benzyl ketone (II) and irradiation in the presence of acid catalysts gives tricyclic ketones, III and IV respectively.[1] This feature of 1-cycloalkenyl benzyl ketones (I and II) is in sharp contrast with the photochemical-behavior of 1-cycloalkenyl phenethyl ketones (V and VI) described here. We previously proposed the importance of a π-aryl interaction in the excited state of the BF_3-complexes of 1-cycloalkenyl benzyl ketones for photo-cyclization.[1] The nature of this π-aryl interaction in the ketones V and VI must be a little different from that of ketones I and II due to the extension of the methylene chain. In the case of ketone VI, however, the π-aryl interaction is still effective enough to cause the photocyclization (Eq. 2) in the presence of an acid catalyst or in a protic solvent. Though the π-aryl interaction is still effective, the existence of benzylic hydrogen adequately located in relation to the enone moiety must alter the reactivity of ketone V. β-Carbon of 1-acylcyclopentenones has been reported to have a strong ability to abstract hydrogen intramolecularly.[3] The excited state of non-substituted cyclopentenone has a strong $n\pi^*$ character,[4] and the photo-reactivity of ketone V can be understood by means of the preferential hydrogen abstraction by triplet $n\pi^*$ excited state.[3]

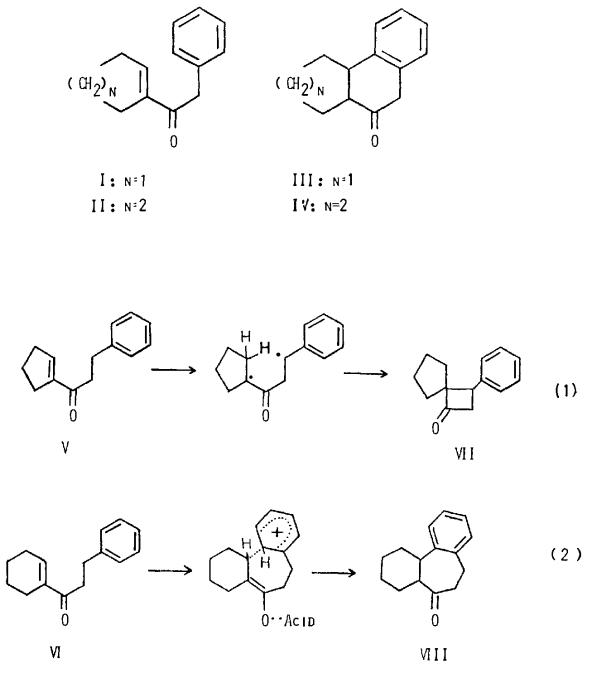

Fig. 1.

Experimental

Preparation of 1-Cyclopentenyl Phenethyl Ketone (V) and 1-Cyclohexenyl Phenethyl Ketone (VI). Stannic chloride (10.4 g, 0.04 mol) in dry dichloromethane (25 ml) was cooled below −70 °C and was then treated, drop by drop, with a mixture of freshly distilled 3-phenylpropionyl chloride (6.6 g, 0.04 mol) and one of the cycloalkenes (0.04 mol) over the period of 3 h. During the reaction the system was maintained below −70 °C and kept in a nitrogen atmosphere. After the completion of the treatment, the reaction mixture was slowly warmed up to 0 °C and poured onto a mixture of ice and concd hydrochloric acid. The dichloromethane layer was separated, and the aqueous layer was extracted with ether. The combined organic layer was washed with water and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent *in vacuo* gave the crude 2-chloro-1-cycloalkenyl phenethyl ketone. The chloro ketone thus obtained was dissolved in benzene (25 ml) and heated to refluxed in the presence of triethylamine (7 g) for 20 h. After cooling, the reaction mixture was washed with 1M-hydrochloric acid, a saturated sodium hydrogencarbonate solution, and water. The evaporation of the solvent after drying over anhydrous sodium sulfate gave the oily 1-cycloalkenyl phenethyl ketone in a high yield. The ketone V was essentially pure after distillation under reduced pressure, while ketone VI was further purified by chromatography on silica gel eluted by hexane-benzene. V, 129—130 °C/0.7 mmHg. IR(neat): 1655, 1615, 1503, 750, and 695 cm^{-1}. NMR(CCl_4): 7.36(5H), 6.76 (1H, diff. s), 2.94 (4H, s), 2.75—2.33 (4H, m), and 2.12—1.15 ppm (δ) (2H, m). Semicarbazone, mp 124—124.5 °C. Found: C, 69.72: H, 7.25; N, 16.15%. Calcd for $C_{15}H_{19}N_3O$: C, 70.00; H, 7.44; N, 16.33%. VI, 100 °C/0.1 mmHg. IR(neat): 1662, 1613, 1505, 754, and 693 cm^{-1}. NMR(CCl_4): 7.36 (5H, s), 6.97 (1H, diff. s), 2.90 (4H, s), 2.50—2.12 (4H, m), and 1.88—1.60 ppm (δ) (4H, m). Semicarbazone, mp 146—147 °C. Found: C, 70.55; H, 7.81; N, 15.38%. Calcd for $C_{16}H_{21}N_3O$: C, 70.82; H, 7.80; N, 15.49%.

General Procedure for the Photoreaction. Irradiations were carried out externally with a 500-W high-pressure mercury lamp through a Pyrex filter in (a) benzene containing 0.05 M BF_3–Et_2O, (b) benzene containing 0.05 M CF_3COOH, (c) benzene, and (d) methanol under argon or nitrogen. In each run, a 0.1 M solution of the ketone V or VI was irradiated and the progress of the reaction was monitored by means of the IR spectra and by GLC analyses. The reaction mixture was passed through a column of alumina, using benzene as the eluent, to remove the acid catalyst and other polar by-products. The eluates were condensed and further purified by chromatography on silica gel, using hexane-chloroform as the eluent, to give an essentially pure product, VII or VIII. These products, VII and VIII, were further purified by a preparative GLC for spectral measurements. VII, colorless oil. MS: m/e=200 (M^+). IR(neat): 1780, 1505, 765, and 699 cm^{-1} NMR(CCl_4): 7.60 (5H, m), 3.73—3.36 (3H, ABC pattern), and 2.45—1.20 ppm (δ) (8H, m). Semicarbazone, mp 175—176 °C. Found: C, 69.69; H, 7.29; N, 16.09%. Calcd for $C_{15}H_{19}N_3O$: C, 70.00; H, 7.44; N, 16.33%. VIII, colorless oil. Found: C, 84.13; H, 8.53%. Calcd for $C_{15}H_{18}O$: C, 84.07; H, 8.47%. MS: m/e=214 (M^+). IR (neat): 1695, 1502, 762, and 698 cm^{-1}. NMR (CCl_4): 7.20—6.80 (4H, m), 3.20—2.4 (4H, m), and 2.4—0.90 ppm (δ) (8H, m).

Triplet-Triplet Energy Transfer between Like Molecules

Akinori INOUE, Hiroshi CHUMAN, and Nozomu EBARA

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received February 5, 1977)

The previously proposed method of studying T-T energy trasfer between like molecules using isotopic mixtures was further improved and applied to an investigation of naphthalene and phenanthrene molecules. Critical transfer distances of 15 and 13 Å were determined for naphthalene and phenanthrene, respectively. The present method has the advantage that it is free from the effect of S-S energy transfer.

Triplet-triplet energy transfer between organic molecules in rigid media has been investigated extensively. Most of the previous works were concerned with energy transfer between unlike molecules. The phosphorescence intensities of donor molecules have been measured as a function of acceptor concentration[1,2] and their time dependences have been analyzed.[3-5] However, not much of the most fundamental information about T-T energy transfer between like molecules is available, possibly due to experimental difficulties. The above methods, which use donor-acceptor systems, are not applicable to this case. The previous studies employed the methods of concentration depolarization[7,8] or magneto-photoselection of phosphorescence.[9] These methods, however, have the fatal drawback that the results are masked by the effect of singlet-singlet energy transfer, whenever it occurs. Studies have been made with several molecules like naphthalene and phenanthrene using these methods;[7,9] in these studies the authors assumed that the singlet-singlet transfer was not efficient. However, as is shown in a later section, the critical transfer distances of these molecules for S-S transfer, estimated from Förster's theory,[10] are comparable to those in the T_1 state. The effect of S-S transfer seems to be large enough in these cases to preclude determination of reliable critical transfer distances in the triplet states, so that the earlier methods should be used only with reservation.

In a previous paper (I),[11] we have developed a new method of studying T-T transfer between like molecules, using isotopic mixtures, and have made an investigation of naphthalene molecules. Phosphorescence decay curves for equal amounts of protonated and perdeuterated naphthalene in poly(methylmethacrylate) were measured as a function of concentration. The new method utilized the fact that the phosphorescence lifetime of a protonated compound (H) and that of a deuterated compound (D) usually differ greatly, while their electronic properties are quite similar.

In (I), however, a somewhat oversimplified model was introduced, which might lead to a rather large value for the critical transfer distance R_0. In the present paper, measurements of phosphorescence decay curves were made again for naphthalene molecules in order to get more accurate data than in (I). The results were analyzed beased on an improved model. The present method was also successfully applied to the investigation of phenanthrene molecules.

Experimental

The methods used for the purification of naphthalene isotopic isomers and for the phosphoresence measurements are the same as in (I). Commercial phenanthrene-d_0 and -d_{10} were sublimed *in vacuo* and then used for the measurements. Plastic specimens including phenanthrene molecules were also prepared by the same method as in (I), *i.e.*, by polymerizing methyl methacrylate solutions at about 80 °C, with no inhibitor being used. Specimens were annealed at about 100 °C for a few hours. The concentration change due to polimerization were taken into account by the use of the specific gravities of methyl methacrylate and its polymer (PMMA). The specific gravity of 1 M naphthalene in PMMA was approximately 1.18, almost identical to that of pure PMMA (1.19). Thus, the change of density for PMMA because of the presence of solute molecules can be ignored.

All the measurements were made at 77 K. The volume contraction of PMMA by cooling from room temperature to 77 K was estimated to be only a few percent. Hence, this effect was also ignored. The fluorescence and absorption spectra were measured for EPA solutions of naphthalene and phenanthrene and their deuterated compounds at 77 K with a hand-made spectrofluorimeter.

Results and Discussion

The previous experiments[11] on naphthalene isotopic mixtures can be summarized as follows:

a) The phosphorescence decay curves could be expressed in terms of two exponential functions in the concentration region studied;

$$f(t) = D_1 \exp(-k_1 t) + D_2 \exp(-k_2 t). \quad (1)$$

b) The decay rate of each component varied little with concentration.

c) The decay rate of the long-lived component (k_2) was similar to that of the phosphorescence of the solution of pure D (β), whereas the short-lived component had a slightly smaller decay rate (k_1) than that of the H molecule (α).

d) The ratio of the pre-exponential factors, the short-lived over the long-lived components, r ($=D_1/D_2$), increased with increasing concentration. The change was drastic at higher concentrations.

e) The phosphorescence spectrum of the isotopic mixture was simply a susperposition of those for H and D, indicating that impurity molecules or triplet excimers or exciplexes are not responsible for the concentration dependence of the phosphorescence decay curves.

Our new results have features similar to the above. The concentration dependences of k_1, α, β, and r are

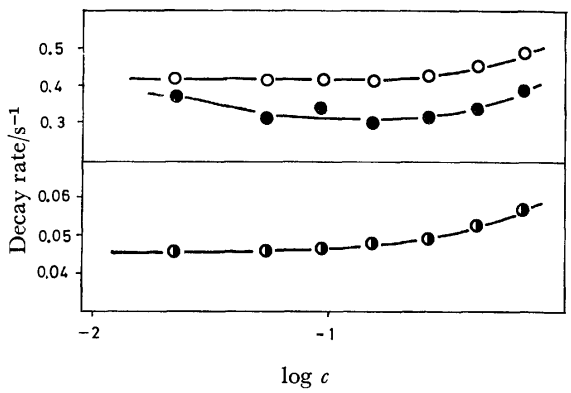

Fig. 1. Concentration dependences of α(○), β(◑), and γ(●) for naphthalene.

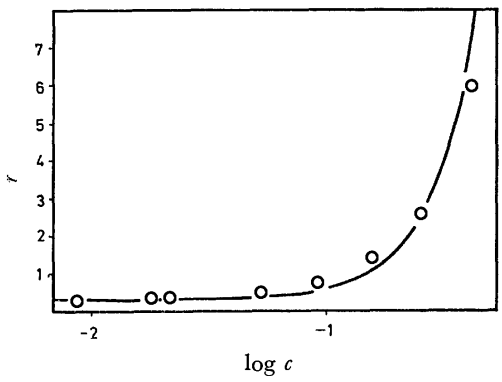

Fig. 2. Concentration dependence of r for naphthalene; -○- experiments; —calculated using Eq. 8.

shown in Figs. 1 and 2.

The previous data were interpreted in terms of triplet-triplet energy transfer between H and D molecules. It was assumed that energy transfer took place only between H-D pairs whose intermolecular separations were smaller than the critical transfer distance R_0. This gave the value of $R_0=17$ Å for naphthalene molecules. This value is relatively large compared with those reported for the energy transfer between unlike molecules.[1-6] The difference of the values may not be due to any intrinsic difference in the transfer mechanism, but may instead be ascribed to the assumptions included in (I). In (I), energy transfer was assumed to take place only between pairs and transfer among more than three molecules was ignored. This assumption may not be valid at higher concentrations.

In the present analysis, we have developed an improved model. The following emitting species were assumed to be present in the rigid solutions: A) isolated H molecules and clusters composed only of H molecules, B) isolated D molecules and clusters composed only of D molecules, and C) clusters containing both H and D molecules. Here, the word "cluster" is used to represent a group of molecules in which no molecules are isolated by distances larger than R_0 from all other members of the group, but they are separated by distances larger than R_0 from all molecules which do not belong to this group. Thus the rate of energy transfer between molecules within a cluster is much faster than the intramolecular decay process, whereas the energy transfer between two clusters can be assumed to be forbidden. The molecules in a cluster can be assumed to retain their individualities.

Phosphorescence decay rates of A and B clusters are identical to those of the isolated molecules, α for H and β for D, respectively, while the phosphorescence from C clusters has various lifetimes, depending on their compositions.

The decay rate of a cluster composed of n_H H molecules and n_D D molecules is

$$\gamma_s = (s\alpha+K\beta)/(s+K), \tag{2}$$

with

$$s = n_H/n_D,$$

where K is the ratio of the rate constants of the T-T transfer processes H→D and D→H.

In a cluster with the same total number of molecules, n, the ratio s shows a binomial distribution. For a C cluster with two molecules, which is certainly the most numerous one when the concentration is not so high, s is exactly unity. Hence, among all C clusters the most numerous clusters are those with the ratio s not much different from unity. Moreover, γ_s is a relatively slowly varying function of s, as can be verified easily ($\gamma_{1/2}=0.25$, $\gamma_1=0.30$, and $\gamma_2=0.34$ when $\alpha=0.40$, $\beta=0.047$ s^{-1}, and $K=0.37$). It can then be shown that the decay rates of C clusters extend from α to β with a very sharp peak at γ_1, so that they can be safely approximated by a single rate constant $\gamma=\gamma_1$.

Each decay curve is thus expected to be composed of three exponential functions:

$$f(t) = A[(k_H^r\rho_H/\alpha)\exp(-\alpha t) + (k_D^r\rho_D/\beta)\exp(-\beta t) + (k_{HD}^r\rho_{HD}/\gamma)\exp(-\gamma t)], \tag{3}$$

where k_H^r and k_D^r are the radiative rate constants for the phosphorescence of A and B clusters, and ρ_H, ρ_D, and ρ_{HD} are the probabilities that molecules belong to the respective clusters, when they are excited. k_{HD}^r is an effective radiative rate constant for C clusters:

$$k_{HD}^r = (k_H^r+Kk_D^r)/(1+K). \tag{4}$$

The singlet absorption cross section and the rate for intersystem crossing are assumed to be the same for H and D molecules. Equation 4 applies to a phosphorescence decay of the mixture after the steady state condition for excitation is established.

The observed phosphorescence decay curves for isotopic mixtures consisted of two exponential functions instead of three over a wide concentration range, as mentioned before. This was because γ is close to α and, in the distribution of decay rates, the peak at α is too low compared with that at γ. That such a distribution of rate constants can be represented by a single rate constant can be shown by a model calculation, so that

$$k_1 = \gamma,$$

and

$$D_1 = A[(k_H^r\rho_H/\alpha)+(k_{HD}^r\rho_{HD}/\gamma)]. \tag{5}$$

The value of K is equal to the ratio of overlap of the phosphorescence and S-T adsorption spectra in the framework of Dexter's theory.[12] Due to the lack of spectroscopic data, the constant was equated in (I) to

the Boltzman factor, 0.13, as is often employed. In this approximation, however, several factors such as the correction for spectral line width cannot be taken into account. Hence, we discard this value. K was estimated to be 0.37 using Eq. 2 and the values of α, β, and γ. This valus was found to be constant for 0.1 to 0.4 M solutions.

The ratio, r, of the pre-exponential factors of the short-lived to long-lived components is then

$$r = [(k_H^r\rho_H/\alpha) + (k_{HD}^r\rho_{HD}/\gamma)]/(k_D^r\rho_D/\beta). \quad (6)$$

Since we are dealing with solutions containing equal amounts of H and D molecules, it is evident that

$$\rho_H = \rho_D,$$

and

$$\rho_{HD} = 1 - (\rho_H + \rho_D) = 1 - 2\rho_D,$$

so that

$$r = p\beta/\alpha - 2(\beta/\gamma)(p+K)/(1+K) + (\beta/\gamma\rho_D)(p+K)/(1+K), \quad (7)$$

where p is the ratio k_H^r/k_D^r. Denoting as w_n the fraction of clusters composed of n molecules altogether, regardless of H or D molecules,

$$\rho_D = \sum_n 2^{-n}w_n.$$

If the concentration is not too high, the terms with large n are expected to be small, since each w_n is small and is accompanied by a factor 2^{-n}. Thus, we can retain only w_1 and w_2 and neglect higher terms. By this approximation only clusters composed of not more than two molecules are considered for A and B clusters. On the other hand, since the factor 2^{-n} is not present for C clusters, all possibilities are taken into account by using $\rho_{HD}=1-2\rho_D$. The present approximation is valid in the concentration range where $w_1>w_2$; otherwise, higher terms must be taken into account for ρ_H and ρ_D. The validity of this condition will be examined below. Equation 7 then leads to

$$r = p\beta/\alpha - 2(\beta/\gamma)(p+K)/(1+K) + (\beta/\gamma)(p+K)/(1+K)[(w_1/2)+(w_2/4)]. \quad (8)$$

w_1 is the probability of a molecule having no neighbors within the active sphere, $v=4\pi R_0^3/3$ (cm^3), so that

$$w_1 = \exp(-Nvc). \quad (9)$$

Here, $N=6.02\times10^{20}$ mol^{-1} and c is the total concentration of H and D together (M). w_2 is given by[13]

$$w_2 = 4\pi Nc \exp(-4\pi R_0^3 Nc/3) \times \int_0^{R_0} R^2 \exp[-\pi Nc(R_0^2R - R^3/12)]dR. \quad (10)$$

Figure 2 depicts the comparison of the concentration dependence of the experimental value of r to that calculated using Eq. 8, with experimentally determined parameters α, β, and γ. The value of p was taken from the paper by Kanamaru.[14] The best fit was obtained with $R_0=15$ Å. This value is smaller than the previous value of 17 Å.

We applied the same method to phenanthrene systems. In this case, decay curves were also found to be consistent with two exponential functions. No anomalous emission which might be ascribed to an impurity or excimer (exciplex) was observed in the phosphorescence spectra. The value of each decay rate, whose concentration dependence is shown in Fig. 3, does not change much with concentration. The ratio r changes greatly with concentration (Fig. 4). The calculated curve based on Eq. 8 with $R_0=13$ Å fitted well with the experiments.

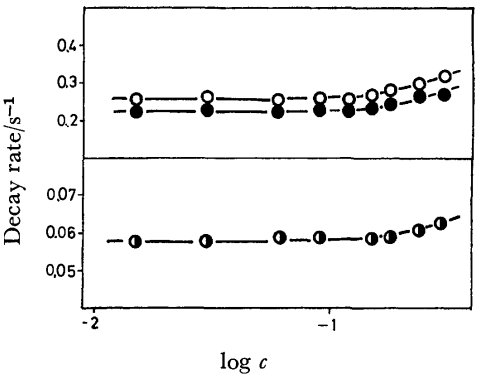

Fig. 3. Concentration dependences of α(○), β(◑), and γ(●) for phenanthrene.

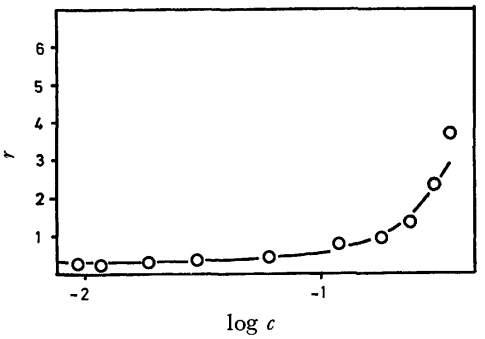

Fig. 4. Concentration dependence of r for phenanthrene;
-○- experiments; — calculated using Eq. 8.

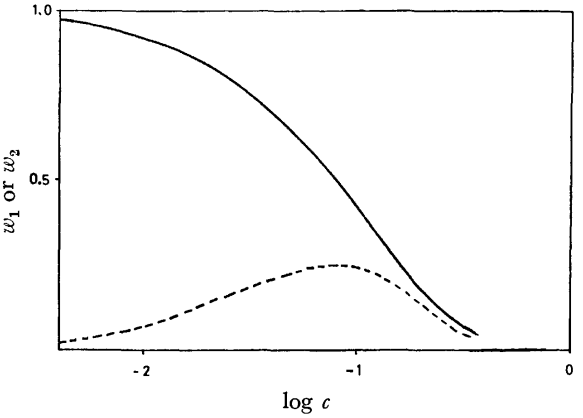

Fig. 5. Calculated w_1 (—) and w_2 (---) with $R_0=15$ Å as a function of concentration.

The concentration dependences of w_1 and w_2 with $R_0=15$ Å are depicted in Fig. 5. The condition $w_1>w_2$ is shown to be obeyed in the concentration range studied, and it is evident that this inequality holds for smaller values of R_0. Thus, neglecting higher terms in w_n is justified in the present case.

In the above approximation, the initial steady state

triplet population in each kind of cluster is assumed to be proportional to its lifetime. This requires that the redistribution of excitation among different kinds of clusters should be forbidden also in the singlet state, or that the initial equilibrium populations in the excited singlet state are the same for all kinds of clusters. We have measured the absorption and fluorescence spectra of H and D molecules at 77 K for naphthalene and phenanthrene, from which the critical concentrations c_{HD} for singlet-singlet energy transfer H→D and c_{DH} for D→H were calculated by the standard method.[10] These were 0.17 and 0.15 M for naphthalene and 0.31 and 0.31 M for phenanthrene. The critical distances for S-S transfer are then 14 Å for naphthalene and 11 Å for phenanthrene. These are close to, but do not exceed the critical distances for T-T transfer, and assure that the transfer between clusters in the singlet state is forbidden.

In quite a few cases the S-S critical transfer distances between like molecules never exceed the T-T transfer distances,[15] so that the present method can very often be used without any correction. In cases where the S-S critical distances R_{0s} is larger than R_0, the following small correction may suffice:

The fractions of A and B clusters which are not isolated in an S-S transfer but are isolated in a T-T transfer are

$$\Delta\rho_H = \Delta\rho_D = \rho_D(R_0) - \rho_D(R_{0s}),$$

in which the probability ρ is considered to be a function of isolation distance. The populations of singlet excitation in these portions are to be modified by $2/(1+q)$ for A clusters and $2q/(1+q)$ for B clusters. Here q is an equilibrium constant and can be derived from Förster's theory:[16]

$$q = (\eta_{HD}/\eta_H)(1-\eta_{DH}/\eta_D)/(\eta_{DH}/\eta_D)(1-\eta_{HD}/\eta_H). \quad (11)$$

η_H and η_D are the fluorescence quantum yields of H and D molecules, respectively, in the absence of S-S transfer to their isotopic isomers and η_{HD} and η_{HD} are those in the presence of the latter. The probabilities ρ_H and ρ_D in Eq. 6 are then to be replaced by $\rho_H + \Delta\rho_H(1-q)/(1+q)$ and $\rho_D - \Delta\rho_D(1-q)/(1+q)$, respectively.

In the present case, no such correction was required, as mentioned above, and the calculation of this value by using Förster's formulae[10]

$$\eta_{HD}/\eta_H = 1 - \sqrt{\pi}x \exp(x^2)[1-2\Phi(\sqrt{2}x)],$$

$$\Phi(y) = (1/\sqrt{2\pi})\int_0^y \exp(-t^2/2)dt,$$

$$x = \sqrt{\pi}c/2c_{HD},$$

shows that q is almost unity within the concentration range studied.

In this way, the present method seems to have wide applicability for investigations of T-T energy transfers, because the effect of S-S transfer is usually ignorable, or, if not, correction for it can be made easily. On the contrary, the conventional methods such as photoselection of phosphorescence cannot be used when even a small amount of S-S transfer manifests itself.

The critical transfer distance for the triplet energy transfer between identical molecules obtained in the present work is of the same order of magnitude as those reported previously for unlike molecules.[1-6] The difference of the values for naphthalene and phenanthrene may not be important when we consider the experimental errors and the precision of approximation employed in the analysis.

The Effect of High Density Excitation on the Phosphorescence Spectra and Decay Times of Several Crystalline Uranyl(VI) Salts

Takayoshi KOBAYASHI

The Institute of Physical and Chemical Research, Wako, Saitama, 351

(Received January 22, 1977)

The effect of high density excitation on the phosphorescence spectra and their decay curves of crystalline uranyl(VI)nitrate hexahydrate, uranyl(VI)acetate dihydrate, and zinc uranyl(VI)acetate heptahydrate was studied using a nitrogen laser as the exciting light source. The relative emission intensity of the spectra in the shorter wavelengths decreased and the vibrational structure became broader at higher density excitations; these changes were attributed to the saturation in excitation and to the temperature increase in the irradiated volume of the sample crystal caused by the heat released in the radiationless decay process. A decrease in the decay time was also observed at high density excitations; this shortening was attributed to bimolecular quenching of triplet excitons in the crystal. The rate constant for this process in crystalline uranyl nitrate hexahydrate was measured at several temperatures between 77 and 295K; it was 2.6×10^{-13} cm^3 s^{-1} at 295K for example. From this rate constant the hopping rate for a triplet exciton in crystalline uranyl nitrate hexahydrate was obtained: 4.3×10^{8} cm^3 s^{-1} at 295K. The activation energy for the exciton migration was found to be 320 cm^{-1}.

Uranyl salts with the simplest monomolecular type of luminescence have been extensively investigated for more than a century.[1,2] Tolstoi *et al.* observed decreases in both the phosphorescence lifetime and the quantum yield at high density excitations.[3,4] They measured the relative quantum yield and the average lifetime at various excitation densities. They determined the bimolecular quenching rate constants in a uranyl(VI)-nitrate hexahydrate crystal by matching the theoretical curves to the experimental points. The bimolecular quenching rate constant obtained by them is erroneous because of the following two reasons: (i) The decay curve is not exponential when both monomolecular and bimolecular decay processes are present, as is shown in the later part of this paper, whereas they assumed it to be exponential, and (ii) the decrease in the phosphorescence yield was assumed to be caused only by biexcitonic quenching; the saturation effect in the excitation and other effects were disregarded.

In the present paper the effect of high density excitation on the phosphorescence decay curves was studied for crystalline uranyl(VI)nitrate hexahydrate ($UO_2(NO_3)_2\cdot6H_2O$), uranyl(VI)acetate dihydrate ($UO_2(CH_3COO)_2 : 2H_2O$), and zinc uranyl(VI)acetate heptahydrate ($Zn(UO_2)_2(CH_3COO)_6\cdot7H_2O$) (hereafter abbreviated as UN, UA, and ZUA, respectively) and the rate constants for bimolecular quenching and hopping of excitons in a UN crystal were obtained as a function of temperature between 77 and 295 K by analyzing the phosphorescence decay curves.[5,6] The critical concentration for bimolecular quenching and the activation energy for the exciton hopping were also obtained.

The effect of high density excitation on the phosphorescence spectra was also studied for the three uranyl salts. The cause of the spectral change at high density excitation is interpreted in terms of the saturation in excitation and the temperature increase in the irradiated volume of the sample crystal which is caused by the heat released in the radiationless decay process.[6]

Experimental

A nitrogen laser described in a previous paper[7] was used as the excitation light source for observing the phosphorescence decay curves and their time-resolved spectra. The laser beam intensity was attenuated by quartz plates with evaporated aluminium. The intensity of the phosphorescence from the crystalline samples was also reduced by appropriate neutral density filters of copper mesh. A Spex 1704 monochromator, an EMI 6256S photomultiplier, and a Hitachi V1000 oscilloscope were used to record the phosphorescence decay curves. The time constant of the detecting system was about 10 μs. A PAR model 160 boxcar integrator was used in order to obtain time resolved phosphorescence spectra and to improve the signal to noise ratio. The aperture time, time base, and time constant of the boxcar integrator were 10 μs, 0.1 ms, and 0.1 ms, respectively. The phosphorescence was detected at right angles to the excitation light beam.

The triplet-triplet ($T_n\leftarrow T_1$) absorption spectrum of UN in acetonitrile solution was measured by a newly developed method which was described in a previous paper.[8]

Reagent grade UN and UA (Wako Pure Chemical Industries) and GR grade ZUA (Kanto Chemical Co., Inc.) were used without further purification. For study of the high density excitation effect, crystalline powder was used. The spectral dependence of the phosphorescence lifetimes was checked for these three crystals at 295, 201, and 77 K. The phosphorescence lifetimes were constant all over the spectral region for the three crystals, UN, UA, and ZUA, at these three temperatures. This shows that the effect of the impurity emission on the phosphorescence spectra of these three crystals of the uranyl salts is negligibly small.[9,10]

The phosphorescence excitation spectrum of the UN crystal was measured on a HITACHI MPF spectrophotofluorometer at Ochanomizu University.

Results and Discussion

Spectral Changes. Phosphorescence spectra of UN, UA, and ZUA within the first 10 μs after the laser excitation were measured at 295 K at high and low excitation densities; the results are shown in Fig. 1(a).

Vibrational bands in the phosphorescence spectra of the three kinds of crystals, UN, UA, and ZUA, are hereafter referred to as bands h, a, b, c, d, and e, as

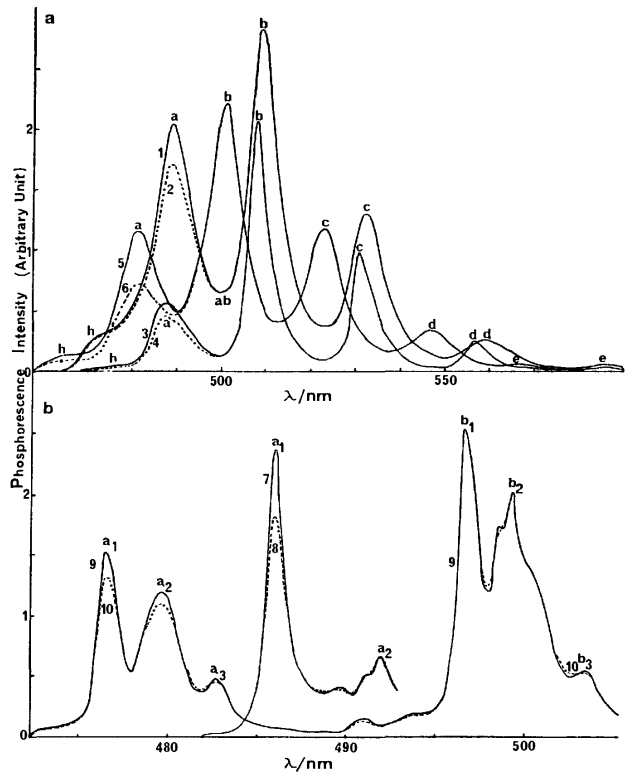

Fig. 1, (a) Time resolved phosphorescence spectra of crystalline UN (curves 1 and 2), UA (curves 3 and 4), and ZUA (curves 5 and 6) just after low (solid curves) and high (broken curves) density excitations at 295 K. Exciting light intensity at high density excitation is about 100 kW per 0.08 cm² (=1.25 MW/cm²).
(b) Time resolved phosphorescence spectra of UA (curves 7 and 8) and ZUA (curves 9 and 10) crystals just after low (solid curves) and high (broken curves) density excitations at 77 K. Only band a and bands a and b are shown in the spectra for UA and ZUA, respectively, since the change is observed only in the regions of those bands.

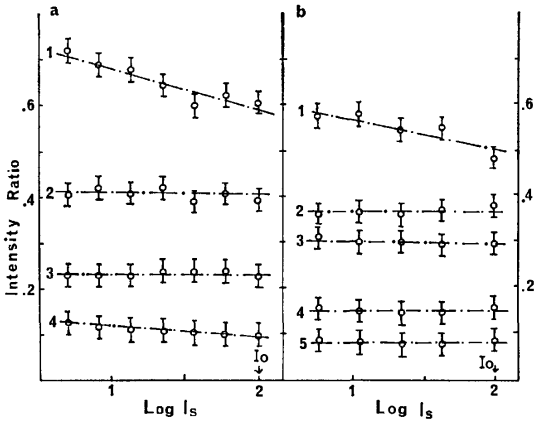

Fig. 2. Phosphorescence intensities of crystalline UN(2a) and UA(2b) at intensity maxima h, a, c, d, and of minima ab and bc relative to that at the maximum b in the time resolved spectrum just after excitation, as functions of logarithmic exciting light intensity (I_s). I_0 is the highest intensity in the present experiment, 100 kW per 0.08 cm². Plotted lines 1, 2, 3, and 4 in Fig. (2a) indicate I_a/I_b, I_c/I_b, I_{ab}/I_b, and I_h/I_b respectively, and those 1, 2, 3, 4, and 5 in Fig. (2b) indicate I_a/I_b, I_c/I_b, I_{ab}/I_b, I_{bc}/I_b, and I_d/I_b, respectively.

indicated in Fig. 1. Band h is a hot band. The intensity minima between the two maxima are referred to as ab, bc, cd, and de, *etc.* (Fig. 1). I_a and I_{ab} represent the emission intensities at the wavelength of band a and at the intensity minimum ab in the spectrum, respectively.

The common change in the phosphorescence spectra of UN, UA, and ZUA crystals with high density excitation at room temperature is the decrease in the intensity relative to that at the peak position of the phosphorescence spectra at shorter wavelengths. The relative intensities of bands h and a are weaker at high density excitation than at low density excitation. This can be shown more clearly from Figs. 2a and 2b, where the ratios of phosphorescence intensities at several wavelengths are shown for various excitation intensities, I_s. We can see that I_h/I_b and I_a/I_b decrease as I_s increases, while I_c/I_b, I_{ab}/I_b, and I_{bc}/I_b remain constant.

The effect of high density excitation on the phosphorescence spectra of UA and ZUA at 77 K is shown in Fig. 1(b). A change in the phosphorescence spectra of UA is observed in the spectral region between 483 and 493 nm, as shown in Fig. 1(b). Vibrational bands in the phosphorescence spectra of UA and ZUA are hereafter referred to as a_1, a_2, and a_3··· and b_1, b_2, and b_3···, as indicated in Fig. 1(b).

The relative intensities of band a in the spectrum of UN,[11] of band a_1 in the spectrum of UA, and of band a_1, a_2, and a_3 of ZUA decrease at high density excitations, as shown in Figs. 1 and 2. The amount of the decrease is in the order of $a_1 > a_2 > a_3$ for the spectrum of ZUA at 77 K.

In the spectra shown in Fig. 1(b) another spectral change can be found for UA and ZUA crystals. This is a vibrational band broadening. The vibrational bands become slightly obscure at the high density excitation in the 489—492 nm region of the UA spectrum, and in the 476—483, 490—493, and 498—500 nm regions of the ZUA spectrum. This broadening is also observed in the 506—509 nm region of the UN spectrum at 77 K.[12] The spectral change caused by high density excitation is observed also at 201 K. The change observed at this temperature is quite similar to that at 295 K.

The changes commonly observed to appear in the spectra of UN, UA, and ZUA crystals at high density excitations are therefore summarized as follows.

(1) The relative intensity of the spectra in the shorter wavelengths decreases at high density excitations.

(2) The vibrational band at 77 K becomes obscure at high density excitation. These spectral changes are reversible. Neither color change nor decomposition of the crystals was observed after exposure to about 10^4 shots. Furthermore, low density excitations before and after the high density excitation at the same spot on the sample crystal gave the same spectral distribution of fluorescence intensity, within 1%. Therefore, the main cause of the spectral change at high density excitation is not an irreversible chemical reaction.[13]

There are four possible interpretations for the observed

reversible spectral change (1):[14] (a) At the high density excitation the temperature in the irradiated volume of the crystal is increased not only by the heat given off in the ordinary linear radiationless decay processes of the molecules whose number increased at the high density excitations but also by the heat released in the nonlinear bimolecular quenching process referred to in a later part of the present paper. This temperature increase causes an increase in the absorbance of the hot band. Therefore, the relative intensity of the spectra at the shorter wavelengths is decreased because of their large overlap with the hot band of the absorption spectra. (b) The ratio of the phosphorescence emitted from the surface of the crystal to that from the inner part decreases at high density excitations because of the saturation effect.[7] Since the phosphorescence was detected at right angles to the excitation light beam, the phosphorescence suffers from the reabsorption because the phosphorescence and $T_1 \leftarrow S_0$ absorption spectra overlap with each other to some extent. The phosphorescence emitted from the inner part is more seriously affected by the reabsorption than that emitted from the surface of the crystal. Therefore the reabsorption effect becomes more prominent at high density excitations. (c) Induced emission appears at high density excitations. (d) The emission spectrum is affected by reabsorptions due to transitions from the lowest excited triplet state (T_1) to higher triplet states (T_n).

Possibility (c) can be excluded since no spectral narrowing, but only broadening, could be found. In order to check possibility (d) we measured the $T_n \leftarrow T_1$ absorption spectrum of a saturated solution of uranyl nitrate in acetonitrile. The result is shown in Fig. 3. The $T_n \leftarrow T_1$ spectrum of UN has maxima at 570 nm.[15] Figure 3 shows $A_a < A_{ab} < A_b < A_c < A_d$, where A_a and A_{ab} are the absorbances of T_1 at the wavelength of band a and of intensity minimum b. Therefore, if possibility (d) is the main cause of spectral change (1), then I_h/I_b and I_a/I_b should increase in the spectrum of UN measured at 295 K with the increase in excitation intensity. However, as is shown in Fig. 2a, the actual spectral change of (1) is in the opposite direction. This implies that possibility (d) is not the main cause of spectral change (1) at high density excitations for UN crystals.

If possibilities (a) and (b) are the main causes of spectral change (1), I_h/I_b and I_a/I_b should increase with high density excitation for all three crystals, since bands a and h suffer from reabsorption less seriously than the other bands. This was what was actually observed for UN, UA, and ZUA crystals; therefore, it is concluded that (a) and (b) are the dominant causes of spectral change (1).

Two tentative explanations for spectral change (2) are as follows: (a) The vibrational structure becomes obscure at high density excitations because of the temperature increase caused by the heat given off by radiationless decay at high density excitations. (b) The new emission which appears is caused by the exciton-exciton interaction.

Possibility (b) is ruled out by the fact that the change in the phosphorescence decay time which accompanies the high density excitation can be completely interpreted in terms of the bimolecular collisional quenching of the triplet exciton, there is no evidence that there appears any new emission originating from some interacted state of two excitons with a possibly different decay time from that of the normal phosphorescence at low density excitation.

In order to check possibility (a), the phosphorescence spectra of a ZUA crystal at low density excitations at several temperatures higher than 77 K by steps of ten degrees were measured (Fig. 4); these were compared with that at the high density excitation at 77 K. From the comparison of Figs. 2 and 4, the ratio $I_{a_2}/I_{a_1a_2}$ at the high density excitation at 77 K is between those at 95 and 103 K with low density excitations. This shows that the temperature increase, ΔT, in the irradiated volume of crystalline ZUA at the high density excitation can be estimated at between 18 and 26 K.

The ratio $I_{a_1}/I_{a_1a_2}$ is much more seriously decreased

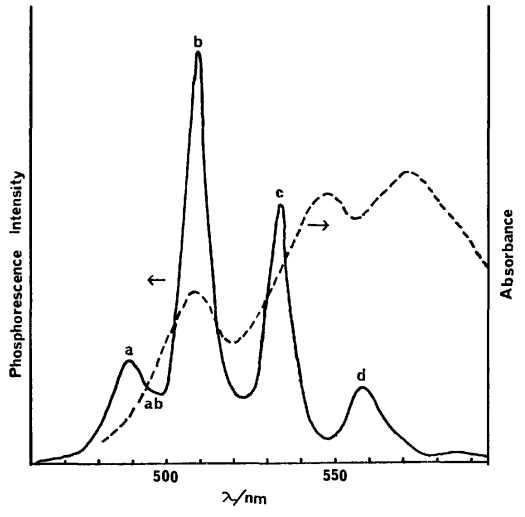

Fig. 3. Time resolved phosphorescence spectrum of UN crystal at 295 K just after low density excitation (curve 1) and the $T_n \leftarrow T_1$ absorption spectrum of a saturated solution of UN in CH_3CN (curve 2).

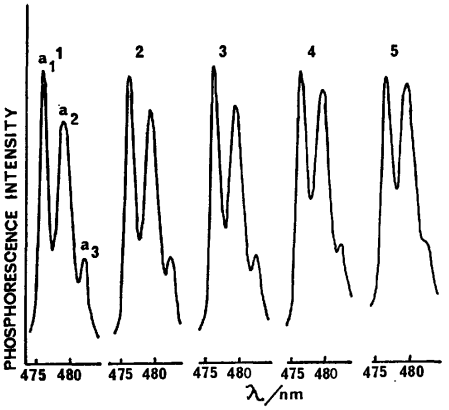

Fig. 4. Time resolved phosphorescence spectra of crystalline ZUA just after low density excitation at different temperature between 77 and 108 K. Figs. 1, 2, 3, 4, and 5 indicate the spectra at 77, 93, 95, 103, and 108 K, respectively.

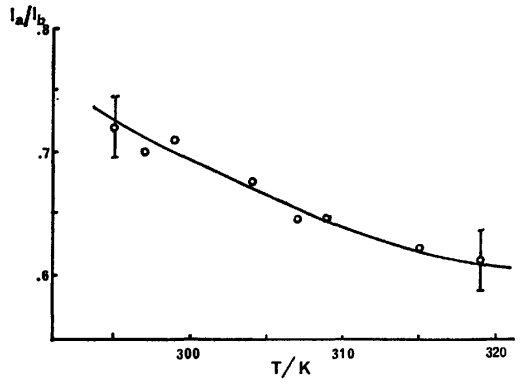

Fig. 5. Temperature dependence of the intensity ratio I_a/I_b between 295 and 319 K in the time-resolved spectrum just after low density excitation of UN.

than $I_{a_2}/I_{a_1a_2}$. This is because the band a_1 is decreased not only by the increase of the reabsorption effect caused by the temperature increase but also by the excitation saturation of the sample crystal already mentioned as possibility (b) for the cause of spectral change (1).

The temperature increase in the irradiated volume in crystalline UN can be also estimated to be ≈25 °C by a comparison with Figs. 3a and 5, which show the intensity ratio I_a/I_b as functions of temperature at low density excitation and of excitation density at 295 K, respectively.

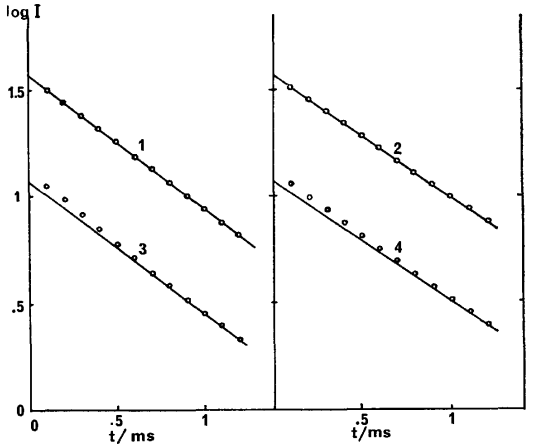

Fig. 6. Semilogarithmic plots of phosphorescence intensities *versus* time after excitation at low (1 and 2) and high (3 and 4) density excitations at 295 (1 and 3) and at 77 K (2 and 4).

Change in Decay Curve. In Fig. 6, the logarithm of the phosphorescence intensity (I) of the UN crystal is plotted against time for high and low density excitations at 295 and 77 K. The phosphorescence lifetimes, τ's, at the low density excitation are 697 μs at 295 K and 764 μs at 77 K. The decay times obtained from the initial slope of the phosphorescence decay curve are 620 μs at 295 K and 690 μs at 77 K at the high density excitation. Therefore, the decreases in the lifetimes τ are 77 μs at 295 K and 74 μs at 77 K. This is contrary to the expected effect of temperature upon τ. From Fig. 7, it can be seen that $\Delta\tau/\Delta T$ is smaller at high

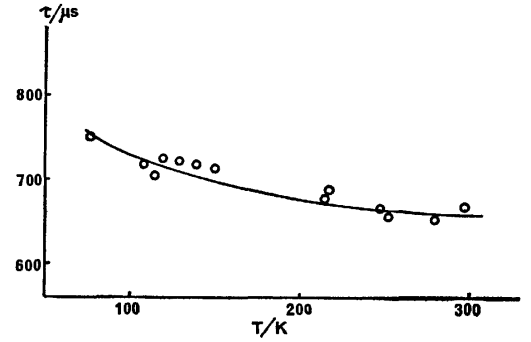

Fig. 7. Temperature dependence of phosphorescence lifetime of crystalline UN.

temperatures, where $\Delta\tau$ and ΔT are the change in lifetime and temperature. The decreases in the phosphorescence lifetimes, $\Delta\tau$, caused by the temperature increase, $\Delta T \cong 25$ °C, estimated above by the spectral change, were calculated to be much less than 10 μs at 295 K and 25 μs at 77 K. These decreases are too small to be the cause of the decrease in the lifetime. Induced emssion has also been ruled out. Therefore, the only possible cause of the lifetime shortening is biexcitonic quenching of triplet excitons in the crystal. When the bimolecular quenching process becomes significant, the time dependence of the exciton density $n(t)$ is given by the following equation:

$$1/n(t) = (1/n_0 + \gamma/\alpha)\exp(\alpha t) - \gamma/\alpha, \quad (1)$$

where n_0 is the initial excitation density and α and γ are the rate constants for the monomolecular and bimolecular decay processes, respectively. As is expected, $1/n(t)$ was found to be linearly proportional to $\exp(\alpha t)$ at several temperatures between 295 and 77 K. From the slopes of the lines, γ was obtained at various temperatures, the results are given in Fig. 8. This figure shows that the plot of $\log\gamma$ *versus* $1/T$ is approximately linear and, therefore, γ can be written in the form

$$\gamma = \gamma_0 \exp(-\Delta E/kT). \quad (2)$$

From the slope of the line in Fig. 8, ΔE was found to be 320 cm^{-1}. The following relation between γ and the exciton hopping rate, λ, has been derived in a previous paper:[6]

$$\gamma = \frac{\lambda\mu}{\lambda+\mu}\frac{z_n V_0}{z_u}(2-A), \quad (3)$$

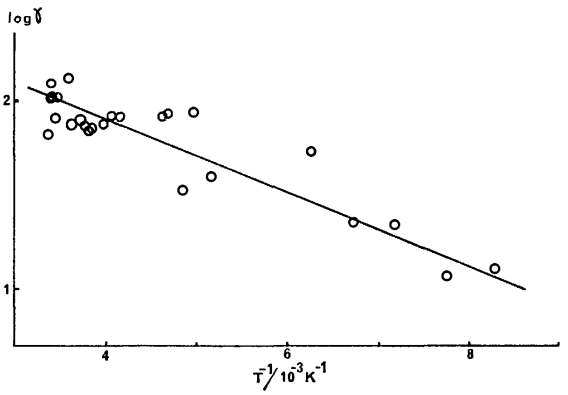

Fig. 8. Temperature dependence of γ of an exciton in crystalline UN. γ is in an arbitrary unit.

where μ, z_n, z_u, V_0, and A have the same meaning as in the previous paper.[6] As is expected for a triplet exciton, if the exciton hopping rate, λ, is much slower than the monomolecular quenching rate constant, μ, of the two neighboring excitons, Eq. 3 may be simplified to

$$\gamma = \lambda \frac{z_n V_0}{z_u}(2-A). \quad (4)$$

By combining Eqs. 2 and 4, we obtain

$$\lambda = \lambda_0 \exp\left(\frac{-\Delta E}{kT}\right), \quad (5a)$$

$$\lambda_0 \equiv \gamma_0 \frac{z_u}{z_n V_0} \frac{1}{2-A}. \quad (5b)$$

We found the activation energy for bimolecular quenching and hence for exciton migration to be 320 cm^{-1}.

The Absolute Values of γ and λ. In order to estimate the absolute values of γ and λ, it is necessary to know the concentration of the triplet excitons. The triplet exciton concentration in the irradiated volume the exciton is estimated from the following equation, since the intersystem crossing yield is nearly equal to unity in uranyl salts because of the heavy atom effect:[1,2]

$$n_0 = LI_0 \frac{0.6321\varepsilon_{3371}c}{\Delta S}, \quad (6)$$

where L is a loss factor of the laser pulse intensity caused by reflections off the surfaces of the lens, the sample tube, and the crystalline sample; ΔS is the area of the focused spot; I_0 is the number of photons per pulse; ε_{3371} is the molar extinction coefficient of the sample at the excitation wavelength; and c is the molar concentration of UN in the crystalline state. I_0 and ΔS were measured experimentally to be 1.0×10^{14} photons per pulse and 0.08 cm^2, respectively. From the crystal structure,[16] c was found to be 5.37 M.

When the laser intensity is greater than 3×10^{14} photons/pulse, the phosphorescence intensity is not proportional to the laser intensity. This saturation effect may be caused by two photon excitations (both simultaneous and stepwise), by reabsorption of the phosphorescence associated with the $T_n \leftarrow T_1$ transitions, and by ground state depletion.

The absorption spectrum of UN in CH_3CN solution and the uncorrected phosphorescence excitation spectrum of a UN crystal were measured at room temperature (295 K), the result is shown in Fig. 9. The vibrational structures of the spectra resemble each other, and the crystal shift is very small; thus, ε_{3371} of UN in the crystalline state is not much different from that in solution. Therefore, ε_{3371} for crystalline UN is assumed to be 9.2 M^{-1} cm^{-1}, the same as the molar extinction coefficient of UN in CH_3CN solution.

By substituting these experimental data in Eq. 6, n_0 was found to be 2.2×10^{18} cm^{-3} s^{-1}.[17] Since it is difficult to determine A experimentally,[6] it is assumed to be zero. This assumption only changes the calculated exciton hopping rate by a factor of two and the error caused by this assumption is smaller than possible experimental errors which accompany the determination of n_0 and, therefore, γ and λ as well.

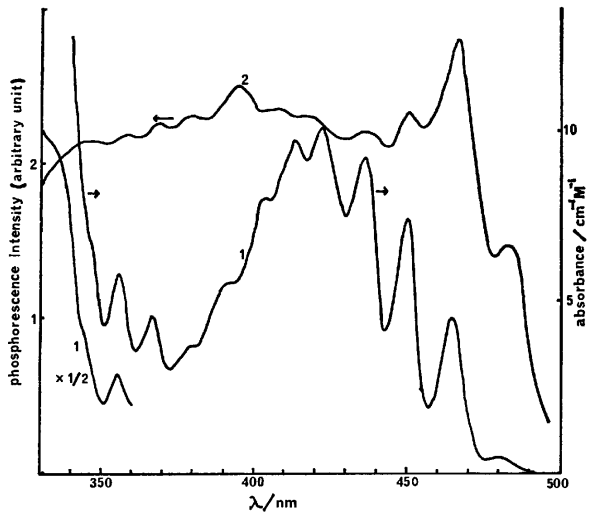

Fig. 9. Absorption spectrum of UN in CH_3CN solution (curve 1) and phosphorescence excitation spectrum of crystalline UN (curve 2) at 295 K.

With this assumption, we obtained 4.3×10^8 s^{-1} for λ at 295 K. This value is reasonable for the migration rate of a triplet exciton. From the values of λ and τ at 295 K, we deduce that the exciton travels over about 3×10^5 sites in crystalline uranyl nitrate during its lifetime.

Table 1. Characteristic data for triplet excitons in crystalline uranyl nitrate hexahydrate at 295 K

τ	697 μs
α	1.43×10^3 s^{-1}
γ	2.6×10^{-13} cm^3 s^{-1}
λ	4.3×10^8 s^{-1}
n_c	5.5×10^{15} cm^{-3}
R_c	352 Å
D	5.5×10^{-6} cm^2 s^{-1}
l	8800 Å
d	7.8×10^5 Å

In the same manner as was used in the preceding work,[6] we determined the critical concentration, n_c, the diffusion coefficient, D, the mean diffusion length, l, and the critical radius, R_c, for bimolecular quenching at room temperature (295 K). The results are shown in Table 1. The relations between these parameters are as follows:

$$n_c\gamma = \alpha, \quad \frac{4\pi}{3}(R_c)^3 n_c = 1, \quad D = 2a^2\lambda, \quad l = (2D\tau)^{1/2}, \quad (7)$$

where $a = V_0^{1/3}$ is the mean distance between neighboring sites and V_0 is the volume of a unit cell. This table shows that the mean diffusion length, l, is much smaller than the absorption depth of the exciting light, d, in crystalline uranyl nitrate, which was found to be $d = 7.8\times10^5$ Å by use of the relation $d = (2.303\varepsilon_{3371}c)^{-1}$. Therefore, almost none of the triplet excitons initially generated by the nitrogen laser pulse escape from the irradiated region during their lifetime. This justifies the neglect of the diffusion term,

$$\sum_{i,j} D_{ij} \frac{\partial^2 n(t,x)}{\partial x_{ij}^2},$$

in the equation determining the behavior of $n(t,x)$, *viz.*,

$$-\frac{dn}{dt} = \alpha n + \gamma n^2 + \sum_{i,j} D_{ij} \frac{\partial^2 n}{\partial x_{ij}^2}. \quad (8)$$

The neglect of the last term on the right hand side of Eq. 8 leads to Eq. 1. The diffusion coefficient of the triplet exciton at room temperature was obtained for anthracene (2×10^{-4} cm^2 s^{-1}),[18] pyrene (($8\pm4)\times10^{-4}$ cm^2 s^{-1}),[19] and *p*-dibromobenzene (($2\pm1)\times10^{-4}$ cm^2 s^{-1}).[20] The diffusion coefficient at room temperature obtained for the UN crystal in the present paper is about 100 times smaller than those in the three aromatic molecular crystals. The difference may be explained in the following way. The magnitude of the diffusion coefficient of the triplet exciton in the crystal is closely related to the exchange interaction between two neighboring molecules. The average distance between two neighboring molecules in the UN crystal is 10.6 Å which is much longer than those of anthracene (6.2 Å), pyrene (6.4 Å), and *p*-dibromobenzene (5.5 Å). Therefore the exchange interaction between two neighboring molecules and therefore the exciton hopping rate in the UN crystal are much smaller than those in anthracene, and *p*-dibromobenzene crystals.

The author wants to express his sincere gratitude to Professor Saburo Nagakura, Tokyo University, for his discussion and encouragement during the research. He also thanks Professor Haruo Hosoya of Ochanomizu University for the use of the HITACHI MPF spectrophotometer, and Dr. Akinori Inoue for the use of a program for obtaining γ. He also wants to express his thanks to Dr. John M. Morris, Melbourne University, for his critical reading.

11) The spectra of UN at high and low density excitations at 77K are not shown, but they are quite similar to that at room temperature except that a slight sharpening of the bands are observed. The changes observed at 77K are quite similar to those at room temperature.

12) The reason why the vibrational band broadening is only observed in the spectra measured at 77K is as follows: The vibrational bands in the spectra measured at 295 and 201K are much broader than those measured at 77K, and the slight change which appears in the vibrational bands is more difficult to be detected for the broad spectra. So it is reasonble to consider that the undetectably slight vibrational band broadening is also occurring in the spectra mesured at higher temeratures.

13) More than 10^4 repetitions of high and low density excitations at the same spot of the crystal caused slight changes in the phosphorescence spectrum of the uranyl nitrate crystal. The following discussion uses only data obtained before the sample showed any irreversible change.

14) T. Kobayashi and S. Nagakura, *Mol. Cryst. Liq. Cryst.*, **25**, 153 (1974).

15) Since the phosphorescence spectra of UN in the crystalline state are quite similar to those in solution, the electronic state of the lowest triplet in the crystalline phase and that in solution are considered to be quite similar to each other. Therefore the absorption spectrum of T_1 shown in Fig. 9 is thought to be quite similar to that in the crystalline phase. From this it is assumed that the $T_n \leftarrow T_1$ absorption in the crystalline phase is the same as that in solution.

16) V. M. Vdovenko, E. V. Stroganov, A. P. Soklov, and V. N. Zandin, *Radiokhimiya*, **2**, 24 (1960).

17) This value is 12 times greater than 1.8×10^{-14} cm^3 s^{-1} the value determined by Tolstoi *et al.*[3]

Their value is erroneous for the following two reasons.

(1) The saturation effect was not taken into account and therfore, the number of excitons was overestimated and, hence, the value for γ was underestimated.

(2) The γ value of Tolstoi *et al.* results from their method of analysis of the experimental data. They determined γ from the initial slope of the phosphorescence decay curve. In practice, γ can not be determined with high enough accuracy by this method, because not enough data can be obtained with small errors in the short interval of time during which the initial slope is measured. In the present paper the exact solution of the equation was applied. To determine γ from the experimental data by using the exact solutions, one makes use of all the data points, not just the ones which are taken during the short time interval. Therefore the slopes can be determined from the experimental data with greater accuracy and, hence, γ can be calculated more accurately than by the method of Tolstoi *et al.*

Study of the Quasi-peaks in the Ion Cyclotron Double Resonance

Katsuyuki AOYAGI[1)]

JEOL Ltd., 1418 Nakagami, Akishima-shi, Tokyo 196

(Received August 16, 1976)

Quasi-peaks which do not correspond to any reactant ion in the ion-molecule reaction were observed in the ion cyclotron double-resonance spectrum. The field-sweep quasi-ICDR spectrum was also observed. Expressions giving the frequencies of the quasi-peaks observed in the ion cyclotron double-resonance spectrum were obtained; the results agreed with those obtained previously. Both the ion mass and ion drift-voltage dependences of the quasi-peaks were shown. A close agreement between the calculated and measured values was obtained. A method to repress the quasi-peaks is discussed.

It has been demonstrated that ion cyclotron double-resonance (ICDR) spectroscopy is useful in elucidating the mechanism of ion-molecule reactions.[2)] In an ion-molecule reaction, $R^+ + M \longrightarrow P^+ + N$, R^+ is the reactant ion, P^+, the product ion, and M and N, the reactant molecule and the neutral product. The signal from the product ion can be continuously monitored while an irradiating rf field is swept through the range of cyclotron frequencies. When the irradiating frequency matches the cyclotron frequency of the reactant ion, the energy from the irradiating rf field is absorbed by the reactant ion and the translational energy of reactant ion is increased. Since most reaction-rate constants are dependent on the ion velocity, the concentration of the product ion will change, and this change is presented as a peak in the ICDR spectrum. If the product ion is observed at its cyclotron frequency of f_1 while the irradiating frequency, f_2, is swept, the signals will be observed for values of f_2 corresponding to the cyclotron-resonance frequencies of the reactant ions which yield the product ion. At a low irradiating-field strength, a change in the monitored ion intensity reflects a change in the reaction rate constant as the kinetic energy of reactant ion is increased.[3)] At a high irradiating-field strength, however, intense peaks which do not correspond to any reactant ion are observed in the ICDR spectrum. These quasi-peaks accompanying a negative response are recorded symmetrically about the irradiating frequency of $f_2=f_1$. These peaks have been recognized as spurious peaks by Freiser, McMahon, and Beauchamp.[4)] However, it is important to recognize the detailed nature of these quasi-peaks in order to avoid an erroneous interpretation of the ICDR spectrum.

The motion of an ion which moves under the simultaneous application of the magnetic and electric fields appropriate for an ICR cell has been described in detail.[5)] The electrostatic trapping field of the same polarity as the ions under investigation is used to prevent ion loss in the direction parallel to the magnetic field. The ions execute an oscillatory motion in the trapping field. The frequency, f_t, of this oscillatory motion is given by[6,7)]

$$f_t = \frac{1}{2\pi}\left[\frac{8e}{m(d_x^2+d_z^2)}\left(V_t - \frac{V_{ud}+V_{ld}}{2}\right)\right]^{1/2}, \qquad (1)$$

where e/m is the charge-to-mass ratio of an ion, d_x, the spacing between the drift plates, d_z, the spacing between the trapping plates, V_t, the trapping voltage, and V_{ud} and V_{ld}, the drift voltages applied to the upper- and lower-drift plate respectively. The quasi-peaks discussed herein were observed using a square-type cell ($d_x=d_z$); the cell has been described in detail previously.[2d)]

In the present paper, we wish to report the features of the quasi-peaks, especially the drift-voltage dependence of their resonant frequencies for the quasi-peaks, and present a method to suppress them.

Experimental

The quasi-ICDR spectra recorded with a JEOL JIC-3B spectrometer have been described in detail.[7)] The ICR cell was of a three-section square type ($2.5\times2.5\times14$ cm) similar to the conventional one.[2a)] Single-resonance spectra of krypton and *t*-butyl alcohol were obtained by fixing the marginal oscillator frequency of 100.00 kHz, while that of 2-methylpropene was obtained by means of a Twin-T bridge detector with the oscillator frequency fixed of 99.986 kHz and sweeping the magnetic field using a field-modulation phase-sensitive detection scheme. The double-resonance experiments were carried out in the pulsed-modulation mode while sweeping the frequency of the irradiating oscillator. The field-sweep quasi-ICDR spectra of 2-methylpropene were obtained by fixing the observing and irradiating frequencies at 99.986 and 118.00 kHz respectively, using a pulsed-modulation mode of the irradiating field. The other experimental conditions were as follows: energy of ionizing electron, 70 eV; modulation frequency, 80 Hz; trapping voltage, +0.25 V; upper analyzer-drift voltage, 0 V, and lower analyzer-drift voltages in the −1.2—0 V range.

Results and Discussion

a) Frequency-sweep Quasi-ICDR Spectra. The quasi-ICDR spectrum of the *m/e* 84 ion of krypton at 2×10^{-5} Torr is shown in Fig. 1. Irradiation at $f_2=120.9$ and 79.6 kHz resulted in a decrease in the intensity of the peak due to the ion with *m/e* 84. The peaks observed with the frequencies of 120.9 and 79.6 kHz correspond to the *m/e* 69.5 and 105.5 ions which were not present in the single-resonance spectrum of krypton. Therefore, these peaks are not the actual double-resonance peaks. The spectrum exhibits the quasi-peaks symmetric about the frequency of the irradiating rf field of $f_2=f_1$.

Figure 2 shows the quasi-icdr spectrum of $(CH_3)_2$-COH^+ (*m/e* 59) of *t*-butyl alcohol obtained at 2.2×10^{-5} Torr. Irradiation at $f_2=124.6$ and 76.0 kHz caused a decrease in the intensity of the peak due to the ion with *m/e* 59. The spectrum indicates the quasi-peaks at the distances of f_1+2f_t and f_1-2f_t respectively from

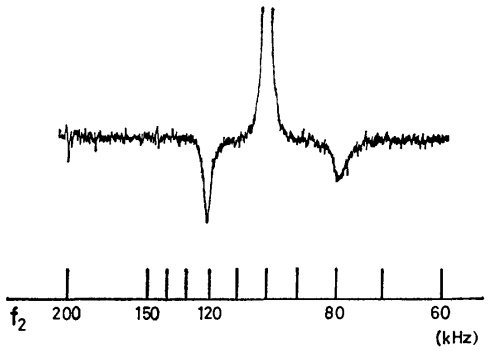

Fig. 1. Frequency-sweep quasi-ICDR spectrum of the *m/e* 84 ion of krypton with the pressure of 2×10^{-5} Torr, the observing rf field of 0.04 V/cm, the irradiating rf field of 0.32 V/cm, the trapping voltage of +0.25 V, and the upper and lower analyzer-drift voltages of 0 and −0.55 V. The large spike appearing at the 100 kHz frequency results from the interaction of the irradiating and observing oscillators, while the small spike at the 200 kHz frequency is due to the irradiating oscillator exciting the first sub-harmonic of the observing frequency.

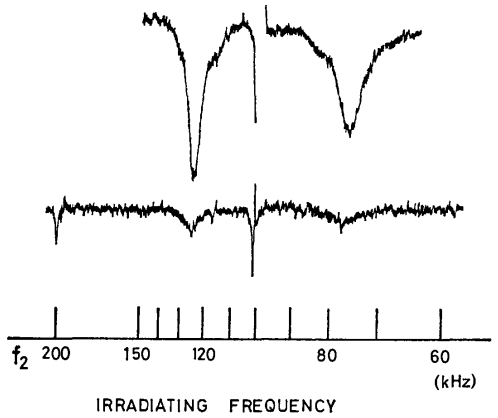

Fig. 2. Frequency-sweep quasi-ICDR spectrum of the $(CH_3)_2COH^+$ (*m/e* 59) of *t*-butyl alcohol with the pressure of 2.2×10^{-5} Torr; the other conditions are identical with those under which Fig. 1 was recorded. The sharp spike appearing at the 100 kHz frequency results from the interaction of the irradiating and observing oscillators, while the small feature at the 200 kHz frequency is due to the irradiating oscillator exciting the first overtone of the marginal oscillator.

the frequency of $f_2=f_1$. The peak observed with the frequency of 124.6 kHz corresponds to the *m/e* 47.3 ion, which was not present in the single-resonance spectrum of *t*-butyl alcohol. The *m/e* 59 ion derived from electron-impact ionization of *t*-butyl alcohol is an α-cleavage product that is, a primary ion.[8] Therefore, these peaks observed with the frequencies of 76.0 and 124.6 kHz corresponding to the *m/e* 47.3 and 77.6 ions are not the actual double-resonance peaks.

When ICDR studies were made of 2-methylpropene, the following results were obtained. In the case of $C_3H_5^+$ (*m/e* 41), irradiation at $f_2=123.7$ and 75.4 kHz resulted in a decrease in the intensity of the peak due

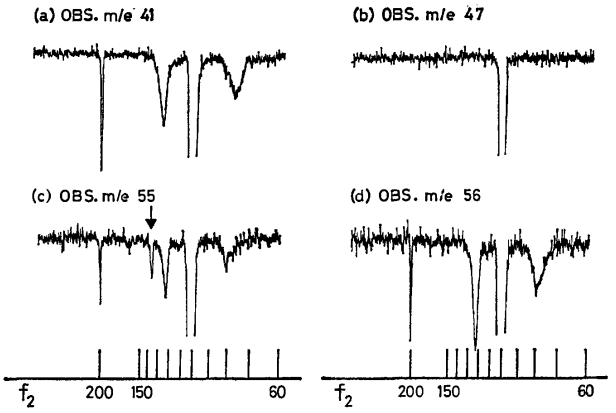

Fig. 3. (a) Frequency-sweep quasi-ICDR spectrum of the $C_3H_5^+$ (*m/e* 41) of 2-methylpropene with the pressure of 3×10^{-5} Torr, the observing rf field of 0.02 V/cm, the irradiating rf field of 0.24 V/cm, the trapping voltage of +0.25 V, and the upper and lower analyzer-drift voltages of 0 and −0.3 V. (b) Frequency-sweep quasi-ICDR spectrum of the *m/e* 47 ion of 2-methylpropene with the conditions are identical with those under which (a) was recorded. The ion corresponding to *m/e* 47 is absent from the single-resonance spectrum of 2-methylpropene; therefore, the quasi-peaks are not observed either. (c) Frequency-sweep quasi-ICDR spectrum of the $C_4H_7^+$ (*m/e* 55) of 2-methylpropene with the conditions are identical with those under which (a) was recorded. The peak at 134.6 kHz (indicated by an arrow) is the actual double-resonance peak corresponding to the reaction producing *m/e* 55. (d) Frequency-sweep quasi-ICDR spectrum of the $C_4H_8^+$ (*m/e* 56) of 2-methylpropene with the conditions are identical with those under which (a) was recorded. In this figure, the large spikes appearing at the 100 kHz frequency result from the interaction of the irradiating and observing oscillators, while the sharp spikes appearing at the 200 kHz frequency are due to the irradiating oscillator exciting the first sub-harmonics of the observing frequency.

to the $C_3H_5^+$, as is shown in Fig. 3a. Irradiation at $f_2=121.3$ and 79.6 kHz give rise to a decrease in the intensity of the peak due to the $C_4H_7^+$ (*m/e* 55), as is shown in Fig. 3c. In another case, that of $C_4H_8^+$ (*m/e* 56), the intensity of the peak due to the $C_4H_8^+$ is decreased by the irradiation at $f_2=121.1$ and 79.2 kHz, as is shown in Fig. 3d. The peaks observed with the frequencies of 123.7 and 75.4 kHz; 121.3, and 121.1 kHz correspond to the *m/e* 33.1 and 54.4; *m/e* 45.3, and 46.2 ions respectively, but these ions were absent from the single-resonance spectra. The quasi-peaks appearing at the frequencies of 79.6 and 79.2 kHz corresponding to the *m/e* 69.1 and 70.7 ions are not associated with any resonable ion-molecule reaction. Therefore, these peaks observed in the double-resonance spectra are also false peaks.

b) Frequencies of Occurrence of the Quasi-peaks.

From the experimental results described above, it follows that the quasi-peaks occur when the difference between the observing and irradiating frequencies is equal to $2f_t$, *i.e.*; $|f_1-f_2|=2f_t$, where f_t is given by

Eq. 1. This result agrees with that of Freiser *et al.*[4]

In the ICR spectrometers,[2a-d] naked electric wires are usually employed as the rf feeders in the vacuum chamber of the icr detector, because the coaxial cable used in a ultra high-vacuum is absent. Similarly, a naked wire is also employed to feed the electrostatic trapping voltage to the icr cell. As a result of the use of the naked wires, the observing and irradiating rf voltages are picked up by the wire for trapping voltage. In the ICR cell, thus, leakage of the rf field results from the rf voltages superimposed on the trapping voltage. Therefore, the generation of quasi-peaks is considered to be caused by the ejection of the ion from the trapping field by the leakage of the rf field. That is, when the observing frequency is fixed and the irradiating frequency is swept, the oscillatory motion of an ion increases in its amplitude in the trapping field at $|f_1-f_2|=2f_t$. Then, the ion is neutralized when it strikes the trapping plate, and the ion is ejected from the trapping field. Therefore, the quasi-peaks are observed with the frequencies of the irradiating rf field which are given by

$$f_2 \doteq f_1 \pm 2f_t, \qquad (2)$$

and the frequency-sweep quasi-ICDR spectrum is recorded as the quasi-peaks accompanying the negative response. Equation 2 has been reported in a slightly different form.[4] Using as practical units V_t, V_{ud}, and V_{ld} in volts, M in atomic mass unit, and f_1, f_2, and f_t in Hz, the frequencies, f_{2q}, of the occurrence of the quasi-peaks observed are given by

$$f_{2q} = f_1 \pm 246\left[\frac{V_t-(V_{ud}+V_{ld})/2}{M}\right]^{1/2} \text{ kHz}. \qquad (3)$$

The frequencies of the occurrence of all the quasi-peaks described in the preceding item are calculated from Eq. 3; they are listed in Table 1. The calculated results agree well with the experimental values.

As predicted by Eq. 3, the frequencies of the occurrence of the quasi-peaks vary with the square root of the ion mass or the difference between the trapping voltage and half of the drift voltage. On the other hand, the frequency of the irradiating rf field of the actual double-resonance peak is independent of the trapping and drift voltage. The variation in the frequency of occurrence of the quasi-peak observed in 2-methylpropene with the square root of the ion mass is shown in Fig. 4. Under these conditions the trapping and drift voltages remain constant; the observation of several ionic species confirms the inverse linear variation in the frequency of the occurrence of the quasi-peaks with the square root of the ion mass, as predicted by Eq. 3. Moreover, the variation in the frequency of the occurrence of the quasi-peak of $C_4H_7^+$ (*m/e* 55) in 2-methylpropene with

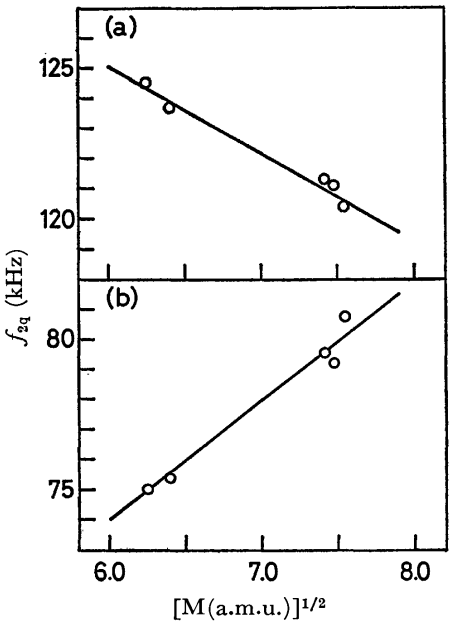

Fig. 4. Linear variation in the frequency of occurrence with the square root of the ion mass for 2-methylpropene. (a) $f_{2q}>f_1$, (b) $f_{2q}<f_1$.

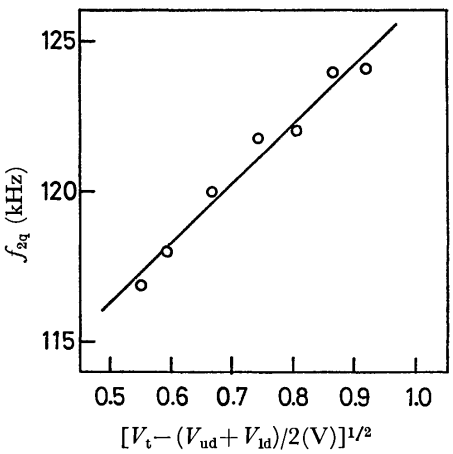

Fig. 5. Linear shift in the frequency of occurrence with the square root of the difference between the trapping voltage and half of the analyzer-drift voltage for $C_4H_7^+$. The trapping voltage is fixed at +0.25 V.

Table 1. Observed and calculated frequencies for some ionic species

Compound	Observed ion *m/e*	Species	Frequencies of occurrence (kHz) Obsd		Calcd	
Krypton	84		120.9	79.6	119.45	80.55
t-Butyl alcohol	59	$(CH_3)_2COH^+$	124.6	76.0	123.21	76.80
2-Methylpropene	39	$C_3H_3^+$	124.5	≈75	124.89	75.07
	41	$C_3H_5^+$	123.7	75.4	124.28	75.69
	55	$C_4H_7^+$	121.3	79.6	120.96	79.01
	56	$C_4H_8^+$	121.1	79.2	120.78	79.20
	57	$C_4H_9^+$	120.4	80.8	120.59	79.38

the square root of the difference between the trapping voltage and half of the drift voltage is illustrated in Fig. 5. When the trapping voltage is fixed, the observation of the quasi-peaks at several drift voltages confirms the linear variation in the frequency of the occurrence of the quasi-peak with the square root of the difference between the trapping voltage and half of the drift voltage.

Compared with the quasi-peaks, the most remarkable feature of the actual double-resonance peak is the constancy of the frequency of the irradiating rf field. The frequencies of the irradiating rf field at which the actual double-resonance peak corresponding to the ion-molecule reaction,

$$C_3H_5^+ + C_4H_8 \longrightarrow C_4H_7^+ + C_3H_6,$$

is observed at several drift voltages, are independent of the drift voltage, as Table 2 shows.

TABLE 2. OBSERVED AND CALCULATED FREQUENCIES AS FUNCTIONS OF THE ANALYZER-DRIFT VOLTAGE FOR THE $C_4H_7^+$ OF 2-METHYLPROPENE

Analyzer-drift voltages (V)		Frequencies of occurrence (kHz)		Irradiating frequencies(kHz) Obsd in $C_4H_7^+$—$[C_3H_5^+]$[a]
Upper	Lower	Obsd	Calcd	
0	−1.2	≈124	124.59	b)
0	−1.0	124.0	123.44	134.30
0	−0.8	122.0	122.24	134.87
0	−0.6	121.85	120.96	134.60
0	−0.4	120.10	119.61	134.60
0	−0.2	118.0	118.15	135.0
0	−0.1	116.9	117.38	134.4
0	−0.0	b)	116.57	b)

a) $C_4H_7^+ - [C_3H_5^+]$ indicated that $C_4H_7^+$ is observed when $C_3H_5^+$ is irradiated.
b) Too weak for the frequency to be determined.

c) Field-sweep Quasi-ICDR Spectrum. If the magnetic field, H, is swept, while the observing and irradiating frequencies described in Eq. 3 are fixed and the trapping and drift voltages are held constant, an oscillatory ion in the trapping field is translationally excited at the field of $H=aM$ (a is the costant); then, the field-sweep quasi-ICDR spectrum is obtained. Figure 6 shows the field-sweep quasi-ICDR spectra of 2-methylpropene obtained by sweeping the magnetic field with $f_2/f_1=118.00/99.986$. The spectrum exhibits the quasi-peaks of each ion which is observed in the single-resonance spectrum, but the relative intensity ratio of the quasi-peaks is not proportional to the ionic concentrations of each ion, because the exact f_2/f_1 ratios are not satisfied for any of them except for the m/e 55 ion. The quasi-peaks intensities decrease with a decrease in the strength of the irradiating rf field. This behavior of the quasi-peak intensity indicates that the generation of quasi-peaks can be minimized by the reduction of the leakage of the rf field. By using the shielded feeders, the quasi-peak intensity decreased by approximately 80 db compared with the previous result. This experimental result reveals that the generation of quasi-peaks is due to the ejection of the ion from the trapping field by the leakage of the rf field.

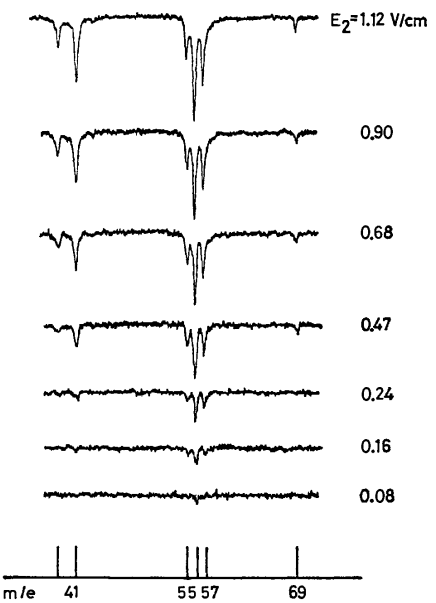

Fig. 6. Field-sweep quasi-ICDR spectra of 2-methylpropene at various irradiating field strengths. f_2/f_1 is fixed in the ratio of 118.00/99.986. The pressure is 3×10^{-5} Torr; trapping voltage, +0.25 V; upper and lower analyzer-drift voltages, 0 and −0.2 V.

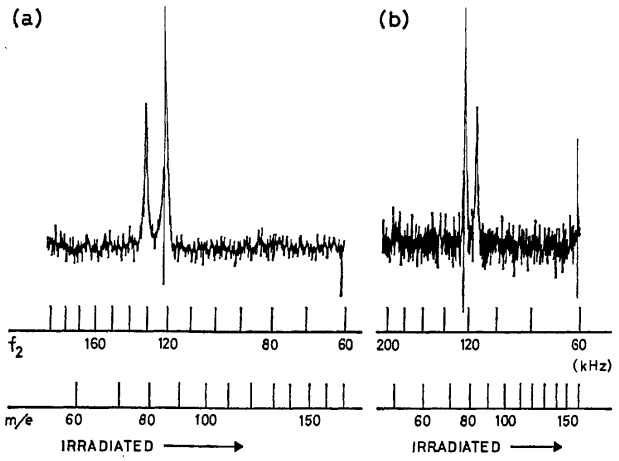

Fig. 7. (a) Double-resonance spectrum of $C_6D_6^+$ in a 1: 1 mixture of benzene and benzene-d_6 with the pressure of 2×10^{-5} Torr, the observing rf field of 0.05 V/cm, the irradiating rf field of 0.24 V/cm, the trapping voltage of +0.25 V, and the upper and lower analyzer-drift voltages of 0 and −0.4 V. (b) Double-resonance spectrum of $C_6H_6^+$ in a 1: 1 mixture of benzene and benzene-d_6 with the conditions are identical with those under which (a) was recorded. In this figure, the large spikes appearing at the 122.8 kHz frequency result from the interaction of the irradiating and observing oscillators, while the sharp spikes at the 61.4 kHz frequency are due to the irradiating oscillator exciting the first sub-harmonics of the observing frequency.

The double-resonance spectra of the $C_6D_6^+$ and $C_6H_6^+$ molecular ions in a mixture of benzene-d_6 and benzene (1: 1 ratio) are shown in Figs. 7a and 7b respectively.

The irradiation of $C_6H_6^+$ caused an increase in the intensity of $C_6D_6^+$, and the intensity of $C_6H_6^+$ was increased when $C_6D_6^+$ was irradiated. These double-resonance responses indicate that the charge-transfer reaction occurs between $C_6D_6^+$ and $C_6H_6^+$ as follows:

$$C_6H_6^+ + C_6D_6 \rightleftharpoons [C_6H_6 \cdot C_6D_6]^+ \rightleftharpoons C_6D_6^+ + C_6H_6.$$

This charge-transfer reaction corresponds to the equilibrium reaction reported by Field, Hamlet, and Libby.[9] The double-resonance spectra were obtained using a strong irradiating rf field (the strength of the irradiating field is 4.8 times as strong as that of the observing field), but the quasi-peaks are not observed in the spectra.

We may conclude from the experimental results described above that the quasi-peaks are caused by the leakage of the rf field, especially by the leakage of the strong irradiating rf field. The suppression of the leakage of the rf fields is important for eliminating the quasi-peaks and thus for the proper interpretation of the double-resonance spectra.

Stark Effect on the Electronic Bands of a Symmetric-top Molecule

Yoshito AMAKO, Yoshi-ichi SATO, and Akiyoshi WATANABE
College of General Education, Tohoku University, Sendai 980

(Received April 4, 1977)

Calculations have been performed on the energy matrix of a rigid symmetric-top molecule, HCHO, in order to determine the transition energies and intensities of the rotational sub-bands of the electronic spectrum under various magnitudes of external electrostatic fields. Though HCHO is an asymmetric-top molecule, the rotational structure of the 3390 Å band of this molecule is close to that of a perpendicular band of a symmetric-top molecule, at least, for not too small values of K. The variation in the band structures with the applied fields can be illustrated by the behavior of several selected bands, ^{p}P, ^{p}Q, ^{r}R, and ^{r}Q. Below 100 kV/cm, the overall Stark splittings have been linearly dependent on the field strength, regardless of the branch types. Over 100 kV/cm, however, a deviation from the linear dependence has been found for a certain branch. Changes in the band shape have appeared at such small values of external fields that no deviation from the linear field dependence of the overall Stark splitting has been observed. Such changes are dependent on the branch types, especially in the cases of branches with small J values and with $K<J$. The intensity enhancement of some forbidden bands has also been observed, the magnitude of which is proportional to the square of the field strength below 100 kV/cm. However, the relation between the intensity enhancement and the electric fields has been found to be complicated at fields over 100 kV/cm, the enhanced intensity being proportional to a coupled sum of E^2 and higher terms. At a fixed electric field, a linear relation has been found between the overall Stark splitting and the various μ values assumed for the excited state. The analysis of the data has enabled us to determine the electric dipole moment of the lowest $n\rightarrow\pi^*$ excited state of HCHO as 1.65 D.

Electric dipole moments in excited electronic states of gaseous molecules have been measured by means of electric-field-induced spectra, or the optical Stark effect.[1] When an electric field is applied to a molecule with a fine rotational structure in the electronic spectrum, some rotational lines may split into their Stark components. The splitting will be a function of the magnitude of the applied field and the dipole moments of the molecule in both states related to the transition. Thus, this method affords an important means for us to obtain some exact structural information on the short-lived excited molecules as well as on the ground-state molecules.

The first-order perturbation theory is usually used for the estimation of the dipole moments of electronic excited states from the Stark splittings of a symmetric-top molecule. However, the value of the splitting calculated on the basis of this theory differs greatly from the one observed at high electric fields, and sometimes gives a significant discrepancy even at low electric fields.

Therefore, in order to improve the calculation, we need to include higher-order terms in the perturbation theory. From this point of view, Shirley[2] has given an extensive treatment of the energy levels for all the rotational states through $J=4$, obtained from the direct diagonalization of the energy matrix of a rigid symmetric-top molecule under an electric field. On the other hand, as for an asymmetric-top molecule, West and Mizushima[3] have calculated the Stark effect of the lower rotational levels of H_2S and SO_2. However, both these calculations have been carried out only for molecules in one electronic state, *i.e.*, the electronic ground state.

Lombardi[4] was the first to make calculations of the Stark splittings and the band shapes of certain selected rotational sub-branches associated with *an electronic transition* of an asymmetric-top molecule under an electric field. In principle, Lombardi's calculation appears to cover all cases, and so it may seem unnecessary to do a similar calculation on a symmetric-top molecule.

However, for asymmetric-top molecules, the Stark effect is essentially of the second order, while it is of the first order for symmetric-top molecules. Moreover, so far there have been no such calculations made on symmetric-top molecules or on asymmetric-top ones whose behavior may be actually considered to be those of symmetric-top ones. For these molecules, it will be necessary to get detailed information about the Stark effect on their electronic transitions, because so far there has been no discussion on how large magnitudes of electric fields can make invalid the results obtained by the first-order perturbation theory, on how the band shapes in various branches may change with the electric fields, and on how the forbidden bands of a symmetric-top molecule in a zero field can get their intensities with electric fields, *etc.*

Moreover, the recent progress of very high resolution spectroscopy[5] free from Doppler broadening, especially the progress of a tunable cw dye laser technique, has attracted much attention. Then, also in the very-high-resolution spectra of the Stark splitting of electronic bands, it would be necessary to know the detailed M structures rather than the overall doublet splitting usually observed in moderately-high-resolution spectra, even though such very-high-resolution spectroscopy has not yet been well established.

In consideration of these circumstances, our calculation has been performed with special interest taken in the details of the intensity variation of each Stark component in different types of transitions with the field strengths and in the limits of the application of the perturbation theory for a symmetric-top molecule under an external electric fields.

Theoretical

The main program of the diagonalization of the energy matrix of a symmetric-top molecule under an external electric field closely parallels Shirley's. However, here we need eigenfunctions for the intensity calculation as well as the eigenvalues of the energy matrices for each set of J, K, and M. Therefore, we must directly diagonalize the fixed dimensions of the energy matrices.

The term values of each rotational state are expressed as

$$F(\mathrm{II}) = B(\mathrm{II}) \times E(\mathrm{II}, J, K, M) + \{A(\mathrm{II}) - B(\mathrm{II})\} \times K^2, \quad (1)$$

where $A(\mathrm{II})$ and $B(\mathrm{II})$ are the rotational constants of the related states and where $E(\mathrm{II},J,K,M)$ are the eigenvalues of the matrix to be mentioned below. The frequencies of the rotational bands associated with an electronic transition are given by

$$\nu = \nu_0 + F(2) - F(1), \quad (2)$$

where ν_0 is the frequency of vibronic origin.

The energy matrix for the determination of $E(\mathrm{II},J,K,M)$ is

$$\begin{vmatrix} a_1-E & \sqrt{b_2} & 0 & \cdot & \cdot \\ \sqrt{b_2} & a_2-E & \sqrt{b_3} & \cdot & \cdot \\ 0 & \sqrt{b_3} & a_3-E & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \end{vmatrix} = 0, \quad (3)$$

where

$$a_k = (J_0+k-1)\times(J_0+k) - \frac{R(\mathrm{L},\mathrm{II})\times M\times K}{(J_0+k-1)\times(J_0+k)}, \quad (4)$$

$$b_k = \frac{R(\mathrm{L},\mathrm{II})^2\times\{(J_0+k-1)^2-K^2\}\times\{(J_0+k-1)^2-M^2\}}{(J_0+k-1)^2\times\{4\times(J_0+k-1)^2-1\}}, \quad (5)$$

and

$$R(L,\mathrm{II}) = \mu(\mathrm{II})\times V(L)/B(\mathrm{II}).$$

Throughout these equations, the notation II is used to distinguish the ground state (II=1) or the excited state (II=2). $\mu(\mathrm{II})$ denotes the dipole moment of the ground or excited state, and $V(L)$, various field strengths, with $L=1, 2, 3, \cdots$ J_0 is the lowest J value for the special set of the K and M quantum numbers; it is equal to the larger of the two quantities, $|K|$ and $|M|$. For example, $J_0=5$ for each set of $|K|=0$—5 and $|M|=5$.

The energy matrices are diagonal for the K and M quantum numbers, but not for the J quantum number because the nondiagonal element, b_k, induces the mixing between the rotational states of $\Delta J=\pm1$, $\Delta K=\Delta M=0$. Therefore, the exact energy matrices for each set of K and M are infinite in dimensions. For the purpose of computation they must be truncated. The truncated matrices of definite dimensions are then expanded to give two types of continued fractions, both of which are solved by an iteration method improved by the application of the Newton-Raphson procedure discussed by Swalen and Pierce.[6] A program which has been written for this purpose is available from the authors on request.

Table 1. Comparison of the eigenvalues for the energy matrices of 5×5 and 6×6[a]

II	L	J_0	J	K	M	$K2$	$W(k2)$	$W(k2)$
1	9	5	5	5	5	1	29.24844	29.24844
1	9	5	6	5	5	2	41.46239	41.46239
1	9	5	7	5	5	3	55.59698	55.59698
1	9	5	8	5	5	4	71.68682	71.68682
1	9	5	9	5	5	5	89.75537	89.74968
1	9	5	10	5	5	6		109.8012

a) The first and second columns show those eigenvalues obtained for the ground state (II=1) and under an applied electric field of $V(L=9)=28.1$ kV/cm. The last two columns show the eigenvalues of the energy matrices of 5×5 and 6×6 respectively.

In the present calculation, we truncated all the matrices into 5×5, whose eigenvalues are classified by J_0, J_1, J_2, J_3, and J_4, J_0 being the lowest. However, as is shown in Table 1, the truncation of the matrices into 5×5 will remain a sufficiently good approximation for at least the lower four states from J_0 to J_3 unless extremely high fields are achieved. Table 1 shows the comparison of each eigenvalue of the 5×5 and 6×6 matrices for the states of $J_0=5$, $K=5$, and $M=5$ at an applied field of $V(9)=28$ kV/cm.

Table 2. Rotational sub-states J_{KM} calculated in the present work[a]

J_0	Rotational sub-states
0	0_{00}, 1_{00}, 2_{00}, 3_{00} ;
1	1_{01}, 2_{01}, 3_{01}, 4_{01} ; 1_{11}, 2_{11}, 3_{11}, 4_{11} ; 1_{1-1},2_{1-1},3_{1-1},4_{1-1};
2	2_{02}, 3_{02}, 4_{02}, 5_{02} ; 2_{12}, 3_{12}, 4_{12}, 5_{12} ; 2_{22}, 3_{22}, 4_{22}, 5_{22} ; 2_{1-2},3_{1-2},4_{1-2},5_{1-2}; 2_{2-2},3_{2-2},4_{2-2},5_{2-2};
3	3_{03}, 4_{03}, 5_{03}, 6_{03} ; 3_{13}, 4_{13}, 5_{13}, 6_{13} ; 3_{23}, 4_{23}, 5_{23}, 6_{23} ; 3_{33}, 4_{33}, 5_{33}, 6_{33} ; 3_{1-3},4_{1-3},5_{1-3},6_{1-3}; 3_{2-3},4_{2-3},5_{2-3},6_{2-3}; 3_{3-3},4_{3-3},5_{3-3},6_{3-3};

a) The energy matrices are symmetric for K and M. Therefore, the eigenvalues for $J_{\pm K\pm M}$ and $J_{\pm M\pm K}$ are the same, but the state energies of Eq. 1 are different for $|K| \neq |M|$. In the table the states of $J_{\pm M\pm K}$ and also of higher J_0 values than $J_0=3$ are not written because the space is limited, though we have calculated all the states through $J_0=9$.

In the case of $J_0=5$, the present truncation limits the states of $K=5$ and $M=5$ to the states of $J=5$ to 8. The highest state 9_{55}, (in the notation of J_{KM}), of the 5×5 matrix has been omitted because the approximation obtained is not good enough compared with that for lower states, as is shown in Table 1. Accordingly, if we take the energy matrices to be of definite dimensions, we will inevitably get only limited information for each set of K and M, as is shown in Table 2. Table 2 shows the rotational sub-states of J_{KM} calculated by the present method, but the states of $J_{\pm M\pm K}$ and J_0 values higher than $J_0=3$ are not shown.

The eigenfunctions corresponding to each eigenvalue have been obtained by solving the simultaneous equations derived from Eq. 3 and by using the normalization conditions. In the present approximation, the general form of the eigenfunctions of a symmetric-top molecule

under the Stark effect is written as

$$\Psi(\mathrm{II}, J_0^{KM}) = T(\mathrm{II}, 1, 1)\times\phi(J_0^{KM}) + T(\mathrm{II}, 2, 1)\times\phi(J_1^{KM}) + \cdots + T(\mathrm{II}, 5, 1)\times\phi(J_4^{KM}), \quad (7)$$

where the superscript in J^{KM} denotes a state that has a definite K and M, and $T(\mathrm{II}, \xi+1, \eta+1)$, the coefficients of the symmetric-top bases, $\phi(J_\xi^{KM})$, in $\Psi(\mathrm{II}, J_\eta^{KM})$.

The transition moment, TM, of a rotational sub-band associated with an electronic transition is, then, given by

$$TM = \int\Psi(1, J_{\eta''}^{K''M''})\times\phi_{Fg}\times\Psi(2, J_{\eta'}^{K'M'})\times d\tau = \sum_{\xi'',\xi'} T(1, \xi''+1, \eta''+1)\times T(2, \xi'+1, \eta'+1) \times\int\underline{\phi(J_{\xi''}^{K''M''})\times\phi_{Fg}\times\phi(J_{\xi'}^{K'M'})\times d\tau}, \quad (8)$$

where ϕ_{Fg} are the direction cosines between space-fixed F and molecule-fixed g coordinate axes and where $''$ and $'$ refer to the ground and excited states respectively.

The transition intensity, I, is written as

$$I = |TM|^2\times\exp\{-E(1, J'', K'', M'')/kT\}. \quad (9)$$

In Figs. 1—4 the transition intensities have been calculated with Eqs. 8 and 9, although the matrix element associated with the direction consine, the integral underlined in Eq. 8, is taken from the table given by Allen and Cross.[7]

Results and Discussion

To carry out the numerical calculation with the program stated in the previous section, it is necessary to know the rotational constants of the ground and excited states of a symmetric-top molecule.

In the previous experimental work,[8] we studied the Stark effect on the 3390 Å band of formaldehyde. Several reports[1] have also been given on the same problem of this molecule. In this calculation we shall take the rotational constants of formaldehyde given in Table 3. The following discussion will be mainly concerned with the Stark effect on the spectrum of formaldehyde.

Table 3. Rotational constants of H_2CO[a]

States	a	b	c
$^1A''$	8.7517	1.1245	1.0123
$^1A_1$	9.4053	1.2953	1.1342

a) Taken from "Molecular Spectra and Molecular Structure," III, ed by G. Herzberg, Van Nostrand Reinhold Company (1966), p. 612.

Strictly, formaldehyde is an asymmetric-top molecule, but it is very close to a symmetric-top one, the two larger moments of inertia being nearly equal and much greater than the moment of inertia around the C=O axis. When the value of K is not too small, the rotational structure of the 3390 Å band is almost the same as that of a perpendicular band of a symmetric-top molecule* whose rotational constants are taken as $A=a$, $B=(b+c)/2$ at both states related to the transition, where a, b, and c are those of formaldehyde.

For the perpendicular transition of a symmetric-top, the selection rules are $\Delta K=\pm1$ and $\Delta J=0$ and ±1. The transitions are designated as ^{r}R, ^{r}P, and ^{r}Q for $\Delta K=+1$, and ^{p}R, ^{p}P, and ^{p}Q for $\Delta K=-1$. In the series of sub-bands with $\Delta K=+1$, the ^{r}R branches are much stronger than the ^{r}Q branches, while the ^{r}P branches are too weak to be observed. In the series with $\Delta K=-1$, the situation is reversed, the ^{p}P and ^{p}Q branches being observed, while the ^{p}R branches are absent.

In the present work we have calculated the transition energies and intensities for all possible transitions among the Stark components of the rotational sub-branches shown in Table 2. However, it is impossible to show all of them in our limited space. Thus, it will be more instructive to choose the intense branches in a zero field, such as ^{r}R, ^{r}Q, ^{p}P, and ^{p}Q, and to show how the band splittings and shapes of these branches vary with the increase in the electric field.

The results of our calculation are shown in Figs. 1—4. Figures 1 and 2 show the field dependence of the Stark splittings of the ^{r}R 5(5) and ^{p}P 5(5) sub-branches of

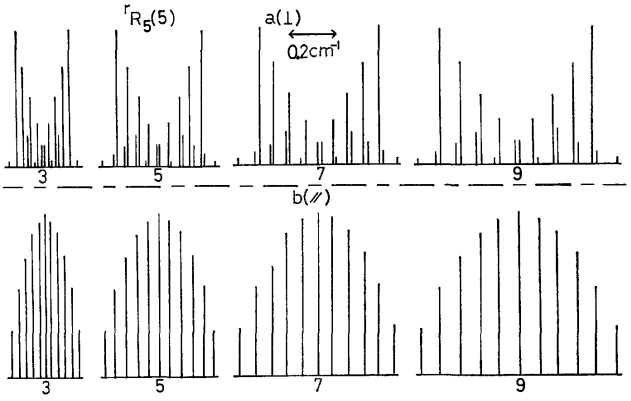

Fig. 1. The Stark splitting of ^{r}R 5(5) branch and its change with field strengths. Throughout Figs. 1 to 4 (a) and (b) correspond to the absorption with perpendicular and parallel polarizations to the direction of the applied field, and $\mu(2)=1.44$ D is assumed. The numbers written under each figure mean the values of the field strength $10\times\mu(1)\times V(L)/B(1)$.

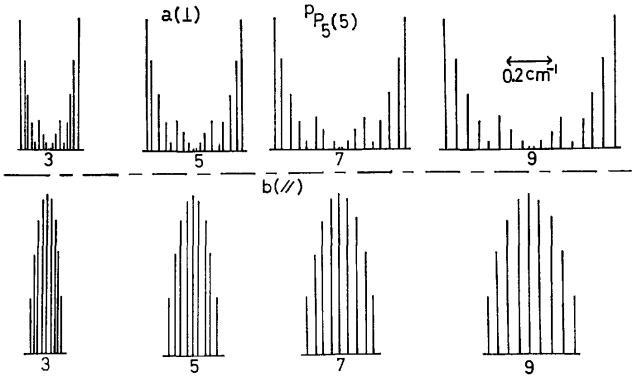

Fig. 2. The Stark splitting of ^{p}P 5(5) branch and its change with field strengths.

* For a slightly asymmetric-top, the asymmetric splitting is, in general, unobservably small for the state with $K>3$.

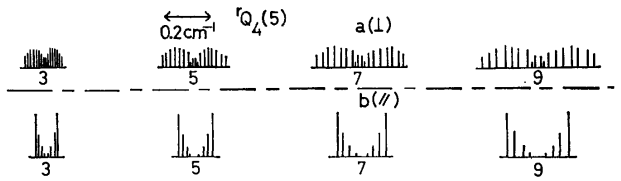

Fig. 3. The Stark splitting of ^{r}Q 4(5) branch and its change with field strengths.

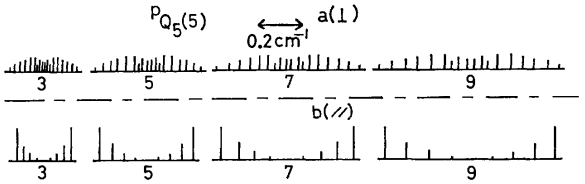

Fig. 4. The Stark splitting of ^{p}Q 5(5) branch and its change with field strengths.

the 3390 Å absorption band for the light polarized perpendicular and parallel respectively to the field direction. Here, to show explicitly the lower-state quantum numbers of the ^{r}R and ^{p}P transitions, the notation $K''(J'')$ has been inserted after the branch notations. Figures 3 and 4 also show the field dependence of the Stark splittings for the ^{r}Q 4(5) and ^{p}Q 5 (5) sub-branches under the same conditions as in Figs. 1 and 2.

Table 4. Intensity criteria of the profiles of incompletely resolved Stark patterns

	$\Delta J=-1$	$\Delta J=0$	$\Delta J=+1$
$\Delta M=0$ (parallel polarization)	broadening	doublet	broadening
$\Delta M=\pm 1$ (perpendicular polarization)	doublet	broadening	doublet

Throughout Figs. 1—4 the general features of each band are in agreement with those suggested by the criteria based on the intensity rule shown in Table 4. Certainly, the envelopes of the ^{r}R and ^{p}P absorption lines in the perpendicular spectra seem to show a doublet splitting, while those for the parallel spectra seem to show line-broadenings. However, it must be noted that the detailed features of these spectra are rather different from those obtained by the usual perturbation theory, especially for the ^{r}Q and ^{p}Q branches in the perpendicular spectra shown in Figs. 3 and 4.

Figure 5 shows how the overall splittings $\Delta\nu$ of the ^{p}P 5(5) branch in the perpendicular spectra vary with the increase in the electric field. There, we can see a linear relation between the overall splittings, $\Delta\nu$, and the field strengths. This linear relation indicates the validity of the usual perturbation theory, which we shall consider in our later discussion of the same problem in other branches.

The calculated spectra shown in Figs. 1—4 are obtained by assuming the dipole moments in the

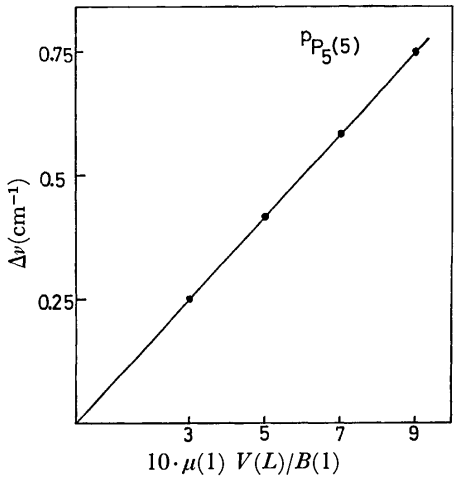

Fig. 5. The linear relation between the overall splittings of ^{p}P 5(5) and the field strengths. $10\times\mu(1)\times V(9)/B(1)=9$ corresponds to a field strength 28.1 kV/cm, and $\mu(2)=1.44$ D is assumed.

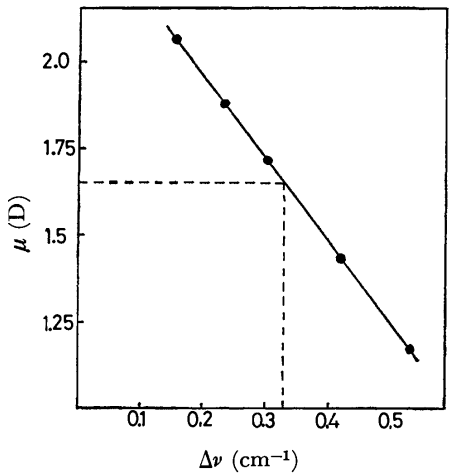

Fig. 6. The change of the overall Stark splitting of ^{p}P 5(5) branch with various assumed dipole moments of the excited state under a constant electric field 15.6 kV/cm. The dotted line is drawn to determine the dipole moment of the excited state corresponding to the observed doublet splitting of HCHO spectrum under the same field strength.

electronic ground and excited states to be 2.34[9] and 1.44 D respectively. Figure 6 shows how the overall splitting, $\Delta\nu$, of ^{p}P 5(5) varies when only the dipole moment of the molecule in the electronic excited state is changed, while other quantities, such as the dipole moment in the ground state and the applied field strength, keep constant. In this figure we see that, as the value of the dipole moment in the excited state becomes smaller compared with that in the ground state, the overall splitting becomes larger.

The dipole moment of the excited state can be determined from Fig. 6 if the overall splittings $\Delta\nu$ have been established experimentally. However, it must be noted that the available data on the overall splittings have been obtained from moderately-high-resolution spectra, that is, from a blended doublet splitting, but

not from well-resolved splittings such as were those in Figs. 1—4.

Before making use of the experimental overall splitting values, it will be useful to know how to get a blended doublet pattern from the resolved splitting, or *vice versa*. For this purpose, we have assumed a Gaussian distribution with a half-band width of 0.1 cm^{-1} for each resolved splitting line.**

Naturally the band shapes obtained through such blending depend not only on the type of branch, but also on the magnitude of the assumed excited state dipole moment and on the applied fields. We have obtained a factor of 1.13 to be multiplied for the transformation from an observed blended doublet to a resolved overall splitting, especially for the case of the ^{P}P 5(5) branch under the same conditions as those of our experiment.

The value on the abscissa shown by a dotted line in Fig. 6 shows the $\Delta\nu$ recalculated from the observed doublet splitting with the above factor. The intersection of the dotted line with the ordinate gives the value of the dipole moment of the excited state obtained by this calculation.

The value of 1.65 D obtained here for the excited-state dipole moment is comparable with the 1.61 D obtained when the first-order perturbation theory (also *cf.* Ref. 1a) is applied to our experimental results. It should be noted that there is a little discrepancy between the dipole moment obtained by the first-order perturbation theory and that obtained in the present work, because the present calculation includes implicitly higher-order perturbation terms together with the usual first-order perturbation theory.

The calculated μ value is, of course, obtained from the experimental correspondence, as has been stated above. The experimental value of the Stark splitting has been obtained from the spectra observed by the use of a newly designed Fabry-Perot interferometer spectroscope,

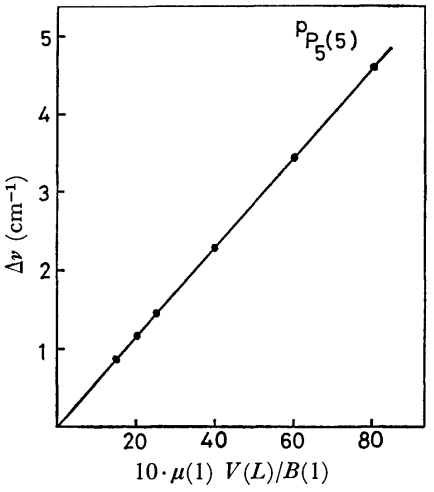

Fig. 7. The linear relation between the overall splittings of ^{P}P 5(5) and the field strengths over 30 kV/cm. The abscissa shows the field strengths $10\times\mu(1)\times V(L)/B(1)$, and $\mu(2)=1.75$ D is assumed.

** The value of 0.1 cm^{-1} was taken from the observation for half-band widths in a field-free spectrum.

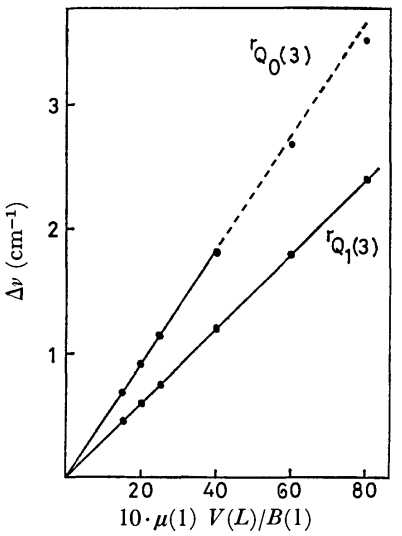

Fig. 8. The change of the overall Stark splittings of ^{r}Q 0(3) and ^{r}Q 1(3) branches with field strengths.

whose details have previously been described.[8,10] The Stark cell is a parallel-plate condenser, the two brass plates (100 cm long, 5 cm wide, 0.7 cm thick) being separated (0.5 cm) by Teflon spacers. The overall errors of our experimental work are within 5%. The value of 1.65 D obtained here for the $n\rightarrow\pi^*$ excited state of formaldehyde is, then, in good agreement with the other data: 1.56 ± 0.1 D,[1a] 1.67 ± 0.15 D (Method I), and 1.4 ± 0.1 D (Method II).[1b]

Let us return to the problem of the linear relation between the overall splitting of ^{P}P 5(5) and the applied field strength observed in Fig. 5, where applied fields are varied below 30 kV/cm. In Fig. 7 it should be noted that the linear relation holds up to such a high field strength as 200 kV/cm or more. Certainly this seems to reflect the validity of the usual first-order perturbation theory in such a high field. However, it is certain that the linear relation is also dependent on the type of branch. In Fig. 8 the same relation is shown for ^{r}Q 0(3) and ^{r}Q 1(3).*** Especially for the ^{r}Q 0(3) branch, we can observe a noticeable departure from the linear relation around 100 kV/cm, while the ^{r}Q 1(3) branch still shows a linear field dependence. However, as for the band shape of the latter branch as well as of the former, the symmetric pattern at low fields changes to an asymmetric one even at rather small field strengths, and presents a quite different appearance around 200 kV/cm, as is shown in Fig. 9.

It may be considered that such characteristic behavior of the ^{r}Q 0(3) and ^{r}Q 1(3) branches clearly shows the existence of higher-order interactions, even at rather low field strengths.

At least under field strengths below 100 kV/cm, and so long as the magnitude of the overall splittings is in question, there seems to be no serious disagreement between the first-order perturbation theory and the

*** These branches with $K<3$ should show a large asymmetric effect in the spectrum of HCHO, and so here they were only chosen as prototypes of such bands in a symmetric-top molecule.

Table 5. The intensity enhancement of the forbidden band $1''_{01}$ to $1'_{01}$ in a zero-field limit[a)]

Field strength	0.1	0.3	0.5	0.7	0.9	1.5	2.0	2.5	4.0	6.0	8.0
Intensity	0.0001	0.0006	0.0017	0.0035	0.0057	0.0181	0.0310	0.0463	0.0999	0.1735	0.2377

a) As the field strength we used the value of $\mu(1)V/B(1)$. The intensities at the field strengths from 0.1 to 0.9 are those obtained under the assumption of $\mu(2)=1.44$ D, but the others were obtained under the assumption of $\mu(2)=1.75$ D.

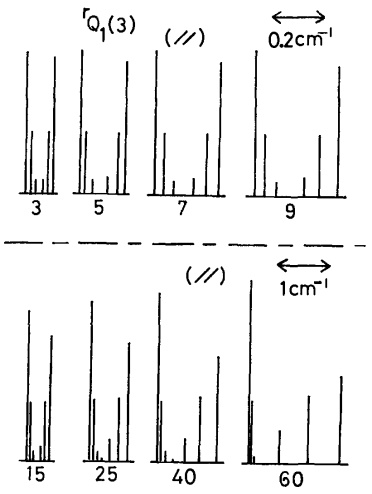

Fig. 9. The Stark splitting of ^{r}Q 1(3) branch and its change with field strengths.

present treatment, regardless of the type of branch. However, as for the band shapes or the band structure, it should be noted that a serious discrepancy may occur depending on types of the branches. This is especially remarkable for the branches with small J values and with $K<J$.

Lastly, we shall discuss the intensity enhancement of the forbidden branches of a symmetric top in a zero field. Table 5 shows the intensities of the transition from the $1''_{01}$ to the $1'_{01}$ rotational sub-branch. This transition is, of course, a forbidden one† due to the selection rule of $\Delta J=\pm 1$ for $K=0$ of a symmetric-top in a zero field. From the table we can see that the intensity of the transition is appreciable at a field strength of 30 kV/cm, and that it increases with a quadratic dependence on the field strengths. With a further increase in the field strengths, the intensity increases more and more, until beyond 100 kV/cm it is no longer distinguishable from that of the allowed transition and also shows an appreciable deviation from the quadratic-field dependence.

Conclusion

By way of conclusion, we may summarize the present work as follows:

(1) By the direct diagonalization of the energy matrices of a symmetric top under an external electric field, we have calculated the Stark splittings and intensities of the rotational sub-branches associated with the 3390 Å band of HCHO. For some selected branches we have given the detailed band structures, which can, it is hoped, be used as model spectra of the Stark splittings in very-high-resolution spectroscopy.

(2) Below 100 kV/cm, the overall Stark splittings are dependent linearly on the field strength, regardless of the branch type. Over 100 kV/cm the deviation from the linear-field dependence becomes appreciable, depending on the branch type.

(3) The change from a symmetric to an asymmetric appearance of the band shapes of a certain band occurs even below 30 kV/cm, and becomes appreciable with a further increase in the field strength. The effects depending on the branch types stated in (2) and (3) are especially remarkable for the branches with small J values and with $K<J$.

(4) Between the assumed dipole moments of the excited state and the overall splitting of the ^{p}P 5(5) branch, there exists a linear relation at field strengths below 100 kV/cm. From this relation, the value of 1.65 D has been determined for the dipole moment of the first excited $n\rightarrow\pi^*$ state of HCHO.

(5) The intensity enhancement of the forbidden bands of a symmetric-top molecule in a zero field shows a quadratic dependence on the applied field strength below 100 kV/cm, but comes to show an appreciable deviation from the quadratic-field dependence over 100 kV/cm.

The numerical calculations have been carried out with an NEAC 2200-700 electronic computer at Tohoku University.

† In this work we carried out the calculations for both parallel- and perpendicular-type bands of a symmetric-top. The transition from $1''_{01}$ to $1'_{01}$ is the forbidden branch ^{q}Q 0(1) of a parallel-type band.

Isomerization of *cis*-2-Butene Caused by Electronically-excited Sulfur Dioxide ($^3B_1$) Adsorbed on Porous Vycor Glass

Kiyoshi Otsuka, Masaki Fukaya, and Akira Morikawa

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 14, 1977)

The *cis-trans* isomerization of *cis*-2-butene caused by electronically-excited sulfur dioxide has been studied at the gas-solid interface of porous Vycor glass. All of the quantum yields for the isomerization obtained gave values larger than ≈30. Infrared studies show that the product on the glass is the polysulfone formed through the copolymerization of sulfur dioxide and *cis*-2-butene. These results and the kinetic data for the isomerization can be explained satisfactorily by the proposed mechanism in which the isomerization occurs through the addition and elimination of 2-butene molecules at the terminal of the polysulfone formed on the glass; the copolymerization is initiated by an electronically-excited SO_2 ($^3B_1$) state.

The photochemistry of sulfur dioxide is of special interest to the scientist who is concerned with the rates and mechanisms for the removal of sulfur dioxide in sunlight-irradiated atmospheres. There is substantial evidence that the harmful effect of sulfur dioxide on health is enhanced when there are significant levels of suspended particulates in polluted atmospheres.[1] This leads to a consideration of the effect of suspended particulates on photochemical reactions involving sulfur dioxide, through excitation due to the absorption of sunlight in the first allowed absorption band ($SO_2(^1B_1) \leftarrow SO_2(\tilde{X}, {}^1A_1)$), which extends from 340 to 240 nm.

The chemical reactions between photochemically-excited sulfur dioxide and olefin hydrocarbons have been studied by a number of investigators.[2-9] All these studies, however, have been limited to homogeneous systems of gas or liquid phase, and there appear to be no published studies on these reactions at the gas-solid interface.

Recently, Otsuka *et al.* have reported that sulfur dioxide adsorbed on porous Vycor glass catalyzes the geometrical isomerization of 2-butenes.[10] The rate of this reaction is enhanced to a great extent by ultraviolet irradiation. Hence, in this report, the isomerization of *cis*-2-butene induced by electronically-excited sulfur dioxide over porous Vycor glass is described in detail. This system can be regarded as a very basic model of the system which involves the atmospheric reaction of sulfur dioxide with olefins over solid particulates in sunlight-irradiated atmospheres. Porous Vycor glass was chosen as the solid adsorbent because of its large surface area and high transparency to ultraviolet radiation down to wavelengths of about 210 nm, which is advantageous for ultraviolet spectral measurements of the adsorbed molecules and for a kinetic investigation of the photo-excited adsorbed molecules.

Experimental

The porous Vycor glass (Corning No. 7930, 30×8×1 mm plate, surface area=149 m^2/g), sulfur dioxide, *cis*-2-butene and apparatus used were described previously.[10]

Procedure. Before each run, the porous Vycor glass (0.50 g) placed in the reactor was calcined at 600 °C in dried oxygen and then degassed for 2 h in a vacuum down to about 8×10^{-5} Torr at the same temperature. Following the introduction of sulfur dioxide into the reactor, which was maintained at a given temperature, the reaction was initiated by irradiating the glass immediately after introducing the *cis*-2-butene and circulating the sulfur dioxide-*cis*-2-butene gas mixture through the reactor. A small amount of the reacting gases was periodically collected for analysis by gas chromatography, and the amount of *trans*-2-butene produced was determined. The ultraviolet light generated by a Toshiba H-400-P medium-pressure mercury lamp was filtered upon passage through 1 cm of water, a Corning 7-54 glass filter and either a Toshiba UV-29 (transparent to 270—410 nm) or a UV-31 (290—410 nm) glass filter. The temperature of the reactor was controlled to within ±0.2 °C using the air or water bath shown in Fig. 1.

Estimation of Absorbed Light Intensities and Quantum Yields. The emission intensity distribution of the mercury lamp (from Toshiba Technical Data No. 21-HM-11) and the transmission of the combined filters provided the energy distribution of the incident light, $I_0(\lambda)$. The relative light intensity absorbed by the sulfur dioxide adsorbed on the glass, I_r, was calculated using the equation,

$$I_r = \int_0^\infty I_0(\lambda)\left\{1-\frac{T(\lambda)}{100}\right\}\left\{\frac{D_{SO_2}(\lambda)}{D_{SO_2}(\lambda)+D_G(\lambda)}\right\}d(\lambda),$$

where $D_{SO_2}(\lambda)$ and $D_G(\lambda)$ are the optical densities of the adsorbed sulfur dioxide and of the porous glass, at wavelength λ, respectively,[11] and $T(\lambda)$ is the transmittance of the glass–sulfur dioxide system.

A quantitative determination of the incident light intensity at the cell face was made employing potassium ferrioxalate

actinometry, and the absolute light intensity absorbed by sulfur dioxide, I_a, was calculated using the equation,

$$I_a = I_t I_r \Big/ \int_0^\infty I_0(\lambda)\mathrm{d}(\lambda),$$

where I_t is the incident light intensity at the cell face. The absolute quantum yield of the isomerization of *cis*-2-butene is given by $R_{c\to t}/I_a$, where $R_{c\to t}$ is the rate of geometrical isomerization.

Results

The cis-trans *Isomerization of* cis-*2-Butene.* The light of wavelength longer than 270 nm applied in this study induces no reaction of *cis*-2-butene in the absence of sulfur dioxide. If sulfur dioxide is present on the porous Vycor glass, selective *cis-trans* isomerization occurs thermally.[10] The initial rate of this thermal isomerization, $R^T_{c\to t}$, or the rate of *trans*-2-butene formation, is plotted against the amount of adsorbed sulfur dioxide, V_{SO_2}, in Fig. 2, where the experiments were carried out at 25 °C at an initial pressure of *cis*-2-butene of 150 Torr.

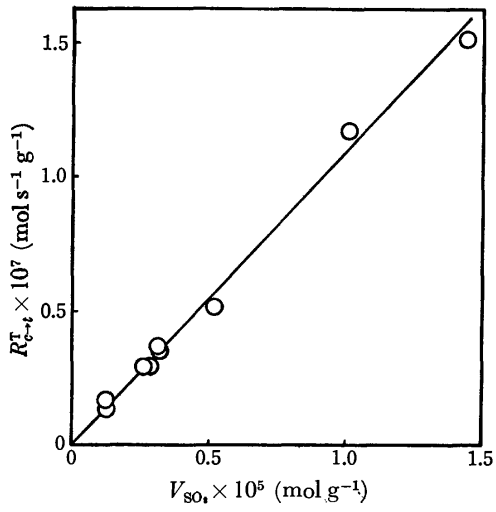

Fig. 2. Plot of the rate of thermal isomerization, $R^T_{c\to t}$, *vs.* the amount of sulfur dioxide adsorbed, V_{SO_2}, at $P_{cis\text{-but}}=105$ Torr; the reactions were carried out at 25 °C.

Ultraviolet irradiation of the glass, onto which sulfur dioxide had been adsorbed, markedly accelerated the rate of isomerization. The rate of photo-induced isomerization, $R^P_{c\to t}$, calculated from the difference between the rate measured under irradiation and $R^T_{c\to t}$, was obtained for various *cis*-2-butene pressures and amounts of adsorbed sulfur dioxide. Figure 3 shows the plot of $R^P_{c\to t}$ as a function of the *cis*-2-butene pressure. $R^P_{c\to t}$ does not depend on the pressure for pressures higher than 100 Torr. The effect of V_{SO_2} on $R^P_{c\to t}$ is indicated in Fig. 4. It has been confirmed in advance that the sulfur dioxide preadsorbed on the glass does not desorb after the addition of *cis*-2-butene for the experimental conditions under which the data in Figs. 3 and 4 were obtained.

The relative quantum yields of isomerization for the data in Fig. 4 are plotted against the amount of adsorbed

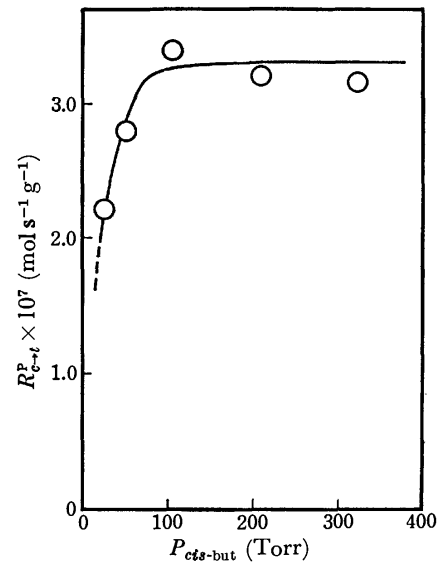

Fig. 3. Plot of the rate of photo-induced isomerization, $R^P_{c\to t}$, *vs.* the pressure of *cis*-2-butene, $P_{cis\text{-but}}$. The filters were Corning 7-54 and UV-31 filters. The amount of sulfur dioxide adsorbed is 2.5×10^{-6} mol/g; the reactions were carried out at 25 °C.

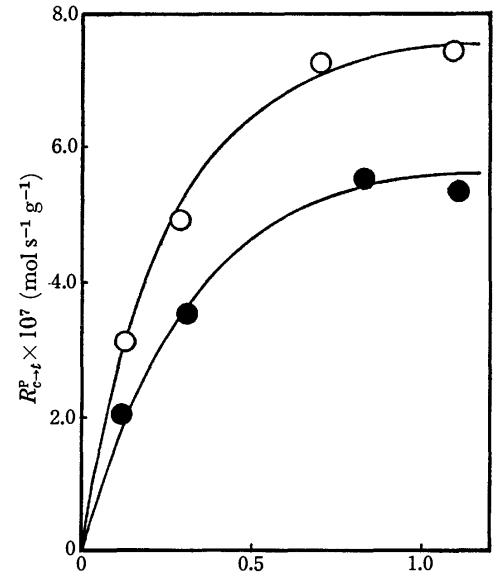

Fig. 4. Plot of $R^P_{c\to t}$ *vs.* V_{SO_2}, at $P_{cis\text{-but}}=105$ Torr and at 25 °C. Filters: (○); Corning 7-54 and UV-29, and (●); Corning 7-54 and UV-31.

sulfur dioxide in Fig. 5. It can be seen that the quantum yield decreases with the amount of sulfur dioxide adsorbed. The estimated absolute quantum yield, $R^P_{c\to t}/I_a$, for the lowest value in Fig. 5 is about 30. This high quantum yield suggests that the reaction proceeds *via* a chain process.

The addition of a small amount of nitric oxide (0.77×10^{-5} mol) to a system of sulfur dioxide (0.55×10^{-5} mol) and *cis*-2-butene (1.44×10^{-3} mol) completely poisons the photo-induced isomerization, suggesting that the reaction intermediate is a radical.

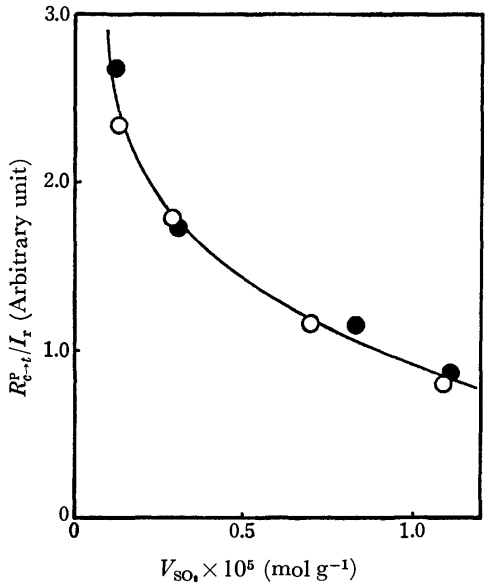

Fig. 5. Plot of the relative quantum yield of the photo-induced isomerization, $R^p_{c\to t}/I_r$, as a function of the amount of adsorbed sulfur dioxide. Filters: (○); Corning 7-54 and UV-29, and (●); Corning 7-54 and UV-31.

The Copolymerization of Sulfur Dioxide with cis-*2-Butene.* All the experiments described in this section were carried out with a sulfur-dioxide concentration (2.1×10^{-3} mol) compared to that applied in the preceding section ($<1.3\times 10^{-5}$ mol).

After a photo-induced geometrical isomerization for 150 min at 0 °C, the product on the glass was extracted with dioxane. The solution was dropped onto a KBr film and the dioxane solvent was evaporated. After several repetitions of this procedure, the infrared spectrum of the film was recorded (Fig. 6). This spectrum exhibits the two characteristic absorption bands of the polysulfone from *cis*-2-butene, one at 1300 cm^{-1} and the other at 1105—1140 cm^{-1} due to the symmetrical and asymmetrical stretching vibrations of the sulfone group, respectively.[12]

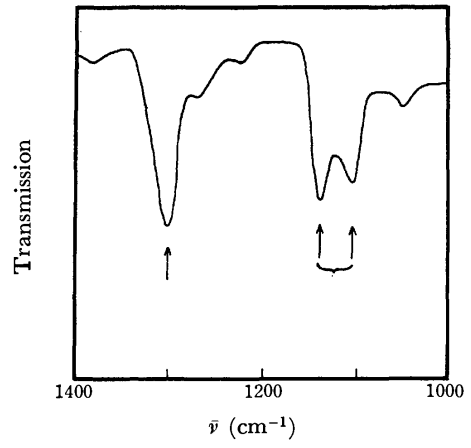

Fig. 6. Infrared spectrum of the polysulfone formed on the glass from *cis*-2-butene and sulfur dioxide under irradiation. The reaction was carried out at 0 °C under initial pressures of *cis*-2-butene and sulfur dioxide of 105 Torr (2.10×10^{-3} mol).

During the progress of the isomerization, the pressure decrease due to the reaction of SO_2 with *cis*-2-butene on the glass was followed by reading a glass Bourdon gauge at different temperatures. After the initial rapid adsorption, no reactants were consummed in the gas phase when the temperature was higher than ≈40 °C. However, a considerable consumption of gas was observed at low temperatures (<20 °C). Without irradiation, no gas consumption was detected after the initial adsorption for all temperatures in the range from 0 to 60 °C. The average rate of gas consumption under irradiation for times of 10—30 min, $\Delta V_g/\Delta t$, and the rate of photo-induced isomerization are plotted as a function of temperature in Fig. 7. The rate of isomerization has a maximum value at just the temperature for which the consumption of reactants becomes negligible (≈30 °C). It was shown that at a low sulfur-dioxide concentration (0.15×10^{-5} mol) the rate of isomerization decreases monotonically with a rise in temperature from 0 to 70 °C.

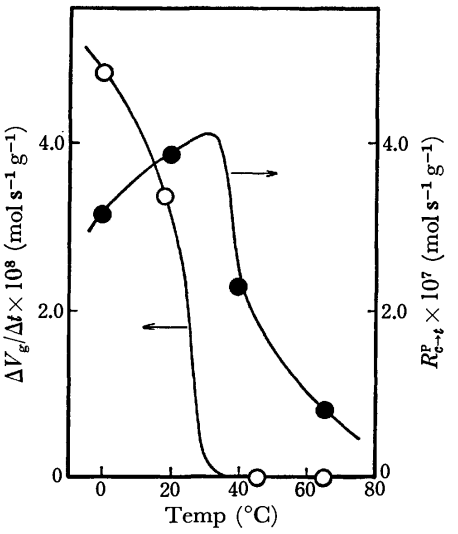

Fig. 7. Temperature effects on the rate of gas consumption, $\Delta V_g/\Delta t$, and on that of photo-induced isomerization, $R^p_{c\to t}$, (○); $\Delta V_g/\Delta t$ and (●); $R^p_{c\to t}$. The initial pressures of *cis*-2-butene and sulfur dioxide were 105 Torr.

Discussion

Many studies of the gas-phase photolysis of sulfur dioxide–olefin hydrocarbon mixtures have suggested that electronically-excited sulfur dioxide sensitizes the geometrical isomerization of the olefins.[4,6–9,13–17] Furthermore, it has been observed that the $^3B_1$ state of sulfur dioxide is the only excited electronic state of sulfur dioxide participating in the geometrical isomerization of 2-butenes,[6,8,9] 1,2-dichloroethylenes,[13] 1,2-difluoroethylenes,[14,15] and 2-pentenes.[16,17] In these gas-phase studies, however, the absolute quantum yield for isomerization never exceeds unity. The high quantum yields (>30) obtained in the present work cannot be explained by means of the mechanism proposed for the photosensitized isomerization in the gas phase.

Bristow and Dainton first observed that irradiated mixtures of *cis*- or *trans*-2-butene in liquid sulfur dioxide result in a fast *cis-trans* isomerization, in addition to the polysulfone formation *via* the copolymerization of SO_2 and 2-butene.[3] The formation of polysulfone over glass confirmed in the present work (Fig. 6) suggests that the isomerization at the gas-solid interface occurs *via* a mechanism similar to that proposed for the reaction in the liquid phase.[3]

Assuming $^3B_1$ is the only electronically-excited state of SO_2 initiating the copolymerization, the following mechanism is proposed:[3,10]

$$SO_2 + h\nu \xrightarrow{I_a} {}^1SO_2(^1B_1),$$

$$^1SO_2(^1B_1) + \textit{cis}\text{-2-butene} \longrightarrow {}^3SO_2(^3B_1) + \textit{cis}\text{-2-butene}, \quad (1)$$

$$\longrightarrow SO_2 + \textit{cis}\text{-2-butene}, \quad (2)$$

$$^3SO_2(^3B_1) + \textit{cis}\text{-2-butene} \longrightarrow P_s + P_b, \quad (3)$$

$$\longrightarrow SO_2 + \textit{trans}\text{- or }\textit{cis}\text{-2-butene}, \quad (4)$$

$$P_s + \textit{cis}\text{-2-butene} \longrightarrow P_b, \quad (5)$$

$$P_b + SO_2 \longrightarrow P_s, \quad (6)$$

$$P_b \longrightarrow P_s + \textit{trans}\text{-2-butene}, \quad (7)$$

$$\longrightarrow P_s + \textit{cis}\text{-2-butene}, \quad (8)$$

$$P_s \longrightarrow P_b + SO_2, \quad (9)$$

$$P_b \longrightarrow \text{stabilized}. \quad (10)$$

$$P_s \longrightarrow \text{stabilized}, \quad (11)$$

where the mechanism is considered for a low isomerization conversion rate and a low sulfur-dioxide concentration compared to those for *cis*-2-butene. All species appearing in the above reactions are in the adsorbed layer. For low sulfur-dioxide concentrations the unimolecular decay of the $^1B_1$ and $^3B_1$ states of sulfur dioxide and the quenching of these states by ground-state sulfur dioxide molecules are unimportant[18,19] and have not been included in the above process. P_s and P_b represent the terminal group of active polysulfone ($P_s \rightarrow \dot{S}O_2CH(CH_3)CH(CH_3)\cdots\cdots SO_2CH(CH_3)\dot{C}H(CH_3) \leftarrow P_b$). The strong poisoning effect of nitric oxide must be due to the quenching of these terminal groups through a reaction with nitric oxide. The selective *cis-trans* isomerization occurs mainly through depropagation Steps 7 or 8 of the copolymerization since the contribution from Reaction 4 can be neglected because of the low quantum yield (<1.0).[8,9,15-17]

If the consumption of reactants during the isomerization is due to polysulfone formation, the results shown in Fig. 7 (open circles) indicate that the copolymerization of sulfur dioxide and *cis*-2-butene on the glass has a ceiling temperature around 30 °C. Above the ceiling temperature, the rates of the depropagation steps exceed those of the propagation steps and, thus, polymerization can no longer occur. The decrease in the rate of isomerization above the ceiling temperature (Fig. 7 closed circles) can reasonably be explained as a consequence of the decrease in the number of long-chain polysulfone sites necessary for the isomerization.

Dainton and Ivin have shown that the ceiling temperature for the polysulfone formation decreases with decreasing concentrations of comonomers.[22] The fact that, at low sulfur-dioxide concentrations, no maximum of the isomerization rate has been observed within the temperature range down to 0 °C, may be due to a shift of the ceiling temperature to a lower value below 0 °C.

According to the Reactions 1—11 indicated above, the rate of photo-induced isomerization can be described by Eq. i:

$$R^p_{c\rightarrow t} = I_a k_7 \left(\frac{k_1}{k_1+k_2}\right)\left(\frac{k_3}{k_3+k_4}\right) \times \left\{\frac{2(k_5[\textit{cis}\text{-2-but}]+k_9)+k_{11}}{k_{10}(k_5[\textit{cis}\text{-2-but}]+k_9+k_{11})+k_{11}(k_6[SO_2]+k_7+k_8)}\right\}, \quad \text{(i)}$$

where the concentrations for *cis*-2-butene and sulfur dioxide are those on the surface, and I_a is the light intensity absorbed by sulfur dioxide on the glass; we have neglected the contribution of photo-sensitized isomerization (Reaction 4). At high *cis*-2-butene pressures (>100 Torr), it has been shown that the rate of isomerization is independent of the pressure (Fig. 3). This must be attributed to saturation of the active site on the glass by the chemically-adsorbed *cis*-2-butene which is involved in propagation Step 5.[23]

We can rearrange Eq. i to Eq. ii in order to observe the effect of the adsorbed sulfur-dioxide concentration, thus,

$$I_a/R^p_{c\rightarrow t} = A + B[SO_2], \quad \text{(ii)}$$

where

$$A = \frac{(k_1+k_2)(k_3+k_4)}{k_1k_3k_7} \times \left\{\frac{k_{10}(k_5[\textit{cis}\text{-2-but}]+k_9+k_{11})+k_{11}(k_7+k_8)}{2(k_5[\textit{cis}\text{-2-but}]+k_9)+k_{11}}\right\}$$

and

$$B = \frac{(k_1+k_2)(k_3+k_4)}{k_1k_3k_7}\left\{\frac{k_6k_{11}}{2(k_5[\textit{cis}\text{-2-but}]+k_9)+k_{11}}\right\}.$$

At high *cis*-2-butene pressures (>100 Torr), A and B can be regarded as constant (Fig. 3). Using the data in

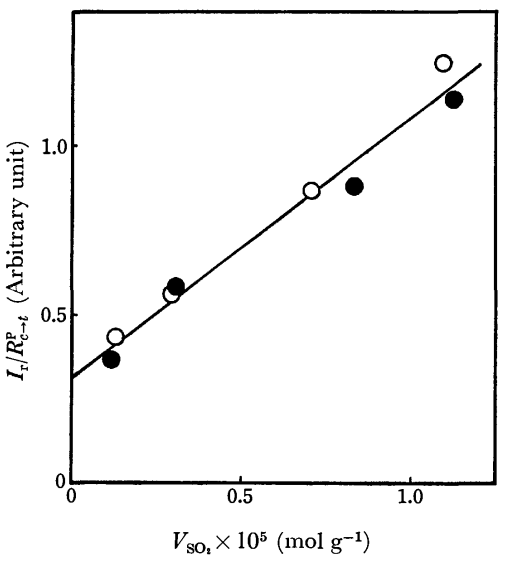

Fig. 8. Plot of $I_r/R^p_{c\rightarrow t}$ *vs.* V_{SO_2}. Filters: (○); Corning 7-54 and UV-29, (●); Corning 7-54 and UV-31.

Fig. 4, which were obtained in experiments carried out at a constant *cis*-2-butene pressure of 105 Torr, $I_r/R^p_{c\to t}$ is plotted against the amount of adsorbed sulfur dioxide in Fig. 8. A reasonably good linear relation between these variables supports the proposed process.

As described above, all the results and the kinetic data obtained in this work can be explained satisfactorily by the reaction mechanism in which the geometrical isomerization of *cis*-2-butene accompanies the copolymerization of sulfur dioxide with *cis*-2-butene, which is initiated by the electronically-excited $^3B_1$ state of sulfur dioxide.

11) The ultraviolet spectra of the sulfur dioxide-*cis*-2-butene system adsorbed on porous Vycor glass has been studied in detail in a preceding paper.[10] When sulfur dioxide coadsorbs with *cis*-2-butene, the absorbance for the first allowed transition, $SO_2(^1B_1)\leftarrow SO_2(\tilde{X}, {}^1A_1)$, is enhanced in the long wavelength region by the proximity of the π-donating *cis*-2-butene molecules. As a consequence of this, the threshold of the absorption band shifts to a longer wavelength of about 420 nm.

23) Adsorption experiments for *cis*-2-butene on porous Vycor glass have shown that a considerable increase in the amount of adsorption with increasing pressure, even in the range between 100 and 200 Torr. This is natural since most of the *cis*-2-butene on the glass may be physically adsorbed. The chemisorption of *cis*-2-butene occurs presumably at the Al^{3+} site, which is an impurity in the glass.[10]

Reactions of Isomeric Transition-Activated ^{80}Br in the $H^{80m}Br$–CH_4 System

Kenjiro KONDO and Masuo YAGI

Laboratory of Nuclear Science, Faculty of Science, Tohoku University, 1-Kanayama Tomizawa, Sendai 982

(Recieved April 15, 1977)

The reaction of isomeric transition-activated ^{80}Br was studied in the gaseous $H^{80m}Br$–CH_4($HBr/CH_4=0.1\pm 0.01$) system. $CH_3{}^{80}Br$, $CH_2{}^{80}BrBr$ and $CH^{80}BrBr_2$ were identified as the products, and their absolute yields were 1.60, 2.65, and 0.05%, respectively. The effects of Kr and Xe additives show that these products were produced only through kinetic-energy independent (thermal ionic) processes. The results are compared with those obtained in the $^{80m}BrBr$ (or $^{82m}BrBr$)–CH_4 system, in which the C–*Br formation proceeds mainly *via* kinetic-energy dependent processes, and the difference between them is explained on the basis of the cross sections for charge neutralization and capture collision complex formation of bromine ions as a function of the kinetic energies initially acquired by the ^{80}Br and ^{82}Br atoms. The persistent complex ion, $CH_4{}^{80}Br^+$, is considered to be a precursor of the product formations, and the formation of individual products is discussed on the basis of ion-molecule reactions of $CH_4{}^{80}Br^+$ with surrounding molecules. Furthermore, the effect of HCl and $CH_2{=}CH_2$ additives on the yield distribution were examined to elucidate the reaction mechanisms of the product formations.

The chemical effects associated with the nuclear transformations of bromine atoms in gaseous systems have been studied extensively,[1–10] and one of the most interesting subjects is to determine the relative importance of kinetic energy and charge in the recombination reactions involving recoiling bromine atoms.

So far the reactions of (n,γ)[1,2,4] and/or fission[11] activated bromine in gaseous CH_4 have been found to proceed principally through kinetic processes. Similary, it has been reported that the recoiling halogen atoms produced by the $^{19}F(\gamma,n)^{18}F$[12] and $^{40}Ar(\gamma,p)^{39}Cl$[13] reactions enter into organic combinations only through kinetic-energy dependent (hot) reactions as neutral atoms in a gaseous CH_4 system. It is conceivable that these recoiling atoms initially have positive charges. However, these experimental results indicate that the charge neutralization of positively-charged recoiling atoms proceeds fast and is nearly completed before the recoiling atom reaches the energy region causing hot reactions.

On the other hand, in the case of isomeric transitions (IT) of ^{80m}Br and ^{82m}Br, the initial high positive charge on the bromine atom, as a consequence of the Auger process following the isomeric transition, is partially neutralized by intra-molecular electron transfer, resulting in Coulombic repulsion. Therefore, the bromine atom can acquire appreciable kinetic energy. When $^{80m}BrBr$ is used as a source molecule, the kinetic energy of the ^{80}Br is calculated to be 40.3 eV[14] on the average, assuming that the original charge of the ^{80}Br is 8 and is equally divided between the bromine atoms. This value is fairly small compared with those for the other nuclear transformations stated above. It has been reported that, not only the kinetic energy, but also the positive charge plays a very important role in the reactions of ^{80}Br and/or ^{82}Br activated by isomeric transitions for the Br_2–CH_4 system.[3,7,15–17] These results indicate that some of the positively-charged bromine atoms lose their kinetic energies and have the opportunity to undergo ion-molecule reactions leading to C–*Br formation before charge neutralization occurs. The cross sections for charge neutralization and ion-molecule reactions depend largely on the kinetic energy of the ions. Thus, it is very interesting to estimate the organic yields due to the thermal ionic process on the basis of the kinetic energy of the charged bromine atom.

This is the record of an experiment of I.T.-activated ^{80}Br reactions with CH_4 using HBr as the source molecule. In this case, the kinetic energy of the ^{80}Br atoms is 0.75 eV on the average,[5] and therefore, this experiment is considered to be highly suited to evaluating the role of the charge and kinetic energy of the ^{80}Br atom on recombination reactions in the near-thermal energy region. The results were compared with those obtained from (n,γ) and IT experiments using Br_2,[1,2,10] and can be explained in terms of competition between charge-transfer and ion-molecule reactions involving bromine ions.

Furthermore, the formation mechanisms of individual products were examined by adding HCl and $CH_2{=}CH_2$ to the system. These are discussed on the basis of ion-molecule reactions involving the $^{80}Br^+$ ion.

Experimental

Materials. All gaseous reagents were used directly as supplied by Takachiho Chemical Co. without further purification. The nominal purities are 99.95% for Kr and CH_4, 99.9% for Xe, 99.8% for $CH_2{=}CH_2$, and 99.5% for HCl. The purities of all other reagents purchased from the Junsei Chemical Co., Ltd., were extremely high.

Preparation of $H^{80m}Br$. First, the $^{80m}Br_2$ molecules were obtained by the thermal decomposition of palladium bromide irradiated by bremsstrahlung, which was produced by the impact of 40—60 MeV electrons from the linear electron accerelator of Tohoku University on a Pt plate (2 mm thick). The bombardment was carried out for about 2 h at an average electron-beam intensity of 150 μA. The $^{80m}BrBr$ molecules thus obtained were introduced into a vessel containing red phosphorus and a small amount of distilled water. Then, the vessel was closed with a stopcock and the temperature of the vessel was increased to about room temperature. After completion of the Br_2 reaction, the $H^{80m}Br$ thus obtained was further purified by distillation through a P_2O_5 column and a Dry Ice trap for the sake of complete removal of trace amounts of unreacted species.

Sample Preparation. The amount of CH_4, HBr, and other additives required was measured with a mercury manometer, all reaction mixtures were sealed into cylindrical

pyrex glass ampoules with capacities of 50, 100, and 200 ml and fitted to the long neck of a capillary tube.

All these procedures were carried out using a vacuum line incorporating greaseless stopcocks and joints. The ratio of HBr to CH_4 and total pressure were maintained constant at 0.1 ± 0.01 and 660 ± 30 mmHg, respectively, throughout the series of addition experiments.

Extraction Procedures, Activity Measurements, and Yield Determinations. The reaction mixture was allowed to stand for more than 2 h in the dark at 40 °C to permit a ^{80m}Br–^{80}Br parent-daughter equilibrium to be established. Then, the tip of the ampoule was broken, and 4 ml of 0.5 N Na_2SO_3, 1 ml of 0.5 N KBr and 5 ml of CCl_4 were added to the ampoule which was cooled to liquid-nitrogen temperature. Care was taken so that these solutions did not come into direct contact with reactants deposited on the walls during the cooling of the ampoule. Then the temperature was increased to approximately −100 °C to exclude air liquefied in the ampoule. Then, radioactive bromine was extracted into the organic and inorganic layers by vigorous shaking. The organic layer was washed twice with distilled water. After the addition of carriers, such as CH_3Br, CH_2Br_2, CH_2BrCl, *etc.*, a portion of the organic fraction was submitted to gas chromatography and product analysis was carried out using a column (75 cm long, 3 mm in diameter) filled with 60—80 mesh celite 545, which was coated with silicone oil (20% in weight).

A fraction of each product was collected in a glass tube cooled in a Dry Ice–ethanol bath at the outlet of the column. The radioactive emissions from each product were measured with a NaI(Tl) scintillation counter, and the relative yields of the individual products were determined. Also the organic and inorganic fractions in a given quantity were pipetted into test tubes. The inorganic fraction was allowed to stand for more than 1.5 h to establish ^{80m}Br–^{80}Br equilibrium, and only the 0.618 MeV photopeak from ^{80}Br was counted for a period of about eight half-lifes of ^{80m}Br (4.38 h). No other radioactive contamination was observed in the organic fraction. The radioactivity measurements of the organic fractions were usually started about 7 min after extraction. The radioactivity measurements of these fractions was performed with a high-resolution Ge(Li) semiconductor detector (36 ml in volume) connected to a 4096-channel pulse-height analyzer.

The activities of both the inorganic and organic fractions were corrected for the separation time. The organic yields were determined as the percent ratio of the radioactivity of the organic fraction to the total radioactivity, and the individual product yields were obtained by simply multiplying the relative yield of each product by the organic yield. For several runs, the product yields were determined by the radio gas chromatographic technique adopted by Tachikawa and Kahara for the $^{80m}BrBr$–CH_4 system.[3] However, there was no difference in the yields for both methods.

The experimental error resulting from statistical fluctuations in the counting were approximately 7—15%. The experimental error due to inefficiencies in the extraction and collection of the products at the outlet of the gas chromatograph column were almost negligible.

Results

The bromine exchange reactions were first examined in the $H^{82}Br$–CH_3Br and/or CH_2Br_2 (HBr/CH_3Br (or CH_2Br_2) $=0.1\pm0.01$) systems at a constant pressure of 150 mmHg prior to the actual experiment. After storage in the dark for 2 h at 40 °C, the radioactivity of the organic fraction after extraction was less than 0.1% of the total activity. Furthermore, no dependence of the yields on the storage period of the reaction vessels was found for storage periods between 2 and 10 h.

From the radio gas chromatograms of the organic fractions, $CH_3{}^{80}Br$, $CH_2{}^{80}BrBr$, and $CHBr_2{}^{80}Br$ were identified as the products in the $H^{80m}Br$–CH_4 system. However, the $CHBr_3$ yields were very small and in most cases less than 0.1%. On the other hand, $CH_2{}^{80}BrCl$ and $CH_3CH^{80}BrCl$ for the system with the HCl additive and $CH_3CH_2{}^{80}Br$ for that with the $CH_2{=}CH_2$ additive were observed, in addition to $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$, respectively.

No pressure dependence of the organic and product yields was observed in the range from 100 to 1400 mmHg at a constant HBr/CH_4 ratio of 0.1 ± 0.01.

In order to differentiate the kinetic-energy dependent from the kinetic-energy independent (thermal ionic) yield for the $H^{80m}Br$–CH_4 system, Kr and Xe were added as moderators for ^{80}Br while the HBr/CH_4 ratio was maintained constant at 0.1 ± 0.01. The results are given in Table 1 and depicted graphically in Fig. 1. The $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ yileds were 1.60 and 2.65% for 0 mf of additives, respectively. The $CH_2{}^{80}BrBr$ yield was much greater than that for $CH_3{}^{80}Br$ over the entire additive concentration range, contrary to the results obtained from the IT-experiments of the $^{80m}Br_2$[1,10] and/or $^{82m}Br_2$[3,15]–CH_4 systems. No change in the yield distribution was observed for additive concentrations less than about 0.6 mf, while the $CH_2{}^{80}BrBr$ yiled showed a tendency to increase gradually at concentrations greater than 0.6 mf, as was observed for

the $H^{82m}Br$–CH_4[18] and $^{80m}BrBr$–CH_4[19] systems. However, the $CH_3{}^{80}Br$ yield decreased slightly at high additive concentrations.

The effect of the HCl additive on the yield distributions is shown in Fig. 2. The organic yield is almost constant for 0—0.6 mf of HCl, and the decrease in the $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ yileds nearly offset the increase in the $CH_2{}^{80}BrCl$ and $CH_3CH^{80}BrCl$ yields.

In addition, the effect of the CH_2=CH_2 additive on the yield distribution is shown in Fig. 3. From preliminary experiments using ^{77}Br-labeled HBr($t_{1/2}$=57 h for ^{77}Br) under the same experimental conditions, no addition reaction of HBr with CH_2=CH_2 was observed and therefore, this indicates that the yields are derived from reactions associated with the isomeric transition of ^{80m}Br. A sharp increase in the $CH_3CH_2{}^{80}Br$ yield was observed upon the addition of a small amount of CH_2=CH_2, and for concentrations above about 0.05 mf, the yield gradually increased. However, the addition of a small quantity of CH_2=CH_2 resulted in a sharp decrease in the $CH_2Br^{80}Br$ yield, and the $CH_3{}^{80}Br$ yields decreased relatively slowly with increasing CH_2=CH_2 concentration.

Discussion

Evaluation of the Yields via *Kinetic and Thermal Process.* Up to the present time, many investigations have been carried out on the reactions of bromine produced by a variety of nuclear transformations in gaseous systems, especially in order to evaluate the role of the charge and kinetic energy of the bromine atom in the recombination reactions. The most convenient way to differentiate an energetic reaction from a kinetic energy independent (thermal ionic) reaction is by the addition of an inert gas which can serve as an energy sink for the energetic Br atoms. Kr is the most effective moderator since the mass of Kr is almost equal to that of Br, and Kr is also found to have small cross sections for quenching excited species and for undergoing charge transfer with Br^+ ions due to its high ionization potential of 13.99 eV.[15] Therefore, if the yield decreases upon the addition of Kr, it must be due to the removal of the ^{80}Br kinetic energy, and the remainder, which is insensitive to the Kr additive, can be derived from thermal ionic reactions. The high electron affinity of Br^{+n} ($n\geq2$) suggests that the thermal ionic reaction concerns mostly the reaction involing the $^{80}Br^+$ ion.

As Fig. 1 shows, no change in the $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ yields was observed in the range from 0 to 0.6 mf of Kr and Xe. This indicates that both products are formed *via* thermal ionic reactions. These findings are very different from those obtained for the $^{80m}BrBr$-($^{82m}Br_2$)–CH_4[3,15,20] and (n,γ)-activated ^{80}Br–CH_4 systems,[4] for which the organic yields resulted mainly from kinetic-energy dependent reactions. This difference

can be explained on the basis of the kinetic energy acquired initially by the Br atom.

In the case of the isomeric transition of ^{80m}Br, the kinetic energy of ^{80}Br ranges from 0 eV to maxima of 1.3 and 158 eV when HBr and Br_2, respectively, are used as source molecules, with the most probable energies being 0.75 and 37 eV, respectively.[5]

On the other hand, it is known from neutron binding-energy data[21] that the ^{80}Br and $^{82m}Br+^{82}Br$ produced by (n,γ) activation have kinetic energy spectra ranging from 0 to 417 eV, and from 0 to 378 eV, respectively. Wexler has also determined that approximately 18 and 25% of the neutron activation processes resulted in positively-charged ^{80}Br and ^{82}Br, respectively.[8] The present data are compared with those obtained from the IT and (n,γ) experiments in Table 2. Thermal ionic yields increase with decreasing kinetic (recoil) energy, E_{max}, but on the contrary, the kinetic-energy dependent yields tend to increase with increasing E_{max}. It is considered that the thermal ionic yield largely depends on the probability of the bromine ions reaching the thermal energy region upon escaping from the charge neutralization. Therefore, it is very interesting to estimate the cross sections for charge neutralization and ion-molecule reactions as a function of the $^{80}Br^+$ kinetic energy.

Rapp and Francis[22a] have calculated the cross section for resonant charge transfer at intermediate impact velocities (10^5—10^8 cm/s) using the semiclassical impact-parameter method. The values obtained are in good agreement with experimental values in many cases. The cross sections for the resonant charge-transfer reaction of Br^+ with Br, which is the highest of the charge-transfer reactions involving the Br^+ ion, can be obtained by interpolating the resonant charge-transfer cross sections calculated by Rapp and Francis.[22a] Whereas the velocity, v_{max}, for which the asymmetric charge-transfer cross section is maximum, was calculated from

$$v_{max} = \frac{|\Delta E|a}{h}, \quad (1)$$

assuming that the asymmetric charge-transfer cross section is close to that for resonant charge transfer at velocities above v_{max}.[22a] The threshold energy (E_{th})[23] for *endo*-energetic charge-transfer reactions was calculated using the relation

$$E_{th} = \frac{M_{Br^+} + M_{target}}{M_{target}}, \quad (2)$$

where ΔE, h, a, and M are the energy defect, Planck's constant, the adiabatic parameter (7×10^{-8} cm),[24] and the mass, respectively. The values of v_{max} and E_{th} are tabulated in Table 3.

On the other hand, the cross sections for capture collisions between Br^+ and CH_4 were calculated using[22b]

$$\sigma(v) = (2\pi e/v)(\alpha/\mu)^{1/2}, \quad (3)$$

where μ, α, v and e are the reduced mass of the collision pair, the polarizability of CH_4 (2.60×10^{-24} cm^3/mol),[25] the relative velocity of the ion and the charge on the ion, respectively. Pottie *et al.*,[26] Boelrük and Hamill,[27] and Kubose and Hamill[28] have indicated that Eq. 3 is applicable to ions with energies below about 1 eV. The cross sections thus obtained are shown in Fig. 4 as a function of the Br^+ velocity (lower abscissa). The velocity dependence for reactions C and D in Fig. 4 are hypothetical and are drawn on the basis of values of v_{max} and E_{th}. E_{max} for the $^{79}Br(n,\gamma)^{80}Br$ reaction and the isomeric transition of ^{80m}Br in Br_2 and HBr are shown by arrows pointing downward on the upper abscissa of this figure.

This figure indicates that the charge-neutralization reaction is predominant in the high-energy region above about 1 eV, and the formation of a capture collision complex is favorable at energies below 1 eV. Therefore, most Br^+ ions produced by the (n,γ) reaction and IT in Br_2 lose their charges before reaching the energy region in which the collision-complex formation reactions preferentially occur. In the present case, the kinetic energy initially acquired by the ^{80}Br atom is 0.75 eV on the average.[5] Therefore, the formation of the capture collision complex competes with the charge transfer reaction, as is seen in Fig. 4 and occurs with higher probability in the energy region below 1 eV.

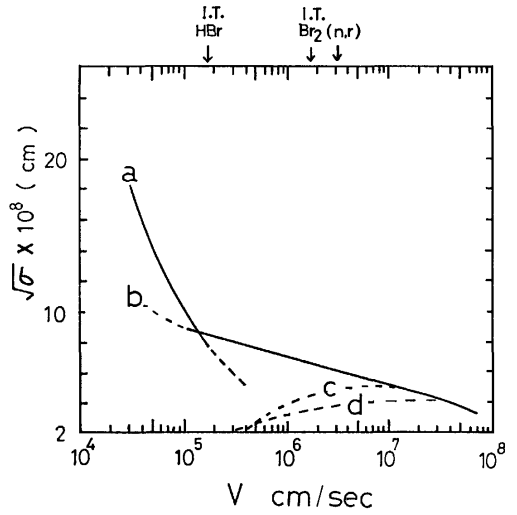

Fig. 4. Relationship between the velocity of Br^+ and cross sections for ion-molecule and charge neutralization reactions.
(a): Capture collision $Br^+ + CH^4 \rightarrow CH_4Br^+$,
(b): resonant charge transfer $Br^+ + Br \rightarrow Br^0 + Br^+$,
(c): $Br^+(^3P_2) + CH_4 \rightarrow Br + CH_4^+$,
(d): $Br^+(^3P_2) + Kr \rightarrow Br + Kr^+$.

Here, the charge transfer reaction of Br^+ with HBr is exothermic by 0.2 eV and is expected to occur efficiently from a consideration of the vibrationally-excited states of HBr. Even if neutralization occurs, the ^{80}Br cannot undergo any kinetic-energy dependent reaction leading to C–^{80}Br bond formation because its kinetic energy is not sufficient for H and/or Br substitution reactions to proceed. Thus, the present data can be explained in terms of competition between the charge neutralization and ion-molecule reactions.

On the other hand, Kazanjian and Libby[14] have studied the reaction of IT-activated ^{80}Br using HBr as the source molecule in a solution of *n*-PrBr with 1% HBr, and found that the type of products and the organic yields are almost the same as those obtained in the (n,γ) experiment for a pure *n*-PrBr system. They explained these results assuming that the IT-activated ^{80}Br can acquire appreciable kinetic energy due to Coulomb repulsion during partial inter-molecular neutralization and then reacts in a manner identical to the hot bromine produced by the (n,γ) reaction.

However, the present experimental results indicate that even if the ^{80}Br atoms acquire kinetic energy to some extent by a similar process, this kinetic energy is not sufficient for hot reactions to occur.

Formation of $CH_2{}^{80}BrBr$ and $CH_3{}^{80}Br$ via *Thermal Ionic Processes.* It was indicated in the previous section that the $CH_2{}^{80}BrBr$ and $CH_3{}^{80}Br$ molecules are formed through thermal ionic reactions involving the $^{80}Br^+$ ion. From the energetics of the reactions, the capture collision complexes, such as $CH_4{}^{80}Br^+$ and $HBr^{80}Br^+$ will be formed first by the reactions

$$^{80}Br^+ + CH_4 \longrightarrow CH_4{}^{80}Br^+ \quad (4)$$

and

$$^{80}Br^+ + HBr \longrightarrow HBr^{80}Br^+, \quad (5)$$

since generally no activation energy is required for these reactions.

Although there is no direct evidence for the presence of these complexes in the present case, the presence of sticky collision complexes of a similar type has been confirmed in various alkyl halide and hydrocarbon systems by mass-spectroscopic studies.[29-31] Henglein and Muccini have pointed out that the complex ion, CH_4I^+, had a lifetime longer than about 10^{-6} s.[32] From a calculation of the lifetime of the $CH_4{}^{80}Br^+$ ion, using the equation proposed by Magee and Burton,[33] it is expected that the $CH_4{}^{80}Br^+$ ion has a relatively long lifetime ($\approx 10^{-2}$ s).[34]

As a possible explanation for the formation of $CH_2{}^{80}BrBr$ *via* thermal ionic processes in IT experiment involving the $^{80m}BrBr$–CH_4 system, Tachikawa[35] has previously suggested that the $CH_4{}^{80}Br^+$ formed by Reaction 4 undergoes charge neutralization following decomposition to fragments, such as $CH_3{}^{80}Br$ and $CH_2{}^{80}Br$, and the $CH_2{}^{80}Br$ radical thus formed can easily be scavenged by Br_2 to form $CH_2{}^{80}BrBr$. If this is the case, the reaction

$$CH_2{}^{80}Br + HBr \longrightarrow CH_3{}^{80}Br + Br, \quad (6)$$

which leads to $CH_3{}^{80}Br$ formation will be more energetically favorable than the reaction

$$CH_2{}^{80}Br + HBr \longrightarrow CH_2{}^{80}BrBr + H, \quad (7)$$

which gives the $CH_2{}^{80}BrBr$ of this experiment using HBr as the source molecule, since Reaction 6 is exothermic by 6.8 kcal/mol, while Reaction 7 is endothermic by 24.9 kcal/mol.[36] However Fig. 1 showed that the $CH_2{}^{80}BrBr$ yield was greater than that of $CH_3{}^{80}Br$ over a whole range of additive concentrations.

Similarly, it is thought that the $CH_2{}^{80}Br$ radical in the HCl-additive system reacts with HCl to form $CH_3{}^{80}Br$ in preference to the formation of $CH_2{}^{80}BrCl$, since the reaction

$$CH_2{}^{80}Br + HCl \longrightarrow CH_3{}^{80}Br + Cl \quad (8)$$

is less endothermic than the reaction

$$CH_2{}^{80}Br + HCl \longrightarrow CH_2{}^{80}BrCl + H. \quad (9)$$

However, both $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ yields decreased almost linearly with increasing HCl concentration, as is seen in Fig. 2, and the $CH_2{}^{80}BrCl$ yield was greater than that of $CH_3{}^{80}Br$ at HCl concentrations above 0.35 mf. Therefore, the assumption that the $CH_2{}^{80}Br$ radical is present in this system as a precursor for $CH_2{}^{80}BrBr$ formation is unacceptable.

On the other hand, if $CH^{80}Br$ (bromocarbene) is present as a precursor, which can be produced through decomposition following the charge neutralization of $CH_4{}^{80}Br^+$ or through some other pathway, it is believed that the $CH^{80}Br$ present reacts readily with HBr and/or HCl to form $CH_2{}^{80}BrBr$ and $CH_2{}^{80}BrCl$, respectively, since these reactions are energetically very efficient.

In order to determine this point, an experiment using a $CH_2{=}CH_2$ additive was conducted. $CH_2{=}CH_2$ reacts instantaneously with $CH^{80}Br$ to form arylbromide or cyclo-bromopropane.[37]

$$CH^{80}Br + CH_2{=}CH_2 \longrightarrow \begin{matrix} CH_2{-}CH_2 \\ \diagdown\ \diagup \\ CH^{80}Br \end{matrix} \text{ or } CH_2{=}CHCH_2{}^{80}Br \text{ or } CH_3CH{=}CH^{80}Br. \quad (10)$$

However, the radio gas chromatogram showed no radioactive peaks at retention times corresponding to

these compounds and, therefore, the above assumption also unacceptable.

In the study of ion-molecule reactions using mass spectrometers, it has been observed that collision complex ions are formed effectively at high pressures and have ample opportunity to react with surrounding molecules during subsequent collisions.[38] Under the present experimental conditions, the possibility exsits that the $CH_4{}^{80}Br^+$ reacts with surrounding molecules giving the individual products.

Although no precise information is available concerning the ion-molecule reactions leading to $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ because of lack of knowledge concerning the chemical behaviour of complex ions at high pressure, the possibility of formation of $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ by ion-molecule reactions of $CH_4{}^{80}Br^+$ with CH_4 and/or HBr were evaluted from a thermodynamic viewpoint.

Loberg *et al.*[39] have studied reactions of thermal $^{123}I^+$ ions, formed by the $^{123}Xe \xrightarrow{EC,\beta^+} {}^{123}I$ process, in gaseous CH_4, and the formation of $CH_3{}^{123}I$ was explained in terms of the H^+-transfer reaction from the complex ion, $CH_4{}^{123}I^+$, to CH_4. Assuming that the intermediate $CH_4{}^{80}Br^+$ is a persistent collision complex rather than a molecular ion, we can estimate the $\Delta H^\circ{}_{298}$ for Reaction 4. The potential energy (V) between $^{80}Br^+$ and CH_4, which is stored in the $CH_4{}^{80}Br^+$ ion as binding energy, is calculated to be 5.5 kcal/mol, using the relation,[40]

$$V = -\frac{1}{2}\cdot\frac{\alpha e^2}{r^4}, \qquad (11)$$

where α is the polarizability of CH_4 (2.69×10^{-24} cm/mol),[25] r is the distance between ^{80}Br and CH_4 (3 Å),[41] and e is the charge. From this calculation, the heat of reaction for the reactions

$$CH_4{}^{80}Br^+ + CH_4 \longrightarrow CH_3{}^{80}Br + CH_5^+, \qquad (12a)$$

and

$$CH_4{}^{80}Br^+ + HBr \longrightarrow CH_3{}^{80}Br + H_2Br^+, \qquad (12b)$$

can be calculated roughly to be exothermic by 47 and 63 kcal/mol for ground-state Br^+, respectively. Therefore, it is conceivable that the H^+-transfer reactions from $CH_4{}^{80}Br^+$ to CH_4 and/or HBr are the principal reactions for the formation of $CH_3{}^{80}Br$.

On the other hand, it appears reasonable to assume that $CH_3{}^{80}Br$, $CH_2{}^{80}BrBr$, $CH_2{}^{80}BrCl$, and $CH_3CH^{80}BrCl$ are formed *via* the same precursor on the basis of the fact that both the $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ yields decrease linearly with increasing HCl concentration, and the decrement in their yields is almost equal to the increment of the $CH_2{}^{80}BrCl$ and $CH_3CH^{80}BrCl$ yields, as is shown in Fig. 2. As far as was observed, no ion-molecule reactions of $CH_4{}^{80}Br^+$ and $HBr^{80}Br^+$ with additives leading directly to the formation of these products are favored because of their high endothermicities. Of the various types of ion-molecule reactions concerning the intermediate ions, the following reactions are all exothermic, and probably one-step, reaction routes leading to the final products:

$$CH_4{}^{80}Br^+ + HBr \longrightarrow CH^{80}BrBr^+ + 2H_2 \quad (\Delta H^\circ = -45 \text{ kcal/mol}), \qquad (13)$$

$$CH_4{}^{80}Br^+ + HCl \longrightarrow CH^{80}BrCl^+ + 2H_2 \quad (\Delta H^\circ = -28 \text{ kcal/mol}), \qquad (14)$$

$$CH_4{}^{80}Br^+ + CH_2{=}CH_2 \longrightarrow CH_4 + CH_2CH_2{}^{80}Br^+ \quad (\Delta H^\circ = -88 \text{ kcal/mol}), \qquad (15)$$

and

$$CH_4{}^{80}Br^+ + CH_2{=}CH_2 \longrightarrow CH_3{}^{80}Br^+ + CH_3CH_2 \quad (\Delta H^\circ = -29 \text{ kcal/mol}). \qquad (16)$$

However, along which pathways the product ions thus formed lose their charges, and result in the end products appears to be rather complicated. If these ions lose their charge through free-electron capture, the high exothermicity resulting from these processes is dissipated in the form of internal energy of the molecule and probably results in the rupture of the C–^{80}Br bond. Therefore, these processes could not lead to the formation of $CH_3{}^{80}Br$, $CH_2{}^{80}BrBr$, and $CH_2{}^{80}BrCl$. Further, charge-transfer reactions of these ions with additives cannot occur because these reactions are also highly endothermic.

However, if these product ions lose their charges through charge-transfer reactions with the impurities present in the system or with the walls of the reaction vessel, and the energy defects (ΔE) for charge transfer are not so large as to lead to C–^{80}Br bond rupture, there is the possibility that the radicals and molecules in somewhat excited states thus formed are stabilized by collisions with their surroundings and undergo H-abstraction to give corresponding products.

Thus, ion-molecule reactions (13—16) may finally lead to the formation of $CH_2{}^{80}BrBr$, $CH_2{}^{80}BrCl$, $CH_3CH_2{}^{80}Br$, and $CH_3{}^{80}Br$, respectively, and the effect of additives on the yield distributions in Figs. 2 and 3 can be explained on the basis of these competitive reactions involving the precursor, $CH_4{}^{80}Br^+$.

Generally, it is known that thermal ions at high pressure form ion clusters containing several molecules held together by the electrostatic force between the ion and the molecules.[42–44] If this is the case, the energy ΔE deposited on the radical or molecule during the neutralization process can be effectively dissipitated to the cluster molecules. Even if the lifetimes of these excited radicals are relatively short, the radicals can be stabilized easily by collisions under liquid-like conditions,[33] and undergo H-abstraction reactions with surrounding molecules to form corresponding products, since the H-abstraction reactions are energetically most favorable. The above discussion is somewhat qualitative, but details of it will be elucidated upon the further accumulation of knowledge concerning ion-molecule reactions involving Br^+ in gases at atmospheric pressure.

The most prominent feature in Fig. 3 is the sharp increase in the $CH_3CH_2{}^{80}Br$ yield for a small amount of $CH_2{=}CH_2$. This can be explained on the basis of the thermal ^{80}Br reaction with $CH_2{=}CH_2$ (Reaction 17), in which ^{80}Br is produced through charge neutralization of $^{80}Br^+$ with HBr, CH_4 and/or $CH_2{=}CH_2$, thus

$$^{80}Br + CH_2{=}CH_2 \longrightarrow CH_2CH_2{}^{80}Br, \qquad (17a)$$

$$CH_2CH_2{}^{80}Br + HBr \longrightarrow CH_3CH_2{}^{80}Br + Br. \qquad (17b)$$

However, the gradual increase in the $CH_3CH_2{}^{80}Br$ yield at concentrations above 0.03 mf is attributable to reactions of ^{80}Br and $^{80}Br^+$ with $CH_2{=}CH_2$ and/or Reaction 15.

As Fig. 1 shows, the marked change in the yield curves is due to the additional formation of $CH_2{}^{80}BrBr$ for Kr and Xe concentrations greater than 0.6 mf. A similar increase in the CH_2BrBr yield was observed for

a highly-moderated system in IT-experiments of the $^{80m}BrBr$[19] and $H^{82m}Br$–CH_4 systems.[18] The collision frequency of $^{80}Br^+$ ions with Kr and Xe atoms increases abruptly for concentrations over 0.6 mf. This additional formation of $CH_2{}^{80}BrBr$ may thereby be explained in terms of (i) the increase in the number of $^{80}Br^+$ ions with lower kinetic energies and of electronically-excited states, since the kinetic energy spectra of $^{80}Br^+$ shifts to lower energies at high concentrations of Kr and Xe, and (ii) ion-molecule reactions involving complex ions containing inert gas molecules. If assumption (i) is valid, a similar increase in the $CH_3{}^{80}Br$ yield will be observed, because $CH_3{}^{80}Br$ formation greatly depends on the number of $^{80}Br^+$ ions. However, no increase in the $CH_3{}^{80}Br$ yield was observed, as can be seen in Fig. 1. Although no information on ion-molecule reactions of Br^+ with inert gases is available, there may be some reaction pathways for the additional formation of $CH_2{}^{80}BrBr$ involving, presumably, the reactions of the $Kr^{80}Br^+$ (or $Xe^{80}Br^+$) ion with the surrounding molecules. However, the details of the reaction pathways leading to the additional formation of $CH_2{}^{80}BrBr$ must await further experiments.

The authors wish to thank the laboratory crew for operating the linear accelerator.

Kinetic Studies of Photosensitized Oxygenation by Singlet Oxygen in Aqueous Micellar Solutions

Yoshiharu Usui, Michio Tsukada, and Hiroko Nakamura

Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310

(Received April 28, 1977)

Singlet oxygen produced by the dye-sensitized reaction in an aqueous solution penetrates into the interior of the surfactant micelles of sodium dodecyl sulfate (SDS) and dodecyltrimethylammonium chloride (DTAC), reacting with the solubilized acceptors such as 9,10-dimethylanthracene, 2,5-diphenyloxazole, and 1,3-diphenylisobenzofuran. From the acceptor concentration effect on the photooxygenation quantum yield, the reactivity index (β), the ratio of the rate constant of the spontaneous decay of singlet oxygen to that of the reaction with an acceptor, is obtained in the aqueous micellar solution. It has been shown that the lifetime of singlet oxygen is mainly dependent on the solvent composition in the bulk phase from the kinetic analysis of the mixed solvent effect on the quantum yield in SDS and DTAC micellear solutions and that in a homogeneous solution.

Singlet oxygen is one of the active species for the oxidative process in a biological system as well as supperoxide ion, hydroxyl radical, hydrogen peroxide, ozone, *etc.* Investigation of the dye-sensitized photooxidation by singlet oxygen in a solution in which an acceptor is dissolved in the surfactant micelles affords significant information on their use in the study of photodynamic inactivation of enzyme and cells.[1-5] Since a surfactant micelle serves as both structural and functional models for complex bioaggregates of proteins or biomembrances, kinetic investigations are required to determine the mechanism of the micelles with singlet oxygen produced by the energy transfer from the dye bound on micelles or dissolved in a liquid phase.

Studies on the fluorescence quenching of aromatic compounds within some surfactant micelles by oxygen dissolved in an aqueous solution suggest that an oxygen molecule can undergo unrestricted diffusion into the micelles.[6,7] In the case of singlet oxygen, although such diffusion into the micelles is also expected, its lifetime in the liquid phase which is highly dependent on the type of solvent can be responsible for the reaction efficiency for the micellar system. In order to explain the solvent effect on the lifetime of singlet oxygen an electronic-to-vibrational energy transfer theory (*i.e.*, to the C–H or O–H streching vibrational mode of solvent) was introduced.[8] It seems that singlet oxygen is subjected to deactivation by water and surfactant micelles. However, despite the fact that the lifetime in aqueous solution (2 μs) is the shortest among those observed in a number of solvents, it is of interest that singlet oxygen is scarcely quenched by micelles itself and reacts with the acceptor dissolved in micelles efficiently.[9,10]

In this paper, the reaction mechanism in some micellar systems has been discussed from the concentration effect of singlet oxygen acceptor and the mixed solvent effect upon the quantum yield of the disappearance of the acceptor in micelles as compared with the effects in the homogeneous solutions.

Experimental

Materials. Sodium dodecyl sulfate and dodecyltrimethylammonium chloride (Tokyo Kasei, G. R.) were recrystallized from methanol. 9,10-Dimethylanthracene, 2,5-diphenyloxazole, 2,5-dimethylfuran, tryptophan, histidine (Tokyo Kasei, G. R.), and 1,3-diphenylisobenzofuran (Aldrich Co.) were used without further purification. Methylene blue (MB) and eosine (EOS) were recrystallized twice from 1-butanol and ethanol, respectively. Singlet oxygen acceptors were solubilized in each surfactant (0.1 M) by gentle stirring of the mixture at 50—70 °C in the dark.

Procedures. A fresh sample in a $1\times1\times4$ cm^3 or $0.3\times1\times4$ cm^3 cell was irradiated by a cross-illumination apparatus with a steady light at 25.0 °C. The experimental procedure to determine the quantum yield was similar to that described previously.[11] Flash photolysis experiments were carried out by using a Q-switched ruby laser (NEC, SLG-2007). A suitable cut-off filter and an interferance filter (λ=410 nm) were placed in the analyzing beam from a tungsten lamp in order to avoid the photolysis of singlet oxygen acceptor. The fluorescence spectra were measured with a Shimadzu RF-500 fluorimeter.

Results and Discussion

Acceptor Concentration Dependence on the Quantum Yield in a Homogeneous Solution. The essential reaction scheme and the disappearance quantum yield Φ_{-A} of a singlet oxygen acceptor (A) in solution are expressed as follows:[11-13]

$$^1\mathrm{Sens} \xrightarrow{h\nu} {}^3\mathrm{Sens}^* \qquad \phi_{st} \quad (1)$$

$$^3\mathrm{Sens}^* \longrightarrow {}^1\mathrm{Sens} \qquad k_d \quad (2)$$

$$^3\mathrm{Sens}^* + {}^1\mathrm{Sens} \longrightarrow \mathrm{Sens}^+ \cdots \mathrm{Sens}^-,\ {}^1\mathrm{Sens} + {}^1\mathrm{Sens} \qquad k_D \quad (2')$$

$$^3\mathrm{Sens}^* + {}^3\mathrm{O}_2 \longrightarrow {}^1\mathrm{Sens} + {}^1\mathrm{O}_2 \quad (k^r_{O_2}) \qquad (3)$$

$$\searrow\ {}^1\mathrm{Sens} + {}^3\mathrm{O}_2,\ \mathrm{Sens}^+ \cdots \mathrm{O}_2^- \qquad k^s_{O_2} \quad (4)$$

$$^3\mathrm{Sens}^* + \mathrm{A} \longrightarrow {}^1\mathrm{Sens} + \mathrm{A} \qquad k^s_{TA} \quad (5)$$

$$^1\mathrm{O}_2 \longrightarrow {}^3\mathrm{O}_2 \qquad k'_d \quad (6)$$

$$^1\mathrm{O}_2 + \mathrm{A} \longrightarrow \mathrm{AO}_2 \quad (k'^r_A) \qquad (7)$$

$$\searrow\ \mathrm{A} + {}^3\mathrm{O}_2 \qquad k'^s_A \quad (8)$$

$$\Phi_{-A} = \Phi_{so}\alpha r\frac{[A]}{\beta+[A]} \qquad (9)$$

where $\Phi_{so}=\phi_{st}\gamma_{so}$ (yield of singlet oxygen formation), $r=k'^r_A/k'^s_A$ (reaction probability of A with singlet oxygen), $\beta=k'_d/k'^s_A$ (reactivity index of A with singlet oxygen), γ_{so} stands for the singlet oxygen formation probability ($=k^r_{O_2}/k^s_{O_2}$) from triplet sensitizer (^{3}Sens) *via*

process 3, and α is the reaction probability of AO_2 to its successive processes. If these is no successive reaction following AO_2, the relation of the double reciplocal plot of Φ_{-A}^{-1} *vs.* $[A]^{-1}$ on Eq. 9 would be linear. From the slope and intercept the value of β can be obtained and the k'^{s}_{A} value is estimated by substituting the value of k'_d in the solvent.

The values of k'_d and k'^{s}_{A} are independently determined by means of the laser flash photolysis utilizing the kinetic analysis proposed by Kearns *et al.*,[8] Adams and Wilkinson,[14] and Young *et al.*[15] The reaction parameters obtained by these methods are given in Table 1 including some of the reference data.

Table 1. Rate constants of decay and reactions of singlet oxygen in various solution

Acceptor	Solvent	Sens	$k'_d\ 10^{-3}$ (s^{-1})	$k'^{s}_{A}\ 10^{-8}$ ($M^{-1}\ s^{-1}$)	β (M)

a) Data of Kearns *et al.* for k'_d are used in the calculation of k'^{s}_{A} values.[8] b) $\chi_{MeOH}=0.3$, $\chi_{D_2O}=0.5$. c) $\chi_{D_2O}=0.5$. Abbreviations: Histidine (HIS), histamine (HISA), methanol (MeOH), ethanol (EtOH), 1-butanol (*n*-BuOH), 1,1,2,2-tetrachloroethane (TeCE), 1,1-dichloroethane (DeCE), and erythrosine (ERY). L denotes the value obtained by laser flash experiment.

In air-saturated aqueous or ethanol solution, the triplet state of methylene blue reacts predominantly with dissolved oxygen; $k^{s}_{O_2}[O_2] \gg k_d + k_D[MB] + k^{s}_{TA}[A]$. Thus, the value of Φ_{so} would be that of ϕ_{st} ($=0.52$) since γ_{so} is approximately equal to unity.[8] For efficient acceptors such as 9,10-dimethylanthracene (DMA), 1,3-diphenylisobenzofuran (DPBF), and 2,5-dimethylfuran (DMF) which can react without the deactivation reaction of singlet oxygen (Eq. 8, $r\simeq1$), the maxmum value for the reaction quantum yield Φ_A^{max} should be close to ≈0.52 (ϕ_{st} value). However, the observed value of Φ_A^{max} is about twice of ϕ_{st} (≈1.2) as shown in Fig. 1. Although it can be expected that a complex chain reaction is involved to consume a couple of these acceptor molecules, the following results seems to deny the existence of the chain reaction in the case of the photooxygenation of DMF in an aqueous solution.

1) The UV-absorption spectrum of the MB–O_2–DMF system changes with an isobestic point at 233 nm during the course of irradiation.

2) *cis*-3-Hexene-2,5-dione is a main oxidation product from DMF, the concentration of the peroxide produced being smaller than 20% of the initial concentration of DMF at $\approx10^{-4}$ M. From the results it can be proposed that the following successive reaction of A with AO_2 occurs efficiently at higher concentrations of acceptors:[11,16]

$$AO_2 + A \longrightarrow 2AO. \tag{10}$$

If we assume that AO_2 is a certain intermediate such as the collisional adduct or the charge transfer complex between A and $^1O_2$, the quantum yield of Φ_{-A} including the competitive unimolecular decay of AO_2 (rate constant ratio; γ) *via* process 10 is given by

$$\Phi_{-A} = \Phi_{so}\frac{[A]}{\beta+[A]}\left(1+\frac{[A]}{\gamma+[A]}\right), \tag{11}$$

where $1+([A]/(\gamma+[A]))$ corresponds to α in Eq. 9. When Reaction 10 is predominant in the decay of AO_2 ($\gamma \ll [A]$), Eq. 11 approximately becomes

$$\Phi_{-A} = 2\Phi_{so}\frac{[A]}{\beta+[A]}. \tag{12}$$

In the case that AO_2 is an *endo*-peroxide and Reaction 10 is involved, Eq. 12 can similarly be applied. Thus, the maximum value of Φ_{-A} at higher concentrations of A ($\gamma \ll \beta \ll [A]$) tends to be $2\Phi_{so}$ which approaches the value of ≈1.2 as shown in Fig. 1.

By addition of the acceptor in high concentration, Process 5 can compete with Process 3 for the singlet oxygen formation. When the acceptor on a triplet sensitizer causes mostly its deactivation and the decomposition of A is negligible in Process 5, the quantum yield of disappearance of A is given by

$$\Phi_{-A} = \phi_{st}\alpha\frac{k^{r}_{O_2}[O_2]}{k_d + k^{s}_{TA}[A] + k^{s}_{O_2}[O_2]}\frac{r[A]}{\beta+[A]}. \tag{13}$$

Thus, the concentration effect of A on Φ_{-A} has a maximum where the concentration of A is given by $\sqrt{(k_d + k^{s}_{O_2}[O_2])/k^{s}_{TA}}$. In the system of MB–$O_2$–DPBF for example, Φ_{-DPBF} decreases at higher concentration

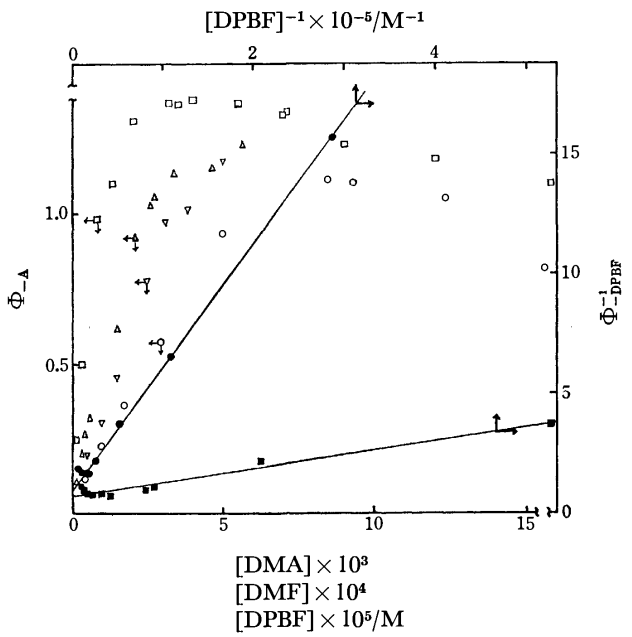

Fig. 1. Effect of [A] on Φ_{-A} and the double reciprocal plots. A: DMF in H_2O (▽), DMA in EtOH (△), DPBF in TeCE (□ and ■), and MeOH (○ and ●). [MB]: 10 μM.

of DPBF as shown in Fig. 1. The rate constant k^s_{TA} for MB and DPBF was estimated to be 2.7×10^9 M^{-1} s^{-1} (in 1,1,2,2-tetrachloroethane, TeCE) and 5.8×10^9 M^{-1} s^{-1} (in methanol, MeOH) by means of the laser flash apparatus. If we use the values of β in Table 1 and those of $(k_d+k^s_0[O_2])$, 1.5×10^6 s^{-1} in TeCE and 4.0×10^6 s^{-1} in MeOH, the calculated concentrations of DPBF give the maximum quantum yield at 9.7×10^{-5} M and 2.1×10^{-4} M for the respective solvents. The coincidence of these values with the results in Fig. 1 shows that Process 5 is appreciable to the concentration of DPBF above $\approx1\times10^{-4}$ M. Thus, when a reactive acceptor is added with a sensitizer it should be noted that the reaction scheme switches from the singlet oxygen reaction (Type II mechanism) to the direct reaction of A with the triplet sensitizer (D–R or D–O mechanism[17]) depending on the concentration of A.

Solvent Effect of the Quantum Yield in a Homogeneous Solution. The lifetime of singlet oxygen ($^1\Delta_g$) depends highly on the type of solvent. Kearns *et al.* ortedrep that the lifetime is related to the optical densities (O.D.) of the solvents at the waven umbers of 7880 and 6280 cm^{-1} corresponding 0-0 and 0-1 components of the $^1O_2(^1\Delta)-{}^3O_2(^3\Sigma)$ transition as follows:[8]

$$k'_d\times10^{-6}\simeq0.5(\text{O.D.})_{7880}+0.05(\text{O.D.})_{6280}\equiv D. \quad (14)$$

Under the conditions $\beta\gg$[A] in Eq. 9, the solvent effect on the value of Φ_{-A} should explicitly reflect the solvent sensitivity of k'_d, k'^s_A, Φ_{so}, and αr. If the maximum quantum yields Φ^{max}_{-A} $(=\Phi_{so}\,\alpha r)$ in two kinds of solvents are equal to each other, the possibility that Φ_{so} and αr afford the large solvent effect on Φ_{-A} can be neglected. Further, since the rate constant k'^s_{-DPBF} does not seem to be so sensitive to solvents as compared with the solvent sensitivity of k'^s_d (Table 1), the large solvent effect on Φ_{-DPBF} could reflect the solvent sensitivity of the lifetime of singlet oxygen to the photooxygenation of DPBF.

In the mixture of solvent 1 and 2 at the mole fractions of χ_1 and χ_2, it can be assumed that Kearns'-type equation for the solvent quenching to singlet oxygen is expressed as

$$k'_d\times10^{-6}\simeq D_{mix}=\chi_1D_1+\chi_2D_2, \quad (15)$$

where D_1 and D_2 stand for the sum of Eq. 14 to solvents 1 and 2, respectively. When the condition $\beta\gg$ [DPBF] holds for the mixed solvent, Φ_{-DPBF} in the mixture would be given by

$$\Phi_{-DPBF}=\Phi_{so}\alpha r(k'_d/k'^s_A)^{-1}[DPBF]. \quad (16)$$

Substituting Eq. 15 into Eq. 16 and neglecting the solvent effects on the values of Φ_{so}, αr, and k'^s_A, we obtain the ratio of $\Phi^{(2)}_{-DPBF}$ in the pure solvent 2 against Φ_{-DPBF} in the mixture in a linear form with respect to χ_1 as follows.

$$\Phi^{(2)}_{-DPBF}/\Phi_{-DPBF}=1-\left(1-\frac{D_1}{D_2}\right)\chi_1. \quad (17)$$

In several mixtures (Fig. 2) where the relation $D_{mix}=\chi_1D_1+\chi_2D_2$ holds, the experimental points of $\Phi^{(2)}_{-DPBF}/\Phi_{-DPBF}$ coincide with the predicted lines from Eq. 17. The relation can be applied to the mixture of water and deuterium oxide too.

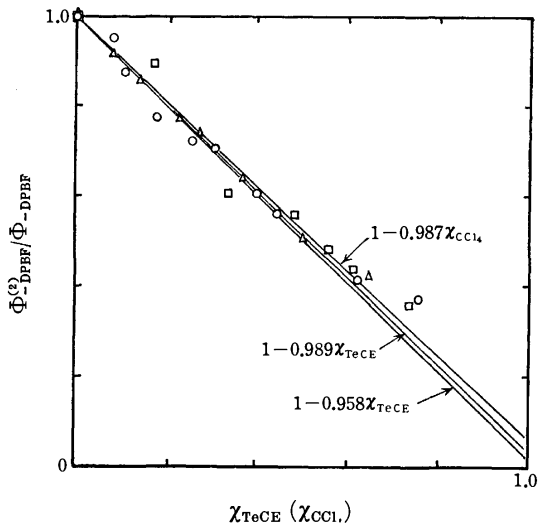

Fig. 2, Effect of mixed solvent on Φ_{-DPBF}. [MB]: 4 μM. [DPBF]: 35 μM. MeOH (solv. 2)-TeCE (solv. 1) (△), Hexane (solv. 2)-TeCE (solv. 1) (○), and Hexane (solv. 2)-CCl_4 (solv. 1) (□).

The relation $D_{mix}=\chi_1D_1+\chi_2D_2$ does not hold for the mixture of water and ethanol. In such case, the k'_d value has to be estimated directly by measuring the values of D_{mix} over each ratio of the mixture. If the value of k'^s_A does not depend on the mole fraction of alcohol, the following equation can be derived in the range $\beta\gg$[A] since Φ^{max}_{-A} equals to $\Phi_{so}\,\alpha r$.

$$\frac{\Phi^{(1)}_{-A}}{\Phi^{max(1)}_{-A}}\Big/\frac{\Phi_{-A}}{\Phi^{max}_{-A}}=\frac{D_{mix}}{D_1}=k'_d/k'^{(1)}_d \quad (18)$$

However, for the systems of MB–O_2–DMF and MB–O_2–DPBF in the water–ethanol or water–methanol mixture,

the quantum yields differ a great deal from what is expected in Eq. 18. The solvent effect on Φ_{-A} shows a maximum around $\chi_{ethanol} \simeq 0.3$, decreasing gradually in the region of $\chi_{ethanol}$ over 0.3. Since Young *et al.* reported the values of k'^{s}_{DPBF} as 1.2—1.3$\times 10^9$ M^{-1} s^{-1} in methanol and 5.1$\times 10^9$ M^{-1} s^{-1} in 1:1 methanol–water mixture, the k'^{s}_{DPBF} value depends on the mole fraction of methanol.[15] Using these values of k'^{s}_{DPBF}, the ratio of the quantum yield (2.3) in the 1:1 mixture of methanol and water to that in methanol is explained by the corrections ($\approx$2.9) for both k'_d and k'^{s}_{DPBF} values.

Sensitized Photooxygenation in Micelles. Acceptor Concentration Dependence on the Quantum Yield: Recently it was reported that DPBF and 2,5-diphenylfuran solubidized in sodium dodecyl sulfate (SDS) micelles can be oxidized by the photosensitized reaction.[9,10] In order to determine the reaction mechanism in other micellar systems for several combinations of the sensitizing dyes, the acceptor and the micelles, kinetic investigations were carried out on the effects of the acceptor concentration, solvent composition, and the surfactant concentration upon the quantum yield.

In the region of 1st CMC of dodecyltrimethylammonium chloride (DTAC) micelles, most of MB does not bind to the micelle but exists in a bulk phase because of an electrostatic repulsion between the cationic DTAC micelle and dye. Thus, DMA or 2,5-diphenyloxazole (DPO) which is dissolved into Hartley's cubic micelles of DTAC, reacts with singlet oxygen produced by energy transfer from dye in the bulk phase.

The concentration effect of DMA/DTAC on $\Phi_{-DMA/DTAC}$ is shown in Fig. 3 and the reciprocal plot of $1/\Phi_{-DMA/DTAC}$ against 1/[DMA/DTAC] exhibits a linear relationship similar to that in a homogeneous solution. The β value obtained from Eq. 19 in a water–micellar solution is about ten times greater than that in a deuterium oxide –micellar solution (Table 1). Since the same value of $\Phi^{max}_{-DMA/DTAC}$ is obtained both in water– and deuterium oxide–micellar solutions it is resposible for the result that the k'_d value in water is just ten times greater than that in deuterium oxide as shown by Kearns *et al.*[8] The $\Phi^{max}_{-DMA/DTAC}$ value $\approx$0.5, which is about a half of that obtained from the concentration effect in ethanol, may be explained as reasonable since photooxygenated DMA in the micelles is hard to react with another DMA molecule, indicating that process 10 is not involved in this system. The deuterium oxide effect on β and $\Phi^{max}_{-DPO/DTAC}$ value was also observed in the case of DPO/DTAC-oxygenation sensitized by MB in the bulk phase. The results suggest that the α value in Eq. 9 is close to unity. The following equation can be written for an aqueous micellar solution.

$$\Phi_{-DMA/DTAC} = \Phi_{so}\frac{k'^{r}_{A}[DMA/DTAC]}{k'_d + k'^{s}_{A}[DMA/DTAC]}. \quad (19)$$

The DMA/DTAC concentration dependence on $\Phi_{-DMA/DTAC}$ was investigated in the photooxygenation sensitized by an anionic dye of eosine (EOS) adsorbed on the micelles. The result also gives a linear relationship between $1/\Phi_{-DMA/DTAC}$ and 1/[DMA/DTAC] ([EOS/DTAC]: 10 μM, [DTAC]: 50 mM, and [DMA/DTAC]: 0.6—18.5$\times 10^{-5}$ M). Referring to the case sensitized

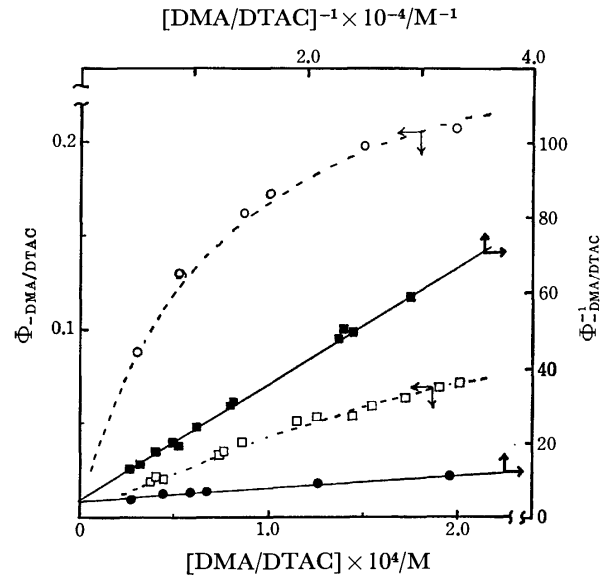

Fig. 3. Effect of [DMA/DTAC] on $\Phi_{-DMA/DTAC}$ in H_2O and in D_2O. [MB]; 10 μM. [DTAC]: 50 mM.

by MB, a similar β value 5.5$\times 10^{-4}$ M is obtained in the water–micellar solution. If we substitute the k'_d value obtained in an aqueous solution for the micellar systems into Eq. 19, the estimated rate constant $k'^{s}_{DMA/DTAC}$ becomes greater than that for DMA in ethanol. Thus, it is confirmed that singlet oxygen readily penetrate into the micellar phase, reacting with DMA efficiency in spite of whether dye is electrostatically bound on the ionic surfactant micelles or not. From the results putting A/micelle instead of A, the schemes (1)—(8) might be accepted.

Solvent Effect on the Quantum Yield in Micellar Solution. From the results mentioned above, the mixed solvent effect on the quantum yield for a micellar system can be

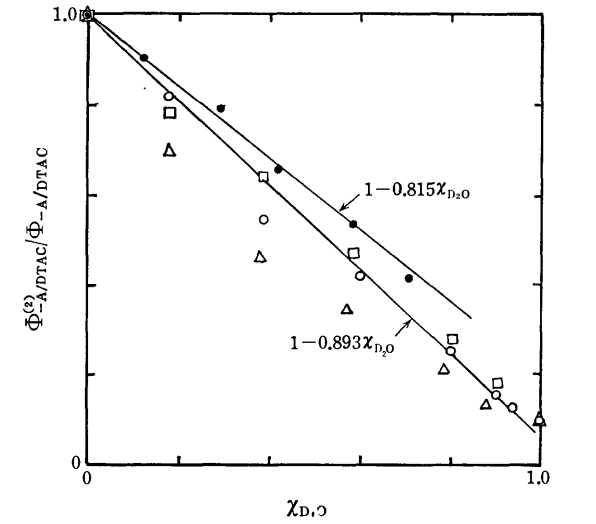

Fig. 4. Effect of mixed solvent of H_2O–D_2O on Φ_{-DMA} in water and $\Phi_{-A/DTAC}$ in DTAC micellar solution (50 mM). ●; [MB]: 10 μM, [DMA]: 1.0$\times 10^{-4}$ M, [DTAC]: 0 M, χ_{EtOH}=0.3. △; [MB]: 10 μM, [DMA/DTAC]: 100 μM. ○; [MB]: 5 μM, [DPO/DTAC]: 25 μM. □; [EOS/DTAC]: 10 μM, [DMA/DTAC]: 37 μM.

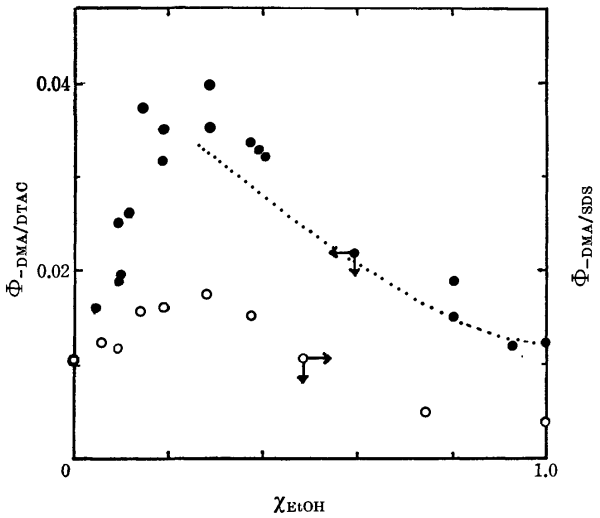

Fig. 5. Effect of mixed solvent of H_2O-EtOH on $\Phi_{-DMA/DTAC}$ and $\Phi_{-DMA/SDS}$. [MB]: 5 μM, [DMA/DTAC]: 26 μM, [DTAC]: 50 mM (●) and [EOS]: 20 μM, [DMA/SDS]: 14 μM, [SDS]: 20 mM (○). Data on the mixture without DTAC (dotted line) are normalized at $\chi_{EtOH}=1$.

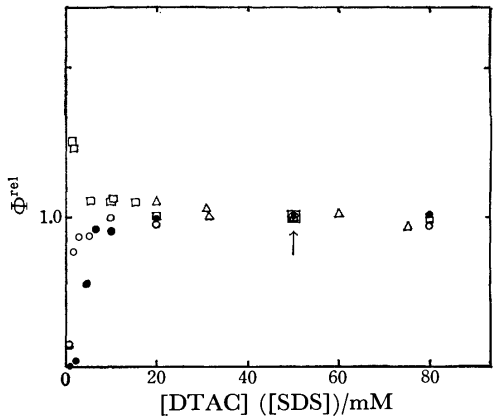

Fig. 6. Surfactant concentration effect on the relative quantum yields normalized at 50 mM. MB–O_2–DMA/DTAC (△), MB–O_2–DPO/DTAC (□), MB/SDS–O_2–DPBF/SDS (●) and EOS–O_2–DPBF/SDS (○).

treated by means of Eq. 17, and specified by the lifetime of singlet oxygen in bulk phase as well as in a homogeneous solution. The effect of deuterium oxide on the $\Phi_{-DMA/DTAC}$ (or $\Phi_{-DPO/DTAC}$) value sensitized by MB or EOS/DTAC can be explained by Eq. 17 as shown in Fig. 4.

In the case of water and ethanol mixture, the results for MB–O_2–DMA/DTAC and EOS–O_2–DMA/SDS systems are anomalous. At the mole fraction of ethanol $\chi_{EtOH}\approx 0.2$, $\Phi_{-DMA/DTAC}$ has a maximum (≈ 0.04 for the system of MB–O_2–DMA/DTAC), decreasing in the χ_{EtOH} region over 0.3 where the degree of decrement coincides with the dotted line in Fig. 5. This seems to be due to the decomposition of DTAC micelles in the region $\chi_{EtOH}>0.3$. On the other hand, the Φ_{so} value could not be affected by the addition of ethanol in the region $\chi_{EtOH}\lesssim 0.3$. The β values at $\chi_{EtOH}=0$ and 0.2, were about 6.6×10^{-4} and 5.2×10^{-4} M, respectively. If DMA/DTAC micelles start to decompose into the homogeneous solution even in the region $\chi_{EtOH}<0.3$, the quantum yield of DMA disappearance would decrease with increasing χ_{EtOH} beyond 0.3, since the β values at $\chi_{EtOH}>0.3$ are greater than that at $\chi_{EtOH}=0$. However as shown in Fig. 5, the effect of ethanol on $\Phi_{-DMA/DTAC}$ shows a reverse tendency. The increment in $\Phi_{-DMA/DTAC}$ may be due to the DMA liberation from the micelles by the swelling effect of ethanol because the existence of free DMA molecules contributes to the disappearance of DMA in the region $\chi_{EtOH}<0.3$ (Eq. 9).

Micelle Concentration Effect on the Quantum Yield. In order to check the deactivation of the excited states of sensitizer and singlet oxygen by micelles, the micelle concentration effect on the quantum yield was tested. As shown in Fig. 6, in the region between 1st and 2nd CMC the quantum yield does not depend on the micelle concentration, the effect being negligible for the systems of MB–O_2–DMA/DTAC, MB–O_2–DPO/DTAC, MB/SDS–O_2–DPBF/SDS, and EOS–O_2–DPBF/SDS. In contrast, under 1st CMC the complex features are shown for each case.

Effect of N_3^- Addition on DPO Fluorescence and the Quantum Yield. Fluorescence quenching of some substances in the micelles by an ionic quencher deviates from the Stern-Volmer plot because of the electrostatic interaction on the Stern layer of charged micelle.[18] In the case of the quenching of DPO in DTAC micelles by azide ion N_3^-, the Stern-Volmer plot deviates from the concentration of N_3^- ion over 80 mM, becoming saturated around 300 mM as shown in Fig. 7. The quenching of DPO fluorescence in the micelles by N_3^- is about ten times greater than that in a 10% EtOH–H_2O solution. Since the Stern-Volmer plot in the solution does not deviate at the concentration of N_3^- around $\approx 10^{-1}$ M, the quenching of DPO in DTAC micelles can occur by N_3^- adsorbed electrostatically on

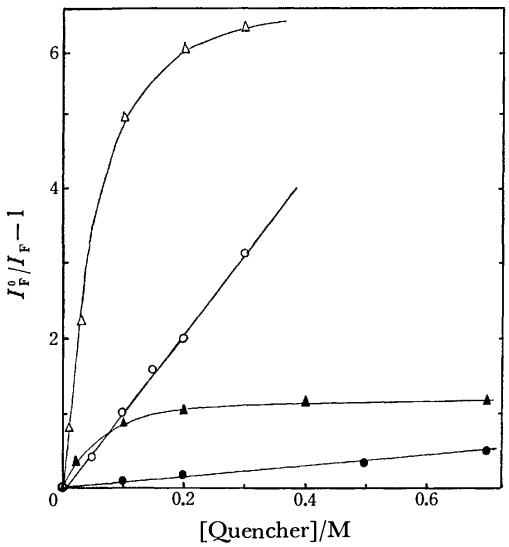

Fig. 7. Stern-Volmer plots for the fluorescence quenching of DPO/DTAC. Quencher; NaN_3 (△; in 50 mM DTAC and ○; in 10% EtOH–H_2O) and NaBr (▲; in 50 mM DTAC and ●; in 10% EtOH–H_2O).

the micelles, simultaneously. A similar feature was observed on NaBr quenching (Fig. 7).

It is well-known that the N_3^- ion is an efficient quencher to singlet oxygen. In the case of photooxygenation of DPO/DTAC the quantum yield $\Phi_{-DPO/DTAC}$ becomes small by the addition of NaN_3 of 50 mM (3.1×10^{-4}, [DPO/DTAC]: 14.4 μM), no deuterium oxide effect being observed on the $\Phi_{-DPO/DTAC}$ value. Singlet oxygen would be predominantly deactivated by N_3^- bound to the micelles and in solution, where DPO/DTAC is protected from the attack by singlet oxygen. Although the effect of N_3^- bound to the DPO/DTAC micelles on the DPO fluorescence seems to be significant at the order of 10^{-1} M (Fig. 7), the degree of N_3^- bound on the micellar periphery is too small to affect the quantum yield in the concentration lower than 1 mM. The binding effect on the singlet oxygen reaction was checked by measurements of $\Phi_{-DMA/DTAC}$ values in the presence of another anion (1 mM NaCl) or the high micelle concentration ([DTAC micelle]: 0.936 mM). Since both effects of the NaCl addition and the micelle concentration are scarcely observed, the contribution of bound N_3^- ion is negligible for the singlet oxygen reaction in such lower concentration of N_3^-.

Table 2. Rate constants of N_3^- ion with singlet oxygen in aqueous and micellar solutions

System (solv. pH)	k_N (M^{-1} s^{-1})
MB-O_2–Tryptophan (H_2O, 8.37)	$1.7\pm0.2\times10^9$
MB-O_2–DPO/DTAC (H_2O, 7.0)	$2.2\pm0.3\times10^9$
MB-O_2–DMA/DTAC (H_2O, 7.0)	$2.3\pm0.3\times10^9$

In order to confirm the results of solvent effect on the quantum yield in a micellar solution which shows that the lifetime of singlet oxygen is restricted by the property or the composition of a solvent mixture in the bulk phase, we studied the effect of N_3^- on $\Phi_{-DPO/DTAC}$ in the range $[N_3^-] < 1$ mM, where the reaction of N_3^- with the excited state of sensitizer is negligible.[20] The quenching rate constant of singlet oxygen by N_3^- (k_N) can be estimated from the slope and intercept in the following equation:

$$1/\Phi_{-DPO/DTAC} = \frac{k_d' + k_A'^s[DPO/DTAC] + k_N[N_3^-]}{\phi_{st}k_A'^r[DPO/DTAC]}. \quad (20)$$

The value of k_N obtained are given in Table 2. The coincidence of k_N values both in micellar solutions and in an aqueous solution within experimental error shows that singlet oxygen is quenched in the bulk phase as in the aqueous solution. There is no specific effect on the surface in the dilute concentration of N_3^-. Therefore, this supports the view that the lifetime and behaviour of singlet oxygen are mainly affected by the condition or the solvent composition in the bulk phase.

The authors wish to express their thanks to Miss Setsuko Kodera, Miss Akiko Sakamoto, and Mrs. Mieko Sakaue for their contribution to this work.

ENDOR Relaxation Study of the Effects of Intramolecular Cation Migration on the Ion-pair System*

Masaharu OKAZAKI and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 16, 1977)

The ENDOR spectra of the ion-pair system of the 2,5-di-*t*-butyl-*p*-benzoquinone anion and the alkali metal cation in 1,2-dimethoxyethane were observed. The influence of the intramolecular cation migration on both the linewidth and the intensity of the ENDOR spectra was experimentally examined. The results obtained were discussed theoretically using the Kaplan-Alexander formula. The intramolecular exchange due to the cation migration was shown to be effective in ENDOR.

Many studies of the dynamic processes in the ion-pair system of a radical anion and an alkali cation in solution have been carried out.[1] As an example of these processes, the so-called linewidth alternation in the ESR spectrum due to the intramolecular cation migration among more than two sites is well known.[2] Kinetic study by measuring the changes in the linewidth of the ESR spectrum is difficult when the rate of the process is smaller than the apparent width of the inhomogeneously broadened line.

ENDOR is useful for the study of the dynamic processes with such small rates. The ENDOR intensity is sensitive to the combination and the competition among various relaxation processes including such a dynamic process.[3–5] Moreover, the ENDOR linewidth does not depend on the secular terms of the *g*-anisotropy of electron and the hf-anisotropy of the nucleus whose resonance frequencies are different from that of the pumping NMR transition.[4] The approach using the ENDOR linewidth has been applied to the kinetic study by a few groups.[6–10] Recently Möbius *et al.* have investigated the restricted rotation by analyzing the ENDOR linewidth quantitatively.[8–10] The study with the ENDOR linewidth, however, has the difficulty that the saturation broadening tends to hide the slight changes due to dynamic processes when the ESR and the NMR transitions are saturated to observe the ENDOR.

The investigation with the ENDOR intensity is more reliable in principle for the study of relaxation processes including such dynamic processes. The linewidth alternation of the ESR spectrum in the system of the 2,5-di-*t*-butyl-*p*-benzoquinone anion and the alkali cation in 1,2-dimethoxyethane was first studied by Chippendale *et al.*[11] In the present investigation the ENDOR study of this system was pursued and the observed results for both the ENDOR intensity and the linewidth were well reproduced by the introduction of the intramolecular exchange process into the theoretical calculation. It was confirmed that the intramolecular exchange due to such a dynamic process has large effects on the ENDOR intensity.

Experimental

The purification of 2,5-di-*t*-butyl-*p*-benzoquinone (DBQ) was done by recrystallization from ethanol. 1,2-Dimethoxyethane (DME) was dehydrated by refluxing over Na–K alloy for 10 h. The sample solution of the DBQ anion was prepared by the alkali metal reduction of DBQ in DME. The concentration of the DBQ anion in the sample solution was about 5×10^{-4} mol dm^{-3}.

In the observation of ENDOR the temperature at the sample position was monitored using a copper-constantan thermocouple, and was controlled by varying the flow rate of the chilled nitrogen in the temperature range from 185K to 243K. The ENDOR spectra were taken with a home-made spectrometer.[12] The microwave power was greater by 5 db than the power which gave the maximum amplitude of the ESR signal. The rf-power was kept constant at about 0.5 mT in the rotating frame. The rf-power was roughly estimated from the coherent splitting of the ENDOR spectrum of K^+DBQ^- in isopropyl alcohol according to the procedure of Freed *et al.*[5]

Method of Calculation

By the introduction of the effects of the intramolecular exchange, the equation of motion for the density operator of the spin system can be given as[13–15]

$$d\rho/dt = i[\rho, \mathcal{H}] - \Gamma(\rho-\rho^0) + (\boldsymbol{P}\rho\boldsymbol{P}-\rho)/\tau_{ex}, \qquad (1)$$

where $\boldsymbol{P}$ is an exchange operator[15] which represents the exchange between the two spin states shown in Fig. 1. These states are connected *via* the transition of k. τ_{ex} is the reciprocal of the exchange rate. $\Gamma(\rho-\rho^0)$ represents the relaxation of ρ to its thermal equilibrium state, ρ^0, due to the perturbational Hamiltonian modulated

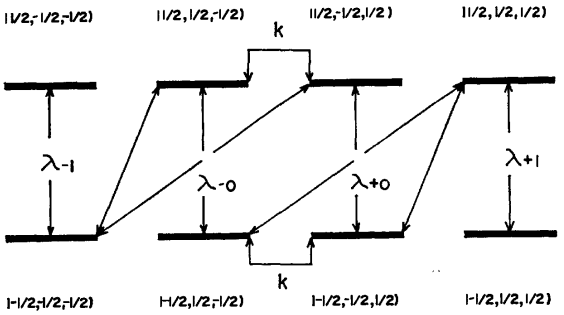

Fig. 1. Energy diagram of the system. Each level is expressed using wave function $|\sigma_e, \sigma_n^1, \sigma_n^2)$. Oblique lines are flip-flip or flop-flop transitions arising from the modulation of the END interaction. Horizontal line with arrow shows the transition corresponding to the intramolecular exchange. $\lambda_{\pm1}$, $\lambda_{\pm0}$ designate the ESR transitions.

* This work was presented at the 15th symposium on ESR Spectroscopy, Kumamoto, Oct. 1976.

by the random molecular motions. $\mathcal{H}$ is the spin Hamiltonian given by

$$\hbar\mathcal{H} = g_e\beta_e B_0 S_z + \sum_i(-\gamma_n\hbar B_0 I_z^i + a_i I_z^i S_z - 2B_2\gamma_n\hbar I_x^i \cos\omega_n t) + 2B_1 g_e\beta_e S_x \cos\omega_e t, \quad (2)$$

where B_1 and B_2 are the strengths of the microwave and the rf-field at the frequencies of ω_e and ω_n respectively, and where g_e and γ_n are the g-factor of the electron and the magnetogyric ratio of the nuclei respectively. B_0 is the strength of the static field, I_z^i and S_z are the z components of the nuclear and electron spin angular momentum, β_e represents the Bohr magneton, and a_i is the isotropic hfsc for the nucleus numbered "i."

The energy levels of the system are shown in Fig. 1, where t-butyl protons are omitted from consideration. Each ESR transition is designated using the sum of the quantum numbers for the ring protons, such as λ_{-1}, λ_{-0}, λ_0, and λ_1. For example, λ_{-0} is the transition between $|1/2, 1/2, -1/2)$ and $|-1/2, 1/2, -1/2)$; here $|\sigma_e, \sigma_n^1, \sigma_n^2)$ represents the spinwave function of the system. The subscripts "e" and "n" indicate electron and nucleus respectively.

The ENDOR intensity observed at the λ_j ESR transition is expressed as E_j. The ENDOR spectra have three peaks, 17.7, 16.2, and 13.8 MHz in the frequency region higher than the free proton frequency of 13.75 MHz. The intensity of the highest frequency peak of 17.7 MHz is expressed as E_j^{high}; it is defined as follows

$$E_j^{high} = (Z''(\lambda_j\text{: rf on}) - Z''(\lambda_j\text{: rf off}))/Z''(\lambda_j\text{: rf off}), \quad (3)$$

where Z'' corresponds to the absorption signal. E_j^{low} and $E_j^{t\text{-butyl}}$ are defined in the same manner as E_j^{high}. RE is defined as

$$RE = E_{-1}/E_{-0}. \quad (4)$$

The ENDOR spectra were calculated according to the theory developed by Freed, using Eqs. 1 and 2 for an eight-level system as is shown in Fig. 1. The coherent effects were omitted for the sake of brevity in the calculation.[5] The matrix elements in Eq. 1 were calculated by the standard procedure.[16] The correlation time was approximated according to the model developed by Debye and Einstein.[17] These results are listed in Tables 1 and 2. The temperature dependence of the reciprocal of the correlation time $(\tau_{ex})^{-1}$ in Eq. 1 was described by means of the Arrhenius equation as

$$k = (\tau_{ex})^{-1} = A\exp(-E_a/RT), \quad (5)$$

where A is the preexponential factor and E_a is the activation energy of the cation migration. The hfsc and the g-factor used in the calculation are listed in Table 3. The viscosity data for DME were taken from the literature.[18] The hydrodynamic radius was tentatively taken as 300 pm** on the basis of the molecular model.

** The radius of the DBQ molecule was estimated using the Stewart model, and the cubic root value was 370 pm. Atherton and Day have employed 350 pm for the 2,6-di-t-butyl-4-methylphenoxy radical; *cf.* N. M. Atherton and B. Day, *Mol. Phys.*, **27**, 145 (1974).

Table 1. Transition probabilities[a)]

$W_e^{g'}$	$10^{-1}\hbar^{-2}(\beta B_0)^2(g'\text{: }g')(\tau_r/1+\omega_e^2\tau_r^2)$
W_e^{sr}	$18^{-1}(\Delta g\text{: }\Delta g)\tau_r^{-1}$
W_n^i	$40^{-1}(A_1'\text{: }A_1')\tau_r$
$W_{x_1}^i$	$60^{-1}(A_1'\text{: }A_1')(\tau_r/1+\omega_e^2\tau_r^2)$
$W_{x_2}^i$	$10^{-1}(A_1'\text{: }A_1')(\tau_r/1+\omega_e^2\tau_r^2)$
Intramolecular exchange	k

a) The contributions of the hf interaction term and its cross terms with g-anisotropy to the electronic transition were disregarded. $W_e^{g'}$ and W_e^{sr} mean the electronic-transition probabilities arising from the modulation of the anisotropic g-tensor and the spin-rotation interaction respectively. W_n^i is the transition probability of the number i nucleus; *i.e.*, W_n^1 is of the nucleus at a low resonance frequency, while W_n^2 is of the nucleus at a high resonance frequency. $W_{x_1}^i$ and $W_{x_2}^i$ are the cross-relaxation probabilities arising from the END interaction of the "i" nucleus. 1 and 2 in the subscripts mean flip-flop and flop-flop or flip-flip transitions respectively. g' and Δg are the traceless part of the g-tensor and the deviation of g from the free-spin value respectively. (X: Y) denotes the inner product of the X and Y tensors.

Table 2. ESR and NMR linewidths[a)]

ESR	$\lambda_{\pm1}$	$7/3(\sum_i W_n^i) + W_e^{g'}(7/3+4/3\omega_e^2\tau_r^2) + W_e^{sr}$
	$\lambda_{\pm0}$	$7/3(\sum_i W_n^i) + W_e^{g'}(7/3+4/3\omega_e^2\tau_r^2) + W_e^{sr} + k$
NMR	high freq.	$7/3W_n^2 + W_e^{g'} + W_e^{sr} + W_n^1 + k$
	low freq.	$7/3W_n^1 + W_e^{g'} + W_e^{sr} W_n^2 + k$

a) These expressions are given by disregarding the contributions from various cross terms, and also the cross relaxations.

Table 3. Input parameters[a)]

Hyperfine tensors	proton 1	$A_{xx}=-0.21$G, $A_{zz}=1.90$G	$A_{yy}=-1.69$G
	proton 2	$A_{xx}=-0.14$G, $A_{zz}=1.24$G	$A_{yy}=-1.11$G
g-Tensor		$g_{xx}=2.0076$, $g_{zz}=2.0024$	$g_{yy}=2.0036$

a) The elements of the hf tensors of Na^+DBQ^- in DME were calculated using McConnell-Strathdee's formula.[27] Here only the contribution of the electron at the adjacent carbon atom was assumed, and Q_{CH} was taken as 2.30 mT.

Results and Discussion

Figures 2 and 3 show the temperature dependencies of E_j^{high}, E_j^{low}, RE^{high}, and RE^{low} for Na^+DBQ^- in DME. At temperatures higher than 220 K, E_{-1} is greater than E_{-0}. This tendency continued throughout the extrapolation of B_1 to infinity. The dependence on the rf-power was not examined for the lack of a reliable way to examine the incident rf-power on the sample, but the theoretical calculations show that RE^{high} and RE^{low} have small dependencies on the rf-power.

In solution, a difference in ENDOR intensity has been found among hf lines with same degeneracy, and

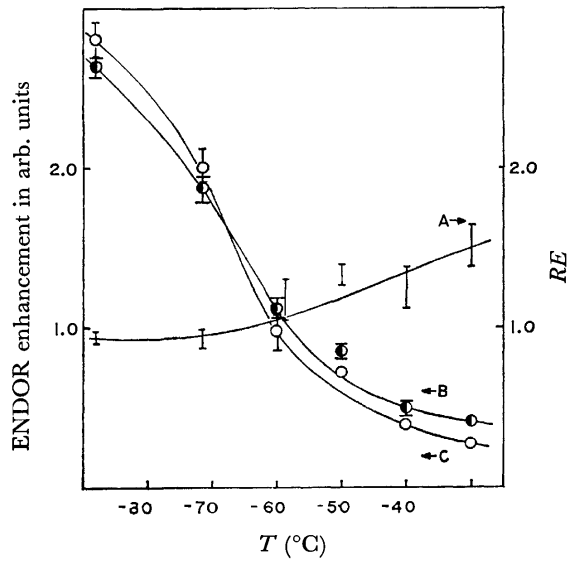

Fig. 2. ENDOR enhancements and the ratio as a function of temperature. B: E_{-1}^{high}; C: E_{-0}^{high}; A: RE^{high}.

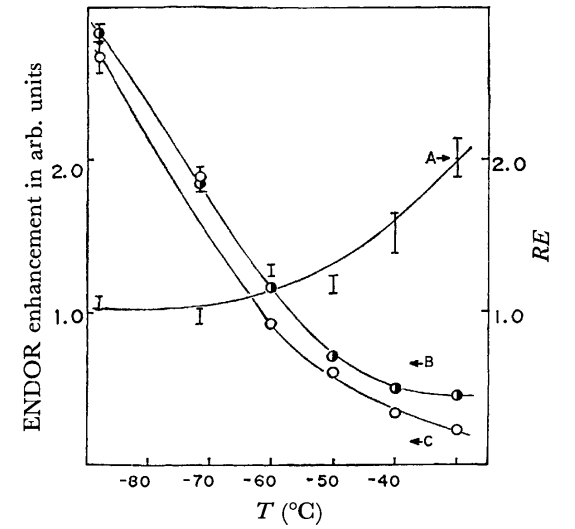

Fig. 3. ENDOR enhancements and the ratio as a function of temperature. B: E_{-1}^{low}; C: E_{-0}^{low}; A: RE^{low}.

this phenomenon has been explained on the basis of the cross relaxations due to the modulation of the isotropic hfc and electron nuclear dipole (END) interactions.[19-22] In the present system, however, the observed results could not be interpreted by the cross relaxations because E_{-1}^{high} and E_{-0}^{high} should be equal in the case of the cross relaxations. As is shown in the calculated results in Fig. 4, the temperature dependencies of RE's can be well interpreted by the introduction of the effect of the cation migration. The parameters used in the calculations in Figs. 4 and 5 were 3.0×10^{10} s^{-1} for A and 6.0 kcal mol^{-1} for E_a in Eq. 5. RE^{low} was larger than RE^{high} in the temperature range of the present experiment and also in the calculated results. Because this difference in the calculation comes from the cross relaxation, flip-flip, or flop-flop relaxation due to the modulation of the END interaction, this W_{x_2} may play an important role in the higher temperature region.

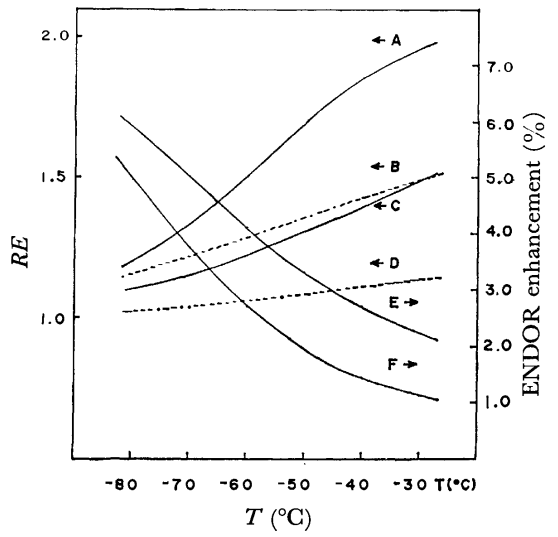

Fig. 4. ENDOR enhancement (calculated) as a function of temperature. A: RE^{low}; B: RE^{low} (without intramolecular exchange); C: RE^{high}; D: RE^{high} (without intramolecular exchange); E: E_{-1}^{low}; F: E_{-0}^{low}. The parameter B_1 was set as, $B_1=\sqrt{1.5}\,(T_1T_2)^{-1/2}(g_e\beta_e)^{-1}\hbar$ for each temperature. The parameter B_2 was set to be 0.5 mT throughout the calculation.

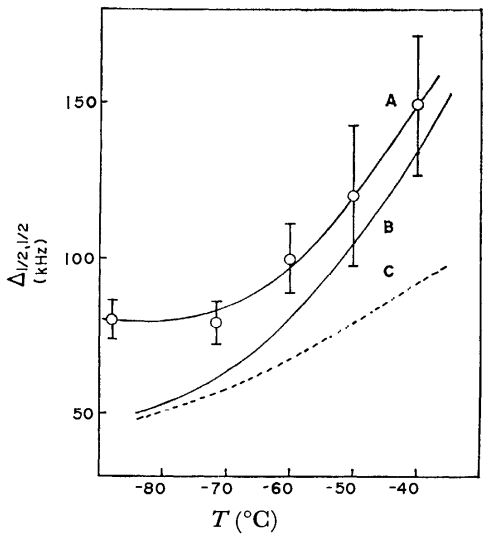

Fig. 5. ENDOR linewidth *vs.* temperature for Na^+-DBQ^- in DME. A: experimental; B: calculated with intramolecular exchange; C: calculated without intramolecular exchange. The parameters were the same as those taken in the calculation demonstrated in Fig. 4. The experimental conditions were shown in the text.

In the present system, all the levels are nondegenerate; thus, Heisenberg spin exchange contributes to all the nuclear transitions to the same extent. Therefore, it can not be the origin of the difference between E_{-1} and E_{-0}.

The ENDOR linewidth is a parameter which reflects the cation migration. The experimental and calculated results for the linewidth are shown together in Fig. 5. No difference was found between linewidths in the ENDOR spectra at the λ_{-1} and λ_{-0} ESR transitions.

The solid line shows the result of the calculation including intramolecular exchange, while the dotted line shows those of the calculation without exchange. The ENDOR linewidth rises steeply with the temperature. It increases by about 70 kHz as the temperature increases from −71.5 to −40 °C. There is no distinct change in the ESR spectra in this temperature range.

The Heisenberg spin exchange is a mechanism, the temperature dependence of whose rate is similar to that of the observed ENDOR linewidth. Leniart *et al.* have obtained the ESR linewidth of semiquinones in DME and have reported the rates of spin exchange at various temperatures.[23] Their results give an increase in the ENDOR linewidth of about 30 kHz in the concentration of about 5×10^{-4} mol dm^{-3} in the temperature range from −71.5 to −40 °C.[24] Thus, the contribution of this mechanism was ignored throughout the present calculation.[24]

Both the experiment and the calculation were carried out under the conditions of partial saturation; the saturation broadening is probably one of the main causes of the linewidth. Though the results obtained under partial saturation are less reliable than the ENDOR linewidth extrapolated to zero microwave and rf-power, it is useful only practically in the study of the systems which give merely a weak ENDOR signal.

In the case of K^+DBQ^-, *RE* departs from 1.0 at a lower temperature than in the case of Na^+DBQ^-. This fact corresponds to the results obtained for the ESR linewidth by Chippendale *et al.*, who have reported that the potassium ion starts its migration between two oxygen atoms at a lower temperature than does the sodium ion.[11]

Figure 6 shows the E_{-1} and E_{-0} of *t*-butyl protons at various temperatures, where superscripts denote the counter ions. A large difference between E_{-1} and E_{-0} was found; it may be considered to be another piece of evidence for the effect of the intramolecular exchange on the ENDOR intensity. The optimum temperatures for E_{-1} and E_{-0} were also different, as was to be expected from the fact that the temperature dependence of the intramolecular exchange is different from that of the other relaxation mechanisms.

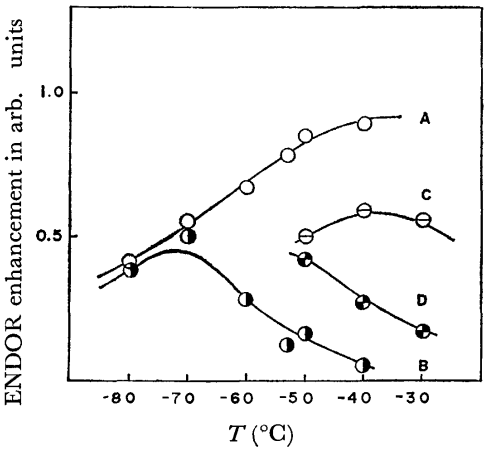

Fig. 6. ENDOR enhancement *vs.* temperature for the *t*-butyl protons of DBQ anion in DME. A: $E_{-1}(K^+)$; B: $E_{-0}(K^+)$; C: $E_{-1}(Na^+)$; D: $E_{-0}(Na^+)$. Counter ions are given in the parentheses.

As the hfsc of the *t*-butyl protons is of the same order as the ESR linewidth of the spin packet, the effect which has been pointed out by Allendoerfer and Maki becomes important.[25] This relationship gives the relative ENDOR intensities as a function of T_2 and hfsc:

$$E = E^0(T_2\Delta\omega)^2/[2.5+(T_2\Delta\omega)^2], \quad (6)$$

where E^0 is the ENDOR enhancement in the case of $T_2\Delta\omega\gg1$ and where $\Delta\omega$ is hfsc expressed in s^{-1}. The observed results, however, can not be described in terms of this effect because: 1) the spin packets of the ESR transitions, λ_{-1} and λ_{-0}, are equally broadened by the intramolecular exchange when the rate is much smaller than the hfsc of the *t*-butyl protons; 2) a tentative calculation using Eq. 6 shows that $RE^{t\text{-butyl}}$ is much smaller than 1.2 at 230 K, even if the value of k is simply added to the linewidth of the λ_{-0} ESR transition. Here 1.0×10^6 s^{-1} and 1.1×10^6 s^{-1} were used for the reciprocals of the spin-spin relaxation time of the λ_{-1} and λ_{-0} ESR transitions respectively.

The effect of the intramolecular cation migration on the ENDOR intensity is also apparent in the case of *t*-butyl protons.

Conclusion

The intramolecular cation migration in the system of the DBQ anion and the Na cation in DME was investigated by means of ENDOR at the smaller exchange rate. The ENDOR intensities of the DBQ anion at λ_{-1} and λ_{-0} ESR transitions were different from each other. The ratio (*RE*) of the ENDOR intensities, E_{-1} and E_{-0}, increased when the temperature was raised, becoming greater than 1.5 at temperatures higher than 240 K. This feature was successfully explained using the Kaplan-Alexander theory.

Besides the various mechanisms which determine the ENDOR intensity,[12,26] a new mechanism, the intramolecular exchange, was shown also to be important in ENDOR.

The fact that RE^{low} is greater than RE^{high} for the ring protons suggests a contribution of the flop-flop or flip-flip relaxation due to the END interaction with the ENDOR intensity[19] at high temperatures. The study of the dynamic process with both the linewidth and the intensity of ENDOR was shown to be more reliable than the study with only the linewidth.

Cyclohexadienyl Radicals in γ-Irradiated *catena*-μ-Ethylenediaminecadmium(II) *catena*-Tetra-μ-cyanomercurate(II)-Benzene (1/2) and the Analogous Clathrates

Toschitake IWAMOTO, Mamoru KIYOKI, and Niro MATSUURA

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro, Tokyo 153

(Received June 24, 1977)

Cyclohexadienyl radicals produced by γ-ray irradiation are thermally stable up to 423 K in the mother benzene clathrates $Cd(en)Hg(CN)_4\cdot 2C_6H_6$, $Cd(en)Cd(CN)_4\cdot 2C_6H_6$, $Cd(tn)Hg(CN)_4\cdot 2C_6H_6$, and $Cd(NH_3)_2Hg(CN)_4\cdot 2C_6H_6$. However, no thermally stable $C_6H_7\cdot$ radicals have been observed in $Cd(NH_3)_2Ni(CN)_4\cdot 2C_6H_6$ and $Cd(en)Ni(CN)_4\cdot 2C_6H_6$ even immediately after irradiation. The ESR spectra of $C_6H_7\cdot$ show the hyperfine splitting constants of the methylene, para, ortho, and meta protons 48, 13, 9, and 3 G, respectively.

The cavity for a guest molecule is expected to be a good reservoir of chemically unstable species in the host structure of a clathrate compound when the interaction between the guest and the host is negligibly weak. As has been demonstrated in the crystal structures determined by X-ray diffraction,[1] the guest benzene molecules in Hofmann type and the analogous benzene clathrates are individually imprisoned in the cavities surrounded by three-dimensional bridged metal complex host structures. Each benzene molecule apprears to be an isolated molecule trapped in a container of the volume slightly larger than that of the molecule itself. If a chemically unstable radical is once trapped in the container surrounded by an inactive wall, the radical may survive for a long time even at high temperature. From this point of view the present authors undertook to produce paramagnetic radicals from the guest species by γ-ray irradiation of diamagnetic Hofmann type and the analogous clathrates, and to investigate the stability of the radicals in the mother clathrates. A preliminary communication[2] gave a brief account of the thermal stability of the cyclohexadienyl $C_6H_7\cdot$ radicals up to 423 K which were produced by γ-irradiation of $Cd(en)M(CN)_4\cdot 2C_6H_6$ (M=Cd or Hg) clathrates. This paper reports on detailed experimental results obtained from γ-irradiated $Cd(diam)M(CN)_4\cdot 2C_6H_6$ (diam=en, tn, or $(NH_3)_2$; M=Cd, Hg, or Ni) clathrates, and on the correlation of clathrate structure with stability of the radicals.

Experimental

The benzene clathrates examined are as follows: $Cd(en)Hg(CN)_4\cdot 2C_6H_6$,[3] $Cd(en)Cd(CN)_4\cdot 2C_6H_6$,[3] $Cd(tn)Hg(CN)_4\cdot 2C_6H_6$,[15] $Cd(NH_3)_2Hg(CN)_4\cdot 2C_6H_6$,[4] $Cd(en)Ni(CN)_4\cdot 2C_6H_6$,[5] and $Cd(NH_3)_2Ni(CN)_4\cdot 2C_6H_6$.[6] $Cd(en)Hg(CN)_4\cdot 2C_6D_6$, $Cd(en)Hg(CN)_4\cdot 2C_4H_5N$, and $Cd(en)Hg(CN)_4$ were also irradiated for the sake of comparison.

The polycrystalline specimens were evacuated at 195K and sealed in silica ampoules at 1.3×10^{-3} Pa. The sealed specimens were irradiated with 6.5×10^3 J/kg ^{60}Co γ-rays at liquid nitrogen temperature. The irradiated specimens were kept at liquid nitrogen temperature till their ESR measurements. The ESR spectra were recorded on a JEOL-JES-PE-3X spectrometer with an X-band frequency and a field modulation of 100 kHz in the temperature range 77—423 K.

Results and Discussion

General Features of the ESR Spectra. At liquid nitrogen temperature all the irradiated specimens gave ESR signals due to radicals produced from the host constituents. Also observed were strong signals due to organic radicals centered at $g=2.003$ for the pyrrole and the benzene clathrates except for $Cd(en)Ni(CN)_4\cdot 2C_6H_6$ and $Cd(NH_3)_2Ni(CN)_4\cdot 2C_6H_6$. The signals due to the host constituents are thought to be those of the hot ions Cd(I) and Hg(I),[7] H·, and other unidentified radicals. These signals were observed over a wide (0.2 T) range of magnetic field with intensities far lower than those of the organic radicals as shown in Fig. 1. Their features differ with specimen, depending on host constituent. As the temperature is increased to 200 K, the signals due to the host constituents decay showing their thermal instability. Furthermore, the hyperfine structure in signals centered at $g=2.003$ becomes more clearly resolved with increasing temperature. For the benzene clathrates, the strong absorptions are assigned to cyclohexadienyl $C_6H_7\cdot$ radicals produced from the

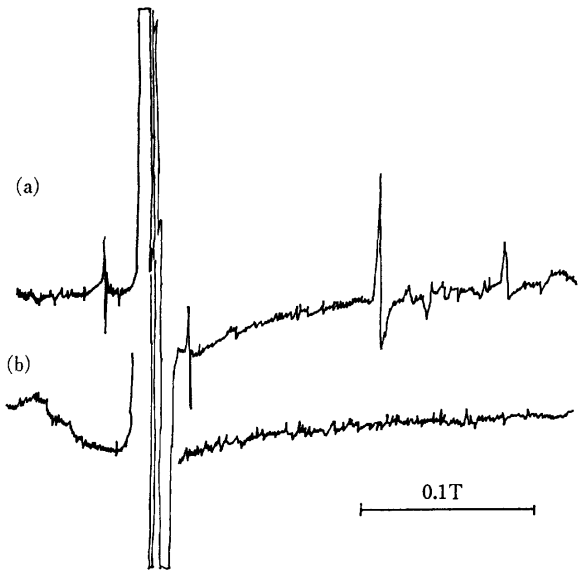

Fig. 1. ESR Spectra of the irradiated $Cd(en)Hg(CN)_4\cdot 2C_6H_6$ measured (a) at 100 K and (b) at 200 K. The strongest absorption centered at $g=2.003$ in due to organic radicals, and it is omitted is (b).

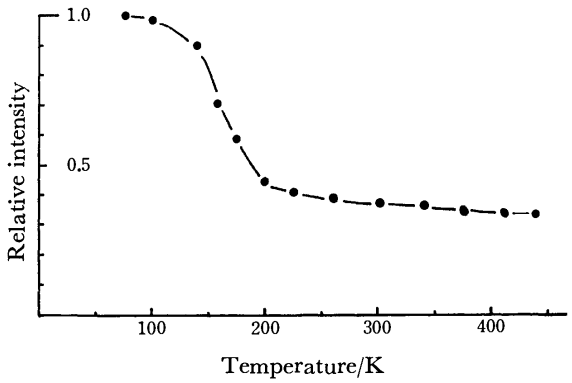

Fig. 2. Temperature dependence of the relative ientensity of the C_6H_7· absorption in the ESR spectrum of the irradiated Cd(en)Hg(CN)$_4$·2C_6H_6. The intensity was measured at each temperature with 1 h interval successively from 77 to 423 K.

enclathrated benzene molecules. The apparent intensity of the C_6H_7· absorption decreases strongly with increasing temperature up to 200 K where it is approximately 40% of that at liquid nitrogen temperature, the decrease becoming more gradual from 200 to 423 K (Fig. 2). The spectral linewidths become narrower with increasing temperature. Except for the two cases mentioned above, the thermal behavior of the C_6H_7· ESR signal is the same for all the irradiated benzene clathrates. Above 423 K the host metal complex begins to decompose thermally in the sealed ampoules.

The irradiated pyrrole clathrate also gave ESR signals due to organic radicals produced from the guest pyrrole. The spectral analysis, however, has not yet been completed.

Spectral Assignment of C_6H_7·. The ESR spectrum assigned to C_6H_7· has a main triplet of the intensity ratio 1:2:1 with about 48 G splitting, where G=10^{-4} T. The 48 G splitting of the triplet has been observed by a number of workers.[8-12] The 1:2:1 intensity ratio excludes significant formation of C_6H_5· observed for irradiated neat benzene.[8] The triplet is due to the hyperfine coupling of the electron spin with two methylene protons. The irradiated benzene-d_6 clathrate Cd(en)Hg(CN)$_4$·2C_6D_6 gave a broad doublet (*ca.* 40 G) structure in its ESR spectrum at low temperature. With increasing temperature the spectra became so complicated that the hyperfine structures except for a doublet (41.5 G) with a triplet (7.2 G) substructure could hardly be interpreted. The doublet may be due to the proton in the methylene position of C_6D_6H· and the triplet to the deuteron in the same position.[10] According to these observations, the formation scheme of C_6H_7· in the irradiated benzene clathrate is suggested as follows:

$$\text{HostH} \xrightarrow{\gamma\text{-rays}} \text{Host}\cdot + \text{H}\cdot$$

$$\text{H}\cdot + C_6H_6 \longrightarrow C_6H_7\cdot$$

The H· may be produced from the diamine or diammine ligand of the host metal complex.

Each component of the 48 G triplet shows a pseudoquartet structure with a 13 G splitting between the inner pair and a 9 G splitting between the outer and the inner components. A third hyperfine splitting (hfs) of a triplet (3 G) becomes clearer in each component of the pseudoquartet with increasing temperature above 200 K owing to the motional narrowing of linewidths. As has been demonstrated by wide-line ^{1}H-NMR of the benzene clathrates,[13] the enclathrated benzene molecules begin to reorientate about the molecular sixfold axis at 125 K and rotate with little hindrance above 160 K. The motional behavior of the C_6H_7· resembles that of the benzene molecule judging from the narrowing of ESR linewidths.

No radicals other than C_6H_7· have been identified, although in some cases broad and very weak signals are observed which overlap with the C_6H_7· absorption up to 323 K.

The Hfs Constants of C_6H_7·. According to the calculations by Shida and Hanazaki,[12] the hfs constants for the *p*-proton and the *o*-protons of C_6H_7· are 11.2 G and 10.6 G, respectively. Morokuma *et al.*[14] reported another set of −11.4 and −11.1 G. However, the

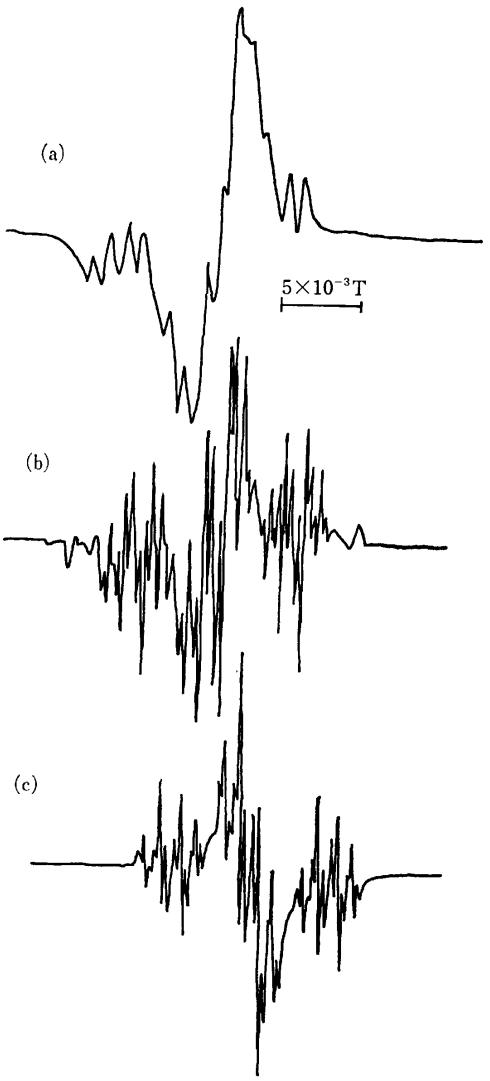

Fig. 3. ESR Spectra of the irradiated Cd(en)Cd(CN)$_4$·2C_6H_6 measured (a) at 77 K and (b) at 293 K, and that of the irradiated Cd(en)Hg(CN)$_4$·2C_6H_6 measured (c) at 373 K.

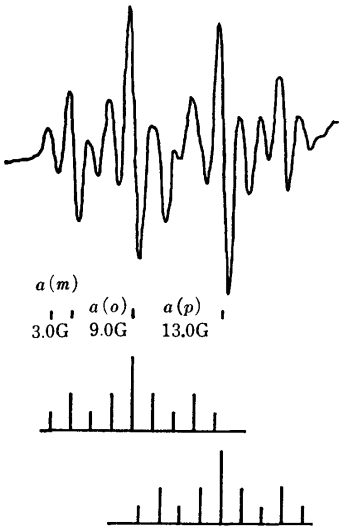

Fig. 4. The ESR hyperfine structure of $C_6H_7\cdot$ in the irradiated $Cd(en)Hg(CN)_4\cdot 2C_6H_6$ observed at 423 K. The lower field side of the 48.3 G main triplet is shown along with Fessenden-Schuler's scheme.[11]

difference between these hfs constants has never been observed for $C_6H_7\cdot$ produced by the irradiation of neat benzene or benzene solutions because of the thermal instability of the $C_6H_7\cdot$ radicals in the matrices used. The previous workers assigned the observed pseudo-quartet to the hfs due to the three protons at the para and ortho positions with nearly the same hfs constants. As shown in Fig. 3 for the present clathrates, it is possible to observe the ESR spectrum of $C_6H_7\cdot$ with a fairly good resolution up to such a high temperature that all of the unstable species collapse and the intermolecular dipole interactions become negligible. Although the resolution is still not high enough to make all the hfs components split clearly, we can discriminate between the hfs constants of the *p*-proton and the *o*-protons (Fig. 4). It is clearly seen that the spectrum of $C_6H_7\cdot$ in the irradiated $Cd(en)Hg(CN)_4\cdot 2C_6H_6$ is composed of a main triplet due to methylene protons (a(methylene)=48.3 G), a doublet due to the *p*-proton ($a(p)$=13.0 G), a triplet due to *o*-protons ($a(o)$=9.0 G), and a triplet due to *m*-protons ($a(m)$=3.0 G). The magnitude of the respective splitting constants is nearly the same for the $C_6H_7\cdot$ radicals in all the irradiated benzene clathrates. These observations do not agree with the previous observations with low resolution spectra for which approximately the same hfs constants were assigned for the *p*-proton and *o*-protons. However, the present results are in good agreement with those of Fessenden and Schuler.[11] They observed the ESR spectrum of liquid 1,4-cyclohexadiene during the course of irradiation with 0.4 μA of 2.8 mV electrons. Although their spectrum was not displayed, 72 resolved lines were assigned to $C_6H_7\cdot$ with a(methylene)=47.71 G, $a(p)$=13.04 G, $a(o)$=8.99 G, and $a(m)$=2.65 G. They observed that the central region of the main triplet splits into two sets of 18 lines owing to the release of degeneracy of the two m=0 states because of the second order effect for the large splitting constant. In the present spectrum of the solid specimen, the 1.5 G linewidth hides the second order splitting (0.69 G), only 13 lines being observed even in the central region. However, the spectrum can be interpreted substantially in terms of the scheme by Fessenden and Schuler.

Clathrates as Chemical Reservoir of Radicals. The $C_6H_7\cdot$ radicals produced in these benzene clathrates are thermally stable up to 423 K and survive for at least a few hours at 423 K. When the irradiated clathrates were kept at liquid nitrogen temperature even after the temperature of the specimen had been raised up to 423 K, the radicals still survived for at least a few weeks. Thus, the host metal complex Cd(diam)$M(CN)_4$ (diam=en, tn, or $(NH_3)_2$; M=Cd or Hg) is an excellent reservoir for the $C_6H_7\cdot$ radicals. However, it should be noted that no ESR spectrum for $C_6H_7\cdot$ was observed for the γ-irradiated $Cd(en)Ni(CN)_4\cdot 2C_6H_6$ and $Cd(NH_3)_2Ni(CN)_4\cdot 2C_6H_6$ even at liquid nitrogen temperature, although signals due to the thermally unstable radicals originating from the host constituents were observed.

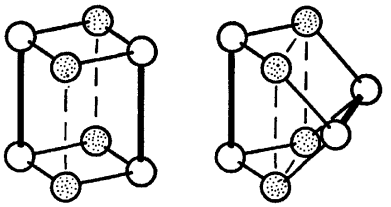

Fig. 5. Two kinds of guest cavities in Cd(diam)$M(CN)_4\cdot 2C_6H_6$ clathrates. (a) Tetragonal or rhombic frame is built up with square-planar $Ni(CN)_4$, or tetrahedral $Cd(CN)_4$ or $Hg(CN)_4$ moieties. (b) Biprismatic frame is possible only with the tetrahedral moieties. Open circle: Cd, dotted circle: M, thick line: diam (en, tn, or $(NH_3)_2$), thin line: CN.

The Hofman type $Cd(NH_3)_2Ni(CN)_4\cdot 2C_6H_6$ and the Hofmann-en type $Cd(en)Ni(CN)_4\cdot 2C_6H_6$ have a host of two-dimensionally extended $CdNi(CN)_4$ sheets containing the square-planar $Ni(CN)_4$ moieties. In the Hofmann type host two ammonia molecules protrude from adjacent sheets at the Cd atoms; in the Hofmann-en type host the protrusions between adjacent sheets are replaced by an ambident en ligand. These hosts have only one kind of guest cavity with a tetragonal or rhombic shape, as is shown in Fig. 5, while the hosts of the other clathrates, which stabilize $C_6H_7\cdot$, have both tetragonally and biprismatically shaped cavities due to the linkages of tetrahedral $Cd(CN)_4$ or $Hg(CN)_4$ moieties.[15] It appears that only the biprismatic cavity is effective in stabilizing $C_6H_7\cdot$. The partial volume of unit cell per benzene molecule was found to be *ca.* 270 Å^3 (Å=10^{-10} m) for the clathrate having biprismatic cavity. It is larger by *ca.* 30 Å^3 for the Hofmann type and Hofmann-en type, which gave no stable $C_6H_7\cdot$. The effective volume of the cavity might also be a critical factor in radical stability.

The authors' thanks are due to Professors Shizuo Fujiwara and Katsumi Tokumaru for their kind

permission to use their ESR spectrometers at the Department of Chemistry, Faculty of Science, this University, in the preliminary stage of this investigation.

Emission Spectra of Naphthalene Derivatives by Controlled Electron Impact

Teiichiro OGAWA, Nobuaki MIYAMOTO,* and Nobuhiko ISHIBASHI
Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812
(Received June 30, 1977)

Naphthalene, 1-methylnaphthalene, 2-methylnaphthalene, 1-naphthol, 1-naphthylamine, 2-chloronaphthalene, 1-bromonaphthalene, 2-bromonaphthalene, and tetralin were excited in a very low pressure by controlled electron beam of 150—400 eV. The molecules, except those with a halogen atom, revealed an intense emission band similar to fluorescence. The band was assigned to the transition from their lowest-excited singlet state to their ground state. It was concluded that the most important process of photoemission is the excitation into a higher excited state in the primary collision and the subsequent non-radiative transfer to the lowest-excited state. The molecules showed photoemission of such excited fragments as H, CH, C_2, $C_4H_2^+$, CN, NH, OH, CO, CO^+, HCl^+, and HBr^+. A two-electron process by way of an intermediate was found to be important for the formation of such fragments as CN from naphthylamine.

The electron impact method has certain advantages for the investigation of the elementary process of molecular excitation, ionization, and dissociation. A comparatively intense photoemission can be obtained in a very low pressure and the excitation energy can be controlled easily in a wide range. The discharge method was used for this purpose; however, the use of a controlled electron beam in a low pressure has made it possible to investigate the elementary process without collision participation. The emission spectra of benzene,[1] its derivatives,[1,2] and naphthalene[3] by this method have been reported and the primary process of their excitation and dissociation has been investigated.[4]

The emission spectra of naphthalene derivatives, noteworthy for a stronger fluorescence than that of benzene derivatives, will be presented in this report. The excitation process of these molecules and the effect of a substituted group on the spectrum will be discussed in reference to the results of the benzene derivatives.

Experimental

The experimental apparatus was essentially the same as the one described previously.[1] The collision chamber was made of glass and was separated into two parts by a brass plate with a hole of 4 mm at its center. The thermal electrons were accelerated and collimated in the upper part, and introduced into the collision region (the lower part) through the hole. The sample was deaerated and introduced into the collision region through a nozzle (0.1—8 mm). When necessary, the sample manipulation line could be heated for the purpose of increasing the vapor pressure of sample. The collision chamber was continuously evacuated with two oil-diffusion pumps, the sample pressure in the collision region being estimated to be 10^{-2}—10^{-3} Torr. The sample vapor revealed photoemission upon collision with the electron beam. The photoemission was observed photoelectrically by use of a Jasco CT-50 monochromator (blazed for 300 nm). The energy of the electron beam was 150—400 eV, and the electron-beam current was 10—200 μA.

The excitation spectrum of fluorescence in a solution was recorded on a Hitachi MPF-4 fluorescence spectrophotometer. The spectral response of this instrument was calibrated down to 250 nm in references to the fluorescence of rhodamine B.

The naphthalene derivatives (Tokyo Kasei Co. and Kishida Chem. Co.) and cyclohexane, the solvent for the measurement of the excitation spectrum (luminasol, Dojindo Chem. Co.), were used.

Results

A typical spectrum of 2-methylnaphthalene is shown in Fig. 1. A diffuse band in the 315—390 nm region was assigned to the transition from the lowest-excited electronic state (S_1) to the ground electronic state (S_0), since its fluorescence spectrum was located in the same region[5] and the similar spectrum was obtained for toluene.[1] Some vibrational structures appeared on the spectrum of toluene[1] and naphthalene.[3] However, the spectrum of 2-methylnaphthalene indicated no definite structures even by measurement with a 2.5 Å resolution. The hydrogen Balmer lines and the bands of CH(A-X) and CH(B-X) were observed in the spectrum. The bands of C_2 and $C_4H_2^+$ were also observed in the longer wavelength region. The spectrum of 1-methylnaphthalene was very similar to that of 2-methylnaphthalene.

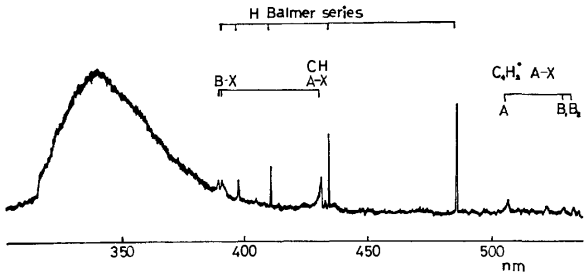

Fig. 1. Emission spectrum of 2-methylnaphthalene by controlled electron impact. Electron energy, 200 eV; electron-beam current, 30 μA.

The spectrum revealed no appreciable alteration with a change in the electron energy (150—400 eV). The intensity of the bands of the parent molecule, $H(H_\beta)$, and CH(A-X) was proportional to the electron-beam current at 200 eV excitation. This indicates that the excitation of the parent molecule and the dissociative excitation of H and CH proceed through one-electron primary processes.

* Present address: Ariake Technical College, Omuta, Fukuoka 836.

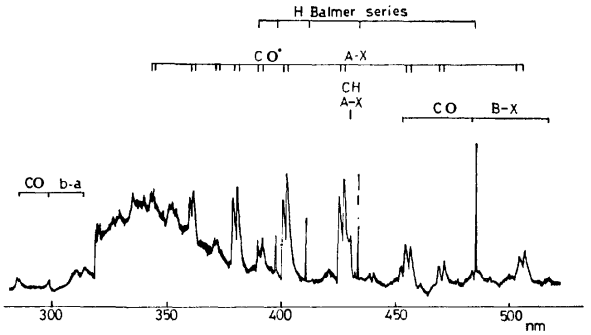

Fig. 2. Emission spectrum of 1-naphthol by controlled electron impact. Electron energy, 200 eV; electron-beam current, 80 μA.

A typical emission spectrum of 1-naphthol is shown in Fig. 2. The band of the S_1-S_0 transition of the parent molecule was diffuse, its peak being located at *ca.* 340 nm. The hydrogen Balmer lines, and the bands of CH(A-X), CO^+(A-X), CO(b-a), and CO(B-A) were also observed. The intensity of the emission of the parent molecule, H, and CH was proportional to the electron-beam current, indicating that these excited species are produced in one-electron primary processes. The intensity of the band of CO^+, however, was found to be proportional to about 1.5 powers of the electron-beam current; its formation should involve some secondary process.

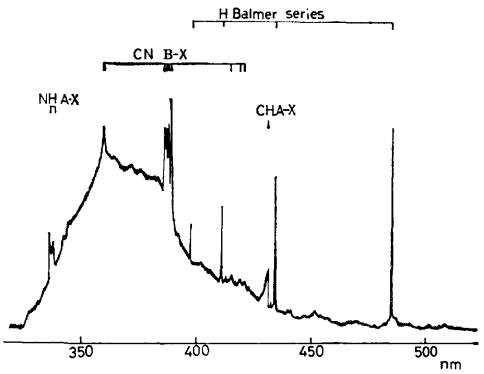

Fig. 3. Emission spectrum of 1-naphthylamine by controlled electron impact. Electron energy, 200 eV; electron-beam current, 20 μA.

A typical emission spectrum of 1-naphthylamine is shown in Fig. 3. The band of the S_1-S_0 transition of the parent molecule was diffuse, its peak being located at *ca.* 370 nm. The bands of NH(A-X), and CN(B-X) were observed in addition to those of H and CH. The intensity relationship of these bands excited at 200 eV is shown in Fig. 4. The intensity of the bands of the parent molecule, H, and CH was proportional to the electron-beam current as in the case of other molecules. However, that of CN was proportional to *ca.* 1.2 powers of the electron-beam current.

The emission spectra of 2-chloronaphthalene and 1- and 2-bromonaphthalene were similar to those of chloro- and bromo-benzene,[2] respectively. In both cases, no features identifiable as the S_1-S_0 transition

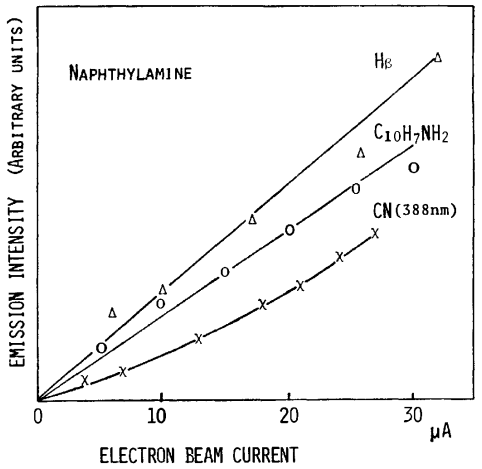

Fig. 4. Dependence of emission intensities on the electron-beam current. Electron energy, 200 eV.

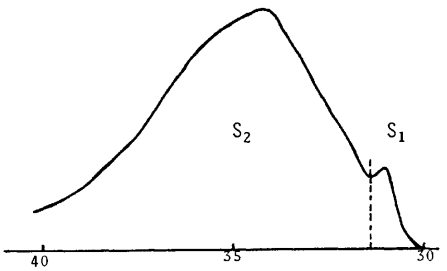

Fig. 5. Excitation spectrum of fluorescence of 1-naphthol in a cyclohexane solution. The spectral response of the spectrophotometer was corrected.

of the parent molecule could be observed, partly because the intense bands of HCl^+(A-X) or HBr^+(A-X) were located in the interesting region. The emission spectrum of tetralin revealed a band in the 270—315 nm region, which could be assigned to the S_1-S_0 transition of the parent molecule, since the location and band shape were similar to those of xylene.[1]

A typical excitation spectrum of fluorescence at 338 nm of 1-naphthol is shown in Fig. 5. Its absorption maxima were reported to be at 31300 and 34100 cm^{-1} for the S_1-S_0 and S_2-S_0 transitions, respectively.[6] The band was divided into two parts in the valley at 31400 cm^{-1} and the relative intensity was determined by the band area. Identical measurements were also carried out for naphthalene and 2-methylnaphthalene and the results are shown as ϕf in Table 1.

Table 1. Relative contribution of the two excitation process

		ϕf	$\phi f/E$
Naphthalene	S_1	1	1
	S_2	45	40
2-Methyl-naphthalene	S_1	1	1
	S_2	34	30
1-Naphthol	S_1	1	1
	S_2	22	20

Discussion

The Spectrum. The results of emission spectra observed in the present study are summarized in Table 2. The bands are classified according to their intensity relation to the electron-beam current.

TABLE 2. EMISSION SPECTRA OF NAPHTHALENE DERIVATIVES BY CONTROLLED ELECTRON IMPACT

Compound	S_1-S_0[a]	H	CH	$C_4H_2^+$	Others[b]
Naphthalene	○	○	○	○	
1-Methylnaphthalene	○	○	○	▽	
2-Methylnaphthalene	○	○	○	▽	
1-Naphthylamine	○	○	▽	▽	CN ●, NH ▽
1-Naphthol	○	○	▽		CO^+●, CO▽
2-Chloronaphthalene	×	▽	▽	▽	HCl^+ ▽
1-Bromonaphthalene	×	▽	▽	▽	HBr^+ ▽
2-Bromonaphthalene	×	▽	▽	▽	HBr^+ ▽
Tetralin	○	○	○	▽	

○: Band observed; intensity proportional to the electron-beam current. ●: Band observed; intensity not proportional to the electron-beam current. ▽: Band observed; intensity not measured. ×: No band observed.
a) Band of the parent molecule from the lowest excited state (S_1) to the ground state (S_0). b) Bands of excited fragment species.

The bands of the S_1-S_0 transition of the naphthalene derivatives are broad, lacking remarkable structures in contrast to their fluorescence spectra in cyclohexane.[5] Although the resonance fluorescence of naphthalene (0.05 Torr) is sharp and has many structures, it becomes broad and diffuse upon irradiation into the second excited state (S_2).[7] Thus, the band shape of the emission spectra by electron impact is similar to that of the resonance fluorescence obtained by the S_2 excitation. This is due to the fact that the excitation into higher excited states (such as S_2) is important in the electron-beam excitation.

The location and intensity of the S_1-S_0 transition of parent molecule depend on the kind of substituted group. The bands of the methyl and hydroxyl derivatives shift a little to the longer wavelength region as compared with that of naphthalene; the band of the amino derivative shifts considerably in the same direction. Although some fluorescence band was observed for the halogen derivatives in the cyclohexane solution, its quantum efficiency was small,[5] and no emission could be identified as their S_1-S_0 transition under electron-impact excitation. Heavy halogen atoms, such as Cl or Br, attached to an aromatic molecule are known to accelerate the rate of intersystem crossing and reduce the quantum efficiency. Furthermore, the C–X bond is susceptible to the bond scission and this can also contribute to the reduction of the emission intensity.

Excitation Process. Most fluorescent molecules, in a vapor phase or in a solution, emit fluorescence radiation mostly from the S_1 state, even when they are excited into a higher state. This is also the case with the emission spectra by controlled electron impact. Since an electron can excite a molecule into various excited states below the electron energy, it is significant to determine which excited state is actually contributing the observed photoemission.

The probability of the excitation of a molecule from the S_0 state to the S_i state is proportional to f_i/E_i, where f_i and E_i denote the oscillator strength and the transition energy of the i-th transition, respectively.[9] The probability of photoemission from the S_i state after the non-radiative transfer from the initially prepared state (S_i) to the S_1 state is represented by the fluorescence quantum yield (ϕ_i). Thus, the intensity of photoemission (I_i), which involves the S_i state in the primary process, is[3]

$$I_i = a\phi_i f_i/E_i, \quad (1)$$

where a is a proportionality constant.

Although the values of ϕ_i, f_i, and E_i measured in a vapor phase should be used to estimate I_i, no such spectroscopic parameters of naphthalene derivatives seem to have been reported. The fluorescence quantum yield of naphthalene was reported to be 0.23 in a cyclohexane solution[5] and 0.4—0.8 in vapor;[8] its f value did not show a large variation in proceeding from vapor to solution.[10] The results indicate that the difference of the optical parameters in vapor and in a solution is not significant and the spectroscopic parameters in a cyclohexane solution may be carried over for a semi-quantitative estimation of the excitation process by use of Eq. 1.

The relative intensity of the excitation spectrum of fluorescence can be set to the relative value of $\phi_i f_i$ in this approximation. The results of $\phi_2 f_2$ relative to $\phi_1 f_1$ are shown in Table 1. The spectrum is similar to the absorption spectrum. This indicates that the quantum yield varies little in this region and the present estimation should be taken as a semi-quantitative one.

There are two excitation processes: The direct excitation process, in which the molecule is excited primarily into the S_1 state and radiates from this state directly, and the indirect excitation process, in which the molecule is excited in the S_2 state primarily, relaxes to the S_1 state non-radiatively and then emits radiation from the S_1 state. As shown in Table 1, the indirect excitation process is more important. Since naphthalene and its derivatives have large f_2 and f_3 and the rate of non-radiative transition to the S_1 state is relatively large, the indirect process gives a larger contribution to the photoemission than the direct process.[3] This is partly due to a larger conjugate system and a smaller difference of the energies between the S_1 state and the S_2 and S_3 states than that of benzene derivatives.[11]

The band of the S_1-S_0 transition of the parent molecules is more diffuse and structureless than that of fluorescence in a solution and shifts to the longer wavelength region. This has much to do with the excitation process. In a solution large intermolecular interaction induces a fast non-radiative transfer of the initially prepared excited state to the ground vibrational level of the S_1 state and the transition from this level reveals some vibrational structures. However, when the collisional deactivation within the lifetime of the radiative excited state is negligible, the initially

prepared highly excited state transfers intramolecularly to the higher vibrational levels of the S_1 state and then the molecule emits radiation. Since high vibrational levels are involved and the naphthalene derivatives have more complicated vibrational levels than the benzene derivatives, the emission band becomes diffuse and structureless and shifts to the red as compared with that in a solution. This is consistent with the fact that the resonance fluorescence becomes broad and structureless with increase in excitation energy.[7]

Dissociative Excitation. The emission spectra excited by controlled electron impact have many bands of excited fragment species as summarized in Table 2. The intensity of bands of H and CH is proportional to the electron-beam current. It can be concluded that these species are produced in one-electron primary processes as in the case of benzene derivatives.[4] The sum of the dissociation energy and the excitation energy in the formation of H* and CH* is larger than the ionization energy of the parent molecules. This may indicate that the formation of H* and CH* proceeds by way of a superexcited state.[12]

The emission intensities of CO^+ from 1-naphthol and of CN* from 1-naphthylamine are not proportional to the electron-beam current as indicated in Fig. 4 and Table 2. The formation of CN* from aniline also exhibits a non-linear relationship,[2] but not that of CO^+ from phenol.[11]

The excited fragment species, the intensity of which was not proportional to the electron-beam current, often have two or more heavy atoms (C, N, O, *etc.*) and are also produced by breaking two or more skeletal bonds of the parent molecule.[13] The formation of such species was elucidated by the scheme in which two dissociative excitation processes contribute to an appreciable extent:[11,13]

$$C_{10}H_7NH_2 + e \longrightarrow CN^* \quad \text{(one-electron process)}$$

$$\left.\begin{array}{l} \searrow\ M \\ M + e \longrightarrow CN^* \end{array}\right\} \text{(two-electron process)}$$

where M stands for an unidentified intermediate species. Although the collision probability of a radiative species is negligible, any fragment species in the metastable or ground electronic states may be affected by collision. The relative importance of these two processses are dependent on the reactivity of the species concerned. In the formation of such species as H* and CH*, the two-electron process is of negligible importance in the region studied.

In brief, the emission spectra of naphthalene derivatives agree qualitatively with those of benzene derivatives; however, there are some quantitative differences.

The authors thank Mr. Masaharu Tsuji of the Research Institute of Industrial Science for his discussion and Mr. Kenyu Kina for his cooperation in the measurement of the excitation spectrum of fluorescence.

Barrier to Internal Rotation around the Isopropyl-Nitrogen Bond of Some *N,N*-Diisopropyl-1,3-dithia- and 1,3-diselenacycloalkan-2-iminium Salts, $[\overline{X(CH_2)_nXCN(i\text{-}Pr)_2}]^+Y^-$ (X=S, Se; Y=Br, PF_6; n=2,3)

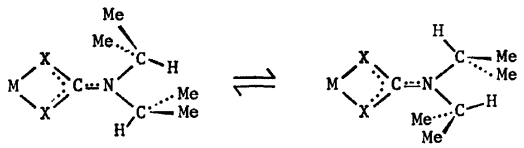
Yu-ichi TAKEDA, Tsuneo MATSUDA, and Toshio TANAKA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received July 4, 1977)

Activation parameters for rotation around the isopropyl-nitrogen bond of the title compounds were determined by the line shape analysis of ^1H NMR spectra. The E_a values lie in the ranges of 58—60 kJ/mol for X=S and 52—54 kJ/mol for X=Se. The activation parameters are little influenced by the ring size of the 1,3-diheteracycloalkane moiety and the counter anions.

Internal rotation around the isopropyl-nitrogen bond in metal complexes of diisopropyldichalcogenocarbamate is well known to cause interconversion between two stable equivalent rotamers as follows.[1-3]



X=S, Se

The barriers (E_a) to rotation of this kind have been reported for some metal complexes of diisopropyldithiocarbamate (dtc) and diisopropyldiselenocarbamate (dsc). The E_a values obtained so far, however, are rather scattered; $Ni(dtc)_2$, 19;[1] $Co(dtc)_3$, 21;[1] $Ti(dtc)_nCl_{4-n}$, 42.3 for n=2 and 41.0 for n=3, 4;[2] $R_2Sn(dtc)_2$, 76.6 for R=Cl and 68.6 for R=Me;[3] and $R_2Sn(dsc)_2$, 69.0 for R=Cl and 58.2 for R=Me[3] (the values in kJ/mol). The values for the Ni(II) and Co(III) complexes were obtained by line shape analysis of the methine proton signal, and those for the other complexes by the same analysis of the isopropyl-methyl proton signal. A similar interconversion between two equivalent rotamers has been proposed for (diisopropylamino)bis(methylthio)methylium perchlorate, $[(MeS)_2CN(i\text{-}Pr)_2]^+ClO_4^-$, only $\Delta G^{\ddagger}$ value being obtained.[4]

This paper reports the results of line shape analysis of the isopropyl-methyl proton signal of *N,N*-diisopropyl-1,3-dithia- and 1,3-diselenacycloalkan-2-iminium bromides and hexafluorophosphates, $[\overline{X(CH_2)_nXCN(i\text{-}Pr)_2}]^+Y^-$ (X=S, Se; Y=Br, PF_6; n=2, 3). The purpose of this work is to elucidate both effects of the hetero atoms in the 1,3-dichalcogenacycloalkane ring and the ring size on the activation parameters for rotation around the isopropyl-nitrogen bond.

Experimental

N,N-Diisopropyl-1,3,-dithiacyclohexane- and -cyclopentan-2-iminium bromides and their diselena analogs, $[\overline{X(CH_2)_nXCN(i\text{-}Pr)_2}]^+Br^-$ (n=3, X=S (**1a**); n=2, X=S (**2a**); n=3, X=Se (**3a**); n=2, X=Se (**4**)), were prepared by the reaction of 1,3-dibromopropane or 1,2-dibromoethane with Na(dtc) or $Me_2Sn(dsc)_2$ according to the method described for the *N,N*-dimethyl derivatives.[5] The corresponding hexafluorophosphates, $[\overline{X(CH_2)_nXCN(i\text{-}Pr)_2}]^+PF_6^-$ (n=3, X=S (**1b**); n=2, X=S (**2b**); n=3, X=Se (**3b**)), were obtained by the addition of an ethanol solution of NH_4PF_6 to the bromide salts in ethanol.

All the compounds were recrystallized from a mixture of CH_2Cl_2 and petroleum ether. The elemental analysis and properties are summarized in Table 1.

Measurement of ^1H NMR spectra in dichloromethane (0.01—0.1 M) and line shape analysis were carried out as described previously.[3] The ^1H chemical shift data of **1a—3a**, **4**, and **1b—3b** are given in Table 2.

Results and Discussion

Figure 1a depicts variable temperature ^1H NMR spectra of **1a** in dichloromethane. At room temperature **1a** exhibits a doublet signal due to the isopropyl-methyl

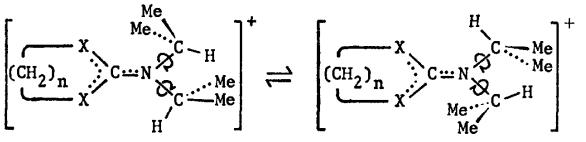
protons (not shown in Fig. 1a). With fall in temperature, the signal coalesces into a broad one, splitting into two broad signals at about −18 °C. On further fall in temperature, the methyl protons appear as two doublets with identical intensities. A similar temperature dependence was also observed in the ^1H NMR spectra of all the other compounds. The spectra show no concentration dependence for solutions in the range 0.1—0.01 M. The spectral patterns of all the compounds in the range from room temperature to −30 °C are very similar to those of some diisopropyldithiocarbamato and -diselenocarbamato complexes of tin(IV), $R_2Sn(dtc)_2$ and $R_2Sn(dsc)_2$ (R=Me and Cl).[3] It is therefore suggested that the rotation around the isopropyl-nitrogen bond is restricted at relatively low temperatures, while that near room temperature occurs rapidly on the NMR time scale, resulting in interconversion between two identical rotamers as shown below.



X=S, Se; n=3, 2

The rate constants of the interconversion, k, were determined by line shape analysis of the isopropyl-methyl signal. Figure 1 shows an example of the best fits between the observed and calculated spectra of **1a**. The plots of $\ln k$ *vs.* $1/T$ and $\ln(k/T)$ *vs.* $1/T$ of **1a**, **2a**, **3a**, and **4** are given in Figs. 2 and 3 respectively, from

2b	58.7±2.4	56.6±2.4	7.8±9.8	54.3±3.8
3b	52.1±0.4	49.9±0.4	−27.5±1.7	58.1±0.7

a) Errors were estimated at the 95% confidence level.

which the Arrhenius and Eyring activation parameters, E_a, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$, were calculated by the least-squares method. The results together with the $\Delta G^{\ddagger}$ value are summarized in Table 3.

The barriers to the rotation around the isopropyl-nitrogen bond, E_a (52—60 kJ/mol) are close to those in $PhC(S)N(i\text{-}Pr)_2$ and $PhCH_2C(S)N(i\text{-}Pr)_2$ (51.0 and 59.4 kJ/mol at −25 °C, respectively).[6] This seems to indicate that the 1,3-dichalcogenacycloalkane moiety of the present compounds does not appreciably influence the barrier to rotation around the isopropyl-nitrogen bond. In fact, there is little difference in the E_a value between any of the pairs of cyclohexane and cyclopentane compounds, **1a**—**2a**, **3a**—**4**, and **1b**—**2b**. The E_a values of the bromide salts, **1a**, **2a**, and **3a**, are essentially the same as those of the hexafluorophosphate salts, **1b**, **2b**, and **3b**, respectively (Table 3). On the other hand, the dithia compounds, **1a**—**3a** and **4** give E_a values larger by 5—8 kJ/mol than the diselena analogs, **1b**—**3b**. The difference is compared with that between the E_a values of $R_2Sn(dtc)_2$ and $R_2Sn(dsc)_2$ (7.5 and 10.4 kJ/mol when R=Cl and Me, respectively)[3] where the steric repulsion of the isopropyl group with the sulfur atoms has been suggested to be larger than that with the selenium atom owing to the shorter length of the C–S bond than that of the C–Se bond. The absolute values of ΔS^* obtained are not so large (less than 28 J/(K mol)), suggesting the occurrence of an intramolecular process in solution.

The Effect of Σ-Π Interaction on the Electronic Structure of Molecules in the Excited States. II. Oscillator Strength

Izumi MAKI, Kazuo KITAURA, and Kichisuke NISHIMOTO

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 27, 1977)

The effect of Σ-Π interaction on the oscillator strength of π-π^* transition has been investigated in terms of the configuration interaction method considering all singly excited configurations. It has been found that the transition moment associated with π-π^* excitation is modified by σ-electrons. The correction term of the transition moment resulting from the Σ-Π interaction can be expressed by the bond index matrix. The present theory has been applied to the calculation of the oscillator strength of benzene and naphthalene derivatives. Agreement between the calculated values and experimental data is satisfactory. The effect of Σ-Π interaction on the transition moment has been demonstrated pictorially.

In the previous paper,[1] the effective π-electron Hamiltonian for the excited state which includes the Σ-Π interaction was derived using the partitioning technique.[2] The effective electron repulsion integrals were represented in terms of the bond index matrix.

The oscillator strength calculated by the traditional π-electron theory is generally larger than that obtained by experiments.[3] This discrepancy might be caused by neglecting the Σ-Π interaction[4] and the π-electron correlation.[5] In the present paper, we consider the effect of Σ-Π interaction on the oscillator strength of π-π^* transition.

The theoretical procedure is as follows. We consider the wave function including the σ-σ* configurations in the excited state, and represent the transition moment in terms of the bond index matrix. Applying this theory to benzene, naphthalene, pyridine, pyrazine, phenol, aniline, quinoline, and isoquinoline, we show the role of the σ-electrons on the transition moments associated with the π-π^* transitions. We then analyze the effect of induced σ-electron polarization on the π-π^* transition moment, and show that the induced σ-electron polarization can be assigned to the individual localized σ-bonds.

Theoretical

The effective total π-electron Hamiltonian for the excited state is expressed as follows:[1]

$$\tilde{\boldsymbol{H}}(\pi) = \boldsymbol{H}(\pi) - \boldsymbol{V}\boldsymbol{P}\frac{1}{\boldsymbol{H}-\boldsymbol{E}\boldsymbol{I}}\boldsymbol{P}\boldsymbol{V}, \tag{1}$$

where $\boldsymbol{V}$ denotes the electron repulsion interaction between σ and π electrons and $\boldsymbol{P}$ is the projection operator defined by

$$\boldsymbol{P} = \sum_{kr}\left|\begin{matrix}\gamma\\ k\end{matrix}\right\rangle\left\langle\begin{matrix}\gamma\\ k\end{matrix}\right|, \tag{2}$$

where $\left|\begin{matrix}r\\ k\end{matrix}\right\rangle$ is the singly excited configuration associated with the excitation of an electron from the k-th occupied σ-MO to the γ-th unoccupied σ*-MO. In this paper the following notations are used: i,j for the occupied π-MO, α,β for the unoccupied π^*-MO, k,l for the occupied σ-MO, γ,δ for the unoccupied σ*-MO, μ,ν for the π-AO and r,s for the σ-AO. In accordance with the prescribed P-P-P method,[6] the zero differential overlap (ZDO) approximation is also used.

With use of the effective total π-electron Hamiltonian[1] the corresponding excited wave function, $|\Phi\rangle$, expressed by the linear combination of the π-π^* singly excited configurations, can be obtained from the following equation:

$$\tilde{\boldsymbol{H}}(\pi)|\Phi\rangle = \boldsymbol{E}|\Phi\rangle, \tag{3}$$

where

$$|\Phi\rangle = \sum_{i\alpha} C_{i\alpha}\left|\begin{matrix}\alpha\\ i\end{matrix}\right\rangle, \tag{4}$$

$|\Phi\rangle$ is normalized in the subspace associated with π-π^* configurations, and $C_{i\alpha}$ is the variation parameter.

On the other hand, the actual wave function, $|\Psi\rangle$, for the lower excited state is given by the linear combinations of the π-π^* and σ-σ* singly excited configurations as follows:

$$|\Psi\rangle = \frac{1}{\sqrt{N}}\left[\sum_{i\alpha} C_{i\alpha}\left|\begin{matrix}\alpha\\ i\end{matrix}\right\rangle + \sum_{kr} C_{kr}\left|\begin{matrix}\gamma\\ k\end{matrix}\right\rangle\right], \tag{5}$$

where $\sqrt{N}$ is the normalization factor. According to the partitioning technique,[2] C_{kr} in Eq. 5 is written as follows:

$$C_{kr} = -\sum_{i\alpha}[(\boldsymbol{H}-\boldsymbol{E}\boldsymbol{I})_{kr,kr}]^{-1}\left\langle\begin{matrix}\gamma\\ k\end{matrix}\right|\boldsymbol{V}\left|\begin{matrix}\alpha\\ i\end{matrix}\right\rangle C_{i\alpha}. \tag{6}$$

Substituting Eq. 6 into Eq. 5, we obtain

$$|\Psi\rangle = \frac{1}{\sqrt{N}}\left(|\Phi\rangle - \boldsymbol{P}\frac{1}{\boldsymbol{H}-\boldsymbol{E}\boldsymbol{I}}\boldsymbol{P}\boldsymbol{V}|\Phi\rangle\right). \tag{7}$$

The normalization factor is given by

$$N = 1 + \sum_{i\alpha}\sum_{j\beta} C_{i\alpha}C_{j\beta}\sum_{kr}\frac{4V_{ik\alpha r}V_{jk\beta r}}{[(\boldsymbol{H}-\boldsymbol{E}\boldsymbol{I})_{kr,kr}]^2}, \tag{8}$$

where $V_{ik\alpha r}$ means the exchange type MO integral which is defined as follows:

$$V_{ik\alpha r} = \iint i^*(1)k^*(2)v_{12}\alpha(1)\gamma(2)\,d\tau_1 d\tau_2.$$

As we did in the previous paper,[1] the averaged energy parameter is used instead of the denominator in Eq. 8. Then, the normalization factor can be written as

$$N = 1 - \frac{1}{e^2}\sum_{i\alpha}\sum_{j\beta} C_{i\alpha}C_{j\beta}\sum_{\mu\nu}\sum_{AB} d_{i\mu}d_{j\nu}d_{\alpha\mu}d_{\beta\nu}\gamma_{\mu A}\mathbf{B}_{AB}\gamma_{B\nu}, \tag{9}$$

in terms of the bond index matrix $\mathbf{B}$. $d_{i\mu}$ is the coefficient of the μ-th AO of the i-th MO. e is an averaged energy parameter. The bond index matrix element $\mathbf{B}_{AB}$ is defined as follows:[1]

$$\mathbf{B}_{AB} = -\sum_{r}^{A}\sum_{s}^{B}\sum_{k}^{\sigma}\sum_{\gamma}^{\sigma^*} 4d_{kr}d_{ks}d_{\gamma r}d_{\gamma s}.$$

The value of $\sqrt{N}$ calculated by means of Eq. 9 is almost 1.0. Thus $\sqrt{N}$ is put to be 1.0 in the calculation.

The transition moment $\mathbf{m}$ associated with the excitation of an electron from the ground state to an excited singlet state, Ψ, is given by

$$\mathbf{m} = \langle 0|\sum_i \mathbf{r}_i|\Psi\rangle, \tag{10}$$

Substituting Eq. 7 into Eq. 10, we obtain the transition moment including the effect of Σ-Π interaction as follows:

$$\mathbf{m} = \langle 0|\sum_i \mathbf{r}_i|\Phi\rangle - \langle 0|\sum_i \mathbf{r}_i P\frac{1}{\boldsymbol{H}-\boldsymbol{EI}}\boldsymbol{P}\boldsymbol{V}|\Phi\rangle, \tag{11}$$

where $\mathbf{r}_i$ is the position vector of the i-th electron. The first term of Eq. 11 corresponds to the transition moment of the traditional P-P-P scheme, the second term being the correction due to the Σ-Π interaction. According to the usual P-P-P method, the transition moment from the ground state to the excited configuration, $\left|{}^{\beta}_{j}\right\rangle$, can be expanded by means of LCAO coefficients as

$$\langle 0|\sum_i \mathbf{r}_i\left|{}^{\beta}_{j}\right\rangle = \sqrt{2}\sum_\mu d_{j\mu}d_{\beta\mu}\mathbf{r}_\mu, \tag{12}$$

where $\mathbf{r}_\mu$ represents the coordinate of the μ-th atom. Therefore, Eq. 11 becomes

$$\mathbf{m} = \sqrt{2}\sum_{i\alpha}C_{i\alpha}\sum_\mu d_{i\mu}d_{\alpha\mu}\left(\mathbf{r}_\mu + \frac{1}{2e}\sum_{AB}\mathbf{r}_A\mathbf{B}_{AB}\gamma_{B\mu}\right). \tag{13}$$

By means of this equation, the oscillator strength, f, including the Σ-Π interaction is written as follows:

$$f = 0.0875 \times \mathbf{m}^2 \times \Delta E \times G, \tag{14}$$

where ΔE (in eV) is the excitation energy and G is the degree of the degeneracy of the excited state.

Let us further consider the transition moment $\mathbf{m}$. Equation 13 can be rewritten as

$$\mathbf{m} = \mathbf{m}_0 + \Delta\mathbf{m},$$

where $\mathbf{m}_0$ and $\Delta\mathbf{m}$ are given by

$$\mathbf{m}_0 = \sqrt{2}\sum_{i\alpha}\sum_\mu C_{i\alpha}d_{i\mu}d_{\alpha\mu}\mathbf{r}_\mu,$$

$$\Delta\mathbf{m} = \frac{1}{\sqrt{2}\,e}\sum_{i\alpha}\sum_\mu C_{i\alpha}d_{i\mu}d_{\alpha\mu}\sum_{AB}\mathbf{r}_A\mathbf{B}_{AB}\gamma_{B\mu}. \tag{15}$$

$\Delta\mathbf{m}$ is rewritten as

$$\Delta\mathbf{m} = \sum_{AB}\mathbf{r}_A\mathbf{B}_{AB}\mathbf{X}_B, \tag{16}$$

where $\mathbf{X}_B$ is given by

$$\mathbf{X}_B = \frac{1}{\sqrt{2}\,e}\sum_{i\alpha}\sum_\mu C_{i\alpha}d_{i\mu}d_{\alpha\mu}\gamma_{B\mu}.$$

Since $\Sigma\mathbf{B}_{AB}=0$, $\Delta\mathbf{m}$ becomes as follows:

$$\begin{aligned}
\Delta\mathbf{m} &= \frac{1}{2}\sum_A\sum_B(\Delta\mathbf{m}_{AB}+\Delta\mathbf{m}_{BA}) \\
&= \frac{1}{2}[\sum_A\sum_B\mathbf{r}_A\mathbf{B}_{AB}\mathbf{X}_B+\sum_A\sum_B\mathbf{r}_B\mathbf{B}_{BA}\mathbf{X}_A] \\
&= \frac{1}{2}[(\sum_A\sum_B\mathbf{r}_A\mathbf{B}_{AB}\mathbf{X}_B-\sum_B\mathbf{r}_B\mathbf{X}_B\sum_A\mathbf{B}_{AB}) \\
&\quad +(\sum_B\sum_A\mathbf{r}_B\mathbf{B}_{BA}\mathbf{X}_A-\sum_A\mathbf{r}_A\mathbf{X}_A\sum_B\mathbf{B}_{BA})] \\
&= \frac{1}{2}[\sum_A\sum_B(\mathbf{r}_A-\mathbf{r}_B)\mathbf{B}_{AB}\mathbf{X}_B+\sum_B\sum_A(\mathbf{r}_B-\mathbf{r}_A)\mathbf{B}_{BA}\mathbf{X}_A] \\
&= \sum_{A>B}(\mathbf{r}_A-\mathbf{r}_B)\mathbf{B}_{AB}(\mathbf{X}_B-\mathbf{X}_A) \\
&= \sum_{A>B}\Delta\mathbf{M}_{AB},
\end{aligned} \tag{17}$$

where

$$\Delta\mathbf{M}_{AB} = (\mathbf{r}_A-\mathbf{r}_B)\mathbf{B}_{AB}(\mathbf{X}_B-\mathbf{X}_A).$$

Thus, $\Delta\mathbf{m}$ can be decomposed into the contributions of individual σ-bonds. $\Delta\mathbf{M}_{AB}$ is the induced σ-polarization associated with the σ-bond, A–B, caused by the π-π^* transition. The present theory has been applied to the calculation of the oscillator strength of π-π^* transition of some aromatic compounds.

Results and Discussion

The calculated transition moments and oscillator strengths of benzene and naphthalene are summarized in Table 1. The calculated and experimental excitation energies and oscillator strengths of benzene and naphthalene are compared in Fig. 1, where PPP-NM denotes the conventional P-P-P calculation using Nishimoto-Mataga formula[6] for the two center electron repulsion integrals. We see that the calculated results based on the present theory agree with the experimental ones satisfactorily for both the singlet and triplet states. It should be noted that the present theory brings about an appreciated improvement in the oscillator strength. The conventional P-P-P method gives too large values of oscillator strengths. The Σ-Π interaction gives rise,

a) Singlet state is placed in the order of increasing energy. b) x and y denote the component of the transition moment. c) f_0 and f are calculated by using $\mathbf{m}_0$ and $\mathbf{m}$, respectively.

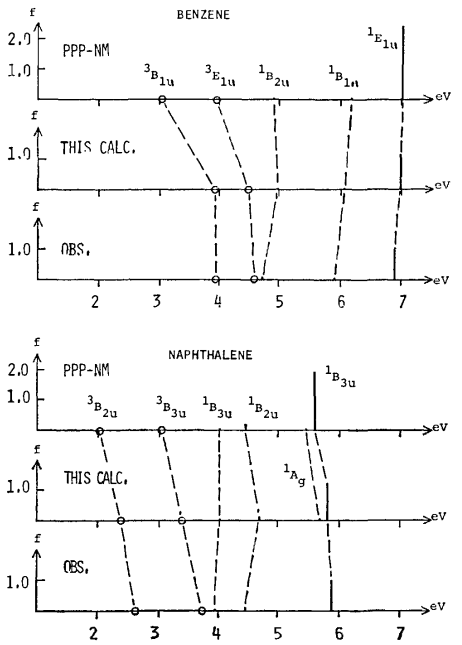

Fig. 1. The calculated experimental (OBS) excitation energies and oscillator strengths of benzene and naphthalene. (The experimental values are taken from Ref. 8.)

therefore, to a substantial reduction in the conventionally calculated oscillator strength. For an example, the calculated f-value (oscillator strength) associated with the $^1A_{1g} \rightarrow {}^1E_{1u}$ transition of benzene varies from 2.40 to 1.17, when the Σ-II interaction is considered (experimental value, 1.0[8]). The f-value of naphthalene corresponding to the transition with a medium intensity ($^1A_g \rightarrow {}^1B_{2u}$) and that with the strongest intensity ($^1A_g \rightarrow {}^1B_{3u}$) also vary from 0.23 and 2.00 to 0.10 and 1.24, respectively. The corresponding experimental values are 0.10 and 1.0,[8] respectively. The reason for this improvement in the oscillator strength is that the π-π^* transition induces the polarization of σ-electrons in the direction opposite to the π-π^* transition moment.

It is convenient to demonstrate the effect of Σ-II interaction on the transition moment pictorially. Figure

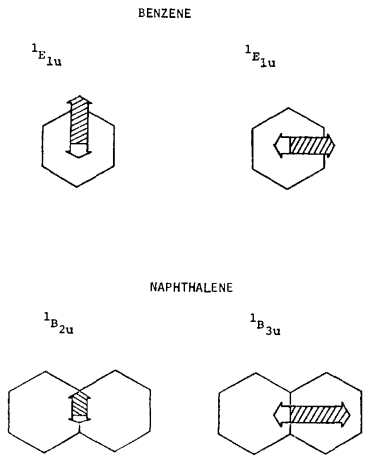

Fig. 2. The transition moments of benzene and naphthalene. $\mathbf{m}_0$ and $\Delta\mathbf{m}$ are represented by a shaded and a hollow arrows, respectively.

2 shows the transition moments of benzene and naphthalene, where $\mathbf{m}_0$ (Eq. 15) is shown by a shaded arrow and induced moment $\Delta\mathbf{m}$ is shown by a hollow arrow. The total transition moment is the sum of these two moments. In the case of the lower $^1B_{2u}$ state of naphthalene, the value of $\mathbf{m}_0$ is 0.76 eÅ (in unit of electron angstrom) and $\Delta\mathbf{m}$ is −0.26 eÅ, so that the sum is to be 0.50 eÅ. Consequently, the oscillator strength is to be reduced to about one-half of its initial value. The value of $\mathbf{m}_0$ of the strongly allowed transition ($^1A_g \rightarrow {}^1B_{3u}$) is 1.98 eÅ and that of induced moment is −0.42 eÅ. Generally speaking, the larger π-π^* transition moment causes the larger induced moment

in the opposite direction. However, there is no quantitative relation between these two moments.

According to Eq. 17, the induced moment, $\Delta\mathbf{m}$, for a given transition can be divided into $\Delta\mathbf{M}_{AB}$ associated with the σ-bond A–B. Figure 3 shows such $\Delta\mathbf{M}_{AB}$ for benzene and naphthalene. The values of ΔE and f in this figure are the calculated transition energy and oscillator strength, respectively.

The calculated transition moment and oscillator strength of pyridine, pyrazine, aniline, phenol, quinoline, and isoquinoline are summarized in Table 2. The calculated and experimental excitation energies and oscillator strengths (f) of these molecules are compared in Figs. 4—6. The divided induced moment, $\Delta\mathbf{M}_{AB}$, associated with each transition of molecules is shown in Figs. 7—12.

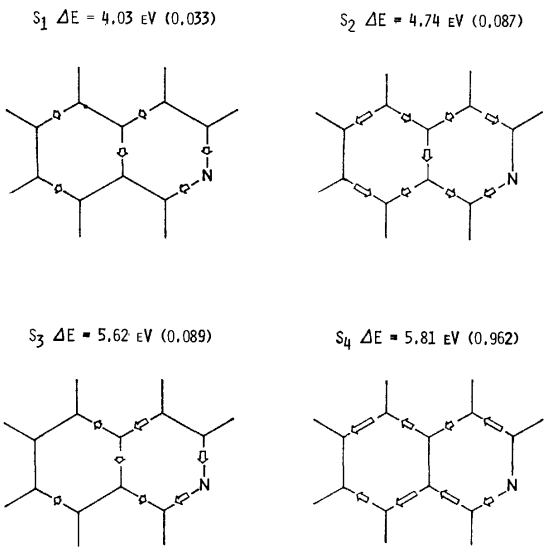

Fig. 12. The divided induced transition moments, $\Delta\mathbf{M}_{AB}$'s, of isoquinoline.

For the molecules considered in the present study, the absolute value of $\Delta\mathbf{m}$ is *ca.* 1/5—1/3 of the corresponding $\mathbf{m}_0$ (Tables 1 and 2). Thus the ratio of f (oscillator strength calculated by $\mathbf{m}$) to f_0 (oscillator strength calculated by $\mathbf{m}_0$) is found to be *ca.* 0.4—0.6. The oscillator strength of π-π^* transition calculated by the conventional P-P-P method is larger by about twice that obtained by experiment.[5,7] For azanaphthalenes, Baba and Yamazaki[7] showed that when the value of the oscillator strength calculated by P-P-P method is multiplied by 0.596, it is in a good agreement with the experimental ones. From Tables 1 and 2, it is found that their prescription is appreciated as a good approximation. In the cases of quinoline and isoquinoline which have no molecular symmetry, the two moments, $\mathbf{m}_0$ and $\Delta\mathbf{m}$, do not lie on a straight line. Thus the π-π^* transition moment is not only reduced but also altered it's direction by means of the Σ-Π interaction. For *N*-heterocycles, the diagonal matrix element of the bond index matrix associated with *N* atom is set to be -2.0, namely the lone pair orbital is treated as completely localized. In spite of this approximation, the results for these molecules are good for both the excitation energies and oscillator strength, (Figs. 4-6). This suggests that the present method is also applicable to *N*-heterocycles.

In the present theory, the electron correlation between π-electrons which reduces the oscillator strength has not been considered. Although Σ-Π interaction is a kind of electron correlation, the effect might be overestimated in the present method. It is obvious that the Σ-Π interaction has a very large effect on the π-π^* excitation energies and oscillator strengths.

We would like to express our gratitude to the Data Processing Center, Kyoto University, for its generous permission to use the FACOM M-190 computer.

Preparation and Electrical Conductivity of Some Simple and Complex Salts Formed between *N,N*-Dialkyl-1,3-dichalcogenacycloalkan-2-iminium and $TCNQ^{\cdot-}$

Shingo ARAKI, Hiromi ISHIDA, and Toshio TANAKA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received July 11, 1977)

Four simple salts and six complex salts of $TCNQ^{\cdot-}$ radical anion with *N,N*-dialkyl-1,3-dichalcogenacycloalkan-2-iminium cations, $(CH_2)_n^{Y}C{=}\overset{+}{N}R_2\cdot TCNQ^{\cdot-}$ and $(CH_2)_n^{Y}C{=}\overset{+}{N}R_2\cdot(TCNQ)_2^{\cdot-}$ (n=2 or 3, Y=S or Se, R=Me or Et) were prepared. The electrical resistivity of $(CH_2)_2^{Se}C{=}\overset{+}{N}Et_2\cdot TCNQ^{\cdot-}$ (1.1×10^4 ohm cm) was more than 10 times lower than other three simple salts ($(6.1-8.7)\times10^5$ ohm cm). Electronic absorption spectra and magnetic susceptibilities suggest that the latter three involve dimeric $(TCNQ)_2^{2-}$, while in the former the interaction between two $TCNQ^{\cdot-}$ radical anions is weak in the solid state. All the complex salts with compaction samples exhibited the resistivity of 2.4—4.0 ohm cm with very low activation energies (0.018—0.087 eV). Electronic spectra and magnetic susceptibilities show that the interaction between two $TCNQ^{\cdot-}$ radical anions decreases owing to the implication of neutral TCNQ.

There has been reported the preparation of various salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ) radical anion with inorganic and organic cations which show a wide range of electrical conductivities, largely depending on the properties of the counter cations. Some of those are known as best electrically conductive organic salts, such as quinolinium-$(TCNQ)_2^{\cdot-}$ [1] and *N*-methylphenazinium-$TCNQ^{\cdot-}$.[2] Charge-transfer complexes between TCNQ and tetrathiafulvalene or its derivatives also were reported to display high electrical conductivities.[3] The cationic moieties of these electrically conductive organic salts or complexes generally not only adopt a planar structure but also involve hetero atoms with large polarizability. Garito and Heeger have mentioned the importance of these two factors for obtaining organic complexes with high electrical conductivities.[4]

Some time ago, one of the authors prepared *N,N*-dimethyl-1,3-dithia- and 1,3-diselenacycloalkan-2-iminium dimethyltin(IV) halides, $(CH_2)_2^{Y}C{=}\overset{+}{N}Me_2\cdot Me_2SnBr_3^-$ (Y=S and Se) and $[(CH_2)_3^{S}C{=}\overset{+}{N}Me_2]_2\cdot Me_2SnBr_4^{2-}$.[5-7] The iminium cations of these salts adopt a planar Y_2CN moiety[6] involving largely polarizable hetero atoms. This fact prompted us to prepare $TCNQ^{\cdot-}$ radical anion salts of these iminium cations. This paper reports the synthesis and the electrical conductivity of several simple and complex salts of $TCNQ^{\cdot-}$ with the iminium cations, $(CH_2)_n^{Y}C{=}\overset{+}{N}R_2\cdot TCNQ^{\cdot-}$ and $(CH_2)_n^{Y}C{=}\overset{+}{N}R_2\cdot(TCNQ)_2^{\cdot-}$ (n=2, 3; Y=S, Se; R=Me, Et; but not all combinations). Electronic spectra and magnetic properties of these salts also are described in terms of interaction between the $TCNQ^{\cdot-}$ radical anions.

Experimental

Materials. *N,N*-Dimethyl-1,3-dithia- and 1,3-diselenacyclopentan-2-iminium dimethyltin(IV) tribromide, $(CH_2)_2^{Y}C{=}\overset{+}{N}Me_2\cdot Me_2SnBr_3^-$ (Y=S, Se), and bis(*N,N*-dimethyl-1,3-dithiacyclohexan-2-iminium) dimethyltin(IV) tetrabromide, $\left[(CH_2)_3^{S}C{=}\overset{+}{N}Me_2\right]_2\cdot Me_2SnBr_4^{2-}$ were prepared as described in the previous papers.[5-7] The corresponding *N,N*-diethyliminium compounds, $(CH_2)_n^{Y}C{=}\overset{+}{N}Et_2\cdot Me_2SnBr_3^-$, mp 97—99 °C for n=2 and Y=S, 130—132 °C for n=3 and Y=S, and 122—124 °C for n=2 and Y=Se, were similarly synthesized by reaction of bis(diethyldithiocarbamato or diethyldiselenocarbamato)dimethyltin(IV), $Me_2Sn(Y_2CNEt_2)_2$ (Y=S, Se), with 1,2-dibromoethane or 1,3-dibromopropane.

*N,N-Dialkyl-1,3-dichalcogenacycloalkan-2-iminium–TCNQ Simple Salts, $(CH_2)_n^{S}C{=}\overset{+}{N}Me_2\cdot TCNQ^{\cdot-}$ (n=2 (**1**), 3 (**2**)) and $(CH_2)_2^{Se}C{=}\overset{+}{N}R_2\cdot TCNQ^{\cdot-}$ (R=Me (**3**), Et (**4**)).*

To a solution of $Li^+TCNQ^{\cdot-}$ (2.8 mmol) in boiling ethanol (40 cm³) was added a hot ethanol (20 cm³) solution of $(CH_2)_2^{S}C{=}\overset{+}{N}Me_2\cdot Me_2SnBr_3^-$ (2.8 mmol). The mixture was allowed to stand at room temperature, giving purple plates of **1**, which were recrystallized from ethanol, 71% yield. Other three simple salts were similarly prepared by reactions of $TCNQ^{\cdot-}$ with the appropriate iminium cations in ethanol, 60—77% yields.

*N,N-Dimethyl-1,3-dithiacycloalkan-2-iminium–TCNQ Complex Salts, $(CH_2)_n^{S}C{=}\overset{+}{N}Me_2\cdot(TCNQ)_2^{\cdot-}$ (n=2 (**5**), 3 (**6**)).*

To a boiling acetonitrile (50 cm³) solution of **1** obtained above (2.0 mmol) was added neutral TCNQ (2.0 mmol) in boiling

Table 1. Properties and analytical data of the TCNQ$^{\cdot}$ salts

acetonitrile (30 cm^3). After filtration, the mixture was allowed to stand in a refrigerator overnight to afford black needles of **5**, 88% yield. Complex salt **6** was similarly prepared by reaction of **2** with TCNQ at the mole ratio of 1: 1 in acetonitrile, 85% yield.

N,N-*Diethyl-1,3-dithiacycloalkan-2-iminium-TCNQ Complex Salts,*  *(n=2 (7), 3 (8)).*

To a boiling ethanol (30 cm^3) solution of Li$^+$TCNQ$^{\cdot}$ (2.2 mmol) was added  (2.2 mmol) in hot ethanol (20 cm^3). The mixture was allowed to stand in a refrigerator overnight to give black needles of **7**, which were recrystallized from acetonitrile, 62% yield based on Li$^+$TCNQ$^{\cdot}$. A similar reaction of  with TCNQ$^{\cdot}$ at the mole ratio of 1: 1 in ethanol afforded **8**, 60% yield based on TCNQ$^{\cdot}$.

N,N-*Dialkyl-1,3-diselenacyclopentan-2-iminium-TCNQ Complex Salts,*  *(R=Me (9), Et (10)).*

These complex salts were prepared by reaction of the appropriate simple salt, **3** or **4** with TCNQ in acetonitrile by the procedure described in **5** and **6**.

Elemental analyses and properties of the simple and complex salts obtained are listed in Table 1.

Physical Measurements. Electrical resistivities were measured by two-probe method in the 20—90 °C range; current measurements were performed with a TOA DEMPA KOGYO PM-18 micro volt-ammeter or a TAKEDA RIKEN-TR-6355 multimeter, and voltage measurements with a NATIONAL VP-653B pen-recorder calibrated by the use of the multimeter. A compaction sample, 20 mm in diameter and about 1 mm thick, for the measurement was prepared by pressing at 270 kg/cm^2, followed by vacuum-evaporating gold metal as electrodes. The resistivities of some complex salts were also measured by four-probe method; the values obtained were very close to those by two-probe method (see Table 2).

Electronic absorption spectra were recorded in Nujol mulls and in acetonitrile (10^{-5} M) on a HITACHI EPS-03 spectrophotometer (3850—16700 cm^{-1}) and a HITACHI 124 spectrophotometer (12500—40000 cm^{-1}). Infrared spectra were measured in hexachlorobutadiene mulls on a HITACHI 215 grating infrared spectrophotometer. Magnetic susceptibilities were measured for micro-crystalline materials by the Gouy method at room temperature.

Results and Discussion

Synthesis. *N,N*-Diethyl-1,3-dithiacycloalkan-2-iminium cations reacted with TCNQ$^{\cdot}$ to give the complex salts, **7** and **8**, whereas the reaction of the remaining iminium cations with TCNQ$^{\cdot}$ afforded the simple salts, **1**—**4**, irrespective of the mole ratio of the reactants. These simple salts further reacted with an equimolar amount of neutral TCNQ to yield the complex salts, **5**, **6**, **9**, and **10**. All the TCNQ$^{\cdot}$ salts obtained here are stable to air in the solid state.

Electrical Properties. Figures 1 and 2 show the electrical resistivity (ρ) of the simple and the complex salts at various temperatures, respectively. The ρ values

3	6.1×10^{5}	0.37
4	1.1×10^{4}	0.27
Complex salt		
5	3.8	0.041
6	3.5	0.076
7	3.3	0.018
8	2.9(2.6)	0.060
9	4.0(3.4)	0.087
10	2.4	0.046

a) The values in parentheses were obtained by four-probe method.

at 25 °C and the activation energies (E_a) calculated from the equation $\rho=\rho_0\exp(E_a/kT)$ are summarized in Table 2. It is noted that the ρ value of **4** was more than 10 times lower than those of the other simple salts, although the E_a values of the four simple salts were in the same order of magnitude.

The electrical resistivity of TCNQ$^{\cdot}$ complex salts is known to markedly depend on the nature of counter cations. The ρ values of the present complex salts are relatively small compared with those of many TCNQ$^{\cdot}$ complex salts reported so far,[1] but larger by one order of magnitude than that of the highest conductive complex salt with a compaction sample, quinolinium-(TCNQ)$_2^{\cdot}$ (0.5 ohm cm).[1] The E_a values of the complex salts obtained here also are small, in particular that of **7** (0.018 eV) is compared with the activation energy of quinolinium-(TCNQ)$_2^{\cdot}$ (0.013 eV).[1]

Electronic Spectra and Magnetic Properties. An acetonitrile solution of **1** exhibited absorption bands around 12000 and 24000 cm^{-1}. Essentially the same spectra were observed for **2**—**4** in the same solvent, irrespective of the counter iminium cations. The appearance of these spectra also closely resembles that of K$^+$TCNQ$^{\cdot}$[8] and Et$_3$NH$^+$TCNQ$^{\cdot}$[1] in acetonitrile, where they are known to dissociate into monomeric TCNQ$^{\cdot}$ and K$^+$ or Et$_3$NH$^+$.

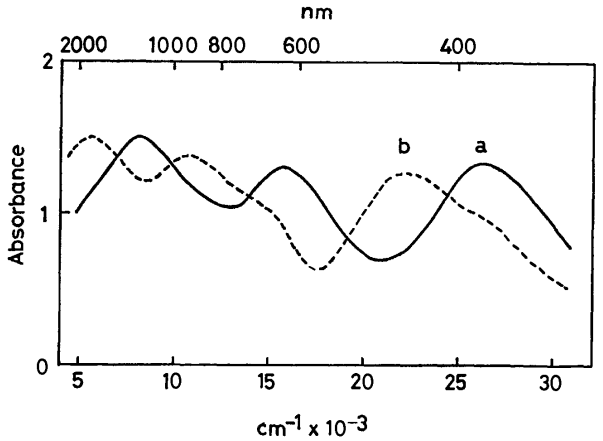

Fig. 3. Absorption spectra of **1** (a) and **4** (b) in Nujol mulls.

Figure 3 illustrates the electronic absorption spectra of two representative simple salts, **1** and **4**, in the solid state. Compound **1** exhibits three absorption maxima, whose wave numbers (see Table 3) are close to those observed in the reflectance spectra of several TCNQ$^{\cdot}$ simple salts such as with Li$^+$, NH$_4^+$, and MePh$_3$P$^+$ (around 9000, 16000, and 27000 cm^{-1}) reported previously; the lowest energy band has been assigned to the charge-transfer (CT) transition between TCNQ$^{\cdot}$ radical anions,[8,9] and the two remaining bands to the (TCNQ)$_2^{2-}$ dimer.[8] The band around 16000 cm^{-1} has also been suggested to be characteristic of the dimer type electron configuration of TCNQ$^{\cdot}$ crystals.[9] It is therefore suggested that **1** consists of the iminium cation and dimeric (TCNQ)$_2^{2-}$ anion in the solid state. The existence of (TCNQ)$_2^{2-}$ is also evidenced from the fact that **1** exhibited a diamagnetic susceptibility of -1.7×10^{-4} emu mol^{-1} at 25 °C, which is in good agreement with the value calculated from Pascal's constants (-1.697×10^{-4} emu mol^{-1}). This diamagnetism indicates that two TCNQ$^{\cdot}$ radical anions may be coupled completely with each other. The same conclusion can be drawn for **2** and **3** on the basis of similarity of their electronic spectra to that of **1**, although the highest energy band of **3** was found at a little low frequency, as shown in Table 3.

The spectrum of **4** in the solid state showed three absorption maxima at 5600, 10800, and 22200 cm^{-1}.

Table 3. Absorption maxima of the electronic spectra of the $TCNQ^{\cdot}$ salts in nujol mulls

Compound	$cm^{-1} \times 10^{-3}$ a)				
1	8.3			15.9	26.3
2	8.3			15.6	27.0
3	8.1			15.2	24.4
4	5.6	10.8		(15)	22.2 (27)
5		10.0	11.4	17	26.7
6		9.9	11.4	17	26.7
7		10.0	11.4	17	27.0
8		9.9	11.2	17	27.0
9		9.9	11.4	17	26.7
10		9.9	11.2	17	27.0

a) Shoulders in parentheses.

The lowest energy band may tentatively be assigned to the CT transition between $TCNQ^{\cdot}$ radical anions, although the wave number is considerably lower than that of **1**—**3** (Fig. 3 and Table 3). On the other hand, the 10800 and 22200 cm^{-1} bands, which are assignable to locally-excited transitions of the $TCNQ^{\cdot}$ moiety, LE_1 and LE_2 respectively,[9] showed no appreciable blue shift compared with the corresponding bands arising from monomeric $TCNQ^{\cdot}$ in acetonitrile. Thus, the absorption spectrum has not revealed the electronic state of $TCNQ^{\cdot}$ in solid **4**. It is, however, noted that the magnetic susceptibility of **4** in the solid state was 1.5×10^{-4} emu mol^{-1} at 25 °C. Such a paramagnetism which is unusual in various simple salts, may be correlated with somewhat higher electrical conductivity of **4** than **1**—**3**.

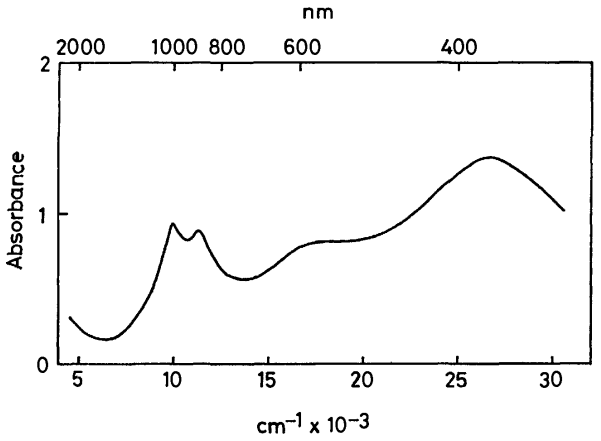

Fig. 4. Absorption spectra of **5** in Nujol mulls.

Complex salt **5** in acetonitrile gave a similar spectrum in appearance to some $TCNQ^{\cdot}$ complex salts, such as with Et_3NH^{+}[1] and $MePh_3P^{+}$,[8] in the same solvent. The solid state spectrum of **5** is illustrated in Fig. 4, which shows three absorption bands around 10000, 17000, and 27000 cm^{-1}. The latter two frequencies are close to those of the two high energy bands observed in solid **1**—**3** (Table 3). The intense absorption around 27000 cm^{-1} may be contributed from both the LE_2 state of $TCNQ^{\cdot}$ and the excited state of neutral TCNQ.[9] The band around 10000 cm^{-1} is due to the $TCNQ^{\cdot}$ monomer, as previously described in the reflectance spectra of some $TCNQ^{\cdot}$ complex salts.[8] More quantitatively, this band is assigned to a transition to the LE_1 state of $TCNQ^{\cdot}$ or the coupled transition of the LE_1 state of $TCNQ^{\cdot}$ and the CT state between $TCNQ^{\cdot}$.[9] The presence of monomeric $TCNQ^{\cdot}$ does not contradict the fact that **5** exhibited a large paramagnetic susceptibility of 6.5×10^{-4} emu mol^{-1} at 25 °C. This magnitude of the paramagnetism is commonly found in many $TCNQ^{\cdot}$ complex salts.[10] Other complex salts **6**—**10** exhibited essentially the same spectra as **5** in the solid state. In addition, all the complex salts displayed a very broad band ranging from 3400 to 2700 cm^{-1}, which was never seen in the spectra of the simple salts. This band is assignable to the charge-transfer transition between $TCNQ^{\cdot}$ and TCNQ.[8] It may therefore be concluded that the interaction between two $TCNQ^{\cdot}$ radical anions in the solid complex salts decreases owing to the implication of neutral TCNQ.

The Construction of an Energy-dispersive X-Ray Diffractometer for Liquids and Its Application to CCl_4

Yoshitada MURATA* and Keiko NISHIKAWA

Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171

(Received July 15, 1977)

An energy-dispersive X-ray diffractometer using a solid-state detector is constructed for the determination of the liquid structure. It has two merits over the usual angle-dispersive diffractometer, *i.e.*, a higher resolution of the s-value and a wider measurable s-region. The procedure of the data analysis and the results for liquid CCl_4 are described. The absorption correction is important in the reflection method. By taking advantage of the energy-dispersive method, it is shown that liquid CCl_4 has a long-range correlation at room temperature.

The intensity measurement of X-rays by using a solid-state detector (SSD), since it was introduced by Giessen and Gordon,[1] has been used in various experiments on X-ray scattering, for example, the Compton profile,[2] diffractometry for a single crystal[3] or for a powdered sample,[4] and the determination of the anomalous scattering factor at energies near the absorption edge.[5] However, the X-ray diffraction of liquids has scarcely been studied by means of the energy-dispersive method with the SSD.[6]

The energy-dispersive method in X-ray diffraction is carried out by using white X-rays as the primary beam and the SSD for the energy analysis of the scattered X-rays. In other words, a parameter in the diffraction of a liquid, $s=4\pi \sin\theta/\lambda$ (λ: wavelength, 2θ: scattering angle), *i.e.* the scattering vector, is determined mainly by measuring λ, while only θ is changed in the traditional angle-dispersive method.

Energy-dispersive diffractometry has the following merits in comparison with the angle-dispersive one:

(1) A higher resolution of the s-value can be obtained. The resolution of the s-value is determined by two factors, as is shown by the following relation;

$$\Delta s/s = \Delta E/E + \cot\theta \cdot \Delta\theta. \quad (1)$$

The first term on the right side of Eq. 1 indicates the energy resolution, which is determined by that of the SSD and which varies with the energy.[7] The second term, the angular resolution, is determined by the beam divergence in a collimator system. A small beam divergence is achieved without increasing the time of measurement, since the integrated intensity of the white X-ray radiations is much stronger than that of a characteristic X-ray radiation. Though the diffraction pattern of a liquid forms diffuse halos, a high resolution of the s-value is essential if we are to investigate the presence of a long-range correlation.

(2) The fluctuation in the primary beam intensity does not influence the scattering intensity, since scattered photons corresponding to the various s-values are collected simultaneously. This is effective in getting relative-intensity curves with high precision.

(3) It is possible to expand the observable region of the s-values. This diminishes the termination error in the Fourier transformation, since the diffraction intensities can be measured from small to large s-values.

(4) The design of the diffractometer is simple, because no scanning mechanism is necessary. Accessories such as sample holders for high and low temperatures can be mounted easily.

A vertical goniometer is adopted in the present experiment instead of the usual horizontal one, though this selection is not necessarily related to energy-dispersive diffractometry. In the horizontal goniometer, the free surface of a liquid is measured and an X-ray tube and a detector are moved simultaneously on the vertical plane. On the other hand, in the vertical goniometer an X-ray tube or a detector travels on the horizontal plane around the sample; hence, the mechanism of the apparatus is simplified. In addition, the vertical goniometer system makes it possible to measure both reflection and transmission intensities. This expands the measurable region of s, especially to very small s-values.

However, there are some demerits and difficulties in the energy-dispersive method:

(1) When a liquid specimen includes such elements as heavy metal ions, the fluorescent X-ray emissions disturb the intensity curve.

(2) The absorption and Compton corrections may introduce a significant error.

(3) The intensity curves obtained at different scattering angles must be connected adequately.

The difficulties arising from (2) and (3) were resolved as will be described below.

The present paper will describe the construction of an energy-dispersive diffractometer for liquids. The procedure of the data analysis applied to liquid CCl_4 at room temperature will also be described.

Construction of the Apparatus

The experimental arrangement is shown in Fig. 1.

Goniometer. An X-ray tube can be rotated around the vertical axis of a goniometer, which has a θ-2θ scanning system. An SSD with a heavy cryostat is fixed. The movable range of the tube is from -20 to $100°$ in 2θ. When the white X-ray radiations from a tungsten tube are used at the target voltage of 45 kV, the scattering intensity is obtained over the range from $s=0.15$ to $30\ \text{Å}^{-1}$.

X-Ray Source. A fine-focus Phillips tube with a tungsten target is used, because strong white X-rays can be obtained without any disturbance by characteristic X-rays. Although radiations from the tungsten

* Present address: The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106.

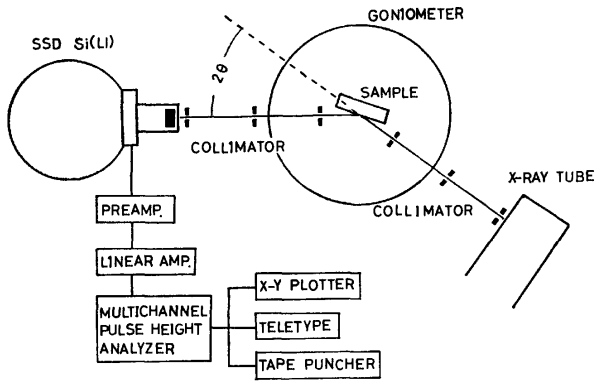

Fig. 1. Shematic diagram of the experimental apparatus. The arrangement for the reflection method is shown.

tube have the L radiations in the 8—11 keV region (λ=1.2—1.4 Å), as shown in Fig. 5, they do not disturb the present measurements. A high-voltage power supply for X-rays of the Rigaku Denki Co. was used. The stability of the high voltage is better than 0.1%. The X-ray tube was usually operated at 45 kV and 20 mA. However, in the energy-dispersive method it is necessary to measure the spectrum of the incident beam by means of the voltage and collimating system used for the measurement of the intensity scattered from the sample. Since the 20 mA beam is too strong for the direct-beam measurement, we modified the power supply system so as to operate it in the microampere region.

Detecting System. The scattered X-rays were analyzed by means of a Si(Li) detector made by the JEOL Co., Tokyo. The energy resolution of the detector ΔE is 200 eV FWHM at 21.99 keV (Ag $K\alpha_2$), and $\Delta E/E$ is less than 1% in the energy region used in this apparatus (E=12—32 keV). It is connected to a linear amplifier (NAIG D-130) and a multichannel pulse-height analyzer (MCA) with 1024 channels (Canberra Model 8100). The gain of the linear amplifier was set so that the energy width per channel of the MCA was about 40 eV.

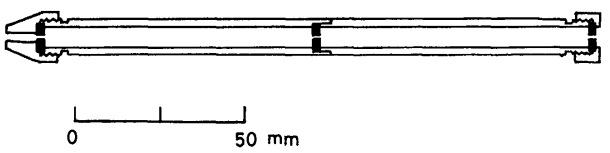

Fig. 2. Collimator. It is 180 mm long and has three apertures with diameter of 1 or 2 mm. Apertures are made of W or Pb.

Collimator. The resolution in the s-value is determined by two factors, as shown by Eq. 1. The second term of Eq. 1, in which $\Delta\theta$ is the beam divergence, is determined by the design of the collimator system. In this respect it is desirable to use a collimator of an appreciable length and a small diameter. However, this induces a decrease in the X-ray intensities. An optimum condition was realized by keeping the first term in Eq. 1 a little smaller than the second term. We made a couple of collimators 180 mm in length and 1 or 2 mm in diameter, as is shown in Fig. 2. Three stages of collimating apertures were effective in getting a well-collimated X-ray beam. If two stages of collimating apertures are used for the measurement; not only is the beam divergence increased, but also a significant error is introduced into the absorption correction in the reflection method, as will be described later. In this system, $\Delta\theta$ is 0.3 or 0.6°. The latter value, 0.6°, is used only at large scattering angles, which correspond to small $\cot\theta$ values.

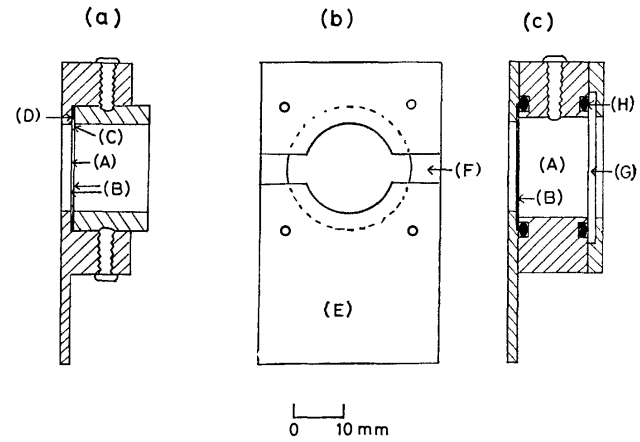

Fig. 3. Sample holder (a) for the transmission method and (b), (c) for the reflection method. (A) sample, (B) Myler film or Be plate, (C) stainless steel ring to determine the thickness of sample (0.5 mm in thickness), (D) rubber ring to seal, (E) stainless steel plate to set the holder to the goniometer, (F) ditch to expand the observable region of the scattering angle, (G) glass plate, (H) O-ring.

Sample Holder. The sample holders are shown in Fig. 3. Figure 3(a) illustrates a sample holder for the transmission method, which is used for the measurements at small scattering angles. Myler films (20 μm thick) or Be thin plates (0.2 mm thick) were used for the window of the sample holder. The window was sealed with epoxide resin, which is not insoluble in the CCl_4 sample. For other organic liquid samples, the window was made by welding the Be plate with a Cu block by diffusion bonding in a vacuum oven. A sample holder for the reflection method is shown in Figs. 3(b) and (c).

Measurements of CCl_4

Carbon tetrachloride is one of the simplest molecules which are liquid at room temperature, and so it has been studied well.[8-11] Therefore, it was selected as a suitable sample for the first experiment with this apparatus. The carbon tetrachloride molecule has a nearly spherical electron cloud and has no heavy atoms to disturb the energy distribution curve by fluorescent X-rays in the energy-dispersive measurements.

In order to obtain the relation of the energy *vs.* the channel number in the MCA, the fluorescent X-rays from Ba, Ag, Mo, and Cu were measured. The results are shown in Fig. 4. The channel numbers of these peaks in the MCA were fitted to the energies of the

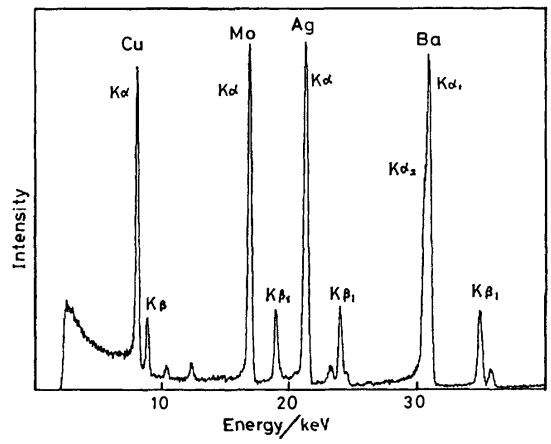

Fig. 4. A spectrum of the fluorescent X-rays from several targets for the calibration of the energy scale in the MCA.

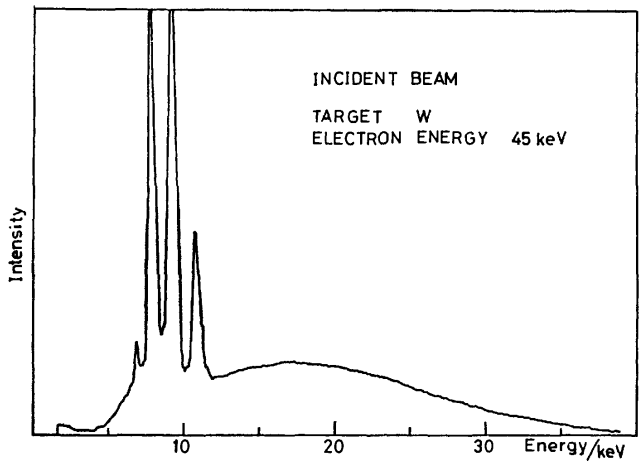

Fig. 5. A tungsten spectrum for the incident white X-rays. The X-ray source was operated at 45 kV and 10 μA.

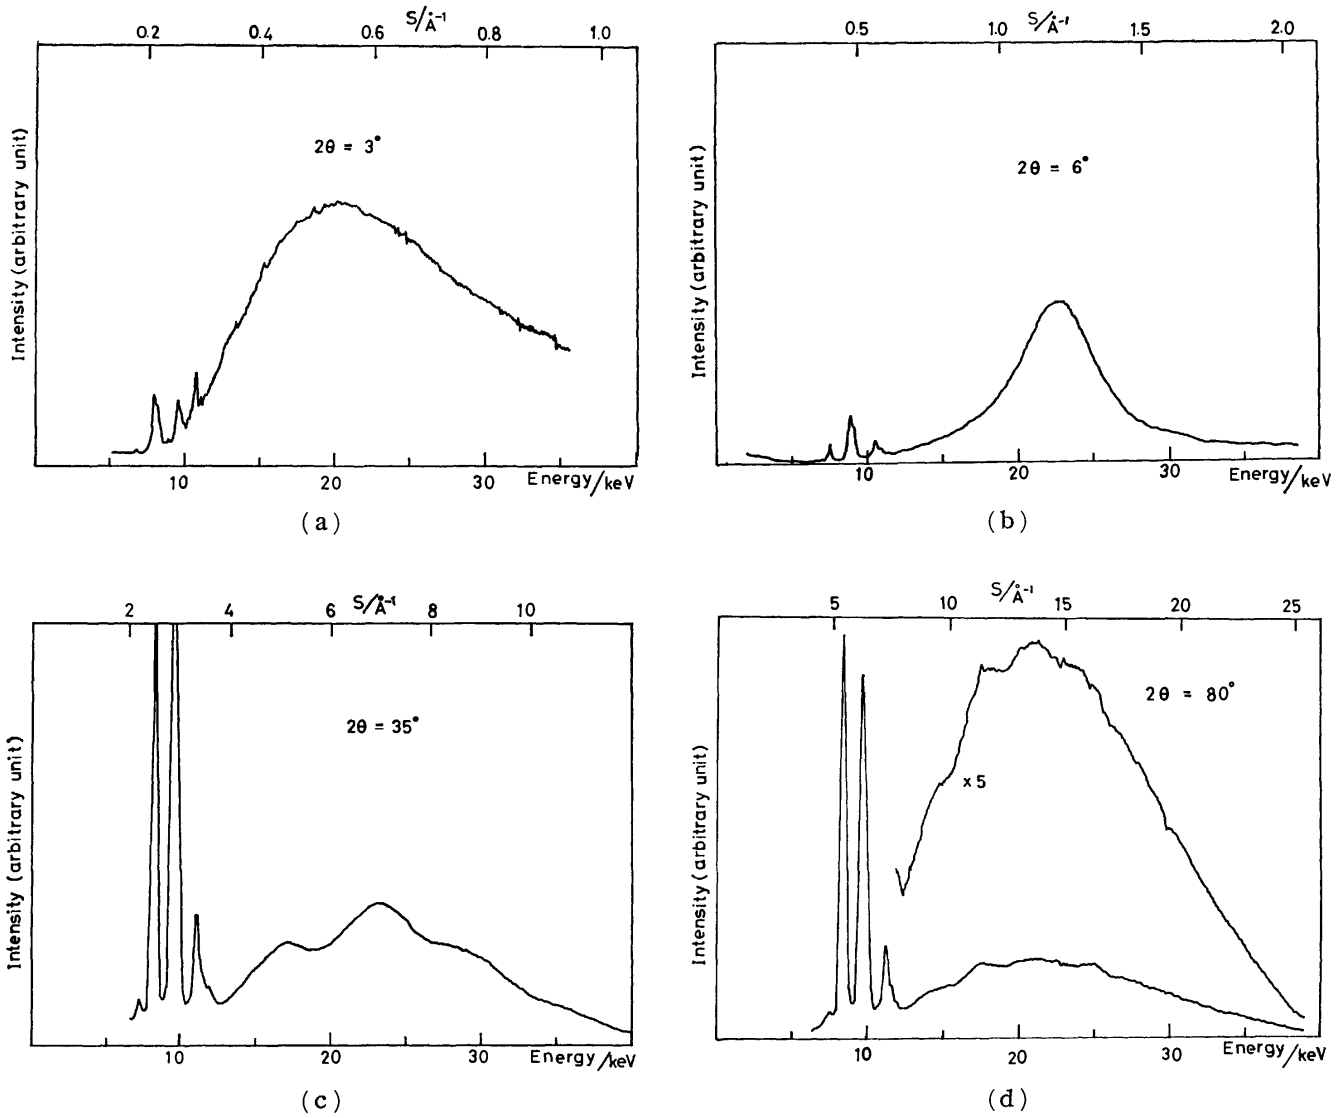

Fig. 6. Scattered intensities from liquid CCl_4 at room temperature. (a) $2\theta=3°$, (b) $2\theta=6°$, (c) $2\theta=35°$, (d) $2\theta=80°$; (a), (b) transmission method, (c), (d) reflection method.

corresponding characteristic X-ray radiations by using a table by Bearden.[12] Since the doublets of Cu $K\alpha$, Mo $K\alpha$, and Ag $K\alpha$ can not be separated by the SSD, the weighted mean energy of $K\alpha_1$ and $K\alpha_2$ was used. The radiations of $K\alpha_1$, $K\beta_1$ in Ba and $K\beta_1$ in Mo and Ag were also used for the calibration. A linear relation between the energy and the channel number was obtained.

The observed energy distribution curve of the incident beam is shown in Fig. 5. This spectrum was obtained from the tungsten target operated at 45 kV and 10 μA.

X-Rays scattered from liquid CCl_4 were collected at the scattering angles of $2\theta=1.5$, 3, 6, 18, 35, 56, and 80°. The specimen was held at room temperature. The data for $2\theta=1.5$, 3, 6, and 18° were measured by means of the transmission method. The reflection method was applied to $2\theta=35$, 56, and 80°. The setting of $2\theta=1.5$, 3, 6, 18, 35, 56, and 80° made it possible to measure $s=0.15$—0.41, 0.30—0.83, 0.56—1.86, 1.75—4.91, 3.78—9.45, 5.90—14.8, and 8.08—23.0 Å^{-1} respectively. The measuring time at each scattering angle was $5\times10^4-10^5$ s, and more than 4000 counts per channel were obtained. The diffraction patterns collected in the MCA are shown in Fig. 6. The $s=0.30$—0.82 Å^{-1} region, $2\theta=3°$, is shown in Fig. 6(a), where no halo due to interference between atoms appears. In Fig. 6(b), $2\theta=6°$, the peak at $s=1.2$ Å^{-1} indicates the first halo due to interference. Figures 6(c) and (d) show the diffraction patterns obtained at $2\theta=$ 35 and 80° respectively; we can see several halos whose amplitudes gradually decrease as the s-value increases.

The scattering from the Myler film or the Be thin plate of the window of the sample holder was also measured. This curve was denoted as I_w. The magnitude of I_w was about 5% of the total scattering intensity from liquid CCl_4.

Data Analysis

Smoothing and Normalization. Smoothing was done by adding the counts collected in each group of five channels, because the resolution of the SSD is about 200 eV and the linear amplifier was so set that the energy width for each channel in the MCA was about 40 eV. The counts at each point after smoothing were more than 2×10^4, which were sufficient to diminish the statistical random error. Each scattering intensity from which the intensity, I_w, was subtracted was divided by the energy distribution curve of the incident beam (normalization).

Absorption Correction. The most important correction in energy-dispersive diffractometry of liquids is the absorption correction, because the linear absorption coefficient, μ, changes with the energy of the X-rays and the effect of the path length in scattering must also be taken into account.

We checked whether or not the calculated values of μ agreed with the observed ones. The value of μ was calculated as follows

$$\mu/\rho = \tau + \sigma, \tag{2}$$

where ρ is the density of the liquid, τ is the photo-electric absorption and σ is the absorption due to the Compton effect. The empirical relation of τ is given by

$$\tau = C\lambda^3 - D\lambda^4, \tag{3}$$

where λ is the X-ray wavelength in Å and where C and D are constants characteristic of atoms. These constants are tabulated in the International Tables. The C's for carbon and chlorine are 1.22 and 33.4 respectively, and the D's are 0.0142 and 3.03 respectively.[13] The absorption due to the Compton effect was given by Klein and Nishina[14] as

$$\sigma = \frac{2\pi e^4}{m^2c^4}\left[\frac{1+\alpha}{\alpha^2}\left\{\frac{2(1+\alpha)}{1+2\alpha}-\frac{1}{\alpha}\ln(1+2\alpha)\right\}+\frac{1}{2\alpha}\ln(1+2\alpha)-\frac{1+3\alpha}{(1+2\alpha)^2}\right], \tag{4}$$

where $\alpha=h/mc\lambda$ and m is the electron rest mass.

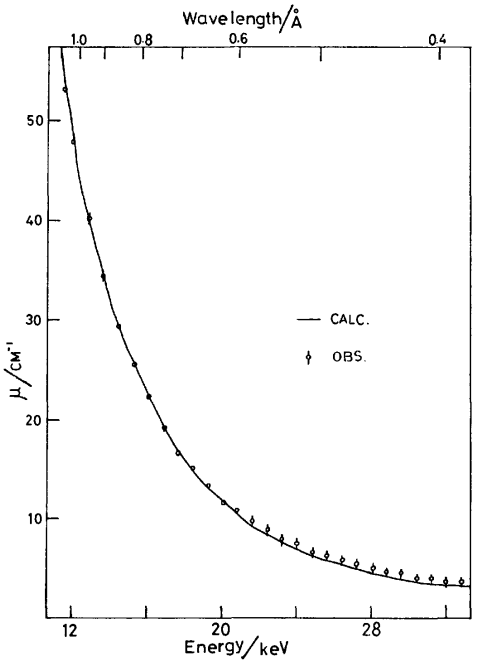

Fig. 7. Calculated and observed linear absorption coefficient, μ, of liquid CCl_4.

The observed values of μ were measured from the trasmittance of the sample at $\theta=0°$. The observed and calculated values are shown in Fig. 7. A good agreement was obtained except in the high-energy region, where the latter values are somewhat smaller than the former. The observed values were used for the data analysis.

The path length in the case of the transmission method can be estimated easily as shown in Fig. 8(a), because the θ-2θ scanning system has been used in this experiment. The path length is given by $t\cdot\sec\theta$, where t is the thickness of the sample. The absorbed intensity, I', is given by

$$I' = I\exp(-\mu t\sec\theta), \tag{5}$$

where I is the intensity without absorption.

In the reflection method, the absorption correction is complicated, because the path length differs depending on the position at which the X-ray is scattered, as shown in Fig. 8(b). The absorbed intensity in the

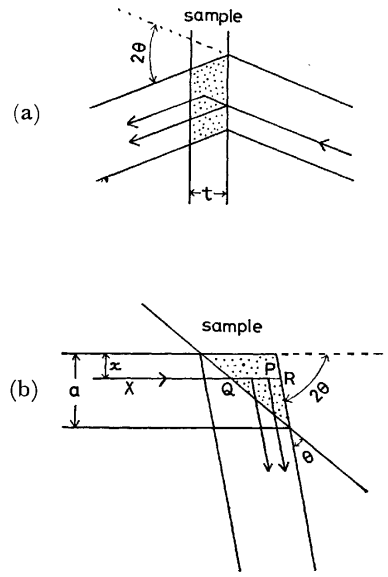

Fig. 8. Path length for the absorption correction. (a) Transmission method. The path length is always t sec θ wherever X-rays are scattered. (b) Reflection method. The path length depends on the position where X-rays are scattered. The X-rays scattered in the dotted area reach the detector.

reflection method is given by

$$I' = I\frac{a^2}{4\mu}\left[\frac{\pi}{2}-\int_{\pi/2}^{3\pi/2}\cos^2\phi\,\exp\{-\mu a(1+\sin\phi)/\sin 2\theta\}\mathrm{d}\phi\right], \quad (6)^{**}$$

where a is the beam diameter on the sample. The derivation of this equation is given in the Appendix.

For the absorption correction, it is important to estimate the effective value of the beam diameter on the sample. A criterion for the estimation of the effective beam diameter is that the background intensity for the observed intensity curve after the Compton correction is proportional to the calculated curve of $\sum_n f_n(s)^2$, where $f_n(s)$ is the atomic scattering factor for a component atom, n, of the molecule. The background intensity means a monotonically decreasing curve corresponding to $\sum_n f_n(s)^2$. The effective beam diameter was 1.2 times as large as the diameter of the aperture at $2\theta=35°$ and grew a little larger as the scattering angle increased. The presence of multiple scattering is probably the reason for the dependence of the effective diameter on the scattering angles. In this apparatus, each collimator has three stages of apertures, as shown in Fig. 2. When each collimator has only two apertures, the effective value of the beam diameter can not be obtained. Figure 9 indicates the importance of the estimation of the effective value of the beam diameter by showing three curves of I'/a^2I in Fig. 6. Curve (a) in Fig. 9 shows the contribution from the first term in the brackets. This is the usual absorption correction in the reflection method for a strong absorption case, in which

** The reflection from the wall of the sample holder is ignored in Eq. 6. This is justified in the present experiment.

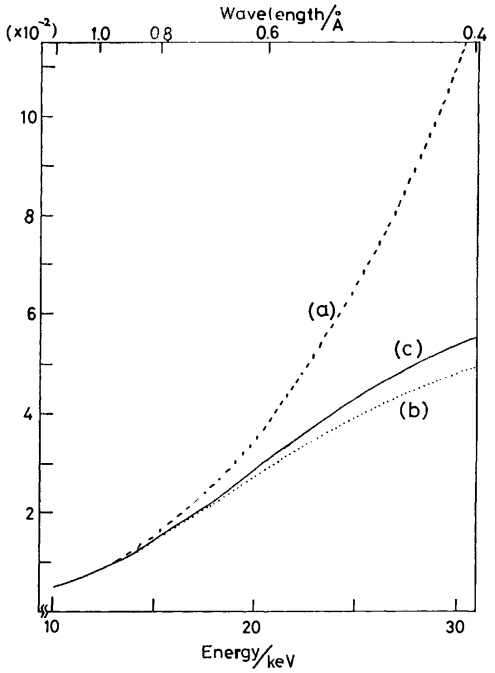

Fig. 9. Curve (a) (broken line) denotes $\pi/8\mu$. Curves (b) (dotted line) and (c) (full line) are

$$\frac{1}{4\mu}\left[\frac{\pi}{2}-\int_{\pi/2}^{3\pi/2}\cos^2\phi\cdot\exp\{-\mu a(1+\sin\phi)/\sin 2\theta\}\mathrm{d}\phi\right]$$

where a is 1.0 mm in (b) and 1.2 mm in (c).

a is much larger than μ^{-1}. Curve (b) shows the result for $a=1$ mm, in which a agrees with the diameter of the apertures. Curve (c) is calculated using the effective beam diameter on the sample in which $a=1.2$ mm. We can recognize from Fig. 9 that the second term in the brackets of Eq. 6 is important for the absorption correction. The second term becomes more significant as the X-ray energy increases (*i.e.* μ decreases) and as a decreases. Therefore, this correction is characteristic of this energy-dispersive method. The curvature of these curves influences the background intensity of the observed intensity curve.

Compton Correction and Absorption Intensity. The scattered intensity, $I(s)$, after the absorption correction is given by

$$I(s) = K[\sum_n f_n(s)^2 + i_1(s) + i_2(s) + kI_C I_0(\lambda)/I_0(\lambda')], \quad (7)$$

where I_C is the intensity of the Compton scattering, k is the recoil factor, and K is the conversion factor from the experimental to absolute intensity (in electron units). $I_0(\lambda)$ and $I_0(\lambda')$ are the intensities of the incident beam at the wavelengths of λ and λ' respectively, and $\lambda'-\lambda$, the Compton shift, is given by $(h/mc)(1-\cos 2\theta)$. The first term in Eq. 7 represents the scattering from individual atoms. The second term is called the molecular term, which is the interference from each atom pair within a molecule. The third term represents the interference from atom pairs between different molecules.

The molecular term for CCl_4 is represented by

$$i_1(s) = 8f_C f_{Cl}\frac{\sin sr_{C-Cl}}{sr_{C-Cl}}\exp\left(-\frac{l^2_{C-Cl}s^2}{2}\right) + 12f^2_{Cl}\frac{\sin sr_{Cl-Cl}}{sr_{Cl-Cl}}\exp\left(-\frac{l^2_{Cl-Cl}s^2}{2}\right), \quad (8)$$

where l_{ij} denotes the root mean-square amplitude due to the vibration of the atom pair around the mean internuclear distance, r_{ij}. Since $i_2(s)$ vanishes at large s-values, the absolute intensities are obtained by adjusting the experimental intensities to the calculated intensities, which are obtained by adding the first, second, and fourth terms of Eq. 7 at large s-values. In the calculation, the r_{C-Cl}, r_{Cl-Cl}, l_{C-Cl}, and l_{Cl-Cl} values obtained by gas electron diffraction of CCl_4[15] were used and the intensities of the Compton scattering calculated by Cromer[16] were employed.

The conversion factor from the experimental to absolute intensity, K, were easily obtained for $2\theta=35$, 56, and 80°; the agreement of the intensity curves in the overlapping region was good. In the cases of $2\theta=$ 1.5, 3, 6, and 18°, an approximation of $i_2(s)=0$ is not so good. Accordingly, each intensity curve was successively connected with that of $2\theta=35°$ after the absorption correction. Then, K was obtained for each intensity curve.

The total coherent intensity

$$I_{co}(s) = \sum_n f_n(s)^2 + i_1(s) + i_2(s), \quad (9)$$

was obtained by subtracting the fourth term in $I(s)/K$ of Eq. 7. The Compton correction was carried out by using the calculated values reported by Cromer.[16] Figure 10 shows the observed coherent intensity of liquid CCl_4 at room temperature, together with the calculated value corresponding to independent atoms of carbon tetrachloride, $\sum_n f_n(s)^2$.

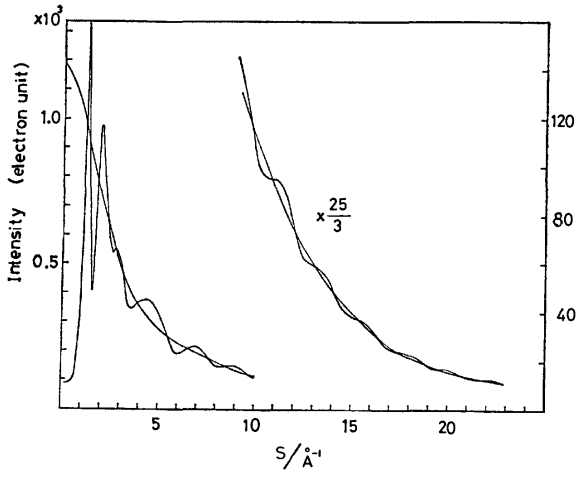

Fig. 10. Observed total coherent intensity I_{co} for liquid CCl_4 at room temperature and calculated one assuming that atoms in CCl_4 are independent.

The weighted structure function, $si(s)$, of liquid CCl_4 is shown in Fig. 11, where $i(s)=i_1(s)+i_2(s)$ is the reduced intensity. An electronic pair correlation function, $g_e(r)$, was defined by the Fourier transformation of $si(s)$;

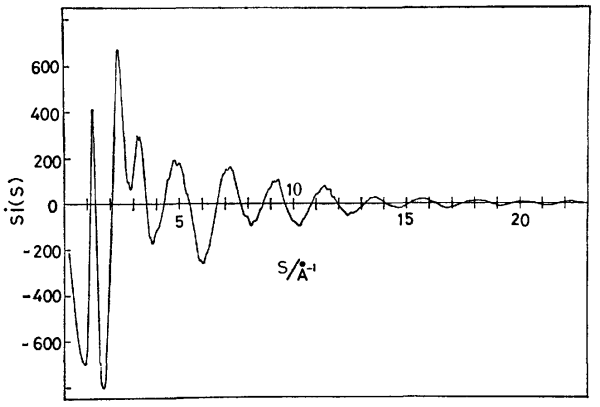

Fig. 11. Weighted structure function $si(s)$ for liquid CCl_4 at room temperature.

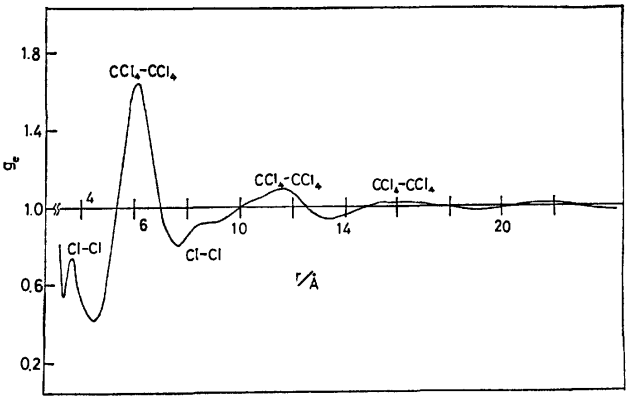

Fig. 12. Electronic pair correlation function $g_e(r)$ for liquid CCl_4 at room temperature.

$$g_e(r) = \frac{1}{2\pi^2 r\rho_0\sum_n Z_n^2}\sum_{s=0}^{s_{max}} si(s)\sin sr\cdot\Delta s + 1, \quad (10)$$

where ρ_0 is the bulk liquid density and Z_n is the atomic number of a component atom n (Fig. 12). In the transformation, only the observed values of $si(s)$ were used throughout the whole region except for $s=0.05$ and 0.10, at which $si(s)$ were extrapolated. This extrapolation can not cause any significant error, since I_{co}'s have a constant value at these positions, as shown in Fig. 10. The $\Delta s=0.05$ Å^{-1} interval and $s_{max}=23.0$ Å^{-1} were used. This range of s is sufficient to eliminate the termination error for Fourier transformation.

The electronic pair correlation function calculated from Eq. 10 is different from the usual pair correlation function, which corresponds to the distribution of the nucleus. The former expresses the distribution of the electron, since, in the present paper, $i(s)$ is $\sum_{i\neq j} f_i f_j(\sin sr/sr)\exp(-l_{ij}^2 s^2/2)$. Therefore, the mean square amplitude obtained directly from Fig. 12 includes the effect of the distribution of the electron cloud. If we try to obtain the usual pair correlation function, $g(r)$, by multiplying $(\sum_n f_n(s)^2)^{-1}$, which is a convenient factor to change from the electron density to the nuclear density, some errors may be introduced by the correction.

Results and Discussion

Figure 12 shows that liquid CCl_4 at room temperature

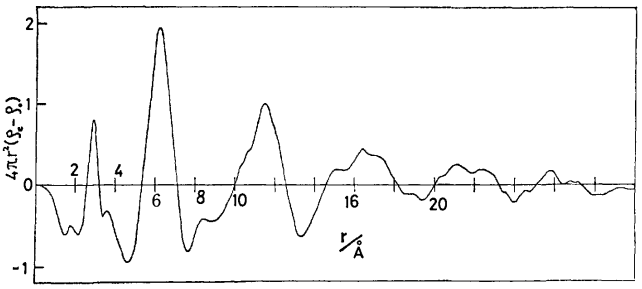

Fig. 13. Electronic radial distribution function from which the bulk density was subtracted, $4\pi r^2(\rho_e-\rho_0)$.

has a long-range correlation. In order to see it more clearly, the electron radial distribution function from which the bulk density was subtracted, $4\pi r^2(\rho_e-\rho_0)$, is shown in Fig. 13. The peak at 6.3 Å corresponds to the first nearest neighbor molecules, while the three other peaks, appearing at 11.4, 16.3, and 21.5 Å, are due to interference between molecules. The interference with the fourth nearest neighbor molecules has a distinct peak in the radial distribution function.

Though information on the long-range order in the liquid is confined mainly to the $s\lesssim 2$ region of the weighted structure function, it is clearly recognized elsewhere. Figure 11 shows that the intensity curve has a fine structure with a short periodicity at small s-values.*** The fine structure near the top and bottom of the halos, such as those at $s=3.2$ and 4.7 Å^{-1}, was reproducible not only in repeated measurements but also in measurements at different scattering angles. The periodicity in this fine structure was 0.2—0.3 Å^{-1}, which was larger than the estimated resolution in the s-value ($\Delta s=0.14$ Å^{-1} at these s-values) in the present experiment. The difference between the collected counts of the top and the bottom of these small waves was about 500 counts, more than the statistical radom error ($\sqrt{n}=170$; $n=3\times10^4$). In the energy-dispersive method, the scattered intensity is scarcely influenced by the fluctuation in the incident-beam intensity. Therefore, the statistical random error given by the square root of the total counts at each position is the main origin of the noise. Though attention has not yet been paid to this fine structure in the liquid structure analysis, the fine structure may indicate that CCl_4 in the liquid phase at room temperature has a long-range order.

The scattering intensities at small s-values contain information about the density fluctuation. The decrease in the total coherent intensity near $s=0$ shown in Fig. 10 is due to the intermolecular correlation. The fluctuation in the number density of a liquid can be estimated from the absolute value of the total coherent intensity at $s=0$, which is obtained by extrapolating the observed intensities. A constant value in the intensity, I_{co}, was obtained at small s-values, as shown in Fig. 10, so that the extrapolation to $s=0$ is easy. According to liquid theory,[17,18] the mean square of the fluctuation in the number density is given by

$$\langle(N_v-\langle N_v\rangle)^2\rangle = \langle N_v\rangle I_{co}(0)/(\sum_n Z_n)^2, \qquad (11)\dagger$$

where N_v is the number of molecules in a small volume v, $\langle N_v\rangle$ means the average value of N_v, $I_{co}(0)$ is the total coherent intensity at $s=0$ in electron units (e.u.), and Z_n is the atomic number. As shown in Fig. 10, $I_{co}(0)$ equals 87 e.u. Hence, $\langle(N_v-\langle N_v\rangle)^2\rangle$ was $9.9_5\times10^{-5}v$ in Å units. This means that $\langle(N_v-\langle N_v\rangle)^2\rangle$ becomes unity when v is 1.00×10^4 Å^3, in which there are 63 molecules, on the average. In other words, there are 63 ± 1 molecules in 1.00×10^4 Å^3 and 252 ± 2 molecules in 4.00×10^4 Å^3. Of cource, this estimation includes some error because the absolute intensity at small s-values was not measured directly, but obtained successively from that observed at $2\theta=35°$. This value is, though, in good agreement with the compressibility of liquid CCl_4 $\kappa=10.34\times10^{-11}$ cm^2 dyn^{-1} (at 20 °C).[19] The details of the results for liquid CCl_4 including the temperature dependence will be reported elsewhere.[20]

Finally, let us compare this apparatus with a usual angle-dispersive diffractometer.[21] The resolution in the s-value is given by Eq. 1. The first term of Eq. 1, $\Delta E/E$ (≈0.01), in this apparatus is much larger than that in the usual one. On the other hand, the $\Delta s/s$ in the usual apparatus is at least twice as large as that in the present one, because $\cot\theta\cdot\Delta\theta\lesssim0.01$ over the range from $s=1.5$ to 30 Å^{-1} in this apparatus, since the collimating system is so designed that the beam divergence, $\Delta\theta$, is 0.3 or 0.6°, in contrast to the usual 2—4°. This difference in $\Delta s/s$ is significant, because the periodicities of the fine structures observed in the scattering intensity value, $si(s)$, $\Delta s=0.2$—0.3 Å^{-1}, are about twice as large as the resolution of this apparatus. Moreover, these fine structures are hardly influenced at all by the intensity fluctuation of the primary beam in the present experimental method.

Diffraction intensities can be obtained over the range from $s=0.15$ to 30 Å^{-1} in the present apparatus by using white X-rays. On the contrary, the intensities in the usual apparatus are taken s-values from 0.4 to 16 Å^{-1}, in which the scattering angle, 2θ, is varied from 4 to 140° if Mo $K\alpha$ ($\lambda=0.7107$ Å) is used. Therefore, the electronic radial distribution function without the termination error in Fourier transformation can be obtained with the present apparatus by using only the observed intensities.

The total time required for collecting the data with this apparatus is comparable to that with the usual one. Nevertheless, a higher resolution in s-value and a wider region of observable intensity can be obtained with this apparatus.

The authors wish to express their thanks to Dr. Teruo Nomura, Rikkyo University, for his collaboration, and

*** The fine structure at large s-values is random noise, because the ratio of the reduced intensity $i(s)$ to the total scattering intensity is small.

† In the above discussions, we have done the calculations considering the atomic distribution, but in the estimation of the density fluctuation we must consider the molecular distribution by taking $(\sum_n Z_n)^2$ instead of $(\sum_n Z_n^2)$ as the denominator.

to Dr. Tomoe Fukamachi and Prof. Sukeaki Hosoya, The Institute for Solid State Physics, for their discussion and for allowing us to do our preliminary experiments in their laboratory. We also would like to thank Prof. Kozo Kuchitsu, The University of Tokyo, for permission to use a computer program for gas electron diffraction and Messrs. Kyozuka, Kimura, Kato, and Yamada, JEOL Co., for making the detector. Thanks are also due to Dr. Masahiro Kotani of Gakushuin University for reading the manuscript. The present work was partially supported by Grants-in-Aid for Scientific Research and a Grant-in-Aid for Developmental Scientific Research from the Ministry of Education.

Appendix

The derivation of Eq. 6 is as follows. In Fig. 8(b), when the beam, X, is scattered at the point P, the contribution of absorption becomes $\exp(-2\mu\overline{PQ})$, where $\overline{PQ}$ means the distance between P and Q. Because P can change from the point Q to R in the case of the X beam, the possible range of $\overline{PQ}$ becomes from 0 to $(a-x)/\sin 2\theta$, where x is as is shown in Fig. 8(b) and varies from 0 to a. The total contribution of absorption in the X beam is given by

$$A_x = \int_0^{(a-x)/\sin 2\theta} \exp(-2\mu y)\mathrm{d}y$$
$$= \{1-\exp(-2\mu(a-x)/\sin 2\theta)\}/2\mu.$$

The absorption correction for incident and scattered parallel beams, the diameters of which are equal to a, is given by

$$A_{\text{total}} = \int_0^a 2\sqrt{\left(\frac{a}{2}\right)^2-\left(\frac{a}{2}-x\right)^2}A_x\mathrm{d}x.$$

If we put $1-2x/a=\sin\phi$, we get

$$A_{\text{total}} = \frac{a^2}{4\mu}\int_{\pi/2}^{3\pi/2}\cos^2\phi\,[1-\exp\{-\mu a(1+\sin\phi)/\sin 2\theta\}]\mathrm{d}\phi$$
$$= \frac{a^2}{4\mu}\left[\frac{\pi}{2}-\int_{\pi/2}^{3\pi/2}\cos^2\phi\,\exp\{-\mu a(1+\sin\phi)/\sin 2\theta\}\mathrm{d}\phi\right].$$

The Molecular Sieving Action of Ion-exchanged Zeolites A

Tatsuo OHGUSHI, Atsushi YUSA, Kunio KINOSHITA, and Yoshifumi YATSURUGI

Komatsu Electronic Metals Co., 2612 Shinomiya, Hiratsuka 254

(Received July 16, 1977)

K_{12}-A zeolite was ion-exchanged with Mg^{2+}, Mn^{2+}, Co^{2+}, Cd^{2+}, or Pb^{2+}, and molecular sieving properties of the resultant zeolites were studied, mainly for PH_3 and SiH_4. (K, Mg)-A and (K, Mn)-A adsorbed PH_3 but not SiH_4, and hence are usable as a purifier for SiH_4. (K, Co)-A, (K, Cd)-A, and (K, Pb)-A decomposed both PH_3 and SiH_4, and are unsuitable as an adsorption purifier for SiH_4. By using adsorption columns containing (K, Mn)-A or (K, Mg)-A, breakthrough curves were obtained for PH_3 in SiH_4. The breakthroughs of (K, Zn)-A and (K, Ca)-A columns were also measured for comparison. The breakthrough point increased in the order of (K, Ca)-A$<$(K, Mg)-A$<$(K, Mn)-A$<$(K, Zn)-A. The mechanism of the molecular sieving is discussed. It is concluded that introduced bivalent cations increase the Debye-Waller factor of K^+ blocking the windows. A large Debye-Waller factor causes a decrease in the activation energy required for adsorbate molecule to pass through the blocked window.

Zeolite A is synthesized in its sodium form, Na_{12}-$(AlO_2)_{12}(SiO_2)_{12}(NaAlO_2)_\delta \cdot nH_2O$ with $0 \leq \delta \leq 1$, whose twelve Na^+'s are easily ion-exchanged with univalent cation M^I or bivalent cation M^{II}, and $(AlO_2)_{12}(SiO_2)_{12}$ constitutes the zeolite framework. [$(AlO_2)_{12}(SiO_2)_{12}$-$(NaAlO_2)_\delta \cdot nH_2O$ is generally abbreviated as -A.] A large cavity is located at the center of a cubic unit cell. There are three 8-membered oxygen rings per unit cell. The 8-ring is on each of the {100} faces of the unit cube, and constitutes a window to the cavity. In Na_{12}-A and K_{12}-A zeolites, all windows in them are blocked by Na^+ and K^+, respectively. Their molecular sieving properties, classified as 4A and 3A, respectively, are determined by the width of the aperture of the partially blocked window. In other words, the sieving character is directly controlled by the radius of the blocking cation.

Recently, Takaishi *et al.*[1] found another possible control mechanism. In (K,Zn)-A, the Debye-Waller factor of K^+ blocking the window is markedly influenced and increased by Zn^{2+} occupying sites other than window sites.[2] Such K^+ is easily pushed aside by a visiting adsorbate molecule, making way for the visitor.[1] PH_3 having a rather large molecular diameter is not adsorbed with Na_{12}-A, but is with $(K_{7.6}Zn_{2.2})$-A[1] in which the above mechanism operates. This result is of practical importance, being applied to the purification of SiH_4 which contains a small amount of PH_3.

In a subsequent section, the phenomenon of the indirect control is further discussed with respect to (K,Mg)-A, (K,Mn)-A, (K,Co)-A, (K,Cd)-A, and (K,Pb)-A. Their adsorption properties were measured for N_2, Ar, butane, 1-butene, *trans*-2-butene, *cis*-2-butene, PH_3 and SiH_4. The results are discussed from a practical point of view, for instance, which is the best adsorbent for the purification of SiH_4.

Experimental

Materials and Chemical Analysis. The starting material was Shōwa-Unox molecular sieve 4A powder (lot No. 490401). After the standard treatment of the sample, its composition was determined by the usual procedure.[3] The chemical formula was $Na_{11.8}H_{0.2}(AlO_2)_{12} \cdot (SiO_2)_{12}(NaAlO_2)_\delta$ with $0.2 \leq \delta \leq 0.3$. This differs from the stoichoimetric composition $Na_{12}(AlO_2)_{12}(SiO_2)_{12}$.[4,5] The deficiency of sodium may be ascribed to partial hydrolysis, though protons, which had replaced alkaline metal cations, were not analyzed. The value of δ was further examined by the following method. It has been established that $(NaAlO_2)_\delta$ molecule is contained in the β-cage (the sodalite unit) and its Na^+ cannot be exchanged with Ca^{2+}. After fully ion-exchanging Na^+ in the starting zeolite with Ca^{2+}, the residual amount of Na^+ in the resultant zeolite was determined, by activation analysis, to be 0.21 ions per unit cell ($\delta = 0.21$).

A fully ion-exchanged K_{12}-A was obtained by decanting the starting material repeatedly with 1 M KCl solutions, and washing it with distilled water. This zeolite contained 11.4 K^+ per unit cell. $(K_{12-2x}M_x^{II})$-A zeolites were prepared by treating K_{12}-A with solutions of a mixture of KCl and $M^{II}Cl_2$, of 0.2 total metal ion normality, at 80 ± 2 °C. As for (K, Pb)-A, nitrate solution was used instead of chloride. In most cases, the composition of an ion-exchanged zeolite was calculated from that of the ion-exchanging solution and material balance. The composition of the ion-exchanging solution was determined by the titration with ethylenediaminetetraacetic acid. On the other hand, zeolites of high contents of Mg^{2+} and Mn^{2+} were obtained only after repeated treatment with pure solutions of $MgCl_2$ and $MnCl_2$, respectively. In these cases, the composition of the zeolites was directly analyzed by usual methods. Zeolites containing Mg^{2+} or Mn^{2+} in amount more than 5 ions per unit cell could not be prepared.

All chemical reagents used were S.P. grade, and common adsorbate gases contained in glass cylinders (supplied by the Takachiho Chemical Co.) had nominal purities better than 99.9% as determined by mass-spectroscopic analysis. Less common gases, such as SiH_4 and PH_3, were obtained from the Nihon Oxygen Co., and were of special high purities, *i.e.*, semiconductor grade.

Measurements of Adsorbed Amounts of Gases. Adsorption measurements were made with a McBain type quartz spring balance and electrobalance (Chan Instrument Co., Model No. RG2050). The former had a sensitivity of 0.5 m/g and an accuracy of ± 0.5 mg. Prior to adsorption measurements, adsorbents were baked-out at 390 °C for 4 h under a vacuum better than 10^{-5} Torr.

Results

Amounts Adsorbed. *(K,Mg)-A Series*: Adsorptive capacities of (K,Mg)-A zeolite are shown in Fig. 1.

(b) Adsorption of polar gas and unsaturated hydrocarbons on $(K_{12-2x}Mg_x)$-A zeolites. (○) PH_3, 95 Torr, 0 °C; (□) 1-butene, 160 Torr, 0 °C; (■) *trans*-2-butene, 160 Torr, 0 °C; (△) *cis*-2-butene, 160 Torr, 0 °C.

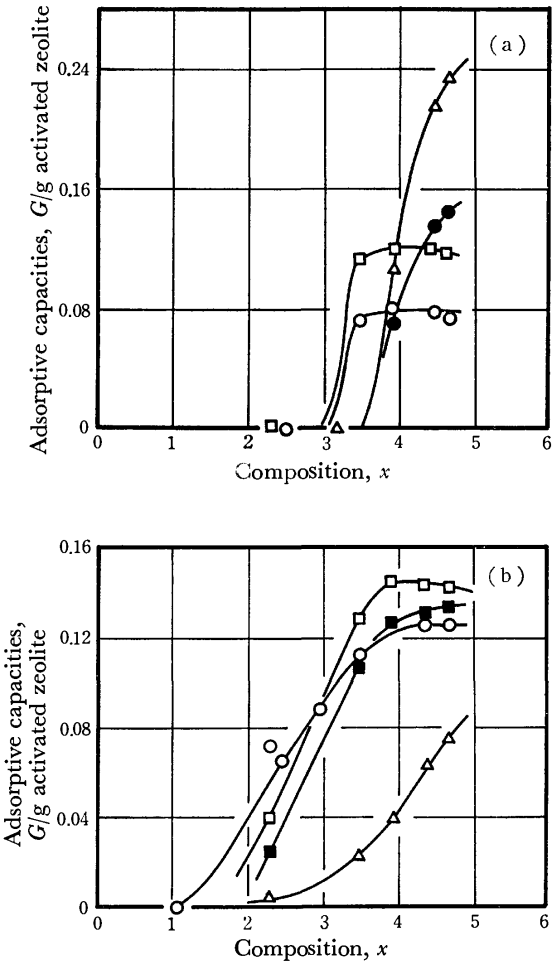

Fig. 2. (a) Adsorption of non-polar gases on $(K_{12-2x}Mn_x)$-A zeolites. (△) argon, 150 Torr, −196 °C; (●) nitrogen, 130 Torr, −196 °C; (□) butane, 160 Torr, 0 °C; (○) SiH_4, 150 Torr, 0 °C.
(b) Adsorption of polar gas and unsaturated hydrocarbons on $(K_{12-2x}Mn_x)$-A zeolites. (○) PH_3, 95 Torr, 0 °C; (□) 1-butene, 160 Torr, 0 °C; (■) *trans*-2-butene, 160 Torr, 0 °C; (△) *cis*-2-butene, 160 Torr, 0 °C.

Curves in Fig. 1(a), which refer to non-polar gases, rise steeply at the same composition, for instance $x=4.1$. On the other hand, curves in Fig. 1(b), which refer to polar gas or unsaturated hydrocarbons, have gentle slopes.

(K,Mn)-A Series: Figures 2(a) and (b) show adsorption properties of (K,Mn)-A series for non-polar molecules, and for polar and unsaturated hydrocarbon molecules, respectively. Slopes of curves in Fig. 2(b) are more gentle than those in Fig. 1(b).

(K,Co)-A, (K,Cd)-A, and (K,Pb)-A Series: These were colored when either PH_3 or SiH_4 was introduced, and yielded a gas uncondensable with liquid nitrogen. The weight of the zeolite sample was irreversibly increased on contact with PH_3 or SiH_4, that is, it was not decreased outgassing at temperatures up to 350 °C. This means that PH_3 or SiH_4 was decomposed and hydrogen was produced. The higher the degree of ion-exchange, the higher the catalytic activity for the decomposition. These features are not suitable for a purifier, since the non-volatile residuals block the zeolite window and degrade the adsorption activity.

Dynamic Characteristics of the Adsorption Column. Another important property of the purifier, the dynamic property of adsorbent, was studied. Breakthrough curves of columns, containing (K,Mg)-A or (K,Mn)-A zeolite of promising compositions, were plotted for PH_3 contained in SiH_4 by the aid of gas-chromatographic techniques. The breakthroughs of (K,Zn)-A and (K,Ca)-A columns were also measured for comparison. A gas mixture of PH_3 and SiH_4 in 5.5: 10^4 volume ratio was passed through the column at a flow rate of 350 ml/min and 0 °C. Results are given in Fig. 3, which shows that the breakthrough point for (K,Zn)-A is longer than others.

Discussion

As can be seen from Figs. 1 and 2, the curves for non-polar molecules have forms considerably different from those for polar and unsaturated. The latter two have gentle slopes and the former steep ones. This difference originates from the difference in the sieving mechanism. That is, non-polar molecules are adsorbed into zeolite A by passing through windows whose aperture width is larger than the molecular diameter. The width of the window aperture is simply determined by the ionic radius of a cation occupying the 8-ring site. The present authors have named this mechanism of the control of sieving action the direct control mechanism. In the adsorption of polar molecules, on the other hand, the following additional factor operates. The potential experienced by the ion on the 8-ring site is changed by ion-exchanges. If the change is such that the curvature of the potential surface is reduced and becomes fairly gentle, the amplitude of the oscillation of the ion, or its Debye-Waller factor, is increased. Then, the window-blocking action of the ion concerned becomes incomplete with increasing temperature. Hence, molecules having a diameter slightly larger than the width of the window aperture can be adsorbed, the rate of adsorption depending upon the incompleteness. The former phenomenon is confirmed by Takaishi *et al.*[6] in the systems of (Na,Ca)-A and (K,Ca)-A. This control mechanism of the sieving action has been named the indirect control mechanism. The above change in the potential form is induced by electrostatic forces due to cations, and hence is influenced further by the dipole or quadrupole of a visiting adsorbate. Consequently, the indirect control mechanism markedly operates on the adsorption of a polar molecule. Owing to this mechanism, zeolites having windows blocked by K^+, such as $(K_{12-2x}Mg_x)$-A with $1.5<x<3.5$ and $(K_{12-2y}Mn_y)$-A with $1.1<y<3.0$, can remove PH_3 contained in SiH_4, as well as (K,Zn)-A.[1,7] The degree of the indirect control is delicately affected by the ionicity and location of the bivalent cation, and is of the order of

$$Mn^{2+}, Zn^{2+} > Mg^{2+}, Ca^{2+}.$$[8]

Now, let us compare and discuss breakthrough points of (K,Mg)-A, (K,Mn)-A, (K,Zn)-A, and (K,Ca)-A having the similar content of bivalent cation, say about 2.3 cations per unit cell. In general, the breakthrough point is to be affected by two factors, the capacity and rate of adsorption. Experimental results are recapitulated as follows:
for the capacity

$$(Mn), (Mg) > (Zn) > (Ca),$$[8]

for the rate[7]

$$(Zn), (Mn) \gg (Mg) > (Ca),$$[8]

and for the breakthrough point

$$(Zn) > (Mn) > (Mg) > (Ca),$$

where symbols (Zn), (Mn), (Mg), and (Ca) designate zeolites containing the respective bivalent cations. The order of the breakthrough point is similar to that of the rate of adsorption. Thus, it may be said that the breakthrough point is mainly determined by the rate of adsorption in the present system. However, at composition 3.6 bivalent cations per unit cell, the breakthrough point of (Ca) is larger than that of (Mg). Hence, the point may also be affected by other factors, such as heat of adsorption for PH_3 and for SiH_4, though these values were not measured in the present work. (K,Zn)-A was concluded to be the best purifier among those studied.

Finally, let us discuss the role of the indirect control mechanism in a fine molecular sieving action for other gases. $(K_{12-2x}Mg_x)$-A with $2.4<x<4.0$ and $(K_{12-2y}Zn_y)$-A with $1.5<y<3.6$[1] can sieve 1-butene and *trans*-2-butene from *cis*-2-butene. If the shape of a butene molecule is roughly approximated by a prolate spheroid, the minor axis of *cis*-2-butene is larger than that of 1-butene or *trans*-2-butene. Then, *cis*-2-butene requires, to pass through the window, a larger displacement of the blocking K^+, or a larger activation energy. Thus, the fine separation of these isomers can be realized by the adsorption.

The present authors are deeply grateful to Professor T. Takaishi of Rikkyo University, who kindly read and discussed the manuscript. The authors are also grateful to Professor Gene S. Lehman of Rikkyo University for his language corrections to the manuscript.

ESR Spectra of Bis(acetylacetonato)oxovanadium(IV) and Related Chelates in Molten *o*-Terphenyl and Some Other Organic Compounds

Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 18, 1977)

All the patterns from the isotropic ESR spectrum to the anisotropic one of bis(acetylacetonato)oxovanadium-(IV) and related chelates are recorded by employing molten *o*-terphenyl as a solvent and by changing the temperature above and below the melting point. The results are qualitatively explained in terms of the anisotropic molecular motion and are considered to be evidence for the presence of clusters in the melt. Similar observations are made with some derivatives of 2,4,6-trinitrodiphenylamine, but only partially with *m*-terphenyl and the 3′-methoxy and 3′-ethoxy derivatives of 2,4-dinitrodiphenylamine. The implications of the results concerning the structure of the melts are discussed.

The ESR spectra of oxovanadium(IV) chelates are known to be substantially modified by the medium.[1] The isotropic spectra obtainable in liquid solutions consist of eight hyperfine lines arising from the nuclear spin $I=7/2$ of vanadium 51. On the other hand, each of the randomly oriented paramagnetic species immobilized in glasses separately contributes eight transitions to the spectrum; therefore, a superposition of the spectra associated with each orientation, weighted in proportion to the probability of finding the chelate molecules at that particular orientation, may be observed. In several liquid solutions, the appearance of an anisotropic molecular reorientation has been suggested in order to explain a marked deviation from the isotropic spectra.[2] If the viscosity of a solvent varies by many orders of magnitude upon a change in the temperature, one may observe all the patterns from the isotropic spectrum to the entirely anisotropic one. Knowledge of such spectral patterns is expected to be useful in studies of motional behavior in general, not only of liquids but also of solids, since the reorientation of the chelate molecule manifests the motion of the solvent or host molecules. In order to standardize the pattern, we initiated our work with an examination of the ESR spectra of three oxovanadium(IV) chelates dissolved in molten *o*-terphenyl, the viscosity of which has been reported in detail by Ubbelohde and his collaborators and also by Greet and Turnbull.[3–5] Then, attempts were made to study the motional behavior in melts of some derivatives of 2,4-dinitro- and 2,4,6-trinitrodiphenylamines.

Experimental

The bis(acetylacetonato)oxovanadium(IV), hereafter abbreviated $VO(acac)_2$, was commercially obtained. The bis(benzoylacetonato)oxovanadium(IV), $VO(bza)_2$, and bis(dibenzoylmethanato)oxovanadium(IV), $VO(dbm)_2$, were prepared following the procedures reported by Selbin *et al.*[6] The terphenyls were freed from polar impurities by chromatography on a column of activated alumina, using petroleum ether as the elutrient; they were then recrystallized from the same solvent. The melting points of the *o*- and *m*-terphenyls agreed well with the literature values of 55.5 and 87 °C.[3] The derivatives of the 2,4-dinitro- and 2,4,6-trinitro-diphenylamines were obtained by the condensation of appropriate derivatives of aniline with 2,4-dinitro- and 2,4,6-trinitrochlorobenzenes respectively. The concentrations of the paramagnetic probe dissolved in the organic melts were in the order of 10^{-3} M. As our work is not concerned with the linewidth, the solutions were not degassed. The spectra were recorded on a JEOL model JES-ME-3X spectrometer with 100 kHz modulation in the range from room temperature to 160 °C. The magnetic-field scan was calibrated with Mn^{2+}-doped MgO powder (86.9 G).

Results and Discussion

The oxovanadium chelates employed here are known to have approximately axial hyperfine and *g* tensors.[7–9] Their components parallel and perpendicular to the V=O bond direction will be denoted by $A_{\parallel}$ and $A_{\perp}$,[10]

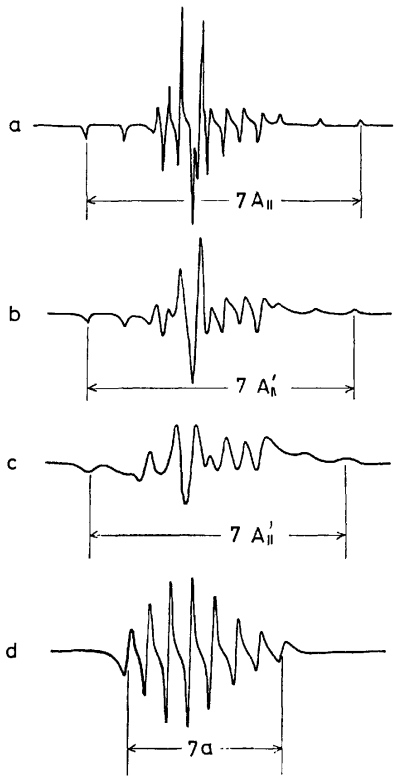

Fig. 1. ESR spectra of bis(acetylacetonato)oxovanadium(IV) in molten *o*-terphenyl at 24 °C (a), 40 °C (b), 50 °C (c), and 100 °C (d).

and by $g_{\parallel}$ and $g_{\perp}$, respectively. However, the rather small anisotropy in the latter will be ignored for the sake of simplicity in the following discussion. Some representative spectra of $VO(acac)_2$ in molten *o*-terphenyl observed at four different temperatures are presented in Fig. 1. At room temperature the supercooled melt exhibits an ESR spectrum typical of glasses. Here, the $VO(acac)_2$ molecules may be supposed to be randomly and rigidly oriented in the space. Although the central portion is complicated by an overlap of the parallel and perpendicular resonance lines, the $M_I=\pm 7/2$ and $\pm 5/2$ parallel resonance lines are well resolved. The values of $7A_{\parallel}$ are given by the distance between the outermost lines corresponding to the $M_I=\pm 7/2$. Thus, $A_{\parallel}$ is estimated to be 189 G.

The spectrum recorded at 40 °C is shown in Fig. 1b. The main feature of the room-temperature spectrum is still noticeable; however, each line has become much broader, and the distance between the outermost lines is markedly diminished, $7A'_{\parallel}$. Although it is not easy to observe, the perpendicular resonance spectrum is expected to be expanded; that is, $A'_{\perp}>A_{\perp}$. These are the spectral characteristics exhibited by a paramagnetic probe undergoing slow motion.[11] The spectrum taken at 50 °C indicates increased molecular motion (see Fig. 1c). If the probe molecules are tumbling rapidly, both $A'_{\parallel}$ and $A'_{\perp}$ are reduced to a, the isotropic hyperfine constant. As is shown in Fig. 1d, the isotropic eight-line pattern normally expected under such conditions is observed at 100 °C. The coupling constant is 107 G; therefore, $A_{\perp}$ may be estimated to be 66 G by the $(A_{\parallel}+2A_{\perp})=3a$ relation. The former value can be well compared with that of 108 G observed in a benzene solution by Stoklosa and Wasson.[9] Some years ago, Luckhurst and Ockwell examined the ESR spectrum of $VO(acac)_2$ in molten *o*-terphenyl.[12] Their measurements were apparently carried out at too high temperatures for the drastic change to be observed.

When the temperature is not high enough to observe the isotropic spectrum, the motion of the present probe molecule may be supposed to be anisotropic. If this motion is rapid, the parameter

$$S = (3\langle\cos^2\theta\rangle - 1)/2 \qquad (1)$$

is known to be equal to

$$(A'_{\parallel}-A'_{\perp})/(A_{\parallel}-A_{\perp}) \text{ or } (A'_{\parallel}-a)/(A_{\parallel}-a), \qquad (2)$$

where the θ angle is that between the V=O bond direction and the magnetic field, and where the average is temporal.[13] Upon a further lowering of the temperature, the anisotropic molecular motion may become so slow in the time scale of ESR spectroscopy that the average must be considered to be spatial. Nevertheless, for the sake of convenience, we will continue to employ the $(A'_{\parallel}-a)/(A_{\parallel}-a)$ ratio, denoted by S, as a measure of molecular motion throughout the temperature range examined. As a matter of fact, the S value can be estimated by means of the above equation only in the range from 1.00 (as the rigid limit) to about 0.55. Beyond the latter value, it is not possible to locate the outermost lines. Therefore, the rapid anisotropic molecular motion model may be not valid at all in the observable temperature range.

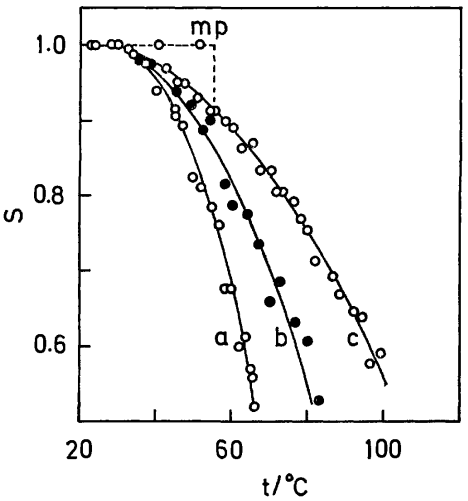

Fig. 2. Temperature dependence of the parameter S for $VO(acac)_2$ (a), $VO(bza)_2$ (b), and $VO(dbm)_2$ (c) in *o*-terphenyl. The horizontal line is for $VO(dbm)_2$ in solidified *o*-terphenyl.

The variation in S with the temperature for $VO(acac)_2$ is plotted in Fig. 2, along with those for $VO(bza)_2$ and $VO(dbm)_2$. At the melting point of pure *o*-terphenyl, the values of S are 0.77 for $VO(acac)_2$, 0.87 for $VO(bza)_2$, and 0.91 for $VO(dbm)_2$. Thus, the larger the chelate molecule, the more difficult the motion round two axes lying in the flat plane of the molecule appears to be. In order to achieve the same value of S, say 0.80, *o*-terphenyl must be heated to 73 °C in the case of $VO(dbm)_2$ compared with 53 °C in the case of $VO(acac)_2$. The agreement in S does not mean that the motional behavior of one chelate is the same as that of the other, since the mode of the molecular motion expressed as a function of θ depends upon the size and shape of the chelate molecule.

As the melting point is approached, molten *o*-terphenyl is known to show a marked departure from the linearity in the plot of the logarithm of the viscosity against $1/T$. On the basis of this departure, the formation of interlocked clusters in molten *o*-terphenyl near and below the melting point has been postulated by Ubbelohde and his collaborators.[3,4] According to them, clusters of a few molecules exist from temperatures of about 195 down to 70 °C. At the latter temperature the volume fraction of the cluster is estimated to be about 0.3. As the motion of the chelate molecule is largely governed by the volume of the solvent to be displaced by it, interlocking to this extent is enough to affect the ESR spectra of $VO(bza)_2$ and $VO(dbm)_2$ markedly. Between 70 °C and the melting point, clusters of a higher order appear to be formed in appreciable concentrations. In this temperature range, the rotation of even the smallest chelate molecule, $VO(acac)_2$, is clearly restricted. When the temperature is lowered still further, the clustering mechanism becomes more complex, eventually leading to the ESR spectra of the immobilized chelate molecule.

Upon a rise in the temperature, the viscosity, η, of the medium and also the kinetic energy of the probe molecule change. The two changes certainly contribute to the decrease in the parameter, S. Therefore, the

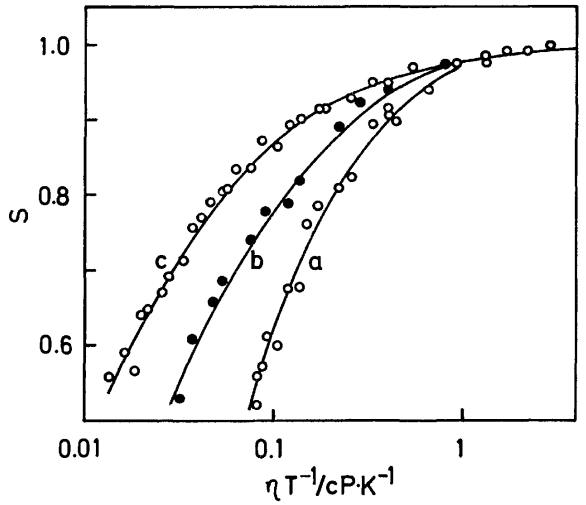

Fig. 3. Variation of the parameter S with η/T for VO(acac)$_2$ (a), VO(bza)$_2$ (b), and VO(dbm)$_2$ (c) in *o*-terphenyl.

variation in S with η/T shown in Fig. 3 may be more useful than the variation in S with t (or T) shown in Fig. 2. The viscosity values of the molten *o*-terphenyl required for the plots were calculated by means of the equation of Greet and Turnbull applicable to the range from -16 to 250 °C.[5] The η/T ratio appears in the well-known equation relating the viscosity of a medium to the Debye correlation time, τ

$$\tau = 4\pi r^3\eta/3kT, \quad (3)$$

where r is the radius of the probe molecule rotating in the medium. As r may not be constant in the slow-motion model, the plots in Fig. 3 may be different from the variation in S with τ.

Now, let us comment on the observation made by Stoklosa *et al.*[2] Their spectra of VO(bza)$_2$ in quinoline and 2-methylbenzoxazole measured at room temperature are well approximated by our spectra in *o*-terphenyl at 80 °C (S=0.61) and 83 °C (S=0.53) respectively. The spectral pattern is so sensitive to the temperature that one can easily differentiate such a small change. The viscosities of quinoline and 2-methylbenzoxazole have been reported by them to be 2.314 and 3.403 cP at 25 °C. The corresponding values of η/T, 0.0078 and 0.011 cP K^{-1}, are markedly smaller than the values of *o*-terphenyl at the above-mentioned temperatures, as can readily be seen by Fig. 3. Therefore, it is apparent that viscosity alone cannot account for the deviations from the isotropic ESR spectra observed by Stoklosa *et al.* It must be added that, in this temperature range, the viscosities calculated by means of the equation of Greet and Turnbull are larger than those of Andrews and Ubbelohde. Fortunately, the choice does not affect the present conclusion. When the size of the probe molecule is larger, the viscosity effect becomes more dominant in the determination of the ESR spectrum. The spectrum of VO(dbm)$_2$ recorded in 2-methylbenzoxazole can well be compared with that observed in *o*-terphenyl at 92 °C (S=0.65), the η/T value being 0.022 cP K^{-1} (Greet and Turnbull) or 0.015 cP K^{-1} (Andrews and Ubbelohde). The latter value agrees almost entirely with the observed one.

When *o*-terphenyl solidifies, VO(acac)$_2$ and VO(bza)$_2$ exhibit single broad absorptions, indicating the segregation of the chelates, but VO(dbm)$_2$ remains dissolved. Although the spectrum of the last-mentioned substance consists of rather broad lines, the pattern is similar to that shown in Fig. 1a. No temperature dependence was observed up to the melting point, as is indicated by the horizontal line in Fig. 2. In sharp contrast to this, VO(dbm)$_2$ has been found to move slowly in some solid charge-transfer complexes. The results of these measurements will be the subject of forthcoming papers.

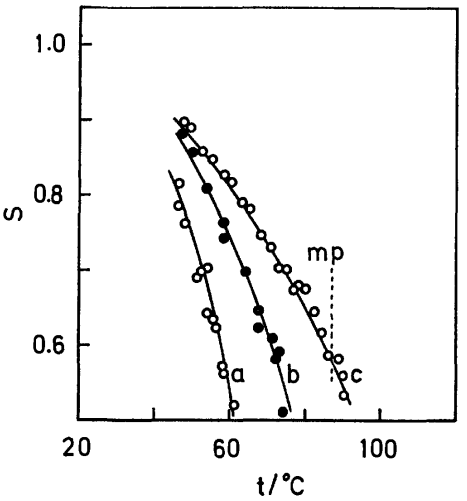

Fig. 4. Temperature dependence of the parameter S for VO(acac)$_2$ (a), VO(bza)$_2$ (b), and VO(dbm)$_2$ (c) in *m*-terphenyl.

m-Terphenyl behaves similarly, but less significantly than *o*-terphenyl, in the transport process.[3] In this terphenyl, too, a dramatic change in the ESR spectra could be recorded. The values of S measured with the three chelates are plotted against the temperature in Fig. 4. As the melts could not be cooled low enough for the anisotropic spectra to be observed, the $A_{\parallel}$ values determined in *o*-terphenyl were applied to these systems. The melting point of *m*-terphenyl is higher by about 30 °C than that of *o*-terphenyl; nevertheless, the temperature ranges shown in Fig. 4 are lower than the corresponding ones in Fig. 2. For example, an S value of 0.58 is found at the melting point in the case of VO(dbm)$_2$. If one assumes that the η/T value of *m*-terphenyl at this temperature is equal to that in *o*-terphenyl at S=0.58, the viscosity may be estimated to be 6.2 cP. This is in fair agreement with the value of 5.4 cP calculated by means of the equation of Andrews and Ubbelohde.[3]

The results presented above strongly suggest that extensive molecular interlocking in organic melts may be detected by measurements of the ESR spectra of dissolved oxovanadium chelates. Furthermore, the viscosity of the medium may be estimated by comparing these spectra with the ESR spectra recorded in molten *o*-terphenyl. As we have seen in the cases of VO(bza)$_2$ dissolved in quinoline and 2-methylbenzoxazole, the apparent viscosity obtained by the ESR technique is

significantly larger than the actual one if some other interactions between the probe and the medium are conceivable. The present author earlier reported that the melts of some derivatives of 2,4,6-trinitrodiphenylamine are colored more deeply than the crystals and that they are readily supercooled without fading.[14] The presence of a strong molecular entanglement, assisted by the charge-transfer interaction between the electron-donating moiety of a molecule and the accepting moiety of the neighboring molecule, was suggested to account for this phenomenon. As will be described in the following paragraphs, the ESR spectra of dissolved $VO(acac)_2$ revealed that the viscosities at their melting points are as large as the corresponding values of molten o-terphenyl. The $A_{\parallel}$ values were found to be essentially the same as that in molten o-terphenyl. On the other hand, the a values could not be measured because of the rapid decomposition of $VO(acac)_2$ at high temperatures. Therefore, the latter was assumed to be 107 G.

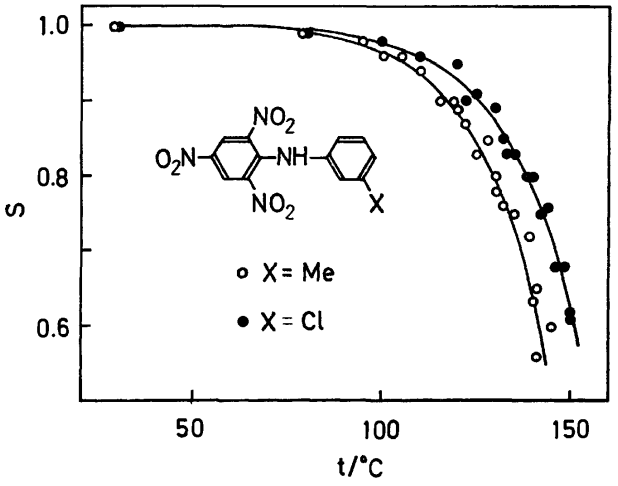

Fig. 5. Temperature dependence of the parameter S for $VO(acac)_2$ in 2,4,6-trinitro-3′-methyldiphenylamine (○) and 2,4,6-trinitro-3′-chlorodiphenylamine (●).

In Fig. 5, the results obtained by the use of the 3′-methyl and 3′-chloro derivatives are presented. The melting point of the former compound is 133 °C (130 °C by Busch and Pungs[15]) and that of the latter, 142—143 °C (137—139 °C by Wedekind[16]). The substituents are similar in size, but the bond moments are very different from each other. The higher melting point of the 3′-chloro derivative may be ascribed to the contribution of the large C–Cl bond moment to the intermolecular forces. The curve for the 3′-chloro derivative in Fig. 5 appears to be shifted to a higher temperature than that for the 3′-methyl derivative by just the difference in the melting point. As is shown by the electronic absorption spectra, the intermolecular charge-transfer interaction in melts is more pronounced in the 3′-methyl derivative than in the 3′-chloro derivative. However, its effect on the S value could not be detected. The S values at the melting points are 0.75 in both cases. The apparent viscosities are 65—67 cP. In these cases, the S values vary more gradually with

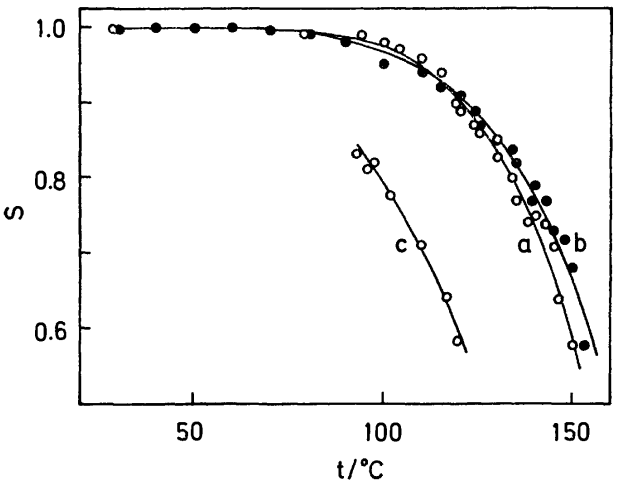

Fig. 6. Temperature dependence of the parameter S for $VO(acac)_2$ in 2,4,6-trinitro-2′-methoxydiphenylamine (a), 2,4,6-trinitro-3′-methoxydiphenylamine (b), and 2,4-dinitro-3′-methoxydiphenylamine (c).

the temperature than that in molten o-terphenyl. In other words, the temperature dependence of the viscosity of the diphenylamines is less than that of o-terphenyl.

The values of S displayed by the 2′- and 3′-methoxy derivatives are plotted against the temperature in Fig. 6. The substituent is more strongly electron-donating and more polar than methyl group. These factors favor a strong intermolecular interaction, but the bulkiness opposes it. As a result, the former compound melts at 148 °C (143 °C by James *et al.*[17]) and the latter, at 123—124 °C. Once melted, the 3′-methoxy derivative is slightly more viscous than the 2′-methoxy derivative in most of the examined temperature range. Two curves are nearly superimposed on the curve for the 3′-chloro derivative given in Fig. 5. The S value at the melting points are 0.63 and 0.89 respectively. Hence, the viscosities are about 44 and 130 cP. One may conclude that the intermolecular interaction in the 3′-methoxy derivative is drastically intensified upon melting.

Before reporting our attempts with 2,4-dinitro-2′-methoxydiphenylamine, it will be interesting to note other information. In the first place, this compound is known to be dimorphic. The unstable orange-yellow form transforms into the bright red form around 145 °C, and then melts at 165.5 °C.[18] The second outstanding feature of interest is that the melting point is markedly higher than that of 2,4,6-trinitro-2′-methoxydiphenylamine. Moreover, the color of the stable form is deeper than that of the trinitro compound. In contrast to the melt of the latter, the melt of the former compound could not be supercooled. The 3′-methoxy derivative is yellow and melts at 141—142 °C. This temperature, too, is higher than the melting point of the corresponding trinitro compound. Nonetheless, the curve for this compound (shown in Fig. 6) is located about 35 °C lower. Besides, the crystallization takes place around 93 °C. It is clear that no extensive formation of clusters occurs near the melting point of this compound. Thus, the absence of the nitro group at the

6 position increases the stability of the crystalline state, but decreases the cluster-forming potential in the melt. The clusters are some form of structural association into groups different from crystal nuclei; therefore, spontaneous crystallization may be prevented by extensive cluster formation. In addition to the stability of the crystalline state, the difficulty in cluster formation helps to explain why the dinitro compounds show a pronounced tendency to crystallize.
