Intermolecular Chelate Linkage Isomerism of the Hydroxyimino Group in the Nickel(II), Copper(II), and Palladium(II) Complexes of Quadridentate Schiff-base Ligands

N. S. Dixit, B. P. Sudha, and C. C. Patel*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560012, India

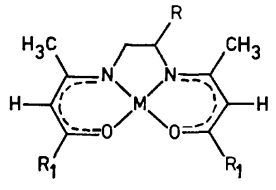
(Received February 21, 1977)

The C-nitrosation of bivalent quadridentate β-imino ketone complexes of nickel(II), copper(II), and palladium(II), with nitrosating reagents has been investigated. The chemical analysis and spectroscopic results reveal that one of the α-CH groups of the coordinated lignad undergoes selective nitrosation forming mono(hydroxyimino) derivative. The hydroxyimino group introduced coordinates through either N- or O- atom to metal(II) by dislodging the carbonyl group already coordinated. This gives rise to two linkage isomers, one with N-bonded and the other with O-bonded hydroxyimino group in the case of nickel(II) (except for **1d**) and palladium(II), and a single isomer with O-bonded hydroxyimino group in copper(II) complexes. The isomers obtained from **1b** and **1i** have been separated by column chromatography. In chloroform each of the isomers of nickel(II) isomerizes to give an equilibrium mixture of two isomers, but not those of copper(II) and palladium(II).

The α-CH proton of coordinated β-diketones[1–3] and β-imino ketones[4–9] can be substituted by a variety of electrophiles. However, reports on the nitrosation of these chelates are scanty.[10–12] Nitrosation reactions of coordinated β-diketones and its nitrogen analogs assume special importance, for in these reactions the α-CH group is generally converted into hydroxyimino group. The latter being potentially ambidentate can coordinate to metal(II) through either nitrogen or oxygen giving chelate linkage isomers.

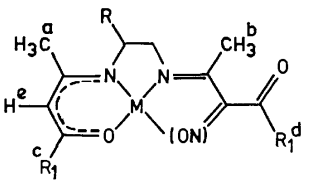
The linkage isomers of monooximato complex have been isolated by nitrosation of [*N*,*N*′-bis(1-methyl-3-oxobutylidene)ethylenediaminato]nickel(II) (**1a**) and a single isomer (hydroxyimino O-bonded) for the corresponding copper(II) complex.[13–14] The structure of the latter compound has been confirmed by X-ray diffraction studies.[15]

In continuation of our work on the linkage isomerism of the hydroxyimino group, we report here the preparation and characterization of a series of monooximato Ni(II), Cu(II), and Pd(II) complexes (**2b**—**2i**) from corresponding complexes of quadridentate β-imino ketones(**1b**—**1i**). The linkage isomers of the hydroxyimino group in Pd(II) complexes has been isolated for the first time.



1a — 1i

	M(II)	R	R_1
1a	Ni	H	CH_3
1b	Ni	CH_3	CH_3
1c	Ni	CH_3	C_6H_5
1d	Ni	H	C_6H_5
1e	Cu	CH_3	CH_3
1f	Cu	H	C_6H_5
1g	Cu	CH_3	C_6H_5
1h	Pd	H	CH_3
1i	Pd	CH_3	CH_3



2a — 2i

Schiff-base ligands of the monooximato complexes, **2a**—**2i** corresponding to **1a**—**1i** are listed below:

- **a, h**: 3-hydroxyimino-4,9-dimethyl-5,8-diaza-4,8-dodecadiene-2,11-dione
- **b, e, i**: 3-hydroxyimino-4,7,9-trimethyl-5,8-diaza-4,8-dodecadiene-2,11-dione
- **d, f**: 2-hydroxyimino-3,8-dimethyl-1,10-diphenyl-4,7-diaza-3,7-decadiene-1,10-dione
- **c, g**: 2-hydroxyimino-3,6,8-trimethyl-1,10-diphenyl-4,7-diaza-3,7-decadiene-1,10-dione.

Experimental

Materials and Physical Techniques. The quadridentate Schiff-base ligands and their complexes (**1b**—**1i**) were prepared by the reported methods.[16] Nitrogen monoxide was generated by the method of Blanchard.[17] Nickel(II) acetate tetrahydrate, copper(II) acetate monohydrate, sodium nitrite (A.R. grade) and palladium(II) chloride (Johnson Mathey, Ltd.) were used. Alumina (neutral, Brockmann activity,1) was obtained from National Chemical Laboratory, Poona, India. Silica gel (60—120 mesh, BDH) was used for chromatographic separation. All the organic solvents used were of A.R. grade.

The conductivity, magnetic susceptibility, and spectral measurements of the complexes were carried out according to the reported procedure.[18] The molecular weights of the nickel(II) complexes which are soluble in benzene were determined by cryoscopic method, while those of Pd(II) complexes were determined by mass spectrometry using an Atlas Mat Breman Massen CH4 spectrometer. ESR spectra of the Cu(II) complexes in chloroform were recorded at 28 °C on a spectrometer, constructed at TIFR, Bombay, operating at 9.52 GHz klystron frequency. Proton probe was used to measure the magnetic field.

Palladium and nickel in their complexes were estimated as their dimethylglyoximates, and copper(II) by iodometry.[19] C, H, and N were analyzed by microanalytical methods.

Preparation of Complexes. All the complexes (Table 1) were prepared by two methods. In both methods, limited quantities of nitrosating reagents were used to avoid the formation of dioximato complexes, indicated by their precipitation due to low solubility as compared to that of monooximato complexes. Qualitatively, the rate of nitrosation of the complexes was found to be in the order Ni>Cu>Pd.

Method I. A solution of a Schiff-base complex (**1b**—

Abbreviations: dec=decomposes; Dia.=diamagnetic.
Calculated analytical values are in the parentheses.

1i) in 100 ml chloroform was degassed at 0 °C by bubbling nitrogen. Gaseous nitrogen monoxide, dried over sodium hydroxide pellets was then passed through the above solution for 30—50 min at a rate of 10 bubbles per minute. The resulting solution was concentrated *in vacuo* to obtain a crystalline product. The crystals were separated by filtration, washed with ether or benzene to remove the unreacted compound. The complexes were recrystallized from benzene, methanol, or chloroform. Yields, 80—90%.

Method II. A solution containing copper(II) acetate, or nickel(II) acetate or palladium(II) chloride (0.01 mol) and sodium nitrite (0.5 mol) in 150 ml water was treated with an appropriate Schiff-base ligand (10 mmol). The reaction mixture was stirred at ambient temperature for about 1 h in the case of Ni(II) and Cu(II) complexes, and 2—3 days in the case of Pd(II) complexes. The crystals of the complexes (80—95%) deposited were filtered, washed with water and recrystallized as before. The rate of nitrosation was found to be catalyzed in the presence of a few drops of glacial acetic acid.

Preliminary TLC experiments showed the presence of two components for Ni(II) and Pd(II) complexes of **1b**, **1c**, **1h**, and **1i** indicating the presence of two isomers, and a single component in the Ni(II) complex of **1d** and all the Cu(II) complexes.

*Separation of the Isomers of the Reaction Product of **1i**.* A concentrated solution of the nitrosation product of **1i** (250 mg) dissolved in a chloroform–methanol mixture (9 : 1 v/v) was poured into a silica gel column. Elution with the same solvent mixture gave a rapidly moving yellow band followed by a slowly moving orange yellow band. Collection of yellow and orange-yellow eluates and removal of the solvent at room temperature yielded yellow (isomer A) and orange-yellow (isomer B) crystals, respectively. The crystals were recrystallized from cold benzene.

The isomers obtained from **1b** were separated by the same procedure using an alumina column instead of silica gel column. Isomer A was more rapidly eluted than the isomer B. Attempts to separate the isomers derived from **1c** and **1h** were not successful. However, isomer A of oximato nickel complex from **1c** was obtained in pure form by fractional crystallization from ethanol.

Results and Discussion

Colors, melting points, and analytical data of the complexes are given in Table 1. The elemental analyses of the complexes indicate that they are monooximato complexes (**2b**—**2i**). The molar conductances ($\Lambda_M < 1\ \Omega^{-1}\ cm^2\ mol^{-1}$) in acetone show that they are non-electrolytes. The complexes with $R_1=CH_3$ are more soluble in common organic solvents as compared to those with $R_1=C_6H_5$. Molecular weights of the isomers of nickel complex **2b** in benzene [calcd for $NiC_{13}H_{19}O_3N_3$ 328; found 324] indicate their monomeric nature. The mass spectra of the isomer A or B of palladium complex **2i** and the mixture of isomers of **2h** show ion peaks at m/e=371 and 357 corresponding to the parent molecular ions $C_{13}H_{19}N_3O_3Pd^+$ and $C_{12}H_{17}O_3N_3Pd^+$, respectively. Insufficient solubility of the remaining complexes in benzene preclude their molecular weight determination by cryoscopic method. Ni(II) and Pd(II) complexes are diamagnetic suggesting square-planar geometry around the metal(II), while Cu(II) complexes are paramagnetic with $\mu_{eff} \approx 1.90$ B.M., a value expected for monomeric Cu(II) complexes without any magnetic coupling.

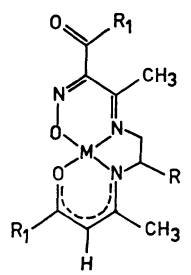
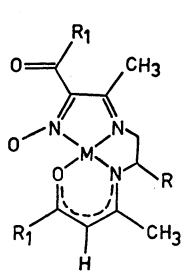
a) Abbreviations: s=strong; w=weak.

The electronic absorption spectra of isomers of the Ni(II) complexes in chloroform display a shoulder around 23300 cm^{-1}, assignable to the d-d transition of the square-planar Ni(II) complexes. Similarly Cu(II) complexes exhibit a broad absorption band in the 18000—25000 cm^{-1} region (ε=400—500 l mol^{-1} cm^{-1}). The isomers of Pd(II) complexes, on the other hand, show an intense band at 25000 cm^{-1}. Since the intensity of this band (ε=4000—6000 l mol^{-1} cm^{-1}) is rather high, it appears to be a charge-transfer transition, which has obsured the possible d-d transition of the planar Pd(II) complexes.

Structure of Nickel(II) and Palladium(II) Complexes. Since the hydroxyimino group can coordinate to a metal ion ambidentatively, two structures, **2A** and **2B**, are expected for the monooximato complexes. The relevant IR frequencies along with their assignments are given in Table 2. The IR spectra of all the complexes show an intense band in the region 1645—1690 and 1520 cm^{-1}, assignable to the non-coordinated and coordinated CO vibrations, respectively. They further show the characteristic bands around 760(s) and 1185(vw) cm^{-1} attributable to the out-of-plane and in-plane vibrations of α-CH, respectively.



2A



2B

The position of the non-coordinated ν_{CO}, sensitive to the bonding site of the hydroxyimino group, has been used as a probe for differentiating the structures **2A** and **2B**.[13-14] For example, ν_{CO} of N- and O-bonded isomers of nickel complex **2a** occurs at 1644 and 1684 cm^{-1}, respectively. The IR spectra of isomers A of **2b**, **2h**, and **2i** are very close to that of the hydroxyimino O-bonded isomer of Ni(II) complex **2a** and corresponding Cu(II) complex. Based on these results, the structure of type **2A** has been assigned to the isomers A. Similar structures have been suggested for nickel complex **2d** and isomer A of **2c**. The IR spectra of these complexes display the non-coordinated ν_{CO} around 1658 cm^{-1}. Furthermore, the occurrence of an intense band in the 1125—1180 cm^{-1} region, which is characteristic of coupled O-bonded ν_{CO} vibration[13] also supports the hydroxyimino O-coordination for the isomers A.

The IR spectra of isomers B of **2b**, **2c**, **2h**, and **2i** display the non-bonded ν_{CO} in the range expected for the hydroxyimino N-bonded moiety.[13-14] The structure of type **2B** has thus been proposed for the isomer B. However, it has not been possible to identify the N-bonded ν_{CO}. It is evident that isomers A and B differ only in bonding site of the hydroxyimino group. The dual modes of bonding of donor atoms of the hydroxyimino group are displayed in two different molecules. The isomerism of this type has been referred to as "intermolecular chelate linkage isomerism."

The available spectroscopic data of the isomers of the complexes led us to draw a significant conclusion about the non-bonded ν_{CO} vibrational frequency. For a given isomeric pair, the ν_{CO} of isomer A appears at a higher frequency (by $\approx$25—30 cm^{-1}) than that of isomer B. However, the dependence of ν_{CO} on the mode of attachment of hydroxyimino group is not yet clear. It is plausible that the resonance form **3A** contributes more to the structure of isomer

TABLE 3. PMR SIGNALS[a] (δ, in ppm) OF THE MONOOXIMATO COMPLEXES ALONG WITH THEIR ASSIGNMENTS

Metal	Complex	a	b	c	d	e	Diamine skeleton protons		
							CH_3	CH_2	CH

	Isomer B	2.03(s, 3)	2.32(s, 3)	1.97(s, 3)	2.54(s, 3)	4.90(s, 1)		3.42(m, 4)	
Pd	**2i**								
	Isomer A	2.05(s, 3)	2.23(s, 3)	1.96(s, 3)	2.40(s, 3)	4.86(s, 1)	1.31(d, 3) (J=6.0 Hz)	3.40(m, 2)	4.10(m, 1)
	Isomer B	2.05(s, 3)	2.35(s, 3)	2.00(s, 3)	2.43(s, 3)	4.92(s, 1)	1.40(d, 3) (J=6.0 Hz)	3.38(m, 2)	4.02(m, 1)

a) Key: s=singlet; d=doublet; m=complex multiplet.
Complexity and relative peak intensities of the signals are in parentheses.

A than of isomer B.

$$R_1\text{-}\underset{\underset{O}{\|}}{C}\text{-}C{=}N\text{-}O^- \longleftrightarrow R_1\text{-}\underset{\underset{O^-}{|}}{C}{=}C\text{-}N{=}O$$

3A **3B**

As expected the PMR spectra of **2b**, **2h**, and **2i** show four distinct methyl signals of the chelate ring, the assignments of which are given in Table 3. It can be seen that the proton signals of isomer A except $COCH_3$ protons and α-CH proton of isomer A are more shielded than those of isomer B. Similar spectral features are found in the isomers of nickel complex **2c**.

Chelate Linkage Isomerization. In the solid state, isomer A of **2b** is hydroxyimino O-bonded, while isomer B is hydroxyimino N-bonded. In chloroform at 40 °C, each of these isomerizes giving an equilibrium mixture of A and B isomers. The transformation is irreversible. This is due to the fact that

$$\text{Nickel complex } \mathbf{2b} \text{ isomer A or B} \xrightarrow[40\,^\circ C]{CDCl_3} \text{isomers(A+B)} \quad (1)$$

the IR as well as PMR spectra of the complexes obtained by refluxing each isomer in chloroform at 40 °C, corresponded to those containing mixture of the isomers A and B. Similarly isomer A of **2c** also isomerizes in $CDCl_3$. Its room temperature PMR spactrum displays two methyl signals and a complex multiplet due to phenyl protons with intensity ratio of 3 : 3 : 10, respectively. However, the spectrum of

$$\text{Nickel complex } \mathbf{2c} \text{ isomer A} \xrightarrow[50\,^\circ C]{CDCl_3} \text{isomers(A+B)} \quad (2)$$

isomer A, which was previously refluxed at 50 °C in $CHCl_3$, showed a pattern corresponding to the mixture of isomers A and B. In Eqs. 1 and 2, the isomers are produced by the reorganization in the donor sites of the hydroxyimino group of the same ligand. This phenomenon may be referred to as "chelate linkage isomerization," the occurrence of which is rare in organic chelating ligands. It is, however, common in the case of inorganic ligands, particularly the complexes of chalcogenocyanates.[20] The isomerization is not favoured in **2d** (hydroxyimino O-bonded), Pd(II) and Cu(II) complexes under similar conditions. Probably, the high activation energies associated with these complexes appear to be responsible for their failure to isomerize.

Structure of the Copper(II) Complexes. In contrast to Ni(II) and Pd(II) complexes, a single isomer is obtained by nitrosation of the Cu(II) Schiff-base complexes. The ν_{CO} (non-bonded) and ν_{NO} in the Cu(II) complexes appear in the region 1650—1680 cm^{-1} and at 1160 cm^{-1}, respectively. The positions of these bands are compatible with those of the corresponding isomer A of the Ni(II) complexes. Hence, the bonding of the hydroxyimino group in all the Cu(II) complexes is suggested to be through oxygen.

The first derivative ESR spectra of the Cu(II) complexes consist of four main groups of equally spaced lines, which result from the coupling of ^{63}Cu (I=3/2) with the unpaired electron. The hyperfine structure of the first two high field signals consists of five peaks of intensity ratio 1 : 2 : 3 : 2 : 1. These peaks result from the splitting by two nitrogens (I=1) of the diamine skeleton. Thus, the hyperfiine structure of the main peaks suggests that the coordination sphere around Cu(II) is N_2O_2. This conclusion is in line

with that derived from IR data. The average values of ESR parameters are 2.07(g), 90.0 G (A_{Cu}), 12.5 G (A_N) and 7.6 (covalency factor α^2). These values are compatible with the square-planar Cu(II) complexes with N_2O_2 ligational environment.[21-24]

In conclusion, nitrosation of **1b—1i** gives monooximato complexes under the experimental conditions employed, unlike the conventional substitution reactions. Further, the hydroxyimino group introduced at the ring CH carbon dislodges the coordinated carbonyl group and coordinates to metal ion either through nitrogen or oxygen, giving rise to chelate linkage isomers. The preferential mode of coordination of the hydroxyimino group essentially depends upon the metal ion.

Chemical Equilibria of Methyl-, Ethyl-, and Propylmercury(II) Chlorides and Their Complexes with L-Cysteine in Liquid-Liquid Distribution Systems

Masaru NIITSU,* Teruo MANRI, and Nobuhiko IRITANI

Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama, 350-02

(Received August 11, 1977)

Synopsis. The distribution constants for methyl-, ethyl-, and propylmercury(II) chlorides (RHgCl) between aqueous 1 mol dm^{-3} (H, Na)Cl and benzene were determined to be $10^{1.04}$, $10^{1.60}$, and $10^{2.20}$ respectively. The formation constants for the complexes of these organomercury(II) chlorides with L-cysteine (R'SH), $K=[RHgSR'][H^+][Cl^-][RHgCl]^{-1}[R'SH]^{-1}$, were determined to be $10^{1.71}$ $10^{1.55}$, and $10^{1.49}$ respectively.

The formation of highly stable complex with L-cysteine has been employed in analytical procedures for methylmercury(II),[1,2] on the basis that organomercury(II) is highly extractable into organic solvents as halides but the extractability disappears in an exchange of the halide ion with L-cysteine.[3,4]

In the present study, the distribution equilibria of methyl-, ethyl-, and propylmercury(II) chlorides and the exchange equilibria of the chloride ion in these compounds with L-cysteine in the aqueous phase were studied in systems containing two liquid-phases, aqueous 1 mol dm^{-3} (H, Na)Cl and benzene.

Experimental

The methyl-, ethyl-, and propylmercury(II) chlorides were obtained from Mitsuwa Chemical Co. and Soekawa Rikagaku Co., and the L-cysteine from Wako-Pure Chemical Co. The other reagents were of an analytical grade.

All the procedures were carried out at 25 °C. Benzene containing a certain amount of an organomercury(II) chloride was washed with 0.1 mol dm^{-3} hydrochloric acid and used. A portion of the benzene solution and the same volume of an aqueous 1 mol dm^{-3} (H, Na)Cl solution containing none or 1×10^{-3} mol dm^{-3} of L-cysteine were placed in a stoppered glass tube, agitated vigorously for 2 min and centrifuged. The organomercury(II) in the aqueous phase was extracted into carbon tetrachloride containing diphenyl thiocarbazone and the absorption of the organic phase at 620 nm was measured.[5]

Results and Discussion

For the analysis of the distribution data, the following equations were employed:

$$D = [RHgCl]_{org}([RHgCl]+[RHgSR'])^{-1} \quad (1)$$

$$RHgCl \rightleftharpoons RHgCl(org)$$

$$K_d = [RHgCl]_{org}[RHgCl]^{-1} \quad (2)$$

$$RHgCl + R'SH \rightleftharpoons RHgSR' + H^+ + Cl^-$$

$$K = [RHgSR'][H^+][Cl^-][RHgCl]^{-1}[R'SH]^{-1} \quad (3)$$

where R denotes an alkyl group, and R'SH denotes L-cysteine. The subscript "org" and the lack of subscript denote the chemical species in the organic and aqueous phases respectively. The formation constant K was calculated by introducing Eqs. 1 and 2 into the following equations:

$$[RHgSR'] = [RHg(II)]_{total} - [RHgCl] \quad (4)$$

$$[R'SH] = [R'SH]_{total} - [RHgSR'] \quad (5)$$

In the preliminary experiments, it was found that the distribution ratios of these organomercury(II) chlorides were independent of both the hydrogen-ion concentration in the aqueous phase and their own concentration in the organic phase in ranges of 3×10^{-3} to 1 mol dm^{-3} and 3×10^{-4} to 2×10^{-2} mol dm^{-3} respectively. The effect of the chloride ion on the distribution of methyl-, ethyl-, and propylmercury(II) chlorides was also measured when the aqueous phase was 1 mol dm^{-3} (H, Na)(Cl, ClO_4) containing 0.1 mol dm^{-3} of hydrogen-ion and the initial concentration of methyl-, ethyl-, and propylmercury(II) chlorides was 5.0×10^{-4}, 1.1×10^{-3}, and 5.7×10^{-3} mol dm^{-3} respectively. It was found that the distribution ratio was independent of the chloride ion concentration in the range 10^{-3} to 1 mol dm^{-3}. The distribution constants, K_d, between 1 mol dm^{-3} (H, Na)Cl and benzene were thus determined to be $10^{1.04}$, $10^{1.60}$, and $10^{2.20}$ respectively for methyl-, ethyl-, and propylmercury(II) chlorides.

The distribution ratio of these organomercury(II) as a function of the hydrogen-ion concentration was

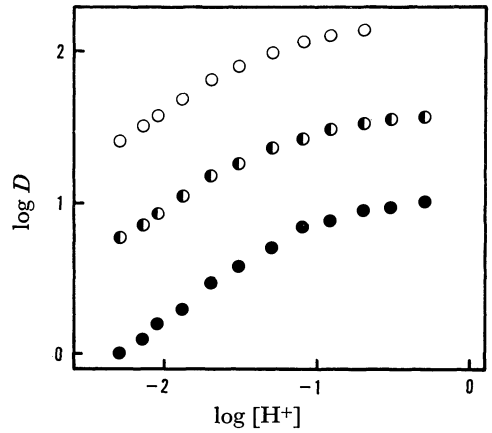

Fig. 1. Distribution ratio of methyl- (●), ethyl- (◐), and propyl (○) mercury(II) between benzene and 1 mol dm^{-3} (H, Na)Cl containing 10^{-3} mol dm^{-3} L-cysteine as a function of the hydrogen-ion concentration in the aqueous phase.

Table 1. The formation constants for the complexes of methyl-, ethyl-, and propylmercury(II) chlorides with L-cysteine in the 1 mol dm^{-3} (H,Na)Cl in Eq. 3

[H$^+$]	log K (CH_3Hg(II))	log K (C_2H_5Hg(II))	log K (C_3H_7Hg(II))

1.3×10^{-2}	1.75	1.53	1.49
9.0×10^{-3}	1.70	1.54	1.49
7.0×10^{-3}	1.70	1.54	1.48
5.0×10^{-3}	1.72	1.51	1.47
mol dm^{-3}	Av 1.71	Av 1.55	Av 1.49

also measured in the presence of L-cysteine and illustrated in Fig. 1.

For the analysis of the data, no extraction of organomercury(II) as a L-cysteine complex was assumed.[1-4] The values of K calculated on this assumption in Table 1 were reasonably constant.

From these results, it can be concluded that K_d of these organomercury(II) chlorides increases by a factor of four by the addition of one $-CH_2-$ into the alkyl chain. This is an observation similar to that found among a series of organic compounds.[6] Simpson reported[4] a value of K_d of methylmercury(II) chloride between water and toluene to be $10^{1.04}$, and Budevsky, *et al.*[7] reported the value between 1 mol dm^{-3} (Na, H)ClO_4 and *o*-xylene to be $10^{1.07}$; they are similar to the present value.

The value of K is somewhat greater in the order of propylmercury(II) < ethylmercury(II) < methylmercury(II). This order may correspond with the basicity order of these organomercury(II).

It is readily seen that the electron density of the oxygen in the carboxyl group of L-cysteine (pK_a=1.96)[8] is affected by a change in the hydrogen-ion concentration but that of the sulfur in the thiol group (pK_a=10.28)[8] should remain constant. This seems to indicate coordination of the central mercury(II) in the complexes with the sulfur in the thiol group since the formation constant, K, was not affected by changes in the hydrogen-ion concentration. This agrees with the general tendency that mercury(II) is a soft acid which interacts with sulfur stronger than oxygen.

Reactivity of Organic Ions by Chemical Ionization Mass Spectrometry. II. Chemical Ionization Mass Spectra of Alkylbenzenes with Methane by Using a Quadrupole Mass Spectrometer

Kozo Iseda

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received September 13, 1977)

Synopsis. The titled spectra have been determined at 75 °C. The $(M+H)^+$ ion intensities for methylbenzenes decrease linearly with the number of methyl substituents. The $(M+H)^+$ ion intensities for dialkylbenzenes decrease in the order *o*->*m*->*p*-, while those of trimethylbenzenes decrease in the order 1,2,3->1,3,5->1,2,4-, and those of tetramethylbenzenes decrease in the order 1,2,3,4->1,2,3,5->1,2,4,5-.

In the previous paper the author reported chemical ionization mass spectra (CIMS) of alkylbenzenes with isobutane as reactant gas.[1] The result has been interpreted as showing that the order of the $(M+H)^+$ ion intensities of alkylbenzenes is dependent on the basicities of these compounds.

Since the $C_2H_5^+$ ion from methane is a stronger Brønsted acid than the t-$C_4H_9^+$ ion from isobutane,[2] in the case of methane some different results can be expected. No study has been reported on the CIMS of alkylbenzenes with three isomers with methane except that on diethylbenzenes by Munson and Field.[3] Methylbenzenes are suited for the study of the relationship between the number of methyl groups and the ion intensity of the formed ions, because of their small dealkylation.

The purpose of this paper is to explore the difference of reactivity due to the difference of properties between the two reactant gases.

Experimental

The mass spectra were measured with a Finnigan Model 3000 GC mass spectrometer which has been modified to operate under chemical ionization conditions.[1] The experimental conditions are the same as those used previously, which were as follows: ion source pressure, 1 mmHg; ion source temperature, 75 °C; electron energy, 90 eV. Low boiling samples were admitted to the ion source with a Nupro bellows metering valve SS-4BMG. High boiling and solid samples were admitted with the solid probe equipped with a heater. All values used in this work are the average of more than three measurements.

Methane (99.7%) obtained from Tokyo Methane Co., Ltd. was employed without further purification as the reagent gas. The following alkylbenzenes (Tokyo Kasei Kogyo Co., Ltd., extra pure or more) were studied: benzene (B), toluene(T), xylenes(X), ethyltoluenes(ET), diethylbenzenes(DEB), diisopropylbenzenes(DIPB), trimethylbenzenes(TrMB), tetramethylbenzenes(TeMB), pentamethylbenzene(PMB), and hexamethylbenzene(HMB).

$(M-1)^+$	79.9±0.3	$(M+1)^+$	42.1±0.3
$(M+29)^+$	5.5±0.1	$(M+29)^+$	3.1±0.0
$(M+41)^+$	1.6±0.0	$(M+41)^+$	0.6±0.1

a) Average of four replicates±average deviation.

Results and Discussion

Table 1 shows the reproducibility of the intensities for benzene and hexamethylbenzene. Such a good reproducibility is adequate for the purpose of this study. The spectra of 21 alkylbenzenes with methane are given in Table 2. The intensities of $(M+H)^+$ ions tend to decrease from benzene to *p*-diisopropylbenzene as the number of alkyl carbon atoms in the aromatic molecule increases. For methyl-substituted compounds there is a decrease in intensity of $(M+H)^+$ ions with increasing the number of methyl substituents on the benzene ring, that is, the protonated hydrocarbons decrease with increasing electron density on the benzene ring. These results are not consistent with those of usual chemical reactions and of reactions with isobutane. The $(M+H)^+$ intensities of dialkylbenzenes decrease in the order *o*->*m*->*p*-, while those of trimethylbenzenes decrease in the order 1,2,3->1,3,5->1,2,4,-, and those of tetramethylbenzenes decrease in the order 1,2,3,4->1,2,3,5->1,2,4,5-. These orders also are not the same as those obtained with isobutane.

As shown in Table 2, the $(M-H)^+$ ion intensities tend to increase from toluene to *p*-diethylbenzene with increasing the carbon number of the side chain. The $(M-H)^+$ intensities for methylbenzenes also increase with the methyl substituents on the benzene ring. The intensities of $(M-H)^+$ ions increase in the order *o*-<*m*-<*p*- in the disubstituted compounds, 1,2,3-<1,3,5-<1,2,4- in the trimethylbenzenes, and 1,2,3,4-<1,2,3,5-<1,2,4,5- in the tetramethylbenzenes. The order of the $(M-H)^+$ ion intensities for all the isomers is obviously opposite to that of the $(M+H)^+$ ion intensities.

As can be seen from Table 2, the intensities of $(M+29)^+$ ions for toluene, xylenes, ethyltoluenes, diethylbenzenes, and trimethylbenzenes are higher than that of benzene. This seems to be a result of the hyperconjugation effect due to the alkyl groups. On the contrary, the intensities of the $(M+29)^+$ ions for the compounds which have four or more methyl substituents are lower than that of benzene, and decrease

with the methyl substituents. This decrease results from the steric hindrance due to the methyl substituents. There is also a nearly similar tendency for the $(M+41)^+$ ions. Both $(M+29)^+$ and $(M+41)^+$ ions formed in all compounds in contrast with the $(M+57)^+$ ion observed in the case of isobutane; this can be explained on the basis of the differences of ionic volume.

The relationship between the $(M+H)^+$ ion intensities and the number of methyl substituents is different from the results with isobutane; this can be ascribed to the difference of Brøsted acid strength between the ion from methane and the ion from isobutane. The ion from methane is $C_2H_5^+$, which is a stronger Brønsted acid than t-$C_4H_9^+$ from isobutane,[2] so the $C_2H_5^+$ ion is both a stronger proton addition and hydride abstraction reactant than t-$C_4H_9^+$.[2] Actually the $(M+H)^+$ ion intensity of benzene is higher than that with the isobutane,[1] and the $(M-H)^+$ ion intensities of tetramethylbenzenes are higher than those with the isobutane.[1] The attack by a strong acid, such as $C_2H_5^+$ ions, is not appreciably affected by the basicity of aromatics in contrast with the attack by the weaker acid of t-$C_4H_9^+$ ions. Therefore, in this case, the basicity for the aromatics is not necessary for the proton addition. Since the $C_2H_5^+$ ion can abstract hydride in proportion to the number of methyl substituents, as described above, because of its strong acidity, the formation of $(M+H)^+$ ion is affected rather by the formation of the $(M-H)^+$ ion than the basicity of aromatics. That is to say, in the proton addition reaction, a strong Brønsted acid, such as the $C_2H_5^+$ ion, counteracts any effect resulting from the electron density on the benzene ring. Accordingly, in the case of a methane reactant, the order of the proton addition reactions is not consistent with the order of the basicities for alkylbenzenes.

In spite of the higher basicity of *m*-xylene compared with *o*-xylene,[4] the $(M+H)^+$ intensity for *m*-xylene is lower than that for *o*-xylene, which is opposite to the result with isobutane.[1] This discrepancy also may be explained in the same way as ascribed above: that is, in the case of a methane reactant, the formation of $(M+H)^+$ is affected rather by the formation of $(M-H)^+$ ion than by the basicity of aromatics. However, in this case, while each xylene has the same methyl number, the reason why the hydride is easily abstracted from *m*-xylene is not known at present. Thus, it can be considered that the stability of the ions can not be determined only from the order of formation for the ions, for that order depends on the kind of reactant gas. The alkylbenzene isomers can be identified by the exchange of reactant gas.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (7), 2169—2170 (1978)

The Preparation of Phosphonic Acids Having Labile Functional Groups

Tsuyoshi MORITA,* Yoshiki OKAMOTO, and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received September 19, 1977)

Synopsis. Phosphonic acids having labile functional groups have been prepared quantitatively by the hydrolysis of bis(trimethylsilyl) phosphonates, were prepared by the reaction under mild conditions of the corresponding dialkyl phosphonates with bromotrimethylsilane.

The biological activity of phosphonic acids has become of interest in recent years.[1] Phosphonic acids may be capable of inhibiting or perturbing the regular metabolism.[2] The phosphonic acid esters need re-examination as the corresponding acids which may be more readily assimilated by organisms. A convenient method for the preparation of phosphonic acids from dialkyl phosphonates (**1**) has been recently reported, which includes the reaction of **1** with chloro- or bromotrimethylsilane (**2**) and the subsequent hydrolysis under mild conditions of the resulting bis(trimethylsilyl) phosphonates (**3**).[3,4] Dialkyl phosphonates react more readily with **2** to give **3** than with chlorotrimethylsilane. The limitation for silylation of **1** with **2** has not yet been reported. The conditions for silylation were investigated by the reaction of **1** having different labile functional groups with **2**, a modification of the procedures of Mckenna[3] and Rabinowitz.[4]

The silylation of **1** with double the molar quantity of **2** was carried out at room temperature for 1 h to give **3** in good yields. The reaction, which was monitored by the NMR of the reaction mixture, was completed within 1 h. The results are summarized in Table 1.

$$\underset{(1)}{RP(O)(OR')_2} + 2\underset{(2)}{Me_3SiBr} \longrightarrow \underset{(3)}{RP(O)(OSiMe_3)_2} + 2R'Br$$

1a R=$(MeO)_2CH$, R'=Me
1b R=MeCO, R'=Et
1c R=Me_2NCO, R'=Et
1d R=$MeOCOCH_2$, R'=Et
1e R=$PhOCOCH_2$, R'=Et
1f R=MeOCO, R'=Et
1g R=$NCCH_2$, R'=Et
1h R=H_2NCOCH_2, R'=Et
1i R=EtOCH=CH, R'=Me

For the silylation of **1h**, different conditions were required, namely, a slight excess of **2** (2.3 times). In the reaction of diethyl 2,3-epoxypropylphosphonate with an equimolar amount of **2**, diethyl 2-bromo-3-trimethylsiloxypropylphosphonate was produced instead of bis(trimethylsilyl) 2,3-epoxypropylphosphonate. The reaction appears to proceed *via* an onium type intermediate formed by the attack of phosphinyl sp^3 oxygen on the silicon atom of **2**, which in turn decomposes to the trimethylsilylated esters of phosphonic acid and alkyl bromide.

The hydrolysis of **3** was carried out with a water–ether mixture at room temperature for a few minutes to afford the phosphonic acids (**4**), which were isolated as the anilinium or cyclohexylammonium salts in good yields. These salts were recrystallized from a mixture of methanol–acetone. The results are summarized in Tables 2 and 3.

$$\underset{(3)}{RP(O)(OSiMe_3)_2} + H_2O \longrightarrow \underset{(4)}{RP(O)(OH)_2} + Me_3SiOSiMe_3$$

a) Monoanilinium salt. b) Dianilinium salt. c) Monocyclohexylammonium salt. d) Dicyclohexylammonium salt.

Experimental

All the melting and boiling points are uncorrected. NMR spectra were obtained by a JNM-TS-100 spectrometer with TMS or DSS as an internal reference. IR spectra were obtained by a Shimadzu IR-400.

*Preparation of Dialkyl Phosphonates (**1**).* The phosphonates (**1b**—**1h**) were prepared by the Arbuzov reaction of the corresponding chlorides with triethyl phosphite. The phosphonate (**1a**) was prepared from PCl_3 and trimethyl orthoformate accroding to the method of Gross and Freiberg.[5] The phosphonate (**1i**) was prepared from ethyl vinyl ether and PCl_5 according to the method of Anisimov and Nesmeynov.[6]

*Preparation of Bromotrimethylsilane (**2**).* Bromotrimethylsilane (**2**) was prepared from hexamethyldisiloxane and PBr_3 according to the method of Gilliam *et al.*[7]

*Preparation of Bis(trimethylsilyl) Phosphonates (**3**).* Bromotrimethylsilane (**2**) (20 mmol) was added dropwise to **1** (10 mmol) with stirring at room temperature for 1 h. After the removal of the resulting methyl or ethyl bromide, **3** was obtained by distillation.

*Preparation of Phosphonic Acids (**4**).* Compound **3** (10 mmol) was dissolved in ether (50 ml) and the solution extracted with three portion of water (3×30 ml). The combined aqueous solution was neutralized by the addition of aniline or cyclohexylamine (20 mmol) and concentrated to dryness under reduced pressure to give a solid. The solid was recrystallized from a mixture of methanol-acetone (1:5 v/v) to afford the salt of **4**.

Asymmetric Synthesis of Alanine by Alkylation of Optically Active *N*-Alkyl-*N*-formylaminoacetonitriles[1)]

Kaoru HARADA,* Minoru TAMURA, and Shinnichiro SUZUKI
Department of Chemistry, The University of Tsukuba, Ibaraki 300-31

(Received November 30, 1977)

Synopsis. Optically active *N*-alkyl-*N*-formylaminoacetonitriles were prepared and the nitriles were alkylated with methyl iodide. The products were hydrolyzed and hydrogenolyzed to form optically active alanine. The optical yields of alanine ranged from 2 to 18%. The effects of the reaction temperature and of the asymmetric moieties on the optical yields were examined. The optical yields were also determined by the NMR spectra of the resulting diastereomers.

So far numerous asymmetric syntheses of α-amino acids have been reported.[2)] However, only a few papers deal with the asymmetric synthesis of α-amino acids by alkylation.[3)] An asymmetric synthesis of aspartic acid through β-lactams using optically active *N*-(alkylamino)acetonitriles[4)] has been reported.

In the present paper, sterically controlled synthesis of alanine from opitcally active *N*-alkyl-*N*-formylaminoacetonitriles(**3a—e**) by asymmetric alkylation with methyl iodide is described(Scheme 1). After hydrolysis and subsequent hydrogenolysis of the products, alanine was obtained. The *N*-(alkylamino)acetonitriles(**2a—e**) were prepared from racemic and optically active amines(**1a—e**) and chloroacetonitrile. The **2a—e** were converted in to the corresponding formylated compounds(**3a—e**). They were treated with sodium hydride and methyl iodide in DMF at various temperatures. The products were hydrolyzed with 6 M hydrochloric acid without isolation. The resulting *N*-alkyl-alanines(**4a—e**) were isolated by the use of a Dowex 50 column and were hydrogenolyzed with palladium hydroxide on charcoal to yield alanine. Yields of the synthesized alanine were in the range 2—66%, and the optical yields in the range 2—18%. When (*S*)-(−)-amines were used, (*R*)-(−)-alanine was obtained for all reaction temperatures. When α-methylbenzylamine was used, the optical yield of the resulting alanine was low. The use of 1-(1-naphthyl)-ethylamine slightly increased the optical yield of alanine. However, when α-ethylbenzylamine was used, the optical purity of alanine clearly increased. This suggests that the small(S) and the middle(M) groups among the large(L), M, and S groups of the asymmetric center might play an important role in the asymmetric synthesis.

The temperature effect on the optical yield was observed; the lower the reaction temperature, the higher the optical yield of alanine. However, the temperature effect was not so large. The results are summerized in Table 1.

In some cases, the optical yields of the asymmetric syntheses could be estimated by the NMR spectra of the resulting mixture of diastereomers.[5)] In the NMR spectrum of **4c**, the two sets of doublet signals observed are referred to (*S*-*R*) and (*S*-*S*) isomeric methyl protons (H_a, Scheme 1). The lower doublet

a) The NMR spectra measured in D_2O with a 60 MHz spectrometer using DSS as an internal standard. b) Defined as $[(S\text{-}R)-(S\text{-}S)/(S\text{-}R)+(S\text{-}S)]\times 100$, or $[(R\text{-}S)-(R\text{-}R)/(R\text{-}S)+(R\text{-}R)]\times 100$.

signal with larger area was assigned to the methyl proton (H_a) of (*S-R*) isomer, from which (*R*)-alanine was obtained by hydrolysis and hydrogenolysis. The optical yield was determined by the ratio of the doublet signals of the diastereomers. The optical yield of **4d**, was also determined in the same way. The optical yields of **4c,d** determined by the NMR spectra(Table 2) agreed with those determined by the specific rotation of 2,4-dinitrophenyl(DNP)-alanine (Table 1).

Experimental

The amino acid analyses were carried out with a Yanagimoto LC-5S instrument. The NMR spectra were obtained with Hitachi H-60 and R-24 A instruments. The specific rotations were measured with a JASCO ORD-CD 20 C spectropolarimeter using a 10 mm cell. The boiling points and melting points were uncorrected. The optically active amines used were as follows. **1b**($[\alpha]_D^{25}$ −41.3°, benzene),[6,7] **1c**($[\alpha]_D^{25}$ −21.0°, benzene),[7,8] **1d**($[\alpha]_D^{25}$ +23.3°, benzene),[7,8] **1e**($[\alpha]_D^{25}$ −90.9°, benzene).[9] *N*-alkylaminoacetonitriles (**2a—d**) were prepared as described.[4]

(S)-(−)-N-α-Ethylbenzyl-N-formylaminoacetonitrile (3c). Compound **2c**(4.77 g, 27.4 mmol) and formic acid (6.30 g, 0.137 mol) were dissolved in 100 ml of dry benzene. The solution was stirred at room temperature for 2 h and then refluxed for 3 h with use of a Dean Stark distillation tube. After the reaction was over, the benzene solution was washed with 3% sodium hydrogencarbonate. The benzene solution was dried with anhydrous sodium sulfate and the solvent was evaporated. Compound **3c** was obtained by distillation under reduced pressure, yield, 3.42 g, 61.8%, bp 142—143 °C/1 Torr, $[\alpha]_D^{25}$ −99.3° (*c* 0.826, benzene). After distillation the nitrile **3c** crystallized. This was recrystallized from ethanol; mp, 56—57 °C, Found: C, 71.37; H, 6.91; N, 13.94%. Calcd for $C_{12}H_{14}N_2O$: C, 71.26; H, 6.98; N, 13.85%. IR(KBr): 2950, 1655, and 1390 cm^{-1}; $\delta(CDCl_3)$: 1.05(3H, t, J=7.2 Hz), 2.15(2H, quintet, J=7.2 Hz), 2.94(2H, ABq, J=17.4 Hz), 4.59(1H, t, J=7.2 Hz), 7.39(5H, s), 8.45(1H, s). Other nitriles were prepared in a similar way. The physical properties were as follows: **3a**; bp 156—157 °C/2 Torr, Found: C, 69.93; H, 6.48; N, 14.95%. Calcd for $C_{11}H_{12}N_2O$: C, 70.19; H, 6.43; N, 14.88%. **3b**; bp 157—158 °C/2 Torr, $[\alpha]_D^{25}$ −63.7°(*c* 0.97, benzene). Found: C, 70.12; H, 6.45; N, 14.82%. Calcd for $C_{11}H_{12}N_2O$: C, 70.19; H, 6.43; N, 14.88%. **3d**; bp 164—165 °C/3 Torr, $[\alpha]_D^{25}$ +103.1°(*c* 0.62, benzene); Found: C, 71.28; H, 6.98; N, 13.88%. Calcd for $C_{12}H_{14}N_2O$: C, 71.26; H, 6.98; N, 13.85%. **3e**; bp 195—197 °C/1 Torr, $[\alpha]_D^{25}$ −76.1°(*c* 0.18, benzene). Found: C, 75.49; H, 5.99; N, 11.72%. Calcd for $C_{15}H_{14}N_2O$: C, 75.61; H, 5.92; N, 11.76%.

N-[(S)-α-Ethylbenzyl]-(R)-alanine (4c). The formylated nitrile **3c**(0.510 g, 2.52 mmol) and methyl iodide(0.526 g, 3.71 mmol) were dissolved in 15 ml of anhydrous DMF. The solution was cooled to −25 °C and sodium hydride(0.140 g, 2.74 mmol, 47%, suspension in mineral oil) was added with stirring. The reaction mixture was stirred for 24 h at −25 °C. After the reaction was over the solvent was evaporated at 30 °C under reduced pressure. The residue was refluxed with 20 ml of 6 M hydrochloric acid for 20 h. After evaporation of hydrochloric acid, the hydrolyzate was applied on a Dowex 50 column(H^+ form). The column was eluted with 3 M aqueous ammonia and the solution was evaporated to dryness under reduced pressure. A part of **4c** was dissolved in 3 M hydrochloric acid and the solvent was removed under reduced pressure to crystallize **4c** hydrochloride. The salt was subjected to NMR analysis $\delta(D_2O)$: 0.80(3H, t, J=7.2 Hz), 1.45(3H, d, J=7.2 Hz), 1.55(3H, d, J=7.2 Hz), 2.10(2H, quintet, J=7.2 Hz), 7.50(5H, s).

(R)-Alanine (5). Compound **4c** was dissolved in a mixture of water(10 ml) and ethanol(10 ml) and was hydrogenolyzed with palladium hydroxide on charcoal(0.5 g) for 24 h at 1 atm. After the reaction was over the catalyst was removed by filtration. A part of the solution was diluted appropriately and analyzed with an automatic amino acid analyzer to determine the yield of alanine(60%). A part of alanine was converted to 2,4-dinitrophenyl(DNP)-alanine in the usual way,[4] and the resulting DNP-alanine was purified with use of a celite column treated with a citrate-phosphate buffer(pH 4 and pH 7).[10] The DNP-alanine was further confirmed by thin layer chromatography using ether-AcOH-H_2O(100 : 1 : 1 v/v) solvent system. DNP-(*R*)-alanine, $[\alpha]_D^{25}$ −18.4°(*c* 1.25, 1 M NaOH); optical purity 13%.

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education. The authors wish to express their thanks to Dr. Takenori Kusumi for his valuable discussions and for taking some of the NMR spectra.

Photochemical Oxidation of Toluene with Nitrogen Dioxide in Gas Phase. "Effects of Oxygen"

Hiroshi ISHIKAWA, Kazuo WATANABE, and Wataru ANDO*

Department of Chemistry, The University of Tsukuba, Niiharigun, Ibaraki 300-31

(Received December 22, 1977)

Synopsis. The products and mechanism of the reaction of toluene with nitrogen dioxide have been investigated in the presence of oxygen. The volatile products observed were benzaldehyde, *o*-, *m*-, and *p*-nitrotoluene, along with 6-nitro-*o*- and 2-nitro-*p*-cresol.

Myriad descriptions of the mechanism of photochemical oxidation of aromatic hydrocarbons with nitrogen oxides have appeared over the last ten years.[1-4] These reviews have been accompanied by an even greater number of discriptions of the properties of reactive intermediates and of reaction rates. While much work has been carried out on the products and mechanism of the gas phase reaction of alkylbenzene with NO_2, mainly by Kato[5] and Akimoto *et al.*,[6] the major part of the reaction products was unfortunately a material of low volatility which could not be characterized. The present work was undertaken in the hope of obtaining additional information about the photooxidative products from the reaction of toluene with nitrogen dioxide in the presence of oxygen.

Experimental

A conventional high vacuum apparatus utilizing Teflon stopcocks was employed. A cylindrical reaction vessel made of Pyrex glass (22.5 liter), 1.5 m long and 16 cm in diameter, was connected to the storage bulbs for the reactants, to the trapping system equipped with gas-chromatographic take off bulbs, and to the high vacuum system.

Commercially available toluene was dried completely and distilled with rejection of appropriate first and last fraction until it was gas-chromatographically pure. Nitrogen dioxide dried by phosphorus pentaoxide was purified by repeated trap to tarp distillation under vacuum. The gases used were Nihon Tokushu Gas Co. extra dry grade nitrogen and oxygen, and Nihon Sanso Co. special grade air.

Known amounts of toluene and nitrogen dioxide were admitted to the reaction vessel and diluted with dry nitrogen or air to atmospheric pressure. The samples were irradiated for periods of 10 h with four Toshiba fluorescent light-bulbs, FLR40SBL-A(wavelength 300—420 nm, maximum at 360 nm, light intensity range of 4—8 $\mu W/cm^2$). The irradiated products were fractionally collected in a sample tube for gas-chromatographic analysis cooled at Dry Ice temperature. The products which were non-condensable in the Dry Ice trap were condensed in liquid nitrogen. The GLC analyses were carried out using a Hitachi 163 flame ionization detector with a 20 m long OV-101 capillary glass column. In all cases, the gas chromatographic evaluation of product yield was based on the internal standard 1-methylnaphthalene. There was an appreciable scatter in the quantitative yields of benzaldehyde and benzyl nitrate, perhaps because of some spurious loss of these highly oxidizable substances. The yields of these two compounds reported in the present work must therefore be regarded as only approximate. A maximum error of $\pm 10\%$ in the product yields was expected in all other cases.

Non-volatile products in the reaction vessel were washed out with methanol and analyzed by GLC; they were mainly 4,6-dinitro-*o*-cresol.

Results and Discussion

Photolysis of Nitrogen Dioxide in Toluene and Nitrogen or Air System. The reaction was studied extensively at 25—30 °C at the concentration of 1000 ppm of nitrogen dioxide and toluene, respectively, for irradiation times ranging from 2—10 h. The reaction products observed were benzaldehyde(1), *o*-nitrophenol(2), *o*-nitrotoluene(3), benzylnitrate(4), α-nitrotoluene(5), *m*-nitrotoluene(6), *p*-nitrotoluene(7), 6-nitro-*o*-cresol(8), 2-nitro-*p*-cresol(9), and 4,6-dinitro-*o*-cresol(10). The yields of major products are given in Table 1.

No benzyl alcohol, *o*-, *m*-, or *p*-cresol were detected under these reaction conditions. In addition, a small amount of methane and ethane was observed for non-condensable products at 196 °C. On the other hand, there was some formation of *o*- and *p*-nitrotoluene without irradiation, but the yields are less than 1 ppm.

It can be seen that there is a general agreement in the product yields under the reaction conditions.

The available evidence suggests that in the photolysis of toluene with nitrogen dioxide in nitrogen atmosphere, nitrogen dioxide is the major light absorbing species in the region of less than 398 nm, forming nitric oxide and ground state oxygen atoms. Thus it seems likely that atomic oxygen is the predominant agent involved in the initial attack on the aromatic ring to form biradical [A], followed by isomerization of phenolic compounds, which then react with nitrogen dioxide to form nitrocresol. On the other hand, the intermediate biradical [A] and [B] may react with nitrogen dioxide, followed by dehydration to give *o*-, *m*-, and *p*-nitrotoluene. A possible reaction sequence is shown in Scheme 1.

The formation of *o*-nitrophenol could be explained by the ipso-attack of oxygen atom at the position of methyl group to form phenol, which then reacts with nitrogen dioxide to give nitrophenol. By analogy with the formation of nitrocresol, the formation of 4,6-

TABLE 1. YIELDS (ppm) OF THE REACTION PRODUCTS IN THE REACTION OF TOLUENE AND NITROGEN DIOXIDE IN ATOMOSPHERE OF NITROGEN[a)]

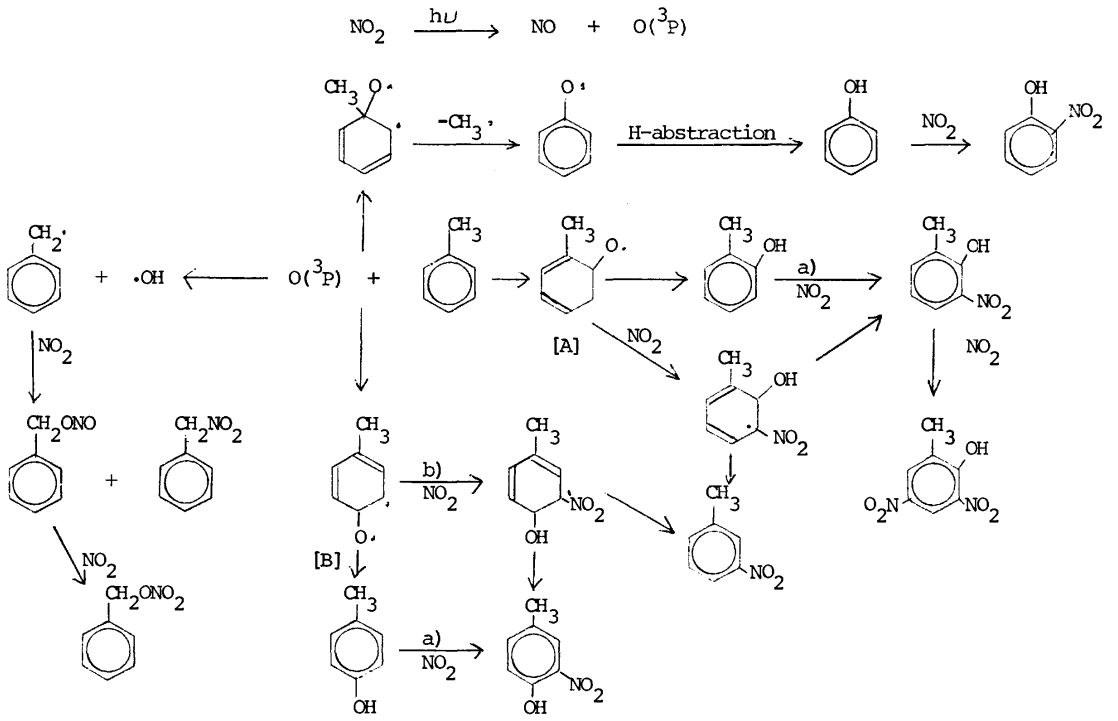
a) 10 h irradiation for 1000 ppm toluene and 1000 ppm No_2.

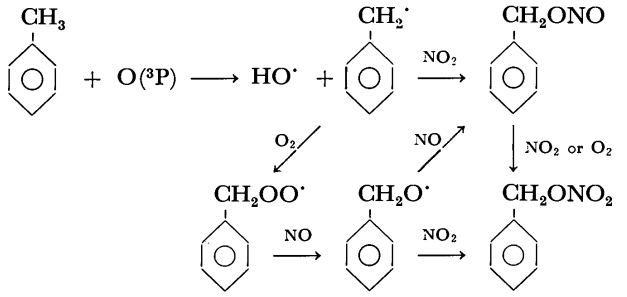


Scheme 1.

dinitro-*o*-cresol presumably proceeds by addition of nitrogen dioxide to 6-nitro-*o*-cresol to give an encounter pair, followed by intramolecular nitro group attack on the paraposition and subsequent aromatization to produce the 4,6-dinitro-*o*-cresol.

Although the activation energy of hydrogen abstraction is generally much higher than that for addition, and there is no report of the hydrogen abstraction of toluene with oxygen atom, one anticipates that in the reaction of nitrogen dioxide with toluene hydrogen abstraction may occur in view of the formation of α-nitrotoluene and benzyl nitrate. The presence of methane and ethane suggests the formation of methyl and phenyl radicals which can abstract a hydrogen atom to form methane and benzene, or recombine to form ethane.

The Role of Oxygen in the Photochemical Reaction of Toluene and Nitrogen Dioxide. In the presence of air, the products distribution for the photolysis of nitrogen dioxide and toluene was studied; the results are given in Table 2. There is a drastic increase in the yield of the products, in comparison to the oxygen free system. This is readily understandable in terms of the conversion of nitric oxide to nitrogen dioxide by oxygen. Oxygen must play an especially important role in the formation of benzyl nitrate. Benzyl nitrate may be formed from the strong interaction of the intermediate of the benzyl radical with oxygen, followed by a reaction most likely with nitric oxide or nitrogen dioxide.



From this and previous work, the reaction of the aromatic hydrocarbons with nitrogen dioxide can be satisfactory explained in terms of the general reaction mechanism of an oxygen atom with an aromatic ring. The difference in the yield of products between nitrogen and air systems arises because of the recyclization of nitric oxide to nitrogen dioxide.

Table 2. Effects of oxygen on product yields (ppm) (NO_2 1000 ppm, toluene 1000 ppm, irradiation time 10 h, temperature 25—30 °C.)

Product	1	2	3	4	5	6	7	8	9	10

Preparation and Reactions of Di-1,3,5-triazinyl Ethers. I. Preparation of Di-1,3,5-triazinyl Ethers

Ryuta SAKURAI, Yoji HASHIDA, and Kohji MATSUI*
Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received January 6, 1978)

Synopsis. Di-1,3,5-triazinyl ethers have been prepared by the condensation of 2-chloro-1,3,5-triazines with potassium 1,3,5-triazin-2-olate in acetonitrile in the presence of a small amount of cyclic polyether. Di-1,3,5-triazinyl ether was also prepared by the reaction of 2-chloro-1,3,5-triazine with potassium nitrite.

A number of derivatives of 1,3,5-triazine have been prepared by the condensation of 2-chloro-1,3,5-triazines with various nucleophiles.[1] Among the compounds investigated amines[2] and sulfides[3,4] containing two or three triazine nuclei on the same N or S atom are of particular interest because of their unique chemical behavior. This paper reports two preparative methods for di-1,3,5-triazinyl ethers.

Results and Discussion

Reaction of 2-Chloro-1,3,5-triazines with 1,3,5-Triazin-2-ol. The Williamson synthesis which involves the reaction of sodium alkoxide with an alkyl halide was considered applicable to the synthesis of di-1,3,5-triazinyl ethers. 1,3,5-Triazine nuclei are electron-withdrawing, and therefore the di-1,3,5-triazinyl ethers would be expected to have properties similar to those of acid anhydrides. Consequently a proper choice of solvent is important in the preparation of di-1,3,5-triazinyl ethers, because a solvent of high nucleophilicity will react with the di-1,3,5-triazinyl ethers formed to afford derivatives of the mono triazine nucleus.

Among the solvents investigated acetonitrile was found to be the most suitable. In acetonitrile, reaction took place very slowly when potassium 4,6-dimethoxy-1,3,5-triazin-2-olate (**1**, Scheme 1) was heated with an equimolecular amount of 2-chloro-4,6-dimethoxy-1,3,5-triazine (**3c**); after heating for 48 h, di-1,3,5-triazinyl ether (**4c**) was obtained (yield 44%; No. 4, Table 1). The addition of a small amount of 18-crown-6 accelerated the reaction; chlorotriazine (**3c**) disappeared within 30 min to give di-1,3,5-triazinyl ether (**4c**) (yield 58%; No. 5). From the mechanism[5] generally accepted, the catalytic effect of the cyclic polyether can be explained in terms of the presence of a "bared" triazinolate anion which attacks chlorotriazine much more readily.

The product (**4c**) had a parent mass peak of 296 and a PMR signal for the methyl protons was observed as a sharp singlet at δ 4.09. In addition, the IR spectrum of **4c** did not show the presence of C=O group. 1,3,5-Triazin-2-ol is known to exist as a tautomeric mixture of (**1**) and (**2**); thus, there is a possible isomer (**5**) as shown in Scheme 1. However, from the evidence the indication is that the product has the structure (**4**). The yield of di-1,3,5-triazinyl ether was found to be sensitive to the amount of cyclic polyether employed, *e.g.*, when dibenzo-18-crown-6 was used, yield of di-1,3,5-triazinyl ether (**4c**) increased to 65% (No. 6).

b: X=Cl, Y=OCH_3
c: X=Y=OCH_3
d: X=OCH_3, Y=NEt_2
e: X=Y=NEt_2

Scheme 1.

The condensation of triazinol with chlorotriazine is affected by the substituents in the triazine nucleus. In the reaction with **1**. chlorotriazines having electron-withdrawing substituents such as Cl– (**3a**, **3b**) and/or CH_3O– (**3c**) afforded the di-1,3,5-triazinyl ether (**4a**—**c**). However, chlorotriazines (**4d**, **4e**) containing electron-donating substituents such as dialkylamino groups gave only the starting materials, and no desired di-1,3,5-triazinyl ether (No. 7, 8). When chlorotriazine possessed more than one active halogen atom, ditriazinyl ethers involving more than one ether oxygen atom were obtained. For example, in the reaction of potassium 4,6-dimethoxy-1,3,5-triazin-2-olate (**1**) with cyanuric chloride (**4a**) in a molar ratio of 2:1, 2-chloro-4,6-bis(4,6-dimethoxy-2-triazinyloxy)-1,3,5-triazine was obtained (No. 1). When the reaction was carried out in a molar ratio of 3:1, all active chlorine atoms were replaced by dimethoxytriazinyloxy groups (No. 2).

Di-1,3,5-triazinyl ether was also prepared by treating chlorotriazine with potassium nitrite. In the attempt to prepare the nitrous acid ester of triazinol by treating chlorotriazine (**3c**) with potassium nitrite, instead of nitrous acid ester, di(triazinyl)ether (**4c**) was obtained. In this case, the presence of the cyclic polyether (18-crown-6) greatly accelerated the reaction (see, Experimental Section).

Although the mechanism of this reaction is not still clear, the reaction is assumed to proceed by the fol-

a) The reaction was carried out in the presence of 1/5 equimolar amount of 18-crown-6. b) The reaction was carried out in the absence of cyclic polyether. c) The reaction was carried out in the presence of 1/5 equimolar amount of dibenzo-18-crown-6.

lowing sequence (Scheme 2), analogous to the reaction of active chlororbenzene derivatives with potassium nitrite.[6] This reaction did not occur in the triazine derivatives bearing electron-donating substituents. For instance, in the reaction of 2-chloro-4,6-bis(diethylamino)-1,3,5-triazine (**3e**) with potassium nitrite in the presence of cyclic polyether, only the starting material was recovered even after long heating (120 h). This indicates that the first step in Scheme 2 did not occur.

$$\mathbf{3c} + 2KNO_2 \longrightarrow \mathbf{1} + N_2O_3 + KCl$$

$$\mathbf{1} + \mathbf{3c} \longrightarrow \mathbf{4c} + KCl$$

Scheme 2.

This method is limited to the preparation of the symmetric ditriazinyl ether, while the synthetic method by condensation of chlorotriazine with triazinol is applicable for the preparation of symmetric and unsymmetrical derivatives.

Experimental

All the melting points are uncorrected.

Preparation of Di-triazinyl Ethers by Condensation of Chlorotriazines with Triazinol. A example is shown of the reaction of 2-chloro-4,6-dimethoxy-1,3,5-triazine (**3c**) with potassium 4,6-dimethoxy-1,3,5-triazin-2-olate (**1**). A solution of **3c**(3.00 g, 17.1 mmol) in acetonitrile (50 ml) was added, drop by drop, into a solution of a mixture of **1** (3.37 g, 17.1 mmol) and 18-crown-6 (0.90 g, 3.41 mmol) in acetonitrile (50 ml) at room temperature. After stirring for 1 h under reflux, the solvent was removed *in vacuo*. The residue was chromatographed on a silica gel column with benzene–acetone (10:1, v/v) as eluent to give a crude product of di-1,3,5-triazinyl ether (**4c**). The recrystallization from benzene gave the pure material.

The reaction in the absence of cyclic polyether was carried out in a similar way as described above.

Reaction of 2-Chloro-4,6-dimethoxy-1,3,5-triazine (3c) with Pottassium Nitrite. To a solution containing potassium nitrite (2.01 g, 23.6 mmol) and 18-crown-6 (1.03 g, 3.88 mmol) in acetonitrile (50 ml) was added dropwise a solution of **3c** (2.50 g, 14.3 mmol) in acetonitrile (50 ml) and the mixture stirred for 3 h at room temperature. After removal of the solvent, the residue was chromatographed on a silica gel column with benzene–acetone (10:1, v/v) as eluent to give di-1,3,5-triazinyl ether (**4c**); yield, 1.27 g (61%).

The reaction in the absence of cyclic polyether was carried out in a similar way in refluxing acetonitrile for 48 h to afford the same product (45%) and starting triazine derivative (18%).

The Reaction of Ethylbenzene with Methylbenzene–$AlCl_3$–HCl Complex

Nobuyoshi NAMBU, Sawako HAMANAKA, and Masaya OGAWA*

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

(Received January 12, 1978)

Synopsis. Toluene, *m*-xylene, and mesitylene complexes prepared with $AlCl_3$ and HCl, were separated from the upper hydrocarbon layer and allowed to react with ethylbenzene at 2 and 30 °C. The proton exchange between methylbenzenium ions and ethylbenzene, and the transalkylation of ethylbenzene were investigated by ^{13}C NMR spectroscopy.

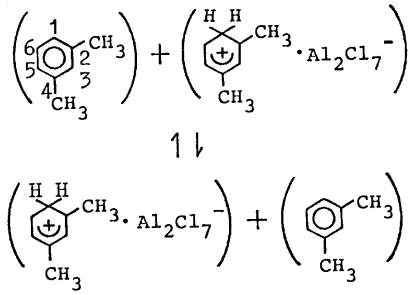
In a previous paper,[1] it was reported that methylbenzenes–$AlCl_3$–HCl complexes give fairly stable methylbenzenium ions even at room temperature due to the extraordinary stability of the methyl group for rearrangement. However, NMR spectroscopic studies[2] indicate that proton exchange between the methylbenzenium ions and their parent methylbenzenes takes place in these complex layers.

In order to clarify the behavior of the proton exchange in these complex layers, we have studied the reactions of the methylbenzenes complexes with ethylbenzene which is easily transalkylated in a strong acid.

Reaction with m-*Xylene Complex.* Equimolar ethylbenzene to *m*-xylene was added as an upper layer to a *m*-xylene complex layer prepared by the same procedure as reported.[1] The mixture was then agitated vigorously at 2 and 30 °C for 1 h. The reaction attained equilibrium. After the reaction was completed, the hydrocarbon and complex layers obtained were analyzed separately by VPC. The results are given in Table 1.

In the reaction at 2 °C no transalkylated products were obtained, no proton transfer from *m*-xylenium ion to ethylbenzene taking place in the complex layer. However, proton transfer proceeded in the reaction at 30 °C, giving di- and trisubstituted products. 5-Ethyl-*m*-xylene was obtained in a substantial amount in the complex layer. The complex layers were studied by ^{13}C NMR spectroscopy. The spectra measured at 2 and 30 °C are shown in Fig. 1.

The spectrum of the *m*-xylene complex layer (Fig. 1(a)) gave a set of fused ring signals[1] resulting from *m*-xylenium ion and *m*-xylene, indicating that fast proton exchange between *m*-xylenium ion and *m*-xylene takes place in the complex layer, as follows.[3]



The protonation of *m*-xylene probably occurs at 1- and 5-positions. The formation of 3-protonated *m*-xylene is also expected, but no evidence of the 3-protonated *m*-xylene was obtained in the spectrum.[4]

Figure 1(b) shows a spectrum of the *m*-xylene complex layer in the reaction with ethylbenzene at 2 °C. When ethylbenzene was added to the *m*-xylene complex layer, some parts of ethylbenzene were dissolved into the complex layer and some parts of unprotonated *m*-xylene were transferred to the upper hydrocarbon layer. However, no transalkylated products were obtained in the complex layer. The spectrum indicates that ethylbenzene dissolved is not protonated by proton exchanging with *m*-xylenium ion and that a set of fused ring signals of *m*-xylenium ion is found in a slightly broader range of field than that of Fig. 1(a), *viz.*, the signals of (1—1°, 5—5°) and (3—3°) are shifted to higher field, and the signals of (2—2°, 4—4°) and (6—6°) to lower field. This is because the content of unprotonated *m*-xylene in the complex layer is less than that of the initial complex layer and hence the relative intensity of ring signals of *m*-xylenium ion is enhanced in the fused signals.

On the other hand, the spectrum of the complex layer obtained at 30 °C (Fig. 1(c)) shows that the ring signals of the *m*-xylene complex have disappeared and a new set of ring signals is observed besides those of *m*-xylene and ethylbenzene.

In order to investigate the new signals, 5-ethyl-*m*-xylene was prepared with *m*-xylene and ethyl bromide by the Friedel-Crafts reaction and allowed to react with an equimolar amount of HAl_2Cl_7. The complex thus obtained consists of only 5-ethyl-*m*-xylenium ion. The NMR spectra of 5-ethyl-*m*-xylene and its complex are shown in Figs. 1(d) and (e), respectively. All the signals of 5-ethyl-*m*-xylenium ion in Fig. 1(c) show almost the same chemical shifts as those in Fig. 1(e) except for the ring methylene signal (1'') which broadens, becoming obscure (Fig. 1(c)). This indicates that no proton exchange between 5-ethyl-*m*-xylenium ion and the other alkylbenzenes occurred in the complex layer. Consequently, almost all 5-ethyl-*m*-xylene found in the complex layer was protonated, giving benzenium ion. It is of interest that no 5-ethyl-*m*-xylene was found in the upper hydrocarbon layer. On the other hand, di- and triethylbenzene were not

TABLE 1. REACTION OF ETHYLBENZENE WITH *m*-XYLENE COMPLEX LAYER (Reaction time: 1 h)

detected in the NMR spectra owing to the small contents. Probably, the former was unprotonated and the latter gave a benzenium ion[5] such as 5-ethyl-*m*-xylene. However, the content of triethylbenzene might be too small to have serious influence on the spectrum.

Reaction with Toluene Complex. The reaction products are given in Table 2. In both the reactions at 2 and 30 °C for 1 h (equilibrium conditions), transalkylated products were obtained as in the reaction with *m*-xylene at 30 °C.

In the reaction at 2 °C, trisubstituted products were obtained in a negligible amount, disubstituted products being found predominantly in the toluene complex layer. This indicates the formation of disubstituted benzenium ions. Proton exchange occurred probably between the disubstituted benzenium ions and their parent disubstituted benzenes.

However, in the reaction at 30 °C, substantial amounts of trisubstituted products were obtained in the complex layer. Almost all the benzenium ions might arise from trisubstituted benzenes as in the reaction

Table 2. Reaction of ethylbenzene with toluene complex layer (Reaction time: 1 h)

Reaction temp (°C)	Layer	Reaction products (mol%)						
		C_6H_5Me	C_6H_5Et	C_6H_6	MeC_6H_4Et	$C_6H_4Et_2$	$MeC_6H_3Et_2$(3,5-)	$C_6H_3Et_3$-(1,3,5-)
2	Hydrocarbon	38.8	35.3	16.0	7.8	2.1	—	—
	complex	37.1	27.8	15.1	15.0	3.0	2.0	trace
30	Hydrocarbon	35.6	22.2	27.4	12.2	2.6	—	—
	complex	31.3	15.3	26.8	10.0	2.3	11.5	2.8

with the *m*-xylene complex at 30 °C. All the results were confirmed by NMR spectroscopy.

Reaction with Mesitylene Complex. No transalkylation took place in both the reactions at 2 and 30 °C. Ethylbenzene was partly dissolved into the mesitylene complex layer and mesitylene was also partly transferred into the upper layer. The NMR spectrum of the complex layer shows a set of fused signals resulting from mesitylene and its ion. Proton exchange between mesitylene and mesitylenium ion then took place, but ethylbenzene remained unchanged in the complex layer. The reaction of ethylbenzene with the mesitylene complex layer was initiated at about 50 °C (for 1 h), giving a small amount of transalkylated products.

All the present reactions provide the following order in the relative stability of the methylbenzenium ions: toluenium ion<*m*-xylenium ion<mesitylenium ion. This is in line with the basicity of the parent methylbenzenes: toluene<*m*-xylene<mesitylene.[6] Thus the reactivity of the methylbenzenium ions for transalkylation shows the opposite trend.

Experimental

All alkylbenzenes used in the reaction were dried over metallic sodium and distilled prior to use. VPC analyses were performed on a Shimadzu GC-3AF chromatograph using a 3 m × 3 mm column packed with Apiezon grease L (10 wt%). All the reaction mixtures were treated with water before VPC analyses. NMR spectra were obtained on a JEOL JNM-PS-100/EC-100 spectrometer equipped with a Fourier transform unit at 25.15 MHz under complete proton decoupling. The spectra were observed at 6250 Hz (data point 8191), the pulse width 12 μs (about π/4 pulse), and repetition time 6 s. The sample was placed in a 10 mmφ tube with an internal lock standard (acetone-d_6 and TMS) in a coaxially centered capillary tube (3 mmφ). All chemical shifts are referred to TMS standard.

Electroorganic Chemistry. XXVI.[1] Electrooxidation of Enamines, Haloolefins, and Enol Ethers

Tatsuya SHONO,* Yoshihiro MATSUMURA, Hiroshi HAMAGUCHI, Tamotsu IMANISHI, and Kaoru YOSHIDA

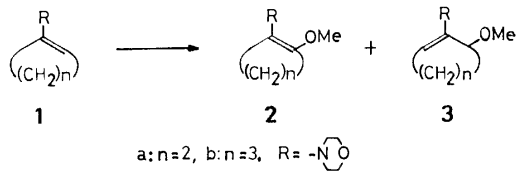
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo, Kyoto 606

(Received October, 31 1977)

Synopsis. Electrooxidation of enamines in methanol afforded two types of methoxylated enamines. Similar treatment of enol ethers gave trimethoxylated compounds. The products formed by the electrolysis of haloolefins in acetic acid were α-acetoxy haloolefins and α-acetoxy ketones.

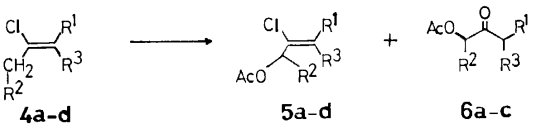
Because of mild reaction conditions and non-polluting nature, anodic oxidation is a highly promising method for the oxidation of organic compounds. The electrooxidation of some alkenes[2] or enol esters[3] has been studied from both synthetic and mechanistic points of view. The utility of electrooxidation in organic synthesis prompted us to extend it to the oxidation of such olefinic systems as enamines, haloolefins, and enol ethers.

Anodic Oxidation of Enamines. As shown in Scheme 1 the anodic oxidation of enamines **1a** and **1b** gave two types of enamine, namely, the methoxylated compounds at the vinylic **2** and allylic **3** positions of the starting enamine, though the two compounds were hardly separated from each other by distillation or gas chromatography. A mixture of the products **2b**+**3b** was identified by comparison of its NMR and IR spectra with those of the mixture of enamines **2b**+**3b** prepared independently from 2-methoxy-1-cyclohexanone[4] by the standard method.[5] Furthermore, the hydrolysis[5] of the mixture of products gave 2-methoxy-1-cyclohexanone in 80% yield. The elemental analysis of the product mixture **2a**+**3a** or **2b**+**3b** gave a satisfactory result.



Scheme 1.

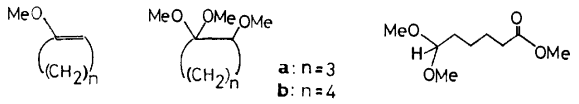
Anodic Oxidation of Haloolefins. Haloolefins **4a—d** were anodically oxidized to afford haloolefins **5** acetoxylated at the allylic position and the α-acetoxyketones **6** as shown in Scheme 2.



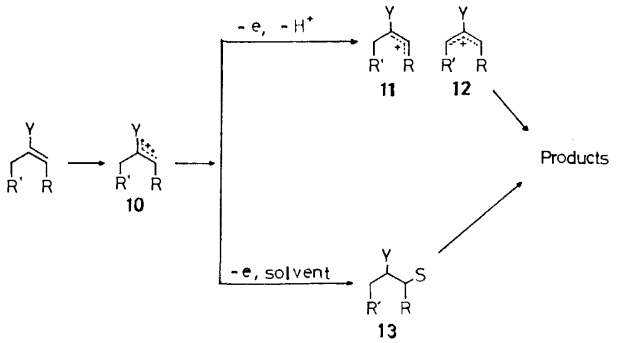
a: R^1=H, R^2, R^3=$-(CH_2)_2-$,
b: R^1=H, R^2, R^3=$-(CH_2)_3-$,
c: R^1=H, R^2=*n*-C_5H_{11}, R^3=H,
d: R^1=Cl, R^2, R^3=$-(CH_2)_3-$

Scheme 2.

Anodic Oxidation of Enol Ethers. Enol ethers **7a** and **7b** were electrooxidized to give the trimethoxylated compounds **8**. Upon hydrolysis with aqueous hydrochloric acid, compound **8b** gave 2-methoxy-1-cyclohexanone[4] in 73% yield. Furthermore, **8b** could be anodically oxidized easily to the acetal ester **9**, which can hardly be obtained by the conventional chemical methods.



Reaction Pathway. The reaction pathways might be as shown in Scheme 3 in which the initiation step is the electron-transfer to the anode from the conjugating olefinic system involving a hetero atom and a double bond. Further reactions of the first intermediate **10** can be controlled by several factors such as the nature of substituent Y and solvents, and reaction conditions. The products determining intermediates, however, would be allylic cations **11** and **12**, and a cation **13**. No product was formed from the allylic cation **11** formation, of which has been observed in the anodic oxidation of alkenes.[2] This method of oxidation of such olefinic compounds is promising for the synthesis of ketone derivatives hardly obtainable by other methods.



Scheme 3.

Experimental

Materials. Enamines, haloolefins and enol ethers were prepared from the corresponding ketones by reported methods.[5-7] The spectroscopic data of NMR and IR and the result of elemental analysis of the compounds (**2**, **3**, **5**, **6**, **8**, and **9**) are summarized in Table 1.

Electrooxidation of Enamines. Anodic oxidation of an enamine (50 mmol) in methanol (50 ml) containing sodium

methoxide (50 mmol) as a supporting electrolyte was carried out with carbon rod electrodes at room temperature. After 3 *F*/mol of electricity had been passed, methanol was removed by evaporation, and the residue was washed with three portions of ether. The combined ethereal solution was filtrated and distilled.

Electrolysis of ***1a*** (7.65 g, 50 mmol) at the anode potential of 1.65—1.75 V *vs.* SCE gave a mixture of **2a** and **3a** (6.95 g); bp 101—104 °C/mmHg.

*Enamine (**1b**) (8.35 g, 50 mmol) was electrooxidized* at the anode potential of 1.90—2.20 V *vs.* SCE to give a mixture of **2b** and **3b** (7.29 g); bp 121—124 °C/mmHg.

Electrolysis of Haloolefins. Electrolysis of a haloolefin (50 mmol) in acetic acid containing potassium acetate was carried out according to the reported method.[8] The amount of electricity passed through the cell was 5.5 *F*/mol. The product was analyzed after it had been separated by gas chromatography.

Anodic Oxidation of ***4a*** (5.125 g, 50 mmol) gave **5a** (2.81 g) and **6a** (0.945 g). **5a** and **6a**: Bp 100—120 °C/20 mmHg.

Electrolysis of Enol Ethers. A solution of an enol ether (50 mmol) in methanol (50 ml) containing sodium methoxide (50 mmol) as a supporting electrolyte was electrooxidized with carbon rod electrodes at room temperature until 3.5 *F*/mol of electricity was passed. After the usual work-up, the product was obtained by distillation.

Anodic oxidation of **7a** yielded **8a** (3.60 g). **8a**: Bp 71—73 °C/11 mmHg.

Electrolysis of ***7b*** gave **8b**: Bp 83—85 °C/13 mmHg.

1,1,2-Trimethoxycyclohexane (**8b**) (1.74 g, 10 mmol) was anodically oxidized according to the reported method[9] to give **9**, yield being 75%. **9**: Bp 121—123 °C/18 mmHg.

Electroorganic Chemistry. XXXIV. Novel Intramolecular Cyclization through Anodic Oxidation of Enol Acetates

Tatsuya SHONO,* Ikuzo NISHIGUCHI, Shigenori KASHIMURA, and Masahisa OKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo, Kyoto 606

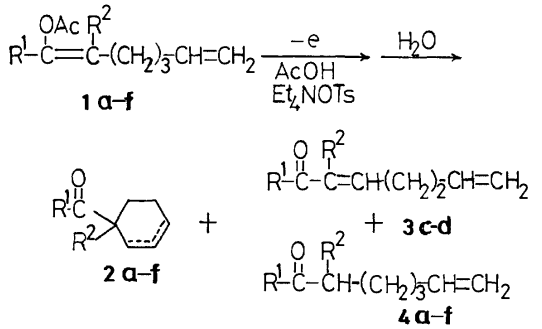
(Received January 25, 1978)

Synopsis. The anodic oxidation of 1-acetoxy-1,6-heptadiene homologues in acetic acid gave mainly intramolecular cyclization products, cyclohexenyl ketones. The cyclization takes place through the electrophilic attack of the cationic center generated from the enol ester moiety to the double bond.

It has been demonstrated by our recent studies[1,2] that the anodic oxidation of enol acetates leads to the selective formation of α,β-unsaturated enones or α-acetoxy ketones under suitably arranged conditions. Although the nature of radical cations, the first intermediates formed from the starting esters, is not necessarily clear, the product determining intermediate in the reaction may possess cationic character at the β-carbon atom of the enol acetate moiety. Thus, it seems interesting to examine the intramolecular cycloaddition between the cationic species generated by anodic oxidation of enol acetates and an olefinic bond in a reasonable position, and the formation of new carbon–carbon bond at the adjacent position to the carbonyl group.

Results and Discussions

Anodic oxidation of enol acetates **1a—f** in acetic acid containing tetraethylammonium *p*-toluenesulfonate as a supporting electrolyte was carried out in an undivided cell equipped with carbon rod electrodes under constant current conditions. After 4 *F*/mol of electricity was passed, the usual work-up and distillation afforded three types of products, namely the expected cyclized ketones **2a—f**, the conjugated enones **3c, d**, and the ketones **4a—f**[3] formed by hydrolysis of the starting enol acetates.



The results are summarized in Table 1. All the products were isolated by preparative gas chromatography, and characterized through IR, NMR, and MS analyses. Further identification of **2a—e** was accomplished by the comparison of spectroscopic and gas chromatographic behaviors of the corresponding saturated ketones **5a—e** obtained by the hydrogenation of **2a—e** with those of authentic samples.[4-8] Although the position of the double bond in the cyclohexenyl ring of **2a—f** was not definitely determined, spectroscopic and gas chromatographic analyses clearly indicated that each of **2a—f** was a single isomer.

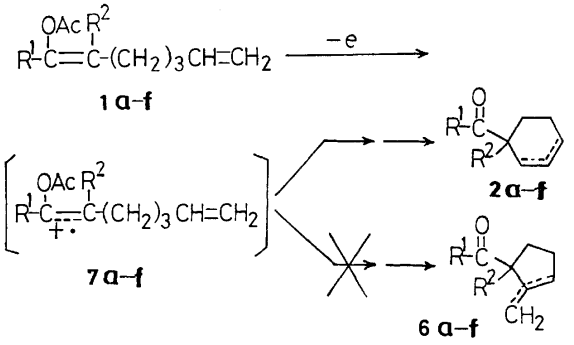
Table 1. Anodic oxidation of enol acetates **1a—f**

	Enol acetates **1** R^1	R^2	Anodic potential (V *vs.* SCE)	Product (Yield[a,b] %) **2**	**3**	**4**
a	CH_3	H	1.8—1.9	35(47)	—	25
b	CH_3	CH_3	1.8—1.9	40(47)	—	15
c	$-(CH_2)_3-$		1.8—2.0	25(28)	33(37)	10
d	$-(CH_2)_4-$		1.8—2.0	19(22)	12(14)	13
e	$-(CH_2)_5-$		1.6—1.8	18(32)	—	44
f	$-(CH_2)_6-$		2.2—2.4[c,d]	30(50)	—	40

a) Isolated. b) The number in the parentheses shows the yield calculated on the basis of the consumed **1**. Unconsumed starting esters were recovered as the ketones **4**. c) The reaction was continued until 10 *F*/mol of electricity was passed. d) Anodic oxidation of **1f** in a divided cell gave a mixture of **2f** and **4f** in 35 and 53% yields, respectively.

Extensive studies[9-11] have already been carried out on the intermolecular anodic coupling of electron-rich olefins, though the nature of the key intermediate has been not always clear. It has well been established, however, that in the intramolecular cyclization of 5-hexenyl cations or radicals, electrophilic reaction gives predominantly six-membered ring[12] products, while five-membered ring products are the main products in homolytic reaction.[13,14]

Hence, the exclusive formation of **2a—f** rather than **6a—f** from **1a—f** may indicate that the cyclization takes place through the electrophilic attack of the cationic center generated from the enol ester moiety to the double bond.[15]



This result may also suggest that the radical cations **7a—f** generated by the first electron transfer from **1a—f**, do not show any reactivity as a free radical.

Experimental

Preparation of Enol Acetates ***1a—f.*** Nonconjugated olefinic ketones, 7-octen-2-one (**4a**),[17] 3-methyl-7-octen-2-one (**4b**),[18] 2-(4-pentenyl)cyclopentanone (**4c**),[19] 2-(4-pentenyl)-cyclohexanone (**4d**),[20] 2-(4-pentenyl)cycloheptanone (**4e**), and 2-(4-pentenyl)cyclooctanone (**4f**), were prepared through β-keto ester condensation.[21,22] Enol acetates **1a—f** were prepared from the corresponding ketones **4a—f** according to the procedure similar to the method of Bedoukian[23] or House.[24] Satisfactory NMR, IR, and mass spectra were obtained for **1a—f** as shown below. **1a**, bp 90 °C/30 Torr; IR (neat), 3080, 3010, 1750, 1640, 1160, 910 cm^{-1}; NMR (CCl_4), δ 6.1—4.9 (3H, m, $-CH=CH_2$), 4.7—4.5 (1H, m, $>C=CH-$), 2.10 (3H, s, $COCH_3$), 2.4—1.3 (9H, m, $-CH_3$ and $-CH_2-$); MS, *m/e* 168 (M^+). **1b**, bp 110 °C/35 Torr; IR (neat), 3080, 1750, 1640, 1140, 910 cm^{-1}; NMR (CCl_4), δ 6.2—4.6 (3H, m, $-CH=CH_2$), 2.10 (3H, s, $COCH_3$), 1.75 (3H, s, $-CH_3$), 1.7—0.9 (6H, m, $-CH_2-$); MS, *m/e* 182 (M^+). **1c**, bp 90 °C/2 Torr; IR (neat), 3080, 1750, 1640, 1220, 910 cm^{-1}; NMR (CCl_4), δ 6.2—4.6 (3H, m, $-CH=CH_2$), 2.05 (3H, s, $COCH_3$), 2.7—1.0 (12H, m, $-CH_2-$); MS, *m/e* 194 (M^+). **1d**, bp 85—87 °C/20 Torr; IR (neat), 3080, 1750, 1630, 1220, 910 cm^{-1}; NMR (CCl_4), δ 6.2—4.7 (3H, m, $-CH=CH_2$), 2.05 (3H, s, $COCH_3$), 2.0—1.9 (14H, m, $-CH_2-$); MS, *m/e* 208 (M^+). **1e**, bp 100—102 °C/2 Torr; IR (neat), 3080, 1740, 1630, 1210, 900 cm^{-1}; NMR (CCl_4), δ 6.3—4.8 (3H, m, $-CH=CH_2$), 2.10 (3H, s, $COCH_3$), 2.6—1.1 (16H, m, $-CH_2-$); MS, *m/e* 222 (M^+). **1f**, bp 95—98 °C/0.7 Torr; IR (neat), 3080, 1750, 1640, 1220, 910 cm^{-1}; NMR (CCl_4), δ 6.2—4.8 (3H, m, $-CH=CH_2$), 2.10 (3H, s, $COCH_3$), 2.5—1.1 (18H, m, $-CH_2-$); MS, *m/e* 236 (M^+).

General Procedure for the Anodic Oxidation of Enol Acetates ***1.*** Into a 30 ml undivided electrolysis cell equipped with carbon rod electrodes and a reference electrode (SCE) was placed a solution of 0.01 mol of an enol acetate and 0.01 mol of tetraethylammonium *p*-toluenesulfonate in 10 ml of glacial acetic acid. Stirred with a magnetic bar and cooled with running water, the solution was electrochemically oxidized at the constant current of 200 mA. After 4 *F*/mol of electricity was passed, the reaction mixture was poured into 100 ml of a cold saturated potassium carbonate solution and extracted with three 50 ml portions of ether. The combined ethereal solution was dried over anhydrous magnesium sulfate and evaporated. The residue was distilled *in vacuo*. The isolated yield of the products, **2a—f**, **3c**, **d**, and **4a—f**, are summarized in Table 1. **2a**, bp 90—93 °C/30 Torr; IR (neat), 3020, 1710, 735 cm^{-1}; NMR (CCl_4), δ 5.6—5.5 (2H, m, $-CH=CH-$), 2.10 (3H, s, $-COCH_3$), 2.3—1.4 (7H, m, $-CH_2-$ and $>CH-$); MS, *m/e* 124 (M^+). **2b**, bp 80—83 °C/20 Torr; IR (neat), 3020, 1705, 740 cm^{-1}; NMR (CCl_4), δ 5.6—5.5 (2H, m, $-CH=CH-$), 2.10 (3H, s, $-COCH_3$), 2.4—1.2 (6H, m, $-CH_2-$), 1.09 (3H, s, $-CH_3$); MS, *m/e* 138 (M^+). **2c**, 60—62 °C/2.0 Torr; IR (neat), 3020, 1725, 760 cm^{-1}; NMR (CCl_4), δ 5.5—5.4 (2H, m, $-CH=CH-$), 2.5—1.3 (12H, m, $-CH_2-$); MS, *m/e* 150 (M^+). **2d**, bp 60—63 °C/0.5 Torr; IR (neat), 3020, 1700, 760 cm^{-1}; NMR (CCl_4), δ 5.6—5.5 (2H, m, $-CH=CH-$), 2.5—1.4 (14H, m, $-CH_2-$); MS, *m/e* 164 (M^+). **2e**, bp 81—83 °C/0.5 Torr; IR (neat), 3010, 1700, 770 cm^{-1}; NMR (CCl_4), δ 5.7—5.5 (2H, m, $-CH=CH-$), 2.7—1.2 (16H, m, $-CH_2-$); MS, *m/e* 178 (M^+). **2f**, bp 91—93 °C/0.5 Torr; IR (neat), 3020, 1695, 760 cm^{-1}; NMR (CCl_4), δ 5.7—5.5 (2H, m, $-CH=CH-$), 2.7—1.2 (18H, m, $-CH_2-$); MS, *m/e* 192 (M^+). **3c**, bp 120 °C/25 Torr; IR (neat), 3080, 1690, 1630, 910 cm^{-1}; NMR (CCl_4), δ 7.1—7.0 (1H, m, =CH– of enone), 6.0—4.7 (3H, m, $-CH=CH_2$), 2.6—0.9 (10H, m, $-CH_2-$); MS, *m/e* 150 (M^+). **3d**, bp 130 °C/20 Torr; IR (neat), 3080, 1670, 1640, 910 cm^{-1}; NMR (CCl_4), δ 7.2—7.1 (1H, m, =CH– of enone), 6.1—4.9 (3H, m, $-CH=CH_2$), 2.7—1.0 (12H, m, $-CH_2-$); MS, *m/e* 162 (M^+).

Hydrogenation of ***2a—f*** was carried out by a standard method. The products, saturated ketones **5a—e** showed identical spectroscopic and gas chromatographic behavior with authentic samples.[4-8] Spiro[5.7]tridecan-6-one (**5f**) was characterized by IR, NMR, MS, and elemental analyses. **5f**, bp 85—87 °C/0.5 Torr; IR (neat), 1700 cm^{-1}; NMR (CCl_4), δ 2.5—2.2 (2H, m, $-COCH_2-$), 2.1—0.9 (20H, m, $-CH_2-$); MS, *m/e* 194 (M^+). Found: C, 80.18; H, 11.42%. Calcd for $C_{13}H_{22}O$: C, 80.35; 11.41%.

A Simple Preparative Method of Alkylthiotrimethylsilanes

Isao KUWAJIMA* and Toru ABE

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 2, 1978)

Synopsis. Treatment of *sym*-disulfides with metallic sodium in the presence of trimethylchlorosilane in an appropriate solvent affords the corresponding alkylthiotrimethylsilanes in high yield.

The utility of alkylthiotrimethylsilanes has recently been recognized. They can be efficiently used for conversion of the carbonyl group into the corresponding thioacetal or (1-alkylthioalkyl)trimethylsilanes.[1,2] Several methods have been developed, including silylation of lead mercaptides,[3] silylation of thiols with trialkylsilane catalyzed by transition metal[4] or with hexamethyldisilazane catalyzed by imidazole.[5]

In this paper we wish to describe a convenient method of preparation, starting from disulfides. As a part of studies on the reductive silylation reactions with metallic sodium and trimethylchlorosilane,[6] we have examined the reaction of disulfides with this reductive system.[7] *sym*-Disulfide was added to a solution of trimethylchlorosilane in an appropriate sodium suspension. After stirring or heating for an appropriate length of time, the substance deposited was filtered off. Removal of the solvent, followed by fractional distillation, afforded the corresponding alkylthiotrimethylsilane. By this procedure, various disulfides can be converted into the thiosilane derivatives, including primary, secondary, or tertiary alkyl, and phenyl groups, in high yield and with high purity.

$$(R\text{-}S)_2 \xrightarrow{Na\text{--}Me_3SiCl} \begin{cases} \longrightarrow 2R\text{-}S\text{-}SiMe_3 \\ \longrightarrow R\text{-}S\text{-}R + (Me_3Si)_2S \end{cases}$$

For the preparation of *n*-alkylthio derivatives, choice of solvent is important. Non-polar ones such as pentane or hexane should be used for efficient conversion. When ether was employed, the corresponding dialkyl sulfide was formed in sufficient amount along with alkylthiotrimethylsilane. For *s*- or *t*-alkylthio and phenylthio derivatives, ether can be used equally well as pentane, hexane and benzene.

In the cases of dimethyl and dibenzyl disulfides, carbon–sulfur bond cleavage took place predominantly or competitively and they could not be converted into the corresponding thiosilanes, giving instead, bis(trimethylsilyl) sulfide as the major product with any solvent. The reductive silylation procedure of dimethyl disulfide affords one of the most convenient methods for the preparation of bis(trimethylsilyl) sulfide,[8,9] since it can be isolated with high purity through simple fractional distillation.

$$(R\text{-}S)_2 \xrightarrow[R=CH_3 \text{ or } C_6H_5CH_2]{Na\text{--}Me_3SiCl} 2(Me_3Si)_2S + 2R\text{-}SiMe_3$$

Experimental

Materials. Disulfides were used after purification of commercial products by distillation. Trimethylchlorosilane was purified by distillation over CaH_2. Solvents were purified shortly before use by drying and distillation over sodium or sodium-benzophenone. Sodium dispersion was prepared in xylene in the usual way and used after complete removal of xylene.

General Procedure. Disulfide (17.5 mmol) and trimethylchlorosilane (4.2 g, 38.7 mmol) in an appropriate solvent (30 ml) was added to a sodium suspension (0.97 g, 0.422 g atom) in the same solvent (60 ml) over a period of 5 min at room temperature under argon atmosphere. After being stirred at room temperature or under refluxing for an appropriate time, the dark-purple colored reaction mixture was filtered through a pad of Celite and washed with the solvent (30 ml). The solvent was removed under atmo-

Reactive Troponoids and *o*-Aminophenol. I. Synthesis of Cyclohepta[*b*][1,4]benzoxazine[1)]

Tetsuo NOZOE,* Harue OKAI, and Taichi SOMEYA†

Tokyo Reseach Laboratory of Kao Soap Co., Ltd., Bunka, Sumida-ku, Tokyo 131

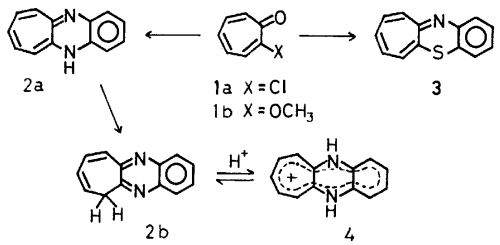
† *Central Reseach Laboratory of Takasago Perfumery Co., Ltd., Kamata, Ohta-ku, Tokyo 144*

(Received December 15, 1977)

Synopsis. Cyclohepta[*b*][1,4]benzoxazine and 2-(*o*-hydroxyanilino)tropone were obtained by the reactions of 2-chloro- and 2-methoxytropone with *o*-aminophenol. A similar reaction with *o*-methoxylaniline gave 2-(*o*-methoxyanilino)tropone and 1-(*o*-methoxyanilino)-7-(*o*-methoxyphenylimino)-1,3,5-cycloheptatriene. The chemical and physical properties of cyclohepta[*b*][1,4]benzoxazine were discussed.

Benzotropazine (**2a**)[2)] and cyclohepta[*b*][1,4]benzothiazine (**3**),[3)] which are heterocyclic compounds containing two hetero atoms, with a 6,6,7-ring system, were obtained by the reactions of 2-chloro- (**1a**) or 2-methoxytropone (**1b**) with *o*-phenylenediamine and with *o*-aminobenzenethiol, respectively.

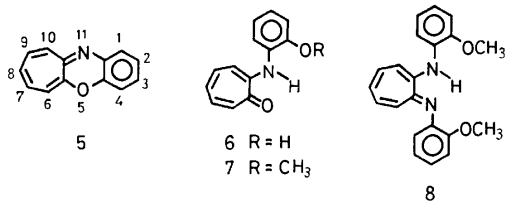
The correct structure of 6*H*-cyclohepta[*b*]quinoxaline (**2b**) was proposed for **2a** by means of NMR.[4,5)] We wish to report on the reaction of **1a**, **b** with *o*-aminophenol giving cyclohepta[*b*][1,4]benzoxazine (**5**), which is a heterocyclic compound with a 6,6,7-ring system containing an oxazine ring, and its chemical and physical properties.



Results and Discussion

Heating of **1a** with *o*-aminophenol in acetic acid under reflux yielded two condensation products **5** and **6** in 48 and 40% yields, respectively. In a similar manner, the reaction of **1b** with *o*-aminophenol also gave **5** and **6** in 16 and 70% yields, respectively. When these reactions were carried out in ethanol, the product was almost solely **6**. This indicates that **5** is formed from **6** in acidic medium. In fact, heating of **6** in acetic acid, in the presence of concd sulfuric acid, afforded **5** in a quantitative yield. Heating of **5** in ethanol with dilute alkali gave **6** quantitatively. However, longer heating with exess alkali resulted in its decomposition into tropolone and *o*-aminophenol. The results reveal that **6** is 2-(*o*-hydroxyanilino)tropone and **5** is cyclohepta[*b*][1,4]benzoxazine. The structures were also supported by elemental analyses and mass and IR spectra.

The reactions of **1a** and **1b** with *o*-methoxyaniline chiefly gave **7**, with 1—3% of **8**. Since **7** was also obtained by the methylation of **6**, **7** was identified as 2-(*o*-methoxyanilino)tropone, and **8** was identified as 1-(*o*-methoxyanilino)-7-(*o*-methoxyphenylimino)-1,3,5-cycloheptatriene by elemental analysis and spectral data. Moreover, **8** gave a copper(II) chelate as brown crystals, mp 234—236 °C, by the known method for 2-aminotropone imines.[6)] Formation of **8** suggests that, in the reaction of **1** with *o*-aminophenol in acidic conditions, the amino group of the reagent reacts not only at the carbon atom with leaving group but also at the carbonyl group of **1**.



Fukunaga reported that tetrafluoroborate (**4**) of **2b** is a resonance stabilized (aromatic) $4n\pi$ system by comparison of the NMR spectrum of **4** in acetonitrile-d_3 with the related compounds.[4)] On the other hand, measurement of the NMR spectra of **3** in trifluoroacetic acid and chloroform-*d*, shows that the seven-membered ring protons of the cation (**9**) derived from **3** shift about 1.0 ppm towards lower magnetic field, while the benzene ring protons hardly shows any shift. Thus the positive charge of the cation (**9**) is not thought to be delocalized over the benzene ring.[7)]

The NMR data of **5** measured in trifluoroacetic acid and chloroform-*d*, show shift of the seven-membered ring protons by 1.22—1.40 ppm and that of the benzene ring protons by 0.10—0.22 ppm towards lower magnetic field. This indicates that the positive charge of the cation (**10**) derived from **5** is also delocalized over both the seven-membered ring and the heterocyclic part as in the case of **9**.

Experimental

All the melting points are uncorrected. TLC and preparative TLC were carried out on Kiesel gel 60 F_{254} (Merck) and Wakogel BF 5 (Wako), respectively, developed with benzene, spots being detected with a UV lamp. IR and UV spectra were taken on Hitachi EPI-G2 and Hitachi 124 spectrometers, respectively. UV spectra of acidic or basic medium were measured by adding three drops of 1 M HCl or 1 M NaOH to the sample solution. NMR spectra were

recorded on 60 MHz Hitachi R-24A and 100 MHz Varian HA-100 spectrometers with TMS as an internal standard. Mass spectra were recorded on a Hitachi RMU-6M mass spectrometer operating at 75 eV.

2-(o-Hydroxyanilino)tropone (6). A mixture of **1a** (1.0 g, 7.1 mmol), *o*-aminophenol (1.0 g, 9.2 mmol), and acetic acid (15 ml) was refluxed for 75 min. After removal of acetic acid under reduced pressure, water (30 ml) was added to the residue and precipitate A was separated from filtrate B. Recrystallization of A from benzene gave 0.16 g (40%) of **6** as yellow needles: mp 163 °C; λ_{max}^{MeOH} nm (log ε): 205 (4.40), 231 (4.40), 342 (4.00), and 404 (4.18); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 239 (4.36) and 382 (4.03); $\lambda_{max}^{MeOH+NaOH}$ nm (log ε): 231 (4.48), 340 (3.95), and 411 (4.06); IR (KBr): 3260 (NH), 3100 (OH), and 1610 cm^{-1} (C=O); NMR ($CDCl_3$, 60 MHz); δ 9.50 (br s, 1H, OH), 8.70 (br s, 1H, NH), and 6.50—7.40 ppm (m, 9H). Found: C, 72.95; H, 5.19; N, 6.51%; M^+, 213. Calcd for $C_{13}H_{11}NO_2$: C, 73.22; H, 5.20; N, 6.57%; M, 213.

Cyclohepta[b][1,4]benzoxazine (5). Filtrate B was extracted with chloroform. After removal of the solvent, the residue was dissolved in ethanol and treated with picric acid to precipitate the picrate. The picrate was washed with ether, and decomposed with 2 M NaOH in ethanol. The solution was extracted with benzene. The extract was washed with water, dried over Na_2SO_4, and evaporated to give 0.66 g (48%) of **5** as dark brown needles. Recrystallization from hexane gave an analytical sample: mp 93 °C; λ_{max}^{MeOH} nm (log ε): 215 (4.33), 262 (4.38), 270^{sh} (4.35), and 410 (4.05); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 225 (4.34), 265^{sh} (4.35), 273 (4.38), 320 (3.87), and 435 (3.93); NMR ($CDCl_3$, 100 MHz): δ 6.73 (m, 3H, $C_{1,2,3}$–H), 6.36 (m, 1H, C_4–H), 6.03 (m, 2H, $C_{6,7}$–H), 5.92 (d d, 1H, J=11.0 and 9.0 Hz, C_9–H), 5.77 (m, 1H, C_8–H), and 5.36 ppm (d d, 1H, J=9.0 and 1.0 Hz, C_{10}–H); NMR (CF_3COOH, 100 MHz): δ 6.83 ($C_{1,2,3}$–H), 6.58(C_4–H), 7.35 ($C_{6,7}$–H), 7.17 (C_9–H), 7.00 (C_8–H), and 6.76 ppm (C_{10}–H). Found: C, 80.13; H, 4.80; N, 7.14%; M^+, 195. Calcd for $C_{13}H_9NO$: C, 79.98; H, 4.65; N, 7.11%; M, 195. Picrate: dark red needles (from EtOH), mp 203.5—204 °C (dec); Found: C, 53.88; H, 3.09; N, 13.34%. Calcd for $C_{19}H_{12}N_4O_8$ C, 53.78; H, 2.85; N, 13.21%.

Reaction of 2-Methoxytropone (1b) with o-Aminophenol. A mixture of **1b** (1.0 g, 7.3 mmol), *o*-aminophenol (1.0 g, 9.2 mmol), and acetic acid (15 ml) was refluxed for 2 h. After the same treatment as described above, 1.1 g (70%) of **6** and 0.23 g (16%) of **5** were obtained.

Reactions of 1a and 1b with o-Aminophenol in Ethanol. A mixture of **1a** or **1b** and *o*-aminophenol was refluxed in ethanol for 3 h. The reaction mixture was found to be a mixture of **6** and *o*-aminophenol by TLC.

Conversion of 6 into 5. A solution of **6** (200 mg) in 5 ml of acetic acid and one drop of concd H_2SO_4 was refluxed for 30 min. After removal of acetic acid, the residue was dissolved in benzene, washed with aq $NaHCO_3$ and water, dried and evaporated. Recrystallization of the residue from hexane gave 175 mg (95%) of **5.**

Conversion of 5 into 6. A solution of **5** (150 mg) in 8 ml of ethanol and 1 M NaOH (4 ml) was refluxed for 30 min. After removal of ethanol, the residue was dissolved in water (10 ml) and neutralized with 1 M HCl. The resulting precipitate was filtered and dried in a desicater. Recrystallization from benzene gave 155 mg (95%) of **6**. A solution of **6** in ethanol and large excess 1 M NaOH was refluxed for 2 h. The neutralized solution was found to be a mixture of tropolone and *o*-aminophenol by TLC.

2-(o-Methoxyanilino)tropone (7). A mixture of **1a** (1.5 g, 10.7 mmol), *o*-methoxyaniline (2.5 g, 20.3 mmol), and acetic acid (6 ml) was refluxed for 1.5 h. The solution was concentrated to dryness and the residue was recrystallized from benzene to yield 2.2 g (91%) of **7** as yellow prisms, mp 117 °C; λ_{max}^{MeOH} nm (log ε): 205 (4.70), 231 (4.69), 344 (4.38), and 404 (4.56); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 205 (4.70), 240 (4.71), and 382 (4.47); IR (KBr): 3270 (NH), 1610 (C=O), 2850, 1240, and 1025 cm^{-1} (OMe); NMR ($CDCl_3$, 60 MHz): δ 8.75 (br s, 1H, NH), 6.50—7.45 (m, 9H), and 3.78 ppm (s, 3H, OMe). Found: C, 73.99; H, 5.86; N, 6.11%; M^+, 227. Calcd for $C_{14}H_{13}NO_2$: C, 73.99; H, 5.77; N, 6.16%; M, 227.

1-(o-Methoxyanilino)-7-(o-methoxyphenylimino)-1,3,5-cycloheptatriene (8). From the mother liquor of the recrystallization of **7**, 35 mg (1%) of **8** was obtained by preparative TLC as orange red oil; λ_{max}^{MeOH} nm (log ε): 213 (4.89), 236 (4.89), 285 (4.54), 370 (3.60), and 415 (3.68); $\lambda_{max}^{MeOH+HCl}$ nm (log ε): 215 (4.89), 252 (4.88), and 415 (3.75); IR (neat): 3230 (NH), 2850, 1250 and 1025 cm^{-1} (OMe); NMR ($CDCl_3$, 60 MHz): δ 9.20 (br s, 1H, NH), 6.85—7.30 (m, 8H, brezene ring protons), 6.05—6.75 (m, 5H, cycloheptatriene ring protons), and 3.76 ppm (s, 6H, OMe); MS *m/e* (rel intensity): 332 (M^+, 10), 224 (36), 181 (37), 167 (46), 155 (38), 92 (58), 77 (100), 65 (70), and 51 (80). Picrate: yellow prisms, mp 193 °C (dec). Found: C, 57.48; H, 3.94; N, 12.21%. Calcd for $C_{27}H_{23}N_5O_9$: C, 57.75; H, 4.12; N, 12.47%.

Reaction of 1b with o-Methoxyaniline. A mixture of **1b** (1.5 g, 11.0 mmol), *o*-methoxyaniline (2.0 g, 16.2 mmol), and acetic acid (6 ml) was refluxed for 1.5 h. By the same procedure as described above, **7** (2.1 g, 85%) and **8** (0.1 g, 3%) were obtained.

The authors wish to express their thanks to Dr. Tadamichi Fukunaga, E. I. Du Pont de Nemours & Co. U.S.A. and Dr. Kazuko Takahashi, Tohoku University for their kind communications. Thanks are also due to Dr. Masao Sugimura and Sankyo Co., Ltd. for the measurements of mass spectra, 100 MHz NMR spectra and elemental analyses.

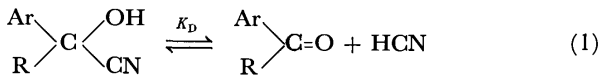
Dissociation Constants of the Cyanohydrins of Substituted Acetonaphthones

P. Ananthakrishna NADAR,* C. GNANASEKARAN, and J. CHANDRASEKARAN
Post-graduate Department of Chemistry, V.H.N.S.N. College, Virudhunagar 626002, India

(Received February 27, 1978)

Synopsis. The dissociation constants of the cyanohydrins of 4-substituted 1-acetonaphthones and 6-substituted 2-acetonaphthones were determined at 30 °C in 80% dioxan-water(v/v). 1-Acetonaphthone Cyanohydrin has a greater dissociation constant than 2-acetonaphthone cyanohydrin due to steric interaction between the reaction centre and *peri*-H. The Hammett equation is well obeyed by both the series. The ρ values are found to be -1.18 and -2.36 for the 1-series and the 2-series respectively. The significant difference in the ρ values suggests that the electronic transmission is different in these two cases.

The position of equilibrium in the reversible dissociation of cyanohydrins of aralkyl ketones (Eq. 1) is governed by both steric and electronic effects. Steric



(1)

strain in the cyanohydrin favours the dissociation since there is a change in the coordination of the reaction centre from tetrahedral to trigonal.[1] The carbonyl group can mesomerically conjugate with the aryl group and stabilise the product. Hence electron-donating substituents in the aromatic ring favour the dissociation while the reverse is the case for electron-attracting substituents.[2] This is borne out by the negative ρ value obtained for the dissociation of the cyanohydrins of *meta*- and *para*-substituted benzaldehydes.[3] In an attempt to understand the degree of electronic transmission in substituted acetonaphthones, we measured the dissociation constants of the cyanohydrins of 4-substituted 1-acetonaphthones and 6-substituted 2-acetonaphthones. We report herein our results.

Experimental

Material. The substituted acetonaphthones were prepared by known methods.[4] Commercial dioxan was refluxed with 1M hydrochloric acid (100 ml for 1 litre of dioxan) with occasional passing of air, treated with excess sodium hydroxide and distilled. It was finally fractionated over sodium.[5] Doubly distilled water was used for all purposes. Solutions of HCN were obtained by mixing equal volumes of equimolar solutions of potassium cyanide and perchloric acid in the reaction medium and decanting the clear solution from precipitated potassium perchlorate.

Determination of Equilibrium Constants. The titrimetric method of Lapworth and Manske[6] was followed. The required quantity of the ketone was weighed into a volumetric flask (50 ml), dissolved in a small amount of the solvent and treated with exactly 20.0 ml of the stock solution of HCN. A 2% solution of piperidine (1 ml) was then added and the volume was made up to 50 ml. The flask was stoppered, sealed with paraffin wax and kept in a thermostat at 30 °C for 36 h. At the end of this period, the unreacted hydrogen cyanide was estimated by pipetting out aliquots (10 ml) into a known excess of silver nitrate containing 1% HNO_3 and back titrating with ammonium thiocyanate. A blank run was carried without the ketone in order to determine the initial concentration of HCN. The dissociation constant K_D, was calculated from the relation,

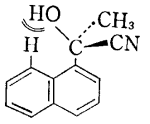
$$K_D = \frac{(a-x)(b-x)}{x},$$

where a is the initial concentration of ketone, b is that of HCN and x is the equilibrium concentration of cyanohydrin.

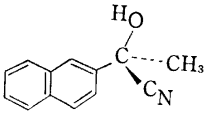
Results and Discussion

In Tables 1 and 2 are given the dissociation constants of the cyanohydrins of 4-substituted 1-acetonaphthones and 6-substituted 2-acetonaphthones respectively.

The data indicate that the cyanohydrin of 1-acetonaphthone (I) dissociates to a greater extent than that of 2-acetonaphthone (II). In the case of I, interaction



I



II

with adjacent *peri*-H is relieved on dissociation leading to a higher K_D value; such an interaction is absent in II. Based on the electronic effect of the 2,3-benzo group($\sigma=0.5$) and 3,4-benzo group($\sigma=0.04$)[7] alone, one would expect the cyanohydrin of 2-acetonaphthone to dissociate to a greater extent. Our present results obviously indicate that steric effect outweighs the electronic effect in this reaction.

The Hammett equation is obeyed both by 1- and 2-series (Figs. 1 and 2). The ρ value is found to be -1.18($r=0.997$) for the dissociation of the cyanohydrins of 4-substituted 1-acetonaphthones and -2.36 ($r=0.991$) for the dissociation of 6-substituted 2-acetonaphthone cyanohydrins. For the Hammett plots, the

σ constants derived by Baliah and Ananthakrishna Nadar[4] were used. In 1-acetonaphthone the acetyl group has a difinite tendency[8] to go out the plane of the aromatic ring due to the *peri*-H. Owing to the difficulty in attaining coplanarity the mesomeric interaction of the acetyl group with the ring will be less in 1-acetonaphthones than in 2-acetonaphthones. This is reflected in a smaller ρ value for the 1-series than that for 2-series. A similar result was obtained by

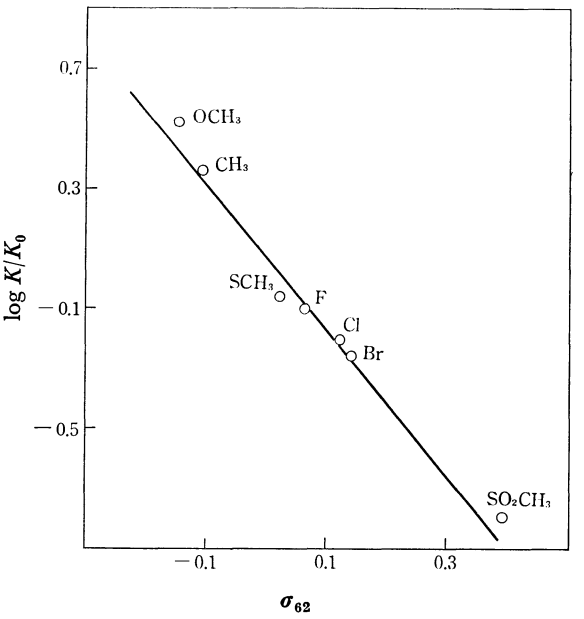

Fig. 2. Hammett plot of 6-substituted 2-acetonaphthones.

us in the reduction of substituted acetonaphthones by sodium tetrahydroborate[9].

Bromate Ion Specific Adsorption at Hg/$KBrO_3$(aq) Interface

M. V. RAMANAMURTI,* A. QAYUM, and R. K. SINGH

Department of Chemistry, Faculty of Science, Banaras Hindu University, Varanasi 221005, India

(Received May 20, 1977)

Synopsis. Adsorption analysis at polarized Hg/$KBrO_3$ (aq) interface through capacity measurements at 25 °C indicates bromate ion specific adsorption by the cathodic shift of zero charge potential with bulk electrolyte activity confirmed by means of q^1 (charge due to specifically adsorbed anions) *vs.* q^m(electrode charge) curves. At any concentration, $q^1 > q^m$ revealed bromate ion superequivalent adsorption. At fixed q^m, q^1 increases with electrolyte activity.

It was confirmed by Grahame and Soderberg[3] that the specific adsorption of inorganic oxoanions, *e.g.* nitrate,[1] perchlorate,[2] at Hg/solution interface is more complex than that of simpler halide ions. This communication presents evidence (both qualitative and quantitative) of specific adsorption of BrO_3^- (an oxoanion) at Hg/$KBrO_3$ (aq) interface through capacity measurements.

Experimental

Differential capacity measurements were made on an a.c. bridge, described by Grahame[4,5] using a dropping mercury electrode (DME) with a thin walled capillary and drop time *ca.* 8s at zero charge potential (E_{pzc}) of mercury in 0.10 mol·kg^{-1} KCl-solution. The a.c. frequency used was 1000 Hz with an amplitude less than 5 mV across the cell. An electronic magnetic drop detacher helped to knock off the drop at about two-thirds of its natural life. The time between two successive knocks was determined with a stop watch, measuring time-interval up to 0.05 s. The bridge was balanced at the instant of drop detachment. The out of balance of the bridge amplified by a multistage transistor preamplifier (Marconi Type TM6591A) was displayed on a Dumont Oscillograph (Type 274). A large mercury pool electrode and 1 M KCl calomel electrode (NCE) were used as auxiliary and reference electrodes, respectively. Direct contact was made between the reference electrode and the test solution by a saturated-KCl salt bridge which minimized the liquid junction potential to be negligible. The potential applied, measured on a portable potentiometer (Pye-Cambridge), was accurate up to one millivolt. Differential capacities were measured in the potential range from −0.10 to −1.40 V *vs.* NCE. The zero charge potential was determined separately, using streaming mercury electrode.[6] All the measurements were carried out in an air-thermostat controlled at 25±0.1 °C.

Mercury was purified by the procedure described by Trasatti.[7] Twice crystallized $KBrO_3$ (BDH/AnalaR) was used. Solutions at required molalities were prepared in conductivity water and deoxygenated with purified and presaturated nitrogen gas before the experiments were carryied out.

Results and Discussion

The differential capacities of the double layer as a function of ploarization potential, for eight concentrations of $KBrO_3$ in the range 0.025—0.500 mol kg^{-1}, are shown in Fig. 1. The characteristic capacity-hump occurs at anodic polarization with respect to E_{pzc} which shifts towards more negative potential with bulk electrolyte activity. Activity values were derived from graphical interpolation of the reported data.[8] A clear diffuse layer minimum appears for 0.025 mol kg^{-1} at more cathodic potential than E_{pzc}, due to the effect of superimposed steeply rising inner layer capacity. Complete disappearance of diffuselayer minimum in the capacity curves as the concentration approaches 0.10 mol kg^{-1} gives a clear indication of anionic specific adsorption.[9]

The shift of E_{pzc} (from its value *viz.*, −0.476 V *vs.* NCE in systems with no specific adsorption, *e.g.*, fluoride solution) for the anion under investigation to more cathodic values with the increase in bulk electrolyte activity (*cf.* Fig. 2) can be taken as a semi-quantitative estimate of the extent of specific adsorption; $|\Delta E_{pzc}|$ is an approximate measure of the specific adsorption (Esin Markov effect[10]).

The charge on the electrode surface (q^m) was obtained by integration of capacity curves. Knowledge of E_{pzc} facilitated the evaluation of integration constant. The charge due to specifically adsorbed bromate ions (q^1) has been calculated from the equations developed by Grahame and Soderberg[3] following diffuse layer theory. q^1 thus obtained, accurate up to ±1 μC cm^{-2}, has been plotted against q^m at four concentrations in the range 0.05—0.40 mol kg^{-1} (*cf.* Fig. 3). At any concentration the magnitude of q^1 is greater than $q^m(>0)$, indicating superequivalent adsorption of bromate ions. At the highest concentration studied, there exists a finite value of q^1 even at $q^m = -6$ μC cm^{-2}, revealing a strong affinity of BrO_3^- to the metal. At any electrode charge, the magnitude of q^1 increases with increase in electrolyte activity.

Dizirconium Trioxide Sulfate——$Zr_2O_3SO_4$

G. V. JERE,* V. RAMAN, and M. T. SANTHAMMA
Department of Chemistry, Indian Institute of Technology, New Delhi 110029, India

(Received August 16, 1977)

Synopsis. Dizirconium trioxide sulfate $Zr_2O_3SO_4$ has been isolated and characterised. It is obtained as a thermally degraded product of peroxosulfatozirconium(IV) complex, $Zr_2(O_2)_3SO_4 \cdot 8—10H_2O$, around 400—500 °C. It contains zirconium, oxide oxygen and sulfate in its lattice.

The TGA curve[1] of peroxosulfatozirconium(IV) complex, $Zr_2(O_2)_3SO_4 \cdot 8—10H_2O$, shows a relatively flat plateau in the region 350—600 °C. This indicates the formation of a stable intermediate compound. The present note deals with isolation and characterisation of this intermediate compound.

Experimental

The peroxosulphatozirconium(IV) complex — $Zr_2(O_2)_3SO_4 \cdot 8—10H_2O$— was prepared by the method reported.[1,2] The dried solid was heated in a muffle furnace at *ca.* 450 °C for an hour in order to obtain the stable intermediate product. Several samples were prepared and analyzed for zirconium and sulfate contents. The difference in percentage, after subtracting the total value for zirconium and sulfate was assigned to the oxide oxygen. The analytical results are given below:

Composition (%)			Molar ratio		
Zr	SO_4^{2-}	O^{2-}	Zr :	SO_4^{2-} :	O^{2-}
55.92	28.60	15.48	1	0.49	1.58
56.69	28.78	14.53	1	0.48	1.46
56.44	29.02	14.54	1	0.49	1.47
		Average composition			
56.35	28.80	14.85	1	0.49	1.50

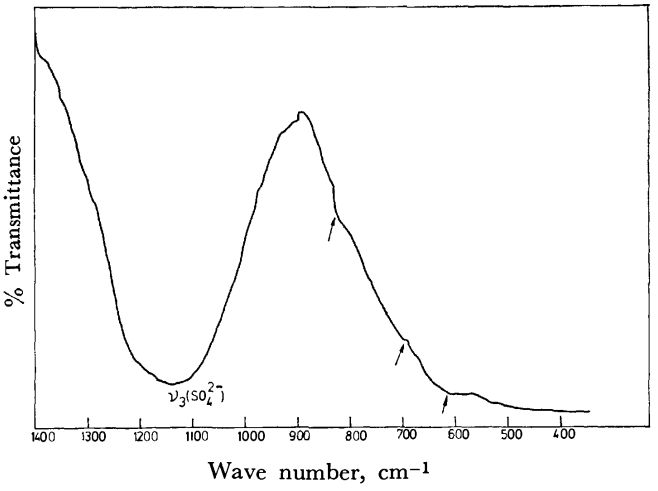

Fig 1. Salient features of the IR spectrum of $Zr_2O_3SO_4$.

The IR spectra of the samples were recorded in Nujol mull, on a Perkin Elmer double beam IR spectrophotometer, model 225. Salient features of the spectrum are given in Fig.1. TGA was carried out on a Stanton recording thermobalance, HT-D, with a 6 °C/min heating rate.

Discussion

We see that the molar composition of the species approximates $Zr : SO_4^{2-} : O^{2-}$ as 1 : 0.5 : 1.5. The compound is formulated as $Zr_2O_3SO_4$. The formation of this compound as a thermally degraded product of the parent peroxo complex can be visualized as follows:

$$\underset{\text{(peroxo compound)}}{Zr_2(O_2)_3SO_4 \cdot 8—10\,H_2O} \xrightarrow{400—450\,^\circ C} \underset{\text{(loss of water + peroxo oxygen)}}{} \underset{\text{(oxide sulfate)}}{Zr_2O_3SO_4}$$

This was indicated earlier also by Tikhomirov *et al.*[2] The molar ratio zirconium to sulphate (1 : 0.5)remains the same both in the intermediate and its parent peroxo compound. It is seen from TGA study that the decomposition of sulfate group from the oxide sulfate commences at *ca.* 600 °C, showing that the sulfate is intact in it. In the IR spectrum of the compound (Fig.1), the ν_3 (SO_4) and ν_4 (SO_4) appear as strong and broad absorptions in the region 1200—1000 cm^{-1} and around 600 cm^{-1} respectively. These two degenerate modes show no splitting. ν_1 and ν_2 do not appear in the IR spectrum. This indicates that sulfate is ionic in nature[3] in the oxide sulfate, unlike the case of the parent peroxo compound where it is of coordinated and bridging type.[1] The sulfate group might have undergone some internal rearrangement during the thermal decomposition of the parent peroxo compound. It is seen that $Zr_2O_3SO_4$ characterised for the first time is an oxide sulfate of zirconium containing zirconium, oxide oxygen and sulfate in its lattice.

One of the authors (M.T.S.) is grateful to the Council of Scientific and Industrial Research (India) for a research fellowship.

The Radiolysis of Binary Mixtures of Tetrahydrofuran with Benzene, Thiophene, Pyridine, and Nitrobenzene

Masao MATSUI* and Masashi IMAMURA†

Department of Pharmacy, Hokuriku University, Kanagawa-machi, Kanazawa-shi, Ishikawa 920-11

†*The Institute of Physical and Chemical Research, Wako-shi, Saitama 351*

(Received January 17, 1978)

Binary mixtures of tetrahydrofuran (THF) with benzene, thiophene, and nitrobenzene were subjected to radiolysis with γ-rays. The THF–benzene mixture was also irradiated with 28.6 MeV ^{4}He- and 90.9 MeV ^{12}C-ions. For THF–benzene mixtures, similar deviations of $G(H_2)$ from the mixture law were observed for all the radiolyses; these results are regarded as being due to energy transfer from THF^+, the precursor of hydrogen, to benzene. The total ionization yield of THF was calculated as 3.0—3.3 in G-units, irrespective of radiation and additives. This is on the basis of Hardwick's procedure, in which the deviations of $G(H_2)$ are divided by the efficiency of the energy transfer. This result also indicates that the total ionization yield is independent of the nature of radiation, whose LET range is from 0.02 to 49.2 eV/Å.

In the radiolysis of binary mixtures of organic liquids, a deviation from the mixture law[1] is sometimes observed. This deviation has been interpreted as a result of an energy or charge transfer from one component to the other.

Hardwick[2] has shown that the efficiency of an energy or charge transfer can be estimated from these deviations. When a radiolysis product is formed from an ionic precursor which can transfer its charge to the other component of the binary mixture, one can calculate a total ionization yield by combining the limiting efficiency of the charge transfer with the deviation of the product yield from the expected one.

One of the present authors[3] has previously reported that the hydrogen yield from a binary mixture of tetrahydrofuran (THF) and furan shows a deviation from the mixture law in the γ radiolysis and that the decrease in $G(H_2)$ is due to the charge transfer from THF to furan.

In the present study, binary mixtures of THF with benzene, thiophene, pyridine, and nitrobenzene as well as furan were subjected to irradiation with γ rays; the THF–benzene mixture was also irradiated with He- and C-ions. Moreover, the total ionization yields of THF, calculated by Hardwick's procedure, were compared with that of γ radiolysis.

Experimental

Materials. The THF was purified as has been described in a previous paper.[4] The thiophene (Tokyo Kasei Guaranteed Reagent) and benzene (Junsei Pure Chem. Guaranteed Reagent) were purified gas-chromatographically using a 3-m column of PEG-1000 at 100 °C. The pyridine (Wako Pure Chem. Extra Pure Reagent) and nitrobenzene (Wako Pure Chem. Guaranteed Reagent) were kept on sodium hydroxide and calcium chloride respectively for several days before rectifying.

Irradiation. γ-irradiation was carried out with a 10-kCi ^{60}Co source at a dose rate of 5.85×10^{17} eV $g^{-1}min^{-1}$ (9370 rad min^{-1}), which was determined by using a Fricke dosimeter on the basis of $G(Fe^{3+})=15.6$. The G-values were calculated after the correction of the absorbed dose for the electron densities of the solutions used. The He-(28.6 MeV) and C-(90.9 MeV) ions were accelerated with the cyclotron at the Institute of Physical and Chemical Research. The current intensity and total dose for charged particles were $\approx$1 nA and $(3.6—5.0)\times10^{19}$ eV respectively. The samples were vigorously stirred with a magnetic stirrer during irradiation at an ambient temperature.

The details of the irradiation arrangement and experimental procedures for charged-particle radiolysis were the same as those described previously.[5]

Analysis of Products. The gaseous fraction at −196 °C was determined on a conventional calibrated gas burette and a Toepler pump. The hydrogen and carbon monoxide were determined by gas chromatography using a Molecular Sieve 5A.

Results and Discussion

γ Radiolysis of THF–Benzene and THF–Thiophene Mixtures. The yield of hydrogen from pure liquid THF was $G=3.5$ in the present study, in agreement with several values previously reported.[4,6] The hydrogen yields for the binary mixtures of THF–benzene and THF–thiophen are plotted as a function of the electron fractions of benzene and thiophene respectively in Figs. 1 and 2. In both cases, the yields are lower than those to be expected from the mixture law. A similar trend of $G(H_2)$ has been observed for the THF–furan mixture,[3] whose concave variation of $G(H_2)$ was interpreted as being due to charge transfer from THF cations to furan molecules. For the THF–benzene and THF–thiophene mixtures, the deviation from straight

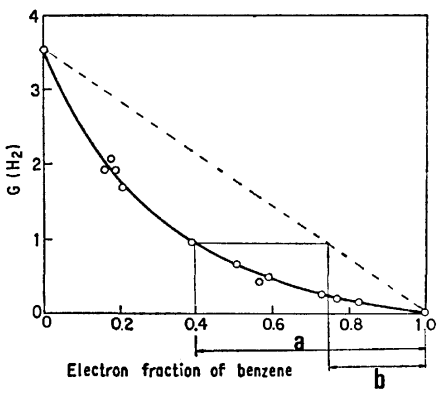

Fig. 1. Hydrogen yields from THF–benzene mixtures in γ radiolysis.

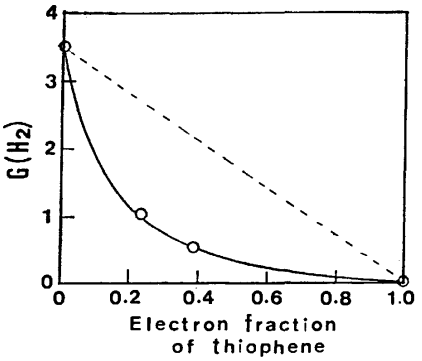

Fig. 2. Hydrogen yields from THF–thiophene mixtures in γ radiolysis.

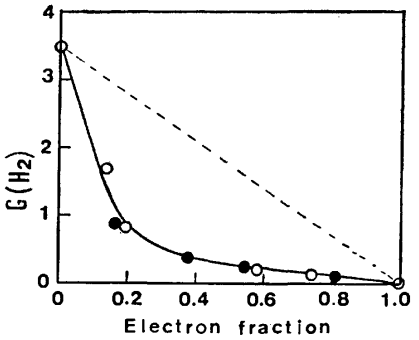

Fig. 3. Hydrogen yields from THF–pyridine (○) and THF–nitrobenzene (●) mixtures in γ radiolysis.

lines connecting the $G(H_2)$'s of THF and additives may also be explained on the same basis. In the γ radiolysis of THF, hydrogen was found to be produced molecularly; *i.e.*, the $G(H_2)$ was not affected by adding radical scavengers.[3] Most of the hydrogen is considered to be formed by rapid ion-molecule reactions of THF^+.[7] Therefore, the deviation of $G(H_2)$ from the mixture law may reasonably be explained in terms of charge transfer from THF^+ to the additives whose hydrogen yields are lower than that of THF.

This argument is supported by the facts that the ionization potentials[8] of benzene, thiophene, and furan are lower (9.25, 8.86, and 8.89 eV respectively) than that of THF (9.54 eV) and that the maximum deviations of $G(H_2)$, which appear at an electron fraction of about 0.25 for the above three additives, are in the order of the ionization potentials of the additives.

A similar relation has been observed in the production of D_2 and HD for the liquid-phase radiolysis of several binary mixtures of ethane-d_6, propane-d_8, and butane-d_{10} in liquid hydrocarbons at 195 K. That is, solvents with higher ionization potentials enhance the production of D_2 and HD from deuterated solutes with lower ionization potentials. There is also a great deal of evidence indicating that charge transfer to, or the positive-ion scavenging of, benzene takes place in liquid and glassy solutions.[10-18]

The occurrence of the charge transfer from THF^+ to benzene is further supported by the fact that the $\Delta G(H_2)$ of the THF–benzene mixture was reduced on the addition of triethylamine, that is, a positive-ion scavenger. For example, $\Delta G(H_2)=1.10$ in the THF–benzene ($a=0.2$) mixture was reduced to 0.55 on the addition of both benzene ($a=0.12$) and triethylamine ($a=0.08$) to THF. Since the $G(H_2)$ from pure triethylamine is higher than that of THF, the $G(H_2)$ for the THF–triethylamine mixture is increased by transferring the charge from THF^+ to triethylamine.

In contrast to $G(H_2)$, $G(CO)$ varies linearly with the electron fraction of the additives. Carbon monoxide has been shown to be produced from excited THF,[3] therefore, its yield is expected not to be affected by the presence of charge scavengers.

γ Radiolysis of THF–Pyridine and THF–Nitrobenzene Mixtures. Concave variations in $G(H_2)$ apparently similar to those observed for the THF–benzene and THF–thiophene mixtures described in the previous section were also observed for THF–pyridine and THF–nitrobenzene mixtures. It should be noted, however, that no substantial difference was observed between the two mixtures, as is shown in Fig. 3.

Either of these two additives has not only an ionization potential higher than that of THF, but also a high rate-constant toward hydrated electrons: $k(\text{pyridine}+e^-_{aq})=3.7\times10^9\ M^{-1}\ s^{-1}$ and $k(\text{nitrobenzene}+e^-_{aq})=3.0\times10^{10}\ M^{-1}\ s^{-1}$,[19] which are 10^2—10^3 times those of benzene ($k=1.4\times10^7\ M^{-1}\ s^{-1}$), thiophene ($k=3.0\times10^6\ M^{-1}\ s^{-1}$), and furan ($k=6.5\times10^7\ M^{-1}\ s^{-1}$).[19]

These facts indicate that, in the THF–pyridine and THF–nitrobenzene mixtures, the additives could act as efficient electron scavengers to reduce $G(H_2)$ from THF. Hydrogen is produced from THF by the reaction of electrons with the $THFH^+$ produced by the ion-molecule reaction ($THF^+ + THF$) as well as by the decomposition of excited THF molecules within spurs. Therefore, insofar as additives react with solvated electrons at a diffusion-controlled rate, the variation in $G(H_2)$ with the electron fraction should be independent of the nature of the additive. In fact, the $G(H_2)$-values from THF–pyridine solutions containing carbon tetrachloride were found to fit the curve in Fig. 3 when plotted *vs.* the sum of the electron fractions of pyridine and carbon tetrachloride.

He- and C-ion Radiolysis of THF–Benzene Mixture. The radiolysis of the THF–benzene mixture was carried out with 28.6 MeV He- and 90.9 MeV C-ions. The results are shown in Fig. 4, where the observed $G(H_2)$'s are plotted as a function of the electron fraction of benzene. Although the hydrogen yields from both THF and benzene are higher than those in the γ radiolysis, the variations in the $G(H_2)$ are qualitatively similar to those in the γ radiolysis. Thus, the charge transfer from THF^+ to benzene can be assumed to explain the concave variation in $G(H_2)$ in the He- and C-ion radiolysis.

Total Ionization Yields and Their LET-Dependence. Assuming that the additives act as charge acceptors (benzene, thiophene, and furan) or electron acceptors (pyridine and nitrobenzene) in the THF solutions, and that hydrogen is produced only from THF^+ and excited THF, one can calculate the total ionization yields in γ and heavy-ion radiolyses by using the procedure proposed by Hardwick.[2]

When a stands for the electron fraction of THF in the

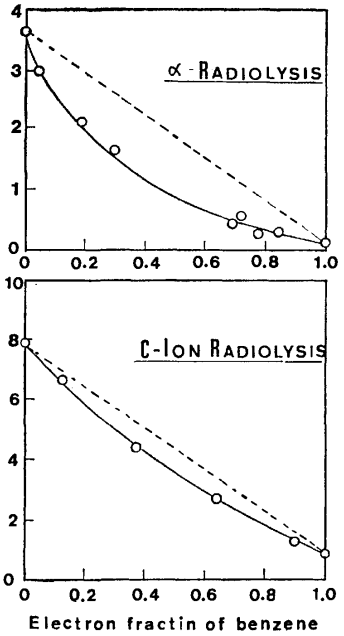

Fig. 4. Hydrogen yields from THF–benzene mixtures in He- and C-ion radiolysis.

mixture, and b, the apparent fraction of THF, as indicated by the measured value of $G(H_2)$ (see Fig. 2), the amount of THF which transfers energy is given by $(1-b)-(1-a)=a-b$. The fraction of THF molecules transferring a charge to acceptor molecules is, therefore, $(a-b)/a$.

The limiting values of $(a-b)/a$ can be obtained by plotting $(a-b)/a$ as a function of the electron fractions of the additives. In the γ radiolysis, such plots gave the limiting values of 0.70—0.75, identical within the range of experimental error for the THF–benzene, THF–thiophene, and THF–furan mixtures; these results are in accord with those obtained for alkane mixtures.[2] As Hardwick has stated, the identical limiting values for these mixtures may indicate that the characteristics of the donor molecule rather than those of the acceptor molecule govern the transfer process.

The limiting values of $(a-b)/a$ obtained with THF–benzene mixtures for He- and C-ion radiolysis were 0.65 and 0.50 respectively. Since THF in the THF–benzene, THF–thiophene, and THF–furan mixtures has an ionization potential lower than those of the additives, the energy transfer taking place in these systems may be regarded as a charge transfer. This assumption may also support the above findings as to the very close limiting values of $(a-b)/a$ for these mixtures. The remaining molecules, which do not transfer but decompose to give products, may, as Hardwick argued, be considered to be electronically excited. As has been mentioned above, in the He- and C-ion radiolyses the limiting values of $(a-b)/a$ were found to be 0.65 and 0.50 respectively for the THF–benzene mixtures. These values are lower than that obtained in γ radiolysis and show a substantial LET dependence. This fact, on the assumption mentioned above, indicates that the relative yield of electronically excited states which decompose to give products is substantially increased in high LET radiolyses.

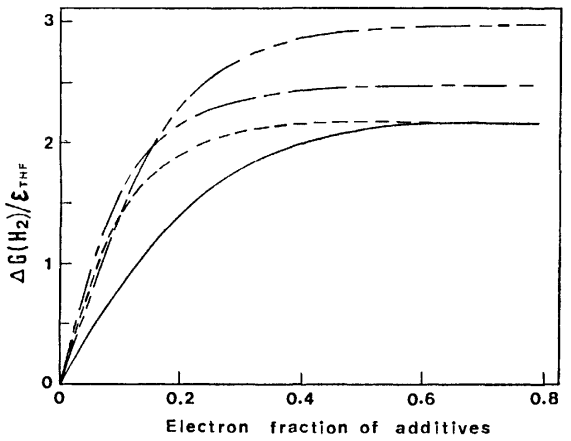

Fig. 5. Effectiveness of additives in γ radiolysis. Benzene (——), thiophene (– – –), furan (– – – –), pyridine and nitrobenzene (— — —).

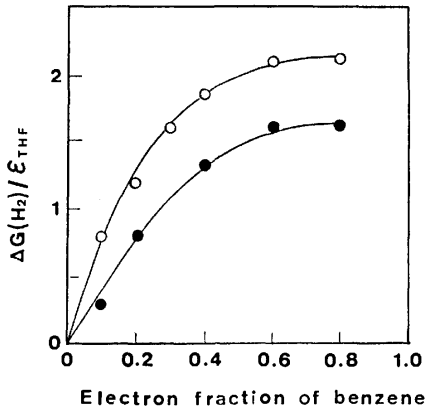

Fig. 6. $\Delta G(H_2)/\varepsilon_{THF}$ against the electron fraction of benzene for He- (○) and C- (●) ion radiolysis.

The effectiveness of additives may be seen from the curves shown in Fig. 5, where the deviations of $G(H_2)$ from the mixture law divided by the electron fraction of THF are plotted against the electron fraction of additives. For the He- and C-ion radiolyses, the deviations from the mixture law divided by the electron fraction of THF, $\Delta G(H_2)/\varepsilon_{THF}$, are shown in Fig. 6 as a function of the electron fraction of benzene. From Figs. 5 and 6 it is apparent that the limiting values of $\Delta G(H_2)$ corresponding to the limiting fraction of the THF-transferring charge are 2.2—2.5 for γ radiolysis and 2.1 and 1.6 for He- and C-ion radiolyses respectively.

On the other hand, a limiting $\Delta G(H_2)$-value of 2.9 is obtained by a similar treatment of the results observed for the γ radiolysis of THF–pyridine and THF–nitrobenzene mixtures in Fig. 5. Since these additives are thought to act as electron scavengers to reduce $G(H_2)$ from THF, and since the limiting value of $\Delta G(H_2)$ obtained is much the same as that of $G(e^-)$ reported by Baxendale *et al.*,[20] this value may represent the yield of electrons. They have determined the G(ion pair) values of 2.6 and 2.7 for the pulse radiolysis of THF–pyrene (5 mM)–$LiAlH_4$ (maximum$\simeq$0.45 M) and the γ radiolysis of THF–carbon tetrachloride (maximum$\simeq$ 0.1 M) mixtures respectively.

Shaede *et al.*[21] have also observed a total ionization yield of 3.75 for the nanosecond pulse radiolysis of a THF–pyrene mixture. The difference between $G(THF^+)$ and $G(e^-)$ estimated by the above-described treatment is probably attributable to the discrepancy of the efficiency between electron transfer and electron capture.

If one can assume that benzene acts solely as a charge acceptor in the present binary mixtures, the "total ionization yield" may be obtained by dividing the limiting value of $\Delta G(H_2)$ by that of $(a-b)/a$. The value of 3.0—3.1 is obtained for the γ radiolysis systems and that of 3.2—3.3 for the heavy-ion radiolysis systems. No substantial difference in the total ionization yield is seen between the two systems. These results reflect the fact that the ionization yield of liquid THF is independent of LET over a wide range and that the increased yields of hydrogen observed for heavy-ion-radiolysis systems may be attributable to the increased yields of the excited states.

The author's thanks are due to Messrs. Kazuo Otsuka and Yasuo Harata, who helped us throughout this work.

Carrier Effect on the Nature of V^{4+} and Active Oxygen Species in Vapor-phase Oxidation of Butadiene over Supported Divanadium Pentaoxide Catalysts

Masamichi AKIMOTO,* Masahiro USAMI, and Etsuro ECHIGOYA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 13, 1978)

The reactivity of V^{4+} with gaseous oxygen formed on various kinds of supported V_2O_5 catalysts has been investigated by ESR. The results are discussed as carrier effect in relation to the selectivity for maleic anhydride formation during the course of the vapor-phase oxidation of butadiene. V^{4+} formed on Al_2O_3 (V/Al$\leq$10/90 atom ratio) and MgO (V/Mg$\leq$30/70) showed a hyperfine ESR structure and was hardly oxidized whereas V^{4+} formed on SiO_2 (V/Si$\geq$5/95) had the singlet ESR signal and was easily oxidized. Formation of these two kinds of V^{4+} was observed on V_2O_5–Al_2O_3 (V/Al$\geq$20/80). They were similarly observed in the case of V_2O_5–TiO_2, but some portion of V^{4+} having the hyperfine structure was also oxidized. The selectivity was high over the catalysts forming the reactive V^{4+} as compared with those forming the unreactive one. The reactive V^{4+} was shown by X-ray diffraction to be preferentially formed in crystalline V_2O_5. Study of the reduction and reoxidation of unsupported crystalline V_2O_5 by means of IR and the effect of addition of alkali metal oxide on the catalytic activity of the supported V_2O_5 were discussed. The important role of double bond type lattice oxygen V=O in maleic anhydride formation was proposed.

In heterogeneous catalysis, a carrier is generally used for supporting the active component. However, the nature of the active site is strongly influenced by the kind of carrier, the supporting not always leading to better result. Thus, there are some observations which imply a chemical interaction between active component and carrier which may give rise to a carrier effect.[1-3] In heterogeneous oxidation of hydrocarbons, in which use of a carrier is strongly desirable, the role of carrier is not fully understood. In a previous paper,[4] a report was given on the carrier effect on the nature of supported molybdena catalyst in vapor-phase oxidation of butadiene. It was shown that the catalyst forming Mo^{5+} which is easily oxidized by gaseous oxygen has higher selectivity to maleic anhydride formation than that giving Mo^{5+} which is not oxidized. We have carried out a detailed investigation of carrier effect in the same catalytic oxidation using various supported V_2O_5 catalysts. Alumina, silica, titania, and magnesia were used as carrier, and the physical and chemical properties of these catalysts were investigated by X-ray analysis, ESR and IR spectroscopy in relation to the selectivity for maleic anhydride formation. Oxygen species, which is active and selective for the production of maleic anhydride, was also studied.

Experimental

The apparatus and procedure used for the oxidation were the same as those reported.[4] Pure butadiene (99.9% up) was used. Various supported V_2O_5 catalysts were prepared by mechanically kneading either alumina gel, silica gel, titania gel, or magnesium hydroxide with an aqueous solution of ammonium metavanadate for 3 h, evaporating the cake to dryness on a water bath and sieving the dried mass obtained into particles of 32—60 mesh. The catalysts were then calcined in an air current at 550 °C for 3 h. Titania gel was prepared by hydrolysis of titanium tetrachloride of reagent grade. Supported V_2O_5 catalysts modified with alkali metal oxide were prepared similarly. As a source of the metal oxide, extra pure alkali metal nitrates were used.

The gaseous effluent from the reactor was analyzed by gas chromatography. PEG 20M 20 wt% on Neopak 1A (60 °C, furan, acrylaldehyde, acetaldehyde), propylene carbonate 40 wt% on Celite 545 (room temp, butadiene, CO_2) and molecular sieve 13X (room temp, CO, N_2, O_2) were used as separating columns. Since maleic anhydride was the only acid obtained, the product was absorbed into water followed by titration with an aqueous solution of sodium hydroxide (0.1 M) after boiling off carbon dioxide. The structure of the catalysts was investigated by X-ray diffraction using nickel-filtered Cu $K\alpha$ radiation. The surface area of the catalysts was determined by the BET method using nitrogen as an adsorbate. A JEOL JES-PE-2X ESR spectrometer was used, in which microwave frequency was the X band and 100 kHz modulation was adopted. The amount of V^{4+} was measured using Mn^{2+} and DPPH as an internal standard. A Hitachi EPI-G3 spectrometer was used for IR studies.

Results

The Oxidation of Butadiene over Various Supported V_2O_5 Catalysts. Alumina, silica, titania, and magnesia showed negligible activity in the oxidation of butadiene. The carriers promoted only complete combustion of butadiene without formation of maleic anhydride. Figure 1 shows the result of oxidation over V_2O_5–Al_2O_3 catalyst. The catalyst containing V_2O_5 at V/Al=5/95 atom ratio had a negligible activity. However, further addition of V_2O_5 enhanced the activity to reach a maximum value at V/Al=20/80. The selectivity to maleic anhydride was low, *i.e.*, 6.5% over the catalyst of V/Al=10/90 in contrast to those (30—35%) over the catalysts of V/Al$\geq$20/80.

The catalytic activity of V_2O_5–SiO_2 increased with increase in the content of V_2O_5 (Fig. 2). V_2O_5–TiO_2 showed a tendency similar to that of V_2O_5–Al_2O_3 (Fig. 3). However, in contrast to the latter catalyst, the former two catalysts had an ability of producing maleic anhydride in spite of the low content of V_2O_5, *i.e.*, V/Si=5/95 and V/Ti=5/95. V_2O_5–MgO (V/Mg$\leq$30/70) formed no maleic anhydride; conversion of butadiene and yield of CO_2 and CO were 24.9, 24.2% (V/Mg=5/95), 39.6, 33.7% (10/90), 58.9, 55.4%

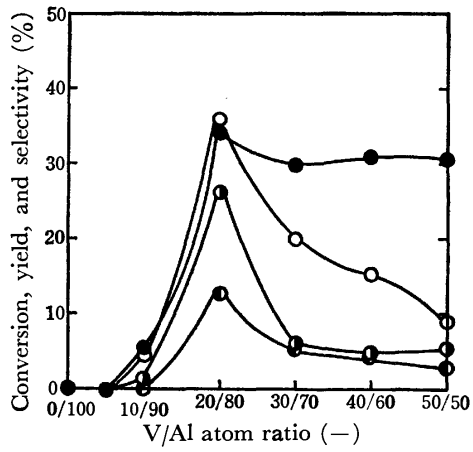

Fig. 1. The oxidation of butadiene over various V_2O_5–Al_2O_3 catalysts. Reaction temp (bath): 310 °C, feed: butadiene 1.45 vol% in air, contact time: W/F=0.373 g-cat·h/g-mol.
○: Conversion of butadiene, ◑: yield of CO_2+CO, ◐: yield of maleic anhydride, ●: selectivity to maleic anhydride.

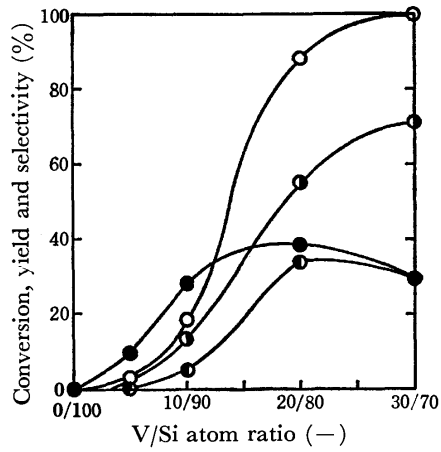

Fig. 2. The oxidation of butadiene over various V_2O_5–SiO_2 catalysts. Reaction temp (bath): 380 °C, feed: butadiene 1.45 vol% in air, contact time: W/F=0.373 g-cat·h/g-mol. Symbols are the same as those in Fig. 1.

(20/80), and 57.0, 57.4% (30/70), respectively, at 425 °C, contact time W/F=1.490 g-cat·h/g-mol and butadiene 1.45 vol% in air.

Based on the selectivity to maleic anhydride formation, these catalysts can be divided into the following three groups;

(A) V_2O_5–Al_2O_3 (V/Al=5/95 and 10/90), V_2O_5–MgO (V/Mg≤30/70).

The selectivity is negligible or very low.

(B) V_2O_5–SiO_2 (V/Si=5/95), V_2O_5–TiO_2 (V/Ti=5/95).

The selectivity is 10—16%.

(C) V_2O_5–Al_2O_3 (V/Al≥20/80), V_2O_5–SiO_2 (V/Si≥10/90), and V_2O_5–TiO_2 (V/Ti≥10/90).

The selectivity is 30—39%.

X-Ray Studies on the Supported V_2O_5 Catalysts. Al_2O_3 and SiO_2 were almost amorphous, the former showing weak X-ray diffraction at 2θ=46.0 and 67.0°. Thus, Al_2O_3 was γ-type. In the case of V_2O_5–Al_2O_3, the diffraction due to crystalline V_2O_5 appeared from

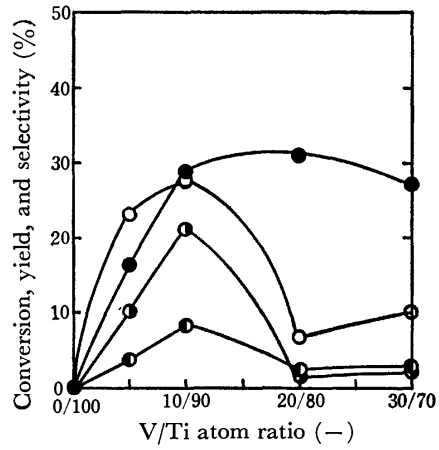

Fig. 3. The oxidation of butadiene over various V_2O_5–TiO_2 catalysts. Reaction temp (bath): 300°C, feed: butadiene 1.32 vol%, oxygen 9.11 vol%, diluent–nitrogen, contact time: W/F=0.325 g-cat·h/g-mol. Symbols are the same as those in Fig. 1.

V/Al=20/80 (2θ=25.6°), its strength increasing with rise in the content of V_2O_5; *i.e.*, V_2O_5–Al_2O_3 (V/Al=40/60) showed diffraction at 2θ=20.5, 26.1, 31.0° (strong), 15.5, 21.8, 32.4, and 34.4° (medium). On the other hand, the presence of crystalline V_2O_5 was observed from V/Si=10/90 (2θ=15.4, 26.0, and 32.2°), its amount increasing with rise in content. TiO_2 was of anatase-type (2θ=25.2, 37.9, 48.0, and 54.0°), formation of the V_2O_5 being distinctly observed at V/Ti≥20/80 (2θ=15.2, 20.2, 26.2, and 31.3°). In contrast, V_2O_5–MgO (V/Mg≤30/70) showed strong X-ray diffraction due to periclase-type MgO at 2θ=36.9, 42.7, and 62.1° with a very weak diffraction due to V_2O_5 at 2θ=35.1° (V/Mg≥10/90). Thus, the group C catalysts contain crystalline V_2O_5 in contrast to groups A and B.

ESR Spectrum of V^{4+} and Its Reactivity to Gaseous Oxygen. Formation of paramagnetic species in various V_2O_5 catalysts preevacuated at 450 °C under 10^{-5} mmHg was investigated by means of ESR. V_2O_5–SiO_2 (V/Si=5/95) gave a singlet spectrum, its g-factor being 1.98 and the linewidth expressed by maximum slope separation 107G. The line shape was nearly Lorentzian. This spectrum agreed with that of V^{4+} which forms a cluster in pure V_2O_5 and on Alundum carrier.[5] However, the linewidth increased with further rise in the content of V_2O_5 (V/Si=20/80, ΔH_{msl}=213G).

A completely different spectrum was observed for V_2O_5–Al_2O_3 (V/Al≤10/90), V_2O_5–TiO_2 (V/Ti=5/95), and V_2O_5–MgO (V/Mg≤30/70), which clearly showed hyperfine splitting caused by the nuclear magnetic moment of vanadium I=7/2 (Fig. 4, V/Al=5/95). V_2O_5–Al_2O_3 (V/Al≥20/80) and V_2O_5–TiO_2 (V/Ti≥10/90) gave ESR spectra consisting of hyperfine structure and singlet. Analysis of the complicated spectrum having the hyperfine structure was carried out by the method developed by Hecht and Johnstone.[6] The spectrum was analyzed with an axial symmetric spin Hamiltonian[7]

$$\mathcal{H} = \beta(g_{\parallel}H_zS_z + g_{\perp}H_xS_x + g_{\perp}H_yS_y) + A_{\parallel}S_zI_z + A_{\perp}S_xI_x + A_{\perp}S_yI_y, \quad (1)$$

where β is the Bohr magneton, $g_{\parallel}$ and $g_{\perp}$ are the parallel and perpendicular principal components, respectively, of the g-tensor; $A_{\parallel}$ and $A_{\perp}$ are the parallel and perpendicular principal components, respectively, of the hyperfine-coupling tensor; H_x, H_y, H_z are the components of the magnetic field; S_x, S_y, S_z, and I_x, I_y, I_z are the components of spin operators of the electron and nucleus, respectively, the coordinate system being fixed to the molecule. The absorption peaks are related to $2I+1$ values of m_I, the peaks appearing in the field of

$$H_{\parallel} = 2H_0/g_{\parallel} - (A_{\parallel}/g_{\parallel}\beta)m_I \quad (\text{for } \theta = 0), \qquad (2)$$

$$H_{\perp} = 2H_0/g_{\perp} - (A_{\perp}/g_{\perp}\beta)m_I \quad (\text{for } \theta = \pi/2), \qquad (3)$$

where θ is the angle spanning between H_0 and the axial symmetry axis of the ion site. Plotting the magnetic field of the observed peaks corresponding to either $H_{\parallel}$ or $H_{\perp}$ against the nuclear quantum number m_I, we obtain a linear relation. The slopes and the intercepts with the $m_I=0$ line can be used to obtain values of the parameters, $g_{\parallel}$, $A_{\parallel}$, $g_{\perp}$, and $A_{\perp}$. Assignment of the peaks of the observed spectrum was attained according to the method used by Takahashi *et al.*[5] The result is illustrated as two sets of octets as shown in Fig. 4 (V/Al=5/95). The values of the parameters are given in Table 1. The observed components of the g-factor show that the g-tensor of V^{4+} ion has axial symmetry. The observed parameters agree with those of the V^{4+} formed separately on Neobead carrier.[5]

Reactivity of V^{4+} with gaseous oxygen was investigated by introduction of 20 mmHg O_2 followed by heating at various temperatures for 30 min. The amount of V^{4+} existing after the reaction was determined at room temperature. V^{4+} in V_2O_5–Al_2O_3 (V/Al≤10/90) was scarcely oxidized even at 450 °C, but a large portion of V^{4+} in V_2O_5–Al_2O_3 (V/Al≥20/80) was oxidized to V^{5+} above 200 °C with simultaneous appearance of the hyperfine structure. V^{4+} in V_2O_5–MgO (V/Mg≤30/70) was also hardly oxidized at 450 °C whereas that in V_2O_5–SiO_2 (V/Si≤30/70) was easily oxidized. Thus,

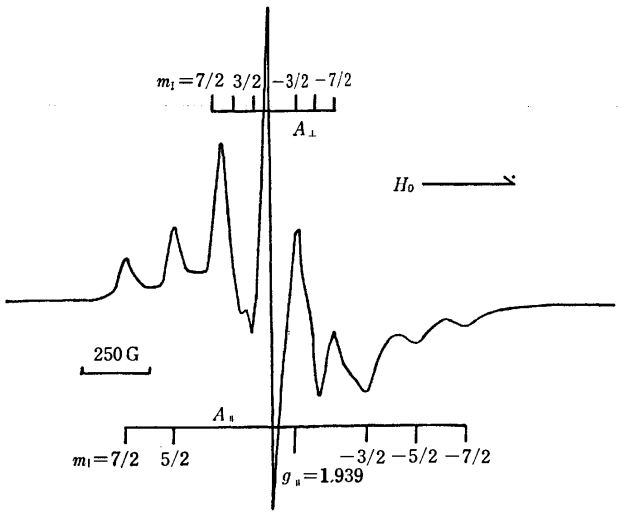

Fig. 4. ESR spectrum of V^{4+} formed in V_2O_5–Al_2O_3(V/Al=5/95). Catalyst: evacuated at 450 °C and 10^{-5} mmHg for 2 h. ESR: measured at room temperature.

V^{4+} having the singlet spectrum is reactive to oxygen, but not the one having hyperfine structure. However, some portion of V^{4+} formed in V_2O_5–TiO_2 (V/Ti=5/95) was easily oxidized irrespective of the hyperfine structure. V^{4+} in V_2O_5–TiO_2 (V/Ti≥10/90) showed a reactivity similar to that in V_2O_5–Al_2O_3 (V/Al≥20/80). The observations are summarized in Table 2. The catalysts forming reactive V^{4+} have high selectivity as compared with those having unreactive V^{4+}. The reactive V^{4+} is preferentially formed in crystalline V_2O_5.

Correlation Existing between the Amount of V^{4+} and the Catalytic Activity. The amount of V^{4+} formed by the evacuation of various V_2O_5–Al_2O_3 at 450 °C and decreased on contact with gaseous oxygen at 350 °C were determined (Table 3). 0.4—1.2% of vanadium present in the catalyst is V^{4+}, in line with the other catalysts. The amount of V^{4+} which is reactive to

50/50	66	2.80×10^{19}	0.66	0.31×10^{19}

a) Evacuated at 450 °C and 10^{-5} mmHg for 2 h. b) The amount of V^{4+} (spins/g-cat.) decreased on contact with gaseous oxygen (20 mmHg) at 350 °C for 30 min.

oxygen increased suddenly with increase in the content of V_2O_5, reaching a maximum value at V/Al=20/80, decreasing gradually with further increase. The amount is not that of reactive V^{4+} existing on the surface. However, increase in the yield of maleic anhydride with increase in amount also indicates the important role of the reactive V^{4+} in the anhydride formation.

IR Studies on the Reduction and Reoxidation of V_2O_5. The above results reveal that the reactive V^{4+} formed in crystalline V_2O_5 is important for anhydride formation. In order to clarify the kind of lattice oxygen participating in the reduction-oxidation of V_2O_5, unsupported crystalline V_2O_5 was used in IR studies instead of the group C catalysts. Absorption bands were obtained at about 1020 cm^{-1} ($\nu_{V^{5+}=O}$) and 830 cm^{-1} (ν_{V-O-V}).[8-10] Effect of the reduction of this V_2O_5 with a current of hydrogen at 512 °C on the ratio of the peak area of these absorption bands was investigated. Gradual decrease in the ratio with rise in the reduction time was observed, a small lower shift of these bands taking place

Table 4. Change in the ratio of IR absorption peak area ($\nu_{V^{5+}=O}/\nu_{V-O-V}$) with the reduction of unsupported V_2O_5[a]

Reduction time/min	$\nu_{V^{5+}=O}$ / cm^{-1}	ν_{V-O-V} / cm^{-1}	Ratio of the peak area ($\nu_{V^{5+}=O}/\nu_{V-O-V}$)
0	1017	830	—
5	1014	820	0.473
10	1008	825	0.454
15	1005	825	0.403

a) KBr disk technique: Reduction temp: 512 °C, V_2O_5: 0.5 g, Flow rate of hydrogen: *ca.* 50 NTPml/min.

(Table 4). Formation of V^{4+}=O or VO_2 was confirmed by the appearance of a new absorption band at 980 cm^{-1},[8,11] its intensity increasing with increase in reduction time. The results are the same as those reported.[12,13] The original absorption bands were easily recovered by the reoxidation of the reduced V_2O_5 with a current of air at the same temperature. Thus, double bond type lattice oxygen V^{5+}=O in crystalline V_2O_5 is first reduced to give reactive V^{4+} and is recovered by reoxidation.

Effect of the Addition of Alkali Metal Oxide on the Catalytic Activity of Supported V_2O_5 Catalysts. The effect of addition of alkali metal oxide on the formation of maleic anhydride was studied using V_2O_5–Al_2O_3 (V/Al=20/80) and V_2O_5–SiO_2 (V/Si=20/80). The rate of maleic anhydride formation per unit surface area measured by means of a differential reactor was enhanced with a decrease in the electronegativity of the metal ion added (Table 5).

Table 5. Effect of the addition of alkali metal oxide on the catalytic activity of supported V_2O_5 in the oxidation of butadiene

Alkali metal oxide	Electronegativity of alkali metal element[a]	Rate of maleic anhydride formation (g-mol/m^2-cat·h)

Discussion

The change in catalytic activity of V_2O_5–Al_2O_3 can be attributed not to that in the surface area but to the formation of active species by the addition of V_2O_5 to Al_2O_3 (Table 3). The active species is V^{4+}, which is the case in the other catalysts. However, the results obtained indicate that the nature of V^{4+} formed has strong effect on the selectivity to maleic anhydride formation. The catalysts having reactive V^{4+} had high selectivity to the anhydride, this kind of V^{4+} being formed preferentially in the crystalline V_2O_5 (Tables 2 and 3).

During the catalytic oxidation, V^{5+}=O in the crystalline V_2O_5 is first reduced to give V^{3+} as shown by IR studies (Table 4). The V^{3+} then forms V^{4+} and V^{4+}=O by donation of its one electron to a neighbouring V^{5+}=O, *i.e.*, $V^{3+}+V^{5+}=O\rightarrow V^{4+}+V^{4+}=O$. The V^{4+}=O is further reduced or recovered into original V^{5+}=O when V^{4+} is oxidized to V^{5+}=O. On the reactive V^{4+}, various electronegative oxygen species such as O_2^- and O^- are formed when gaseous oxygen is adsorbed.[14] At elevated temperature, these oxygen species change rapidly to lattice oxygen O^{2-}, instead V^{4+} being oxidized to V^{5+}. The lattice oxygen formed is of double bond type as shown by IR studies on the reoxidation of reduced V_2O_5. The high selectivity of V_2O_5 catalysts forming the reactive V^{4+} strongly suggests a very important role of the negatively charged oxygen species formed by the oxidation of V^{4+}. The reactive V^{4+} plays a role of a precursor which forms the oxygen species.

Generally, the strength of metal-oxygen bond increases in proportion to the electronegativity of metal ion.[15,16] Thus the reactivity of lattice oxygen decreases with rise

in the electronegativity of metal ion. In contrast, the amount of oxygen species adsorbed increases with rise in electronegativity, rate of catalytic oxidation increasing when oxygen species adsorbed is important. This was confirmed by the oxidation of various hydrocarbons over MoO_3,[17] TiO_2,[18] and Bi_2O_3[19] catalysts modified with oxide of 5B group element or of alkali metal. The electronegativity of these metal ion was shown to have changed in proportion to that of the metal ion added. On the analogy of the rsults, it can be expected that the electronegativity of vanadium ion modified with alkali metal oxide is $Li^+>Na^+>K^+>Rb^+>Cs^+$ as a sequence of alkali metal ion added, the reactivity of its lattice oxygen being $Cs^+>Rb^+>K^+>Na^+>Li^+$. Thus, increase in the rate of maleic anhydride formation with decrease in the electronegativity of alkali metal ion (Table 5) strongly supports participation of lattice oxygen rather than the adsorbed oxygen species in maleic anhydride formation over these catalysts. This lattice oxygen is considered to be of double bond type V=O as shown by IR studies. This is in line with the important role of Mo=O in the oxidation of butadiene to maleic anhydride over MoO_3 catalyst[4] and with the special activity of the double bond type lattice oxygen proposed.[10,20-22]

Lattice oxygen of transition metal oxide serves to abstract hydrogen irrespective of the type of metal-oxygen bonding (σ- and double bond one).[20,23] However, the former lattice oxygen is not always incorporated into selective oxidation product.[23] Maleic anhydride is formed from butadiene by the repetition of oxygen addition and hydrogen abstraction.[24,25] Thus, it was considered that V=O is requisite as oxygen species incorporated into the anhydride. Possibly, this lattice oxygen also plays a role of hydrogen abstraction from intermediates leading to maleic anhydride. The oxygen species participating in the complete oxidation over the group A catalysts was not clarified. However, it is apparent that the electronegative oxygen species were hardly formed during the course of catalytic oxidation, as suggested by the unreactivity of V^{4+} to oxygen. Oxygen species participating in maleic anhydride formation over V_2O_5–SiO_2 (V/Si=5/95) seems to be the same as that over the group C catalysts as judged from the similarity in the ESR spectrum of V^{4+}. Those over V_2O_5–TiO_2 (V/Ti=5/95) were not clarified.

Structures of the catalysts are discussed. V^{4+} formed in a cluster has a singlet ESR spectrum and that formed separately a hyperfine structure, the distance between the nearest neighbour V^{4+} being <5 Å in the former V^{4+} and ≈ 9 Å in the latter.[5] Vanadium ions in V_2O_5–MgO (V/Mg$\leq$30/70) are finely dispersed in the carrier whereas V_2O_5 on SiO_2 (V/Si$\geq$5/95) forms cluster. In the case of V_2O_5–Al_2O_3 and V_2O_5–TiO_2, vanadium ions are finely dispersed when the content of V_2O_5 is low (V/Al$\leq$10/90, V/Ti$\leq$5/95). Formation of V_2O_5 cluster takes place with increase in the content, thus giving the spectra made by overlap of these two kinds of ESR spectra. This explanation is in line with the observation of crystalline V_2O_5 by X-ray studies. V^{4+}, which is not oxidized with oxygen, is possibly formed from finely dispersed vanadium ions by a solid-phase reaction when the catalysts were prepared. V^{4+}, on the other hand, formed at the sites where lattice oxygen in V_2O_5 cluster is lost by evacuation, appears to be easily oxidized. The reactive nature of V^{4+} formed in V_2O_5–TiO_2 (V/Ti=5/95) to oxygen irrespective of the hyperfine structure is presumably attributed to a relatively large mobility of lattice oxygen in the titania as compared with the other carriers.

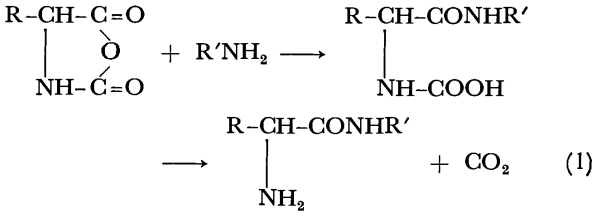
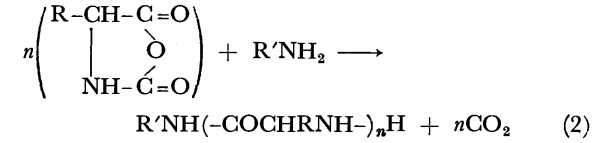
(Received January 26, 1978)

The structure of *N*-carboxy-γ-benzyl-L-glutamate anhydride has been determined by X-ray analysis. The crystal is orthorhombic; space group, $P2_12_12_1$; $Z=4$ with $a=7.766(1)$, $b=27.470(4)$, and $c=5.948(1)$ Å. The structure was deduced by the direct method and refined to a final R value of 0.057 for 1504 observed reflections by the block-diagonal least-squares method. The hydrogen bond is formed between the imino group and the carbonyl group of the side chain. The dimension of the five-membered ring is affected by the intermolecular hydrogen bond as compared with the crystal structures of the other *N*-carboxy anhydrides of α-amino acid.

The *N*-carboxy anhydrides of α-amino acids (amino acid NCAs) are often used for the syntheses of polypeptides. The polymerization mechanism differs with the kind of initiator. When a primary amine is used as an initiator, polymerization is considered to proceed as follows,[1] the first step being the formation of an amino acid derivative by interaction of the NCA and the initiator.



The amino acid derivative formed in (1) can react successively with amino acid NCA in a similar manner, leading to polymeric products. The over-all process is written as follows.



The polymerization of amino acid NCA was carried out not only in the homogeneous system but also in the heterogeneous system and in crystalline state. When butylamine (an initiator) is added into the suspension of the crystals of amino acid NCA in hexane, polymerization occurs in the solid state and a polypeptide of a considerably high molecular weight can be obtained. Polymerizability differs a great deal from that in a heterogeneous system using acetonitrile as a solvent of NCA.[2] In order to interpret the polymerization of amino acid NCAs in the solid state, we have attempted to analyze their crystal structures. In previous studies, the crystal structures of glycine NCA[3] and L-alanine NCA[4] were reported. This paper deals with the crystal structure of γ-benzyl-L-glutamate NCA, which is most extensively used for the study of synthetic polypeptides.

Experimental

γ-Benzyl-L-glutamate NCA (BLG NCA) was synthesized in the same way as that for glycine NCA, and purified by crystallization with ethyl acetate–hexane several times. BLG NCA thus obtained (about 100 mg) was dissolved in an appropriate vessel with 5 ml of ethyl acetate. The vessel was placed in a covered bottle containing hexane and allowed to stand at room temperature for a few days. Colorless plate crystals were obtained. The unit-cell dimensions were determined by the least-squares refinement with 25 high-angle reflections. The crystal data are summarized in Table 1.

Table 1. Crystal data

$C_{13}NO_5H_{13}$	Space group: $P2_12_12_1$
$M.W.$: 263	$Z=4$
Orthorhombic	$D_x=1.40$ g·cm^{-3}
$a=7.766(1)$ Å	$D_m=1.38$ g·cm^{-3}
$b=27.470(4)$	μ(Mo $K\alpha$)$=1.30$ cm^{-1}
$c=5.948(1)$	
$U=1268.9(4)$ Å^3	

With use of a $0.3\times0.4\times0.4$ mm crystal, intensity data up to $2\theta=55°$ were collected on a Rigaku four-circle diffractometer with graphite monochromated Mo $K\alpha$ radiation. The usual ω-2θ scan technique was employed with a scan speed 4° (2θ)min^{-1}. A total of 1735 independent reflections were obtained, in which 231 with $|F_o|<3\sigma(|F_o|)$ were regarded as zero reflections. The usual Lorentz and polarization corrections were made. Absorption was uncorrected.

Structure Determination

The structure was determined by the direct method using the program MULTAN. Refinement of the structure was carried out by the block-diagonal least-squares method. After several cycles of refinement, two strong reflections, 020 and 060, were excluded since they seem to undergo secondary extinction. All the hydrogen atoms were revealed on a difference map. The final refinement was performed including these hydrogen atoms with isotropic temperature factors. The weighting scheme: $w=0.25$ for $|F_o|<1.95$ and $|F_o|>15.62$, and $w=(5.959-1.127|F_o|+0.0642|F_o|^2)^{-1}$ for the other reflections. The final R value became 0.057 for all the non-zero reflections. In the final stage, no peaks higher than 0.2 eÅ^{-3} were found on the difference map. The atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[5] The final atomic parameters and their standard devia-

tions for non-hydrogen atoms and hydrogen atoms are given in Tables 2 and 3, respectively. A list of the observed and calculated structure factors is kept in the office of the Chemical Society of Japan (Document No. 7821). Computation was carried out on the HITAC 8700 computer at this Institute.

Description of the Structure

Bond distances and angles are shown in Fig. 1, together with the numbering system. The dimensions involving hydrogen atoms are given in Table 4. There is a significant difference between the distances of C(1)–O(2) and C(2)–O(2) in the *N*-carboxy anhydride ring (NCA ring). This feature is similar to that of L-alanine NCA[4] but differs from that of glycine NCA[3] and L-leucine NCA,[6] in which C(1)–O(2) has nearly the same distance as C(2)–O(2). The other bond distances, C(2)–C(3), C(1)–N(1), and C(3)–N(1), are comparable to the corresponding lengths in glycine NCA, L-alanine NCA, and L-leucine NCA. The characteristic dimensions in the NCA ring of the present compound are discussed in detail and compared with those of the other amino acid NCAs. The fluctuation of the distances in the benzene ring can be explained by the thermal vibration around C(8)–C(11).

Table 4. Bond lengths and angles involving hydrogen atoms in γ-benzyl-L-glutamate NCA

The estimated standard deviations are 0.03—0.04 Å in distances and 2—3° in angles.

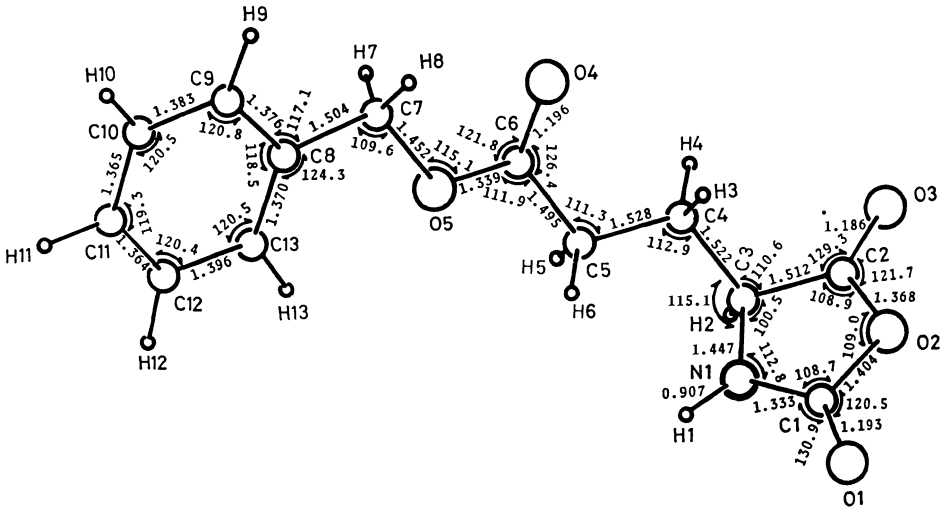

Fig. 1. A perspective view of γ-benzyl-L-glutamate NCA along the c axis with the numbering of the atoms, bond lengths(l/Å), and angles(ϕ/°). The estimated standard deviations are 0.004—0.006Å in distances and 0.2—0.4° in angles.

The equations of the least-squares planes, plane I through the NCA ring, plane II through the carbonyl group and plane III through the benzene ring, are given in Table 5, together with the deviations of the atoms from the planes. Three oxygen atoms, O(1), O(2), and O(3) deviate distinctly from plane I. This is also the case in the other amino acid NCA crystals. Plane I makes angles of 56.8 and 69.7° with planes II and III, respectively. Plane II makes an angle of 13.0° with plane III.

Conformations of the side chain by Newman projections are shown in Fig. 2. Both of the conformations about C(4)–C(3) and C(5)–C(4) are trans.

A stereoscopic view of the crystal structure is shown in Fig. 3. The hydrogen bond (broken lines) is formed between N(1)–H(1)···O(4′). The length of N(1)···O(4′)

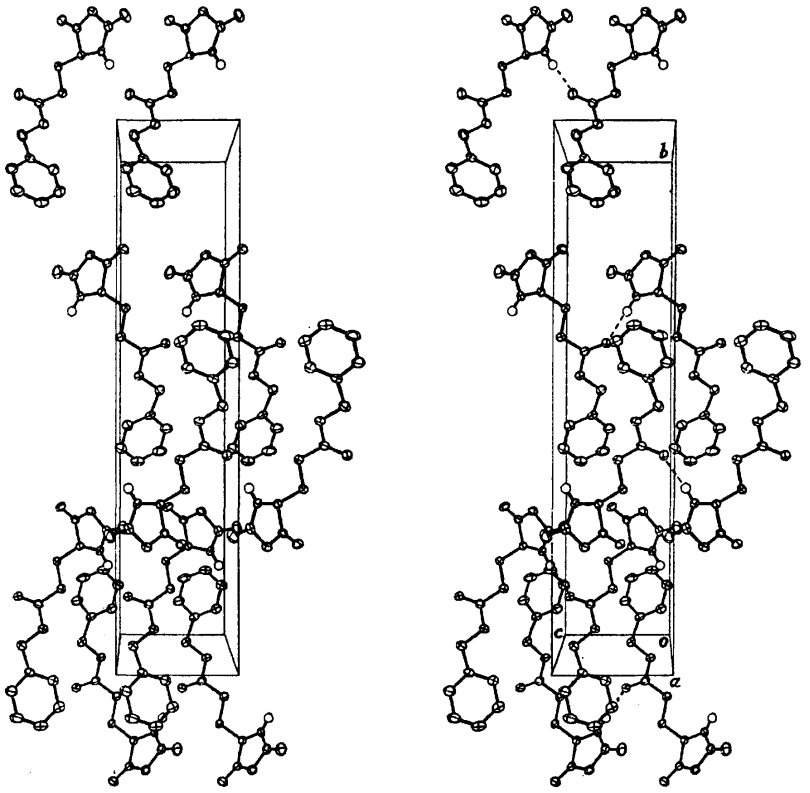

Fig. 3. Stereoscopic drawing of the crstal structure of γ-benzyl-L-glutamate NCA viewed along the a axis. The thermal ellipsoids are drawn at 50% probability level. Hydrogen atoms are omitted for clarity except for H(1) with circles. Hydrogen bond are shown by broken lines.

and the angle of N(1)–H(1)···O(4′) are 2.898(4) Å and 174(3)°, respectively. This type of hydrogen bond is in marked contrast to that in the crystals of the other amino acid NCAs, in which the oxygen atom of either carbonyl group in the NCA ring participates in the hydrogen bond. There is no unusually short contact among the other intermolecular distances.

Discussion

The bond distances in the NCA rings of four amino acid NCAs are given in Table 6. A significant difference in the distances C(1)–O(2) and C(2)–O(2) is seen among these compounds. In glycine NCA and L-leucine NCA, the distances of two bonds are similar to each other. On the other hand, C(1)–O(2) is significantly greater than C(2)–O(2) in L-alanine NCA and BLG NCA. The difference in L-alanine NCA is more distinct than that in BLG NCA. It is plausible that the difference is caused by the hydrogen bond in the crystalline state.

The hydrogen bonds of these amino acid NCA crystals are divided into three types:

(1) N(1)–H(1)···O(1′) as observed in glycine NCA and L-leucine NCA,

(2) N(1)–H(1)···O(3′) in L-alanine NCA,

(3) N(1)–H(1)···O(4′) in BLG NCA.

Since no oxygen atoms of carbonyl groups in the NCA ring form the hydrogen bond with N(1)–H(1) in BLG NCA, it is reasonable to take the dimensions of this NCA ring as the standard ones.

It was pointed out by Leiserowitz and Nader[7] that the oxygen atom of the amide group is more negative than that of the carbonyl group in the amide-dicarboxylic acid complexes. This implies that the limiting structure (II), shown in Fig. 4, might contribute to the resonance state in the NCA ring. However, in BLG NCA, C(2)–O(2) is shorter than C(1)–O(2), C(1)–O(1) having the same distance as C(2)–O(3). This suggests that the limiting structures (II) and (IV), which is given in a simplified form by (V), should contribute to the state in the NCA moiety.

Table 6. Comparison of the bond distances (Å) in the four NCAs
Estimated standard deviations are in parentheses.

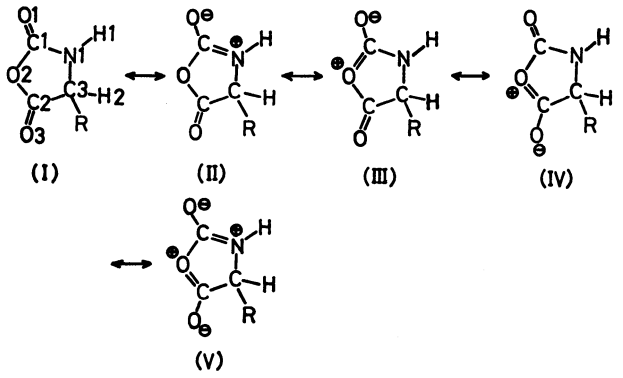

Fig. 4. The limiting canonical structures.

When O(1) forms the hydrogen bond with N(1)–H(1) as observed in glycine NCA and L-leucine NCA, the limiting structure (III) could contribute to the resonance state, on the assumption that the negative charge is attracted to the N–H···O hydrogen bond. In the glycine NCA and L-leucine NCA crystals, C(1)–O(2) is shorter and C(2)–O(2) is longer than the corresponding ones in BLG NCA. When O(3) forms the hydrogen bond with N(1)–H(1), the limiting structure (IV) would contribute for the same reason. In L-alanine NCA, C(1)–O(2) is longer and C(2)–O(2) shorter than the corresponding bonds in BLG NCA.

As for the C–O distances of carbonyl group and the N–C length, the difference is made obscure owing to the contribution of the limiting structure (II), except for the C–O distances in glycine NCA.

In the course of the polymerization process, the bonds of C(2)–O(2) and C(1)–N(1) are cleaved to release CO_2. Since the limiting structure (III) contributes to the resonance state in glycine NCA and L-leucine NCA, it is quite adequate to consider that the C(2)–O(2) bond of these amino acid NCAs should be more easily cleaved than that of the other amino acid NCAs. Contrary to such expectation, glycine NCA shows very low reactivity in the crystalline state, although the crystal of L-leucine NCA is observed to have the highest polymerizability.[2] This implies that the other factors should be taken into account. In the succeeding paper,[6] the effect of the crystalline field will be discussed.

The Crystal and Molecular Structure of *N*-Carboxy-L-leucine Anhydride at −70 °C

Hitoshi KANAZAWA,* Tohru KAWAI, Yuji OHASHI,** and Yoshio SASADA**

Department of Polymer Technology, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

***Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227*

(Received January 26, 1978)

The crystal structure of *N*-carboxy-L-leucine anhydride has been determined by means of X-ray. The crystal is orthorhombic; space group, $P2_12_12_1$; $Z=4$ with $a=6.527(1)$, $b=23.920(4)$, and $c=5.527(1)$ Å. The structure was deduced by the direct method and refined to the final R value 0.049 for 624 observed reflections by the block-diagonal least-squares method. The *N*-carboxy anhydride rings are arranged in a layer form sandwiched by hydrophobic side chains. The highest polymerizability of this compound in the crystalline state is due to the sandwich structure.

The *N*-carboxy anhydrides of α-amino acids (amino acid NCAs) are the most useful for preparing polypeptides with high degree of polymerization. Serial crystal structures of amino acid NCAs[1-3] were reported for interpreting their polymerization in the crystalline state. Of the various amino acid NCAs, the title compound is the most reactive in the solid state, polymerizing more rapidly in the crystalline state than in the heterogeneous system using acetonitrile as the solvent of NCA.[4] In a previous paper,[3] we proposed that the charge distribution of the five-membered ring of the amino acid NCA affects its polymerizability. However, this factor alone is not sufficient to explain the high reactivity. We have examined other factors, especially the crystalline field.

Experimental

The title compound was synthesized in the same way as glycine NCA,[1] and purified by recrystallization several times with ethyl acetate–hexane and diisopropyl ether–hexane. L-Leucine NCA thus obtained (*ca.* 100 mg) was dissolved in an appropriate vessel with 20 ml of diisopropyl ether. The vessel was placed in a covered bottle containing hexane and allowed to stand overnight at about 6 °C. Colorless rod-like crystals suitable for X-ray work were obtained.

Since the crystal decomposes easily owing to polymerization at room temperature, data collection was carried out at −70 °C, using a cooling equipment with liquid nitrogen. The unit cell dimensions were determined by the least-squares refinement with 25 high-angle reflections at −70 °C and room temperature. The crystal data are summarized in Table 1.

TABLE 1. CRYSTAL DATA OF L-LEUCINE NCA AT −70 °C (a) AND AT ROOM TEMPERATURE 20 °C (b)

(a)	(b)

M.W.: 157	
Orthorhombic	
$a=6.527(1)$ Å	$a=6.518(4)$ Å
$b=23.920(4)$	$b=23.983(14)$
$c=5.527(1)$	$c=5.531(5)$
$U=862.9(3)$ Å^3	$U=864.7(11)$ Å^3
Space group: $P2_12_12_1$	
$Z=4$	
$D_x=1.21$ g·cm^{-3}	$D_x=1.21$ g·cm^{-3}
$D_m=\cdots$	$D_m=1.21$ g·cm^{-3}
μ(Mo $K\alpha$)$=1.13$ cm^{-1}	

The intensities for the reflections with $2\theta\leqq 40°$ were collected on a Rigaku automated diffractometer with graphite monochromated Mo $K\alpha$ radiation. The usual ω-2θ scan technique was employed with a scan speed $4°(2\theta)\text{min}^{-1}$. A total of 693 reflections were observed, in which 69 with $|F_o|<3.0\sigma(|F_o|)$ were considered as zero reflections. The usual Lorentz and polarization corrections were made. Absorption was uncorrected.

Structure Determination

The structure was determined by the direct method using the program MULTAN. Refinement of the structure was carried out by the block-diagonal least-squares method. All the hydrogen atoms were revealed on a difference map. The final refinement was performed including these hydrogen atoms with isotropic temperature factors. The weighting scheme, $w=0.3$ for $|F_o|<2.52$ and $|F_o|>37.75$, and $w=(4.0476-0.3027|F_o|+0.00758|F_o|^2)^{-1}$ for the other reflections. The final R value became 0.049 for all the non-zero reflections. At the final stage, no peaks higher than 0.11 eÅ^{-3} were found on the difference map. The atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[5] The final atomic parameters and their standard deviations are given in Table 2. A list of the observed and calculated structure factors is kept in the office of the Chemical Society of Japan (Document No. 7822). Computation was carried out on the HITAC 8700 computer at this institute.

Description of the Structure

The bond lengths and angles and the numbering of the atoms are shown in Fig. 1. The distances of C(1)–O(2) and C(2)–O(2) are in good agreement with the corresponding ones in glycine NCA and distinct from the corresponding ones in L-alanine NCA and γ-benzyl-L-glutamate NCA (BLG NCA). Other bond distances in the five-membered ring are close to the corresponding ones in these three NCAs. The C(4)–C(5) and C(5)–C(6) bonds are slightly shorter probably due to ignoring of the high-angle reflections. The angles in the five-membered ring are also in good agreement with the corresponding ones of the other three NCAs. The bond lengths and angles involving the hydrogen atoms are

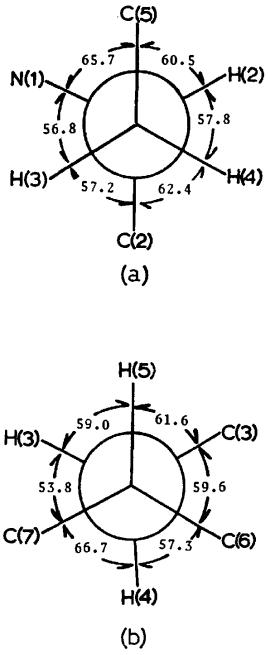

Fig. 2. Newman projection along the bonds (a) C(4)–C(3) and (b) C(5)–C(4).

explains the fact that polymerization cannot proceed along the b axis, the cleavage plane of the crystal being perpendicular to the b axis.

Discussion

The hydrogen bonding schemes differ for the four amino acid NCA crystals so far determined. The distances and angles are summarized in Table 5. The hydrogen bonds are fairly strong.[6] In the crystal of glycine NCA, the molecules form dimers through two hydrogen bonds around the center of symmetry. In the crystals of L-alanine NCA, L-leucine NCA and BLG NCA, the hydrogen bonds extend as linear chains along the b, a, and c axes, respectively.

When the amino acid NCA molecules polymerize progressively, N(1) should attack the C(2) atom of the neighboring molecule nucleophilically.[7] This indicates that in the crystal the C(2) atom of the amino acid NCA molecule contiguous to the terminal amino group of the polymer comes close to the amino group. The distance of the movement required to make a bond is 2.0—5.0 Å for these amino acid NCA crystals.

The dimer structure, as found in the glycine NCA crystal, is unfavorable for progressive polymerization, since two hydrogen bonds should be broken or two molecules as a dimer should move in the crystal. Low reactivity was thus observed for the glycine NCA crystal.

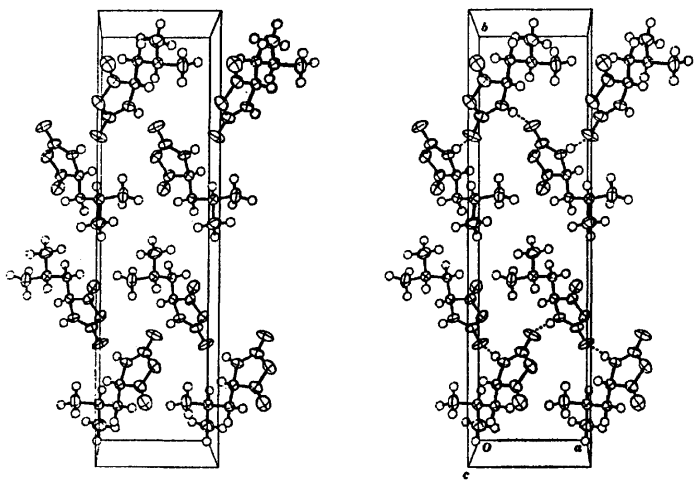

Fig. 3. Stereoscopic drawing of the crystal structure of L-leucine NCA viewed along the c axis. The thermal ellipsoids are drawn at a 50% probability level and the hydrogen atoms are shown in circles.

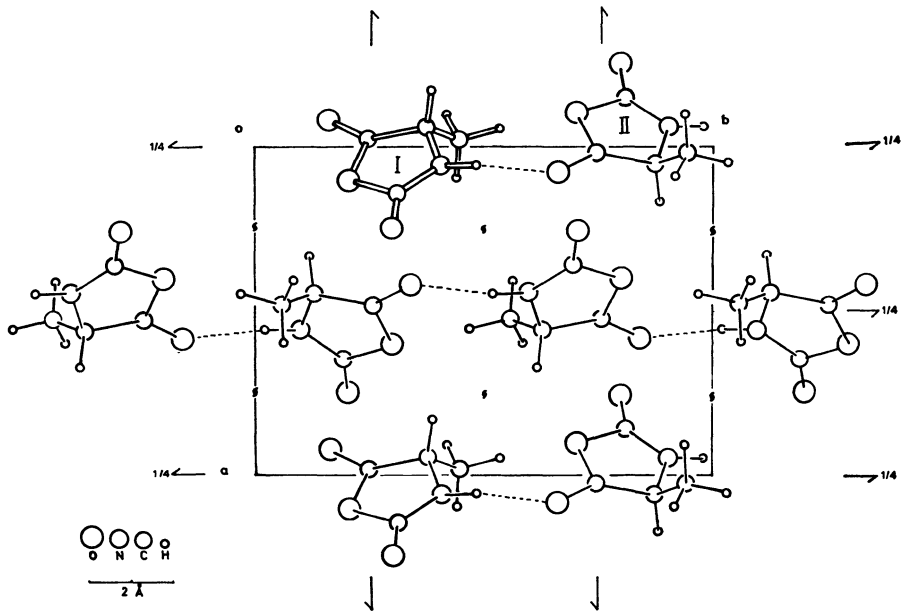

Fig. 4. Projection of the crystal structure of L-alanine NCA viewed along the c axis. I,(x,y,z); II, $(-x,1/2+y,1/2-z)$. Hydrogen bonds are shown by broken lines.

In the BLG NCA crystal, the hydrogen bond is formed between N(1)–H(1) and the oxygen atom of the carbonyl group in the side chain of the neighboring molecule. Since the five-membered ring would drag the side chain of the neighboring molecule, polymerization cannot occur easily. The reactivity of BLG NCA in the crystalline state is not so high as in the heterogeneous system.[4]

On the other hand, the crystal of L-leucine NCA has the following favorable conditions:

(1) because of the sandwiched layer structure, the polymerization proceeds within one sandwich and would not destroy the molecular arrangement in the neighboring sandwich, (2) within a sandwich, the side chains do not hinder the five-membered rings from approaching each other, (3) the side chain can move easily since it does not entwine with side chains of the neighboring molecules and relatively loose contacts are observed between them (compare the structure and the density of the L-leucine NCA crystal with the corresponding ones of the BLG NCA crystal), and (4) in the process of polymerization, the crystal should be easily cloven between sandwichs, leaving a gap between them, and carbon dioxide goes out through the gap without deteriorating the alignment of the amino acid NCA molecules.

The crystal of L-alanine NCA, whose structure viewed along the c axis is shown in Fig. 4, has no such favorable conditions as a result of the N(1)–H(1)···C(3′) hydrogen bond. For example, the shortest distance 3.591 Å of N(1)···C(2), is found between molecules I and II. However, the methyl group prevents molecule II from approaching I. Polymerization does not seem to proceed without destroying the arrangement of the monomers. The L-alanine NCA crystal is very stable in the air, having very low reactivity.

The type of hydrogen bond, N(1)–H(1)···O(1′), is the most favorable for polymerization, taking into account the charge distribution of the five-membered ring and facility of the ring opening.[3] However, high reactivity cannot be attained only by this factor, as suggested by the low reactivity of the glycine NCA crystal. Thus, it is quite reasonable that the sandwich structure accelerates the reactivity in the crystalline state. Because of the sandwich structure and the charge distribution in the NCA ring, L-leucine NCA is more reactive in the crystalline state than in the solution state, and even in the molten state.

Recently a Weissenberg photograph of a polymer crystal formed by keeping an L-leucine NCA crystal on the goniometer head for a few days, indicated that the polymer has the α-helical structure elongated along the c axis. This can be interpreted easily on the basis of the present crystal structure.

A Stereoselective Rule for the Cross-bicyclization in Linear Conjugated Polyenes

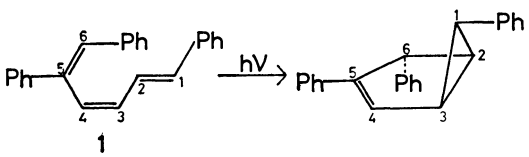
Kazuyoshi TANAKA and Kenichi FUKUI*

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

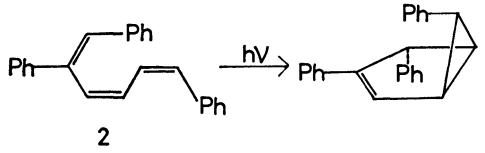
(Received January 27, 1978)

A concept of the cross-bicyclization complementary to that of the cycloaddition is defined for interpreting the mechanism of the simultaneous bicyclizations in linear conjugated polyenes based on the perturbation treatment in the frame of Hückel MO's. Stereoselective modes in thermal and photo-induced reactions are shown to depend on the sign of the bond-bond-polarizability, $\Pi_{rs,tu}$, of the concerned polyene, where r, s, t, and u refer to the atomic positions at which the bicyclization occurs. From the properties of $\Pi_{rs,tu}$ of linear conjugated polyenes, these modes are simply determined by the relationship among r, s, t, and u in thermal cases, but not in photo-induced ones. The predicted stereoselective modes are discussed in line with experimental observations. It is demonstrated that the "symmetry-disfavored" reactions inferred from the usual cycloaddition mechanism can be interpreted as the concerted cross-bicyclization reactions.

The stereoselective rules from the concept of the concerted cycloaddition reactions by Woodward and Hoffmann[1] or those from the orbital interaction approach, particularly among the highest occupied (HO)MO, the lowest unoccupied (LU)MO, and the singly occupied (SO)MO, by the present authors' group[2] have clearly interpreted steric control modes of both thermal and photo-induced (2+2) or (4+2) cycloadditions and so on. These rules have also been applied to most of the intramolecular cases without hesitation. Some of the recent experimental informations, however, have shown discrepancies with the predictions issued from the above rules with regard to the stereoselections in photo-induced (2+2) and (4+2) cycloadditions in the conjugated dienes and trienes, respectively. For instance, Padwa *et al.* have essentially provided (4_s+2_a) photoisomerizations of **1** and **2** in accordance with the rules of cycloadditions,[3]

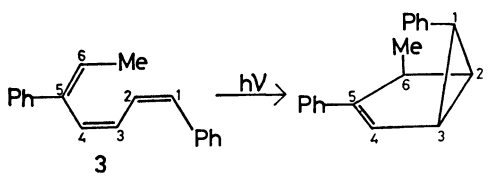


1

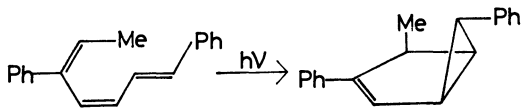


2

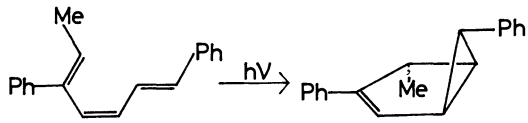
while, on the contrary, Courtot *et al.* have unambiguously observed disfavoured (4_a+2_a) modes in those of **3**, **4**, and **5** with monitoring by NMR.[4]



3



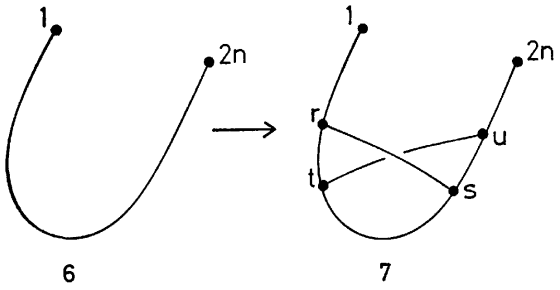
4



5

Other examples of disfavored modes in photoisomerizations of dienes or trienes have also been found out[5-8] as will be shown later. Almost all of these "troublesome" reactions within the category of the usual cycloadditions have been excluded out from the concerted reactions. But why concerted in **1** and **2**, and non-concerted in **3**, **4**, and **5**? Can we not interpret the concertedness and the stereoselective modes of these bicyclizations in conjugated polyenes? The answer is yes. At first it should be pointed out that the stereoselective rules of the cycloaddition mentioned above are suitable for merely cyclic additions between two separate conjugated polyene parts whichever they are in different molecules or in a molecule. Therefore, from the theoretical point of view, one had better distinguish the nature of the bicyclizations in a conjugated polyene from the usual cyclic additions. In this paper, we will present a new theoretical interpretation, which is complementary to the concept of the concerted cycloaddition reactions, so that one might comprehend the concertedness and the stereoselective rules of the above reactions with "disfavored" mode.

We define a simultaneous bicyclization between the r-th and the s-th and between the t-th and the u-th carbons (**6**→**7**) in a linear conjugated polyene containing $2n$ π electrons as a $[r,s/t,u]$ *cross-bicyclization* under the condition that r and s are odd and t and u are even or *vice versa*, where the numbering of carbons is counted from the end of conjugated carbon chain and $r<t<s<u$ holds.

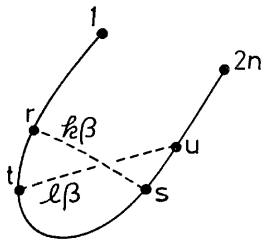


6 7

In the cross-bicyclization thus defined, the conjugation between the s-th and the t-th carbons generally exists throughout the process of reaction. This is the point of essential importance. If this conjugation does not exist, the reaction would turn out as a usual cycloaddition. In what follows, we try to establish a simple but reasonable method in such reactions employing the perturbation theory in the scheme of the Hückel MO approach.[9] Similar method has been used successfully to treat the stereospecific ring-closure of conjugated polyenes.[10] Then the predicted stereoselective rules will be applied to interpret the latest several experimental results.

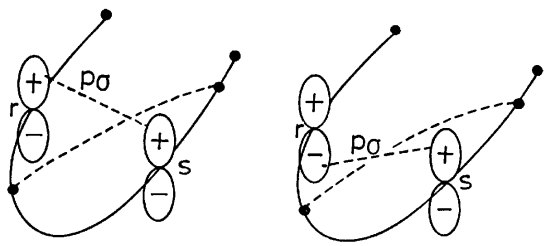
Formulation

Consider two simultaneous conjugations, $k\beta$ and $l\beta$, appearing as a perturbation as indicated in **6'**.



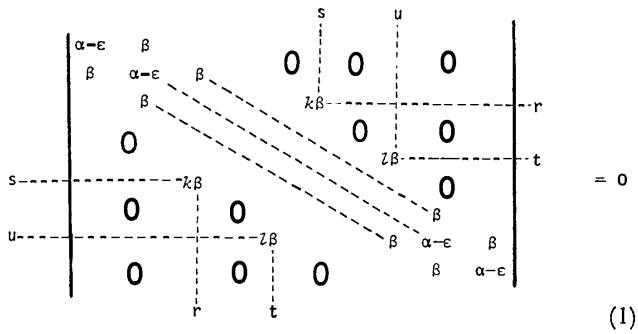
6'

The quantity β is the resonance integral between two adjacent 2pπ atomic orbitals (AO's). Hence, $k\beta$, for instance, is adopted to be the resonance integral between ϕ_r and ϕ_s when σ-like overlapping of these two AO's in the distorted π electron system occurs, where ϕ_r denotes 2pπ AO of the r-th carbon. The signs of $k\beta$ and $l\beta$ concern the mode of overlap stabilization as indicated below.



$k\beta<0(k>0)$; Disrotatory $k\beta>0(k<0)$; Conrotatory

Letting α be the Coulomb integral of 2pπ AO, the perturbed secular determinant in the present case becomes as follows.



(1)

According to the procedure previously reported ("method of perturbed secular determinant"),[11] we get the following formula within the second-order perturbation treatment.

$$\frac{\Delta E}{\beta} = 2kP_{rs} + 2lP_{tu} + k^2\Pi_{rs,rs} + 2kl\Pi_{rs,tu} + l^2\Pi_{tu,tu} \qquad (2)$$

Here ΔE represents the change in the π-electronic energy, and P_{rs} and $\Pi_{rs,tu}$ are the same quantities as the usual bond-order and bond-bond-polarizability, respectively, defined as

$$P_{rs} = \sum_i^{\text{all}} n_i C_r^i C_s^i, \qquad (3)$$

$$\Pi_{rs,tu} = \frac{1}{2}\sum_i^{\text{all}}\sum_{j(\neq i)}^{\text{all}} \times n_i(2-n_j)\frac{(C_r^iC_s^j + C_r^jC_s^i)(C_t^iC_u^j + C_t^jC_u^i)}{x_i - x_j} \left(x_i = \frac{\varepsilon_i - \alpha}{\beta}\right) \qquad (4)$$

where n_i, ε_i, and C_r^i represent the occupation number, the orbital energy, and the coefficient of ϕ_r, respectively, of the i-th MO of the unperturbed system **6**. Since the sign of β is negative, the overlap stabilization is brought about in the system when the sign of the right hand side in Eq. 2 becomes positive. We have only to judge the sign of the next formula, because the required values of P_{rs} and P_{tu} vanish in the case of the present $2n$ conjugated polyene.

$$\frac{\Delta E}{\beta} = k^2\Pi_{rs,rs} + 2kl\Pi_{rs,tu} + l^2\Pi_{tu,tu} \qquad (2')$$

It is easily shown that this quadratic form is positive by the Cauchy-Schwartz' inequality. According to the sign of the $\Pi_{rs,tu}$ value, the mode of cross-bicyclization may be classified into the following four types of rotations in the direction of increasing value of $\Delta E/\beta$.

$\Pi_{rs,tu}$	k	l	Rotating mode
positive	positive	positive	A(disrotatory-disrotatory)
	negative	negative	B(conrotatory-conrotatory)
negative	positive	negative	C(disrotatory-conrotatory)
	negative	positive	D(conrotatory-disrotatory)

No distinction can be made of mode A from B, nor of

mode C from D within the present second-order perturbation treatment. However, in some favorable cases, consideration of steric circumstances, which is important in such cases as the cross-bicyclization, may assist in predicting the more probable mode. It is not difficult to show that, in thermal case, the sign of $\Pi_{rs,tu}$ is positive or negative according as $(s-r)+(u-t)$ is equal to $4m+2$ or $4m$, respectively, from the integral representation for $\Pi_{rs,tu}$ obtained by Coulson and Longuet-Higgins.[9c] On the contrary, in photo-induced case, there is no such a simple relationship between the sign of $\Pi_{rs,tu}$, which is calculated in regard to the first excited configuration, and r, s, t, and u. Hence one has to examine the numerical value of the concerned $\Pi_{rs,tu}$ in order to predict the mode of photo-induced cross-bicyclization.

Stereoselective Modes of Cross-bicyclization and Cycloaddition

For the cases of diene, triene, and tetraene, we show all kinds of rotating modes in thermal and photo-induced cross-bicyclizations in Table 1 along with the numerical values of $\Pi_{rs,tu}$. Interestingly, it is seen that the predicted stereoselective modes make no difference in both thermal and photo-induced reactions in each cross-bicyclization of diene, triene, and tetraene.[12] These predictions are remarkably different from those issued from the concept of the cycloaddition by Woodward and Hoffmann or from the frontier orbital interaction approach. It should also be emphasized that modes A and B are favored when $(s-r)+(u-t)$ is equal to $4m+2$, while modes C and D are favoured when it is $4m$ in these polyenes. The cases of longer polyenes could also be treated by a simple extension of the present calculations, with which we will not further deal in this study.

Let us treat here some of the usual cycloadditions with our formulation for the sake of comparison. In the case of the (4+2) cycloaddition, for instance, the triene is divided into a diene and an olefin and thus the conjugation between C_2 and C_3 is cut off as shown in Fig. 1(A). In this case, the amplitudes of the frontier orbitals on C_1, C_2, C_3, and C_6 are large and the orbital energy differences among them are small as a matter of fact, so $\Pi_{rs,tu}$ defined by Eq. 4 mainly depends on the expansion terms of $(i,j)=(2,4)$ and $(3,5)$ in the thermal process, while of $(i,j)=(2,3)$ and $(4,5)$ in the photo-induced process. In other words, the HOMO-LUMO interactions in the former process and the HOMO-SOMO and the SO'MO-LUMO interactions in the latter between a diene and an olefin shown in Figs. 1(B) and (C), respectively, are essentially important in order to predict the distinct stereoselective mode in

Table 1. Rotating modes in cross-bicyclization

Polyene	$[r,s/t,u]$	Thermal ($\Pi_{rs,tu}$)	Photo-induced ($\Pi_{rs,tu}$)
Diene	[1,3/2,4][a]	C,D(−0.3578)	C,D(−0.1789)
Triene	[1,3/2,6][b]	A,B(0.2352)	A,B(0.0762)
	[1,3/2,4]	C,D(−0.2906)	C,D(−0.0694)
	[1,5/2,6]	C,D(−0.3597)	C,D(−0.1661)
	[3,5/2,4]	C,D(−0.0274)	C,D(−0.2072)
Tetraene	[1,3/2,4]	C,D(−0.2659)	C,D(−0.0410)
	[1,3/2,6]	A,B(0.2013)	A,B(0.0053)
	[1,3/2,8][c]	C,D(−0.1809)	C,D(−0.0029)
	[1,5/2,6]	C,D(−0.2998)	C,D(−0.1269)
	[1,5/2,8]	A,B(0.2359)	A,B(0.0725)
	[1,5/4,6]	A,B(0.1863)	A,B(0.0830)
	[1,5/4,8][d]	C,D(−0.1685)	C,D(−0.1135)
	[1,7/2,8]	C,D(−0.3548)	C,D(−0.1965)
	[3,5/4,6]	C,D(−0.2270)	C,D(−0.0878)
	[3,5/2,4]	C,D(−0.0311)	C,D(−0.1626)
	[3,7/2,6]	C,D(−0.0515)	C,D(−0.1649)
	[3,7/2,4]	A,B(0.0054)	A,B(0.0801)

a), b), c), and d) have been classified into (2+2), (4+2), (6+2), and (4+4) cycloaddition, respectively, up to now.

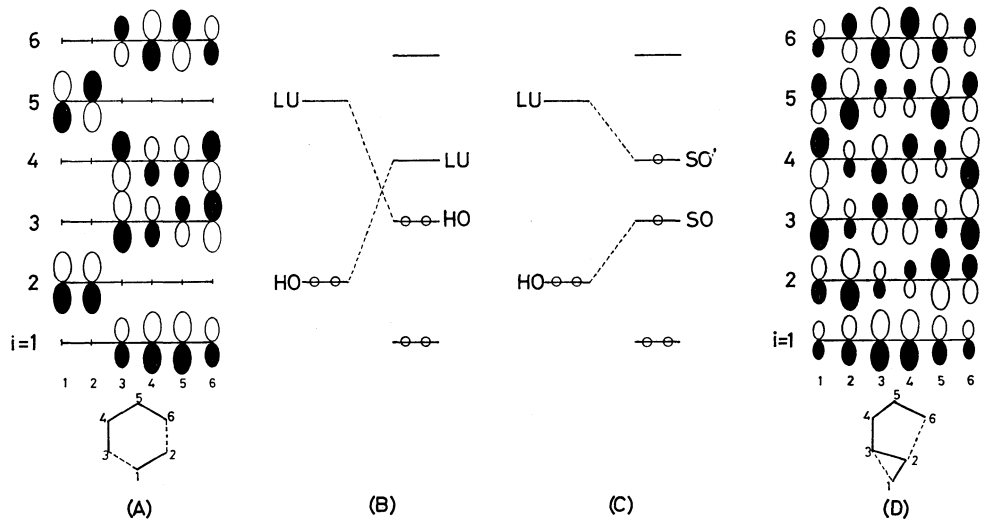


Fig. 1. Orbital patterns of the systems composed of (A) an olefin and a diene, and (D) a triene. (B) and (C) show the frontier orbital interactions in (A) in thermal and photo-induced processes, respectively. It should be noted that σ bond between C_2 and C_3 may remain in (A).

TABLE 2. STEREOSELECTIVE MODES IN CYCLOADDITION THROUGH THE TREATMENT OF THE PRESENT FORMULATION

Type of Cycloaddition	Thermal ($\Pi_{rs,tu}$; its main term[a])	Photo-induced ($\Pi_{rs,tu}$; its main term[b])
2+2	C,D(−0.5000; −0.5000) (2_s+2_a or 2_a+2_s)	A,B(+∞; +∞) (2_s+2_s or 2_a+2_a)
4+2	A,B(0.3416; 0.4472) (4_s+2_s or 4_a+2_a)	C,D(−0.8292; −0.9472) (4_a+2_s or 4_s+2_a)
6+2	C,D(−0.2588; −0.3759) (6_a+2_s or 6_s+2_a)	A,B(0.4185; 0.4893) (6_s+2_s or 6_a+2_a)
4+4	C,D(−0.2683; −0.4236) (4_s+4_a or 4_a+4_s)	A,B(+∞; +∞) (4_s+4_s or 4_a+4_a)

a) Contribution to $\Pi_{rs,tu}$ from the HOMO-LUMO interactions between two separate polyene parts. b) Contribution to $\Pi_{rs,tu}$ from the HOMO-SOMO and the SO'MO-LUMO interactions between two separate polyene parts.

each process of the cycloaddition. On the contrary, in the case of the cross-bicyclization in a triene, the same criterion would no longer serve because of the alterations of the amplitudes in the MO's with i=2, 3, 4, and 5 on the concerned carbons as shown in Fig. 1(D). In this sense one can not always expect a conspicuous difference of the stereoselective mode between the thermal and photo-induced processes and has to sum up extending over all MO's such as in Eq. 4 in order to judge the signs of $\Pi_{rs,tu}$'s in the cross-bicyclization apart from the cycloaddition.

The values of $\Pi_{rs,tu}$ and the predicted stereoselective modes for cycloadditions in the cases of (2+2), (4+2), (6+2), and (4+4) are listed in Table 2 along with the main terms in $\Pi_{rs,tu}$ arising from the frontier orbital interactions. For cycloaddition reactions, the required $\Pi_{rs,tu}$'s are formally evaluated on the basis of the secular determinant in Eq. 1 with setting the resonance integral to be zero at the position where the conjugation is cut off. In photo-induced (2+2) and (4+4) cases, the degeneracies between the HOMO and the SOMO and between the SO'MO and the LUMO invalidate to evaluate the required $\Pi_{rs,tu}$. Actually, however, these degeneracies would be reduced by the energetical splittings between these MO's on account of the presence of the electron correlation as illustrated in Fig. 2.[13] Therefore, we tentatively set here the

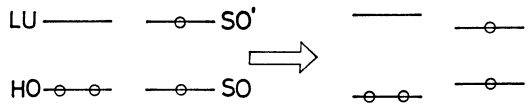

Fig. 2. The splittings of the levels between the HOMO and the SOMO and between the SO'MO and the LUMO.

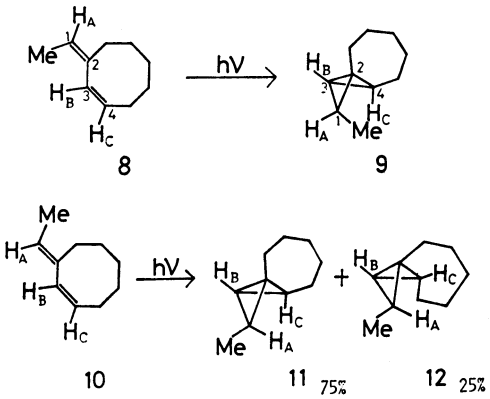
values of ($x_{HO}-x_{SO}$) and ($x_{SO'}-x_{LU}$) in Eq. 4 to be infinitely small positive, from which the concerned $\Pi_{rs,tu}$'s are positive infinite. This means that photo-induced [1,3/2,4] cross-bicyclization of diene or [1,5/4,8] case of tetraene might rather favour the (2+2) or (4+4) cycloaddition, respectively, from the viewpoint of the energetical stabilization, as will be seen in the next section.

Application

[1,3/2,4] Cross-bicyclization of Diene. Dauben and Ritscher have early obtained the photoproducts **9**, **11**, and **12** from ethylidenecyclooctenes **8** and **10**.[5]



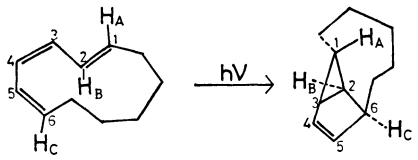
Both **9** and **11** are the results of mode B and compatible with the usual (2_a+2_a) cycloaddition. However, **12** is the result of the disfavoured mode C or D ((2_s+2_a) or (2_a+2_s)), so they have supposed an anomalous concerted reaction from a vibrationally relaxed singlet having an electronic configuration composed of an allyl anion and a methyl cation, while, from the standpoint of the cross-bicyclization, **12** is a reasonable product but **9** and **11** are not. The reason why these reactions rather favor these products can be explained by not a little energetical stabilizations in the photo-induced (2+2) cycloadditions as has been stated above. Furthermore, some steric hindrance in connection with the cyclooctene ring might play a role in separating the C_2–C_3 conjugation. Therefore, the photo-induced [1,5-/4,8] case of tetraene, which has not been reported, would also be of interest because of the possibility of the competition with (4+4) cycloaddition.

[1,3/2,6] Cross-bicyclization of Triene. In the photoinduced [1,3/2,6] case of triene, mode A or B is favored, which predicts exactly the products from **3**, **4**, and **5** provided by Courtot *et al.*[4] The products from **1** and **2** by Padwa *et al.*,[3] however, show the opposite mode of stereoselection in the sense of the cross-bicyclization. In order to examine these discrepancies, we have evaluated $\Pi_{13,26}$ values as functions of the resonance integrals between C_2 and C_3 (β_{23}) of **1** or **2**, and **3**, **4**, or

TABLE 3. THE VALUES OF $\Pi_{13,26}$ AS FUNCTIONS OF β_{23} IN **1** OR **2**, AND **3**, **4**, OR **5** IN THEIR FIRST EXCITED CONFIGURATIONS

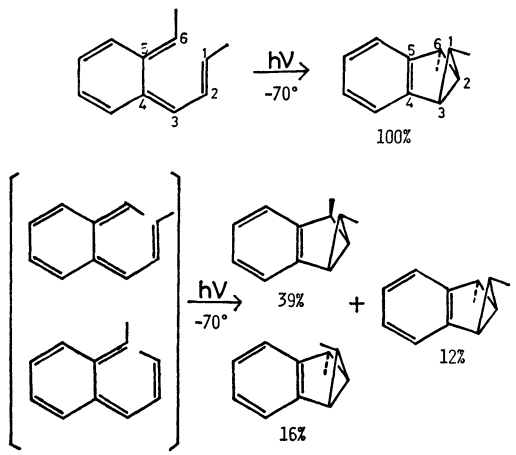
β_{23}	**1** or **2**	**3**, **4**, or **5**
β	0.0382	0.0859
0.7β	0.0042	0.0822
0.6β	−0.0219	0.0686
0.5β	−0.0599	0.0391

5 in their first excited configurations taking phenyl groups into considerations as listed in Table 3. It is evidently seen that the $\Pi_{13,26}$ of **3**, **4**, or **5** used by Courtot *et al.* is less sensitive to the weakening of β_{23}, while that of **1** or **2** by Padwa *et al.* is the smaller at $\beta_{23}=\beta$ and changes its sign at $\beta_{23}=0.6\beta$. That is, the stereoselective modes in photo-induced [1,3/2,6] cases of **1** and **2** will more easily change into that issued from the (4+2) cycloaddition than those of **3**, **4**, and **5**, according to the weakening of the conjugation between C_2 and C_3, if it takes place for some reason. We infer that these situations are reflected in the reactions of Padwa *et al.* to a certain extent, although more detailed calculation including σ electrons is requisite to provide a definite information on these species. An example as to the hexatriene free from the conjugated substituents has also been shown. Dauben and Kellogg have obtained the photoproduct *via* (4_a+2_a) cycloaddition from 1,3,5-cycloundecatriene,[6]

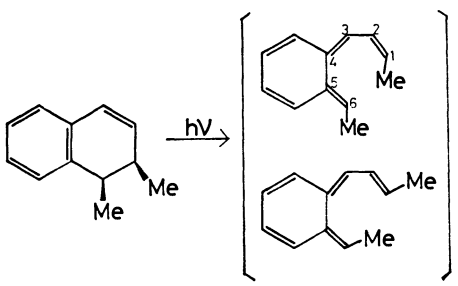


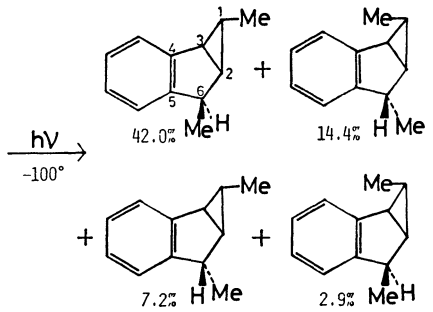
and supposed that the cyclization is initiated from the vibrationally relaxed first excited singlet state like the above case of ethylidenecyclooctene. But this stereoselective mode is easily explained by the cross-bicyclization of triene.

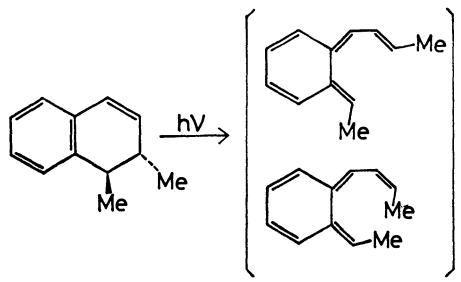
There have been other examples of the cross-bicyclizations that are found out in the photoisomerizations of benzohexatrienes reported by Seeley,[7]

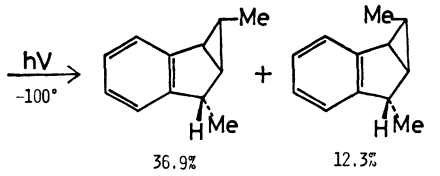


and by Sieber *et al.*[8]









Since the major products of these reactions are not controlled by the stereoselective modes from the cycloaddition, these authors have ascribed these results to non-concerted reactions. But we are now in a position to tell that these reactions are concerted as well with the aid of the concept of the cross-bicyclization.

Summary

We have defined the concept of the cross-bicyclization complementary to that of the cycloaddition and pointed out the essential difference between these two. The predicted stereoselective modes from the cross-bicyclization are in reasonable agreement on the whole with the experimental observations that have been discarded from the category of the concerted reactions because of the faith in the cycloaddition rules. However, one should pay attention to the application of the rules to photo-induced [1,3/2,4] case of diene or [1,5/4,8] case of tetraene as well as to the case of polyene with conjugated substituents. To the authors' knowledge, any stereospecific bicyclizations in a conjugated polyene treated by the concept of the cycloaddition up to the present have been probed in this study.

It is also an interesting conclusion, in diene, triene, and tetraene, that the thermal and photo-induced processes happen to yield quite identical results and that there occurs a distinct difference in the stereoselective mode according as $(s-r)+(u-t)$ is equal to $4m+2$ or $4m$. Further experimental observations are desirable in order to assess the utility of the present concept of the cross-bicyclization.

This work was supported by Grant-in-Aid for Scientific Research from the Ministry of Education of Japan (No. 139012). One of the authors (K.F.) wishes to thank Prof. P. Courtot for letting him know interesting photochemical results.

12) The identity of the predicted stereoselective modes in thermal cases with those in photo-induced ones is quite accidental. For instance, $\Pi_{13,210}$ of pentaene is positive (0.1491) in thermal case, whereas it is negative (−0.0341) in photo-induced case. Therefore, thermal and photo-induced [1,3/2,10] cases of pentaene will show different stereoselective modes each other.

Potential of Hydrocarbons for Photochemical Conversion of NO to NO_2

Nobuaki WASHIDA,* Gen INOUE, Hajime AKIMOTO, and Michio OKUDA
The National Institute for Environmental Studies, P.O. Yatabe, Tsukuba, Ibaraki 300-21
(Received January 31, 1978)

The factor F, the number of NO molecules which are converted photochemically into NO_2 when one hydrocarbon molecule is consumed, was determined for fourteen different hydrocarbons in the photochemical oxidation process. Experiments were carried out in a 67 dm^3 Pyrex reaction chamber in which a mixture of hydrocarbon, NO, H_2O, and air was irradiated by a xenon short arc lamp. In the range from low to middle conversion, hydrocarbons and NO decayed nearly exponentially, NO being converted into NO_2. The observed value of F was approximately two for most of the hydrocarbons studied. The value is in line with the long chain mechanism involving OH radicals predicted by Heicklen *et al.* Only *m*-xylene gave a larger F value. Reaction sequences of the long chain mechanism caused by OH radicals were discussed, a generalized kinetic model for the chain mechanism being proposed. This will be useful for the atmospheric modeling of photochemical smog.

When mixtures of hydrocarbons and nitrogen oxides (NO and NO_2) in air are irradiated with ultraviolet radiation, NO is converted into NO_2 as hydrocarbons are consumed.[1,2] After the concentration of NO_2 passes through a maximum, O_3 and other oxidants such as PAN are produced as the NO_2 is consumed.

Heicklen *et al.*[3] proposed a long chain mechanism involving OH radicals for the photochemical conversion of NO into NO_2 in urban atmospheres. According to their mechanism, the conversion is promoted by the reaction of NO with $RO_2\cdot$ radicals which are formed in the reaction of organic free radicals and O_2.

$$RO_2\cdot + NO \longrightarrow RO\cdot + NO_2 \quad (1)$$

In the reaction with propylene,[4] 2-methylpropene,[3] and butane,[3] Heicklen *et al.* proposed the following overall reactions.

$$C_3H_6 + 2NO + 2O_2 \longrightarrow CH_3CHO + CH_2O + 2NO_2 \quad (2)$$

$$C_4H_8 + 2NO + 2O_2 \longrightarrow C_3H_6O + CH_2O + 2NO_2 \quad (3)$$

$$C_4H_{10} + 2NO + 2O_2 \longrightarrow C_4H_8O + H_2O + 2NO_2 \quad (4)$$

According to their suggestion, two NO molecules should be converted into NO_2 when one hydrocarbon molecule is consumed. However, if the intermediate radicals degrade further to form simpler aldehydes such as CH_2O in Reactions 2, 3, and 4, three to five NO molecules should be converted into NO_2 when one hydrocarbon molecule is consumed.[2]

This report deals with the measurement of the number of NO molecules (factor F) which would be converted into NO_2 when one hydrocarbon molecule is consumed.

Experiments were carried out for fourteen different hydrocarbons. The results would be useful for the computer simulation studies of atmospheric photooxidation processes.

Experimental

Experiments were carried out with use of a Pyrex cylinder as the reaction chamber, inner diam 240 mm, length 1660 mm and volume 67 dm^3, which can be evacuated to less than 1×10^{-6} Torr. Each end of the reaction chamber was sealed with a Pyrex window 20 mm thick. The light source was a 500 W xenon short arc lamp and a parallel light beam of 200 mm ϕ was obtained with an elliptic mirror, a lens, and an off-axis parabolic mirror. The effective light intensity for the primary photo-decomposition rate of NO_2 was 0.08 min^{-1}.

An oil free pumping system consisting of an ion pump, titanium getter pump, cryo-sorption pump, and oil rotary pump with a liquid nitrogen cooled foreline trap was used in order to avoid oil contamination of the reaction chamber.

Hydrocarbons and NO were first subjected to pressure reading in a 105 ml flask, and then expanded to the reaction chamber. After that, water vapor and air were introduced through four inlets. In order to verify that all the gases had been mixed homogeneously, four sampling outlets were attached to the chamber, at the center, at one-fourth the distance from one end, and at both ends. After one and a half hours, the contents of sample gases from the four different ports reached the constant values. After this, sampling was done through the center port.

The decay of hydrocarbons were measured by a F.I.D. gas chromatograph, and the concentrations of NO and NO_2 were monitored by a chemiluminescent NO_x analyzer (Monitor Labs. Model 8440). The analyzer is capable of measuring simultaneously the concentrations of NO and total NO_x, where total NO_x is the sum of NO, NO_2, and other nitrogen containing compounds which can be reduced to NO by a molybdenum converter.

The concentration of reactants was 0.5—2 ppm of hydrocarbons and 1—2 ppm of NO in 1 atm of air, the relative humidity being about 60%. The mixture was irradiated until 50—60% of NO was converted into NO_2. In the case of T.M.E. (2,3-dimethyl-2-butene), the reaction proceeded too fast for consecutive GC analysis. Mesh screens were placed between the chamber and the light source in order to reduce the light intensity. The reaction mixture was drawn first into a constant volume glass bulb (700 cm^3) and then concentrated in a GC sampling tube cooled by liquid nitrogen. After being subjected to the concentration process, the sampling tube was heated and the sample was fed into the gas chromatograph directly.

Sampling to the GC and to the NO_x analyzer was done every 20 or 30 min. When sampling had been carried out 7—10 times, the pressure of the reaction chamber decreased to *ca.* 600 Torr. The pressure drop effect on the measurements was calibrated in advance and all the data are corrected for the pressure change.

Chemicals (research grade, Wako Pure Chemical Ind.) were used without further purification except degassing. The gases, propylene and *cis*-2-butene (research grade, Takachiho

Kogyo Co.), pure air (pure gas B, Nippon Sanso), and NO (research grade, Matheson) were used without purification.

Before irradiation, the initial concentrations of NO and NO_2 in the mixture were measured by a NO_x analyzer. Usually, *ca.* 0.1 ppm of NO_2 was detected in a mixture containing *ca.* 1 ppm of NO.

The impurity of air and organic compounds adsorbed on the wall of the reaction chamber might convert NO into NO_2 by irradiation. In order to check the impurity effect a mixture of NO, water, and air was irradiated. The effect was found to be negligible.

Results and Discussion

When a dry mixture of hydrocarbon and NO with a small amount of NO_2 is irradiated, the initial decay of hydrocarbon and NO is very slow, showing an induction period, then the decay becomes faster as the reaction proceeds.[1,2] The time dependency of the concentrations of hydrocarbon and NO could not be followed by an exponential decay. On the other hand, if water vapor is added to the mixture, for example, at a humidity of 50%, the decrease of hydrocarbon and NO is much faster than for the dry mixture and is well approximated by an exponential decay up to the middle conversion region.[5] This could be explained by an equilibrium reaction between NO, NO_2, and H_2O and HONO.[6]

$$NO + NO_2 + H_2O \rightleftarrows 2HONO \qquad (5)$$

The HONO formed is photolyzed, giving OH radicals.[7]

$$HONO + h\nu(290\text{—}400\ \text{nm}) \longrightarrow OH + NO \qquad (6)$$

Thus, in the wet system the reaction can be initiated by OH radicals and is followed by long chain reactions involving-OH radicals.[3] In this case the steady state concentration of OH radicals will be reached in a shorter reaction time.[8]

The result in the $C_3H_6/NO/H_2O$/air system is shown in Fig. 1. Propylene and NO decay nearly exponentially except for a few points after starting, the total NO_x remaining unchanged. According to reports by Winer *et al.*[9] and Spicer and Miller,[10] the commercial chemiluminescent NO_x analyzer responds to nitrogen containing compounds such as PAN, nitrates and nitrites. Thus we cannot state that all the amount of NO consumed was converted into NO_2. However, since the production of nitrates and nitrites could not be observed by F.I.D. gas chromatography and the conversion of C_3H_6 is not large (30%), the formation of nitrates and nitrite is thought to be very small and the great part of NO consumed would be NO_2. The ratio of the NO consumed to the C_3H_6 consumed is about 2. The net photochemical loss of the NO_2 formed is also negligibly small due to the following reaction sequences:

$$NO_2 + h\nu \longrightarrow NO + O \qquad (7)$$

$$O + O_2 + M \longrightarrow O_3 + M \qquad (8)$$

$$O_3 + NO \longrightarrow NO_2 + O_2 \qquad (9)$$

Figure 2 shows the results of the *m*-xylene/NO/H_2O/air system. In this case the amount of the total NO_x decreases as *m*-xylene and NO are consumed. This could be explained by the formation of nitrates and nitrocompounds which was observed by F.I.D. gas chromatography. NO report seems to have appeared on the response of commercial chemiluminescent NO_x analyzer to aromatic nitrates and nitrocompounds. However, the result in Fig. 2 shows that it should be much lower than that to NO and NO_2. The ratio of the NO consumed to *m*-xylene consumed is *ca.* 3.2.

The amount of NO_2 produced (total NO_x—NO) was almost equal to that of NO consumed in the system of alkenes and alkanes. On the other hand, in the system of aromatic compounds, the amount of NO_2 produced

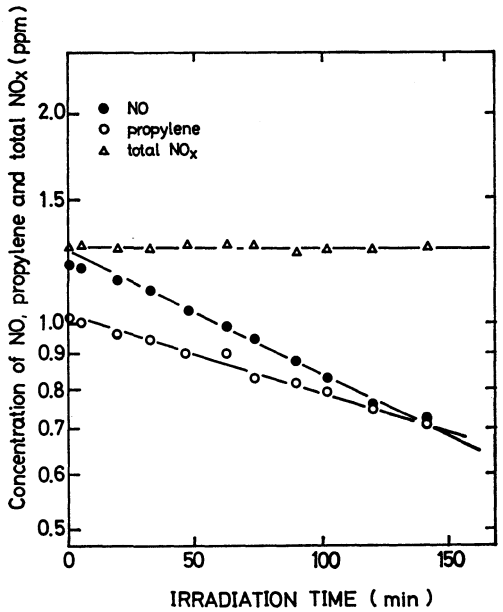

Fig. 1. Concentrations of NO (●), propylene (○), and total NO_x(△) *vs.* irradiation time. The concentration of NO_2 is the difference between total NO_x and NO.

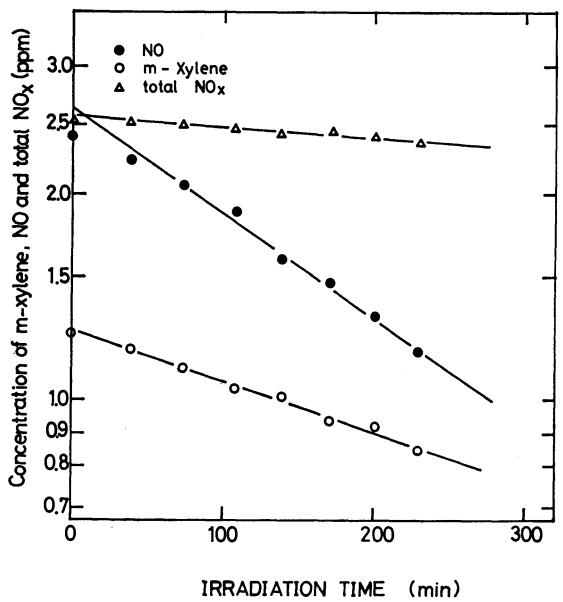

Fig. 2. Concentrations of NO (●), *m*-xylene (○), and total NO_x (△) are plotted against irradiation time.

was always smaller than that of NO consumed. Benzyl nitrate and *m*-nitrotoluene are produced in the photooxidation of the toluene/HONO/air system.[11,12] These nitrates and nitrocompounds are produced in other aromatic compounds. This would account for the loss of NO_2 as compared to the NO consumed in the reaction system involving these compounds.

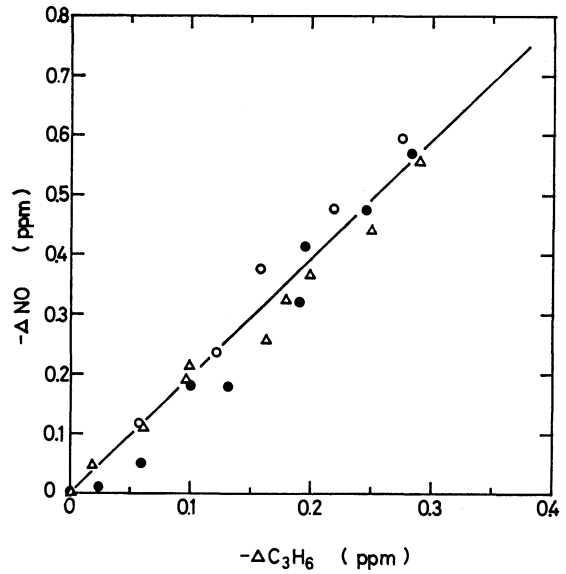

Fig. 3. Consumed NO, $-\Delta NO$, is plotted against comsumed propylene, $-\Delta C_3H_6$, for three different conditions.
Initial conditions are: (○) $[C_3H_6]=1.06$ ppm, $[NO]=1.85$ ppm; (△) $[C_3H_6]=1.01$ ppm, $[NO]=1.20$ ppm; (●) $[C_3H_6]=0.68$ ppm, $[NO]=2.20$ ppm.

In order to obtain the ratio of the NO consumed ($-\Delta NO$) to the hydrocarbons consumed ($-\Delta H.C.$), $-\Delta NO$ was plotted against $-\Delta H.C.$ Figure 3 shows an example of propylene. The results under three different initial conditions lie on a straight line. The least-squares method was used in order to obtain factor *F*, *i.e.*, the number of NO molecules converted into NO_2 when one propylene molecule is consumed. The factors thus obtained are given in Table 1. Numbers in parentheses give the error limits, ±, calculated by the least squares standard deviation (5%).

Taking into consideration the error limits, the *F* value is found to be approximately 2 for most of the compounds studied. This value was predicted by Heicklen *et al.* for propylene,[4] 2-methylpropene,[3] and butane[3] and by Niki *et al.* for propylene.[1] Although there is a small difference between the mechanisms proposed by Heicklen *et al.* and Niki *et al.*, the overall reaction for propylene can be described by Reaction 2 in both mechanisms. Referring to the mechanism of Heicklen *et al.* and also that of Niki *et al.*, the reactions for *cis*-2-butene can be explained by the following:

$$C_4H_8 + OH \longrightarrow \cdot C_4H_8OH \quad (10)$$
$$\cdot C_4H_8OH + O_2 \longrightarrow HOC_4H_8O_2\cdot \quad (11)$$
$$HOC_4H_8O_2\cdot + NO \longrightarrow HOC_4H_8O\cdot + NO_2 \quad (12)$$
$$HOC_4H_8O\cdot \longrightarrow CH_3CHO + \cdot C_2H_4OH \quad (13)$$
$$\cdot C_2H_4OH + O_2 \longrightarrow HOC_2H_4O_2\cdot \quad (14)$$
$$HOC_2H_4O_2\cdot + NO \longrightarrow HOC_2H_4O\cdot + NO_2 \quad (15)$$
$$HOC_2H_4O\cdot \longrightarrow OH + CH_3CHO \quad (16)$$

The overall reaction is

$$C_4H_8 + 2NO + 2O_2 \longrightarrow 2CH_3CHO + 2NO_2 \quad (17)$$

Table 1. *F* factors for organic compounds

Compound	Run number	Initial conditions Hydrocarbon(ppm)	NO(ppm)	Final concentration of hydrocarbon(ppm)	$F(\pm)$
Propylene	1	1.06	1.85	0.08	1.8 (0.2)
	2	1.01	1.20	0.70	2.2 (0.2)
	3	0.68	2.20	0.44	2.3 (0.3)
cis-2-Butene	4	0.92	2.03	0.67	2.0 (0.1)
	5	0.55	1.93	0.34	2.1 (0.3)
T.M.E.[a] (2,3-Dimethyl-2-butene)	6	1.11	1.99	0.78	2.0 (0.3)
Cyclopentene	7	1.08	2.02	0.40	1.9 (0.1)
Cyclohexene	8	1.26	1.71	0.70	2.3 (0.6)
Pentane	9	1.31	2.20	0.93	2.2 (0.3)
Hexane	10	2.00	2.21	1.60	2.0 (0.4)
Cyclopentane	11	0.84	1.83	0.61	2.2 (0.4)
Cyclohexane	12	1.21	2.03	0.92	2.3 (0.5)
	13	1.43	1.67	0.78	1.8 (0.1)
Toluene	14	1.34	1.69	1.00	2.2 (0.2)
	15	1.07	1.72	0.82	2.3 (0.3)
Ethylbenzene	16	1.46	1.96	1.05	1.9 (0.3)

m-Xylene	18	0.97	2.18	0.76	3.4 (0.5)
	19	1.25	2.42	0.83	3.2 (0.3)
p-Xylene	20	0.91	1.83	0.57	2.4 (0.1)
	21	0.96	1.70	0.50	2.1 (0.3)
Mesitylene	22	0.92	1.75	0.56	2.3 (0.1)

a) Irradiation light intensity reduced to 1/8. Irradiation time 2—4 h for all measurements.

In the case of *cis*-2-butene, Demerjian *et al.*[2] proposed a reaction, which forms formic acid, instead of Reaction 16.

$$HOC_2H_4O\cdot \longrightarrow CH_3\cdot + HCOOH \quad (18)$$

The reaction sequence is

$$CH_3\cdot + O_2 \longrightarrow CH_3O_2\cdot \quad (19)$$

$$CH_3O_2\cdot + NO \longrightarrow CH_3O\cdot + NO_2 \quad (20)$$

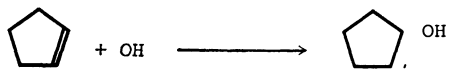
$$CH_3O\cdot + O_2 \longrightarrow H_2CO + HO_2\cdot \quad (21)$$

$$HO_2\cdot + NO \longrightarrow OH + NO_2 \quad (22)$$

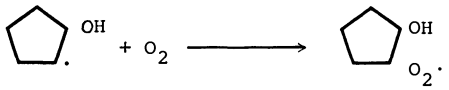
In this case four NO molecules should be converted into NO_2 as one *cis*-2-butene molecule is consumed. Our results, (F=2 for *cis*-2-butene), support the mechanism of Heicklen *et al.* and Niki *et al.*, and refute that of Demerjian *et al.* The results for T.M.E. could also be explained by the following overall reaction:

$$(CH_3)_2C_2(CH_3)_2 + 2NO + 2O_2 \longrightarrow 2(CH_3)_2CO + 2NO_2 \quad (23)$$

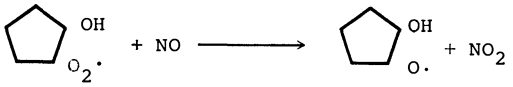
For cyclopentene, the sequence would be



(24)



(25)



(26)

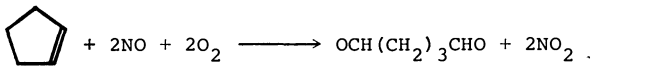
(27)

$$OCH(CH_2)_3\dot{C}H(OH) + O_2 \longrightarrow OCH(CH_2)_3CH(OH)O_2\cdot \quad (28)$$

$$OCH(CH_2)_3CH(OH)O_2\cdot + NO \longrightarrow OCH(CH_2)_3CH(OH)O\cdot + NO_2 \quad (29)$$

$$OCH(CH_2)_3CH(OH)O\cdot \longrightarrow OCH(CH_2)_3CHO + OH \quad (30)$$

The overall reaction is



(31)

The photooxidation of cyclohexene could be explained in a similar way.

For alkanes, Heicklen *et al.*[3] proposed a mechanism for butane.[3] In a similar manner, the sequence for pentane is

$$C_5H_{12} + OH \longrightarrow C_5H_{11}\cdot + H_2O \quad (32)$$

$$C_5H_{11}\cdot + O_2 \longrightarrow C_5H_{11}O_2\cdot \quad (33)$$

$$C_5H_{11}O_2\cdot + NO \longrightarrow C_5H_{11}O\cdot + NO_2 \quad (34)$$

$$C_5H_{11}O\cdot + O_2 \longrightarrow C_5H_{11}O + HO_2\cdot \quad (45)$$

$$HO_2\cdot + NO \longrightarrow NO_2 + OH \quad (22)$$

The overall reaction is

$$C_5H_{12} + 2NO + 2O_2 \longrightarrow C_5H_{10}O + H_2O + 2NO_2 \quad (36)$$

For hexane, the overall reaction is

$$C_6H_{14} + 2NO + 2O_2 \longrightarrow C_6H_{12}O + H_2O + 2NO_2 \quad (37)$$

Carter *et al.*[14] suggested an isomerization mechanism in the alkane reaction. In the case of pentane, $C_5H_{11}O\cdot$ formed in Reaction 34 can be isomerized in part *via* the following reaction:

$$C_5H_{11}O\cdot \longrightarrow \cdot C_5H_{15}(OH) \quad (38)$$

The reaction might proceed *via*

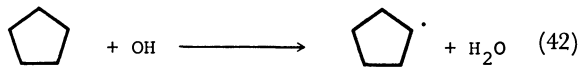
$$\cdot C_5H_{10}(OH) + O_2 \longrightarrow \cdot O_2C_5H_{10}(OH) \quad (39)$$

$$\cdot O_2C_5H_{10}(OH) + NO \longrightarrow \cdot OC_5H_{10}(OH) + NO_2 \quad (40)$$

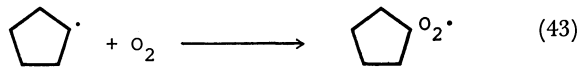
$$\cdot OC_5H_{10}(OH) + O_2 \longrightarrow (OH)C_5H_9O + HO_2 \quad (41)$$

$$HO_2 + NO \longrightarrow OH + NO_2 \quad (22)$$

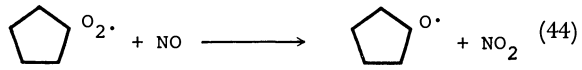
In this case, the value of factor F should be between 2 and 3, according to the competition between Reactions 35 and 38. Considering the error limit in Table 1, the mechanism proposed by Carter *et al.* is also acceptable in the case of pentane and hexane. In the case of cyclopentane, the sequence might be as follows:



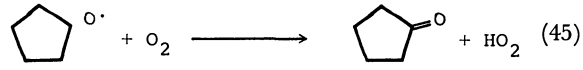
(42)



(43)



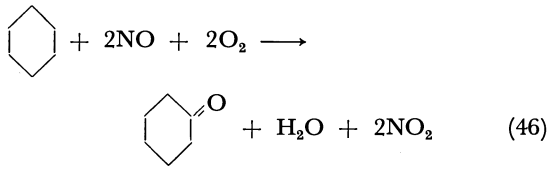
(44)



(45)

$$HO_2 + NO \longrightarrow NO_2 + OH \quad (22)$$

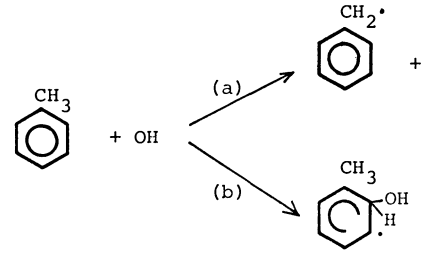
The overall reaction for cyclohexane is



(46)

The above mechanisms might explain the fact that factor F is usually about 2 for alkenes and alkanes.

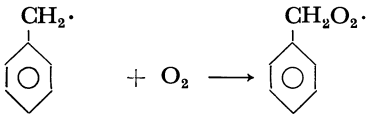
In the reaction of aromatic hydrocarbons the mechanism is not so simple. For example, for toluene the reaction mechanism[11,12] might be



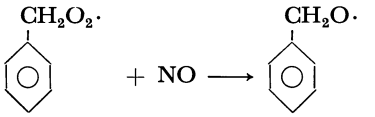
(47)

(48)

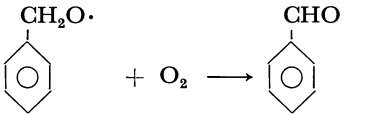
For path (a)



(49)



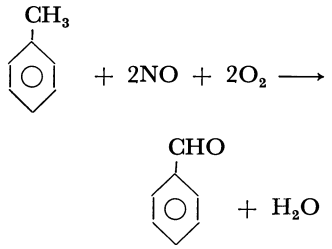
(50)



(51)

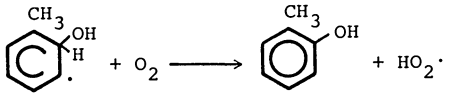
$$HO_2\cdot + NO \longrightarrow NO_2 + OH \qquad (22)$$

The overall reaction for path (a) is



(52)

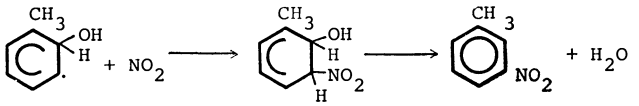
For path (b)



(53)

$$HO_2\cdot + NO \longrightarrow NO_2 + OH \qquad (22)$$

and



(54)

The formation of benzaldehyde, cresols, and *m*-nitrotoluene has been reported[11,12] in the photooxidation of the toluene/HONO/air system. According to the above mechanism, factor F for toluene should be less than two. However, small amounts of glyoxal and methylglyoxal have been detected in the photooxidation of the toluene/NO_2 system.[15] These products are also found in the photooxidation of the toluene or xylene/NO/H_2O/air systems.[13] The formation mechanism of these compounds is not yet clear, but it is most probable that they are formed after the aromatic ring is opened. Probably factor F for toluene becomes about 2 due to the radicals which are formed by the ring rupture.

The reaction mechanism of other aromatic compounds might be similar to that of toluene. The F factors for aromatic compounds are generally a little larger than 2, except for *m*-xylene. It is not known why the F factor of only *m*-xylene is larger than 3. Among the reaction rate constants of OH with xylene, only *m*-xylene is about twice faster than other *o*- and *p*-xylenes.[16] Probably the fraction of aromatic ring opening is larger in *m*-xylene.

In addition to the compounds listed in Table 1, determination of factor F was made for ethylene, which is of theoretical interest as the simplest alkene. Due to the poor efficiency of liquid nitrogen trapping of ethylene, the value for F scattered from 1.0 to 3.0, and is therefore not given in Table 1.

It has been suggested[17,18] that OH is the most important intermediate species during the initial stages of smog chamber experiments and that the contribution to attack on hydrocarbons by OH is much larger than O_3, HO_2, and $O(^3P)$. The contribution of O_3 to the consumption of hydrocarbons in the present study can be estimated as follows.

According to Reactions 7—9, the final steady state concentration of O_3 in our experiments is given by

$$[O_3]_{ss}^{final} = \frac{k_7[NO_2]^{final}}{k_9[NO]^{final}} \qquad (I)$$

where the value of k_7 is 0.08 min^{-1} except for the case of T.M.E. where it is 0.01 min^{-1}. The most recent value for k_9 is 26.5 $ppm^{-1}\ min^{-1}$.[19] The ratio of NO_2 to NO in the final measurement could be obtained experimentally, assuming that the concentration of NO_2 is equal to the value of total NO_x minus NO. The calculated final steady state concentrations of O_3 for several selected hydrocarbons are given in Table 2.

If hydrocarbons are consumed by OH and O_3, the concentration of hydrocarbons is given by the following equation, assuming that the concentrations of OH and O_3 are constant:

$$\frac{\ln[\text{hydrocarbon}]_0 - \ln[\text{hydrocarbon}]}{t} = k_a[OH] + k_b[O_3] \qquad (II)$$

where $[\text{hydrocarbon}]_0$ refers to the initial concentration of hydrocarbons, and k_a and k_b are the rate constants for the reaction of OH and O_3, respectively, with hydrocarbons. Since the initial and final concentrations for hydrocarbons and irradiation time, which is 2—3 h for alkenes, are known, the left hand side of Eq. II can be calculated. The values for k_b are reported for propylene,[20] *cis*-2-butene,[21] and T.M.E.[21] as 1.56×10^{-2}, 1.85×10^{-1}, and 1.55 $ppm^{-1}\ min^{-1}$, respectively. Therefore, the contribution of O_3 to the consumption of hydrocarbons at the final point of measurement can be

TABLE 2. CALCULATED VALUES FOR $[O_3]_{ss}^{final}$, $k_b\,[O_3]_{ss}^{final}$ AND THE LEFT HAND SIDE OF EQ. II FOR SELECTED ALKENES GIVEN IN TABLE 1

Compound	Run number in Table 1.	Irradiation time (min)	Calculated $[O_3]_{ss}^{final}$ (ppm)	$k_b\,[O_3]_{ss}^{final}$ (min^{-1})	$\frac{1}{t}\cdot\ln\frac{[hydrocarbon]_0}{[hydrocarbon]}$ (min^{-1})
Propylene	1	180	1.64×10^{-3}	2.6×10^{-5}	1.6×10^{-3}
	2	140	2.50	3.9	2.6
	3	140	1.29	2.0	3.1
cis-2-Butene	4	135	1.11	21	2.3
	5	150	1.05	19	3.2
T.M.E.[a] (2,3-Dimethyl-2-butene)	6	160	0.16	25	2.2
Cyclopentene	7	115	4.06	85[b]	8.6

a) Irradiation light intensity reduced to 1/8. b) Calculated using the rate constant for *cis*-2-butene+O_3 as k_b.

calculated by the form of $k_b[O_3]_{ss}^{final}$. The experimental decay rate of hydrocarbons and the calculated contributions of O_3 are given in Table 2 for propylene, *cis*-2-butene and T.M.E. The contribution of O_3 is less than 2 and 10% for propylene and *cis*-2-butene, respectively, and for T.M.E. nearly 10% at the final points in the measurements. These contributions of O_3 to other measured points would be much smaller, since ozone increases exponentially with irradiation time. The value for k_b is unknown for cycloalkanes. The effect on cyclopentene was calculated with use of the value of k_b for *cis*-2-butene. In this case the contribution by O_3 was also less than 10% (Table 2).

The contribution by O_3 should be very small in the case of alkanes and aromatics, because the reaction of ozone with alkanes and aromatics is extremely slow.

The results in Table 1 show that the long chain mechanism proposed by Heicklen *et al.*[3] and by Niki *et al.*[1] may be right and the value of factor F nearly equal to 2 can be used in computer simulation studies of the photooxidation process of a hydrocarbon and NO mixture.

The finding that factor F is approximately 2 regardless of the type and carbon number of hydrocarbons might allow us to propose a generalized oxidation chain mechanism which would be useful for the mathematical modeling of photochemical air pollution in an urban airshed. For alkenes the NO oxidation mechanism could be generalized as follows, referring to the mechanism given for *cis*-2-butene,

$$\text{(A)}\quad RH + OH \xrightarrow{+O_2} RO_2\cdot + H_2O$$
$$RO_2\cdot + NO \longrightarrow RO\cdot + NO_2$$
$$RO\cdot + O_2 \longrightarrow R'_2CO + R''O_2\cdot$$
$$R''O_2\cdot + NO \longrightarrow R'''_2CO + NO_2 + OH$$

where R'_2CO and R''_2CO represent aldehydes or ketones. Similarly, a generalized model for alkanes can be written as

$$\text{(B)}\quad RH + OH \xrightarrow{+O_2} RO_2\cdot + H_2O$$
$$RO_2\cdot + NO \longrightarrow RO\cdot + NO_2$$
$$RO\cdot + O_2 \longrightarrow RCHO + HO_2\cdot$$
$$HO_2\cdot + NO \longrightarrow OH + NO_2$$

Model (B) is equivalent to model (A) if $HO_2\cdot$ is recognized as $R'O_2\cdot$ and the difference in the type and the stoichiometric number of carbonyl compounds formed in the chain is ignored. In the case of aromatic hydrocarbons, path (a) initiated by H atom abstraction can be generalized just as for paraffins. However path (b) initiated by the OH addition and aromatic ring rupture path is difficult to be generalized at this stage since the reaction mechanism is far from being clarified. Nevertheless, from the evidence that the overall factor F is approximately 2 for most of the aromatic compounds, it is reasonable to adopt the generalized model of reaction (A) or (B) even for these compounds if the difference in the stoichiometric number and the type of oxidized compounds is ignored.

Thus, we propose a generalized kinetic model (A) or (B) for the NO oxidation chain processes in the presence of alkanes, alkenes, and aromatic hydrocarbons commonly present in the polluted urban atmosphere. This would be useful for the development of atmospheric photochemical air pollution modeling. Sveral reports[22–24] have appeared on the mathematical modeling of photochemical air pollution in an urban airshed. The mathematical modeling requires a kinetic reaction model for atmospheric reactions as well as models for atmospheric diffusion and transport processes. A kinetic model must satisfy certain requirements to be applicable to the atmospheric simulations. First, the model should predict the behavior of a complex mixture of hydrocarbons since a polluted urban atmosphere contains various hydrocarbon species. Second, since an atmospheric simulation model consists of a set of partial differential equations for diffusion and transport, the kinetic model must be compact enough to avoid excessive computation time for numerical integration. Model (A) or (B) satisfies these requirements. Since the models are common for various types of hydrocarbons, the chemical behavior of various hydrocarbon species is characterized only by the reaction rates with OH, O, and O_3. Thus, if it is combined with other typical reactions among NO, NO_2, O_3, RH, OH, and $RO_2\cdot$, the atmospheric simulation could be made by model (A) or (B).

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received February 13, 1978)

X-Ray crystal structure analyses of three (acetylacetonato)organoantimony(V) compounds have been conducted. Crystals of [(acac)$MeSbCl_3$] belong to the tetragonal system: $a=13.865(1)$, $c=24.935(5)$ Å, space group $I4_1/a$ with $Z=16$. [(acac)Me_2SbBr_2] forms monoclinic crystals: $a=9.247(1)$, $b=7.695(1)$, $c=9.104(1)$ Å, $\beta=106.94(1)°$, space group $P2_1/m$ with $Z=2$. Crystals of [(acac)Ph_2SbCl_2] (high-melting point form) belong to the monoclinic system: $a=14.733(11)$, $b=7.541(1)$, $c=16.014(13)$ Å, $\beta=92.66(1)°$, space group $P2_1/c$ with $Z=4$. All structures have been elucidated by the heavy atom method and refined by the block-diagonal least-squares procedure. Through the three compounds, the antimony atoms have a slightly distorted octahedral geometry with substituents on apical positions, slightly bent towards the planar acetylacetonato groups.

The chemistry of (acetylacetonato)organoantimony-(V) compounds of the type [(acac)R_nSbCl_{4-n}] ($n=1$ and R=Me, Et, or Ph; $n=2$ and R=Me, Et, or Ph; $n=3$ and R=Ph; and $n=4$ and R=Me, Et, or Ph)†† has been the subject of a number of recent papers.[1-6] Among them there are two possible configurations for [(acac)-$RSbCl_3$], and three for [(acac)R_2SbCl_2] (Fig. 1). Spectroscopic studies of these two types of compound left some ambiguities on their molecular structures.[2,4,5,7] In order to determine the exact configuration of these molecules by X-ray diffraction, (acetylacetonato)methyltrichloroantimony(V) [(acac)$MeSbCl_3$], (acetylacetonato)dimethyldibromoantimony(V) [(acac)Me_2SbBr_2], and (acetylacetonato)diphenyldichloroantimony(V) [(acac)Ph_2SbCl_2] have been chosen as typical examples of [(acac)$RSbCl_3$] and [(acac)R_2SbCl_2]. As [(acac)-Me_2SbCl_2] was untsable in the solid state, crystals of [(acac)Me_2SbBr_2] which were considered to have the same configuration as [(acac)Me_2SbCl_2] were subjected to X-ray structure analysis. Recrystallization of ([acac)-Ph_2SbCl_2] from benzene gave two kinds of crystals in different forms: long prismatic (mp 192 °C) and rhombohedral (mp 184.5 °C) crystals (Table 1). This promoted the crystal structure analysis of two forms which may consist of molecules of different configurations. Kroon[8] determined the X-ray molecular structure of the low-melting point form, independently, which agrees well with the results obtained by the present authors.[9] Therefore, the crystal structure analysis of only the high-melting point form will be described. Brief accounts of the X-ray molecular structure of the above-mentioned compounds have been published.[10-12]

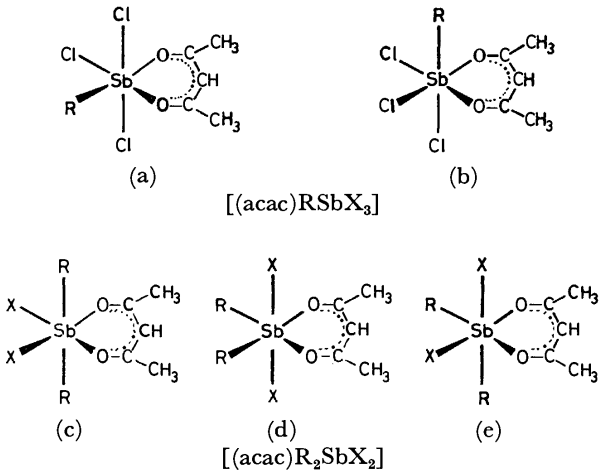

Fig. 1. Possible configurations of [(acac)$RSbX_3$] ((a) and (b)) and [(acac)R_2SbX_2] ((c), (d), and (e)). X=Cl or Br.

Experimental

Crystal Data. Crystals were all supplied by Professor R. Okawara and co-workers of this university. The unit-cell dimensions of [(acac)$MeSbCl_3$] and [(acac)Me_2SbBr_2] were determined by the least-squares fit of 2θ values of high angle reflections measured on a G. E. Single Crystal Orienter equipped on a Rigaku SG-2 goniometer. Those of [(acac)-Ph_2SbCl_2] were determined from Weissenberg photographs taken around the b and c axes, on which the Debye lines of tungsten were superimposed for calibration. In all cases nickel-filtered Cu $K\alpha$ radiation ($\lambda=1.5418$ Å) was used. Density measurements were carried out by the flotation method. Crystal data are given in Table 1.

Crystal structure analysis of [(acac)Me_2SbCl_2] instead of [(acac)Me_2SbBr_2] had been first intended, however, it was found during the preliminary X-ray work that all the [(acac)-Me_2SbCl_2] single crystals examined readily decomposed at room temperature to give powder patterns. Approximate unit-cell parameters were determined from oscillation and Weissenberg photographs: $a=9.00$, $b=7.59$, $c=9.05$ Å, $\beta=107.4°$, $U=590$ Å^3, space group $P2_1$ or $P2_1/m$, $D_c=1.82$ g·cm^{-3} for $Z=2$. These facts suggest that [(acac)Me_2SbCl_2] is isomorphous or at least iso-structural with [(acac)Me_2SbBr_2].

Intensities. *[(acac)$MeSbCl_3$] and [(acac)Me_2SbBr_2]:* Intensities were measured on a Rigaku automated, four-circle-

a) Our observation.

diffractometer using zirconium-filtered Mo $K\alpha$ radiation. The θ-2θ scan technique was employed, scan rate being 4° min^{-1}. The scan width in 2θ was from $-1.0°$ from the $K\alpha_1$ to 1.0° from $K\alpha_2$ peak, where θ_c is the calculated value of the Bragg angle using λ(Mo $K\alpha_1$) (=0.70926 Å). Backgrounds were measured for 10 s before and after the scan of each peak. Totals of 2270($\sin\theta/\lambda \leqq 0.64$) and 1454($\sin\theta/\lambda \leqq 0.64$) independent reflections were collected, of which 206 and 72 reflections were classified as unobserved, respectively. Two and three standard reflections (004 and 080, and 400, 005, and 040) were measured after every 25 and 50 reflections for [(acac)MeSbCl$_3$] and [(acac)Me$_2$SbBr$_2$], respectively. Lorentz and polarization corrections were made by the AICOM-C$_2$ computer attached to the diffractometer. Absorption correction was made for the [(acac)Me$_2$SbBr$_2$] data.

[*(acac)Ph$_2$SbCl$_2$*]: Using nickel-filtered Cu $K\alpha$ radiation, layers from 0 through 4 around the b axis were recorded by the multiple-film Weissenberg technique. Reflections of the layers from 0 through 2 around the c axis were also collected mainly for the interlayer scaling. Intensities were estimated visually by using a calibrated standard scale. A total of 1720 (1453 non-zero) independent reflections were obtained. Lorentz and polarization effects were corrected but no absorption correction was made.

Elucidation of the Structure

All the structures of the three complexes have been elucidated by the heavy atom method.

[*(acac)MeSbCl$_3$*]: The position of the antimony atom was readily reduced from a three-dimensional Patterson map, and the positions of the non-hydrogen atoms by the successive Fourier syntheses.

[*(acac)Me$_2$SbBr$_2$*]: The systematic absence of reflection determined the corresponding space group as either $P2_1/m$ or $P2_1$. Since the unit-cell contains two molecules, the following three possible cases have been examined: (1) $P2_1/m$, with the acac ligand positioned on the mirror plane, (2) $P2_1/m$, with the acac perpendicular to the mirror plane, or (3) $P2_1$, with the molecule itself having no symmetry. Approximate positions of the antimony and two bromine atoms obtained from the three-dimensional Patterson function excluded case (2). All the non-hydrogen atoms were located by the successive Fourier syntheses.

[*(acac)Ph$_2$SbCl$_2$*]: From the three-dimensional Patterson map, two sets of possible locations were obtained for the antimony and two chlorine atoms; (1) Sb (0.24, 0.25, 0.43), Cl (1) (0.30, 0.07, 0.53) and Cl(2) (0.14, 0.03, 0.39), or (2) Sb (0.24, 0.25, 0.43), Cl (1) (0.30, 0.43, 0.53), and Cl (2) (0.14, 0.03, 0.39). The successive two sets of Fourier syntheses favored the former parameters set, and located the non-hydrogen atoms.

Refinement

The structures determined were all refined by the block-diagonal least-squares procedure, the function minimized being $\Sigma w(\Delta F)^2$ using the HBLS V program.[13] Neutral atomic scattering factors used were taken from those of Hanson and co-workers.[14]

[*(acac)MeSbCl$_3$*]: The final $R_1=\sum||F_o|-|F_c||/\sum|F_o|=0.059$ and $R_2=\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2=0.059$ for 2064 non-zero reflections. The weighting scheme applied was: $w=(|F_{max}|/|F_o|)^2$ for $|F_o| \geqq 40.0$, $w=1.0$ for $40.0 \geqq |F_o| \geqq 15.0$, and $w=0.2$ for $|F_o|<15.0$.

[*(acac)Me$_2$SbBr$_2$*]: Two possible space group struc-

tures, $P2_1$ and $P2_1/m$ were refined isotropically, and a reasonable result obtained for $P2_1/m$. At the final stage of the refinement $F(020)$ was omitted from the calculation since it was largely affected by the extinction. Final anisotropic refinements with unit weight gave $R_1=0.076$ for 1381 non-zero reflections.

[(acac)Ph_2SbCl_2]: Anisotropic temperature factors were applied for the antimony and two chlorine atoms and w was taken as unity. The final $R_1=0.12$ for 1453 non-zero reflections.

The final positional and thermal parameters are given in Tables 2 and 3,[†††] respectively.

Results and Discussion

Molecular Structure. The atom numbering scheme is given in Fig. 2. A stereoscopic drawing of the molecules are shown in Fig. 3. Bond lengths and bond angles are listed in Table 4. Least-squares planes of various groups are presented in Table 5.

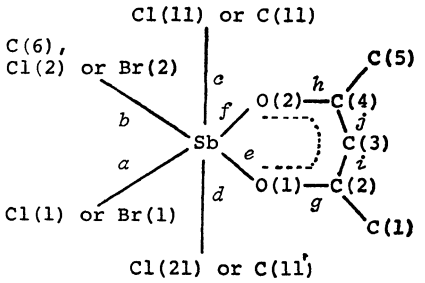

Fig. 2. The numbering scheme of atoms.

As seen in Fig. 3, the antimony atoms have slightly distorted octahedral geometries through the three compounds. In all cases the substituents are on apical positions, slightly bend towards the acetylacetonato groups.

In [(acac)$MeSbCl_3$] the methyl group has been located on the basal plane: of the two possible configurations in Fig. 1, (a) has been established. In [(acac)-Me_2SbBr_2] and [(acac)Ph_2SbCl_2] the alkyl or aryl groups occupy the apical positions: the (c) configuration being found among the three possible ones in Fig. 1. From the PMR study[5] it has been concluded that both phenyl groups in [(acac)Ph_2SbCl_2] are approximately perpendicular to the bisector of the Cl–Sb–Cl angle. In the high-melting point form, one phenyl ring (C(11)–C(16)) is approximately perpendicular [89°] to the bisector, however, the other (C(21)–C(26)) is approximately parallel [3°]: the dihedral angle between two rings being 92° (Fig. 4). In the low-melting point form, both phenyl rings are neither perpendicular nor parallel to the bisector: each phenyl ring makes an angle of about 65 or 77° to the bisector, and the dihedral angle between them is about 38° (Fig. 4).[8] This appears to be the main difference between the molecular structures of the two isomers.

Among the three Sb–Cl bond lengths in [(acac)-$MeSbCl_3$] those on apical positions [2.380(3) and 2.366(3) Å] are slightly longer than those on the basal plane [2.345(3) Å]. The Sb–Cl bond lengths in the high- and low-melting point forms are equal [av. 2.42 Å]. All of these Sb–Cl lengths are significantly longer than those in other antimony compounds.[15–20] The Sb–Br bond lengths in [(acac)$MeSbBr_2$] are 2.610(3) and 2.603(3) Å, which are slightly longer than those in $SbBr_3$ [2.52(3) Å].[21]

††† The observed and calculated structure factors are kept at the Chemical Society. Document No. 7824.

TABLE 3. THERMAL PARAMETERS ALONG WITH THEIR ESTIMATED STANDARD DEVIATIONS IN PARENTHESES
Anisotropic thermal parameters ($\times 10^5$) are of the form: $\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{23}kl+\beta_{13}hl)$, and isotropic ones are B (in Å^2).

a) Calculated from the data of Kroon *et al.*[8] The original numbering scheme of atoms are converted into as those given in Fig. 2.

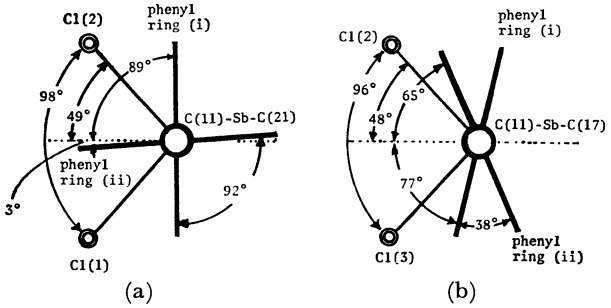

Fig. 4. The dihedral angles between the bisector(dotted line) of chloro substituents and phenyl groups in [(acac)-Ph_2SbCl_2]. (a) high-melting point form, and (b) low-melting point form.

The Sb–C(Me) bond lengths in [(acac)$MeSbCl_3$] and [(acac)Me_2SbBr_2] are standard values [2.134(11) and 2.144(20) Å, respectively] compared with those in hexa-coordinated antimony compounds: 2.10 and 2.14 Å in $Sb(CH_3)_3$[22] and 2.02(5) Å in $Me_3SbFe(CO)_4$.[23] The Sb–C(Ph) bond lengths in the high-melting point form of [(acac)Ph_2SbCl_2] are also standard values [2.16(4) and 2.19(4) Å] compared with those in the low-melting point form [2.132(12) and 2.127(12) Å] and also in $Ph_4Sb_2Cl_6$ [2.125(9) Å].[24]

The Sb–O bond lengths in [(acac)$MeSbCl_3$] [2.069(7) and 2.048(6) Å] are shorter than those in [(acac)Me_2-$SbBr_2$] [2.104(14) and 2.150(15) Å] and [(acac)Ph_2-$SbCl_2$] [2.13(3) and 2.11(3) Å].

The acetylacetonato groups are planar: in [(acac)-Me_2SbBr_2] being exactly planar because it lies on a crystallographic mirror plane together with the antimony and two bromine atoms. In [(acac)$MeSbCl_3$] and [(acac)Ph_2SbCl_2] (low-melting point from) the acetylacetonato groups are also planar: maximum deviations of atoms from the plane, Δ_{max} being 0.02 and 0.06 Å, respectively. The mean planes are almost coplanar with the plane defined by Sb, O(1), and O(2) atoms, the dihedral angles between them being 1.2 and 1.4°, respectively. However, the planarity of the acetylacetonato group in [(acac)Ph_2SbCl_2] (high-melting point form) is not standard [Δ_{max}=0.11 Å], the mean plane being bent by 15.0° away from the plane made by Sb, O(1), and O(2) atoms. This kind of bending has been found in other acetylacetonato compounds, [$Zr(acac)_4$][25] [22.6°] and [$Y(acac)_3 \cdot 3H_2O$][26] [18.9°]. In all cases the bond lengths and bond angles around the acetylacetonato ligands are standard compared with those of Lingafelter's standard data.[27]

The average bond length of the phenyl groups in [(acac)Ph_2SbCl_2] is 1.42 Å (high-melting point form)

a) Calculated from the data of Kroon *et al.*,[8)] in which e.s.d.'s are not given. The original numbering scheme of atoms are converted into as those given in Fig. 2.

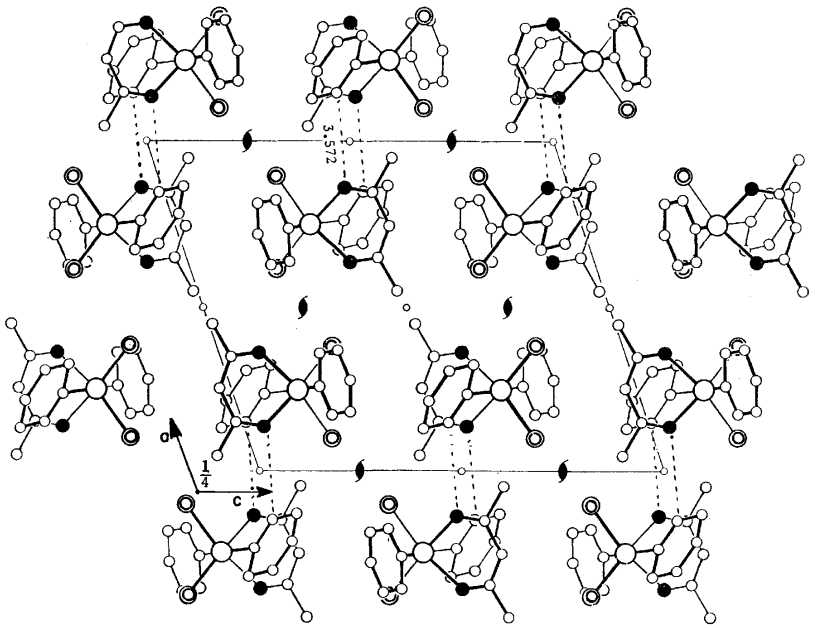

Fig. 8. The crystal structure of [(acac)Ph_2SbCl_2] (low-melting point form) projected along the b axis. (Drawn by using the data of the present authors.[9])

and 1.39 Å (low-melting point form[8]) respectively.

Crystal Structure. Crystal structures of the three compounds are respectively shown in Figs. 5, 6, and 7. In Fig. 8 the crystal structure of [(acac)Ph_2SbCl_2] (low-melting point form) is given using the data of Kroon *et al.*[8] Figures 9 shows a stereoscopic drawing of the packing of the former three crystals. Short intermolecular atomic contacts less than 3.8 Å are listed in Table 6.

[*(acac)$MeSbCl_3$*]: As seen in Fig. 5, in the tetragonal unit-cell molecules are arranged in helical manner along the crystallographic 4_1 screw axis, and each of these molecules is paired by the center of symmetry with a molecule to form a double helical arrangement along the c axis. In the four-fold helical arrangement of molecules, the closest atomic contacts occur between the methyl groups and the oxygen atoms of the acetylacetonato groups of the adjacent molecules of upper and lower steps [C(5)···O(1)=3.493(13) Å, Fig. 5].

[*(acac)Me_2SbBr_2*]: Along the b axis a pile of molecules forms a column, in which both methyl groups in apical positions of the molecule have the closest contacts with the other molecules above and below [C(11)···C(11′)^a =C(11′)···C(11)^b=3.409(28) Å, Fig. 6(a)]. Each molecule in the column has close contact with molecules in the adjacent column, related by the two-fold screw axis [C(11)···O(2)^g and O(2)···C(11′)^g, both 3.596 (24) Å, Fig. 6(b)], by which the two columns are tied. An infinite sheet parallel to the b and c axes is formed by rather close contacts with the adjacent tied columns along the c axis, and the parallel stack of these infinite sheets produces the crystal (Fig. 6(b)).

[*(acac)Ph_2SbCl_2] (High-melting point form)*: Figure 7 shows that the molecules lie approximately parallel to the (101) plane. There are many close atomic contacts, the closest one being [O(2)···C(24)^h or C(24)···O(2)^h, 3.357(51) Å] between a pair of molecules related by the center of symmetry. Along the b axis each molecule has rather close contacts with the other molecules above and below: the shortest distance being 3.603(62) Å [C(1)···C(16)^b or C(16)···C(1)^c]. Molecules related by the center of symmetry have additional close contacts between the acetylacetonato and phenyl carbon atoms.

(Low-melting point form): Molecules lie approximately parallel to the (100) plane (Fig. 8). There are several close atomic contacts including the closest one [O(1)··· C(26)^a or C(26)···O(1)^a, 3.572 Å] between a pair of molecules related by the center of symmetry. Comparison of the crystal structures of the two forms indicates that the low-melting poing form has a looser packing and smaller number of short inter-atomic contacts than the high-melting point form (Table 6). These facts possibly contribute to the difference in melting point between the two forms.

Computations throughout the present study were carried out on a NEAC 2200-700 computer at Osaka University. Figures 3, and 9 were drawn on a NUMERICON 7000 system at Osaka University using a local version of ORTEP.[28]

The authors wish to express their deep thanks to Professor Rokuro Okawara and his co-workers for many helpful discussions and kindess in supplying crystals.

Solubility and Diffusion Coefficient of Sulfur in Copper

Kazuo FUEKI* and Yasumasa OUCHI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received March 3, 1978)

The solubility and diffusion coefficient of sulfur in copper were determined by a new method, wherein a thin copper(I) sulfide film was formed on the surface of a copper specimen and the decrement of its thickness after diffusion annealing was determined coulometrically. It was found that the solubility C_s could be represented by

$$\log C_s \text{ (ppm)} = -0.616 - 0.410 \ (10^4/T),$$

and the diffusion coefficient is given by

$$D = 0.834 \times \exp(-40900/RT) \text{ cm}^2 \text{ s}^{-1}.$$

When a binary alloy is oxidized in an oxygen atmosphere, oxygen diffuses into the alloy and forms dispersed oxide particles with the less noble component. This phenomenon, called internal oxidation, has a significant effect on the oxidation rate of the alloy. Therefore, the solubility and diffusion coefficient of oxygen in the metal are most important for the elucidation of internal oxidation. Similarly, the solubility and diffusion coefficient of sulfur in metals are necessary in order to elucidate the mechanism and rate of alloy sulfidation.

The concentration of non-metallic elements in metals is usually determined by the vacuum fusion method, and in some cases by the combustion method or the tracer method. If physical properties such as resistivity and hardness are known as a function of the concentration of non-metallic elements, the solubility can be determined from the break point in the slope of the plot of physical quantity against concentration.

The diffusion coefficient of non-metallic elements is usually determined by the tracer method. In some cases, it is determined by the chemical relaxation method, which utilizes the change of physical property with time after the step-like change of ambient conditions.

The purpose of the present work is to determine the solubility and diffusion coefficient of sulfur in copper by a new method, wherein a thin copper(I) sulfide film is formed on the surface of high purity copper specimen and the decrement of the surface film after the diffusion annealing is determined by the coulometric method.

Theoretical

When a copper specimen covered with a thin copper(I) sulfide film on its surface is annealed *in vacuo* at a high temperature the copper(I) sulfide decomposes into sulfur and copper by the reaction

$$Cu_2S = 2Cu + S(\text{in Cu}), \quad (1)$$

and the sulfur diffuses inwards. If the concentration of sulfur is represented by $C(x,t)$, its differential with respect to time can be given by

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2}, \quad (2)$$

where D is the diffusion coefficient. Solving the differential equation with the boundary conditions

$$C(0,t) = C_s, \quad (3)$$

$$C(l,t) = C_s, \quad (4)$$

and

$$C(x,0) = 0 \quad \text{for } 0 < x < l, \quad (5)$$

one obtains[1]

$$C = C_s - \frac{4C_s}{\pi}\sum_{j=0}^{\infty}\frac{1}{2j+1}\sin\frac{(2j+1)\pi}{l} \times \exp\left[-\left(\frac{(2j+1)\pi}{l}\right)^2 Dt\right], \quad (6)$$

where C_s is the solubility and j is an integer. The mean concentration $\bar{C}(t)$ is

$$\bar{C}(t) = \frac{1}{l}\int_0^l C(x,t)\mathrm{d}x = C_s - \frac{8C_s}{\pi^2}\sum_{j=0}^{\infty}\frac{1}{(2j+1)^2}\exp\left[-\left(\frac{(2j+1)\pi}{l}\right)^2 Dt\right]. \quad (7)$$

In the present study, $\bar{C}(t)$ is determined by the difference in sulfide film thickness between time zero and time t. For $\bar{C} \geq 0.2C_s$ the first term of the series is an excellent approximation. Therefore, Eq. 7 can be simplified to

$$\bar{C} = C_s - \frac{8C_s}{\pi^2}\exp\left(\frac{-\pi^2 Dt}{l^2}\right). \quad (8)$$

Accordingly, from the saturation value of the $\bar{C}$-t/l^2 curve, the solubility C_s is determined. Equation 8 is rewritten into

$$\frac{C_s - \bar{C}}{C_s} = \frac{8}{\pi^2}\exp\left(-\frac{\pi^2 Dt}{l^2}\right). \quad (9)$$

Taking the logarithm of both sides of this equation, one gets

$$\log\frac{C_s - \bar{C}}{C_s} = \log\frac{8}{\pi^2} - \frac{\pi^2 D}{2.303}\cdot\frac{t}{l^2}. \quad (10)$$

Equation 10 indicates that the diffusion coefficient D is determined from the slope of the plot of $\log(C_s - \bar{C})/C_s$ against (t/l^2).

Experimental

Copper Specimens. Electrolytic copper, 99.999% pure and 5 mm thick, was used for samples. The result of chemical

TABLE 1. RESULT OF CHEMICAL ANALYSIS

Impurity	Content
Pb	1 ppm
As	1
Sb	1
Fe	1
Ni	1
S	6

analysis of the copper is given in Table 1. The electrolytic copper was cut into rectangular specimens with a small knob at one corner. The size of each specimen was 15 mm × 7 mm × (0.2—1)mm. The copper specimens were polished with emery paper and then with alumina polishing powder of 10, 5, 0.5, and 0.3μ successively. The size of polished specimens was measured by means of a vernier caliper and the thickness was calculated from the weight and the surface area. In order to remove the strain and non- metallic elements dissolved in copper, the specimens were placed in a Vycor basket, suspended in a tube kept at 600 °C, and heat-treated in a 5% H_2–95% N_2 gas mixture for 5 h.

Formation and Determination of Surface Sulfide. The essential point of the present work is the determination of $\bar{C}(t)$, in other words, the determination of sulfide film thickness at time zero and time t. The sulfide film was as thin as about 1000 Å, so the electrochemical method was employed for the formation of sulfide film and the determination of its thickness. Figure 1 shows the drawing of the electrochemical cell and the electrical circuit for these purposes. In the first cell a 0.1 M KCl-solution was used as electrolyte. The solution was deaerated by passing nitrogen gas bubbles for 10 min and a heat-treated copper specimen was immersed in the solution. The current was made to flow between the specimen and two counter electrodes to reduce the surface oxide on the copper. The cathodic current density was 1 mA/cm². Then the specimen was taken out of the cell, washed with water, and transferred to the second cell which contained a 6.3×10^{-3} M Na_2S solution as electrolyte. The specimen was anodized at a current density of 0.1 mA/cm² for 10 to 20 min to form thin sulfide films of the desired thickness on both surfaces of copper. Usually, the thickness was chosen to be about twice or three times greater than the thickness after the diffusion annealing. Then, the specimen was taken out and washed with pure water.

The sulfide film thickness was determined by means of the coulometric method. The specimen was immersed in a 0.1 M KCl solution and the surface sulfide was reduced cathodically at a constant current density of 0.1 mA/cm². The potential with reference to S. C. E. was recorded. The potential was constant while the residual sulfide existed on the metal surfaces, shifted to a less noble value in an instant where the sulfide was completely removed, and remained at another constant value which corresponded to the potential of hydrogen evolution on the bare metal surface. From the reflection of the potential-time curve, the electric charge necessary for the reduction of sulfide was calculated. The charge determined from the reduction of sulfide was found to be always about 10% larger than that determined from the formation of sulfide. It was considered that the difference might be due to the reaction of copper with polysulfide ions contained in the Na_2S solution as an impurity. So the Na_2S solution of the same concentration was used for the formation of sulfide, and the film thickness formed by the reaction of copper with polysulfide ions was taken into account for the determination of the initial film thickness.

Diffusion Annealing. The copper specimen covered with copper(I) sulfide film was placed in a Vycor tube in which nitrogen gas was made to flow for 10 min to replace the air in it. Then the tube was evacuated to 10^{-4} Torr and sealed by means of a hydrogen-oxygen torch. Care was taken so that the sample would not be heated. The sealed tube was placed in an electric furnace kept at a desired annealing temperature within ±2 °C, and after a pre-determined length of time the tube was taken out from the furnace. The thickness of the remaining sulfide film was determined coulometrically and the mean concentration $\bar{C}$ in copper was calculated.

Results and Discussion

Soubility of Sulfur in Copper. The plot of $\bar{C}$ *vs.* t/l^2 is given in Figs. 2 and 3. As is seen in these figures, $\bar{C}$ approaches to a saturation value C_s with the increase of t/l^2. Figure 4 shows the plot of log C_s *vs.* $1/T$. Clearly, a linear relationship exists between log C_s and $1/T$. The equation is

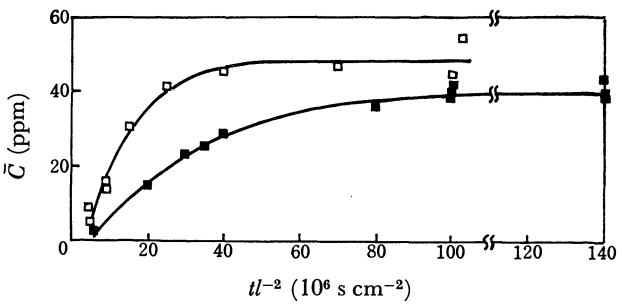

Fig. 2. Change of $\bar{C}$ with time.
■: 800 °C, □: 850 °C.

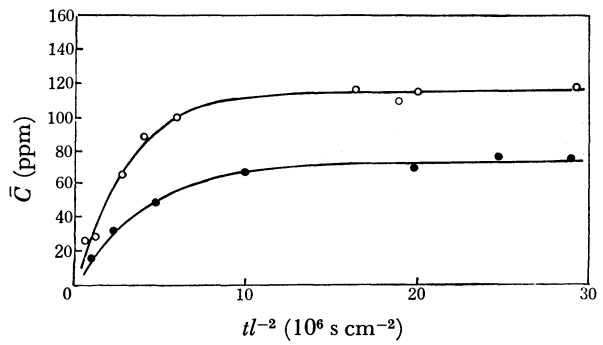

Fig. 3. Change of $\bar{C}$ with time.
●: 900 °C, ○: 950 °C.

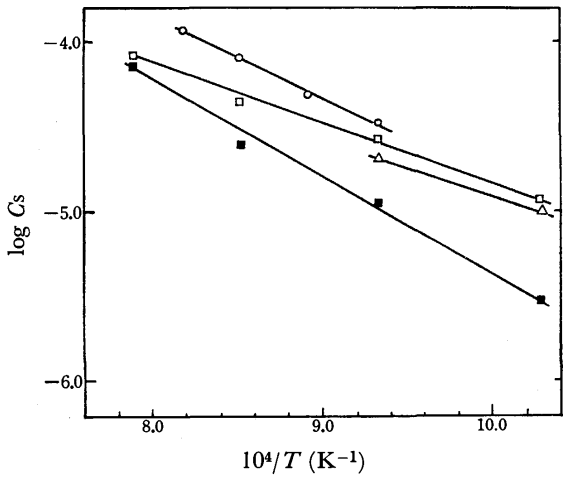

Fig. 4. Plot of log C_s *vs.* $1/T$.
○: This work, □: (Oudar): HPCu, ■: (Oudar): OFHC, △: Smart *et al.*

$$\log C_s(\text{ppm}) = -0.616 - 0.410\left(\frac{10^4}{T}\right). \qquad (11)$$

If the solubility is represented in terms of mole fraction N,

$$\log N(\text{ppm}) = -0.319 - 0.410\left(\frac{10^4}{T}\right). \qquad (12)$$

For comparison, Oudar's result[2] obtained by the tracer method and Smart's result[3] obtained from the relationship between sulfur content and resistivity of copper are also given in this figure These results are in good agreement with each other. The enthalpy and entropy of sulfur dissolution in copper in accordance with Eq. 1 are calculated to be 18.7 and −1.46 cal/mol·deg, respectively. The small entropy is probably due to the transfer of sulfur from solid to solid, as given by Eq. 1.

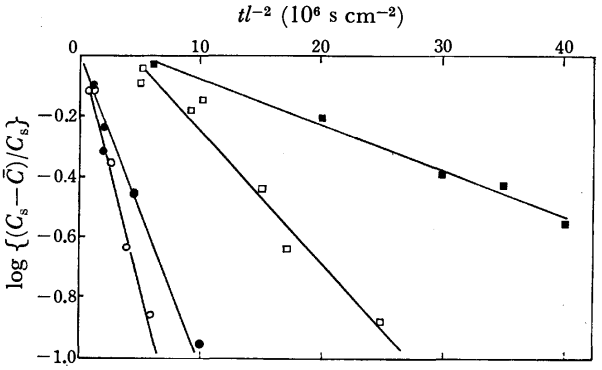

Fig. 5. Plot of log $\{(C_s-\bar{C})/C_s\}$ *vs.* t/l^2.
■: 800 °C, □: 850 °C, ●: 900 °C, ○: 950 °C.

Diffusion Coefficient. Figure 5 gives the relationship between log $(C_s-\bar{C})/C_s$ and t/l^2. A good linear relationship indicates that Eq. 9 holds for the present case and the diffusion coefficient D can be determined from the slope of the plot. The Arrhenius plot for D is given in Fig. 6. For comparison, Moya's result[4,5] obtained by the tracer method and the result obtained

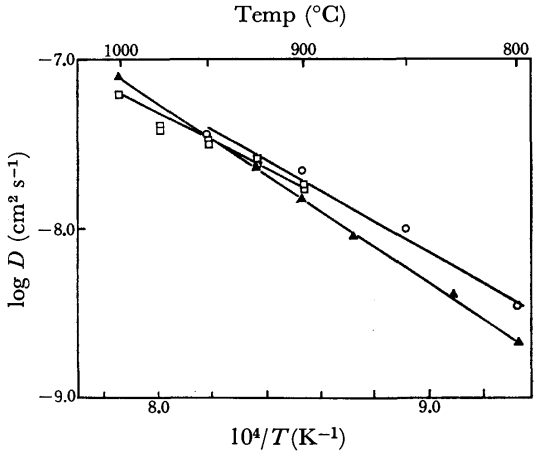

Fig. 6. Arrhenius plot for D.
○: This work, □: Wang and Grabke, ▲: Hoya.

by Wang and Grabke[6] by means of the relaxation method are shown in the same figure. These results agree with each other. The Arrhenius equation for the present work is

$$D = 0.834 \times \exp\left(-\frac{40900}{RT}\right)\text{cm}^2\,\text{s}^{-1}. \qquad (13)$$

Summary

(1) For the determination of solubility and diffusion coefficient of non-metallic elements in metals a new method was proposed. A thin compound film was formed on the metal surface and the film thicknesses before and after diffusion annealing were determined by the coulometric method.

(2) The solubility of sulfur in copper determined by the new method was given in terms of mole fraction by the equation

$$\log N_s(\text{ppm}) = -0.319 - 0.410\left(\frac{10^4}{T}\right).$$

This result was in good agreement with those obtained by other methods.

(3) The diffusion coefficient of sulfur in copper in the present investigation was represented by

$$D = 0.834 \times \exp\left(-\frac{40900}{RT}\right)\text{cm}^2\,\text{s}^{-1}.$$

This result agreed with the previous results obtained by other methods.

Molecular Structure and Conformation of Ethyl Methyl Ether as Studied by Gas Electron Diffraction

Kazuko OYANAGI and Kozo KUCHITSU*

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received March 20, 1978)

The bond distances (r_g) and angles (r_a) in ethyl methyl ether have been determined by gas electron diffraction as follows: average of C(methyl)–O and C(methylene)–O=1.418±0.002 Å, C–C=1.520±0.004 Å, C–H=1.118±0.004 Å, ∠C–O–C=111.9±0.5°, ∠O–C–C=109.4±0.3°, ∠H–C–H=109.0±0.4°, where uncertainties represent estimated limits of experimental error. The two r_g(C–O) distances have been estimated independently with the aid of the rotational constants for the *trans* conformer reported by Hayashi *et al.*: C(methyl)–O=1.413±0.009 Å and C(methylene)–O=1.422±0.007 Å. The dihedral angle for the *gauche* conformer, 84±6°, and the relative abundance of the *trans* and *gauche* conformers in the gas phase at 20 °C, $n_t/(n_t+n_g)=0.80\pm0.08$, have also been determined.

The conformation and the barrier to internal rotation about a C–O axis are of great importance in wide fields of chemistry, such as in polymer chemistry, and have been studied extensively by vibrational spectroscopy.[1–8] Ethyl methyl ether (Fig. 1) is one of the simplest molecules enabling such a study. This molecule is known to be a mixture of two conformers in the gas phase.[5–8] The infrared spectra observed by Kitagawa and Miyazawa[5] indicated that the more stable conformer was *trans*, and the enthalpy difference in the gas phase was measured to be 1.5±0.2 kcal/mol. The rotational constants for the *trans* conformer have been determined by Hayashi *et al.* by microwave spectroscopy, from which the r_s atomic coordinates have been derived.[9] On the other hand, the conformation of the less stable conformer has only been inferred by vibrational spectroscopy to be *gauche*. Since electron diffraction provides direct information on interatomic distances, it is one of the most powerful methods for determining the mixing ratio of the conformers and the dihedral angle for the less stable conformer.[10]

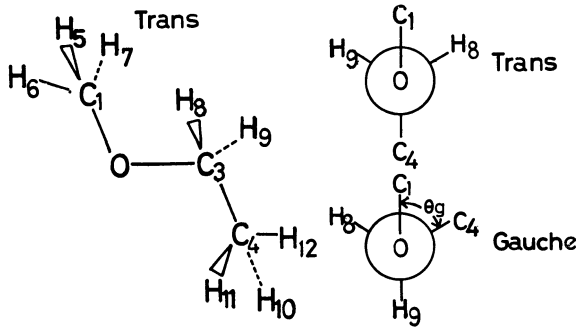

Fig. 1. Ethyl methyl ether. The dihedral angle for the *gauche* conformer measured from *cis* position is denoted by θ_g.

There are two non-equivalent C–O bonds in ethyl methyl ether. Though the average of these bond lengths can be obtained by electron diffraction, they cannot be determined individually. The moment of inertia I_a depends sensitively on these distances. Therefore, a joint analysis of electron diffraction intensity and the rotational constants can determine these nearly equal C–O distances separately, though the moments of inertia alone are not sufficient to determine a complete structure.

In the present study, the structure of ethyl methyl ether is determined first by use of the electron diffraction data alone. Then the difference of the two C–O distances is estimated by the use of the diffraction data and the rotational constants. Finally, the conformation is investigated and the structure of this molecule is compared with those of related molecules.

Experimental

The sample for spectroscopic use was supplied by Dr. Kitagawa.[7] Diffraction patterns were taken with an r^3-sector at camera lengths of 243.3 and 107.7 mm with 40 kV electrons. The electron wavelength was calibrated with reference to the r_a(C=O) distance of carbon dioxide (1.1646 Å) within 0.10%.[11] The sample reservoir was held in a Dry Ice–acetone bath in order to control the pressure of the sample at about 40 Torr during the experiment, and the sample gas was introduced into the diffraction chamber through a nozzle of 0.2 mm i.d. The exposure times were about 60 and 100 s for the long and short camera lengths, respectively. Other experimental conditions are described elsewhere.[11,12]

Four photographic plates taken at each camera length were selected for the intensity measurement by means of automated microdensitometry and data processing.[13] The optical densities (0.2—0.5) were assumed to be proportional to electron intensities. Molecular intensities in the ranges s=3.1—18.8 and 9.4—37.3 Å^{-1} were obtained from the long and short distance data, respectively, by use of hand-drawn backgrounds.

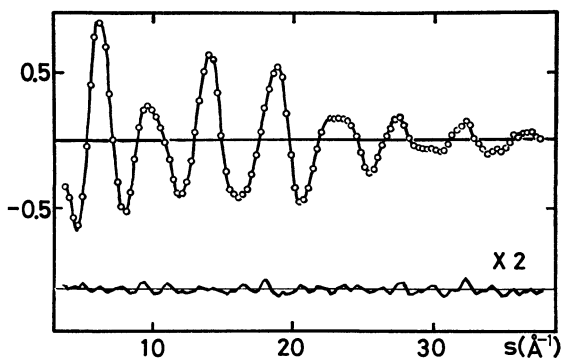

Fig. 2. Molecular intensities for ethyl methyl ether. Observed values are shown as open circles, and the solid curves represent the best-fit theoretical intensities. The lower solid curve represents the residuals.

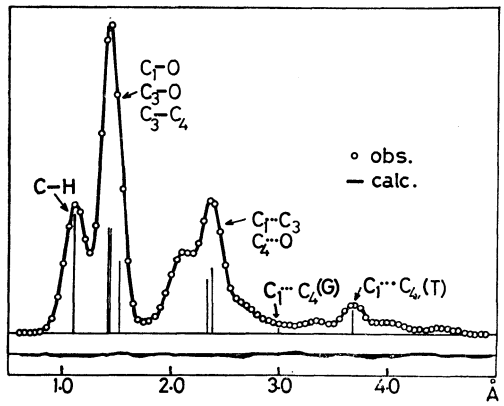

Fig. 3. Experimental and theoretical radial distribution curves. Damping factor, $\exp(-0.0016\,s^2)$, was used. The residuals are shown below in the same scale.

Since they agreed with each other in the overlapping region within experimental error, they were joined at $s=12.6$ Å^{-1}. Four independent molecular intensity curves covering the whole s range were obtained by arbitrary combinations of four intensity curves for each camera length. The elastic and inelastic scattering factors and the phase shifts were taken from the tables prepared by Schäfer *et al.*[14] The molecular intensity and the corresponding radial distribution curve are shown in Figs. 2 and 3, respectively.[15] Most of the calculations were carried out on a HITAC 8800/8700 in the Computer Center of the University of Tokyo.

Analysis

The essential information on the conformation is contained in the distance of the C(methyl)···C(methyl) nonbonded pair. This distance for the *trans* conformer appears in the radial distribution curve (Fig. 3) as a peak at 3.7 Å, while the small shoulder at 3.0 Å consists of the corresponding distance for the *gauche* conformer. The relative abundance of the two conformers can be derived from the heights of the peak and the shoulder. By comparing the observed radial distribution curve with the curves calculated assuming various mixing ratios, the *trans* conformer was found to be dominant, being in agreement with the results from vibrational spectroscopy.[4,6] The shape of the shoulder at 3.0 Å carries information on the dihedral angle for the *gauche* form. The conformational analysis is discussed in detail in a later section.

In order to obtain a more precise skeletal structure, the molecular intensities were analyzed by a least-squares method with an empirical diagonal weight matrix[16] on the assumption that no stable conformer other than the above two existed in the gas phase at room temperature. The following additional assumptions were made so as to reduce the number of independent parameters without significant loss of accuracy:

1) The *trans* conformer has C_s symmetry in the r_α structure.

2) The *trans* and *gauche* conformers have identical bond distances and angles except for the dihedral angle about the C(methylene)–O bond. (This assumption was modified in the conformational analysis described in a later section).

3) All the C–H bond distances are equal.

4) The difference in the C(methyl)–O and C(methylene)–O bond distances is 0 ± 0.01 Å, on the basis of the structural data for dimethyl ether[17] and ethyl alcohol.[18] (The need for this assumption was removed in the joint analysis of the molecular intensities and the rotational constants).

5) The H–C(methylene)–H plane is perpendicular to the O–C–C plane, and each angle is bisected by the plane defined by the other angle at the methylene carbon atom.

6) Each of the methyl groups has local C_{3v} symmetry and no tilt. With these assumptions, the geometrical parameters were restricted to seven: the C–C, $(C-O)_{av}$, $(C-H)_{av}$ bond distances, the C–O–C, O–C–C, $(H-C-H)_{av}$ bond angles and the dihedral angle for the *gauche* conformer. The dihedral angle for the *trans* conformer was set equal to 180° by assumption 1). In addition, the

a) Calculated at 20°C. See Fig. 1 for the numbers of atoms. Nonlinear shrinkages due to the C(methylene)–O torsion and the methyl torsions are included. (See text.) The values for H···H pairs are not listed.

mixing ratio of the two conformers was taken as a variable parameter.

The mean amplitudes and the vibrational corrections for all interatomic distances,[19,20] listed in Table 1, were calculated with the force constants based on the valence force field.[4] Since the skeletal and methyl torsions were large-amplitude motions, contributions to the vibrational corrections from these motions were estimated by Karle's method[21,22] with the barrier heights (V_3) obtained from far infrared spectroscopy.[7] The contribution from the skeletal torsion to the vibrational correction for the C(methyl)···C(methyl) nonbonded pair, about 0.003 Å, had some influence on the dihedral angle, while those from the methyl torsions affected the corrections for the nonbonded C···H and O···H pairs by about 0.004 Å, and the H–C–H angle was influenced consequently. The asymmetry parameter κ for the bonded C–H distance was estimated to be 1.3×10^{-5} Å^3,[23,24] and the rest of the κ parameters were assumed to be zero, since they had little effect on molecular geometry. Since the C–C bond and two C–O bonds form a single peak in the radial distribution curve, the amplitudes for the C–O and C–C bonds could not be varied independently. Therefore, the amplitudes for the C–H and C–O bonds were taken as parameters and the rest of the mean amplitudes were fixed to the calculated values. The structure obtained in this analysis (average of the structures derived from the four molecular intensities mentioned above) is listed in Table 2. The error limits in the molecular parameters were estimated from random and systematic errors including the uncertainties originating from those in the amplitudes and the vibrational corrections.[25,26] The relative uncertainties in the amplitudes and the vibrational corrections for bonded pairs were tentatively estimated to be 5%. The mean amplitudes and the vibrational corrections for nonbonded pairs consist of the contributions from the small-amplitude and large-amplitude modes. The former contributions were estimated to have relative uncertainties of ±10%, while the latter contributions calculated by Karle's method were estimated to have uncertainties of 100% of the contributions. The uncertainties caused by the assumptions mentioned above were also estimated roughly and included in the errors given in Table 2. A typical error matrix is shown in Table 3.

Table 2. Molecular structure and mean amplitudes for ethyl methyl ether determined by electron diffraction[a]

r(C–C)	1.520(4)	∠C–O–C	111.9(5)

l(C–H)$_{av}$[c]	0.082(5)		

a) Bond distances (r_g) are in Å units. Angles (r_α) are in degrees. The numbers in parentheses represent estimated limits of error attached to the last significant digits. b) These distances were separately determined by the joint analysis. The other parameters obtained by the joint analysis were essentially equal to those given in this table. c) Observed mean amplitudes. d) The dihedral angle for the *gauche* conformer measured from the *cis* position. e) % *trans* form. $\Delta G=1.23\pm0.27$ kcal/mol.

Electron Diffraction and Microwave Data. The r_α structure derived from the electron diffraction data was used to calculate the rotational constants. For this purpose the r_α distances were extrapolated to zero kelvin by estimating the difference $r_\alpha^0-r_\alpha$.[19] The rotational constants, A_α^0, B_α^0, and C_α^0, for the *trans* conformer were calculated from the average r_α^0 structure, and are listed in Table 4. On the other hand, the zero-point average rotational constants, A_z, B_z, and C_z, for the *trans* conformer were derived by making vibrational corrections[27] from the A_0, B_0, and C_0 determined by microwave spectroscopy.[9] The uncertainties in A_z,

a) Diagonal elements of error matrix. Units ($\times10^{-4}$) for the distances and mean amplitudes are Å, those for the indices and the relative abundance of the *trans* form are dimensionless. b) Correlation matrix. Units ($\times10^{-2}$) are all dimensionless. c) k_1,k_2=indices of resolution for the long and short distance data, (0.94±0.02 and 1.03±0.07) respectively, x_1=relative abundance of the *trans* form, $x_2=r$(C–C), $x_3=r$(C–O)$_{av}$, $x_4=r$(C–H)$_{av}$, $x_5=\angle$C–O–C, $x_6=\angle$O–C–C, $x_7\angle=$H–C–H, x_8=dihedral angle for the *gauche* form, $l_1=l$(C–H)$_{av}$ and $l_2=l$ (C–O)$_{av}$.

Table 4. Observed and calculated rotational constants for *trans* ethyl methyl ether (in cm^{-1})

	0[b]	z[c]	α^0 [d]	av[e]
A	0.933712(1)	0.941(3)	0.940(4)	0.937(4)
B	0.138745(1)	0.1388(3)	0.1375(12)	0.1383(5)
C	0.129796(1)	0.1298(2)	0.1289(10)	0.1295(4)

a) Uncertainties attached to the last significant digits are given in parentheses. b) Observed rotational constants for the ground vibrational state, Ref. 9. c) Zero-point average rotational constants calculated from A_0, B_0, and C_0 with corrections for vibrational effects. d) Rotational constants calculated from the r_α^0 parameters which are compatible with the structure given in Table 2 determined in the analysis of electron diffraction intensities. Uncertainties are estimated from those in the r_α parameters. e) Best fit rotational constants obtained by the combined analysis of diffraction and microwave data. The structural parameters (r_{av}) which reproduce these constants are essentially equal to those given in Table 2 if the distances are transformed into r_g. Uncertainties represent 2.5 times the estimated standard deviations.

B_z, and C_z were estimated from the following sources: a) Uncertainties in the corrections for the large-amplitude modes were estimated to be $\pm 100\%$ of the corrections. b) The uncertainties in the corrections for all the small-amplitude modes were estimated to be $\pm 10\%$ of the corrections. The rotational constants, A_α^0, B_α^0, and C_α^0, calculated from the r_α^0 structure agreed with the zero-point average rotational constants, A_z, B_z, and C_z, within their uncertainties. This suggests that the frame structures of the *trans* and the *gauche* conformers do not differ greatly.

The rotational constants, A_z, B_z, and C_z, were thus combined with diffraction intensities into a joint least-squares analysis.[23,28] The weights for A_z, B_z, and C_z used in the analysis were so chosen that 2.5 times their standard deviations were approximately equal to the estimated uncertainties in the rotational constants. They were 1×10^3, 1×10^5, and 1×10^5, respectively, where a unit weight was assigned to the molecular intensities from $s=6.3$ to 26.7 $Å^{-1}$ taken at $\pi/10$ $Å^{-1}$ intervals. The r_{av} structure agreed with the r_α^0 structure, and the mean amplitudes also converged to essentially the same values as those obtained in the analysis of the electron diffraction data alone. The assumption 4) made in the analysis of the diffraction intensities was now excluded, and the two C–O bond distances were varied independently. The average of the two C–O bond lengths determined separately in the present analysis (listed in Table 2) is equal to that obtained from electron diffraction.

Rotational Isomerism. The differences in the geometrical parameters for the *trans* and *gauche* conformers have influence on the conformational analysis. For this molecule the dihedral angle for the *gauche* conformer is derived from the bonded distances, the skeletal angles and the nonbonded C(methyl)···C(methyl) distance. Among their uncertainties those in the skeletal angles have much influence on that of the dihedral angle. Since at present there are no experimental data on the differences of the geometrical parameters for the *trans* and *gauche* conformers, the O–C–C and C–O–C angles were assumed to be 0—3° larger in the *gauche* form than in the *trans* form on the basis of the structural data for analogous molecules.[29,30] The error limit in the dihedral angle listed in Table 2 includes the influence of these uncertainties.

The effective temperature of the sample system at the scattering point must be defined when the "thermal-equilibrium" fractions of rotational isomers are discussed. The following assumptions were made: When the sample gas leaves the jet, it has reached thermal equilibrium with the nozzle throat. With our nozzle design the cooling of the gas in the passage from the nozzle tip to the scattering point is negligible.[31] Therefore, the effective vibrational temperature was assumed to be equal to the room temperature. The population of the *trans* conformer given in Table 2, $80\pm8\%$, then implies that the *gauche-trans* free energy difference ΔG is 1.23 ± 0.27 kcal/mol, the uncertainty including that in the effective temperature. This estimate is compatible with the enthalpy difference ΔH, 1.5 ± 0.2 kcal/mol, obtained by the temperature dependence of spectral intensities.[5]

In order to further examine the rotational isomerism in ethyl methyl ether, the molecular intensities in the range from $s=3.5$ to 8.2 $Å^{-1}$ were analyzed by the method of background function.[32,33] The background functions $I_b(s)$ were derived from the experimental total intensities $I_t(s)$ and from the theoretical molecular intensities $sM(s)$ based on models. The smoothness of the $I_b(s)$ function, *i.e.* the absence of systematic fluctuations with periods similar to that of the molecular terms, was taken as a criterion for the choice of a proper conformational model. The theoretical molecular intensities $sM(s)$ were calculated with the structural parameters determined in the preceding section, and the mixing ratio and the *gauche* dihedral angle were varied. Typical I_b curves for a number of models are illustrated in Fig. 4. The I_b curve corresponding to a *trans* population of 80% and a *gauche* dihedral angle of 85° is acceptable since it has no fluctuation exceeding 0.5% of I_b, whereas all the other models shown in the figure are unacceptable because they result in systematic oscillations in the I_b curves.

The limit of uncertainty in the background function was estimated from two principal sources of error:[32,33] the random and systematic errors in the intensity measurement and the uncertainties in the structural

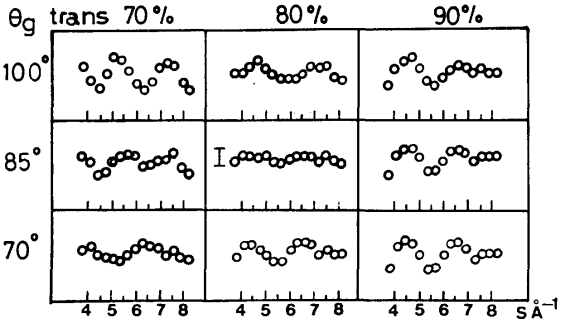

Fig. 4. Background functions I_b for different compositions of the *trans* and *gauche* conformers and dihedral angle (θ_g) for the *gauche* form. The vertical bar represents 0.5% of I_b. See text.

parameters assumed in this background analysis. The effect of the former was estimated by checking the reproducibility of the intensities obtained from different photographic plates and by examining various sources of systematic error.[26] The systematic error originating from the error in the frame structure was checked by calculating the background function with sets of the geometrical parameters varied within the limit of their estimated uncertainties. The limit of uncertainty in the background function was thus estimated to be $\pm 0.5\%$. This value corresponds to the limit of uncertainty of less than 10% in the mixing ratio and that of less than 10° in the dihedral angle. Consequently, the conformational parameters determined by the method of background function agree with those obtained from the least-squares method.

Comparison with Related Molecules

The skeletal structure of ethyl methyl ether is compared with those of analogous molecules (Table 5). The $(C-O)_{av}$ bond length and the C–O–C bond angle agree with those in dimethyl ether [17] within their uncertainties. The C–C bond distance (1.520 ± 0.004 Å) is significantly shorter than that in butane (1.531 ± 0.004 Å).[29] The C–H bond length is very similar to that in butane. The r_g C–C bond length and the C–O–C and H–C–H bond angles in the r_α structure are nearly equal to those in the r_s structure,[9] while the C–H and $(C-O)_{av}$ bond distances (r_g) are slightly larger than the corresponding r_s distances. In view of the known differences in the r_g and r_s structures for analogous molecules,[34] these r_g and r_s distances seem to correspond well. On the other hand, there seems to be a slight discrepancy between the r_g and r_s structures in regard to the difference of the C(methyl)–O and C(methylene)–O bond lengths: The r_g structure indicates a *positive* difference of the order of 0.01 Å, whereas the r_s structure indicates a *negative* difference of the same order of magnitude. However, neither trend can be regarded as conclusive, since these distance parameters have large uncertainties (particularly the r_s structure has systematic error because the oxygen coordinates were determined with the aid of the first-moment equation).

Table 5. Comparison of related molecules

	$CH_3OCH_2CH_3$[b]	CH_3OCH_3	CH_3CH_2-CH_2CH_3[d]
C–C	1.520(4)	—	1.531(2)
C–O	1.418(2)[e]	1.418(3)[f]	—
C–H	1.118(4)	1.100(6)[f]	1.117(5)
∠C–O–C	111.9(5)	111.5(15)	—
θ_g[g]	84(6)	—	65(6)
$n_t/(n_t+n_g)$[h]	80(8)	—	54(9)
ΔG[i]	1.23(27)	—	0.50(22)

a) Distances in r_g and angles r_α (r_a for c). Uncertainties represent estimated limits of error attached to the last significant digits. b) Present study. c) Ref. 17. d) Ref. 29. e) Average value of the two C–O bond lengths. f) Estimated from the r_a distance reported in the literature by addition of l^2/r_a. g) The dihedral angle for the *gauche* conformer measured from *cis* position. h) % *trans* form. i) Free energy difference (kcal/mol): $\Delta G = G_{gauche} - G_{trans}$.

The *gauche* dihedral angle in ethyl methyl ether ($84 \pm 6°$) obtained in the present study is significantly larger than that in butane ($65 \pm 6°$).[29]

Structures of a number of polyether crystals were recently determined by X-ray diffraction.[35-37] The C–C bond lengths adjacent to C–O bonds, determined to be about 1.48—1.52 Å, are shorter than the usual C–C bond distances. This trend is similar to that observed in the C_1–C_2 bond lengths in ethyl methyl ether. The conformation about the C–O bonds in polyethers is found to be most commonly *trans*. However, some intra- and intermolecular forces make the *gauche* conformation stable in some parts of a polymer, and in this case the dihedral angles about the C–O bonds for the *gauche* conformation are about 70—90°. This trend is analogous to that observed for small molecules in the gas phase by electron diffraction.

The authors are indebted to Professor Tatsuo Miyazawa, Professor Michiro Hayashi, and Dr. Teizo Kitagawa for helpful discussions, to Dr. Tsutomu Fukuyama for his technical assistance in the diffraction experiment and analysis, and to Miss Mami Mikami for her assistance in the initial stage of the present study.

Molecular Structure and Conformation of Ethyl Methyl Sulfide as Studied by Gas Electron Diffraction

Kazuko OYANAGI and Kozo KUCHITSU*

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received April 21, 1978)

The bond distances (r_g) and angles (r_a structure) in ethyl methyl sulfide have been determined by gas electron diffraction as follows: average of C(methyl)–S and C(methylene)–S=1.813±0.004 Å, C–C=1.536±0.008 Å, C–H=1.111±0.008 Å, ∠C–S–C=97.1±1.1°, ∠S–C–C=114.0±0.5°, ∠H–C–H=109.6±1.4°, where uncertainties represent estimated limits of experimental error. The two C–S lengths have been estimated independently with the aid of the rotational constants for the *trans* conformer reported by Hayashi *et al.*: C(methyl)–S=1.806±0.027 Å, C(methylene)–S=1.818±0.027 Å. The dihedral angle for the *gauche* conformer (66±9°) and the relative abundance of the *trans* and *gauche* conformers in the gas phase at 20 °C, $n_t/(n_t+n_g)=0.25\pm0.15$, have also been determined.

In the preceding paper,[1] the conformation of ethyl methyl ether was studied by gas electron diffraction, and the *trans* conformer was found to be more stable than the *gauche* conformer. The conformations of normal alkanes have also been investigated in detail by this method.[2,3] Electron diffraction is an important tool for such a conformational analysis,[4,5] since it provides, in principle, information on all interatomic distances in a molecule. However, conformations about the C–S bond in saturated compounds have never been studied by gas electron diffraction except for that in ethyl methyl disulfide.[6] Ethyl methyl sulfide is one of the simplest compounds that have internal rotation about the C–S bond. The vibrational spectra of this molecule have been observed and the conformation has been discussed.[7–11] The conformation was also investigated by a calculation based on molecular mechanics.[12] These studies have shown that there exist two conformers, the *gauche* and *trans* forms, in the gas and liquid phases. Spectroscopic experiments concluded that the two conformers had nearly the same energy in the gas phase,[8] the *gauche* conformer being 30±50 cal/mol more stable.[11]

In the present study, the frame structure and the mixing ratio of the two conformers have been derived from electron diffraction. In addition, the rotational constants of the *trans* conformer of the normal species determined by microwave spectroscopy[13] were used with our electron diffraction data to estimate the individual C–S bond lengths.

Experimental

A commercial sample (Tokyo Kasei Co., Ltd.) was purified by distillation. The purity was checked by gas chromatography, and the sample was found to be more than 99% pure.

Diffraction photographs were taken at camera lengths of 107.7 and 243.3 mm with an apparatus equipped with an r^3-sector.[14] The accelerating voltage was about 40 kV and was stabilized within 0.01% during the experiment. The sample was maintained at thermal equilibrium with its liquid phase at room temperature. The vapor pressure was about 100 Torr, and the exposure times were about 15 and 30 s for the long and short camera lengths, respectively. The scale factors of the diffraction patterns were calibrated with reference to the C=O distance (r_a) of carbon dioxide (1.1646 Å) measured under the same experimental conditions. Other experimental details are described elsewhere.[14,15]

Three photographic plates at each camera length were selected for the analysis. The optical density (0.15—0.45) was measured by a microphotometer and an integrating digital voltmeter, and it was assumed to be proportional to the molecular intensities. After correction for the imperfections of the r^3-sector shape and hand drawing of a smooth background, molecular intensities were obtained in the range s=3.7—18.8 (long) and 7.9—34.5 Å (short) at intervals of $s=\pi/10$ Å^{-1}.[16]

Since they agreed with each other in the overlapping region within their experimental errors, they were joined at s=11 Å^{-1}. The elastic and inelastic scattering factors and the phase shifts, which were required to remove the atomic and inelastic scattering, were taken from the tables prepared by Schäfer *et al.*[17] A typical molecular intensity and the corresponding

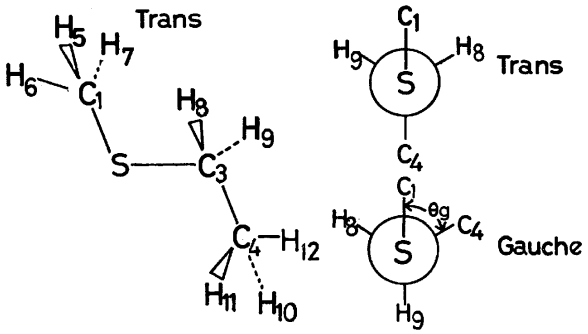

Fig. 1. Ethyl methyl sulfide. The dihedral angle for the *gauche* conformer measured from *cis* position is denoted by θ_g.

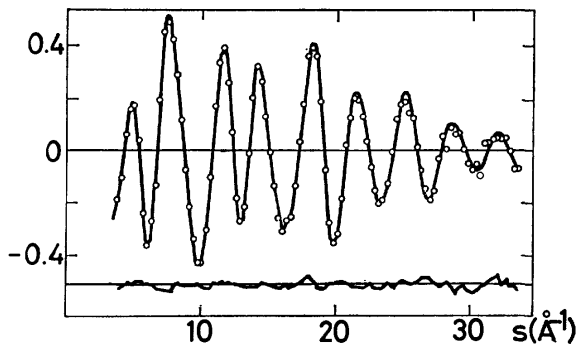

Fig. 2. Molecular intensities for ethyl methyl sulfide. Observed values are shown as open circles, and the solid curve represents the best-fit theoretical intensity. The lower solid curve represents the residuals.

radial distribution curve are illustrated in Figs. 2 and 3, respectively. Most of the calculations were carried out on a HITAC 8800/8700 in the Computer Center of the University of Tokyo.

Results and Discussion

Analysis of the Diffraction Data. The radial distribution curve has the following features: All the distances are contained in the 1.0—2.0 Å region. The peak at 1.1 Å is due to the C–H distance, and the C–C distance makes a small peak at 1.5 Å. The prominent peak contains the two C–S distances. The peaks at 2.4 and 2.9 Å are due to the nonbonded distances independent of the torsion about the C(methylene)–S axis. The shoulder at 3.2 Å and the small peak at 4.2 Å are due to the torsion-dependent C(methyl)···C(methyl) distances; the former shoulder and the latter peak come from the *gauche* and the *trans* conformers, respectively. Thus, their relative populations in the gas phase are determined from the contour of these peaks, *i.e.*, from the contributions of the C(methyl)···C(methyl) distances. On the basis of this analysis, it was concluded that two principal conformers existed in the gas phase at room temperature. By comparing the observed radial distribution curve with the curves calculated from various mixing ratios, the *gauche* conformer was inferred to be dominant. This is consistent with the conclusion derived from spectroscopy. The mean amplitudes for the C(methyl)···C(methyl) nonbonded pairs are so large that the intensity contributions from these pairs fade out in larger scattering angles. Therefore, the ratio of the two conformers is determined by the molecular intensities in the range of $s<5$ Å^{-1}. On the other hand, the r_α structure of the skeleton is determined by a least-squares analysis of molecular intensities in the larger s range ($s>5$ Å^{-1}), since in this range correlation between the parameters for the frame structure and the mixing ratio is not significant.

In this least-squares analysis the following approximations were made in order to decrease the number of the structural parameters:

1) Each of the methyl groups has C_{3v} symmetry and has no tilt.

2) For the methylene group, the bisectors of the H–C–H angle and the S–C–C angle are colinear.

3) All the C–H bond lengths are equal.

4) The difference in the two C–S bond distances is 0 ± 0.01 Å, on the basis of the structural data for dimethyl sulfide,[18] 1,2-ethanedithiol.[19] (The need for this assumption was removed in a later stage).

5) The geometrical parameters of the two conformers are equal except for the dihedral angles about the C(methylene)–S bond. (This assumption was examined in a later stage).

6) The *trans* conformer has C_s symmetry.

With these assumptions, the molecular structure is described by six parameters: the C–C bond length, the average of the C–S bond lengths, the C–H bond length, the S–C–C angle, the C–S–C angle, the weighted average of the H–C–H angles, and the dihedral angle about the C(methylene)–S bond for the *gauche* conformer. The corresponding dihedral angle for the *trans* conformer was fixed to 180° according to assumption 6).

Table 1. Mean amplitudes (l_{ij}) and shrinkage corrections (r_a-r_α) for *trans* and *gauche* ethyl methyl sulfide[a] (in 10^{-4} Å)

a) Calculated at 20 °C. See Fig. 1 for the numbering of the atoms. Nonlinear shrinkages due to the C (methylene) –S torsion and the methyl torsions are included. (See text.) The values for H···H pairs are not listed.

The asymmetry parameter κ[20] for the C–H bond was estimated to be 1.3×10^{-5} Å^3 from the anharmonicity parameter a_3 for the C–H bond, which was assumed to be 1.98 Å^{-1}.[21] The asymmetry parameters for other atom pairs were ignored, since they did not contribute to molecular intensities significantly. The mean amplitudes and the shrinkage corrections (r_a-r_α)[22,23] for all the atom pairs were calculated on the basis of the modified Urey-Bradley force field,[9] as listed in Table 1. The frequencies of the skeletal and methyl torsions may be so low that a large-amplitude treatment is necessary. Since the frequencies and the potential functions for the skeletal torsions were not known, the contributions from these vibrational modes were estimated by Karle's method.[24-26] The three-fold potential barrier for the C(methylene)–S torsion was estimated to be about 500 cm^{-1} from those of methanethiol[27] and ethanethiol[28] assuming additivity of the contributions from substituted atoms or atom groups to the potential barrier.[29] The mean amplitudes estimated from the barrier height

turned out to be smaller than those estimated by the usual approximation of infinitesimal displacements. Karle's correction had the largest effect on the mean amplitude of the C(methyl)···C(methyl) nonbonded pair for the *gauche* conformer. The only significant effect of this torsion on the $r_a - r_\alpha$ is that for the C(methyl)···C(methyl) nonbonded atom pair, 0.0094 Å. The effect of the methyl torsions was estimated from the threefold potential barrier of about 700 cm^{-1} for the C(methyl)–S group and about 1400 cm^{-1} for the C(methyl)–C group, which were assumed from those of related molecules.[28,30] The uncertainties in the mean amplitudes and the shrinkage corrections were assumed to be 100% for the contributions from the C(methylene)–S and methyl torsions and 10% for those from the other modes.

The mean amplitudes of the C–C, the average of the C–S amplitudes and the weighted average of the C–H amplitudes were varied as parameters in the subsequent analysis. Other mean amplitudes were fixed to the values listed in Table 1. A conventional diagonal weight matrix was used in the analysis.[31] In this stage, the structural parameters obtained were the weighted *trans* and *gauche* parameters. The r_α structure and the r_g distances derived from the r_α structure are listed in Table 2. The error limits listed in this table were estimated from random and systematic errors including those originating from the approximations mentioned above.[32,33]

Table 2. Structure and mean amplitudes for ethyl methyl sulfide derived from electron diffraction data (in Å and degrees)

	r_α	r_g	ε[a]
$(C-S)_{av}$	1.811	1.813	0.004
$C_{methyl}-S$[b]	1.804	1.806	0.027
$C_{methylene}-S$[b]	1.816	1.818	0.027
C–C	1.534	1.536	0.008
C–H	1.096	1.111	0.008
∠C–S–C	97.1		1.1
∠S–C–C	114.0		0.5
∠H–C–H	109.6		1.4
θ_g[c]	66		9
$n_t/(n_t+n_g)$[d]	0.25		0.10
l(C–H)	0.079		0.005
l(C–C)	0.058		0.007
$l(C-S)_{av}$	0.054		0.004

a) Estimated limits of error. b) These distances were determined separately by a joint analysis. The rest of the parameters obtained by the joint analysis were essentially equal to those given in this Table. c) The dihedral angle for the *gauche* conformer measured from the *cis* position. d) Relative abundance of the *trans* conformer at room temperature estimated by the method of background function. See text.

Analysis of Diffraction Data with Supplementary Use of the Rotational Constants. The observed diffraction intensity carries information on the structures of the two conformers. On the other hand, the rotational constants are known only for the less abundant *trans* conformer, but the structure of this conformer has not been determined from the rotational constants. In order to take these rotational constants into the analysis as additional experimental information, the difference in the geometrical parameters for the *trans* and the *gauche* conformers had to be assumed. In the analysis of normal alkanes,[34] the C–C–C angle in the *gauche* conformer was estimated to be $0.1 \pm 1°$ larger than the corresponding angle in the *trans* conformation on account of the *gauche* C–C interaction, while their C–C bond lengths were assumed to be equal. Since existing spectroscopic data[11] and calculations based on molecular mechanics[12] suggest little enthalpy difference between the two conformers, it seems unlikely that intramolecular strain in the *gauche* conformer causes its skeletal structure to differ greatly from that of the *trans* conformer. Therefore, the possible differences in the skeletal C–C–S and C–S–C angles in the *gauche* and *trans* conformers were assumed to be 0—2°. It was also assumed that all the bond lengths were equal in the two conformers. Since the rotational constants for the *trans* conformer have different dependence on the two C–S bond lengths, it was possible to treat these distances as independent parameters in the joint analysis.

Table 3. Observed and calculated rotational constants for *trans* ethyl methyl sulfide[a] (in cm^{-1})

	B_0[b]	B_z[c]	$B_\alpha{}^0$[d]	B_{av}[e]
A	0.5342879	0.537(5)	0.526(15)	0.533(5)
B	0.106293	0.1063(2)	0.1056(20)	0.1058(8)
C	0.0933749	0.0934(1)	0.0923(12)	0.0930(5)

a) Uncertainties attached to the last significant digits are given in parentheses. b) Observed rotational constants for the ground vibrational state. Uncertainties are not listed in the original reference. Ref. 13. c) Zero-point average rotational constants calculated from A_0, B_0, and C_0 with corrections for vibrational effects. d) Rotational constants calculated from r_α parameters given in Table 2 determined in the analysis of electron diffraction intensities. Uncertainties are estimated from those in the r_α parameters. e) Best-fit rotational constants corresponding to the r_α sturcture, listed in Table 2, derived from the combined analysis of diffraction and microwave data. Uncertainties represent 2.5 times the estimated standard deviations.

The rotational constants for the ground vibrational states, A_0, B_0, and C_0, were converted to the zero-point average rotational constants, A_z, B_z, and C_z, by the harmonic corrections[35] listed in Table 3. The uncertainties in these corrections were assumed to be 100% for the contributions from the C–S and methyl torsions and 10% for those from all the other small amplitude modes. The uncertainties in the average rotational constants originate mainly from these corrections. The r_α structure determined by electron diffraction was extrapolated to zero kelvin by estimating the difference $r_\alpha - r_\alpha{}^0$.[23] In order to check the consistency of the diffraction data and the rotational constants, the rotational constants, $A_\alpha{}^0$, $B_\alpha{}^0$, and $C_\alpha{}^0$ for the *trans* conformer were calculated from the $r_\alpha{}^0$ structure and compared with A_z, B_z, and C_z. The agreement was

a) Error matrix. Units ($\times 10^{-4}$) for the distances and mean amplitudes are Å, those for the angles are rad, and those for the indices are dimensionless. b) Correlation matrix ($\times 10^{-2}$). c) k_1,k_2=indices of resolution for the long and short distance data, respectively, $x_1=r$(C–C), $x_2=r$(C–S)$_{av}$, $x_3=r$(C–H)$_{av}$, $x_4=\angle$C–S–C, $x_5=\angle$S–C–C, $x_6=\angle$H–C–H, x_7=dihedral angle for the *gauche* conformer, $l_1=l$(C–H), $l_2=l$(C–S), and $l_3=l$(C–C).

within the experimental uncertainties of A_α^0, B_α^0, and C_α^0, as shown in Table 3. Hence, these constants were used with the diffraction intensities as subsidiary observables. The weights for the rotational constants used in this analysis were estimated by the procedure mentioned in Ref. 1; they are 1×10^3, 1×10^4, and 1×10^4 for A_z, B_z, and C_z, respectively, where a unit weight was assigned to the molecular intensities from $s=10.5$ to 25.1 Å^{-1} taken at $s=\pi/10$ Å^{-1} intervals. A typical error matrix is shown in Table 4. The r_{av} structure[23] agreed with the r_α^0 structure, and the mean amplitudes also converged to essentially the same values as those obtained in the analysis of the electron diffraction data alone. The assumption 4) made in the analysis of the diffraction intensities was now removed, and the two C–S bond distances were varied independently. The two C–S bond lengths estimated separately in the present analysis are listed in Table 2. Their limits of uncertainty include the systematic uncertainties caused by the various assumptions described above, the main origin of the uncertainties being the assumed differences in the skeletal C–C–S and C–S–C angles in the *gauche* and *trans* conformers. The average of the C–S distances is equal to that obtained from electron diffraction.

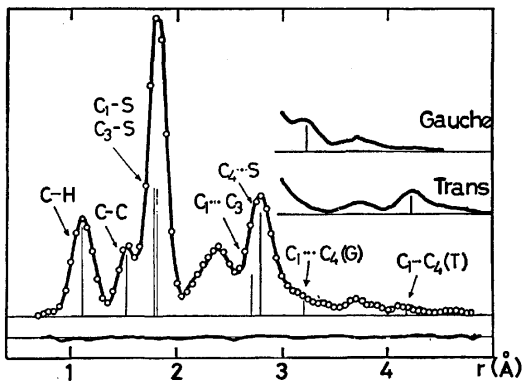

Fig. 3. Experimental and theoretical radial distribution curves. Damping factor, exp(−0.0016 s^2), was used. The residuals are shown below in the same scale.

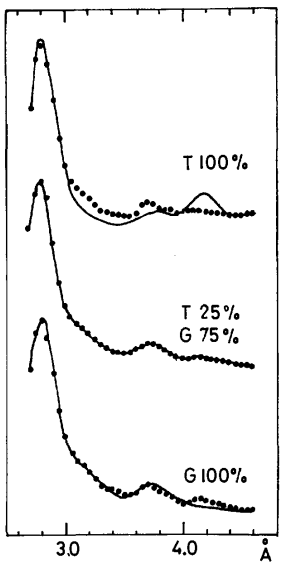

Fig. 4. Experimental and theoretical radial distribution curves illustrating the dependence on internal rotation.

Rotational Isomerism. The experimental radial distribution curve is compared in Fig. 4 with the theoretical radial distribution curves based on several different compositions of the *gauche* and *trans* conformers. The peaks from 3 to 4 Å^{-1} in the experimental curve show that in the gas phase at room temperature** the *gauche* form occupies more than 60% of the total population.

The essential experimental information about the conformation is contained in the molecular intensities from $s=2.2$ to 5.0 Å. The molecular intensity in this range is slightly influenced by the electron distributions forming chemical bonds. However, this effect[36] is less

** As discussed in Ref. 1, the above estimate of the sample temperature is based on the assumption that the thermal equilibrium at the temperature of the nozzle (room temperature) was retained in the gas jet when the electron beam was diffracted by the gas molecules.

than the error limits estimated below. The molecular intensities in this range measured at intervals of $s=\pi/10$ Å^{-1} were analyzed by the method of background function.[37,38] This method makes use of a background function $I_b(s)$ derived from the experimental total intensities $I_t(s)$ and the molecular intensities $sM(s)$ calculated from a structural model. If the structural model is correct, the I_b function should be free from fluctuations with a period similar to that of the molecular term. In other words, whether or not the I_b function oscillates with an amplitude exceeding a certain noise level is a sensitive criterion for selecting an acceptable conformation model. The I_b functions based on several different assumptions of the mixing ratio are shown in Fig. 5. Theoretical molecular intensities based on the

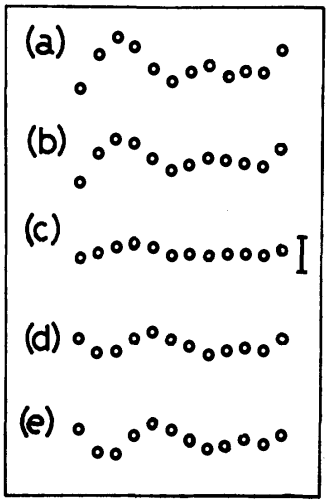

Fig. 5. Background functions I_b for different compositions of the *gauche* and *trans* isomers. (a) 60%, 40%, (b) 70%, 30%, (c) 75%, 25%, (d) 80%, 20%, and (e) 90%, 10%. The vertical bar represents 0.8% of I_b. See text.

geometrical parameters determined in the preceding section were used for the calculation of I_b. Models of A, B, C, D, and E correspond to the *trans* fractions of 40, 30, 25, 20, and 10%, respectively. A nearly flat I_b function is obtained for Model C. On the other hand, systematic fluctuations with a period of 1.6 Å^{-1} corresponding to the C_1–C_3 distance in the *trans* conformer appear in A, B, D, and E. They demonstrate that these models contain unacceptable assumptions regarding the *trans* fraction.

The limit of uncertainty of this background-function method depends on two sources: uncertainties in the model used for calculating the molecular terms, and random and systematic errors in the experimental intensities. In order to check the former uncertainties, background functions were calculated with various sets of the geometrical parameters. The effect of the latter was estimated by checking the reproducibility of the intensities obtained from the three different photographic plates and by examining various sources of systematic error. As a consequence, the limit of uncertainty in the background function is estimated to be $\pm 0.8\%$. This leads to the uncertainties of 15% in the estimates of the *gauche* and the *trans* fractions in the gas phase at room temperature, 75 and 25%, respectively.

Comparison of Structures. The skeletal structure of ethyl methyl sulfide is compared with those of related molecules in Table 5. The average of the two C–S bond lengths is nearly equal to those in dimethyl disulfide[6] and ethyl methyl disulfide.[6] There has been little information about the difference of the C(methyl)–S and C(methylene)–S distances. The present analysis suggests that the C(methylene)–S distance is slightly larger than the C(methyl)–S distance, which is nearly equal to those of dimethyl sulfide[18] and methyl vinyl sulfide.[39] This trend is similar to that observed in the C(methyl)–O and C(methylene)–O bond distances in ethyl methyl ether.[1] The C–C bond length is equal to those in normal alkanes[40,41] within the limits of error. This bond length is not affected by the adjacent sulfur atom, whereas the C–C bond in ethyl methyl ether[1] is shortened by the adjacent oxygen atom. The C–S–C angle is nearly equal to that in dimethyl sulfide and 6° smaller than that in methyl vinyl sulfide.

The population of the *gauche* conformer of ethyl methyl sulfide, $75\pm15\%$ in the gas phase at room temperature, implies that the *gauche* conformer is slightly more stable than the *trans* conformer by ΔG of 0.18 ± 0.35 kcal/mol. This conclusion is compatible with that obtained from recent Raman spectroscopy. The energy difference between the conformers may be contrasted with those for butane[2] and ethyl methyl ether,[1] where the *trans* conformer is more stable than the *gauche* conformer by 0.50 ± 0.22 and 1.23 ± 0.26 kcal/mol, respectively. The stability of the *gauche* conformer for ethyl methyl sulfide is the largest among these molecules.

Table 5. Comparison of the structures of related molecules[a]

	C–S	C–C	C–S–C	$n_t/(n_t+n_g)$[l]	ΔG[m]
CH_3–S–CH_2–CH_3[b]	1.813(4)[j]	1.536(8)	98.0(7)	25(15)	−0.18(35)
CH_3–S–CH_3[c]	1.807(2)	—	99.05(4)	—	—
CH_3–S–S–CH_3[d]	1.816(3)	—	—	—	—

CH_3–S–CH=CH_2[f]	1.808(3)[k]	1.532(3)	104.6(8)	—	—
CH_3–CH_2–CH_3[g]	—	1.532(3)	—	—	—
CH_3–O–CH_2–CH_3[h]	—	1.520(4)	—	80(8)	1.23(27)
CH_3–CH_2–CH_2–CH_3[i]	—	1.531(2)	—	54(9)	0.50(22)

a) Distances (Å) in r_g and angles (deg) in r_{av} (r_a for f)). b) Present study. c) Ref. 18. d) Ref. 6. e) Ref. 6. f) Ref. 39. g) Ref. 40. h) Ref. 1. i) Ref. 2. j) Average of C_{methyl}–S and $C_{methylene}$–S distances. k) C_{methyl}–S distance. l) % *trans* form. m) Free energy difference (kcal/mol): $\Delta G=G_{gauche}-G_{trans}$.

The H···H nonbonded distances among the two methyl groups in these molecules make a reverse order; those in ethyl methyl ether are the smallest, and those in ethyl methyl sulfide are the largest. Steric effect of the rotors seems to play a dominant role in determining the relative stability of the conformers.

The authors are indebted to Professor Tatsuo Miyazawa and Professor Michiro Hayashi for their helpful comments and to Dr. Tsutomu Fukuyama for his technical assistance in the experiment and analysis.

Correlation between Relative Sensitivities for Electron Capture Detector and Chemical Structure of Aromatic Halogeno and Nitro Compounds

Yukikazu HATTORI,* Yoshio KUGE, and Shigeru NAKAGAWA
Environmental Pollution Control Center of Osaka Prefecture, Nakamichi, Higashinari-ku, Osaka-shi, Osaka 537
(Received July 13, 1977)

Relative sensitivities of an electron capture detector (ECD, ^{63}Ni) for aromatic halogeno and nitro compounds were measured at detector temperatures of 230, 290, and 320 °C. The effects of various substituents on the sensitivity of ECD were determined. A good correlation was recognized between the relative sensitivities of ECD and the positions of substituents for aromatic chloro, bromo, and nitro compounds. The plotted logarithm values of ECD sensitivities for aromatic chloro and bromo compounds *vs.* Hammett's σ values of various substituents are not linear, but the plots for aromatic nitro compounds follow a straight line. Modified σ values (σ_H) were determined on the basis of the relative sensitivities of aromatic chloro compounds. Plots of aromatic chloro, bromo, and nitro compounds *vs.* σ_H values gave straight lines. The temperature dependence of electron capture coefficients for these compounds was determined using D.C. mode. The electron capture spectra obtained are similar to those using pulsed mode.

Various organic compounds containing a halogen, oxygen, and sulfur atom exhibit electron capture sensitivities. Many reports of ECD sensitivities for these compounds have been published.[1-5] Lovelock and others reported the electron absorption coefficients for polychlorinated benzenes using a ^{3}H detector (pulsed mode).[1] The correlation between the sensitivity of various pesticides and their molecular structure was examined by Zielinski and others[2-4] using a ^{3}H detector. But in these studies the complete rule of the correlation could not be established and the temperature dependence of the sensitivity was not considered.

Wentworth *et al.*[6-12] have studied the thermal electron attachment to various compounds using the pulse-sampling technique. In their reports, the temperature dependence of electron capture coefficients (K values) was elucidated. Activation energies for electron capture reactions and the electron affinities of these compounds were also calculated.

Vessman *et al.*[13] investigated the correlation of the temperature dependence of sensitivities with the molecular structure for benzophenone derivatives by using a ^{3}H detector (D.C. mode).

Recently, Kojima and Satouchi *et al.*[14-19] investigated minutely the temperature dependenc of K values by using a ^{63}Ni detector which could operate at a higher detector temperature than the ^{3}H detector used by Wentworth *et al.* They pointed out that electron capture reactions for aromatic halogeno compounds were similar to bimolecular nucleophlic substitution.

In this work, sensitivities of ECD for aromatic halogeno and nitro compounds at three different detector temperatures were determined by using a ^{63}Ni detector. Moreover, the temperature dependence of electron capture coefficients was investigated. The relationships between ECD response and the molecular structure of these compounds were studied with D.C. mode. We intend to use this relationship for prediction of ECD sensitivity and for identification of unknown samples.

Experimental

Apparatus and Materials. A Varian aerograph 2100 type gas chromatograph with an electron capture detector (^{63}Ni, 8.5 mCi) was used in this experiment. Applied voltage was supplied with D. C. mode. The glass column (2 mm$\phi \times$ 1.5 m) was packed with Gaschrom Q (100—120 mesh) coated with 5% Bentone 34 and 5% Silicone DC-200. Nitrogen gas was used as a carrier gas; the flow rate was 30 ml/min. The temperature of the sample injection part was kept at 200 °C. The column temperature was set ordinarily at 100 °C. The temperature of the detector cell (foil temperature) was changed from 150 (130) to 350 °C (290 °C). The reagents used were all commercially available (special and guaranteed grade from Tokyo Chemical Co.). All reagents were checked by gas chromatography and distilled before use if necessary.

Procedure. The relative sensitivity (hereafter abbreviated to *R.S.*) was obtained by calculating the relative peak area per mole of the compound, using *p*-dichlorobenzene as a standard. The sample size was so chosen as to keep the peak area within a linear range on the calibration curve. The area under the chromatographic peak was obtained by multiplying the peak height by the width at half point of peak height. The relative retention time (hereafter abbreviated to *R.R.T.*) was also obtained by using *p*-dichlorobenzene as a standard, ordinarily at a column temperature of 100 °C. The electron capture coefficient (K value) was calculated from the following equation 1 derived by Wentworth:

$$K = (F/S \cdot N)\int (I_b - I_e)/I_e \cdot dx, \quad (1)$$

where F is the carrier gas flow rate (l/min), S is the chart speed (cm/min), N is the amount of sample injected (mol), and I_b and I_e are the detector current without and with capturing species in the detector, respectively. Since the detector signal is proportional to $(I_b - I_e)$, we can convert the term of $(I_b - I_e)/I_e$ to $(I_b - I_{ep})/I_{ep}$. $(I_b - I_{ep})$ is the recorder response corresponding to the maximum peak height; I_{ep} can be obtained by subtracting $(I_b - I_{ep})$ from I_b. So Eq. 1 can be converted to

$$K = (F/S \cdot N)\{(I_b - I_{ep})/I_{ep}\} \cdot W. \quad (2)$$

The integral in the Eq. 1 corresponds to the peak area on the chromatogram in Eq. 2, where W is the width at the half peak height.

TABLE 1. RELATIVE SENSITIVITY FOR ECD AND RELATIVE RETENTION TIME OF AROMATIC CHLORO COMPOUNDS

Compound	Relative sens. (230 °C)	Relative sens. (290 °C)	Relative sens. (320 °C)	Relative retention time
Chlorobenzene	0.0013	0.00170	0.00140	0.526
p-Dichlorobenzene	1.00	1.00	1.00	1.00
m-Dichlorobenzene	2.18	2.16	1.91	1.31

1,2,4-Trichlorobenzene	11.0	12.6	12.4	3.07
1,3,5-Trichlorobenzene	22.3	19.1	18.2	1.88
1,2,3,4-Tetrachlorobenzene	82.1	42.6	63.6	9.79[a]
1,2,3,5-Tetrachlorobenzene	84.0	44.4	51.8	5.41[a]
1,2,4,5-Tetrachlorobenzene	36.2	24.5	28.9	5.75[a]
Pentachlorobenzene	642.0	109.7	232.4	11.6[b]
Hexachlorobenzene	498.9	102.2	217.6	25.5[b]

a) Determined at a column temperature of 120 °C.
b) Determined at a column temperature of 140 °C.

Results and Discussion

Relative Sensitivity for ECD and Relative Retention Time. *R.S.* for ECD and *R.R.T.* of polychlorinated benzenes are tabulated in Table 1. *R.S.* of ECD becomes larger as the number of chlorine atoms increases, except that the result of *R.S.* for pentachlorobenzene (PCB) is larger than that of hexachlorobenzene (HCB). This tendency is similar to that of the electron absorption coefficient determined with a ^3H detector by Lovelock *et al.*[1] Shimokawa *et al.*[20] measured the relative electron capture efficiencies of halobenzenes, compared with biphenyl as a reference material, in glassy 2-methyltetrahydrofuran at 77 K by absorption spectrometry. They defined the relative electron capture efficiency (K_s/K_{ϕ_1}) as follows:

$$OD°/OD = 1 + (K_s/K_{\phi_1}) \cdot ([s]/[\phi_2]),$$

where $OD°$ and OD represent the optical densities of biphenyl anion (410 nm) in the absence and presence of solute, K_s and K_{ϕ_1} are the electron capture coefficients of the given solute and of biphenyl, and [s] and $[\phi_2]$ are the concentrations of given solute and of biphenyl. $OD°$ and OD correspond to I_b and I_e, respectively, in our report. Their report also shows that the relative electron capture efficiency becomes larger with increasing the number of chlorine atoms. The relative electron capture efficiency of PCB is also larger than that of HCB. They attributed this fact to the shielding effect of the π-orbital system by the substituent chlorine atom on the benzene ring. The same effect was observed in the electron capture reaction of polychlorinated benzenes in our gas chromatographic study.

R.R.T. values of polychlorinated benzenes ordinarily become larger as the number of chlorine atoms increases.

R.S. for ECD and *R.R.T.* of aromatic chloro, bromo, and nitro compounds with diverse substituents are summarized in Table 2. *R.S.* of monosubstituted benzenes are in the order of NO_2>Br>Cl. *R.S.* of nitrobenzene becomes higher with decreasing detector temperature. *R.S.* of disubstituted benzenes are in the order of Br(dibromobenzene)>Cl(dichlorobenzene). This order is in accordance with that of the ECD reactivity of disubstituted benzenes which was investigated with plasma chromatography by Karasec *et al.*[21] *R.S.* for ECD of these compounds varies greatly with the kind of substituents. The effects on *R.S.* of ECD with changing substituents for disubstituted compounds are clearly recognizable in Table 2. *R.S.* for ECD of a methyl-substituted compound which was derived from a monosubstituted one becomes lower than that of the original one. For example, *R.S.* for ECD of bromotoluene is smaller than that of bromobenzene. The same result was obtained for chlorotoluene. An exceptional result was observed for nitrotoluene only at a detector temperature of 230 °C. *R.S.* for ECD of the compound which was derived from an electron donative substituent such as a methyl group becomes smaller than the

original one. On the other hand, if a chloro, bromo, or nitro group which is an electron attractive substituent is introduced into the monosubstituted compound, *R.S.* for ECD of the compound becomes higher than that of the original. *R.S.* for ECD of the compound into which a nitro substituent was introduced becomes larger as the detector temperature decreases.

In order to investigate the effect of substituents on the ECD sensitivity in more detail, logarithm values of *R.S.* for these compounds were plotted against varying isomeric (*o*-, *m*-, and *p*-) positions and various kinds of substituents. The correlation between *R.S.* for ECD of aromatic chloro compounds ($Cl-C_6H_4-X$, X: substituent) and bromo compounds ($Br-C_6H_4-X$, X: substituent) is shown in Fig. 1 (a). The line was drawn by the least squares procedure. The correlation coefficient was 0.9813. Good correlation was obtained. The correlation between *R.S.* of aromatic chloro compounds ($Cl-C_6H_4-X$) and nitro compounds ($O_2N-C_6H_4-X$) is shown in Fig. 1 (b). Excellent correlation was given between chloro and nitro compounds. At detector temperatures of both 230 and 320 °C excellent correlations were observed. From these facts, the substituted effect for the electron capture reaction can be deduced. Logarithm values of *R.S.* for disubstituted compounds *vs.* Hammett's σ values were also plotted (Figs. 2 (a), (b), (c)). In Figs. 2 (a) and (b), most of plots deviate from the straight lines which were drawn using the average method. But the plots for the original compounds (chlorobenzene and bromobenzene) and the *meta*-substituted compounds are found to be linear, except for *m*-Br and *m*-NO_2 in Fig. 2(a) and *m*-NO_2 in

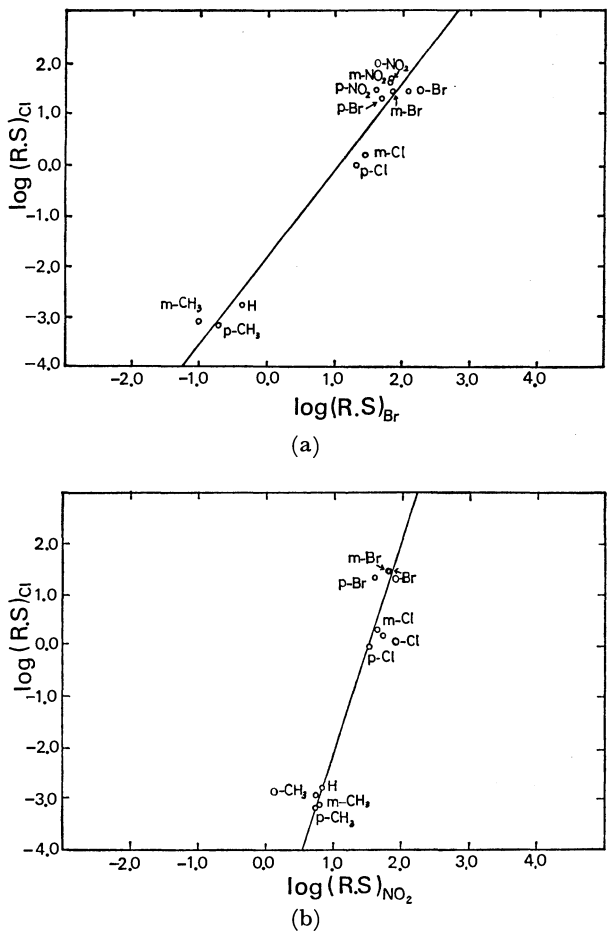

Fig. 1. (a) Correlation between *R.S.* for ECD of aromatic chloro compounds ($Cl-C_6H_4-X$) and bromo compounds ($Br-C_6H_4-X$) with varying substituents X. (*D.T.*: 290 °C). (b) Correlation between *R.S.* for ECD of aromatic chloro compounds and nitro compounds ($O_2N-C_6H_4-X$) with varying substituents X. (*D.T.*: 290 °C).

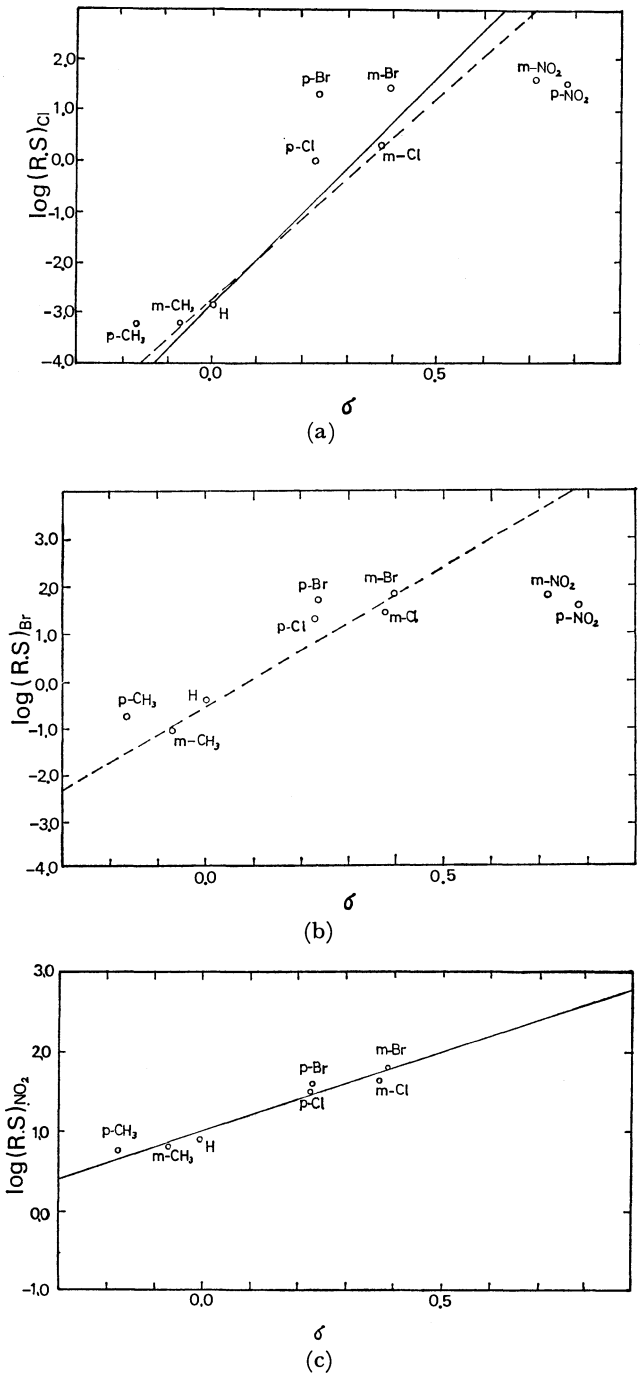

Fig. 2. (a) *R.S.* for ECD of aromatic chloro compounds *vs.* Hammett's σ values. (*D.T.*: 290 °C). (b) *R.S.* for ECD of aromatic bromo compounds *vs.* Hammett's σ values. (*D. T.*: 290° C). (c) *R. S.* for ECD of aromatic nitro compounds *vs.* Hammett's σ values. (*D.T.*: 290 °C).

Fig. 2(b). The plot of *m*-Br lies above the dotted straight line in Fig. 2(a), because the reactivity of bromo substituent is greater than that of the chloro substituent. The plots of *para*-substituted compounds are also above the dotted line. These facts suggest, as noted by Satouchi *et al.*,[17,18] that the electron capture reaction of these compounds seems to be the radical reaction. The plot of Hammett's σ values *vs.* *R.S.* of aromatic nitro compounds are shown in Fig. 2(c). Each plot was found to be almost linear by calculating with the least-squares procedure. The electron capture reactions of aromatic nitro compounds seem to obey Hammett's law and thus seem to take place in a different way from other aromatic halogeno compounds. Generally, the reactions of aromatic nitro compounds in an electron capture detector are described as taking place by the non-dissociative mechanism. Since those reactions obey Hammett's law, it is considered that a polar effect by substituents has a direct effect on the first stage of reaction, namely, on the stage of electron attachment. The modified σ values (σ_H) which are suitable for *R.S.* of these aromatic chloro and bromo compounds were determined at a detector temperature of 290 °C. These values were calculated from the line in Fig. 2(a) which was drawn by the average method as $\sigma_H=0$ for the hydrogen atom. The σ_H values are listed in Table 3.

TABLE 3. SIGMA σ_H VALUES[a]

Substituent	σ_H value	Substituent	σ_H value
p-CH_3	−0.044	*p*-Br	+0.454
m-CH_3	−0.035	*m*-Br	+0.469
o-CH_3	−0.017	*o*-Br	+0.469
p-Cl	+0.307	*p*-NO_2	+0.473
m-Cl	+0.343	*m*-NO_2	+0.487
o-Cl	+0.329	*o*-NO_2	+0.499

a) σ_H values were determined at a detector temperature of 290 °C.

The plots of σ_H values *vs.* the logarithm values of *R.S.* of aromatic bromo compounds are shown in Fig. 3 (a) Every plot gives a straight line. The plots of σ_H values *vs.* the logarithm values of *R.S.* of aromatic nitro compounds are shown in Fig. 3(b). Each plot also gives a straight line. At detector temperatures of 230 and 320 °C, the plots of σ_H values *vs.* the logarithm values of *R.S.* of these compounds also give straight lines. Even for *ortho*-substituted compounds, the plots fit a straight line, too. It seems that the steric effect does not take part in the electron capture reaction at least for *ortho*-substituted compounds. Then, if *R.S.* for ECD of a few compounds are known, *R.S.* of other compounds can be predicted from σ_H values. The plots of σ_H value *vs.* sigma values which were determined for ESR nitrogen coupling constants[22] of *para*-substituted derivatives of nitrobenzene are shown in Fig. 4. Except for NO_2 substituent, good correlation is shown. This fact suggests that the σ_H values are parameters related to the stability of anion radicals for these compounds. The plot of the activation energy E^*(kcal/mol) in electron capture reactions reported by Satouchi *et al.* *vs.* the values of $\rho^*\sigma_H$ are shown in Fig. 5. The values

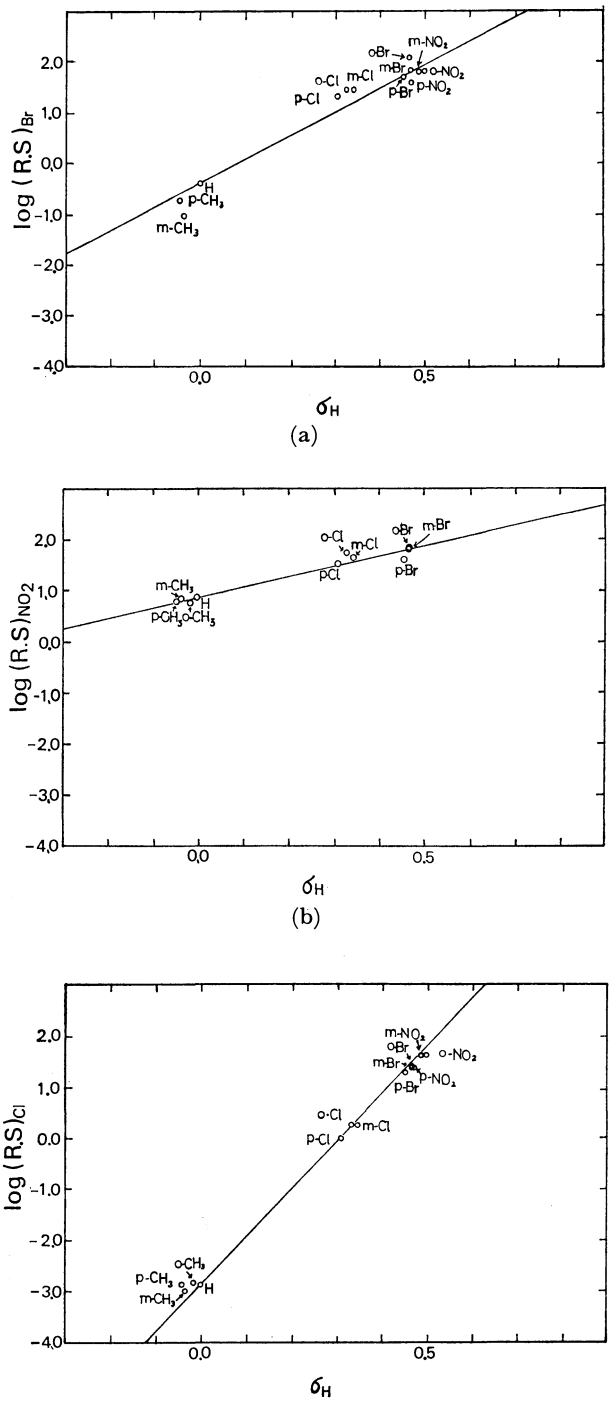

Fig. 3.(a) *R.S.* for ECD of aromatic bromo compounds *vs.* modified σ value (σ_H). (*D.T.*: 290 °C). (b) *R.S.* for ECD of aromatic nitro compounds *vs.* σ_H value. (*D.T.*: 290 °C). (c) *R.S.* for ECD of aromatic chloro compounds *vs.* σ_H value. (*D.T.*: 320 °C).

of $\rho^*\sigma_H$ are directly proportional to the E^* values. The ρ^* value represents the slope of the plot of the logarithm values of *R.S.* *vs.* σ_H. Thus $\rho^*\sigma_H$ values represent log *R.S.*

Temperature Dependence of Electron Capture Coefficients. The temperature dependence of electron capture coefficients (*K* values) was examined to investigate more

minutely the mechanism of electron capture reaction by D.C. mode. The temperature dependences of K values for aromatic chloro, bromo, and nitro compounds are shown in Figs. 6(a) and (b). They were measured at a column temperature of 100 °C. The temperature dependences of K values which were measured at a column temperature of 140 °C are shown in Fig. 6(c). The temperature dependences of mono, di, tri, and tetrachlorobenzene have negative slopes. The magnitude of the negative slope becomes smaller with increasing numbers of chlorine atoms. For PCB and HCB, the temperature dependences of K values have positive slopes. The slope of PCB is larger than that of HCB. The temperature dependences of these chlorobenzenes show inflection points which are not observed in pulsed mode. For aromatic nitro compounds, the temperature dependences of K values show the positive slopes at the higher detector temperatures. Wentworth *et al.*[10] suggested that information on electron capture reaction mechanisms can be obtained from the temperature dependence of K values by not only pulsed mode but also D.C. mode. They gave the formula for $\{(b-[e^-])/[e^-]\}$ by assuming only either a non-dissociative reaction or a dissociative reaction. They expected that the magnitude of the slope given by D.C. mode would be smaller than that of pulsed mode. The values of apparent activation energies E^* and electron affinities EA' are tabulated in Table 4. They were calculated from the magnitude of slopes.

The patterns of temperature dependence of K values were classified into the following three types (Fig. 7).

A) Chlorobenzene type (chlorobenzene and chlorotoluene isomers)

The temperature dependence of K value shows a negative slope at the higher temperature and zero or a small

positive slope at the lower detector temperature. This type of compound appears to undergo mainly dissociative electron attachment at the higher detector temperature. The magnitude of the negative slope in D.C. mode is smaller than in pulsed mode.

B) Dichlorobenzene type (dichlorobenzene, trichlorobenzene, bromobenzene, and bromotoluene isomers)
The temperature dependence of K value shows a negative slope which has an inflection point. The magnitude of the negative slope at the lower detector temperature is smaller than at the higher temperature. The reaction of this type may proceed chiefly according to dissociative electron attachment. The E^* values calculated from the magnitude of slopes at the higher

detector temperature with D.C. mode are smaller than those with pulsed mode. The inflection points, whose physical meaning is not obvious, could be used for identification of unknown samples.

C) Nitrobenzene type (nitrobenzene, nitrotoluene isomers, PCB, HCB, and other nitro compounds) The temperature dependence of K value gives a positive slope at the higher temperature and a negative or zero slope at the lower temperature. In pulsed mode, this type of compound undergoes non-dissociative electron capture reaction. Similarly they seem to undergo non-dissociative electron attachment in D.C. mode. But for bromonitrobenzene and chloronitrobenzene isomers the magnitude of the positive slope is smaller than that in pulsed mode at the higher temperature. At the lower detector temperature, a negative slope is observed. Therefore, it is considered that these compounds undergo both dissociative and non-dissociative electron capture reactions. Since plots of both σ_H values and of Hammett's σ values *vs.* *R.S.* of aromatic nitro compounds give straight lines, the stage of electron attachment and elimination of the halogen atom may be important in the electron capture reaction of nitro compounds such as chloronitrobenzene isomers.

As mentioned above, the temperature dependence of K value in D.C. mode was similar to that in pulsed mode. Ordinarily, the magnitude of the slope, which corresponds to the calculated value of apparent activation energy (E^*) or electron affinity (EA'), was smaller than in pulsed mode. For example, the E^* value of chlorobenzene was found to be 5.96 kcal/mol in D.C. mode and 8.6 kcal/mol in pulsed mode by Satouchi *et al.*[17] As pointed out by Wentworth *et al.*,[10] this result may be attributed to the fact that electrons in the detector of D.C. mode have an additional energy given by the applied voltage. With this applied voltage in D.C. mode, the negatively charged ion of a sample molecule moves to the anode and discharges an electron. This effect is also observed in the case of disubstituted compounds containing electron attractive substituents. As regards this effect, an interesting phenomenon was observed. At the tailing part of the peak, some shape deformation (negative dip) was observed, as shown in

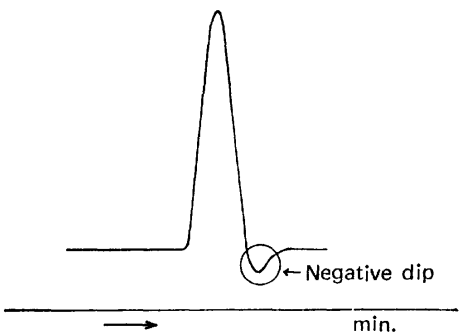

Fig. 8. Negative dip in the peak of gaschromatogram.

Fig. 8. This phenomenon was not caused by detector contamination. This deformation could not be observed at higher temperatures. The reason for the appearance of the negative dip is not obvious, but the following experimental results were obtained. This negative dip can be observed in electron capture response of dissociative type compounds such as chlorobenzene, but is not observed or is less observed in non-dissociative type compounds such as nitrobenzene and other nitro compounds. The depth of negative dip for *meta*-substituted compounds is larger than for *para*- and *ortho*-substituted compounds.

Summary

The mechanism in electron capture reaction can be determined by measuring the temperature dependence of K value in D.C. mode as well as in pulsed mode. We have used chromatographic data such as shape, slope, and inflection point in the curve of the temperature dependence of K value along with the data of retention time for identification of unknown substances.

The authors are very grateful to Dr. M. Satouchi for his valuable advice and useful suggestions.

A Redetermination of Diphenanthro[5,4,3-*abcd*: 5′,4′,3′-*jklm*]perylene

Isao Oonishi, Shoji Fujisawa,* Junji Aoki, and Takaaki Danno
Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274
(Received September 14, 1977)

It has been shown that the true unit cell of diphenanthro[5,4,3-*abcd*: 5′,4′,3′-*jklm*]perylene consists of three subcells in which the atomic arrangements differ slightly from each other. The model for the ordered structure has been deduced from the consideration of weak reflections. The average structure of the subcell with $a=30.80$, $b=3.837$, $c=19.87$ Å, $\beta=112.5°$, and $Z=4$ has been redetermined. The final R value is 0.103 for 1244 independent reflections. The two naphthanthrone planes in the molecule make an angle of 36°, which shows a large distortion from a planar structure.

Recently, the photoconductivities of tetrabenzo-[*a*,*cd*,*j*,*lm*]perylene (hereafter TBP) and diphenanthro-[5,4,3-*abcd*: 5′,4′,3′-*jklm*]perylene (hereafter DPP) have been observed.[1] DPP was found to have a very high photoconductivity.

In order to discuss the relation between such high photoconductivities and the intramolecular electronic states or molecular arrangement, the details of molecular geometries must be known.

The crystal structure of TBP has been determined by Kohno *et al.*[2] The R value is 0.056. That of DPP has been determined by Robertson and Trotter,[3] but the R values reported by them were rather high (0.111 for $h0l$ and 0.26 for $h1l$ reflections), which suggests that the y coordinates were not accurate. Therefore, we have attempted a redetermination of this material.

Experimental

The DPP crystals used in the present investigation were obtained by condensation of naphthanthrone with copper powder, zinc chloride, and sodium chloride, by a method similar to that described by Aoki *et al.*[5] The method of preparation was different from that used by Robertson and Trotter.[4]

The crude product was dissolved in toluene and passed through a column of alumina to obtain the pure crystals. Small orange-red needles elongated along the b axis were grown by slow sublimation in a glass tube under a nitrogen atomosphere (5 mmHg).

The cross section of the crystal used for X-ray work (normal to the b axis) is 0.02×0.2 mm, which is smaller than that of 0.25×0.18 mm used by Robertson and Trotter.[3] The lattice constants of the crystal reported by Robertson and Trotter are: $a=30.73$, $b=3.855$, $c=19.87$ Å, and $\beta=113.0°$. Weissenberg photographs of the crystal used in the present investigation showed that the true a axis length is three times the above length. We observed essentially the same diffraction patterns for 10 different crystals. However, when very weak reflections are not taken into account, the unit cell corresponds to that of Robertson and Trotter (see below). This means that the true unit cell is divided into three parts, and the atomic arrangements in these subcells differ only slightly from each other. In the work by Robertson and Trotter, such weak reflections were not found, but diffuse streaks parallel to a* through Bragg reflections were found. On the contrary, such diffuse streaks are negligibly weak on our Weissenberg photographs (Plates 1 and 2). However, intense reflections corresponding to the subcell show the same features in the crystals used by both us and Robertson and Trotter. These facts suggest that there are different disorders in the two crystals, which seem to have been caused by a difference of purity.

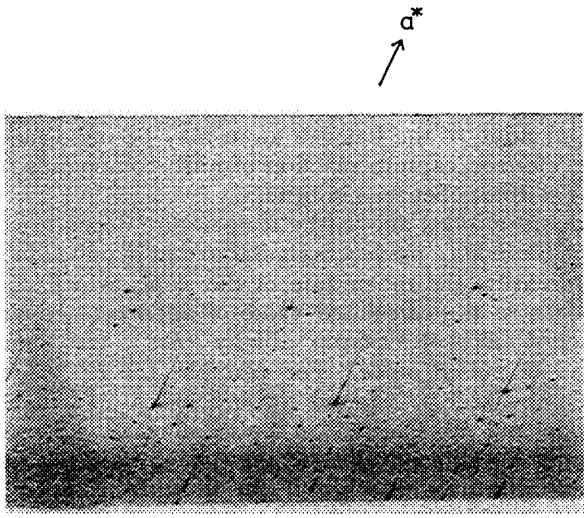

Plate 1. Weissenberg photograph of (h01).

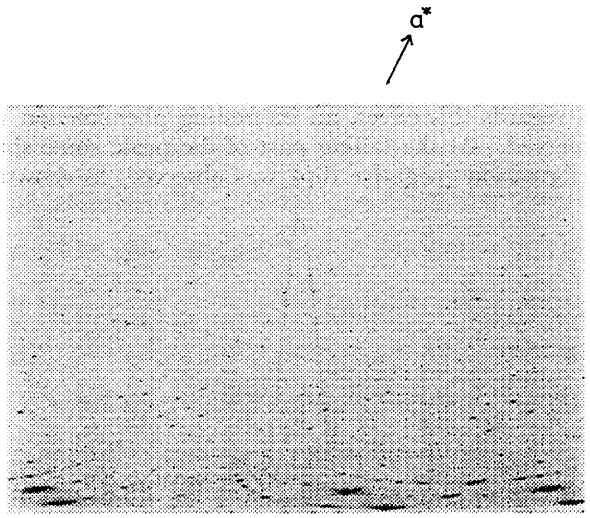

Plate 2. Equi-inclination Weissenberg photograph of ($h1l$).

Crystal Data for Subcell. $C_{38}H_{22}$, $M=478.60$, mp 340 °C, Space group: C2, $Z=4$; $a=30.80\pm0.04$, $b=3.837\pm0.005$, $c=19.87\pm0.03$ Å, $\beta=112.5\pm0.2°$, $v=2169.4$ Å^3; $D_x=1.465$, $D_m=1.45$ g cm^{-3}; $F(000)=1000$; μ(Cu $K\alpha$)$=6.3$ cm^{-1}. These values agree with those given by Robertson and Trotter within the experimental errors.[3]

Sets of multiple-film equi-inclination Weissenberg photographs were taken about the b axis (0th to 3rd layers) and about the c axis (0th layer). Cu $K\alpha$ radiation was employed throughout. The intensities were estimated by means of a

Rigaku photometer MP3. Weak intensities were visually estimated with a standard film strip. They were corrected for Lorentz and polarization factors, but no absorption correction was applied. The range of relative intensities was from 1 to 50000. 1244 independent reflections fell within this range, whereas 869 others were too weak to be observed.

The Model of Ordered Structure

When weak reflections have been taken into consideration, the extinction rules for the true unit cell are $h+k=2n$ in hkl reflections; $h=6n$ when $l=2n$ and $h=2$ when $l=2n+1$ in $h0l$ reflections. The latter cannot be explained with ordinary symmetry elements.

On the other hand, the distribution of intense reflections is $h=3(2n)$ when $k=0$, $h=3(2n+1)$ when $k=1$, $h=3(2n)$ when $k=2$, and so on. Thus, the only extinction rule for the subcell is $h'+k=2n$ in $h'kl$ reflections where $h'=h/3$. Both the true unit cell and the subcell are **C**-base centered lattices. The total intensity of weak reflections (281 in number) is less than 1% of that of the intense reflections.

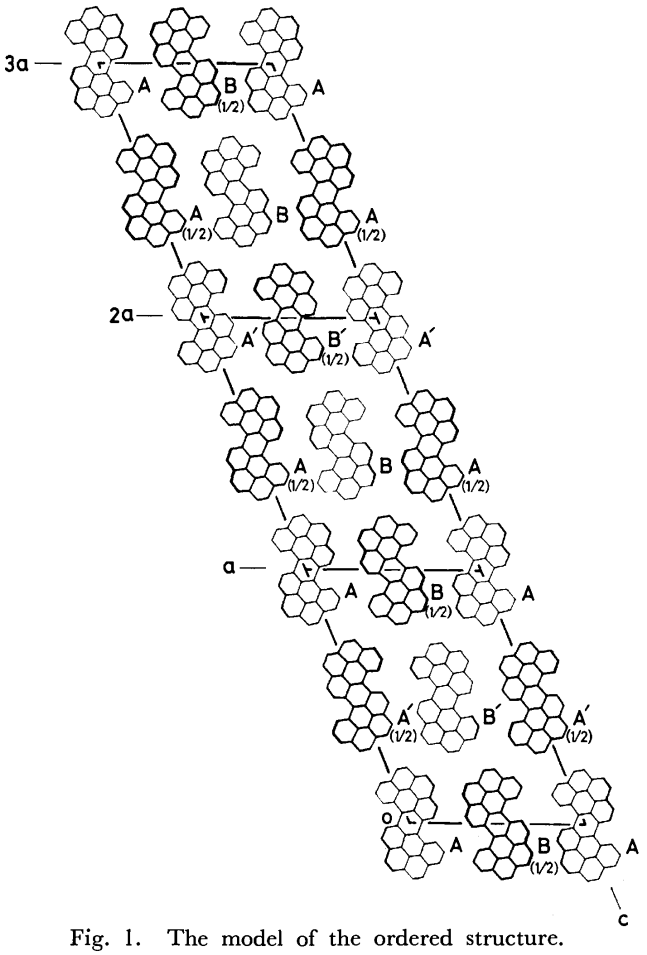

Fig. 1. The model of the ordered structure.

We have deduced the model pictured in Fig. 1 to explain the extinctions. In Fig. 1, a and c correspond to the subcell. A and B are enantiomer, and A′ and B′ are related to A and B by an approximate twofold rotation perpendicular to the ab-plane and a following translation of (3a/6, b/2), respectively. A and B′ (A′ and B) have the same shape when projected along the b axis. The molecules with the subscript of (1/2), for example A′(1/2) and B(1/2), have the height of b/2 relative to the ones without subscript.

In the true unit cell, the 4A molecules and 2B′ molecules (4B and 2A′) are in the positions of (x, z), $(1/6+x, z)$, $(3/6+x, z)$, $(4/6+x, z)$, $(2/6+x, 1/2+z)$ and $(5/6+x, 1/2+z)$, respectively. Only such a relative configuration is able to explain the extinction rules described above.

The structure is built of two kinds of energetically equivalent layers parallel to the bc-plane. Along the a direction, the two kinds of layers exist laterally in the ratio of 2: 1. The former can be expressed as ABAB— and the latter as A′B′A′B′—. They are related by a reflection on the ac-plane and a following translation of (3a/6, b/2, c/2).

According to the model of Robertson and Trotter, the two kinds of layers mentioned above exist randomly in the ratio of 1: 1 along the a direction. However, they have reported that this model cannot explain the appearance of $h0l$ reflections with l odd.

Refinement of the Average Structure

The average structure is a superposition of three subcells. The overlappings of the molecules in the average structure are AAA′ and BBB′. Thus, molecules A and B are given 2/3 factors, and A′ and B′ are given 1/3 factors.

We started refinement with the parameters given by Robertson and Trotter.[3] In the least squares calculations, molecules A and B were independently refined with isotropic temperature factors. After three cycles of least squares calculations, the R value converged to 19%. The three dimensional electron density map, calculated at this stage, revealed peaks with about 1/3 the height of a carbon atom, which have also been found on the two dimensional electron density given by Robertson and Trotter.[3] We assigned 1/3 factors to the peaks according to the model described above. At the same time, the factors of C(4) and C(5) atoms were changed to 2/3 (see the numbering scheme in Fig. 2). Hydrogen atoms except H(C4), H(C5), H(4′), and H(C5′) have also been found on the electron density map. However, since the shapes of the molecules A and A′ (B and B′) are very similar, only C(4), C(4′), C(5), and C(5′) atoms were separated on the electron density map.

After the introduction of anisotropic temperature factors for carbon atoms, six more cycles of refinement were carried out. The following weighting scheme was employed: $w=0.3$ if $F_o<F_{\min}$ (4.0), $w=1.0$ for the others. The final R value was 10.3% for all observed reflections. The atomic scattering factors were taken from International Tables for X-Ray Crystallography.[6] The final atomic parameters and their estimated standard deviations are given in Table 1(a) for carbon atoms and in Table 1(b) for hydrogen atoms. The positional and thermal parameters except those of the separated atoms need to be considered as the weighted average values of the overlapped atoms of molecules A and A′ (B and B′).

Table 1. Atomic parameters

(a) Positional and thermal parameters for non-hydrogen atoms ($\times 10^4$), with e.s.d.'s in parentheses ($\times 10^3$ for y, β_{22}, β_{12}, β_{23}).

The β_{ij}'s are defined by $\exp[-(h^2\beta_{11}+k^2\beta_{22}+l^2\beta_{33}+2hk\beta_{12}+2hl\beta_{13}+2kl\beta_{23})]$.

Description and Discussion

Figure 2 shows the average structure projected along the b axis and at the same time the bond lengths and angles in the molecules. When the atoms C(4) and C(5) are changed to the atoms C(4′) and C(5′), the molecules A and B change to the molecules A′ and B′, respectively. Since A and A′ (B and B′) have not been separated, as explained above, we cannot discuss the details of the bond lengths and angles, but only the shapes of molecules A and B.

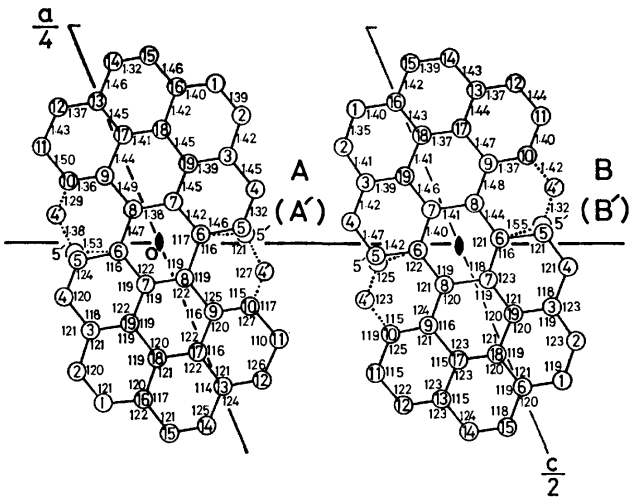

Fig. 2. The projection of the average structure along the b axis, and the bond lengths and bond angles.

Figure 3 shows the diagrams of DPP and TBP. In the molecule A, the downward naphthanthrone is twisted in a clockwise direction and the upper one is twisted in a counterclockwise direction around the arrow in Fig. 3. Figure 4 shows the perspective drawing of the molecule A, looking down along the arrow in Fig. 3 which runs through the two carbon atoms of the central ring. The molecules A and B are significantly distorted from a planar structure due to repulsions between the hydrogen atoms at the positions denoted with * in Fig. 3. Such distortion forces the central ring to adopt a twisted boat form. The molecules A and B are left- and right-handed propeller-shaped respectively. There exist short contacts at the positions marked * in Fig. 3. The

** Table 2 has been deposited with the office of Chemical Society of Japan, 1-5 Kanda-Surugadai, Chiyoda-ku, Tokyo 101 (Document No. 7826).

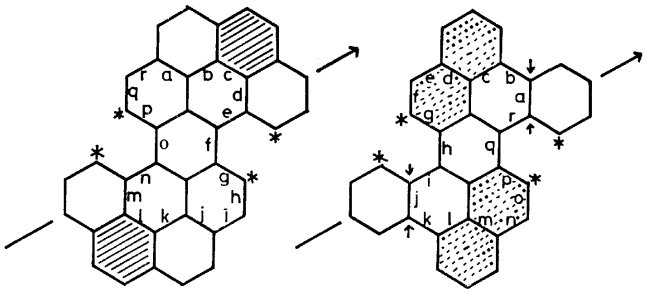

Fig. 3. The diagrams of DPP and TBP.

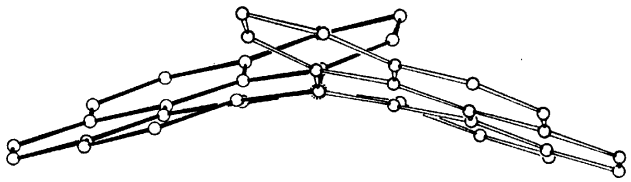

Fig. 4. A perspective drawing of DPP.

distances of C(5)···C(10) are 3.01 Å in the molecule A, and 2.87 Å in the molecule B. They correspond to the mean value of 2.953 Å reported by Robertson and Trotter, and are comparable to 2.971 and 2.944 Å in TBP.

The molecule DPP consists of two naphthanthrone skeletons. The deviations of the atoms from the mean planes through naphthanthrone moieties range from −0.11 to 0.34 Å in the molecule A, and from −0.31 to 0.12 Å in the molecule B. The two planes in the molecule A (B) make an angle of 36° (36°), which are larger than 30.5° in the molecule TBP described below.

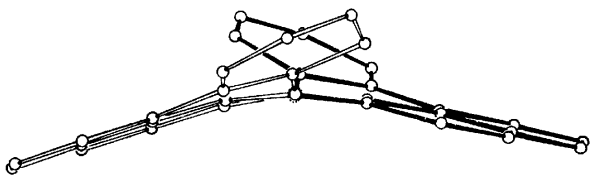

Fig. 5. A perspective drawing of TBP.

To compare DPP with TBP, the right-handed propeller-shaped TBP is drawn in Fig. 5, according to the parameters given by Kohno *et al.*[2] It is taken looking down along the large arrow in Fig. 3. The molecule TBP consists of two benzanthrone skeletons. The two naphthalene moieties, shaded with the dotted lines in Fig. 3, are planar within ±0.05 Å, and the two planes make an angle of 30.5°. On the other hand,

the atoms in the [*a*]- and [*j*]-benzene rings significantly deviate from the planes. The largest deviations are 0.670 and 0.624 Å, respectively. Thus, the benzanthrone moieties in TBP are largely bent in the parts indicated with the small arrows in Fig. 3. Twisting of the central ring is partially relaxed due to such bending, compared to the twisting in DPP.

However, in the naphthanthrone moieties of DPP such a large bending is prevented by an additional benzene ring, shaded with the solid lines in Fig. 3. The strain distributes over the whole molecule.

Thus, the distortions of DPP and TBP are clearly different, and the overlappings of molecules in the DPP and TBP crystals are different as well. These differences seem to be the reason why the photoconductivity of DPP is larger than that of TBP.

In order to give a detailed discussion of the mechanism of photoconduction, we need to gather more data of photoconductivity and crystal structure for polycyclic aromatic hydrocarbons where there are repulsions between hydrogen atoms.

All these calculations were carried out on a HITAC 8700/8800 at the Computer Center of University of Tokyo with a local version of the Universal Crystallographic Computation Program System, UNICS (1967).

The Application of a Modified Dubinin-Radushkevich Equation to Adsorption on Active Carbon with Heterogeneous Micropore Systems

Ryoichi TSUNODA

Industrial Research Institute of Kanagawa Prefecture, Showa-machi, Kanazawa-ku, Yokohama 236

(Received September 20, 1977)

The Dubinin-Radushkevich plots of active carbons, curved concavely for a high value of $\log^2 P_0/P$, on methanol adsorption at 30 °C have been characterized by using a modified Dubinin-Radushkevich equation, *i.e.*:

$$V = CV_0 \exp [- B_0A^2] \exp [A^4\Delta^2/2] [1 - \mathrm{erf}(X)]/2,$$

where $\mathrm{erf}(X)$ is the error function, $A=RT \ln P_0/P$, V_0 is the micropore volume, C is the correcting coefficient for fitting the equation to the experimental data, and $X=(A^2-B_0/\Lambda^2)\Delta/\sqrt{2}$, with B_0 being the average value of a measure of the micropore size and Λ, the heterogeneity parameter of the micropore size. The significance of the equation was discussed, and it was shown that the equation can describe the heterogeneous micropore systems of active carbons with suitable parameters.

The Dubinin-Radushkevich equation,[1]

$$V = V_0 \exp [- k(A/\beta)^2], \quad (1)$$

has been used to characterize microporous carbons. In this equation, V is the volume adsorbed at a relative pressure of P/P_0; V_0 is the micropore volume, $A=RT \ln P_0/P$, and k and β are constants. The linear form of the Dubinin–Radushkevich equation,

$$\log V = \log V_0 - D \log^2 P_0/P, \quad (2)$$

where $D=2.303\, kR^2T^2/\beta^2$, is usually used to plot the adsorption data.

However, although the plot may show a linear range, it is rarely linear over a wide pressure range.[2-5] Rand[4] has recently reported three general types of Dubinin-Radushkevich plots which show deviations from linearity. These three types are designated as Type A, B, and C Dubinin-Radushkevich curves. The Type A, curve has two linear sections with a gentle slope for low values of $\log^2 P_0/P$. The Type B curve is curved concavely over the whole range of $\log^2 P_0/P$. The Type C curve shows two inflection points, indicating a bimodal distribution of the adsorption potential. Especially in the case of the Type B curve, the plots can be linearized by means of the Dubinin-Astakhov equation,

$$V = V_0 \exp [- k(A/\beta)^n], \quad (3)$$

with a suitable value of n, and the micropore volume is obtained by extrapolation of the plot.

However, the characterization of the Dubinin-Radushkevich plot by use of the Dubinin-Astakhov equation is contrary to the original nature of the Dubinin-Radushkevich equation, and the Dubinin-Radushkevich plot should be characterized by an equation maintaining the original nature of the Dubinin-Radushkevich equation.

Stoeckli[7] has recently proposed an adsorption equation maintaining the nature of the Dubinin-Radushkevich equation. Assuming that the Dubinin-Radushkevich equation has a general validity, but applies to homogeneous systems of micropores, he has described adsorption by heterogeneous micropore systems by means of a sum of the Dubinin-Radushkevich equation:

$$V = \sum_j V_{pj} \exp [- B_jA^2], \quad (4)$$

where $B_j=k_j/\beta^2$.

Equation 4 may be replaced by the integral,

$$V(A^2) = \int_0^\infty V_p f(B) \exp [- BA^2]\, dB, \quad (5)$$

where $f(B)$ is the normalized Gaussian distribution and is described as follows:

$$f(B) = \frac{1}{\sqrt{2\pi}\,\Delta} \exp [- (B - B_0)^2/2\Delta^2], \quad (6)$$

with B_0 being the avarage value of B, and Δ, the standard deviation, *i.e.*, the heterogeneity parameter.

Moreover, Eq. 5 leads to,

$$V(A^2) = V_p \exp [- B_oA^2] \times \exp [A^4\Delta^2/2] [1 - \mathrm{erf}(X)]/2, \quad (7)$$

where $X=(A^2-B_0/\Delta^2)\Delta/\sqrt{2}$ and $\mathrm{erf}(X)$ is the error function. Equation 7 is expected to be applied to the Type B curve of the Dubinin-Radushkevich plot.

Meanwhile, as to the determination of the micropore volume from the non-linear Dubinin-Radushkevich plots, the present author[5,6] has previously reported that the adsorption volume (V) corresponding to the adsorption potential (A), at which the plot of $dV/d(-A)$ *vs.* A has its minimum value, is the value of the micropore volume (V_0) in cases where the extrapolation of the Dubinin-Radushkevich plot cannot be applied because of the non-linearity of the plot.

In this paper, micropore systems of active carbon showing Type B curve by Rand's classification[4] or plots gradually curved concavely for a high value of $\log^2 P_0/P$ on methanol adsorption have been characterized by means of the modified Dubinin-Radushkevich equation, and the significance of the modified Dubinin-Radushkevich equation discussed.

Experimental

Active Carbons. Commercially available Pittsburgh Filtrasorb 100- and SGL-type active carbons and Hokutan active carbon were used. For the SGL-type active carbon, the adsorption isotherm reported in a previous paper[5] was used.

Methanol Adsorption. The adsorption of methanol on active carbons at 30 °C was measured gravimetrically by means

of a conventional quartz spring balance. Prior to the adsorption measurement, active carbon dried overnight at 110 °C was outgassed at a pressure of 10^{-6} Torr at 30 °C for 14 h. In all cases, the adsorption equilibrium was established within 45 min.

Results and Discussion

Micropore Volume. The adsorption isotherms, Dubinin-Radushkevich plots, and characteristic curves are sown in Figs. 1—3.

The micropore volumes (V_0) of active carbons were obtained by the method[5,6] described above; they are listed in Table 1.

Modified Dubinin-Radushkevich Equation and Its Application to the Experimental Data. In this paper, following Stoeckli,[7] the micropore systems of active carbon are classified into "homogeneous" and "heterogeneous" micropore systems. Actually, active carbon with a homogeneous surface does not exist. However, when the structural constitution of micropores is considered as a system, the micropore system determined by a given constant, k, in Eq. 1 can be said to be a homogeneous micropore system, and, in this case, the Dubinin-Radushkevich plot is strictly linear in form. On the

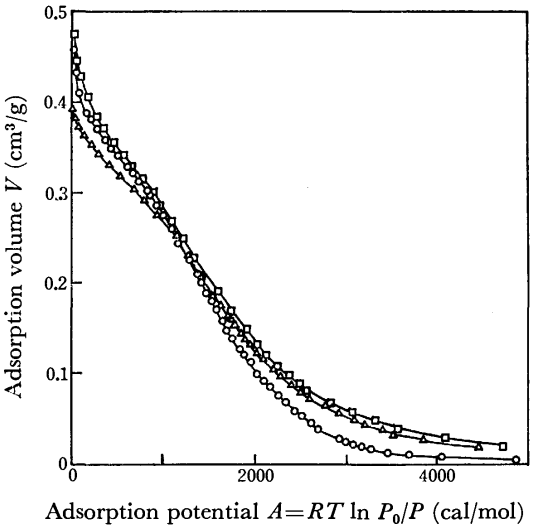

Fig. 3. Characteristic curves of methanol adsorption at 30 °C on active carbons.
○ SGL, △ Filtrasorb 100, □ Hokutan.

Table 1. Parameters in Eqs. 10, 11, and 11′

Active carbon	V_0 (cm³/g)	$B_0\times10^6$ (mol²/cal²)	$A\times10^6$ (mol²/cal²)	C	C'
SGL	0.305	0.35	0.10	1.19	1.001
Filtrasorb 100	0.305	0.27	0.135	1.17	1.023
Hokutan	0.325	0.27	0.15	1.27	1.037

The micropore volume, V_0, is the experimental value determined from the adsorption volume (V) at the $dV/d(-A)$=minimum on the distribution curve of the adsorption potential ($A=RT\ln P_0/P$). The parameters, B_0, A, and C, are values so determined that Eq. 11 fits the adsorption data obtained using V_0.

other hand, in the case of the non-linear Dubinin-Radushkevich plot, k is not constant and the micropore system can be designated as a heterogeneous micropore system.

According to Dubinin,[1] the k constant in Eq. 1 is a measure of the average micropore size, while the β constant is the relative differential molar work of vapor adsorption with the chosen standard substance, often called the affinity coefficient of the characteristic curve. Therefore, as to the heterogeneous micropore systems, the $B_j=k_j/\beta^2$ expression in Eq. 4 has validity. However, B_j is a positive value; therefore, using the distribution function, $f(B)$ (Eq. 6), in Eq. 5 is not adequate. In order to integrate the distribution function over $B>0$, we must use a new distribution function, $g(B)=C'f(B)$, instead of $f(B)$; C' is defined by the following equation:

$$\int_0^\infty g(B)\mathrm{d}B = \int_0^\infty C'f(B)\,\mathrm{d}B = 1 \tag{8}$$

and Eq. 7 is written as follows:

$$V(A^2) = C'V_0 \exp[-B_0A^2] \times \exp[A^4\Delta^2/2]\,[1-\mathrm{erf}(X)]/2. \tag{9}$$

The coefficient C''s are listed in Table 1. However, in order to fit Eq. 9 to the experimental data of the micropore-volume range, the C' coefficient must be multiplied by the correcting coefficient, C'', to give

$$C = C' \times C''. \tag{10}$$

The following equation is written in order to describe the experimental data:

$$V(A^2) = CV_0 \exp[-B_0A^2] \times \exp[A^4\Delta^2/2]\,[1-\mathrm{erf}(X)]/2 \tag{11}$$

or

$$\log V = \log V_0 - 2.303\,B_0R^2T^2\log^2 P_0/P + \frac{1}{2}2.303^3\Delta^2R^4T^4\log^4 P_0/P + \log\frac{1-\mathrm{erf}(X)}{2} + \log C,$$

where

$$X = (2.303^2R^2T^2\log^2 P_0/P - B_0/\Delta^2)\Delta/\sqrt{2}. \tag{11'}$$

The application of the modified Dubinin-Radushkevich equation (Eq. 11') with the best-fit parameters, listed in Table 1, to the experimental data is shown in Fig. 4. The value of B_0 is a measure of the average value of the micropore size, and at the same time, a measure of the higher adsorptive capacity for a smaller value of B_0 at a low relative pressure (see Figs. 1(b), 2, and 3). The heterogeneity parameter, Δ, is the standard deviation of B, and also a factor influencing the pore-size distribution at a given value of B_0, with a larger value of Δ giving a broader shape of the pore-size distribution. Moreover, both parameters, B_0 and Δ, are responsible for the pore-size distribution and for the adsorptive capacity on the Dubinin-Radushkevich plots at a high value of $\log^2 P_0/P$.

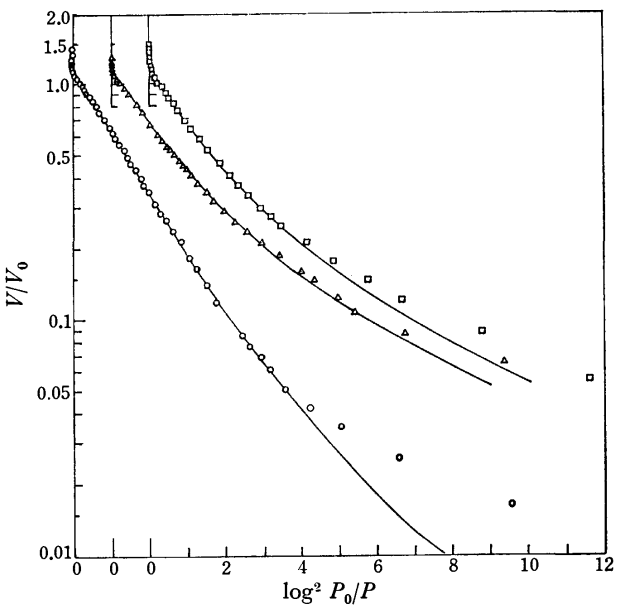

Fig. 4. Application of the modified Dubinin-Radushkevich equation (Eq. 11') to the Dubinin-Radushkevich plots.
○ SGL, △ Filtrasorb 100, □ Hokutan.
The solid curves were calculated by use of Eq. 11'.

From these results, the modified Dubinin-Radushkevich equation can be said to have the following characteristics:

Equations 11 and 11' are based on the original Dubinin-Radushkevich equation, and they maintain their general validity. Although the Dubinin-Astakhov equation is successful in linearizing the Dubinin-Radushkevich plots, it is empirical, and so it is more difficult to make a physical interpretation of the Dubinin-Radushkevich plots compared with the use of Eqs. 11 and 11'. On the other hand, the modified Dubinin-Radushkevich equation enables us to describe the heterogeneous micropore systems of active carbon on the Dubinin-Radushkevich plots by means of 4 parameters, V_0, B_0, Δ, and C.

The author wishes to express his thanks to Mr. Yoshiyuki Fukazawa for his helpful discussions.

The Two n,π^* Transitions of Monohalogenoanthraquinones

Sanae Y. MATSUZAKI* and Akira KUBOYAMA

National Chemical Laboratory for Industry, Shibuya-ku, Tokyo 151

(Received October 3, 1977)

The n,π^* absorption and phosphorescence spectra of 1-fluoro-, 2-fluoro, 1-chloro-, 2-chloro-, 1-bromo-, and 2-bromoanthraquinones were studied in solutions, mainly at 77 K. These phosphorescence spectra and their lifetimes resemble those of anthraquinone (AQ), except for those of 1-F-AQ. The phosphorescence spectrum of 1-F-AQ is at longer wavelengths than that of AQ, and its lifetime is 0.8 ms in the methylcyclohexane solution, much shorter than that of AQ. All of the 1-halogenoanthraquinones showed two distinct n,π^* singlet-singlet absorption bands at 77 K, and 1-Br-AQ showed an additional band of the n,π^* singlet-triplet transition at 492 nm. The low-energy n,π^* singlet and triplet states of these compounds are discussed on the basis of these experimental results.

The lowest excited singlet and triplet states of carbonyl compounds including quinones are generally assigned to the n,π^* states. These n,π^* states are thought to be largely localized at the carbonyl groups, because of the strong Coulomb attraction between the excited electron and the remaining non-bonding positive hole. In quinones which have two carbonyl groups, each of the lowest excited singlet and triplet states is expected to consist of two n,π^* states close to each other in energy, as in the case of *p*-benzoquinone.[1] Previously, we have studied the n,π^* phosphorescence spectra of AQ in solutions at 77 K.[2] Recently, high-resolution n,π^* phosphorescence spectra of AQ in crystals and in solutions have been reported on by many authors.[3] In 1-halogenoanthraquinones, as the lone electron-pair of the oxygen and halogen atoms are close to each other, the interaction between them should be large. Therefore, it is very interesting how the n,π^* singlet and triplet levels would be affected by the halogen atom introduced to the 1-position of anthraquinone. Shcheglova *et al.*[4] have already discussed this problem on the basis of the emission spectra obtained by the photographic method, but some problems have remained to be clarified. For instance, no actual n,π^* absorption and emision spectra of monohalogenoanthraquinones have been reported. We have, therefore, studied the n,π^* absorption and emission spectra of monohalogenoanthraquinones at 77 K and discussed the above-mentioned problem.

Experimental

Measurements. The emission spectra and their lifetimes were measured in the methylcyclohexane solutions at 77 K by the way described in our previous paper.[2] A Cary Model 14 spectrophotometer was used to measure the absorption spectra. In the measurement of the absorption spectra at 77 K, the 1-cm cell and the Dewar vessel used in our previous work[5] were used again.

The absorption spectra were obtained in the heptane solutions at room temperature (R. T.) and at 77 K, in the benzene and heptane solutions, which were poly-crystalline at this temperature. Using these poly-crystalline solutions at 77 K, clear and about ten-times-intensified spectra were obtained in comparison with those at R. T., when the concentrations of solutes were regulated for their absorbances so as not to exceed 0.1 at R. T. This enhancement in absorbance is based on a mechanism similar to that which holds in the case of the diffuse-reflectance spectra. Both the benzene and heptane solutions gave almost the same spectra, but the spectra of the former were clearer than those of the latter.

Materials. 1-F-AQ and 2-F-AQ were synthesized from 1- and 2-aminoanthraquinones by diazotization and by the substitution of the diazo group by a fluorine atom[6] respectively. The other monohalogenoanthraquinones were commercially available. All of these quinones were refined by the two methods of vacuum sublimation and liquid column chromatography on alumina (the developer; toluene). The refined sample were melted within 1 °C of their melting points, as is shown in Table 1. The solvents—hexane, methylcyclohexane, benzene, and toluene—were all commercially available spectrograde reagents.

TABLE 1. MELTING POINTS OF MONOHALOGENOANTHRAQUINONES (°C)

1-F-AQ	232.0—233.0 (226—227[5])
1-Cl-AQ	160.5—161.5 (162[7])
1-Br-AQ	190.0—191.0 (188[7])
2-F-AQ	199.0—200.0 (203—204[5])
2-Cl-AQ	208.5—209.5 (208—209[7])
2-Br-AQ	208.4—209.1 (204—205[7])

Results

The observed n,π^* absorption spectra of monohalogenoanthraquinones are shown in Figs. 1 and 2. The spectra of 2-F-AQ and 2-Cl-AQ, which are not shown in these figures, quite resemble that of 2-Br-AQ. The wavelengths of the peaks and shoulders in these absorption spectra are listed in Table 2. The emission spectra of 1- and 2-halogenoanthraquinones in solutions at 77 K are shown in Figs. 3, 4, and 5, while the wave-

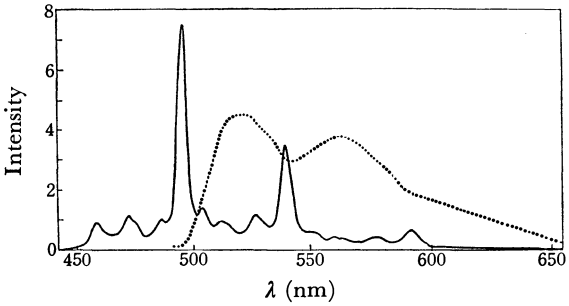

Fig. 5. The two components of the phosphorescence of 1-Cl-AQ in the methylcyclohexane solution at 77 K, ——: the phosphorescence with longer lifetime, and ····: that with shorter lifetime.

lengths of their peaks and their lifetimes are listed in Tables 3 and 4 respectively. The shoulder at 493 nm in the emission spectrum of 1-F-AQ became smaller and smaller as the sample was refined repeatedly, and its position was the same as those of the highest peaks of 1-Cl-AQ and AQ (see Fig. 3). Therefore, it may be considered to be due to some impurities.

The total emission of 1-Cl-AQ consists of two components which are different in lifetime. The emission spectrum with the longer lifetime of 3.5 ms could be observed separately with a sector, while that with the shorter lifetime was obtained as the difference between the total spectrum and the spectrum obtained with the sector. This shorter lifetime was too short to be measured. The intensity ratio of the longer-lifetime spectrum to the shorter-one was about 1 : 2. These two spectra are shown in Fig. 5.

Discussion

In 1-halogenoanthraquinones, one of the two carbonyl groups is adjacent to the halogen atom, and the lone electron-pair orbital of its oxygen atom is thought to overlap considerably with that of the halogen atom. 1-Halogenoanthraquinones may be destabilized by this overlapping in the ground state, and stabilized by the charge-transfer interaction between the vacant n-orbital of the carbonyl group and the occupied n-orbital of the halogen atom in the n,π^* excited state. Therefore, one of these two lowest-energy n,π^* states, which is mainly localized at the carbonyl group adjacent to the halogen atom, may be considerably lower in energy than the other, which is mainly localized at the other carbonyl group. The order of the magnitudes of the separations between these two n,π^* levels is thought to be equal to the order of the van der Waals radii of the halogen atoms; Br>Cl>F.

As may be seen in Fig. 1, the n,π^* absorption spectra of the 1-halogenoanthraquinones at R.T. are similar to that of 2-Br-AQ, which in form is very similar to that of AQ, except for the long tails in the region of 430—500 nm. These tails and the shorter-wavelength absorption bands are considered to be due to the transition from the ground state to the above-mentioned lower and higher n,π^* singlet excited states respectively. As for the n,π^* absorption spectra at 77 K, which are shown in Fig. 2, the spectra of the 1-halogenoanthraquinones show structures up to 500 nm; the spectrum of 1-Br-AQ, for example, has three shoulders, at 416.5, 435, and 460 nm, and one peak, at 492 nm. The shoulder at 416.5 nm may be assigned to the shorter-wavelength n,π^* band, and the shoulders at 435 and 460 nm, to the longer-wavelength n,π^* bands. The absorption peak at 492 nm may be assigned to the n,π^* singlet-triplet absorption band intensified by the internal heavy-atom effect of the bromine atom, since the corresponding absorption in 1-Cl-AQ and 1-F-AQ cannot be found. This absorption peak may not be assigned to the π,π^* singlet-triplet absorption band, because a corresponding absorption cannot be observed in 2-Br-AQ. Since the n,π^* bands and the tails of the lowest π,π^* band of monohalogenoanthraquinones shift toward blue and red to a considerable extent at 77 K compared with those at R.T. (see Figs. 1 and 2), the spectra at 77 K are thought to be those of aggregates. In general, the n,π^* states in aggregates may be considered to be similar to those in solutions because of their localizing character. In this discussion, the electronic structures of the n,π^* states in these aggregates were assumed to be similar to those in isolated molecules, except for small energy shifts.

The emission spectra of the monohalogenoanthraquinones in solutions at 77 K can all safely be assigned to the n,π^* phosphorescence, since they have, as may be seen in Figs. 3, 4, and 5, the principal vibrational structure of the carbonyl stretching frequency (*ca.* 1640 cm^{-1}) and the short lifetime of the order of a millisecond (see Table 4). These phosphorescence spectra quite resemble that of AQ in position, shape, and lifetime, except for that of 1-F-AQ and the shorter lifetime spectrum of 1-Cl-AQ.

As for the phosphorescence spectrum of 1-F-AQ, it lies at longer wavelengths (the energy difference is *ca.* 900 cm^{-1}) and has a shorter lifetime, than the spectra of the other monohalogenoanthraquinones. The phosphorescence quantum yields of 1-F-AQ, 1-Cl-AQ (total), and 1-Br-AQ were roughly estimated to be in the ratio of 3 : 1 : 1 by considering the relative absorbances at 420 nm of the n,π^* S_1-S_0 bands in nearly

saturated methylcyclohexane solutions at R.T. and the relative intensities of the phosphorescences with excitations at 420 nm in the same solutions. According to this estimation, the phosphorescence of 1-F-AQ would have a much shorter natural lifetime than the others. The shorter-lifetime spectrum of 1-Cl-AQ, which has the vibrational structure of the C–O stretching and which lies at an energy lower by *ca.* 1000 cm^{-1} than that of 1-F-AQ is too broad to discuss in detail, but it may be assigned to the same kind of emission as that of 1-F-AQ.

On the basis of these facts, it may be concluded that the phosphorescence of 1-F-AQ and the shorter-lifetime emission of 1-Cl-AQ correspond to the emission from the above-mentioned lower n,π* triplet state, and that the phosphorescence of 1-Br-AQ and the longer-lifetime emission of 1-Cl-AQ correspond to that from the upper n,π* triplet state. In 1-Br-AQ and 1-Cl-AQ, the internal conversion between the two n,π* triplet states may be slow, since these states are considered, as has been mentioned before, to be mainly localized on the two carbonyl groups separately, far from each other and with a large energy difference between them. Therefore, the phosphorescence from the upper state can be observed in these molecules. However, this internal conversion may be faster in 1-F-AQ because of the small energy difference between these two states, so the emission from the upper state cannot be observed.

As for the phosphorescence of 1-F-AQ and the shorter-lifetime emission of 1-Cl-AQ, their lifetimes may be shortened by the relatively fast, radiationless process from the phosphorescent lower n,π* triplet state, which is due to the before-mentioned interaction between lone-pair orbitals of the oxygen atom and the adjacent halogen atom. In the case of 1-Br-AQ, the emission from the lower state may not be observed because of the slow internal conversion between the two n,π* states and the fast radiationless process from the lower n,π* state to the ground state, mainly due to the heavy atom effect of the bromine atom.

The n,π* singlet and triplet levels of 1-halogenoanthraquinones and the phosphorescent processes, considered on the basis of the above discussion, are shown in Fig. 6.

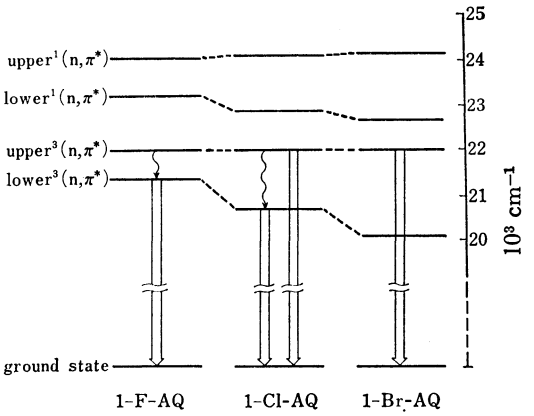

Fig. 6. Energy levels and phosphorescent processes of 1-halogeno AQ's, ⟹; phosphorescence, ⇝; internal conversion.

Shcheglova *et al.* have given a similar discussion of the two n,π* triplet states of the 1-halogenoanthraquinones based on their experimental results, and they have claimed that lower n,π* states of 1-Cl-AQ and 1-Br-AQ are not discrete but continuous states. This explanation may be rejected on the basis of this work.

Catalysis by Supported Metal Crystallites from Carbonyl Clusters. I. Catalytic Methanol Synthesis under Mild Conditions over Supported Rhodium, Platinum, and Iridium Crystallites Prepared from Rh, Pt, and Ir Carbonyl Cluster Compounds Deposited on ZnO and MgO

Masaru ICHIKAWA

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received December 6, 1977)

Methanol synthesis by the catalytic hydrogenation of carbon monoxide proceeded under atmospheric pressure and at 150—250 °C over rhodium, platinum and iridium crystallite catalysts, prepared from well-defined Rh, Pt, and Ir carbonyl cluster compounds highly dispersed on ZnO and MgO. The activity and selectivity of methanol formation depended considerably on the kind of metal carbonyl clusters and metal oxides employed as inorganic carriers. The catalysts prepared by the pyrolysis of smaller Rh, Pt, and Ir carbonyl clusters on ZnO, MgO, CaO, and BeO exhibited a higher selectivity of methanol synthesis. A small amount of ethanol was also produced besides methanol in CO–H_2 reaction over the pyrolysed catalysts of Rh carbonyl clusters on MgO, CaO, and BeO. Other metal oxides such as SiO_2 gel, γ-Al_2O_3, SnO_2, and WO_2 were employed for preparation of the dispersed Rh catalysts from carbonyl clusters, which catalysed mainly formation of methane and higher hydrocarbons with negligible selectivity of the oxygenated products under the reaction conditions.

The dispersion of metal plays, in many cases, an important role in exhibiting high activity and selectivity of metal supported catalysts. The proportion and fraction of metal atoms in the dispersed metal aggregates present on surface depend on the system and conditions of catalyst preparation. Various devices have been proposed for the preparation of highly dispersed metal, such as in the conventional impregnation methods and ion exchange methods.[1] In some cases, molecular metallic cluster compounds have been used as specific precursors for the generation of dispersed metal aggregates.[2] The pyrolysed Pt_3–Pt_{15} carbonyl clusters deposited on γ-Al_2O_3 or silica gel catalyse the selective dehydrocyclization of hexane, the particle size of which being conventionally estimated to be down to 10 Å.[3]

The work has been extended to rhodium, platinum and iridium crystallites similarly prepared on ZnO and MgO from the corresponding carbonyl clusters which catalysed selective methanol synthesis from CO and H_2 under atmospheric pressure. The rates and selectivity of methanol formation have been measured by changing the reaction conditions and preparation of the catalysts uning various carbonyl clusters and metal oxides as inorganic carriers.

Experimental and Procedures

The catalyst preparation and reaction of CO and H_2 were carried out in a closed circulating glass reactor (total volume 420 ml) operating in a continuous circulating flow mode. Analysis of the products was based on gas chromatography using Porapak Q 4 m (200 °C He carrier) and Polyethylene glycol 1500 2 m (80 °C He carrier) columns for alcohol and water, alumina–DMF (38 wt%) 4 m (0 °C He carrier) for C_2—C_5 hydrocarbons and active carbon 1 m (25 °C) for CH_4, CO, and H_2 in the gas phase. Highly pure hydrogen and CO were used from the respective cylinders. Alcohols and water produced were separately obtained at the cooling part equipped with a Dry Ice trap in the circulating reaction systems. $Rh_4(CO)_{12}$ was synthesized by the method of Chini and Matinengo[4] and identified by the IR carbonyl absorption of its hexane solution and by mass spectrometry. $Rh_2(\pi\text{-}C_5H_5)_2(CO)_3$ was prepared from $Rh(\pi\text{-}C_5H_5)(CO)_2$ by prolonged UV illumination (with a high pressure Hg lamp) of hexane solution at 25 °C under N_2 atmosphere, and purified by recrystallization.[5] The deep-red crystal was identified with with $Rh_2(\pi\text{-}C_5H_5)_2(CO)_3$ from its IR spectra in solid and solution, and by mass spectrometry. $Rh_6(CO)_{16}$ and $Ir_4(CO)_{12}$ (Strem Chem. Co.,) were used without purification. The trigonal prismatic carbonyl cluster salts $[Pt_3(\mu_2\text{-}CO)_3(CO)_3]_n 2NR_4$ (n=3, 4, and 5, R=C_2H_5 and n-C_4H_9) were separately obtained by the reaction with alkaline–methanol solution of $PtCl_6^{2-}$ under CO atmosphere in a similar way to that described[3] and isolated as tetra-alkylamine salts, which were stored under inert atmosphere in ampoules. $Rh_{13}(CO)_{23}H_{2-3}2N(C_4H_9)_4$ was synthesized by the method of Albano *et al.*[6] by the reaction with $Rh_{12}(CO)_{30}2N(C_4H_9)_4$ under hydrogen atmosphere and identified by IR carbonyl absorption of is tetrahydrofuran solution. The carbonyl clusters were deposited in high dispersion from the solution onto the metal oxides such as ZnO, MgO, CaO, BeO, SiO_2 gel and γ-Al_2O_3 powders. The entire procedure was performed in a vacuum or inert atmosphere of He and N_2. Pyrolysis of each dispersed metal carbonyl cluster compound on various oxides proceeded in a vacuum or hydrogen atmosphere by raising the temperature up to 180—200 °C in order to remove CO and the pyrolysed organic residues. The infrared spectra of the Rh and Pt carbonyl clusters on metal oxides were recorded in the range 2200—1600 cm^{-1} with a Hitachi EPI-G3 grating spectrometer.

Results and Discussion

Catalytic Hydrogenation of CO over the Supported Rh Crystallites on ZnO and MgO Prepared by Pyrolysis of $Rh_4(CO)_{12}$. $Rh_4(CO)_{12}$ was deposited from hexane solution onto zinc oxide (Kadox 25 ZnO from New Jersey Co. 22 m^2/g) and magnesium oxide powders, (MgO Merck Chem. Co., 99.9%, 34 m^2/g) evacuated at 320 °C for 15 h prior to use. The solvent was removed by evaporation at room temperature. Removal of CO was accomplished by heating the material charged in a Pyrex-reactor at 160 °C for 2 h *in vacuo* (10^{-3}—10^{-4}

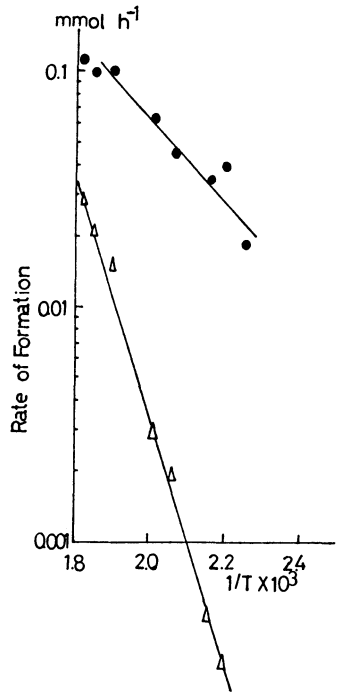

Fig. 1a. Arrhenius plots of methanol and methane formation over the pyrolysed catalyst on ZnO prepared from $Rh_4(CO)_{12}$. $Rh_4(CO)_{12}$ 0.11 g (0.15 mmol) and ZnO (Kadox 25) 20 g, 0.75% Rh wt dispersion. The volume of the reactor was 320 ml. CO: H_2=15 cmHg: 45 cmHg.
-●-: Formation of methanol (mmol/h),
-△-: formation of methane (mmol/h).

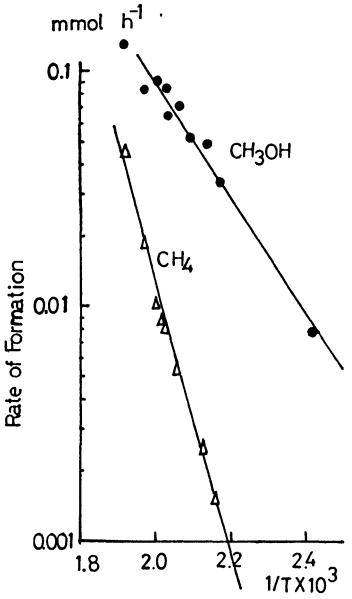

Fig. 1b. Arrhenius plots of methanol and methane formation over the pyrolysed catalyst on MgO prepared from $Rh_4(CO)_{12}$. $Rh_4(CO)_{12}$ 0.11 g (0.15 mmol) and MgO 20 g, 0.75% Rh wt dispersion. The volume of the reactor was 320 ml. CO: H_2=20 cmHg and 45 cmHg.
-●-: Formation of methanol (mmol/h),
-△-: formation of methane (mmol/h).

mmHg). The desorption of CO from the dispersed $Rh_4(CO)_{12}$ on ZnO and MgO proceeded sharply under He flow (1 atm 45 ml/min) in the temperature range 125—135 °C. This was confirmed by temperature-programmed technique using gas chromatography with active-carbon 1 m column. The infrared spectra of $Rh_4(CO)_{12}$ dispersed on ZnO were measured before and after the heattreatment *in vacuo*, and by introducing CO onto it. The sample wafer for infrared study was prepared by pressing the supported $Rh_4(CO)_{12}$ on Kadox 25 ZnO (1.8 Rh wt% dispersion) in a 2 cm diameter die and area force of 500 kg/cm². The IR spectra of the sample showed strong bands at 2050 and 1845 cm^{-1}, assigned to the terminal and bridged carbonyl absorptions, respectively, of the corresponding carbonyl cluster in solution and in crystal.[7] Both carbonyl bands completely disappeared by evacuation of the sample wafer at 120—150 °C for 1 h, probably due to desorption of CO. After evacuation 10—250 mmHg of CO was admitted at 25 °C, a broad and intense bands at 2000 and 1840—1870 cm^{-1} being observed. After pyrolysis, a mixture of CO and H_2 (molar ratio 1: 2 under total pressure of 45—65 cmHg) was introduced onto the pyrolysed catalysts at 150—250 °C, methanol being catalytically obtained after some induction period (*ca.* 5 h) in Dry-Ice cooling part of the circulating reactor. A small amount of methane was formed in gas phase. Carbon dioxde and C_2—C_5 hydrocarbons were detected in a minute quantity in the reaction products over these catalysts. The material balance of the methanol and methane produced was confirmed by means of the total amount of consumed CO through the reaction. The rates of methanol and methane formation over the pyrolysed catalysts were found to obey approximately the first order kinetics in each run, after the stationary state of the reaction was realized. The initial rates of methanol and methane formation (mmol/h) over the pyrolysed $Rh_4(CO)_{12}$ on ZnO and MgO were plotted against the reaction temperature (Figs. 1a and 1b). The apparent activation energies of methanol and methane formation were estimated at 11—12 kcal/mol and 32—37 kcal/mol, respectively, in the given temperature range. The selectivity of methanol synthesis over the catalysts was over 90% per CO consumed at 180—220 °C. Magnesium oxide was completely inactive for methanol synthesis under the reaction conditions. A small amount of methanol and methane was only detected over ZnO powder (Kadox 25 or 99.9% purity zinc oxide from Kishida Chem. Reagent Co.) at 260 °C in 125 h when CO (20 cmHg) and H_2 (45 cmHg) was admitted onto it, after the prolonged hydrogen reduction. A small amount of ethanol besides methanol was catalytically produced in CO–H_2 reaction over the pyrolysed $Rh_4(CO)_{12}$ catalyst dispersed on MgO. At temperatures above 220 °C, methane formation proceeded considerably, the proportion of ethanol and C_2—C_4 hydrocarbons slightly increasing (Table 1). Methane and C_2—C_4 hydrocarbons were markedly suppressed by increasing the CO/H_2 molar ratio from 0.2 to 2.0 under a constant total pressure.

Selectivity of Methanol Synthesis over the Rh Crystallite

Table 1. Product distribution in CO–H_2 reaction over pyrolysed catalysts on MgO prepared from $Rh_4(CO)_{12}$

CO	H_2 (cmHg)	T (°C)	CO conv. in 10 h (%)	Product distribution (mmol in 10 h)[a]							Methanol[b] select. (%)

a) O.P.: other oxygenated products. $C_2=C_2H_4+C_2H_6$, $C_3=C_3H_6+C_3H_8$, $C_4=C_4H_8+C_4H_{10}$ (+) less than 0.001 mmol (—) negligible. b) (Methanol)/(CO consumed) $\times 100$ (%).

Catalysts Prepared from Various Rh Carbonyl Clusters Deposited on ZnO. Rhodium carbonyl clusters such as $Rh_2(\pi\text{-}C_5H_5)_2CO)_3$, $Rh_6(CO)_{16}$ and $Rh_{13}(CO)_{23}H_{2-3}2N(C_4H_9)_4$ were employed instead of $Rh_4(CO)_{12}$ to disperse Rh crystallite on ZnO. $Rh_2(\pi\text{-}C_5H_5)_2(CO)_3$ (0.10 g) was deposited from a hexane solution on ZnO (20 g from Kishida Chem. Reagent Co.,) and pyrolysed under hydrogen atmosphere at 180 °C for 2 h in order to remove CO and cyclopentadiene residue. $Rh_6(CO)_{16}$ and $Rh_{13}(CO)_{23}H_{2-3}2N(C_4H_9)_4$ were dispersed from tetrahydrofuran solutions onto ZnO powders (Kadox 25 and Kishida Chem. Reagent Co.,) and pyrolysed *in vacuo* by raising the temperature up to 180 °C and treated with hydrogen at 200 °C for 2 h. When a CO–H_2 mixture reactant was admitted onto the pyrolysed catalysts, methanol was catalytically produced with a small amount of methane at 180 and 250 °C. The rates and selectivity of methanol formation over the Rh crystallite catalysts prepared from various Rh carbonyl clusters were measured in the stationary state of reaction. The results are summarized in Table 2. The optimal yield of methanol was obtained over the catalysts by pyrolysis of $Rh_4(CO)_{12}$ and $Rh_6(CO)_{16}$. The relative activity of methanol formation (mmol/h·g_{Rh}, g_{Rh}=Rh weight) varied with the kind of rhodium carbony cluster employed:

$$Rh_3(\pi\text{-}C_5H_5)_2(CO)_3 < Rh_4(CO)_{12} < Rh_6(CO)_{16} < Rh_{13}(CO)_{23}H_{2-3}2N(C_4H_9)_4$$

For comparison, the conventional Rh metal catalyst was prepared from impregnated $RhCl_3 3H_2O$ on ZnO (Kadox 25) in 1.0 and 2.5 Rh wt% loading followed by hydrogen reduction (1 atm 350 °C 10 h). The resulting Rh catalyst catalysed mainly methane formation with less than 15% selectivity.

Catalytic Hydrogenation of CO over the Rh Crystallites Deposited on Various Metal Oxides. A number of metal oxides were found to act as alternative carriers such as BeO and CaO. $Rh_4(CO)_{12}$ was deposited from a hexane solution over BeO (Merck Co., 99.99% purity) and CaO powders, (Merck Co., 99.9%) which were preheated *in vacuo* at 320 °C for 15 h. After pyrolysis of the substance *in vacuo* at 160 °C, the CO–H_2 reaction was carried out in the circulating reactor. Methanol was selectively, obtained but with lower CO conversion, over the pyrolysed catalyst on CaO at 200—260 °C. Over the Rh crystallites on BeO, methanol and a trace of ethanol were formed but with lower methanol selectivity. Typical results of catalytic hydrogenation of CO over the catalysts on CaO, and BeO are summarized in Table 3. For comparison, other metal oxides such as SiO_2 gel (AEROSIL-300, Yokohama Aerosil Co., 300 m^2/g), γ-Al_2O_3 (A-11, Harshaw Co.,

CO: H_2=(15 cmHg: 50 cmHg). The volume of the reactor was 420 ml. a) A trace of CH_3CHO, C_3H_7OH, and C_4H_9OH was detected in the oxygenated products.

280 m^2/g), SnO_2 (Nakarai Chem. Co., 99.9% purity) WO_3 (Nakarai Chem. Co., 99.9%) and V_2O_5 (Kishida Chem. Reagent Co., 99.9% purity) were employed to prepare the dispersed Rh catalysts by the pyrolysis of $Rh_4(CO)_{12}$. All the pyrolysed catalysts produced mainly methane with lower CO conversion in $CO-H_2$ reaction. Over the catalysts on SiO_2 and γ-Al_2O_3, a trace of methanol and ethanol was detected in the condensed products at temperatures above 200 °C. The pyrolysed catalysts on other metal oxides such as SnO_2, WO_3, and V_2O_5 yielded a negligible amount of methanol or other oxygenated products. At elevated temperatures methane was obtained in a large amount over these catalysts. The metal oxides used in the experiments were completely inactive for CO hydrogenation. This suggests that the reactivities of the supported Rh crystallites from carbonyl clusters are markedly dependent on the kind of metal used as inorganic carrier. The basic metal oxides such as ZnO, MgO, CaO, and BeO were found to be the optimal carriers to prepare highly selective Rh crystallite catalysts for methanol synthesis under mild reaction conditions.

Catalytic Hydrogenation of CO over the Supported Platinum and Iridium Crystallites on ZnO and MgO Prepared by Pyrolysis of the Carbonyl Cluster Compounds. Pt carbonyl cluster anion salts such as $Pt_9(CO)_{18}2NEt_4$ and $Pt_{15}(CO)_{30}2NEt_4$ were dispersed from tetrahydrofuran solutions onto ZnO and MgO powders in 0.5—1.0 Pt wt% loading. After removal of the solvent at room temperature, the resulting substance charged in the closed circulating Pyrex-reactor (*ca.* 420 ml) was heated *in vacuo* up to 180 °C. The desorption of CO from each dispersed Pt carbonyl cluster salt proceeds almost completely in a vacuum or H_2 flow (1 atm).[3] This was confirmed by temperature-programmed technique using gas chromatography and mass spectrometry. The desorption temperatures of the Pt clusters on γ-Al_2O_3 and ZnO were 150 °C for $Pt_{15}(CO)_{30}2NEt_4$ and 165 °C for $Pt_9(CO)_{18}2NEt_4$, respectively. The hydrogenation of CO took place reproducibly at 180—250 °C by introducing a $CO-H_2$ (1 : 2 molar ratio) gas onto the pyrolysed catalysts. Methanol was also catalytically produced with a small amount of methane. Ethanol and higher hydrocarbons (C_2—C_4) were detected in a negligible amount in the reacton. The methanol yields per Pt weight over the catalyst on MgO were higher than that on ZnO under similar reaction conditions. For comparison, the conventional Pt metal catalyst was prepared from the impregnated H_2PtCl_6 on ZnO (Kadox 25) in 2.5 Pt wt% loading, followed by hydrogen reduction at 350 °C for 15 h. The resulting catalyst showed considerably lower CO conversion, producing mainly methane with less than 5% selectivity of methanol formation in $CO-H_2$ reaction under atmospheric pressure.

$Ir_4(CO)_{12}$ was dissolved in tetrahydrofuran, and

CO: H_2=15: 45 cmHg. The volume of the reactor was 420 ml. (+) denotes less than 0.001 mmol.

deposited on 20 g of ZnO or MgO powder. On coming in contact with MgO powder, the pale-yellow solution of $Ir_4(CO)_{12}$ turned deep-red, probably due to the formation of Ir_6-carbonyl clusters such as $Ir_6(CO)_{15}^{2-}$ salt[8] completely adsorbed on MgO. Removal of CO, after evaporating the solvent, was accomplished *in vacuo* at 180 °C for 2 h. Methanol was catalytically produced at higher temperatures above 240 °C after a long induction period over the pyrolysed Ir crystallite catalyst on ZnO. No ethanol and higher hydrocarbons were obtained in CO–H_2 reaction over Ir crystallite catalyst. The catalyst prepared by pyrolysis of $Ir_4(CO)_{12}$ on MgO gave a trace of methanol for the oxygenated product, and mainly methane from CO–H_2 mixture reactant. Typical results of methanol synthesis over the Pt and Ir crystallite catalysts are summarized in Table 4. It is suggested that the pyrolysed catalysts of Pt and Ir carbonyl clusters on ZnO and MgO also catalyse methanol synthesis under atmospheric pressure, although the specific methanol conversions were relatively lower than those from Rh carbonyl clusters. The activity and selectivity of methanol formation in CO–H_2 reaction depend on the catalyst preparation by selecting metal carbonyl clusters as well as metal oxides as inorganic carriers.

Catalysis by Supported Metal Crystallites from Carbonyl Clusters. II. Catalytic Ethanol Synthesis from CO and H_2 under Atmospheric Pressure over Supported Rhodium Crystallites Prepared from Rh Carbonyl Clusters Deposited on TiO_2, ZrO_2, and La_2O_3

Masaru ICHIKAWA

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received December 6, 1977)

Ethanol was catalytically produced in the CO–H_2 reaction under atmospheric pressure and at 150—250 °C over rhodium crystallite catalysts prepared from Rh carbonyl cluster compounds highly dispersed on La_2O_3, TiO_2, and ZrO_2. The activity and selectivity of ethanol formation depend on the kind of metal carbonyl cluster and metal oxide used as inorganic carriers. The catalysts prepared by the pyrolysis of smaller Rh carbonyl clusters such as $Rh_2(C_5H_5)_2(CO)_3$, $Rh_4(CO)_{12}$, and $Rh_6(CO)_{16}$ on La_2O_3, TiO_2, and ZrO_2 show higher selectivity of the oxygenated products containing ethanol (main), acetaldehyde, and methanol. The ethanol contents in the oxygenated products increased considerably above 200 °C over the catalysts. CeO_2 and ThO_2 were also employed in the preparation of the pyrolysed catalysts to disperse the Rh carbonyl clusters, which catalyses the ethanol formation in the CO–H_2 reaction at atmospheric pressure.

The catalytic synthesis of hydrocarbons and oxygen-containing compounds from CO and H_2 (Fischer-Tropsch synthesis and synthesis of alcohols) is of interest from both a practical and theoretical point of view.[1] The conventional metal catalysts containing Fe and Co are not selective, exhibiting considerably broad spectra of the product distribution. The formation of hydrocarbons and alcohols from CO–H_2 mixture is thermodynamically favorable, although higher pressures (in excess of 1 atm) are necessary to facilitate the formation of higher molecular weight products. It is important to study the surface reactions in catalytic hydrogenation of CO over supported metal catalysts to control rates and selectivity for the possible products in connection with the surface composition of the catalysts. The purpose of this study is to correlate the reactivities of highly dispersed noble metal catalysts in the CO–H_2 reaction with their chemical compositions, being associated with the dispersion of metal and composition on the surface, which depend on the systems and conditions of ctalyst preparations. The author has developed a method for the preparation of the dispersed metal crystallites on various metal oxides by using molecular metallic cluster compounds as specific precursors.[2] Recently, Muetterties and others[3] demonstrated that the metal carbonyl clusters such as $Ru_3(CO)_{12}$ and $Ir_4(CO)_{12}$ slowly produce methane and higher hydrocarbons in homogeneous hydrogenation of CO at 140—200 °C and 1—2 atm. The supported Rh, Pt, and Ir crystallites on ZnO and MgO prepared from the carbonyl clusters catalyse a selective methanol synthesis in catalytic hydrogenation of CO under atmospheric pressure.[4] In this paper, a report is given on the direct catalytic ethanol formation from CO–H_2 mixture at atmospheric pressure over the Rh crystallites prepared from the carbonyl clusters deposited on specific metal oxides such as TiO_2, ZrO_2, and La_2O_3. The rates and product distribution in the CO–H_2 reaction over the supported Rh crystallite catalysts were observed by changing the reaction conditions and catalyst preparation using various Rh carbonyl cluster compounds and metal oxides as inorganic carriers.

Experimental

The catalyst preparation and CO–H_2 reaction were carried out in a closed circulating glass-reactor. Experiments were performed under atmospheric pressure in a pyrex glass tubular reactor operating in continuous flow in order to measure the one-path yields and selectivity of the reaction through the fixed-bed catalysts. Analysis of the oxygenated products and hydrocarbons was carried out by gas chromatography using Porapak Q, PEG 1500, alumina–DMF and active carbon columns, as reported.[4] The oxygenated products in the CO–H_2 reaction were separately obtained in the condensed part with a Dry-Ice cooling trap in the circulating reactor. In the continuous flow reaction system, the gaseous product was collected at intervals in a glass flask containing water and analyzed by FID (Hitachi-FD6) gas chromatography with a 4 m PQ column. The rhodium carbonyl cluster compounds such as $Rh_2(C_5H_5)_2(CO)_3$, $Rh_4(CO)_{12}$, $Rh_6(CO)_{16}$ and Rh_{13}-$(CO_{23}H_{2-3}2NBu_4$ were obtained.[4] $Rh_7(CO)_{16}3NEt_4$ was synthesized in the reaction with $Rh_4(CO)_{12}$ under CO atmosphere by the method of Martinengo and Chini[5] and isolated as tetra ethylammonium salt, which was stored in a glass ampoule under He atmosphere. The Rh carbonyl clusters were deposited in high dispersion from their solutions onto the metal oxides such as La_2O_3, CeO_2, TiO_2, ZrO_2, and ThO_2. The removal of CO and residual organics (amines and cyclopentadiene) was accomplished in a vacuum or H_2 atmosphere by heat treatment of the supported samples. The procedure of catalyst preparation was carried out *in vacuo* or under an inert atmosphere of He and N_2 because of air-sensitivity of the carbonyl cluster compounds.

Results and Discussion

Catalytic Etanol Formation from CO and H_2 over the Rh Crystallites on La_2O_3 Prepared from $Rh_4(CO)_{12}$. 0.11 g of $Rh_4(CO)_{12}$ was deposited from a hexane solution onto 20 g of lanthanum oxide (La_2O_3, 99.9% purity, Nakarai Chem. Reagent Co.,) which was evacuated at 320 °C for 13 h prior to use. The solvent was then removed by evaporation at room temperature. The sample pellets

The volume of the reactor was 320 ml. + denotes less than 0.001 mmol in 10 h.

(*ca.* 5—10 mesh) for the $CO-H_2$ reaction were prepared by pressing the supported material under pressure of 400 kg/cm², and charged in a Pyrex glass reactor. Desorption of CO from the supported $Rh_4(CO)_{12}$ sample proceeded under evacuation (10^{-3}—10^{-4} mmHg) by raising the temperature upto 180 °C for 2 h. After pyrolysis, a mixture of CO and H_2 (molar ratio 1 : 1—2 under total pressure of 45—65 cmHg) was circulated with *ca.* 50 ml/min flow rate through the catalyst pellets. The oxygenated products containing C_2H_5OH, CH_3CHO, and CH_3OH were catalytically obtained in a certain induction period (*ca.* 5 h) at 150—250 °C. Methane and a small amount of C_2—C_4 hydrocarbons were also formed in gas phase. The reproducible rates of the oxygenated products and hydrocarbons were measured by changing the reaction temperatures and ratios of CO to H_2 partial pressure in a wide range. Typical results are summarized in Table 1. The carbon efficiency of oxygenated products per CO consumed was between 60 and 90% over the pyrolysed catalyst in the temperature range 150—200 °C. At temperatures below 190 °C, methanol contents in the oxygenated products were relatively high, the yields of ethanol increasing considerably with temperature rise above 200 °C. The apparent activation energy of methanol, ethanol and methane formation was estimated at 11, 20, and 28 kcal/mol, respectively. At higher CO/H_2 ratios of the mixture gas, the formation of C_1—C_4 hydrocarbons was suppressed and ethanol selectivity increased comparatively, although total CO conversion decreased. It should be noted that lanthanum oxide as an inorganic support was completely inactive for the $CO-H_2$ reaction at 120—320 °C, even after prolonged heat treatment under hydrogen.

Hydrogenation of CO over the Rh Crystallites on La_2O_3 Prepared from Various Rh Carbonyl Clusters. A number of Rh carbonyl cluster compounds, such as $Rh_2(C_5H_5)_2(CO)_3$, $Rh_6(CO)_{16}$, $Rh_7(CO)_{16}3NEt_4$, and $Rh_{13}(CO)_{23}2NBu_4$ were employed instead of $Rh_4(CO)_{12}$, as precursors in the preparation of pyrolysed catalysts on lanthanum oxide. Each carbonyl cluser compound (0.10 g) was deposited onto the La_2O_3 powder (20 g) from the solution of tetrahydrofuran ($Rh_6(CO)_{16}$ and $Rh_{13}(CO)_{23}H_{2-3}2NBu_4$) and of acetone ($Rh_7(CO)_{16}3NEt_4$). The supported material was loaded in the reactor of the closed circulating reaction system (total volume 420 ml). After pyrolysis at 180 °C for 2 h and hydrogen treatment at 200 °C for 1 h, the $CO-H_2$ reaction took place by circulation of a mixture gas (CO/H_2=*ca.* 0.5, 65 cmHg) over the catalysts. $Rh_2(C_5H_5)_2(CO)_3$ was dispersed on La_2O_3 from the hexane solution.

Decomposition of the supported cluster was accomplished under H_2 atmosphere (60 cmHg) at 180 °C for 2 h and evacuated for a few minutes. The rates and product distribution in a catalytic hydrogenation of CO were measured over these pyrolysed catalysts in the temperature range 150—250 °C. The reproducible results are given in Table 2. It was suggested that the pyrolysed catalysts from smaller Rh clusters such as Rh_2—Rh_6 exhibit a relatively higher selectivity of oxygenated products containing mainly ethanol and methanol. On the contrary, C_2—C_4 hydrocarbons were produced at higher contents of the products over the catalysts prepared from larger carbonyl clusters such as Rh_7—Rh_{13}. The composition in the oxygenated products exhibited almost the same spectra over all the pyrolysed Rh cluster catalysts. With a rise in the reaction temperature above 200 °C, the content of acetaldehyde in the products increased a little and C_2—C_4 hydrocarbons were produced with higher yields over the catalysts from larger Rh carbonyl clusters. It is of interest that the catalyst based on $Rh_2(C_5H_5)_2(CO)_3$ and La_2O_3 produced catalytically methyl acetate in the $CO-H_2$ reaction above 200 °C. The catalysts kept almost the same rates and selectivity of ethanol formation in prolonged runs of about 20 days. Accordingly, with Rh carbonyl clusters as precursors, the relative yields of ethanol per unit Rh weight changed over the pyrolysed catalysts on La_2O_3 in the order:

$$Rh_2(C_5H_5)_2(CO)_3 < Rh_4(CO)_{12} > Rh_6(CO)_{16} > Rh_7(CO)_{12}3NEt_4 > Rh_{13}(CO)_{23}H_{2-3}2NBu_4.$$

For comparison, the Rh catalyst was prepared conventionally by hydrogen reduction (350 °C 15 h) of the impregnated $RhCl_3$ on La_2O_3 (2.5% Rh weight loading) from the aqueous solution. When a $CO-H_2$ mixture was admitted onto the catalyst at 200 °C, a small amount of the oxygenated products containing ethanol and methanol was obtained after a long induction period of several days. The reproducible results in the $CO-H_2$ reaction over the catalyst showed relatively smaller CO conversion and lower selectivity of the oxygenated products. Methane and higher hydrocarbons were preferentially produced above 200 °C (Table 2). The results suggest that the Rh carbonyl clusters play the role of specific precursor to prepare the supported catalyst on La_2O_3, which catalyses the selective formation of oxygenated products in a CO hydrogenation

under mild reaction conditions.

Ethanol Formation in $CO-H_2$ Reaction over the Pyrolysed Catalysts of $Rh_4(CO)_{12}$ and $Rh_6(CO)_{16}$ Deposited on TiO_2, ZrO_2, CeO_2, and ThO_2. Other metal oxides such as TiO_2, ZrO_2, CeO_2, and ThO_2 were found to act as promoters for ethanol formation in catalytic hydrogenation of CO over the supported Rh crystallite catalysts. $Rh_4(CO)_{12}$ and $Rh_6(CO)_{16}$ (0.10 g) were similarly deposited onto each metal oxide (TiO_2 99.9% Merck Co., ZrO_2 99.9% Nakarai Chem. Reagent Co., CeO_2 99.9% Wako Pure Reagent Co., and ThO_2 99.9% Kishida Chem. Reagent Co.,)[6] 20 g from the solutions. The pressed pellets of the supported materials were charged in the closed circulating reactor (320 ml). After pyrolysis *in vacuo* at 180 °C for 2 h, a mixture of CO and H_2 was introduced and circulated at 150 and 250 °C. The oxygenated products containing mainly ethanol were produced in a wide temperature range over the pyrolysed catalysts. The reproducible rates and product distribution in the $CO-H_2$ reaction are given in Table 3. The product distribution illustrates a remarkable specificity for ethanol formation in the oxygenated products. The selectivity of the oxygenated products was relatively higher over the catalyst on ZrO_2 than that on TiO_2 and CeO_2, and gave comparatively smaller formation of C_1–C_4 hydrocarbons. The olefinic products of C_2—C_4 hydrocarbons increased considerably by employing the liquid nitrogen trap, instead of Dry-Ice cooling, to collect the hydrocarbon products at higher temperatures. The CO—H_2 reaction readily proceeded over the pyrolysed Rh carbonyl cluster catalysts on ThO_2 at 150—180 °C to produce the oxygenated products containing methanol and ethanol. By raising the temperature above 190 °C, the higher hydrocarbons such as C_5H_{12}, C_6H_{14}, and C_7H_{16}[7] were considerably formed, and the yields of the oxygenated products decreased although CO conversion was very high. TiO_2 and ThO_2 may accelerate the condensation and dehydration of the oxygenated products at a catalyst surface. The product distribution and rates in the $CO-H_2$ reaction over the Rh crystallite catalysts markedly depend on the kind of metal oxide.[4] The pyrolysed catalysts prepared from Rh carbonyl clusters on ZnO, MgO, BeO, and CaO (Ia and IIa metal

oxides) selectively produced methanol in the reaction. Ethanol and C_2-oxygenated products were obtained over the catalysts dispersed on La_2O_3 and CeO_2 (IIIa metal oxides) and TiO_2, ZrO_2, and ThO_2 (IVa metal oxides). In contrast, C_1—C_5 hydrocarbons (mainly methane) were preferentially produced with less than 5% selectivity of the oxygenated products (mainly ethanol) over the Rh crystallites on SiO_2 gel and γ-Al_2O_3 (IIIb and IVb metal oxides). Methane was selectively formed with lower CO conversion over the catalyst on SnO_2, V_2O_5, and P_2O_5 in the CO–H_2 reaction. It seems that the half-hydrogenated intermediates in catalytic hydrogenation of CO are influenced by the surface properties of the metal oxides dispersing Rh crystallites. Surface properties such as acidity or basicity of metal oxides might be correlated with product distribution in the CO–H_2 reaction over those supported Rh crystallite catalysts.

CO–H_2 Reactions in Continuous Flow System under Atmospheric Pressure over the Pyrolysed Catalysts Prepared from $Rh_4(CO)_{12}$ on La_2O_3 and TiO_2. The CO–H_2 reaction was carried out operating the continuous flow mode using a 50 cm Pyrex glass tubular reactor, 18 mm in diameter. A pellet catalyst (*ca.* 20 ml) of the supported $Rh_4(CO)_{12}$ on La_2O_3 or TiO_2 (in 0.5% Rh loading) was charged in the reactor, and 2 mm glass beads were packed above and below the catlayst bed. The reactor was placed vertically in an electric furnace. CO and

(ethanol)/(methanol)+(ethanol) × 100.

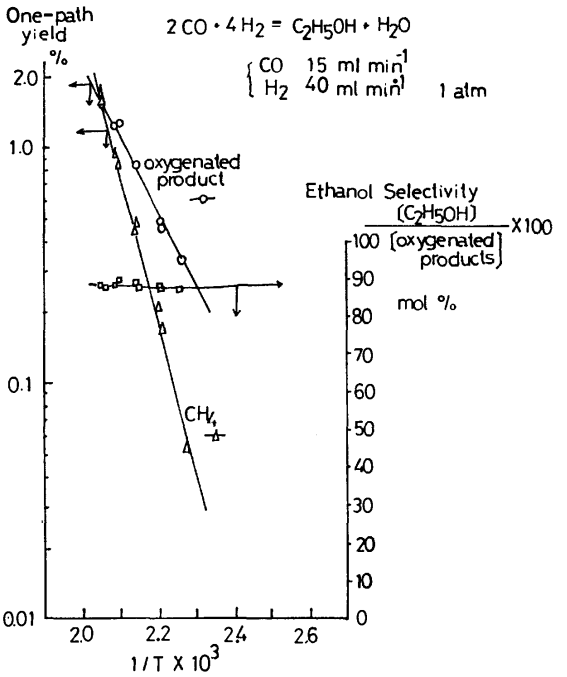

Fig. 2. Temperature dependency of the formation of oxygenated products and methane over the pyrolysed catalyst on TiO_2 prepared from $Rh_4(CO)_{12}$. $Rh_4(CO)_{12}$ 0.35 g (0.47 mmol) and TiO_2 38 g in 0.50 Rh wt % dispersion. Activated under hydrogen stream (1 atm, 40 ml/min). CO(15 ml/min) and H_2 (40 ml/min). -○-: One-path yield (% per CO inlet) of the oxygenated products containing ethanol, methanol and acetaldehyde, -△-: one-path yield (% per CO inlet) of methane, -□-: mol % of ethanol in the oxygenated products formed.

hydrogen were supplied from the respective cylinders. After measuring the flow rates of CO and H_2 separately, the gases were mixed and brought to contact with the catalyst bed at the flow rates 30—100 ml/min. The gaseous product was transferred from the bottom of the reactor in a 100 ml flask containing water. The oxygenated products collected at intervals were analyzed by FID gas chromatography using PQ column, and C_1—C_4 hydrocarbons by alumina–DMF and active carbon columns. Removal of CO was accomplished by slow heating of the catalysts at 180—200 °C in a stream of pure hydrogen for 2 h. The 1:1—2 mixture of CO and H_2 was reacted at 180—250 °C. The stationary rates and product distribution of the reaction were attained in the continuous flow for 10 h at 200 °C. The one-path yields of methanol, ethanol, and methane were measured at various temperatures under constant space velocity. The results are shown in Figs. 1 and 2. The formation of other C_2-oxygenated products and C_2—C_4 hydrocarbons was negligibly small. The ethanol content in the oxygenated products was found to be almost constant over the pyrolysed catalyst on TiO_2 in a wide temperatures range. On the other hand, the ethanol content was markedly dependent on the reaction temperature over the catalyst on La_2O_3, increasing with rise in temperature. By increasing the ratios of CO/H_2 the selectivity of the oxygenated products increased and the C_1—C_4 hydrocarbon forma-

tion was suppressed considerably, as measured over the catalysts in the closed circulating reactor system.

Structures of Lanthanoid Complexes of Glyceric Acid, Gluconic Acid, and Lactobionic Acid from the Lanthanoid-Induced ^{1}H NMR Shifts: pH Dependence of the Lanthanoid-Substrate Equilibria

Tooru TAGA,* Yoshihiro KURODA, and Makoto OHASHI
Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 8, 1977)

Lanthanoid-induced ^{1}H NMR shifts of glyceric acid, gluconic acid, and lactobionic acid were observed in D_2O. Stoichiometric analysis using the shift data at various pH values indicated that the concentration of a 1:1 complex between substrates and lanthanoid ions was higher than that of a 2:1 complex at a low pH. The structure of an axially symmetric 1:1 complex was obtained on the assumption of a predominant pseudo-contact interaction between a europium ion and the ligand nuclei. All the title glycosidic acids were found to chelate the cation with α-carboxy, α-hydroxy, and β-hydroxy oxygens. The relative position of β-hydroxy oxygen is particularly important for the complex formation between β-hydroxy carboxylic acids and metal ions.

In previous papers[1,2] dealing with calcium binding to polyhydroxy dicarboxylic acid, DL-glucaric acid, we have reported that the α-carboxyl group chelates the cation with α-carboxy, α-hydroxy, and β-hydroxy oxygens in an aqueous solution, while the δ-carboxyl group is not bound to the cation either in solution or in the crystalline state. The configuration about the carbon chain of glyceric acid, **1**, gluconic acid, **2**, and lactobionic acid, **3**, is the same as that of glucaric acid, **4**, with respect to the α-carboxyl part (Fig. 1). We were, therefore, interested in the chelating geometry of Compounds **1**, **2**, and **3** to a lanthanoid ion in relation to that of glucaric acid, **4**. It has been known that acidic and neutral carbohydrates occasionally well chelate a metal ion with hydroxyls.[3] The chelating stability depends on the steric arrangement of hydroxyls

in the substrate and on the size of the cation. For instance, an axial-equatorial-axial hydroxyl arrangement about a six-membered ring of inositol or pyranose sugar is suitable for the chelation to an alkaline-earth ion, as has been pointed out by Angyal.[4] X-Ray and neutron diffraction studies[5–8] have revealed that **1** and **2** have two different conformations in the crystalline states, and that Compounds **1**, **2**, and **3** have a large flexibility. However, it is possible for them to have a conformation suitable for the stable complexing with a lanthanoid ion in solution. Thus, we studied the structures of the lanthanoid complexes of these compounds in D_2O by the lanthanoid probe method of ^{1}H NMR.

Since the "fast exchange" assumption for complexing between the substrate and the lanthanoid ion in D_2O may be correct, and since complexes with three or more substrates may be negligible, the paramagnetic lanthanoid-induced shift of the ith nucleus in the substrate should conform to the following equation:[9]

$$\Delta\delta_i = \frac{1}{S_0}(x\Delta_{1i} + 2y\Delta_{2i}), \quad (1)$$

where Δ_{1i} and Δ_{2i} are the shifts depending intrinsically on 1:1 and 2:1 complexes respectively, where x and y are the concentrations of the corresponding complexes, and where S_0 is the total concentration of substrates in solution. The Δ_{1i} and Δ_{2i} shifts have usually been derived from chemical shifts observed by changing the molar ratio, ρ, between lanthanoid ions and substrates or by changing the total concentration, S_0, at a constant ρ.[10–12] However, the present complexes are precipitated in an aqueous alkaline solution, and the chemical shift below pK_a depends largely on the pH of the solution. Hence, the evaluation of Δ_{1i} and Δ_{2i} from the data given by the pH change of a solution is desirable.

This paper will describe a treatment of the pH dependence of the lanthanoid-induced shift and will show an application of this method for the cases of three carboxylate complexes. The pseudo-contact shift for an axially symmetric cmoplex is given by the McConnell-Robertson equation:[13]

$$\Delta\nu_i/\nu_0 = A\cdot(3\cos^2\theta_i - 1)/r_i^3, \quad (2)$$

where A is a constant for a lanthanoid ion at a given temperature, where r_i is the distance between the

paramagnetic ion and the ^1H nucleus, and where θ_i is the angle between the principal magnetic axis of the complex and the vector, r_i. As has been reported by many authors,[14,15] the application of Eq. 2 in establishing the ligand conformation in a lanthanoid complex has been successful. The structure can be determined by minimizing the square errors between observed and calculated shifts for trial complex models.

Experimental

The ^1H NMR spectra were recorded on a VARIAN HA-100D spectrometer in the frequency-sweep mode at 100 MHz, using HDO or tetramethylsilane sealed in a capillary tube as an internal lock signal. The probe temperature was kept at 30 °C. The chemical shifts were measured from the acetone peak as an internal standard. The D_2O stock solution of 0.5 M glyceric acid was prepared from *ca.* 70% DL-glyceric acid, whose exact concentration was determined by the titration of 1 M NaOH. The D_2O solutions of sodium gluconate and lactobionic acid were prepared from commercial reagents supplied by the Tokyo Kasei Company. Europium nitrate, $Eu(NO_3)_3 \cdot 6H_2O$, and praseodymium nitrate, $Pr(NO_3)_3 \cdot 6H_2O$, were used as paramagnetic shift reagents, while lanthanum nitrate, $La(NO_3)_3 \cdot 6H_2O$, was used as a diamagnetic shift reagent. The pH of the solution was adjusted by adding concd DCl and NaOD, using a CE-150A glass electrode (Toko Chemical Laboratory Co. LTD) connected with a Hitachi-Horiba M-7E pH meter.

Calculations of the stoichiometry and structures of lanthanoid-substrates complexes were performed on a NOVA 1200 computer operating in connection with a DIABLO-31 disk drive, using the FORTRAN IV programs written by the present authors.

Results and Discussion

Stoichiometry of Lanthanoid-Substrate Complexes. Figures 2, 3, and 4 show the pH dependence of Eu(III)-induced shifts for Compounds **1**, **2**, and **3** respectively in D_2O solutions. Since diamagnetic effects may be included in the Eu(III)-induced shifts,[16,17] the effect was corrected by means of La(III)-induced shifts observed under the same experimental conditions, on the assumption that Eu(III) and La(III) form complexes with similar structures in solution. All the protons bonded to the carbons in **1** and **2**, and three protons of H(2), H(3), and H(1') in **3** were assigned to the observed signals. The other protons of **3** could not be assigned because of the heavy overlapping of the peaks. When the pH value increases, the peaks of H(2) and H(3) for all compounds were shifted upfield, while the other peaks were shifted downfield. The J values given in Table 1 do not change greatly in this experimental pH range.

The pH dependence of the concentrations, x and y, corresponding respectively to the 1 : 1 and 2 : 1 complexes

		J_{5-6}	3.0		

can be derived from the following stoichiometric consideration. If we denote the lanthanoid ion as L, the protonated carboxylic acid as SH, and the unprotonated carboxylate anion as S, the following equilibria may exist in solution:

$$SH \overset{K_a}{\rightleftharpoons} S + H, \quad (3)$$

$$L + S \overset{K_s}{\rightleftharpoons} LS, \quad (4)$$

$$L + SH \overset{K_{sh}}{\rightleftharpoons} LSH, \quad (5)$$

$$LS + S \overset{K_{ss}}{\rightleftharpoons} LSS, \quad (6)$$

$$LSH + S \overset{K_{shs}}{\rightleftharpoons} LSHS, \quad (7)$$

$$LS + SH \overset{K_{ssh}}{\rightleftharpoons} LSSH, \quad (8)$$

$$LSH + SH \overset{K_{shsh}}{\rightleftharpoons} LSHSH, \quad (9)$$

where K_a is a dissociation constant of carboxylic acid given as

$$K_a = [S]\cdot[H]/[SH], \quad (10)$$

and where K_s, K_{sh}, K_{ss}, K_{shs}, K_{ssh}, and K_{shsh} are association constants corresponding to each complex. Since the total concentration of lanthanoid ions, $L_0 = [L]+x+y$, and that of substrates, $S_0 = [S]+[SH]+x+2y$, the concentrations for each complex are expressed in terms of x and y by using Eq. 10 as follows:

$$[LS] = K_s(L_0 - x - y)(S_0 - x - 2y)/(1 + h), \quad (11)$$

$$[LSH] = K_{sh}(L_0 - x - y) \times (S_0 - x - 2y)h/(1 + h), \quad (12)$$

$$[LSS] = K_{ss}K_s(L_0 - x - y) \times (S_0 - x - 2y)^2/(1 + h)^2, \quad (13)$$

$$[LSHS] = K_{shs}K_{sh}(L_0 - x - y) \times (S_0 - x - 2y)^2h/(1 + h)^2, \quad (14)$$

$$[LSSH] = K_{ssh}K_s(L_0 - x - y) \times (S_0 - x - 2y)^2h/(1 - h)^2, \quad (15)$$

$$[LSHSH] = K_{shsh}K_{sh}(L_0 - x - y) \times (S_0 - x - 2y)^2h^2/(1 + h)^2, \quad (16)$$

where $$h = [H]/K_a = 10^{(pK_a - pH)}. \quad (17)$$

The following quadratic equations are obtained from Eqs. 11—16 by using the $x=[LS]+[LSH]$ and $y=[LSS]+[LSHS]+[LSSH]+[LSHSH]$ relations:

$$x = \eta(L_0 - x - y)(S_0 - x - 2y), \quad (18)$$

$$y = \xi x(S_0 - x)/(\eta + 2\xi x), \quad (19)$$

where $$\eta = (K_s + hK_{sh})/(1 + h), \quad (20)$$

$$\xi = \{(K_{ss} + hK_{ssh})K_s + (K_{shs} + hK_{shsh})hK_{sh}\}/(1 + h)^2. \quad (21)$$

From Eqs. 18 and 19,

$$x^3 + Ax^2 + Bx + C = 0, \quad (22)$$

where $$A = \{-2\rho S_0 + \eta/\xi - 4/\eta\}/\{1 - 4\xi/\eta^2\}, \quad (23)$$

$$B = \{(2\rho - 1)S_0^2 - (\rho + 1) \times (\eta/\xi)S_0 - 1/\xi\}/\{1 - 4\xi/\eta^2\}, \quad (24)$$

$$C = \{\rho(\eta/\xi)S_0^2\}/\{1 - 4\xi/\eta^2\}. \quad (25)$$

Equations 22—25, which are similar to the Shapiro-Johnston equations,[9] are a general expression including the pH dependence for the "two-step mechanism." If the pK_a of the carboxylate in D_2O is known, and if a suitable value of the association constant is assumed, the concentration, x, at a given pH can be obtained by solving Eq. 22, while y can be given by Eq. 19. If the induced shifts of the proton signals of the LS and LSH complexes are the same, and if those of the LSS, LSSH, LSHS, and LSHSH complexes are also the same, (the total lanthanoid-induced shift of the ith nucleus can be calculated by means of Eq. 1. The best fit parameters, Δ_{1i} and Δ_{2i}, can be obtained by the least-squares method, minimizing the sum of errors between the observed and calculated induced shifts.[9]

TABLE 2. ASSOCIATION CONSTANTS ASSIGNED FOR 1:1 AND 2:1 COMPLEXES, AND THE pK_a OF EACH ACID

		Glyceric acid	Gluconic acid	Lactobionic acid

a) A minus sign denotes a downfield shift.

and 0.042 for the cases of Compounds **1**, **2**, and **3** respectively. Figure 5 shows the ρ and S_0 dependences of the Eu(III)-induced shifts in the case of glyceric acid, **1**. The full curves were theoretically calculated from the association constants assumed in the case of the pH dependence. Since the observed points lie approximately on the curves, the data obtained by analysis based on the pH dependence will be consistent with those obtained on the basis of the ρ and S_0 dependences. Figure 6 shows the pH dependence of the concentrations of 1: 1 and 2: 1 complexes. For all compounds, the concentration of the 1: 1 complex is higher than that of the 2:1 complex at low pH's. When the pH value increases to pK_a, the concentration of the 2: 1 complex increases markedly. A large amount of lanthanoid ions in solution results in a high concentration of the 1: 1 complex, as is indicated in the case of glyceric acid (Fig. 6a). The concentrations, [LSH], [LSHS], [LSSH] and [LSHSH], calculated by means of Eqs. 12 and 14—16 are negligible for all cases. Only an unprotonated carboxyl substrate is bound to the lanthanoid ion; they form a stable complex.

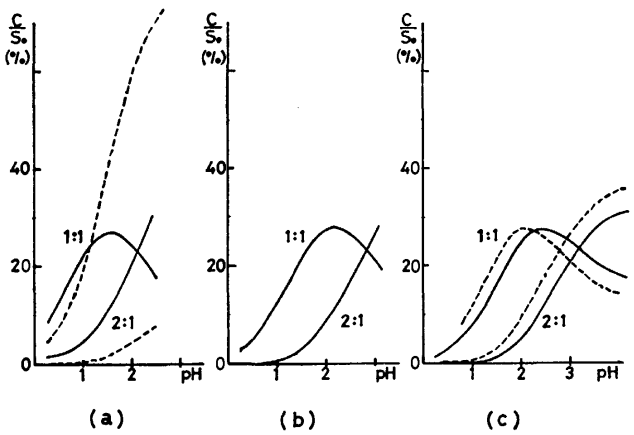

Fig. 6. PH dependence of concentrations of 1: 1 and 2: 1 complexes in D_2O solutions; (a) for glyceric acid, where the full curves are for ρ=0.5 and S_0=0.5 M, and the dotted curves are for ρ=2.0 and S_0=0.05 M, (b) for gluconic acid, where the full curves are for ρ=0.5 and S_0=0.1 M, and (c) for lactobionic acid, where the full curves are for ρ=0.5 and S_0=0.1 M, and the dotted curves are for ρ=0.5 and S_0=0.2 M.

Structure of the 1: 1 Complex. The Δ_1 and Δ_2 shifts generally include two different interactions, contact and pseudo-contact. The contact interaction is usually strong at the nucleus, which is only a few bonds away from the complexing sites, and the shift value depends on the kind of paramagnetic ion.[18] When praseodymium nitrate was added to a glyceric acid solution, ^{1}H peaks were shifted in the direction opposite to that in the case of europium nitrate. The shift ratios of each signal observed in both cases agree within an error of 10%. Thus, the effect of europium ions on the present ^{1}H signals should be attributed mainly to the pseudo-contact interaction.[16] Thus, Eq. 2 can be used in the structure determination of axially symmetiric complexes. Figure 7 shows the structures of 1: 1 complexes obtained by the application of Eq. 2, and Table 4 lists the observed and calculated shifts for each complex; the agreement factors are 0.009, 0.090, and 0.092 for **1**, **2**, and **3** respectively. The carboxyl parts of the ligand anions have similar conformations for all com-

plexes, α-hydroxy oxygen being approximately on the same plane as the four carboxy atoms and β-hydroxy oxygen being *gauche-gauche* to the α-substituents. The anions chelate a europium ion through three oxygens, α-carboxy, α-hydroxy, and β-hydroxy oxygens. The Eu–O distances are given in Table 5. The magnetic axis of the complex is assumed as the mean direction of the three Eu–O vectors. Two β-protons of glyceric acid **1**, were nonequivalent in the experimental pH range, and the glycerate anion may have two or more stable conformations in D_2O.[19] Two favorable conformations, of **1** have been found in the crystal structure of calcium glycerate dihydrate.[5] The β-protons in one conformer are *gauche-gauche* to the α-proton, while those in other conformer are *trans-gauche*. The ligand conformation of the 1:1 complex established here (Fig. 7a) is similar to the former. The C(1)–C(2)–C(3)–O(3) torsion angle is 30°, compared with that of 48° in the crystal structure. Two stable conformations of the gluconate anion, **2**, have also been found as dimorphic crystals in the potassium salts.[6] One has a straight chain conformation stabilized by the intramolecular hydrogen bond between the two *syn* axially related hydroxyls, while the second has a bent chain conformation. The present ^1H NMR study indicates that the gluconate anion in the 1:1 complex (Fig. 7b) has the latter bent conformation. The torsion angles are −60 and −144° for H(3)–C(3)–C(4)–H(4) and H(4)–C(4)–C(5)–H(5) respectively. The gluconic acid moiety of lactobionic acid **3** also has a bent conformation in solution (Fig. 7c). Not only is the conformation of the lactobionate anion similar to that observed in the crystal structure[8] as a whole, but also the chelating structure to the cation is similar to that in the crystal, the cation being bound to the gluconic acid moiety rather than to the neutral galactoside moiety. The torsion angles about the glycosidic bond in the complex are 133 and −167° for C(3)–C(4)–O(1′)–(1′) and C(4)–O(1′)–C(1′)–C(2′) respectively.

As has previously been described, the three carboxylates have the same type of "three O atoms" chelation. The chelating structure is similar to that of glucaric acid, **4**, reported previously.[2] The difference in calcium affinities between the two carboxyl groups in glucaric acid, **4**, may be due to the configurations of hydroxyls about the C–C bonds located near each carboxyl group. The configuration given in Fig. 8a, corresponding to the cases of the present three compounds and the α-carboxyl part of glucaric acid, is favored for the complex formation with a cation, while the configuration given in Fig. 8b, corresponding to the case of the δ-carboxyl part of glucaric acid, is not favored for the chelation because of repulsion between parallel C(1)–O(1′) and C(3)–C(4) bonds. Hence, the relative arrangement of hydroxyl groups, particularly that of

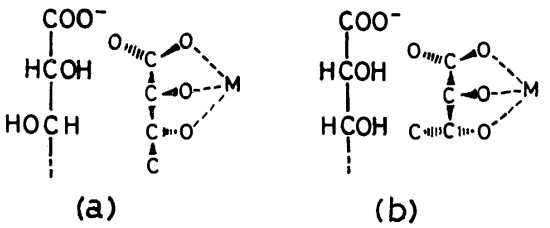

Fig. 8. Two types of configurations and possible 'three O atoms' chelations to a metal ion M.

β-hydroxyl, is important for a stable complex formation. Generally, the carboxylic acid of acyclic polyol, which has the Fig. 8a configuration, forms a stable chelating complex with a metal ion.

In conclusion, the data analysis based on the pH dependence of lanthanoid-induced NMR shifts is useful for the structural study of lanthanoid–carboxylates complexes in D_2O. The application of this method to the three carboxylates showed that glycosidic acids of acyclic polyol form a stable complex with a lanthanoid ion in the "three O atoms" chelation including the β-hydroxy oxygen.

We wish to thank Professor Kenji Osaki for his kind support of this work and Miss Ritsuko Yamaguchi for her experimental assistance. This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Electron Configuration Analysis for Many-System Interactions. Electron Delocalization in Pyracylene, Acepleiadylene, and Dipleiadiene

Satoshi INAGAKI* and Yoshio HIRABAYASHI

Department of Synthetic Chemistry, Faculty of Engineering, Gifu University, Kakamigahara, Gifu 504

(Received December 21, 1977)

The method of electron configuration analysis for many-system interactions (ECAMSI) has been developed and applied to the π electronic structures of polycyclic molecules. The HMO-ECAMSI calculations have been carried out on acenaphthylene, pleiadiene, pyracylene, acepleiadylene, and dipleiadiene. Electron delocalization in the naphthalene core predominates in these molecules and remains unchanged from acenaphthylene to dipleiadiene; the central cross-linked π bond is not a small perturbation. There are four electron-delocalizing modes for the cyclic peripheral conjugation in acepleiadylene which give rise to an additional but appreciable delocalization, while the peripheral delocalization in pyracylene and dipleiadiene is almost completely depressed. The substituent effects on the delocalization have been predicted on the basis of the ECAMSI results and on the concept of the continuity-discontinuity of cyclic conjugation which has recently been developed.

The Hückel $4n+2\pi$ rule[1] is not directly applicable to polycyclic π conjugation. More than two decades ago two theoretical proposals[2,3] appeared about the "aromaticity" of the polycyclic systems. Platt[2] assumed that many polycyclic molecules were composed of peripheral polyene and intraannular cross-links. Assuming the cross-links are small perturbations, the Hückel rule may be applied to the peripheral polyenes. Craig's rules[3] predict the valence bond wavefunction of a given polycyclic system to be totally symmetric (aromatic) or not (pseudoaromatic). The qualitative evidence and the simple conclusions drawn stimulated many organic synthesists, but there are limitations.[4] The concept of resonance energy has frequently been used in both the LCAO and the VB methods for estimating the stabilities.[5-7] The improvement and the development of the methods are developing spheres of theoretical chemistry. A recent noticeable development has been the application of the graph theory.[8-12] The question of bond alternation, a measure of the electron delocalization is another property discussed for conjugated systems.[13,14]

In this paper a method for the electron configuration analysis for many-system interactions (ECAMSI) as an extension of the method of Baba *et al.* for two-system interactions has been presented.[15] The ECAMSI calculation enables the investigation of the constitution rather than the gross properties of the π electronic structures. The eigenfunctions have been analyzed from the point of view that polycyclic π conjugated molecules are composite systems of constituent ethylenic π subsystems. The main Kekulé structure of a given polycyclic system is uniquely determined and the mode of electron delocalization is visualized by investigating the mixing of electron-transferred configurations into the "zero" configuration which corresponds to the main Kekulé structure. The ECAMSI method has been applied to acenaphthylene (**1**), pleiadiene (**2**), pyracylene (**3**), acepleiadylene (**4**), and dipleiadiene (**5**). The tetracyclic nonbenzenoid hydrocarbons, **3**—**5**, were of theoretical interest.[16-19] The ECAMSI calculations have numerically solved such interesting questions as to whether the peri-bridges conjugate with the naphthalene core such that the intrinsic conjugation in the naphthalene substantially breaks down; the vinyl cross-links are involved almost exclusively in a naphthalene-like conjugation or the electrons are delocalized on the periphery without disturbing the naphthalene conjugation.

Theoretical

The total wavefunction of polycyclic π electron systems may be expressed as a linear combination of a basis set of electron configuration functions constructed as Slater determinants from the orbitals of the constituent subsystems. An electron configuration is denoted by the zero-configuration, Φ_0, where neither electron transter from one ethylenic unit to another nor electron promotion within any unit takes place. The second type of configuration is the electron-transferred configuration, $\Phi_{K\to L}$, in which an electron is shifted from the π bonding orbital of one ethylenic unit (K) to the π^* antibonding orbital of another (L). The third type of configuration is the locally excited configuration, Φ_{K^*}, in which an electron is promoted from the π orbital to the π^* orbital within the same unit (K). The other configurations have been neglected for simplicity in this study. The total wavefunction is then approximated as

$$\Psi \simeq C_0\Phi_0 \sum_{K,L} C_{K\to L}\Phi_{K\to L} + \sum_K C_{K^*}\Phi_{K^*}, \qquad (1)$$

where

$$\Phi_0 = N_0|a\bar{a}b\bar{b}\cdots z\bar{z}|,$$

$$\Phi_{K\to L} = \frac{1}{\sqrt{2}}N_{K\to L}\{|a\bar{a}b\bar{b}\cdots k\bar{l}^*\cdots z\bar{z}| + |a\bar{a}b\bar{b}\cdots l^*\bar{k}\cdots z\bar{z}|\},$$

$$\Phi_{K^*} = \frac{1}{\sqrt{2}}N_{K^*}\{|a\bar{a}b\bar{b}\cdots k\bar{k}^*\cdots z\bar{z}| + |a\bar{a}b\bar{b}\cdots k^*\bar{k}\cdots z\bar{z}|\}.$$

The normalization factors for Φ are denoted by N with the subscript. The π and π^* orbitals of A, B,···Z are denoted by a, b,···z with and without an asterisk. The total wavefunction,

$$\Psi = N|\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\cdots\phi_n\bar{\phi}_n|,$$

can be expanded by applying the following relation,

$$\phi_i = \sum_X(\lambda_{ix}x + \lambda_{ix^*}x^*).$$

The occupied MO's of the whole system are denoted by ϕ's and x and x* are the bonding and antibonding molecular orbitals of the subsystem, X, λ being the coefficient. The coefficients of the configurations are

then (the overlap integrals having been neglected):

$$C_0 = D_0^2,$$

$$C_{K\to L} = \sqrt{2}\, D_0 D_{K\to L},$$

$$C_K^* = \sqrt{2}\, D_0 D_K^*,$$

where

$$D_0 = \begin{vmatrix} \lambda_{1a} \cdots \lambda_{1k} \cdots \lambda_{1z} \\ \vdots \quad \vdots \quad \vdots \\ \lambda_{na} \cdots \lambda_{nk} \cdots \lambda_{nz} \end{vmatrix},$$

$$D_{K\to L} = \begin{vmatrix} \lambda_{1a} \cdots \lambda_{1l}^* \cdots \lambda_{1z} \\ \vdots \quad \vdots \quad \vdots \\ \lambda_{na} \cdots \lambda_{nl}^* \cdots \lambda_{nz} \end{vmatrix},$$

$$D_K^* = \begin{vmatrix} \lambda_{1a} \cdots \lambda_{1k}^* \cdots \lambda_{1z} \\ \vdots \quad \vdots \quad \vdots \\ \lambda_{na} \cdots \lambda_{nk}^* \cdots \lambda_{nz} \end{vmatrix}.$$

Polycyclic π conjugated molecules have usually many Kekulé structures. Each of them can be a basis set of ethylenic units in the ECAMSI calculations. The use of the main Kekulé structure as a basis set is, however, chemically the most acceptable. The main Kekulé structure may be defined as a set of ethylenic units of which the corresponding zero-configuration represents the most appropriate electronic structure, that is, a Kekulé structure which has the largest C_0. In this sense the coefficient of the zero-configuration can be used as an index demonstrating the degree of contribution from a given Kekulé structure.

The degree of electron delocalization in a molecule has been examined by investigating the magnitude of the coefficients, $C_{K\to L}$. Direct comparison between the coefficients of the different molecules may, however, make no chemical sense since a large molecule usually has a large number of possible configurations and then a small C_0. Reasonable comparison is made in terms of the absolute value of the coefficient ratio (CR), $|C_K/C_0|$.

A relative value as the criterion to determine the significant configurations has been proposed. The comparable units in **1**—**5** have been denoted by the same letters, A, B,···I (see **1a**—**5a**). The value, δ, has been defined as the difference between the maximum and the minimum of the CR's for a set of the configurations represented by the same symbol, K→L or K*. One or more significant configurations may then be found in the set of the configurations with a large δ. Tentatively 0.05 was chosen as the critical value, δ_c. A second critical value, CR_c, has been used. Whether $\delta > \delta_c$ is not important if each configuration in a set has a small CR or contributes little to the corresponding molecule. No account has been taken of the sets of configurations in which all CR's are smaller than $CR_c(=0.2)$, even if $\delta > \delta_c$.

Results

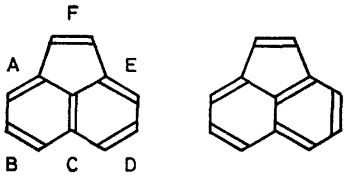
The main purpose of this paper has been to present a procedure which allows a numerical examination of the qualitative many-system interaction theory[20,21] applicable to polycyclic π conjugated molecules where many subsystems interact with one another. A sophisticated molecular orbital calculation was not necessary. The HMO method was employed.

TABLE 1. KEKULÉ INDICES[a]

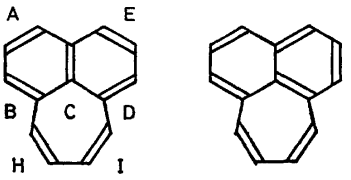
	a	b	c
1	0.299	0.257	
2	0.255	0.219	
3	0.264	0.225	0.000
4	0.159	0.140	0.098
5	0.185	0.160	0.000

a) See the definition in the text.

The Kekulé indices of the possible structures of **1**—**5** were calculated and are listed in Table 1. The values show that the main Kekulé structures contain benzenoid ones, **1a**, **2a**, **3a**, **4a**, and **5a**, in both six-membered rings of the naphthalene cores. The contribution from any quinonoid structure is small. A further important implication is found in the Kekulé indices of **3c**, **4c**, and **5c**. These structures should contribute more or less if the molecules enjoy the peripheral delocalization of electrons; a complete delocalization gives the equivalent Kekulé indices for **a** and **c**. The zero values for **3c** and **5c** indicate the absence of peripheral delocalization in **3** and **5**, while a non-zero value (0.098) implies that the electrons in **4** delocalize to some degree.



1a **1b**



2a **2b**

The CR's of the transferred configurations are listed in Table 2; those of the locally excited configurations have been omitted since they are much smaller (<0.069) than CR_c. Table 2 shows that the degree of electron shift depends on the distance between the ethylenic units where the shift occurs. The CR's for the adjacent-unit shifts range from 0.265 (F→A of **3**) to 0.547 (B→A of **4**) while the maximum for the nonadjacent-unit shifts is 0.260 (H→A of **4**). This result may be explained in terms of the perturbation theory for many-system interactions.[20,21] The adjacent-unit shifts correspond to first-order mixing of the transferred configurations while the nonadjacent-unit shifts correspond to higher-order mixing.

In the Platt model, the intraannular cross-links in **3**—**5** are assumed to be small perturbations and the electron shifts from and to the central double bond are negligibly small. In the first-order approximation of the naphthalene-core conjugation the delocalization is

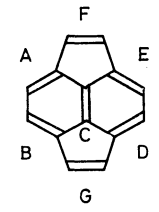
a) $|C_M/C_O|$. b) The difference between the maximum and the minimum values in the row (see the text).

discussed in terms of the adjacently transferred configurations. These configurations contain A→B, A→C, B→A, B→C, C→A, C→B, and the eqivalents. Each set of configurations has δ smaller than δ_c except in the case of B→A. The large δ value for B→A is due to an extraordinarily large CR for **4**. These results show that the electrons in **1**—**5** delocalize in the naphthalene cores to a similar degree although the B→A shift in **4** is appreciably enhanced. This argues against the Platt assumption that the intraannular cross-links are small perturbations.

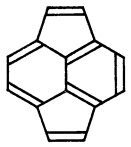
Secondly, adjacent-unit transfer has been restricted to five- and seven-membered rings, *i.e.*, A⇄F, B⇄H, and H⇄I. The CR's of these configurations are smaller (0.265—0.402) than those of the configurations corresponding to the electron shifts in the naphthalene cores (0.397—0.547). This shows that electrons delocalize in the five- and seven-membered rings to a lesser extent than in the naphthalene cores. The peri-bridge double bond, F, in the five-membered ring was found to accept rather than donate electrons (compare the CR's between A→F and F→A in **1**, **3**, and **4**). The butadienic parts (H or I) in the seven-membered ring tended to release electrons (compare the CR's between B→H and H→B in **2**, **4**, and **5**). An important observation was that the electron shifts to the five-membered ring and from the seven-membered ring were enhanced in **4** and depressed in **3** and **5** to an appreciable degree. Both A→F and H→B have δ values larger than δ_c while the others do not. The CR of A→F is largest in **4** and smallest in **3**, and the CR of H→B is largest in **4** and smallest in **5**.

Some distantly transferred configurations characterize the electronic structures of **3**—**5**. The B→F, H→A, H→D, and A→D configurations have δ larger than δ_c. They are enhanced in **4** but depressed in **3** and **5**. A significant difference in the transfers between the peri-bridges should also be noted. The H→F in **4** has a large CR while the F→G transfer in **3**, the H→J and H→K transfers in **5** have small ones. The ECAMSI results are summarized in **6**—**8**. The characteristic transfers are all enhanced in **4** (→) and depressed in **3** and **5** (⇢).

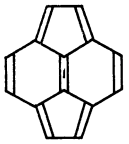
Now the cyclic electron delocalization on the molecular periphery will be examined. A cyclic delocalization among n units is described as a set of n−1 modes of transfer which have particular relations with one another.[21)] Firstly, an adjacent-unit transfer mode is necessary. The transferred electron in the acceptor should be shifted further to a neighboring acceptor,



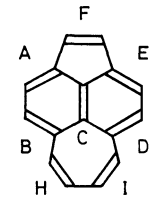
3a



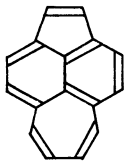
3b



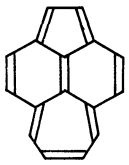
3c



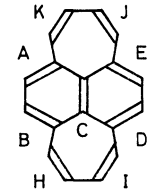
4a



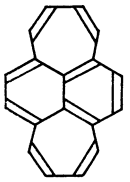
4b



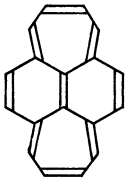
4c



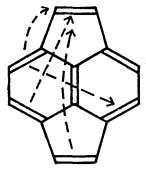
5a



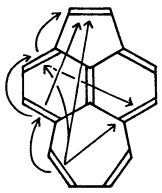
5b



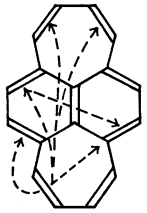
5c



6

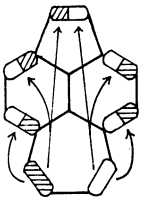


7

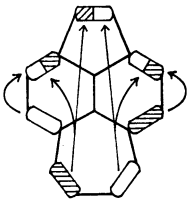


8

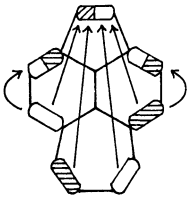
or the resulting hole in the donor should be supplied with an electron by a neighboring donor. These processes are expressed as the interaction of the first transferred configuration with the second configuration where an electron is shifted from the first donor to the second acceptor or from the second donor to the first acceptor. The second configuration is required to interact with the third one which satisfies a similar condition. The complete description ends with another adjacently transferred configuration. For **4** four electron-delocalizing modes (**9**—**12**)[21] can be constructed from the enhanced transfers (**7**). The shadow and the blank represent the orbital phase relation. The coupled shadow-blank and the single shadow or blank stand for the LUMO and the HOMO of the ethylenic π-bond units, respectively. It may be seen that **9**—**12** meet the orbital-phase continuity requirements for electron delocalization among many systems.[20,21] As a result, the peripheral delocalization is unequivocally confirmed by the ECAMSI calculations while the delocalization is depressed in **3** and **5**.



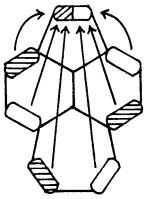
9



10



11



12

From this the effects of electron-releasing (R) and -withdrawing (W) substituents on the stabilities of **3**—**5** may be predicted. The delocalization in the naphthalene core has been found to be insensitive to the peri-bridges and is probably so to other substituents. The stabilities are, therefore, expected to depend on the peripheral delocalization. All electron-delocalizing modes, **9**—**12**, of **4** contain the diene bridge as a donor and the monoene as an acceptor, the peripheral parts on the naphthalene playing the dual roles. This suggests that the introduction of R into the diene and of W into the monoene (**14**) enhances the delocalization. In **3** the peri-bridges tend to accept electrons. The derivatives with R on the naphthalene core and with W on the bridges (**13**) may be more stable than the parent molecule. The electron-donability of the diene parts in **5** suggests that R-substituents on the dienes and W-substituents on the naphthalene core (**15**) stabilize the derivatives. Fortunately, the donor and acceptor groups arrange alternately along the periphery in the substituted molecules, **13** and **15**. Such alternation has recently been shown to make the cyclic conjugation discontinuous.[21] The degree of delocalization is not restricted by the Hückel rule; **13** and **15** avoid the disadvantage of 4n π periphery.

Discussion

Pullman *et al.*[16] calculated the HMO delocalization energy which predicted that **4** would be aromatic.

Zahradnik *et al.*[17] also drew a similar conclusion. Boekelheide and Vick[22] synthesized **4** and showed that **4** did not react with maleic anhydride under the conditions under which maleic anhydride gave the Diels-Alder adduct with **2**. Afterwards Jones *et al.*[23] concluded from the relatively narrow carbon-13 chemical shift range and the high-field shifts of the intraannular quarternary carbon atoms that **4** was highly conjugated on the periphery. The properties of **4**, predicted theoretically and suggested by the observed chemical reactivity and NMR shifts, seem to substantially confirm Platt's peripheral conjugation of $4n+2\pi$ electrons.

Yamaguchi and Nakajima,[18] using the semiempirical SCF LCAO-π-MO method, showed that the bond lengths of the naphthalene core of **4** were almost the same as those of the free naphthalene molecule, and that there was a marked bond fixation in the remainder of the periphery although the extent was smaller in **4** than in **3** and **5**. This implication is in good agreement with the ECAMSI results: (1) the degree and the mode of electron delocalization in the naphthalene core remains almost unchanged on the peri-bridging, (2) the degree of electron delocalization is smaller between the naphthalene core and the peri-bridges than in the naphthalene core, (3) electrons delocalize on the molecular periphery to an appreciable degree. As a result, the peripheral delocalization is significant but additional to the naphthalene-core delocalization.

The application of Platt's peripheral conjugation model suggests a description of **3** and **5** as antiaromatic perturbed [12]annulenes. This contradicts the prediction made by Craig's rules that they are aromatic. Using the HMO method, Zahradnik *et al.*[17] predicted that **3** and **5** were unstable. Pyracylene has been synthesized by Trost and Bright[24] while **5** is not yet known. The up-field shift of the NMR spectrum and the unusually low value of the first half wave potential were found and from this the conclusion drawn was that the peripheral model was a better representation than the peri-bridged naphthalene core model. Comparison of carbon-13 NMR spectra of **3** and its dihydro derivatives supported the indication that **3** exhibits paratropism.[25] The relative instability was suggested from the failure to isolate **3** and the reluctance of pyracene into **3**.[26] These results are compatible with Platt's model.

Lo and Whitehead[19] concluded from PPP-MO calculations that the most stable configuration of **3** corresponds to the peri-bridged naphthalene core model, a result similar to that of Yamaguchi and Nakajima.[18] The ECAMSI calculations also support this model. The degree and mode of electron delocalization in the naphthalene core are very similar to those in other molecules, the peripheral delocalization being appreciably depressed.

Conclusion

The ECAMSI calculations contribute to the understanding of the electronic properties of molecules as well as the nature of the interactions of many molecules. In this paper the polycyclic nonbenzenoid aromatics have been investigated. The ECAMSI calculations numerically showed how the polycyclic molecules were composed of the constituent ethylenic π bond units, *i.e.*, the kinds of electronic rearrangements occuring among the subsystems in the molecules. The calculations were successful in disclosing the mode of electron delocalization on the periphery and in estimating the degree of it.

The authors would like to thank Professor Ichiro Murata of Osaka University for his visit to this laboratory which, as well as his article with Dr. Kagetoshi Yamamoto [*Kagaku Sosetsu*, **15**, 211 (1977)], directed the authors attention to the polycyclic π conjugation. The present work was partially supported by a Grant-in-Aid from the Ministry of Education (No. 139012). The calculations were carried out by the FACOM 230-28 computer of Gifu Univesity, the FACOM 230-75 computer of the Nagoya University Computer Center, and FACOM M-190 computer of the Data Processing Center, Kyoto University.

(Received December 26, 1977)

The reaction of carvomethene oxide (a mixture of *cis*- and *trans*-forms) over solid acids and bases gives *trans*- and *cis*-1-methyl-3-isopropyl-1-cyclopentanecarbaldehyde (III), carvomenthone (IV), 1(7)-*p*-menthen-2-ol of *trans*-(V) and *cis*-form and carvotanacetol of *trans*-(VI) and *cis*-form. A large amount of III was formed together with IV over SiO_2–Al_2O_3, SiO_2–TiO_2 and zeolite H-F9. $LiClO_4$, H_2SO_4/SiO_2, $FeSO_4$, and solid H_3PO_4 gave preferentially IV, while TiO_2–ZrO_2 formed mainly V and VI. With respect to aluminas, carbonyl compounds (III and IV) were predominantly formed over Al_2O_3D, while allylic alcohols (V and VI) were preferentially given by Al_2O_3 A and B.

Several workers have studied the isomerization reaction of terpene epoxides such as α-pinene, limonene, carvomenthene, and caryophyllene oxides,[2)] some products being valuable as raw material for perfume, flavor cosmetic and pharmaceutical materials. Settine and his co-workers found that, in the case of carvomenthene oxide, the oxide in the presence of zinc bromide rearranges with ring contraction to 1-methyl-3-isopropyl-1-cyclopentanecarbaldehyde and methyl (3-isopropylcyclopentyl) ketone, undergoing isomerization to carvomenthone.[3)] Eschinasi reported that the rearrangement of the oxide in the presence of a catalytic amount of aluminum isopropoxide is utilizable for selective preparation of allylic alcohols (carvotanacetol and 1(7)-*p*-menthen-2-ol) in high yields.[4)]

Previous studies disclosed that the isomerization of *d*-limonene oxide catalyzed by solid acids and bases shows strikingly different selectivity depending on the type of catalyst.[5)] Since the studies on the isomerization of carvomenthene oxide were performed in a homogeneous system, the oxide in the present experiment has been isomerized over solid acid and base catalysts under heterogeneous conditions.

Experimental

Carvomenthene oxide (Takasago Perfumery Co., a 1:1 mixture of *cis*- and *trans*-forms, purity 97%) and toluene of guaranteed grade were used. The latter was purified by distillation over sodium metal.

Standard Reaction Procedure. The reaction was carried out in the presence of toluene as a solvent at 80 °C for 75 min. A mixture of 0.5 ml of the epoxide, 2.5 ml of toluene, and about 0.3 g of catalyst ground to below 100 mesh, was stirred in a reaction vessel with a magnetic stirrer. At appropriate time intervals, a small amount of the sample was taken out with a 1 ml syringe, separated from the catalyst by centrifugation, and analyzed with a gas-liquid chromatograph with a TCD detector using a 3 m column of 20% polyethylene glycol 20 M on Celite 545 SK (150 °C; He, 1.0 kg/cm²). For the separation of two peaks of III, a 45-m capillary column of Ucon LB-550-X (112 °C; N_2, 2.0 kg/cm²) was used. The yields of products were based on the unreacted epoxide and calculated by measurement of GLC peak areas (uncorrected.)

Catalysts. SiO_2–Al_2O_3 [N361(L)(Al_2O_3; 15 wt%) of Nikki Chemical Co.] was calcined at 500 °C. SiO_2–TiO_2 (molar ratio=1:1) was prepared by coprecipitation of a mixed solution of ethyl orthosilicate and titanium tetrachloride with aqueous ammonia. The precipitate was aged over a water bath for 1 h, washed with distilled water until no chloride ion was detected, dried at 100 °C for 20 h and calcined at 500 °C. Zeolite H-F9 was prepared from zeolite F-9 (Tekkosha Co.,) by a conventional ion-exchange method using NH_4Cl and by calcination at 500 °C. $LiClO_4 \cdot 3H_2O$ (guaranteed grade, Nakarai Chemical Co.) was dried at 120 °C for 3 days. H_2SO_4/SiO_2 was prepared as follows. 10 g of granular silica gel was immersed in 12 ml of 0.5 M H_2SO_4, evaporated, dried and then calcined at 150 °C. $FeSO_4$ and $NiSO_4$ were prepared by calcining their heptahydrates (guaranteed grade) at 600 and 350 °C, respectively. Solid phosphoric acid, N501 (Nikki Chemical Co.) was calcined at 400 °C. TiO_2–ZrO_2 (molar ratio=1:1) was prepared by thermal decomposition at 500 °C of H_4TiO_4–$Zr(OH)_4$, precipitated by heating a mixed aqueous solution of titanium tetrachloride, zirconium oxychloride and an excess amount of urea on a boiling water bath, followed by thorough washing of the precipitate with distilled water until no chloride ions were detected in the filtrate, and drying in air at 110 °C. ThO_2 was prepared by thermal decomposition at 500 °C of $Th(OH)_4$, precipitated by hydrolysis of $Th(NO_3)_4$ with 28% ammonia. Al_2O_3 A (KAT 6, Nishio Chemical Co.) was subjected to heat-treatment at 500 °C. Al_2O_3 B, C, and D, *viz.*, Albes FF, Albes FE, and Albes C (Showa Tansan Kaisha, Ltd.) were calcined at 500 °C before use. All the catalysts were heat-treated in the air for 3 h and stored in sealed ampoules.

Identification of Products. Catalytic activities of various solid acids and bases and the product distributions are given in Tables 1 and 2. The reaction products are given in the order of elution (Table 1) on a GLC PEG 20 M column at 150 °C. Product IV, a mixture of V and VI, and VII, was isolated from the isomerized mixture catalyzed by solid H_3PO_4 by column chromatography using silica gel and eluting with petroleum ether–diethyl ether (1:1). IV was identified as carvomenthone by its IR, NMR, and MS:** IR (neat): 1710 cm^{-1} ketone, 1380, 1360 cm^{-1}, isopropyl;[6)] NMR (δ): 1.8—1.1 (m, 6H, CH_2), 0.8—1.0 ppm (m, 9H, CH_3–); MS: important ions at *m/e* 154 (M^+), 111 (100%), 55 (70%), 41 (43%), 83 (27%) (Lit,[6)]: 154 (M^+), 111 (100%) 55 (51%), 41 (33%), 83 (23%)). VII was identified as carvotanacetol by its IR, NMR, and MS:** IR (neat): 1385, 1370 cm^{-1} isopropyl, 1060, 1035 cm^{-1} secondary alcohol, 915 cm^{-1} vinyl; NMR (δ): 5.5 (t, 1H, C=CH), 4.2 (s, 1H, OH), 1.8 (s, 3H, $C=CCH_3$), 0.9 ppm (d, 6H, $C(CH_3)_2$); MS: important ions at *m/e* 154 (M^+), 84 (100%), 82 (83%), 43 (67%), 93 (65%), 69 (63%), (lit,[7)]:

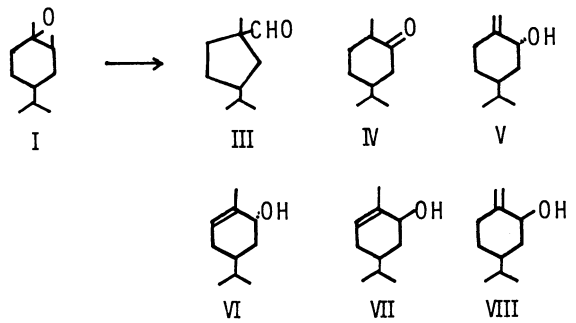
154 (M^+), 82 (100%), 84 (88%), 43 (75%), 69 (72%)). A mixture of V and VI was revealed to consist of 1(7)-*p*-menthen-2-ol and carvotanacetol by IR, NMR, and MS: IR (neat): 1380, 1370 cm^{-1} isopropyl, 1070, 1050, 1030 cm^{-1} secondary alcohol, 900 cm^{-1} methylene;[7] NMR (δ): 5.5 (C=CH), 4.8 (C=CH_2), 4.4 and 4.1 (OH), 1.8 (C=CCH_3), 0.85 ppm ($C(CH_3)_2$); MS of V: 154 (M^+), 82 (100%), 111 (91%), 93 (83%), 55 (80%), 41 (80%), 43 (70%); MS of VI: 154 (M^+), 84 (100%), 82 (78%), 43 (73%), 93 (71%) [Lit,[7]: *trans*-1(7)-*p*-menthen-2-ol: 154 (M^+), 111 (100%), 93 (95%), 55 (84%), 82 (83%), 43 (80%)]. V, VI, and VII were recognized to be *trans*-1(7)-*p*-menthen-2-ol, *trans*- and *cis*-carvotanacetol, respectively, from the following experimental results: (1) the mass spectra of VI and VII are identical, indicating the *cis-trans* relationship, (2) the GLC column gives the elution order of *trans-exo*-carveol, *trans-endo*-carveol, *cis-endo*-carveol and *cis-exo*-carveol for the isomerized products of *d*-limonene oxide.[5] The same order of elution was also obtained on a Carbowax 20 M column for the allylic alcohols selectively prepared from *d*-limonene and carvomenthene oxides by aluminum isopropoxide. Nearly the same isomeric ratio was observed in both reactions.[4] The catalytic selectivity of the present catalysts (Tables 1 and 2) is also analogous to that expected from the results in the case of *d*-limonene oxide.[5]

For the identification of III, a mixture of *cis*- and *trans*-carvomenthene oxide (50 g) was reacted with 5 g of Davison silica-alumina (W. R. Grace Company, Grade 160) at 70—150 °C with vigorous stirring, a sufficient amount of III for analysis being obtained. The two compounds (IIIa and IIIb), bp 76 °C/10 mmHg could not be separated on a 61 cm Nester-Faust spinning band column. However, the mixture showed NMR and IR spectra in line with the structure of *cis*- and *trans*-1-methyl-3-isopropyl-1-cyclopentanecarbaldehyde. The mass spectra of the two compounds were identical. IR (neat): 1715 cm^{-1} aldehyde, 1377, 1357, 934 cm^{-1} isopropyl; NMR (δ): 9.36 (s, 1H, CHO), 2.3—1.2 (m, 6H, $>CH_2$), 1.13 (s, 3H, $-CH_3$), 0.89 ppm (d, 6H, $C(CH_3)_2$; MS: seven most intense peaks at *m/e*, 154 (M^+), 69, 55, 41, 83, 43, 125, 57 for IIIa and IIIb.

Results and Discussion

The reaction products of carvomenthene oxide (*cis* and *trans* in a 1:1 ratio) (I) catalyzed by solid acids and bases were 1-methyl-3-isopropyl-1-cyclopentanecarbaldehyde (III), carvomenthone (IV), *trans*-1(7)-*p*-menthen-2-ol (V), *trans*-carvotanacetol (VI), *cis*-carvotanacetol (VII) and unidentified compound (II).



The products are given in the order of elution on a GLC column. II is the first eluted compound of the products, *i.e.*, immediately after toluene as a solvent. It might be a diene formed by the dehydration of the allylic alcohols, since cymene formation was observed in the rearrangement of *d*-limonene oxide.[5] The mass spectrum of II was not identical with that of cymene, 1,3-*p*-menthadiene or 1,4-*p*-menthadiene. Thus II is considered to be a compound with double bonds in other positions.

A minor compound observed immediately after VII in GLC is supposed to be *cis*-1(7)-*p*-menthen-2-ol (VIII) from the elution order of four allylic alcohols produced from carvomenthene and *d*-limonene oxide (see Experimental). No detailed analysis was performed, it being a minor product. Since VII and VIII were not separated satisfactorily, summation of their percentage is given in Tables 1 and 2.

III consists of two compounds, *cis*- and *trans*-form. The aldehyde was identified by Settine and McDaniel from the reaction of zinc bromide with carvomenthene oxide.[8] However, they made no mention of using a mixture of *cis*- and *trans*-oxides or the kind of aldehyde obtained (*cis*-, *trans*- or the mixture). In our case, two aldehydes were neither separated nor identified spectroscopically, but IIIa, eluted earlier, and IIIb are considered to be *trans*- and *cis*-forms, respectively, from the view point that *trans*-forms of allylic alcohols and ketones in the rearrangement of *d*-limonen[5] and carvomenthene[4] oxides were eluted earlier in high yields on a GLC column. The formation of IIIa is shown to predominate over the catalysts used in this investigation. From the product distribution, *trans*-oxide seems to be more reactive than *cis*-one (Tables 1 and 2). Similar observations were reported in the case of *d*-limonene oxide.[5b] The higher reactivity of *trans*-oxides was also observed by Eschinasi for the rearrangement of limonene and menthene oxides catalyzed by aluminum isopropoxide.[4] A large amount of ring-contracted aldehydes (III) was formed together with ketone (IV) over SiO_2–Al_2O_3, SiO_2–TiO_2, and zeolite H-F9, the selectivity for the carbonyl compounds (III+IV) being 90%. SiO_2–Al_2O_3 and SiO_2–TiO_2 are known to have exceedingly strong acid sites on their surfaces, *viz.*, 0.34 mmol/g at $H_0=-8.2$ for SiO_2–Al_2O_3[9] and the analogous acidic properties for SiO_2–TiO_2.[10] Thus, the remarkable activity for isomerization as well as high selectivity for the carbonyl formation of these catalysts can be explained by the formation of a tertiary carbonium ion intermediate *via* the breaking of α-bond of oxygen adsorbed on the strong acid sites.

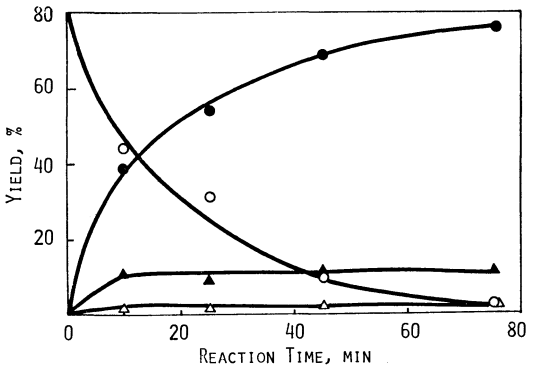


Fig. 1. Isomerization of carvomenthene oxide over $LiClO_4$ at 80 °C.
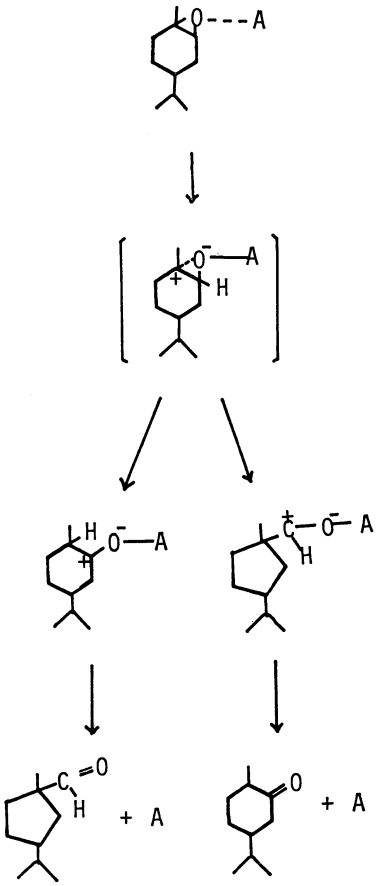
I (○), II (△), III (▲), IV (●).

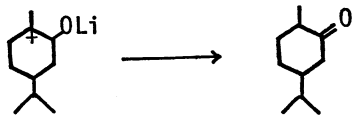
The reaction mechanism for the preferential formation of carbonyl compounds is illustrated as follows.



A: acid site on catalyst surface, protonic (Brönsted) or Lewis acid.

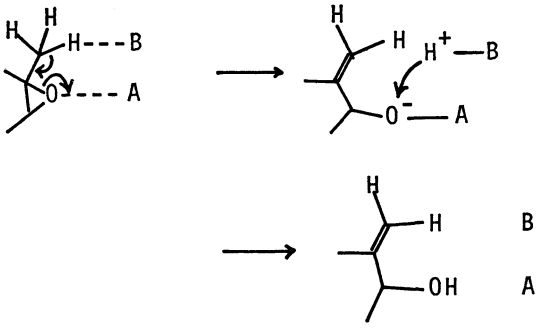
Lithium perchlorate, H_2SO_4/SiO_2 and $FeSO_4$ gave preferentially ketone (IV). The high activity of $LiClO_4$ for the ketone formation is similar to the observation of Rickborn and Gerkin that 80% of 2-methylcyclohexanone is formed from 1-methylcyclohexene oxide over $LiClO_4$.[11] The relation of the product distribution *vs.* reaction time over $LiClO_4$ is shown in Fig. 1. The yield of ketone increases remarkably following almost first-order reaction kinetics with respect to oxide

concentration. Since the partial dissolution of the catalyst was observed, Li^+ is considered to be catalytically significant. The ketone formation over $LiClO_4$ is interpreted by a process *via* tertiary carbonium ion produced with Li^+, as was shown by Rickborn and Gerkin.



Sulfuric acid mounted on silica gel gave only a small amount of II which was formed by the dehydration of carvomenthene oxide, though it gave a large amount of *p*-cymene formed by dehydration in the case of *d*-limonene oxide. The difference might be due to high stability of *p*-cymene. The preferential formation of ketone (IV) was observed over H_2SO_4/SiO_2, $FeSO_4$, $NiSO_4$, and solid phosphoric acid. The tertiary carbonium ion formed by the breaking of α-bond of oxygen adsorbed on strong acid sites of SiO_2–Al_2O_3 and SiO_2–TiO_2 should be strong enough to be attached to the 3-position of cyclohexane ring to form a five-membered ring, while the carbonium ion formed by relatively weak acid sites[12] on H_2SO_4/SiO_2, $FeSO_4$, $NiSO_4$ or solid phosphoric acid does not seem to be so. A hydrogen at the 2-position of ring seems to migrate as a hydride ion to the cleaved tertiary center, 1-position, during the course of formation of a weak carbonium ion, probably a partially ionized cation.

Titania-zirconia shows a remarkable activity for the allylic alcohol formation. TiO_2–ZrO_2 is known to have both acidic acid basic sites, acting as an acid-base bifunctional catalyst.[13] Epoxide opening to allylic alcohols can be illustrated in terms of the bifunctional character of TiO_2–ZrO_2 as follows.



B: basic site.

In the formation of allylic alcohols over TiO_2–ZrO_2, VI exceeded V. According to electronic considerations, the preferential formation of V is expected due to the more enhanced acidity of primary hydrogen. Such observations were reported by Eschinasi; isomerization of menthene oxide catalyzed by aluminum isopropoxide gives 70% of V and 30% of VI.[4] From the above acid-base bifunctional mechanism, the acidic and basic properties of TiO_2–ZrO_2 seem to be quite specific.

Thorium oxide, which is known to produce selectively 1-alkene in the dehydration of secondary alcohol,[14,15] is almost inactive in the reaction of carvomenthene oxide.

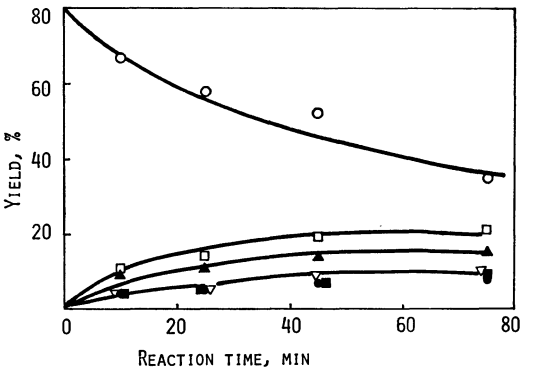


Fig. 2. Isomerization of carvomenthene oxide over Al_2O_3 B at 80 °C.
I (○), III (▲), IV (●), V (□), VI (■), VII+VIII (▽).

This catalyst would become active at higher reaction temperature.

It is of interest that the selectivity of aluminas differs a great deal with the type of alumina (Table 2). Carbonyl compounds (III) and (IV) were predominantly formed over Al_2O_3 D, the yield being about 80%. Allylic alcohols (V) and (VI) were preferentially given by Al_2O_3 A and B. It is remarkable that Al_2O_3 D is extremely active for the isomerization. Thus, Al_2O_3 A and B are expected to have both acidic and basic sites, while Al_2O_3 D is expected to have high acidity on its surface. In this respect Al_2O_3 C falls into the intermediate category of acid-base property. An example of time-variation of the products is shown in Fig. 2, where the catalyst is Al_2O_3 B. The yields of all products increase almost parallel to each other during the course of reaction. A similar time-variation of product was observed over other catalysts, suggesting that they are not precursors of each other and that there is little possibility of interconversion after the formation.

The authors are indebted to Dr. J. O. Bledsoe, the Organic Chemical Division, SCM Corp., for his assistance in the identification of compound III.

Differential Pulse Polarographic Determination of *N*-Nitroso-2-pyrrolidinemethanol

Kiyoshi HASEBE*,** and Janet G. OSTERYOUNG***

Department of Civil Engineering and Microbiology, Colorado State University, Fort Collins, Colorado, 80523, U.S.A.

(Received March 29, 1977)

The pulse polarographic behavior of a new *N*-nitroso compound, *N*-nitroso-2-pyrrolidinemethanol, in buffered solutions has been studied. The effects of temperature, mercury pressure, modulation amplitude, surfactant concentration and solvent, and supporting electrolyte have been investigated. The reduction process is complicated and pH-dependent. In acid solutions, *N*-nitroso-2-pyrrolidinemethanol gives one irreversible reduction wave over a wide pH range below 7. The reduction of the *N*-nitroso compound is diffusion-controlled in d.c. and of normal pulse polarographic modes. In basic solutions, the reduction is also diffusion-controlled. The 10^{-7} mol dm^{-3} content of *N*-nitroso-2-pyrrolidinemethanol has been determined.

In recent years, interest in the electrochemical behavior of biologically important compounds such as nitrosamines and derivatives of hydantoin has increased since some of these compounds are carcinogenic, mutagenic, or teratogenic.[1-5] We are interested in the electrochemical behavior of nitrosamine, *N*-nitroso derivatives of pyrrolidine skeleton. Of many analytical techniques,[6-17] differential pulse (DP) polarography provides both qualitative and quantitative information on both non-volatile and volatile *N*-nitroso compounds.[17] The kinetics and mechanism of the electrochemical process have been discussed.[15-19] L-2-Pyrrolidinemethanol is an important inhibitor of protein synthesis in biochemistry and biology.[20] L-2-Pyrrolidinemethanol (prolinol) reacts in the presence of acid with nitrite to form the relatively non-volatile compound, *N*-nitroso-2-pyrrolidinemethanol (NOProlinol). No determination of the product of prolinol nitrosation seems to have been described. Sensitivity and detection limits for this compound were determined.

Experimental

Apparatus. Polarograms were recorded with a Model 174 Polarographic Analyzer with a Model 174/70 Drop Timer. The measurement conditions were the same as those reported.[17] Measurements of pH were made with a Corning Model 110 expanded scale digital pH meter. Except for temperature dependence studies, all the measurements were carried out at room temperature (20±1) °C.

Materials. The chemicals used were of reagent grade and were dissolved in deionized water. NOProlinol was prepared from L-2-pyrrolidinemethanol (Aldrich Chemical Company, Inc.). A stock solution of 1.95×10^{-2} mol dm^{-3} NOProlinol was prepared in 0.1 mol dm^{-3} HCl and kept in a refrigerator. This solution was found to be stable for over 5 months by means of polarography. The pH of the polarographic solutions was adjusted with Britton-Robinson buffer in the pH range 1.82—11.5. Measurements were made in HCl or H_2SO_4 below pH 1 and in NaOH above pH 12.

Results and Discussion

Effects of pH on the NOProlinol Reduction. The effect of pH on the reduction wave is shown in Fig. 1. The results are in line with those on other nitrosamines, supporting the mechanism of reduction of the protonated form in acid solution. Free NOProlinol like *N*-nitrosopyrrolidine is directly reduced in basic solutions since NOProlinol is present in the solution as a neutral molecule. The slopes of the potential *vs.* pH curves indicate involvement of one proton per electron in the rate determining step in the pH range 3—7 (*ca.* −65 mV/pH). The larger slope below pH 3 (*ca.* −116 mV/pH) seems to indicate involvement of two proton per electron. Complications of adsorption and the double layer structure make it difficult to interpret these data and account for values of the slope which differ from integral multiples of 58 mV.

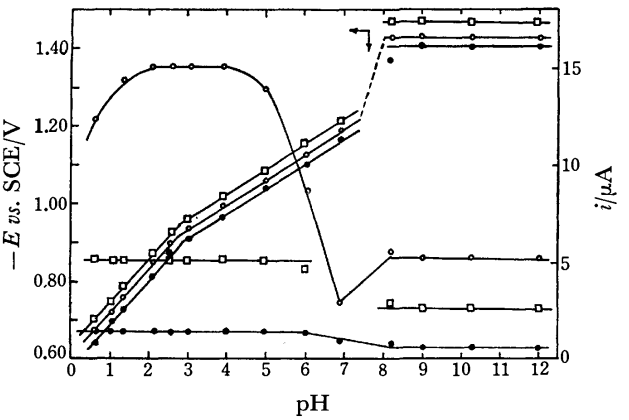

Fig. 1. Effect of pH on the wave height and half-wave or peak potentials for *N*-nitroso-2-pyrrolidinemethanol in 0.1 mol dm^{-3} LiCl containing 50% (volume fraction) B-R buffer.
Concentration: 9.75×10^{-5} mol dm^{-3}; scan rate, v: 2 mV s^{-1}; modulation amplitude, ΔE: −50 mV; ●: d.c. mode; □: NP mode; ○: DP mode.

NP and d.c. current for NOProlinol were constant over a wide range of pH as in the case of *N*-nitrosopyrrolidine.[17] This might be due to the presence of neutral molecules of both *N*-nitroso compounds in basic solu-

** Present address: Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060.
*** Present address: National Science Foundation, Washington DC, 20550.

tions. On the other hand, the decrease in the DP current at low pH might be due to a decrease in the reduction rate, whereas the NP and d.c. current remains constant (Fig. 1). When the concentration of the B-R buffer was less than 50%, the peak potential shifted to more negative values with decreasing buffer concentration, DP peak height and NP and d.c. waves remaining constant. Therefore, it is desirable to use at least a 50% B-R buffer.

In acid solutions, the dependence on modulation amplitude of DP peak height and peak potential showed the same tendency as in basic solutions. This dependence is similar to that of *N*-nitrosopyrrolidine. It is advantageous to work at larger pulse amplitudes to get better sensitivity when the electrode process is irreversible.

Reversibility. The NP and d.c. polarographic waves were analyzed logarithmically in order to obtain $n_a\alpha$, where n_a is the number of electron involved in potential-determining step and α transfer coefficient. Typical results for the d.c. waves are given in Table 1. In acid solutions, the $n_a\alpha$ values were 0.75. However, the values in basic solutions were 0.58. In ethanol–water mixtures, the same tendency was also observed (Tables 3 and 4). The irreversible reduction gives the DP current theoretically less than the reversible DP current, the current-concentration relation depending on rate parameters. The peak resolution is measured by the peak width at half height, $W_{1/2}$. The results for $W_{1/2}$ are given in Tables 2, 3, and 4. The values are larger than the theoretical values for reversible reductions, indicating that the reduction is irreversible.

Diffusion Control. For diffusion-controlled waves, the wave height in d.c. mode is approximately proportional to $h_{corr}^{1/2}$ when the natural drop time is used, and that in NP mode is approximately proportional to $h_{corr}^{2/3}$ with a mechanically drop time; h presents the height of the mercury reservoir. The values of p, the power of h_{corr}, obtained by logarithmic plots (Table 1), indicate that the limiting currents are diffusion-controlled. The relative standard deviation of these values is 0.019, lying in the range of reported values.[21] The results in ethanol–water or methanol–water mixtures are almost the same as those for aqueous solutions. The diffusion-controlled character was confirmed according to the criteria of the time dependence of the limiting currents of the first drops and the agreement of the ratio of limiting currents in d.c. and NP modes with the theoretical value. The diffusion coefficients of NOProlinol were estimated by using the d.c. polarographic data and the Ilkovič equation and checked by the value of the diffusion coefficient of thallium(I) ions measured under the same conditions; the latter was in agreement with the reported value 2.00×10^{-5} cm^2 s^{-1}.[21] The diffusion coefficient of NOProlinol in 0.1 mol dm^{-3} LiCl containing 50% B-R buffer solution was $(7.90\pm0.35)\times10^{-6}$ cm^2 s^{-1} at pH 2.59, and that in the same supporting electrolytes was $(7.55\pm0.30)\times10^{-6}$ cm^2 s^{-1} at pH 9.03 with a 99% probability.

Temperature Dependence. Half-wave potentials of reversible processes are known to be nearly independent of temperature. Although NOProlinol is reduced

irreversibly, its half-wave potential, $E_{1/2}$ and peak potential, E_p, observed in the mixtures containing 40% (volume fraction) ethanol (apparent pH 2.10) were independent of temperature within experimental error as those in mixtures containing 40% (volume fraction) ethanol (apparent pH 9.13). $E_{1/2}$ or E_p of NOProlinol in aqueous solutions was also temperature independent. This result supports the view that the reduction rate depends on adsorption of reactants.[17,22]

Some of the relative temperature coefficients of the current for NOProlinol reduction in the temperature range 1—45 °C are given in Table 2. The results correspond to activation energies of diffusion. The relative temperature coefficients of the limiting current in ethanol–water mixture also lie in the range 1.0—2.0% K^{-1}.

Effect of Organic Solvents. If miscible organic solvents are present in the polarographic solution without specific chemical effects, the limiting current should decrease due to changes in the drop time and the diffusion coefficient with changing ionic strength and the viscosity of the medium. Figure 2 shows the effect of ethanol on the limiting current and $E_{1/2}$ or E_p for the reduction of NOProlinol in the polarographic solutions of apparent pH 9.13. A similar behavior was observed in a solution of apparent pH 2.10 as well as in a methanol–water mixture. Current change in the DP mode becomes more pronounced than in the d.c. or NP mode. However, the reduction of NOProlinol is also diffusion-controlled in ethanol– or methanol–water mixtures (Tables 2 and 3). This is not surprising, since the rate determining step for the reduction involves reactant adsorption,[17] *i.e.*, the alcohol molecules compete with the reactant for adsorption sites easier than water molecules do. Therefore, the decrease in the reaction rate would decrease the DP peak current.

Presence of Surfactants and i-t Curve. The effects of peptone (an enzyme of digest of proteins), Triton X-100, and gelatin were studied. These compounds are reasonable model surfactants, and important matrices to protein synthesis. None of them affected the DP peak current at concentrations less than 10^{-3}%, the slopes of lg *i*-lg *t* being in the range 0.19—0.20. At higher concentrations than 10^{-3}%, they were strongly adsorbed at the dropping mercury electrode, DME, the reaction mechanism being affected.

Choice of Supporting Electrolyte. Cation adsorption would lower the reaction rate by competition with reactant adsorption and by reduction of the proton activity in the reaction layer. Several supporting

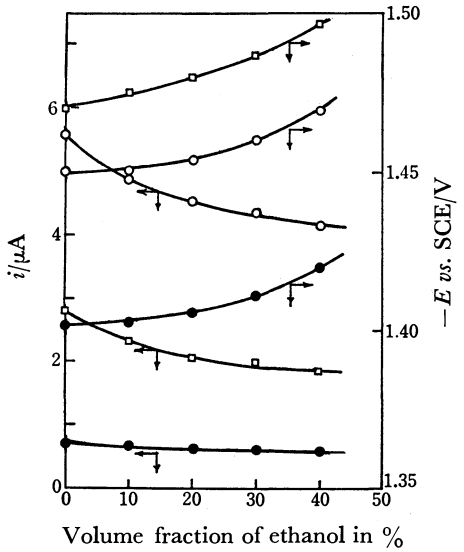

Fig. 2. Effect of the volume fraction of ethanol on the wave or peak height and half-wave or peak potentials for NOProlinol. Apparent pH=9.13; other conditions and symbols same as Fig. 1.

Concentration=0, 1.00, 3.00, 5.00, 7.00, 9.00, 11.00, and 13.00×10^{-7} mol dm^{-3} NOProlinol; *v*: 2 mV s^{-1}; ΔE: −100 mV.

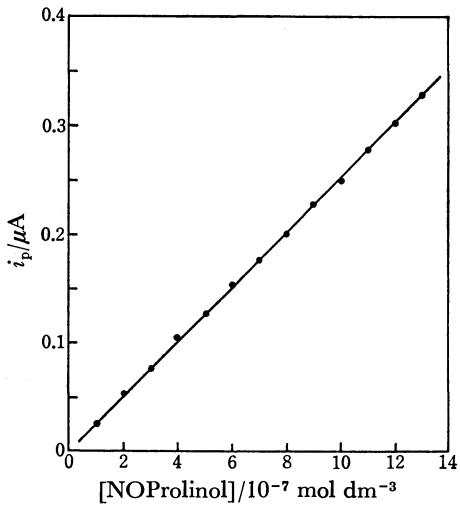

Fig. 4. Calibration curve of *N*-nitroso-2-pyrrolidinemethanol by DP mode.
Conditions same as Fig. 3.

electrolytes were studied in the pH range 2—4, there being no change in current with pH (Fig. 1). Sodium hydrogensulfate–sodium sulfate (0.1 mol dm^{-3}) is suitable for the determination of NOProlinol (Figs. 3 and 4). Potassium chloride (0.1 mol dm^{-3})–hydrochloric acid medium is also suited as supporting electrolyte.

Calibration Curve and Detection Limit. Figure 3 shows typical DP polarograms at the 10^{-7} mol dm^{-3} content of NOProlinol in 0.1 mol dm^{-3} sodium hydrogensulfate and 0.1 mol dm^{-3} sodium sulfate. The DP peak height is proportional to the concentration of NOProlinol between 8×10^{-8} and 1.4×10^{-6} mol dm^{-3} (Fig. 4). The detection limit for NOProlinol under the same conditions shown in Fig. 4 was 6×10^{-8} mol dm^{-3}, as estimated statistically.[23] The detection limit for NOProlinol is somewhat lower than that for the other carcinogenic nitrosamines.

In a sample containing NOProlinol and *N*-nitrosoproline 10^{-7} mol dm^{-3} (pH 4.0), we can determine NOProlinol quantitatively because the difference of E_p of NOProlinol from that of *N*-nitrosoproline is *ca.* 120 mV at $\Delta E=-50$ mV. In the mixture of NOProlinol and *N*-nitrosopyrrolidine, these nitrosamines could not be determined separately since both the compounds show a similar behavior in both acid and basic solutions, and the difference between the two E_p is insignificant.

Use of Ion Microanalyzer in the Analysis of Passive Layers on Stainless Steel

Yoshiaki OKAJIMA,* Yukiyoshi AIZAWA, and Yasushi SUGAWARA
Hitachi Research Laboratory, Hitachi Ltd., Kuzi-machi, Hitachi-shi, Ibaraki 319-12
(Received September 6, 1977)

Passive layers on various stainless steels were studied with an ion microanalyzer. An argon ion beam was directed on the specimen surface in an oxygen atmosphere. The use of oxygen atmosphere effectively minimized the difference in ion yields of the elements in the oxidized layers and matrices, making it possible to determine these elements with good reproducibility. 18% Cr–8% Ni and 18% Cr–8% Ni–0.4% Ti stainless steel was exposed to neutral water containing 8 ppm oxygen at 289 °C. The passive layers contained larger amounts of iron and smaller amounts of chromium than the matrices.

The remarkable resistance of stainless steel to corrosion in various atmospheres is due to the protective nature of the passive layers on the surface. Studies of passive layers have been carried out by means of electrochemistry,[1] impedance and capacitance measurements,[2,3] ellipsometry,[4,5] and infrared spectroscopy.[2] However, no quantitative analyses can be carried out. In order to clarify the nature of passive layer, it is necessary to determine the concentration of elements in the layer, but passive layers are too thin to make analysis by conventional means possible. Recently, Auger electron spectroscopy (AES)[6] and X-ray photoelectron spectroscopy (XPS)[2,6–8] have been used for the determination of the composition of passive layers. The mean escape depth of Auger electrons or photoelectrons from a surface is about 20 Å or less. Thus these methods can be used for the analysis of surface elements. The compositional depth profiles in a thin layer are obtained by ion bombardment. Since these methods are not quantitative, comparison of variations in the ratio of chromium and nickel to iron in specimens is only used for the analyses of passive layers.

The composition profiles of thin layers can be obtained with an ion microanalyzer (IMA) just as with AES and XPS. A quantitative method using an IMA has been examined with calibration[9] and thermodynamical techniques.[10] However, the techniques were developed for elements in matrices.

An oxidized layer, such as a passive layer, gives off much larger quantities of secondary ions than those of a matrix when argon ions are used as primaries. This is due to the difference in the ion yields of elements in oxidized layers and those in matrix. In order to estimate the difference in the concentration of an element between oxidized layer and matrix, it is necessary that the ion yield of the element is the same in both places.

Oxygen ions have been used as primary ions. Andersen and Hinthorne[11] and Nishimura and Okano[12] reported that the difference in the relative sensitivities of element is smaller in the case of oxygen primary ions than in the case of argon primary ions. This seems to result from the oxidation and temperature rise at specimen surface.

We have carried out bombardment by argon ions in an oxygen-atmosphere in order to minimize the difference in the ion yields of elements in the oxidized layers and matrices. The results are applied to analyses of passive layers on stainless steel.

Experimental

Materials. The specimens used in quantitative study of element concentration in a matrix were Japanese Standards of Stainless Steel. Table 1 gives the composition of the main constituents. The specimens were cut into 5 mm cubes, polished with diamond paste and cleaned ultrasonically in alcohol and ether.

The specimens used for the study of element concentration in passive layers were commercial AISI type 304 and 321 stainless steel. The specimens were treated in neutral water containing 8 ppm oxygen. The temperature and time of passivation treatment were 289 °C and 2000 h, respectively.

TABLE 2. WORKING CONDITIONS FOR DETERMINATION

Ionic species	Ar^+
Accel. voltage for primary ions	10 kV
Current density of primary ions	0.1 mA/cm^2
Beam diameter	0.8 mm
Sample chamber pressure	
without oxygen	27 μPa
with oxygen	5.3 mPa
Accel. votage for secondary ions	3 kV

Experimental Procedure. An Hitachi type IMA-2 Ion Microanalyzer was used. Typical working conditions are given in Table 2. Argon ionized by duoplasmatron was accelerated at 10 kV. The current density of the primary ions was 0.1 mA/cm^2, making the analysis of a very thin layer satisfactory. The sputtering rate of the stainless steel was 0.04 nm/s.

Figure 1 shows the apparatus for the introduction of oxygen gas into the sample chamber. Oil particles in oxygen gas were removed by means of a filter. The sample chamber was evacuated with a diffusion pump and liquid nitrogen trap. Pressure of the sample chamber was 27 μPa in the absence of oxygen gas. Oxygen gas was introduced with a pressure of up

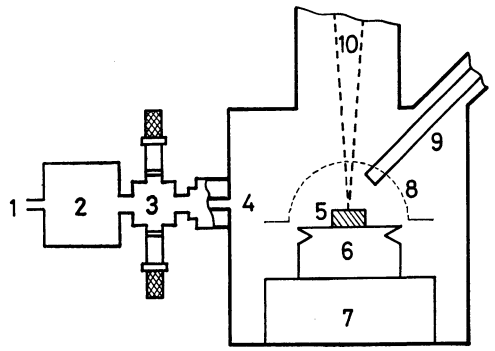

Fig. 1. Apparatus for introduction of oxygen gas into the sample chamber.
1. Oxygen gas inlet; 2. filter; 3. needle valve; 4. sample chamber; 5. specimen; 6. specimen holder; 7. plate for shifting samples; 8. hemispherical shield made of wire gauze; 9. extracting electrode; 10. argon ion beam.

to 5.3 mPa by controlling with a needle valve.

Principle of Quantitative Analysis. The secondary ion current I_X of a specific isotope of element X is given by[9]

$$I_x = \eta_x S_x^+ C_x I_p, \quad (1)$$

where η_X is the transmission coefficient of the instrument between the sample and the collector, S_X^+ the ion yield of element X, C_X the concentration of element X and I_P the current density of the primary ions. Thus the ratio of the secondary ion current of an element X to a reference element (matrix) R is given by

$$\frac{I_x}{I_R} = S(\mathrm{rel})^+ \frac{C_x}{C_R}, \quad (2)$$

where I_R is the secondary ion current of reference element R, C_R the concentration of a reference element R and $S(\mathrm{rel})^+$ the ratio of the ion yield of element X to a reference element R. This can be used for the determination of the constituents of stainless steel, when a straight line is obtained for I_X/I_R plotted as a function of C_X/C_R.

Results

Effect of Oxygen Atmosphere on Sputtering. Figure 2 shows the texture of the surface of a nickel specimen sputtered by argon ion bombardment. The results were obtained by surface roughness measurement. There is pronounced surface unevenness under a pressure of 27 μPa (without oxygen). On the other hand, the surface resulting from the sputtering in oxygen atmosphere under pressure of 5.3 mPa is very smooth. When the other conditions are the same, the sputtering rates are 0.2 and 0.03 nm/s under pressure of 27 μPa and 5.3 mPa, respectively. The sputtering rate of the stainless steel was 0.04 nm/s under pressure of 5.3 mPa.

The results demonstrate that bombardment by argon ions in oxygen atmosphere is effective for the analysis of a very thin layer such as the passive layers on the surface of stainless steel.

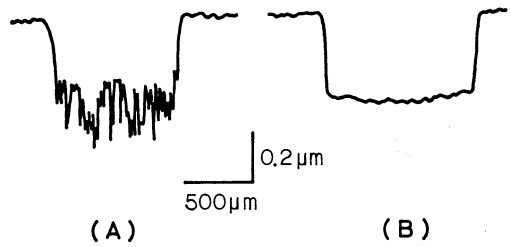

Fig. 2. Texture of surface sputtered by argon ion. Accelerating voltage and current density of argon ion were 10kV and 0.1 mA/cm², respectively. (A) Sample chamber pressure was 27 μPa and nickel bombardment time was 30 min. (B) Sample chamber pressure was 5.3 mPa and nickel bombardment time was 180 min.

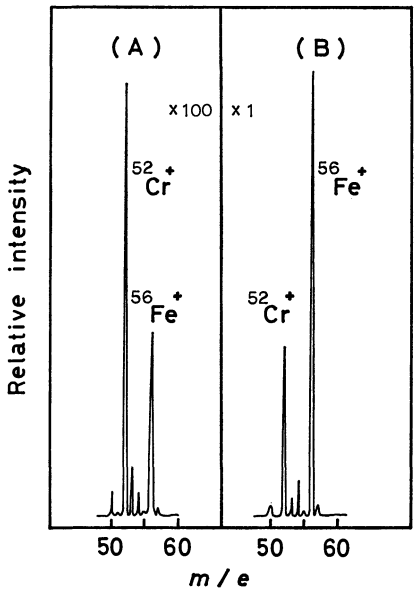

Fig. 3. Mass spectra of chromium and iron ion sputtered from stainless steel. Sample chamber pressure was (A) 27 μPa (without oxygen) and (B) 5.3 mPa(with oxygen).

Effect of Oxygen Atmosphere on Intensity of Secondary Ions. Figure 3 shows the mass spectra of chromium and iron ions. The pressure in the sample chamber is 27 μPa (without oxygen) for the specimens on the left side and 5.3 mPa (with oxygen) for the specimens on the right side. The specimen contained 82% Fe and 16% Cr. The peaks of $^{52}Cr^+$ and $^{56}Fe^+$ in the case with oxygen are *ca.* 40 and 240 times that in the case without oxygen, respectively. The other elements contained in stainless steel also show the same tendency. However, the peak height multiple differs from one element to the other. The relative ion yield of each element as compared to iron was calculated in the cases of pressure 27 μPa and 5.3 mPa. Table 3 gives the results where the secondary

Table 3. Relative ion yield of each element to iron

Element	Relative ion yield[a] (A)	(B)
Fe	1.0	1.0
Cr	8.6	2.7
Ni	0.3	0.4
Mn	5.6	2.1
Si	1.8	0.4

a) Sample chamber pressure 27 μPa for (A) (without oxygen) and 5.3 mPa for (B) (with oxygen).

ion intensity of each element is divided by the concentration and the value of each element is divided by the value of iron. The relative ion yield of elements is in the range 0.3—8.6 for 27 μPa, and in the range 0.4—2.7 for 5.3 mPa. The results show that the introduction of oxygen into the sample chamber causes increase in the sensitivity of elements and decrease in the difference in the relative ion yield of elements.

Selection of Reference Element. Iron is used as a reference element for analyses of steels containing more than 90% Fe. Thus the secondary ion peak of iron does not vary even when the secondary ion peak values of other elements vary. However, in the analysis of stainless steel containing less than 80% Fe, the percentage varies from specimen to specimen, and neither iron nor any other element can be used as a reference element.

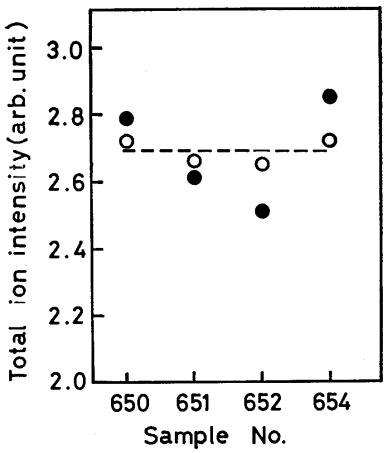

Fig. 4. Variations in total ion intensity with different specimens. Sample chamber pressure was (●) 27 μPa (without oxygen) and (○) 5.3 mPa(with oxygen).

Equation 2 cannot be used without a reference element. The secondary ion peak values of all the elements in steel are summed and the value obtained is assumed to be a composite reference. Figure 4 shows variations in the sums of the secondary ion peak values (total ion intensity) with different specimens. The total ion intensity varies widely with specimen when no oxygen is introduced into the sample chamber, but varying very little when it is introduced.

Figure 5 shows the relation between the ratio of secondary ion peak value to total ion intensity and concentration. A linear relation is obtained in an oxygen atmosphere. The total ion intensity could be used as a reference. The reproducibility of the method when the total ion intensity is used as a reference is given in Table 4.

Analysis of Passive Layers. Figure 6 shows the variation of total ion intensity below the surface of a specimen with a passive surface layer. In the case without oxygen, there is a large difference in total ion intensity between the passive layer and the matrix, while in an oxygen atmosphere, total ion intensity is the same for both. Consequently, the calibration curve shown in Fig. 5 can be used in the quantitative analysis of sub-surface concentration profiles in specimens with passive surface layers.

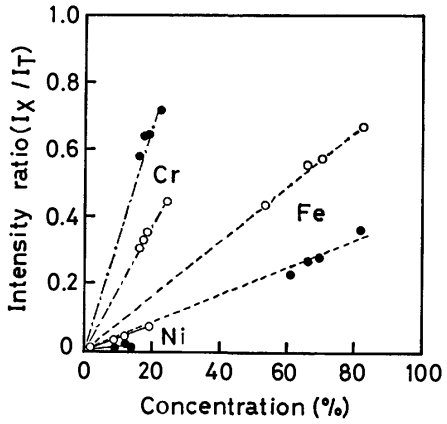

Fig. 5. Relation between the ratio of secondary ion intensity to total ion intensity and concentration. Sample chamber pressure was (●) 27 μPa(without oxygen) and (○) 5.3 mPa(with oxygen). -•-•-: Chromium,----: iron,——: nickel.

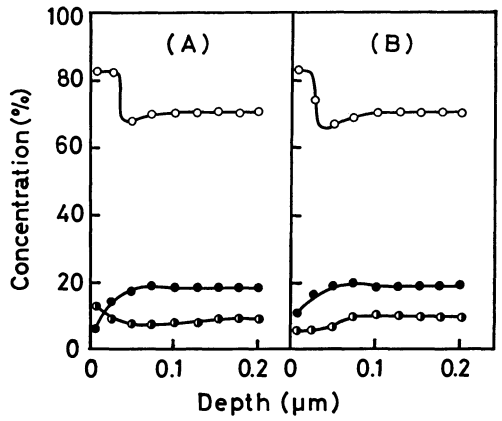

Fig. 7. Indepth concentration profiles for (A) 304 and (B) 321 stainless steels treated in neutral water containing 8 ppm oxygen. Specimens were treated for 2000 h at 289 °C.
○: Fe, ●: Cr, ◑: Ni.

The present method has been used to determine the concentration profiles in the surface layer of 304 and 321 stainless steel specimens treated in neutral water containing 8 ppm oxygen. Figure 7 shows the results obtained with specimens treated at 289 °C for 2000 h. The passive layers on the surfaces of 304 and 321 stainless steel are about 20 and 10 nm in thickness, respectively. These layers contain a larger amount of iron and a smaller amount of chromium than the matrices of the same steel.

It was found by carbon furnace atomic absorption spectrometry that iron, chromium, and nickel dissolve in water in a concentration of 239, 320, and 48.7 ppb, respectively. The concentration ratios of chromium and nickel to iron are 0.24 and 0.18 in matrices and 1.34 and 0.20 in water, respectively. The amount of nickel in water was nearly equal to that in the matrices, but the amount of chromium in water was much greater than that in matrices.

Thus, the decrease in the amount of chromium in passive layers corresponds to the increase in the amount of chromium in water.

A number of studies have been carried out on the composition of the passive film on 18% Cr–8% Ni stainless steel. Castle and Clayton[8] analyzed the passive film by X-ray photoelectron spectroscopy. They reported that the passive film prepared in low temperature (313 and 353 K), neutral, de-oxygenated water has a duplex layer structure, the outer layer being rich in iron and inner layer rich in chromium. A duplex layer structure was reported by Kowaka and Nagata,[13] and Bittel *et al.*[14] They prepared the passive layer in steam at temperatures 600—650 °C[13] and 1200—1300 °C, and analyzed the cross section of passive film with an electron probe microanalyzer. The results show that the passive layer consists of an outer layer of hematite rich in iron and inner layer of spinel and fcc metal rich in chromium.

Our result shows that the passive layer is rich in iron, corresponding to the composition of the outer layer.

Studies on the Ammonium Form of Crystalline Zirconium Phosphate. II.[1,2] Ammonium–Lithium Ion-exchange Isotherms

Yoshitsugu HASEGAWA* and Yoshimitsu KOMIYAMA†

Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei Tokyo 184

(Received October 3, 1977)

The ion-exchange isotherms for the NH_4^+–Li^+ system on crystalline zirconium phosphate have been determined at 25 °C, and the structural change and water content of the exchanger have also been investigated by means of X-ray diffraction and thermal analysis. The isotherms showed that the ion-exchange reaction took place in one stage, that is, the ammonium-form was converted into the lithium-form in the forward process, and *vice versa* in the reverse process. However, the results of X-ray diffractometry indicated that the ion-exchange reactions proceeded in three stages in each direction. The isotherms also showed a hysteresis loop. This phenomenon can be ascribed to the difference in the water content of the exchangers, because the X-ray powder patterns of the exchanger phases were essentially identical at similar ionic mole fraction of lithium ion in the exchangers of the two processes.

Many inorganic ion-exchangers have been extensively investigated in the field of nuclear energy, water desalination, analytical chemistry, *etc.* Crystalline zirconium bis(monohydrogen orthophosphate) monohydrate, $Zr(HPO_4)_2 \cdot H_2O$, generally called α-zirconium phosphate, is one of the most studied materials. α-Zirconium phosphate as well as its cation-exchanged form has a layered structure, and the ion-exchange reaction is strongly influenced by the interlayer distance of the exchanger and by the ionic radius of an exchanging cation.[3] Also, the hydration and dehydration of cations affect the ion-exchange. Of alkali metal cations, lithium ion has the largest standard free energy for hydration and dehydration,[4,5] and its ionic radius is the smallest. When lithium ion exchanges on a cation-exchanged form with a cation having a larger ionic radius, not all the water molecules bound to the lithium ion are dehydrated.

During an investigation of the ammonium–hydrogen ion-exchange on α-zirconium phosphate prepared by the reflux method, the pH titration curves indicate that the solid phase of $Zr(NH_4PO_4)_{4/3} \cdot (HPO_4)_{2/3} \cdot nH_2O$ is present instead of $Zr(NH_4PO_4)(HPO_4) \cdot n'H_2O$.[6] The interlayer distance of the ammonium-form is shorter than that to be expected from the ionic radius of ammonium ion.[7,8] The behavior of the ammonium–hydrogen ion-exchange is similar to that observed in the hydrogen–lithium ion-exchange.[9]

Thus, it is of interest to study how the relatively short interlayer distance of the ammonium-form exchanger affects its selectivity from the points of view of the mechanism of the ion-exchange and the application to the recovery of metals, and how the ionic hydration and the similar behavior of the ion-exchange reactions affect the ammonium–lithium ion-exchange.

In the present work, the ammonium–lithium ion-exchange isotherms at 25 °C, the structural change, and the water content per mole of the exchanger will be reported.

† Present address: 4-13-5 Sengen-cho, Fuchu, Tokyo 183.

Experimental

Reagents and Preparation of Exchangers. All the chemicals were of reagent grade and were used without purification.

The ammonium-form exchanger, $Zr(NH_4PO_4)_2 \cdot H_2O$, was prepared according to Hasegawa and Aoki.[6] The lithium-form exchanger, $Zr(LiPO_4)_2 \cdot 4H_2O$, was prepared by the continuous percolation of a 0.1 mol dm^{-3} lithium chloride solution through a column filled with the ammonium-form exchanger. Both the exchangers were dried over a saturated sodium chloride solution (with a relative humidity of about 75% at room temperature). The identification of the exchanger was made by means of the X-ray diffraction pattern and the loss of ignition.

Analytical Procedure. The concentration of ammonium ions in the solution was determined gravimetrically.[10] The concentration of lithium ions was determined by atomic absorption spectrophotometry with a Hitachi atomic absorption spectrophotometer 208. In order to determine the structural change in the exchanger phase during the ion-exchange, X-ray powder patterns were obtained with nickel-filtered Cu $K\alpha$ radiation with a Geigerflex (Rigaku Denki Co., Ltd.). The exchanger was conditioned before measurement over a saturated sodium chloride solution at room temperature.

TABLE 1. DEPENDENCE OF X_{Li} ON THE TIME

Time (day)	0.25	0.5	1	2	3
X_{Li}[a)]	0.93	0.94	0.93	0.94	0.93

a) X_{Li}=the mole fraction of lithium ion in the solution of F8 in Fig. 1.

Ion-exchange Isotherms. A weighed amount of the exchanger (100 mg) was shaken continuously with 10.0 cm^3 of a solution containing a total of 0.100 M of ammonium and lithium chlorides at 25 °C. In order to select the reaction time, the concentration of lithium ions in the solution was determined after a given period of time for the F8 sample in Fig. 1. The concentration of lithium ions varied within the limits of experimental error (Table 1). A reaction of at least 48 h was thus chosen. Near the end point (the mole fraction of lithium or ammonium ion, X_{Li} or $X_{NH_4}=1.0$) the volume of the solution was increased and/or the amount of the exchanger was decreased to prompt the reaction, and also a shaking period longer than 48 h was taken.

Results and Discussion

In order to investigate the effect of the pH's of solutions on the ion-exchange isotherms and to calculate the ionic fraction of exchanging cations in the exchanger phase, the concentrations of ammonium and lithium ions and pH values in the solution phase were determined separately. As is shown in Table 2, the sum of the ionic fraction of the solution phase for ammonium and lithium ions was equal to unity in all cases, within the limits of experimental error. The pH values were slightly higher than the pH's which were determined for the solutions containing the same ionic fraction of ammonium and lithium ions and no exchanger. The difference in the hydrogen-ion concentration was very small, and it is possible to neglect the effect of the pH value of the solution on the ion-exchange reaction.

F and R denote the forward and reverse processes respectively. F1...R10 correspond to those in Fig. 1. X_{Li} and X_{NH4} represent the mole fractions of the respective ions.

Forward Process (The Ammonium-form→the Lithium-form). The ion-exchange isotherm is shown in Fig. 1(a). It was found that the isotherm showed a steep sloping when the mole fraction of lithium ion in the solution, X_{Li}, was larger than 0.7. No clear plateaus or vertical portions were observed in the isotherm. These facts indicate that the ammonium-form was converted into the lithium-form without the formation of an intermediate, half-exchanged form, $Zr(NH_4PO_4)(LiPO_4)\cdot mH_2O$. Since it took a long time to prepare the lithium-form, perfect conversion seems to be difficult.

It is known that α-zirconium phosphate and its sodium-form have a layered structure and that the first reflection in the X-ray powder pattern corresponds to the interlayer spacing.[3] This means that when two solid phases coexist, two reflections are observed at lower diffraction angles. As the ammonium-form has a layered structure,[8] similar phenomena can be expected. Based on this hypothesis, it has been possible to deduce the structural change of the exchanger phase during the ion-exchange. The precise estimation of the intensity of two peaks is difficult in this case, however, because two peaks overlapped at lower diffraction angles. Hence, the intensity ratio in Table 3 is only approximate.

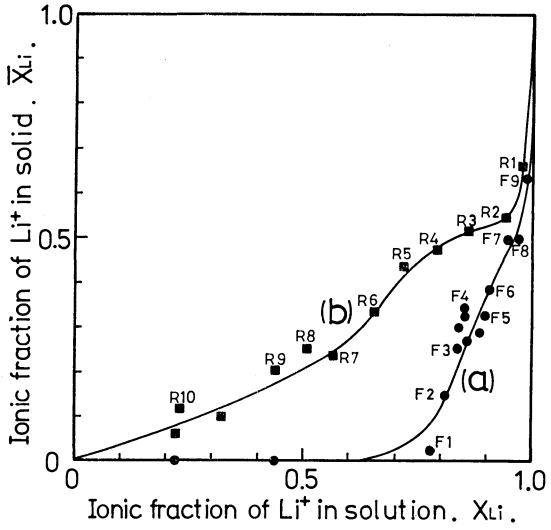

Fig. 1. Ion-exchange isotherms, (a) forward and (b) reverse process. X_{Li}: the mole fraction of lithium ion in the solution phase. $\bar{X}_{Li}$: the mole fraction of lithium ion in the solid phase.

Table 3. Relative intensities of the interlayer distances in the forward process

Symbol[a]	Interlayer distances

F9 (0.63)	—	3.0	10
Li form (1.0)	—	10	—

a) Symbols correspond to those in Fig. 1(a).

In the region of the mole fraction of lithium ion in the exchanger phase $\bar{X}_{Li}=0-0.03$, the interlayer distance remained constant (9.4 Å), corresponding to that of the ammonium-form. When $\bar{X}_{Li}$ was above 0.15, a peak appeared at 10.0 Å, and its intensity increased with an increase in $\bar{X}_{Li}$. Between F3 and F4 ($\bar{X}_{Li}\fallingdotseq 0.3$), the

peak at 9.4 Å diminished and another peak appeared at 10.5 Å. This change in the exchanger phase indicates that a new phase with an interlayer distance of 10.0 Å was present in the very narrow region of X_{Li}.

Two peaks, at 10.0 and 10.5 Å, were observed in the region of $\bar{X}_{Li}$=0.3—0.4. The intensity of the former decreased with an increase in $\bar{X}_{Li}$, and only the peak at 10.5 Å was present at F7 and F8 ($\bar{X}_{Li} \fallingdotseq 0.5$).

Above $\bar{X}_{Li}$=0.5 the peak at 10.5 Å disappeared gradually, and the intensity of the peak at 10.0 Å increased again. This peak at 10.0 Å should be considered as a different one from that observed in the region of $\bar{X}_{Li}$=0.15—0.4, because it is not probable that the same phase exists in another region of $\bar{X}_{Li}$. The interlayer distance of 10.0 Å was identical to that of the lithium-form reported by Alberti *et al.*[11] It can thus be inferred from the X-ray studies that the ion-exchange reaction took place in three stages, while the isotherm showed no clear stages.

In order to determine the water content per mole of the exchanger, the solid obtained during the ion-exchange process was heated to 420 °C and the weight loss was measured. The molecular formula of the exchanger can be assumed to be $Zr(NH_4PO_4)_a \cdot (LiPO_4)_{2-a} \cdot nH_2O$. Since the exchanger loses its water of hydration and ammonia in the temperature range of 100—420 °C, the water content is calculated by means of the following equation:

$$n = [295.0p + (11.0p - 17.0)a]/18.0(1 - p), \quad (1)$$

where a and n are moles of NH_4^+ and H_2O per formula weight of the exchanger, as shown above, and p is the portion of weight loss to the molecular weight.

The relationship between the water content per mole of the exchanger (n) and $\bar{X}_{Li}$ is shown in Fig. 2(a). The value of n increased linearly with $\bar{X}_{Li}$. The change in n can be represented as follows;

$$n = 3(\bar{X}_{Li}) + 1$$
$$= (3/2)(2 - a) + 1. \quad (2)$$

Equation 2 shows that the net water molecules diffusing with a lithium ion into the crystal lattice of the exchanger were equal to 1.5. The water content of the ion-exchanger of the lithium-form was equal to $3.9H_2O$/mol, less than that previously reported.[11,12] This is due to the tendency of the lithium-form to lose the water of hydration.[11]

Reverse Process (the Lithium-form→the Ammonium-form). The ion-exchange isotherm of the reverse process is shown in Fig. 1(b). In contrast with the forward process, this ion-exchange reaction took place at $X_{NH_4} < 0.03$. The isotherm showed an almost vertical sloping in the region of $\bar{X}_{Li}$=1.0—0.5. Near R2 and R3 ($\bar{X}_{Li} \fallingdotseq 0.5$) the curve tended to have a plateau, and then it again sloped below $\bar{X}_{Li}$=0.5.

Table 4 shows the change in the peaks in the powder patterns at lower diffraction angles. Even at the beginning of the reaction the peak at 10.5 Å appeared and two phases coexisted. The peak at 10.5 Å showed its maximum intensity at R2, while the peak at 10.0 Å was present as a shoulder. The intensity of the peak at 10.0 Å increased again at R3. This peak after R3 should be regarded as another, separate one, as has been

TABLE 4. RELATIVE INTENSITIES OF THE INTERLAYER DISTANCES IN THE REVERSE PROCESS

s: Shoulder.

stated above. The findings indicate that the phase with the interlayer distance of 10.5 Å was formed at the narrow region of X_{Li} between R2 and R3. In the region of $\bar{X}_{Li}$=0.5—0.3, two peaks at 10.0 and 10.5 Å were observed. The intensity of the 10.0 Å peak increased with a decrease in $\bar{X}_{Li}$ and showed its maximum at R6. The peaks at 10.0 and 9.4 Å coexisted below $\bar{X}_{Li}$=0.3. The latter corresponds to the interlayer distance of the ammonium-form. Near the end point (X_{Li} and $\bar{X}_{Li}$=0), only the ammonium-form was present. The results showed that the ion-exchange reaction proceeded in three stages.

The change in the water content per mole of the exchanger, n, calculated by means of Eq. 1 is shown in Fig. 2(b). The value of n was approximately represented as follows above $\bar{X}_{Li}$=0.3:

$$n = 2(\bar{X}_{Li}) + 2$$
$$= (2 - a) + 2. \quad (3)$$

Below this point the equation changes to approximately:

$$n = 5(\bar{X}_{Li}) + 1$$
$$= 5/2(2 - a) + 1$$

(the dashed line in Fig. 2). Equation 3 shows that one water molecule migrates with a lithium ion and that the water content of the exchanger phase was higher in the reverse direction than in the forward one.

The X-ray powder patterns of the exchanger phase with a similar $\bar{X}_{Li}$ were essentially identical and made no noticeable difference in the crystal structure. The water content of the exchanger in the forward process was different from that in the reverse one at the same $\bar{X}_{Li}$. Consequently, the hysteresis phenomenon can be ascribed to the difference in the number of water molecules involved in the ion-exchange reactions.

At the first stage in both processes, the interlayer distance of the exchanger expanded, though the change was larger in the forward process than in the reverse one. This indicates that more energy is needed and that

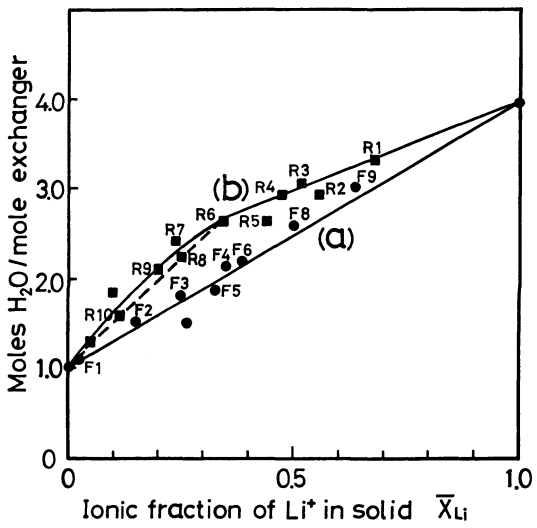

Fig. 2. Change in the water content per one mole of the exchanger phase (n). (a) forward and (b) reverse process.

it is more difficult for the ion-exchange reaction to take place in the forward process. In the second stage, the interlayer distance expanded in the forward process, but contracted in the reverse one. Hence, the ion-exchange reaction in the forward process may need a higher X_{Li}.

While hydration in the exchanger phase is an important factor in affecting the ion-exchange reaction,[6,10] ionic hydration in the solution phase must also be taken into account. During the ion-exchange process, bare or partially hydrated cations diffuse into the exchanger because of the steric factor.[3,8] Ions must lose hydrated water molecule(s) in order to exchange. Kim and Rubin calculated the activation energy for dehydration of alkali cations.[5] Though the activation energy for ammonium ion has not been estimated, it can be considered, according to the model employed by them, that the activation energy for dehydration of ammonium ion will be less than that for lithium ion, mainly because of the crystal ionic radius and the mass of ammonium ion. Thus, it is easier for ammonium ion than lithium ion to diffuse into the exchanger. The activation energy for dehydration of primary hydrated lithium ion was estimated to be greater than that of sodium ion if each ion loses the same number of bound water molecules.[5] A comparison with the obtained isotherms for NH_4^+–Li^+ and NH_4^+–Na^+ systems suggests that the lithium ion is partially dehydrated,[10] for the ion-exchange reaction took place at a low ionic fraction of lithium ion in the solution.

The relationship between the formation of a new phase and the absence of the step-by-step change in the isotherm can be explained by the following factors: (1) the two ion-exchange reactions ocurred in a very narrow X_{Li} region, as shown in the NH_4^+–Na^+ systems, and (2) two phases formed the solid solution over a wide range of composition, because the exchanger used showed a good crystallinity but was not fully crystalline, as was pointed out in the case of the Li^+–H^+ exchange.[13]

The authors would like to thank Professor Isao Tomita, the University of Tsukuba, for his many helpful discussions. The authors are also much indebted to Professor Shuji Abe for his valuable discussions.

Studies of Inorganic Ion Exchangers. II.[1] Effects of Sulfuric Acid on the Synthesis of $Ti(HPO_4)_2 \cdot 0—1/2H_2O$

Etsuro KOBAYASHI

National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo 151

(Received December 8, 1977)

In order to develop an inorganic ion exchanger for industrial use, sulfuric acid has been added to the reaction system of amorphous titanium(IV) phosphate and phosphoric acid. The effects of the additive on the formation of titanium(IV) hydrogenphosphate, a compound observed to have ion exchange affinities towards K^+ and Cs^+, have been investigated. $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ has been synthesized using the sulfuric acid solution of $TiOSO_4$, an intermediate in the production process of titanium dioxide. The addition of sulfuric acid to phosphoric acid and a resulting mole ratio of H_2SO_4/H_3PO_4 greater than 0.14, produced a borderline in the formation of the monohydrate and hemihydrate within the temperature range of 148—155 °C. Titanium(IV) hydrogenphosphate crystallized as fine particles (1—3 μ) by the double decomposition between the sulfuric acid solution of $TiOSO_4$ and phosphoric acid. The X-ray diffraction pattern of the product obtained using the sulfuric acid solution of $TiOSO_4$ above 160 °C compared favourably with that of the hemihydrate already reported. The composition was shown by the formula of $Ti(HPO_4)_2 \cdot 0—1/2H_2O$. In the X-ray diffraction pattern of $Ti(HPO_4)_2 \cdot 0—1/2H_2O$, two characteristic diffraction lines appeared at 11.6 and 9.21 Å; thus it has been assumed that the product is not a pure crystallite but a mixture of two or more species.

Some phosphates of polyvalent metals have been known as inorganic ion exchangers, zirconium phosphate being especially useful in analytical chemistry.[2,3] Previous investigations of the ion exchange properties of some phosphates,[4,5] lead to this investigation of titanium phosphate. The crystalline titanium(IV) bis(hydrogenphosphate) monohydrate, $Ti(HPO_4)_2 \cdot H_2O$, can absorb Li^+ and Na^+,[6,7] but not the ions of larger radius, such as K^+ and Cs^+. In a previous work,[1] titanium(IV) bis(hydrogenphosphate) hemihydrate, $Ti(HPO_4)_2 \cdot 1/2H_2O$, was formed by refluxing amorphous titanium(IV) phosphate with concentrated phosphoric acid. The X-ray diffraction pattern of the hemihydrate differed considerably from that of the monohydrate, and larger *d*-values appeared. It has been observed that this compound has ion exchange capacities towards K^+ and Cs^+. In the present work, an attempt has been made to prepare $Ti(HPO_4)_2 \cdot 1/2H_2O$ by the reaction of concentrated phosphoric acid with the sulfuric acid solution of titanium oxide sulfate, $TiOSO_4$, the intermediate in the production process of titanium dioxide. The effects of sulfuric acid on the formation of titanium phosphate have been investigated by refluxing amorphous titanium(IV) phosphate with a mixture of H_2SO_4 and H_3PO_4. Subsequently, $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ has been synthesized using the sulfuric acid solution of $TiOSO_4$ or titanium(IV) oxide monohydrate (metatitanic acid, $TiO_2 \cdot H_2O$).

Experimental

Starting Materials. Amorphous titanium(IV) phosphate has been prepared by the method described in a previous paper.[1] Synthesising conditions and analytical data are given in Table 1.

The sulfuric acid solution of $TiOSO_4$, which is the polish for titanium dioxide as a white pigment and does not contain iron as an impurity, was obtained from Ishihara Sangyo Kaisha Ltd. The composition is shown as a footnote in Table 2. $TiO_2 \cdot H_2O$ used was a commercial grade powder.

Preparation of Titanium(IV) Bis(hydrogenphosphate). An appropriate quantity of titanium compound and other materials (amorphous titanium(IV) phosphate, H_2SO_4 soln of $TiOSO_4$, $TiO_2 \cdot H_2O$: 25 g, 30 ml, 9.18 g) were placed in a three-necked flask, and H_3PO_4–H_2SO_4 solution (900 ml) was added. The mixture was refluxed for 50 h after which a condenser and a thermometer were connected to the flask. The resulting precipitate was separated centrifugally from the mother liquor, water added, the mixture vigorously shaken up, and the precipitate was separated centrifugally. This procedure was repeated several times, and the product finally dried at 50—60 °C for 24 h.

Analysis. The components of the product, P_2O_5, TiO_2, and H_2O, were determined by previously reported methods.[1] The quantity of H_2SO_4 in the mother liquor was determined gravimetrically as barium sulfate. The X-ray diffraction patterns were obtained using a Rigaku-Denki model 2001 diffractometer with Ni-filtered Cu *Kα* radiation, with 20 kVP and 15 mA, or 30 kVP and 20 mA.

Results and Discussion

Reaction of Amorphous Titanium(IV) Phosphate with H_3PO_4–H_2SO_4 Solution. The effects of sulfuric acid on the formation of titanium(IV) bis(hydrogenphosphate) have been investigated by using amorphous titanium(IV) phosphate as the starting material. The conditions of synthesis and the results of analysis are summarized in Table 1.

Proportion of Titanium Compound with Mother Liquor. When the quantity of amorphous titanium(IV) phosphate is small compared with the volume of mother liquor, the reflux is smooth; this production is, however, commercially unprofitable. When a large amount of the titanium compound is refluxed with the mother liquor, the operation is not smooth, and the growth of the crystal of titanium(IV) bis(hydrogenphosphate) is obstructed. As may be seen from Table 1(Nos. 1—4), the quantity of amorphous titanium(IV) phosphate mixed with H_3PO_4 as the mother liquor was varied. The X-ray diffraction patterns of the products thus obtained are shown in Fig. 1. It is evident that the crystallinities of the products increase in the order Nos. 1, 2, and 3. The ratios (*R*) of the volume of mother liquor to the

a) The mixture of amorphous titanium(IV) phosphate and mother liquor was refluxed at boiling point.

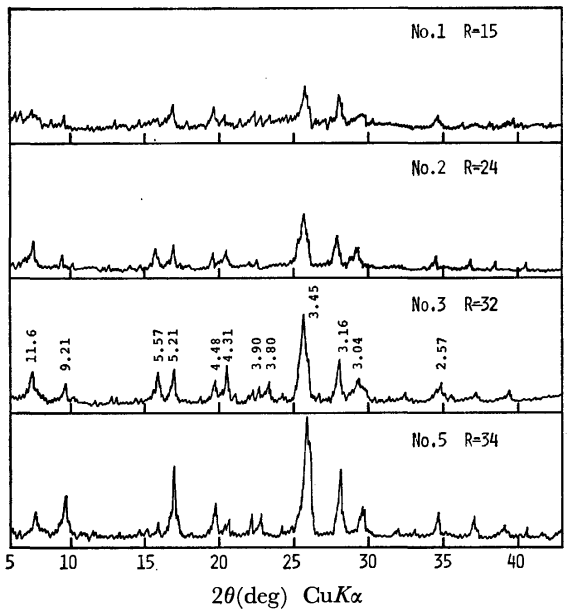

Fig. 1. X-Ray diffraction patterns of $Ti(HPO_4)_2 \cdot 1/2H_2O$. Effect of amount of amorphous titanium(IV) phosphate to mother liquor.
R: Mother liquor(ml)/amorphous titanium(IV) phosphate(8). Nos. 1, 2, and 3: H_3PO_4 used as mother liquor, No. 5: H_3PO_4–H_2SO_4 mixed solution used as mother liquor. Numerals near peaks indicate corresponding *d* values.

weight of titanium compound were found suitable within 32 to 50 (ml/g). In No. 5 the H_3PO_4–H_2SO_4 solution was used as the mother liquor, and the crystallinity of product improved more than in the case of only H_3PO_4.

Effect of Concentration of H_2SO_4. The effect of concentration of H_2SO_4 added to the mother liquor was examined (Nos. 5—7). The initial volume ratios of 18 M H_2SO_4 to 14.5 M H_3PO_4 were 1: 9, 2.5: 7.5, and 4: 6 in Nos. 5, 6, and 7, respectively. In these cases, the concentrations of H_3PO_4 and H_2SO_4 in the mother liquor after reflux are shown in Table 1. In the product X-ray diffraction patterns, the intensities decreased slightly with increase in H_2SO_4. However, the compositions of products and X-ray diffraction patterns were all the same with those of $Ti(HPO_4)_2 \cdot 1/2H_2O$. Therefore, an obstacle to the formation of the hemihydrate did not appear until a volume ratio of 4: 6 was reached. But the existence of a different phosphate was recognized from the X-ray diffraction pattern and analytical data (TiO_2: 35.2%, P_2O_5: 35.6%, SO_3: 19.5%, H_2O: 8.5%) of the product formed in the case of a volume ratio 9: 1 of H_2SO_4 to H_3PO_4.

Effect of Reaction Temperature. As previously reported, $Ti(HPO_4)_2 \cdot 1/2H_2O$ was formed by refluxing amorphous titanium(IV) phosphate with H_3PO_4 containing more than 64% P_2O_5 at above 170 °C.[1] $Ti(HPO_4)_2 \cdot H_2O$ was also formed as the solid phase in equilibrium with the mother liquor containing 13—64% P_2O_5. Variations in the mixing ratio of H_2SO_4 to H_3PO_4 and the refluxing temperature were conducted (Nos. 5 and 8—15). From the results of analysis and the X-ray diffraction data, the species of titanium phosphate are shown in Fig. 2. As seen from the figure a mother liquor consisting of only phosphoric acid

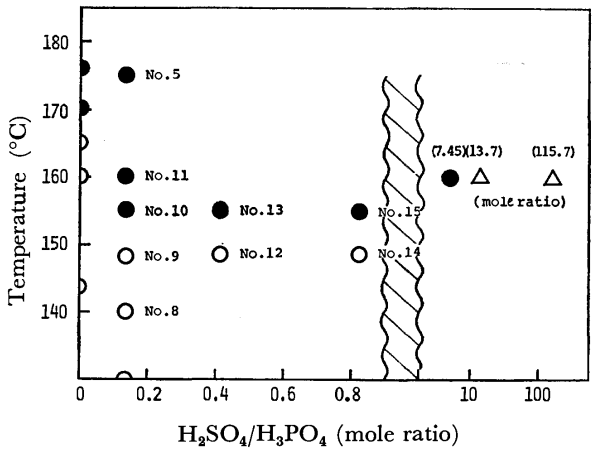

Fig. 2. Effects of sulfuric acid in mother liquor and reaction temperature on formed salts.
●: $Ti(HPO_4)_2 \cdot 1/2H_2O$, ○: $Ti(HPO_4)_2 \cdot H_2O$, △: unknown salt.

produced a border in the formation of the monohydrate and the hemihydrate between 160 and 170 °C. When the mole ratio of H_2SO_4 to H_3PO_4 exceeded 0.14, a borderline appeared in the range of 148—155 °C, *i.e.* the reaction temperature for formation of the hemihydrate was lowered by about 15 °C by the addition of H_2SO_4. Since the fraction of water in the mother liquor decreased by the addition of 18 M H_2SO_4, the water required for the formation of the monohydrate was not sufficient, and the resulting hemihydrate was formed as the stable solid phase in equilibrium with the mother liquor. It is possible that the sulfuric acid in the heated mother liquor dehydrated the water of crystallization.

Determination of Reaction Time. The effects of reaction time in the synthesis of $Ti(HPO_4)_2 \cdot 1/2H_2O$ have been examined (Nos. 11(12h), 16(24h), and 17(50h)). With the H_3PO_4–H_2SO_4 solution as mother liquor, the X-ray diffraction patterns showed the crystallinity of product improved until a reaction time of 24 h. The reaction time in the synthesis of the monohydrate has been reported to be 50[6] and 200 h.[7] Therefore, in terms of hemihydrate formation as an ion exchanger and the commercialization of the process the reaction time has been set at 50 h.

Synthesis of $Ti(HPO_4)_2 \cdot 0$—$1/2H_2O$ Using the Sulfuric Acid Solution of $TiOSO_4$. The synthesizing conditions of titanium(IV) bis(hydrogenphosphate) and their analytical results are summarized in Table 2.

The reaction between $TiOSO_4$ and H_3PO_4 is shown in the following equation

$$TiOSO_4 + 2H_3PO_4 \longrightarrow Ti(HPO_4)_2 \cdot H_2O + H_2SO_4.$$

Titanium(IV) bis(hydrogenphosphate) crystallizes in the mother liquor, and then sulfuric acid is newly formed. When the $TiOSO_4$–H_2SO_4 solution was used as the starting material, a gelatinous product of undefined composition was initially produced. To avoid aggregation of the gel, the $TiOSO_4$–H_2SO_4 solution was added little by little to the stirred H_3PO_4–H_2SO_4 solution. A second method was to stir the reaction mixture without refluxing in a mother liquor having the boilling point higher than the appointed reaction temperature. This method is called the precipitate method compared with the previous one, the refluxing method. In No. 18, which used a mother liquor of boilling point 160 °C, the monohydrate was formed by the precipitate method at 100 °C. The diameter of the product thus obtained was 10—30 μ, and appeared larger than that of the product formed by the refluxing method. Upon investigation through a microscope the product was shown to be an aggregation of fine particles. This aggregation gradually separated into fine particles as the temperature of the mother liquor rose. In Nos. 19—21 (precipitate method) and Nos. 22—25 (refluxing method) the monohydrate, hemihydrate and anhydride were obtained as fine particles with a diameter of about 1—3 μ. The X-ray diffraction patterns of $Ti(HPO_4)_2 \cdot H_2O$ formed by the precipitate method and $Ti(HPO_4)_2 \cdot 0$—$1/2H_2O$ formed by the refluxing method are shown in Fig. 3.

The X-ray diffraction patterns of the products obtained using the sulfuric acid solution of $TiOSO_4$ at

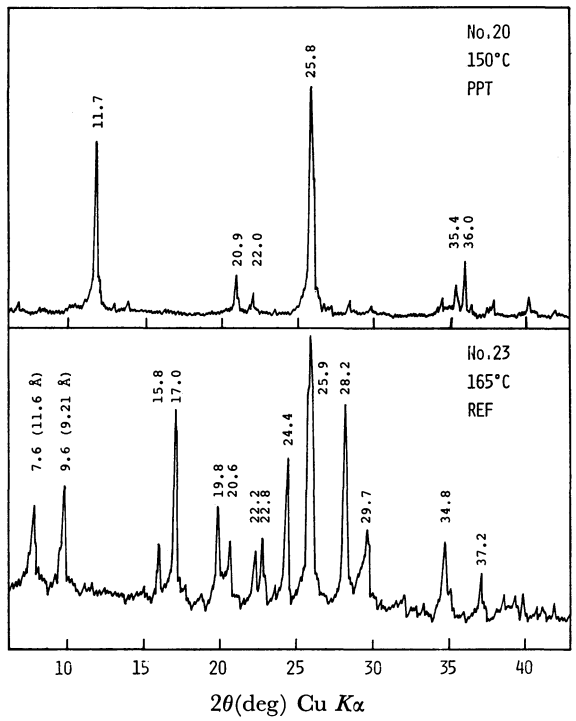

Fig. 3. X-Ray diffraction patterns of $Ti(HPO_4)_2 \cdot H_2O$ (No. 20) and $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ (No. 23). No. 20: 15 mA, 20 kVP, No. 23: 20 mA, 30 kVP.

above 160 °C were almost the same with those of the hemihydrate obtained using amorphous titanium(IV) phosphate. However, from the results of analysis, the compositions of product were shown by $Ti(HPO_4)_2 \cdot 0—1/2H_2O$, and the products (Nos. 23, 25) corresponding to the anhydride were also formed at times. In the X-ray diffraction pattern of $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ the intensity was lower than that of the monohydrate, two characteristic diffraction lines appearing at 11.6 and 9.21 Å. The lines also differed slightly in the 2θ values. It may be assumed from these X-ray diffraction patterns that $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ is not a pure crystallite, but consists of two or more species. Generally, it is considered that the diffusion of phosphoric acid on the solid of titanium(IV) oxide monohydrate ($TiO_2 \cdot H_2O$) is the rate determining step. The powders of $TiO_2 \cdot H_2O$ were clearly dissolved with sulfuric acid, and therefore, the rate of formation of $Ti(HPO_4)_2 \cdot 0—1/2H_2O$ would be accelerated using a H_3PO_4–H_2SO_4 solution as compared with the pure phosphoric acid solution. The refluxing method, in which the suspended TiO_2–H_2O actively reacts with the mother liquor, is more suitable than the precipitate method.

Solubility of Hexaamminenickel(II) Complexes in Aqueous Ammonia Solution and the Thermal Decomposition of Ammine Complexes of Nickel(II)

Tsugio SATO,* Takeshi SUDA, Hideki UCHIDA, and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received December 20, 1977)

The solubility of hexaamminenickel(II) complexes in aqueous ammonia solution (0 to 37 g-free NH_3/100 g-solv.) was investigated at temperatures 0—55 °C. It rapidly decreases with increase in free ammonia concentration but increases with rise in temperature. Hexaamminenickel(II) carbonate, sulfate, and chloride are slightly soluble at ammonia concentration above 30 g-free NH_3/100 g-solv., but nitrate is considerably soluble even at ammonia concentration of 35 g-free NH_3/100 g solv. The thermal decomposition of ammine complexes of nickel(II) was also investigated by means of TG and DTA under a streaming nitrogen gas atmosphere. Ammine complexes of nickel(II) decompose as shown in the following, the reaction orders and activation energies for steps a, b, c, and d being 0.5, 1.5, 1.0, and 0.5, and 16.5, 38.8, 25.3, and 79.4 kcal/mol, respectively.

$$[Ni(NH_3)_6](NO_3)_2 \xrightarrow{a} [Ni(NH_3)_4](NO_3)_2 \xrightarrow{b} [Ni(NH_3)_{2.5}](NO_3)_2 \longrightarrow NiO$$

$$[Ni(NH_3)_6]SO_4\cdot 2H_2O \longrightarrow [Ni(NH_3)_6]SO_4 \longrightarrow [Ni(NH_3)_2]SO_4 \xrightarrow{c} [Ni(NH_3)_{0.5}]SO_4 \longrightarrow$$

$$[Ni(NH_3)_5]SO_4\cdot H_2O \longrightarrow$$

$$NiSO_4 \xrightarrow{d} NiO$$

$$[Ni(NH_3)_6]CO_3\cdot 4H_2O \longrightarrow [Ni(NH_3)_4]CO_3\cdot 3H_2O \longrightarrow [Ni(NH_3)]CO_3\cdot H_2O \longrightarrow$$

$$[Ni(NH_3)]CO_3 \longrightarrow NiCO_3 \longrightarrow NiO$$

X-Ray diffraction data for $[Ni(NH_3)_6]Cl_2\cdot 0.5H_2O$, $[Ni(NH_3)_6](NO_3)_2$, $[Ni(NH_3)_5]SO_4\cdot H_2O$, and $[Ni(NH_3)_2]SO_4$ powder are given.

Various processes have been developed for the extraction of nickel from ores. Recently hydrometallurgical processes have drawn attention, since the recovery of nickel from low grade ores and non-sulfide ores is possible without any pollution problem. They are classified into two processes, leaching by an acid solution and that by an ammoniacal alkaline solution. The latter process has an advantage of little contamination by iron and magnesium. Some commercial operations based on the ammonia leaching process have been established, such as the Sherritt-Gordon process[1] of leaching sulfide ore, and the Nicaro process[2] of leaching laterite ore. In both processes, nickel is first leached as ammine complexes of nickel(II), but the subsequent steps differ a great deal. In the Sherritt-Gordon process, nickel metal is recovered by the reduction of hexaamminenickel(II) sulfate solution with compressed hydrogen. In the Nicaro process, nickel(II) oxide is recovered by the thermal decomposition of basic nickel(II) carbonate produced by heating the hexaamminenickel(II) carbonate solution and purging ammonia. In the present study it was found that the solubility of hexaamminenickel(II) complexes decreases rapidly with increase in free ammonia concentration in solution, and that the complexes decompose by releasing ammonia at considerably low temperature. This paper deals with studies of the solubility of hexaamminenickel(II) complexes in aqueous ammonia solution, and the thermal decomposition of solid ammine complexes of nickel(II) for the purpose of recovering highly purified nickel(II) salts or oxide by the thermal decomposition of solid ammine complexes separated by blowing ammonia gas into the leaching solution containing ammine complexes of nickel(II). Ammine complexes of nickel(II) are produced by blowing ammonia gas into aqueous nickel(II) salt solutions.[3-6] However, nickel has not been found to be completely recovered as hexaamminenikel(II) complex powder by an extreme increase of the free ammonia concentration. No report seems to have appeared on the solubility of hexaamminenikel(II) complexes in aqueous ammonia solution. Although several studies of thermal decomposition of hexaamminenickel(II) chloride,[7-12] nitrate,[7-9] and sulfate[7-9] have been reported, the thermal decomposition processes of hexaamminenickel(II) nitrate and sulfate are not clarified. No investigation of the thermal decomposition of hexaamminenickel(II) carbonate seems to have been carried out.

Part I. Solubility of Hexaamminenickel(II) Complexes in Aqueous Ammonia Solution

Experimental

Chemicals. Basic nickel(II) carbonate ($2NiCO_3\cdot 3Ni(OH)_2\cdot 3H_2O$) of reagent grade was used. All other chemicals were of analytical reagent grade.

Preparation of Hexaamminenickel(II) Complexes. Hexaamminenickel(II) carbonate was prepared as follows. Ten grams of ammonium carbonate and 19.5 g of basic nickel(II) carbonate were mixed in 100 ml of 16.5 wt% aqueous ammonia solution with a magnetic stirrer for 24 h. After the mixture had been filtered, ammonia gas was blown into the filtrate while being cooled with ice to precipitate hexaamminenickel(II) carbonate. Hexaamminenickel(II) chloride, sulfate, and nitrate were prepared by blowing ammonia gas into saturated aqueous solutions of nickel(II) chloride, sulfate, and nitrate, respectively. These complexes were washed with liquid ammonia and then kept in a

desiccator under ammonia atmosphere. The compositions of these complexes are given in Table 1.

Procedure. The apparatus for measurement of the solubility is shown in Fig. 1. The solubility of hexaamminenickel(II) complexes was determined as follows. Each 25 ml of sealed glass tube(A) was sealed soon after the transfer of 15 ml of aqueous ammonia solution of the desired concentration and excess amount of the sample complex, placed in a thermostat and agitated at 15 r.p.m. for 1 h. The sealed glass tube(A), glass filter(B) and sampling tube(C) were connected with each other. After the pressure of sampling tube(C) was reduced with an aspirator, stopcock(3) was closed, and stopcocks(1) and (2) were opened. A clear supernatant solution was withdrawn.

Analysis. Sampling tube(C) was separated from glass filter(B) and weighed. The sampling solution was acidified with excess standard sulfuric acid solution, diluted to a suitable concentration and subjected to the analysis of nickel(II) and ammonia. The amount of nickel(II) was determined by reacting nickel(II) with excess standard disodium ethylendiaminetetraacetate solution, and back-titrating the excess disodium ethylendiaminetetraacetate with standard zinc(II) chloride solution using Eriochrome Black T for end point detection. The total amount of nickel(II) and ammonia was determined by titrating excess sulfuric acid with standard sodium hydroxide solution using methylred for end point detection. The amount of ammonia was determined by subtracting the amount of nickel(II).

Results and Discussion

The solubility of hexaamminenickel(II) carbonate, chloride, sulfate, and nitrate in aqueous ammonia solution at temperatures 0—55 °C is given in Tables 2, 3, 4, and 5, respectively. The solubility of hexaamminenickel(II) carbonate and of sulfate linearly decreases with increase in free ammonia concentration up to 20 g free NH_3/100 g solvent. The complexes are slightly soluble at the free ammonia concentration above 30 g free NH_3/100 g solvent. The solubility of hexaamminenickel(II) carbonate increases with temperature when the free ammonia concentration is kept constant. The solubility at 55 °C is about twice that at 0 °C. The solubility of hexaamminenickel(II) sulfate

also increases with temperature up to 35 °C, remaining constant above 35 °C. The solubility of hexaamminenickel(II) chloride and of nitrate also decreases with increase in free ammonia concentration, but increases with rise in temperature. However, the decrements of solubility of these complexes with increase in free ammonia concentration are less than those of carbonate and sulfate. On the other hand, the increments of solubility of the former with temperature are larger than those of the latter; the solubility of hexaamminenickel(II) chloride and of nitrate at 55 °C is about four times as much as that at 0 °C.

Figure 2 shows the solubility of each hexaamminenickel(II) complex in aqueous ammonia solution at 25 °C. It is clear that the solubility of hexaamminenickel(II) carbonate and of chloride at low free ammonia concentration is similar to that of sulfate and nitrate respectively. The solubility of hexaamminenickel(II) carbonate and of sulfate is 3—4 times as much as that of chloride and nitrate at low free ammonia concentration. On the other hand, hexaamminenickel(II) carbonate, sulfate, and chloride are slightly soluble for free ammonia concentration above 30 g free NH_3/100 g solvent, nitrate, however, being considerably soluble even for free ammonia concentration of 35 g free NH_3/100 g solvent.

Part II. Thermal Decomposition of Ammine Complexes of Nickel(II)

Experimental

Preparation of Ammine Complexes of Nickel(II). Ammine complexes of nickel(II) except hexaamminenickel(II) complexes were prepared as follows. Tetraamminenickel(II) carbonate trihydrate: hexaamminenickel(II) carbonate tetrahydrate was left to stand in a desiccator under dilute ammoia atmosphere for at least 24 h. Monoamminenickel(II) carbonate monohydrate: hexaamminenickel(II) carbonate tetrahydrate was heated at 60 °C for 2 h. Pentaammine-

Apparatus. A Rigaku Denki Thermoflex high temperature type TG-DTA instrument was used for TG and DTA studies. Samples, 10—20 mg in weight, were pyrolyzed under a streaming nitrogen gas atmosphere. The flow rate of nitrogen gas was 40 ml/min. The heating rate of the furnace was 10 and 20 deg/min. Ignited alumina was used as a reference material in the DTA sample block. X-Ray diffraction patterns were recorded over the range $2\theta = 10$—60° with an X-ray diffractometer, Rigaku Denki Geigerflex, using nickel filtered Cu $K\alpha$ radiation at 30 kV and 15 mA as the X-ray diffraction source, with a 2°/min scanning speed, a 1 s time constant, a 1° divergency slit and 0.2 mm receiving slit.

Results and Discussion

Thermal Decomposition Process. The TG and DTA curves, in nitrogen, for hexaamminenickel(II) sulfate dihydrate and pentaamminenickel(II) sulfate monohydrate are shown in Fig. 3.

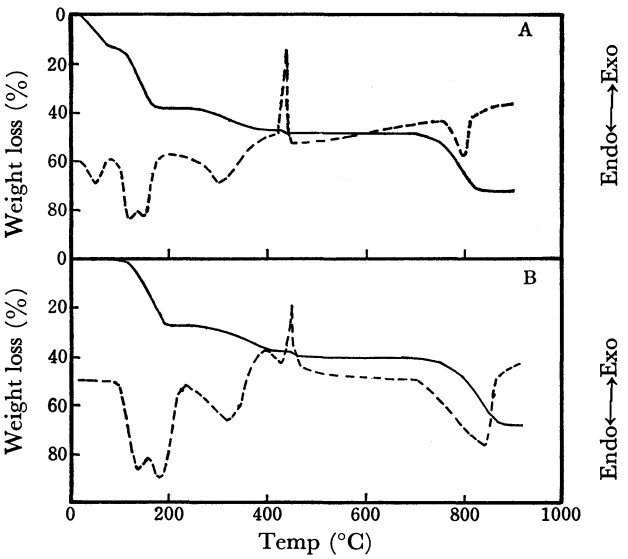

Fig. 3. TG and DTA curves of hexaamminenickel(II) sulfate dihydrate and pentaamminenickel(II) sulfate monohydrate under a nitrogen gas atmosphere.
A: $[Ni(NH_3)_6]SO_4 \cdot 2H_2O$, B: $[Ni(NH_3)_5]SO_4 \cdot H_2O$, flow rate of nitrogen gas: 40 ml/min, heating rate of furnace (deg/min)—A: 10, B: 20, amount of sample (mg)—A: 13.4, B: 16.6, —: TG, ---: DTA.

Hexaamminenickel(II) sulfate dihydrate appears to decompose in five steps as follows:

(I) $[Ni(NH_3)_6]SO_4 \cdot 2H_2O \longrightarrow [Ni(NH_3)_6]SO_4 + 2H_2O$

(II) $[Ni(NH_3)_6]SO_4 \longrightarrow [Ni(NH_3)_2]SO_4 + 4NH_3$

(III) $[Ni(NH_3)_2]SO_4 \longrightarrow [Ni(NH_3)_{0.5}]SO_4 + 1.5NH_3$

(IV) $[Ni(NH_3)_{0.5}]SO_4 \longrightarrow NiSO_4 + 0.5NH_3$

(V) $NiSO_4 \longrightarrow NiO + SO_2 + (1/2)O_2$

The complex, $[Ni(NH_3)_6]SO_4 \cdot 2H_2O$, begins to decompose at room temperature and loses two moles of water of crystallization per mole of compound to form $[Ni(NH_3)_6]SO_4$ up to 80 °C. The second step, corresponding to the loss of four moles of ammonia per mole of compound, begins immediately after the first step at *ca.* 80 °C, showing a definite break in the TG curve at *ca.* 180 °C. The third step of the decomposition results in the gradual loss of one and half moles of ammonia per mole of compound up to 350 °C. The fourth step of the decomposition begins at *ca.* 350 °C to gradually form $NiSO_4$ up to 450 °C. $NiSO_4$ begins to decompose at *ca.* 650 °C, resulting in the formation of NiO up to 820 °C. Endothermic peaks in the DTA curve at

50, 120—140, 300, 426, and 790 °C seem to correspond to steps I, II, III, IV, and V, respectively. The following studies have been performed on the thermal decomposition process of hexaamminenickel(II) sulfate.

(1) Paris:[8] $[Ni(NH_3)_6]SO_4 \longrightarrow [Ni(NH_3)_2]SO_4 \longrightarrow [Ni(NH_3)]SO_4 \longrightarrow [Ni(NH_3)_{0.5}]SO_4 \longrightarrow NiSO_4$

(2) Ephraim:[9] $[Ni(NH_3)_6]SO_4 \longrightarrow [Ni(NH_3)_4]SO_4 \longrightarrow [Ni(NH_3)_2]SO_4 \longrightarrow [Ni(NH_3)]SO_4 \longrightarrow [Ni(NH_3)_{0.5}]SO_4 \longrightarrow NiSO_4$

(3) Viltange:[10] $[Ni(NH_3)_6]SO_4 \xrightarrow{80-230\,^\circ C} [Ni(NH_3)_2]SO_4 \xrightarrow{230-350\,^\circ C} [Ni(NH_3)_{0.5}]SO_4 \xrightarrow{350-450\,^\circ C} NiSO_4$

(4) George and Wendlandt:[7] $[Ni(NH_3)_6]SO_4 \xrightarrow{100-190\,^\circ C} [Ni(NH_3)_2]SO_4 \xrightarrow{190-500\,^\circ C} NiSO_4$

Our results agree with the thermal decomposition process given by Viltange,[10] although the temperature we obtained for DTA peaks is lower by 10—20 degrees. A sharp exothermic peak in the DTA curve at 420—440 °C does not seem to have been reported so far.

Pentaamminenickel(II) sulfate monohydrate appears to decompose in four steps. The first step begins at *ca.* 110 °C, showing a definite break in the TG curve at *ca.* 180 °C. The weight loss up to this point corresponds to the loss of three moles of ammonia and one mole of water of crystallization per mole of compound. The thermal decomposition proceeds afterward in a similar manner to that after the third step of hexaamminenickel(II) sulfate dihydrate. The reason why the peaks in DTA curve of pentaamminenickel(II) sulfate monohydrate are situated at higher temperature region than those of hexaamminenickel(II) sulfate dihydrate seems to be due to the fact the heating rate of the furnace in the thermal decomposition of the former is faster than that of the latter.

Figure 4 shows the results of the thermal decomposition of hexaamminenickel(II) nitrate and carbonate tetrahydrate and tetraamminenickel(II) carbonate trihydrate. Tetraamminenickel(II) carbonate trihydrate and monoamminenickel(II) carbonate monohydrate (Table 6) are formed by the isothermal decomposition of hexaamminenickel(II) carbonate tetrahydrate at room temperature under a dilute ammonia atmosphere and at 60 °C in the air, respectively. Hexaamminenickel(II) carbonate tetrahydrate appears to decompose in five steps as follows:

(I) $[Ni(NH_3)_6]CO_3 \cdot 4H_2O \longrightarrow [Ni(NH_3)_4]CO_3 \cdot 3H_2O + 2NH_3 + H_2O$

(II) $[Ni(NH_3)_4]CO_3 \cdot 3H_2O \longrightarrow [Ni(NH_3)]CO_3 \cdot H_2O + 3NH_3 + 2H_2O$

(III) $[Ni(NH_3)]CO_3 \cdot H_2O \longrightarrow [Ni(NH_3)]CO_3 + H_2O$

(IV) $[Ni(NH_3)]CO_3 \longrightarrow NiCO_3 + NH_3$

(V) $NiCO_3 \longrightarrow NiO + CO_2 + (1/2)O_2$

Although no clear distinction is found between the first step and the second step from the TG curve, the

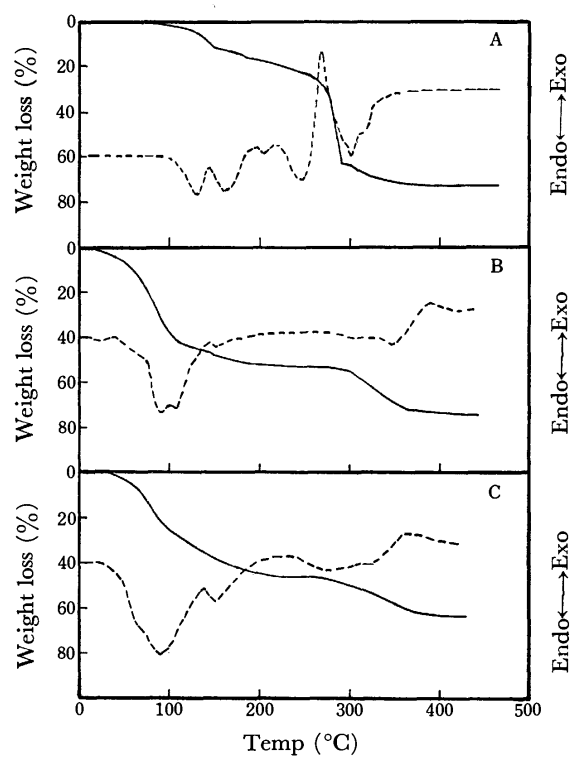

Fig. 4. TG and DTA curves of hexaamminenickel(II) nitrate and carbonate tetrahydrate and tetraamminenickel(II) carbonate trihydrate under a nitrogen gas atmosphere.
A: $[Ni(NH_3)_6](NO_3)_2$, B: $[Ni(NH_3)_6]CO_3 \cdot 4H_2O$, C: $[Ni(NH_3)_4]CO_3 \cdot 3H_2O$, flow rate of nitrogen gas: 40 ml/min, heating rate of furnace (deg/min)—A, B: 10, C: 20, amount of sample (mg)—A: 13.6, B: 16.6, C: 15.6, —: TG, ---: DTA.

complex, $[Ni(NH_3)_6]CO_3 \cdot 4H_2O$, seems to decompose *via* the complex, $[Ni(NH_3)_4]CO_3 \cdot 3H_2O$, because two endothermic peaks are found in the DTA curve at a temperature between 25 and 140 °C, and because $[Ni(NH_3)_4]CO_3 \cdot 3H_2O$ is produced from $[Ni(NH_3)_6]CO_3 \cdot 4H_2O$ at room temperature under a dilute ammonia atmosphere and is comparatively stable. Namely, $[Ni(NH_3)_6]CO_3 \cdot 4H_2O$ begins to decompose at room temperature and becomes $[Ni(NH_3)]CO_3 \cdot H_2O$ up to 140 °C *via* $[Ni(NH_3)_4]CO_3 \cdot 3H_2O$. The third step, corresponding to the loss of remaining water of crystallization, begins immediately after the second step at 140 °C to form $[Ni(NH_3)]CO_3$ up to 220 °C. The fourth step of the decomposition results in the gradual loss of remaining ammonia with the formation of $NiCO_3$ up to 300 °C. The fifth decomposition step begins at *ca.* 300 °C and results in abrupt weight loss with the formation of NiO up to 400 °C. The endothermic peaks in DTA curve at 95, 105, 153, and 345 °C seem to correspond to steps I, II, III, and IV, respectively.

The decomposition of tetraamminenickel(II) carbonate trihydrate seems to proceed in four steps. The first step of the decomposition begins at *ca.* 40 °C, showing a definite break in the TG curve at *ca.* 140 °C. The weight loss up to this point corresponds to the loss of three moles of ammonia and two moles of water of crystallization per mole of compound. The next steps

are similar to the processes after the third step of hexaamminenickel(II) carbonate tetrahydrate.

Hexaamminenickel(II) nitrate seems to decompose in three steps as follows:

$$\text{(I)}\quad [Ni(NH_3)_6](NO_3)_2 \longrightarrow [Ni(NH_3)_4](NO_3)_2 + 2NH_3$$

$$\text{(II)}\quad [Ni(NH_3)_4](NO_3)_2 \longrightarrow [Ni(NH_3)_{2.5}](NO_3)_2 + 1.5NH_3$$

$$\text{(III)}\quad [Ni(NH_3)_{2.5}](NO_3)_2 \longrightarrow NiO$$

The complex $[Ni(NH_3)_6](NO_3)_2$ begins to decompose at *ca.* 80 °C, showing a definite break in the curve at *ca.* 145 °C. The weight loss up to this point corresponds to the loss of two moles of ammonia per mole of compound. The second step begins immediately after the first step, losing one and half moles of ammonia per mole of compound up to 200 °C. The third step of the decomposition results in the abrupt weight loss with the formation of NiO at *ca.* 380 °C. Endothermic peaks at 140 and 160 °C, and exothermic peak at 250 °C seem to correspond to steps I, II, and III, respectively. George and Wendlandt[7] indicated that the ratio of evolved ammonia to nickel up to 180 °C is 2.76: 1. However, the ratio of that up to 200 °C has been found to be 3.5: 1 in the present study. Since the third step of the decomposition does not seem to be a single elementary reaction and is difficult to analyze, the detailed mechanism of the reaction has not been clarified. George and Wendlandt[7] observed that only nitrogen, water and oxygen are present in the decomposition gases above 260 °C by mass spectrographic analysis, and considered that the reaction between nitrate and ammonia should proceed. This conclusion has been confirmed on the basis of the appearance of the large exothermic peak at 250 °C.

Kinetics. The methods of Freeman-Carroll[13] and Coats-Redfern[14] were used to study the kinetics. The methods can be used only when the reaction is a single elementary reaction. Thus the kinetics was studied only for the first and second steps of hexaamminenickel(II) nitrate decomposition, and the third and the fifth steps of hexaamminenickel(II) sulfate dihydrate decomposition. The formula of the Freeman-Carroll method can be written as

$$\Delta \log (dW/dt)/\Delta \log W_r = x - E\Delta(1/T)/2.303RT(\Delta \log W_r), \quad (1)$$

where dW/dt is the weight change in mg·per minute, x the order of the reaction, T the absolute temperature and $W_r = W - W_c$, where W is the weight (mg) at time T, and W_c the weight (mg) of the sample at the end of the reaction. E is the energy of activation. If the plot of the ratio $\Delta \log (dw/dt)/\Delta \log W_r$ values *vs.* $\Delta(1/T)/\log W_r$ lie on a straight line, the activation energy and the reaction order will be given by its slope and intercept, respectively. This is illustrated in Figs. 5 and 6 for the decomposition of hexaamminenickel(II) nitrate and sulfate dihydrate, respectively.

The formula of the Coats-Redfern method can be written as

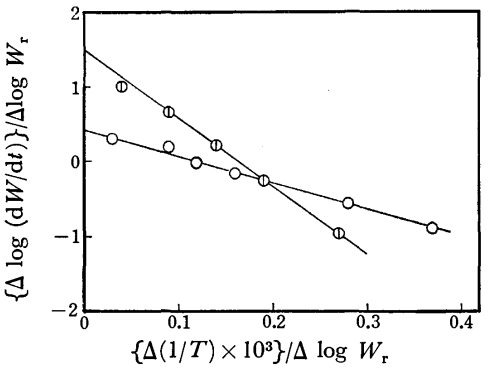

Fig. 5. Freeman-Carroll straight line for the I and II steps of hexaamminenickel(II) nitrate decomposition.
-○-: Step I, -◑-: Step II.

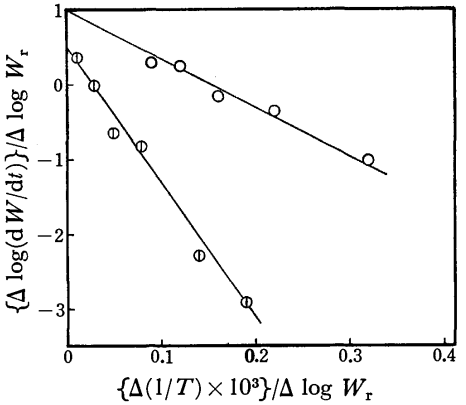

Fig. 6. Freeman-Carroll straight line for the III and V steps of hexaamminenickel(II) sulfate dihydrate decomposition.

sentation of the $\log\{1-(1-\alpha)^{1-x}/(1-x)\,T^2\}$ or $\log\{-\log(1-\alpha)/2.303T^2\}$ values as a function of $1/T$ gives a straight line of slope $-E/2.303R$ for the correct value of x. This is illustrated in Figs. 7 and 8 for the decomposition of hexaamminenickel(II) nitrate and sulfate dihydrate, respectively. The results are given in Table 7.

X-Ray Diffraction Data for Nickel(II) Ammine Complexes Powders. X-Ray diffraction data of four kinds of nickel(II) ammine complexes powders are given in Table 8. Hexaamminenickel(II) carbonate tetrahydrate and sulfate dihydrate decompose so rapidly in the air even at room temperature that their X-ray diffraction data have not been investigated.

This study is a part of studies on *Gasification of Coals Treated with Non-aqueous Solvents* being carried out by Coal Gasification Research Group (representative, Prof. Y. Tamai) in the Chemical Research Institute of Non-aqueous Solutions, Tohoku University. The object of the study is the recovery of nickel used as a catalyst in the coal gasification process.

Kinetic Studies of the Aluminium Acetate Complex Formation Reaction in Aqueous Solutions by the Pressure-Jump Method

Michinori HIRAISHI,* Shoji HARADA,** and Tatsuya YASUNAGA**

Department of Chemistry, Faculty of Education, Miyazaki University, Funatsuka, Miyazaki 880
***Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730*

(Received December 26, 1977)

The pressure-jump method was applied to aqueous solutions of aluminium acetate. Relaxation effects were observed in ms and s regions. Both relaxation times depend a great deal on the pH of solution. They were ascribed to the following complex formation reactions.

$$Al^{3+} \underset{Ac^-}{\overset{\text{slow}}{\rightleftharpoons}} AlAc^{2+} \underset{Ac^-}{\overset{\text{fast}}{\rightleftharpoons}} AlAc_2^+$$

Detailed studies on the fast relaxation effect revealed that the hydrolyzed ionic species accelerate the overall reaction. The mechanism of the fast reaction was discussed, the kinetic parameters being obtained.

The relaxation method mainly developed by Eigen *et al.*[1] has made it possible to study kinetically the fast metal complex formation reaction. Considerable kinetic information now exists on the complexations of metal ions with organic and inorganic ligands.[2,3] Many relaxation phenomena can be interpreted by the step-by-step association picture.

On the complexation of aluminium ion, a few kinetic studies have so far been reported, such as pressure-jump studies of aluminium sulfate[4,5] and aluminium ferricyanide.[6] The present study was undertaken in order to obtain kinetic information on the complex formation reaction of aluminium ion with acetate ion by means of the pressure-jump method at different concentrations, acidities and temperatures.

Experimental

Chemicals of reagent grade were used without purification. A stock solution of aluminium acetate was prepared by mixing a stoichiometric amount of $Al_2(SO_4)_3$ with barium acetate and removing the $BaSO_4$ produced by centrifugation. Barium acetate was prepared by neutralizing acetic acid with $Ba(OH)_2$. The concentration of aluminium in the resulting solution was gravimetrically determined by means of oxine precipitation. Each solution was prepared by diluting the standard solution with an acetic acid solution of known concentration to the desired concentration and pH. No supporting electrolyte was added in order to avoid a decrease in relaxation amplitude.

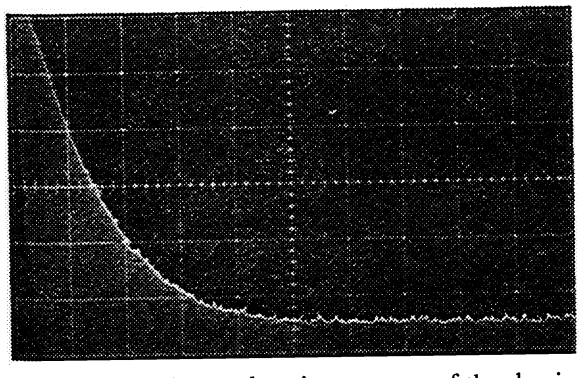

Fig. 1. Pressure-jump relaxation spectrum of the aluminium acetate system at 25 °C: $\sum Al = 2.46 \times 10^{-3}$ M, $\sum Ac = 0.105$ M, pH=3.76; sweep 20 ms/div.

The measurement of the relaxation effect was carried out by pressure-jump technique with a conductivity readout. A representative relaxation spectrum in ms region is shown in Fig. 1. The apparatus realizes a pressure jump of about 100 atm within 100 μs.[7] The temperature of the sample was controlled to ±0.1 °C by circulating thermostated water around the pressure-jump cell.

Results and Discussion

Two relaxation phenomena were observed in all the aluminium acetate solutions: a fast reaction with ms order time constant and a slow reaction with s order time constant. Both relaxation times depend a great deal on the pH of the solution.

In the blank test, neither $Al(NO_3)_3$ nor acetic acid aqueous solution showed relaxation phenomena under the same experimental conditions and in the same time region. This indicates that the relaxation effects observed in the aluminium acetate system can be ascribed to the complex formation reaction of aluminium ion with acetate ion, and are not directly associated with either the hydrolysis reaction of aluminium ion or the dissociation reaction of acetic acid.

In comparison with the rate constants of the water exchange reaction of aluminium ion measured by NMR[8,9] and those of the complex formation reaction of other aluminium complexes,[4-6] the relaxation effects observed in the present experiment are attributed to the following reactions.

$$Al^{3+} \underset{Ac^-}{\overset{\text{slow}}{\rightleftharpoons}} AlAc^{2+} \underset{Ac^-}{\overset{\text{fast}}{\rightleftharpoons}} AlAc_2^+ \qquad (1)$$

Two series of measurements were performed: (i) variation of pH by the addition of acetic acid, the total concentration of aluminium being kept constant (Table 1) and (ii) variation of the total concentrations of aluminium and acetic acid, the pH being kept at 3.76 (Table 2). The reciprocal relaxation times represent an average of at least four runs, the maximum errors being less than ±10%.

In the present study, the following equilibria are assumed to be present.

$$Al^{3+} + Ac^- \overset{K_1}{\rightleftharpoons} AlAc^{2+} \qquad (2)$$

$$AlAc^{2+} + Ac^- \overset{K_2}{\rightleftharpoons} AlAc_2^+ \quad (3)$$

$$Al^{3+} + H_2O \overset{K_3}{\rightleftharpoons} AlOH^{2+} + H^+ \quad (4)$$

$$AlOH^{2+} + Ac^- \overset{K_4}{\rightleftharpoons} Al(OH)Ac^+ \quad (5)$$

$$HAc \overset{K_5}{\rightleftharpoons} Ac^- + H^+ \quad (6)$$

In order to analyze the kinetic data and elucidate the reaction mechanism, it is necessary to evaluate the equilibrium concentrations of each ionic species in solution. For this purpose, the equilibrium constants of Eqs. 2—6 should be known. However, no stability constants of aluminium acetate complexes are found in literature. The equilibrium constants of equilibria 2 and 3 were evaluated to be the same as those of the propionate ligand,[10] *i.e.*, $K_1=60$ M^{-1} and $K_2=43$ M^{-1}. The other equilibrium constants were taken from literature as follows. $K_3=10^{-5.0}$ M,[11] $K_4=10^{2.4}$ M^{-1} [12] and $K_5=10^{-4.7}$ M.[13] The result of calculations revealed that the concentrations of the hydrolyzed species $AlOH^{2+}$ and $Al(OH)Ac^+$ are very small as compared to those of unhydrolyzed complex ions and can be neglected.

If we take account of the fact that the relaxation times in the present system depend a great deal on the concentration of the hydrogen ion, the overall mechanism of Eq. 3 can be expressed by the following reaction scheme.

$$\begin{array}{ccccc} & & HL & & \\ & & +H\uparrow\downarrow -H\ K_5 & & \\ L+LM & \overset{K_{12}}{\rightleftharpoons} & LMO\begin{matrix}H\\ \diagup\\ \diagdown\\ H\end{matrix}L & \overset{k_{23}}{\underset{k_{32}}{\rightleftharpoons}} & ML_2 \\ +H\uparrow\downarrow -H & & +H\uparrow\downarrow -H & & +H\uparrow\downarrow -H \\ L+LM(OH) & \overset{K_{45}}{\rightleftharpoons} & LM(OH)O\begin{matrix}H\\ \diagup\\ \diagdown\\ H\end{matrix}L & \overset{k_{56}}{\underset{k_{65}}{\rightleftharpoons}} & L_2M(OH) \end{array} \quad (7)$$

where L is the ligand (=acetate ion), LM the metal complex ion (=$AlAc^{2+}$), K_{12} and K_{45} are the outer-sphere complex formation constants.

All the vertical steps are protolytic reactions and very fast, while in the horizontal steps the outer-sphere complex formation reactions (①⇌② and ④⇌⑤) are fast as compared to the inner-sphere complex formation reactions. Thus, the reactions within the coordination sphere (②⇌③ and ⑤⇌⑥) are the rate-determining steps of the complex formation. The reciprocal relaxation time for this system, then, is given by

$$\tau^{-1} = A(k_{32} + k_{65}K_{36}/C_H), \quad (8)$$

where K_{36} is the hydrolysis constant of inner-sphere complex and

$$A = 1 + K_{23}\cdot\frac{K_{12}\{C_{LM}/(1+\alpha)+C_L\}}{1+K_{12}\{C_{LM}/(1+\alpha)+C_L\}}, \quad (9)$$

with

$$\alpha = \frac{C_H}{K_5 + C_L}. \quad (10)$$

From calculation of ionic concentrations, α was found to be smaller than unity under the present experimental conditions. Thus, Eq. 9 becomes

$$A = 1 + K_{23}\cdot\frac{K_{12}(C_{LM}+C_L)}{1+K_{12}(C_{LM}+C_L)}. \quad (11)$$

In order to use this equation, the values of K_{23} and K_{12} should be known. K_{12} was estimated by means of the Fuoss equation.[14,15] K_{23} is related to K_{12} as regards

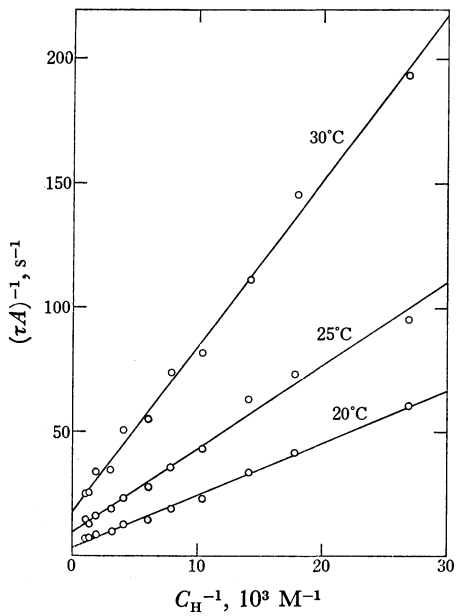

Fig. 2. $(\tau A)^{-1}$ *vs.* C_H^{-1} plot at various temperatures. $\sum$Al was kept constant to be 0.99×10^{-2} M.

the conventional stability constant K_2 as follows:

$$K_2 = K_{12}(1 + K_{23}). \quad (12)$$

In the pH variation measurement, the values of $(\tau A)^{-1}$ are plotted against C_H^{-1} to give k_{32} and $k_{65}K_{36}$ from the intercept and the slope of the line, respectively. Plots of values in Table 1 lie on straight lines for each temperature (Fig. 2). Taking into account the small variation of A, *i.e.*, 1.8—2.3, τ^{-1} depends predominantly on the concentration of the hydrogen ion and only slightly on those of other ionic species. Thus, k_{32} and $k_{65}K_{36}$ were obtained from Fig. 2 and k_{23} was calculated by means of the relation $K_{23}=k_{23}/k_{32}$. The values obtained are given in Table 3.

Table 3. Kinetic data for the aluminium acetate complex formation reaction of mechanism (7) at 25 °C and $\mu=0.03$

K_{12}	M^{-1}	2.9
K_{23}		13.9
k_{23}	s^{-1}	132
k_{32}	s^{-1}	9.5
$\Delta E_{32}^{\ddagger}$	kcal mol^{-1}	29.9
$\Delta H_{32}^{\ddagger}$	kcal mol^{-1}	29.3
$\Delta S_{32}^{\ddagger}$	cal deg^{-1} mol^{-1}	46.6
$k_{65}K_{36}$	$M\,s^{-1}$	0.0034

In the pH constant measurement, the terms in parenthesis of Eq. 8 remain constant, τ^{-1} being affected only by A. Under the present conditions of pH 3.76, the ratio of $k_{65}K_{36}/C_H$ to k_{32} was found to be 2.0 at 25 °C (Fig. 2). Applying this ratio to Eqs. 8 and 11, the following equation is obtained as an empirical formula at pH 3.76 and 25 °C:

$$\tau^{-1} = 3.0\left\{k_{32} + k_{23}\cdot\frac{K_{12}(C_{LM} + C_L)}{1 + K_{12}(C_{LM} + C_L)}\right\}. \quad (13)$$

The values of τ^{-1} in Table 2 are plotted against $K_{12}(C_{LM}+C_L)/\{1+K_{12}(C_{LM}+C_L)\}$ and are shown in Fig. 3. The intercept and the slope of the straight line gave k_{32} and k_{23} to be 7.4 and 112 s^{-1} respectively, K_{23} being calculated to be 15.0 by means of the relation $K_{23}=k_{23}/k_{32}$. The values are comparable to those in Table 3. The fact that the values of the rate constants obtained in two different measurements coincide approximately indicates that reaction mechanism 7 and the relaxation formulas are reasonable.

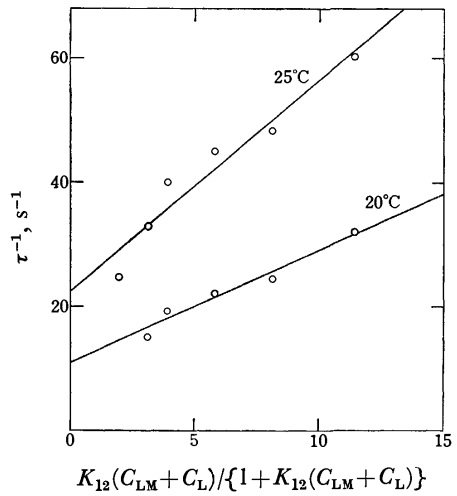

Fig. 3. τ^{-1} *vs.* $K_{12}(C_{LM}+C_L)/\{1+K_{12}(C_{LM}+C_L)\}$ plot at 25 °C. pH was kept constant to be 3.76.

In the aqueous solutions of aluminium ion and its complex ions, the rate constant of the coordinated water exchange, k_{H_2O}, has also been measured by means of NMR. The value of k_{H_2O} of Al^{3+} is about 1 s^{-1}, [8] smaller by a factor of 10^2 than that of k_{23}. This is why the slow relaxation effect was attributed to equilibrium 2 and the fast to equilibrium 3. Although k_{23} should be discussed in comparison with k_{H_2O} of $AlAc^{2+}$ ion, the value of the latter has not been found in literature. In the DMF solutions of Al^{3+} and $Al(acac)^{2+}$, the rate constants of the coordinated solvent molecule exchange have been reported. The value of $Al(acac)^{2+}$ [16] is accelerated by a factor of 10^2 as compared to that of Al^{3+}. [17] This increment may be caused by the instabilization of the coordinated solvent molecule owing to the electrostatic charge effect. Applying the same idea to the aqueous solution system of aluminium acetate, the value of k_{23} may be recognized as the rate constant of the coordinated water exchange of $AlAc^{2+}$.

The temperature dependence of the rate constants, k_{32}, gave the Arrhenius energy of activation, $\Delta E_{32}^{\ddagger}$, enthalpy of activation, $\Delta H_{32}^{\ddagger}$, and entropy of activation, $\Delta S_{32}^{\ddagger}$ (Table 3).

It is predicted that the slow relaxation effect in the present observation can be ascribed to the reaction of equilibrium 2.

Trimethylenediamine Complexes. V.[1] Preparative and Kinetic Studies on the Reactions of (Ethylenediamine)tetranitro- and Tetranitro(trimethylenediamine)-cobaltates(III) with Several Nucleophiles

Yoshiaki Ito and Shinichi Kawaguchi*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received January 9, 1978)

Substitution reactions of a nitrite ligand in $Co(NO_2)_4(en \text{ or } tn)^-$ with NH_3, py, N_3^-, and NCS^- have been investigated. The product trinitro complexes were isolated and their geometrical structures were assigned on the basis of NMR data. The preparation method for the two conformational isomers of *mer*-$Co(NO_2)_3NH_3(en)$ was established. The kinetic data of substitution with azide were analyzed according to the **D** mechanism. The relative nucleophilicity of ligands towards $Co(NO_2)_3(AA)$ is in the order: $OH^- \gg N_3^- > NO_2^-$, CH_3COO^-, $NCS^- \gg H_2O > Cl^-$, I^-. Dinitro complexes, $[Co(NO_2)_2(phen)(en \text{ or } tn)]NO_2 \cdot H_2O$ and $K[Co(NO_2)_2(ox)(tn)]$ were also prepared.

In a previous paper[1] the acid and base hydrolysis reactions of (diamine)tetranitrocobaltates(III), $Co(NO_2)_4(AA)^-$, where AA is ethylenediamine (en) or trimethylenediamine (tn), were reported to proceed *via* the **D** mechanism with $Co(NO_2)_3(AA)$ as a common intermediate, and the relative reactivity towards the five-coordinate intermediate was found to be in the order: $OH^- \gg NO_2^- \gg H_2O$. The present paper is concerned with preparation and characterization of $Co(NO_2)_3X(AA)$ ($X = NH_3$, py, N_3^-, or NCS^-) and other related complexes, and also with competitive reactions of some nucleophiles with $Co(NO_2)_3(AA)$.

Experimental

Preparation of Complexes. Potassium Tetranitro(ethylenediamine or trimethylenediamine)cobaltate(III), K[Co(NO$_2$)$_4$(AA)]: These complexes were prepared by the literature method[2] and recrystallized twice from water–methanol. The trimethylenediamine complex was obtained as a hemihydrate in a 46% yield.[1]

Trinitro(pyridine)(ethylenediamine or trimethylenediamine)cobalt(III), Co(NO$_2$)$_3$(py)(AA): In an aqueous solution (20 ml) $K[Co(NO_2)_4(en)]$ (1.0 g) was allowed to react with pyridine (0.25 ml) at 60 °C for 1 h. The mixture was then cooled with ice–water and a precipitate (monohydrate) was filtered and washed with methanol. The yield was 19% (0.2 g). The tn complex (anhydrous) was also obtained by a similar reaction at 60 °C for 30 min in a 42% (0.4 g) yield.

The Yellow Form and Brown Form of Ammine(ethylenediamine)-trinitrocobalt(III), Co(NO$_2$)$_3$NH$_3$(en): To a solution (20 ml) of $K[Co(NO_2)_4(en)]$ (1 g) was added 28% aqueous ammonia (0.41 ml) and the mixture was stirred at 60 °C. After *ca.* 45 min white amorphous powder began to deposit on the wall around the liquid surface. On further heating yellow crystallites gradually increased. After reaction for about 2 h the mixture was cooled with ice. The precipitate was filtered and washed with methanol. The yield was 25% (0.2 g).

When the above reaction mixture was cooled with ice before the white powder appeared, a brown precipitate was produced, which was filtered and washed with methanol. The yield was also 25% (0.2 g).

Amminetrinitro(trimethylenediamine)cobalt(III), Co(NO$_2$)$_3$NH$_3$(tn): The reaction of $K[Co(NO_2)_4(tn)] \cdot 1/2H_2O$ with ammonia in the same composition as above at 60 °C for about 20 min afforded a yellow precipitate. Only one kind of product was obtained in a 38% (0.3 g) yield in this case.

Potassium Azido(ethylenediamine)trinitrocobaltate(III), K[Co(NO$_2$)$_3$(N$_3$)(en)]: $K[Co(NO_2)_4en]$ (1 g) was allowed to react with sodium azide (0.19 g) in aqueous solution (55 ml) at 60 °C for 75 min. After cooling in ice–water, potassium iodide (*ca.* 5 g) was added to the solution, and a small amount of precipitate was filtered. Ethanol (*ca.* 10 ml) was added to the filtrate, and the solution was kept in a refrigerator for several days. Crude crystals of Isomer A (0.3 g) was separated and recrystallized from methanol–water (5: 1) in a refrigerator (below 0 °C). The final yield was 8% (0.08 g).

After the prolonged reaction in aqueous solution (25 ml) at 60 °C for 2 h and addition of potassium iodide at 0 °C as described above, an equal volume (*ca.* 25 ml) of methanol was added to the solution and the mixture was kept in a refrigerator overnight. A red powder (0.1 g), which gave Isomer A on recrystallization, was filtered and the filtrate was kept in a refrigerator for 2—3 months to deposit dark red crystals of Isomer B, which were separated and washed with methanol. The yield was 35% (0.35 g).

Potassium Azidotrinitro(trimethylenediamine)cobaltate(III) K[Co(NO$_2$)$_3$N$_3$(tn)]: In aqueous solution (15 ml) at 60 °C $K[Co(NO_2)_4(tn)] \cdot 1/2H_2O$ (1.0 g) was allowed to react with sodium azide (0.18 g) for 20 min. After filtration, potassium iodide (*ca.* 0.5 g) was added to the filtrate followed by 15 ml of methanol and the mixture was kept in a refrigerator for a week. A dark red precipitate was recrystallized from methanol–water (5: 1 by volume). The final yield was 19% (0.2 g) and the compound was analyzed to contain two molecules of lattice water and proved to be a mixture of fac and mer isomers (Table 2). When the filtrate, which had been separated from the crude reaction product, was kept in a refrigerator for a few weeks, dark red crystals deposited on the glass wall in a 10% yield (0.1 g). This specimen was a monohydrate of the mer isomer as will be described in Results. Then the separation of a mixture of the geometrical isomers was tried. A solution of $K[Co(NO_2)_3N_3(tn)] \cdot 2H_2O$ was passed through a column ($\phi 1 \times 10$ cm) containing an anion exchanger QAE-Sephadex A-25 which was cooled by ice–water circulating in a jacket. Two adsorbed bands were observed and eluted with an aqueous solution (0.4 mol·l^{-1}) of sodium chloride. The early portion of eluates containing the lower band showed an absorption spectrum which is identical with that of $K[Co(NO_2)_3N_3(tn)] \cdot H_2O$, and is concluded to be the mer isomer. The upper adsorbed band may be attributed to the fac isomer and showed an absorption maximum at 470 nm with $\varepsilon = 380$ l·mol^{-1}·cm^{-1}. The cobalt content in the eluate was deter-

mined by the photochemical reduction to cobalt(II) followed by the spectrophotometric analysis of the latter as the tetrakis (isothiocyanato)cobaltate(II) complex.[3]

Potassium Isothiocyanatotrinitro(trimethylenediamine)cobaltate(III) Monohydrate, $K[Co(NO_2)_3NCS(tn)]\cdot H_2O$: The reaction of $K[Co(NO_2)_4(tn)]\cdot 1/2H_2O$ (0.5 g) with potassium thiocyanate (0.133 g) in aqueous solution (20 ml) at 60 °C was conducted for 15—20 min. To the solution cooled in ice–water was added potassium iodide (*ca.* 5 g) followed by an equivolume of methanol and the mixture was kept in a refrigerator for 2—3 days to precipitate small reddish plates in a 15% (0.08 g) yield.

Dinitro(1,10-phenanthroline)(ethylenediamine or trimethylenediamine)cobalt(III) Nitrite Monohydrate, $[Co(NO_2)_2(phen)(AA)]NO_2\cdot H_2O$: To an aqueous solution (20 ml) of $K[Co(NO_2)_4(AA)]$ (1 g) at 60 °C was added a small quantity of methanol solution containing 1,10-phenanthroline (0.579 g) and the mixture was stirred for about 5 min to deposit red-brown (AA=en) or brown (AA=tn) crystals in a 60% (0.8 g) or a 70% (0.9 g) yield, respectively.

Potassium Dinitro(oxalato)(trimethylenediamine)cobaltate(III), $K[Co(NO_2)_2(ox)(tn)]$: A solution (20 ml) of oxalic acid (2 g) was added to a suspension of $K[Co(NO_2)_4(tn)]\cdot 1/2H_2O$ (5 g) in water (30 ml), and the mixture was kept at 60 °C under reduced pressure to vaporize the solvent. The concentrate was filtered during hot and the filtrate was kept standing at room temperature. The product was filtered and recrystallized from water containing potassium nitrite. The method is an extension of that used for preparation of the corresponding en complex,[4] and the yield was 4% (0.2 g) in the present tn case.

Measurements. The hydrogen ion activity in solution was determined by means of a Beckman "Century" SS-1 pH meter with a Beckman 39301 glass electrode and a Beckman 39400 calomel electrode, and converted to the hydrogen ion concentration by virtue of the activity coefficient $f_H=0.83$ at 25 °C and $\mu=0.1$.[5] Absorption spectra were recorded on a Hitachi EPS-3T spectrophotometer and NMR spectra on a JEOL C-60HL with tetramethylsilane as an internal reference. IR spectra were measured in Nujol with JASCO IR-E (4000—600 cm^{-1}) and Hitachi EPI-L (700—200 cm^{-1}) Infrared Spectrophotometers.

The kinetic measurement was performed by the spectrophotometric method. In a dark measuring flask were placed desired amounts of a sodium nitrite solution and a NaX solution ($X^-=Cl^-$, I^-, N_3^-, NCS^-, or CH_3COO^-). Solutions of perchloric acid and sodium perchlorate were added to the mixture to adjust pH and maintain the ionic strength at 0.1. Into the flask kept in a thermostat at 25 °C was poured a solid specimen of $K[Co(NO_2)_4(AA)]$ by the help of thermostated pure water, and a 100 ml reaction mixture was made up. The complex was rapidly dissolved on agitation and the reaction started. Aliquots were pipetted at appropriate time intervals and spectra were recorded over the 400—550 nm region.

Results and Discussion

In order to examine the possibility of studying the competitive reactions of some nucleophiles with the five-coordinate species $Co(NO_2)_3(AA)$ postulated as an intermediate in the hydrolysis reactions of $Co(NO_2)_4(AA)^-$, the reaction products $Co(NO_2)_3X(AA)$ ($X=NH_3$, py, N_3^-, or NCS^-) and the related complexes $Co(NO_2)_2(BB)(AA)$ (BB=phen or an oxalate anion) were prepared (Table 1).

Characterization of Newly Prepared Complexes. $K[Co(NO_2)_3N_3(en)]$, A-form and B-form: As was described in Experimental section, two forms of the azido(ethylenediamine)trinitrocobaltate(III) were obtained. Each of them shows a single absorption maximum in the visible region in aqueous solution at 2 °C, but the exact position is a little different: A, $\lambda_{max}=466$ nm ($\varepsilon=508$); *B*, $\lambda_{max}=480$ nm ($\varepsilon=480$). The spectra in the ultraviolet region are also different: A, $\lambda_{max}=346$ ($\varepsilon=8.10\times10^3$) and 258 nm ($\varepsilon=1.59\times10^4$); B, $\lambda_{max}=316$ ($\varepsilon=1.09\times10^4$) and 259 nm ($\varepsilon=1.94\times10^4$). The most remarkable difference in the IR spectra is noticed on the $\delta(NH_2)$ band. A-form shows a broad band at 1574 cm^{-1}, while B-form two distinct bands at 1593 and 1571 cm^{-1}. Thus the two forms seem to constitute a couple of geometrical isomers, *viz.* facial and meridional, such as depicted in Fig. 1.

The chelate rings in both ethylenediamine and trimethylenediamine complexes are known to undergo a rapid interconversion among possible conformations

Table 1. Newly prepared complexes

Compound	Found (%)			Calcd (%)

a) The electronic spectra were measured in aqueous solutions at 2 °C, and NMR spectra in DMSO-d_6 at room temperature with TMS as an internal reference. b) Figures in parentheses show the relative area. c) Masked by the impurity band. d) NH_2 trans to the NO_2 ligand. e) NH_2 trans to the NH_3 ligand. f) Not stable in DMSO at room temperature.

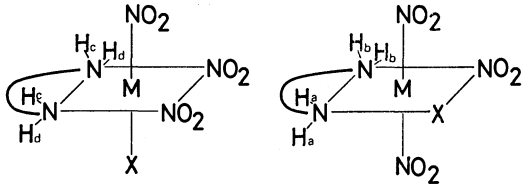

Fig. 1. Geometrical isomers of the $Co(NO_2)_3X(AA)$ complex.

in solution.[6)] Then both of the (diamine)tetranitrocobaltates(III) have a pseudo C_2 axis and the amine protons are all equivalent. However, the trinitro complex has a lower symmetry and the amine protons are no longer equivalent. In *mer*-$Co(NO_2)_3X(AA)$ one amine group occupies a site trans to a nitro ligand and the other to X. Different chemical shifts will be observed for $NH_2{}^a$ and $NH_2{}^b$ protons and the separation between them will depend on the nature of X.

In the case of *fac*-$Co(NO_2)_3X(AA)$ both amine groups are trans to the nitro ligands, but the magnetic environments of H^c and H^d are not strictly equal due to non-equivalence of the nitro and X ligands, although the difference in chemical shifts of the two type of protons will be smaller than in the mer form. Thus when a couple of the geometrical isomers are available, the proton NMR spectra will be helpful in identifying them.

As is listed in Table 2, the spectrum of A-form in DMSO-d_6 exhibits a broad band of amine protons at 4.06 ppm from TMS, whereas the amine signal of B-form shows two maxima at 4.19 and 4.25 ppm, suggesting that A-form is facial and B-form is meridional. Interconversion between the two forms cannot be studied since the complex is liable to hydrolysis and other ligand substitution reactions.

The corresponding tn complex, $K[Co(NO_2)_3N_3(tn)]\cdot 2H_2O$ seems to be a mixture of mer and fac isomers, since the amine protons show two resonances at 3.93 and 4.23 ppm with the area ratio of 1 : 2. The signals assignable to the $CH_2(\alpha)$ and $CH_2(\beta)$ protons in NH_2-$CH_2(\alpha)CH_2(\beta)CH_2(\alpha)NH_2$ also have two double maxima at 2.26, 2.32 ppm and 1.40, 1.46 ppm, respectively, maintaining the area ratio of 2 : 1. On the other hand the monohydrate species which separated from the mother liquor exhibits a simpler spectrum, the amine protons resonating at 3.93 and 4.23 ppm in the area ratio of 1 : 1 and the methylene protons at 2.26 and 1.40 ppm in the area ratio of 2 : 1. Then the monohydrate is considered to be meridional, and the fac isomer, which has not been isolated, may be responsible for the signals at 4.23 (NH_2), 2.32 (α-CH_2) and 1.46 (β-CH_2) ppm. These chemical shifts nearly coincide with those for $K[Co(NO_2)_3NCS(tn)]\cdot H_2O$.

$Co(NO_2)_3NH_3(en)$: The compound exists in two forms which have different crystal habits, colors and IR spectra in Nujol, but give identical absorption spectra in solution. Both of the brown and yellow forms were concluded by MacDermott and Barfoed[7a)] to be meridional on the basis of NMR spectra. This conclusion was ascertained by X-ray analysis.[8)] The essential difference is the conformations of the nitro groups, and the two forms were termed rotational or conformational isomers.

This interesting compound was prepared by other methods and a mixture of two forms in an unfixed ratio was obtained in each case.[7a)] The reproducible synthetic method to prepare each isomer exclusively has not been established.[7b)] Now it is possible to obtain either form selectively by controlling the temperature of crystallization. As was described in Experimental section, if a solution containing $K[Co(NO_2)_4(en)]$ and ammonia is kept at 60 °C to allow deposition of the product, the yellow form is obtained solely. On the other hand, when he reaction mixture is rapidly cooled with ice prior to deposition of crystallites, the brown form is produced exclusively. The yellow form looks more stable than

the brown form, and it is easier to convert the brown form into the yellow isomer than the opposite transformation in the recrystallization processes.

The corresponding tn complex, $Co(NO_2)_3NH_3(tn)$ was prepared under various conditions, but only one form has been isolated so far. The NMR spectra were assigned by reference to those of $Co(NO_2)_3NH_3(en)$,[7a] and the meridional structure is inferred.

K[Co(NO$_2$)$_3$NCS(tn)]·H$_2$O: The linkage isomerism displayed by the thiocyanate ion in metal complexes has been amply documented,[9] and IR spectra are utilized as the convenient and useful technique for structural assignments.[10] In the case of cobalt(III) complexes, $[CoNCS(NH_3)_5](ClO_4)_2$[11] and $K_3[CoNCS(CN)_5]$[12] exhibit broad ν(CN) bands at 2125 and 2065 cm^{-1}, and the ν(CS) bands at 806 and 810 cm^{-1}, respectively, whereas $[CoSCN(NH_3)_5](ClO_4)_2$[11] and $K_3[CoSCN(CN)_5]$[13] show sharp ν(CN) bands at 2100 and 2110 cm^{-1}, and weak ν(CS) bands at 710 and 719 cm^{-1}, respectively. In the IR spectrum of $K[Co(NO_2)_3NCS(tn)]\cdot H_2O$, a strong band at 2120 cm^{-1} assignable to the ν(CN) band is broad in the lower frequency side and a small peak at 825 cm^{-1} accompanying a sharp strong $\delta(NO_2)$ band at 835 cm^{-1} may be attributed to the ν(CS) vibration. Thus the thiocyanate ligand in $K[Co(NO_2)_3NCS(tn)]\cdot H_2O$ is considered to be N-bonded rather than S-bonded.

The NMR spectrum of this complex in DMSO-d_6 shows a single broad peak at 4.24 ppm which is ascribed to the amine protons, suggesting that the complex has a facial structure. The reaction of $K[Co(NO_2)_4(en)]$ with an equimolar amount of potassium thiocyanate in water has been carried out to prepare $K[Co(NO_2)_3NCS(en)]$, but a product of satisfactory purity has not yet been obtained.

Other Complexes: $[Co(NO_2)_3py(en)]\cdot H_2O$ shows a single peak of amine protons at 4.73 ppm and seems to have a facial structure. The corresponding tn complex is not stable enough in DMSO to allow the NMR measurement at room temperature. For the $CoX_2(AA)_2$ complexes too, the NMR spectra are usually most helpful in assigning the geometrical structure. The amine protons of a trans isomer will resonate as a single peak, whereas those of a cis isomer will exhibit two or more peaks.[14-16] Both of $[Co(NO_2)_2(phen)(en)]NO_2\cdot H_2O$ and $[Co(NO_2)_2(phen)(tn)]NO_2\cdot H_2O$, which were produced by the reactions of the tetranitro(diamine) complexes with 1,10-phenanthroline, show two broad bands attributable to the amine protons, and seem to have the cis structure. Recently properties of *cis*-$K[Co(NO_2)_2(ox)(en)]$ were reported by Ito and Shibata.[17] The structural assignment of $K[Co(NO_2)_2(ox)(tn)]$ now prepared is not unambiguous as yet.

In Table 2 are collected the absorption maxima (the first band) together with the NMR data. As was noted in previous papers,[18] the first band of each trimethylenediamine complex lies at a little longer wavelength side than that of the corresponding ethylenediamine complex, indicating that the ligand field of trimethylenediamine is weaker than that of ethylenediamine.

Kinetic Studies. The Reactions of (Diamine)tetranitrocobaltates(III) with Azide Ions: The absorption spectra in the 400—550 nm region of $K[Co(NO_2)_4(en)]$, $Co(NO_2)_3(H_2O)(en)$, *fac*- and *mer*-$K[Co(NO_2)_3N_3(en)]$ in aqueous solutions at 2 °C are displayed in Fig. 2. The spectral change accompanying the reaction of $Co(NO_2)_4(en)^-$ with excess azide ions exhibits two isosbestic points at 424 and 443 nm up to about 70% conversion. These two wavelengths correspond to the isosbestic points of $Co(NO_2)_4(en)^-$ and *fac*-$Co(NO_2)_3N_3(en)^-$, indicating that the facial isomer is primarily produced in this substitution reaction. The reaction was followed spectrophotometrically by measuring the

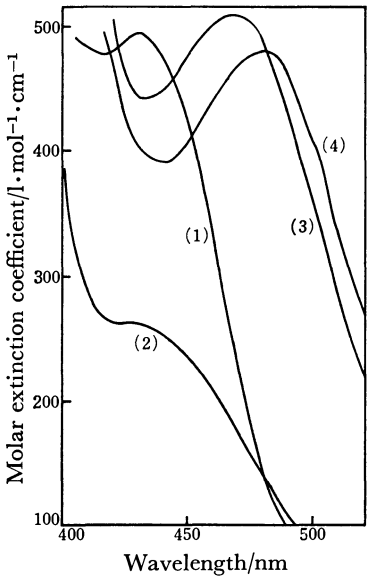

Fig. 2. The absorption spectra in the 400—550 nm region of $K[Co(NO_2)_4(en)]$ (1), $Co(NO_2)_3(H_2O)(en)$ (2), *fac*-$K[Co(NO_2)_3N_3(en)]$ (3), and *mer*-$K[Co(NO_2)_3N_3(en)]$ (4) in aqueous solutions at 2 °C.

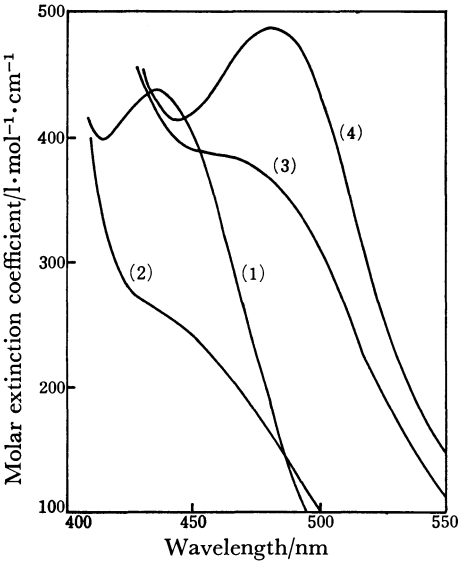

Fig. 3. The absorption spectra in the 400—550 nm region of $K[Co(NO_2)_4(tn)]\cdot 1/2H_2O$ (1), $Co(NO_2)_3(H_2O)(tn)$ (2), *fac*-$Co(NO_2)_3N_3(tn)^-$ (3), and *mer*-$K[Co(NO_2)_3N_3(tn)]\cdot H_2O$ (4) in aqueous solutions at 2 °C.

absorbance at 476 nm. The first order rate law was obeyed up to *ca.* 70% conversion in the presence of excess nitrite and azide ions.

Figure 3 shows the visible absorption spectra of *mer*-$K[Co(NO_2)_3N_3(tn)]\cdot H_2O$ and *fac*-$Co(NO_2)_3N_3(tn)^-$ which was isolated in solution, together with those of $K[Co(NO_2)_4(tn)]\cdot 1/2H_2O$ and $Co(NO_2)_3(H_2O)(tn)$. The change of spectrum accompanying the reaction of $Co(NO_2)_4(tn)^-$ with excess azide ions shows two isosbestic points at 432 and 452 nm up to *ca.* 80% conversion which coincide exactly with the isosbestic points of $Co(NO_2)_4(tn)^-$ and *fac*-$Co(NO_2)_3N_3(tn)^-$, revealing that the facial isomer of the trinitroazido complex is produced specifically in the case of the trimethylenediamine complex, too. The pseudo first order plot based on the absorbance at 484 nm also gives a good straight line through the duration of 80% reaction.

$$Co(NO_2)_4(AA)^- + N_3^- \xrightarrow{k_{obsd}} Co(NO_2)_3N_3(AA)^- + NO_2^- \quad (1)$$

The pseudo first order rate constants (k_{obsd}) of Reaction 1 decrease with increase in the nitrite ion concentration. According to the mechanism proposed in a previous paper,[1] the ligand substitution reactions of $Co(NO_2)_4(AA)^-$ should proceed *via* a five-coordinate intermediate.

$$Co(NO_2)_4(AA)^- \underset{k_{NO_2}}{\overset{k_{-NO_2}}{\rightleftharpoons}} Co(NO_2)_3(AA) + NO_2^- \quad (2)$$

$$Co(NO_2)_3(AA) + H_2O \underset{k_{-H_2O}}{\overset{k_{H_2O}}{\rightleftharpoons}} Co(NO_2)_3(H_2O)(AA) \quad (3)$$

$$Co(NO_2)_3(AA) + OH^- \xrightarrow{k_{OH}} Co(NO_2)_3(OH)(AA)^- \quad (4)$$

$$Co(NO_2)_3(AA) + N_3^- \xrightarrow{k_{N_3}} Co(NO_2)_3(N_3)(AA)^- \quad (5)$$

Since the isosbestic points of the tetranitro, and trinitroazido complexes are maintained in the present experimental conditions, the concentration of trinitroaqua complexes, of which spectra are included in Figs. 2 and 3, is negligible and the reverse step of Eq. 3 may be ignored. Assuming a steady state for $Co(NO_2)_3(AA)$, the pseudo first order rate constant of the azide complex formation may be expressed by

$$k_{obsd} = \frac{k_{-NO_2}k_{N_3}[N_3^-]}{k_{H_2O} + k_{OH}[OH^-] + k_{NO_2}[NO_2^-] + k_{N_3}[N_3^-]}, \quad (6)$$

which is transformed into Eq. 7.

$$\frac{k_{-NO_2}}{k_{obsd}} = 1 + \frac{k_{H_2O} + k_{OH}[OH^-]}{k_{N_3}[N_3^-]} + \frac{k_{NO_2}[NO_2^-]}{k_{N_3}[N_3^-]}. \quad (7)$$

In a previous paper,[1] the value of k_{-NO_2} was obtained as $(2.08\pm0.01)\times10^{-4}$ and $(9.27\pm0.03)\times10^{-4}$ s^{-1} for AA=en and tn, respectively, at 25 °C and μ=0.1. Thus, if k_{obsd} is determined at various nitrite concentrations with constant azide and hydrogen ion concentrations, the plot of k_{-NO_2}/k_{obsd} against the nitrite concentration will give a straight line with

$$\text{slope} = k_{NO_2}/k_{N_3}[N_3^-], \quad (8)$$

$$\text{intercept} = 1 + (k_{H_2O} + k_{OH}[OH^-])/k_{N_3}[N_3^-]. \quad (9)$$

In fact the observed rate data give rise to straight lines which are shown in Fig. 4. Since nitrite and azide ions were used in large excess as compared with the complex anions, the concentrations of added nitrite and azide, c_{NO_2} and c_{N_3}, were used for the calculation instead of $[NO_2^-]$ and $[N_3^-]$. From the slopes of the straight lines, the values of k_{NO_2}/k_{N_3} were calculated to be 0.65 ± 0.02 and 0.25 ± 0.04 for AA=en and tn, respectively, at 25 °C and μ=0.1.

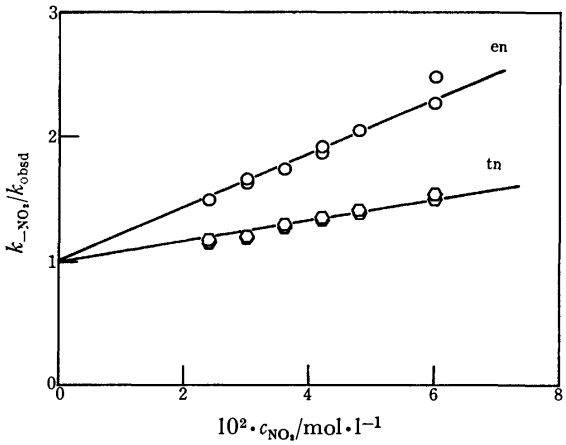

Fig. 4. The linear plots of rate data for the reaction (1) referring to Eq. 7: $c_M = 1.169\times10^{-3}$ mol·l^{-1} (in the case of AA=en) or 1.369×10^{-3} mol·l^{-1} (AA=tn), $c_{N_3} = 3.000\times10^{-2}$ mol·l^{-1}, pH=6.5—6.7, μ=0.1, 25 °C.

In Fig. 4 both of the two straight lines intercept the ordinate at 1.0, indicating that for both systems

$$(k_{H_2O} + k_{OH}[OH^-])/k_{N_3}[N_3^-] \ll 1. \quad (10)$$

In the studies on the hydrolysis reactions of $Co(NO_2)_4(AA)^-$, k_{H_2O}/k_{NO_2} was reported to be $(2.15\pm0.14)\times10^{-3}$ and $(1.79\pm0.13)\times10^{-2}$ mol·l^{-1} for AA=en and tn, respectively, at 25 °C and μ=0.1.[1] Thus $k_{H_2O}/k_{N_3} = (1.39\pm0.13)\times10^{-3}$ and $(4.4\pm1.0)\times10^{-3}$ mol·l^{-1} for AA=en and tn, respectively. The concentration of azide added, c_{N_3}, is 3×10^{-2} mol·l^{-1} and hence $k_{H_2O}/k_{N_3}[N_3^-]=0.046$ (AA=en) and 0.14 (AA=tn), nearly satisfying a part of Eq. 10.

Since pK_a of hydrazoic acid is 4.44 at 25 °C and μ=1 mol·l^{-1}($NaClO_4$),[19] pH of the reaction system was kept in the 6.5—6.7 region in order to prevent participation of HN_3, and thus contribution of the base hydrolysis (Eq. 4) must be taken into account. In the previous studies of hydrolysis,[1] k_{OH}/k_{NO_2} was estimated to be $\gg5\times10^3$ for both the en and tn systems. Now Eq. 10 gives the upper limit of k_{OH}. In order to satisfy Eq. 10, the condition $k_{OH}\leq0.1\ k_{N_3}[N_3^-]/[OH^-]$ must be met. Since $[N_3^-]/[OH^-]\fallingdotseq6\times10^5$ in the present experiments, $k_{OH}/k_{N_3}\leq6\times10^4$, leading to the estimation: $9.3\times10^4\geq k_{OH}/k_{NO_2}\gg5\times10^3$ for AA=en and $2.4\times10^5\geq k_{OH}/k_{NO_2}\gg5\times10^3$ for AA=tn. In this way the relative nucleophilicity of OH^-, NO_2^-, and N_3^- toward $Co(NO_2)_3(AA)$ is estimated as listed in Table 3 with reference to H_2O.

The Reactions of (Diamine)tetranitrocobaltates(III) with Other Nucleophiles: In the presence of excess nitrite and azide ions, substitution of a nitrite ligand in $Co(NO_2)_4(AA)^-$ with an azide ion seems to proceed to completion, although displacement of the second nitrite ligand

Table 3. Relative nucleophilicity of some ligands toward $Co(NO_2)_3(AA)$ at 25 °C and $\mu=0.1$

AA	H_2O	NO_2^-	N_3^-	OH^-
en	1	$(2.59\pm0.17)\times10^4$	$(4.02\pm0.37)\times10^4$	$\gg1.3\times10^8$ and $\leq2.4\times10^9$
tn	1	$(3.11\pm0.23)\times10^4$	$(1.25\pm0.29)\times10^4$	$\gg1.6\times10^7$ and $\leq7.8\times10^8$

contributes in a later stage of the reaction. On the contrary halide ions such as chloride and iodide cannot replace the nitrite ligand, but give rise to the aqua complex alone. The thiocyanate and acetate ions can compete with water and yields the trinitro(aniono) complex besides the trinitro(aqua) complex, but the quantitative competition ratios are not obtained. The relative nucleophilicity of ligands examined towards $Co(NO_2)_3(AA)$ is in the order: $OH^-\gg N_3^->NO_2^-$, CH_3COO^-, $NCS^-\gg H_2O>Cl^-$, I^-. The order coincides with that of the proton affinity of these ions (except the thiocyanate ion), suggesting that $Co(NO_2)_3(AA)$ is a hard acid.

The authors are grateful to Mr. J. Gohda for the elemental analysis and to Dr. T. Kinoshita for the NMR measurements. The financial aid by the Ministry of Education is also acknowledged.

Inter- and Intramolecular Rhodium-Rhodium Interactions in Bis-(bidentate isocyanide)rhodium(I) Hexafluorophosphates

Katsuhiko KAWAKAMI, Masaki OKAJIMA, and Toshio TANAKA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565,

(Received February 4, 1978)

The reaction of $[RhCl(1,5\text{-}C_8H_{12})]_2$ with the stoichiometric amount of bidentate isocyanide followed by metathesis affords complexes of the types $[Rh(L\text{–}L)_2]PF_6$ (L–L=$CN(CH_2)_8NC$ (**1**), $CN(CH_2)_7NC$ (**2**)) and $[Rh_2(L\text{–}L)_4](PF_6)_2$ (L–L=$CN(CH_2)_6NC$ (**3**), $CN(CH_2)_4NC$ (**4**)). The electronic spectra at various concentrations reveal that in dilute solutions **1** and **2** exist as monomers with chelating isocyanides, while **3** and **4** form dimers with bridging isocyanides through intramolecular rhodium–rhodium interactions as the smallest unit. On the other hand, in concentrated solutions **1** and **2** form dimers and **4** tetramers through intermolecular Rh–Rh interactions.

Much attention has been paid to one-dimensional inorganic complexes in order to synthesize materials of anisotropic electrical conductivity. One of the most promising compounds is square planar d^8 metal complexes, the representative example of which is $K_2Pt(CN)_4\cdot Br_{0.30}\cdot 3H_2O$.[1] In this respect tetrakis(isocyanide)rhodium(I) and -iridium(I) cations are interesting because of their deep coloration.[2] Actually they have been found to exhibit oligomerization in solution.[3–5] Rhodium(I) complexes containing monodentate isocyanides are well known,[2,6] however, studies are relatively sparse on those containing bidentate isocyanides.[5] This paper reports the synthesis of some rhodium(I) complexes coordinated by bidentate isocyanides, $CN(CH_2)_nNC$ (n=4, 6, 7, or 8) and their electronic spectra, which reveal the presence of rhodium–rhodium interactions in these complexes in solution.

Experimental

Materials. Rhodium trichloride trihydrate was of reagent grade and used as supplied. Di-μ-chlorobis(1,5-cyclooctadiene)dirhodium(I), $[RhCl(1,5\text{-}C_8H_{12})]_2$, was prepared according to the literature.[7] The bidentate isocyanides $CN(CH_2)_nNC$ (n=4, 6, 7, or 8) were prepared by slightly modifying the literature method.[8] Dimethyl sulfoxide (DMSO) was distilled twice under reduced pressure after drying over $CaSO_4$ to give specific conductance, $k=1.1\times10^{-6}$ $ohm^{-1}\,cm^{-1}$.

Physical Measurements. Physical data were obtained in DMSO solutions. Infrared spectra (1×10^{-2} M) were measured on a Hitachi Perkin-Elmer 225 Spectrophotometer, electric conductivity (1×10^{-3} M) by using a Yokogawa F-255A universal bridge and a cell with the cell constant of 0.322 cm^{-1}, and electronic spectra on a Hitachi 124 Spectrophotometer by using 1, 0.1, and 0.01 cm quarz cells.

*Preparation of $[Rh(L\text{–}L)_2]PF_6$ (L–L=$CN(CH_2)_8NC$ (**1**), $CN(CH_2)_7NC$ (**2**)) and $[Rh_2(L\text{–}L)_4](PF_6)_2$ (L–L=$CN(CH_2)_6NC$ (**3**), $CN(CH_2)_4NC$ (**4**)).* An ethanol (10 ml) solution of hexamethylene diisocyanide (0.32 g, 2.4 mmol) was added dropwise to a stirred suspension of $[RhCl(1,5\text{-}C_8H_{12})]_2$ (0.29 g, 0.58 mmol) in ethanol (10 ml). The mixture was stirred for 1 h, followed by the addition of NH_4PF_6 (2.30 g, 1.4 mmol) in water (5 ml). The resulting product was reprecipitated from a mixture of dichloromethane and heptane to give a dark blue powder of **3** (60%): ν(NC), 2169 cm^{-1}; Λ_M=62 $cm^2\,ohm^{-1}\,mol^{-1}$. Found: C, 36.84; H, 4.78; N, 10.71%. Calcd for $C_{32}H_{48}F_{12}N_8P_2Rh_2$: C, 36.94; H, 4.65; N, 10.77%.

Other complexes were similarly prepared. **1** was reprecipitated from acetonitrile–water (73%): ν(NC), 2165 cm^{-1}; Λ_M=31 $cm^2\,ohm^{-1}\,mol^{-1}$. Found: C, 41.81; H, 5.78; N, 9.82%. Calcd for $C_{20}H_{32}F_6N_4PRh$: C, 41.68; H, 5.60; N, 9.72%. **2** was purified as **3** and contains a half molecule of dichloromethane (82%): ν(NC), 2170 cm^{-1}; Λ_M=34 $cm^2\,ohm^{-1}\,mol^{-1}$. Found: C, 37.71; H, 4.89; N, 9.23%. Calcd for $C_{18.5}H_{29}ClF_6N_4PRh$: C, 37.61; H, 4.95; N, 9.48%. **4** was purified as **3** (81%): ν(NC), 2175 cm^{-1}; Λ_M=58 $cm^2\,ohm^{-1}\,mol^{-1}$. Found: C, 31.77; H, 3.97; N, 11.80%. Calcd for $C_{24}H_{32}F_{12}N_8P_2Rh_2$: C, 31.05; H, 3.47; N, 12.07%.

Results and Discussion

The complexes obtained exhibit dark violet or blue color in the solid state, which is reminicent of metal-metal interactions. Conductivity measurements indicated that they are all electrolytes in DMSO. Infrared spectra of the complexes in DMSO showed only one strong band in the ν(N≡C) region, implying the equivalence of four isocyanide groups coordinated to the rhodium atom.

a) See text. b) Observable only in concentrated solutions.

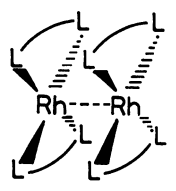
Electronic spectra of these complexes in DMSO show concentration dependence, which is illustrated by the spectra of **2** in DMSO at various concentrations (Fig. 1). A dilute solution (3.5×10^{-5} M) exhibit four absorption bands. The wavelengths and molar extinction coefficients of these bands (Table 1) are close to the charge transfer bands of tetrakis(ethyl isocyanide)-rhodium(I) perchlorate observed in acetonitrile (308 (ε 24000), 333[sh], 380 (8400), 435 nm (260)). This complex was reported to exist as the discrete rhodium(I) cation.[9] In addition, a molecular model suggests that the methylene chain of $CN(CH_2)_7NC$ is long enough for chelation to the rhodium(I) ion. Thus, the four absorption bands observed in dilute solutions are due to monomeric $[Rh(CN(CH_2)_7NC)_2]^+$. A more concentrated solution of **2** exhibits a new broad band at 505 nm, which is intensified relatively at the expense of the 387 and 440 nm bands as the concentration increases. The 505 nm band may therefore be assigned to dimeric $[Rh(CN(CH_2)_7NC)_2]_2^{2+}$ by analogy with $[Rh(C_6H_5NC)_4]^+$, which was reported to exhibit an absorption arising from its dimer at 568 nm in concentrated acetonitrile solutions.[4] If one can assume that an equilibrium exists between monomeric $[Rh(CN(CH_2)_7NC)_2]^+$ and its dimeric dication, the equilibrium constant, K_1, is expressed by the following equation (Eq. 1), where C, A, and ε stand for the concentration, absorbance, and molar extinction coefficient of the monomeric and dimeric species denoted by the subscripts M and D, respectively.

$$K_1 = \frac{C_D}{C_M^2} = \frac{A_D/\varepsilon_D}{(A_M/\varepsilon_M)^2} \quad (1)$$

Equation 1 can be transformed as follows:

$$A_M^2 = \frac{\varepsilon_M^2}{K_1 \varepsilon_D} \times A_D. \quad (2)$$

This equation predicts a linear relationship between A_M^2 and A_D. In fact, a plot of the absorbance at 505 nm *vs.* the square of that at 387 nm[10] gave a straight line shown in Fig. 2. It is therefore suggested that **2** exists as an equilibrium mixture of the monomeric and dimeric species in concentrated solutions. The association of $[Rh(CN(CH_2)_7NC)_2]^+$ may be formed through Rh–Rh interactions as illustrated in **A**. A similar result



A

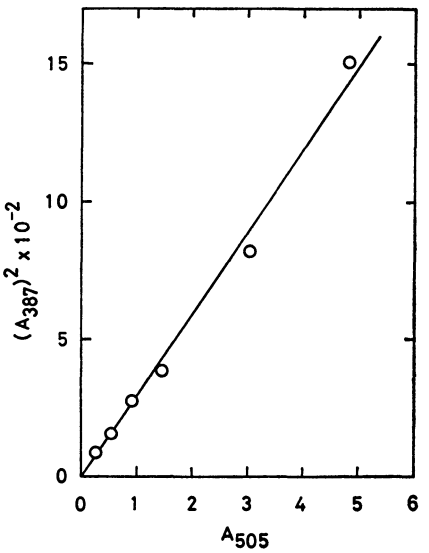


Fig. 2. A plot of the absorbance at 505 nm, A_{505}, *vs.* the square of that at 377 nm, $(A_{387})^2$, for $[Rh(CN(CH_2)_7NC)_2]PF_6$ (**2**) in DMSO at 25 °C.

was obtained for **1** (see Table 1). Unfortunately, the K_1 and ε_D values have not been determined in the present study, because limited solubilities of **1** and **2** have precluded the spectral measurements over a concentration range wide enough to warrant the least squares analysis[11] to calculate these two values.

Figure 3 displays electronic spectra of **4** in DMSO at various concentrations. A dilute solution (4.2×10^{-4} M) exhibits four absorption bands. These wavelengths

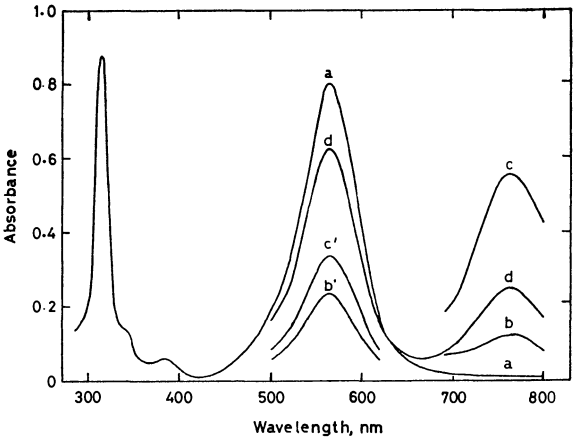

Fig. 3. Electronic spectra of $[Rh_2(CN(CH_2)_4NC)_4](PF_6)_2$ (**4**) in DMSO at various concentrations at 25 °C (cell length, cm): a (0.1), 4.2×10^{-4} M; b (0.1) and b′ (0.01), 8.4×10^{-4} M; c (0.1) and c′ (0.01), 1.7×10^{-3} M; d (0.01), 3.5×10^{-3} M.

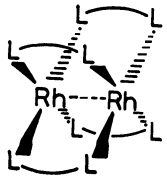
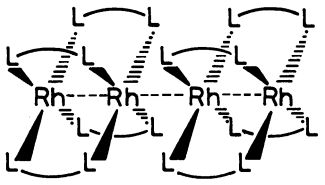
(Table 1) except 383 nm (*vide infra*) are close to those of absorptions of the $CN(CH_2)_3NC$ analog in a dilute methanol solution (318, 342, 555 nm), for which a dimeric structure with bridging isocyanides has recently been suggested.[5] A molecular model indicates that $CN(CH_2)_4NC$ will not be able to chelate to the rhodium(I) ion. Therefore, **4** probably contains bridging isocyanides to form a dimer with an intramolecular Rh–Rh interaction as the smallest unit in dilute solutions, **B**. The intensity of the rather weak band at 383



B

nm decreases considerably on addition of $CN(CH_2)_4NC$ to its Rh(I) complex in DMSO. In view of this result and the fact that monomeric **1** and **2** show absorptions at 387 nm (Table 1), the band may arise from such a monomeric species as, for example, $[Rh(CN(CH_2)_4NC)_2(DMSO)_2]^+$ involving unidentate $CN(CH_2)_4NC$. Thus, the 314 and 340 nm bands of **4** (Table 1) may be contributed from the monomeric species to some extent, since monomeric **1** and **2** exhibit absorptions at similar wavelengths. A more concentrated solution of **4** exhibits a new broad band at 765 nm, which is intensified at the expense of the 564 nm band as the concentration increases. The 765 nm band can be assigned to tetrameric $[Rh_2(CN(CH_2)_4NC_4]_2^{4+}$ by analogy with the $CN(CH_2)_3NC$ analog.[5] Moreover, a linear relationship was obtained between the absorbance at 765 nm *vs.* the square of that at 564 nm (the dimer band), supporting the assignment. It is therefore suggested that in concentrated solutions the dimeric **4** undergoes an intermolecular association to form the tetramer **C**. No similar association of **3** has been observed



C

in the electronic spectrum because of its poor solubility, although in dilute solutions it exhibited a spectrum similar to that of **4** (Table 1). The absorptions at long wavelengths of these four complexes will be explained to be due to the dimeric and tetrameric species by a simple MO diagram proposed by Gray *et al.*[4,5]

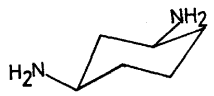
(Received February 6, 1978)

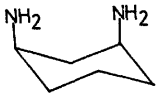
The structure of bis(*cis*-1,3-diaminocyclohexane)palladium(II) chloride has been determined from X-ray diffraction data collected by the counter method. The crystal is orthorhombic with space group Pnnm, $a=17.728(5)$, $b=6.418(4)$, $c=6.914(2)$ Å, and $Z=2$. The crystal structure has been determined by Patterson and Fourier techniques and refined by a least-squares method to $R=0.026$ for 1151 independent reflections for which $F_o^2>3\sigma(F_o^2)$. The Pd atom has a planar coordination of 4 N atoms and the complex cation has a crystallographically imposed C_{2h} symmetry, the two *cis*-1,3-diaminocyclohexane ligands being related to each other by a two fold axis. The six-membered chelate ring Pd–NH_2–CH–CH_2–CH–NH_2 (with a $-(CH_2)_3-$ bridge) is of the envelope conformation.

The structural features of the ligating *cis*-1,3-diaminocyclohexane have been described. The crystal of bis(*cis*-1,3-diaminocyclohexane)platinum(II) (orthorhombic, $a=17.727(8)$, $b=6.371(3)$, $c=6.965(2)$ Å) was found to be isomorphous with that of the palladium analogue.

The *cis*-1,3-diaminocyclohexane (1,3-dach) molecule usually exists in the diequatorial conformation in which the disposition of the two NH_2 groups is highly unfavorable to chelation. However, the molecule is capable of chelating to the metal ion when it assumes the diaxial conformation.



The diequatorial conformation



The diaxial conformation

Two of the authors (R. S. and Y. K.) have found that 1,3-dach reacts with some transition metal ions and have synthesized several Pd(II) and Pt(II) chelates of 1,3-dach with the formula $[MX_2(1,3\text{-dach})]$ and $[M(1,3\text{-dach})_2]Cl_2$, where M stands for Pd(II) or Pt(II) and X for Cl or Br.[1] Thus the presence of a metal ion which has a strong affinity towards the N atom promotes the interconversion from the diequatorial to the diaxial conformation, giving rise to a metal chelate of 1,3-dach. With these complexes it was found that the electronic spectra were indicative of a planar 4-coordinate configuration, and furthermore, the ^1H NMR and IR spectra suggested the diaxial conformation of the 1,3-dach ligand. In order to investigate the structural features of the ligating 1,3-dach molecule in detail, the single crystal X-ray structure analysis of $[Pd(1,3\text{-dach})_2]Cl_2$ has been performed.

Experimental

The preparations of $[Pd(1,3\text{-dach})_2]Cl_2$ and $[Pt(1,3\text{-dach})_2]Cl_2$ have been reported elsewhere.[1]

Crystal Data. $[Pd(1,3\text{-dach})_2]Cl_2$: $C_{12}H_{28}N_4Cl_2Pd$, $F.W.=405.7$, Orthorhombic, $a=17.728(5)$, $b=6.418(4)$, $c=6.914(2)$ Å, $U=786.7(6)$ Å^3, $D_m=1.71$, $D_c=1.71$ g/cm^3, $Z=2$, μ(Mo $K\alpha$)$=16.1$ cm^{-1}, space group Pnnm or Pnn2 from systematic absences: $h0l$ when $h+l$ is odd, $0kl$ when $k+l$ is odd. The former space group was used in the structure analysis and confirmed by the successful refinement of the structure.

$[Pt(1,3\text{-dach})_2]Cl_2$: $C_{12}H_{28}N_4Cl_2Pt$, $F.W.=494.4$, Orthorhombic, $a=17.727(8)$, $b=6.371(3)$, $c=6.965(2)$ Å, $U=786.7(3)$ Å^3, $D_m=2.08$, $D_c=2.09$ g/cm^3, $Z=2$, μ(Mo $K\alpha$)$=105.6$ cm^{-1}, space group Pnnm or Pnn2; X-ray diffraction pattern showed the same space-group extinctions as those of the Pd analogue.

The Laue symmetries, space groups, and the approximate unit-cell dimensions were determined from oscillation and Weissenberg photographs taken with Cu $K\alpha$ radiation. The unit cell dimensions of the respective compounds were refined by the least-squares analyses of the θ values (16 reflections for the Pd- and 14 for the Pt-compound) measured on a Philips PW 1100 four-circle diffractometer with Mo $K\alpha$ radiation.

Data Collection. Intensity data for one octant of the reciprocal space were collected by the ω-2θ scan technique with graphite-monochromated Mo $K\alpha$ radiation. The specimen size was $0.14\times0.12\times0.15$ mm. A scan speed of 0.017° s^{-1} in ω and a scan range $(0.8+0.2\tan\theta)°$ were chosen. The background was counted for half of the scan time at each end of the scan range. Three standard reflections (200, 040, 002), monitored every 3 h throughout the data collection, showed no significant variation in intensity. Of the 1752 reflections collected in the range of $2\theta\leq66°$, 1151 reflections having $F_o^2>3\sigma(F_o^2)$ were used in the structure analysis. Intensity data were processed by the computer program of Hornstra and Stubbe.[2] A spherical absorption correction ($r=0.07$ mm) was applied.

Structure Determination and Refinement. The crystal structure of $[Pd(1,3\text{-dach})_2]Cl_2$ was solved by the heavy-atom technique. Of the two possible space groups, Pnnm and Pnn2, the former was chosen. The positional and thermal parameters were refined by the block-diagonal least-squares method. The minimized function was $\sum w(|F_o|-|F_c|)^2$. The weighting scheme, $w=p$ for $|F_o|<F_{min}$, $w=1.0$ for $F_{min}\leq|F_o|\leq F_{max}$, and $w=(F_{max}/F_o)^2$ for $|F_o|\geq F_{max}$, was used. The p, F_{min} and F_{max} were varied as indicated by F_o and $(\sin\theta/\lambda)$ analysis of $\sum w\Delta F^2$. The difference Fourier map, calculated after the refinement of the parameters for the nonhydrogen atoms by the use of anisotropic temperature factors, clearly showed the peaks of all H atoms. These H atoms were

included in the following least-squares calculation, isotropic temperature factors being used. The convergence was attained at R 0.026 ($R'=[\sum w\Delta F^2/\sum wF_o^2]^{1/2}=0.030$). In the final cycle of the refinement all parameter shifts were less than 0.2σ. The $F_{min}=8.7$, $F_{max}=42.0$ and $p=0.4$ were found to be optimum.

The atomic scattering factors of Pd^0, Cl^-, N, and C were taken from Ref. 3 and that of H from Ref. 4. Real parts of the anomalous dispersion corrections were applied for Pd^0 and Cl^-. Atomic coordinates and temperature factors are given in Table 1. A complete list of the observed and calculated structure factors is preserved by the Chemical Society of Japan (Document No. 7823). All the computations were carried out on a FACOM 230-60 computer of Osaka City University, by the use of the RSSFR-5, HBLS-IV, and DAPH programs in the UNICS.[5]

Results and Discussion

The perspective drawing of the complex cation is shown in Fig. 1. The complex has a crystallographically imposed two fold axis and a symmetry plane; the two fold axis runs through the Pd atom and bisects the N–Pd–N″ angle, whereas the symmetry plane is perpendicular to the two fold axis and passes through the Pd, C(1) and C(4) atoms. The primed atoms are related to the unprimed ones by the symmetry plane. Thus

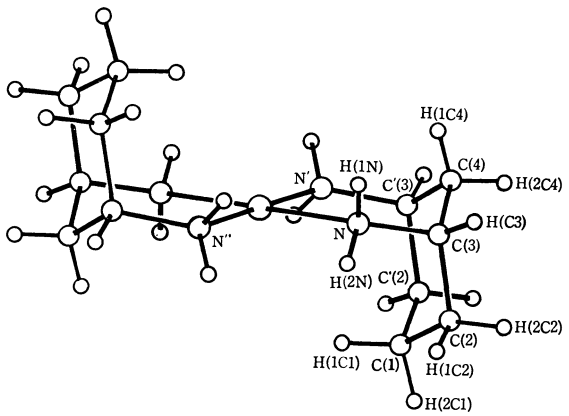

Fig. 1. Structure of $[Pd(1,3\text{-dach})_2]^{2+}$.

the complex has an exact C_{2h} symmetry, the Pd atom being located at the center of inversion.

The six-membered chelate ring composed of the Pd, N, C(3), C(4), C′(3), and N′ is of the envelope conformation. However, the [Pd, N, N′] plane is not exactly coplanar with the [N,C(3),C′(3),N′] plane; as can be seen in the elevation of the complex (Fig. 2), the latter plane is slightly bent away from the former plane so as to deform the chelate ring toward the chair conformation. The interplanar angle is 169.2° (Table 3).

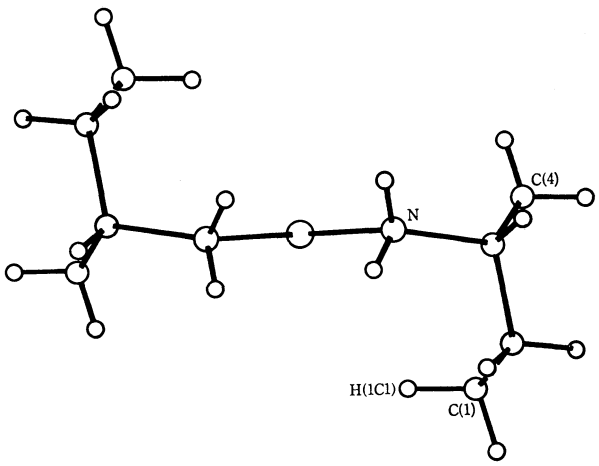

Fig. 2. Elevation of $[Pd(1,3\text{-dach})_2]^{2+}$.

Bond lengths and angles are given in Table 2. The Pd–N bond length (2.058(2) Å) is slightly longer than those in $[Pd(en)_2]Cl_2$ (2.030(6) and 2.043(7) Å),[6] $[PdCl_2(meso\text{-}2,3\text{-diaminobutane})]$ (2.029(6) Å),[7] and $[Pd(N^1\text{-Me-}(S)\text{-pn})_2]Cl_2\cdot 2H_2O$ (2.040(5) Å),[8] although the magnitude of elongation is not "highly significant." The electronic spectra of the present complex shows two bands at 27000 cm^{-1} (shoulder) and 34200 cm^{-1}.[1] These bands are displaced slightly to a lower energy relative to the corresponding bands of $[Pd(R\text{-pn})_2]Cl_2$ (29000 and 34800 cm^{-1}).[9] As the Pd–N bond length in the *R*-pn complex should presumably not be different from those in the en and *meso*-2,3-diaminobutane complexes, the slight elongation of the Pd–N bond in the 1,3-dach complex seems to be responsible for the low energy shift of the d→d bands.

N–C(3)–C(4)–C′(3)	−74.2
C′(2)–C(1)–C(2)–C(3)	55.6
C(1)–C(2)–C(3)–C(4)	−52.1
C(2)–C(3)–C(4)–C′(3)	48.5

a) All four atoms lie exactly on one plane.

The N–Pd–N′ bond angle (94.8(2)°) is significantly larger than those in the Pd complexes with five-membered chelate rings of diamines (82.9—83.6°).[6-8] Although the Pd–N–C bond angle (122.6(2)°) is fairly larger than the tetrahedral angle, it is comparable to those in the metal chelates with six-membered chelate rings.[10]

The cyclohexane ring is of the diaxial conformation, as inferred from ^{1}H NMR and IR spectra.[1] Bond lengths and angles are in reasonable agreement with those in the cyclohexane II,[11] *trans*-1,2-diaminocyclohexane,[12] and *trans*-1,4-diaminocyclohexane.[13] However, the C(3)–C(4)–C′(3) bond angle (114.2(4)°) is larger than any C–C–C angles (≈112.3°) in the molecules cited for comparison.

Various torsion angles are also given in Table 3. The torsion angles of the –C–C–C–C– fragments are generally smaller than those in the cyclohexane and its substituted derivatives (55.4—58.4°)[11-13] and particularly, that of the –C(2)–C(3)–C(4)–C′(3)– is the smallest (48.5°) among them. This value is comparable to that (47.0°) found in the $-CH_2-CH(COOH)-CH(COOH)-CH_2-$ portion of the *trans*-1,2-cyclohexanedicarboxylic acid,[14] the small value of which has been ascribed to the steric repulsion between the two carboxyl groups.[15] Interpretation for the present case of –C(2)–C(3)–C(4)–C′(3)– is as follows. In the scaled model of the diaxial 1,3-dach molecule, the distance between N and N′ is 2.7 Å[16] (the same atom numbering as the one given for coordinating 1,3-dach (Fig. 1) is used for the scaled model but expressed in bold-faced type). In order to increase the **N**···**N′** distance to 3.029 Å as found in the present 1,3-dach ligand it is necessary to synchronously rotate the –**C(3)**(**N**)(**C(4)**) and –**C′(3)**(**C(4)**)(**N′**) segments about **C(2)**–**C(3)** and **C′(2)**–**C′(3)** axes, respectively. Such rotations give rise to i) decrease of torsion angle in the –**C(2)**–**C(3)**–**C(4)**–**C′(3)**– fragment, ii) increase of the interplanar angle between [**C(2)**, **C(3)**,**C′(3)**,**C′(2)**] and [**C(3)**,**C(4)**,**C′(3)**] planes, and iii) increase of **C(3)**–**C(4)**–**C′(3)** bond angle. Actually, in ligating 1,3-dach the corresponding interplanar angle is larger by 5.6° than the [C(2),C(3),C′(3),C′(2)]–[C(2),C(1),C′(2)] interplanar angle which is in agreement with the average value in cyclohexane II (130.3°). Moreover, the C(3)–C(4)–C′(3) bond angle is the largest among the C–C–C bond angles. In the intermolecular contacts in which the H atoms of the cyclohexane group participate, none of the interatomic distances is less than the sum of the van der Waals

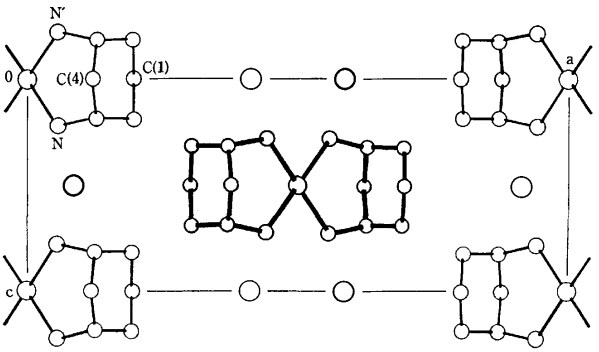

Fig. 3. Crystal structure viewed down the b axis. Complexes drawn by thin lines lie at $y=0$, while that shown by thick lines is located at $y=1/2$. For Cl anions thin circles have $y\approx0.23$, and thick ones $y\approx0.73$.

radii. Therefore, the structural features of the cyclohexane ring found in ligating 1,3-dach should be regarded as arising from an intramolecular potential energy but not from an intermolecular one.

Figure 3 shows the crystal structure. All H atoms of the NH_2 groups participate in the N–H···Cl hydrogen bonding. Data concerning the hydrogen bonds are listed in Table 2.

The unit-cell dimensions of $[Pt(1,3\text{-dach})_2]Cl_2$ are very close to those of $[Pd(1,3\text{-dach})_2]Cl_2$ and furthermore, the intensity distribution in the reciprocal space of the former has similar features to that of the latter. Accordingly the crystal in the former case may be regarded as isomorphic with the present Pd compound.

The H(1Cl) atom has a short contact with the Pd atom. The Pd···H distance is comparable with that found in the bis(L-ornithinato)palladium(II) (2.79 Å).[17] In the ^1H NMR spectrum of the $[Pt(1,3\text{-dach})_2]Cl_2$ it was found that one of the eight methylene protons resonates at lower field than those for the remainders. The spectrum of the Pd analogue is almost identical with that of the Pt complex.[1] The proton which shows down-field shift is thought to be the H(1Cl) atoms, although in solution the M···H distance varies as the ligand molecules make some motion, *e.g.*, the rapid oscillation of the 1,3-dach ligand about N···N′ axis.

16) The coordinates of C atoms in the cyclohexane II[11] were utilized in the estimation of the N···N′ distance in the scaled model. The coordinates of the two axial N atoms, each of which is bonded to C(2) or C′(1) atom of the cyclohexane II (C′(1), C(1) at equivalent position $1/2-x,1/2-y,-z$), were calculated on the assumption that the C–N bond length is 1.494 Å and each C atom has sp^3 hybridization with C_{2v} symmetry. From such a model the N···N′ distance was calculated to be 2.68 Å.

Studies on Mixed Valence Complexes of Platinum and Palladium. I. Preparation and Characterization of Pt(II)-Pt(IV), Pd(II)-Pt(IV), and Pd(II)-Pd(IV) Complexes of the General Formula, $[M(AA)_2][M'X_2(AA)_2]Y_4$

Naohide MATSUMOTO, Masahiro YAMASHITA, and Sigeo KIDA*

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Fukuoka 812

(Received February 6, 1978)

A series of deeply colored mixed valence complexes of the general formula $[M(AA)_2][M'X_2(AA)_2]Y_4$ were prepared and characterized, where M–M′=Pt(II)–Pt(IV), Pd(II)–Pt(IV), and Pd(II)–Pd(IV); (AA)=ethylenediamine, propylenediamine, and trimethylenediamine; X=Cl, Br, and I; Y=ClO_4, BF_4. The relationships between the reflection spectra and the nature of the constituents (X, (AA), Y and M–M′) of the compounds were studied. The value of $\bar{\nu}_{max}$ of the main absorption band in the visible region decreases in the order: Cl→Br→I, pn→tn→en, ClO_4→BF_4, Pd(II)–Pt(IV)→Pt(II)–Pt(IV)→Pd(II)–Pd(IV). On the basis of dichroism of the crystals, it can be predicted that the X–M′(IV)–X···M(II) atoms in these complexes are arrayed in a straight line parallel to the crystal needle.

Of a group of platinum compounds which appear to contain Pt(III), the most typical ones are PtA_2X_3 and PtA_4X_3, where A represents ammonia or organic monoamine, and X halogen or other monovalent anions.[1] These compounds are not simple Pt(III) compounds, but mixed valence compounds containing Pt(II) and Pt(IV) in 1 : 1 ratio, since they are diamagnetic and display strong color.[2] This was verified by sigle-crystal X-ray analysis.[3–8] It was found that they consist of square planar Pt(II) and tetragonal bipyramidal Pt(IV) complexes arrayed in lines as shown in Fig. 1.

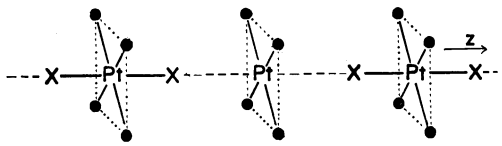

Fig. 1. The skeletal structure of Pt(II)–Pt(IV) mixed-valence complexes.

Yamada and Tsuchida studied the polarized single-crystal spectra of these compounds and attributed the strong absorption to the charge transfer transition from Pt(II) to Pt(IV), assuming a considerable electron exchange interaction between Pt(II) and Pt(IV) through the intervening halogen atom.[9] Recently, Clark *et al.* have shown on the basis of resonance Raman study that such an interaction actually exists between Pt(II) and Pt(IV) through the halogen atom.[10]

In spite of an increasing interest in the Pt(II)–Pt(IV) mixed valence compounds,[11] only a limited number of such compounds are known so far. Wolffram's red salt $[Pt(ea)_4][PtCl_2(ea)_4]Cl_4\cdot 4H_2O$ (ea=ethylamine) is known to be of the PtA_4X_3 type. However, no other homologs were known except the bromo derivative,[1] until Kida reported the synthesis of $[Pt(en)_2][PtCl_2(en)_2](ClO_4)_4$, suggesting the possibility of the synthesis of other homologous compounds.[12]

We have synthesized numerous Pt(II)–Pt(IV) compounds of the type, $[Pt(AA)_2][PtX_2(AA)_2]Y_4$ (AA= ethylenediamine(en), propylenediamine(pn), or trimethylenediamine(tn); X=Cl, Br, or I; Y=ClO_4 or BF_4). We have succeeded in the preparation of Pd(II)–Pt(IV) and Pd(II)–Pd(IV) compounds of similar type. We measured powder reflectance spectra of the compounds in order to elucidate the relationship between the band positions and the constituents of the compounds such as diamine, halogen, counter ion, and metal ion.

Experimental

Starting Materials. $[Pt(AA)_2]Cl_2$,[13] $[Pd(AA)_2]Cl_2$,[14] and $[PtX_2(AA)_2]X_2$[15] (AA=en, pn, tn; X=Cl, Br) were prepared according to the reported methods.

Pt(II)–Pt(IV) Compounds. Compounds of this type were prepared by a procedure similar to that for $[Pt(en)_2][PtCl_2(en)_2](ClO_4)_4$.[12] The tetrafluoroborates were prepared by the same method as that for the perchlorate except for use of a 42% tetrafluoroboric acid solution instead of a 60% perchloric acid solution. Some typical examples are shown below. The procedure of Bekaroglu *et al.* was employed[16] for iodo derivatives.

i) $[Pt(en)_2][PtBr_2(en)_2](BF_4)_4$: Equimolar amounts of $[Pt(en)_2]Cl_2$(386 mg) and $[Pt(en)_2Br_2]Br_2$(635 mg) were dissolved in 20 ml of water. To this solution was added dropwise a 42% tetrafluoroboric acid solution to yield dark green needles with metallic luster, which were filtered and then washed with a small amount of water and then acetone. Recrystallization was carried out from a dilute tetrafluoroboric acid solution.

ii) $[Pt(tn)_2][PtI_2(tn)_2](ClO_4)_4$: One millimole of $[Pt(tn)_2]Cl_2$(414 mg) was dissolved in 20 ml of water. To this solution was added an excess amount of I_2 dissolved in ethanol. The solution was evaporated almost to dryness in a rotary evaporator under reduced pressure in order to remove unreacted I_2. To this residue were added 414 mg (1 mmol) of $[Pt(tn)_2]Cl_2$, 440 mg of $NaClO_4$, and 5 ml of 42% tetrafluoroboric acid. Golden needles with metallic luster were separated from the solution. They were filtered and recrystallized from a dilute perchloric acid solution.

Pd(II)–Pt(IV) Compounds. The compounds were obtained by a procedure similar to that for the Pt(II)–Pt(IV) compounds using $[Pd(AA)_2]Cl_2$ instead of $[Pt(AA)_2]Cl_2$.

Pd(II)–Pd(IV) Compounds. $[PdX_2(AA)_2]X_2$ was not isolated because of its low stability. However, in the mixed valence state Pd(IV) is much stabilized. Hence, $[Pd(AA)_2]^{2+}$ was oxidized by X_2 to form $[PdX_2(AA)_2]^{2+}$, which immediately reacted with the remaining $[Pd(AA)_2]^{2+}$ in a perchloric acid solution. Preparation of iodo homologs of this series was

not successful. Typical examples of the procedure are shown below.

i) $[Pd(en)_2][PdCl_2(en)_2](ClO_4)_4$: One half gram of $[Pd(en)_2]Cl_2$ was dissolved in 10 ml of water. Ten millilitres of 60% perchloric acid was added to this solution, and chlorine gas was passed into the solution under ice-cooling. Dark green fine needles with metallic luster immediately separated out. The crystals were dissolved in a small amount of cold water and filtered. To the filtrate was added 60% $HClO_4$ under ice-cooling in order to obtain the crystals, which were filtered and washed with water and acetone. It should be noted that the Pd(IV) oxidation state is stable only in the crystal lattice of the mixed valence compound. Thus, recrystallization was carried out as quikly as possible.

ii) $[Pd(en)_2][PdBr_2(en)_2](ClO_4)_4$: This was prepared by a procedure similar to that described above except for use of Br_2 instead of Cl_2.

Measurement. Powder reflectance spectra were obtained with a Shimadzu Multipurpose Spectrophotometer Model MSP-5000.

Results and Discussion

The results of elemental analyses are given in Table 1. All the compounds crystallized from aqueous solutions forming strongly colored needles or long prisms, exhibiting remarkable dichroisms, *i.e.*, strongly colored for the

light polarized along the needle and only slightly colored for the light polarized perpendicular to the needle. The colors and band maxima of the powder reflectance spectra in the visible region are given in Table 2. Some spectra are shown in Figs. 2 and 3. Since no intense coloration of the crystals is observed in aqueous solutions and in either of the constituent complexes $[M(AA)_2]Y_2$ and $[MX_2(AA)_2]Y_2$, the strong absorption in the visible region should be attributed to the charge transfer transition from M(II) to M(IV) (M=Pt or Pd) effected by the interaction between M(II) and M(IV) through the halogen atom.[9] Thus, the band can be assigned to the transition from d_{z^2}-{M(II)} to the molecular orbital consisting of p_z (halogen) and d_{z^2}-{M(IV)}, assuming the model depicted in Fig. 1. Since this transition corresponds to the $^1A_1 \leftarrow {}^1A_1{}^*$ in the model (C_{2v} symmetry), it is only allowed for the z axis. Thus, from the fact that the crystals absorb light polarized along the crystal needle only, we can predict that the –Pt–X···Pt··· axis is arrayed parallel to the crystal needle.

On the basis of the theory of charge-transfer complex[2,17] we can assume that the position of the visible band is a measure of the interaction between M(II) and M(IV), *i.e.* the lower the wave-number of the band the stronger the interaction. From the data given in Table 2, it is seen that the $\tilde{\nu}_{max}$ of the main absorption band decreases in the order: 1) Cl→Br→I, 2) pn→tn→en, 3) $ClO_4 \rightarrow BF_4$, 4) Pd^{II}–$Pt^{IV} \rightarrow Pt^{II}$–$Pt^{IV} \rightarrow Pd^{II}$–$Pd^{IV}$.

The Oxidative Amination of Tropone and Tropolone

Katsuo KIKUCHI,* Yuji MAKI, and Kazuo SATO

Department of Chemistry, Faculty of Science, Yamagata University, Koshirakawa-cho, Yamagata 990

(Received March 22, 1978)

The reaction of tropone with aniline, *p*-toluidine, *p*-anisidine, and *p*-chloroaniline in the presence of copper(II) acetate gave 2-arylaminotropones and 2-arylamino-*N*-aryltroponeimines. However, when *o*-toluidine and *o*-anisidine were used, only the corresponding 2-arylaminotropones were obtained. The reaction of tropolone with methylamine, ethylamine, and isopropylamine afforded 3-aminotropolone derivatives, while the reaction with dimethylamine, pyrrolidine, and morpholine gave 3- and 5-aminotropolone derivatives, the latter being minor products.

Aminotropones and aminotropolones have usually been obtained 1) by the nucleophilic substitution of 2-alkoxy, 2-halo, and 2-tosyloxytropones; 2) by the reduction of the appropriate nitro, nitroso, or arylazotropolones; 3) by the hydrolysis of 3-(arylsulfonylamido)tropolones; and 4) by the reaction of 3-iodotropolone with liquid ammonia to give 4-aminotropolone.[1] Recently, however, a novel nuclear amination of 3-dialkylaminotropones and 3-alkoxytropones under mild conditions to give 7-aminated tropone derivatives was reported.[2] Also, previously one of the present authors reported that the reaction of tropone and 2-phenyltropone with ammonia, methylamine, and dimethylamine in the presence of copper(II) salt gave 2-aminotropone derivatives and/or salicylaldehyde derivatives.[3] As one of a series of systematic investigations of the oxidative amination of seven-membered aromatics, the reaction of tropone with aromatic primary amines, and the reaction of tropolone with several kinds of primary and secondary amines in the presence of copper(II) salt were investigated; these results will be reported in this paper.

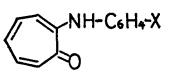
Results and Discussion

When tropone was treated in a closed vessel with a solution of copper(II) acetate and *p*-toluidine in methanol at room temperature for several days, 2-*p*-toluidinotropone (**1a**) and 1-(*p*-toluidino)-7-(*p*-tolylimino)-1,3,5-cycloheptatriene (**2a**)[4] were obtained in about 39 and 17% yields respectively. That the reaction must involve an oxidation step was suggested by the observations that the color of the solution gradually turned greenish brown from deep greenish blue, and that, in some instances, copper(I) oxide was separated on the wall of the reaction vessel. The yields of **1a** and **2a** *versus* the reaction times are listed in Table 1. The ratio of **1a** to **2a** remained almost constant after 5 days' reaction time. Moreover, the reaction of **1a** with *p*-toluidine in the presence or absence of copper(II) acetate was investigated, but in both cases **2a** was not obtained at all. Therefore, the possibility that **1a** was an intermediate for **2a** was eliminated. 7-*p*-Tolylimino-1,3,5-cycloheptatriene,[5] which formed at a slow and reversible step, is considered to be aminated to give **2a**, though the reaction of tropone and *p*-toluidine in the absence of copper(II) salt did not afford a detectable amount of the 7-*p*-tolylimino compound. A similar treatment of tropone with aniline, *p*-anisidine, and *p*-chloroaniline gave the corresponding 2-arylaminotropones (**1b**, **1c**, and **1d**) and, in addition, 1-arylamino-7-arylimino-1,3,5-cycloheptatrienes (**2b**, **2c**, and **2d**). However, the reaction of tropone with *o*-toluidine and *o*-anisidine afforded only the corresponding 2-arylaminotropone derivatives (**1e** and **1f**).

Table 1. The yields of **1a** and **2a** *versus* the reaction times[a]

Reaction time (day)	Temp (°C)	Yields (%)[b] **1a**		**2a**	
1.0	22—24	25.1	(21.4)	4.8	(3.8)
5.0	22—24	42.1	(36.8)	21.0	(16.1)
10.0	22—24	45.2	(39.1)	22.6	(16.6)
20.0	22—24	49.1	(41.1)	26.1	(18.2)

a) Tropolone (5 mmol), *p*-toluidine (20 mmol), copper(II) acetate (10 mmol), and methanol (10 ml) were used. b) The yields of **1a** and **2a** were estimated by the TLC separation of a known amount of the reaction product, followed by the measurement of the absorbance at 407 nm for **1a** and at 417 nm for **2a**. The isolated yields are indicated in parentheses.



1a: X=*p*-CH_3
1b: X=H
1c: X=*p*-CH_3O

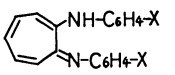
1e: X=*o*-CH_3
1f: X=*o*-CH_3O



2a: X=*p*-CH_3
2b: X=H
2c: X=*p*-CH_3O
2d: X=*p*-Cl

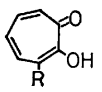
When tropolone and aqueous methylamine was allowed to react for a long period of time, 2-methylaminotropone (**3**) was obtained in a moderate yield. On the other hand, when tropolone was treated with methylamine in the presence of copper(II) sulfate in water, 3-methylaminotropolone (**4a**) and yellow prisms (**5**) were obtained besides **3**. The UV spectrum of **5** showed maxima at 229 (4.32), 277 (4.35), 360 (4.37), and 433 nm (log ε 3.88). In the IR spectrum, a carbonyl absorption appeared at 1595 cm^{-1}. A sharp *N*-methyl singlet (6H) appeared at 2.98 ppm besides the aromatic and NH protons in the NMR spectrum, indicating the symmetrical structure of **5**. The benzoylation of **5** gave monobenzoyl (**6**) and dibenzoyl compound (**7**). The alkaline hydrolysis of **6** gave 3-(*N*-benzoylmethylamino)-tropolone (**8**), which was also obtained by the benzoyla-

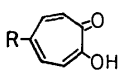
Table 2. The yields of **3**, **4a**, and **5** *versus* the reaction temperature[a)]

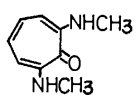
Reaction temp (°C)	Reaction time (day)	Yields (%)			
		3	**4a**	**5**	Recovery
8—10	30	0	6	23	34
18—20	10	0	3	21	18
30—32	10	11	15	21	8
50—52	2	13	25	5	8
70—72	1	27	25	0	0

a) Tropolone (20 mmol), copper(II) sulfate (40 mmol), and aqueous methylamine (30%, 25 ml) were allowed to react. The yields were based on the tropolone used.

tion of **4a**, followed by the alkaline hydrolysis of the resulting product. These results indicate that **5** is 2,7-bis(methylamino)tropone. It is interesting here to note that raising the reaction temperature increases the yields of **3** and **4a**, and that at 70 °C **5** was not isolated at all (see Table 2). The further treatment of **3** or **4a** under similar conditions did not afford **5**; it is thought that **5** must be formed through a different reaction pathway. The reaction of tropolone with ethylamine and isopropylamine under similar conditions gave 3-ethylaminotropolone (**4b**) and 3-isopropylaminotropolone (**4c**) respectively.

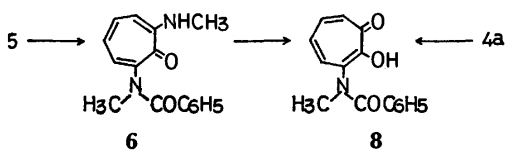






4a: R=CH_3NH **9a**: R=1-pyrrolidinyl **5**
4b: R=C_2H_5NH **9b**: R=morpholino
4c: R=*i*-C_3H_7NH **9c**: R=$(CH_3)_2N$
4d: R=1-pyrrolidinyl
4e: R=morpholino
4f: R=$(CH_3)_2N$

The reactions of tropolone and secondary amines have also been investigated. When tropolone was allowed to react with pyrrolidine in the presence of copper(II) sulfate, yellow prisms (**4d**) ($C_{11}H_{13}O_2N$, mp 98—99 °C) and yellow plates (**9a**) ($C_{11}H_{13}O_2N$, mp 236—238 °C (decomp.)) were obtained; the latter was a minor product. The elemental analysis and UV spectrum of **4d** showed it to be 3-(1-pyrrolidinyl)tropolone. The compound (**9a**) was also confirmed to have a tropolone nucleus from its UV spectrum and its characteristic iron(III) chloride test. The compound (**9a**) was also obtained when 5-bromotropolone was allowed to react with pyrrolidine in the presence of copper(II) acetate, though the yield was poor. Therefore, **9a** must be 5-(1-pyrrolidinyl)tropolone. Similar treatment of tropolone with morpholine and dimethylamine gave 3-(and 5-)-morpholinotropolones (**4e** and **9b**) and 3-(and 5-)-dimethylaminotropolones (**4f** and **9c**) respectively. The reaction of 5-chlorotropolone wtih pyrrolidine in the presence of copper(II) acetate gave 5-chloro-3-(1-pyrrolidinyl)tropolone (**10**), while the reaction of 3-bromotropolone with methylamine under similar conditions afforded 3-methylaminotropolone (**4a**).



6 **8**

Experimental

The Reaction of Tropone with Aniline, p-Toluidine, p-Anisidine, p-Chloroaniline, o-Toluidine, and o-Anisidine in the Presence of Copper(II) Acetate. Into a suspension of copper(II) acetate (2.00 g) in methanol (10 ml), *p*-toluidine (2.14 g) and tropone (0.530 g) were added successively with stirring. After several minutes, voluminous precipitates were separated. The mixture was allowed to stand for 10 days at 22—24 °C in an atmosphere of nitrogen. The reaction mixture was diluted with water, neutralized with dilute hydrochloric acid, and extracted thoroughly with chloroform. Hydrogen sulfide was passed through the chloroform solution, the copper(II) sulfide was filtered off, the filtrate was washed with water, and the solution was diluted with chloroform to 100 ml. A one-thousandth portion of this solution was separated on thin-layer chromatography using Merck Silica Gel PF_{254}. The fractions corresponding to 2-*p*-toluidinotropone (**1a**) and 1-(*p*-toluidino)-7-(*p*-tolylimino)-1,3,5-cycloheptatriene (**2a**) were eluted with methanol (10.0 ml), and the yields of **1a** and **2a** were estimated spectrophotometrically using the absorbances at 407 nm (for **1a**) and at 417 nm (for **2a**).

For the isolation of **1a** and **2a**, the solvent was removed under reduced pressure, and the residue was dissolved in a mixture of benzene and cyclohexane (1:1) and chromatographed on a column containing 10 g of silica gel. The fraction eluted with the same solvent mixture gave orange crystals, which were subsequently recrystallized from the same solvent mixture to give 250 mg (17%) of **2a** as orange prisms; mp 139—140 °C (lit,[4)] mp 143—144 °C). The fractions eluted with benzene and chloroform gave yellow crystals. Recrystallization from cyclohexane gave 415 mg (39%) of **1a**, mp 108—109 °C (lit,[6)] mp 108.5—109.5 °C).

The reaction of tropone with aniline, *p*-anisidine, *p*-chloroaniline, *o*-toluidine, and *o*-anisidine was carried out in a similar manner to give the following 2-arylaminotropones and 2-arylamino-*N*-aryltroponeimines:

2-Anilinotropone (**1b**), oil, picrate; mp 141—142 °C (lit,[6)] oil, picrate, mp 141—142 °C).

1-Anilino-7-phenylimino-1,3,5-cycloheptatriene (**2b**); mp 84—86 °C (lit,[4)] mp 86—88 °C); yield, 22%.

2-*p*-Anisidinotropone (**1c**); mp 90—91 °C (lit,[7)] mp 91—92 °C); yield, 22%.

1-(*p*-Anisidino)-7-(*p*-anisylimino)-1,3,5-cycloheptatriene (**2c**); mp 110.5—111.5 °C (lit,[4)] mp 112.5—113.5 °C); yield, 31%.

2-*p*-Chloroanilinotropone (**1d**); mp 143—144 °C (lit,[4)] 147 °C); yield, 37%.

1-(*p*-Chloroanilino)-7-(*p*-chlorophenylimino)-1,3,5-cycloheptatriene (**2d**); mp 165—166 °C (lit,[4)] mp 168—170 °C); yield, 14%.

2-*o*-Toluidinotropone (**1e**). Recrystallization from cyclohexane gave yellow prisms; mp 52—53 °C; yield, 14%. UV (methanol) max: 238 (log ε 4.36), 341 (4.09), and 404 nm (4.19). Found: C, 79.61; H, 6.16; N, 6.45%. Calcd for $C_{14}H_{13}ON$: C, 79.59; H, 6.20; N, 6.63%.

2-*o*-Anisidinotropone (**1f**). Recrystallization from a mixture of benzene and cyclohexane gave yellow prisms; mp 111—113 °C; yield, 44%. UV (methanol) max: 234 (log ε 4.33), 345 (4.04), and 406 nm (4.21). Found: C, 74.19; H, 5.80; N 6.02%. Calcd for $C_{14}H_{13}O_2N$: C, 73.99; H, 5.77; N, 6.16%.

The Reaction of Tropolone with Methylamine Tropolone (1.22 g) was dissolved in aqueous methylamine (40%, 10 ml), and the mixture was allowed to react at room temperature for 15 days. The reaction mixture was diluted with water, neutralized with dilute hydrochloric acid, and extracted with chloroform. The chloroform solution was extracted with a sodium hydroxide solution and dilute hydrochloric acid successively. The alkaline solution gave 475 mg of tropolone (mp 48—50 °C), while the acidic solution afforded 683 mg (51%) of 2-methylaminotropone (**3**) (mp 80—82 °C). A similar reaction of tropolone with aqueous pyrrolodine, however, did not afford 2-(1-pyrrolidinyl)tropone.

The Reaction of Tropolone with Primary Amines in the Presence of Copper(II) Salt. The example to be cited is the reaction of tropolone with methylamine. A deep blue solution obtained by dissolving tropolone (2.44 g) and copper(II) sulfate (10.0 g) in aqueous methylamine (30%, 25 ml) was heated at 50—52 °C for 48 h, during which time the color of the solution turned greenish brown and brown crystals began to separate. Water (75 ml) was then added to the reaction mixture, and the precipitate was collected by filtration.

The precipitate was dried and dissolved in chloroform, and hydrogen sulfide was passed through the solution. The copper(II) sulfide was filtered off, and the filtrate was washed successively with an excess of a dilute sodium hydroxide solution and dilute hydrochloric acid. The alkaline solution was acidified with acetic acid, and the yellow crystals (**A**, 850 mg, mp 100—110 °C) that separated were collected by filtration. The filtrate was extracted with chloroform, the chloroform solution was washed with water and dried, and the solvent was evaporated to give a red oil (**B**, 164 mg).

The acid solution was neutralized with sodium hydrogencarbonate, and the yellow crystals that separated were collected, washed, and dried. These crystals were dissolved in a mixture of benzene and chloroform (1:1) and chromatographed on an alumina column to obtain yellow crystals (**C**, 154 mg, mp 117—127 °C). The aqueous solution was extracted with chloroform, the chloroform solution was washed with water and dried, and the solvent was removed to give brown crystals (505 mg). These crystals were dissolved in a mixture of benzene and cyclohexane and treated with a copper(II) acetate solution. The copper(II) complex that was thus obtained was again treated with hydrogen sulfide to regenerate copper-free yellow crystals (**D**, 400 mg, mp 74—80 °C). The portion which did not afford copper(II) salt gave further crops of yellow crystals (**C**, 40 mg; mp 115—124 °C).

The aqueous solution, obtained at first by the dilution of the reaction mixture and the filtration of the precipitate, was acidified with dilute hydrochloric acid and extracted with chloroform, while the chloroform solution was similarly treated to give yellow crystals (**A**, 10 mg), a red oil (**B**, 380 mg), and a small amount of yellow crystals (a mixture of **C** and **D**).

The recrystallization of **A** from ethanol gave 3-methylaminotropolone (**4a**) as yellow plates; mp 113.5—115 °C (lit,[8] mp 113—114 °C; yield, 765 mg (25.3%). (Found: C, 63.67; H, 6.04; N, 8.94%).

The recrystallization of **C** from ethanol gave 2,7-bis(methylamino)tropone (**5**) as yellow needles; mp 128—130 °C; yield, 4.8%. Found: C, 65.67; H, 7.50; N, 16.92%. Calcd for $C_9H_{12}ON_2$: C, 65.83; H, 7.37; N, 17.06%.

The recrystallization of **D** from a mixture of benzene and cyclohexane gave 2-methylaminotropone (**3**); mp 81—82 °C; yield, 13%.

The red oil (**B**) was dissolved in chloroform and washed with dilute hydrochloric acid to remove the basic compounds. The chloroform solution was washed with water and dried, and the solvent was removed. The recrystallization of the crystalline residue from cyclohexane gave 205 mg of tropolone as pale yellow crystals.

The reaction of tropolone with ethylamine and isopropylamine was carried out in a similar manner.

3-Ethylaminotropolone (**4b**); yellow plates (from ethanol); mp 57—58 °C (lit,[8] mp 51—53 °C); yield, 20%. (Found: C, 65.75; H, 6.82; N, 8.42%).

3-Isopropylaminotropolone (**4c**); yellow prisms (from dilute methanol); mp 72—73.5 °C (lit,[8] 72—73 °C); yield, 23%. (Found: C, 66.48; H, 7.28; N, 7.75%).

Benzoylation of 2,7-Bis(methylamino)tropone (5). Into a solution of **5** (600 mg) in pyridine (5 ml), benzoyl chloride (2.5 ml) was added under ice cooling and with stirring. After 1 h, the reaction mixture was poured into water, acidified with hydrochloric acid, and extracted with chloroform. The solution was washed with water, the solvent was removed, and the crystalline residue was washed with benzene. The crystals were recrystallized from 1-butanol to give 2,7-bis(*N*-benzoylmethylamino)tropone (**7**) as yellow prisms; mp 230—232 °C. UV (methanol) max: 282 (log ε 4.00), and 355 nm (3.81). Found: C, 73.70; H, 5.51; N, 7.31%. Calcd for $C_{23}H_{20}O_3N_2$: C, 74.17; H, 5.41; N, 7.52%.

The benzene solution was chromatographed on a silica gel column, and the fraction eluted with chloroform was recrystallized from benzene to give 2-(*N*-benzoylmethylamino)-7-methylaminotropone (**6**) as yellow prisms; mp 183—184 °C; yield, 202 mg. UV (methanol) max: 253 (log ε 4.25) 345 (4.04), and 420 nm (4.20). Found: C, 71.40; H, 6.10; N, 10.34%. Calcd for $C_{16}H_{16}O_2N_2$: C, 71.62; H, 6.01; N, 10.44%.

Alkaline Hydrolysis of 6. A solution of **6** (150 mg) in ethanol (3 ml) was refluxed with 10% aqueous sodium hydroxide (0.6 ml) for 4 h. The reaction mixture was then diluted with water, acidified with acetic acid, and extracted with chloroform. The evaporation of the solvent gave a crystalline residue, which was recrystallized from a mixture of benzene and cyclohexane to give 65 mg of 3-(*N*-benzoylmethylamino)-tropolone (**8**) as pale yellow prisms; mp 115—116 °C. UV (methanol) max: 331 (log ε 3.79) and 368 nm (3.78). Found: C, 70.52; H, 5.12; N, 5.32%. Calcd for $C_{15}H_{13}O_3N$: C, 70.58; H, 5.13; N, 5.49%.

3-(N-Benzoylmethylamino)tropolone (8) from 4a. Into a solution of **4a** (100 mg) in pyridine (1 ml), benzoyl chloride (0.6 ml) was added under ice cooling and with stirring. After 1 h, the mixture was poured into water, and a viscous oily product was separated from the water. This oil was, without further purification, dissolved in ethanol (5 ml) and refluxed with an excess of an aqueous sodium hydroxide solution for 2 h. The mixture was then diluted with water, acidified with acetic acid, and extracted with chloroform. The solvent was removed, and the residue was chromatographed on a silica gel column. The fraction eluted with chloroform gave **8** (58 mg); mp 114—116 °C, which was identical with that obtained from **5**.

The Reaction of Tropolone with Secondary Amines in the Presence of Copper(II) Salt. The example cited will be for the reaction of tropolone with pyrrolidine. A deep blue solution obtained by dissolving copper(II) sulfate (5.00 g), ammonium chloride (3.00 g), and tropolone (1.22 g) in a mixture of pyrrolidine (12 ml), and water (12 ml) was heated at 50—55 °C for 5 days. Water (150 ml) was added to the reaction mixture, neutralized with hydrochloric acid, and the precipitate was collected by filtration. The filtrate was extracted with chloroform, the precipitate and chloroform extract were combined, and hydrogen sulfide was passed through the solution. The copper(II) sulfide was removed, and the filtrate was washed with a dilute sodium hydroxide solution. The aqueous layer was acidified with acetic acid, and the precipitate (**A**)

was filtered and washed with water. The filtrate was extracted with chloroform, and the chloroform solution was washed with water and dried. The subsequent evaporation of the solvent and distillation of the residue under reduced pressure afforded 496 mg of tropolone; mp 48—51 °C.

The crystals (**A**, 763 mg) were distilled under reduced pressure (2 Torr). The **B** fraction (distilled at a bath temperature of 120—130 °C) was recrystallized from methanol to give 552 mg (29%) of 3-(1-pyrrolidinyl)tropolone (**4d**), while the **C** fraction (sublimed under a free flame) was recrystallized from methanol, followed by dimethylformamide, to give 95 mg (5%) of 5-(1-pyrrolidinyl)tropolone (**9a**).

3-(1-Pyrrolidinyl)tropolone (**4d**); yellow prisms (from methanol); mp 98—99 °C. UV (methanol) max: 269 (log ε 4.34), 361 (4.19), and 422 nm (3.79). Found: C, 69.26; H, 7.18; N, 7.48%. Calcd for $C_{11}H_{13}O_2N$: C, 69.09; H, 6.85; N, 7.33%.

5-(1-Pyrrolidinyl)tropolone (**9a**); yellow plates (from dimethylformamide); mp 236—238 °C (dec). UV (methanol) max: 240 (log ε 4.32), 286 (3.51), 374 (4.29), and 394 nm (sh, 4.23). Found: C, 69.30; H, 7.09; N, 7.40%. Calcd for $C_{11}H_{13}O_2N$: C, 69.09; H, 6.85; N, 7.33%.

The reaction of tropolone with morpholine and dimethylamine was carried out in a manner similar to that described above, and the following 3- and 5-aminotropolone derivatives were obtained.

3-Morpholinotropolone (**4e**); yellow plates (from cyclohexane); mp 84—86 °C; yield, 21%. UV (methanol) max: 226 (log ε 4.24), 273 (4.19), and 355 nm (4.03). Found: C, 64.17; H, 6.42; N, 6.99%. Calcd for $C_{11}H_{13}O_3N$: C, 63.75; H, 6.32; N, 6.76%.

5-Morpholinotropolone (**9b**); yellow prisms (from dioxane); mp 201—202 °C; yield, 2%. UV (methanol) max: 236 (log ε 4.32), 283 (3.54), and 363 nm (4.12). Found: C, 63.39; H, 6.39; N, 6.95%. Calcd for $C_{11}H_{13}O_3N$: C, 63.75; H, 6.32; N, 6.76%.

3-Dimethylaminotropolone (**4f**); yellow prisms (from cyclohexane); mp 54.5—56 °C; yield, 24%. UV (methanol) max: 226 (log ε 4.14), 271 (4.26), and 360 nm (4.04). Found: C, 65.62; H, 6.95; N, 8.44%. Calcd for $C_9H_{11}O_2N$: C, 65.44; H, 6.71; N, 8.48%.

5-Dimethylaminotropolone (**9c**); yellow needles (from ethanol); mp 163—164.5 °C (lit,[9] 160—162 °C); yield, 2%. (Found: C, 65.36; H, 6.73; N, 8.66%).

The Reaction of 5-Chlorotropolone and 5-Bromotropolone with Pyrrolidine in the Presence of Copper(II) Salt. 5-Chlorotropolone (0.64 g) was added to a solution obtained by dissolving copper(II) acetate (1.60 g) in pyrrolidine (4 ml) and ethanol (10 ml), and the mixture was heated at 55—60 °C for 24h. The mixture was then diluted with water, and the precipitate was collected by filtration. The filtrate was neutralized with dilute hydrochloric acid and extracted with chloroform. The precipitate and the chloroform extract were then combined, and hydrogen sulfide was passed through the solution. Copper(II) sulfide was filtered off, and the filtrate was treated with a dilute sodium hydroxide solution. The separated sodium salt and the aqueous solution were combined, acidified with acetic acid, and extracted with chloroform, and the chloroform solution was again treated with 6M-hydrochloric acid. The acid-insoluble portion gave 232 mg of 5-chlorotropolone. The acid-soluble portion was neutralized with sodium hydrogencarbonate to give 215 mg of yellow crystals. These crystals were recrystallized from ethanol to give 5-chloro-3-(1-pyrrolidinyl)tropolone (**10**) as yellow crystals; mp 90—92 °C; yield, 190 mg (21%). UV (methanol) max: 277 (log ε 4.38), 368 (4.19), and 430 nm (3.82). Found: C, 58.68; H, 5.53; N, 6.19%. Calcd for $C_{11}H_{12}O_2NCl$: C, 58.54; H, 5.37; N, 6.21%.

A solution of copper(II) acetate (1.60 g), pyrrolidine (6 ml), methanol (6 ml), and 5-bromotropolone (0.80 g) was heated at 55—60 °C for 24 h, after which the reaction mixture was treated much as above. The portion soluble in both the sodium hydroxide solution and 6M-hydrochloric acid gave 30 mg of 5-(1-pyrrolidinyl)tropolone (**9a**) as yellow crystals (mp 235—237 °C (dec)) identical with the sample obtained by the reaction of tropolone and pyrrolidine described above.

The Reaction of 3-Bromotropolone with Methylamine in the Presence of Copper(II) Salt. To a deep blue solution obtained by dissolving copper(II) acetate (2.00 g) in methanol (10 ml) and methylamine (30%, 5 ml), 3-bromotropolone (1.00 g) was added, after which the mixture was heated at 60—65 °C for 20 h. The precipitate was then removed, and the filtrate was concentrated under reduced pressure. The residue was diluted with water, and hydrochloric acid was added to the solution to adjust the pH at about 3. The precipitate that formed was filtered and washed with water, while the filtrate was extracted with chloroform. The precipitate and chloroform extract were then combined, hydrogen sulfide was passed through, and the copper(II) sulfide was filtered off. The filtrate was washed with 4M-hydrochloric acid, and the acid-soluble portion was neutralized with sodium hydrogencarbonate. The crystals that separated out were recrystallized from ethanol to give yellow scales (mp 111—113 °C; 85 mg) which were identical with 3-methylaminotropolone (**4a**).

Constituents of the Essential Oil of *Chrysanthemum japonense*. Nojigiku Alcohol and Its Acetate

Yasuto UCHIO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda, Hiroshima 730

(Received November 24, 1977)

The essential oil of *Chrysanthemum japonense* has been analyzed to isolate a new monoterpenoid named nojigiku alcohol together with its acetate, the structure of which has been elucidated as (5*R*)-2,2-dimethyl-3-methylenebicyclo[2.2.1]heptan-5-ol. In addition, fifteen monoterpenoids including (+)-α-pinene, (+)-camphene, β-pinene, sabinene, 1,8-cineole, *p*-cymene, filifolone, (+)-chrysanthenone, (+)-camphor, (+)-borneol, (−)-*cis*- and (+)-*trans*-chrysanthenyl acetate, *cis*- and *trans*-carveyl acetate, (+)-bornyl acetate and nine sesquiterpenoids including α-copaene, β-elemene, β-caryophyllene, germacrene-D, γ-cadinene, calamenene, β-caryophyllene oxide, T-muurolol and α-cadinol were identified in the essential oil.

In Japan about twenty species of the *Genus Chrysanthemum* (the *family* of *Compositae*) are distributed as native plants. The plants are known to be a typical group, the chromosome number of which are the multiple such as $2n=18$, 36, 54, 72, and 90.[1] Consequently, they have been investigated by many workers in the field of the botany, especially taxonomy, morphology, cytology and genetics. However, there has been little chemical investigation on the constituents of the essential oils except for the isolation of chrysanthenone from *Chrysanthemum sinense* Sabin, (an agricultural species) and its structural elucidation by Kotake and Nonaka.[2]

The present author is continuing the investigation on the essential oils of the species, and has already reported the structural elucidations of (+)-*trans*-chrysanthenyl acetate,[3] two new acetylenic compounds,[4] and also the analyses of the essential oils of *Ch. boreale* Makino ($2n=18$),[5] *Ch. makinoi* Matsum. *et* Nakai ($2n=18$),[5] *Ch. shiwogiku* Kitam. ($2n=54$)[3] and *Ch. japonense* var. *devile* Kitam. ($2n=54$).[6] In the present work, the essential oil of *Ch. japonense* (Makino) Nakai ($2n=54$) has been analyzed and a new monoterpene alcohol isolated of good aroma, (5*R*)-2,2-dimethyl-3-methylenebicyclo[2.2.1]heptan-5-ol (**1**), together with its acetate (**2**). The alcohol has been named nojigiku alcohol and its structure elucidated as 5-hydroxycamphene. This is the first example of an oxygenated derivative of camphene having been isolated in nature. The details of the structural elucidation and the analytical results on other mono and sesquiterpenoids are described. Part of the work has been presented in a prelininary report.[7]

Results and Discussion

Structural Elucidation of Nojigiku Alcohol and Its Acetate. Nojigiku alcohol (**1**), mp 52.0—53.0 °C, $[\alpha]_D^{25}$ +12.0° (*c* 1.10, $CHCl_3$), has been isolated, together with an oily acetate, $[\alpha]_D^{25}$ +20.9° (*c* 0.58, $CHCl_3$) from the essential oil by a combination of fractional distillation and elution chromatography.

The alcohol has been analyzed for $C_{10}H_{16}O$ (M^+ 152) and afforded a crystalline 3,5-dinitrobenzoate, mp 107.0—108.0 °C. The IR and ^{1}H-NMR spectra revealed the alcohol to contain a secondary hydroxyl group (δ 3.71, 1H, dd, $J=7.0$ and 3.0 Hz; ν 3350 and 1050 cm^{-1}), a *gem*-dimethyl (δ 0.91 and 1.01, each 3H, s; ν 1380, 1375, and 1360 cm^{-1}), an allylic methine (δ 2.63, 1H, br s), and an *exo*-methylene group (δ 4.60 and 4.81, each 1H, s; ν 3060, 1655, and 885 cm^{-1}).

Examination of the ^{13}C-NMR spectrum showed a close resemblance to that of camphene, which is a bicyclic monoterpene hydrocarbon containing all the functional groups mentioned above except the secondary hydroxyl group. The chemical shifts and the signal multiplicities are shown in Table 1. In the catalytic hydrogenation over Adams catalyst in AcOH, the alcohol took up one molar equivalent of hydrogen to afford two saturated alcohols attributable to the *endo*- and *exo*-methyl isomers in a ratio of 4: 1, a similar reaction to that of camphene; the major product (**4**), $C_{10}H_{18}O$ (M^+ 154), after isolation by preparative GLC, exhibited a doublet due to the newly formed secondary methyl group at δ 0.90. These results suggested the alcohol to be a bicyclic monoterpene alcohol. The alcohol was oxidized with Jones reagent to give a nonconjugated cyclopentanone derivative (**3**), $C_{10}H_{14}O$ (M^+ 150.1049); mp 47.0—48.0 °C (semicarbazone, mp 189.0—190.0 °C); ν 1755 cm^{-1}, leaving the *exo*-methylene group unaffected (δ 4.82 and 5.06, each 1H, s; ν 3075, 1655, and 899 cm^{-1}). In the spectra of this ketone, an absorption band attributable to the newly formed active methylene appeared at ν 1420 cm^{-1} and the broad singlet of the allylic methine showed a much lower shift (δ 3.00) owing to the anisotropic effect of the carbonyl group compared with the original alcohol. Thus, nojigiku alcohol was characterized as a camphene derivative bearing the hydroxyl group on the C-5 position, that is, the planar structure of nojigiku alcohol was determined as 2,2-dimethyl-3-methylenebicyclo-[2.2.1]heptan-5-ol.

On treatment with acetic anhydride in pyridine, the

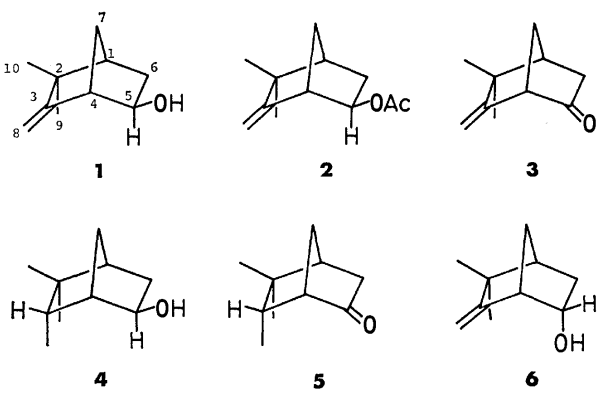

Table 1. ^{13}C-NMR spectral data[a] of nojigiku alcohol (**1**), its acetate (**2**) and camphene (**7**), and shielding differences

Carbon atom	**1**	**2**[b]	**7**[c]	$\Delta\delta$(**1**—**7**)[d]	$\Delta\delta$(**2**—**7**)[d]
1	48.4(d)	47.5(d)	48.8(d)	−0.4(γ)	−1.3(γ)
2	41.5(s)	41.2(s)	42.3(s)	−0.8(δ)	−1.1(δ)

10	25.7(q)	25.4(q)	26.2(q)	−0.5	−0.8

a) The spectra were measured in $CDCl_3$ with an internal standard of TMS. Multiplicities given in parentheses were determined by off-resonance ^{1}H decoupled spectra. b) For the additional $-COCH_3$ 170.6(s) and 21.4(q) were given. c) The assignment depended upon Ref. 14. d) Effects of hydroxy or acetoxy group are reported at designated position relative to camphene (**7**).

alcohol gave an oily monoacetate, $C_{12}H_{18}O_2$ (M^+ 194); ν 1740 and 1250 cm^{-1}, which was identical with the co-occurring acetate in IR, ^{1}H-NMR, and MS spectra. The reduction of the co-occurring acetate with $LiAlH_4$ afforded an alcohol showing the same TLC behavior as nojigiku alcohol.

With regard to the ^{13}C-NMR spectra of nojigiku alcohol and its acetate the shielding differences of the carbon atoms ($\Delta\delta$ in Table 1) were calculated for those of camphene. In this case the differences showed the same trend as in the case of 5-*exo*-hydroxynorbornane towards norbornane.[8] In the ^{1}H-NMR spectra of the alcohol, its acetate, and dihydro alcohol the carbinyl protons uniformly showed a double doublet (J=7.0 and 3.0 Hz) at δ 3.71, 4.55, and 3.97, which indicated the protons on C-5 to have the *endo* configuration.[9] Furthermore, the cyclopentanone derivative (**3**) was reduced with $LiAlH_4$ to give two epimeric alcohols in a ratio of 9: 1. Of these products the minor alcohol was identical with nojigiku alcohol in IR, ^{1}H-NMR, and MS spectra. The major alcohol could be characterized as its epimer (**6**) holding the hydroxyl group in the *endo* configuration based on the fact that a broad doublet (δ 2.67) of the allylic bridgehead proton had a coupling constant of about J=4.0 Hz as well as that of (J=3.8 Hz) in *endo*-norborneol.[9] These facts clearly designated the hydroxyl group of nojigiku alcohol to have the *exo* configuration. The proposed structure for nojigiku alcohol, however, has been reported to a chlorination product of camphene by some workers.[10a–d] For confirmation of the identity, the compound was synthesized from *dl*-camphene according to the reports;[10b,d] the IR, ^{1}H-NMR, and MS spectra were respectively coincident with those of nojigiku alcohol.

In order to determine the absolute configuration of nojigiku alcohol, its dihydro alcohol (**4**) was oxidized with Jones reagent to a saturated ketone (**5**) which showed a negative Cotton effect ($[\phi]_{297}$ −4690, $[\phi]_{265}$ +1600, *c* 0.039, MeOH) on the ORD curve. This indicated, according to the relation between the Cotton effect and stereostructure in a bicyclo[2.2.1]heptan-2-one system,[11] that the saturated ketone had an absolute configuration as shown by (**5**). Consequently, the absolute configuration of nojigiku alcohol and its acetate isolated from *Ch. japonense* may be represented as formulae (**1**) and (**2**) holding the chirality of *d*-camphene. The configuration of the hydroxyl group in this formula (**1**) agreed with the determination by Horeau's method.[12]

Other Constituents of the Essential Oil. From the essential oil of *Ch. japonense* fifteen monoterpenoids and nine sesquiterpenoids were identified other than nojigiku alcohol and its acetate as shown in Table 2. The composition, calculated from the relative GLC peak areas and identification methods are also listed. Total amounts of the monoterpenoids and sesquiterpenoids were *ca.* 87 and 13%, respectively, in the oil. The monoterpenoids thus identified have been classified into the camphane type ((+)-camphene, (+)-camphor, nojigiku alcohol and its acetate, (+)-borneol, and (+)-bornyl acetate), the pinane type ((+)-α-pinene, β-pinene, (+)-chrysanthenone, (+)-*trans*- and (−)-*cis*-chrysanthenyl acetate), *p*-menthane type (1,8-cineole, *p*-cymene, *trans*- and *cis*-carveyl acetate), and others (sabinene and filifolone). The camphane, pinane and *p*-menthane types were respectively 74.8, 6.5, and 5.5% of the total oil. Thus, the major part of the oil consisted of bicyclic monoterpenoids, in which (+)-camphor was the main (60.0%), and the other monoterpenoids were in trace amounts except for 1,8-cineole. As to the pinane type, (+)-*trans*-chrysanthenyl acetate has been previously isolated from the essential oil of *Ch. shiwogiku*[3] by the present author *et al.*, and (−)-*cis*-chrysanthenyl acetate has been reported as the main component of *Centipeda Cunninghami*[13] by Pinhey and Southwell. Both isomers, however, co-occurred in this essential oil. (+)-Chrysanthenone, (+)-*trans*- and (−)-*cis*-chrysanthenyl acetate should be counted in the series of (−)-α-pinene in the chirality, but any oxygenated derivative of (+)-α-pinene could not be identified in the oil.

The essential oil of *Ch. japonense* remarkably differed from that of *Ch. japonense var. devile*,[6] which contains borneol and bornyl acetate as major components but not nojigiku alcohol and its acetate, although the latter has been classified as a variety of the former.

Table 2. Constituents of the essential oil of *Ch. japonense*

	Compound	Content (% in total oil)		Method of identification
Monoterpenoids				
Camphane type	(+)-Camphene	2.3		IR, NMR, MS
	(+)-Camphor	60.0		IR, NMR, MS
	(+)-Nojigiku alcohol	5.4	74.8	IR, NMR, MS
	(+)-Borneol	1.5		IR, NMR, MS
	(+)-Bornyl acetate	4.3		IR, NMR, MS
	(+)-Acetate of nojigiku alcohol	1.3		IR, NMR, MS
Pinane type	(+)-α-Pinene	1.4		IR, MS
	β-Pinene	0.6		IR, MS
	(+)-Chrysanthenone	2.4	6.5	IR, NMR, MS
	(+)-*trans*-Chrysanthenyl acetate	1.3		IR, NMR, MS
	(−)-*cis*-Chrysanthenyl acetate	0.8		IR, NMR, MS
p-Menthane type	1,8-Cineole	4.8		IR, NMR, MS
	p-Cymene	0.4	5.5	IR, MS
	trans-Carveyl acetate	0.2		IR, NMR, MS
	cis-Carveyl acetate	0.1		IR, NMR, MS
Other	Sabinene	0.2	0.6	IR, MS
	Filifolone	0.4		IR, NMR, MS
Sesquiterpenoids				
Hydrocarbons	α-Copaene	0.1		IR, NMR, MS
	β-Elemene	1.0		IR, NMR, MS
	β-Caryophyllene	1.2	9.6	IR, NMR, MS
	Germacrene-D	6.7		IR, NMR, MS
	γ-Cadinene	0.3		IR, NMR, MS
	Calamenene	0.2		IR, MS
Oxygenated compounds	β-Caryophyllene oxide	1.1		IR, NMR, MS
	T-Muurolol	1.6	3.5	IR,[15] NMR, MS
	α-Cadinol	0.1		IR,[15] NMR, MS
	Unidentified	0.7		

Experimental

All melting and boiling points are uncorrected. The IR spectra were measured in CCl_4. The ^{1}H-NMR spectra were obtained on a Hitachi R-20 or Varian T-60 spectrometer in CCl_4 using TMS as the internal standard. The ^{13}C-NMR spectra were recorded on a JEOL-PFT-100 spectrometer operating at 25.5 MHz. The mass spectra were measured on a Hitachi RMS-4 spectrometer, and the high mass measurements on a Hitachi RMU-7L spectrometer. The TLC was carried out using a Merck Kiesel Gel G, and the elution chromatography using a Merck Kiesel Gel Type 60. The analytical GLC was performed with a separation column (3 mm×2 m) packed with 3% PEG-6000, PEG-20M, DEGS, and SE-30 on Chromosorb AW (60—80 mesh) under the flow rate of 20 ml/min of N_2, and preparative GLC with a separation column (6 mm×2 m) packed with 10% PEG-6000, PEG-20M, DEGS, and SE-30 on Chromosorb AW (60—80 mesh) using He as a carrier gas (30 ml/min).

Separation and Fractionation of the Essential Oil[1] *Ch. japonense* used in the experiment was collected at the sea side of Suzaki city in Kochi prefecture in October prior to efflorescence. After being dried in the shade for one day, the plant (8.1 kg) was steam distilled to obtain the essential oil (6.0 g, yield 0.07%), $[\alpha]_D^{25}$ −1.86°, n_D^{25} 1.4800, d_4^{25} 0.9388, including an ether extract from the distilled water. The essential oil showed twenty six GLC peaks using a SE-30 column under a temperature programme of 3 °C/min from 80 to 200 °C.

The oil was fractionated through a small size-spinning band distillation column (6×500 mm) under reduced pressure and separated into the following fractions and residue (2.4 g). Fr. 1 (bp 40—60 °C/30 Torr): 1.2 g; fr. 2 (60—80 °C/20 Torr): 1.0 g; fr. 3 (80—100 °C/20 Torr): 0.9 g. The residue was then eluted stepwise over a silica gel column by hexane (100 ml), a hexane and ethyl acetate mixture (v/v, 3: 1, 200 ml), and diethyl ether (100 ml) to give three additional fractions, R-1, R-2, and R-3, respectively.

Isolation of Nojigiku Alcohol (1) and Its Acetate (2). Fraction R-2 was again eluted over a silica gel column with a mixed solvent of hexane and ethyl acetate (v/v, 5: 1) and nojigiku alcohol isolated from the last eluate in a homogeneous state for GLC (SE-30 and PEG-20M). MS *m/e* 152 (M^+, $C_{10}H_{16}O$, 0.5%), 137 (M−CH_3, 3%), 135 (M−OH, 4%), 134 (M−H_2O, 3%), 108 (base), 119 (14), 93 (62), 91 (39), 81 (13), 79 (29), 67 (21), and 41 (34). 3,5-Dinitrobenzoate, Found: C, 58.97; H, 5.23; N, 8.06%. Calcd for $C_{17}H_{18}N_2O_6$: C, 58.95; H, 5.24; N, 8.09%.

Acetylation of the alcohol (30 mg) with Ac_2O (1 ml) in pyridine (1 ml) gave an oily monoacetate (35 mg). $[\alpha]_D^{25}$ +11.6° (*c* 1.20, $CHCl_3$). The IR, ^{1}H-NMR, and MS spectra were respectively superimposable on those of the co-occurring acetate described in the following.

The early eluate in the column chromatography of fraction R-2 afforded an oily mixture of monoterpene acetates showing six GLC peaks, the fourth peak of which was characterized, after isolation by preparative GLC (PEG-20M, 110 °C), as the acetate (**2**) of nojigiku alcohol based on the following data.

MS *m/e* 194.1309 (M^+, 1.9%, calcd for $C_{12}H_{18}O_2$, 194.1312), 179 (3), 150 (35), 134 (4), 119 (12), 107 (58), 93 (13), 91 (13), 89 (17), 79 (11), 77 (7), 67 (8), 65 (5), 53 (8), 43 (base), and 41 (18); IR *ν* 3075, 1740, 1655, 1375, 1365, 1250, 1035, and 895 cm^{-1}; ^{1}H-NMR *δ* 1.07 (6H, s), 1.95 (3H, s), 2.73 (1H, br s), 4.55 (1H, dd, *J*=7.0 and 3.0 Hz), 4.73 (1H, s), and 4.99 (1H, s). Found: C, 74.35; H, 9.41%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

The acetate was applied to the TLC plate, and some drops of an ethereal solution of $LiAlH_4$ applied. After standing for a times, the plate was developed with $CHCl_3$ and a mixture of hexane and ethyl acetate (v/v, 5: 1), giving an R_f 0.30 or 0.35. This mobility agreed with that of nojigiku alcohol.

Catalytic Hydrogenation of Nojigiku Alcohol. The alcohol (70 mg) was subjected to hydrogenation over Adams catalyst (5 mg) in AcOH (3 ml) at room temperature until the uptake of H_2 ceased. The hydrogenated mixture was treated in the usual manner to give a product showing two peaks attributable to two diastereoisomers of dihydronojigiku alcohol in GLC (DEGS) with a relative peak intensity of about 4: 1. The major product was isolated by preparative GLC (DEGS) to give the 3-*endo*-methyl isomer (**4**) as colorless needles, mp 68.0—69.0 °C. MS *m/e* 154 (M^+, $C_{10}H_{18}O$, 3%), 139 (5), 121 (6), 110 (6), 95 (29), 84 (14), 81 (12), 71 (22), 67 (30), 55 (47), and 41 (base); IR *ν* 3620, 3320, 1390, 1375, 1365, and 1040 cm^{-1}; ^{1}H-NMR *δ* 0.75 (3H, s), 0.87 (3H, s), 0.90 (3H, d, *J*=6.0 Hz), 1.70 (1H, br s, OH exchanged with D_2O), and 3.97 (1H, dd, *J*=7.0 and 3.0 Hz).

*Oxidation of 3-*endo*-Methyl Alcohol (**4**).* The 3-*endo*-methyl alcohol (45 mg) was oxidized with Jones reagent (1 ml) in acetone (5 ml) at room temperature. After the usual work up, the mixture gave a crystalline ketone (**5**) (30 mg), mp 58.0—59.0 °C. MS *m/e* 152 (M^+, 21%), 137 (10), 123 (4), 119 (12), 117 (14), 110 (34), 95 (96), 83 (20), 81 (29), 69 (41), 67 (32), 55 (59), and 41 (base); IR *ν* 1750, 1420, 1390, 1380, and 1365 cm^{-1}; ^{1}H-NMR *δ* 0.83 (3H, d, *J*=6.0 Hz), 0.92 (3H, s), 1.17 (3H, s), and 2.35 (1H, br d, *J*=4.0 Hz).

*Oxidation of Nojigiku Alcohol (**1**).* To the alcohol (120 mg) in acetone (10 ml) Jones reagent (2 ml) was added drop by drop at room temperature. After the brown color of the reaction mixture disappeared, it was treated according to the usual procedure and purified over a silica gel column with $CHCl_3$ to give an unsaturated ketone (**3**) as a colorless solid. $[\alpha]_D^{25}$ +33.7° (*c* 0.86, $CHCl_3$). MS *m/e* 150.1049 (M^+, 27%, calcd for $C_{10}H_{14}O$, 150.1044), 135 (17), 121 (11), 107 (81), 106 (86), 91 (77), 79 (69), 77 (41), 67 (25), 65 (24), 53 (44), and 41 (base); IR *ν* 3075, 1755, 1665, 1420, 1390, 1370, 1150, and 899 cm^{-1}; ^{1}H-NMR *δ* 1.13 (3H, s), 1.22 (3H, s), 3.00 (1H, br s), 4.82 (1H, s), and 5.06 (1H, s).

*Reduction of the Unsaturated Ketone (**3**).* To a suspention of $LiAlH_4$ (20 mg) in dry diethyl ether (5 ml) an ethereal solution of the ketone (**3**) (75 mg/2 ml) was added drop by drop and the mixture stirred at room temperature for 3 h. After the excess reagent was decomposed by adding H_2O (1 ml), the ethereal layer was separated, washed with 1% H_2SO_4 and H_2O, dried over Na_2SO_4 and concentrated to give a colorless oil (69 mg). GLC (DEGS) showed two peaks with an intensity ratio of 9: 1, which were eluted over a silica gel column with $CHCl_3$. The major compound thus obtained gave an R_f 0.37 in TLC using $CHCl_3$ as a solvent and it was thus characterized as the *endo*-hydroxy isomer (**6**) of nojigiku alcohol. mp 67.5—68.5 °C. MS *m/e* 152.1189 (M^+, 1%, calcd for $C_{10}H_{16}O$, 152.1200), 137 (4), 135 (3), 134 (2), 119 (14), 108 (87), 93 (54), 91 (34), 81 (15), 79 (20), 77 (32), 67 (35), 65 (22), 55 (34), 53 (44), 51 (22), 43 (30), and 41 (base); IR *ν* 3540, 3075, 1660, 1398, 1380, 1125, 1045, and 895 cm^{-1}; ^{1}H-NMR *δ* 1.12 (6H, s), 2.68 (1H, br d, *J*=4.0 Hz), 4.03 (1H, m), and 4.93 (2H, s). 3,5-Dinitrobenzoate, mp 136.5—138.0 °C.

The minor compound gave R_f 0.30 in TLC which was identical with nojigiku alcohol in IR, ^{1}H-NMR, and MS spectra.

Absolute Configuration of the Hydroxyl Group in Nojigiku Alcohol by Horeau's Method.[12] α-Phenylbutylic anhydride was prepared by refluxing racemic α-phenylbutylic acid with acetic anhydride for 5 h and evaporation of the solvent *in vacuo*. The racemic anhydride (1.2 mmol) was added to a solution of the alcohol (0.4 mmol) in pyridine (2 ml), and the mixture allowed to stand for 20 h at room temperature. After the excess anhydride was decomposed with H_2O (1.0 ml), the mixture was diluted with benzene and titrated with 0.1 M NaOH using phenolphthalein as indicator. The aqueous layer was separated, acidified with 0.5 M H_2SO_4 and extracted with benzene. The benzene solution was dried and evaporated under reduced pressure to give an oily α-phenylbutylic acid. The acid thus recovered was dissolved in benzene (5 ml), and the optical rotation measured in a 0.5 dm cell as $[\alpha]_D^{25}$ +10.0°. Thus the optical yield was calculated as +56.3%.

Synthesis of Nogigiku Alcohol. Camphene (1.0 g) was sealed in a pyrex tube with *t*-butyl hypochlorite (1.2 g) and irradiated with a tungsten lamp (40 W) for 9 h in an ice bath.[10b] The mixture was fractionated under reduced pressure (70 °C/1 Torr) to give a distillate, which separated by preparative GLC (PEG-20M, 125 °C) to afford *exo*-6-chlorocamphene. MS *m/e* 172 and 170 (7 and 19%, M^+ for $C_{10}H_{15}Cl$), 157 (9), 155 (24), 135 (37), 121 (30), 119 (27), 107 (50), 93 (base), 91 (50), 79 (40), 77 (47), 67 (27), 53 (20), and 41 (45); IR *ν* 3060, 1660, 1385, 1360, 1300, 1095, 890, and 770 cm^{-1}; ^{1}H-NMR *δ* 0.98 (3H, s), 1.06 (3H, s), 2.81 (1H, br s), 3.80 (1H, dd, *J*=7.0 and 3.5 Hz), 4.68 (1H, s), and 4.93 (1H, s).

The chlorocamphene (120 mg) was then refluxed[10d] with Li_2CO_3 (60 mg) in water for 10 h. The resulting alcohol was extracted with ether, and purified by preparative GLC (PEG-20M, 125 °C). The compound thus synthesized was identical with nojigiku alcohol in IR, ^{1}H-NMR, and MS spectra.

Identification of Other Monoterpenoids in the Essential Oil. Fraction 1 and 2, which were separated by fractional distillation from the oil, were further treated by preparative GLC (PEG-6000, 80 °C) to isolate six hydrocarbons which were identified on the spectra listed in Table 2. Among them, (+)-α-pinene: $[\alpha]_D^{25}$ +17.1° (*c* 0.80, $CHCl_3$), (+)-camphene: $[\alpha]_D^{25}$ +82.7° (*c* 1.60, $CHCl_3$).

Fraction R-2, which was separated from the fractional distillation residue of the oil by elution chromatography, was again chromatographed over silica gel with hexane and ethyl acetate (v/v, 5: 1). The first eluate was treated with preparative GLC (SE-30, 120 °C and PEG-20M, 110 °C) to give six monoterpene acetates including the acetate of nojigiku alcohol, identified as shown in Table 2. From the middle eluate, three ketones and an alcohol were isolated by a combination of additional chromatography (hexane and ethyl acetate, v/v, 5: 1) and preparative GLC (PEG-20M, 120 °C). Spectral data of these compounds were as follows.

(+)-trans-*Chrysanthenyl Acetate*: $[\alpha]_D^{25}$ +36.7° (*c* 1.40, $CHCl_3$); MS *m/e* 194 (M^+, 1.5%), 179 (1), 151 (5), 137(8), 135 (29), 119 (24), 93 (17), 91 (28), 81 (23), 69 (10), 67 (12), 59 (14), and 43 (base); IR *ν* 3025, 1740, 1375, 1360, 1250, 1180, 1033, and 791 cm^{-1}; ^{1}H-NMR *δ* 0.89 (3H, s), 1.25 (3H, s), 1.57 (3H, q, *J*=2.0 Hz), 1.88 (3H, s), 4.87 (1H, t, *J*=6.0 Hz), and 5.30 (1H, m).

(−)-cis-*Chrysanthenyl Acetate*: $[\alpha]_D^{25}$ −25.5° (*c* 1.10, $CHCl_3$); MS *m/e* 194 (M^+, 1%), 179 (2), 137 (9), 135 (26), 119 (61), 109 (27), 91 (26), 81 (25), 69 (15), 67 (14), 59 (21), 43 (base)

and 41 (37); IR ν 3030, 1740, 1375, 1360, 1240, 1040, and 720 cm^{-1}; ^{1}H-NMR δ 0.91 (3H, s), 1.43 (3H, s), 1.70 (3H, q, J=2.0 Hz), 2.01 (3H, s), 4.45 (1H, s), and 5.23 (1H, m) (IR and ^{1}H-NMR values in agreement with authentic spectra provided by professor J. T. Pinhey, University of Sydney).

trans-*Carveyl Acetate*: ^{1}H-NMR δ 1.67 (3H, m), 1.70 (3H, br s), 1.97 (3H, s), 4.70 (2H, m), 5.18 (1H, m), and 5.65 (1H, br d, J=6.0 Hz).

cis-*Carveyl Acetate*: ^{1}H-NMR δ 1.64 (3H, m), 1.74 (3H, br s), 2.00 (3H, s), 4.73 (2H, br s), and 5.30 (1H, m).

(+)-*Bornyl Acetate*: $[\alpha]_D^{25}$ +20.7° (*c* 5.70, $CHCl_3$)

Filifolone: MS *m/e* 150 (M^+, 30%), 135 (14), 122 (35), 107 (base), 93 (35), 91 (65), 85 (43), 80 (83), 79 (63), 70 (61), 57 (43), 55 (32), 43 (48), and 41 (72); IR ν 1779 cm^{-1}; ^{1}H-NMR δ 1.08 (3H, s), 1.17 (3H, s), 1.75 (3H, br s), 2.53 (3H, m), 4.00 (1H, m), and 5.35 (1H, m) (IR and ^{1}H-NMR spectra in agreement with authentic ones provided by Professor R. B. Bates, University of Arizona).

(+)-*Chrysanthenone*: $[\alpha]_D^{25}$ +61.0° (*c* 1.50, $CHCl_3$); MS *m/e* 150 (M^+, 1.7%), 135 (7), 122 (20), 107 (base), 91 (57), 79 (30), 69 (17), 55 (12), 53 (14), 43 (10), and 41 (32), IR ν 1780 cm^{-1}; ^{1}H-NMR δ 1.18 (3H, s), 1.20 (3H, s), 1.70 (3H, q, J=2.0 Hz), 2.51 (2H, m), and 5.30 (1H, m).

(+)-*Camphor*: Mp 178 °C; $[\alpha]_D^{25}$ +25.4° (*c* 3.10, $CHCl_3$). Oxime: Mp 118.0—118.5 °C. Semicarbazone: Mp 236.0—237.0 °C.

(+)-*Borneol*: Mp 204.0—205.0 °C; $[\alpha]_D^{25}$ +10.8° (*c* 1.80, EtOH). 3,5-Dinitrobenzoate: mp 155.5—156.0 °C.

Identification of Sesquiterpenoids in the Essential Oil. The hexane eluate in the chromatography of fr. R-2 was further treated by preparative GLC (PEG-20M, 150 °C) to give six sesquiterpene hydrocarbons. Fr. R-3 was also treated in combination of silica gel column chromatography (petroleum ether and diethyl ether, v/v, 3: 1) and preparative GLC (SE-30, 200 °C) to give three oxygenated sesquiterpenes. These compounds thus isolated, were identified on the basis of the IR, ^{1}H-NMR, and MS spectra, are listed in Table 2.

The author wishes to express his gratitude to Professor Shûichi Hayashi, Hiroshima University, for many helpful discussions and suggestions in the course of this work. Thanks are also due to Professor Ryuso Tanaka, Botanical Institute, Hiroshima University, for the collection and identification of the plant material.

Carboxylation of Olefins with Carbon Monoxide Using Various Strong Acids-H_2O-Group 1B Metal Carbonyl Catalyst Systems

Norihiko YONEDA,* Tsuyoshi FUKUHARA, Yukio TAKAHASHI, and Akira SUZUKI

Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received December 1, 1977)

Carboxylation of 2,4,4-trimethyl-1-pentene and 1-octene with carbon monoxide was studied in the presence of various strong acids–H_2O–Cu(I) carbonyl catalyst systems in an attempt to find a practical method for the preparation of carboxylic acids. The reaction takes place smoothly at room temperature to give tertiary acids in higher yields than that with the use of sulfuric acid. The procedure is preferable for the ready separation of products from the catalyst layer without quenching by water.

An interesting carboxylation procedure of olefins and alcohols using Cu(I) carbonyl catalyst in the presence of concentrated sulfuric acid has been demonstrated by Souma *et al.*[1] The procedure gives tertiary carboxylic acids in high yields under milder conditions than those of the Koch-Haaf reaction.[2] However, in order to isolate the products, it is necessary to quench the reaction system by adding a large amount of water which leads to the destruction of the catalyst. It was considered that the reaction in strong acids having a water molecule as its component might facilitate the formation of carboxylic acid without the addition of a water molecule at the end of the reaction. We thus investigated extensively the catalytic behavior of Cu(I) carbonyl in the presence of strong acids such as BF_3–H_2O, BF_3–H_3PO_4–H_2O, HF–H_2O and so on. Some of these catalyst systems were found not only to show very high activity on the carboxylation of olefins but also to separate products readily from the reaction mixture with use of a co-solvent such as cyclohexane and chlorobenzene without quenching by intentional addition of water.[3]

Further details of these reaction behaviors will be described hereinafter.

Experimental

Materials. Commercial copper(I) oxide, silver monoxide, boron trifluoride and carbon monoxide of the highest purity were used without further purification. Olefins and organic solvents were purified in the usual way. Distilled hydrogen fluoride was used. BF_3–H_2O complex was prepared by introducing BF_3 gas into water cooled with ice. The desired complexes with given BF_3/H_2O mole ratios could be obtained by adjusting the amount of BF_3 absorbed.[4]

General Procedure of Carboxylation. A solution of Cu_2O (2 g, 14 mmol) in 40—50 g of strong acid was placed in a 200 ml galss reaction vessel fitted with a thermometer and a reflux condenser. Carbon monoxide was then introduced into the reaction mixture under thorough stirring with a magnetic stirrer at a constant flow rate of 20 ml/min to obtain Cu(I) carbonyl at the desired temperature. After complete carbon monoxide absorption, *i.e.*, the completion of cuprous carbonyl formation, 100 mmol of olefin (2,4,4-trimethyl-1-pentene or 1-octene) with or without 50 ml of an appropriate organic solvent was added dropwise by introducing an excess amount of carbon monoxide at a fixed temperature.

A polyethylene reaction vessel was used in the case of HF. All the work was conducted in a well-shielded fume hood.

After completion of the reaction, the reaction mixture separated into two layers, the upper usually being an organic layer and the lower a catalyst layer. The catalyst layer was then hydrolyzed with ice–water and organic materials were extracted with ether. In the case of a recycle experiment of the catalyst, the catalyst layer separated out from the organic layer was subjected to the next run without any treatment.

The yield of individual acids such as 2,2-dimethylpropanoic, tertiary C_6—C_8, tertiary C_9 and polymeric (mainly C_{13} acids) was determined by VPC.[4] The analysis was carried out with a Shimadzu 3AH apparatus, fitted with a 3 m × 3 mm column packed with ethylene glycol succinate–H_3PO_4 at 170 °C. C_9 and C_{13} acids produced by Shell Oil Company were used as references. Tertiary C_6—C_8 acids were synthesized by the Grignard reaction from the corresponding alkyl halides.

The amount of Cu^+ in the organic layer was analyzed as Cu^{2+} after oxidation with the air by the atomic absorption spectroscopic method.

passed through a solution of Cu_2O in various acids at −10—70 °C. The results are shown in Fig. 1.

Remarkable absorption of carbon monoxide was observed in acid media such as BF_3–H_3PO_4–H_2O (molar ratio, 1: 0.9: 0.1), BF_3–HF–H_2O (0.9: 6.8: 1), HF–H_2O (9: 1) and BF_3–H_2O (0.9: 1), as compared with that in concentrated sulfuric acid.[1] Even in HF–H_2O of molar ratio 6: 1, about 3 mol of carbon monoxide was absorbed per one mol of Cu(I) at −10 °C.

As described by Souma and Sano,[1,5] the unstable tricarbonylcopper(I) cation $Cu(CO)_3^+$ formed in acid media acts as a catalyst for the carboxylation of olefins under atmospheric pressure. The active species $Cu(CO)_3^+$ can be considered to show the following equilibrium. The species carbonylcopper(I) cation, $Cu(CO)^+$, shows no catalytic behavior for the carboxylation reaction.[1]

$$Cu(CO)_3^+ \rightleftarrows Cu(CO)^+ + 2CO$$

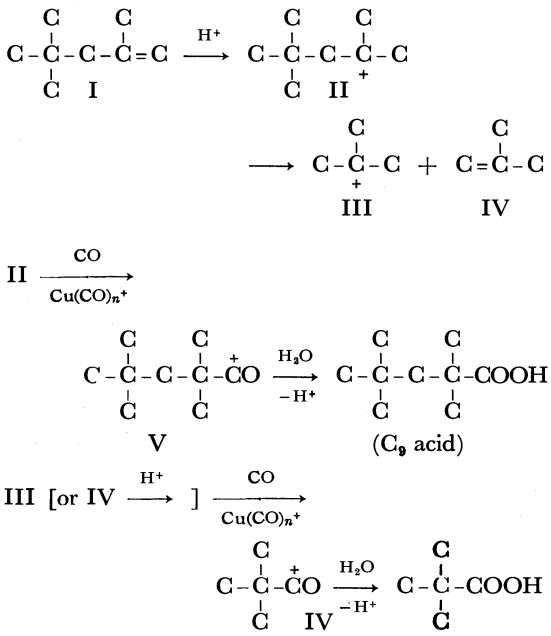
The value of CO(absorbed)/Ag(I) becomes 2 in the H_2SO_4–1/4SO_3 at −10 °C under a carbon monoxide pressure of 20 kg/cm² for silver carbonyl, which is also expected to have the same catalytic activity for the carboxylation of olefins.[6] However, such dicarbonyl silver(I) cation was readily prepared in BF_3–H_2O (0.9: 1 molar ratio) under atmospheric pressure (Fig. 1).

The Cu(I) carbonyl cation with high carbon monoxide coordination can be expected to show a much higher catalytic activity in the carboxylation reaction of olefins. Matsushima *et al.* first reported[7] the formation of tetracarbonylcopper(I) cation, $Cu(CO)_4^+$, in BF_3–H_2O (1: 1.06 molar ratio) solution. However, no investigation seems to have been carried out on the carboxylation of olefins using such acid media involved Ib group metal carbonyl cation before we presented our data.[3]

Reaction of 2,4,4-Trimethyl-1-pentene (Diisobutylene) with Carbon Monoxide in Various Acids–H_2O Containing Copper or Silver Carbonyl Cations. Carboxylation of 2,4,4-trimethyl-1-pentene (TMP) with carbon monoxide was carried out in the presence of BF_3–H_2O, BF_3–H_3PO_4–H_2O, BF_3–H_2SO_4–H_2O, BF_3–HF–H_2O and HF–H_2O having copper carbonyl cation with cyclohexane or chlorobenzene as a co-solvent at 18—30 °C. The results are summarized in Table 1.

The reaction took place in two liquid phase system (upper solvent layer and lower catalyst layer). The carboxylic acids produced were usually present in both layers. The total yield of carboxylic acids, *i.e.*, the sum of yields in both layers, was found to be considerably higher than that obtained in 96% H_2SO_4.

The carboxylic acids thus obtained consist of 2,2-dimethylpropanoic acid and C_9 acids together with small amounts of C_6—C_8 and other acids. Thus, the reaction of TMP with carbon monoxide in the presence of acid–H_2O–group Ib metal carbonyl, is considered to proceed as shown in the following scheme.



$$I + III(\text{or } II + IV) \longrightarrow C_{12}^{+}$$

$$C_{12}^{+} \xrightarrow[Cu(CO)_n^+]{CO} t\text{-}C_{13} \text{ acids}$$

$$C_{12}^{+} \longrightarrow C_5^{+}(\text{or } C_5^{=}) + C_7^{=}(\text{or } C_7^{+})$$

$$C_5^{+} \xrightarrow[Cu(CO)_n^+]{CO} t\text{-}C_6 \text{ acid}$$

$$C_7^{+} \xrightarrow[Cu(CO)_n]{CO} t\text{-}C_8 \text{ acids}$$

The tertiary C_9 acids of various skeletal structures were found in the products, since skeletal isomerization of C_8 carbenium ion (II) takes place easily under such reaction conditions.

The carboxylic acids existing in the solvent layer seem to be produced by the reaction of alkanoyl cations such as V and VI with water in the catalyst, *i.e.*, acid–H_2O–$Cu(CO)_n^+$. Such carboxylic acids were obtained in a high yield in the presence of BF_3–H_2O–$Cu(CO)_n^+$ catalyst. Despite the fact that an almost quantitative total yield of carboxylic acid was obtained in the presence of HF–H_2O–$Cu(CO)_n^+$ or HF–H_2O–BF_3–$Cu(CO)_n^+$, an insufficient amount of carboxylic acids separated into the organic layer under the conditions employed.

Carboxylation of Trimethylpentene Using BF_3–H_2O–$Cu(CO)_n^+$ Catalyst. Carboxylation of TMP with carbon monoxide was studied in the presence of BF_3–H_2O–$Cu(CO)_n^+$ with various BF_3/H_2O molar ratios. The results are given in Table 2.

Table 2. Effect of BF_3/H_2O molar ratio of BF_3–H_2O on the reaction

BF_3–H_2O / BF_3/H_2O Molar ratio	Total yield of acid, % (acid value)	Product distribution (%)	
		Yield of acid found separately from cat. layer (acid value)	Yield of acid found in cat. layer (acid value)
0.6	12.7(366)	97.0(366)	3.0(—)
0.7	47.8(362)	93.8(356)	6.2(461)
0.8	79.0(371)	86.5(356)	13.5(467)
0.9	76.9(395)	62.7(347)	37.3(478)
1.0	80.4(375)	59.9(344)	40.1(440)

Reaction conditions: BF_3, 0.50 mol; Cu_2O, 14 mmol: reaicton temperature, 30 °C, trimethylpentene, 0.10 mol.

The total yield of carboxylic acids increased with increase in the BF_3/H_2O molar ratio of the catalyst. An important feature is that the reaction takes place with the release of a large portion of the carboxylic acids as products from the catalyst layer without addition of water at the end of the reaction. The portion of carboxylic acids thus obtained was found to be over 90% of all the products in the presence of the catalyst having a BF_3/H_2O molar ratio less than 0.7. However, this portion tends to decrease with increase in the BF_3/H_2O molar ratio of the catalyst.

The BF_3–H_2O complex with BF_3/H_2O molar ratio of 1 is known as a stronger acid than concentrated sulfuric acid (96%) and can be described as $H^+BF_3OH^-$. The Ho value of this acid was reported to be −11.4 (Ho of 100% H_2SO_4 is −11.2).[8] The complexes with BF_3/H_2O molar ratio in the range 0.5—1.0 are mainly mixture of $H^+BF_3OH^-$ and $H_3^+OBF_3OH^-$.[9] The latter species (boron trifluoride dihydrate) should be a weaker acid than the former.

$$BF_3 + H_2O \rightleftharpoons H^+BF_3OH^-$$

$$H^+BF_3OH^- + H_2O \rightleftharpoons H_3^+OBF_3OH^-$$

The content of $H^+BF_3OH^-$ increases with increase in BF_3/H_2O.[10] $H^+BF_3OH^-$ appears to have a stronger affinity for carboxylic acids than $H_3^+OBF_3OH^-$. Hence, in the case of a catalyst rich in $H^+BF_3OH^-$, most of the carboxylic acids produced would be readily protonated to form $RCOOH_2^+BF_3OH^-$ and remain in the catalyst layer. However, when we use catalysts rich in $H_3^+OBF_3OH^-$, most of the carboxylic acids are present in the form of free acid and can be found separately from the catalyst layer.

Higher carboxylic acids such as C_9 and C_{13} acids might have smaller affinity for the catalyst as compared with lower ones such as 2,2-dimethylpropanoic acid, since the mean acid value of the products found in the catalyst layer is always higher than that of those obtained separately from the catalyst layer (Table 2).

The reaction may be expected to occur effectively by separating the products and catalyst from each other with heterogeneous use of co-existing organic solvents.

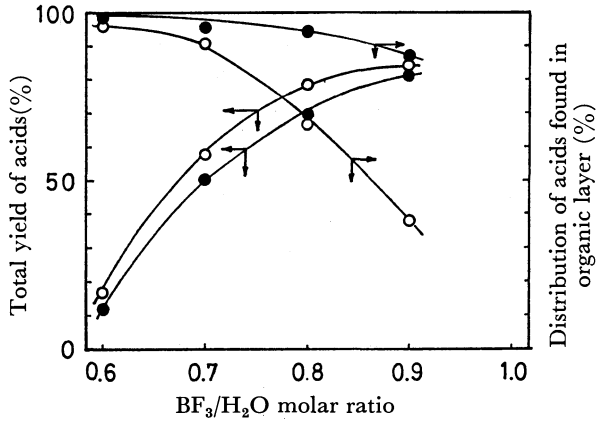


Fig. 2. The effect of BF_3/H_2O molar ratio of BF_3–H_2O on the total yield of acids and distribution of acids found in organic layer.
Reaction conditions: BF_3, 0.50 mol; Cu_2O, 14 mmol; reaction temperature, 30 °C; trimethylpentene, 0.10 mol; organic solvent, 50 ml.
–●–: Chlorobenzene, –○–: cyclohexane.

A solution of TMP in cyclohexane or chlorobenzene was added dropwise to the BF_3–H_2O–$Cu(CO)_n^+$ catalyst with a 0.6—0.9 BF_3/H_2O molar ratio, carbon monoxide being introduced at 30 °C. The results are shown in Fig. 2. All the reactions took place in the heterogeneous liquid phase to give products present in the organic and catalyst layers. The total yield of acids was found to be almost the same as in the case where no organic solvent was used. However, the amount of acids found in the organic layer was greatly affected by the BF_3/H_2O molar ratio in the catalyst, particularly in the case of cyclohexane.

a) Polymeric acids. b) Reaction conditions: BF_3–H_2O, 40 g; BF_3/H_2O molar ratio, 0.9; Cu_2O, 14 mmol; reaction temperature, 30 °C; olefin, 0.10 mol; organic solvent, 50 ml.

Other organic solvents were also examined by using the BF_3–H_2O complex with a 0.9 BF_3/H_2O molar ratio (Table 3). The products were again found in both layers except for the case using tetrachloromethane which resulted in an emulsion. The product distribution between both layers was greatly affected by the kind of solvent.

A significant quantity of the product was found to be distributed in organic solvents such as polyhalogenated alkyl compounds. However, the total yield of carboxylic acid produced was rather low as compared with the case in which no solvent reaction took place. In the course of the reaction using these solvents, the formation of copper carbonyl chloride Cu(CO)Cl, which has no catalytic activity, was observed. This is shown in the following scheme for the case of chloroform.

$$CHCl_3 \rightleftharpoons \overset{+}{C}HCl_2 + Cl^-$$

$$Cu(CO)_n^+ + Cl^- \longrightarrow Cu(CO)Cl + (n-1)CO$$

Although chloroform is known to easily undergo hydrolysis in basic solution, hardly any report is available on its behavior in acidic media.[11,12] However, the reaction of chloroform with aromatic compounds forming triarylmethane is known to be induced by a Lewis acid such as aluminum chloride, iron(III) chloride and so on. Thus the free form of BF_3 liberated in the BF_3–H_2O solution can also be considered to be a catalyst which induces the formation of active species as shown in the following.

$$CHCl_3 + BF_3 \longrightarrow \overset{+}{C}HCl_2BF_3Cl^-$$

This species might be considered to be the source of chloride anion and $\overset{+}{C}HCl_2$ cation.

We examined the behavior of chloroform in BF_3–H_2O solution by adding silver nitrate. In a solution allowed to stand at room temperature with stirring, the formation of silver chloride was observed with the evolution of carbon monoxide.[12] From the results, it seems that chloroform in the BF_3–H_2O liberates chloride anion and $\overset{+}{C}H_2Cl$ cation which undergo hydrolysis to give formic acid and then decompose into water and carbon monoxide.

$$\overset{+}{C}HCl_2 \xrightarrow[-HCl]{H_2O} \begin{matrix} H \\ \diagdown \\ C=O \\ \diagup \\ Cl \end{matrix} \xrightarrow[-HCl]{H_2O} \begin{matrix} O \\ \| \\ HC-OH \end{matrix} \longrightarrow CO + H_2O$$

In the presence of cyclohexane, mesitylene or halobenzenes, the reactions give satisfactory high yields of carboxylic acids (Table 3).

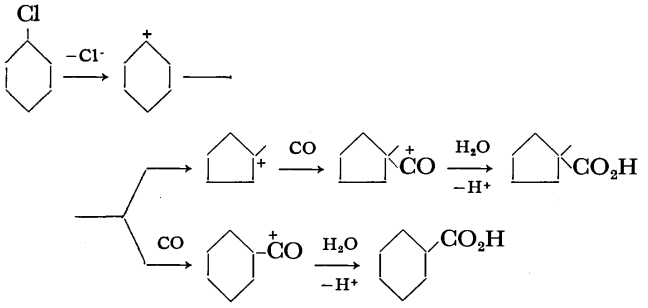
The amount of products in the cyclohexane layer is extremely low as compared with the cases using other organic solvents. This is puzzling. The amount of acid products in the organic layer would be affected by the product composition obtained by the reaction. Namely, the reactions producing rather long chain carboxylic acids with less affinity for the catalyst should give large amounts of products in the organic solvent layer. Although C_5 acids and C_9 acids are the main products in each case, C_6, C_8 and longer chain acids than C_{13} were produced. These carboxylic acids are formed as follows. TMP is depolymerized by acid to give 2-methylpropene and *t*-butyl cation which in turn reacted with another molecule of TMP to form C_{12}^+ or higher cations. On the other hand, C_5^+ and C_7^+ ions are produced by the depolymerization of C_{12}^+ (Scheme 1). In the case of the reaction using a higher acidic catalyst such as one with a 0.9 BF_3/H_2O molar ratio, it is particularly easy to form C_{12}^+ and longer chain carbocations which would be sources of long chain carboxylic acids.

Thus, dilution of the alkene by an organic solvent would more or less prevent the formation of longer acids. This is the case where the reaction in the presence of cyclohexane gave rise to the formation of C_{13} and higher acids in rather low yields in the composition, most of the 2,2-dimethylpropanoic acid in high yields remaining in the catalyst layer.

Such a tendency was clearly seen in the reactions using BF_3–H_2O acid systems with large BF_3/H_2O molar ratios. The reaction in the presence of lower acidic

catalyst of BF_3–H_2O with BF_3/H_2O molar ratio of 0.7 or less gave C_9 acids as the main products which were in the organic solvent layer as shown in Fig. 2.

However, as seen in Table 3, although almost the same composition of products was obtained when cyclohexane and halobenzenes were used as the solvent, the amount of products found in the halobenzene layer was always higher. The solubility of carboxylic acids in such organic solvents may be different. In fact, we found that cyclohexane shows a lower solubility for 2,2-dimethylpropanoic acid at 10 °C (1.07 g/ml) than other solvents (chlorobenzene, 1.34 g/ml; chloroform, 1.44 g/ml). Thus, chlorocyclohexane which has a high solubility for 2,2-dimethylpropanoic acid (1.8 g/ml) should dissolve acid products. However, a remarkable formation of other acids was observed. This might be due to the occurrence of a side-reaction, as shown in the following equation. Cl^- liberated in the course of the reaction should deteriorate the catalyst.



The effect of reaction temperature on the yield of carboxylic acids was also examined. The results are shown in Figs. 3 and 4.

The reaction using 96% H_2SO_4 gave a 56% maximum total yield of products at 40 °C, the catalytic activity decreasing thereafter rapidly because of the decomposition of Cu(I) carbonyl cation. On the other hand, the reaction using BF_3–H_2O complex gave the products in *ca.* 20% yield even at 70 °C. This seems also to indicate

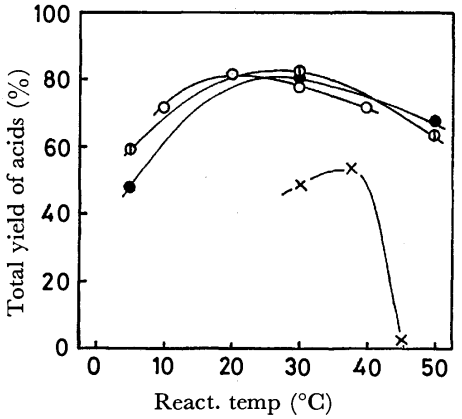


Fig. 3. The effect of reaction temperature on the total yield of acids.
Reaction conditions: BF_3–H_2O, 24 g; BF_3/H_2O molar ratio, 0.90; 96% H_2SO_4, 40 g; Cu_2O, 14 mmol; reaction time, 30 min; amount of solvent, 50 ml; trimethylpentene, 0.10 mol.

the high stability of active species as catalyst, *i.e.*, $Cu(CO)_3^+$ in the BF_3–H_2O complex in a wide range of temperature.

The reaction using BF_3–H_2O complex in the presence of chlorobenzene showed no large difference in yield of acid products found in the organic layer over the entire range of reaction temperature (Fig. 4). However, in the presence of cyclohexane, or in the absence of organic solvent, the amount of such products found to be remarkably decreased at 30 °C. The reactions under these conditions have a tendency to form products rich in 2,2-dimethylpropanoic acid with a high affinity to the catalyst layer. In the reactions carried out at low reaction temperatures, polymerization and depolymerization of TMP resulting in the formation of C_{13} or higher carboxylic acids would be predominant. These long chain carboxylic acids clearly have less affinity to the catalyst and should exist apart from the catalyst layer. In reactions at a temperature higher than 40 °C, the rate of reaction of carbon monoxide with 1,1,3,3-tetramethylbutyl cation derived from initial protonation of TMP would cause a β-cleavage of the cation to give *t*-butyl cation and 2-methylpropene. Hence, the reaction gave products rich in C_9 acids, most of them being observed in the organic layer because of the low affinity of C_9 acids to the catalyst layer.

Repeated Use of the Catalyst. In order to show the advantage of a Cu(I)–carbonyl catalyst in the BF_3–H_2O solution, we have extended our investigation to recycling of the used catalyst. The carboxylation of olefins in various organic solvents was conducted in the same way as described in the previous section. After completion of the reaction, the recovered catalyst layer which had been added to the corresponding amount of water consumed in the first run was used for the second run under the same conditions. The upper organic solvent layer separated out from the reaction mixture was subjected to work-up for the product and analysis for the amount of copper ion as Cu^{2+} after oxidation with

air by the usual atomic absorption spectroscopic method.[13] Some typical results are given in Tables 4—7.

In the reaction of TMP using cyclohexane as a solvent, the activity of catalyst remained unchanged. Only a negligible amount of copper ion was present in the organic solvent layer (Tables 4 and 5).

A gradual accumulation of carboxylic acid was observed in the catalyst layer with successive use of the catalyst. In the case of BF_3–H_2O with a 0.9 molar ratio (Table 4), *ca.* 55% of the total yield of carboxylic acids was found in the catalyst layer after five repeated runs. However, this accumulation of products in the catalyst layer was remarkably decreased when a catalyst with 0.7 BF_3/H_2O molar ratio was used. Only 6% of carboxylic acids was present (Table 5).

In the reaction of 1-octene, there was no accumulation of products in the catalyst layer even in the case of BF_3–H_2O with 0.9 molar ratio (Table 6). Since no cleavage of carbon-carbon bonds in the olefin takes place, almost all the carboxylic acids produced were C_9-acids which have less affinity to the catalyst layer.

On the other hand, in the reaction of TMP using chlorobenzene as a solvent, almost complete recovery of products into the solvent layer was observed even in the presence of the catalyst with 0.9 BF_3/H_2O molar ratio (Table 7). In contrast, the amount of copper ion found in the organic layer was considerably high. This might decrease the concentration of the active species by successive use of the catalyst layer.[14]

The present procedure seems to have a great advantage in the practical preparation of carboxylic acids by carboxylation of olefins with carbon monoxide.

Modification of Aminocyclitol Antibiotics. 6. Preparation of 5-Deoxykanamycin B

Tetsuo SUAMI,* Shigeru NISHIYAMA, Yasuhide ISHIKAWA, and Eijiro UMEMURA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received December 14, 1977)

Aminocyclitol antibiotic kanamycin B has been modified as regards the aminocyclitol moiety by removing a hydroxyl group on C-5. 5-Deoxykanamycin B thus obtained was tested against several microorganisms. The structure of 5-deoxykanamycin B was established by mass and ^{13}C NMR spectrometry. 5,6,3′,4′-Tetradeoxyneamine was prepared as a reference compound for ^{13}C NMR spectrometry.

In connection with the preceding paper,[1] antibiotic kanamycin B[2-5] has been modified as regards the aminocyclitol moiety. It has been disclosed that removal of the hydroxyl group on C-5 of neamine enhances the antimicrobial activity relative to the parent neamine against kanamycin resistant strains.[6]

Recently, 5-deoxygentamicin complex[7] has been prepared by means of bioconversion[8] using 2,5-dideoxystreptamine[9] as a precursor in the culture medium. The antibiotic exhibits improved activity against gentamicin-acetylating strains of resistant bacteria. 5-Deoxysisomicin: Mutamicin 2[10] and 5-deoxykanamycin A[11] have also been prepared by means of bioconversion.

Since removal of the hydroxyl group on C-5 of kanamycin B might enhance its antimicrobial activity, we have attempted to prepare 5-deoxykanamycin B by using analogous reactions employed in the preparation of 5-deoxyneamine.[6]

When 1,3,2′,6′,3″-pentakis-*N*-(ethoxycarbonyl)kanamycin B[12] (**1**) was treated with 22 molar equivalents of benzoyl chloride in pyridine, penta-*O*-benzoyl derivative (**2**) was obtained in 63% yield. As the hydroxyl group on C-5 of **1** is sterically highly hindered, compound **2** was deduced to be 3′,4′,2″,4″,6″-penta-*O*-benzoyl derivative. The proposed structure was rationalized by the fact that successive reactions gave 5-deoxykanamycin B. Chlorination of **2** with sulfuryl chloride in pyridine afforded chloro-deoxy compound (**3**) in which the chlorination occurred on C-5 with an inversion of configuration.[13] Dehalogenation of **3** was performed with tributylstannane[14] in toluene solution, giving deoxykanamycin B derivative (**4**) in 86% yield. Compound **4** was converted into deoxykanamycin B (**5**) by removing the protecting groups. *N*-Acetylation of **5** gave penta-*N*-acetyl-deoxykanamycin B (**6**).

Scheme 1.

The structure of **5** was determined by mass and ^{13}C NMR spectra as follows. The mass spectrum reveals the molecular ion and $[M+1]^+$ peak at *m/e* 467 and 468, respectively, equivalent to M−O and M+1−O ions of kanamycin B.[15] The peaks at *m/e* 335 and 336 are in line with protonated formyl ions. The amino sugar fragments reveal the peaks at *m/e* 161 and 162, observed in the spectrum of kanamycin B.[15] The aminocyclitol fragment ions appear at *m/e* 175, 157, 147, and 129. The results indicate that the aminocyclitol moiety of **5** has been deoxygenated, supporting the proposed structure. The structure of **5** was confirmed by ^{13}C NMR spectroscopy. The spectrum was determined at pD above 11, showing eighteen carbon signals. The signals are assigned in accordance with the data for kanamycin B,[16] neamine, 5-, 6-, 5,6-di- and 5,6,3′,4′-tetradeoxyneamine (**11**). Compound **11** was prepared by a five step reaction from neamine.

When the spectrum of **5** is compared with that of kanamycin B, it is obvious that deoxygenation causes no appreciable shifts of the signals of carbons in the amino sugar moieties, except for anomeric carbon C-1′. In contrast, the signals of the carbons in the aminocyclitol moiety are more or less shifted by deoxygenation.

In fact, the signal of C-1′ shifts toward a higher field by 4.3 ppm. An analogous upfield shift of the signal of C-1′ has been observed in the spectra of 5-, 5,6-dideoxyneamine, and **11**. However, no such shift of the signal of C-1′ was observed in the spectrum of 6-deoxyneamine.

The signals of C-4 and 6 shift upfield by 9.3 and 4.5 ppm, respectively. This is in line with the fact that the signals of C-2 and 4 of methyl 3-deoxy-α-D-glucopyranoside appear in a higher field, as compared to those of methyl α-D-glucopyranoside.[17] The signals of C-1 and 3 shift to a lower field by 2.9 and 2.3 ppm, respectively. This is elucidated by the antiperiplanar arrangement of Eliel *et al.*[18]

The spectra were then determined at pD 1 in order to observe the N-protonation effect, which will supply valuable evidences for structure analysis.[16,19] At pD 1, the signal of C-2 of **5** shifts upfield a great deal (7.8 ppm), that of C-4 and 6 moderately (6.4 and 5.5 ppm) and that of C-5 toward a higher field (2.0 ppm) as compared

to those determined at pD 11. This is in line with the fact that the effect of N-protonation appears strongly on a β-carbon and weakly on a γ-carbon.[19] Thus, the proposed structure of **5** has been confirmed.

Antimicrobial activities of **5** were determined against several microorganisms. The MIC (minimum inhibition concentration) values, given in Table 2, are similar to those of kanamycin B against most of the microorganisms tested so far.

Experimental

General Methods. Melting points were determined in capillary tubes and are uncorrected. Solutions were concentrated under reduced pressure below 40 °C. Optical rotations were measured on a Japan Spectroscopic DIP-SL polarimeter. ^{1}H NMR spectra were recorded on a Varian A-60D spectrometer at 60 MHz. Deuteriochloroform was used as a solvent with an internal standard of tetramethylsilane. The peak positions are given in δ values. ^{13}C NMR spectra were determined on a Varian FT-80 spectrometer at 20 MHz. Deuterium oxide was used as a solvent with an internal standard of dioxane. The resonance signals are expressed in ppm downfield from the signal of tetramethylsilane (δ_C for dioxane= −67.4). Mass spectrum was recorded with a Hitachi RMU-6M single focusing mass spectrometer. TLC was performed on Wakogel B-10 plates (Wako Pure Chemical Co., Ltd.), and silica gel (Wakogel C-300) was employed for column chromatography.

*3′,4′,2″,4″,6″-Penta-*O*-benzoyl-1,3,2′,6′,3″-pentakis-*N*-(ethoxycarbonyl)kanamycin B (2).* Benzoyl chloride (1.5 ml) was added gradually to a solution of 1,3,2′,6′,3″-pentakis-*N*-(ethoxycarbonyl)kanamycin B[12] (**1**, 500 mg) in pyridine (15 ml) with stirring under ice cooling. After 18 h at ambient temperature, the solution was poured into 2.5% $NaHCO_3$ solution. The aqueous mixture was extracted with chloroform repeatedly, and the combined chloroform solution was washed with water. After being dried over Na_2SO_4, the solution was concentrated. The residue was purified on a silica-gel column using 7: 1 (v/v) benzene–methanol. Fractions homogeneous on TLC (R_f 0.32) in the same solvent were combined and concentrated to dryness. The residue was washed with ether and the product **2** (512 mg, 63%) was precipitated from a benzene solution by addition of hexane. Mp 137—143 °C, $[\alpha]_D^{25}$ +82.7° (*c* 0.4, chloroform).

Found: C, 59.61; H, 5.67; N, 5.08%. Calcd for $C_{68}H_{77}N_5O_{25}$: C, 59.86; H, 5.69; N, 5.13%.

*1D-4-*O*-(3,4-Di-*O*-benzoyl-2,6-dideoxy-2,6-bisethoxycarbonylamino-α-D-glucopyranosyl)-6-*O*-(2,4,6-tri-*O*-benzoyl-3-deoxy-3-ethoxycarbonylamino-α-D-glucopyranosyl)-5-chloro-1,2,3,5-tetradeoxy-1,3-bisethoxycarbonylamino*-neo-*inositol (3).* Sulfuryl chloride (0.8 ml) was added to a solution of **2** (868 mg) in pyridine (15 ml) with agitation under ice cooling. After being stirred at 0 °C overnight, the solution was poured into ice-cold water (100 ml). The aqueous solution was extracted with chloroform and the chloroform solution was washed with $NaHSO_4$ solution, $NaHCO_3$ solution and water successively. After being dried over Na_2SO_4, the solution was concentrated. The residue was purified on a silica gel column using 10: 1 (v/v) benzene–methanol. Fractions homogeneous on TLC (R_f 0.29) in the same solvent were combined and concentrated to give 735 mg (84%) of **3**, mp 111—116 °C, $[\alpha]_D^{21}$ +80.8° (*c* 0.4, chloroform).

Found: C, 58.61; H, 5.61; N, 5.00; Cl, 2.90%. Calcd for $C_{68}H_{76}N_5O_{24}Cl$: C, 59.06; H, 5.54; N, 5.06; Cl, 2.56%.

*3′,4′,2″,4″,6″-Penta-*O*-benzoyl-5-deoxy-1,3,2′,6′,3″-pentakis-*N*-(ethoxycarbonyl)kanamycin B (4).* Tributylstannane[3] (1 ml) and bis(α-cyanoisopropyl)diazene (26 mg) were added to a solution of **3** (643 mg) in toluene (30 ml). The reaction mixture was heated at 78 °C for 1.5 h under nitrogen stream. The mixture was concentrated and the residue was washed with hexane. The crude product was purified on a silica-gel column using 7: 1 (v/v) benzene–methanol as an eluant. Fractions showing a single spot at R_f 0.32 in the same solvent were combined and concentrated to give 538 mg (86%) of **4**, mp 134—137 °C, $[\alpha]_D^{20}$ +81.5° (*c* 1.1, chloroform).

Found: C, 60.28; H, 5.65; N, 5.17%. Calcd for $C_{68}H_{77}N_5O_{24}$: C, 60.57; H, 5.76; N, 5.19%.

5-Deoxykanamycin B (5). A solution of **4** (529 mg) in methanol (6 ml) was added to a solution of barium hydroxide octahydrate (4 g) in water (14 ml). The mixture was heated under reflux for 8 h. Carbon dioxide was bubbled into the mixture and the precipitates were filtered off. The filtrate was concentrated and the residue was purified on a column of Amberlite CG-50(NH_4^+) resin. After being washed with water and 0.05 M aqueous ammonia, the column was eluted with 0.3 M aqueous ammonia to give 47 mg (26%) of **5**, mp 179—185 °C (dec), $[\alpha]_D^{22}$ +124° (*c* 0.7, water). The product showed a single spot on TLC (R_f 0.27) in 5: 8: 10: 7 (v/v) 28% ammonia–1-butanol–ethanol–water.

*1,3,2′,6′3,″-Penta-*N*-acetyl-5-deoxykanamycin B (6).* Compound **5** (15 mg) was acetylated with acetic anhydride (0.1 ml) in methanol (2 ml) to give 18 mg (81%) of **6**, mp above 260 °C, $[\alpha]_D^{21}$ +108° (*c* 0.4, water). ^{1}H NMR (D_2O): δ 1.96 (s, 3, NAc), 1.99 (s, 3, NAc), 2.03 (s, 9, 3×NAc), 4.96 (d, 1, J=3 Hz, anomeric H), 5.01 (d, 1, J=3.5 Hz, anomeric H).

Found: C, 48.54; H, 6.85; N, 10.01%. Calcd for $C_{28}H_{47}N_5O_{14}\cdot H_2O$: C, 48.33; H, 7.10; N, 10.07%.

*1,3,2′,6′-Tetrakis-*N*-(ethoxycarbonyl)neamine (7).* The compound was prepared by a similar reaction to that employed in the preparation of 1,3,2′,6′-tetrakis-*N*-(methoxycarbonyl)-neamine.[20] The product, mp 224—227 °C, $[\alpha]_D^{18}$ +45.2° (*c*

0.5, DMF), was obtained in 61% yield.

Found: C, 47.12; H, 6.77; N, 8.81%. Calcd for $C_{24}H_{42}N_4O_{14}$: C, 47.21; H, 6.93; N, 9.18%.

1,3,2',6'-Tetrakis-N-*(ethoxycarbonyl)-5,6,3',4'-tetra*-O-*mesyl-neamine (8).* Compound **7** (2.0 g) was treated with methanesulfonyl chloride (2.0 ml) in pyridine (20 ml). The product was recrystallized from 3: 1 (v/v) acetone–ether to give 1.96 g (65%) of **8**, mp 192—193 °C, $[\alpha]_D^{21}$ +22.5° (*c* 1.06, chloroform). ^1H NMR: δ 3.06 (s, 3, SO_2CH_3), 3.11 (s, 3, SO_2CH_3) 3.24 (s, 3, SO_2CH_3), 3.27 (s, 3, SO_2CH_3), 5.21 (d, 1, J=3.5 Hz, H-1').

Found: C, 36.27; H, 5.47; N, 5.90; S, 13.62%. Calcd for $C_{28}H_{50}N_4S_4O_{22}$: C, 36.27; H, 5.47; N, 5.90; S, 13.62%.

5,6,3',4'-Tetradeoxy-1,3,2',6'-tetrakis-N-*(ethoxycarbonyl)neamine-5,3'-diene (9).* Compound **8** (1.44 g) was heated with zinc powder (11 g) and sodium iodide (20 g) in DMF (35 ml) at 95°C for 2.5 h. The mixture was diluted with chloroform, the insoluble matter being filtered off. The filtrate was washed with sodium chloride solution, sodium thiosulfate solution and water successively. After being dried over Na_2SO_4, the solution was concentrated. The residue was recrystallized from 1: 4 (v/v) ether–methanol to give 0.38 g (45%) of **9**, mp 223—224 °C. From the mother liquor, a second crop of **9** (84 mg, 10%) was obtained. A part of the product was recrystallized for elemental analysis, mp 225—226 °C, $[\alpha]_D^{20}$ +73.6° (*c* 0.84, DMF). ^1H NMR (DMSO-d_6): δ 1.22 (*t*, 12, J=7.0 Hz, 4×$CO_2CH_2C\underline{H}_3$), 5.32 (d, 1, J=3.5 Hz, H-1'), 5.84 (broad s, 4, H-5, 6, 3' and 4').

Found: C, 53.20; H, 7.02; N, 10.20%. Calcd for $C_{24}H_{38}N_4O_{10}$: C, 53.15; H, 7.06; N, 10.33%.

1,3,2',6'-Tetrakis-N-*(ethoxycarbonyl)-5,6,3',4'-tetradeoxyneamine (10).* Compound **9** (306 mg) was hydrogenated in the presence of palladium black in aqueous dioxane (15 ml) in hydrogen atmosphere (3.4 kg/cm²) for 26 h. The product was purified on a silica-gel column using 14: 1 (v/v) benzene–isopropyl alcohol. Fractions homogeneous on TLC (R_f 0.49) in 15: 1 (v/v) chloroform–ethanol were combined and concentrated to give 277 mg (90%) of **10**, mp 196—198 °C, $[\alpha]_D^{20}$ +97.9° (*c* 0.88, chloroform).

Found: C, 52.68; H, 7.62; N, 10.19%. Calcd for $C_{24}H_{42}N_4O_{10}$: C, 52.74; H, 7.74; N, 10.25%.

5,6,3',4'-Tetradeoxyneamine (11). Compound **10** (430 mg) was hydrolyzed in aqueous barium hydroxide solution as in the preparation of **5** to give 94 mg (46%) of **11**, mp 204 °C (dec), $[\alpha]_D^{19}$ +123.8° (*c* 0.63, water). The product was homogeneous on a paper chromatogram (R_f neamine 2.4) in 1: 6: 4: 3 (v/v) acetic acid–1-butanol–pyridine–water. Lit,[21] the sulfate, mp 253—265 °C, $[\alpha]_D^{27}$ +80° (*c* 1, water).

N-Acetylation of **11** (18 mg) with acetic anhydride in methanol afforded 27 mg (91%) of tetra-*N*-acetyl derivative (**12**), mp above 264 °C (dec), $[\alpha]_D^{21}$ +138.3° (*c* 0.94, methanol). ^1H NMR (D_2O): δ 1.95 (s, 3, NAc), 1.96 (s, 6, 2×NAc), 2.01 (s, 3, NAc), 4.93 (d, 1, J=4 Hz, H-1').

Found: C, 56.02; H, 7.91; N, 12.89%. Calcd for $C_{20}H_{34}N_4O_6$: C, 56.32; H, 8.03; N, 13.14%.

The authors would like to express their sincere thanks to Mr. Saburo Nakada for the elemental analyses and to Mr. Kiyoshi Aoki for the determination of ^{13}C NMR spectra. This work was supported by a grant from the Asahi Glass Foundation for Contribution to Industrial Technology.

Conformational Analysis of Some Benzyl *t*-Butyl Sulfoxides by Measurement of Their Dipole Moments

Minoru HIROTA,* Yoshiyuki TAKAHASHI, Motohiro NISHIO,** and Ken NISHIHATA**

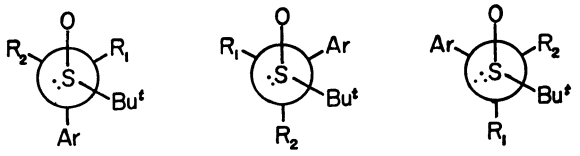
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama 232

***Central Research Laboratories, Meiji Seika Kaisha Ltd., Kohoku-ku, Yokohama 222*

(Received December 27, 1977)

Favored conformations of benzyl *t*-butyl sulfoxides and their α-methyl derivatives in solutions were determined from their dipole moments and compared with those in crystals.

In connection with studies on stereochemistry of the reactions involving α-sulfinyl carbanion, the conformations of the related sulfoxides have been investigated.[1-4] Some of the present authors investigated the methylation and deuteration of benzyl alkyl sulfoxides *via* carbanion intermediates, a highly stereospecific nature of the reaction being revealed.[5-8] Furthermore, the conformations of the above sulfoxides in crystalline states were determined by means of X-ray crystal analysis. The results show that *p*-bromobenzyl *t*-butyl sulfoxide (1b) takes conformation III (where Ar=*p*-BrC_6H_4 and $R_1=R_2=H$),[9] and (*RR*/*SS*)-*t*-butyl 1-(*p*-bromophenyl)-ethyl sulfoxide (2b; $R_1=CH_3$, $R_2=H$)[10] and its (*RS*/*SR*) isomer (3b; $R_1=H$, $R_2=CH_3$)[11] conformations II and I, respectively, in crystalline state. On the other hand, benzyl *t*-butyl sulfoxide (1a) takes conformation II in which the *t*-butyl and phenyl groups are gauche to each other as shown by LIS and ASIS measurements.[12] The stereochemistry of its deuteration was again best rationalized by assuming conformation II.



(I) ϕ 180° (II) 300°(−60°) (III) 60°

Thus, another more decisive evidence on their conformations in solution is necessary to settle this apparent disagreement. Since the dipole moment often offers a very conclusive evidence for the conformation in solution of a molecule carrying two polar substituents at suitable positions, their dipole moments were determined.

Experimental

Materials. The sulfoxides were prepared according to known methods. The new compounds were identified by spectral and elementary analyses. Benzene for the solvent was carrefully purified and dried.

Dielectric Measurement. Dielectric constants of the benzene solution of the sulfoxides were determined at 25 °C with a heterodyne-beat apparatus. The dipole moments were calculated according to the method of Halverstadt and Kumler[13,14] from the observed dielectric constants and densities of the benzene solution at varying concentrations. The molar refraction was calculated from the bond refraction values.[14]

Results and Discussion

The dipole moments of substituted benzyl *t*-butyl sulfoxides are given in Table 1. The substituent effect on the (*RS*/*SR*), or threo, series (3) is apparently anomalous since the dipole moment of *p*-bromo derivative is lower than that of both unsubstituted and *p*-nitro derivatives. Since the conformations of the molecules are governed by the steric circumstances around the bond in question and insensitive to the electronic effect of the substituents far from the bond, the sulfoxide molecules appear to take a similar conformation irrespective of the para-substituents when the configuration is the same. Thus, the anomalous substituent effect is reasonable only when the angle between the C–X (X=Br or NO_2) and the S–O bond moment vectors are larger than a right angle, which is only possible in confor-

TABLE 1. OBSERVED DIPOLE MOMENTS (μ) OF THE SULFOXIDES AND RELATED COMPOUNDS

Compound	R_1	R_2	Ar	No.	μ/D
(*R*/*S*)Benzyl *t*-butyl sulfoxide	H	H	C_6H_5	1a	3.90
(*R*/*S*)*p*-Bromobenzyl *t*-butyl sulfoxide	H	H	*p*-BrC_6H_4	1b	4.72
(*R*/*S*)*p*-Nitrobenzyl *t*-butyl sulfoxide	H	H	*p*-$NO_2C_6H_4$	1c	6.44
(*RR*/*SS*) 1-Phenylethyl *t*-butyl sulfoxide	CH_3	H	C_6H_5	2a	3.84
(*RR*/*SS*) 1-(*p*-Bromophenyl)ethyl *t*-butyl sulfoxide	CH_3	H	*p*-BrC_6H_4	2b	4.23
(*RR*/*SS*) 1-(*p*-Nitrophenyl)ethyl *t*-butyl sulfoxide	CH_3	H	*p*-$NO_2C_6H_4$	2c	5.69
(*RS*/*SR*) 1-Phenylethyl *t*-butyl sulfoxide	H	CH_3	C_6H_5	3a	3.86
(*RS*/*SR*) 1-(*p*-Bromophenyl)ethyl *t*-butyl sulfoxide	H	CH_3	*p*-BrC_6H_4	3b	3.42
(*RS*/*SR*) 1-(*p*-Nitrophenyl)ethyl *t*-butyl sulfoxide	H	CH_3	*p*-$NO_2C_6H_4$	3c	4.26
Methyl phenyl sulfoxide					3.88
p-Bromobenzyl *t*-butyl sulfone					4.90

mation I (see Figs. 1 and 2). The above qualitative assignment of the conformation agrees with the results of its X-ray crystal analysis and is rationalized by a more quantitative computation on the conformation dependence of dipole moments. From a similar discussion on the (*RR*/*SS*) series (2), the privileged conformation can not be determined uniquely, and both conformers II and III are suspected. However, operation of a considerable repulsive force is expected when methyl and *t*-butyl groups are located gauche to each other, as realized in the conformer III of (2). Conformer II should thus be the more stable of the two.

Table 2. Bond and group moment values[16,17]

Bond or group (+) (−)	*m*/D
H − C	0.0
C − S	0.90
C − C_6H_5	0.35
C − $C_6H_4Br(p)$	1.53
C − $C_6H_4NO_2(p)$	4.00
S − O	3.00

In order to estimate the dipole moments of these molecules quantitatively, they were calculated as the sum of the component bond moments by taking the values in Table 2 and the bond lengths and bond angles reported by Kodama and co-workers.[15] The S–O bond moment was re-evaluated by measuring the dipole moments of some sulfoxides. The observed dipole moment of phenyl methyl sulfoxide gives a larger S–O bond moment (3.2 D) than that reported.[16] The best fit value of S–O bond moment is 3.0 D (Table 2) for this series of sulfoxides, which is employed as the bond moment for the present calculations.

Table 3. Dipole moments of the sulfoxides (1a—3c) calculated by assuming the conformations in crystals

Ar	R_1 R_2	Benzyl series (1) H H	(*RR*/*SS*) series (2) CH_3 H	(*RS*/*SR*) series (3) H CH_3

p-BrC_6H_4(b)		4.61	4.23(4.87)	2.31(2.68)
p-$NO_2C_6H_4$(c)		6.62	5.91(6.96)	1.70(2.29)
The conformation in crystal		III	II	I

a) The dipole moments calculated by employing the modified bond moments[17] (m_{S-O}=2.70 D, m_{C-S}= 1.47 D) are given in parentheses.

Dipole moments for the conformations in crystals[10,11] were calculated first. Benzyl *t*-butyl sulfoxides are assumed to exist exclusively in conformation III in which the bulky phenyl and *t*-butyl groups are located anti to each other.[9] The results are given in Table 3. The calculated values for the series of (1)[18] and (2) agree very closely with the observed ones (Table 2). However, those for the series of (3) do not agree with the observed ones at all. The dipole moments of the series of (*RR*/*SS*) (2) and (*RS*/*SR*) (3) were then calculated as the function of dihedral angle around C_{benzyl}–S bond. The results are shown in Figs. 1 and 2, where the abscissa represents the dihedral angle (ϕ) between the S–O and C–Ar bonds. The best fit values for the (*RR*/*SS*) series (2) are attained when the dihedral angle ϕ is near 300° (−60°). This is in line with the conclusion from X-ray and other evidences. However, no dihedral angle reasonable for the (*RS*/*SR*) series (3) could be found (Fig. 2). The dipole moment of (*RS*/*SR*) sulfoxides (3) is interpreted by assuming the conformational equilibria between (or among) conformers I and III (or II). Again conformer II should be excluded since the *t*-butyl and methyl groups are gauche to each other (as in conformer III of the (*RR*/*SS*) series). When the mole fraction of conformer I is *X*, the dipole moment of the mixture (μ) is given by the equation,

$$\mu = \{X\mu_I^2 + (1 - X)\mu_{III}^2\}^{1/2},$$

where μ_I and μ_{III} refer to the dipole moments of conformer I and III, respectively. The calculated dipole moments for the conformational mixtures are given as the function of *X* in Table 4. Near *X*=0.7, the dipole moments of the (*RS*/*SR*) sulfoxides are reproduced almost quantitatively, and the order of magnitude of dipole moments is in line with the observed values in the range of *X*=0.8—0.65.[17] Thus the (*RS*/*SR*) sulfoxides are concluded to exist as a mixture of confor-

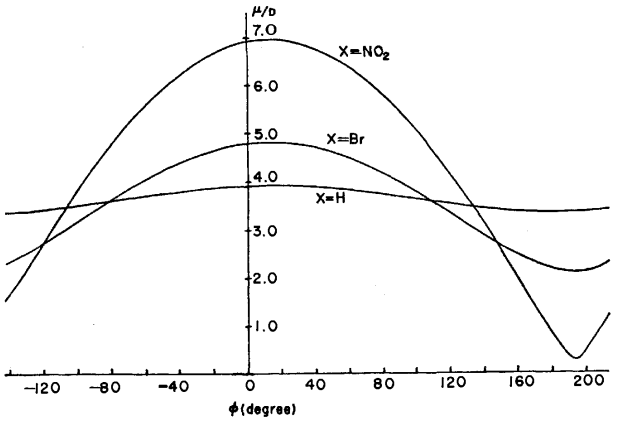

Fig. 1. Dihedral angular dependency of the dipole moments of (*RR*/*SS*)-*t*-butyl 1-phenylethyl sulfoxides.

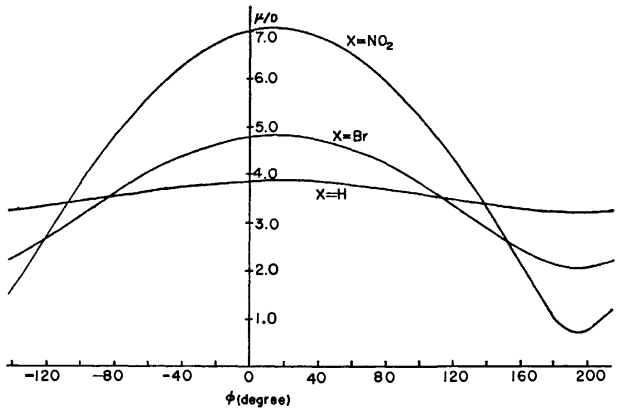

Fig. 2. Dihedral angular dependency of the dipole moments of (*RS*/*SR*)-*t*-butyl 1-phenylethyl sulfoxides.

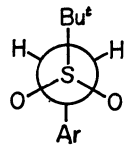
TABLE 4. DIPOLE MOMENTS OF (3)'S CALCULATED BY ASSUMING THE COEXISTENCE OF CONFORMERS I AND III IN VARYING PROPORTIONS

Ar	X[a]					
	0.85	0.80	0.75	0.70	0.65	0.60
C_6H_5	3.38	3.41	3.44	3.46	3.49	3.51
p-BrC_6H_4	2.91	3.04	3.16	3.28	3.40	3.51
p-$NO_2C_6H_4$	3.28	3.57	3.84	4.10	4.34	4.56

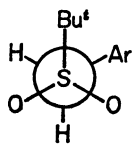
a) Mole fraction of conformer I. Sice the existence of conformer II and other conformers are neglected, the mole fraction of the III should be $1-X$.

mers in which conformer I predominates in benzene solutions.

In conclusion, both the (*RR*/*SS*) and (*RS*/*SR*) isomers of *t*-butyl 1-phenylethyl sulfoxides are shown to take conformations in which bulky *t*-butyl and phenyl groups approach closely. From these observations on dipole moments, the participation of a specific attractive force between the phenyl and the *t*-butyl groups might take place. On the other hand, an alternative explanation in which the repulsive force between the methyl and *t*-butyl groups plays an important role is also possible. In order to decide which of the above effect is more predominant, the conformation of a benzyl *t*-butyl sulfone was determined by measurement of their dipole moments.



(IV)



(V)

The observed dipole moment for *p*-bromobenzyl *t*-butyl sulfone (4) is 4.90 D, while the calculated values for conformers IV and V (where Ar=C_6H_4Br-*p*) are 5.2 and 3.7 D, respectively, and the result favors the anti-conformation in which phenyl and *t*-butyl groups are located farthermost to each other. In view of this, the repulsive force is supposed to play an important role in determining the conformations of these sulfoxides. However, a similar attractive interaction between the alkyl and aromatic groups was reported recently.[12] The conformations of these sulfoxides may also be determined by the cooperation of the repulsive force caused by steric hindrance, the specific attractive force, and other forces in their molecules.

17) A large C–S bond moment (1.46 D) and a smaller S–O bond moment (2.70 D) are proposed by Saito and coworkers, [S. Saito, *Bull. Chem. Soc. Jpn.*, **42**, 663 (1969) and S. Saito and F. Makino, *ibid.*, **45**, 92 (1972)]. The dipole moments of the (*RR*/*SS*) and (*RS*/*SR*) sulfoxides are also calculated on the basis of these bond moments (see Table 3). The calculated values also explain the observed dipole moments qualitatively. However, the agreements is less satisfactory. Calculation by these bond moments on the (*RS*/*SR*) series also suggests the conformation equilibria, the composistion for the best fit dipole moments containing about 40% of the conformer I. (The order of the dipole moment values agrees in the range X= 0.55—0.30).
18) Conformer II is also compatible with the observed dipole moment.

Synthesis of 11-Methyl- and 11,11-Dimethylprostaglandins *via* the Wittig Reaction of α-Dienol[1]

Kenji INOUE, Junya IDE, and Kiyoshi SAKAI*

Central Research Laboratories, Sankyo Co., Ltd., 1-2-58 Hiromachi, Shinagawa-ku, Tokyo 140

(Received January 9, 1978)

The key intermediates for 11-methyl- and 11,11-dimethylprostaglandins corresponding to Corey's lactone were synthesized *via* the Wittig reaction of dimethyl 2-substituted-4,5-dioxocyclopentane-1,3-dicarboxylate with stable ylides. 11,11-Dimethylprostaglandin E_2 was then synthesized.

Recently, a number of groups have done research on the synthesis of methylprostaglandins (PGs) whose biological activities resemble those of PGEs. 11-Methyl-PGE_2[2] was synthesized by 1,4-addition of ate-complex or diazomethane to the natural PGA_2. We have previously reported the synthesis of 11-deoxy- and natural prostaglandins intermediates[1,3] by the Wittig reaction from enolized α-diketone. We wish to describe the synthesis of the intermediates (**8a** and **8b**) for 11-methylated PGs and a total synthesis of 11,11-dimethyl-PGE_2 (**1b**) starting from **8b**.

The Wittig reaction of one equivalent of dimethyl 4,5-dioxo-2-methylcyclopentane-1,3-dicarboxylate (**2a**) (α-dienol) with two equivalents[4] of (methoxycarbonylmethylene)triphenylphosphorane (**3a**) in chloroform under reflux for 24 h afforded a mixture of the corresponding olefins (**4a**, **4b**, and **4d**). This reaction, however, seemed to proceed differently from the usual Wittig reaction. On addition of the ylide **3a** to α-dienol **2a** in chloroform at room temperature, **2a** was rapidly transformed into a polar intermediate (as monitored by TLC), which was gradually converted into the final olefinic products **4a**, **4b**, and **4d** under reflux. Since the starting material **2a** was quantitatively recovered from the polar intermediate by acid (8% HCl) treatment, the polar intermediate seems to be a phosphonium salt. The formation of the phosphonium salt might be due to the relatively strong acidity[5] of **2a** (pK_{a_1} 6.26 and pK_{a_2} 11.1). The reaction mechanism from the salt to olefins remains unsolved. It is noteworthy that the Wittig reaction proceeded in the case of acidic α-dienols,[3] although under the same conditions cyclopentanone, β-keto ester (**13**), and α-keto enol ethers (**14**) and (**15**) with **3a** gave no products.

The purification of the products was effected by silica gel chromatography and successive fractional recrystallization to give the *exo*-olefins **4a** (mp 82—83.5 °C) and **4b** (mp 96—97.5 °C) in a 25.3% total yield, and the oily *endo*-isomer **4d**[6] in a 25.6% yield. In the NMR spectra vinyl protons of **4a** and **4b** appeared at 6.39 and 6.38 ppm, respectively. The methyl group in **4b** was observed at 1.13 ppm as a doublet, due to a shielding effect of the adjacent methoxycarbonyl group which was larger than that of **4a** at 1.31 ppm. These observations support the stereochemical assignments of the methyl group to the methoxycarbonyl group in **4a** and **4b** as *trans* and *cis*, respectively, except for the geometry of the *exo* double bond. Further confirmation of the stereochemistry of **4a** was made in connection with the stereochemistry of the *trans-trans*-keto diester (**5a**) derived from **4a** by successive catalytic hydrogenation and decarboxylation (*vide infra*). The *endo*-isomer **4d** contains no vinyl proton, but the methyl group appeared at 2.35 ppm as a singlet assignable to an olefinic methyl group. The *endo*-isomer **4d** would be obtained from **4a** and/or **4b** by the migration of the *exo* double bound under the employed reaction conditions.

Catalytic hydrogenation of the *trans-exo*-olefin **4a** over 10% Pd–C in methanol, followed by treatment with NaI–AcOH–diglyme,[7] afforded stereoselectively the *trans-trans*-keto diester **5a** in a 72.7% yield. Its stereochemical assignment was based on the following observations: i) No epimerization of **5a** occurred after treatment with sodium methoxide in methanol, which suggested that **5a** was thermodynamically stable in its configuration. ii) In the NMR spectra the *trans*-methyl group on the cyclopentane ring was generally observed at a lower field than the corresponding *cis*-methyl group, as shown in Table. 1[8] The methyl signal of **5a** at 1.20 ppm was also observed at a lower field than the other two isomers, *i.e.* the *cis-trans*-keto diester (**5b**) (1.13 ppm) and the *cis-cis*-keto diester (**5d**) (0.96 ppm) (*vide infra*). Further chemical transformation of **5a** into 11-methylprostaglandin E_2 confirmed its stereochemical features. On the other hand, for both **4b** and **4d**, catalytic hydrogenation followed by decarboxylation gave a stereoisomeric mixture of **5a** (*trans-trans*), **5b** (*cis-trans*), and **5d** (*cis-cis*), in the ratio of 5: 2: 3.

TABLE 1. NMR OF METHYL CYCLOPENTANES CHEMICAL SHIFT AND J VALUE OF METHYL SIGNALS

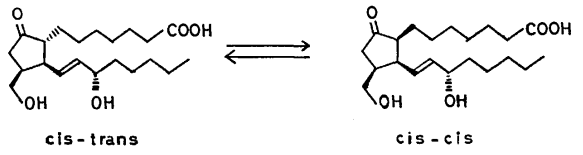
trans δ (JHz)	cis δ (JHz)	trans δ (JHz)	cis δ (JHz)
1.20 (5)	1.04 (6)	 1.17 (5)	1.03 (6)
1.10 (5)	 0.97 (7)	 1.06 (4)	0.98 (6)
1.07 (4)	 0.97 (6)	1.21 (6)	1.15 (6)
 1.14 (6)	1.00 (6)	—	1.09 (6)

The *cis-exo*-olefin **4b** was found to be isomerized to the *endo* double bond in **4d** by treatment with activated 10% Pd–C in methanol under argon atmosphere. The formation of the mixture of **5a**, **5b**, and **5d** from **4b** was thus explained on the assumption that **4b** was

isomerized to **4d** prior to hydrogenation.

Separation of these isomers by silica gel or alumina column chromatography was unsuccessful. HPL chromatography, however, gave the pure isomer **5b** and a mixture of **5a** and **5d**. In the NMR spectra, methyl signals of **5a**, **5b**, and **5d** appeared at 1.20 (doublet, J=5 Hz), 1.13 (doublet, J=8 Hz), and 0.96 ppm (doublet, J=8 Hz). These NMR data indicate that the methyl group of **5d** was more shielded by other substituents on the cyclopentane ring, *i.e.*, methoxycarbonyl and methoxycarbonylmethyl groups, than were the methyl groups of **5a** and **5b**. Therefore, the less shielded isomer **5b** may be assigned as *cis-trans* and the most shielded one **5d** as *cis-cis*.

These assignments are supported by the facts that the *cis-trans*-isomer **5b** readily isomerizes to an equilibrium mixture of **5b** and **5d** in the ratio of 2: 3 under decarboxylation conditions, *i.e.*, NaI–AcOH–diglyme at 120 °C, whereas the *trans-trans*-isomer **5a** underwent no isomerization under the same conditions. The equilibration between *cis-trans*- and *cis-cis*-isomers on the cyclopentanone ring has already been observed: *cis-trans*-PGE_1s and/or *cis-cis*-PGE_1s underwent isomerization to their equilibrium mixture by treatment with bases such as K_2CO_3 or NaOH.[9]



Scheme 1.

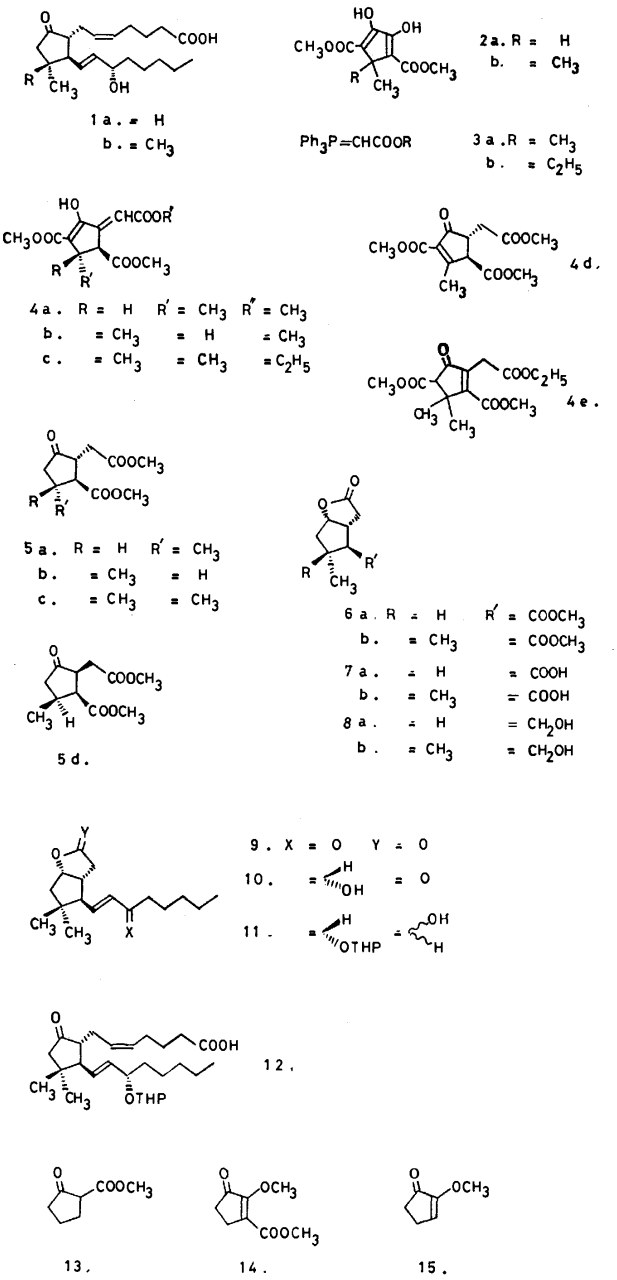
Treatment of a stereoisomeric mixture of **5** with a strong base such as NaOMe furnished predominantly the *trans-trans*-isomer **5a**. Ultimately, the stable isomer **5a** was obtained in a 46.4% yield starting from the α-dienol **2a**, without separation of the products in each step.

The reduction of the keto diester **5a** with potassium tri-*s*-butylborohydride gave the lactone (**6a**) in a 67.8% yield. By hydrolysis with concd hydrochloric acid, crystalline lactone acid (**7a**) (65.5%, mp 116—117 °C) was obtained. On reduction with $NaBH_4$ after conversion into the mixed anhydride ($ClCOOEt$–Et_3N), **7a** gave the key intermediate lactone alcohol (**8a**), which may be easily converted into 11-methyl-PGs by established methods.

11,11-Dimethyl-PGE_2 (**1b**) was obtained from the α-dienol (**2b**) by the same method. The Wittig reaction of **2b** (pK_{a_1} 6.61 and pK_{a_2} 11.1) with stable ylide (**3b**) gave a mixture of the corresponding olefins (**4c** and **4e**) (*ca.* 3: 7) in a 25.4% yield. Catalytic hydrogenation of the mixture over 10% Pd–C, followed by treatment with concd hydrochloric acid, gave the decarboxylated product. This was reesterified with diazomethane to give the keto diester (**5c**) in a 78.5% yield. The keto diester **5c** was stereoselectively reduced with potassium tri-*s*-butylborohydride to give the lactone ester (**6b**) (46.7%, mp 69.5—71 °C). Acid-hydrolysis of **6b** with hydrochloric acid gave the lactone acid (**7b**) (71%, mp 179.5—181 °C); this was reduced *via* the mixed anhydride to the lactone alcohol (**8b**) in a 73.6% yield.

Both side chains required for the prostaglandins were introduced into **8b** by the usual method. The Collins oxidation of **8b** followed by the Wittig reaction gave the enone (**9**), which was reduced with $NaBH_4$ to an epimeric mixture of (**10**) and its 15-OH epimer. By preparative layer chromatography the less polar compound **10** was obtained. This was tentatively assigned as the 15α-OH(*S**) epimer. Treatment of **10** with dihydropyran in the presence of *p*-TsOH, followed by reduction with diisobutylaluminium hydride, provided the lactol (**11**). The Wittig reaction of **11** with sodium 5-(triphenylphosphoranylidene)pentanoate, followed by the oxidation with the Collins reagent, afforded 15-tetrahydropyranyloxy-11,11-dimethyl-PGE_2 (**12**). Removal of the protecting group of **12** with aqueous AcOH afforded 11,11-dimethyl-PGE_2 **1b**.

11,11-Dimethyl-PGE_2 **1b** showed *anti*-ulcer activity



nearly equal to 11-methyl-PGE_1.

Experimental

The melting points were determined on a Micro Melting Point Apparatus (Yanagimoto) and are uncorrected. The infrared spectra were recorded in Nujol mull or neat on a JASCO Model A-2. The NMR spectra were obtained on a Varian T-60 spectrometer with TMS as an internal standard.

The starting materials **2a** and **2b** were prepared from oxalyl ester and dimethyl 3-methyl- or 3,3-dimethylglutarate.[10]

*Dimethyl 2-Hydroxy-3-methoxycarbonylmethylene-*trans*-5-methyl-1-cyclopentene-1,4-dicarboxylate* ***4a****, Its* cis*-Isomer* ***4b****, and* endo*-Olefinic Isomer* ***4d****.* A solution of **2a** (9.15 g) and **3a** (26.8 g) in chloroform was stirred at 60 °C for 24 h. The reaction mixture was washed with 8% HCl and the solvent was evaporated *in vacuo*. The residue was added to hexane–benzene and extracted well with 10% aqueous K_2CO_3. The basic aqueous extracts were combined, acidified with dil HCl, and extracted with ether. The ethereal extracts were washed with water, dried over Na_2SO_4, and evaporated to give a dark oil. The crude product was chromatographed on an acid-washed silica gel to give a mixture of crystalline *exo*-olefins as the less polar fraction, which consisted of two stereoisomers **4a** and **4b** (2.86 g ratio **4a**: **4b**=1: 1), and an oily *endo*-olefin as the more polar fraction **4d**. Recrystallization from ethanol afforded pure **4a** and **4b**. **4a**: Mp 82—83.5 °C; MS: *m/e* 284 (M^+); IR: 3350, 1715, 1705, 1645, and 1610 cm^{-1}; NMR ($CDCl_3$): 9.98 (1H, bs, OH), 6.39 (1H, d, J=2 Hz, olefin), 3.7 (1H, m, >CH–COO), 3.06 (1H, dq, J=2 and 6 Hz, >CH–Me), and 1.31 (3H, d, J=6 Hz, CH_3). Found: C, 54.87; H, 5.57%. Calcd for $C_{13}H_{16}O_7$: C, 54.93; H, 5.67%. **4b**: mp 96—97.5 °C; IR: 3360, 1735, 1715, 1710, 1645, and 1610 cm^{-1}; NMR ($CDCl_3$): 10.02 (1H, s, OH), 6.38 (1H, d, J=2 Hz, olefin), 4.20 (1H, q, J=8 Hz, >CH–COO), 3.36 (1H, dq, J=7 and 8 Hz, >CH–Me), and 1.13 (3H, d, J=7 Hz, CH_3). Found: C, 54.64; H, 5.38%; Calcd for $C_{13}H_{16}O_7$: C, 54.93; H, 5.67%. **4d**: oil; IR: 1730 and 1630 cm^{-1}; NMR ($CDCl_3$): 3.77, 3.66, and 3.60 (3× 3H, s, $COOCH_3$), 3.7 (1H, m, >CH–COO), 3.2—2.6 (3H, m), and 2.35 (3H, s, CH_3). Found: C, 54.75; H, 5.43%. Calcd for $C_{13}H_{16}O_7$: C, 54.93; H, 5.67%.

Hydrogenation and Decarboxylation of ***4a****,* ***4b****, and* ***4c*** *to* ***5****.* A solution of **4a** (0.426 g) in methanol was hydrogenated in the presence of 5% Pd–C under hydrogen atmosphere at room temperature. After removal of the catalyst and evaporation of the solvent, the hydrogenated product was heated at 120—140 °C for 1 h in a mixture of diglyme (6 ml), acetic acid (0.4 ml), and sodium iodide (0.2 g). The reaction mixture was poured into water and extracted with ether. The ethereal extracts were evaporated to dryness and the residue was chromatographed on silica gel to give **5a** (0.27 g), which was homogeneous in TLC, gas chromatography, and HPLC. **5a**; IR: 1740 cm^{-1}; NMR ($CDCl_3$): 3.63 and 3.73 (2× 3H, s, $COOCH_3$) and 1.20 (3H, d, J=5 Hz, CH_3); Found: C, 58.18; H, 7.14%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

Similarly, **4b** and **4c** were hydrogenated and decarboxylated. In each case there was only one spot on TLC, but the NMR spectra of the methyl group showed three components. These mixtures were separated into two fractions by HPLC. The first fraction showed a doublet signal at 1.13 ppm assignable to the methyl of **5b**, the second fraction two doublet signals at 1.20 and 0.96 ppm, to which were assigned **5a** and **5d**, respectively.

A Mixture of Dimethyl 5,5-Dimethyl-3-ethoxycarbonylmethylene-2-hydroxy-1-cyclopentene-1,4-dicarboxylate ***4c*** *and Its Olefinic Isomer* ***4e****.* A solution of **2b** (25.1 g) and **3b** (72.3 g) in chloroform was stirred at 60 °C for 5 days. After evaporation of the solvent *in vacuo*, the residue was added to ether and the precipitate of the unreacted **3b** was filtered off. The filtrate was washed with 8% HCl and then 10% aqueous K_2CO_3, and evaporated *in vacuo*. The residue was redissolved in diisopropyl ether and stored in a refrigerator to give triphenylphosphine oxide. After removal of Ph_3PO by filtration, evaporation of the filtrate gave a reddish oil which was chromatographed on acid-washed silica gel to give a mixture of **4c** (*exo*) and **4e** ((*endo*)(8.21 g). MS: *m/e* 312 (M^+); IR: 1740, 1710, and 1655 cm^{-1}; NMR ($CDCl_3$): 10.5 (s, OH) and 6.4 (d, olefin).

Methyl t*-2-Methoxycarbonyl-*c*-3-methyl-5-oxocyclopentane-*r*-1-acetate* ***5a*** *and 3,3-Dimethyl Derivative* ***5c****.* A solution of the crude Wittig products, obtained from α-dienol **2a** (6.84 g) and 10% Pd–C (4.0 g) in methanol was hydrogenated under atmospheric pressure. After filtration and evaporation *in vacuo*, the oily residue was refluxed in concd HCl for 3 h. The reaction mixture was evaporated to dryness *in vacuo*, and reesterified with CH_2N_2 in ether to give crude **5a** which was equilibrated with NaOMe in methanol at room temperature for 12 h. The chromatography of the crude oil on a silica gel column gave the oil **5a** (3.17 g). MS: *m/e* 228 (M^+); IR: 1740 cm^{-1}; NMR ($CDCl_3$): 3.75 and 3.66 (2× 3H, s, $COOCH_3$) and 1.20 (3H, d, J=5 Hz, CH_3). Found: C, 57.69; H, 7.14%; Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

A similar procedure starting from the crude Wittig products **4c** and **4e** (8.20 g) afforded **5c** (5.03 g), which was homogeneous in TLC; no isomerization was observed after the treatment of **5c** with NaOMe–methanol. MS: *m/e* 242 (M^+); IR: 1740 cm^{-1}; NMR ($CDCl_3$): 1.40 and 1.00 (2× 3H, s, CH_3). Found: C, 59.23; H, 7.42%. Calcd for $C_{12}H_{18}O_5$: C, 59.49; H, 7.49%.

c*-5-Hydroxy-*t*-2-methoxycarbonyl-*c*-3-methylcyclopentane-*r*-1-acetic Acid γ-Lactone* ***6a*** *and 3,3-Dimethyl Derivative* ***6b****.* To a stirred solution of **5a** (2.28 g) in tetrahydrofuran at 0 °C under argon was added dropwise a solution of 0.5 M/L potassium tri-*s*-butylborohydride in tetrahydrofuran (22 ml). The mixture was stirred at 0 °C for 30 min. The reaction was quenched by addition of 4% HCl. The resulting mixture was diluted with brine and extracted with ethyl acetate. The combined extracts were washed with brine, dried over Na_2SO_4, and evaporated *in vacuo* to give a crude oil. The oil was chromatographed on silica gel to give **6a** (1.34 g). IR: 1775, 1740, and 1735 cm^{-1}; NMR ($CDCl_3$): 5.0 (1H, m, lactone), 3.71 (3H, s, $COOCH_3$), and 1.10 (3H, d, J=5.5 Hz, CH_3). Found: C, 60.37; H, 7.25%. Calcd for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12%.

A similar procedure starting from **5c** (5.53 g) afforded **6b** (2.27 g). Mp 69.5—71 °C; MS: *m/e* 212 (M^+); IR: 1775, 1765, and 1730 cm^{-1}; NMR ($CDCl_3$): 4.96 (1H, dt, J=7 and 5 Hz, lactone), 3.70 (3H, s, $COOCH_3$), 1.24 and 0.90 (2× 3H, s, CH_3). Found: C, 62.40; H, 7.61%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%.

t*-2-Carboxy-*c*-5-hydroxy-*c*-3-methylcyclopentane-*r*-1-acetic Acid γ-Lactone* ***7a*** *and 3,3-Dimethyl Derivative* ***7b****.* A solution of **6a** (1.32 g) in concd HCl was refluxed for 2 h. The resulting solution was evaporated *in vacuo* and the residue was recrystallized from benzene–diisopropyl ether to give the lactone acid **7a** (0.803 g). Mp 116—117 °C; NMR ($CDCl_3$): 10.7 (1H, s, COOH), 5.00 (1H, m, lactone), and 1.17 (3H, d, J=5 Hz, CH_3). Found: C, 58.43; H, 6.35%. Calcd for $C_9H_{12}O_4$: C, 58.69; H, 6.57%.

Similarly, **6b** (2.27 g) was converted by the same procedure into **7b** (1.51 g). Mp 179.5—181 °C; MS: *m/e* 198 (M^+); NMR (acetone-d_6): 8.2 (1H, bs, COOH), 5.0 (1H, dt, J=7 and 5 Hz, lactone), 1.32 and 0.93 (2× 3H, s, CH_3). Found: C, 60.34; H, 7.17%. Calcd for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12%.

c*-5-Hydroxy-*t*-2-hydroxymethyl-*c*-3-methylcyclopentane-*r*-1-Acid*

γ-Lactone 8a and 3,3-Dimethyl Derivative 8b. To a solution of **7a** (0.75 g) and triethylamine (0.572 g) in tetrahydrofuran at 0 °C under argon was added ethyl chloroformate (0.61 g) in tetrahydrofuran. After 1 h, the precipitate was filtered off from the reaction mixture. To the filtrate was added dropwise a solution of $NaBH_4$ (0.643 g) in water at 0 °C and the mixture was stirred at ambient temperature for an additional 1 h. After cooling to 0 °C, 8% HCl was added to the reaction mixture, and extraction was carried out with ethyl acetate. The combined extracts were washed with brine, dried over Na_2SO_4, and evaporated *in vacuo* to give a crude oil. This was chromatographed on silica gel to afford the lactone alcohol **8a** (0.552 g). MS: *m/e* 170 (M^+); IR: 3500 and 1770 cm^{-1}; NMR ($CDCl_3$): 4.90 (1H, m, lactone), 3.4—4.0 (3H, m), and 1.07 (3H, d, J=6 Hz, CH_3). Found: C, 63.47; H, 8.18%; Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%.

Similarly, **7b** (1.50 g) was converted by the same procedure into the oil **8b** (1.03 g). MS: *m/e* 184 (M^+); IR: 3450 and 1770 cm^{-1}; NMR ($CDCl_3$): 4.92 (1H, dt, J=7 and 5 Hz, lactone), 3.3—4.0 (3H, m), 1.16 and 0.82 (2× 3H, s, CH_3). Found: C, 65.03; H, 8.72%; Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%.

*3,3-Dimethyl-*c*-5-hydroxy-*t*-2-(3-oxo-*trans*-1-octenyl)cyclopentane-*r*-1-acetic Acid γ-Lactone 9.* To a stirred solution of the Collins reagent prepared from CrO_3 (4.04 g) and pyridine (6.25 ml) in dichloromethane at 0 °C under argon was added a solution of **8b** (1.03 g) in dichloromethane. The resulting solution was stirred at 0 °C for 5 min and then at ambient temperature for 20 min, and added to ether. The precipitate was filtered and the filtrate was washed with 4% sodium hydroxide, water, 4% HCl, water, 3% $NaHCO_3$, and water, dried over Na_2SO_4, and evaporated to give a crude aldehyde (0.92 g). To the solution of this aldehyde in ether was added a solution of (2-oxoheptylidene)tributylphosphorane (2.32 g) in dry ether. The mixture was stirred at ambient temperature for 6 h under argon. After evaporation of the solvent, the residual oil was chromatographed on silica gel to give the enone **9** (1.18 g). IR: 1775, 1700, 1675, and 1630 cm^{-1}; NMR ($CDCl_3$): 6.7 (1H, dt, J=16 and 8 Hz, olefin), 6.1 (1H, d, J=6 Hz, olefin), 5.0 (1H, dt, lactone), and 0.9 (2X 3H, s, CH_3). Found: C, 73.37; H, 9.44%. Calcd for $C_{17}H_{26}O_3$: C, 73.34; H, 9.41%.

*3,3-Dimethyl-*c*-5-hydroxy-*t*-2-[(3S*)-hydroxy-*trans*-1-octenyl)]-cyclopentane-*r*-1-acetic Acid γ-Lactone 10.* A solution of **9** (1.37 g) and $NaBH_4$ (0.205 g) in absolute methanol was stirred at 0 °C for 1 h under argon. The reaction mixture was quenched by addition of aqueous acetic acid. The resulting solution was extracted with ethyl acetate. The combined extracts were washed with brine, dried over Na_2SO_4, and evaporated to give a crude oil. The oil was separated into a less polar oil (0.655 g) and a more polar crystalline part (mp 53—54 °C) (0.562 g) by preparative thin layer chromatography. The former was assigned tentatively as the 15*S**-hydroxy lactone **10** and the latter as the 15*R**-hydroxy epimer. **10**: MS: *m/e* 280 (M^+); IR: 3450 and 1770 cm^{-1}; NMR ($CDCl_3$): 5.4—5.6 (2H, m, olefin), 5.0 (1H, m, lactone), 4.1 (1H, m, >CH–O), 1.0 and 0.8 (2× 3H, s, CH_3). Found: C, 72.88; H, 9.91%; Calcd for $C_{17}H_{28}O_3$: C, 72.82; H, 10.06%.

*3,3-Dimethyl-*c*-5-hydroxy-*t*-2-[(3S*)-(tetrahydropyranyloxy)-trans-1-octenyl]cyclopentane-*r*-1-acetaldehyde γ-Lactone 11.* A solution of **10** (0.641 g), dihydropyran (0.5 ml), and a catalytic amount of *p*-toluenesulfonic acid in dry dichloromethane was stirred at 0 °C for 20 min. After the addition of a few drops of pyridine, the reaction mixture was extracted with ether. The combined extracts were washed with brine, dried over Na_2SO_4, and evaporated to give an oil. This oil was chromatographed on aluminum oxide (Woelum grade III) to give a tetrahydropyranylated lactone (0.864 g). NMR ($CDCl_3$): 4.6 (1H, m, O–CH–O). To a stirred solution of the tetrahydropyranylated lactone in toluene at −70 °C under argon was added a solution of 25% diisobutylaluminium hydride (4 ml) in toluene. After 1.5 h the reaction was quenched by addition of methanol. The resulting mixture was allowed to warm to ambient temperature with stirring and water was added. The mixture was filtered through celite, and washed with ethyl acetate. The organic layer was separated and the aqueous layer was extracted with ethyl acetate. The combined extracts were washed with brine, dried over Na_2SO_4, and evaporated *in vacuo* to give a crude oil. The oil was chromatographed on silica gel to give **11** (0.612 g). MS: *m/e* 366 (M^+); IR: 3425 cm^{-1}; NMR ($CDCl_3$): 5.2—5.7 (3H, m), 1.0 and 0.8 (2× 3H, s, CH_3). Found: C, 71.78; H, 10.48%; Calcd for $C_{22}H_{38}O_4$: C, 72.09; H, 10.45%.

11,11-Dimethyl-15-(tetrahydropyranyloxy) prostaglandin E_2 12. To a solution of sodium 5-(triphenylphosphoranylidene) pentanoate prepared from (4-carboxybutyl)triphenylphosphonium bromide (3.82 g) and NaH (0.78 g) in DMSO under argon was added **11** (0.592 g) in DMSO. The mixture was allowed to stand at room temperature for 2 h. The reaction mixture was poured into ice–water, acidified with acetic acid, and extracted with ether. The combined extracts were washed with brine, dried over Na_2SO_4, and evaporated to give a crude oil. To a solution of the Collins reagent (2.32 g) in dichloromethane at 0 °C under argon was added a solution of the crude oil in dichloromethane. The resulting mixture was stirred at ambient temperature for 30 min and added to ether. The mixture was then filtered through celite. The filtrate was washed with 4% HCl and evaporated to give an oily residue. The residue was chromatographed on silica gel to give **12** (0.467 g). IR: 1740, 1710, and 1020 cm^{-1}; NMR ($CDCl_3$): 10.0 (1H, bs, COOH), 5.0—5.7 (4H, m, olefin), 1.2 and 0.9 (2× 3H, s, CH_3). Found: C, 71.99; H, 9.92%; Calcd for $C_{27}H_{44}O_5$: C, 72.28; H, 9.89%.

11,11-Dimethylprostaglandin E_2 1b. A solution of **12** (0.467 g) in acetic acid, water, and tetrahydrofuran (20: 10: 3) was heated at 40 °C for 6 h. The solvent was evaporated azeotropically with toluene *in vacuo*. The residue was added to water and extracted with ethyl acetate. The combined extracts were washed with brine, dried over Na_2SO_4, and evaporated to give an oily residue. The crude product was chromatographed on an acid-washed silica gel to give **1b** (0.267 g). MS: *m/e* 364 (M^+); IR: 3450 and 1740 cm^{-1}; NMR ($CDCl_3$): 6.9 (2H, bs, COOH and OH), 5.1—5.7 (4H, m, olefin), 4.1 (1H, m, $C_{15}H$), 1.1 and 0.9 (2× 3H, s, CH_3). Found: C, 72.62; H, 9.80%; Calcd for $C_{22}H_{36}O_4$: C, 72.49; H, 9.96%.

Catalytic Activities of Salicylaldehyde Derivatives. VIII. Kinetic Studies of the Catalytic Racemization of L-Glutamic Acid at 25 °C

Makoto Ando* and Sakae Emoto

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received January 10, 1978)

The racemization of L-glutamic acid catalyzed by 15 kinds of salicylaldehyde derivatives has been kinetically studied at 25 °C and pH 10 in the presence of copper(II) ion. When 4- and 5-substituted salicylaldehydes were used as the catalyst, Hammett's plots for the racemization against σ^- were found to be linear with fewer points deviating from the line than the plots against σ. This fact has not been observed previously, since the salicylaldehyde derivatives tested having a substituent of different value between σ and σ^- were degraded during the course of reaction at 80 °C. Hammett's plots for the reaction catalyzed by 3-substituted salicylaldehydes indicated no linear relation with either σ or σ^-. These catalytic racemizations, including the case of the 6-substituted salicylaldehydes have been discussed.

In previous papers,[1-4] the racemization of L-glutamic acid catalyzed by various salicylaldehyde derivatives has been kinetically studied in the presence of copper(II) ion at pH 10 and 80 °C. Eighty degrees has been adopted as the temperature in order to observe the slow catalytic racemization throughout these studies. Hammett's plots for the racemization catalyzed by 4- and 5-substituted salicylaldehydes indicated a linear relation against Hammett's constant, σ.[2,3] It was difficult sometimes to determine the observed rate constants for the catalytic racemization of some salicylaldehyde derivatives such as the dimethylsulfonio derivatives, because of degradation of the catalysts at 80 °C.[4,5]

This paper deals with the determination of the observed rate constants, k_{obsd}, for the catalytic racemization at 25 °C and with the relation between $\log k_{obsd}$ and Hammett's constant. The following 15 salicylaldehyde derivatives were used as the catalysts: salicylaldehyde (SAL), 3-bromo- (3-BR), 5-bromo- (5-BR), 3-nitro- (3-NI), 4-nitro- (4-NI), 5-nitro- (5-NI), 6-nitro-salicylaldehyde (6-NI), 3-trimethylammonio- (3-TA), 4-trimethylammonio- (4-TA), 5-trimethylammonio- (5-TA), 6-trimethylammonio- (6-TA), 3-dimethylsulfonio- (3-DS), 4-dimethylsulfonio- (4-DS), 5-dimethylsulfonio- (5-DS), and the 6-dimethylsulfonio-derivative of salicylaldehyde (6-DS).

As described previously,[1-4] the catalytic racemization of L-glutamic acid has been carried out in the presence of copper(II) ion (L-glutamic acid: copper(II) ion: the catalyst = 1: 0.02: 0.02 in molar ratio) at pH 10 and 25 °C, under which conditions no side reaction such as transamination was observed. Since it is well documented that the catalytic racemization obeys a first-order kinetic law, the catalytic activity, $(\log \alpha_0 - \log \alpha_t)/t$, should be a constant, where t is the time and α_t is the observed optical rotation at t. The observed rate constant, k_{obsd}, has been calculated from the following equation:

$$k_{obsd} = \frac{2.30 \times (\log \alpha_0 - \log \alpha_t)}{t}.$$

Experimental

Preparation of the Catalysts. Commercially available SAL was purified by vacuum distillation. 3-BR,[2] 5-BR,[2] 3-NI,[2] 4-NI,[6] 5-NI,[2] 6-NI,[7] 3-TA,[3] 4-TA,[1] 5-TA,[3] 6-TA,[8] 3-DS,[5] 4-DS,[5] 5-DS,[5] and 6-DS[4] were prepared by methods described in the literature.

Procedure of the Racemization.[1] In a tightly stoppered test tube a mixture of a pH-adjusted solution (pH 10, 2 ml) of sodium L-glutamate (2 mmol) containing copper(II) sulfate (0.04 mmol) and a pH-adjusted 0.05 M borate buffer solution (pH 10, 2 ml) of the catalyst (0.04 mmol) was kept at 25 °C for the required time. After the reaction time as described in Table 1, 6 M hydrochloric acid (5 ml) was added to the mixture in order to stop the reaction. The optical rotation of the resulting solution was measured with a Perkin-Elmer model 141 polarimeter (direct reading, 0.001° with an error of ±0.002°; $\alpha_0 = +1.02°$).

Results and Discussion

As Table 1 shows, the mode of the catalytic activity may be classified into three categories according to the kind of the catalyst used; in the first case, the catalytic activity is nearly constant throughout the reaction (SAL, 3-BR, 5-BR, 3-NI, 5-NI, 3-TA, 4-TA, 5-TA, 3-DS, and 5-DS); in the second one, it is approximately constant only at the early stage of the reaction and then gradually falls (4-NI, 6-TA, 4-DS, and 6-DS); in the last case, it lacks constancy even at the early stage of the reaction (6-NI). The decrease in the catalytic activity has been accompanied by a simultaneous decrease in the absorption maximum of the reaction mixture at *ca.* 380 nm, which has been attributed to the chelation of the Schiff base of glutamic acid with the catalyst and copper(II) ion,[9] as previously reported.[3,10] From these constant values of the catalytic activities, the observed rate constants, k_{obsd}, have been calculated as shown in Table 2. For comparison, k_{obsd} for the reaction catalyzed by pyridoxal has also been calculated from the data in Ref. 10.

It has been found that the plots of $\log k_{obsd}$ against Hammett's constant, σ,[11] were on a straight line for the reaction catalyzed by SAL, 5-BR, 5-NI, 4-TA, 5-TA, and 5-DS except 4-NI and 4-DS. In the cases of 4-NI and 4-DS, $\log k_{obsd}$ were abnormally large against the corresponding σ.

As Fig. 1 shows, the plots of $\log k_{obsd}$ against Hammett's constant, σ^-,[12] indicate a linear relation for all of the 4- and 5-substituted salicylaldehydes

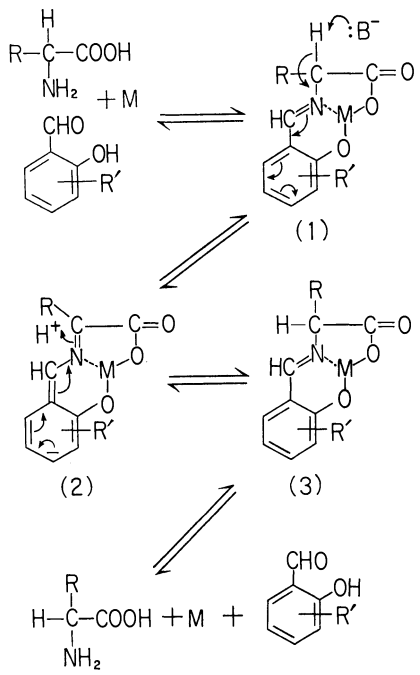
tested including 4-NI and 4-DS. The reaction constant, ρ, has been determined as 0.99. As it has been well documented, σ^- is determined by the ionization constants of substituted phenols or anilines, whereas σ is based on the ionization constants of substituted benzoic acids. Therefore the σ^--values of some substituents such as *p*-nitro and *p*-dimethylsulfonio groups, which can conjugate with hydroxyl or amino groups through quinonoidal-conjugate rings, are considerably larger than the corresponding σ-values. This means that Hammett's constants of *m*- and *p*-substituents such as trimethylammonio group having a negligible quinonoidal-conjugate effect are of no difference between σ and σ^-, since there are two cases, whether the σ^--value includes only an electron-withdrawing effect or a combination of electron-withdrawing and conjugate effects. Probably, this conjugate effect is expected to act between formyl group and nitro or dimethylsulfonio group in the para position on the benzene ring.

The Braunstein-Snell mechanism for non-enzymatic reactions of amino acids catalyzed by pyridoxal in the presence of a metal ion[13] has been generally accepted. When the mechanism is applied to the salicylaldehyde system, the presence of the intermediates, **1**, **2**, and **3** shown in Scheme have to be considered. The contribution of a substituent such as *p*-nitro or *p*-dimethylsulfonio group to the resonance of the quinonoidal form conjugated with a formyl group would stabilize **2**, resulting in an increase in the rate of racemization. Consequently, it is reasonable that in the cases of 4-NI and 4-DS, Hammett's plots against σ^- are linear although those against σ are not.

Table 2. Observed rate constant, k_{obsd}

	k_{obsd}, (min^{-1})		k_{obsd}, (min^{-1})
SAL	3.7×10^{-5}	5-TA	24.7×10^{-5}
3-BR	8.4	6-TA	14.8
5-BR	8.6	3-DS	25.3
3-NI	18.2	4-DS	53.8
4-NI	65.4	5-DS	31.5
5-NI	19.6	6-DS	49.0
3-TA	10.6		
4-TA	23.3	pyridoxal	64.8

As shown in Table 2, The observed rate constants for 5-substituted salicylaldehydes are larger than those for the corresponding 3-isomers in spite of having the same σ^--value. Possibly, the 3-substituents sterically hinder the formation of the chelate ring of the adjacent phenol group with copper(II) ion. Similar phenomena have also been observed at 80 °C.[2,3] The differences in k_{obsd} between 3-TA and 5-TA and 3-DS and 5-DS are considerably larger than those between other 3- and 5-substituted salicylaldehydes. Apparently 3-TA, 5-TA, 3-DS, and 5-DS have a bulky and positively charged substituent, therefore, in the racemization by 3-TA and 3-DS, the formation of the chelate ring is inhibited and this is assumed due to the effects of simple steric hindrance and additional strong ionic repulsion



between the substituent and copper(II) ion.

Since steric effects of the 6-substituents on the adjacent formyl group would not be straightforward and Hammett's constants of the *o*-substituent have not been determined, the evaluation of Hammett's constant of an *o*-substituent based on the racemization catalyzed by 6-substituted salicylaldehyde has not been attempted. The larger catalytic activities of 6-NI and 6-DS compared to the corresponding 5-isomers are thought due to a similar case of *p*-substituents of 4-NI and 4-DS.

As Table 1 shows the orders of the catalytic activities at the early stage of the reaction are 4-NI>6-NI>5-NI>3-NI, 4-DS>6-DS>5-DS>3-DS, and 5-TA>4-TA>6-TA>3-TA. As described above, this order is reasonable qualitatively considering the electron-withdrawing effect, the resonance effect through the conjugate system, and the steric hindrance of a substituent including ionic repulsion. These results show that the steric effect of the 3-substituent on the phenol group seems to be larger than that of the corresponding 6-substituent on the formyl group and that the formation of the chelate ring of the hydroxyl group in the salicylaldehyde with copper(II) ion plays an important role in the catalytic racemization.

The work was supported partially by a Research Grant for Biosciences given by this Institute.

Coordination of Alkanethiolate Anion to Ruthenium(II) Carbonyl Complex of Octaethylporphine: Model for Carbonyl Adduct of Cytochrome P-450

Hisanobu Ogoshi*, Hiroshi Sugimoto, and Zen-ichi Yoshida
Department of Synthetic Chemistry, Kyoto University, Kyoto 606
(Received January 12, 1978)

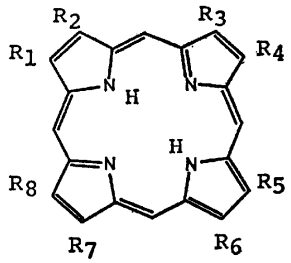
Absorption, infrared, and ^{1}H-NMR spectra of the ruthenium(II) octaethylporphine carbonyl complex [Ru(II)-OEP·CO] were studied in the presence of alkanethiolate anion ($^-$SR) as a model system for the reduced cytochrome P-450 carbonyl complex. The ^{1}H-NMR spectra reveal that alkanethiolate anions coordinte toa the central metal atom of Ru(II)OEP·CO as the sixth ligand. The hexaccordinated complex [Ru(II)OEP·CO·$^-$SR] has anomalous features as compared with the pentacoordinated complex [Ru(II)OEP·CO]: (1) the Soret band is splitted into two peaks, one in the near UV 363—365 nm region and the other in the 419—428 nm region, (2) the carbonyl stretching frequency is shifted by 25 cm^{-1} to lower wave number, (3) the proton signals of porphyrin ligand are shifted to higher magnetic field. Similarity of absorption and infrared spectra of the hexacoordinated complex to those of the reduced cytochrome P-450 carbonyl complex supports the axial ligation of the cysteinate to the central iron atom of the heme-proteins. The low wave number shifts of carbonyl stretching vibration and high field shifts of protons in the ^{1}H-NMR spectra suggest the charge transfer interaction from 3p lone pair electrons of sulfur atom of alkanethiolate anion to the central metal and/or the porphyrin ligand.

Cytochrome P-450 found in bacteria and lever microsomes are a kind of heme-enzymes which activate the molecular oxygen to catalyze the hydroxylation of the organic compounds in drug metabolism.[1,2] Recent investigations have been focused on elucidation of the structure of the active site of the heme enzymes. Simulation to the moiety of the prothetic protoheme in the enzyme by use of model compounds has provided a plausible explanation for the properties of axial ligand to the heme in P-450.[3-6] Spectroscopic studies showed similarity between the oxidized cytochrome P-450 and model compounds.[7-11] Addition of CO to the reduced cytochrome P-450 shows an anomalous red-shifted Soret band at *ca.* 450 nm.[12] This anomalous electronic spectrum has been successfully duplicated with synthetic heme in the presence of alkanethiolate anion and CO.[3,4,6] This gives strong evidence of axial coordination of the cysteinate to the heme-CO complex in P-450.

Divalent and trivalent ruthenium porphyrin complexes have been prepared by Whitten and his coworkers.[13] It is noted that the ruthenium(II) carbonyl porphyrin is isolable as a stable complex with or without the sixth ligand such as amine tetrahydrofuran and alcohol. These Ru(II)porphyrin·CO·L complexes are d^6-metal complexes of diamagnetic low spin state. Thus the electronic structure of the ruthenium(II) carbonyl complex is considered to be similar to that of the ferrous carbonyl porphyrin complex. The divalent metal ions of Ru(II)porphyrin·CO·(base) and Os(II)-porphyrin·CO·(base) are highly insensitive to oxygen as compared with the heme-CO adduct at ambient temperature.[13,14] The advantage of high stability of the ruthenium(II) complexes enables us to study the axial ligation of the alkanethiolate anion to the metal carbonyl porphyrin. Replacement of the iron atom of ferrous carbonyl porphyrin with ruthenium atom might afford an alternative model for the carbonyl adduct of the reduced cytochrome P-450. We wish to report spectroscopic evidence of the interaction between the alkanethiolate anion and the Ru(II) porphyrin·CO.

Experimental

Ruthenium(II) carbonyl octaethylporphine [Ru(II)OEP·CO] and ruthenium(II) carbonyl mesoporphyrin IX dimethyl ester were obtained by the reaction of octaethylporphine and mesoporphyrin IX dimethyl ester with $Ru_3(CO)_{12}$ in dry benzene, respectively.[13] The other chemicals and solvents were purified. Solutions of sodium alkanethiolates (RS$^-$Na$^+$, R=$-CH_2CH_2CO_2CH_3$, $-CH_2CH_3$, and $-C(CH_3)_3$) were prepared by the following procedure. Pulverized sodium hydride was washed with pentane several times and dried in a vacuum. Mercaptan (RSH, R=$-CH_2CH_2CO_2CH_3$, $-CH_2CH_3$, and $-C(CH_3)_3$) was added to NaH under argon atmosphere. After stirring for 15 min, the mixture was evacuated in order to remove excess mercaptan. To the deaerated solvents (benzene, ether, acetonitrile, *N,N*-dimethylformamide, dimethyl sulfoxide; 1 ml containing dibenzo-18-crown-6 (12 mg, 0.032 mmol) was added an equimolar amount of sodium alkanethiolate. The mixture was stirred until the sodium alkanethiolate dissolved completely. To the solution was added Ru(II)OEP·CO (20 mg, 0.032 mmol) and the solution was stirred for 1 h. The red solution turned to yellowish orange gradually. Disappearance of the Soret band due to Ru(II)-OEP·CO was monitored by measurement of the visible



$R_1=R_2=R_3=R_4=R_5=R_6=R_7=R_8=CH_2CH_3$ octaethylporphine

$R_1=R_3=R_5=R_8=CH_3$, $R_2=R_4=$vinyl, $R_6=R_7=CH_2CH_2CO_2CH_3$ protoporphyrin IX dimethyl ester

$R_1=R_3=R_5=R_8=CH_3$, $R_2=R_4=CH_2CH_2$, $R_6=R_7=CH_2CH_2CO_2CH_3$ mesoporphyrin IX dimethyl ester

spectra. Spectral measurements were carried out under argon atmosphere. Infrared spectra were measured on a Hitachi Model G-3 spectrophotometer in NaCl liquid cells with 0.1 mm optical path. Absorption spectra were measured with a Hitachi EPS-3T spectrophotometer in 0.1 mm quartz cells. Proton NMR were obtained with JEOL FX-60 and Varian HA-100 D spectrometers in CD_3CN and referred to tetramethylsilane (TMS) or hexamethyldisiloxane (HMDS).

Results and Discussion

Absorption Spectra. The visible spectra of Ru(II)-OEP·CO in various solvents are summarized in Table 1. The ruthenium complex shows characteristic absorptions of the divalent metalloporphyrin at *ca.* 550 and 520 nm (the α-, β-bands) assigned to the first $\pi\rightarrow\pi^*$ transitions splitted by vibronic interaction and the Soret band at 395 nm due to the second $\pi\rightarrow\pi^*$ transitions.[15] The transition energy for the absorption shows small dependency on polarity of solvent molecule. Slight red shifts of these absorptions were observed in DMF. Nucleophilicities of alkanethiolate anion can be enhanced by the incorporation of alkaline metal ion to crown ether. Addition of an equimolar amount of alkanethiolate anion thus generated (*e.g.* RS^-, R=$-CH_2CH_2CO_2CH_3$, $-CH_2CH_3$, and $-C(CH_3)_3$) to Ru(II)OEP·CO caused the splitting of the Soret band into two bands at 363—366 and 419—428 nm. The absorption strength of both α- and β-bands decreased considerably, a new band appearing at 540 nm. On the other hand, addition of an equimolar amount of mercaptan (*e.g.* RSH, R=$-CH_2CH_2CO_2CH_3$, $-CH_2CH_3$, and $-C(CH_3)_3$) gave no marked change in the transition energies and the absorption strength.

Table 1. Absorption maxima of Ru(II)OEP·CO·L

DMSO	^-SR	366, 428	540	
	Absorption maxima of Fe(II)OEP·CO·L			
Benzene	^-SR[b]	357, 436	540	
DMF	^-SR	370, 447	540	

a) R=$-CH_2CH_2CO_2CH_3$, alkanethiolate anion was solubilized by dibenzo-18-crown-6. [Ru(II)OEP·CO]=0.032 mM, [^-SR]=0.032 mM. b) [Fe(II)-OEP·CO]=0.032 mM, [^-SR]=0.32 mM. The 408 nm peak assignable to the pentacoordinated complex [Fe(II)OEP·CO] did not completely disappear even in the presence of the 100 eq. amount of alkanethiolate anion.

The hexacoordinated complex of ferrous carbonyl porphyrin[Fe(II)OEP·CO·(^-SR)] was obtained by treatment of the ferric porphyrin OEP·Fe(III)Cl with a large excess of alkanethiolate anion in the presence of carbon monoxide.[5,6] Coordination of alkanethiolate anion to Fe(II)OEP·CO in benzene solution caused the appearance of new bands at 357 and 436 nm. However, the absorption at 408 nm due to the pentacoordinated complex [Fe(II)OEP·CO] was observed even in the presence of ten times molar amounts of alkanethiolate anion.[5,6,16] Spectral change due to ligation of alkanethiolate anion was quite similar to that of the ferrous carbonyl complex of protoporphyrin IX dimethyl ester.[5,6] Two vinyl groups at the peripheral positions of protoheme may cause bathochromic shifts of those absorption maxima as compared with the complex of octaethylporphine. Complete formation of the hexacoordinated complex [Fe(II)OEP·CO·(^-SR)] requires large excess amounts (10^5—10^6 eq.) of the alkanethiolate anion.[5,6,16] Splitting of the Soret band of these hexacoordinated complexes depends a great deal on polarity of solvent molecule. In more polar solvent such as DMF the absorptions shift to longer wave length.

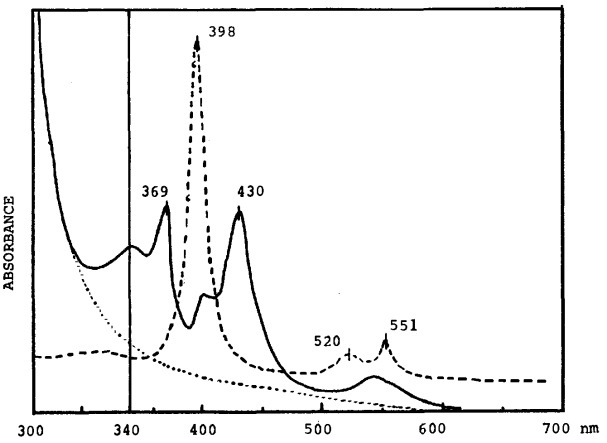

Fig. 1. Absorption spectra of Ru(II) carbonyl mesoporphyrin IX dimethyl ester, (——) with an equimolar amount of $HSCH_2CH_2CO_2CH_3$ in DMF; (——) with equimolar amount of $^-SCH_2CH_2CO_2CH_3$ solubilized by dibenzo-18-crown-6 in DMF; (····) base line.

Similar anomalous absorption spectra can be duplicated by using the ruthenium(II) carbonyl complex of mesoporphyrin IX dimethyl ester with an equimolar amount of the alkanethiolate anion as shown in Fig. 1. Axial ligation of alkanethiolate anion to ruthenium(II) carbonyl porphyrin causes clear splitting of the Soret band to two peaks as has been found for ferrous carbonyl porphyrin. Recently, Hanson and his co-workers have reported that[17] splitting of the Soret band into two bands of the reduced cytochrome P-450 carbonyl adduct and its model compounds can be attributed to the charge transfer transition from the 3p lone pair electrons of the sulfur atom to the lowest vacant π^* orbitals of the porphyrin ring and that the transition may cause strong interaction with the $\pi\rightarrow\pi^*$ (a_{1u}, $a_{2u}\rightarrow e_g^*$) transitions. Recent MCD studies of the cytochrome P-450 and its model compounds seem to support their theoretical interpretation.[11]

Infrared Spectra. The carbonyl stretching vibrations[14] of Ru(II)OEP·CO were observed in various solvents (Table 2). Figure 2 shows the infrared spectra

Table 2. Carbonyl stretching vibrations of Ru(II)OEP·CO·L

R=$-CH_2CH_2CO_2CH_3$. The conditions of measurements are described in Table 2.

of these complexes in the region of carbonyl stretching. Addition of alkanethiolate anion reduced the wave number of the carbonyl stretching by 28—29 cm^{-1} for the ruthenium complex and 25 cm^{-1} for a ferrous complex.[16] In the case of Fe(II)OEP·CO with excess amounts of alkanethiolate anion in benzene, two carbonyl stretching vibrations were observed at 1975 and 1950 cm^{-1}. This provides further evidence of the coexistence of the pentacoordinated complex (**2**) (1975 cm^{-1}) and the hexacoordinated complex (**4**) (1950 cm^{-1}) for the iron complex as has been found for the absorption spectra. These trends can be explained in terms of

$$\text{M(II)OEP·CO} + {}^-\text{SR} \rightleftarrows \text{M(II)OEP·CO·}({}^-\text{SR})$$

M=Ru (**1**) M=Ru (**3**)

M=Fe (**2**) M=Fe (**4**)

π-back donation from dπ-orbitals of metal to the *anti*-bonding π^*-orbitals of the carbonyl. Divalent ruthenium in the pentacoordinated complex (**1**) is considered to be a stronger π-base than ferrous ion in the pentacoordinated complex (**2**) on the basis of the shift of the carbonyl stretching vibration. Enhanced back donation from the dπ-orbitals of ruthenium to the anti-bonding π^*-orbitals of the carbonyl decreases electron density on the ruthenium atom. On the other hand, addition of a strong π-acceptor ligand such as PPh_3 shows appreciable increase of the carbonyl stretching frequency. A similar trend has been found for the osmium(II) carbonyl porphyrin complexes by Buchler and Rohback.[14] These results suggest that ligation of alkanethiolate anion to central metal facilitates charge transfer to the central metal from sulfur atom.[11d] Furthermore, it is noted that carbonyl stretching frequencies are very sensitive to polarity of solvent molecule. Increasing of polarity of solvent from benzene to DMF reduces the frequencies of the carbonyl stretching by 28—29 cm^{-1} for the ruthenium complex and 17 cm^{-1} for the ferrous complex. The carbonyl stretching frequency (1923 cm^{-1}) of the hexacoordinated complex (**4**) in DMF is the same as that (1923 cm^{-1}) of Fe(II) protoporphyrin IX dimethyl ester in *N*,*N*-dimethylacetamide in the presence of both carbon monoxide and 1-butanethiolate.[6] Polar solvent molecules may stabilize the polarization along the axial direction due to the charge transfer from alkanethiolate

Table 3. Proton chemical shifts (60 MHz, ppm from TMS) of Ru(II)OEP·CO·L

a) Measured in $CDCl_3$ at 31.5 °C. b) Measured in CD_3CN at 31.5 °C, [Ru(II)OEP·CO]=0.032 mM, [$^-$SR]=0.032 mM.

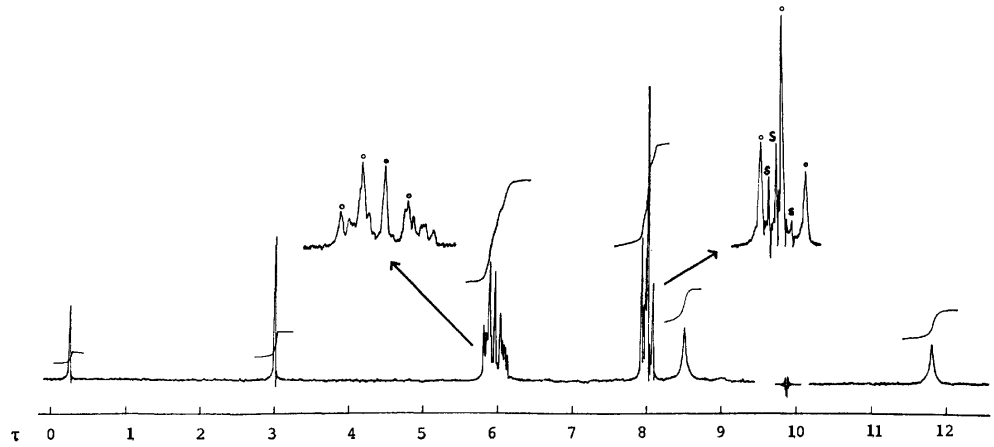

Fig. 3. 100 MHz NMR spectrum of Ru(II)OEP·CO with twice molar amounts of $^{-}SC(CH_3)_3$ solubilized by dibenzo-18-crown-6 in CD_3CN at 31.5 °C. Symbols (o) and (s) denote signals due to ethyl protons of porphyrin ligand and solvent, respectively. Singlet at τ 3 and multiplet at τ 6 are assigned to protons of crown ether. The chemical shifts are calculated from the outernal rock signal of hexamethyldisiloxane (HMDS) to τ values.

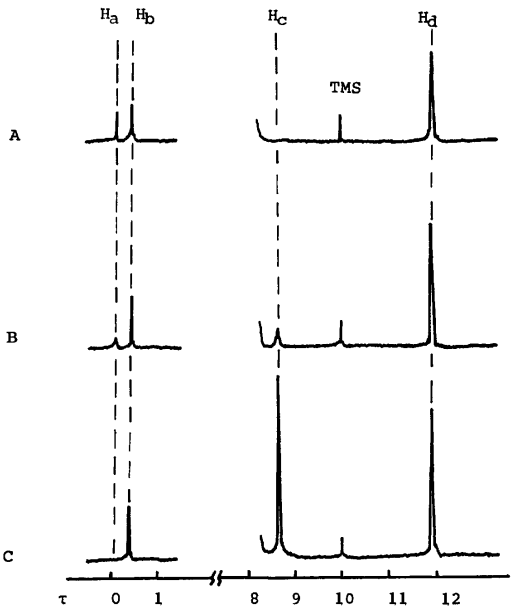

Fig. 4. 60 MHz NMR spectra of Ru(II)OEP·CO at various concentrations of alkanethiolate anion in CD_3CN in the low and high magnetic field regions. [Ru(II)OEP·CO]=0.032 mM, A [$^{-}$SR]=0.016 mM, B [$^{-}$SR]=0.032 mM, and C [$^{-}$SR]=0.045 mM. R=$-C(CH_3)_3$. H_a, H_b, H_c, and H_d are assignable to meso protons of Ru(II)OEP·CO, meso protons of Ru(II)OEP·CO·($^{-}$SR), *tert*-butyl protons of the free alkanethiolate anion, and *tert*-butyl protons of the coordinated alkanethiolate anion, respectively.

anion to the carbonyl group.

^{1}H-NMR Spectra. ^{1}H-NMR spectroscopic study on diamagnetic ruthenium(II) carbonyl porphyrin enables us to obtain insight into the interaction between the divalent metalloporphyrin and the alkanethiolate anion. The ^{1}H-NMR spectra of Ru(II)OEP·CO and the complexes with an equimolar amount of alkanethiolate anions are given in Table 3. In the presence of alkanethiolate anion the signals of the meso protons appear at higher magnetic field than those of Ru(II)-OEP·CO. The up-field shifts might be explained in terms of the increased electron density at the ruthenium atom because of the charge transfer of the negatively charged alkanethiolate anion to the central metal.[11,17] Axial ligation of alkanethiolate anion was rationalized by marked up-field shifts of alkyl protons of alkanethiolate anion due to the diamagnetic ring current of porphyrin ring. For ethanethiolate anion, the signals of the α-methylene and β-methyl group were found at τ 13.00 (quartet 2H) and 11.59 (triplet 3H), respectively. Figure 3 shows 100 MHz ^{1}H-NMR spectrum of Ru(II)OEP·CO with twice molar amounts of 2-methyl-2-propanethiolate anion ($^{-}SC(CH_3)_3$) in CD_3CN. Two signals at τ 8.68 and 11.94 are assignable to the methyl protons of the free $^{-}SC(CH_3)_3$ and those of the coordinated $^{-}SC(CH_3)_3$ to Ru(II)OEP·CO, respectively. Strong affinity of ruthenium atom for alkanethiolate anion was confirmed by ^{1}H-NMR spectra. Figure 4 shows 60 MHz ^{1}H-NMR spectra of Ru(II)OEP·CO with various concentrations of alkanethiolate anion. When a half molar amount of the alkanethiolate anion was added, no signal (H_c) of the free $^{-}S(CH_3)_3$ could be observed. Two meso proton signals appear at τ 0.06 (H_a) and 0.30 (H_b) (Fig. 4A). The former signal appearing at lower magnetic field is due to the meso protons of the Ru(II)OEP·CO. The assignment was confirmed by the measurement in the absence of alkanethiolate anion. The NMR spectrum of the Ru(II)OEP·CO (**1**) with an equimolar amount of the alkanethiolate anion indicates predominant existence of the hexacoordinated complex [Ru(II)OEP·CO·($^{-}$SR)] (**3**) (Fig. 4B). Thus, the affinity of Ru(II)OEP·CO (**1**) to the alkanethiolate anion is much higher than that of the ferrous carbonyl complex (**2**). Figure 5 shows the 100 MHz ^{1}H-NMR spectra of Ru(II)carbonyl mesoporphyrin IX dimethyl ester and its alkanethiolate complex.

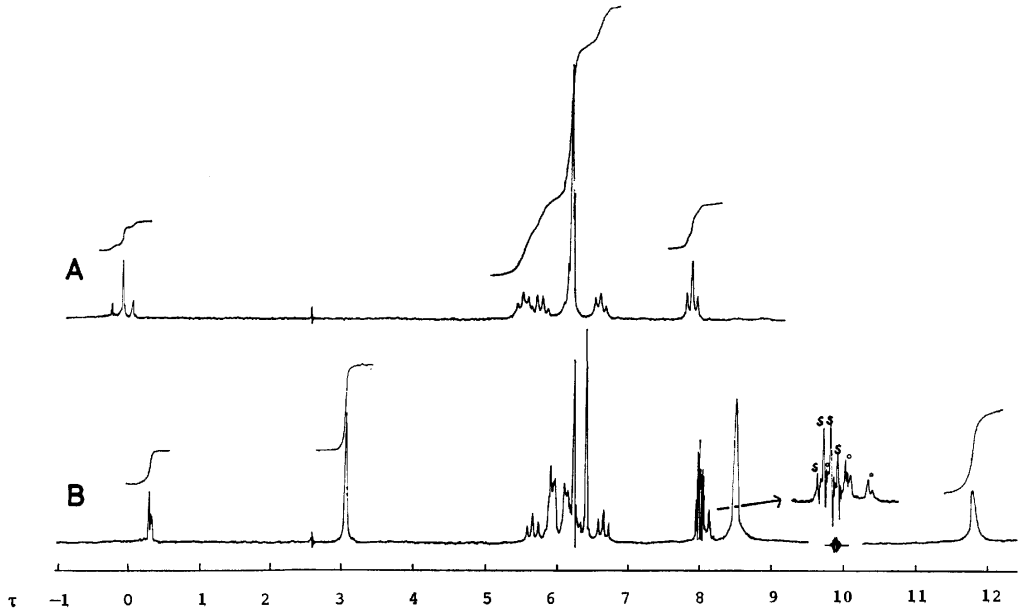

Fig. 5. 100 MHz NMR spectra of CD_3CN solution of (A) Ru(II) carbonyl mesoporphyrin IX dimethyl ester, and (B) Ru(II) carbonyl mesoporphyrin IX dimethyl ester with three equivalents of $^-SC(CH_3)_3$ solubilized by dibenzo-18-crown-6. Symbol (o) denotes the methyl protons of ethyl groups of porphyrin ligand. Singlet at τ 3 and multiplet at τ 6 are assigned to crown ether. The chemical shifts are calculated from the outernal rock signal of hexamethyldisiloxane (HMDS) to τ values.

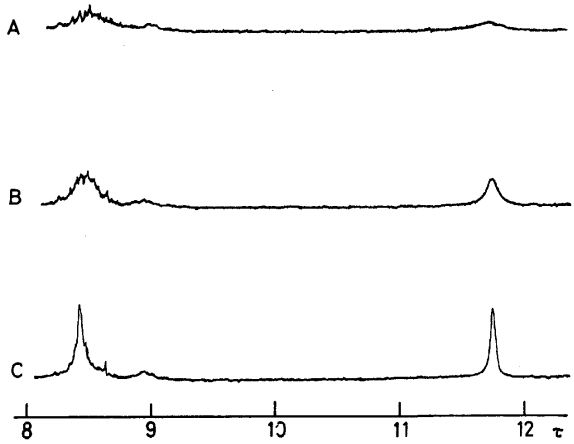

Fig. 6. The high field part of 100 MHz NMR spectra for Ru(II)OEP·CO with twice molar amounts of $^-SC(CH_3)_3$ solubilized by dibenzo-18-crown-6 in CD_3CN; (A) at 80 °C, (B) at 50 °C, and (C) at 32 °C.

Similar up-field shifts were observed for the meso protons, the methyl protons of 1, 3, 5, and 8-positions and the α-methylene protons of 6 and 7-positions of the complex. As shown in Figs. 3 and 5, the broad signals due to the free and coordinated alkanethiolate anion suggest existence of exchange between them. Figure 6 shows the signals of $^-SC(CH_3)_3$ at elevated temperature. The methyl proton resonance is broadened with rise in temperature owing to rapid exchange of ligand. The coalescence temperature could not be determined.

^{1}H-NMR studies of the hexacoordinated complex [Ru(II)OEP·CO·($^-$SR)] show unequivocally that the ligation of the alkanethiolate anion to the ruthenium increases electron density at the central metal. The effect is in line with the observation of anomalous splitting of the Soret band and reduction in the carbonyl stretching vibrations.[11d]

On the other hand, addition of the alkanolate anion to Ru(II)OEP·CO shows no significant changes in absorption and infrared spectra as has been reported for ferrous complexes.[6] The trend was also confirmed by ^{1}H-NMR measurement. Figure 7 shows the 60 MHz ^{1}H-NMR spectrum of Ru(II)OEP·CO in the presence of three equimolar amounts of 2-methyl-2-propanolate anion. Signals of *t*-butyl protons of the free alcoholate anion were observed at τ 8.70.

Strong ligation of alkanethiolate anion might be ascribed to more polarizable 3p lone pair electrons of sulfur atom of alkanethiolate anion than 2p lone pair electrons of oxygen of alkanolate anion. Energy levels of lone pair electrons of the alkanethiolate anion seem to be closer to the anti-bonding orbitals $\pi^*(e_g^*)$ of the porphyrin ring than those of the alkanolate anion.[17] Consequently the lone pair electrons of alkanethiolate anion may be allowed to interact strongly with $\pi^*(e_g^*)$ orbitals of porphyrin ring. In conclusion, NMR, infrared, and absorption studies on the present model systems provide strong evidence to support the axial ligation of the alkanethiolate (cysteinate) to the central iron metal of the heme in the cytochrome P-450, which causes considerable charge transfer from cysteinate to iron and/or porphyrin ring.

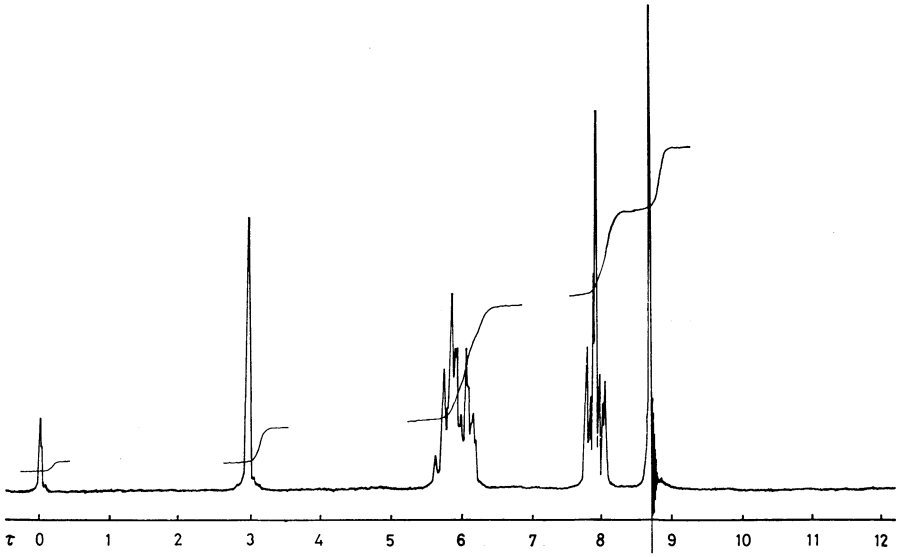

Fig. 7. 60 MHz NMR spectrum of Ru(II)OEP·CO with three amounts of $^{-}OC(CH_3)_3$ solubilized by dibenzo-18-crown-6 in CD_3CN. Singlet at τ 3 and multiplet at τ 6 are assigned to crown ether.

Incorporation of CO_2 in Butadiene Dimerization Catalyzed by Palladium Complexes. Formation of 2-Ethylidene-5-hepten-4-olide

Yoshio INOUE,* Yoshiyuki SASAKI, and Harukichi HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai 980
(Received January 30, 1978)

Reaction of carbon dioxide with butadiene catalyzed by palladium–phosphine complexes was studied. When the reaction was carried out in certain polar, aprotic solvents, such as dimethylformamide (DMF), 2-ethylidene-5-hepten-4-olide was formed in about 5% yield by the incorporation of CO_2 together with the formation of butadiene linear dimers. The main dimer was 1,3,7-octatriene. The ditertiary phosphines, $R_2PCH_2CH_2PR_2$ where R is methyl or phenyl, were found to be suitable as the ligand for the olide synthesis. A possible mechanism involving the intermediate of π-allyl, σ-allyl form from two moles of butadiene and the palladium complex is proposed.

There has been much attention in recent years to the fixation of CO_2, but catalytic reaction is rare. In a preliminary communication[1] we have reported that CO_2 can react with butadiene in the presence of plladium–phosphine complexes to give a small amount of 2-ethylidene-5-hepten-4-olide together with butadiene oligomers in certain polar, aprotic solvents such as DMF. This is the first example of the catalytic formation of a new C–C bond between CO_2 and an organic compound.

The dimerization of butadiene catalyzed by transition metal complexes is well known and it has been shown recently that not only the catalytic activity of metal complexes but also the catalytic properties can be altered when the dimerization reaction is carried out under CO_2 pressure.[2-5] For example, $Pt(PPh_3)_3$ converts butadiene to 4-vinylcyclohexene in 90—97% yield under nitrogen or argon atmosphere, however with CO_2 present, the product is mainly 1,3,7-octatriene with higher conversion of butadiene.[2] Though the role of CO_2 in these reactions is not clear yet, a direct effect on the catalyst has been suggested.

In this paper we wish to report the studies of the factors which affect the incorporation of CO_2 in butadiene dimer catalyzed by palladium–phosphine complexes.

Results and Discussion

The catalytic activity of the following transition metal complexes on butadiene–CO_2 reaction was examined at 120 °C in DMF; $Pd(dpe)_2$, $Pt(dpe)_2$, $Ni(dpe)_2$, $HCo(dpe)_2$, $H_2Fe(dpe)_2$, $Pt(PPh_3)_4$, $RhCl(PPh_3)_3$, $H_2Ru(PPh_3)_4$, and $H_3Ir(PPh_3)_3$, where dpe stands for 1,2-bis(diphenylphosphino)ethane $[Ph_2PCH_2CH_2PPh_2]$. Among these complexes, only the $Pd(dpe)_2$ system afforded a CO_2-incorporated product, *i.e.*, 2-ethylidene-5-hepten-4-olide. Henceforth the catalytic activity of the palladium complex was examined in detail.

When butadiene was reacted with CO_2 in the presence of $Pd(dpe)_2$, butadiene linear dimers (**1**), (**2**), and (**3**) were obtained as the main products together with a small amount of the lactone (**4**).

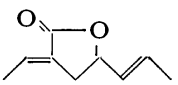
a) Not determined. b) "Others" mainly consists of butadiene trimers.

(3)



(4)

It was found that the distribution of the products depends on the solvent used. The effects of the solvents are summarized in Table 1. In the solvent-free system, 2,4,6-octatriene was the main product whereas 1,3,7-octatriene was the main one in certain solvents. The isomerization of 1,3,7-octatriene to 2,4,6-isomer has been reported to be affected by several palladium(0) phosphine complexes under CO_2 atmosphere.[4] Table 1 shows that polar, aprotic solvents such as DMF, dimethyl sulfoxide (DMSO), and 1-methyl-2-pyrrolidone are suitable for the lactone formation. But in case of hexamethylphosphoric triamide (HMPA), which is a typical polar, aprotic solvent, the decomposition of the catalyst was observed. The yield of the lactone (**4**) was rather small in benzene.

The yield of the lactone (**4**) increased with the increase in the amount of solvent DMF as shown in

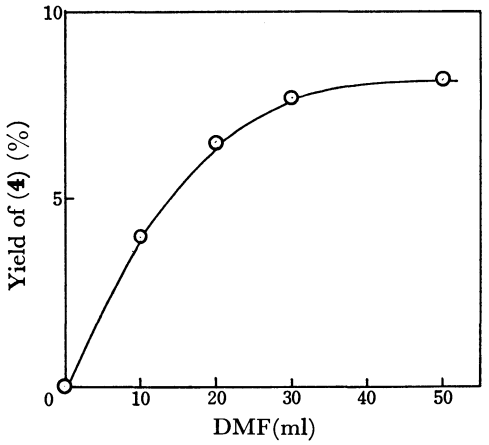


Fig. 1. Effect of the amount of DMF. $Pd(dpe)_2$ 0.2 mmol, butadiene 7.3 g, CO_2 50 atm; 120 °C, 20 h.

Fig. 1. This may be ascribed to the increase in the relative concentration of CO_2 to butadiene, because CO_2 concentration in the solvent is almost constant whereas that of butadiene is lowered with the increase in the amount of the solvent.

When the reaction was carried out at temperature below 100 °C and terminated before the complete conversion of butadiene, then the organic acids, (**5**) and (**6**), were isolated in up to 10% together with the lactone (**4**). Both acids were easily converted into the lactone (**4**) under the conditions given in Table 1, indicating that these acids were the precursors of the lactone (**4**). The CO_2-incorporated products were obtained in the highest yield from the catalyst system involving $Pd(dpe)_2$ in DMF at 84 °C as shown in Fig. 2.

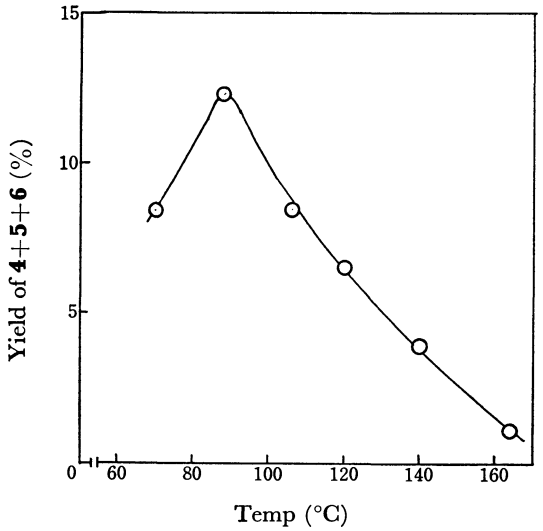

Fig. 2. Effect of temperature on the yield of **4**+**5**+**6** $Pd(dpe)_2$ 0.2 mmol, butadiene 7.3 g, DMF 20 ml, CO_2 50 atm; 20 h.

A study has been made of the effect of ligands on the yield of the lactone (**4**) using a catalyst system derived from $Pd(dba)_2$ (dba=dibenzylideneacetone) and a ligand. Results of the effects of unidentate and bidentate ligands are summarized in Table 2. Linear dimerization was also the main reaction in this catalyst system, and in some cases the activity for the dimerization was lost on addition of certain ligands, *e.g.*, arsines. The yield of the lactone (**4**) was very poor in the monodentate ligand systems in general, though basic ligand systems, *e.g.*, tributylphosphine system, brought about slightly higher yields than less basic ligand ones, *e.g.*, triphenylphosphine system. Among the bidentate ligands, $Ph_2PCH_2CH_2PPh_2$ and $Me_2PCH_2CH_2PMe_2$ appear to be suitable for the lactone formation. The $Ph_2P(CH_2)_3PPh_2$ system catalyzed the dimerization of butadiene in much less conversion. This ligand has such a high coordination ability that it may form a stable six membered chelate ring and occupies the active sites of the metal to stop the reaction.

Table 2. Effect of ligand

$Pd(dba)_2$ 0.2 mmol, ligand (unidentate 0.8 mmol, bidentate 0.4 mmol), butadiene 7.3 g, DMF 20 ml, CO_2 50 atm; 120 °C, 20 h.

Ligand	Product yield (%)[a]		
	Octatrienes	**4**	Others[b]

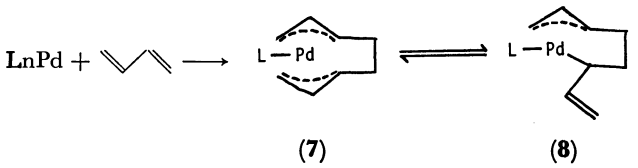
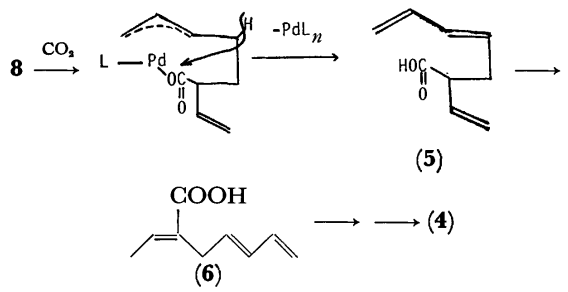
a) Yield is based on the butadiene charged. b) "Others" mainly consists of butadiene trimers. c) $Pd(ligand)_4$ complex was used. d) Mainly 4-vinylcyclohexene.

Wilke,[6] Hagihara[7] and their co-workers have proposed π-allyl intermediates, **7** and **8**, for the palladium-catalyzed linear dimerization of butadiene. It has been assumed that the size of the palladium atom precludes the cyclization, and that a rapid hydrogen transfer occurs.



(**7**) (**8**)

We have proposed the following mechanism for this reaction, which involves the CO_2 insertion at the palladium-carbon bond followed by the transfer of hydrogen to give the acid (**5**).[1]



The distribution of the products is determined by the concentration and reactivity of these intermediates, **7** and **8**, which are influenced, in turn, by the reaction conditions and the steric and electronic properties of the ligands. Similar intermediates have often been proposed for the dimerization of butadiene catalyzed by nickel-phosphine complexes, and it is said that basic ligands stabilize the π-allyl, σ-allyl form, and that less basic ones stabilize the bis-π-allyl form. If this inspection is applicable to the palladium system, the experimental results for the monodentate ligands are in agreement with this hypothesis as can be seen from Table 2. This suggests that the catalyst is behaving as a nucleophile toward CO_2. Ditertiary phosphine-$[Ph_2P(CH_2)_nPPh_2]$ with $n=2$ may have the adequate stabilizing effect on the active intermediate (**8**) by the formation of a five membered chelate ring.

The suitability of polar, aprotic solvents for the lactone synthesis may be ascribable partly to the higher solubility of CO_2 in these media, and partly to their solvation effects; the nucleophilic nature of the intermediate (**8**) is supposed to be enhanced by the solvation of these solvents.

As an extention of the study we investigated the reaction of isoprene with CO_2. In the absence of CO_2, $Pd(dpe)_2$ complex catalyzed the dimerization of isoprene only in low conversions. In the presence of CO_2, the catalytic activity of the palladium complex was enhanced to yield considerable amounts of isoprene dimers. The major dimer was 2,7-dimethyl-1,3,7-octatriene, a tail-to-tail dimer. Several CO_2-incorporated products of five membered lactone structures were also formed in very low yields (about 1%). The detailed results may be published elsewhere.

Experimental

GLC analyses were performed on a Shimadzu GC-3AH instrument [20% Silicone DC 550 (2 m) on Diasolid M (60—80 mesh) and 10% FFAP (2 m) on Chromosorb W (60—80 mesh) (He as the carrier gas)]. The measuring conditions were as follows: for the lactone (**4**); at 205 °C on the FFAP column with benzophenone as an internal standard: for the butadiene dimers; at 145 °C on the Silicone DC 550 column with *t*-butylbenzene as an internal standard. Preparative GLC for the CO_2-incorporated products was performed on a Shimadzu GC-2H instrument at 180 °C using H_2 as the carrier gas [10% FFAP (2.5 m) on Chromosorb W (60—80 mesh)]. The PMR spectra were recorded on a Hitachi R-24 apparatus (60 MHz), using the proton decouple method at the same time. IR and UV spectra were recorded on a Shimadzu IR 430 and a Shimadzu UV 200 apparatus, respectively.

Reagents. Solvents were dried by appropriate drying agents and distilled under nitrogen atmosphere. Butadiene (purity 99.99%) and CO_2 (purity 99.50%) were used without further purification. $BuPPh_2$,[8] Bu_2PPh,[9] $Ph_2PCH_2CH_2OH$,[10] $Ph_2PCH_2CH_2NEt_2$,[11] and $Me_2PCH_2CH_2PMe_2$[12] were prepared according to the published methods. The ditertiary phosphines $[Ph_2P(CH_2)_nPPh_2$ ($n=2$, 3, 4, and 6)] were prepared according to the method described by Hewertson and Watson.[8] The other ligands were commercially obtained. $Pd(dpe)_2$,[13] $Pt(dpe)_2$,[13] $Ni(dpe)_2$,[13] $HCo(dpe)_2$,[14] $H_2Fe(dpe)_2$,[15] $Pd(PPh_3)_4$,[16] $Pt(PPh_3)_4$,[17] $RhCl(PPh_3)_3$,[18] $H_2Ru(PPh_3)_4$,[19] $H_3Ir(PPh_3)_3$,[19] $Pd[P(OEt)_3]_4$,[20] and $Pd(dba)_2$,[21] were synthesized by the reported methods.

Procedure. A typical procedure was as follows. Into a 100 ml stainless steel autoclave equipped with an inductive rotary agitator, $Pd(dpe)_2$ (0.2 mmol), DMF (10 ml), and butadiene (7.3 g) were added under nitrogen atmosphere, then CO_2 was introduced to the pressure of 50 atm. The autoclave was heated to 120 °C and stirred for 20 h. The products were analyzed by GLC.

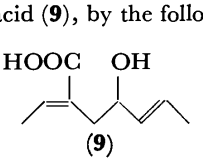
Identification. The octatrienes (bp ≈90 °C/100 mmHg) and the lactone (**4**) (bp ≈138 °C/5—6 mmHg) were distilled from the reaction mixture and purified by preparative GLC. The acids (**5**) and (**6**) were isolated from the reaction mixture by extraction with aqueous NaOH and after acidification were purified by preparative GLC.

1,3,7-Octatriene (1). PMR (CCl_4): δ 2.0—2.3 (m, 4H, $-CH_2-$), 4.7—5.2 (m, 4H, $CH_2=$), and 5.3—6.8 (m, 4H, CH=).

1,3,6-Octatriene (2). PMR (CCl_4): δ 1.6 (d, 3H, CH_3), 2.5—2.9 (m, 2H, $-CH_2-$), 4.6—5.1 (m, 2H, $CH_2=$), and 5.2—6.7 (m, 5H, CH=).

2,4,6-Octatriene (3). PMR(CCl_4): δ 1.7 (d, 6H, CH_3) and 5.2—6.2 (m, 6H, CH=).

2-Ethylidene-5-hepten-4-olide(4). Found: C, 71.20; H, 8.12%. Calcd for $C_9H_{12}O_2$: C, 71.03; H, 7.95%. IR (neat): 1755 (C=O), 1675, and 970 cm^{-1} (*trans* CH=CH). PMR (CCl_4): δ 1.6—1.9 (m, 6H, $CH_3C=$), 2.1—3.3 (m, 2H, CH_2), 4.5—4.9 (m, 1H, HC), 5.1—6.0 (m, 2H, CH=CH), and 6.3—6.7 (m, 1H, $CH_3C\underline{H}=$). UV (EtOH): λ_{max} 217 nm (ε16,300). The methyl proton peaks separated into two parts, centered at δ 1.70 and at δ1.80, which were assigned by PMR spin decoupling method to the methyl group at position 7 and to the one in the ethylidine moiety, respectvely. The ordinal chemical shift value of the methyl group in ethylidine moiety (δ 1.80) indicates that the methyl group is *trans* position to the carbonyl group, becauce if it is *cis* position, the peak might appear in the lower field due to the anisotropy from the carbonyl group. The geminal protons in position 3 are non-equivalent due to the ring formation and give a typical AB pattern signal. In order to confirm this structure, the lactone (**4**) was hydrolyzed by aqueous NaOH. White solid (mp 101—103 °C) was obtained after acidification, which was identified to be a hydroxyl acid, 2-ethylidene-4-hydroxy-5-heptenoic acid (**9**), by the following data. Found:



(**9**)

C, 63.18; H, 8.54%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%. IR(KBr): 3400—3200 (OH), 3000—2500 (COOH), 1680 (C=C-COOH), and 960 cm^{-1} (*trans* CH=C$\underline{H}$). UV (EtOH): λ_{max} 213 nm (ε10480). PMR (CD_3COCD_3): δ 1.61 (m, 3H, CH_3-position 7), 1.82 (d, 3H, CH_3 in ethylidine moiety), 2.51 (d, 2H, CH_2), 4.16 (m, 1H, CH), 5.3—5.6 (m, 2H, CH=CH), 6.93 (q, 1H, $CH_3C\underline{H}=$), and 7.00 (b, 2H,

COOH and OH). The methyl group in the ethylidene moiety confirmed to be *trans* position to the carbonyl group on the basis of the value of its PMR chemical shift.

2-Vinyl-4,6-heptadienoic Acid (5). IR (neat): 3200—2400 (COOH), 1705 (C=O), 1418 (COOH), 1005 and 905 cm^{-1} (CH_2=CH). PMR (CCl_4): δ 2.2 (q, 2H, $-CH_2-$), 2.8 (t, 1H, CH), 4.7—5.2 (m, 2H, CH_2=), 5.3—6.4 (m, 4H, CH=), and 11.2 (s, 1H, COOH).

2-Ethylidiene-4,6-hept-dienoic Acid (6). Found: C, 71.06, H; 7.88%. Calcd for $C_9H_{12}O_2$: C, 71.03, H; 7.95%. IR (neat): 3200—2400 (COOH), 1680 (C=C–COOH), 1635 ($C=CH_2$), 1420 and 1280 (COOH), and 1005 and 900 cm^{-1} (CH_2=CH). PMR(CCl_4): δ 1.80 (d, 3H, CH_3), 3.00 (d, 2H, $-CH_2-$), 4.94 (m, 2H, CH_2=), 5.4—6.2 (m, 3H, CH=), 6.94 (q, 1H, $CH_3C\underline{H}$=), and 11.65 (s, 1H, COOH). UV (EtOH): λ_{max} 209 nm (ε 4900).

We thank the Ministry of Education, for the financial support.

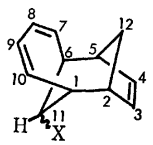
(Received February 3, 1978)

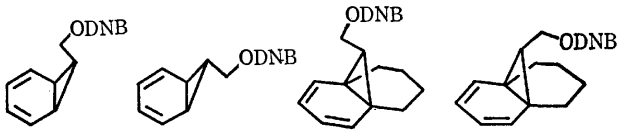
Synthesis and solvolytic behavior of derivatives of the highly hindered title compounds are described. *exo*-Tricyclo[4.4.1.1^{2,5}]dodeca-3,7,9-trien-*syn*-yl tosylate (*syn*-**18**-OTs) and the corresponding perhydro derivative, *syn*-**23**-OTs, solvolyze at rates that are in reasonable agreement with those predicted by Foote-Schleyer calculations. *syn*-**18**-OTs, and its dihydro derivatives, *syn*-**19**-OTs and *syn*-**20**-OTs, give completely rearranged products on solvolysis in acetic acid and 75% dioxane, 80% acetone, and 75% dioxane, respectively (Table 2). These products can be explained by normal cationic rearrangements, probably occurring after ionization. On the other hand, *anti*-**18**-OTs and *anti*-**23**-OTs solvolyze at rates *ca.* 10^2 times slower than those predicted by Foote-Schleyer calculations. Presumably the *anti* derivatives of **18**-OTs, **20**-OTs, **23**-OTs, and the tetrahydro tosylate (**22**-OTs) suffer steric hindrance to ionization. Product formation from *anti*-**18**-OTs (Table 3) and *anti*-**19**-OTs in acetic acid and 75% dioxane, respectively, is explained as a [3_S+3_S] sigmatropic shift induced by ionization, with formation of an allylic ion providing the driving force for rearrangement.

Molecular topologies which induce solvolysis by prior thermal rearrangement, or conversely in which thermal rearrangement is induced by ionization, have not been fully elucidated. Studies of such systems should help to clarify the relationship between reactivity and the orientation of the orbitals and the magnitude of their overlap. We now report the synthesis and solvolytic behavior of a number of derivatives of one such topology, the *exo*-tricyclo[4.4.1.1^{2,5}]dodeca-3,7,9-trien-11-yl system, **1**.††



1

Several papers provide a foundation for understanding the interplay of thermal and ionic processes. In many cases, thermal process occurs prior to the ionization. (2,4,6-Cycloheptatrienyl)methyl 3,5-dinitrobenzoate solvolyzes 5.5×10^5 times faster than its fully saturated analog in 80% acetone yielding unrearranged alcohol and styrene.[1] For the rearrangment to styrene, the valence tautomerism to norcaradiene systems, **2a** and/or **2b** followed by the ionization was suggested. The similar rates of solvolysis for **3** and **4** ($k_{(4/3)}=3.4$) indicate that the 10^5 cyclopropyl-assisted rate acceleration dampens any kinetic effect due to the orientation of the leaving group with respect to the 1,3-diene system.[2] Thus, the influence of geometry, **2a** or **2b**, on the rates of solvolysis of (2,4,6-cycloheptatrienyl)methanol derivatives is probably too small to be important kinetically.[3]



2a **2b** **3** $k_{rel}=1.0$ **4** $k_{rel}=3.4$

1-, 2-, and 3-Chlorocycloheptatrienes rearrange to benzyl compounds, but the 1-chloro derivative reacts faster.[4] In addition, the rate increases with solvent polarity is slower in 80% ethanol than the rate of solvolysis of benzyl chloride. Hence, the rate determining step, though ionic, is not ionization of benzyl chloride. A probable mechanism is tautomerism to the norcaradienyl isomer, **5**, which ionizes *via* disrotatory ring opening to give the benzyl cation in the rate determining step. This mechanism accounts for the slower rates of the 2- and 3-chloro derivatives since they must first rearrange *via* 1,5-hydrogen shifts to the 1-chloro isomer. Another possible mechanism, not excluded but highly unlikely,[5] is σ participation to give the benzyl cation directly. The transition state for this process would probably not benefit from benzyl delocalization.

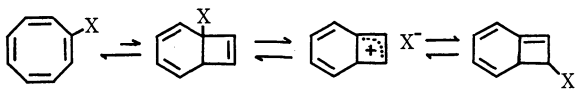
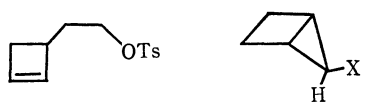
†† Although the tosylates could be named as *cis*-1-*transoid*-1,2-*cis*-2-tricyclo[4.4.1.1^{2,5}]dodeca-3,7,9-trien-11(a)-yl and -11(e)-yl *p*-toluenesulfonates following IUPAC Tentative Rules in their most extended application (IUPAC Tentative Rules for Nomenclature of Organic Chemistry, Section E: Fundamental Stereochemistry, *IUPAC Bulletin*, No. 35), we use in this paper the *exo-endo* (for carbon skeleton) and *syn-anti* (for functional groups) nomenclature for the sake of simplicity.

The rearrangement of halo- and acetoxycyclooctatetraenes **6** to the corresponding *trans*-β-halostyrenes[6] was shown to occur *via* an electrocyclic reaction to **7** followed by ionization and conrotatory ring opening.[7-9] For chloro- and acetoxycyclooctatetraenes (**6**: X=Cl or OAc), the rate determining step is ionization, **7**→**8**. For bromocyclooctatetraene (**6**: X=Br), however, ionization is rate determining in solvents of low polarity, $E_T<42$, while the electrocyclic reaction **6**→**7** is rate determining in more polar solvents. Fluorocyclooctatetraene gives a 12% yield of *trans*-β-fluorostyrene upon heating at 100 °C for 35 h, but the mechanism of this transformation has not been determined.[10]



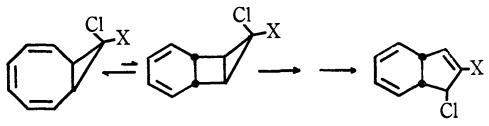
6 **7** **8**

The rate of acetolysis of 2-(2-cyclobutenyl)ethyl tosylate, **9**, reflects a competition between solvent displacement and conrotatory ring opening to a butadiene derivative, which then goes on to product.[11] The estimated rate of ring opening, 1×10^{-5} s^{-1}, in this case is greater than the rate of solvent displacement, 3×10^{-6} s^{-1}.



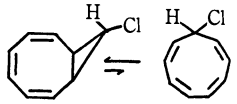
9 **10**

Investigations of the solvolysis kinetics of *anti*-5-bicyclo[2.1.0]pentyl derivatives, **10** (X=OTs, or OPNB),[12] have revealed a remarkable insensitivity to solvent polarity and leaving group. The products, however, are cyclopentadiene and 2-cyclopentenol, typical of cationic intermediates. The expalanation involves rate-limiting epimerization of **10** to the corresponding *syn* isomers, presumably *via* diradical.[13] *syn* Isomers then undergo disrotatory solvolytic ring opening to give the observed products.



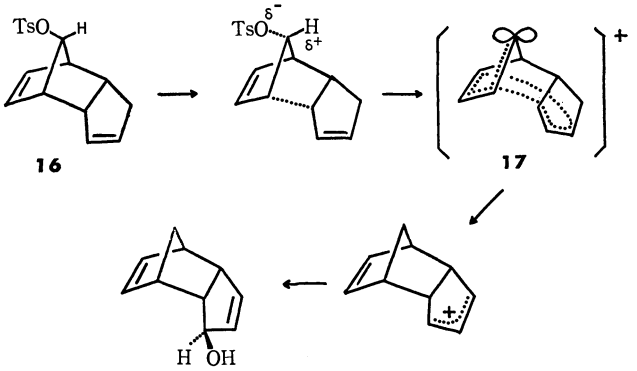
11 **12** **13**

In agreement with Vogel's original proposal,[14] both 9,9-dichlorobicyclo[6.1.0]nonatriene (**11**: X=Cl), and *syn*-9-chlorobicyclo[6.1.0]nonatriene-9-*d* (**11**: X=D), rearrange at a rate independent of solvent to give dihydroindenyl chlorides **13**.[15] An attractive mechanistic proposal is a rate determining electrocyclic reaction to a tricyclo[6.1.0.0^{2,7}]nonadiene ring system **12** followed by rapid disrotatory solvolytic ring opening to an allylic dihydroindenyl cation which gives the observed products. *anti*-9-Chlorobicyclo[6.1.0]nonatriene, **14**, also solvolyzes at a rate independent of solvent to give the same dihydroindenyl chloride. However, the reaction of **14**-*d* revealed the complete deuterium scrambling.[15] This result eliminates an epimerization mechanism similar to that found in **10**, and culminates to a mechanism which involves the rate-determining rearrangement of **14** to 9-chlorocyclononatetraene, **15**, followed by rapid solvolysis *via* the cyclononatetraenyl cation. The mechanism is consistent with the observation that 9-chlorocyclononatetraene **15** behaves exactly same way at −60° in SO_2 while **14** is inert at −20 °C in SO_2.[16]



14 **15**

Apart from these instances in which isomerization takes place prior to solvolysis, Breslow's work on derivatives of dicyclopentadiene has provided an interesting example of the converse process, an electrocyclic reaction induced by solvolysis (Scheme 1).[17] The ionization of **16** to ion pair weakens the β bonds antiparallel to the leaving group and induces a Cope rearrangement (transition state; **17**), the driving force being formation



16 **17**

Scheme 1.

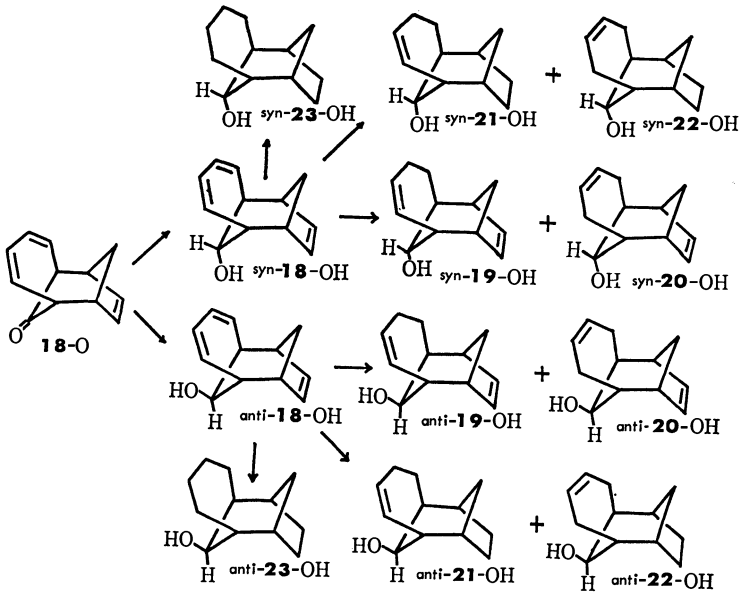
of an allylic ion. Supporting evidence for this mechanism is the fact that the C-8 ketones related to **16** undergo relatively rapid Cope rearrangement which are facilitated by protonation of the carbonyl oxygen.[18]

After the completion of the present study, Haywood-Farmer *et al.* published their preliminary result on the acetolysis of very similar brosylates, with no implication on product analysis.[19] The paper includes the kinetic data of brosylate of our *anti*-**23**-OH (*vide infra*).

Results

Synthesis of Substrates. Ketone **18**-O, the product of [6+4] cycloaddition of tropone with cyclopentadiene,[20] underwent Meerwein-Ponndorf reduction to give 21% of *syn*-**18**-OH and 74% of *anti*-**18**-OH. The conjugated double bonds of these alcohols were selectively reduced by Na/*n*-BuOH to give alcohols, *syn*- and *anti*-**19**-OH and *syn*- and *anti*-**20**-OH. Allowing *syn*- and *anti*-**18**-OH to react with two moles of hydrogen each gave four alcohols, *syn*- and *anti*-**21**-OH and *syn*- and *anti*-**22**-OH, while complete hydrogenation resulted in *syn*- and *anti*-**23**-OH (Scheme 2). Tosylates of these alcohols were obtained by the standard procedure.

Configuration of the alcohols were assigned by correla-



Scheme 2.

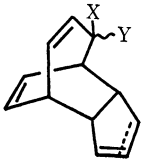
tion of the magnitude of $J_{\underline{C}HOH\text{-bridgehead }\underline{H}}$ with dihedral angle. Molecular mechanics calculations[21] on alcohols *syn*-**23**-OH and *anti*-**23**-OH (Table 1) reveal both the dihedral angles, ϕ, and preferred conformations. *anti*-**23**-OH is less strained by 0.5 kcal/mol in the chair (a) than the boat-like (b) conformation, while *syn*-**23**-OH is less strained by 0.8 kcal/mol in b- form than in

a b

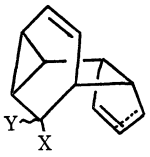
a-form. Thus, both conformers are likely present in each alcohol and tosylate. Dihedral angles for *anti*-**23**-OH range from 43 to 50°, for which J=3.5—4.0 Hz is expected, while dihedral angles of 66° to 75° for *syn*-**23**-OH suggest J=0—0.8 Hz.[22] NMR data described in experimental part agree with the expectations, showing a broad singlet for *syn* compounds and a triplet (J=4—7 Hz) for *anti* compounds.

That the ketone **18**-O is somewhat sterically hindered was evidenced by its failure to react with sodium borohydride or sodium in ethanol. However, reduction by lithium aluminium hydride in tetrahydrofuran yielded a single alcohol *syn*-**18**-OH.[20a] The result is supported by calculations. Thus, hindrance calculations[23] suggest that both *anti* and *syn* sides of the ketone are quite hindered. However, congestion is substantially larger on the *syn* side (116.1) than on the *anti* side (77.5), and therefore kinetically-controlled reduction would be expected to give *syn*-**18**-OH.

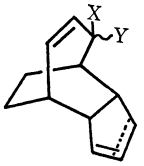
Solvolysis. *anti*-**18**-OTs was heated at 110 °C in acetic acid buffered with sodium acetate for 24 h. The resulting acetate mixture (75% yield) was reduced with lithium aluminium hydride and then oxidized with chromium(VI) oxide–pyridine. The products, separated by column chromatography, consisted of known ketones: **24**-O[24a] and **25**-O.[24b] Thus, the original acetates must have been **24**-OAc and **25**-OAc (Table 2).



24-O: X, Y=O
24-OAc: X=H, Y=OAc
24-OH: X=H, Y=OH,



25-O: X, Y=O
25-OAc: X=H, Y=OAc
25-OH: X=H, Y=OH

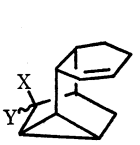


26-O: X, Y=O
26-OH: X=H, Y=OH

A mixture of *anti*-**19**-OTs and *anti*-**20**-OTs was heated at 90 °C for 5 h in 75% aqueous dioxane. The latter was unreactive under these conditions and was recovered quantitatively. The alcohol product from *anti*-**19**-OTs was oxidized to give a mixture of α,β-unsaturated ketones, **26**-O, ν_{CO}=1657 cm^{-1}. The NMR spectrum of the mixture featured absorptions at δ 5.5 (m) and 5.83 ppm (dt, J=6.0 and 2.0 Hz), due to the isolated double bond, and δ 6.15 (d, J=11.0 Hz) and 7.25 ppm (dd, J=11.0 and 9.0 Hz), due to the conjugated double bond. Catalytic hydrogenation of the mixture gave the corresponding, fully saturated ketone.[24a,c] Thus, the original alcohol products consist of **26**-OH.

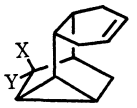
syn-**19**-OTs was heated for 4.5 h in 80% aqueous acetone. The resulting alcohol, **27**-OH, was oxidized to a single ketone, **27**-O, ν_{CO}=1727 cm^{-1}, whose NMR featured a 2H multiplet at δ 6.01 ppm. Dehydrogenation of **27**-O gave the known ketone **28**.[25]

Refluxing *syn*-**20**-OTs in 75% aqueous dioxane resulted in three alcohols. The major alcohol, *syn*-**29**-OH, and the minor alcohol, *anti*-**29**-OH, showed NMR absorptions for two vinyl hydrogens and were oxidized

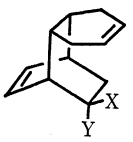


27-O: X, Y=O
27-OH: X=H, X=OH

28

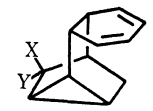


29-O: X, Y=O
syn-**29**-OH: X=H, Y=OH
anti-**29**-OH: X=OH, Y=H



30-O: X, Y=O
30-OH: X=OH, Y=H

31



syn-**32**-OAc: X=H, Y=OAc
anti-**32**-OAc: X=OAc, Y=H

to the same ketone, **29**-O, ν_{CO}=1729 cm^{-1}. Dehydrogenation of this ketone gave **28**. The structure of *syn*-**29**-OH was assigned on the basis of the singlet at δ 4.00 ppm for the >CHOH proton, while that of *anti*-**29**-OH was based on a quartet nature of the same proton at δ 4.46 ppm (dd, J=5.5 and 3.2 Hz). The third alcohol, **30**-OH, featured a carbinyl proton, δ 3.87 ppm, split into a multiplet and vinyl absorptions integrating for four protons: δ 6.08 (2H, m), 6.23 (1H, t, J=5.0 Hz) and 6.37 ppm (1H, t, J=5.0 Hz). Oxidation to a ketone, **30**-O, caused a significant shift only in the last two vinyl absorptions: δ 6.25 (1H, tt, J=7.0 and 1.5 Hz) and 6.67 ppm (1H, tt, J=7.0 and 1.2 Hz). Dehydrogenation of **30**-O gave the aromatic compound **31**.

The solvolysis of *syn*-**18**-OTs afforded *syn*- and *anti*-**32**-OAc and **33**-OAc. While the result of acetolysis has been published,[25] hydrolysis also gave the major product, *syn*-**32**-OH with no trace of fragmentation product. Product data for all compounds are summarized in Table 2. Rates of solvolysis in 60% aqueous acetone with *syn*/*anti* rate ratios and relative rates are presented in Table 3.

Table 2. Solvolysis products

Compound	Condition	Product
anti-**18**-OTs	HOAc, NaOAc 110 °C, 24 h	**24**-OAc (55%) **25**-OAc (12%)

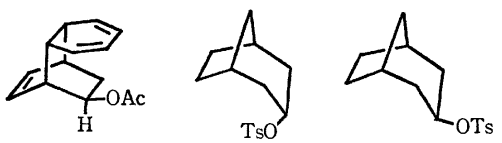
a) 60% acetone, 2,6-lutidine buffer. b) Determined conductimetrically, rate is average of at least two determinations. c) Calculated from data at other temperatures.

Discussion

Using the Foote-Schleyer treatment,[26] the unassisted rates of solvolysis for *syn*-**18**-OTs, *anti*-**18**-OTs, *syn*-**23**-OTs and *anti*-**23**-OTs in 60% acetone, along with several related compounds, can be calculated (Table 4). The difference in strain between chair and boat conformers for both *syn*- and *anti*-**23**-OH is less than 1 kcal/mol[21] (Table 1). Since the effect on conformer population of replacing -OH with -OTs should be small, it seems reasonable that both *syn*- and *anti*-**23**-OTs exist as a chair–boat mixture. Thus, as a crude estimate, rates were calculated for both chair and boat conformers. Dihedral angles for the chair conformation of the hydrocarbon **20**-H were used to approximate those of *syn*- and *anti*-**18**-OTs. The chair form of **20**-H is more stable than the boat form by 4.5 kcal/mol.[21a]



33-OAc **34** **35**

Table 4 reveals that the observed rate of *syn*-**23**-OTs in 60% acetone is $10^{1.4}$ and $10^{0.8}$ times slower than the rates calculated for the chair and boat conformations, respectively. *syn*-Bicyclo[3.2.1]oct-3-yl tosylate, **34**, which lacks only the four-carbon bridge of *syn*-**23**-OTs, would seem to be a plausible model. Jefford, *et al.*,[27] have observed that **34** undergoes acetolysis *ca.* 6 times slower than calculated, perhaps due to the "reflex" effect[28] or steric hindrance to ionization by the ethylene bridge. Although the Foote-Schleyer parameters used in Table 4 differ somewhat from those of Jefford, *et al.*,[27]

Eliel, "Stereochemistry of Carbon Compounds," McGraw Hill Book Co., New York, N. Y. (1962), p. 236.

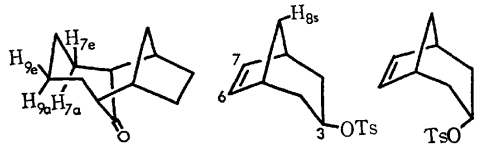
the indication is similar: **34** is $10^{1.5}$ times slower than expected.[29] Hence neither *syn*-**23**-OTs nor **34** solvolyzes *via* σ participation, and both may be somewhat slowed by steric interactions. The rates of *syn*-**23**-OTs and **34** in 60% acetone at 25 °C are quite comparable; $k_{syn\text{-}23\text{-}OTs}/k_{34}=2.0$.[30]

Inclusion of a Δ^8 double bond (*syn*-**22**-OTs), causes a 24 fold rate decrease relative to *syn*-**23**-OTs at 75 °C (Table 3). This seems large for an inductive effect of a γ double bond, as β double bonds usually cause only a 10 fold decrease in rate.[26b] In any case, the double bond in *syn*-**22**-OTs does not seem to be participating.

The observed rate for *anti*-**23**-OTs is $10^{2.2}$ and $10^{3.2}$ times slower than the rates calculated for the boat and chair conformers, respectively. Calculations by Jefford, *et al.*,[27] and those in Table 4 reveal that model compound **35** solvolyzes at a normal, largely unassisted rate in acetic acid. Comparison of the relative rates for *anti*-**23**-OTs and **35** in 60% acetone at 25 °C, $k_{anti\text{-}23\text{-}OTs}/k_{35}=0.003$, seems to indicate that steric hindrance to ionization by the four-carbon bridge in the former may be responsible for its slow rate. Steric effects of a similar magnitude have been observed in crowded norbornanes.[31]

Hindrance calculations[23] on the ketone **23**-O formed on oxidation of *syn*- or *anti*-**23**-OH show a pronounced reversal of congestion, relative to unsaturated ketone **18**-O. Attack by a nucleophile from the *syn* direction is much less hindered (62.4) than attack from the *anti* direction (1441.1). In fact, the ketone **23**-O yielded *anti*-**23**-OH quantitatively on the reduction with lithium aluminium hydride. The value of 1441.1 is quite large; therefore H_{9a} must be displaced 0.7 Å to allow attack of the nucleophile from the *anti* direction.[23] Clearly these observations support the idea that steric hindrance to ionization is a major contributor to the rate deceleration observed in *anti*-**23**-OTs.

Inclusion of a Δ^8 double bond (*anti*-**22**-OTs) causes a rate decrease relative to *anti*-**23**-OTs by a factor of 0.0088 which again seems quite large for an inductive effect (Table 3). This deceleration might be due to steric hindrance to ionization as in the case of *anti*-**23**-OTs. One of the two most hindering atoms in the ketone **23**-O, H_{9a} and H_{7a},[23] remains intact in *anti*-**22**-OTs, while the other has become vinylic. Since molecular mechanics calculations indicate that the twisted form of **22**-O, a similar system, is more stable than the boat by 4.5 kcal/mol,[21] it would seem that the preference for the twisted form in *anti*-**22**-OTs might be even larger due to substitution of -OTs for=O. In contrast, the Δ^7 double bond in *anti*-**21**-OTs causes a rate enhancement of 1.4 over *anti*-**23**-OTs. The actual rate enhancement is probably *ca.* 14 if one assumes that a β-double bond in a nonparticipating system should slow the rate by a factor of 10.[26b] In this case, migration of one of the σ bonds *trans* to the leaving group



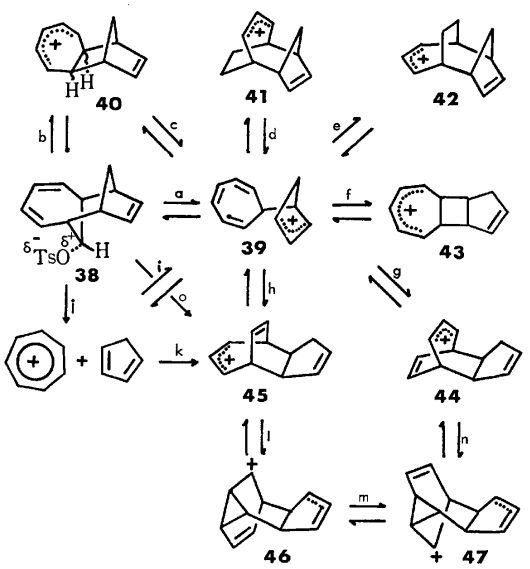
23-O **36** **37**

results in formation of an allyl cation. This is likely the mode of participation. However, products were not determined for this compound.

The rates of *anti*-**22**-OTs, *anti*-**20**-OTs and *anti*-**18**-OTs are within a factor of 2.1 of one another at 75 °C. Since the last tosylate reacts 10^2 times slower than the Foote-Schleyer calculation predicts, and the calculation estimates for the first two should be faster than for *anti*-**18**-OTs, all three seem to be anomalously slow. Since a model compound for *anti*-**18**-OTs and *anti*-**20**-OTs, bicyclic **36** also solvolyzes at a rate which agrees with that calculated by the Foote-Schleyer equation (Table 4), the distance between the double bond and the carbon containing the leaving group in **36** has been postulated to be too far to permit participation.[32] In the *endo* conformation with the 6-membered ring in a chair form of bicyclo[3.2.1]octane, molecular mechanics calculations indicate the distances C-3 to C-6 and C-3 to C-7 to be 2.999 and 2.997 Å, respectively,[21b] while, in the olefin, these would probably be *ca.* 0.1 Å shorter. On the other hand, participation by a double bond has occurred over greater distances. For example, in (*endo*-bicyclo[3.3.1]non-6-en-3-yl)methyl tosylate, in which the rate enhancement is *ca.* 10^4, [33] the distances between the olefinic carbons and the carbon bearing the leaving group are 3.313 and 3.280 Å.[21b] Therefore, it seems also possible that **36** solvolyze from the *exo* conformation (boat form), for which the distances in bicyclo[3.2.1]octane are 3.425 and 3.437 Å.[21b] This conformation would probably not allow "edge-on" interaction[34] of the double bond with the developing cationic center. The *exo* conformation in bicyclo[3.2.1]octane, however, is less stable than the *endo* by ≈5 kcal/mol.[21b] Replacing -H by -OTs should provide increased steric interaction with the H_{8s}, thus accentuating the energy difference between *endo* and *exo*. Compounds *anti*-**18**-OTs and *anti*-**20**-OTs, however, do not have such conformational freedom and the distance from the double bond carbons to C–OTs is only 2.854 Å. Thus, it seems likely that the source of the decelerations for *anti* unsaturated derivatives also lies in the four-carbon bridge.

The rate of *syn*-**18**-OTs shows good agreement with that calculated at 25 °C in 60% acetone. The 12.0 fold rate acceleration of *syn*-**20**-OTs (Table 3) is generally consistent with its having one less double bond than *syn*-**18**-OTs. Thus, neither compound seems to be benefiting from participation to a large degree, as in the model compounds **37**.[32]

Table 2 shows that *anti*-**18**-OTs gives completely rearranged products on acetolysis. Kinetic analysis seems to indicate that rearrangement occurs after ionization. Scheme 3 depicts possible rearrangement pathways available to the ion pair **38**. Breaking the σ bond *trans* to the leaving group (**a**) gives allylic ion **39**. Rotation about the bond joining the two rings of **39** permits reclosure six ways (**c**—**h**) to give six isomeric resonance stabilized cations, **40**—**45**. Ion **40** may also result from **38** directly *via* a Wagner-Meerwein rearrangement or a [1,5] sigmatropy (**b**). Both **38** and **39** may undergo fragmentation (**i**, **j**) to give tropylium ion and cyclopentadiene, which can undergo [4+2] cycloaddition giving **45**.[24b] Finally, **38** can undergo a Cope rearrangement (**o**) also giving **45**. Ions **44** and **45** can be interconverted through vinyl–cyclopropylcarbinyl rearrangements (**l**—**m**—**n**).



Scheme 3.

According to Table 2, however, products form only from **45** and **46**. Formation of **45** *via* reclosure of **39** (**h**) requires a *ca.* 180° rotation about the σ bond joining the rings of the initially formed ion. Since **45** should be similar in stability to **40**—**44**, the failure to observe products deriving from these latter ions argues against reclosure of **39** *via* **h**.

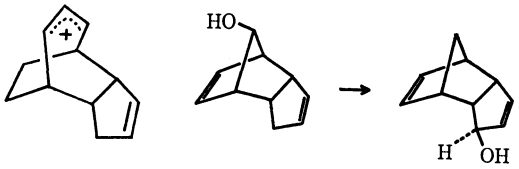
The tropylium ion and cyclopentadiene undergo [4+2] cycloaddition in 66% dioxane or acetic acid to give, after reduction of the acetates in the latter case, **24**-OH and **25**-OH in a ratio of 4.6 to 1.0.[24b] Notably, this is the same ratio in which **24**-OAc and **25**-OAc are formed on acetolysis of *anti*-**18**-OTs (Table 2). Therefore, both the fragmentation-recombination sequences (**j**—**k**) and the Cope rearrangement (**o**) can account for the stereospecific formation of **45**, which in turn forms **46** *via* path **l**.

In order to establish the fragmentation–recombination pathway for *anti*-**18**-OTs, trapping experiments were carried out. Acetylacetone trapped the tropylium ion as tropylacetylacetone (86% in hydrolysis and 51% in acetolysis) and *N*-phenylmaleimide captured cyclopentadiene as its cycloadduct (91%) in acetolysis. Furthermore, acetolysis with constant addition of methylcyclopentadiene resulted in a 6% incorporation of the latter, although this figure is somewhat inaccurate because of extensive polymerization of methylcyclopentadiene during the reaction. Thus, the pathway **j**—**k** was established.

Since the partially hydrogenated derivative, *anti*-**19**-OTs, can react *via* the Cope mechanism but cannot form the highly stable tropylium ion *via* fragmentation, its solvolysis products should help reveal the former pathway (**o**). In this case, fragmentation of the ion corresponding to **39** would form the cycloheptadienyl cation and cyclopentadiene which are incapable of cycloaddition reaction. Furthermore, the fragmentation

would have a driving force comparable to that of the bond rotation-recombination pathways. Accordingly, a mixture of products with various carbon skeleton is expected from *anti*-**19**-OTs, if *anti*-**18**-OTs were reacting by the fragmentation-recombination mechanism. The fact that tricyclic product derived only from **48** (Table 2) implied that the Cope rearrangement path is operative. In addition, the detection of cycloheptariene which is the deprotonation product of cycloheptadienyl cation implied the fragmentation process is also operative to some extent.

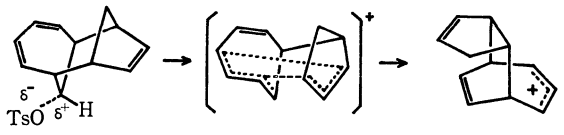
Thus, *anti*-**18**-OTs and *anti*-**19**-OTs solvolyze through the Cope rearrangement and fragmentation, the difference between these cases being that, in the former, the fragmentation products cycloadd to give the same products with those of internal process, while in the latter the fragmentation products are incapable of recombination and are detected as such.



48 **49**

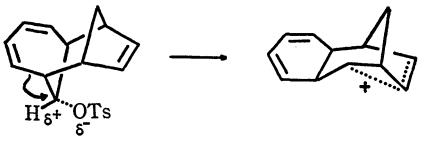
An alternative pathway for the intramolecular rearrangement is initial Cope rearrangement of these tosylates to the allyl tosylate followed by rapid solvolysis. The thermal Cope rearrangement of a similar systems **49**, is rapid only above 140 °C [17b] and *anti*-**18**-OH and its tosylate are stable at 120 °C. Thus, the rate of solvolysis of *anti*-**18**-OTs, if is were indicative of a thermal rate-determining step, should be much slower than that of *anti*-**20**-OTs or *anti*-**22**-OTs which do not contain the 1,5-diene system. At 75 °C, however, the rates of solvolysis for these three are within a factor of 2.1 (Table 3).

Thus, one of the rearrangement pathway for both *anti*-**18**-OTs and *anti*-**19**-OTs appears to be a rather remarkable $[3_s+3_s]$ sigmatropic shift induced by ion pair formation[35] which weakens the σ bonds *trans* to the leaving group.[36] This bond weakening may permit the skew orientation of the 1,5-diene system to distort towards the preferred chair orientation.[37] The aromatic Cope transition state **50** can conjugate with the external carbenium ion, thus stabilizing both;[38] this is similar to the stabilization of an adjacent carbonium ion by a benzene ring.



38 **50** **45**

If the facility with which the *anti* compounds, *anti*-**18**-OTs and *anti*-**19**-OTs, undergo the Cope rearrangement and fragmentation is due chiefly to the weakening of the σ bonds *trans* to the leaving group, then the *syn* compounds should not rearrange in this manner. The data in Table 2 confirm this premise. *syn*-**18**-OTs, *syn*-**19**-OTs, and *syn*-**20**-OTs rearrange completely to the products of the same tetracyclic skeleton and, for *syn*-**18**-OTs, essentially no difference was observed by the change of the solvent. Furthermore, any attempt to trap cyclopentadiene or the tropylium ion failed. The Foote-Schleyer treatment has implied that the *syn* compounds solvolyze at an unassisted rate. To account for >99% rearranged products due to σ participation, a rate enhancement of at least 100 over the calculated unassisted rate is necessary.[39] Clearly such a rate enhancement is lacking. Hence, *syn* compounds likely rearrange after ionization. A possible rearrangement path for *syn*-**18**-OTs is given below. Participation of the Δ^3 double bond gives the cyclopropylcarbinyl ion derivative **51**, solvent capture of which accounts for both tetracyclic *syn*- and *anti*-**32**-OAc as well as tricyclic *anti*-**33**-OAc.



51

Conclusion

Comparison of the kinetic data in Table 3 with the rates calculated *via* the Foote-Schleyer equation and the rates of model compounds seems to indicate that the *anti* compounds solvolyze anomalously slow. In the case of *anti*-**23**-OTs, this is probably due to steric hindrance to ionization by the four-carbon bridge. Steric hindrance to ionization also seems to be a factor also for unsaturated *anti* derivatives. *syn* Compounds solvolyze at rates which agree with those predicted by Foote-Schleyer calculation. Since *syn*-**18**-OTs, *syn*-**19**-OTs and *syn*-**20**-OTs give completely rearranged products but a very small rate enhancement, it seems probable that rearrangement follows ionization. Products from these *syn* tosylates result from normal carbenium ion rearrangements.

anti-**18**-OTs and *anti*-**19**-OTs undergo both fragmentation and a $[3_s+3_s]$ sigmatropic rearrangement induced by ionization. The ease of the latter process results from two factors: (1) The σ bond *trans* to the leaving group, which is weakened on ionization, is also the σ bond broken in the Cope rearrangement; and (2) the Cope transition state can conjugate with the external carbenium ion, thus allowing for mutual stabilization.

Experimental

General. Infrared spectra were taken in a film for liquids and KBr pellets for solids using Hitachi EPI-S2 IR spectrometer. All NMR spectra were measured in $CDCl_3$ solution with TMS internal standard using a Varian HA-100 or A-60D instrument. Tosylation of alcohols was carried out by the standard method.[40]

Rate Measurement. All rates were determined in 60% acetone conductimetrically with a Wayne-Kerr Model B331 Impedence Bridge capable of 0.1% accuracy. The acetone

was purified by refluxing with potassium permanganate, drying with Drierite, and distilling through a 60 cm Vigreux column prior to use. The conductivity cells used had bright platium electrodes, cell constants of 0.2—0.4 and volumes of *ca.* 25 ml. In a typical run, enough tosylate to make a 10^{-3} M solution was placed in the conductivity cell and 20 ml of 60% acetone was added. The cell was sealed and equilibrated with shaking for 4 min in the constant temperature bath. The usual number of measurements was 35. Each reaction was run at least in duplicate, and was followed for at least two half-lives. Good first-order rate plots were obtained in all cases.

Synthesis. Meerwein-Ponndorf Reduction of exo-*Tricyclo*-[*4.4.1.1*^{2,5}]*dodeca-3,7,9-trien-11-one* (**18**-O). *Preparation of* syn-***18**-OH and* anti-***18**-OH*: Ten grams of **18**-O[20] in 200 ml of 2-propanol was heated unser reflux with 10 g of aluminium isopropoxide for 10 h and 100 ml of solvent was distilled during further refluxing for 10 h. The reaction mixture was poured into 50 ml of 2M HCl and extracted with ether. After the ether solution was washed with water and dried, the solvent was removed to yield 10 g of a semisolid material which was recrystallized from petroleum ether to give 5.7 g of *anti*-**18**-OH.

anti-**18**-OH: Mp 80—82 °C. IR: 3500 cm^{-1}. NMR (δ): 1.18 (1H, m), 1.53 (1H, d, J=11 Hz), 1.80 (1H, br. d, $J\approx$ 9 Hz), 2.7—3.0 (4H, complex)[41], 4.10 (1H, m),[41] 5.7—6.3 ppm (6H, complex). Found: C, 82.30; H, 7.99%. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%.

anti-**18**-OTs: Mp 114—115 °C. NMR (δ): 1.18 (1H, m), 1.65 (1H, d, J=11 Hz), 2.44 (3H, s), 2.60—3.00 (4H, complex), 5.05 (1H, t, J=5.5 Hz), 5.5—6.2 (6H, complex), 7.33 (1H, d, J=8.5 Hz), 7.70 ppm (1H, d, J=8.5 Hz). Found: C, 69.51; H, 6.08%. Calcd for $C_{19}H_{20}O_3S$: C, 69.49; H, 6.14%.

The filtrate from the recrystallization of *anti*-**18**-OH was subjected to silica gel chromatography. Elution with a mixed solvent system of petroleum ether–ether gave 1.7 g of *anti*-**18**-OH and 2g of *syn*-**18**-OH.

syn-**18**-OH: Mp 32.5—34.5 °C. UV (MeOH) λ_{max}: 243 nm (ε=4552, sh), 252 (5720), 262 (5668), 273 (3173). IR: 3490 cm^{-1}. NMR (δ): 1.49 (1H, m), 2.21 (1H, d, J=10.4 Hz), 2.74 (5H, br.m), 3.90 (1H, br.s), 5.83 (4H, m), 6.21 ppm (2H, br.s). Found: C, 82.48; H, 8.16%. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%.

syn-**18**-OTs: Mp 138—139.5 °C. NMR (δ): 1.40 (1H, m), 1.98 (1H, d, J=11 Hz), 2.43, (3H, s), 2.70 (4H, m), 4.76 (1H, br.s), 5.90 (6H, m), 7.30 (1H, d, J=9 Hz), 7.68 ppm (1H, d, J=9 Hz). Found: C, 69.23; H, 6.04%. Calcd for $C_{19}H_{20}O_3S$: C, 69.49; H, 6.14%.

Bouveault-Blanc Reduction of exo-*Tricyclo*[*4.4.1.1*^{2,5}]*dodeca-3,7,9-trien*-syn-*11-ol* (syn-***18**-OH). *Preparation of* syn-***19**-OH and* syn-***20**-OH*: To 3.63 g of *syn*-**18**-OH in 100 ml of 1-butanol were added, in several portions, 2 g of sodium at room temperature. The reaction mixture was refluxed gently and 3 g of sodium was added over 0.5 h. The cooled solution was diluted with water, neutralized with 5% HCl and extracted with ether. After the ether solution was washed with water and dried, the solvent was removed to yield 4.5 g of oil. The oil was separated by silica gel chromatography. Elution with a mixture of hexane and ether gave 1.0 g of *syn*-**19**-OH and 1.5 g of *syn*-**20**-OH.

syn-**19**-OH: Oil. IR: 3560, 3460 cm^{-1}. NMR (δ): 4.03 (1H, d, J=10 Hz),[41] 5.65 (2H, complex), 6.39 ppm (2H, m). Found: C, 81.58; H, 9.18%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

syn-**19**-OTs: Mp 96 °C (dec). NMR (δ): 1.60 (1H, dt, J=12 and 5 Hz), 2.45 (3H, s), 4.90 (1H, br.s), 5.60 (2H, m), 6.03 (2H, m), 7.32 (2H, d, J=8.5 Hz), 7.73 ppm (2H, d, J=8.5 Hz). Found: C, 68.91; H, 6.82%. Calcd for $C_{19}H_{22}O_3S$: C, 69.06; H, 6.71%.

syn-**20**-OH: Mp 37—38 °C. IR: 3586, 3450 cm^{-1}. NMR (δ): 1.45 (1H, dt, J=11 and 5.5 Hz), 3.85 (1H, s,) 5.50 (2H, br.s), 6.40 ppm (2H, br.s). Found: C, 81.71; H, 9.12%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

syn-**20**-OTs: Mp 126.5—128 °C. NMR (δ): 1.45 (1H, dt, J=11 and 5 Hz), 2.45 (3H, s), 4.70 (1H, br.s), 5.45 (2H, br.s), 6.10 (2H, d, J=1 Hz), 7.32 (2H, d, J=8.5 Hz), 7.55 ppm (2H, d, J=8.5 Hz), Found: C, 68.89; H, 6.65%. Calcd for $C_{19}H_{22}O_3S$: C, 69.06; H, 6.71%.

Bouveault-Blanc Reduction of exo-*Tricyclo*[*4.4.1.1*^{2,5}]*dodeca-3,7,9-trien*-anti-*11-ol* (anti-***18**-OH). *Preparation of* anti-***19**-OH*: The alcohol *anti*-**18**-OH was reduced similarly to 1: 1 mixture of *anti*-**19**-OH and *anti*-**20**-OH. Separation of these alcohols was unsuccessful. A mixture of *anti*-**19**-OH and *anti*-**20**-OH was also prepared by sodium reduction of **18**-O. As the solvolysis rates of tosylates of *anti*-**19**-OH and *anti*-**20**-OH differ greatly, the mixture was used without separation. The mild solvolysis yielded pure *anti*-**20**-OTs, $LiAlH_4$ reduction of which produced *anti*-**20**-OH.

anti-**20**-OH: Mp 101.5—103 °C. IR: 3450 cm^{-1}. NMR (δ): 1.40 (1H, dt, J=11 and 5 Hz), 4.00 (1H, t, J=6.5 Hz), 5.60 (2H, t, J=2 Hz), 6.02 ppm (2H, m). Found: C, 81.00; H, 8.97%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

anti-**20**-OTs: Mp 132—133 °C. NMR (δ): 1.38 (1H, dt, J=10 and 6 Hz), 2.44 (3H, s), 4.98 (1H, t, J=7 Hz), 5.48 (2H, br.s), 6.03 (2H, d, J=1 Hz), 7.32 (2H, d, J=8.5 Hz), 7.76 ppm (2H, d, J=8.5 Hz). Found: C, 68.93; H, 6.65%. Calcd for $C_{19}H_{22}O_3S$: C, 69.06; H, 6.71%.

Catalytic Reduction of exo-*Tricyclo*[*4.4.1.1*^{2,5}]*dodeca-3,7,9-trien*-syn-*11-ol* (syn-***18**-OH). *Prepartaion of* syn-***21**-OH and* syn-***22**-OH*: Two grams of *syn*-**18**-OH was hydrogenated in 50 ml of methanol with 10% Pd–C catalyst (200 mg) at room temperature. After 2.1 mol of hydrogen uptake, the catalyst and the solvent were removed, giving 2 g of an oil. *syn*-**21**-OH and *syn*-**22**-OH were partly separated by silica gel chromatography eluted with a mixture of hexane and ether.

syn-**21**-OH: Oil. IR: 3300 cm^{-1}. NMR (δ): 1.0 (1H, m), 4.13 (1H, br.s), 5.62 ppm (2H, m). Found: C, 81.02; H, 10.06%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

syn-**21**-OTs: Mp 121—122 °C. NMR (δ): 1.0 (1H, m), 2.44 (3H,s), 4.85 (1H, br.s), 5.60 (2H, complex), 7.46 (2H, d, J=8 Hz), 7.90 ppm (2H, d, J=8 Hz). Found: C, 68.75; H, 7.16%. Calcd for $C_{19}H_{24}O_3S$: C, 68.64; H, 7.28%.

syn-**22**-OH: Oil. IR: 3300 cm^{-1}. NMR (δ): 1.0 (1H, m), 1.5—2.4 (14H, complex), 3.95 (1H, br.s), 5.45 ppm (2H, br.s). Found: C, 80.88; H, 10.08%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

syn-**22**-OTs: Mp 113—114.5 °C. NMR (δ): 1.0 (1H, m), 2.44 (3H, s), 4.73 (1H, br.s), 5.50 (2H, br.s), 7.44 (2H, d, J=8.5 Hz), 7.90 ppm (2H, d, J=8.5 Hz). Found: C, 68.68; H, 7.35%. Calcd for $C_{19}H_{24}O_3S$: C, 68.64; H, 7.28%.

Catalytic Reduction of exo-*Tricyclo*[*4.4.1.1*^{2,5}]*dodeca-3,7,9-trien*-anti-*11-ol* (anti-***18**-OH). *Preparation of* anti-***21**-OH and* anti-***22**-OH*: Compound *anti*-**18**-OH was reduced similarly to a 1: 1 mixture of *anti*-**21**-OH and *anti*-**22**-OH. These alcohols were partly separated by silica gel chromotography.

anti-**21**-OH: Oil. IR 3370 cm^{-1}. NMR (δ); 1.05 (1H, m), 1.4—2.7 (14H, complex), 4.03 (1H, t, J=5.2 Hz), 5.65 (1H, ddd, J=11, 6.5, and 2.5 Hz), 6.90 ppm (1H, dd, J=11 and 4.5 Hz). Found: C, 81.02; H, 10.07%, Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

anti-**21**-OTs: Mp 99—100.5 °C. NMR (δ): 1.05 (1H, m), 2.46 (3H, s), 4.90 (1H, t, J=5 Hz), 5.10 (1H, ddd, J=12, 5, and 2 Hz), 5.88 (1H, dt, J=12 and 4.5 Hz), 7.47

(2H, d, J=8 Hz), 7.89 ppm (2H, d, J=8 Hz). Found: C, 68.62; H, 7.25%. Calcd for $C_{19}H_{24}O_3S$: C, 68.64; H, 7.28%.

anti-**22**-OH: Oil. IR: 3350 cm^{-1}. NMR (δ): 1.00 (1H, m), 1.55 (4H, m), 2.1—2.50 (9H, complex), 4.05 (1H, t, J=5.5 Hz), 5.54 ppm (2H, t, J=2 Hz). Found: C, 81.00; H, 10.10%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

anti-**22**-OTs: Mp 120—121 °C. NMR (δ): 1.0 (1H, m), 1.45—2.20 (13H, complex), 2.42 (3H, s), 4.92 (1H, t, J=5.5 Hz), 5.48 (2H, t, J=2 Hz), 7.35 (2H, d, J=8 Hz), 7.80 ppm (2H, d, J=8 Hz). Found: C, 68.54; H, 7.37%. Calcd for $C_{19}H_{24}O_3S$: C, 68.64; H, 7.28%.

Catalytic Reduction of syn-***18-OH*** *and* anti-***18-OH***. *Preparation of* syn-***23-OH*** *and* anti-***23-OH***: 500 mg of *syn*-**18**-OH was hydrogenated in methanol (10 ml) with 10% Pd-C catalyst (100 mg) at room temperature for two days and the catalyst and solvent were removed. Recrystallization of the residue from petroleum ether yielded 450 mg of *syn*-**23**-OH.

syn-**23**-OH: Mp 80—81 °C. IR: 3350 cm^{-1}. NMR (δ): 0.8—2.3 (18H, complex), 3.92 ppm (1H, s). Found: C, 79.67; H, 11.19%. Calcd for $C_{12}H_{20}O$: C, 79.94; H, 11.18%.

syn-**23**-OTs: NMR (δ): 2.46 (3H, s), 4.68 (1H, br.s), 7.43 (2H, d, J=8 Hz), 7.88 ppm (2H, d, J=8 Hz). Unstable in air.

Catalytic reduction of *anti*-**18**-OH was performed exactly the same way to give *anti*-**23**-OH.

anti-**23**-OH: Mp 73—75 °C. IR: 3400 cm^{-1}. NMR (δ): 1.0 (1H, br.d, J=11 Hz), 1.2—2.2 (18H, complex), 4.15 ppm (1H, br.t, J=4 Hz). Found: C, 79.26; H, 10.99%. Calcd for $C_{12}H_{20}O$: C, 79.94; H, 11.18%.

anti-**23**-OTs: Mp 96.5—97.5 °C. NMR (δ): 0.95 (1H, br.d, J=12 Hz), 1.2—2.2 (17H, complex), 2.45 (3H, s), 4.87 (1H, t, J=5 Hz), 7.35 (2H, d, J=8.7 Hz), 7.80 ppm (2H, d, J=8.7 Hz). Found: C, 68.34; H, 7.89%. Calcd for $C_{19}H_{26}O_3S$: C, 68.23; H, 7.84%.

Solvolysis of anti-***18-OTs***. *anti*-**18**-OTs (4 g) was heated at 110 °C for 24 h in acetic acid (150 ml) with sodium acetate (1.3 g). The resulting cooled solulon was neutralized with sodium hydrogencarbonate and extracted with a mixed solvent of ether and benzene. After the extract was washed with water and dried, the solvent was removed to yield 2 g of an oil. The residue was chromatographed on silica gel (100 g) to give an acetate mixture (1.73 g). No product originated from fragmentation was detected.

The acetate (1.73 g) in dry ether (40 ml) was treated at room temperature for 5 h with $LiAlH_4$ (250 mg) in dry ether (30 ml). After excess reagent was decomposed, the reaction mixture was washed with 2 M HCl and water, dried, and the solvent was removed to give an alcohol mixture (1.16 g).

The alcohol (1.16 g) in dry pyridine (50 ml) was oxidized overnight at room temperature with chromium(VI) oxide-pyridine (1.2 eqv.), poured into ice water (50 ml), neutralized with 2 M HCl and extracted with ether. The extract was washed with water, dried and evaporated, leaving an oil (1.06 g). The residue was chromatographed on silica gel (600 g) to give a mixture of **24**-O[24a] (760 mg), and **25**-O (165 mg).[24b] **24**-O was further chromatographed on silica gel impregnated with $AgNO_3$ afforded the two previously known ketones.[24a]

Solvolysis of anti-***19-OTs***. The mixture of *anti*-**19**-OTs and *anti*-**20**-OTs (550 mg) was solvolyzed in 75% dioxane (20 ml) at 90° for 5 hr. After addition of water (20 ml), the reaction mixture was extracted with a mixed slvent of benzene and ether. The extract was washed with water, dried and evaporated, leaving an oil (400 mg). The residue was chromatographed on silica gel (250 g) to give hydrocarbons (20 mg), *anti*-**20**-OTs (220 mg) and alcohols (120 mg).

The alcohols (100 mg) in dry pyridine (5 ml) were oxidized with chromium(VI) oxide-pyridine complex (2.0 eqv.) to give an oily ketone (90 mg). The oil was purified by chromatography on silica gel (5 g) to give **26**-O (75 mg).

26-O: Oil. MS m/e: 174 (M^+). IR: 1657 cm^{-1}. NMR (δ): 1.4—2.2 (5H, m), 2.5—2.9 (5H, m), 5.5 (1H, m), 5.83 (1H, dt, J=6 and 2 Hz), 6.15 (1H, d, J=11 Hz), 7.25 ppm (1H, dd, J=11 and 9 Hz). Found: C, 82.68; H, 8.16%. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%. Cycloheptatriene was identified by GLC examination of the hydrocarbon fraction.

Catalytic Hydrogenation of ***26-O***. A methanol (10 ml) solution of **26**-O (20 mg) was hydrogenated with 10% Pd-C catalyst (10 mg) at room temperature and the catalyst and the solvent were removed to give previously konwn saturated ketone quantitatively.[24]

Solvolysis of syn-***19-OTs*** *and Oxidation of the Product to* ***27-O***. The mixture of *syn*-**19**-OTs and *syn*-**20**-OTs (2.2 g) was heated for 4.5 h under reflux in 80% acetone (37 ml), and poured into ice water (20 ml), leaving a crystalline substance (720 mg) which was unchanged *syn*-**20**-OTs. The filtrate was extracted with a mixed solvent of benzene and ether, washed with water, dried and evaporated the solvent to give 800 mg of an oil. The oil was chromatographed on silica gel (40 g) to give *syn*-**20**- OTs (100 mg) and an oil (570 mg).

The oil (320 mg) was oxidized (10 min) at room temperature with chromium(VI) oxide-pyridine complex (6 eqv.) in dichlormethane (30 ml), and filtered through silica gel layer, evaporated the solvent to give **27**-O (300 mg).

27-O: Oil. MS m/e: 174 (M^+). IR: 1727 cm^{-1}. NMR (δ): 1.7—2.3 (12H, m), 6.08 ppm (2H, m). Found: C, 82.81; H, 8.06%. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%.

Dehydrogenation of ***27-O***. **27**-O (50 mg) and DDQ (10 eqv.) were heated for 2 days in dry benzene (10 ml), under reflux. The reaction mixture was filtered through alumina layer, evaporated to give semicrystalline material (40 mg). Purification by recrystallization yielded the ketone **28** (38 mg).

28: Mp 70.5—71 °C. NMR (δ): 1.5 (1H, d, J=10.5 Hz), 1.8 (1H, ddd, J=7, 4.5, and 1.4 Hz), 2.3—2.7 (2H, complex), 2.8 (1H, t, J=7 Hz), 3.1 (1H, d, J=6 Hz), 7.0—7.3 ppm (4H, AA'BB').

Solovolysis of syn-***20-OTs***. *syn*-**20**-OTs (720 mg) in 75% dioxane (20 ml) was heated for 18 h under reflux and cooled reaction mixture was extracted with ether. The extract was dried and evaporated to give an oil (490 mg). The residue was chromatographed on silica gel (300 g) to yield *syn*-**29**-OH (162 mg), *anti*-**29**-OH (40 mg) and **30**-OH (90 mg).

syn-**29**-OH: Mp 80—81 °C. MS m/e: 176 (M^+). IR: 3300 cm^{-1}. NMR (δ): 0.94 (1H, tt, J=8 and 1.5 Hz), 1.2—2.0 (12H, m), 4.00 (1H, s), 5.97 ppm (2H, m). Found: C, 81.62; H, 9.20%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

anti-**29**-OH: Oil. MS m/e: 176 (M^+). IR: 3350 cm^{-1}. NMR (δ): 0.81 (1H, tt, J=7 and 1.5 Hz), 1.2—2.3 (12H, m), 4.46 (1H, dd, J=5.5 and 3.2 Hz), 6.05 ppm (2H, m). Found: C, 81.81; H, 9.15%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

30-OH: Mp 86—87 °C. MS m/e: 158 (M^+-H_2O). IR: 3300 cm^{-1}. NMR (δ): 1.6—2.6 (11H, m), 3.87 (1H, m), 6.08 (2H, m), 6.23 (1H, t, J=5 Hz), 6.37 ppm (1H, t, J=5 Hz). Found: C, 81.98; H, 9.21%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

Oxidation of ***30-OH*** *to* ***30-O***. **30**-OH (50 mg) in dichloromethane (13 ml) was oxidized for 10 min. at toom temper-

ature with chromium(VI) oxide–pyridine complex (6 eqv.) and filtered through silica gel layer, evaporated to give the ketone **30**-O (45 mg).

30-O: Oil. MS *m/e*: 174 (M^+). IR: 1723 cm^{-1}. NMR (δ): 1.5—3.0 (10H, m), 6.00 (2H, m), 6.25 (1H, tt, $J=7$ and 1.5 Hz), 6.67 ppm (1H, tt, $J=7$ and 1.2 Hz). Found: C, 82.66; H, 8.14%. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%.

Dehydrogenation of ***30***-O. **30**-O (30 mg) was dehydrogenated to the known ketone **31**[25] (27 mg), by the same procedure as for **27**-O.

Oxidation of syn-***29***-*OH and* anti-***29***-*OH*. *syn*-**29**-OH (10 mg) and *anti*-**29**-OH (110 mg) were oxidized to the same ketone **29**-O by the oxidation with chromium(VI) oxide-pyridine complex under the conditions described previously.

29-O: Oil. MS *m/e*: 174 (M^+). IR: 1729 cm^{-1}. NMR (δ): 1.7—2.4 (12H, m), 6.03 (2H, m). Found: C, 82.88; H, 8.09%. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%.

29-O was oxidized to **28**[25] with DDQ in refluxing benzene for 48 h.

Solvolysis of anti-***18***-*OTs in the Presence of Trapping Reagents. Hydrolysis in the Presence of Acetylacetone*: *anti*-**18**-OTs (135 mg) was heated at 130 °C for 10 days in dioxane–H_2O (3: 1) with sodium acetate (38 mg) and acetylacetone (2 ml). After cooling, sodium *p*-toluenesulfonate (66 mg) was filtered off and the solvent was evaporated. Tropylacetylacetone[42] mp 126—126.5 °C (8 mg) was obtained from the concentrated mixture. NMR spectrum of mother liquor shows to contain *anti*-**18**-OTs (51%), tropylacetylacetone (44%) and acetylacetone (4.5%). Thus, total yield of tropylacetylacetone was 57% with 33% recovery of *anti*-**18**-OTs.

Acetolysis in the Presence of Acetylacetone. *anti*-**18**-OTs (200 mg) was heated at 105 °C for 24 h in acetic acid (10 ml) with sodium acetate (62 mg) and acetylacetone (2 ml). The resulting solution was neutralized with sodium hydrogencarbonate to pH 6, extracted twice with chloroform, washed with brine and dried over sodium sulfate. Removal of solvents under reduced pressure gave 127 mg of oil, NMR spectrum of which revealed the presence of 51% of tropylacetylacetone[42] and 41% of acetate mixture correspond to **24**-OAc.

Acetolysis in the Presence of N-*Phenylmaleimide*. *anti*-**18**-OTs (202 mg) was heated at 105 °C for 15 h in acetic acid (10 ml) with sodium acetate (63 mg) and *N*-phenylmaleimide (500 mg). The resulting reaction mixture was neutralized with sodium hydrogencarbonate and extracted 3 times with chloroform. Organic layer was washed twice with water, once with brine and dried over sodium sulfate. Removal of solvents under reduced pressure, followed by column chromatography on silica gel, gave 134 mg (91%) of cyclopentadiene-*N*-phenylmaleimide adduct.[43]

Acetolysis in the Presence of Methylcyclopentadiene. *anti*-**18**-OTs (500 mg) was solvolyzed for 13 h as in the previous section, with the dropwise addition of methylcyclopentadiene (500 mg) in acetic acid (10 ml). The reaction mixture turned dark immediately. The work up, treatment with $LiAlH_4$ and chromic acid oxidation, carried out exactly as in the previous section, furnished 65 mg of an α,β-unsaturated ketone mixture. NMR spectra of the mixture showed small broad singlet at 1.69 ppm. Mass spectrum (at 15 eV) showed *m/e* 172 with the 1/15 intensity of *m/e* 158.

Solvolysis of syn-***18***-*OTs*. *syn*-**18**-OTs (204 mg) was heated in 75% aq dioxane in the presence of *N*-phenylmaleimide (525 mg) and sodium acetate (62 mg) for 5 h at 95 °C yielded *N*-phenylmaleimide adduct of *syn*-**32**-OH (667 mg) in 95% yield. No cyclopentadiene adduct was detected.

We are indebted to Mrs. Hinako Ando, Mr. Yuji Ikegami and Mr. Akira Nakamura for their technical assistance. Dr. John B. Collins performed the molecular mechanics and Dr. Peter Gund the hindrance calculations. The work at Princeton was supported by grants from the National Science Foundation and the National Institute of Health.

A Remarkable Solvent Effect on the Reductive Silylation of Carboxylic Esters. Preparation of 1,1-Bis(trimethylsilyl)-1-alkanols

Isao KUWAJIMA,* Naoki MINAMI, Toru ABE, and Toshio SATO†

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

†*Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received February 4, 1978)

1,1-Bis(trimethylsilyl)-1-alkanols were obtained in good yields when ethyl esters of the corresponding carboxylic acids were treated with sodium suspension and chlorotrimethylsilane in refluxing tetrahydrofuran followed by acidic hydrolysis.

Various carboxylic esters undergo facile reductive dimerization to afford the corresponding 1,2-bis(trimethylsiloxy)alkenes **1** on treatment with alkali metals such as lithium, sodium, or potassium–sodium alloy in the presence of chlorotrimethylsilane.[1] Bloomfield and Owsley who have studied this type of reaction extensively,[2] suggested that the conventionally adopted mechanism involving dimerization of the radical species is not operative, the reaction proceeding through the nucleophilic attack of the radical anion **3** (Scheme 1) initially formed on the carboxylic ester, followed by several steps. In connection with these reactions, we have found that trimethylsilyl carboxylates give the trimethylsilyl ethers of the corresponding 1,1-bis(trimethylsilyl)-1-alkanols **2** exclusively by a similar treatment in refluxing tetrahydrofuran (THF);[3] several synthetic reactions with use of 1,1-bis(trimethylsilyl)-1-alkanols[4] were developed. In order to establish a precise procedure for the preparation of such kind of alcohols, reductive silylation reactions of various esters have been studied in detail.

$$R\text{-}CO_2R' \longrightarrow \begin{cases} \longrightarrow Me_3SiO\text{-}CR{=}CR\text{-}OSiMe_3 & \mathbf{1} \\ \longrightarrow R\text{-}C(SiMe_3)_2\text{-}OSiMe_3 & \mathbf{2} \end{cases}$$

For studying the difference between reaction paths **1** and **2**, trimethylsilyl and ethyl esters of 3-methylbutyric acid were employed as substrates, and their reactions with metallic sodium in the presence of chlorotrimethylsilane were examined by using benzene, ether, tetrahydrofuran (THF), or 1,2-dimethoxyethane (DME) as the reaction solvent, since benzene and ether are usually employed for the preparation of 1,2-bis(trimethylsiloxy)-alkenes **1**. The reactions were performed with commercial sodium suspension in order to eliminate the effect due to the difference in the grade of dispersion of reducing agent. It was found that the solvent plays a crucial role in deciding the reaction path and **1** or **2** can be prepared selectively through a similar procedure simply by changing the reaction solvent (Table 1). Thus, when tetrahydrofuran or dimethoxyethane was used as a solvent, the type **2** product, silyl ether of 1,1-bis(trimethylsilyl)-3-methyl-1-butanol, was obtained exclusively from both of the starting esters, whereas the reactions with the same esters in benzene or ether afforded the type **1** product, 4,5-bis(trimethylsiloxy)-2,7-dimethyl-4-octene, as the major products. In the latter case, addition of dibenzo-18-crown-6 to the reaction system resulted in appreciable enhancement of the formation of **2**, both types of products being obtained in fair yields. No marked difference in product distribution was observed between the reactions of trimethylsilyl and ethyl esters when the same solvent was employed.

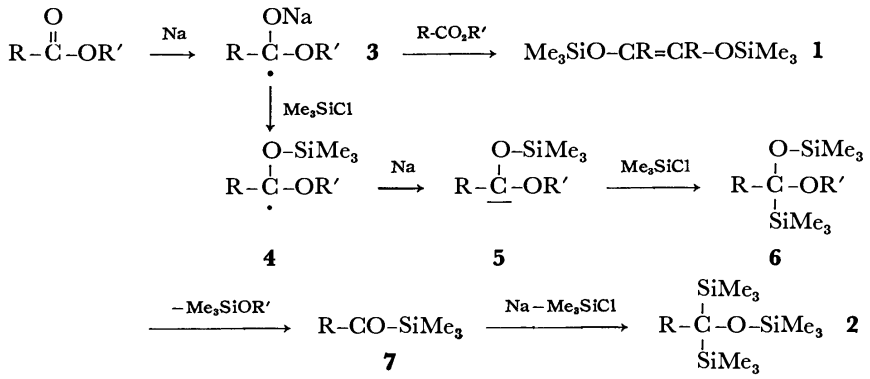
The results indicate that the predominant factor for determining the reaction paths is attributable mainly to the different behavior of the anion radical **3** depending on the solvent. In a non-polar solvent such as benzene or ether, the anion radical **3** seems to react with the parent carboxylic ester preferentially to yield the 1,2-disiloxyalkene type of product **1** *via* the reaction paths proposed by Bloomfield and Owsley.[2] On the contrary, chlorotrimethylsilane seems to be a more efficient anion acceptor in a polar solvent such as tetrahydrofuran or 1,2-dimethoxyethane, trapping the anion radical **3** to afford the corresponding 1-alkoxy-1-(trimethylsiloxy)-alkyl radical **4**. Radical **4** thus formed can not participate in the formation of the 1,2-disiloxyalkene **1**, according to the mechanism of Bloomfield and Owsley, which accounts for exclusive formation of **2**. The only available reaction path for radical **4** is expected to be a further one electron reduction with metallic sodium which yields the anionic species **5** (Scheme 1). Silylation of **5** with the chlorosilane would lead to the formation of 1-alkoxy-1-(trimethylsiloxy)alkyltrimethylsilane **6**.

TABLE 1. SOLVENT DEPENDENCE OF THE REDUCTIVE SILYLATION OF ESTER

$$(CH_3)_2CHCH_2\overset{O}{\overset{\|}{C}}OR \xrightarrow{Na\text{–}Me_3SiCl} \underset{(1)}{(CH_3)_2CHCH_2\overset{Me_3SiO}{\overset{|}{C}}{=}\overset{OSiMe_3}{\overset{|}{C}}CH_2CH(CH_3)_2} + \underset{(2)}{(CH_3)_2CHCH_2\overset{OSiMe_3}{\overset{|}{C}}(SiMe_3)_2}$$

R	Product	THF	DME	Benzene[a]	Benzene	Ether
$SiMe_3$	**1**	—	—	36	62	65
	2	91	88	52	4	2
Et	**1**	5	—	48	68	68
	2	93	91	41	—	—

a) The reaction was performed in the presence of dibenzo-18-crown-6 (an equimolar amount with the ester).



Scheme 1.

This type of product was isolated by Picard *et al.* through the reaction of the corresponding ester with metallic lithium–chlorotrimethylsilane system at low temperature.[5] At a temperature of refluxing tetrahydrofuran, **6** would decompose through removal of alkyl trimethylsilyl ether to yield the corresponding acyltrimethylsilane **7**, which undergoes further reductive silylation to give **2** as the final product. Actually, 3-methylbutyltrimethylsilane was converted into the corresponding **2** by a separate experiment under similar reaction conditions.[6]

We examined the reductive silylation reactions of ethyl esters of various carboxylic acids. All the reactions were performed in a preparative scale (*ca.* 0.2 mol) with a sodium suspension prepared in the usual manner. The results are given in Table 2. All the mono-esters examined afford the corresponding **2** in good yields, without appreciable concomitant formation of type **1** product, when the reactions are carried out at the temperature of refluxing tetrahydrofuran. As compared with the results in Table 1, the yields of the products are smaller, the corresponding acyltrimethylsilanes **7**

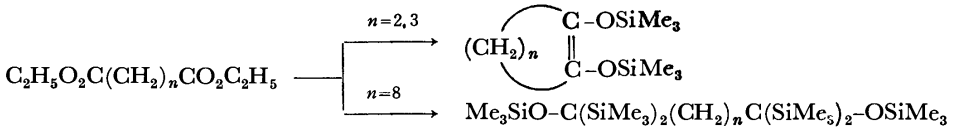

Scheme 2.

being formed as by-products. This can be attributed to the decreased activity of sodium suspension. Silyl ethers **2** usually undergo facile acidic hydrolysis to afford the corresponding 1,1-bis(trimethylsilyl)-1-alkanols in high yields. The only exceptional case was that with the silyl ether of 2,2-dimethyl-1,1-bis(trimethylsilyl)-1-propanol,[7] which could not be hydrolyzed even under severe reaction conditions.

In the reactions with diesters, succinic and glutaric esters gave type **1** products exclusively even when the reactions were carried out in tetrahydrofuran. This can be explained by assuming that the internal nucleophilic attack of the radical anion on the remaining ester carbonyl takes place preferentially since the favorable five- and six-membered intermediates are involved in these processes. In contrast, further elongation of the carbon chain dissecting two ester sites makes the above process less favorable, the corresponding **2** being obtained in good yield. For example, diethyl ester of decane-1,10-dicarboxylic acid could be converted into 1,1,10,10-tetrakins(trimethylsilyl)-1,10-decanediol in 56% yield through the reductive silylation reaction followed by acidic hydrolysis.

Organo-silicon compounds have recently been employed for synthetic purposes in various aspects.[8] The present procedure which provides a simple method for introducing two silyl groups into the same carbon is useful for the preparation of several other types of organo-silicon compounds.[4d-f]

Experimental

All the boiling points are uncorrected. IR spectra were recorded on a Hitachi 260-10 or a Hitachi EPIG3 spectrometer. NMR spectra were taken in a Vatian T-60 spectrometer, using dichloromethane as an internal standard. Elementary compositions of 1,1-bis(trimethyllsilyl)alkyl trimethylsilyl ethers were determined by means of high mass spectra, using a Hitachi RMU-7M mass spectrometer.

Materials. Tetrahydrofuran (THF), 1,2-dimethoxyethane (DME), ether, and benzene were purified shortly before use by drying and distillation over sodium–benzophenone or sodium. Chlorotrimethylsilane was purified by distillation over CaH_2. Esters were purified by distillation. Trimethylsilyl 3-methylbutyrate was prepared by treating the corresponding carboxylic acid with chlorotrimethylsilane in the presence of sidium hydride in tetrahydrofuran in 85% yield.

Two kinds of sodium suspensions were used. (A), a commercial, product (Alfa Ventron), was used after washing three times with hexane and then drying under reduced pressure. (B) was prepared in xylene, according to the usual procedure and was used after xylene had been removed by decantation and then evaporation under reduced pressure.

Reductive Silylation Reactions of Ehtyl or Trimethylsilyl 3-Methylbutyrate in Various Solvents. The ester (3 mmol) and bibenzyl (220 mg) in an appropriate solvent (3 ml) was added dropwise to sodium suspension A (0.03 g atom) suspended in the same solvent (5 ml) containing chlorotrimethylsilane (24 mmol) during a period of 45 min at room temperature under argon atmosphere. Exothermic reaction took place immediately and the temperature rose nearly to the refluxing point of solvent. After being stirred for 1.5 h, the yields were determined by GLC analysis [3 mm×1 m column of 10% SE30 on Diasolid L, column temperature 110 °C] by comparison with the internal standard (bibenzyl). The results are given in Table 1.

Preparation of 1,1-Bis(trimethylsilyl)-1-aklanol. General Procedure: A tetrahydrofuran solution (100 ml) of an ethyl ester (0.2 mol) and chlorotrimethylsilane (174 g, 1.6 mol) was added to sodium suspension B (36.8 g, 1.6 g atom) suspended in boiling tetrahydrofuran (300 ml) during a period of 1 h under argon atmosphere. After addition had been completed, the reaction mixture was heated to refluxing for 30 min under stirring. The materials deposited were filtered off and the solvent was removed under reduced pressure. The residual oil was treated with 10 ml of 6 M hydrochloric acid in 200 ml of dioxane at 50 °C for 1 h, and was neutralized with aq $NaHCO_3$. The corresponding 1,1-bis(trimethylsilyl)-1-alkanol was obtained from the ether extracts after removal of the solvent, followed by distillation using Vigreux column (*ca.* 2×30 cm). Yields, boiling points, and spectral data are given in Table 2.

The authors wish to thank the Ministry of Education, for Grant-in-Aid 247017.

The Reaction of Azidotriazines with Pyridines and Triphenylphosphine

Kenji FUJINUMA, Yoji HASHIDA, and Kohji MATSUI*

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received February 6, 1978)

2-Azido-4,6-dimethoxy-1,3,5-triazine (**1a**) gave an adduct with pyridine in a molar ratio of 1:1. On the contrary, 2-azido-4,6-bis(dimethylamino)-1,3,5-triazine (**1b**) did not react with pyridine. Similarly, **1a** gave an adduct with 3-methylpyridine, whereas in the reactions of **1a** with 2-methyl-, 4-methyl-, and 2,6-dimethylpyridines, 2-amino-4,6-dimethoxy-1,3,5-triazine was obtained instead of the adduct. On the other hand, **1a** and **1b** gave the corresponding triazinyliminophosphoranes with triphenylphosphine.

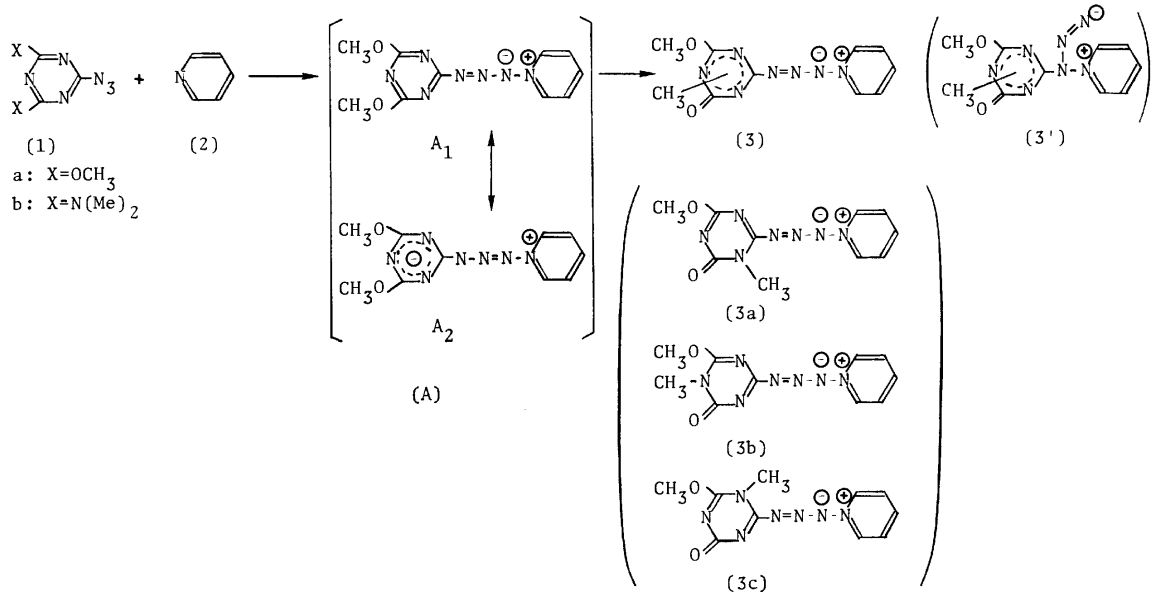
Organic azides are well known to react with organic bases to yield the corresponding ylides.[1] During the course of our study of the reactions of azido-1,3,5-triazines, it has become apparent that azido-1,3,5-triazines have unique properties situated between those of ordinary aryl and acyl azides.[2] Thus, triazinyl ylides, if prepared, are expected to have different characters from those of ordinary acyl and aryl ylides. On the other hand, even though the reaction of azidotriazine with an organic base can be expected to be one of the general routes for the preparation of triazinyl ylides, this reaction has not yet been investigated. This paper will report the thermal reactions of azidotriazines with several pyridine derivatives and triphenylphosphine.

Results and Discussion

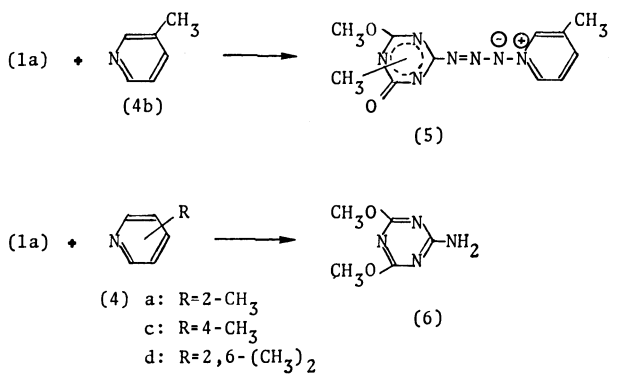
Reactions of Azido-1,3,5-triazines with Pyridine. When 2-azido-4,6-dimethoxy-1,3,5-triazine (**1a**) was heated in pyridine (**2**) under reflux, an 1:1 adduct (**3**) was obtained in a quantitative yield (Scheme 1). On the basis of the spectral data, one of the methyl groups of the adduct was found to be located at the ring nitrogen atom. For the adduct, **3** and **3'** are suggested as possible; of the two, **3** may be more stable. Among three possible structures (**3a**, **3b**, and **3c**), **3a** is most probable, because the highest stabilization by the delocalization of the negative charge can be expected in this case.[3] **3** is considered to result from an intermediate (**A**) produced by the addition of azidotriazine to pyridine, followed by the O→N migration of one methyl group. The facile migration of the methyl group in the intermediate (**A**) is probably due to a decrease in the aromaticity of the triazine ring because of a large contribution of the $\mathbf{A}_2$ formula.

On the other hand, when 2-azido-4,6-bis(dimethylamino)-1,3,5-triazine (**1b**) was refluxed in pyridine, most of the starting material was recovered. The intertness of this azidotriazine is probably due to the weak electrophilic reactivity of the azido group in the presence of two electron-donating dimethylamino groups in the triazine nucleus.

Reaction of Azido-1,3,5-triazine (1a) with Methylpyridines. When 2-azido-4,6-dimethoxy-1,3,5-triazine (**1a**) was refluxed in methylpyridines, the reaction was found to occur in different manners depending upon the position of the methyl group in the pyridine nucleus (Scheme 2). In the reaction with 3-methylpyridine (**4b**), an similar (**5**)[4] adduct to that found in the case of pyridine was formed. However, in the cases of 2-methyl- (**4a**), 4-methyl- (**4c**), and 2,6-dimethylpyridine (**4d**), **1a** gave 2-amino-4,6-



Scheme 1.



Scheme 2.

dimethoxy-1,3,5-triazine (**6**) as the major product. Aminotriazine (**6**) seems to be produced by the hydrogen abstraction of triazinylnitrene formed by the decomposition of azidotriazine (**1a**). However, monoazidotriazines are thermally stable and do not decompose up to 195 °C.[5] Therefore, a process involving triazinylnitrene as a reactive intermediate is improbable. Moreover, azidotriazine (**1a**) was found to decompose slowly in 2-methylpyridine, even at room temperature, to afford the same aminotriazine (**6**). This evidence suggests the existence of another intermediate which can give aminotriazine rather than triazinylnitrene. It would seem reasonable to consider that the adducts which are formed by the combination of azidotriazine with methylpyridine or dimethylpyridine decompose to give aminotriazine when the methyl group is attached at the 2- and/or 4-position (Scheme 3).

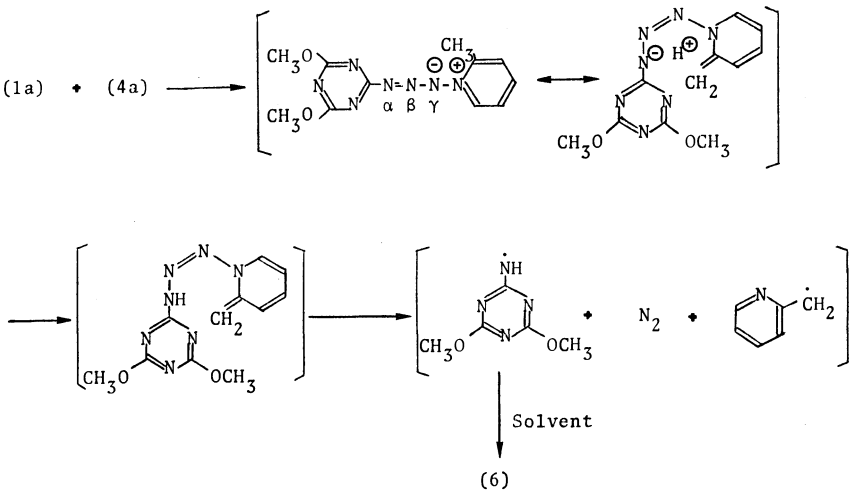
In the adducts to 2- and 4-methylpyridines, methyl hydrogen atoms are readily removable as protons because of the cationic character of the ring nitrogen of pyridine. Thus, in these cases, methyl hydrogen would be abstracted by the α-nitrogen of the adduct as a proton, intra- (in the cases of 2-methyl- and 2,6-dimethylpyridine) or intermolecularly (in the case of 4-methylpyridine), to give *N*-triazinyltriazenes. Ordinary 1,3-diaryltriazenes are known to be thermally not very stable and are known to decompose homolytically at about 140—150 °C, even in the absence of acid.[6] Therefore, if *N*-triazinyltriazene is produced, it can be expected to decompose, even at the boiling points of methylpyridines, to afford pyridylmethyl and triazinylamino radicals. The latter may react with the solvent to give aminotriazine (**6**).

As has been described before, in the case of 3-methylpyridine, the reaction stopped at the stage of adduct formation, because the proton transfer from the methyl group to the α-nitrogen was difficult because of the weak acidity of the methyl hydrogen atoms. In other words, in the reactions of azidotriazines with pyridine derivatives, the initial product was the 1 : 1 adduct in every case. However, a difference was observed in the subsequent process of the reaction depending upon the stability of the adduct. In the cases of pyridine and 3-methylpyridine, the adducts underwent the O→N migration of the methyl group to afford the rearranged product, while in the cases of 2-methyl-, 4-methyl-, and 2,6-dimethylpyridine, the adducts decomposed to give aminotriazine as the final product.

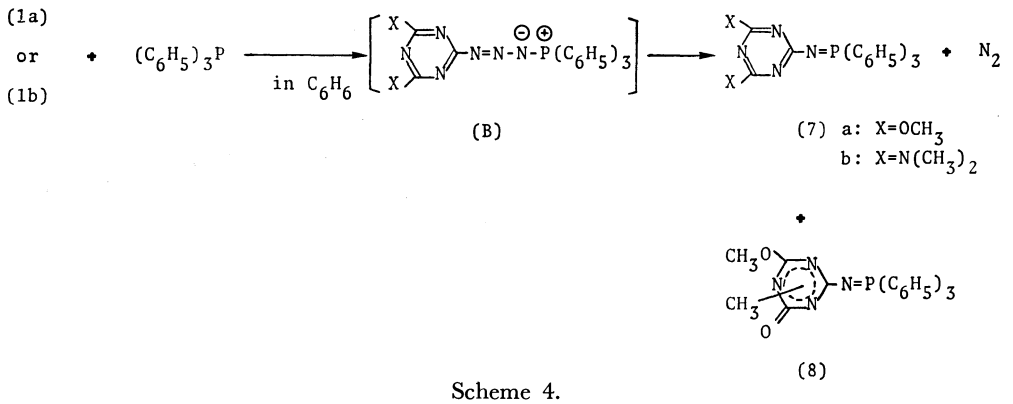
Although various adducts of organic azides to bases have been known, no adducts resulting from organic azides and amines have yet been reported. Thus, it may be said that the **3** and **5** adducts are novel examples of isolable adduct of azide and amine.

The adducts from pyridine and 3-methylpyridine were thermally stable; they did not decompose upon heating at the boiling point of pyridine or methylpyridine. By means of differential thermal analysis, no decomposition was observed below 190 °C; above this temperature, the adducts showed a slight weight loss. The TG curve of the adducts showed a weight loss corresponding to the loss of the pyridine component when they were heated at 220 °C. However, when the adducts were heated at 200—230 °C for 1 h, the resulting products were dark polymeric substances which were insoluble in most of organic solvent; from the reaction mixture *N*-(1-pyridinio)triazinylaminide could not be isolated.

Reaction of Azido-1,3,5-triazines with Triphenylphosphine. The reaction of organic azides with tertiary phosphines



Scheme 3.



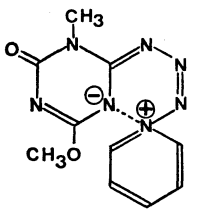
Scheme 4.

is known to be the oldest method for the preparation of iminophosphoranes; in some cases, the 1 : 1 adduct of azide with phosphine is isolated as an intermediate.[7-9] However, these adducts are thermally not very stable and afford iminophosphoranes, with the loss of nitrogen, upon heating.

When a solution of 2-azido-4,6-dimethoxy-1,3,5-triazine (**1a**) in benzene was added to a cold benzene solution of triphenylphosphine, the colorless solution soon became yellow. However, the color disappeared within a few minutes, with an evolution of nitrogen, and colorless crystals seperated out before long. The crystals, obtained in a good yield, were found to be *N*-(4,6-dimethoxy-1,3,5-triazin-2-yl)iminophosphorane (**7a**) (Scheme 4). Along with this major product, a product (**8**) resulting from an O→N migration of one of the methyl groups was also obtained. A similar reaction took place between 2-azido-4,6-bis(dimethylamino)-1,3,5-triazine (**1b**) and triphenylphosphine to give *N*-[4,6-bis(dimethylamino)-1,3,5-triazin-2-yl]iminophosphorane (**7b**) as the sole major product.

Even though attempts to isolate the initial adduct were unsuccessful, the progress of the reaction suggests that the reaction to give iminophosphorane proceeded *via* an 1 : 1 adduct (**B**); since the monoazidotriazines do not decompose under the reaction conditions employed, it may be reasonable to assume that they are not monoazidotriazines, but 1 : 1 adducts (**B**) that decomposed with an evolution of nitrogen.

In summary, it has been shown that the azidotriazine gave the stable 1 : 1 adducts in reactions with pyridines (**2**, **4b**). On the other hand, azidotriazines gave iminophosphoranes with triphenylphosphine, in contrast to the behavior of common organic azides, which give isolable 1 : 1 adducts with tertiary phosphine.[7-9] Although the reasons for the high stability of the **3** and **5** adducts are still ambiguous, one of the general factors may be given here. In the **3** and **5** adducts, the flow of



(**3a**)

the negative charge into a triazine ring is undoubtedly to be expected. Therefore, the adducts could be effectively stabilized by means of the electrostatic attraction between opposite charges, as is shown in the bottom of the left column.

On the other hand, in the 1 : 1 adducts (**B**) of azidotriazines with triphenylphosphine, the presence of three bulky phenyl groups at the phosphorus atom would hinder the approach of the phosphorus and ring nitrogen atoms; consequently, the stabilization by the attraction between the opposite charges would be weakened, and decomposition would take place much more easily.

Experimental

All the melting points are uncorrected.

Materials. The azidotriazines were prepared according to the procedures given in the previous paper.[5] The organic solvents were purified by the standard methods. Commercial pyridines were distilled before use. Triphenylphosphine of a reagent grade was used without purification.

*Reaction of 2-Azido-4,6-dimethoxy-1,3,5-triazine (**1a**) with Pyridine.* A solution of **1a** (17.1 g, 93.7 mmol) in pyridine (20 ml) was refluxed for 3 h. After cooling, the precipitate which resulted was collected by filtration. The recrystallization of the precipitate from EtOH and then from *i*-PrOH gave a pure adduct (**3**): mp 133—134 °C; yield, 17.9 g (73.0%); λ_{max} [EtOH], 242 nm; IR (KBr), 1700 cm^{-1} (C=O): PMR (DMSO-d_6), δ 3.88 (2H, s), 4.48 (3H, s), 8.00—9.30 (5H, m). Found: C, 45.94; H, 4.26; N, 37.52%. Calcd for $C_{10}H_{11}O_2N_7$: C, 45.97; H, 4.24; N, 37.42%.

*Reaction of 2-Azido-4,6-dimethoxy-1,3,5-triazine (**1a**) with 3-Methylpyridine (**4b**).* A solution of **1a** (1.50 g. 8.22 mmol) in 3-methylpyridine (10 ml) was refluxed for 3 h. After cooling, the resulting precipitate was collected by filtration. The recrystallization of the precipitate from *i*-PrOH gave a pure adduct (**5**): mp 161—162 °C; yield, 1.33 g (59%); PMR (DMSO-d_6), δ 2.52 (3H, s), 3.83 (3H, s), 4.37 (3H, s), 8.00—9.00 (4H, m). Found: C, 48.08; H, 4.82; N, 36.10%. Calcd for $C_{11}H_{13}N_7O_2$: C, 47.99; H, 4.76; N, 36.10%.

*Reaction of 2-Azido-4,6-dimethoxy-1,3,5-triazine (**1a**) with 2-Methylpyridine (**4a**), 4-Methylpyridine (**4c**), and 2,6-Dimethylpyridine (**4d**).* A typical example is shown in the case of 2-methylpyridine. A solution of **1a** (2.00 g, 11.0 mmol) in 2-methylpyridine (10 ml) was refluxed for 6 h. After the removal of the solvent, the residue was extracted with hot MeOH. The extract was purified by column chromatography on alumina (eluent: MeOH) to give 2-amino-4,6-dimethoxy-1,3,5-triazine (**6**) (0.575 g, 33.5%, mp 221—222

°C), which was identified by a mixed-melting-point test with an authentic sample.[10]

When the reaction was performed for 10 days at room temperature, **6** was obtained in a yield of 37.5%.

*Reaction of 2-Azido-4,6-dimethoxy-1,3,5-triazine (**1a**) with Triphenylphosphine.* To a stirred solution of triphenylphosphine (2.88 g, 11.0 mmol) in benzene (30 ml) we added, drop by drop, a solution of **1a** (2.00 g, 11.0 mmol) in benzene (50 ml) at 5 °C. After stirring for 1 h at room temperature, the resulting colorless precipitate was collected by filtration and recrystallized from benzene to afford *N*-(4,6-dimethoxy-1,3,5-triazin-2-yl)iminophosphorane (**7a**); mp 184—185 °C; yield, 3.30 g (72%); MS *m/e* 416 (M^+): PMR (DMSO-d_6), δ 3.68 (6H, s), 7.25—8.07 (15H, m). Found: C, 66.33; H, 5.13; N, 13.39%. Clacd for $C_{23}H_{21}N_4O_2P$: C, 66.34; H, 5.08; N, 13.45%.

The filtrate was concentrated and chromatographed on a silica gel column (eluent; benzene: MeOH=10: 1, v/v) to give the crude product of **8**, which was then recrystallized from benzene to give an analytical sample: mp 182—184 °C; yield, 0.074 g (1.6%); MS *m/e* 416 (M^+); IR (KBr), 1694 cm^{-1} (C=O); PMR ($CDCl_3$), δ 3.57 (1H, s), 3.67 (1H, s), 7.28—8.05 (5H, m). Found: C, 66.96; H, 5.05; N, 13.81%. Calcd for $C_{23}H_{21}N_4O_2P$: C, 66.34; H, 5.08; N, 13.54%.

*Reaction of 2-Azido-4,6-bis(dimethylamino)-1,3,5-triazine (**1b**) with Triphenylphosphine.* The reaction of **1b** (1.00 g, 4.81 mmol) with triphenylphosphine (1.27 g, 4.81 mmol) was carried out in a similar way. After stirring for 1 h, the solvent was removed *in vacuo*. The residue was recrystallized from a mixture of benzene and ligroin to give *N*-bis(dimethylamino)-1,3,5-triazinyliminophosphorane (**7b**): mp 207—209 °C; yield, 0.888 g (41.7%); PMR (DMSO-d_6), δ 2.83 (12H, s), 7.46—7.97 (15H, m). Found: C, 67.68; H, 6.11; N, 19.00%. Calcd for $C_{25}H_{27}N_6P$: C, 67.85; H, 6.15; N, 18.99%.

(Received February 15, 1978)

The condensation of 7-benzoyloxy-4'-hydroxyisoflavone with 2-methyl-3-buten-2-ol gave 7-benzoyloxy-4'-hydroxy-3'-(3-methyl-2-butenyl)isoflavone. The hydrolysis of the alkylated isoflavone with dilute alkali afforded neobavaisoflavone [7,4'-dihydroxy-3'-(3-methyl-2-butenyl)isoflavone], which was then converted into isoneobavaisoflavone on heating with formic acid. 7-Benzyloxy-4'-hydroxyisoflavone was condensed with 2-methyl-3-buten-2-ol to give a chroman derivative, which was then converted into isoneobavaisoflavone by hydrolysis. 3'-(3-Methyl-2-butenyl)-5,7,4'-trihydroxyisoflavone was also synthesized from 7-benzoyloxy-5,4'-dihydroxyisoflavone in a similar manner.

Neobavaisoflavone has recently been isolated from *Psoralea corylifolia* seeds (fruits).[2,3)] Its structure has been shown to be 7,4'-dihydroxy-3'-(3-methyl-2-butenyl)-isoflavone (**1**) on the basis of spectral and degradative evidence.[2,3)] In this paper, the unambiguous synthesis of **1** will be reported to confirm the proposed structure of the natural isoflavone. Also, the synthesis of 3'-(3-methyl-2-butenyl)-5,7,4'-trihydroxyisoflavone (**2**) is attempted as an example for the introduction of the 3-methyl-2-butenyl group into the B ring in phloroglucinol-type isoflavone.

The partial benzoylation of daidzein (**3**) in pyridine gave 7-benzoyloxy-4'-hydroxyisoflavone (**4**). In the UV spectrum of **4**, the absorption maximum did not show a bathochromic shift in the presence of sodium acetate. The condensation of **4** with 2-methyl-3-buten-2-ol in the presence of boron trifluoride etherate[4)] afforded 7-benzoyloxy-4'-hydroxy-3'-(3-methyl-2-butenyl)isoflavone (**5**). The mass spectrum of **5** gave a molecular ion at *m/e* 426 and a fragment ion at *m/e* 371 $[M-C_4H_7]^+$. The NMR spectrum exhibited the presence of one methylene group as a doublet centering at δ 3.36 ppm and one vinyl proton as a triplet centering at δ 5.34 ppm. The compound **5** was hydrolyzed with dilute alkali to yield the desired neobavaisoflavone [7,4'-dihydroxy-3'-(3-methyl-2-butenyl)isoflavone] (**1**) (mp 191—192 °C).[2,3)] The acetylation of **1** by the acetic anhydride–pyridine method gave the diacetate (**6**). The isoflavone (**1**) was also heated with formic acid to be cyclized into the corresponding chroman derivative (isoneobavaisoflavone) (**7**) (mp 243—244 °C).[2,3)] The properties of this synthetic isoflavone (**1**) were fully consistent with those of the natural neobavaisoflavone.

The partial benzylation of **3** in acetone–*N*,*N*-dimethylformamide also gave 7-benzyloxy-4'-hydroxyisoflavone (**8**), the UV spectrum of which, like that of **4**, did not exhibit the bathochromic shift upon the addition of sodium acetate. The condensation of **8** with 2-methyl-3-buten-2-ol, in contrast with that of **4**, yielded a chroman derivative (**9**) [MS, *m/e* 412 (M^+)] alone. The hydrogenolysis of **9** with palladium on charcoal in ethyl acetate–methanol gave the chroman (**7**), which was identical with isoneobavaisoflavone.

Furthermore, this condensation was also found to be useful for the introduction of the 3-methyl-2-butenyl group into the B ring of phloroglucinol-type isoflavones such as **11**. 7-Benzoyloxy-5,4'-dihydroxyisoflavone (**11**), derived from genistein (**10**), was converted into 7-benzoyloxy-5,4'-dihydroxy-3'-(3-methyl-2-butenyl)isoflavone (**12**) with 2-methyl-3-buten-2-ol, along with the formation of a slight amount of a cyclization product, whose structure was identified as **13** on the basis of the NMR spectrum. In this condensation, neither 6- nor 8-(3-methyl-2-butenyl)-5,7,4'-trihydroxyisoflavone was obtained. The hydrolysis of **12** and **13** gave 3'-(3-methyl-2-butenyl)-5,7,4'-trihydroxyisoflavone (**2**) and the chroman derivative (**14**) respectively. The latter compound (**14**) was easily obtained from **2** by the

above method.

The condensation described above seems to be a general method which can be used for the introduction of the 3-methyl-2-butenyl group into the B ring of isoflavones.

Experimental

All the melting points are uncorrected. The IR spectra were taken on a Hitachi 215 spectrophotometer, and the UV spectra on a Hitachi 124 spectrophotometer. The NMR spectra were measured with a JEOL PS-100 spectrometer (100 MHz), using tetramethylsilane as an internal standard (δ, ppm). The mass spectra were taken on a Hitachi RMS-4 mass spectrometer with a direct inlet system operating at 70 eV. Column chromatography was carried out on Kieselgel 60 (70-230 mesh) (Merck).

7-Benzoyloxy-4'-hydroxyisoflavone (4). To a solution of daidzein (**3**)[5] (1.0 g) in pyridine (50 ml) was added, drop by drop, a mixture of benzoyl chloride (0.8 ml) and dry ether (5 ml) with stirring and cooling in an ice bath; the mixture was then stirred with cooling for 5 h. The reaction mixture was diluted with cold water and acidified with 2 M-hydrochloric acid to give light yellow precipitates, which were collected and recrystallized from ethyl methyl ketone as light yellow needles (**4**) (640 mg): mp 234—235 °C; UV λ_{max} nm (log ε) (EtOH) 258 (3.86), (EtOH+AcONa) 258 (4.04). Found: C, 73.71; H, 3.84%. Calcd for $C_{22}H_{14}O_5$: C, 73.74; H, 3.94%.

7-Benzoyloxy-4'-hydroxy-3'-(3-methyl-2-butenyl)isoflavone (5). To a solution of **4** (1.0 g) and boron trifluoride etherate (1 ml) in dry dioxane (50 ml) was gradually added a solution of 2-methyl-3-buten-2-ol (0.4 ml) in dry dioxane (10 ml); the mixture was then heated with stirring at 60 °C for 5 h. The reaction mixrure was poured into cold water and extracted with ether. The ethereal solution was washed with 3% aqueous solution of sodium carbonate and dried. After the removal of the solvent, the residue was chromatographed over a silica-gel column with chloroform to give isoflavone (**5**), which was subsequently recrystallized from benzene–ethyl acetate as colorless prisms (105 mg): mp 152—153 °C; UV λ_{max} nm (log ε) (EtOH) 258 (4.51), (EtOH+AcONa) 258 (4.55); NMR (DMSO) δ 1.78 (6H, s, $CH_3\times2$), 3.36 (2H, d, J=7 Hz, $C\underline{H}_2CH$=), 5.34 (1H, t, J=7 Hz, $CH_2C\underline{H}$=), 7.26—8.28 (9H, m, $C_6\underline{H}_5CO$, 6-, 8-, 2'-, 6'-H), 7.99 (1H, s, 2-H), 8.40 (1H, d, J=9 Hz, 5-H); MS *m/e* 426 (M^+), 371, 322. Found: C, 76.00; H, 5.35%. Calcd for $C_{27}H_{22}O_5$: C, 76.04; H, 5.20%.

Neobavaisoflavone [7,4'-Dihydroxy-3'-(3-methyl-2-butenyl)isoflavone] (1). Compound **5** (74 mg) was hydrolyzed with 5% aqueous solution of sodium hydroxide (3 ml) in methanol (7 ml) at 50 °C for 5 min. The reaction mixture was acidified with dilute hydrochloric acid and extracted with ether, and the ethereal solution was washed with water and dried. After the removal of the solvent, the residue was recrystallized from benzene–ethyl acetate to give the desired isoflavone (**1**) as colorless needles (33 mg): mp 191—192 °C (lit,[2,3] 195—196 °C); IR (KBr) 1625 cm^{-1}; UV λ_{max} nm (log ε) (MeOH) 248 (4.41), 258sh (4.37), 305sh (4.00), (MeOH+AcONa) 255 (4.55), 331 (4.11), (MeOH+NaOH) 255 (4.52), 331 (4.23); NMR (DMSO) δ 1.65 (6H, s, $CH_3\times2$), 3.20 (2H, d, J=7 Hz, $C\underline{H}_2CH$=), 5.25 (1H, t, J=7 Hz, $CH_2C\underline{H}$=), 6.78 (1H, d, J=9 Hz, 5'-H), 6.84 (1H, bs, 8-H), 6.90 (1H, q, J=9 and 2 Hz, 6-H), 7.16 (1H, q, J=9 and 2 Hz, 6'-H), 7.21 (1H, s, 2'-H), 7.95 (1H, d, J=9 Hz, 5-H), 8.23 (1H, s, 2-H), 9.48 (1H, s, 4'-OH), 10.84 (1H, s, 7-OH); MS *m/e* 322 (M^+, base), 307 (18), 293 (16), 267 (63), 237 (22), 137 (40), 131 (7). Found: C, 74.50; H, 5.70%. Calcd for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63%.

Diacetate (6) of Neobavaisoflavone (1). After a mixture of **1** (20 mg), acetic anhydride (0.4 ml), and pyridine (0.2 ml) had been allowed to stand at room temperature for 24 h, cold water was added to the mixture. The resulting precipitates were recrystallized from benzene–ethyl acetate as colorless prisms (**6**) (20 mg): mp 115—116 °C (lit,[3] mp 120—121 °C); NMR ($CDCl_3$) δ 1.71 (6H, s, $CH_3\times2$), 2.32 and 2.36 (each 3H, s, CH_3CO), 3.28 (2H, d, J=7 Hz, $C\underline{H}_2CH$=), 5.23 (1H, t, J=7 Hz, $CH_2C\underline{H}$=), 7.06 (1H, d, J=9 Hz, 5'-H), 7.11—7.42 (4H, m, 6-, 8-, 2'-, 6'-H), 7.97 (1H, s, 2-H), 8.30 (1H, d, J=9 Hz, 5-H). Found: C, 71.04; H, 5.56%. Calcd for $C_{24}H_{22}O_6$: C, 70.92; H, 5.46%.

7-Benzyloxy-4'-hydroxyisoflavone (8). To a solution of daidzein (**3**) (800 mg) in acetone (10 ml) and *N,N*-dimethylformamide (10 ml) were addded benzyl chloride (0.5 ml), potassium iodide (600 mg), and 2% aqueous solution of potassium hydroxide (10.6 ml). The mixture was allowed to stand at room temperature for 24 h. The resulting precipitates were recrystallized from ethanol as colorless needles (**8**) (490 mg): mp 234.5—235.5 °C; UV λ_{max} nm (log ε) (EtOH) 262 (4.43), 306sh (4.01), (EtOH+AcONa) 262 (4.44), 306sh (4.02); NMR (DMSO) δ 5.22 (2H, s, $C_6H_5C\underline{H}_2$), 6.80 (2H, d, J=9 Hz, 3'-, 5'-H), 7.19 (1H, q, J=9 and 2 Hz, 6-H), 7.22 (1H, d, J=2 Hz, 8-H), 7.40 (2H, d, J=9 Hz, 2'-, 6'-H), 7.44 (5H, bs, $C_6\underline{H}_5CH_2$), 8.02 (1H, d, J=9 Hz, 5-H), 8.35 (1H, s, 2-H), 9.56 (1H, s, 4'-OH). Found: C, 76.52; H, 4.63%. Calcd for $C_{22}H_{16}O_4$: C, 76.73; H, 4.68%.

7-Benzyloxy-2',3'-dihydro-2',2'-dimethyl-3,6'-bi(4H-1-benzopyran)-4-one (9). To a solution of **8** (650 mg) and boron trifluoride etherate (0.6 ml) in dry dioxane (50 ml) was added a solution of 2-methyl-3-buten-2-ol (0.2 ml) in dioxane (10 ml), after which the mixture was heated with stirring at 60 °C for 5 h. The reaction mixture was then worked up in the same manner as in the preparation of **5**. The resulting product was chromatographed over a silica-gel column with benzene–ethyl acetate (10: 1) to give isoflavone (**9**), which was subsequently crystallized from carbon tetrachloride as colorless prisms (130 mg): mp 152—153 °C; NMR (DMSO) δ 1.28 (6H, s, $CH_3\times2$), 1.76 and 2.73 (each 2H, t, J=7 Hz, CH_2), 5.22 (2H, s, $C_6H_5C\underline{H}_2$), 6.72 (1H, d, J=9 Hz, 5'-H), 7.12 (1H, q, J=9 and 2 Hz, 6-H), 7.21 (1H, d, J=2 Hz, 8-H), 7.28 (1H, s, 2'-H), 7.32 (1H, d, J=9 Hz, 6'-H), 7.42 (5H, bs, $C_6\underline{H}_5CH_2$), 8.00 (1H, d, J=9 Hz, 5-H), 8.36 (1H, s, 2-H); MS m/*e* 412 (M^+), 397, 383, 357, 321. Found: C, 78.73; H, 6.02%. Calcd for $C_{27}H_{24}O_4$: C, 78.62; H, 5.86%.

Isoneobavaisoflavone [2'3'-Dihydro-2',2'-dimethyl-7-hydroxy-3,6'-bi(4H-1-benzopyran)-4-one] (7). Compound (**9**) (100 mg) was hydrogenated over palladium on charcoal (10%; 50 mg) in ethyl acetate–methanol (20 ml, 1: 3) until the uptake of hydrogen ceased. The solvent was then removed under reduced pressure, and the residue was recrystallized from benzene–ethyl acetate to give colorless prisms (**7**) (50 mg): mp 243—244 °C (lit,[2] 232—233 °C); NMR (DMSO) δ 1.29 (6H, s, $CH_3\times2$), 1.78 and 2.76 (each 2H, t, J=7 Hz, CH_2), 6.70 (1H, d, J=9 Hz, 5'-H), 6.85 (1H, bs, 8-H), 6.92 (1H, q, J=9 and 2 Hz, 6-H), 7.24 (1H, q, J=9 and 2 Hz, 6'-H), 7.28 (1H, d, J=2 Hz, 2'-H), 7.94 (1H, d, J=9 Hz, 5-H), 8.26 (1H, s, 2-H), 10.86 (1H, bs, 7-OH); MS *m/e* 322 (M^+), 307, 293, 267. Found: C, 74.30; H, 5.80%. Calcd for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63%.

Isoneobavaisoflavone (**7**) was also prepared from neobavaisoflavone with formic acid according to the procedure of Bajwa *et al.*;[3] it had a melting-point of 243—244 °C (no

depression in a mixed-melting-point determination with the isoflavone synthesized above).

*7-Benzoyloxy-5,4'-dihydroxyisoflavone (**11**).* To a solution of genistein (**10**)[6] (3.0 g) in pyridine (100 ml) was added, drop by drop, a mixture of benzoyl chloride (1.9 g) and ether (20 ml) with stirring and cooling in an ice bath, after which the mixture was stirred with cooling for 6 h. The reaction mixture was then worked up in the same manner as in the case of **4** to give isoflavone (**11**), which was recrystallized from ethyl acetate as colorless needles (2.4 g): mp 245—246 °C; UV λ_{max} nm (log ε) (EtOH) 259 (4.67), 305 (3.81), 332 (3.73), (EtOH+AcONa) 259 (4.69), 305 (4.05), 336 (3.94). Found: C, 70.69; H, 3.90%. Calcd for $C_{22}H_{14}O_6$: C, 70.58; H, 3.77%.

*7-Benzoyloxy-5,4'-dihydroxy-3'-(3-methyl-2-butenyl)isoflavone (**12**) and 7-Benzoyloxy-2',3'-dihydro-2'2'-dimethyl-5-hydroxy-3,6'-bi(4H-1-benzopyran]-4-one (**13**).* To a solution of **11** (2.0 g) and boron trifluoride etherate (2.5 g) in dioxane (150 ml) was gradually added a solution of 2-methyl-3-buten-2-ol (0.72 g) in dioxane (20 ml), after which the mixture was heated with stirring at 50—55 °C for 6 h. The reaction mixture was then poured into cold water to give light yellow precipitates. After the starting material **11** (0.8 g) had been removed from the collected precipitates by recrystallization from methanol, the resulting compounds soluble in methanol were chromatographed over a silica-gel column with chloroform–ethyl acetate (30: 1), giving an oil and a colorless solid. The solid was recrystallized from methanol as colorless needles (**12**) (330 mg): mp 118—119 °C; UV λ_{max} nm (log ε) (EtOH) 262 (4.64), 334sh (3.91), (EtOH+AcONa) 262 (4.64), 334sh (3.92); NMR ($CDCl_3$) δ 1.81 (6H, s, $CH_3\times2$), 3.42 (2H, d, J=7 Hz, C$\underline{H}_2$CH=), 5.34 (1H, t, J= 7Hz, $CH_2C\underline{H}$=), 5.50 (1H, bs, 4'-OH), 6.65—6.9 (3H, m, 6-, 8-, 5'-H), 7.16—7.36 (2H, bs, 2'-, 6'-H), 7.4—7.8 and 8.1—8.3 (5H, m, $C_6\underline{H}_5CO$), 7.91 (1H, s, 2-H), 12.92 (1H, s, 5-OH). Found: C, 73.22; H, 4.92%. Calcd for $C_{27}H_{22}O_6$: C, 73.29; H, 5.01%.

The oil was rechromatographed over a silica-gel column with chloroform–carbon tetrachloride (30: 1) to give colorless needles (**13**) (80 mg): mp 164—165 °C; NMR ($CDCl_3$) δ 1.36 (6H, s, $CH_3\times2$), 1.83 (2H, t, J=7 Hz, CH_2), 2.84 (2H, t, J=7 Hz, CH_2), 6.65—6.92 (3H, m, 6-, 8-, 5'-H), 7.13—7.35 (2H, m, 2'-, 6'-H), 7.4—7.8 and 8.16—8.24 (5H, m, $C_6\underline{H}_5CO$), 7.94 (1H, s, 2-H), 12.95 (1H, s, 5-OH). Found: C, 73.04; H, 5.05%. Calcd for $C_{27}H_{22}O_6$: C, 73.29; H, 5.01%.

*3'-(3-Methyl-2-butenyl)-5,7,4'-trihydroxyisoflavone (**2**).* Isoflavone (**12**) (350 mg) was hydrolyzed with 5% aqueous solution of sodium hydroxide (20 ml) in methanol (30 ml) at 60 °C for 15 min. After the reaction mixture had then been worked up in the same manner as in the case of **1**, the resulting compound was chromatographed over a silica-gel column with chloroform–acetone (30: 1) to give colorless needles (**2**) (210 mg) which were subsequently recrystallized from 1,2-dichloroethane: mp 171—172 °C; UV λ_{max} nm (log ε) (EtOH) 263 (4.54), 295 (4.06), 330 (3.72), (EtOH+AcONa) 273 (3.55), 331 (4.01); NMR (DMSO) δ 1.68 (6H, s, $CH_3\times2$), 3.24 (2H, d, J=7 Hz, C$\underline{H}_2$CH=), 5.28 (1H, t, J=7 Hz, $CH_2C\underline{H}$=), 6.21 (1H, d, J=2 Hz, 6-H), 6.37 (1H, d, J=2 Hz, 8-H), 6.83 (1H, d, J=9 Hz, 5'-H), 7.19 (1H, q, J=9 and 2 Hz, 6'-H), 7.24 (1H, bs, 2'-H), 8.31 (1H, s, 2-H), 9.57 (1H, s, 4'-OH), 10.95 (1H, s, 7-OH), 13.11 (1H, s, 5-OH); MS *m/e* 338 (M^+, base), 323 (23), 309 (20), 283 (93), 253 (40), 153 (65), 131 (18). Found: C, 71.24; H, 5.45%. Calcd for $C_{20}H_{18}O_5$: C, 70.99; H, 5.36%.

*5,7-Dihydroxy-2'3'-dihydro-2'2'-dimethyl-3,6'-bi(4H-1-benzopyran)-4-one (**14**).* Compound (**13**) (60 mg) was hydrolyzed with 5% aqueous solution of sodium hydroxide (3 ml) in methanol (10 ml) under reflux for 15 min. The reaction mixture was then worked up in the same manner as in the case of **12** to give isoflavone (**14**), which was subsequently recrystallized from benzene–ethyl acetate as colorless needles (31 mg): mp 214—215 °C; NMR (DMSO) δ 1.30 (6H, s, $CH_3\times2$), 1.77 (2H, t, J=7 Hz, CH_2), 2.75 (2H, t, J=7 Hz, CH_2), 6.19 (1H, d, J=2 Hz, 6-H), 6.36 (1H, d, J=2 Hz, 8-H), 6.73 (1H, d, J=9 Hz, 5'-H), 7.13—7.40 (2H, m, 2'-, 6'-H), 8.32 (1H, d, 2-H), 10.90 (1H, s, 7-OH), 12.97 (1H, s, 5-OH); MS *m/e* 338 (M^+), 323, 309, 283. Found: C, 71.26; H, 5.43%. Calcd for $C_{20}H_{18}O_5$: C, 70.99; H, 5.36%.

Compound **14** was also obtained from **2** by the same method as in the case of **7**.

(Received February 16, 1978)

A variety of carboxylic acids including simple acids, sterically hindered acids, thermally unstable acids and N-protected amino acids react with alkyl halides in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in benzene to give esters in good yields. The reaction is simple, affording a general method for esterification of carboxylic acids.

Esterification is an important reaction widely used in various fields of chemistry. Although a simple reaction, it often involves unexpected difficulties. For example, other functional groups in the molecule may be sensitive to the acidic or basic conditions, or the reaction may proceed very slowly as is frequently the case with sterically hindered acids. Many useful processes to avoid such difficulties have been reported. Boron trifluoride etherate–alcohol,[1] trialkyloxonium tetrafluoroborate,[2] dialkyl sulfate,[3] and 2-halopyridinum salt–alcohol[4] have been recommended as esterification reagents for a number of cases. Alkyl halides are also useful when the reaction is carried out with use of alkali metal salts of carboxylic acids in dipolar aprotic solvents.[5,6] Caesium salt as an alkali metal salt[5] and hexamethylphosphoric triamide (HMPA)[6] as a solvent are specially effective for esterification with alkyl halides. However, some of these methods are restricted by inconvenience in procedure or expense and inaccessibility of reagents or solvents.[6]

In this paper we wish to report an alternative simple procedure for esterification of carboxylic acids which is based on the reaction of carboxylic acids with alkyl halides in the presence of 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU). The reaction proceeds in a non-polar solvent such as benzene under mild conditions to give esters in good yields. Since alkyl halides are used as the esterification reagent, various esters are easily prepared. Thus, carboxylic acids including sterically hindered acids, thermally unstable acids, heterocyclic carboxylic acids and *N*-protected amino acids are readily converted into the corresponding esters. This new esterification process is noteworthy for converting *N*-protected amino acids into the corresponding esters without observable racemization.

Results and Discussion

Esterification was carried out as follows. A mixture of carboxylic acids, DBU and alkyl halides in benzene was refluxed or kept at room temperature for an appropriate period, after which the DBU-hydrohalides (DBU·HX) were either filtered off or washed out with water from the reaction mixture. The product was purified by distillation or recrystallization. The yields were excellent. Results obtained with various carboxylic acids and alkyl halides are given in Table 1. The esterification is shown by

$$R^1COOH + R^2X \xrightarrow[\text{benzene}]{\text{DBU}} R^1COOR^2 + DBU\cdot HX \quad (1)$$

No difficulties were encountered in the preparation of phenacyl esters,[7] methylthiomethyl esters,[8] esters of sterically hindered acids,[9] or esters of heterocyclic acids,[10] some of which are difficult to prepare by the usual esterification method.[7–10] Thermally unstable carboxylic acids such as malonic or cyanoacetic acid were also esterified by this procedure without decarboxylation. Active methylene compounds are carboxylated by using the reagent of DBU and carbon dioxide,[11] so the reagent system of DBU, carbon dioxide and alkyl halides may afford a new means for introduction of alkoxycarbonyl function to active methylene compounds.

Carboxylic acids having functional groups such as hydroxyl or amino group are esterified without protection of these groups. For example, *p*-aminobenzoic acid, *p*-hydroxybenzoic acid or *N*-benzyloxycarbonyl(*Z*)-threonine were converted into their esters in good yields with alkyl halides and DBU (Tables 1 and 2).

The new method has advantages over the conventional procedure. First, a wide variety of esters can be prepared under mild conditions. Secondly, the procedure is simple and easily scaled up. Thirdly, the reaction proceeds in benzene, making the work-up very simple; for instance, products can be obtained in sufficiently pure form only by removal of DBU·HX and benzene. Furthermore, DBU can be easily recovered by treatment of DBU·HX with a strong base such as sodium hydroxide. Thus, the troublesome preparation of anhydrous alkali metal salts of carboxylic acids or the use of expensive dipolar aprotic solvents becomes unnecessary. In general, it is difficult to carry out the alkylation reaction of carboxylate ions with alkyl halides in a non-polar solvent such as benzene, since few carboxylate ions are soluble in benzene. Recently, alkylation of carboxylate ions with alkyl halides in a non-polar solvent was reported, where the crown ether was used as a catalyst[12] or quarternary ammonium carboxylate was used instead of alkali metal salts.[13] The present method is superior to these methods in the following points. No prior preparation of carboxylate ions is necessary. No competing side reaction of dehydrohalogenation often encountered in the reaction of alkali metal salts of carboxylic acids with *s*-alkyl halides is observed. For example, the reaction of dry potassium acetate with 2-bromooctane in the presence of 18-

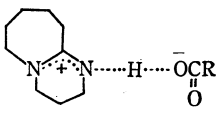
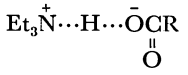
a) Based on carboxylic acids unless otherwise mentioned. b) 2,4,6-Trimethylbenzoic acid. c) Based on alkyl halides. d) Diethyl malonate produced.

crown-6 in dry acetonitrile or benzene produces the corresponding acetate along with 10—15% yield of octenes in about 20 h at reflux temperature.[12] On the other hand, the reaction of acetic acid with 2-bromooctane in the presence of DBU in benzene gave 1-methylheptyl acetate in 91% yield without formation of octenes. No alkene products could also be detected by NMR or VPC technique from the reaction mixture of mesitoic acid or pivalic acid with 2-bromobutane, 2-bromooctane or phenethyl bromide in the presence of DBU. It should be noted that alkenes were produced in good yields in these reactions in the absence of carboxylic acids;[14] *e.g.*, the reaction of 2-bromooctane or phenethyl bromide with DBU gave octenes or styrene in 87 or 60% yield, respectively. The results clearly show that the carboxylate ions formed by the reaction of carboxylic acids with DBU in benzene are sufficiently reactive to alkyl halides to give esters in good yields, but they have not enough basicity to induce the elimination reaction from *s*-alkyl halides or phenethyl bromide. Namely, basicity of both DBU and carboxylate ions is greatly reduced by protonation.

The reaction of carboxylic acids with alkyl halides in the presence of usual amines such as triethylamine is too slow to be useful for the esterification reaction. For example, the reaction of benzoic acid with ethyl iodide in the presence of DBU at room temperature for one hour gave ethyl benzoate in 95% yield, but the same reaction using triethylamine as a base gave only 1% yield of ethyl benzoate under the same conditions. High temperature (*ca.* 150 °C) and long reaction time are usually required for esterification of carboxylic acids by means of alkyl halides and triethylamine.[15] The difference in reactivity between DBU salt and triethylamine salt of carboxylic acids can be attributed to the difference in dissociation of these salts in benzene. DBU or triethylamine reacts with carboxylic acids to form complex I or II, respectively. Complex I is more soluble in benzene than complex II, complex I having a larger and more delocalized cation than complex II.



I



II

The principle of the present esterification reaction using DBU in benzene resembles that of the ion pair extractive alkylation or the method using crown ether. The biggest difference of the present reaction from the others is that the complex is not a free ion pair but is hydrogen-bonded between DBU and the carboxyl protons. The hydrogen bond plays an important role in the control of the reactivity of carboxylate ions. Namely, the free carboxylate ions can attack both the carbon and the hydrogen of alkyl halides, but the hydrogen-bonded complex I attacks carbon rather than hydrogen.

Recently, reports were given on the selective monoalkylation of methyl cyanoacetate[16] or tosylacetonitrile[17] using DBU in benzene as a base. The selectivity of monoalkylation in these reactions using DBU in benzene is much higher than that in the reaction using the ion pair extraction or phase transfer technique. In this case also the selectivity of monoalkylation is mainly controlled by the hydrogen bond between DBU and the active methylene compounds. Another good example of the importance of the hydrogen bonding in organic synthesis was recently demonstrated by Clark and Miller.[18] They showed that the hydrogen-bonded complex between a fluoride anion and carboxylic acids is a mild fluorinating agent but a strong acyloxylating agent.

Since the complex of DBU and carboxylic acids is a strong nucleophile but a weak base, it is expected that the optically active amino acids can be esterified without loss of the optical activities by the present procedure. Esterification of some *N*-*Z*-amino and *N*-*t*-butoxylcarbonyl(Boc)-amino acids was carried out by the use of DBU and alkyl halides in benzene in a similar way to that for the esterification of simple carboxylic acids. From the results of esterification of *N*-*Z*-valine, the standard reaction time, reflux for 2 h, was applied in all cases. The results are summarized in Table 2. Various *N*-protected amino acids were cleanly esterified in excellent yields without observable racemization. They have been esterified by other methods.[19-24] Recently, facile esterification of *N*-protected amino acids and peptides using their caesium salts and alkyl halides in *N*,*N*-dimethylformamide (DMF) was reported.[5] However, the present procedure for esterification of *N*-protected amino acids is superior to those methods as mentioned in esterification of simple carboxylic acids.

Experimental

Solvents and DBU were purified by distillation. Other commercial products were used without purification. Some typical examples of the procedure for esterification of carboxylic acids and the general procedure for esterification of *N*-protected amino acids are described below. The reaction conditions and the physical properties of esters are summarized in Tables 1 and 2.

Ethyl 2,4,6-Trimethylbenzoate. A solution of ethyl iodide (1.56 g, 0.01 mol) in 5 ml of benzene was added to a solution of 2,4,6-trimethylbenzoic acid (1.64 g, 0.01 mol) and DBU (1.52 g, 0.01 mol) in 15 ml of benzene and the mixture was stirred at room temperature for 2 h. The reaction mixture was then washed with water, dried over anhydrous magnesium sulfate, and distilled. Ethyl 2,4,6-trimethylbenzoate; bp 98 °C/3 mmHg, 1.53 g (80% yield) was obtained. NMR (CCl_4) δ=1.31 (t, 3), 2.21 (s, 6), 4.28 (q, 2), 6.72 (s, 2); IR (neat) 1710 cm^{-1} (C=O).

s-*Butyl 2,4,6-Trimethylbenzoate.* A mixture of *s*-buytlbromide (2.0 g, 0.15 mol), 2,4,6-trimethylbenzoic acid (1.64 g, 0.01 mol), DBU (1.52 g, 0.01 mol), and 20 ml of benzene was refluxed for 6 h. The reaction mixture was then washed with water, dried over anhydrous magensium sulfate, and distilled. *s*-Butyl 2,4,6-trimethylbenzoate, bp 115 °C/2 mmHg, 1.90 g (91% yield) was obtained. NMR (CCl_4) δ= 0.99 (t, 3), 1.30 (d, 3), 1.60 (m, 2), 2.22 (s, 9), 4.99 (m, 1), 6.70 (s, 2); IR (neat) 1710 cm^{-1} (C=O).

1-Methylheptyl Acetate. A mixture of 2-bromooctane (3.86 g, 0.02 mol), acetic acid (1.8 g, 0.03 mol), DBU (4.56 g, 0.03 mol), and 40 ml of benzene was refluxed for 10 h. The reaction mixture was then washed with water, dried over anhydrous magnesium sulfate, and distilled. 1-Methylheptyl acetate, bp 87 °C/20 mmHg, 3.1 g (91% yield), was obtained. NMR (CCl_4) δ=0.9—1.3 (m, 16), 1.98 (s, 3), 4.8 (m, 1); IR (neat) 1730 cm^{-1} (C=O).

Phenethyl Pivalate. A mixture of phenethyl bromide (1.9 g, 0.01 mol), pivalic acid (2.05 g, 0.02 mol), DBU (3.04 g, 0.02 mol), and 20 ml of benzene was refluxed for 3 h. The reaction mixture was then washed with water, dried over anhydrous magnesium sulfate, and distilled. Phenethyl pivalate, bp 137 °C/20 mmHg, 1.9 g (90% yield), was obtained. NMR (CCl_4) δ=1.12 (s, 9), 2.90 (t, 2), 4.20 (t, 2), 7.15 (s, 5); IR (neat) 1740 cm^{-1} (C=O).

n-*Butyl Cyanoacetate.* A mixture of *n*-butyl bromide (1.37 g, 0.01 mol), cyanoacetic acid (0.85 g, 0.01 mol), DBU (1.52 g, 0.01 mol), and 20 ml of benzene was refluxed. The reaction mixture was then washed with water, dried over an-

hydrous magnesium sulfate, and distilled. *n*-Butyl cyanoacetate, bp 110 °C/20 mmHg, 1.28 g (91% yield) was obtained. NMR (CCl_4) δ= 1.0(t, 3), 1.55 (m, 4), 3.52 (s, 2), 4.16 (t, 2); IR (neat) 1730 cm^{-1} (C=O).

Reaction of Phenethyl Bromide with DBU. A mixture of DBU (1.6 g, 0.11 mol), phenethyl bromide (1.9 g, 0.01 mol), and benzene (20 ml) was refluxed for 5 h. The reaction mixture was then washed with water, dried over anhydrous magnesium sulfate, and distilled. Styrene, bp 145 °C, 0.64 g (60% yield) was obtained.

General Procedure for Esterification of N-*Protected Amino Acids.* Alkyl halide (1.2 or 2 mmol) in benzene (1—2 ml) was added to a solution of *N*-protected amino acid (1 mmol) and DBU (152 mg, 1 mmol) in benzene (4 ml; 9 ml in the case of Z-Ser-OH, Boc-Asn-OH and Boc-Gln-OH), and the mixture was refluxed with stirring for 2 h. After cooling, the mixture was was diluted with diethyl ether (20 ml), and the precipitate (BDU·HX) was filtered and washed with diethyl ether or ethyl acetate. The filtrate and the washing were combined, washed with water, 1 M HCl (0.5 M citric acid in the case of N-Boc derivatives), 1 M $NaHCO_3$, and water again, and dried over sodium sulfate. The ester obtained after removal of solvent was treated as follows. In the case of ethyl ester, the product itself was satisfactorily pure, while methyl ester was treated with active carbon for removal of a trace of iodine. Benzyl ester and *p*-nitrobenzyl ester were recrystallized from ethyl acetate–petroleum ethrer or diethyl ether–petroreum ether. The results are summarized in Table 2.

The authors are grateful to the Sanyo Chemical Co. Ltd. (Kyoto) for the supply of DBU. The work was supported in part by a Grant-in-Aid from the Ministry of Education (No. 043017 1975—1976).

1,3-Dipolar Cycloadditions to Bicyclic Olefins. III. The Effects of Aromatic Solvents on the exo/endo Product Ratios for the 1,3-Dipolar Cycloadditions of Nitrile Oxides to Norbornadienes[1,2]

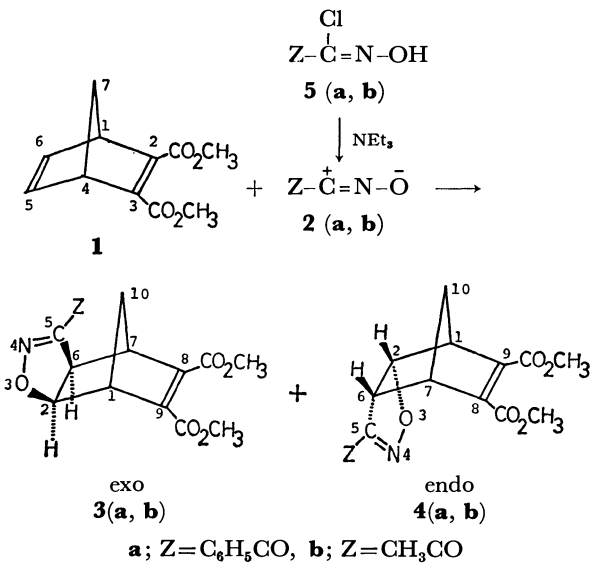
Hisaji TANIGUCHI* and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-umemachi, Sakai, Osaka 591

(Received March 16, 1978)

When no hydrogen-bonded complex is formed between the precursors (α-chloro-α-hydroxyiminoacetophenone (**5a**) and α-chloro-α-hydroxyiminoacetone (**5b**)) of nitrile oxides (phenylglyoxylonitrile oxide (**2a**) and methylglyoxylonitrile oxide (**2b**)) and norbornadienes(2,3-bis(methoxycarbonyl)norbornadiene (**1**) and norbornadiene (**6**)) in solvents, the exo/endo product ratios for the cycloadditions of **2a** and **2b** to **1** or **6** increase or decrease with increasing temperature. When the hydrogen-bonded complex between **5a** and **1** is formed in a solvent cage, however, the ratio keeps a constant value until the temperature is elevated up to a certain temperature, at which the ratio jumps up. After the jumping, the ratio has another constant value, regardless of the temperature. Similar results are obtained in the cycloaddition of **2b** to **1** in the aromatic solvents used.

The 1,3-dipolar cycloaddition of phenylglyoxylonitrile oxide (**2a**) to 2,3-bis(methoxycarbonyl)norbornadiene (**1**) gives both the exo and endo adducts (**3a** and **4a**).[3] When non-aromatic solvents are used, the exo/endo product ratio increases with an increase in the temperature (Fig. 1).[2] However, when aromatic solvents are used, strange phenomena are observed, as is shown in Fig. 2; that is, the plot of the exo/endo product ratio *vs.* the temperature gives horizontal lines, but jumps up at a certain temperature. After the jumping, the ratio takes another constant value, regardless of the temperature. In this paper, a tentative explanation for the phenomena will be given.



a; $Z=C_6H_5CO$, **b**; $Z=CH_3CO$

Results

The Relationship between the exo/endo Product Ratio and the Temperature. (i) The cycloaddition of **2a** to **1**: The results shown in Fig. 2 were obtained when the cycloaddition was carried out as follows: a dilute solution of triethylamine was slowly stirred into a solution of a mixture of **1** and α-chloro-α-hydroxyiminoacetophenone (**5a**), which is the precursor of **2a** (see

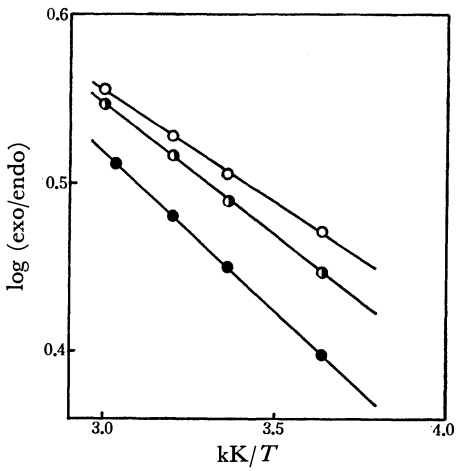


Fig. 1. The linear relationship between $1/T$ and the exo/endo product ratio for the cycloaddition of **2a** to **1** in non-aromatic solvents.
○: THF, ◑: $CHCl_3$, ●: acetone.

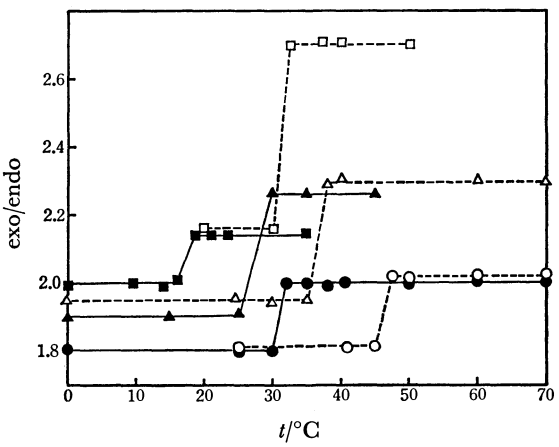

Fig. 2. Plots of exo/endo product ratio *vs.* temperature for the cycloaddition of **2a** to **1** in aromatic solvents.
●: Toluene, ○: benzene, ▲: anisole, △: chlorobenzene, □: nitrobenzene, ■: *o*-xylene.

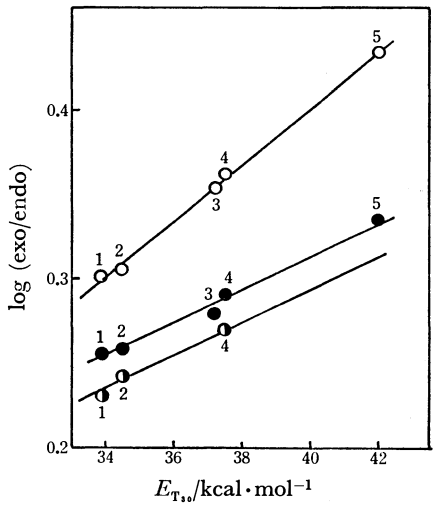

Fig. 3. Height of horizontal line *vs.* $E_{T,0}$ (25 °C) value. ○: exo/endo product ratio after the jumping for the cycloaddition of **2a** to **1**, ●: exo/endo product ratio before the jumping for the cycloaddition of **2a** to **1**, ◑: exo/endo product ratio for the cycloaddition of **2b** to **1**, 1: toluene 2: benzene, 3: anisole, 4: chlorobenzene, 5: nitrobenzene.

Method A in the Experimental section). The plots in Fig. 2 are characterized as follows.

a) The height of the horizontal lines in Fig. 2 can be linearly related to the E_T value[4] of the solvent, as is shown in Fig. 3.

b) The jumping temperature stands to the molar volume[5] of the solvent in a linear relation, as is shown in Fig. 4.

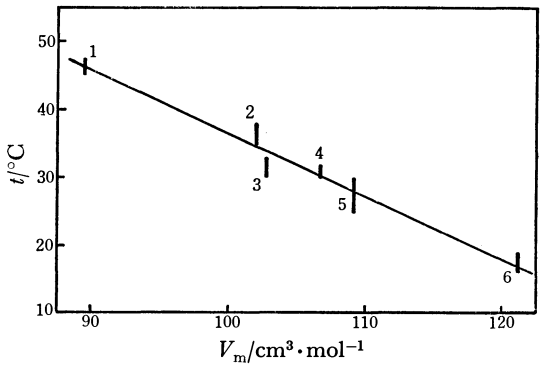

Fig. 4. Jumping temperatures *vs.* molar volumes of solvents (25 °C).
1: Benezene, 2: chlorobenzene, 3: nitrobenzene, 4: toluene, 5: anisole, 6: *o*-xylene.

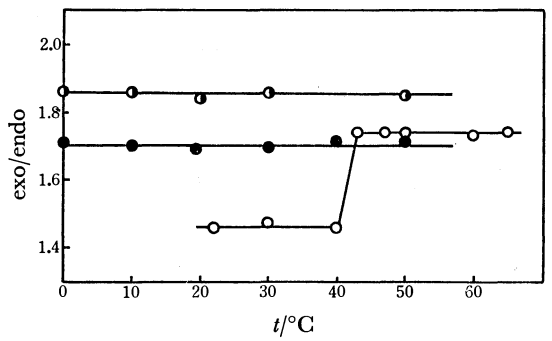

Fig. 5. Plots of exo/endo product ratio *vs.* temperature for the reaction of **2b** with **1**.
○: Benzene, ●: toluene, ◑: chlorobenzene.

(ii) The cycloaddition of **2b** to **1**: The cycloaddition was carried out in the manner described above. Figure 5 shows the results. When benzene was used, the exo/endo product ratio jumped up at about 40 °C. When toluene or chlorobenzene was used, however, the jumping did not occur. Also, in this case the height of the horizontal lines increased with an increase in the E_T value of the solvent (Fig. 3).[6]

(iii) The cycloaddition of **2a** to norbornadiene (**6**): The cycloaddition was carried out in benzene in a manner similar to that described above. The exo/endo product ratio decreased with an increase in the temperature (Fig. 6).

(iv) The cycloaddition of "free **2a**" to **1**: After having been generated in the reaction system, the dipole which we called "free **2a**" was allowed to react with **1** in toluene (Method B in the Experimental section). In this case, the exo/endo product ratio increased with an increase in the temperature (Fig. 7).

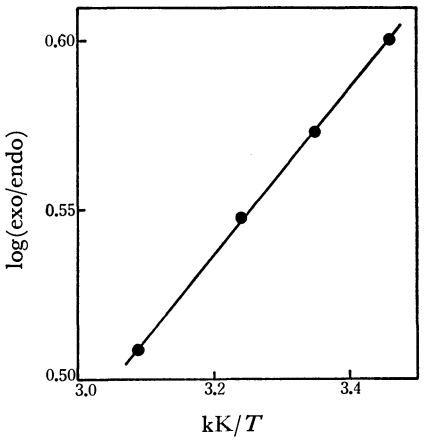

Fig. 6. Plots of exo/endo product ratio *vs.* temperature for the reaction of **2a** with **6**.

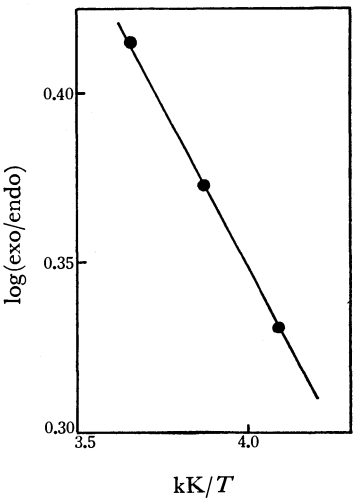

Fig. 7. Plots of exo/endo product ratio *vs.* temperature for the cycloaddition of "free **2a**" to **1** in toluene.

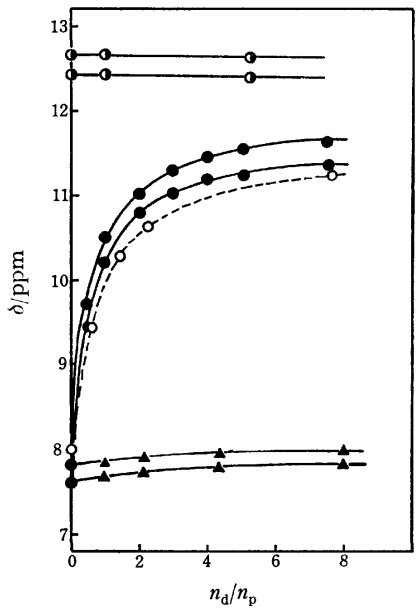

Fig. 8. Chemical sflifts of OH protons of **5a** and **5b** *vs.* n_d/n_p.
n_d=mole number of **1**(or **6**), n_p=mole number of **5a**(or **5b**), ◑: **1** to **5a**(in acetone), ●: **1** to **5a**(in benzene-d_6) ○: **1** to **5b**(in benzene-d_6), ▲: **6** to **5a** (in benzene-d_6).

Behavior of the Precursors of Nitrile Oxides in Solutions. (i) NMR chemical shifts of the precursors: When mixtures of **1** and **5a** in appropriate molar ratios were dissolved in acetone, the δ value[7] of the hydroxylic proton of **5a** did not change, regardless of the n_d/n_p ratio, as is shown in Fig. 8, where n_d is the number of moles of the dipolarophile and n_p is the number of moles of the precursor. In benzene-d_6, however, the δ value changed with the n_d/n_p ratio, as is shown in Fig. 8: The δ value increased rapidly as the value of n_d/n_p changed from 0 to 1. After n_d/n_p had reached 1, the δ value increased gradually with the increase in the n_d/n_p. For the precursor (α-chloro-α-hydroxyiminoacetone (**5b**)) of **2b** also, a similar phenomenon was observed (Fig. 8).[7] These results suggest that a 1:1 hydrogen-bonded complex is formed between **1** and **5a** (or **5b**) in benzene-d_6. When mixtures of **6** and **5a** in appropriate molar ratios were dissolved in benzene-d_6, the δ value of the hydroxylic proton of **5a** scarcely changed (Fig. 8). This result implies that no hydrogen-bonded complex is formed between **6** and **5a** in benzene-d_6.

Table 1. Solubilities of **5a** and **5b** (mg/cm³, 25 °C)

Solvent	**5a**	**5b**
Benzene	9.8	17
Toluene	7.7	15
Anisole	89	
Chlorobenzene	8.9	13
Nitrobenzene	80	
o-Xylene	7.3	
Norbornadiene	19	
BMCND[a)]	500	790
THF	1250	
Acetone	870	
Methyl acetate	620	
Ethanol	740	

a) 2,3-Bis(methoxycarbonyl)norbornadiene.

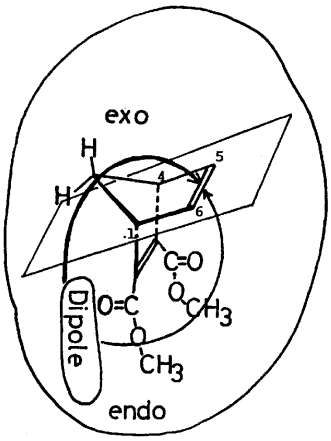
(ii) Solubility of the precursors: The precursors, **5a** and **5b**, are very soluble in non-aromatic solvents and in **1**, but they are only slightly soluble in aromatic solvents and in **1** (Table 1). Moreover, the following phenomena were observed: when 0.25 mmol of **5a** was added to 0.5 cm³ of benzene-d_6, a large portion of the **5a** remained insoluble. The addition of 0.25 mmol of **1** to this suspension gave a clear solution. Such a phenomenon was also observed for the other aromatic solvents used. For **5b** also, a similar phenomenon was observed. These results support the formation of the hydrogen-bonded complex of **1** with **5a** (or **5b**) in aromatic solvents.

Discussion

When no hydrogen-bonded complex is formed between the precursors of nitrile oxides and norbornadiene in solvents, the exo/endo product ratios for the reactions of the nitrile oxides and norbornadienes increase or decrease with an increase in the temperature. The reason for the increase or decrease of the ratios has been reported previously.[2] When the hydrogen-bonded complexes between the precursors of nitrile oxides and the norbornadiene, **1**, are formed in solvent cages, however, stepped lines are obtained, as is shown in Figs. 2 and 5. We will now give a tentative explanation for these phenomena.

At the moment the dipole is generated by the elimination of hydrogen chloride from the precursor, which is a component of the hydrogen-bonded complex in a solvent cage, it must be present near the polar ester groups. Then, it would be transferred to the exo or endo side of the C_5–C_6 double bond of **1**, taking some kind of rotation. The solvent cage can be divided into the exo and endo spaces by the plane containing the four carbon atoms (C_1, C_4, C_5, and C_6) (see the figure). Here, we assume that the exo/endo product ratio depends on the ease of approach of the dipole to the exo and endo sides and that the ease of approach depends on the size of the exo and endo spaces. If the exo and endo spaces are large enough for the dipole to take any pathway of transfer and any mode of rotation, the exo/endo product ratio will become the value obtained when the cycloaddition is carried out in a gas phase. If the solvent cage is small, however, the pathway of the transfer and the mode of rotation of the dipole may be limited. The endo space must be smaller than the exo space, because the ester groups in the endo space would attract the polar solvent. Hence, as the E_T value of the solvent becomes larger, the endo space may decrease more greatly than the exo space. This means that the exo/endo product ratio increases with an increase in the E_T value of the solvent (Fig. 3).

The sizes of the exo and endo spaces of the solvent cage would increase gradually with an increase in the temperature, and the former more rapidly than the



latter. Until the exo space reaches a certain size which is large enough for the dipole to take other pathways of translation and modes of rotation, the exo/endo product ratio keeps a constant value, and then it jumps up suddenly at this size. Since the size of the solvent cage increases with an increase in the molar volume of the solvent, the jumping temperatures will lower with an increase in the molar volume of the solvent, as is shown in Fig. 4.

Experimental

Solvents. Benzene was refluxed for 10 h over sodium and then carefully distilled; bp 80 °C. Toluene was refluxed for 10 h over sodium and distilled; bp 111 °C. Chlorobenzene was dried over $MgSO_4$ and distilled; bp 131—132 °C. Anisole was dried over sodium and then distilled; bp 155—156 °C. Nitrobenzene was dried over $MgSO_4$ and then distilled; bp 210—211 °C. *o*-Xylene was dried over sodium and then distilled; bp 144 °C.

Materials. The norbornadiene, **1**, was prepared by a method described in the literature.[9] Norbornadiene was purchased and distilled before use. The precursors of the nitrile oxides, **5a**[10] (mp, 131—132 °C) and **5b**[11] (mp, 104—105 °C), were also prepared by methods described in the literature.

Products. The cycloadducts obtained in the reaction of **2a** with **6** and the cycloadducts, **3a** and **4a**, have been characterized in a previous paper.[3]

The cycloadducts, 5-acetyl-8,9-bis(methoxycarbonyl)-2,6-exo-3-oxa-4-azatricyclo[5.2.1.$0^{2,6}$]deca-4,8-diene(**3b**), 5-acetyl-8,9-bis(methoxycarbonyl)-2,6-*endo*-3-oxa-4-azatricyclo-[5.2.1.$0^{2,6}$]deca-4,8-diene (**4b**), were isolated using column chromatography on silica gel and chracterized.

3b: Colorless viscous oil; IR (neat) 1720 (ester C=O), 1690 (C=O), and 1625 cm^{-1} (C=N); NMR ($CDCl_3$) δ=1.53 and 1.87 (2H, ABq, J=10.5 Hz, 10-CH_2), 2.44 (3H, s, $COCH_3$), 3.76 (3H, s), 3.79 (3H, s), 3.5—3.9 (3H, m, 1-H, 7-H, and 2-H_{endo}), 5.15 ppm (1H, d, J=8 Hz, 6-H_{endo}). 2,4-Dinitrophenylhydrazone of **3b**: mp 169—171 °C.

Found: C, 50.71; H, 3.78; N, 14.98%. Calcd for $C_{20}H_{19}N_5O_9$: C, 50.74; H, 4.05; N, 14.80%.

4b: Mp 128—130 °C (from MeOH–H_2O); IR(KBr) 1730 (ester C=O), 1690 (C=O), and 1620 cm^{-1} (C=N); NMR ($CDCl_3$) δ=1.50 and 1.90 (2H, ABq, J=10 Hz, 10-CH_2), 2.39 (3H, s, $COCH_3$), 3.5—4.0 (2H, m, 1-H and 7-H), 3.71 (3H, s), 3.75 (3H, s), 4.90 (1H, dd, J=10 and 4 Hz, 2-H_{exo}), 3.71 (3H, s), 3.75 (3H, s), 4.09 (1H, dd, J=10 and 4 Hz, 2-H_{exo}), and 5.56 ppm (1H, dd, J=10 and 4.5 Hz, 6-H_{exo}).

Found: C, 57.51; H, 5.03; N, 4.76%. Calcd for $C_{14}H_{15}NO_6$: C, 57.33; H, 5.16; N, 4.78%.

General Procedure for 1,3-Dipolar Cycloadditions. Method A (Cycloadditions Started from the Hydrogen-bonded Complex): A mixture of a norbornadiene (2.50 mmol) and a precursor of a nitrile oxide (2.50 mmol) was dissolved in an appropriate solvent (40 cm^3). Then, the temperature of the solution was maintained at a given temperature (which was controlled within±0.1 °C). A solution of triethylamine (TEA) (330 mg, 3.26) in the same solvent (10 cm^3) as that used above was added, drop by drop, over a period of 1 h. After an additional 1 h of stirring at the same temperature, the resulting triethylammonium chloride was removed by filtration. The filtrate was evaporated under reduced pressure to give a mixture of the exo and endo adducts. This mixture was then submited to a measurement of the exo/enso product ratio.

For the cycloaddition of **2a** to **6**, two molar equivalents of **6** with respect to **2a** were used.

Method B (Cycloadditions of "Free 2a" to 1): Compound **5a** (520 mg, 2.50 mmol) was dissolved in 40 cm^3 of toluene. The temperature of this solution was maintained at a given temperature by means of a thermostat (±0.1 °C). Into the solution, a solution of TEA (330 mg, 3.26 mmol) dissolved in 5 cm^3 of toluene was added all at once, after which the soultion was stirred for 4 min at the same temperature, A solution of **1** dissolved in 5 cm^3 of the same solvent as that used avobe was then added to the above reaction mixture all at once, after which the solution was stirred for 1 h at the same temperature. The resulting triethylammonium chloride was removed by filtration. The evaporation of the solvent left a mixture of the exo and endo adducts.

Measuerment of the exo/endo Product Ratios. The NMR technique employed for measuring the exo/endo product ratios is described in the literature.[2]

The measurement of each exo/endo product ratio for the cycloadditions of **2a** and **2b** to **1** or **6** at a given temperature was repeated twice using the NMR technique. The difference between the average and the experimental data was within±0.02. (Figs. 2, 5, 6, and 7.)

Measurement of Solubility of the Precursors, 5a and 5b. General procedure: An excess of the precursor of a nitrile oxide was added to an appropriate solvent of a constant volume. The solution was allowed to stand for about 12 h at 25 °C. Then, the insoluble material was removed by filtration. The filtrate was evporated to dryness under reduced pressure to give a residue. The weight of the residue was measured.

Measurement of the Chemical Shifts for OH Protons of 5a and 5b. General procedure: A mixture of a norbornadiene and **5a** (or **5b**) in an arbitary molar ratio was dissolved in a 0.5-cm^3 portion of benzene-d_6 (or acetone) containing a small amount of TMS in an NMR sample tube. Then, the chemical shift for the OH proton of the precusor of the nitrile oxide was measured. (The NMR spectra were recorded on a Hitachi NMR R-24A spectrometer at 60 MHz.)

The authors are indebted to Mr. Yoshimasa Kadoma for measuring the solubilities of **5a** and **5b**.

6) For benzene, the exo/endo product ratio after the jumping was employed.

7) Both precursors, **5a** and **5b**, consist of two isomers, the *E*-form and the *Z*-form. Two sharp OH signals appear in the NMR spectrum of **5a**. This may be attibutable to a very slow chemical exchamge of the OH protons on the NMR time scale between the two isomers.[8] In the case of **5b**, only one broad singlet appears for the OH proton. This may be ascribed to a rapid chemical exchange of the OH protons between the two isomers.[8]

Electrolytic Dissolution and Deposition of Overpotentials of Tantalum in KCl Melts

Ippei NAKAGAWA

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received February 24, 1978)

As part of electrochemical studies on tantalum, the electrolytic dissolution and deposition of solid tantalum in molten salt were studies by measuring its overpotentials in a steady state. The measurements were carried out using the dc current polarization technique in the concentration range of 2.00×10^{-4}—2.79×10^{-1} mole fraction at temperatures between 775 and 875 °C. The kinetic parameters (the exchange current densities, the transfer coefficients, the kinetic averaged valences, and the apparent activation energies) were determined for the anodic and the cathodic reactions in the Tafel region. The over-all reaction was indicated as:

$$(m_1+m_2)Ta^{2+} + (2m_1-2m_2)e \rightleftarrows m_1Ta^0 + m_2Ta^{4+}$$

The Ta^{2+} ion was previously supposed not to form a complex ion; the Ta^{4+}, however, was a complex ion which decomposed at above 850 °C.

Production of refractory metals by fused salt electrolysis has been intensively carried out. Much information on the chemical equilibria in the metal-molten systems has been accumulated in recent years. However, there have been only a few reports on the kinetic data for the refractory metals such as Zr, Hf, Nb, and Ta. Tanaka and Tamamushi[1] compiled the kinetic data in aqueous and in molten salt systems. However, the kinetic data available for the molten salt systems are skimpy by comparison those available for aqueous solutions.

Randles and White applied a relaxation method[2] to the electrode reactions in molten salts. About same time, Laitinen and Osteryoung used the same ac current technique with a platinum electrode in the LiCl–KCl system.[3] Hill *et al.* measured the impedance of tungsten in Ti(II)–Ti(III) couple in the LiCl–KCl eutectic.[4] Laitinen *et al.* measured the exchange current densities of solid metal electrodes (Cd, Zn, Pb, Bi, Ag, Ni, and Pt) and a redox system of V(II)–V(III) in the LiCl–KCl eutectic.[5] T. Kirihara *et al.* have measured the overpotentials of electrolytic dissolution and deposition of Ag,[6] Zr,[7] and Hf[8] in the NaCl–KCl (equiv mole) melts by a galvanostatic method and have evaluated the kinetic parameters (exchange current densities, transfer coefficients, and rate constents).

In the course of the electrochemical studies on Ta,[9-11] the present work was undertaken to determine the kinetic parameters. The electrode processes of dissolution and deposition of solid Ta in the NaCl–KCl (equiv mole) melts will be discussed along with the results of overpotential measurements in a steady state. The values of overpotentials for these processes are also very important in the electrorefining procedure.

Experimental

Chemicals and Procedures. Tantalum plate and wire (99.9%, Fansteel Co.), and tantalum pentachloride (99.9%, Mitsuwa Chemicals Co.) were used. Sodium and potassium chlorides of extra purity were melted under flowing chlorine and argon for further purification and then stored in a desiccator before use.

Electrodes. A working electrode was constructed by connecting a Ta plate with a surface area of 1 cm^2 with a Ta wire to a spectroscopic graphite rod 0.5 cm in diameter. A counter electrode with a surface area of 3 cm^2 and a reference electrode with a area of 1 cm^2 were made in a way similar to the working electrode.

All the electrodes were set in a quartz vessel ($4.5\phi\times45$ cm). An electrical resistance furnace was used to heat the vessel and the temperature was controlled by a current controller with a Pt–Pt·Rh thermocouple within ±2 °C between 775 and 875 °C.

B: Lead storage battery, O: frequency oscilator, Rb: resistance box, R1: recorder, R2: recorder, S: shunt, Cs: switch, E: cell, M: measuring electrode, R: reference electrode, C: counter electrode, SS: synchloscope.

Measurement of Ohmic Overpotential. A schematic diagram of the apparatus for measuerment of ohmic resistance of melt is shown in Fig. 1. A precise value of ohmic overpotential caused by ohmic resistance during polarization between the reference electrode and the working one is required to obtain an intrinsic overpotential. That is, $\eta_{total}=\eta_{MR}+\eta_{IR}$, where η_{MR} is the true overpotential and η_{IR} the ohmic one. Both voltage measurements alternating current (20—2000 Hz) and measurements of the initial jump in dc current were employed to determine the value of η_{IR}. The ohmic overpotentials obtained by those methods were in good agreement with each other. A typical example taken by the intial jump method is represented in Photo. 1. The ohmic drop was determined by the gap at the initial part of the curve, as has already been done by other workers.[12] The values of η_{IR} were 0.15—0.27 Ω at various concentrations and temperatures.

Measurement of Overpotential. A schmatic diagram of the apparatus for measurement of overpotemtial is shown in Fig. 1. A galvanostatic method was employed from a low current density to a higher one. The anodic polarization and the cathodic one were measured alternatively in the concentration range of 2.00×10^{-4}—2.79×10^{-1} mole fraction at

temperatures between 775 and 875 °C. All measurements were carried out under an argon atmosphere.

Results and Discussion

Theoretical. The equilibrium reaction between Ta metal and tantalum chlorides has been found experimentally to be

$$Ta^{4+} + Ta = 2Ta^{2+},$$

in the KCl and in the NaCl–KCl (equiv mol) melts.[9-11] Two types of tantalum chlorides, $TaCl_2$ and $TaCl_4$, were found in the equilibrium state. Therefore, the electrode process can not be a simple process like an ordinary electrode reaction which concerns only a simple ion in the solution.

The theoretical treatment for a simultaneous electrode process has been studied by Gray and Cahill.[13] However, this theory is very complicated and it is difficult experimentally to determine the kinetic parameters. Thus we tried to treat the electrode processes for electrolytic dissolution and deposition of solid tantalum with the mobile equilibrium concept which has been explained for zirconium in the chloride system.[14] A more precise consideration will be given elsewhere for the tantalum–chloride system. In this paper, the author describes briefly the concept of mobile equilibrium for the tantalum electrode reactions.

According to emf measurements,[11] Ta^{2+} and Ta^{4+} ions were stable at the electrode surface. For tantalum electrolysis, the charge transfer reactions are usually expressed as

$$Ta^0 \underset{k_{c1}}{\overset{k_{a1}}{\rightleftarrows}} Ta^{2+} + 2e, \qquad \Delta G_1^\circ < 0 \qquad (1)$$

(ΔG°: free energy)

$$Ta^{2+} \underset{k_{c2}}{\overset{k_{a2}}{\rightleftarrows}} Ta^{4+} + 2e, \qquad \Delta G_2^\circ < 0 \qquad (2)$$

where k_a and k_c are the rate constants of each direction. The direction right to left means the cathodic reaction (deposition) and the opposite the anodic one (dissolution). The over-all reaction becomes

$$m_1Ta^0 \underset{k_c}{\overset{k_a}{\rightleftarrows}} (m_1-m_2)Ta^{2+} + m_1Ta^{4+} + 2(m_1-m_2)e, \qquad \Delta G_3^\circ < 0. \qquad (3)$$

When the Process 1 proceeds by m_1 mol, the Process 2 occurs for m_2 mol. If the electrode potentials are high enough,

$$\Delta G_3^\circ = m_1\Delta G_1^\circ + m_2\Delta G_2^\circ < 0,$$
$$-nFE_3^\circ = m_1\Delta G_1^\circ + m_2\Delta G_2^\circ. \qquad (4)$$

The electrode process will proceed according to Eq. 3.

The equilibrium reaction of tantalum is, however $Ta^{4+}+Ta=2\ Ta^{2+}$. So

$$m_1Ta^0 + m_2Ta^{4+} \underset{k_c}{\overset{k_a}{\rightleftarrows}} (m_1+m_2)Ta^{2+} + 2(m_1-m_2)e, \qquad (3')$$

and $\Delta G_{3'}^\circ = m_1\ \Delta G_1^\circ - m_2\ \Delta G_2^\circ = -nFE_{3'}^\circ$ will occur at lower overpotentials than Eq. 4, because

$$|\Delta G_3^\circ| > |\Delta G_{3'}^\circ|.$$

Accordingly, the charge transfer processes are described as

$$Ta^0 \underset{k_{c1}}{\overset{k_{a1}}{\rightleftarrows}} Ta^{2+} + 2e, \qquad (1')$$

$$Ta^{4+} + 2e \underset{k_{c2}}{\overset{k_{a2}}{\rightleftarrows}} Ta^{2+}. \qquad (2')$$

The mobile equilibrium concept for the electrode reaction means a quasi-equilibrium state which involves the electrical work applied to the solution. Therefore, the American convention was adopted to convenience. When mobile equilibrium was established for the Reaction 3′,

$$nFE + \Delta G = 0.$$

Thus, $nFE+\Delta G^\circ+RT\ln a_2^{m_1-m_1}+RT\ln a_4^{m_2}=0$. Accordingly, overpotentials of the cathodic or the anodic process for the Reaction 3′ can be expressed as

$$\eta = E - E_e = \frac{RT}{2(m_1-m_2)F}\{(\ln a_2^{\circ(m_1-m_1)} - RT\ln a_4^{\circ m_2}) - (\ln a_2^{(m_1-m_2)} - \ln a_4^{m_2})\},$$
$$= \frac{RT}{nF}\left\{\ln\left(\frac{a_2^\circ}{a_2}\right)^{(m_1-m_2)} + \ln\left(\frac{a_4}{a_4^\circ}\right)^{m_2}\right\}, \qquad (5)$$
$$= A\eta + (1-A)\eta,$$

where E_e means the equilibrium electrode potential, and a_2° and a_4° are the activities at the equilibrium state for Ta^{2+} and Ta^{4+}, respectively. A is the transfer coefficient and $n=2(m_1-m_2)$ the kinetic averaged valence.

When the diffusion process can be ignored, the relation between the current density and the overpotential can be expressed in wellknown equations for the deposition process:

$$I_c = I_{0c}\{\exp(-A_c n_c F\eta_c/RT) - \exp(A_a^c n_c F\eta_c/RT)\},$$
$$A_c + A_a^c = 1, \quad (6)$$

and for the dissolution process:

$$I_a = I_{0a}\{\exp(A_a n_a F\eta_a/RT) - \exp(-A_c^a n_a F\eta_a/RT)\},$$
$$A_a + A_c^a = 1, \quad (7)$$

where subscripts a and c represent the anodic and the cathodic reactions, respectively, I_0 is the exchange current density, I the current density, η the overpotential, A the apparent transfer coefficient, A^a and A^c are the apparent transfer coefficients of the opposing reactions, and F, R, and T have their usual meanings. At high overpotentials, the second terms in Eqs. 6 and 7 can be neglected in comparision with the large values of the first terms. Thus, Eqs. 6 and 7 can be simplified as follows:

$$I_c = I_{0c}\{\exp(-A_c n_c F\eta_c/RT)\}, \quad (6')$$

$$I_a = I_{0a}\{\exp(A_a n_a F\eta_a/RT)\}. \quad (7')$$

The logarithmic expression of Eqs. 6 and 7 gives a wellknown Tafel equation. When the overall faradaic current is equal to zero at $\eta=0$, $I_c=I_{0c}$, $I_a=I_{0a}$. If the electrode reactions are reversible on the Tafel line, $I_{0c}=I_{0a}$.

Exchange Current Densities (I_{0a}, I_{0c}). Plots of log I_a *vs.* η_a are shown in Figs. 2, 3, and 4 for the dissolution process at various temperatures and concentrations; similar relations, log I_c *vs.* η_c, are also represented in Figs. 2, 3, and 4 for the deposition process. The exchange current densities can be obtained from the figures stated above by extrapolation of I_a and I_c in the Tafel region to $\eta_a=0$ and $\eta_c=0$. The values of the exchange current densities thus obtained are tabulated in Table 1. It should be noted that $I_{0a}=I_{0c}$ in the concentration range of 2.00×10^{-4}—2.17×10^{-3} mole frac., and a slight difference between I_{0a} and I_{0c} was observed in the range of 5.90×10^{-2}—2.79×10^{-1} mole fraction. The accuracy of the exchange current densities was estimated to be ±0.2 mA/cm^2 at lower concentrations and ±2 mA/cm^2 at higher concentrations (5.90×10^{-2}—2.79×10^{-1} mole fraction).

The values of $A_a n_a$ and $A_c n_c$ were calculated from the slope of each straight line in Figs. 2, 3, and 4, and are given in Table 2. The n_a and n_c values can be calculated if the transfer coefficients A_a and A_c are determined.

Transfer Coefficients (A_a, A_c) and Kinetic Averaged Valences (n_a, n_c). If we can assume that the activity a^{4+} increases and the activity a^{2+} decreases as the anodic overpotentials for the anodic reaction rise, while for the cathodic reaction, the tendensy is reversed, these activities would vary proportionally to the total concentrations, C_o, which are expressed as mole fractions of the solute in the solution. The relation of log I_{0a} *vs.* log C_o, and that of log I_{0c} *vs.* log C_o gave two groups of straight lines, as shown in Figs. 5 and 6. Two values of the transfer coefficients were obtained, for the lower concentrations and for the higher one, respectively; these values are represented in Table 3. The values of n_a and n_c were calculated from the values in Tables 2 and 3, and given in Table 4.

Activation Energies (E_a, E_c). The apparent activation energies for the dissolution and deposition processes are calculated from the relationships between log I_{0a} and $1/T$ and that of log I_{0c} and $1/T$, according to the following equations:

$$I_{0a} = K\exp(-E_a/RT), \quad (8)$$

$$I_{0c} = K'\exp(-E_c/RT), \quad (9)$$

TABLE 2. $A_a n_a$ AND $A_c n_c$ VALUES

(B′) 5.90×10^{-2}	2.2	2.0	2.3	1.5	1.5
2.79×10^{-1}	3.3	3.2	2.6	2.4	2.1

The values in parentheses are uncertain. (A) Calculated by using a) values in Table 3. (B) Calculated by using b) values in Table 3. (A′) Calculated by using c) values in Table 3. (B′) Calculated by using d) values in Table 3.

where K and K' are the frequency terms, $-E_a$ and $-E_c$ the apparent activation energies for the dissolution and the deposition processes, respectively, and T is the absolute temperature. If the electrode reactions do not change at the experimental temperatures, the relationship between the exchange current densities and the reciprocal temperatures should be linear. In almost all the cases, the values above 850 °C deviate from the straight lines (775—825 °C), as seen in Fig. 7. Thus the temperatures were divided into two regions, 775—825 and 850—875 °C. The activation energies obtained are given in Table 5. The values of E_a and E_c calculated from the straight lines (850—875 °C) were usually larger than those of E_a and E_c (775—825 °C). This fact may suggest that the complex ion[15,16] $[TaCl_6]^{2-}$ is stable at 775—825 °C and decomposes at above 850 °C.

Reaction Mechanism. The electrode reactions on the Tafel line were illustrated by Eq. 5. The stable ions related to the electrode reactions were Ta^{2+} and Ta^{4+} ions. According to Eq. 5, the activity of a_2 decreases and that of a_4 increases with rising overpotentials for the anodic process. For the cathodic process, the

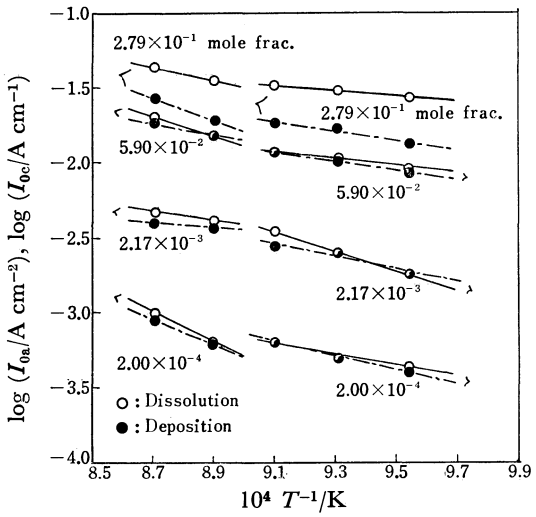

Fig. 7. Relationship between exchange current densities and $1/T^{-1}$/K.

Table 5. Activation energies (E_a, E_c)

	(kcal/mol)			
2.00×10^{-4}	18.8	27.6	21.6	39.1
2.17×10^{-3}	26.7	(11.5)	19.2	(4.6)
5.90×10^{-2}	13.3	23.6	14.6	16.1
2.79×10^{-1}	(7.4)	18.4	14.2	(32.2)

The values in parentheses are uncertain. a) Calculated from the line (775—825°C). b) Calculated from the line (850—875°C).

opposite trend was observed. The transfer coefficients of $(1-A_c)$ values were chosen to calculate the n_a values, because the n_c values were greater than 5 when the A_c values were used. Therefore, the $(1-A_c)$ will be inserted into the first term and the A_c values into the second term in Eq. 7. The replacement of A_c by $(1-A_c)$ can be ascribed to the relation $(1-A)\eta+A\eta$ in Eq. 5. In other words, the $(1-A_c)\eta_c$ will be assigned to the Ta^{2+} ion and the $A_c\eta_c$ to the Ta^{4+} ion in the cathodic process.

At lower concentrations, 2.00×10^{-4}—2.17×10^{-3} mole frac., the Tafel relation was established at relatively high overpotentials as seen in Figs. 2, 3, and 4. At higher concentrations, 5.90×10^{-2}—2.79×10^{-1} mole frac., it was established at comparatively low overpotentials. Thus the electrode reactions at lower concentrations will correspond to Eq. 3′ and those at higher concentrations to Eq. 3.

The author wishes to express his thanks to Professor Tomoo Kirihara of Nagoya University for his helpful discussions.

New 1-ethyl-2-[(2-substituted 3-oxoisoindolin-1-ylidene)methyl]-pyridinium or quinolinium iodide merocyanine dyes were obtained by the reaction of 2-methyl quaternary salts with *N*-substituted phthalimide in the presence of piperidine. 1-Ethyl-2-[(1-substituted 5-oxo-3-pyrrolin-2-ylidene)methyl] quinolinium iodide merocyanines were also prepared. Structural configuration of the synthesised compounds was confirmed by IR and UV spectral determination. 1-Ethyl-2-[[3-oxo-2-(4-phenylthiazol-2-yl)isoindolin-1-ylidene]methyl]-quinolinium iodide has high bactericidal activity againsist *E.Coli*, *Staphylococcus Aureus*, and *Staphylococcus Albas*.

Extensive studies have been made on the preparation and application of merocyanine dyes since their discovery in 1933.[1] In photography, they are widely used as photosensitisers,[2-8] in the production of direct positive photographic emulsions,[9,10] colour films[11-13] electron acceptors,[14] filter dyes,[14,15] and as sensitisers in photoconductive zinc oxide.[16] Phthalimidine dyes of good fastness were patented as dyestuffs for acrylonitrile fibers.[17]

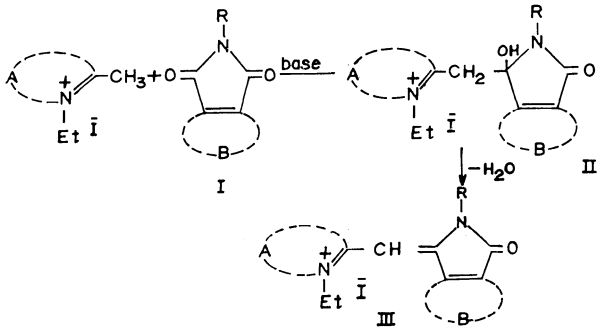
New merocyanine dyes (III-1—22) were prepared. Interaction of 2-methyl quaternary salts with *N*-substituted imides in the presence of piperidine afforded the corresponding compounds (III-1—22) *via* the intermediate (II) which could be separated as colourless needles by the reaction of 1-ethyl-2-methylpyridinium-iodide with *N*-phenylphthalimide. The intermediate (II) is readily soluble in ethanol and in concentrated sulfuric acid from which iodine was liberated on heating. Its IR spectrum revealed an absorption band at 3450 cm^{-1} attributed to –OH group. Dehydration of II to 1-ethyl-2-[(3-oxo-2-phenylisoindolin-1-ylidene)methyl]pyridinium iodide (III-1) was carried out in several ways:

a) Thermal dehydration above melting point.

b) Acid treatment of its ethanolic solution using hydrochloric acid (1 : 1).

c) Prolonged reflux under the reaction conditions and leaving the reaction mixture at room temperature for several days.

The reaction is illustrated as follows:



II. A=Pyridine, R=C_6H_5–, B=C_6H_4–.

III. A=Pyridine, B=C_6H_4–.
1: R=C_6H_5–, 2: R=*p*-CH_3-C_6H_4, 3: R=*p*-CH_3O-C_6H_4, 4: R=*p*-NO_2-C_6H_4, 5: R=*p*-Cl-C_6H_4, 6: R=α-$C_{10}H_7$.

III. A=Quinoline, B=C_6H_4–.
7: R=C_6H_5–, 8: R=*p*-CH_3-C_6H_4, 9: R=*p*-CH_3O-C_6H_4, 10: R=*p*-Cl-C_6H_4, 11: R=*p*-NO_2-C_6H_4, 12: R=*o*-CH_3-C_6H_4, 13: R=*o*-CH_3O-C_6H_4, 14: R=*o*-Cl-C_6H_4, 15: R=α-$C_{10}H_7$, 16: R=β-$C_{10}H_7$, 17: R=CH_2COOH, 18: R=4-phenylthiazol-2-yl.

III. A=Quinoline, B=H.
19: A=*p*-CH_3-C_6H_4, 20: R=*p*-CH_3O-C_6H_4, 21: R=*p*-NO_2-C_6H_4, 22: R=α-$C_{10}H_7$.

Infrared absorption spectra of the newly synthesized compounds showed an absorption band at 1740—1720 cm^{-1} attributed to the carbonyl group >C=O and

another band at 875 cm^{-1} attributed to the terminal double bond on ring -CH=C<. Disappearance of the -NH absorption bands characteristic to the -NH group indicates the disrupture of the *N*-substituted imides.

Absorption spectra of III-1—III-22 showed mainly two or three absorption bands in the UV region; their positions and molar extinction coefficient are dependent on the type of *N*-substituted imides, as well as on that of the quaternary heterocyclic nuclei. The results are given in Tables 1, 2, and 3.

The merocyanine dyes, 1-ethyl-2-[(2-substituted 3-oxoisoindolin-1-ylidene) methyl] quinolinium iodides III-7—III-18 posses mainly two absorption bands in the visible region. Their position and molar extinction coefficient are influenced by the type of *N*-substituents on phthalimide moiety. Thus III-7 possesses two absorption bands at λ_{max} 545 nm, ε_{max} 4000 and another CT band at λ_{max} 582 nm, ε_{max} 5000. Introduction of an electron releasing group to the *p*-position of *N*-phenyl group, causes a red shift which is attributed to the increase of the coplanarity of the molecule (III-8 and III-9).

On the other hand, introduction of an electron withdrawing group to the same position causes a blue shift, (III-10 and III-11). Introduction of the same substituent to the *ortho*- position of *N*-phenyl group causes a blue shift as compared to its *para* isomer (III-8 and III-12; III-10 and III-14), probably due to a hindered rotation of the phenyl ring caused by the *ortho* substituent.

Substitution of the *N*-phenyl moiety with α-naphthyl group causes a blue shift by 26 nm (III-15), whereas the substitution with β-naphthyl group causes a red shift by 22 nm (III-16).

The spectrum of III-18 possesses only one absorption band in the ultraviolet region and two absorption bands in the visible region (Table 3).

Experimental

The IR spectra were determined with a Unicam SP 1200 spectrophotometer using KBr disk wafer technique; absorption spectra in the UV-visible region in ethanol 95% were recorded on a SP 8000 recording spectrophotometer. All melting points are uncorrected.

Preparation of N-*Substituted Phthalimide or Maleimide Derivatives.*[18] A mixture of equimolar proportions of phthalic anhydride (or maleic anhydride) and the amino compound was refluxed in the presence of glacial acetic acid for about 1 h. The product obtained was filtered off and washed with sodium hydrogencarbonate solution, except in the case of glycine when the product was washed with water, then with a few-ml ethanol. The compounds obtained were identical with that reported in litrature, except for the new molecules not reported *e.g. N*-(4-phenylthiazol-2-yl)phthalimide, mp 115—116 °C.

Synthesis of 1-Ethyl-2-[(1-hydroxy-3-oxo-2-phenylisoindolin-1-yl)methyl]pyridinium Iodide (II). Equimolar proportions (0.001 mol) of 1-ethyl-2-methylpyridinium iodide and *N*-phenylphthalimide were dissolved in ethanol (50 ml) to which piperidine (0.5 ml) was added. The mixture was refluxed for 1 h and concentrated to about 15 ml and allowed to cool. Colourless needles precipitated. The product (II) was filtered off, washed with ether and crystallized form aqueous ethanol (1:1) to give colourless needles, mp 156—157 °C. Found: C, 55.62; H, 4.39; N, 5.77, I, 26.5%. Calcd, for $C_{22}H_{21}N_2O_2I$: C, 55.58; H, 4.42; N, 5.89; I, 26.73%

Dehydration of the Intermediate (II). *Thermal Dehydration*: The intermediate was heated at 165—168 °C for 5 min. On colling, orange product was obtained. This was crystallized from dioxane to give orange needles (mp 178 °C).

Acid Treatment: A mixture of II, (0.5 g), ethanol (10 ml) and hydrochloric acid (1 : 1, 10 ml) was allowed to stand for 7 days. Fine orange needles were separated. The product was filtered off, washed with water and few ml of aqueous ethanol (1:1), then crystallized from dioxane to give orange needles, mp with an authentic sample 178 °C.

Prolonged Reflux. A mixture of II (0.5 g), ethanol (10 ml), and piperidine (0.5 ml) was refluxed for 18 h on a water bath. The reaction mixture was concentrated to about 5 ml and allowed to stand at room temperature for 8 days. Orange needles were precipitated. The product (III-1) was collected, washed with ethanol, and crystallized from dioxane to give orange needles, mp and mixed mp 178 °C.

Synthesis of 1-Ethyl-2-[(2-aryl-3-oxoisoindolin-1-ylidene)methyl]pyridinium Iodides, III-1—III-6. A mixture of 1-ethyl-2-methylpyridinium iodide (0.0015 mol), N-arylphthalimide (0.001 mol), ethanol (50 ml), and piperidine (1 ml) was refluxed on a water bath for 14 h. The reaction mixtures were left aside for several days (6—8 day). Coloured crystalline merocyanine dyes III-1—III-6 were deposited. They were filtered off, washed with ether and crystallized from the appropriate solvent. The results are given in Table 1.

Synthesis of 1-Ethyl-2-[(2-substituted 3-oxoisoindolin-1-ylidene)-methyl]quinolinium Iodide Merocyanine Dyes, III-7—III-18. A mixture of 1-ethyl-2-methylquinolinium iodide (0.0012 mol), *N*-substituted phthalimide (0.001 mol), ethanol (50 ml), and piperidine (0.5 ml) was refluxed for 1 h. The mixture was concentrated to about 20 ml and the products were precipitated by addition of water, filtered off, washed with water and then with ether, and crystallized from the appropriate solvent. The results are given in Table 2.

Synthesis of 1-Ethyl-2-[(1-aryl-5-oxo-3-pyrrolin-2-ylidene)-methyl]quinolinium Iodides, III-19—III-22. Equimolar proportions (0.005 mol) of 1-ethyl-2-methylquinolinium iodide, *N*-arylmaleimide, and piperidine (1 ml) in ethanol (50 ml) were refluxed on a water bath for 1 h. The products III-19—III-22 which were precipitated after concentration and dilution with water, were filtered off and crystallized from appropriate solvent. The results are given in Table 3.

Bactericidal Activity of 1-Ethyl-2-[[3-oxo-2-(4-phenylthiazol-2-yl)isoindolin-1-ylidene]methyl]quinolinium Iodide (III-18). The culture medium was normal nutrient agar (NA) medium[19] supplemented with one gram of yeast/litre. The bacterial suspension was prepared by adding one ml of sterile distilled water to a 24 h old culture of the test organism grown on NA slant. One ml aliquots of bacterial suspension were added to Erlenmeyer flasks containing 150 ml of NA and the flasks were incubated for 24 h.

Petri dishes containing sterile modified NA were flooded with the bacterial suspension of the test organisms (2 plates for each organism). Two filter paper discs (one cm diameter) containing merocyanine dye (III-18) dissolved in ethylene glycol (15 mg/l.) were placed on each plate. The plates were incubated at 37 °C for 24 h and the diameter of the inhibition zone was measured. The experiments were repeated 3 times and the results were averaged. Pathogenic bacterial strains *E. Coli*, *Staphylococcus Aureus*, and *Staphylococcus Albas* were supplied by Veterinary Hospital, Ministry of Agriculture, Assiut, Egypt and tested at the Botany Department, Faculty of Science, Assiut University. The results showed remarkable activity towards the tested organisms.

The Ring Transformation of Tetrahydrofuran into 1-Propylpyrrolidine over Y-Zeolites

Kou HATADA, Katsuhiro FUJITA, and Yoshio ONO*

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 13, 1978)

Synopsis. The catalytic activities of Y-zeolites for the synthesis of 1-propylpyrrolidine from tetrahydrofuran and propylamine were examined. Aluminum cation exchanged zeolite was found most active, 65% yield of 1-propylpyrrolidine being attained at 360 °C. The kinetics of the reaction was examined and the reaction mechanism suggested.

The ring transformation of tetrahydrofuran (THF) into 1-alkylpyrrolidine proceeds over alumina.[1-2] Reppe and coworkers obtained 1-ethylpyrrolidine in 61% yield by the reaction of THF and ethylamine at 300 °C for 6 h over ThO_2-promoted alumina.[2] Synthetic zeolites are effective catalysts for the ring transformations of γ-butyrolactone into 1-alkyl-2-pyrrolidinones,[3] and THF into pyrrolidine.[4] This note reports that zeolites are effective also for the ring conversion of THF into 1-alkylpyrrolidine: Tetrahydrofuran is converted into 1-propylpyrrolidine by the reaction with propylamine over zeolites with a flow reactor under atmospheric pressure.

Experimental

THF and propylamine were distilled prior to each run. NaY zeolite (Linde Division of Union Carbide Corp.) was used. Various forms of Y-zeolites were prepared by the conventional cation exchange procedure using aqueous solution of the corresponding salt. The cation exchanged zeolites were pelleted without binder and crushed and sized into 9—16 mesh. A continuous flow reactor was used under atmospheric pressure. A silica tube (13 mm i.d.) placed in a vertical furnace was used as a reactor. The reactants were pumped into the preheating zone of the reactor containing 10 ml quarts powder. Nitrogen used as a diluent for regulating the initial pressure of the reactants was fed through a flow meter. Reaction products collected in the reciver were taken out at certain intervals during the course of run and analyzed by gas chromatography.

Results and Discussion

The reaction of THF and propylamine was carried out at 300 °C and at W/F=5.56 g h mol^{-1} (W is the weight of catalyst and F the molar flow rate), and the catalytic activities of the various cation forms of Y-zeolites for the ring conversion were examined. The results (Table 1) show that HY and zeolites with trivalent cations except CeY have high activity. Of the zeolites studied, the selectivity to 1-propylpyrrolidine was the highest with AlY, further study thus being made exclusively with AlY.

Figure 1 shows the temperature dependence of the

TABLE 1. ACTIVITY AND SELECTIVITY FOR THE REACTION OF THF AND PROPYLAMINE OVER VARIOUS Y-ZEOLITES

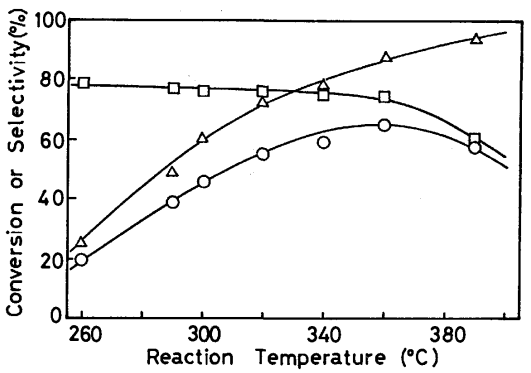

Fig. 1. Effect of reaction temperature on the catalytic behavior of AlY in the reaction of THF and propylamine (△): conversion of THF, (○): yield of 1-propylpyrrolidine, (□): selectivity to 1-propylpyrrolidine.

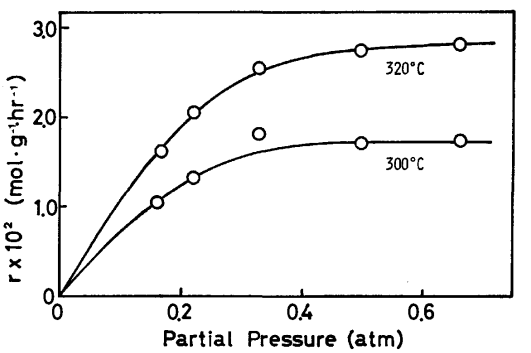

Fig. 2. Dependence of the reaction rate on the partial pressure of propylamine; W/F=2.78 g h mol^{-1}, P_{THF} =0.232 atm.

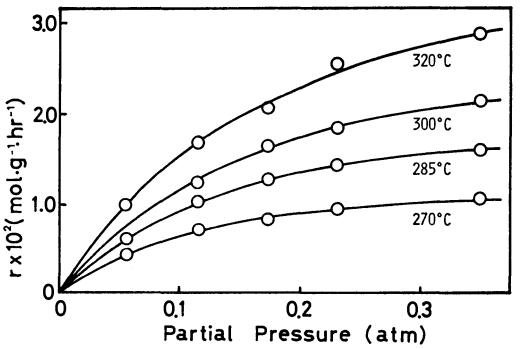

Fig. 3. Dependence of the reaction rate on the partial pressure of THF; $W/F=2.78$ g h mol^{-1}, $P_A=0.334$ atm.

THF conversion, the yield of and the selectivity to propylamine. The maximum yield of propylamine was obtained at 360 °C. A constant selectivity of 75% was obtained in the temperature range upto 360 °C, but the selectivity fell at 380 °C. No attempt was made to identify the byproducts.

The kinetics of the reaction was studied with AlY as a catalyst in the temperature range 270—320 °C under small contact time conditions. Figures 2 and 3 show the dependence of the reaction rate on the partial pressures of propylamine (P_A) and THF (P_{THF}), respectively. In both cases, the rate increases with an increase in the partial pressure of the reactants. The rate (r) is given by

$$r = k \cdot \frac{K_A P_A}{1+K_A P_A} \cdot \frac{K_{THF} P_{THF}}{1+K_{THF} P_{THF}}, \quad (1)$$

where k is the rate constant, and K_A and K_{THF} are the adsorption equilibrium constants of propylamine and THF, respectively. The plots of P_A/r against P_A and P_{THF}/r against P_{THF} give straight lines. The constants k, K_A, and K_{THF} are determined unequivocally. From the temperature dependence of the constants, the activation energy of the reaction, the heats of adsorption of propylamine and THF are determined to be 16 kcal mol^{-1} and 6 kcal mol^{-1}, respectively.

In a previous work,[3] a rate expression similar to Eq. 1 was obtained for the reaction of γ-butyrolactone and propylamine. A mechanism was proposed, in which the lactone and the amine are adsorbed on the metal cation (or proton) and zeolitic oxygen anion, respectively, the reaction of the adsorbed reactants being concluded as the rate determining step.

A similar mechanism may be applied to the reaction of THF and propylamine. Propylamine molecules are adsorbed and dissociated by oxygen anions, while THF molecules open the ring by the interaction with protonic sites, as has been assumed for the reaction of THF and ammonia.[4,5] The fact that the heat of adsorption of propylamine obtained from the kinetics of its reaction with THF (10 kcal mol^{-1}) agrees with that obtained from the kinetics of its reaction with γ-butyrolactone (9.9 kcal mol^{-1})[3] supports the essential similarity of the mechanism of the two reactions.

The Intrinsic Viscosity of Poly(4-vinylpyridine) of a Low Molecular Weight

Yoshiyuki HIRAI* and Taira YANAGIDA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received February 13, 1978)

Synopsis. The intrinsic viscosities of poly(4-vinylpyridine) ($\bar{M}_n$: 1.37×10^3—9.67×10^4) were measured by use of various solvents. For every solvent, $\log[\eta]$-$\log\bar{M}_n$ plots gave lines with a slope of 1/2 in the region of low molecular weights ($\bar{M}_n\leq10^4$). These lines were parallel to one another. This viscosity behavior was interpreted in terms of the influence of solvents on short-range interactions in the polymer chains.

Many studies[1] of the intrinsic viscosities of polymers have shown that, in a region of low molecular weights, the equation $[\eta]=K_0M^{1/2}$ holds in spite of measurements made using good solvents. Here, the constant, K_0, appeared to be independent of the kind of solvent; its value was near that of K_θ, namely, $K_0M^{1/2}\approx K_\theta M^{1/2}$. These experimental facts suggested the possibility of the evaluation of characteristic dimensions from viscosity measurements of polymers of low molecular weights in good solvents. However, the polymer–good solvent systems so far examined have been mainly nonpolar polymer–nonpolar solvent systems, and so the investigation of other systems, such as polar polymer–polar solvent systems, and a better-defined interpretation of the viscosity behavior described above were desired.

On the other hand, a theoretical treatment of the viscosities of short chains (polymers of low molecular weights) was reported by Perico and Rossi.[2] They showed, for some polymer–good solvent systems, that the intrinsic viscosities of short chains could be evaluated from the model of independent hindered rotation by introducing "thickness b" by a parameter.

In the present study, the poly(4-vinylpyridine)–good solvent system is adopted as a specific polymer–solvent system, in which strong polymer-solvent interactions are presented; this polymer–solvent system is a polar polymer–polar solvent system. For such a system the relation of $[\eta]$-M is examined, and the origin of the viscosity behavior of $[\eta]=K_0M^{1/2}$ is investigated by using the theory by Perico and Rossi.[2]

Experimental

Samples of poly(4-vinylpyridine) of various molecular weights were prepared by radical polymerization (monomer: 10 ml, chloroform: 50 ml, α,α'-azobisisobutyronitrile, 60 °C); the polymers were recovered by precipitation in petroleum ether. The average molecular weights of these polymer samples ranges from 1.37×10^3 to 9.67×10^4 (average degrees of polymerization, $\overline{DP}$: 13.1—921). The moleculat weights were determined using a "KUNAUAR vapor-pressure osmometer and membrane osmometer" in chloroform solutions at 37 °C; the vapor-pressure osmometric method was applied to polymer samples of $\bar{M}_n\leq1.32\times10^4$, and the membrane osmometric method, to those of $\bar{M}_n\geq1.32\times10^4$. For these samples, no fractionations were carried out. However, it would have no significant influence on the present discussion because the present investigation is concerned only with the discussion of the dependence of curves of $[\eta]$ plotted against molecular weight on solvents.

The solvents used in the viscosity measurements were methyl alcohol, chloroform, and *t*-butyl alcohol. Ethyl methyl ketone/isopropyl alcohol (85/15 by wt) was also used as a relatively poor solvent (the expansion coefficient for the mixed solvent at 25 °C was evaluated as 1.06 in the viscosity study of poly(4-vinylpyridine) by Boyes and Strauss[3]). These solvent were purified by means of the usual method. The intrinsic viscosities were measured by use of the viscometers of the Ubbelohde type, the efflux times of which were 248.3, 214.1, 352.7, and 277.3 s for methyl alcohol, chloroform, *t*-butyl alcohol, and ethyl methyl ketone/isopropyl alcohol respectively. In the measurements, the temperature of water bath was maintained at 30±0.01 °C, and the efflux time was measured with a stopwatch reading to an accuracy of 0.1 s.

Results and Discussion

Plots of log $[\eta]$ *against log* M. Figure 1 shows the plots of log $[\eta]$ against log $\bar{M}_n$ for poly(4-vinylpyridine) in various solvents at 30 °C (the points for chloroform solutions fall on the line for methyl alcohol solutions; therefore, they are omitted in Fig. 1). In every case, the slope of the line decreases with a decrease in the molecular weight and becomes 1/2 in the region of molecular weights below 10^4.

For the poly(4-vinylpyridine)–good solvent system, as well as for the polymer–good solvent systems[1] examined previously, a slope of 1/2 is observed in the region of low molecular weights. However, the behavior of the lines with a slope of 1/2 is distinct from the previous observations[1] for various polymers; the lines with a slope of 1/2 for poly(4-vinylpyridine) are not concentrated on a line, but are parallel to one another.

The present data clearly indicate that the phenomenon of the slope of 1/2 is not associated with the θ state. The phenomenon should be attributed, rather, to the disappearance of long-range interactions resulting from the decrease in the molecular weights.

EMK/*i*-PrOH	4.5	1.1

Intrinsic Viscosity of Polymers of Low Molecular Weights. According to the theory of Perico and Rossi[2] for short chains,

$$[\eta] = \phi 6^{3/2}(R_s^3/M), \quad (1)$$

$$R_s = (\langle S_0^2 \rangle)^{1/2} + b, \quad (2)$$

where the constant, b, is the "thickness" of the polymer chains. ϕ is a hydrodynamic parameter, and it takes an almost constant value (2.87×10^{21}) for the carbon-number of the backbone (N_c)>20. $\langle S_0^2 \rangle$ is the mean-square radius of gyration.

Table 1 shows the results of applying Eqs. 1 and 2 to poly(4-vinylpyridine) ($\bar{M}_n \leq 10^4$) in methyl alcohol. In the calculation, 2.87×10^{21} was used as the value of ϕ. $\langle S_0^2 \rangle$ was calculated by assuming an independent hindered rotation in the rotational-isomeric model; in Table 1, ΔE represents the energy of the gauche state relative to the trans in the model of independent hindered rotation. Figure 2 shows the experimental viscosities and calculated curves for the methyl alcohol, *t*-butyl alcohol, and ethyl methyl ketone (EMK)/isopropyl alcohol solutions (the points for chloroform solutions are omitted). Figure 2 indicates that the viscosities for the region of low molecular weights can be calculated by choosing the appropriate values of b and ΔE. The b and ΔE values yielding the best-fit curves are summarized in Table 2. The values of b are quite great (the size of the pyridine ring: about 3 Å), while the magnitudes of ΔE are acceptable.

The pyridine ring of poly(4-vinylpyridine) behaves as an electron donor, while methyl alcohol and chloroform can behave as electron acceptors. These solvents could be solvated to the polymer. *t*-Butyl alcohol is known to form hydrogen bonds with poly(4-vinylpyridine)[3] (*t*-butyl alcohol is the most bulky among the solvents used in the present experiments). The solvation power for ethyl methyl ketone/isopropyl alcohol is weaker than that for the other solvents in the present experiments. The solvation and hydrogen bonding must result in the increase in the values of b, and may be effective in the increase of ΔE.

The values of b and ΔE in Table 2 can be well interpreted by considering the solvation and hydrogen bonding (polymer-solvent interaction) described above.

The viscosity data for any other polymer (low molecular weight)–good solvent system could also be explained in a similar manner.

On the basis of the above results and considerations, we can draw a conclusion regarding the polymers with low molecular weights (short chains) in solutions. The long-range interactions are ineffective in the polymers with low molecular weights. The conformations of the short chains are governed by the short-range interactions, in which polymer-solvent interactions are taken into account. The polymer-solvent interactions can be estimated in terms of b and ΔE. In the case of the systems in which the polymer-solvent interactions depend strongly on the solvents, parallel lines with a slope of 1/2 (this means $K_0 M^{1/2} \fallingdotseq K_\theta M^{1/2}$) are observed, and the dependence of b and ΔE on the solvents is detected.

The data for the poly(ethylene oxide) glycol-good solvent system[1,4] rather resemble the present observations. However, the polymer-solvent interaction in this system would be weak in comparison with that in the present system. As a result, the data were treated much like the data for various other polymer-good solvent systems.[1]

In the meantime, it has been pointed out, on the basis of various experiments[5] on polymers with low molecular weights, that the conformations and internal motion of short chains in solutions are somewhat different from those of polymers with high molecular weights. The conclusion derived in the present study would be useful for discussing such problems.

Pore Structure of Iron Oxides

Mahiko NAGAO,* Yasuhiro YOKOTA, and Tetsuo MORIMOTO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received February 20, 1978)

Synopsis. The pore structure of iron oxides, subjected to oxidation into α-Fe_2O_3 as well as reduction into Fe_3O_4, was investigated by means of the *t*-method. The results show that the reduction is accompanied by the formation of slit-shaped pores, width 14 Å, open at both ends.

The mechanism of solid reaction is one of the most incomprehensible problems. The surface chemistry of intermediate and final products will shed light on this problem. de Boer and Lippens[1] investigated the process of thermal decomposition of boehmite and bayerite. They developed the *t*-method and applied it to the N_2-adsorption data, and found the formation of slit-shaped pores during the course of decomposition reaction. The *t*-plots are constructed by plotting the amount of adsorbed nitrogen on a sample against the statistical thickness *t* of the adsorbed layer of nitrogen on a nonporous reference solid. The choice of reference *t*-curve, therefore, is important. Cranston and Inkley[2] and Lippens *et al.*[3] each used a definite standard *t*-curve. Other researchers selected the reference curve from the data on specimens of the same substance.[4,5]

It is known that α-Fe_2O_3 can be reduced to Fe_3O_4 in a mixed gas of H_2 and H_2O, the reverse reaction taking place in O_2 at high temperatures.[6] The purpose of the present work is to investigate the surface chemistry of iron oxides produced by oxidation and reduction, by measuring the N_2-adsorption isotherms and converting them into *t*-plots.

Experimental

The sample of iron oxide was prepared by oxidizing iron rods (purity 99.99%) at 600 °C in an electric furnace. It was ground, heated at 1400 °C for 2 h and evacuated at 1100 °C for 2 h in a vacuum of 1×10^{-3} Pa (sample S). From this sample, four kinds of iron oxides with different compositions were prepared in the following way. Sample H was obtained by oxidizing sample S in O_2 at 300 °C for 48 h, during which time the amount of O_2 taken up was measured. Sample S was reduced with a mixture of H_2 and H_2O (4: 1), the ratio being selected to be suitable for the formation of Fe_3O_4 on the equilibrium phase diagram,[6] at 400 °C for 48 h ,the H_2-uptake being measured (sample M). The other two samples were prepared by reducing sample H as well as by oxidizing sample M under the same conditions as described above. The reactions were continued until the composition of the products gave α-hematite and magnetite in a 1: 1 ratio, from measurement of the amount of absorbed H_2 or O_2 (samples Ih and Im). X-Ray analysis showed that samples H and M are α-hematite and magnetite, respectively, samples S, Ih, and Im being mixtures of them. From the amounts of absorbed O_2 and H_2 when samples H and M were produced, the composition of sample S was found to be 70% α-hematite and 30% magnetite. α-Fe_2O_3 prepared by the calcination of iron(II) sulfate was used as a nonporous reference material.[7]

Prior to the adsorption experiments, *ca.* 20 g of the sample was degassed at 600 °C for 4 h in a vacuum of 1×10^{-3} Pa in order to remove surface impurities such as chemisorbed water and carbon dioxide. Nitrogen adsorption isotherms were measured volumetrically at −196 °C.

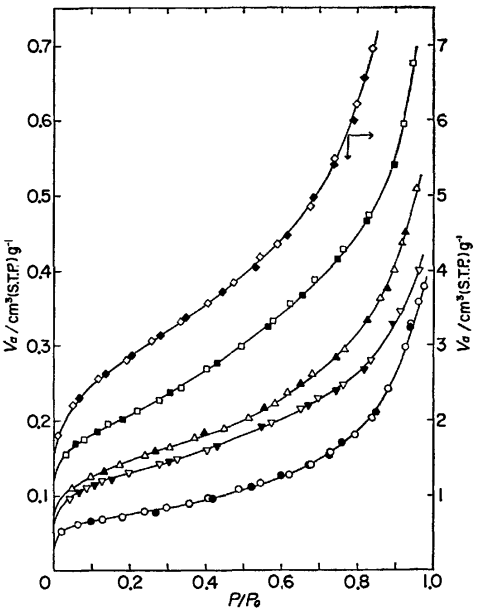

Fig. 1. N_2-adsorption isotherms on iron oxide samples. Sample S, ○; M, □; Ih, ▽; Im, △; preparation (II), ◇ (see the text). Filled points represent desorption.

Results and Discussion

Figure 1 shows the adsorption isotherms of N_2 on iron oxide samples. The isotherm for sample H was almost the same as that for sample S. Desorption isotherm was also measured, the result being consistent with the adsorption branch in the whole pressure range studied. The BET surface area (S_{BET}) is calculated as given in Table 1. It should be noted that oxidation and reduction treatment of iron oxide regularly alter the adsorbability of nitrogen molecules, *i.e.*, the specific surface area of the samples; the amount of adsorbed nitrogen increases in the course of the reduction of oxide, but decreases as the oxidation proceeds. This suggests that the reduction of iron oxide into Fe_3O_4 having the spinel structure is accompanied by the formation of pores in the products.

First, the *t*-plots were constructed on the basis of the standard *t*-curve of Lippens *et al.*[3] and that of Cranston and Inkley.[2] However, they did not give a straight line through the origin, showing disagreement with the BET area S_{BET}. The discrepancy between the *C*-value in the BET equation on a sample and that on the reference solid seriously affects the trend of

Table 1. BET C-VALUES AND SURFACE AREAS OF IRON OXIDE SAMPLES

Sample	C-value	Surface area ($m^2 g^{-1}$)		
		S_{BET}	S_t	S_{out}[a]
S	160	0.271	0.271	—
M	146	0.745	0.739	0.526
Ih	135	0.460	0.460	0.315
Im	140	0.518	0.518	0.397

a) S_{out} represents the outer surface area obtained from the t-plots ($t > 7$ Å).

t-plots.[8] In order to get an appropriate reference t-curve from the data on related substances, a nonporous α-Fe_2O_3 prepared by calcining iron(II) sulfate was treated as follows: evacuation at 600 °C for 4 h (I), followed by rehydration (II), calcination at 800 °C for 4 h and subsequent evacuation at 600 °C for 4 h (III), followed by rehydration (IV). The C-values in the N_2-adsorption isotherm on these preparations were found to be 124, 169, 243, and 253, respectively. We adopted the data on preparation (II) as the reference curve, because of the consistency of the C-value with that of the present samples (Table 1).

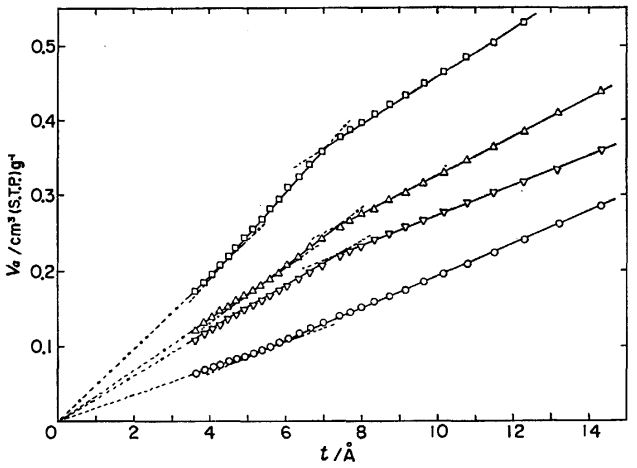

Fig. 2. t-Plots for N_2 adsorption on iron oxide samples. Sample S, ○; M, □; Ih, ▽; Im, △.

Figure 2 shows the t-plots for iron oxide samples subjected to oxidation or reduction treatment. In all cases the first part of the curves is in a straight line through the origin. The surface area S_t can be calculated from the slope of the straight line,[1] being in good agreement with S_{BET} (Table 1). Since S_t is a function of a particular t-curve employed, the agreement between S_t and S_{BET} is a good indicator for the validity of the reference t-curve.[8]

Sample S gives a straight line through the origin up to $t \approx 5$ Å, followed by a separate line with a greater slope. Although an upward deviation from the initial straight line represents a capillary condensation in pores,[1] no hysteresis appears in the isotherm of this sample. This might be due to reversible capillary condensation in wide and slit-shaped pores open at both ends.[9] A remarkable increase in surface area for sample M produced by reduction of sample S suggests the sample to be fairly porous. The t-plots for sample M consist of three straight lines: the first one up to $t \approx 4$ Å, the second one between 4 and 7 Å, and the last one beyond 7 Å. The former two of the three lines might correspond to the monolayer adsorption onto outer and inner surfaces, and the reversible capillary condensation in slit-shaped pores open at both ends, respectively, as on the sample S. Taking account of the density of liquid nitrogen at −196 °C, we obtain the monolayer thickness to be 3.54 Å.[3] Thus, since the pores would be filled when the thickness of the adsorbed layer is equal to half the width of pores, the width is found to be 14 Å. The last line indicates the adsorption in the wider pores as well as on the outer surface, the area calculated from this slope being 0.526 $m^2 g^{-1}$ (Table 1), which gives the inner surface area as 0.213 $m^2 g^{-1}$. The t-plots of sample Im obtained by partial oxidation of sample M have the same tendency as in the case of sample M. However, its surface area is less than the latter, because of partial closing of pores during the course of oxidation of Fe_3O_4. The inner surface of sample Im amounts to 0.121 $m^2 g^{-1}$, smaller than that of sample M. On the other hand, sample Ih shows a straight line with single break at $t \approx 7$ Å, indicating that the sample has pores accessible to nitrogen molecules in two statistical layers. This sample was obtained by partial reduction of sample H prepared by exhaustive oxidation of sample S having wide and slit-shaped pores. It appears evident that such pores were made in the course of reduction, since no change in S_{BET}-value was observed in the oxidizing process as stated above.

Thus, it is concluded that the reduction or oxidation of iron oxide is accompanied by the formation or closing of pores. The fact that the t-plots reveal distinct breaks at two definite t-values indicates the formation of pores of a regular size during the course of conversion into spinel structure. An increase either in the number or in the depth of such pores in the course of the reduction treatment will lead to an increase in surface area. The presence of pores might also lead to an elongation of the adsorption time of water.[10]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (8), 2425—2426 (1978)

Syntheses of 5-Hydroxyflavone-Transition Metal Complexes

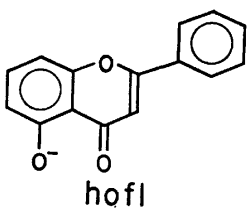
Katsuma HIRAKI,* Masayoshi ONISHI,* Tsuyoshi IKEDA,
Kazuko TOMIOKA, and Yayoi OBAYASHI

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received January 30, 1978)

Synopsis. New complexes $[M(hofl)_2(OH_2)_n]$ (Hhofl=5-hydroxyflavone; M=Co and Ni, $n=2$; M=Cu, $n=1$ and 0) and $[M(hofl)_3]$ (M=V and Fe) were synthesized and characterized by IR and electronic absorption spectroscopy. Polynuclear ethoxo(5-hydroxyflavonato)metal(II) complexes of cobalt and copper were also prepared.

Many hydroxyflavone derivatives are distributed widely in plants.[1,2] Morin and quercetin have been used as reagents for colorimetric and fluorescent analyses of metals.[3] The analyses are based on the chelating ability of the hydroxyflavones with metals.[4-7] However, hardly any work has been reported as regards isolation and characterization of the hydroxyflavone–metal complexes.



hofl

This note deals with the syntheses and properties of some new transition metal complexes with 5-hydroxyflavone (Hhofl), one of the simplest model compounds of hydroxyflavones.

Experimental

Materials. 5-Hydroxyflavone was synthesized from 2,6-dihydroxyacetophenone according to the method of Looker *et al.*,[8] and identified by elemental analysis, melting point and IR spectrum. Commercial metal chlorides were used without further purification. Solvents were dried by the usual methods and distilled.

General Procedure. IR and electronic spectra were measured on Hitachi 285 and 323 spectrometers, respectively. Melting points were determined on a Yanagimoto MP-S3 microstage apparatus in capillary tubes and are uncorrected.

Preparation of Bis- or Tris(5-hydroxyflavonato)metal Complexes. 5-Hydroxyflavone (8.0 mmol) and nickel(II) chloride (3.0 mmol) were mixed in ethanol. An ethanol solution of sodium acetate (10.0 mmol) was added to the mixture with stirring. After the reaction mixture had been refluxed for 4 h, the resulting precipitate was separated, recrystallized from benzene–hexane and dried *in vacuo* to give a yellow solid, $[Ni(hofl)_2(OH_2)_2]$ (yield 32%).

The complexes $[Co(hofl)_2(OH_2)_2]$, $[Cu(hofl)_2OH_2]$, and $[Cu(hofl)_2]$ were prepared similarly. Tris(5-hydroxyflavonato)metal(III) complexes of vanadium and iron were also prepared in a similar way except that anhydrous metal(III) chloride was used in place of divalent metal chloride.

Preparation of Ethoxo(5-hydroxyflavonato)metal(II) Complexes. An ethanol solution containing 5-hydroxyflavone (4.2 mmol) and sodium ethoxide (2.0 mmol) was added gradually to an ethanol solution of cobalt(II) chloride (2.0 mmol). The reaction mixture was refluxed for 3 h. The resulting precipitate was collected and washed with benzene and ethanol to afford a reddish brown solid, $[\{Co(OEt)(hofl)\}_n]$ (yield 63%). The complex, $[\{Cu(OEt)(hofl)\}_n]$ was prepared in a similar way.

Results and Discussion

The yields, properties, and the results of elemental analyses of the complexes are summarized in Table 1. Diaquabis(5-hydroxyflavonato)metal(II) and the tris(5-hydroxyflavonato)metal(III) complexes are soluble in usual organic solvents such as benzene and chloroform but not in hexane. The water content of the mononuclear copper(II) complexes changes with the heating temperature in the drying procedure. $[Cu(hofl)_2OH_2]$ and $[Cu(hofl)_2]$ were obtained by drying *in vacuo* at 125—135 °C for 2 h and at 150—160 °C for 5 h, respectively. No diaqua complex of copper(II) was obtained in a pure state.

The spectroscopic data are summarized in Table 2. IR spectra of the 5-hydroxyflavonato complexes show

Table 1. Yields and some properties of the 5-hydroxyflavone–transition metal complexes

ν(CO) bands, shifting towards a frequency lower by 14—35 cm^{-1} from that observed for free 5-hydroxyflavone, indicating that the 5-hydroxyflavonato ligand is coordinated to the metal ion as a bidentate chelate. Both $[Co(hofl)_2(OH_2)_2]$ and $[Ni(hofl)_2(OH_2)_2]$ are assigned to a tetragonal bipyramid structure in consideration of its composition, by analogy with diaquabis(salicylaldehydato)nickel(II) complex.[9] $[V(hofl)_3]$ and $[Fe(hofl)_3]$ are ascribed to pseudo-octahedral structures.

The mononuclear complexes of iron(III), cobalt(II), nickel(II), and copper(II) exhibit a strong electronic absorption band near 24000 cm^{-1}, virtually independent of the metal ion. The intensity of this band is too strong to be assigned to a d-d transition. The band is located at a wave number lower by *ca.* 5800 cm^{-1} than the minimum energy absorption band of free 5-hydroxyflavone. Each of the iron(III), cobalt(II), nickel(II), and copper(II) ions in a ground state has one or more unoccupied d-orbitals. This indicates that the absorption band near 24000 cm^{-1} is ascribed to a charge transfer from the 5-hydroxyflavonato ligand to the metal d-orbital.

On the other hand, $[V(hofl)_3]$ shows a strong absorption band at 17800 cm^{-1}, besides a very strong band above 21000 cm^{-1}. The intensity of these bands is so strong that it is unlikely that they are associated with the d-d transitions. The vanadium(III) ion with a d^2 configuration has a vacant d-orbital located at a lower energy level than the unoccupied d-orbitals of the nickel(II) and copper(II) ions. The band at 17800 cm^{-1} is assigned to a charge transfer from the 5-hydroxyflavonato ligand to the vacant low-lying d-orbital of the vanadium(III) ion, probably obscuring a low intensity band expected to appear at a similar wave number, owing to the d-d transition.[10]

The electronic spectra and the molecular weights of the ethoxo(5-hydroxyflavonato)metal(II) complexes could not be measured, because of the high insolubility in the usual organic solvents. These complexes are supposed to have polymeric structures, by analogy with alkoxo(salicylaldehydato)copper(II) and its related complexes.[11] Attempts to prepare ethoxo(5-hydroxyflavonato)nickel(II) were unsuccessful.

Syntheses and Properties of *gem*-Diolatotriarylantimony(V)

Akira OUCHI,* Fujio EBINA, Takashi UEHIRO, and Yukichi YOSHINO

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro, Tokyo 153

(Received February 15, 1978)

Synopsis. Titled compounds of the general formula $R_3Sb(R'R''CO_2)$ have been prepared, where R=phenyl, *p*-tolyl or *p*-chlorophenyl, R',R''=CF_3,CF_3; CF_3,H; or CCl_3, H. From the infrared spectra and ^{1}H-NMR data, the *gem*-diolato group appears to bond to the antimony bidentately through two oxygen atoms, as in the 1,1,1-trifluoro-4-oxo-2,2-pentanediolato complex of triarylantimony(V).

Trifluoroacetylacetone reacted with dibromotriarylantimony(V), to give a new type complex, where the β-diketone hydrated and acted as a terdentate.[1,2] In that complex, the ligand bonds to the antimony through one keto oxygen near the methyl group, and two *gem*-diolato oxygens of the hydrated carbonyl group next to the trifluoromethyl one. From the X-ray structure analysis, the bond between antimony and the keto-oxygen is weaker than the other two.[1] Consequently *gem*-diols are also expected to form stable complexes with organoantimony(V), working as a bidentate ligands and making four membered ring chelates. This paper reports the reaction between dibromotriarylantimony(V) and some *gem*-diols, such as chloral hydrate.

Experimental

Synthesis of (2,2,2-Trichloroethane-1,1-diolato)triphenylantimony-(V). Two grams (4 mmol) of dibromotriphenylantimony(V), which was synthesized by the standard technique,[3] and 2,2,2-trichloro-1,1-ethanediol (Wako Pure Chemical Co., Ltd., G. R. grade) (0.83 g, 5 mmol) were dissolved in benzene (20 ml). To the solution, triethylamine (1.0 g, 10 mmol) was added as a deprotonation reagent. After stirring for 1 h at room temperature, the precipitated triethylammonium bromide was filtered off and the filtrate evaporated to dryness using a rotary evaporator (60 °C, water pump). The residue was recrystallized from acetonitrile, the yield being about 1.5 g (75%) on average after one recrystallization.

Seven other kinds of complex having the same formula, $R_3Sb(R'R''CO_2)$, where R=phenyl, *p*-tolyl, or *p*-chlorophenyl, R',R''=CF_3,CF_3; CF_3,H; CCl_3,H; were synthesized by the same technique from the reaction between the appropriate dibromotriarylantimony(V) and hydrated hexafluoroacetone, 2,2,2-trifluoro-1-ethoxyethanol, or chloral hydrate. The products thus obtained were very stable in air at room temperature, and kept for several months without any decomposition. Attempts to synthesize this type of compound using dihalogenotrialkyl antimony(V), or a ketone such as hexachloroacetone, acetophenone, benzophenone, or acetone were not successful.

Infrared spectra of the samples were obtained by a JASCO infrared spectrophotometer, type 403G, using Nujol and hexachloro-1,3-butadiene mull, and ^{1}H-NMR by a JEOL JNM-MH-100 (100 MHz) NMR spectrometer using a 20% $CDCl_3$ solution at 26 °C with TMS as the internal standard. The mp and decomposition points were obtained by the simultaneous TG-DTA technique using a Rigaku Denki M-8075 thermal analyser.

Results and Discussion

The analyses of the products, as well as their calculated values from the formula, $R_3Sb(R'R''CO_2)$, are shown as follows. R=C_6H_5, R'=CF_3, R''=CF_3; Found: C, 47.10; H, 2.84%. examined. Almost all bands originated from the aryl groups, as well as those from the trihalogenomethyl groups which appeared in the same wave number region as those of the dibromotriarylantimonies, or the *gem*-diols, respectively. However, ν(OH) (about 3400 cm^{-1}),[4] as well as ν(C=O) (about 1700 cm^{-1})[4] were absent in the spectra of these compounds. The wave number of the ν(C=O) band[4,5] of the complexes as well as those of the corresponding *gem*-diols are shown in Table 1. As is evident this band splits into two peaks, likely *sym*- and *antisym*-stretching bands, which are also found in the spectra of the hydrated β-diketonato complex as shown in the Table. This strongly supports bonding between the diolato oxygens and the central metal.

The ^{1}H-NMR spectra of these complexes are shown in Table 2, together with those of related substances.[6] In general, the ^{1}H-NMR of the aryl group of Ar_3SbL_2 type organoantimony(V), shifts to the higher field, when the bonded HL is a weaker acid.[6,7] The lower field shifts of the phenyl peaks of these *gem*-diolato complexes were less than those of the carboxylato or halogeno derivatives.[6,7] Therefore, the *gem*-diolato ligands work as less negative ones than the carboxylato or phenolato derivatives. The hydrated β-diketone complex of triarylantimony(V) gives the same order shift for phenyl peaks. The splitting of each aryl proton peak due to the geometrical arrangement of the groups in the complex was not observed; in the case of the *p*-tolyl, or *p*-chlorophenyl derivatives, one sharp quartet of AB pattern was retained.

These results suggest that the *gem*-diolato ligand works bidentately in these complexes; and the central antimony is a penta coordinated one, probably in the trigonal bipyramidal configuration as in the cases of these type quinquevalent organoantimony compounds. From consideration of bond lengths,[2,8,9] the O–C–O bond of the ligand cannot span the central antimony from the equatorial direction, when there is serious deformation in the complex. Therefore, it may be assumed that the bidentate spans between apical and equatorial directions, although some deformation of the shape is inevitable in this case, too. Three aryl groups bonding to the antimony are thus in a facial array. As in the cases of other trigonal bipyramidal compounds,[10,11] Berry's rotation easily occurs, and the splitting of each aryl proton peak in the ^{1}H-NMR due to their situations was not observed, but only the average recognized.

Synthesis and Characterization of Copper Complexes with Schiff Bases Derived from 2-Thiophenealdehyde and Alkylamines

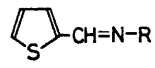
Hiro KUMA, Kyoji MOTOBE, and Shoichiro YAMADA*

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received March 10, 1978)

Synopsis. Copper(I) and copper(II) complexes with Schiff bases derived from 2-thiophenealdehyde and alkylamines were prepared. Probable structures of these complexes are discussed mainly on the basis of electronic and infrared spectra and magnetism.

In a recent work,[1] the present authors have synthesized a number of cobalt(II), nickel(II), and copper(II) complexes with 2-thiophenealdehyde oxime and have concluded that the oxime is bound as a unidentate ligand through the nitrogen atom to the metal ions in these complexes, the sulfur atom not being involved in the bonding with the metal ion. As an extension to the previous study, the present paper describes synthesis and characterization of copper(I) and copper(II) complexes with Schiff bases (abbreviated as tal–R, I) obtained from 2-thiophenealdehyde and alkylamines. A single copper(II) complex of this series was reported in the literature.[2]



I

Experimental

Materials. *N*-(2-Thenylidene)alkylamines were prepared by methods similar to that described previously for the methyl-derivative.[2]

Copper(I) Complexes. Complexes of the type Cu(tal–R)X (R=CH_3, X=Cl, Br; R=*n*-C_3H_7, X=I; R=*i*-C_3H_7, X=Cl, Br, I) were obtained as yellow crystals by the following two methods A and B.

Method A (for R=CH_3, i-C_3H_7; X=Cl, Br). A mixture of $CuX_2 \cdot 2H_2O$ (0.01 mol) and 2,2-dimethoxypropane (25—30 ml) in ethanol (30 ml) was stirred at about 35 °C for 2 h. The solution was evaporated at about 40 °C nearly to dryness, and the residue was dissolved in ethanol (100 ml). To the resulting solution was added a Schiff base (0.02 mol) and heated at 70 °C for 2 h. A yellow precipitate was filtered and recrystallized from chloroform to yield pure crystals of the compound.

*Method B (for R=CH_3, X=Cl, Br; R=*i*-C_3H_7, X=Cl, Br, I; R=*n*-C_3H_7, X=I).* A mixture of CuX (0.01 mol) and a Schiff base (0.02 mol) in ethanol (100 ml) was heated at 50—60 °C for 1 h (R=CH_3, X=Cl, Br) or at 70—80 °C for 5—7 h (R=CH_3, X=I; R=*i*-C_3H_7, X=Cl, Br, I; R=*n*-C_3H_7, X=I). A yellow precipitate was filtered and recrystallized from chloroform or ethanol.

Cu(tal–CH_3)$_2$I was obtained by the method B.

The copper(I) complexes obtained are gradually decomposed in the atmosphere.

Copper(II) Complexes. Complexes of the type Cu(tal–R)$_2X_2$, (R=CH_3, X=Cl, Br; R=C_2H_5, X=Cl) were synthesized by heating a mixture of anhydrous CuX_2 (0.01 mol) and a Schiff base (0.02 mol) in ethanol (100 ml) at 60—70 °C for 2 h. A crystalline precipitate was washed with hot ethanol several times.

μ: BM at room temperature.

The copper(II) compounds obtained, which are brown-yellow (R=CH_3, X=Cl, Br) or grey-olive (R=C_2H_5, X=Cl), are soluble in pyridine but almost insoluble in other common organic solvents.

Analytical data of the complexes are shown in Table 1.

Measurements. Electronic absorption spectra of the complexes in Nujol were recorded on a Shimadzu MPS-50L spectrophotometer. Infrared spectra were measured as Nujol mulls on Hitachi EPI-S2, EPI-L, and FIS-3 infrared spectrophotometers.

Magnetic measurements at room temperature were carried out by the Gouy method using $CoHg(SCN)_4$ as a calibrant.

Results and Discussion

Copper(I) Complexes. The following two types of copper(I) complexes were isolated in the present work: (1) Cu(tal–R)X and (2) Cu(tal–CH_3)$_2$I. Some of the copper(I) complexes were obtained from copper(II) salts when the reactants containing 2,2-dimethoxypropane were refluxed (method B). Otherwise, copper(II) complexes were isolated instead of the copper(I) complexes. It is probable that 2,2-dimethoxypropane undergoes decomposition during the reactions to yield some reducing species in the solution.

These copper(I) complexes are diamagnetic and show

Table 2. Main infrared bands(cm^{-1}) of copper(I) complexes with *N*-(2-thenylidene)alkylamines

Compound	ν(C=N)	ν(Cu–X_{br})
Cu(tal–CH_3)Cl	1615	200
Cu(tal–CH_3)Br	1610	152
Cu(tal–CH_3)$_2$I	1605	135
Cu(tal–*i*-C_3H_7)Cl	1610	194
Cu(tal–*i*-C_3H_7)Br	1605	158
Cu(tal–*i*-C_3H_7)I	1605	130
Cu(tal–*n*-C_3H_7)I	1620	135

no d-d bands in the visible region. As seen in Table 2, ν(C=N) frequencies of the copper(I) complexes shift toward lower frequencies as compared with those (1640—1650 cm^{-1}) of the free ligands, suggesting that the ligands may be coordinated through the nitrogen atom to the copper(I) ion. Inspection of Table 2 also indicates that the halide ions function as bridging ligands, since the copper(I) complexes exhibit ν(Cu–X_{br}) frequencies in the region expected for the bridging Cu–X, and no infrared bands occur in the region (around 250 cm^{-1}) expected for the Cu–S frequencies.[3] All these results combined seem to show that in the copper(I) complexes the ligands tal–R are coordinated as unidentate ligands through the nitrogen atom, the halide ion acting as a bridging ligand. Binuclear, cyclic trinuclear, cubane or other multinuclear structures may be proposed for these copper(I) complexes.

A similar argument as to the infrared spectra applies to Cu(tal–CH_3)$_2$I (Table 2). Thus the ligand tal–CH_3 is coordinated as a unidentate ligand through the nitrogen atom, the iodide ion acting as a bridging ligand. The compound Cu(tal–CH_3)$_2$I may probably have a structure similar to that of Cu(tal–R)X, except that an additional ligand tal–CH_3 is placed on each copper(I) ion in Cu(tal–R)X.

Copper(II) Complexes. Copper(II) complexes of the type Cu(tal–R)$_2X_2$ were obtained in the present work. One of them, Cu(tal–CH_3)$_2Cl_2$, was reported previously.[2] A *trans*-planar configuration was predicted for this complex chiefly from formal analogy of this complex to bis[*N*-(2-pyrrolidene)methylaminato]copper(II). The compound of the same composition obtained in the present work is not soluble enough for the conductivity measurement in nitrobenzne.

The copper(II) complexes Cu(tal–R)$_2X_2$ are paramagnetic with moments corresponding to one spin-free electron (Table 1). They exhibit ν(C=N) bands at 1620—1625 cm^{-1}, which are significantly lower than those of the free ligands (1640—1650 cm^{-1}), showing that the ligands tal–R are coordinated through the nitrogen atom to the copper(II) ion.

The electronic absorption spectrum of Cu(tal–CH_3)$_2$-Br_2 is very similar to that of Cu(tal–C_2H_5)$_2Cl_2$, while the spectrum of Cu(tal–CH_3)$_2Cl_2$ differs from those of the other two complexes (Fig. 1). It is interesting to note that the spectra of Cu(tal–CH_3)$_2Br_2$ and Cu(tal–C_2H_5)$_2Cl_2$ are similar to those of Cu(tox)$_2Cl_2$ and Cu(py)$_2Cl_2$, which were previously concluded to have a multinuclear structure with six-coordinated copper(II)

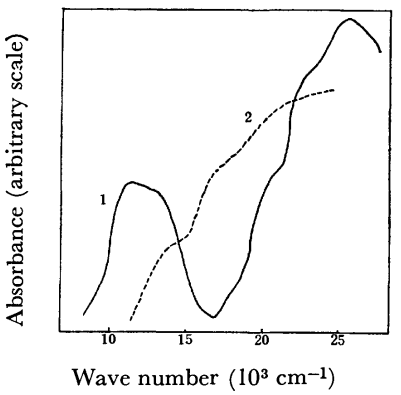

Fig. 1. Electronic absorption spectrum of copper(II) complexes in Nujol: 1, Cu(tal–CH_3)$_2Cl_2$; 2, Cu(tal–CH_3)$_2Br_2$.

ions and bridging chloride ions.[1,4] The notations tox and py represent 2-thiophenealdehyde oxime and pyridine, respectively. The maxima of their main d-d bands (14.6 and 14.7$\times 10^3$ cm^{-1}) are close to those of Cu(tox)$_2Cl_2$ and Cu(py)$_2Cl_2$ (14.3 and 14.5$\times 10^3$ cm^{-1}). It is, therefore, very likely that these two copper(II) complexes, may also have a structure similar to that of Cu(tox)$_2Cl_2$ and Cu(py)$_2Cl_2$.

The sulfur atom of the ligand is not bound with copper(II) ion in Cu(tal–CH_3)$_2Br_2$ and Cu(tal–C_2H_5)$_2$-Cl_2, since they show no charge transfer band characteristic of copper(II) complexes with sulfur-coordinating ligands. It has recently been reported that such copper(II) complexes show a characteristic band of considerably high intensity at about 23—31$\times 10^3$ cm^{-1}.[5] The very low frequency of the d-d band maximum for Cu(tal–CH_3)$_2Cl_2$ requires considerable distortion of the structure and seems to be consistent with a distorted tetrahedral or a trigonal bipyramidal structure.[6,7] A very intense charge transfer band, which is characteristic of the copper(II) complexes with sulfur-coordinating ligand, occurs at 25.7$\times 10^3$ cm^{-1} in the spectrum of Cu(tal–CH_3)$_2Cl_2$, suggesting that the sulfur atom as well as the nitrogen atom of the ligand tal–CH_3 is also bound with the copper(II) ion. A possibility of coordination of the chloride to copper ion or of a multinuclear structure may not be excluded.

The Reduction of Fluorenone Azine with Lithium Aluminum Hydride

Norio EDA,† Masahiro MINABE,* and Kazuo SUZUKI

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321-31

(Received November 28, 1977)

Synopsis. The title reaction yielded fluorenone 9-fluorenylhydrazone and 9,9′-azo(9,9′-bifluorenyl), accompanied by some fragmentary compounds.

The reaction of azine with phenylmagnesium bromide has been reported to give the corresponding hydrazone.[1] The reduction of fluorenone azine (**1**) has yielded 9,9′-hydrazofluorene,[2] which is of interest for its possible use in benzidine-type rearrangements. The present paper will deal with the reduction of **1**, for which some interesting findings will be reported.

The hydrogenation of **1** with hydrazine hydrate in the presence of Ru on C yielded fluorenone 9-fluorenylhydrazone (**2**) (mp 177—178 °C), but not 9,9′-hydrazofluorene (mp 174—175 °C).[2] The acetylation of **2** afforded the corresponding *N*-acetyl compound (**3**). The UV absorption maximum of **2** was observed at a longer wavelength than that of benzophenone benzhydrylhydrazone.[3]

The reduction of **1** with lithium aluminum hydride (LAH) unexpectedly gave 9,9′-azo(9,9′-bifluorenyl) (**4**) accompanied by **2**, fluorenone hydrazone (**5**),[4] 9′-fluorenimine (**6**),[2] 9-fluorenamine (**7**),[4] fluorene (**8**), and 9,9′-bifluorene (**9**). The individual reactions of these products showed that **2** cleaved into **5** and **8**, and that **5** was converted to **7** *via* **6** under similar conditions.

It can be explained that the reduction of **1** yielded **2** and 9,9′-azofluorene (**2a**) through 1,2- and 1,4-addition respectively. The hydrogen atom on the 9-carbon of **2a** is very labile; therefore, the equilibrium between **2** and **2a** lies in the direction of the **2**.[1] The formation of **4** and **9** may be assumed by the generation of the 9-fluorenyl radical from **2a**. The addition of 9-fluorenyl radicals to **1** might form **4** under mild conditions.

Experimental

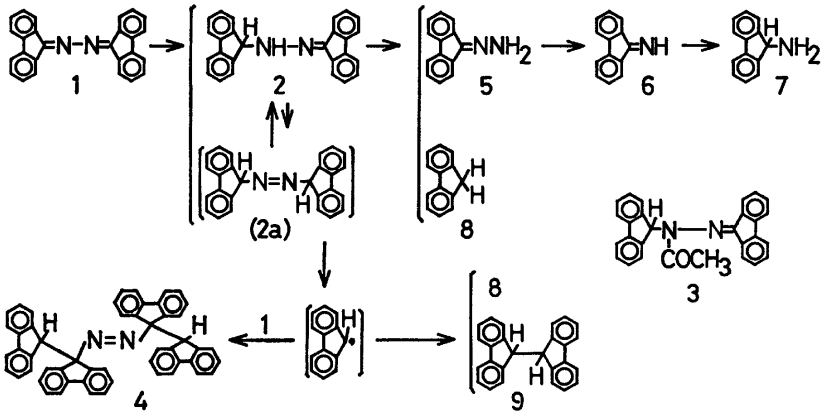
All the melting points are uncorrected. The instruments used in this experiment have been described elsewhere.[5]

Hydrogenation of Azine 1. A solution of 3.56 g (10 mmol) of **1** and 12.8 ml of $H_2NNH_2 \cdot H_2O$ (80%) in 180 ml of pyridine was stirred in the presence of 520 mg of Ru on C (5%) at 70 °C for a period of 3.5 h. Upon filtration, the filtrate was concentrated to a small volume and poured into H_2O. The precipitates were separated by alumina-column chromatography (benzene) and purified by recrystallization from benzene–EtOH (1 : 1) to afford 2.86 g (80%) of **2** (mp 177—178 °C (dec)) and 0.16 g (4%) of **5** (mp 152—153 °C). UV_{max} of **2** (benzene), 350 nm (log ε 4.34); Raman spectrum, 2913 (CH), 3294 cm^{-1} (NH); NMR ($CDCl_3$) δ=5.86 (1H, d, J= 9.0 Hz), 6.67 (1H, d, disappeared by D_2O), 7.07—8.10 (16H, m); MS, *m/e*, 358 (M^+), 356, 193, 180, 165. Found: C, 86.88; H, 5.18; N, 7.96%. Calcd for $C_{26}H_{18}N_2$: C, 87.12; H, 5.06; N, 7.82%.

Acetylation of Hydrazone 2. A mixture of 3.00 g (8.4 mmol) of **2** and 2.64 g of AcCl in 40 ml of benzene was stirred at room temperature for 10 h and then refluxed for an additional 2 h to give 2.91 g (87%) of **3**: mp 173.5—174.5 °C (dec); UV_{max} (isooctane) 378 nm (log ε 3.55); IR 1642 cm^{-1} (C=O); NMR ($CDCl_3$) δ=1.91 (3H, s), 6.61—7.53 (16H, m), 7.97 (1H, s); MS, *m/e*, 400 (M^+), 358, 324, 222, 179, 165. Found: C, 83.82; H, 5.10; N, 6.82%. Calcd for $C_{28}H_{20}N_2O$: C, 83.97; H, 5.03; N, 7.00%.

A solution of **3** (0.40 g; 1 mmol) in EtOH (40 ml) was refluxed with Zn dust (1.0 g) and $CaCl_2$ (0.40 g) in H_2O (3 ml) for 3.5 h to yield 0.22 g (49%) of *N*-9-fluorenylacetamide (mp 260—262 °C (lit,[4] mp 260—261 °C)) and 0.05 g (14%) of **7** (mp 60.5—62.0 °C).

Reduction of Azine 1 with LAH. a): A suspension of 0.86 g (22.6 mmol) of LAH in 30 ml of THF was stirred, drop by drop, into a solution containing 5.00 g (14 mmol) of **1** in 200 ml of THF at room temperature for 10 min; the mixture



Scheme 1.

† Present address: Glaxo-Fuji Pharmaceutical Lab., Ltd., Imaichi 321-12.

was then refluxed for an additional 30 min. Upon cooling, the resulting mixture was decomposed with THF–H_2O and filtered. The filtrate was evaporated to dryness, and the residue was suspended in 50 ml of benzene and 50 ml of 4% hydrochloric acid.

The insoluble fraction was heated with the hydrochloric acid solution for 10 min and then collected. The precipitate was recrystallized from EtOH to give 0.05 g of fluorenone[6] (mp 83—84 °C). The filtrate was concentrated to a small volume to afford 0.96 g of hydrochloride of **7** (mp 220 °C (dec)).

The above-mentioned benzene solution was washed with H_2O, dried (Na_2SO_4), and chromatographed on alumina. The eluate yielded 0.86 g of **8** (mp 114—115 °C) and 0.18 g of **9** (mp 244—245 °C). Additionally, 1.40 g (28%) of **2** (mp 177—178 °C (dec)) and 0.08 g of **5** (mp 152—153 °C) were isolated from each band on the column.

b): A mixture of **1** (3.56 g; 10 mmol) and LAH (0.19 g; 5 mmol) in THF (280 ml) was stirred at room temperature for 4 h. By subsequent treatment similar to that described above, the resulting mixture afforded 0.47 g (14%) of **4**: mp 240—241 °C (dec); UV_{max} (benzene) 355 nm (log ε 4.22); IR 2923, 2852 cm^{-1} (CH); NMR ($CDCl_3$) δ=5.68 (1H, s), 6.89 (1H, s), 6.99—7.88 (32H, m). Found: C, 90.62; H, 4.92; N, 3.89%. Calcd for $C_{52}H_{34}N_2$: C, 90.93; H, 4.99; N, 4.08%.

Reduction of Azo Compound **4**. A solution of **4** (0.500 g; 0.7 mmol) in AcOH (50 ml) was refluxed with Zn dust (1.0 g) for 1 h.

When worked-up in a manner like that described above, the mixture yielded 9-amino-9,9′-bifluorene (0.169 g, mp 179—181.5 °C (dec), lit,[7] mp 181 °C (dec)), a hydrochloride of **7** (0.131 g, mp 218 °C (dec)), **8** (0.012 g, mp 112—114 °C), and **9** (0.007 g, mp 242—243 °C). IR of 9-amino-9,9′-bifluorene, 3350 (NH), 2889 cm^{-1} (CH); NMR ($CDCl_3$) δ=2.04 (2H, s), 4.74 (1H, s), 6.85—7.75 (16H, m); MS, *m/e*, 345 (M^+), 180, 165.

Catalytic Activities of Salicylaldehyde Derivatives. V. Syntheses and Catalytic Activities of Some Trimethylammonio Derivatives of Salicylaldehyde in the Racemization of L-Glutamic Acid

Makoto ANDO* and Sakae EMOTO

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received September 20, 1977)

Synopsis. (3-Formyl-2-hydroxyphenyl)trimethylammonium (**2**) and (3-formyl-4-hydroxyphenyl)trimethylammonium salts (**3**) have been prepared from the corresponding 3- and 5-nitrosalicylaldehydes *via* the 3- and 5-(dimethylamino)salicylaldehydes. The catalytic activities of **2**, **3**, and the (2-formyl-3-hydroxyphenyl)trimethylammonium salt have been studied at pH 10 and at 80 °C in the presence of copper(II) ion.

The rate constants, k_{obsd}, for the racemization of L-glutamic acid catalyzed by various 3-, 4-, and 5-substituted salicylaldehydes at pH 10 and at 80 °C in the presence of copper(II) ion have been examined. The plots of log k_{obsd} *versus* Hammett's constant, σ, for the corresponding substituent were on two straight lines: one corresponding to the 4- and 5-substituted salicylaldehydes and the other to the 3-isomers.[1] (4-Formyl-3-hydroxyphenyl)trimethylammonium bromide (**1**) was found to be the most active catalytically salicylaldehyde derivative.[1] Since the σ-value of the *m*-trimethylammonio group is larger than that of the *p*-group,[2] (3-formyl-2-hydroxyphenyl)trimethylammonium halide (**2**) and (3-formyl-4-hydroxyphenyl)trimethylammonium halide (**3**) may catalyze the racemization to a greater extent than **1**.

The syntheses of **2** and **3** and the catalytic activities of **2**, **3**, and (2-formyl-3-hydroxyphenyl)trimethylammonium salt (**4**)[3] in the racemization of L-glutamic acid under the conditions described above will be described.

Syntheses of 3- (**5**) and 5-(dimethylamino)salicylaldehydes (**6**) were carried out by the catalytic hydrogenation of the corresponding 3- (**7**)[4] and 5-nitrosalicylaldehydes (**8**)[5] over palladium on carbon in the presence of formaldehyde.[6]

For the *N*-methylation of 4-(dimethylamino)salicylaldehyde with methyl iodide to give **1**, it was necessary to add sodium hydroxide in methanol and to reflux the reaction mixture, the resulting products being a mixture of *N*-methylated and *N,O*-dimethylated compounds.[7] In the cases of **5** and **6**, however the corresponding iodides of **2** (**2a**) and **3** (**3a**) were synthesized in good yield at room temperature with neither solvent nor sodium hydroxide. Compounds **2a** and **3a** were converted into the corresponding bromides, **2b** and **3b**, in the usual way. Syntheses of the chloride of **4** (**4c**) and the fluorosulfate of **4** (**4d**) have been reported.[3]

The catalytic racemization of L-glutamic acid was carried out at pH 10 and at 80 °C in the presence of copper(II) ion.[1,7] Since the catalytic racemization follows first-order kinetics, the catalytic activity, (log α_0—log α_t)/t, should be a constant, where t is the time and α_0 and α_t are the observed optical rotations at the reaction time 0 and t min, respectively. The observed rate constant, k_{obsd}, was calculated by the following equation.

$$k_{obsd} = \frac{2.30 \times (\log \alpha_0 - \log \alpha_t)}{t}$$

TABLE 1. CATALYTIC ACTIVITY

Time min	(log α_0—log α_t) × $10^3/t$, (min^{-1})		
	2a	**3a**	**4c**
20	3.58	5.54	2.48
40	3.61	5.70	2.40
60	3.66	5.72	2.30
80	3.67	5.69	2.19
100	3.61	5.47	2.08
120	3.84	5.60	2.04
150	3.70	5.38	1.95
180	3.73	5.35	1.89
210	3.64	5.25	1.69
240	3.65	5.32	1.67
300	3.77	5.28	1.57
360	3.83	5.68	1.44

The catalytic activities of **2a** and **3a** were found to be almost constant, the catalytic activity of **4c** decreasing during the course of reaction, as shown in Table 1. The absorption peak of the reaction mixture at *ca.* 380 nm has been attributed to the chelation of the Schiff base of the catalyst and glutamic acid with copper(II) ion.[8] In the cases of **2a** and **3a**, the absorption peaks were nearly constant throughout the reaction, the absorption peak of **4c** decreasing gradually. Catalytic activity of **4c** also decreased, suggesting the decomposition of **4c**. Thus, the rate constant for the reaction catalyzed by **4c** could not be determined.

The observed rate constants for the racemization catalyzed by **2a** and **3a** were 8.5×10^{-3} and 12.7×10^{-3} min^{-1}, respectively, compared with 11.0×10^{-3} min^{-1} for **1**.[7] As expected from Hammett's constant, σ, the catalytic activity of **3a** was the largest among the salicylaldehyde derivatives examined. The catalytic activity of **2a**, having a bulky 3-substituent was considerably lower than that of **3a**, though both compounds had *m*-trimethylammonio groups with the same σ-value. Similar phenomena were also observed in various salicylaldehyde derivatives having a non-charged substituent at positions 3 and 5.[1] The catalytic activities of the 3-substituted salicylaldehydes were lowered since the phenol group's activity in the catalytic racemization was sterically hindered by the adjacent substituent at position 3.[1]

No conspicuous effect of the anion of the trimethylammonium salt was observed on the racemization yield

Table 2. Comparison of anions in the racemization yield of L-glutamic acid

	$100\times(\alpha_0-\alpha_t)/\alpha_0$, (%)	
	40 min	2 h
2a	40.8	78.7
2b	41.3	79.0
4c	18.3	42.9
4d	18.9	43.3

of L-glutamic acid (Table 2).

The plot of Hammett's constant, σ, versus log k_{obsd} for the racemization catalyzed by **3a** was on a straight line, on which the Hammett's plots for the racemization catalyzed by other 4- and 5- substituted salicylaldehydes were.[1] The Hammett's plot for **2a**, however deviates a great deal from the straight line of the Hammett's plots for the other 3-substituted salicylaldehydes.[1]

Experimental

Boiling points and melting points are uncorrected. Silica gel 60 (Merck No. 7734) was used for the column chromatography. IR spectra were measured with a Shimadzu IR-27G spectrometer.

3-(Dimethylamino)salicylaldehyde (5). A solution of 3-nitrosalicylaldehyde (**7**) (10.0 g) and a 37% formaldehyde solution (40 ml) in ethanol (250 ml) was catalytically hydrogenated over 10% Pd–C (5.0 g) at room temperature at atmospheric pressure. After 5 mol of hydrogen had been absorbed, the reaction mixture was filtered and the filtrate acidified with dilute hydrochloric acid and concentrated. The residue was dissolved in water, treated with charcoal, and neutralized with sodium hydroxide solution. The resulting mixture was extracted with ether, the extract dried ($MgSO_4$) and concentrated to give an oily residue. The residue was chromatographed on a silica-gel column (350 g). Elution with ethyl acetate–cyclohexane (1: 1 v/v) gave 6.8 g (69%) of **5**: bp 96—100 °C/3 mmHg; IR (neat) 1650 cm^{-1}. Found: C, 65.52; H, 6.54; N, 8.53%. Calcd for $C_9H_{11}NO_2$: C, 65.44; H, 6.71; N, 8.48%.

5-(Dimethylamino)salicylaldehyde (6). The compound was prepared from 5-nitrosalicylaldehyde (**8**) (10.0 g) in 71% yield following the method for the preparation of **5** except that 3.0 g of the catalyst was used: mp 33 °C; bp 123—126 °C/4 mmHg; IR (KBr) 3200 and 1660 cm^{-1}. Found: C, 65.70; H, 6.81; N, 8.60%. Calcd for $C_9H_{11}NO_2$: C, 65.44; H, 6.71; N, 8.48%.

(3-Formyl-2-hydroxyphenyl)trimethylammonium Iodide (2a). Methyl iodide (10 ml) was added immediately to **5** (2.5 g) at room temperature and the reaction mixture allowed to stand overnight at room temperature. Upon treatment with acetone, a crystalline product separated. This was recrystallized from water giving 4.1 g (90%) of **2a**: mp 198—199 °C dec; IR (KBr) 1650 cm^{-1}. Found: C, 39.07; H, 4.65; I, 41.16; N, 4.78%. Calcd for $C_{10}H_{14}INO_2$: C, 39.11; H, 4.60; I, 41.33; N, 4.56%.

(3-Formyl-4-hydroxyphenyl)trimethylammonium Iodide (3a). The compound was prepared from **6** in 88% yield following the method for the preparation of **2a**: mp 228—229 °C dec; IR (KBr) 1700 cm^{-1}. Found: C, 39.10; H, 4.63; I, 41.22; N, 4.33%. Calcd for $C_{10}H_{14}INO_2$: C, 39.11; H, 4.60; I, 41.33; N, 4.56%.

(3-Formyl-2-hydroxyphenyl)trimethylammonium Bromide (2b) and (3-Formyl-4-hydroxyphenyl)trimethylammonium Bromide (3b). Compounds **2a** and **3a** were converted in the usual way with silver bromide at room temperature into the corresponding **2b** and **3b** in 90% yields. **2b**: mp 199—200 °C dec. Found: C, 46.23; H, 5.47; Br, 30.58; N, 5.35%. Calcd for $C_{10}H_{14}BrNO_2$: C, 46.17; H, 5.43; Br, 30.72; N, 5.39%. **3b**: mp >300 °C. Found: C, 46.11: H, 5.47; Br, 30.73; N, 5.46%. Calcd for $C_{10}H_{14}BrNO_2$; C, 46.17; H, 5.43; Br, 30.72; N, 5.39%.

Procedure of Racemization. Racemization was carried out as described previously.[7]

The authors wish to thank Dr. Haruo Homma and his co-workers of this Institute for the elementary analyses. The work was partially supported by a Research Grant for Biosciences given by this Institute.

Catalytic Activities of Salicylaldehyde Derivatives. VI.[1] Syntheses of Some Dimethylsulfonio Derivatives of Salicylaldehyde

Makoto ANDO* and Sakae EMOTO

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received September 20, 1977)

Synopsis. 3-, 4-, and 5-dimethylsulfonio derivatives of salicylaldehyde have been prepared from the corresponding 6-, 5-, and 4-bromo-2-methylanisoles *via* the bromo-2-methoxybenzylidene dibromides, bromo-*o*-anisaldehyde diethyl acetals, methylthio-*o*-anisaldehydes, and (methylthio)salicylaldehydes. 4-Methylthio-*o*-anisaldehyde has also been prepared from 2-bromo-5-(methylthio)anisole.

The racemization of L-glutamic acid catalyzed by various salicylaldehyde derivatives at pH 10 and at 80 °C in the presence of copper(II) ion has been examined. The Hammett's plots for the racemization catalyzed by 4- and 5-substituted salicylaldehydes *versus* the Hammett's constant, σ, were on a straight line.[2] Since the σ-values of the dimethylsulfonio groups are the largest among the σ-values obtained,[3] the dimethylsulfonio derivatives of salicylaldehyde appear to be more active catalysts than the known salicylaldehyde derivatives. Syntheses of 3- (**1**), 4- (**2**), and 5-dimethylsulfonio derivatives of salicylaldehyde (**3**) are described.

Treatment of 6- (**4**),[4] 5- (**5**),[5] and 4-bromo-2-methylanisoles (**6**)[6] with bromine gave the corresponding 3- (**7**), 4- (**8**), and 5-bromo-2-methoxybenzylidene dibromides (**9**), which were converted into the corresponding 3- (**10**), 4- (**11**), and 5-bromo-*o*-anisaldehyde diethyl acetals (**12**) with sodium ethoxide. The corresponding 3- (**13**), 4- (**14**), and 5-methylthio-*o*-anisaldehydes (**15**) were synthesized from **10**, **11**, and **12** by the Grignard reaction with dimethyl disulfide and subsequent hydrolysis. In the synthesis of **14**[7] the overall yield was remarkably improved by the Grignard reaction of 2-bromo-5-(methylthio)anisole (**16**)[8] with diethyl phenyl orthoformate.[9]

Demethylation of the methoxyl group in **13** and **15** with hydrogen bromide in acetic acid gave the corresponding 3- (**17**) and 5-(methylthio)salicylaldehydes (**19**). The reaction of **14** with the same reagents gave only a resinous product. Compound **14** was consequently treated with boron tribromide in dichloromethane in the usual way but no demethylation took place. The desired 4-(methylthio)salicylaldehyde (**18**) was obtained when the reaction was carried out in benzene under reflux. Compounds **18** and **19** were *S*-methylated with methyl *p*-toluenesulfonate to give the corresponding dimethylsulfonium *p*-toluenesulfonates, **2a** and **3a**. No *S*-methylation of **17** took place with the same reagent. The desired dimethylsulfonium fluorosulfate (**1b**) was obtained by treatment of **17** with methyl fluorosulfate.

Although these dimethylsulfonium salts are unstable at pH 10 and at 80 °C, the catalytic activities of the dimethylsulfonium salts in the racemization of L-glutamic acid are apparently larger than the salicylaldehyde derivatives examined in the initial stage of reaction.

Experimental

Melting points and boiling points are uncorrected. IR spectra were recorded on a Shimadzu IR-27G instrument. Typical examples of syntheses of the intermediates are described. Reaction conditions, physical properties, and analytical data are given in Table 1.

3-Bromo-2-methoxybenzylidene Dibromide (7). Under illumination with a tungsten lamp, a solution of bromine (167 g) in carbon tetrachloride (100 ml) was added dropwise to a solution of 6-bromo-2-methylanisole (**4**) (99.3 g) in carbon tetrachloride (400 ml) with stirring over a period of 2 h under reflux. After a further 3 h reflux, the mixture was fractionally distilled.

3-Bromo-o-anisaldehyde Diethyl Acetal (10). To a solution of sodium (12.0 g) in absolute ethanol (350 ml) was added dropwise **7** (94.0 g) over a period of 30 min at room temperature with stirring. The mixture was refluxed and the solvent removed. The residue was extracted with water and ether and the ethereal extract dried ($MgSO_4$) and distilled.

3-Methylthio-o-anisaldehyde (13). Under a nitrogen atmosphere, a solution of dimethyl disulfide (20.8 g) in dry THF (100 ml) was added with stirring to a Grignard reagent prepared from a solution of **10** (63.8 g) in dry THF (500 ml) and magnesium (5.4 g), over a period of 20 min at room temperature and then refluxed for 2 h. The mixture was treated with a 20% NH_4Cl solution (1 l) below 20 °C and extracted with ether. The extract was dried ($MgSO_4$) and concentrated. To the residue was added 2 M sulfuric acid (500 ml) and the resulting mixture steam-distilled. The ethereal extract of the distillate was washed with aqueous NaOH and water successively and dried ($MgSO_4$). Re-

moval of the solvent gave crude **13**, which was recrystallized from methanol.

3-(Methylthio)salicylaldehyde (17). A mixture of **13** (10.0 g), anhydrous hydrogen bromide (26.5 g) in acetic acid (100 ml), and a 48% hydrobromic acid (20 ml) was refluxed for 1 h, concentrated, and extracted with water and ether. The ethereal layer was extracted with NaOH solution and the aqueous layer acidified with hydrochloric acid. The resulting oily product was extracted with ether, dried ($MgSO_4$), and fractionally distilled.

(3-Formyl-2-hydroxyphenyl)dimethylsulfonium Fluorosulfate (1b). A solution of methyl fluorosulfate (6.7 g) in dry benzene (10 ml) was added with stirring to a solution of **17** (10.0 g) in dry benzene (50 ml) at room temperature over a period of 10 min. Stirring was continuted for another 1 h and the mixture allowed to stand overnight. The resulting precipitates were recrystallized from methanol giving 6.1 g (36%) of **1b**: mp 137—139 °C; IR (KBr) 3440 and 1650 cm^{-1}. Found: C, 38.22; H, 3.82; S, 22.37%. Calcd for $C_9H_{11}FO_5S_2$: C, 38.29; H, 3.93; S, 22.71%.

4-Methylthio-o-anisaldehyde (14) from 2-Bromo-5-(methylthio)-anisole (16). Under a nitrogen atmosphere, diethyl phenyl orthoformate (5.9 g) was added to a Grignard reagent prepared from a solution of **16** (7.0 g) in dry THF (100 ml) and magnesium (730 mg), over a period of 10 min at room temperature with stirring. The mixture was refluxed for 3 h and worked up in the usual way giving 4.2 g (77%) of **14**: mp 65 °C.

4-(Methylthio)salicylaldehyde (18). A solution of boron tribromide (15.1 g) in dry benzene (50 ml) was added to a stirred solution of **14** (11.0 g) in dry benzene (200 ml) over a period of 20 min in an ice bath. The mixture was stirred for 30 min at room temperature and then refluxed for 5 h. After removal of the solvent, ethanol (200 ml) and sodium acetate trihydrate (10.0 g) in water (30 ml) were added successively to the residue, refluxed for 2 h, and worked up in the usual way.

(4-Formyl-3-hydroxyphenyl)dimethylsulfonium p-*Toluenesulfonate (2a).* A mixture of methyl *p*-toluenesulfonate (2.0 ml) and **18** (1.0 g) was heated at 100 °C for 8 h and cooled. Ethyl acetate (5 ml) was added to the cold mixture. The resulting precipitates were recrystallized from methanol–acetone affording 0.7 g (33%) of **2a**: mp 146—147 °C; IR (KBr) 3450, 1660, 1210, and 1170 cm^{-1}. Found: C, 54.45; H, 5.04; S, 18.02%. Calcd for $C_{16}H_{18}O_5S_2$: C, 54.22; H, 5.12; S, 18.10%.

(3-Formyl-4-hydroxyphenyl)dimethylsulfonium p-*Toluenesulfonate (3a).* A mixture of **19** (5.0 g) and methyl *p*-toluenesulfonate (10 ml) was heated at 100 °C for 3 h and then cooled. Acetone (10 ml) was added to the mixture. The resulting precipitates were 9.6 g (91%) of **3a**: mp 178—179 °C; IR (KBr) 1670, 1200, and 1170 cm^{-1}. Found: C, 54.28; H, 5.20; S, 18.00%. Calcd for $C_{16}O_{18}O_5S_2$: C, 54.22; H, 5.12; S, 18.10%.

The authors wish to express their thanks to Dr. Haruo Homma and his staff of this Institute for the elementary analyses. The work was partially supported by a Research Grant for Biosciences given by this Institute.

Catalytic Activities of Salicylaldehyde Derivatives. VII. Synthesis and Catalytic Activity of (2-Formyl-3-hydroxyphenyl)dimethylsulfonium Salt in the Racemization of L-Glutamic Acid

Makoto ANDO* and Sakae EMOTO

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received January 10, 1978)

Synopsis. The title compound (**1**) was prepared from 6-nitro-*o*-anisidine *via* 2-bromo-*m*-anisidine, 2-bromo-3-(methylthio)anisole, 6-methylthio-*o*-anislaldehyde, and 6-(methylthio)salicylaldehyde. Compound **1** was found to be the most inactive catalyst among the dimethylsulfonio derivatives of salicylaldehyde, but the most active catalyst among the other salicylaldehyde derivatives examined in the racemization of L-glutamic acid at pH 10 and at 80 °C in the presence of copper(II) ion in the initial stage of the reaction.

Since salicylaldehyde derivatives having a dimethylsulfonio group at 3-, 4-, and 5-positions have been found to be active catalysts in the racemization of L-glutamic acid,[1] 6-isomer (**1**) may also actively catalyze the racemization.

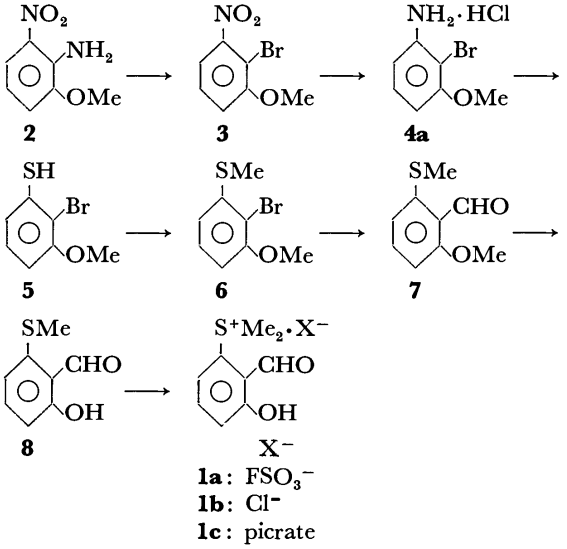
Here we describe a synthesis of **1** from 6-nitro-*o*-anisidine (**2**)[2,3] and the catalytic activity of **1** in the racemization of L-glutamic acid. 2-Bromo-3-nitroanisole (**3**) was prepared from **2** in the usual way. Most of the reagents tested for the reduction of **3** to give 2-bromo-*m*-anisidine (**4**) brought about undesirable debromination. With hydrazine hydrate over Raney nickel W-2,[4] however hydrochloride of **4** (**4a**) was obtained in a good yield. In the usual way, **4a** was converted into 2-bromo-3-methoxybenzenethiol (**5**). *S*-Methylation of **5** afforded 2-bromo-3-(methylthio)anisole (**6**), which gave 6-methylthio-*o*-anisaldehyde (**7**) by the Grignard reaction with diethyl phenyl orthoformate. *O*-Demethylation of **7** to 6-(methylthio)salicylaldehyde (**8**) was successful with boron tribromide in dichloromethane, but not with hydrogen bromide in acetic acid. Although *S*-methylation of **8** was unsuccessful with methyl *p*-toluenesulfonate, methyl fluorosulfate gave the fluorosulfate of **1** (**1a**) which was converted into the chloride (**1b**) *via* the picrate (**1c**).

Following the earlier work,[5,6] the racemization of L-glutamic acid catalyzed by **1b** was carried out at 80 °C and at pH 10 in the presence of copper(II) ion.

As Table 1 shows, the catalytic activity of **1b** decreased gradually during the course of the reaction by its decomposition, similarly to the other dimethylsulfonio derivatives of salicylaldehyde.[1] At an early stage of the reaction, however **1b** was found to be a more active catalyst than the trimethylammonio derivatives of salicylaldehyde,[5,6] but a less active catalyst than the other dimethylsulfonio derivatives of salicylaldehyde.[1]

Table 1. Racemization yield and catalytic activity catalyzed by **1b**

Time min	Racemization yield $100\,(\alpha_0-\alpha_t)/\alpha_0$, (%)	Catalytic activity $(\log \alpha_0/\alpha_t)/t$, ($min^{-1}$)
20	22.6	5.57×10^{-3}
40	34.0	4.50
60	40.6	3.77
120	55.3	2.92
240	69.7	2.16
480	87.0	1.85



Experimental

All the melting points and boiling point are uncorrected. Silica gel 60 (Merck No. 7734) was used for column chromatography. UV, IR, and PMR spectra were recorded on a Hitachi 124, a Shimadzu IR-27G, and a Varian HA-100D spectrometer, respectively.

2-Bromo-3-nitroanisole (3). A solution of 6-nitro-*o*-anisidine (**2**) (56.0 g) in concentrated sulfuric acid (230 ml) was diluted with water (460 ml) and diazotized with $NaNO_2$ (25.0 g) in water (40 ml). The solution was added to a mixture of CuBr (27.0 g), 48% HBr (60 ml), and water (340 ml) with stirring at 60 °C over a period of 1 h and then refluxed for 1 h. The resulting precipitate was recrystallized from ethyl acetate, giving 66.7 g of **3**. Additional **3** in the filtrate was recovered by passing it through a column of silica gel (360 g). Elution with benzene gave 2.6 g of **3** (total yield, 90%): mp 93—94 °C; IR (KBr) 1530 and 1280 cm^{-1}. Found: C, 36.36; H, 2.69; Br, 34.34; N, 5.89%. Calcd for $C_7H_6BrNO_3$: C, 36.24; H, 2.61; Br, 34.44; N, 6.04%.

2-Bromo-m-anisidine Hydrochloride (4a). To a mixture of **3** (78.4 g), Raney Ni W-2 (6.0 ml), and methanol (1.5 l), a solution of 100% hydrazine hydrate (42.3 g) in methanol (50 ml) was added over a period of 90 min under reflux with stirring. After stirring for another 2 h, the cold mixture was filtered and the filtrate was concentrated to a syrup and extracted with benzene and NaOH solution. The concentrated benzene layer was extracted with hot 1 M HCl. The

extract was treated with charcoal and concentrated to give 74.1 g of **4a** (92%): mp 201—202 °C dec. Found: C, 35.37; H, 3.90; Br+Cl, 48.10; N, 5.86%. Calcd for $C_7H_9BrClNO$: C, 35.25; H, 3.80; Br+Cl, 48.36; N, 5.87%.

2-Bromo-3-methoxybenzenethiol (5). A solution of diazonium salt prepared from **4a** (56.4 g) in 2 M HCl (300 ml) with $NaNO_2$ (16.5 g) in water (30 ml) was adjusted to pH 5 by addition of crystalline sodium acetate (60 g) and then added to a solution of potassium *O*-ethyl dithiocarbonate (76.0 g) in water (80 ml) at 60 °C over a period of 30 min with stirring. After being kept at 80 °C for 2 h, the mixture was extracted with ethyl acetate and the ethyl acetate layer was evaporated to a syrup. A mixture of the syrup and NaOH (30.0 g) in 90% aqueous ethanol (300 ml) was refluxed for 6 h and then extracted with ethyl acetate and water. The aqueous layer was acidified with HCl and the resulting oily product was extracted with ethyl acetate. The extract was dried ($MgSO_4$) and distilled under nitrogen atmosphere to give 22.3 g of **5** (42%) and some polymerized residue: mp 36—37 °C; bp 113 °C/3 mmHg. Found: C, 38.28; H, 2.97; Br, 36.59; S, 14.75%. Calcd for C_7H_7BrOS: C, 38.73; H, 3.22; Br, 36.47; S, 14.64%.

2-Bromo-3-(methylthio)anisole (6). To a stirred solution of distilled **5** (22.1 g) and NaOH (20.0 g) in water (200 ml), dimethyl sulfate (25 ml) was added over a period of 20 min at 70 °C and the mixture was then refluxed for 2 h. The resulting precipitate was recrystallized from methanol to give 22.1 g of **6** (94%). The use of undistilled **5** was better in the overall yield (59% based on **4a**) than the use of purified **5**: mp 73 °C; IR (KBr) 1590 and 1270 cm^{-1}. Found: C, 41.49; H, 3.75; Br, 34.53; S, 13.74%. Calcd for C_8H_9BrOS: C, 41.22; H, 3.89; Br, 34.37; S, 13.75%.

6-Methylthio-o-anisaldehyde (7). To a Grignard reagent of **6** (16.3 g) in dry THF (160 ml) with magnesium (1.7 g), diethyl phenyl orthoformate (15.2 g) in dry THF (30 ml) was added at room temperature over a period of 10 min with stirring and refluxed for 20 h. The cooled mixture was treated with a 20% NH_4Cl solution (120 ml) and extracted with benzene. The extract was dried ($MgSO_4$), concentrated, and hydrolyzed in a hot ethanol (150 ml)–2.4 M HCl (100 ml). Recrystallization of the resulting precipitate from methanol gave 9.7 g of **7**. The mother liquor was concentrated and packed on a column of silica gel (75 g). Elution with benzene gave 0.5 g of **7** (total yield, 81%): mp 98 °C; UV_{max} (MeOH) 372 (ε 19000), 298 (ε 24900), and 236 nm (ε 74600); IR (KBr) 1660, 1590, and 1270 cm^{-1}; PMR ($CDCl_3$) δ=10.56 (1H, s, CHO), 3.92 (3H, s, OCH_3), and 2.42 (3H, s, SCH_3). Found: C, 59.42; H, 5.42; S, 17.53%. Calcd for $C_9H_{10}O_2S$: C, 59.33; H, 5.53; S, 17.60%.

6-(Methylthio)salicylaldehyde (8). A solution of boron tribromide (25.0 g) in dry dichloromethane (20 ml) was added with stirring to a solution of **7** (16.5 g) in the same solvent (330 ml) over a period of 20 min at −55—−65 °C. The mixture was kept for another 30 min at the same temperature and then at room temperature for 2 h and concentrated below 30 °C. To the residue ethanol (300 ml) and then sodium acetate trihydrate (16.5 g) in water (80 ml) were added. The mixture was refluxed for 2 h, concentrated, and extracted with benzene and water. From the benzene layer, which was washed with NaOH solution and then with water, 1.0 g of **7** was recovered. The aqueous layer was acidified with HCl and extracted with benzene. The extract was dried ($MgSO_4$) and concentrated, giving crude **8** which was recrystallized from methanol to give 8.7 g of **8**. The mother liquors of **8** were concentrated and chromatographed on a silica-gel column (250 g). Elution with benzene gave 2.6 g of **8** (total yield, 74%): mp 71—72 °C; UV_{max} (MeOH) 353 (ε 23800), 296 (ε 27000), and 237 nm (ε 99000); IR (KBr) 1650 and 1450 cm^{-1}; PMR ($CDCl_3$) δ=11.94 (1H, s, OH), 10.48 (1H, s, CHO), and 2.52 (3H, s, SCH_3). Found: C, 56.89; H, 4.56; S, 18.99%. Calcd for $C_8H_8O_2S$: C, 57.12; H, 4.79; S, 19.06%.

(2-Formyl-3-hydroxyphenyl)dimethylsulfonium Picrate (1c) and Chloride (1b). A solution of methyl fluorosulfate (5.7 g) and **8** (8.4 g) in dry dichloromethane (50 ml) was stirred for 1 h and allowed to stand for 4 days at room temperature. The resulting precipitate of crude fluorosulfate (**1a**) (mp 158—162 °C) was dissolved in methanol, treated with picric acid (11.0 g), and concentrated to give crude **1c**. Its recrystallization from methanol–acetone gave 9.7 g of **1c** (49%): mp 181—182 °C. Found: C, 43.67; H, 3.31; N, 10.00; S, 7.72%. Calcd for $C_{15}H_{13}N_3O_9S$: C, 43.80; H, 3.19; N, 10.22; S, 7.79%.

In the usual way, **1b** was prepared from **1c** in a 84% yield. It was slightly soluble in water and methanol: mp 173—174 °C dec; UV_{max} (H_2O) 380 (shoulder, ε 5500), 332 (ε 20900), and 255 nm (ε 21300); IR (KBr) 1670 cm^{-1}. Found: C, 49.25; H, 5.05; Cl, 15.98; S, 14.70%. Calcd for $C_9H_{11}ClO_2S$: C, 49.43; H, 5.07; Cl, 16.21; S, 14.66%.

Procedure of the Racemization. The racemization was carried out as described previously.[5]

The authors wish to thank Dr. Haruo Homma of this Institute and his staff for the elementary analyses and Mr. Jun Uzawa and Mrs. Tamiko Chijimatsu of this Institute for the measurements of PMR spectra. The work was partially supported by a Research Grant for Biosciences given by this Institute.

Oxidation of Thujopsene with Thallium Triacetate in Acetic Acid

Haruo SEKIZAKI,* Masaaki ITO, and Shoji INOUE**

Chemistry Laboratory, Department of General Education, Higashi Nippon Gakuen University, Onbetsu-cho, Hokkaido 088-01

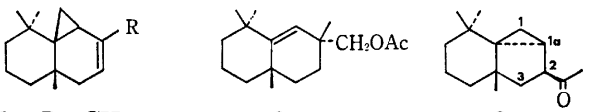
***Faculty of Pharmacy, Meijo University, Tenpaku-ku, Nagoya 468*

(Received January 17, 1978)

Synopsis. Oxidation of thujopsene with thallium triacetate in acetic acid at room temperature gave a stereospecifically ring-contracted ketone (**3**) in 76% yield, whereas oxidation at 50 °C afforded an allylic oxidation product in 72% yield. The configuration of **3** was estimated by the NMR spectrum of a compound derived from it.

Oxidation of thujopsene (**1a**) with metal acetate was first described in 1959 by Nagahama *et al.*,[1] who used lead tetraacetate to try to determine the partial structure of **1a**. Recently, one of us[2] reported that oxidation of **1a** with mercury diacetate gave a mixture of allylic oxidation products, (**1b**) and (**1c**), and an acid-catalyzed isomerization-acetoxylation product (**2**).

This report describes some interesting results about the oxidation of thujopsene (**1a**) with thallium triacetate.[3] We have found that oxidation of **1a** with thallium triacetate in acetic acid at room temperature gave a stereospecifically ring-contracted product (**3**) and **1b** in 76 and 10% yield respectively, whereas, oxidation of **1a** at 50 °C gave mainly the product (**1b**) (72%), resulting from allylic oxidation of **1a**, together with the ketone **3** (8%). The product (**3**) was already reported by Nagahama *et al.*,[1] but the configuration of the acetyl group in **3** has not been reported.

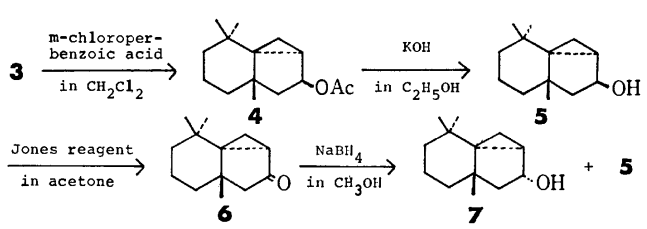


1a: R=CH_3
1b: R=CH_2OAc
1c: R=CHO

2 **3**

We estimated the relative configuration of the ketone **3** as follows. Alcohols, **5** (β-OH) and **7** (α-OH), were derived from **3** according to the method shown in Scheme 1. The structures of **1b**, **3**, **4**, **5**, and **6** were identical with authentic specimens (mp, IR).[1,2]

The NMR spectrum of C_2–H in the ketone **3** shows a doublet of doublets of doublets ($J_{C_2H-C_{1a}H}$=10.0, $J_{C_2H-C_{3\beta}H}$=10.0, and $J_{C_2H-C_{3\alpha}H}$=4.0 Hz) at 3.07 ppm. On the other hand, the spectrum of C_2–H in the β-hydroxy alcohol **5** shows a doublet of doublets of doublets ($J_{C_2H-C_{1a}H}$=8.0, $J_{C_2H-C_{3\beta}H}$=8.0, and $J_{C_2H-C_{3\beta}H}$=1.8 Hz) at 4.46 ppm, but that of C_2–H in the α-hydroxy alcohol **7** shows a doublet of doublets ($J_{C_2H-C_{3\beta}H}$=6.0, and $J_{C_2H-C_{3\beta}H}$=6.0 Hz) at 4.11 ppm. In these results, the spectrum of the C_2–H proton in **3** showed a pattern for the C_2–H which was in close agreement with the corresponding proton observed in β-hydroxy alcohol **5**, and therefore the acetyl group of **3** was assigned to be β.



Scheme 1.

Oxidation of thujopsene (**1a**) with mercury diacetate[2] gave two allylic oxidation products, **1b** and **1c**, in 14.4 and 11.1% yield respectively, together with the other product **2** (5.4%). With lead tetraacetate,[1] **1a** was oxidized to the ring-contracted ketone **3** in 35% yield. However, with thallium triacetate, the ring-contracted ketone **3** was obtained in higher yield at room temperature and the acetate **1b** was obtained in higher yield at 50 °C on allylic oxidation. It is interesting that oxidation of thujopsene (**1a**) with thallium triacetate gives different products up to reaction temperature. The extention of oxythallation reaction to other compounds including allyl methyl moiety in their molecules would be valuable.

Experimental

The melting points were determined on a Yanagimoto micro melting point apparatus and uncorrected. The NMR spectra were recorded on a JEOL PMX-60 spectrometer at 60 MHz and on a JEOL PS-100 spectrometer at 100 MHz, using Me_4Si as an internal standard.

The IR spectra were determined on a Shimadzu IR-400 spectrometer.

Oxidation of Thujopsene (1a) at Room Temperature. To a stirred solution of thallium triacetate (1.19 g, 5 mmol) in acetic acid (10 ml) was added dropwise a solution of **1a** (1.02 g, 5 mmol) in acetic acid (20 ml) under nitrogen atmosphere at room temperature in 30 min. The mixture was stirred for 10 h, then poured into ice-water and extracted with ether. The extract was washed with aqueous $NaHCO_3$ solution, water, dried (Na_2SO_4), and evaporated to give an oily residue (1.32 g). The products were separated by column chromatography using silica gel. Elution with benzene gave **3** (791 mg) and **1b** (130 mg) as colorless liquids. The pure samples of **3** and **1b** were obtained by distillation under reduced pressure. **3**: bp 127—129 °C/7 mmHg. NMR ($CDCl_3$) 0.75 (s, 3, CH_3), 1.15 (s, 3, CH_3), 1.13 (s, 3, CH_3), 2.20 (s, 3, Ac), and 3.07 (ddd, 1, J=10.0, 10.0, and 4.0 Hz, C_2–H); 2,4-dinitrophenylhydrazone: mp 168—169 °C (lit,[1] mp 170—170.5 °C). Found: C, 62.11; H, 7.05; N, 13.99%. Calcd for $C_{19}H_{24}O_4N_4$: C, 62.98; H, 7.05; N, 13.99%. **1b**: bp 148—150 °C/6 mmHg.

Oxidation of Thujopsene (1a) at 50 °C. To a stirred solution of **1a** (1.02 g, 5 mmol) in acetic acid (30 ml), kept at 50 °C, was added thallium triacetate (1.91 g, 5 mmol) in portions under nitrogen atmosphere over 30 min. The mix-

ture was stirred for 7 h at the same temperature, then the same work up as that mentioned above gave **1b** (997 mg) and **3** (83 mg).

Oxidation of ***3***. To a stirred solution of **3** (2.20 g, 10 mmol) in dichloromethane (20 ml), kept at 7 °C, was added dropwise a solution of *m*-chloroperbenzoic acid (2.60 g, 11 mmol) in dichloromethane (20 ml) in 1 h. The mixture was stirred at room temperature overnight, then the usual work up gave crude **4** (2.61 g), which was chromatographed on a silica gel column. Elution with benzene gave **4** (2.28 g): colorless liquid; NMR ($CDCl_3$) 0.56 (s, 3, CH_3), 1.01 (s, 3, CH_3), 1.06 (s, 3, CH_3), 2.01 (s, 3, OAc), and 5.21 (m, 1, olefinic proton).

Hydrolysis of ***4***. The compound **4** (2.28 g) was hydrolyzed in alcohol (20 ml) with potassium hydroxide (860 mg) for 3 h. After the usual workup a crude product (2.23 g) was obtained. Sublimation under a reduced pressure gave **5** (1.91 g): mp 82—83 °C (lit,[1] mp 78 °C; NMR ($CDCl_3$) 0.51 (s, 3, CH_3), 1.01 (s, 3, CH_3), 1.05 (s, 3, CH_3), and 4.46 (ddd, 1, J=8.0, 8.0, and 1.8 Hz, C_2–H).

Oxidation of ***5***. The compound **5** (776.8 mg) was oxidized in acetone (10 ml) with the Jones reagent (8N, 1.1 ml) at room temperature for 2 h. The mixture was evaporated and ice-cooled water was poured into the resulting residue, which was then extracted with ether. The extract was washed with water, dried (Na_2SO_4), and evaporated to give crude crystals (778.2 mg). Recrystallization from hexane gave pure **6** (761.8 mg): mp 126—127 °C (lit,[1] mp 118—121 °C); NMR ($CDCl_3$) 0.66 (s, 3, CH_3), 1.13 (s, 3, CH_3), and 1.21 (s, 3, CH_3).

Reduction of ***6***. The compound **6** (407.8 mg) was reduced in methanol (10 ml) with sodium borohydride (200 mg) at 15 °C for 2 h. The usual workup gave a crude product (414.7 mg), which was chromatographed on a silica gel column. Elution with benzene gave α-hydroxy alcohol **7** (267.8 mg) and β-hydroxy alcohol **5** (100.7 mg). **7**: mp 107—108 °C (hexane); IR (KBr) 3350 (OH) and 3050 (cyclopropyl) cm^{-1}; NMR ($CDCl_3$) 0.60 (s, 3, CH_3), 1.05 (s, 6, CH_3), and 4.11 (dd, 1, J=6.0 and 6.0 Hz, C_2–H); Found: C, 79.17; H, 11.66%. Calcd for $C_{13}O_{20}O$: C, 80.35; H, 11.96%.

The authors are grateful to Takasago Perfumery Co. Ltd. for giving us the sample of crude thujopsene.

Infrared Spectra of ^{13}C-Labelled Diphenylcyclopropenone and Related Derivatives

Yoshikazu TAKEHIRA and Fumio TODA*

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received January 23, 1978)

Synopsis. The infrared spectra of diphenylcyclopropenone-1-^{13}C, its hydrate, 3-dicyanomethylene-1,2-diphenyl-1-cyclopropene-3-^{13}C, and 4-(2,3-diphenylcyclopropenylidene)-2-(diphenylmethylene)-1,3-cyclobutanedione-1'-^{13}C were studied.

Diphenylcyclopropenone (**3**) and related derivatives such as methylenecyclopropene (triafulvene) show complex IR bands. For example, **3** shows two strong bands at *ca.* 1850 and 1620 cm^{-1}, which were found to be mainly due to $\nu_{C=O}$ and $\nu_{C=C}$, respectively.[1] For the sake of confirmation and assignment of the IR bands of the hydrate of **3** (**4**),[2] 3-dicyanomethylene-1,2-diphenyl-1-cyclopropene (**5**),[3] and 4-(2,3-diphenylcyclopropenylidene)-2-(diphenylmethylene)-1,3-cyclobutanedione (**6**),[4] ^{13}C-labelled samples of these compounds were synthesized and their IR spectra were studied.

Experimental

^{13}C-Labelled Compounds. Phenylacetic acid-1-^{13}C (96.2 atom% ^{13}C) was prepared by carbonation of phenylmagnesium bromide with $^{13}CO_2$ evolved from $Ba^{13}CO_3$ (96.2 atom% ^{13}C), according to the standard procedure of isotope experiment.[5] From the phenylacetic acid-1-^{13}C, **3**-1-^{13}C was prepared successively *via* barium phenylacetate-1-^{13}C, 1,3-diphenyl-2-propanone-2-^{13}C (**1**-2-^{13}C), and 1,3-dibromo-1,3-diphenyl-2-propanone-2-^{13}C (**2**-2-^{13}C), according to the reported method[6] of preparation of non-labelled **3**. In ^{13}C-NMR spectrum, **3**-1-^{13}C showed a strong signal of the carbonyl carbon at 155.9 ppm (on $CDCl_3$, from TMS), which is comparable to that of **3**, 155.7 ppm (in $CDCl_3$, from TMS).[7]

Hydrate of **3**-1-^{13}C (**4**-1-^{13}C) was prepared according to the procedure of Toda and Akagi.[2] **5**-3-^{13}C and **6**-1-^{13}C were prepared by the condensation of **3**-1-^{13}C with dicyanomethane and 2-diphenylmethylene-1,3-cyclobutanedione,[4] respectively, following the preparation of non-labelled **5**[3] and **6**.[4]

IR Spectra. IR spectra were recorded with a Hitachi 285 grating spectrometer.

Results and Discussion

IR spectral data are summarized in Table 1. In the case of both **3** and **4**, the bands at *ca.* 1850 cm^{-1} shifts *ca.* 40 cm^{-1} towards lower frequencies when C-1 is labelled with ^{13}C, that at *ca.* 1620 cm^{-1} *ca.* 15 cm^{-1}. The results show that the bands are mainly due to their $\nu_{C=O}$ and $\nu_{C=C}$, respectively. The observed $\Delta\nu_{C=O}$ values agree with the calculated one, 41 cm^{-1}, for 1850 cm^{-1} band on the basis of $\nu^{12}{}_{C=O}/\nu^{13}{}_{C=O}=1.0227$.[8] Almost the same shift of $\nu_{C=O}$ by ^{13}C-labelling was observed for **1** and **2**.

Table 1. IR spectral data (cm^{-1})

Compound	State	ν(non-labelled)	ν(^{13}C-labelled)	$\Delta\nu$
1	Neat	1724[b]	1679	45
		1715[b]	1674	41
2	Nujol	1725[b]	1690	35
		1723[b]	1684	39
3	Nujol	1847[a]	1809	38
		1840[a]	1806	34
		1624[a]	1609	15
		1618[a]	1604	14
4	Nujol	1842[a]	1807	35

		1847[c]	1828	19
		1843[c]	1821	22
		1756[d]	1757	1
		1659[a]	1659	0

a) Very strong. b) Strong. c) Medium. d) Weak.

Since the two bands of **5** at 1872 and 1867 cm^{-1} shift 18 cm^{-1} towards lower frequencies with ^{13}C-labelling, they seem to be mainly due to $\nu_{C=O}$ of *exo*-methylene moiety. However, a small shift of $\nu_{C\equiv N}$ of **5**, 2206 and 2197 cm^{-1}, was observed. No band of $\nu_{C=C}$ of cyclopropene moiety of **5** could be detected. The medium bands of **6** at 1847 and 1843 cm^{-1} would be mainly due to $\nu_{C=C}$ of *exo*-methylene of methylenecyclopropene moiety, since these bands of the ^{13}C-labelled sample appear at 19 and 22 cm^{-1} frequencies lower than those of the unlabelled compounds, respectively. The very

strong band of **6** at 1659 cm^{-1} not affected by ^{13}C-labelling could be assigned to $\nu_{C=O}$, since **7**[4] shows a similar $\nu_{C=O}$ band at 1680 cm^{-1}. However, neither 1888 nor 1756 cm^{-1} band could be assigned.

The authors wish to express their thanks to Professor Yoho Tsuno for his valuable suggestions on ^{13}C-labelling experiment.

A New Route to *o*-Methylthiomethylated Phenols by Use of *S,S*-Dimethylsulfilimines

Tamotsu YAMAMOTO* and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received February 4, 1978)

Synopsis. As convenient intermediates to introduce methyl groups into the *o*-positions of phenols, *o*-methylthiomethylphenols (*o*-MTM-phenols) were prepared in high selectivity and moderate yield by the reaction of phenols with sulfilimines such as *S,S*-dimethyl-*N*-(2,4-dinitrophenyl)- and *S,S*-dimethyl-*N*-tosylsulfilimines.

Phenols having methyl groups at the position ortho to the hydroxyl group are useful intermediates in organic synthesis.

The *o*-methylthiomethylation (*o*-MTM-ation) of phenol followed by reduction is known, as an indirect method to introduce methyl groups into the position ortho to hydroxyl group in phenols. For *o*-MTM-ation, methods using dimethyl sulfoxide together with dicyclohexylcarbodiimide,[1] acetic anhydride,[2] or pyridine–SO_3,[3] and dimethyl sulfide with *N*-chlorosuccinimide[4] have been reported. These methods have disadvantages such as low yield, minor selectivity, and trouble in handling.

We found that easily accessible sulfilimines, *S,S*-dimethyl-*N*-(2,4-dinitrophenyl)sulfilimine (**1a**) and *S,S*-dimethyl-*N*-tosylsulfilimine (**1b**), react with phenols to give the corresponding methylthiomethylated phenols, which are convertible into the corresponding methylated phenols,[1c,4] in good yield and with high selectivity.

2a **1** **3a** **4**

a: R=2,4-$(NO_2)_2C_6H_3$
b: R=Tos

A mixture of *o*-cresol (**2a**) and a half equivalent of **1a** was heated in bulk at 120—130 °C for 3 h. Work-up of the reaction mixture gave 6-MTM-2-methylphenol (**3a**) in 95% yield. The NMR data of **3a** were identical with those in literature.[1b] Similarly, from the reaction between **2a** and **1b** **3a** was obtained in 78% yield (based on reacted **1b**), which was found to be spectroscopically pure by NMR. In contrast with the former case, unreacted **1b** was conveniently recovered. The lower yield in the latter case might be caused by more difficult proton shift from **2a** to **1**.

A similar tendency was observed in the variation of methylthiomethylating agents, *N*-arylsulfonyl-*S,S*-dimethylsulfilimines (**1b**—**1e**) (Table 1): the sulfilimine having electron-donating group on benzene ring tends to give **3a** in a higher yield.

Although **1b** gives **3a** in a lower yield as compared with **1a**, the former is more accessible from dimethyl sulfide and chloramine T. The *o*-MTM-ation of other phenols with **1b** was examined. The corresponding *o*-MTM-phenols were obtained in a reasonable yield and with high selectivity at the position ortho to hydroxyl group (Table 2).

TABLE 1. EFFECT OF SUBSTITUTENT ON THE YIELD OF **3a**

	$Me_2S{=}NSO_2Ar$	Yield of **3a** (%)

$$\underset{\mathbf{2}}{HOAr} + \underset{\mathbf{1b}}{Me_2S{=}NTs} \longrightarrow \underset{\mathbf{3}}{HOAr'\text{-}MTM\text{-}(o)} + \underset{\mathbf{4b}}{H_2NTs}$$

2	**3** Y (%)	**3** Bp (°C/Torr)	**4b** Y (%)
a 2-$CH_3C_6H_4OH$	**a** 43 (73)	$73/3\times10^{-2}$ [$70/10^{-3}$][1b]	52 (≈100)
b 2-$CH_3OC_6H_4OH$	**b** 35 (78)	92—93/ 3×10^{-2}	45 (≈100)
c 2,5-$(CH_3)_2C_6H_3OH$	**c** 69 (96)	oil	72 (≈100)
d 3,5-$(CH_3)_2C_6H_3OH$	**d** 58 (58)[b]	oil	≈100
e 2,3,5-$(CH_3)_3CH_2OH$	**e** 37 (64)	oil	58 (≈100)

a) Data in parentheses show the yields based on the reacted **1b**. b) Bis-TMM-phenol was obtained in 35% yield.

The reaction scheme, in which *o*-MTM-phenols are formed from **2** and **1**, can be described partly from Moffatt's mechanism.[1] Especially in the first stage of the reaction, the proton shift (**2** to **1**), might play the most important role.

Experimental

Materials. Chloramine T and chloramine B of reagent grade were used. Sodium salts of *N*-chloro-*p*-chlorobenzenesulfonamide and *N*-chloromesitylenesulfonamide were prepared by the treatment of corresponding sulfonamides with aq solution of sodium hypochlorite (7%).

Preparation of Sulfilimines. **1a** was prepared by the method described in a previous paper.[5] *N*-Arylsulfonyl-*S,S*-dimethylsulfilimines were prepared by the reaction of dimethyl sulfide with sodium salts of *N*-chloroarenesulfonamides.[6] **1b.** Yield: 92%; Mp: 154—155 °C (MeOH) (lit,[7] 154—155 °C). *N*-Phenylsulfonyl-*S,S*-dimethylsulfilimine (**1d**). Yield: 86%; Mp: 128—129 °C (MeOH) (lit,[8] 131 °C). *N*-(*p*-Chlorophenylsulfonyl)-*S,S*-dimethylsulfilimine (**1d**). Yield: 80%; Mp: 115—116 °C (MeOH); IR(KBr): 1273 ($\nu_{as}SO_2$), 1133 (ν_s SO_2), 958 (S=N), 820 cm^{-1} (*p*-C_6H_4). Found: C, 37.97; H, 3.97; N, 5.57% (Calcd for $C_8H_{10}ClNO_2S_2$: C, 38.16; H, 4.01; N, 5.56%). *S,S*-Dimethyl-*N*-(2,4,6-trimethylphenylsulfonyl)sulfilimine (**1e**). Yield: 83%; Mp: 167—168.5 °C (MeOH); IR(KBr): 1280 ($\nu_{as}SO_2$), 1134 (ν_sSO_2), 945 (S=N), 843 cm^{-1} (*p*-C_6H_4). Found: C, 50.84; H, 6.69; N, 5.49% (Calcd for $C_{11}H_7NO_2S_2$: C, 50.93; H, 6.62; N, 5.40%).

Reaction of 2 with 1. General Procedure: A mixture of 10—20 mmol of **2** and a half equivalent of **1** was heated at 120—130 °C for 3—7 h. After the reaction, excess **2** was removed by distillation under reduced pressure. The resulting residues were extracted with hexane. The combined extracts were evaporated to dryness to give very viscous oils, which were almost pure *o*-MTM-phenols (**3**) as confirmed by NMR. The oils were purified by distillation (for **3a** and **3b**) or column chromatography (silica gel–hexane, for **3c**, **3d** and **3e**) for confirmation of the structures. 2,4-Dinitroaniline (**4a**), *p*-toluenesulfonamide (**4b**) and unreacted **1b** were separated from insoluble parts in hexane by extraction with ether and identified by comparison with authentic samples.

Reaction of o-*Cresol (2a) with 1*: (A) 1.08 g (10 mmol) of **2a** was reacted with 1.12 g (5 mmol) of **1a** at 120—130 °C for 3 h to give 798 mg (95%, based on **1a**) of **3a** and 914 mg of **4a**. (B) 1.08 g of **2a** was reacted with 1.16 g (5 mmol) of **1b** at 120—130 °C for 5 h to give 361 mg of **3a** and 445 mg of **4b**. **3a**: Bp: 73 °C (3×10^{-2}) [lit,[1b] 70 (10^{-3})]. IR(neat): 3400—3300 and 1210—1190 cm^{-1} (OH). NMR ($CDCl_3$): δ 1.96 (s, 3H), 2.26 (s, 3H), 3.75 (s, 2H), 6.62 (s, 1H), 6.7—7.3 (m, 3H).[1b]

Reaction of Guaiacol (2b) with 1b: 2.48 g (20 mmol) of **2b** was reacted with 2.31 g (10 mmol) of **1b** at 120—130 °C for 5h to give 644 mg of 6-MTM-2-methoxyphenol (**3b**) and 770 mg of **4b**. **3b**; Bp: 92—93 °C (3×10^{-2}). IR (neat): 3500—3400 and 1220 (OH), 1260 and 1070 cm^{-1} (C–O–C). NMR ($CDCl_3$): δ 2.08 (s, 3H), 3.75 (s, 2H), 3.89 (s, 3H), 5.92 (s, 1H), 6.7—7.0 (m, 3H).[2a] (Found: C, 58.48; H, 6.73; S, 17.12%. Calcd for $C_9H_{12}O_2S$: C, 58.66; H, 6.58; S, 17.40%.)

Reaction of 2,5-Dimethylphenol (2c) with 1b: 2.44 g (20 mmol) of **2c** was reacted with 2.31 g of **1b** at 120—130 °C for 7 h to give 1.25 g of 6-MTM-2,5-dimethylphenol (**3c**) and 1.23 g of **4b**. **3c**: IR (neat): 3500—3400 and 1220 cm^{-1} (OH). NMR (CCl_4): δ 1.96 (s, 3H), 2.18 (s, 3H), 2.27 (s, 3H), 3.72 (s, 2H), 6.17 (s, 1H), 6.54 (d, 2 H), 6.86 (d, 2H).[1b] MS: *m/e* 182 (M^+).

Reaction of 3,5-Dimethylphenol (2d) with 1b: 2.44 g (20 mmol) of **2d** was reacted with 2.31 g of **1b** at 120—130 °C for 7 to give 1.06 g of 6-MTM-3,5-dimethylphenol (**3d**) and 1.70 g of **4b**. **3d**: IR (neat): 3400 and 1150 (OH), 830 cm^{-1} (C_6H_2). NMR (CCl_4): δ 1.99 (s, 3H), 2.22 (s, 3H), 2.29 (s, 3H), 3.72 (s, 2H), 6.17 (s, 1H), 6.33 (s, 1H), 6.54 (s, 1H). MS: *m/e* 182 (M^+).

Reaction of 2,3,5-Trimethylphenol (2e) with 1b: 2.72 g (20 mmol) of **2e** was reacted with 2.31 g of **1b** at 120—130 °C for 7 h to give 726 mg of 6-MTM-2,3,5-trimethylphenol (**3e**) and 991 mg of **4b**. **3e**: IR (neat): 3400—3350 and1140 cm^{-1} (OH). NMR (CCl_4): δ 1.97 (s, 3H), 2.12 (s, 3H), 2.25 (s, 3H), 3.75 (s, 2H), 6.22 (s, 1H), 6.47 (s, 1H). Found: C, 66.95; H, 8.08%. Calcd for $C_{11}H_{16}OS$: C, 67.29; H, 8.23%.

Effect of Substituents on the Yield of 3a: Reactions of 2 mmol of **2a** with 1 mmol of **1** (**b**—**c**) were carried out at 130 °C for 5 h without solvent. Excess **2a** was removed from the reaction mixtures by distillation *in vacuo*. The residues obtained were analyzed for **3a** by liquid chromatography (a Shimadzu High Speed Chromatograph 840, Permaphase ODS–50% MeOH–H_2O) after evaporation of hexane. The data obtained (yield of **3a**) are given in Table 1.

Catalysis by Phosphine Complexes of Silylruthenium Hydrides of the Addition of Carbon Tetrachloride to 1-Octene[1)]

Hideyuki MATSUMOTO*, Taichi NAKANO, Yoichiro NAGAI, and Hiromichi KONO†

Department of Chemistry, Gunma University, Kiryu, Gunma 376

†*Sagami Central Research Center, Nishi-Ohnuma Sagamihara, Kanagawa 229*

(Received March 1, 1978)

Synopsis. Phosphine complexes of silylruthenium hydrides of types $[RuH_3(SiR_3)(PPh_3)_3]$ (where R_3Si= Et_3Si, Me_2PhSi, and $(MeO)_3Si$) and $[RuH(SiR_3)(PPh_3)_2]$ (where R_3Si=Cl_2MeSi and $(MeO)_3Si$) were found to be much more effective catalysts for the addition of carbon tetrachloride to 1-octene than $RuCl_2(PPh_3)_3$ or $RuH_2(PPh_3)_4$.

The addition reactions of carbon tetrachloride with olefins have been carried out with the aid of various catalysts (*e.g.*, peroxides, metal carbonyls and metal salts, *etc.*).[2)] We have recently found that the addition reactions were effectively catalyzed by a homogeneous ruthenium catalyst, dichlorotris(triphenylphosphine)-ruthenium(II).[3,4)] This catalyst was shown to have definite advantages (*e.g.*, high yields of 1: 1 adducts, unique selectivities and simplicity of the system, *etc.*)[3,4)] compared to usual free-radical addition reactions. Even more effective catalysts have now been found as described below.

We have prepared phosphine complexes of silylruthenium hydrides of types $[RuH_3(SiR_3)(PPh_3)_3]$ (where R_3Si=Et_3Si, Me_2PhSi, and $(MeO)_3Si$) and $[RuH(SiR_3)(PPh_3)_2]$ (where R_3Si=Cl_2MeSi and $(MeO)_3Si$) by the reactions of $RuH_2(PPh_3)_4$ or $RuCl_2(PPh_3)_3$ with hydrosilanes.[5)] and tested the catalytic efficiencies of these complexes for the reaction between carbon tetrachloride and 1-octene. All experiments were carried out in an argon atmosphere under reflux conditions using a 1: 3 mixture of the olefin and the chloride. The results are presented in Table 1 together with those for the reactions catalyzed by $RuCl_2(PPh_3)_3$ and $RuH_2(PPh_3)_4$. The Table also shows the turn-over number of these complexes.

$$n\text{-}C_6H_{13}CH{=}CH_2 + CCl_4 \xrightarrow{[Ru]} n\text{-}C_6H_{13}CHClCH_2CCl_3$$

$$[Ru] = RuH_3(SiR_3)(PPh_3)_3,\ RuH(SiR_3)(PPh_3)_2$$

An inspection of the Table clearly indicates that seven-coordinate ruthenium complexes, $RuH_3(SiR_3)$-$(PPh_3)_3$, are particularly excellent catalysts for the addition reaction. With these catalysts, the 1: 1 adduct was obtained in 57—85% yields with turn-over number 2650—4250 while the values for $RuCl_2(PPh_3)_3$ and $RuH_2(PPh_3)_4$ amounted to be 130 and 370, respectively. Therefore, it is apparent that these silylruthenium complexes are 20—32 times more active than the dichlororuthenium complex and 7—11 times more active than the dihydroruthenium complex.

Although the turn-over number of the complexes, $RuH(SiR_3)(PPh_3)_2$, were smaller than those of the trihydrido analogs, these four-coordinate complexes were also found to be 2—7 times effective than $RuCl_2$-$(PPh_3)_3$ and $RuH_2(PPh_3)_4$.

It has been known that phosphine complexes of ruthenium hydrides often catalyze double-bond migration in some unsaturated system.[6)] Such migration, however, was not found in the present system and only the terminal adduct, 1,1,1,3-tetrachlorononane, was obtained under the conditions employed.

Table 1. Reactions of carbon tetrachloride with 1-octene catalyzed by phosphine complexes of silylruthenium hydrides[a)]

Catalyst	Catalyst concentration, mol%[c)]	Yield of the 1: 1 adduct, %[d)]	Catalytic efficiency[e)]
$RuH_3(SiMe_2Ph)L_3$	0.02	57	2850
$RuH_3(SiMe_2Ph)L_3$	0.02	85	4250
$RuH_3(SiEt_3)L_3$	0.02	58	2900
$RuH_3[Si(OMe)_3]L_3$	0.02	53	2650
$RuH(SiCl_2Me)L_2$	0.05	44	880
$RuH[Si(OMe)_3]L_2$	0.05	46	920
RuH_2L_4	0.10	37	370
$RuCl_2L_3$ ($L=PPh_3$)	0.15	20	130

a) Reactions were carried out in an argon atmosphere under reflux conditions for 5 h using 50 mmol of the olefin and 150 mmol of the chloride. b) The system was carefully degassed by freeze-pump-thaw cycles and then flushed well with argon prior to the reaction. c) Based on the olefin charged. d) Yields (*via* GLC) of the adduct, 1,1,1,3-tetrachlorononane, are based on the olefin charged. e) The catalytic efficiency is meant by (moles of the adduct)/(moles of the catalyst).

Experimental

1-Octene and carbon tetrachloride were commercially available and purified by distillation prior to use. The complexes $RuCl_2(PPh_3)_3$,[7)] $RuH_2(PPh_3)_4$,[8)] $RuH_3(SiR_3)$-$(PPh_3)_3$,[5)] and $RuH(SiR_3)(PPh_3)_2$[5)] were prepared according to literature directions.

Procedure for Testing the Catalytic Efficiencies of Phosphine Complexes of Silylruthenium Hydrides. All runs were conducted in essentially the same manner; therefore, only the reacttion catalyzed by the $RuH_3(SiMe_2Ph)(PPh_3)_3$ complex is described in detail.

In a 50-ml round bottomed flask, equipped with a reflux condenser and a magnetic stirring bar were placed 5.61 g (50 mmol) of 1-octene, 23.05 g (150 mmol) of carbon tetrachloride and 0.11 g (0.010 mmol) of the complex. The system was flushed with argon and the solution was refluxed for 5 h with stirring. GLC analysis of the resulting mixture disclosed that the 1: 1 adduct, 1,1,1,3-tetrachlorononane, had been produced in 57% yield based on the olefin charged. Structural assignment for this adduct was performed by comparing their physical properties (IR and NMR spectra and

GLC retention times, *etc.*) with those of an authetic sample after isolation by GLC.

Another reaction was carried out with a slight modification in order to optimize the yield of the 1:1 adduct. Thus, the same mixture of the olefin, the chloride and the catalyst was cooled in liquid nitrogen, evacuated at 0.3 mm, flushed well with argon and then heated under reflux for 5 h. GLC analysis of the resulting mixture showed production of the 1:1 adduct in 85% yield.

A Photoreaction of 4-Nitrophenylnitromethane in a Micellar System

Kazutoshi YAMADA,* Kiyoshi SHIGEHIRO, Toyohiko KIYOZUKA, and Hirotada IIDA

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho Chiba 280

(Received March 3, 1978)

Synopsis. The photoconversion of 4-nitrophenylnitormethane into 4-nitrobenzaldehyde in an ethanol–water system was found to proceed by an intramolecular rearrangement of oxygen of adjacent nitro group. Cationic surfactant increased the quantum yield of this photorearrangement by a factor of 20, but β-cyclodextrin decreased it.

4-Nitrophenylnitromethanide anion is formed in ethanol–water by removal of a proton from 4-nitrophenylnitromethane (**1**). The nitromethanide anion is thermally stable for at least 24 h. The present paper is concerned with its photorearrangement. The catalytic effect of a cationic surfactant and β-cyclodextrin (β-CDX) was also studied.

Photoreaction. Irradiation of a 20% (vol) ethanolic alkaline aqueous solution of **1** gave 4-nitrobenzaldehyde.

$$\text{Ar-CH}_2\text{-NO}_2 \rightleftharpoons \text{Ar-CH=NO}_2^- \rightleftharpoons \text{Ar-}\bar{\text{C}}\text{H-NO}_2$$

$$\downarrow h\nu$$

$$\left[\text{Ar-CH(O)-N-O}^-\right] \longrightarrow \text{Ar-CH=O}$$

The ionization, removal of a proton from **1**, and the decrease of the aci-nitroate anion of **1** during the course of irradiation followed the pseudo-first-order kinetics. The rate constant of the ionization was greater than that of the decrease under the present conditions.[1] The decrease of aci-nitroate anion is considered to be the rate-limiting step in the overall rate of photoreaction. The photoreaction was followed by ultraviolet spectroscopy. Isosbestic points were found at 312, 256, and 227 nm as the time of irradiation; the maximum absorbance of the aci-nitroate anion of **1** at 384 nm decreased, while a new maximum appeared at 268 nm, the position for λ_{max} of 4-nitrobenzaldehyde.

4-Nitrophenylacetonitrile which has a cyano group instead of a nitro group was photoconverted into 4-nitrobenzaldehyde by oxygen in an ethanol–aqueous alkali solution. It was not allowed to react under anaerobic conditions. The observed quantum yield for the photoconversion of **1**, however, did not change in the presence or absence of oxygen. From these results and the fact that the oxazirane ring decomposes by the action of alkali to the formation of carbonyl compounds[2] it is shown that the photoreaction of **1** proceeds by an intramolecular attack of oxygen on the adjacent nitro group to α-carbon.

In order to confirm the mechanism of this photorearrangement, the relation between the stability of the aci-nitroate anion and the photoreaction was studied. The presence of a cationic surfactant, hexadecyltrimethylammonium bromide (CTAB), and β-CDX caused a red shift in the λ_{max} for the aci-nitroate anion (Table 1). The λ_{max} for 8×10^{-5} M of **1** in 20% (vol) ethanolic aqueous buffer (pH 6.90) began to show the shift at a concentration of CTAB above 2.24×10^{-4} M, which indicates a critical micelle concentration (CMC) of CTAB for **1**.

The presence of CTAB and β-CDX in micellar concentration decreased the pK_a value of **1** (Table 1), indicating the stabilization of aci-nitroate anions This results from (a) electrostatic interaction with cationic head groups of CTAB and the anion form, and (b) electron delocalization by the hydrogen bond between an adjacent hydroxyl group of β-CDX and an oxygen atom of 4-nitro group of the substrate which forms a 1 : 1 inclusion complex with β-CDX.

The quantum yield for the photoreaction of **1** in 20% ethanolic aqueous buffer (pH 6.90) increased in the presence of micellar concentration of CTAB. The quantum yield started to increase above 1.78×10^{-4} M of CTAB in good agreement with CMC. Since the quantum yield reached saturation in high concentration

Table 1. The effect of CTAB and β-CDX on the visible spectra and the pK_a value of 4-nitrophenylnitromethane

	H_2O	CTAB[a]	β-CDX[b]
λ_{max}/nm[c]	384	404	390
pK_a[d]	6.00	4.92	4.84

a) In the presence of 10^{-2} M CTAB. b) In the presence of 4×10^{-3} M β-CDX. c) In 20% ethanolic aqueous buffer (pH 6.90). d) In 20% ethanolic water at room temperature. The pK_a values were measured according to the method of Wolff.[3]

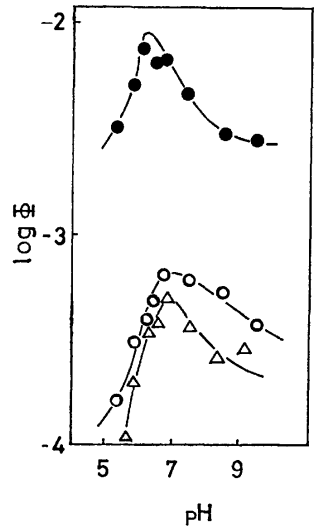

Fig. 1. A pH-quantum yield profile for the photorearrangement of 4-nitrophenylnitromethane. ○: In the absence of surfactants, ●: in the presence of 5×10^{-3} M CTAB, △: in the presence of 4×10^{-3} M β-CDX.

of CTAB, a general mechanism involving the micelle-substrate complex in a manner analogous to that for enzymatic catalysis[40] was applied. Micellar CTAB increased the quantum yield (Φ_{obsd}) for the photoreaction of **1** in 20% ethanolic aqueous buffer (pH 5.38) by a factor of 20, and increased the quantum yield for the formation of product from the micellar phase (Φ_2) by a factor of 12.

Variation of quantum yields over the pH range 5—10 was bell-shaped both in the absence and the presence of CTAB and β-CDX (Fig. 1). When CTAB was present, its maximum moved to a lower pH range. Stabilization of the aci-nitroate anion by CTAB micelle reflects directly on the quantum yield. The difference in OH^- concentration between micellar surface and bulk phase is an important factor. However, no such direct influence of stabilization appeared in the presence of β-CDX. The quantum yields decreased in the presence of β-CDX over all the pH range. Probably the dynamic equilibrium of micell micellar CTAB facilitates the rearrangement of oxygen of adjacent nitro group and the rigid cavity of β-CDX inhibits the rearrangement of substrate forming a complex with β-CDX.

Experimental

UV spectra were taken on a Hitachi ESR-3T or Shimadzu UV-200 spectrometer. The pH value was measured with a model HM-5A pH meter (TOA Electronics, Co., Ltd.). The following buffer solutions were used according to the required pH range: M/15 KH_2PO_4–Na_2HPO_4 (pH 5—9), M/20 H_3BO_3–KCL (pH 9—10), M/20 Na_2HPO_4–NaOH (pH 10—12). Commercial CTAB was recrystallized twice from methanol–ether.[5] Other materials were used without further purification. 4-Nitro-phenylnitromethane was prepared by the procedure of Hantzsch and Veit.[6]

Irradiation of 4-Nitrophenylnitromethane (1). A solution of 500 mg of **1** in 1 liter of ethanol-aqueous NaOH solution was as irradiated with an Ushio UM-452 450 W high pressure mercury lamp for 3 hs. After irradiation, the solvent was removed with a rotary evaporator and the oily residue was chromatographed on silica gel using hexane: benzene mixture as an eluent to give two products. The first product (90 mg) seemed a dimer-like compound, mp 286—290 °C, and MS, *m/e* 270 (M^+). No further effort has been made to determine the structure. The second product (20 mg) was identified as 4-nitrobenzaldehyde.

4-Nitrobenzoic acid analysis was carried out by high speed liquid chromatography with a Hitachi Liquid Chromatograph 634A equipped with a UV monitor. Hitachi gel #3020 was packed into the column (2.1ϕ × 500 mm) with a mobile phase of the mixture of methanol–water (8: 2) system. The flow rate of the phase 0.85 ml/min. with a column pressure of approximately 80 kg/cm². The column temperature was 50 °C. Under these conditions, the retention volume of 4-nitrobenzaldehyde and 4-nitrobenzoic acid was 3.06 ml and 1.79 ml, respectively. Variation of the concentration of 4-nitrobenzoic acid with the time of irradiation of **1** was obtained. The formation of 4-nitrobenzaldehyde was slow as compared with the photoreaction, giving no effect on the kinetics.

Kinetic Method. The kinetics was studied by following the reaction spectrophotometrically at the λ_{max} of the nitronate anion in each buffer solution at room temperature. All the data were treated as those of pseudo-first-order kinetics. The estimated rate constant values were converted into the the quantum yield.[7]

Effect of Dissolved Oxygen on the Reaction. After bubbling argon gas for a certain time in order to remove dissolved oxygen, the solution was irradiated and the rate was measured. The quantum yield obtained was compared with that in the pressure of dissolved oxygen.

References

1) For example, the k_{obsd} value for the ionization was 2.47×10^{-2} s^{-1} and that for the photoreaction was 5.41×10^{-5} s^{-1} in 20% (vol) ethanolic aqueous buffer (pH 6.90) at 15 °C. Avery and Bultler reported that the k_{obsd} for the ionization of **1** at zero buffer concentration is 5.75×10^{-3} s^{-1} in 1% dioxanborax buffer at pH 8.10 and 25 °C: S. P. Avery and A. R. (Received March 30, 1978)

Synopsis. Hydrogenolysis of 4,4-dimethyltricyclo-[6.3.0.0^{1,7}]undecane-2,6-dione with a Pd-C catalyst gave *cis*-4,4-dimethylbicyclo[6.3.0]undecane-2,6-dione and 8,8-dimethylspiro[4.6]undecane-6,10-dione. The *cis* isomer has been shown to isomerize almost completely to the *trans* isomer under acidic and basic conditions.

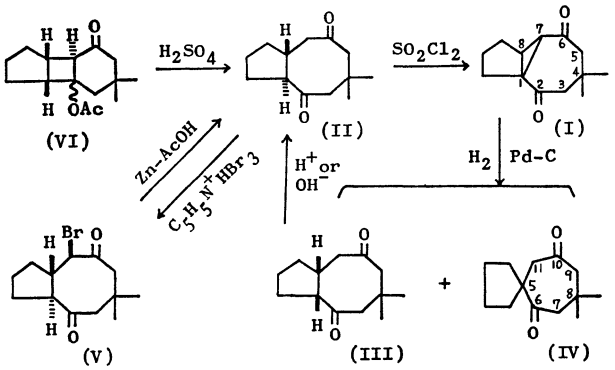
Previously it has been reported that 4,4-dimethyltricyclo[6.3.0.0^{1,7}]undecane-2,6-dione (I) has been formed as the main product in the chlorination by sulfuryl chloride of 4,4-dimethylbicyclo[6.3.0]undecane(II).[1]

Hydrogenolysis of I in ethanol with a palladium-charcoal catalyst at ordinary room temperature and pressure cleaved the three-membered ring with ease to give *cis*-4,4-dimethylbicyclo[6.3.0]undecane-2,6-dione (III), mp 116—117 °C, as the main product together with a small amount of an isomer (IV), mp 62—63 °C. The ratio of III to IV was approximately 10: 1.

A molecular peak appeared at 208 in the mass spectrum of III as in the case of II.[2] The fragmentation of III was identical with that of II, differing only in relative intensity. Furthermore, III isomerized readily to II when left to stand at room temperature in acidic or alkaline methanol. This shows that II and III are the *cis* and *trans* isomers concerning the ring fusion of the 5—8 fused ring and that II is more stable than III. When a solution of either II or III in 0.4 mol/dm^3 KOH–methanol solution was left to stand at 25 °C, NMR and IR spectroscopy showed that only II was present; III was undetectable even after 45 h. It was not possible to separate II and III by gas chromatography, and hence the equilibrium constant for the reaction *cis*⇌*trans* could not determined.

X-Ray analysis of the 7-bromo derivative (V; mp 111—113 °C[1]†) of II showed that the 5—8 ring fusion of V was *trans*.[3] V was synthesised from II, the more stable isomer, by bromination with pyridinium bromide perbromide. The debromination of V by zinc dust[4] in acetic acid at room temperature yielded the starting dione (II). Hence the ring fusion of II was *trans*, the same as that of V. II resulted from the retro-aldol cleavage of a photoadduct VI,[2] and since the 5—4 ring fusion of VI was *cis*,[2] it is likely that the isomerization from an unstable *cis* configuration to a more stable *trans* configuration, occured in the retro-aldol cleavage to give II. The carbonyl group at position 2 in II and III undergoes enolization in an acidic or alkaline solution, facilitating the *cis-trans* isomerization.

IV arising from the hydrogenolysis of I over Pd–C showed the same molecular peak as that of II and III in its mass spectrum. However, the fragmentation of IV differs considerably from that of II or III. In the NMR spectrum of IV, hydrogen atoms other than those in the five-membered ring appear as singlets and there is an absence of coupling. The *gem*-dimethyl groups show a single peak at 1.05 δ(6H) and the three methylene groups at positions 7, 9, and 11 appear as singlets at 2.73 δ (2H), 2.69 δ(2H), and 2.42 δ(2H), respectively. These results suggest that the protons in the carbonyl-containing ring do not assume a fixed conformation and IV has been estimated to be a spiro compound, 8,8-dimethylspiro[4.6]undecane-6,10-dione. Consequently, in the hydrogenolysis of I over Pd–C, the C(1)–C(7) linkage is cleaved preferentially to give III, accompanied by a slight cleavage of the C(7)–C(8) linkage to give IV. However, the cleavage of the C(1)–C(8) linkage did not occur.



Experimental

Hydrogenolysis of I. A suspension of I (0.5 g) and 5% Pd–C (0.5 g) in a solution of ethanol (40 ml) was stirred at room temperature with hydrogen at 1 atm until absorption was complete (3 h). The filtered solution was concentrated under reduced pressure to give a crystalline residue. Crystallization from hexane gave III (0.24 g); mp 114—116 °C. Recrystallization from hexane gave pure III; mp 116—117 °C. IR (Nujol) 1700 cm^{-1}; (CCl_4) 1705 cm^{-1}. NMR ($CDCl_3$): δ 1.10 (3H, CH_3) and 1.20 (3H, CH_3). Found: C, 75.08; H, 9.55%. Calcd for $C_{13}H_{20}O_2$: C, 75.00; H, 9.62%. MS: *m/e* 208 (M^+, 7%), 193 (8), 190 (1), 180 (2), 152 (11), 141 (56), 124 (20), 112 (29), 95 (17), 83 (base, 100), 81 (5), 67 (32), 55 (23), and 41 (27).

The mother liquor afforded III (0.12 g), and IV (36 mg) as needles. IV; mp 60—62 °C, which was recrystallized from hexane; mp 62—63 °C. IR (Nujol) 1700 cm^{-1}; (CCl_4) 1700

† This compound was assumed to be the 5-bromo-derivative in a previous paper,[1] but X-ray analysis[3] showed it to be the 7-bromo derivative.

cm^{-1}. NMR ($CDCl_3$) δ 1.05 (s, 6H, *gem*-$(CH_3)_2$), 1.4—2.2 (broad, 8H, 5-membered ring H), 2.42 (s, 2H, CH_2), 2.69 (s, 2H, CH_2), and 2.73 (s, 2H, CH_2). Found: C, 75.12; H, 9.67%. Calcd for $C_{13}H_{20}O_2$: C, 75.00; H, 9.62%. MS: *m/e* 208 (M^+, 41%), 193 (2), 180 (2), 167 (5), 152 (6), 148 (5), 141 (13), 128 (16), 124 (15), 111 (23), 98 (6), 95 (8), 83 (base, 100), 81 (25), 70 (30), 67 (31), 56 (37), and 41 (39).

Epimerization of III to II. A solution of III (20 mg) in 5% H_2SO_4–methanol was left to stand at room temperature for 2 weeks, and extracted with ether. The extract was washed with aqueous sodium hydrogencarbonate and water, and then dried over sodium sulfate. After the removal of ether, a crystalline residue was obtained (mp 60—62 °C); the IR spectrum was identical with that of II.[2]

Equilibrium for the Reactions II⇌III. Equilibrium was approached from both sides by allowing each compound (II and III, 40 mg) to stand for 45 h in 0.4 mol/dm^3 KOH–methanol solution (5 ml) at 25 °C. The solution was extracted with ether and washed with water, dried and evaporated. In each case the products were identical to II on the basis of their IR and NMR spectra, and III was not detected. In GPC analysis II and III showed the same retention time.

Debromination of V. The bromination of II with pyridinium bromide perbromide in ethanol gave V.[1] To a solution of V (50 mg) in ether (4 ml) and acetic acid (1 ml), zinc dust (90 mg) was added. The reaction mixture was stirred at room temperature for 50 min and diluted with ether (10 ml). The ethereal solution was filtered and the zinc washed with ether. The combined ethereal solution was washed twice with aqueous sodium hydrogencarbonate and finally with water, and then dried over sodium sulfate. After the removal of ether, a crystalline residue was obtained (31 mg), mp 62—63 °C, and identified as II by IR spectroscopy. Recrystallization from hexane afforded pure II; mp 64—65 °C.

ESR Study on Molecular Alignment of Various Nitroxides in a Nematic Liquid Crystal†

Hisao TANAKA*,†† and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received December 5, 1977)

Various nitroxides with characteristic molecular shapes were studied by ESR spectroscopy to determine the relation between the molecular shape and the ordering in the nematic phase. The hyperfine splitting shifts upon going from the nematic to the isotropic phase and the relative widths of the nitroxyl nitrogen hyperfine lines were examined. Together with an estimate of the molecular dimensions, these results revealed that the ordering properties in three types of nitroxides(each of which has its elongated molecular axis along one of the three principal axes of the nitroxyl nitrogen dipolar tensor) can all be understo od well in terms of the slender molecular shape. This led to the deduction that the Saupe-type anisotropic induced dipole-dipole interaction between the overall molecule of nitroxide and the nematic molecule is superior to the local interaction between the substituent moieties of nitroxide and nematic molecule. The dipolar anisotropy of the β-proton of nitroxide was evaluated to be 3 G.

In the nematic mesophase, the solvent molecules which arrange their elongated axes in parallel through the anisotropic potential presented by Maier and Saupe[1] align first in the direction of the external magnetic field; then the solute molecules dissolved in the mesophase are forced to align partially with the field due to the solute-solvent interaction.[2-4] In consequence of this partial orientation of the solute molecules, the anisotropic spin interactions cause characteristic changes of the spin coupling and relaxation in nuclear magnetic[5-8] and electron spin resonances.[9-12]

We have investigated the solute-solvent interaction in a nematic solution by an ESR technique, using nitroxides as solutes. In the course of these studies, nitroxides have shown some advantages: they are generally stable, have large anisotropies of the dipolar spin interaction of the nitroxyl nitrogen, give relatively simple ESR patterns, and also are rich in the variety of their compounds.

In present study we have examined the effect of the molecular shape of nitroxide on its ordering property in the nematic phase. Another approach to the problem has been made using the diamagnetic species as solutes.[13] We have synthesized many stable nitroxides with a variety of molecular shapes, *e.g.* small or large and spherical or slender, and have measured the hyperfine(hf) splittings in the nematic and isotropic phases together with the widths of the nitrogen hf lines. We wish to report here that a complete examination of the various nitroxides led to the idea that the molecular shape makes a major contribution to the ordering property.

Experimental

The nematic liquid crystal *N*-(4-methoxybenzylidene)-4-butylaniline(MBBA) purchased from Fuji Color Co. was purified by a zone refining method with *ca.* 30 repetitions using Dry Ice–methanol as cooling reagent. It was dried with a mixture of molecular sieves 3A and 5A, followed by distillation under vacuum. The melting point of the purified material and its nematic-isotropic transition point were 20 and 43 °C, respectively, as found from differential thermal analysis(DTA).

The nitroxides studied are shown in Fig. 1. 2,2,6,6-Tetramethyl-4-oxo-1-piperidinyloxyl (Tanone; **6**) and 4-hydroxy-2,2,6,6-tetramethyl-1-piperidinyloxyl (Tanol; **4**) were obtained from Frinton Laboratories Co. The hydrazone derivatives of Tanone,**1**, **2**, and **3**, were synthesized by condensation[14] of the corresponding hydrazine and Tanone in water–methanol solvent. The five-membered nitroxides **5** and **7** were produced[15] by the respective 1-pyrroline *N*-oxides and hydrogen atoms which were generated by a microwave discharge in hydrogen gas. The nitroxides **8** and **9** were synthesized through reactions[16] of *N*-*t*-butyl-α-phenylmethanimine *N*-oxide with phenyllithium and with butyllithium, respectively, followed by air oxidation.

The ESR samples were prepared as a nematic solution containing *ca.* 10^{-3} mol/dm^3 of nitroxide in MBBA and were degassed by several repetitions of a freezing and thawing cycle under vacuum. The ESR spectra were recorded using a home-made X-band spectrometer with a JEOL 30 cm magnet under 455 kHz field modulation at the low limits of microwave and modulation powers. The temperature of a given sample was regurated by controlling the flow rate and temperature of dry nitrogen gas which first passed over a heater and then went around a sample tube set in a double-walled quartz tube inside a cavity. The temperature was read from an Ohkura AM-1001 microvoltmeter by placing

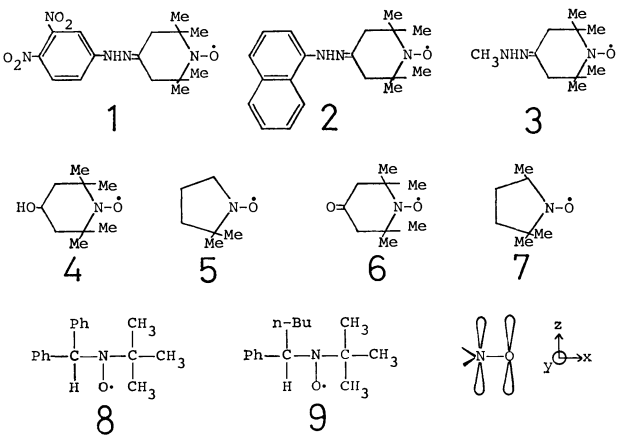

Fig. 1. The nitroxides in present study and the dipolar axes system of nitroxyl nitrogen.

a copper-constantan thermocouple near the sample tube and was constant to within ±1 °C.

Results

For the nitroxides **1**—**4** and **6**, the ESR spectrum consisted of only three hf absorptions due to the coupling of the nitroxyl nitrogen. For **5**, **7**, **8**, and **9** each of these three was further split into a doublet or triplet due to the couplings of one or two protons in β-position to the nitroxyl group. The nitrogen hf splitting a_N^{nem} and proton hf splitting a_H^{nem} measured in the nematic phase of MBBA at 25 °C, together with the a_N^{iso} and a_H^{iso} values in its isotropic phase at 50 °C, are given in Tables 1 and 2. For some nitroxides the temperature dependence of the nitrogen hf splitting in both nematic and isotropic phases is shown in Fig. 2.

The width of the low field nitrogen hf line, ΔH_1, was slightly but apparently different from the width of the central line, ΔH_0, although the linewidth on the high field side, ΔH_{-1}, was greatly broadened for all the nitroxides in the nematic phase. The relative widths $\Delta H_1/\Delta H_0$ and $\Delta H_{-1}/\Delta H_0$ which were estimated from the relation[17] $\Delta H_M/\Delta H_0=\sqrt{h_0/h_M}$ (h; peak to peak height) are listed in Table 3.

Table 1. Nitrogen hf splitting a_N^{nem} in the nematic phase of MBBA at 25 °C, a_N^{iso} in its isotropic phase at 50 °C, shift $a_N^{nem}-a_N^{iso}$, and ordering parameter θ_{zz} (1G=10^{-4} T)

Nitroxide	a_N^{nem}/G	a_N^{iso}/G	$(a_N^{nem}-a_N^{iso})$/G	θ_{zz}
1	12.35	14.56	−2.21	−0.135
2	12.98	14.69	−1.71	−0.104
3	13.74	14.64	−0.90	−0.055
4	15.49	15.51	−0.02[a]	—
5	13.55	13.55	0.00[a]	—
6	13.41	14.61	−1.20	−0.073
7	13.54	14.90	−1.36	−0.083
8	16.71	14.93	+1.78	+0.110
9	16.02	14.73	+1.26	+0.079

a) These are zero within an experimental error of ±0.05 G.

Table 2. Proton hf splitting a_H^{nem} in the nematic phase of MBBA at 25 °C, a_H^{iso} in its isotropic phase at 50 °C, and shift $a_H^{nem}-a_H^{iso}$ for the nitroxides with β-protons (1G=10^{-4} T)

Nitroxide	a_H^{nem}/G	a_H^{iso}/G	$(a_H^{nem}-a_H^{iso})$/G
5	19.17	19.18	−0.01
7	20.35	20.74	−0.39
8	3.16	3.36	−0.20
9	2.33	2.49	−0.16

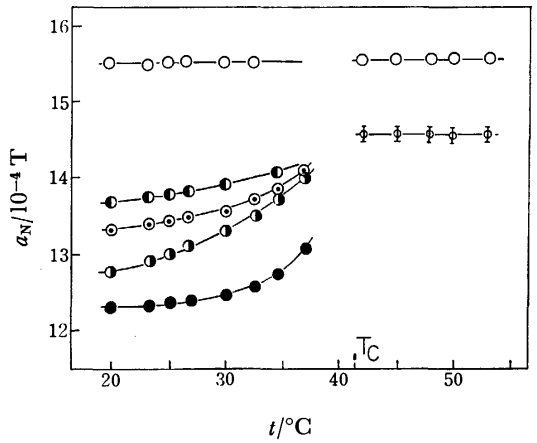

Fig. 2. Temperature dependence of the nitrogen hf splitting for some nitroxides measured above and below the nematic-isotropic transition point of MBBA (T_c): ●: **1**, ◑: **2**, ◐: **3**, ○: **4**, ⊙: **6**, and Φ; **1**—**3** and **6** in the isotropic range.

Table 3. Relative widths $\Delta H_1/\Delta H_0$ and $\Delta H_{-1}/\Delta H_0$ among three nitrogen hf lines, measured in the nematic phase of MBBA at 25 °C

Nitroxide	$\Delta H_1/\Delta H_0$	$\Delta H_{-1}/\Delta H_0$
1	0.94	1.83
2	0.96	1.62
3	0.96	1.55
6	1.04	1.45
7	1.03	1.42
8	1.04	1.85
9	1.04	1.75

As seen in Table 1, the coupling shift $a_N^{nem}-a_N^{iso}$ upon going from the nematic to the isotropic phase is a negative value for the nitroxides **1**—**3**, **6**, and **7**, is zero within experimental error for **4** and **5**, and is a positive value for **8** and **9**. The five nitroxieds with a negative shift are divided into two groups with respect to $\Delta H_1/\Delta H_0$: the three nitroxides **1**—**3** with $\Delta H_1/\Delta H_0$ less than 1.00 and the two **6** and **7** with $\Delta H_1/\Delta H_0$ more than 1.00. Thus, from the viewpoints of both splitting shift and relative width, the present nitroxides can be classified into four groups: **1**—**3**, **4** and **5**, **6** and **7**, and **8** and **9**.

Discussion

*Nitroxides **1**—**3**.* The principal axes system of the nitroxyl nitrogen dipolar tensor in nitroxides is shown in Fig. 1: here the z-axis is along the nitrogen π-orbital, the x-axis is extended along the N–O bond, and the y-axis is perpendicular to both the x- and the z-axes. We adopt the principal values[18] of the tensor of Tanone, *i.e.* $A_{Nzz}=16.4$ and $A_{Nxx}=A_{Nyy}=-8.2$ G for all the nitroxides studied here. Then, taking into account the axial symmetry of the dipolar tensor, the ordering element[19] about the z-axis, θ_{zz} can be simply related to the observed shift $a_N^{nem}-a_N^{iso}$, as in Eq. 1.[20]

$$a_N^{nem}-a_N^{iso}=\theta_{zz}A_{Nzz} \quad (1)$$

The parameter θ_{zz} takes a positive value between 0 and 1 when the z-axis is preferentially along the external magnetic field. It takes a negative value between 0 and −1/2 when the z-axis is preferentially across the field, in correspondence to a partial orien-

tation of the solute molecules in the nematic phase. In the extremes of alignment of the z-axis with respect to the field, the θ_{zz} value ideally reaches 1 or $-1/2$. Of course in the isotropic phase it is 0.

The θ_{zz} values at 25 °C are estimated from Eq. 1 and the $a_N^{nem}-a_N^{iso}$ values and are shown in Table 1. In this table we find that the θ_{zz} values in nitroxides **1**—**3** are all negative, while the absolute values are in the increasing order from **3** to **1**, indicating that the most preferential alignment of the z-axis across the field is in **1**. This order was conserved at all the other temperatures measured in the nematic phase, as shown in Fig. 3.

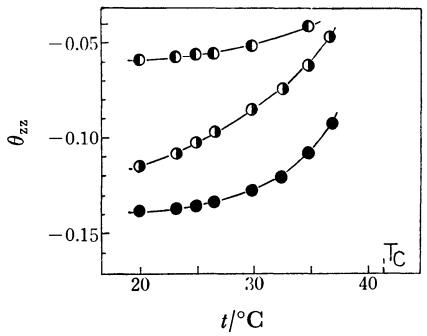

Fig. 3. Temperature dependence of the ordering parameter θ_{zz} for some nitroxides in the nematic phase of MBBA: ●: **1**, ◑: **2**, and ◐: **3**.

From the relative width $\Delta H_1/\Delta H_0$ we can determine the molecular axis directed preferentially to the field, according to the theoretical results[12,21-23] on the anisotropic spin relaxation in a low region of the solute alignment, such as present cases: the molecular axis with the maximum Brownian rotation is near the x-axis of nitroxide when $\Delta H_1/\Delta H_0<1$, while it is near the y- or z-axis when $\Delta H_1/\Delta H_0>1$. In addition, if the molecular shape of the present nitroxide is approximated as an ellipsoid,[13] the axis with the maximum Brownian rotation corresponds to the elongated molecular axis and hence the axis directed along the field.

Thus we can deduce that, for the nitroxides **1**—**3** with ΔH_1 smaller than ΔH_0, the x-axis represents the alignment axis along the field. Supporting this deduction, the Dreiding model for these radicals showed the elongated molecular axis closest to the x-axis. The alignment degrees of the x-axis, θ_{xx}, are calculated from the θ_{zz} values and the relation $\theta_{xx}=-2\theta_{zz}$, which is derived from the assumption of the traceless property of the ordering matrix ($\theta_{xx}+\theta_{yy}+\theta_{zz}=0$) and its axial symmetry in the ellipsoidal molecule ($\theta_{yy}=\theta_{zz}$); they are 0.27. 0.21, and 0.11 for the nitroxides **1**, **2**, and **3**, respectively. These values mean that the nitroxide **1** aligns along the field most preferentially, while **3** aligns the least.[24]

From a glance of Fig. 1, it can be seen that the above order in the alignment degrees is related to the difference in the molecular shapes. Indeed, the Dreiding model allows us to estimate rough molecular dimensions of the nitroxides and to give the $L_x/L_\perp$ values of 1.9, 1.5, and 1.2 for the nitroxides **1**, **2**, and **3**, respectively, where L_x is the molecular length along the x-axis and $L_\perp$ is the larger one of L_y and L_z.

A good agreement between the order of $L_x/L_\perp$ values and that of the θ_{xx} values indicates that the more slender the molecular shape of the nitroxide is, the higher its alignment degree becomes. The bulkiness of the molecule and the properties of the substituent moieties do not seem to exert a primary effect on the molecular ordering of the nitroxides.

*Nitroxides **4** and **5**.* These species showed no appreciable shift in the splitting constants (Table 1 and Fig. 2). An absence of the solute alignment can be explained in terms of the spherical property but not in terms of the smallness.

*Nitroxides **6** and **7**.* Interestingly, these small radicals can align in the nematic phase, giving negative splitting shifts, although the six-membered nitroxides **4** and **6**, as well as the five-membered nitroxides **5** and **7**, are similar to each other in molecular structure and in mass. In the latter two the introduction of the third methyl group into the β-position of the five-membered ring of **7** may lead to a slight extention of the molecular dimension along the y-axis of the dipolar principal axes in **7**. In fact, the $L_\perp/L_y$ value (where $L_\perp$ is the larger one of L_x and L_z) is 0.7 for **7** while it is 0.9 for **5**. This small difference in the molecular shape allows the y-axis of **7** to orient along the external field and prevents **5** from such an alignment. The observation of the relative width ($\Delta H_1/\Delta H_0>1$) could also support the alignment of the y-axis along the field in **7**, in contrast to the alignment of the x-axis along the field in **1**—**3**.

The nitroxide **6** has the carbonyl group in the γ-position of the six-membered ring and **4** has the hydroxyl group in the same position. In addition, as has been previously suggested,[25] **6** prefers a twisted form and **4** prefers a chair form in the ring conformation. Both these facts tend to shorten slightly the molecular dimension of the x-axis in **6**, while keeping the length of the y-axis in both nitroxides constant ($L_\perp/L_y$; 0.8 for **6** and 0.9 for **4**). This allows the y-axis of **6** to orient along the field as in the case of **7**. The relative width $\Delta H_1/\Delta H_0$ of 1.04 does not conflict with the above view.

From the results in the relatively small nitroxides **4**—**7** we recognize that the major factor in determining the solute alignment in the nematic phase is not the mass of the nitroxide but rather its slenderness. The effect of the local interaction between the polar group (hydroxyl in **4** or carbonyl in **6**) and the solvent molecule does not affect primarily the molecular ordering, as shown by the fact that the nitroxide **4** or **6** is analogous to **5** or **7**, respectively, in the ordering property.

*Nitroxides **8** and **9**.* These are unique nitroxides which provide positive splitting shifts and hence have their z-axes in the direction along the external field in the nematic phase. A possible explanation of the preferential alignment of the z-axis along the field is given on the basis of a special configuration: the elongated molecular axis linking the two phenyl moieties in **8** and that linking the phenyl and butyl moieties in **9** are nearly parallel to the respective z-axes; the free rotation around the bond between nitrogen and the carbon attached by those substituents is also restricted.

The above picture could be supported by estimating

the dihedral angle of the β-H–C bond to the π-orbital of the nitroxyl nitrogen in both nitroxides. The observed Fermi coupling of the β-proton, a_H^{iso}, is related to the dihedral angle ϕ_H in the McConnell Eq. 2,[26] where the negligible term independent of ϕ_H is excluded.

$$a_H^{iso} = B\rho_N \cos^2 \phi_H \quad (2)$$

The product $B\rho_N$, where B is a constant and ρ_N is the unpaired electron density on the nitrogen atom, is usually taken for nitroxide as 25 G ($B \simeq 50$G and $\rho_N \simeq 0.5$).[27] Then, from the a_H^{iso} values in Table 2, we can obtain *ca.* 70 ° for ϕ_H in both **8** and **9**. Hence, as seen in the Neumann projection (Fig. 4), the axis linking the two bulky groups which attach to the carbon which is bonded to the β-proton is approximately parallel to the z-axis.

Now we can conclude as follows, summarizing the results of the ordering preferences in all the nitroxides: with respect to the principal axes of the nitroxyl nitrogen dipolar tensor, the nitroxides **1**—**3** orient their elongated x-axes along the field, **6** and **7** orient their elongated y-axes along the field, and **8** and **9** orient their elongated z-axes along the field (Table 4). The nearly spherical nitroxides **4** and **5** do not show any appreciable orientation. The alignment degree becomes higher for the more slender ellipsoid in the molecular shape of the solute, as can be seen from the comparison among **1**—**3**. The substituent groups of the nitroxide mainly act on the ordering property through the effect of their shapes on the overall molecular shape. These results taken together lead us to consider that the major interaction between nitroxide and nematic molecules is the Saupe-typed anisotropic dispersion interaction[1-4] which is most stabilized when the long axes of both solute and solvent molecules, along which the induced dipoles are distributed uniformly over the molecules, are arranged in parallel to each other. Then the slender shape of the nitroxide molecule, corresponding to the high anisotropy of the induced dipole, causes its high ordering in the nematic phase through the effective solute-solvent interaction. These results correspond to the results[13] in the case of the use of diamagnetic species as solutes.

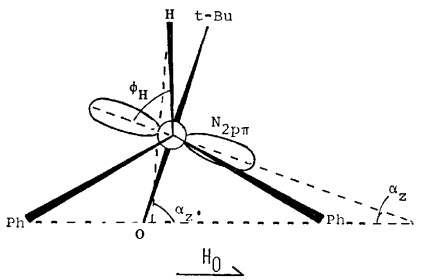

Fig. 4. Neumann projection of nitroxide **8** oriented to the external field in the nematic phase. In nitroxide **9** whether of the two phenyl moieties is only replaced by a butyl moiety. The ϕ_H, α_z, and $\alpha_{z'}$ are defined in the text.

TABLE 4. PREFERENTIAL ALIGNMENT TO THE EXTERNAL FIELD H_0 IN THE PRESENT NITROXIDES

H_0[a] ⟶	Sign of θ_{zz}	Relative width	Preferential axis along H_0[b]	Nitroxides
	−	$\Delta H_0 > \Delta H_1$	x	1, 2, 3
	−	$\Delta H_0 < \Delta H_1$	y	6, 7
	+	$\Delta H_0 < \Delta H_1$	z	8, 9

a) ⟶; the elongated molecular axis. b) x, y, and z; the principal axes of the nitrogen dipolar tensor.

Hf Anisotropy of β-Proton in Nitroxide. As shown in Table 2, the splitting shifts of the β-proton, $a_H^{nem} - a_H^{iso}$, in the nitroxides **7**—**9** are rather small compared with the respective splitting shifts of the nitroxyl nitrogen, indicating the small hf anisotropy of the β-proton. We can estimate the amount of the anisotropy from the example of nitroxide **8**: under a point dipole approximation[28] for the N–O group, the maximal principal value $A_{Hz'z'}(=-2A_{H\perp'})$ of the dipolar spin interaction is found along the axis directed from the β-proton towards the point dipole located in the center of the N–O bond. Then with respect to this axis(z') a relation similar to Eq. 1 exists also in the case of the β-proton ($a_H^{nem} - a_H^{iso} = \theta_{z'z'} A_{Hz'z'}$). From both equations the $A_{Hz'z'}$ is given by

$$A_{Hz'z'} = \frac{\theta_{zz} A_{Nzz} (a_H^{nem} - a_H^{iso})}{\theta_{z'z'} (a_N^{nem} - a_N^{iso})}. \quad (3)$$

The θ_{ii} is written as follows, assuming an ellipsoidal molecular shape:

$$\theta_{ii} = \theta_{mol}(3\cos^2\alpha_i - 1)/2, \quad (4)$$

where θ_{mol} is the alignment degree of the elongated molecular axis and α_i the angle which this makes with the i-axis.

We can take the elongated axis of the nitroxide **8** along the axis linking the centers of the phenyl groups, according to the previous result, and then find the α_z of 20° and $\alpha_{z'}$ of 86° by using the dihedral angle of 70° and the standard bond lengths and angles[29] (Fig. 4). Substituting the A_{Nzz} of Tanone and the $a_N^{nem} - a_N^{iso}$, $a_H^{nem} - a_H^{iso}$, θ_{zz}, and $\theta_{z'z'}$ of **8** into Eq. 3, we obtain 3.1 G for the $A_{Hz'z'}$. This value of the dipolar anisotropy is as small as expected and corresponds to the small splitting shifts in the nematic phase.

The authors wish to thank Professor E. G. Janzen of Georgia University for gifts of *N*-*t*-butyl-α-phenylmethanimine *N*-oxide and 1-pyrroline *N*-oxides and Professor Shyuzo Seki of Osaka University for zone refining and DTA measurements.

24) Such a comparison among the radicals **1**—**3** is justified by the following reasoning: with an ellipsoidal approximation of molecular shape the alignment degree of the molecular i-axis, θ_{il}, can be written as $\theta_{il}=\theta_{mol}(3\cos^2\alpha-1)$, where θ_{mol} is the alignment degree of the elongated molecular axis and α the angle both axes make. The radicals **1**—**3**, all hydrazone derivatives of Tanone, have approximately the same angle of α. Then the structural difference in **1**—**3** changes the θ_{il} value only through the difference of θ_{mol}.

The Crystal Structure of the B-form of Stearic Acid

Midori GOTO* and Eiichi ASADA
National Chemical Laboratory for Industry, Hon-cho, Shibuya, Tokyo 151
(Received December 6, 1977)

The crystal structure of the B-form of stearic acid has been studied by X-ray diffraction. The structural parameters were refined by the block-diagonal least-squares method, and the final R value was 0.084. In this structure, the bond between the second and third carbon atoms was found to be the *gauche* conformation, although the other bonds were in the *trans* conformation usually seen in normal fatty acids.

The crystal structure of the B-form of stearic acid has been studied only by two-dimensional Fourier methods. von Sydow[1] determined the crystal structure in the a-axis projection, and subsequently Larsson and von Sydow[2] determined it in the b-axis projection. Larsson and von Sydow[2] mentioned, however, that an attempted three-dimensional refinement was not successful because of the disorder in the crystal.

The present authors could obtain fairly good single crystals of the B-form of stearic acid, and reinvestigated its crystal structure.

Experimental

Stearic acid was purified by recrystallization from a methanol solution. The B-form crystal was obtained by crystallization in a 2,2,4-trimethylpentane solution, kept for two weeks at room temperature.

The infrared absorption spectrum showed that the crystal was in the B-form, not in the E-form discovered by Holland and Nielsen.[3] Twinning was not observed for the crystal used.

The diffraction intensities were measured by means of a Rigaku-Denki four-circle diffractometer by using graphite monochromated Cu $K\alpha$ radiation.† The crystal data and experimental conditions are given in Table 1, compared with the corresponding data of other workers.[1,2]

Structure Determination

The $|F_c(hkl)|$ values calculated from (x,z) coordinates by Larsson *et al.*[2] and the (y,z) coordinates calculated by von Sydow,[1],†† did not agree with the $|F_o(hkl)|$ values obtained in this experiment; the disagreement of ($11l$) reflections was especially

a) A transformed unit cell given by von Sydow (1955) was chosen for convenience of calculation. However, the c and β values given by Larsson *et al.* might be somewhat erroneously determined; more reasonable values would be c=43.84 Å and β=89.56°. If these corrective values are used, the unit cell given by Larsson *et al.* can be transformed by the following matrix to that of Sydow or the present authors.

$$\begin{vmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 4 & 0 & 1 \end{vmatrix}$$

b) $|F_o^p|$: $|F_o|$ of the present work. $|F_o^A|$: $|F_o|$ by other authors.[1,2]

† The table of the observed and calculated structure factors has been deposited with the Office of the Chemical Society of Japan (Document No. 7828).

†† The z coordinates prepared by Larsson *et al.*[2] are almost identical with those prepared by von Sydow.[1]

noticeable. The least-squares method did not lead to further refinement at the R-value of 37% when their coordinates were used.

The present authors, therefore, reinvestigated the structure, determining the positions of carbon atoms from the Patterson map and the packing of the molecules.

The positions of oxygen atoms were obtained by means of difference synthesis. The hydrogen-atom positions, with the exception of that of the carboxyl hydrogen atom, were calculated by assuming C–H distances of 1.10 Å and a tetrahedral arrangement. The structure was refined by the block-diagonal least-squares method using the HBLS program (Ashida).[4] The R-value was reduced to 0.084. The final atomic parameters obtained are listed in Table 2.

The y and z coordinates obtained by the present authors do not significantly differ from those of von Sydow,[1] but the x coordinates of atoms, especially those near the carboxyl group, were not in agreement with those prepared by Larsson *et al.*[2]

Figure 1 illustrates the difference in the two structures by the projection along the b-axis. The two structures are different, especially near the carboxyl group. The atomic positions prepared by Larsson *et al.*[2] were too erroneous to be refined by the least-

squares calculations.

Discussion

The bond lengths, bond angles, and internal rotation angles are shown in Table 3. An ORTEP[6] drawing is shown in Fig. 2.

It is evident from Fig. 1 or Fig. 2 that the molecules of the B-form of stearic acid do not form an all-*trans* zigzag chain, such as is usually found in fatty acids. The bond between the second and the third carbon atoms is in the gauche conformation. The internal rotation angle of this bond is calculated to be 68°, as is indicated in Table 3(c). von Sydow[1] suggested that the hydrocarbon chain was deformed near the carboxylic group, but he gave no details. Larsson *et al.*[2] did not mention this deformation; their structure was seen to be, rather, an all-*trans* zigzag chain.

The planarity of the chain is shown in Table 4. The dihedral angle between the plane of the carbon main chain and the plane containing the carboxyl group is 70°.

The subcell is orthorhombic, with dimentions of a_s=4.96 Å, b_s=7.39 Å, and c_s=2.50 Å. This is nearly the same as the C-form of lauric acid.[5]

The arrangement of the end group is shown in Fig. 3. As is commonly found in fatty acids, the molecules are bound together to form dimers through hydrogen bonds between the carboxyl groups. The hydrogen bond length is 2.65 Å, and the closest intermolecular

The dihedral angle between the two planes=70°

distance of the end group (except the hydrogen bond) is 3.1 Å. This distance is nearly equal to that of the A-super form of lauric acid[7] and is shorter than that of the C-form of lauric acid,[5] in which the closest distance is 3.4 Å. This is because the C-form, the highest temperature form, is likely to have a looser structure than the B- and A- forms.

We wish to thank Professor Y. Iitaka of the University of Tokyo for his encouragement and helpful discussions. We are also grateful to Dr. J. Hiraishi and S. Tamura of this laboratory for performing the infrared absorption measurements.

Absorption and Fluorescence Spectra of Anthracenecarboxylic Acids. I. 9-Anthroic Acid and Formation of Excimer

Satoshi SUZUKI,* Tsuneo FUJII, Nobuyuki YOSHIIKE,†
Shigeru KOMATSU,†† and Toshiko IIDA
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received December 8, 1977)

The absorption spectra of 9-anthroic acid (9-anthracenecarboxylic acid) in ethanol have been measured as a function of solute concentration. It was revealed that 9-anthroic acid forms a hydrogen-bonded dimer. The equilibrium constant for dimer formation was determined to be 6.6×10^4 mol^{-1} l in ethanol at 298 K. The fluorescence spectra of 9-anthroic acid have been investigated as a function of concentration and temperature in various solvents. An excimer mechanism was proposed for a broad fluorescence of 9-anthroic acid; the hydrogen-bonded dimer is excited and then associates with an unexcited hydrogen-bonded dimer to form an excited tetramer from which the broad fluorescence occurs.

The fluorescence spectrum of 9-anthroic acid (9-anthracenecarboxylic acid) in ethanol is strongly concentration-dependent. At a concentration below 10^{-5} mol/l the spectrum has an anthracene-like structure, while at a concentration above 10^{-3} mol/l it shifts to the red, turning into a broad structureless band. In order to elucidate this spectral change, Bazilevskaya and Cherkasov postulated that the linear-type dimers formed in the ground state rearrange themselves upon excitation into a characteristic excimer configuration, wherein the planes of anthracene rings are parallel.[1,2] On the other hand, Werner and Hercules explained the concentration dependence on the basis of an acid-base equilibrium, assigning the anthracene-like structured fluorescence to an ionized species.[3]

An excimer mechanism for the broad fluorescence of 9-anthroic acid is presented in this paper. In alcoholic solvents, 9-anthroic acid forms a hydrogen-bonded dimer in its ground state. The hydrogen-bonded dimer is excited and then associates with an unexcited hydrogen-bonded dimer to form an excited tetramer from which the broad fluorescence occurs. A discussion is given on an assumption of the excimer mechanism, validity of the assumption being made on the basis of experimental findings.

Experimental

9-Anthroic acid was purified by dissolution in base, precipitation with acid, and sublimation *in vacuo*. Ethanol (Wako Pure Chemical Industries, Inc., Super special grade) and propylene glycol (1,2-propanediol, Wako JIS S grade) were stored over molecular sieves 3A and then passed through a silica gel column. Toluene and methanol (Wako fluorometric grade) and acetonitrile (Wako spectrophotometric grade) were used. Hexane and isooctane (2,2,4-trimethylpentane) were purified in the usual way. The other solvents (JIS S grade) were used without further purification. The absorption spectra were recorded on a Hitachi EPS-3 recording spectrophotometer. The fluorescence and excitation spectra were obtained by means of a Hitachi MPF-2A fluorescence spectrophotometer and are given without corrections on quantum response of detecting and exciting systems and on reabsorption. The temperature was controlled with a metal cryostat (Torisha Laboratory, Ltd.).

Results and Discussion

Absorption Spectra and Dimer Formation. The absorption spectrum of 9-anthroic acid in ethanol closely resembles that of anthracene. The lowest frequency band with a fine structure may reasonably be assigned to the ^1L_a transition and the intense band at higher frequencies to the ^1B_b transition. Figure 1 shows the concentration dependence of absorption spectra of 9-anthroic acid in ethanol. As the concentration of 9-anthroic acid increases, the ^1L_a band shifts to the blue and the fine structure becomes less sharp. The ^1B_b band also shows a blue shift. Several isosbestic points appear in the spectra. These observations indicate that a certain equilibrium is involved in the ground state of this system.

The most probable origin of the appearance of the isosbestic points in the absorption spectra of 9-anthroic acid is monomer-dimer equilibrium or proton dissociation. In the following, discussion is made as to which

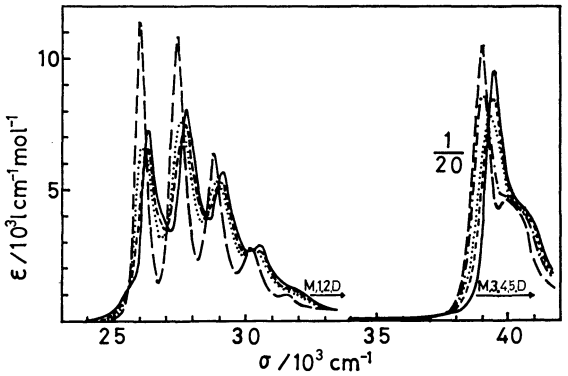

Fig. 1. The absorption spectra of 9-anthroic acid in ethanol at various concentrations and the estimated monomer and dimer absorption spectra. 1: 2.18×10^{-5} mol/l, 2: 1.09×10^{-4} mol/l, 3: 1.63×10^{-6} mol/l, 4: 1.63×10^{-5} mol/l, 5: 1.16×10^{-4} mol/l, M: the estimated monomer spectra, D: the estimated dimer spectra.

origin is valid on the basis of experimental evidence. Hereafter, the absorption band appearing at low concentrations in ethanol will be tentatively referred to as M absorption band, and the band at higher concentrations as D absorption band.

It has been well established that carboxylic acids have pK_a values in ethanol greater by about 5.8 than in water.[4,5] Since the reported pK_a value of 9-anthroic acid in water is 3.0[7] or 3.65,[6] it is estimated that that in ethanol is 8.8—9.4. If we assume that the concentration dependence of the absorption spectra in ethanol is attributed to proton dissociation, a pK_a value of 5.12 is obtained from the analysis of the observed concentration dependence of absorption spectra. This is too small to ascribe the concentration dependence of the absorption spectra to proton dissociation. From this point of view, proton dissociation is unfavorable as the origin of the spectral changes in this system.

When we ascribe the spectral changes to monomer-dimer equilibrium in this system, the equilibrium constant of dimer formation, K_D, can be determined by the usual procedure.[8] Thus, a K_D value of 6.6×10^4 mol^{-1} l was obtained for 9-anthroic acid in ethanol at 298 K. By using the observed spectral data at various concentrations and the K_D value, the monomer and dimer absorption spectra were determined. As shown in Fig. 1, the ^1L_a and ^1B_b bands become less sharp owing to dimer formation, which is consistent with general behavior of hydrogen bonding, but they show a blue shift. The origin of the unusual blue shift will be discussed later.

The formation of hydrogen-bonded dimers in aromatic carboxylic acids has been confirmed under various conditions for benzoic acid[8-11] and 1- and 2-naphthoic acids.[12] Besides the dimer formation, Kitamura and Baba reported that 1- and 2-naphthoic acid dimers further associate to give a higher-order complex which can be assumed to be a tetramer in a hydrocarbon rigid glass matrix at 77 K.[12] Similarly it is quite likely that 9-anthroic acid forms a hydrogen-bonded dimer under appropriate conditions. The monomer-dimer equilibrium constants for these acids are: 7.95×10^3 mol^{-1}. l for benzoic acid in hexane,[8] 7.6×10^4 mol^{-1} l for 1-naphthoic acid, and 3.4×10^4 mol^{-1} l for 2-naphthoic acid in a mixture of isopentane and methylcyclohexane (6:1 by volume).[12] It appears that the equilibrium constants increases with increase in the number of benzene rings and then decrease in solubility. Since 9-anthroic acid is hardly soluble in hydrocarbons, there is little possibility that monomer-dimer equilibrium is involved in hydrocarbon solvents. The monomer-dimer equilibrium of 9-anthroic acid might be observed only when a solvent of higher solubility such as ethanol is used. It thus seems that the K_D value we obtained is reasonable. In conclusion, 9-anthroic acid in ethanol forms a hydrogen-bonded dimer in its ground state.

9-Anthroic acid is hardly soluble in isooctane ($<10^{-5}$ mol/l). The absorption spectra of 9-anthroic acid in isooctane show no concentration dependence in the concentration range 10^{-5}—10^{-7} mol/l. The spectral shape in isooctane closely resembles D absorption band in ethanol. This indicates that 9-anthroic acid dissolves in isooctane in dimer form. The carboxyl group is a typical hydrophilic group, while the anthryl group is a hydrophobic group. The hydrophilic character of the carboxyl group will be masked by the dimer formation, so that the dimer form will be stable in aprotic solvents as compared with the monomer form.

Fluorescence Spectra. The fluorescence spectrum of 9-anthroic acid in ethanol has an anthracene-like structure at a concentration below 10^{-5} mol/l. With increase in concentration the fluorescence spectrum shifts to the red, turning into a broad structureless emission (Fig. 2). The structured fluorescence can tentatively be assigned to a monomer fluorescence and the broad fluorescence to an excimer fluorescence. Hereafter, the structured fluorescence band is referred to as M fluorescence band and the broad fluorescence band as E fluorescence band. The solvents in which 9-anthroic acid emits the structured M fluorescence are: *N*-methylformamide, formamide, ethylene glycol, propylene glycol, glycerol, methanol, ethanol, isobutyl alcohol, *s*-butyl alcohol, and water.

Figure 3 shows the concentration dependence of fluorescence spectra of 9-anthroic acid in toluene. 9-Anthroic acid emits a broad fluorescence which has a shoulder, lying at higher frequency than that of E fluorescence. The fluorescence of 9-anthroic acid in toluene shows no substantial concentration dependence

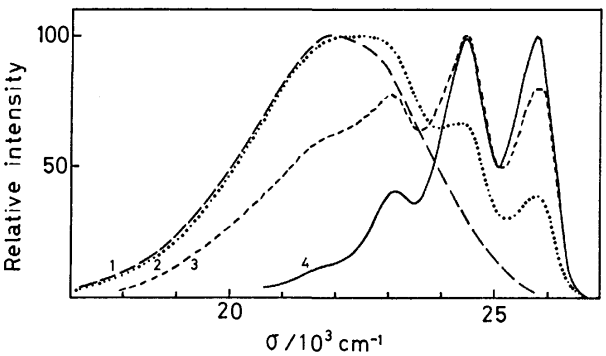

Fig. 2. The fluorescence spectra of 9-anthroic acid in ethanol at various concentrations. 1: 1.16×10^{-3} mol/l, 2: 1.29×10^{-4} mol/l, 3: 2.33×10^{-5} mol/l, 4: 1.16×10^{-6} mol/l. Methanol solution shows the analogous concentration dependence.

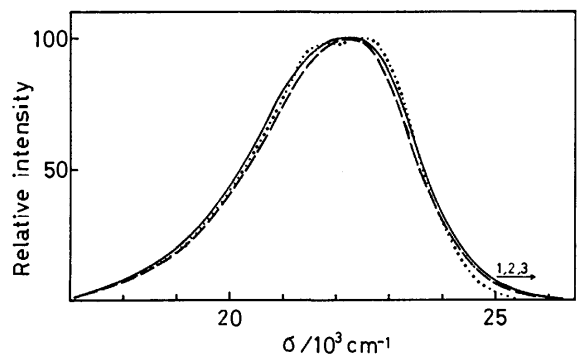

Fig. 3. The fluorescence spectra of 9-anthroic acid in toluene at various concentrations. 1: 1.2×10^{-3} mol/l, 2: 1.5×10^{-5} mol/l, 3: 3.0×10^{-7} mol/l.

down to 10^{-7} mol/l. These findings exclude the possibility of excimer emission for the broad fluorescence of 9-anthroic acid in toluene. The broad fluorescence band can be assigned to a dimer fluorescence and is hereafter referred to as D fluorescence band. The solvents in which 9-anthroic acid emits the broad D fluorescence only are: *N,N*-dimethylformamide, dimethyl sulfoxide, acetonitrile, acetone, 1,2-dichloroethane, tetrahydrofuran, methyl acetate, benzene, toluene, 1,4-dioxane, diethyl ether, hexane, isooctane, and *t*-butyl alcohol.

The spectral dependence of fluorescence spectra on the concentration of 9-anthroic acid in propylene glycol and isobutyl alcohol is given in Figs. 4 and 5. In propylene glycol, 9-anthroic acid emits M fluorescence only at lower concentrations. The fluorescence spectrum of 9-anthroic acid in isobutyl alcohol has M and D bands at 10^{-6} mol/l. The E band becomes obvious at concentration higher than 10^{-4} mol/l. Since 9-anthroic acid shows analogous spectral behavior both in ethanol and in propylene glycol, experimental studies on the temperature dependence of emission spectra were performed by using propylene glycol as a solvent instead of ethanol, because of experimental facility.

Figure 6 shows the excitation spectra of 9-anthroic acid at a concentration of 7.02×10^{-4} mol/l with observation at 410 and 540 nm. At this concentration,

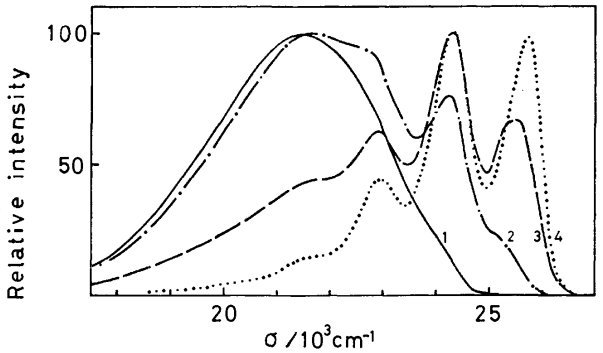

Fig. 4. The fluorescence spectra of 9-anthroic acid in propylene glycol at various concentrations. 1: 3.51×10^{-3} mol/l, 2: 7.02×10^{-4} mol/l, 3: 7.02×10^{-5} mol/l, 4: 1.01×10^{-5} mol/l.

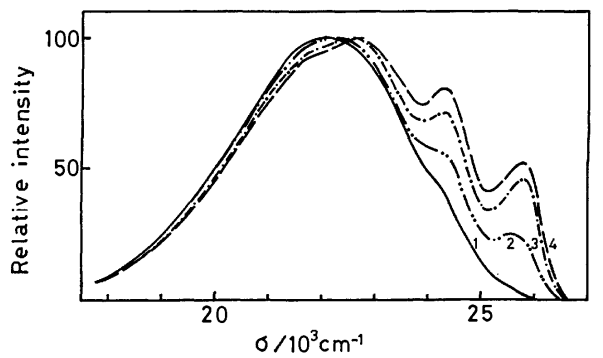

Fig. 5. The fluorescence spectra of 9-anthroic acid in isobutyl alcohol at various concentrations. 1: 10^{-3} mol/l, 2: 10^{-4} mol/l, 3: 10^{-5} mol/l, 4: 10^{-6} mol/l.

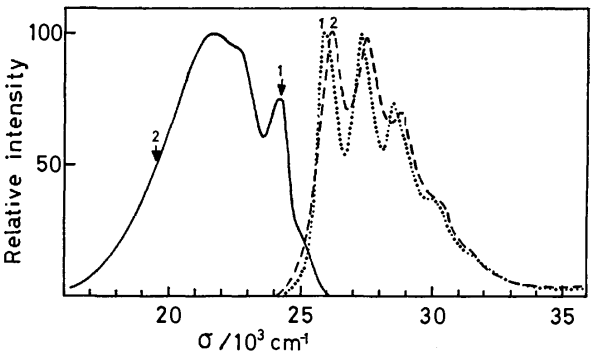

Fig. 6. The fluorescence and excitation spectra of 9-anthroic acid in propylene glycol at 299 K. Solute concentration: 7.02×10^{-4} mol/l. 1: observed at 410 nm, 2: observed at 540 nm.

the fluorescence has both structured and broad components. The excitation spectrum observed at the wavelength of the peak of M emission does not coincide with that observed at the wavelength of E emission. The former excitation spectrum corresponds to M absorption band, while the latter to D absorption band. It is therefore concluded that the broad E emission emerges only as a consequence of excitation of the species involved in solutions of higher concentrations.

As has been suggested by Werner and Hercules,[3] the most probable mechanism to account for a broad fluorescence is one involving rotation of the carboxyl group in the excited state into a position approaching coplanarity with the anthracene ring. A similar rotation may occur for the dimer molecules of 9-anthroic acid.

The results indicate that the use of a solvent having a hydroxyl or an imino group is essential for the appearance of M fluorescence, with exception of *t*-butyl alcohol. For instance, 9-anthroic acid emits M fluorescence in *N*-methylformamide, while it emits D fluorescence only in *N,N*-dimethylformamide. The solvents having a proton-accepting group only, such as acetone, 1,4-dioxane *etc.*, show no M fluorescence.

Werner and Hercules explained the concentration dependence of the fluorescence of 9-anthroic acid on the basis of an acid-base equilibrium.[3] For the molecular form of 9-anthroic acid a structureless fluorescence is observed. The large Stokes shift of the emission is a consequence of an excited state rotation of the carboxyl group into the plane of the anthracene ring. For the ionic form of 9-anthroic acid in protonic solvents, rotation is inhibited owing to strong ground-state solvation and an anthracene-like structured fluorescence is observed.

The simplest electrostatic theory based on Born's model predicts a linear relation between the medium effect on acid-base equilibria and the reciprocal of the dielectric constant of the solvents.[13] The experimental findings indicate that there is no correlation between the appearacne of the structured M fluorescence of 9-anthroic acid and the magnitude of dielectric constant of the solvent used. In view of the facts, we can rule out proton dissociation as the origin of M fluorescence for 9-anthroic acid.

Effect of Hydrogen Bonding. Figure 7 shows the effect of addition of acetic acid on absorption spectra of 9-anthroic acid in ethanol. Addition of acetic acid shifts the absorption spectra to the blue. As seen in Fig. 1, dimer formation also causes the blue shifts. These findings indicate that the blue shift caused by dimer formation is mainly attributed to hydrogen bonding between carboxyl groups rather than the exciton interaction between anthracene moieties.

A strong steric hindrance might exist between the carboxyl group and the peri-hydrogens, which would keep the carboxyl group from lying coplanar with the anthracene ring. It is likely that the hydrogen-bonded dimer in the ground state has a linear-type configuration in which two anthracene rings lie on the same plane and the plane of $-\overset{\diagup O\cdots HO\diagdown}{C\qquad\quad C}-$ bridge is almost $\diagdown OH\cdots O\diagup$ perpendicular to the plane of anthracene rings (Fig. 8). The anthracene-like structure of D absorption band supports this configuration for ground-state dimers, since the perpendicular configuration of the anthracene rings and $-\overset{\diagup O\cdots HO\diagdown}{C\qquad\quad C}-$ group minimizes resonance $\diagdown OH\cdots O\diagup$ interaction between these moieties.

Addition of a solvent having –OH or =NH group breaks the hydrogen bonds between a pair of 9-anthroic acid molecules and new hydrogen bonds are formed between "monomerized" acids and solvent molecules. The anthracene-like structure of M absorption band of 9-anthroic acid in ethanol supports the view that the hydrogen-bonded species with ethanol have a perpendicular configuration of the anthracene ring and the carboxyl group in the ground state.

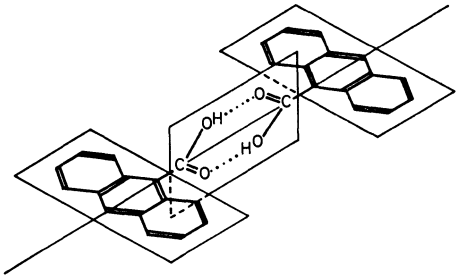

Fig. 8. The probable configuration of the hydrogen-bonded dimer of 9-anthroic acid.

9-Anthroic acid emits the structured fluorescence only when the solvent molecules have both proton-donating and accepting character such as –OH or =NH group. Such solvent molecules can self-associate through hydrogen bonding into a large variety of associated complex species (linear and cyclic polymers).[14,15] Fletcher studied the near-infrared absorption of decane solution of ethanol-*d* at 25 °C.[16] He found it to consist primarily of monomer, acyclic tetramer, and cyclic tetramer in ratios of 1:3.4:10.9, respectively. Kato and Fujiyama studied the local structures of a chloroform–ethanol system by light scattering.[17] They obtained the best fit between the calculated and observed concentration fluctuation by assuming that only an association of $(EtOH)_3CHCl_3$ can exist at 20 °C. The NMR study by Saunders and Hyne also confirmed that monomer-trimer and monomer-tetramer equilibria are dominant in ethanol–carbon tetrachloride system.[18] In the solvents in which 9-anthroic acid emits M fluorescence, the acid may associate with the solvent complex species through hydrogen bonding. This prevents the excited-state rotation of the carboxyl group, M fluorescence thus emerging. In *t*-butyl alcohol, 9-anthroic acid emits only a broad fluorescence. Probably, a bulky *t*-butyl group sterically hinders the formation of complex species, so that the excited-state rotation of a carboxyl group can not be prevented.

When a 9-anthroic acid molecule forms a dimer with another one in ethanol, the excited-state rotation of the carboxyl group will not be hindered because of the lack of the hydrogen-bonded linkages with solvent molecules. This leads to the excited-state rotation of $-\overset{\diagup O\cdots HO\diagdown}{C\qquad\quad C}-$ group into the plane of anthracene $\diagdown OH\cdots O\diagup$ rings, so that D fluorescence emerges. Thus, the appearance of the structured M fluorescence in ethanol may reasonably be interpreted within the framework of monomer-dimer equilibria.

The simplest exciton theory proposed by Kasha *et al.*[19,20] predicts the blue shift of the ^1B_b band and the red shift of the ^1L_a band, on the assumption that 9-anthroic acid dimer has the configuration shown in Fig. 8. Both the ^1B_b and ^1L_a bands of 9-anthroic acid show a blue shift (Fig. 1). The discrepancy on the shift of the ^1L_b band is due to the major contribution of the hydrogen-bonding effect on absorption spectra. This was confirmed experimentally as shown in Fig. 7. The hydrogen-bonded species with acetic acid show an absorption spectrum resembling D absorption band in ethanol. The contribution of exciton splitting is relatively small owing to the large distance of two anthracene rings separated by $-\overset{\diagup O\cdots HO\diagdown}{C\qquad\quad C}-$ linkage $\diagdown OH\cdots O\diagup$

and to small oscillator strength of the ^1L_a transition. The blue shift of the ^1L_a band is mainly attributed to hydrogen bonding.

Temperature Dependence of Fluorescence. Figure 9 shows the temperature dependence of fluorescence spectra of 9-anthroic acid in propylene glycol at higher concentration. Lowering the temperature largely displaces the fluorescence to the blue, but no structured fluorescence appears. The fluorescence observed at lower temperatures lies at a position between E and M fluorescence, having a spectral shape resembling D fluorescence. The excitation spectrum monitored at the maximum of this emission corresponds to D absorption band. The fluorescence observed at low temperature can be assigned to the fluorescence of 9-anthroic acid dimers on the assumption of monomer-dimer equilibrium. The fact that E fluorescence disappears at low temperature suggests an excimer-type mechanism as the origin of the broad E fluorescence.

The temperature dependence of the fluorescence spectra of 9-anthroic acid in propylene glycol at lower concentrations is given in Fig. 10. Lowering of temperature causes no substantial spectral changes except for sharpening of the spectrum. Figure 11 shows the temperature dependence of fluorescence in 1:3 methylcyclohexane and isopentane mixtures. Lowering of temperature shifts the fluorescence to the red, further

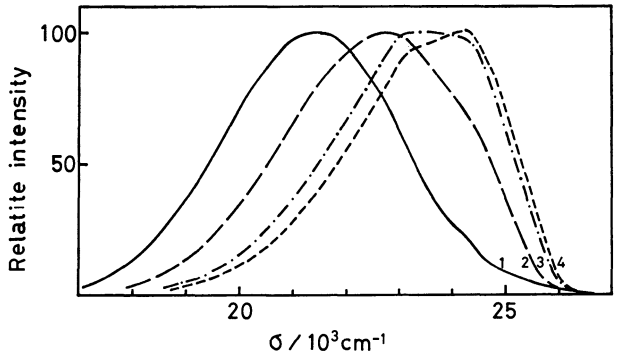

Fig. 9. The fluorescence spectra of 9-anthroic acid in propylene glycol at various temperatures. Solute concentration: 1.87×10^{-3} mol/l. Excitation wavelength: 362 nm. 1: 287 K, 2: 207 K, 3: 173 K, 4: 142 K.

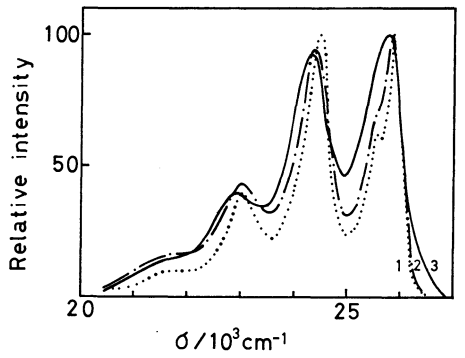

Fig. 10. The fluorescence spectra of 9-anthroic acid in propylene glycol at various temperatures. Solute concentration: 2.0×10^{-6} mol/l. Excitation wavelength: 362 nm. 1: 298 K, 2: 188 K, 3: 103 K.

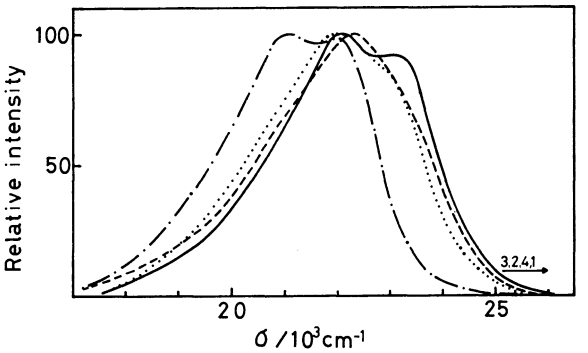

Fig. 11. The fluorescence spectra of 9-anthroic acid in 1:3 methylcyclohexane-isopentane mixture at various temperatures. Solute concentration: 9.6×10^{-6} mol/l. Excitation wavelength: 362 nm. 1: 286.5 K, 2: 260 K, 3: 140 K, 4: 77 K.

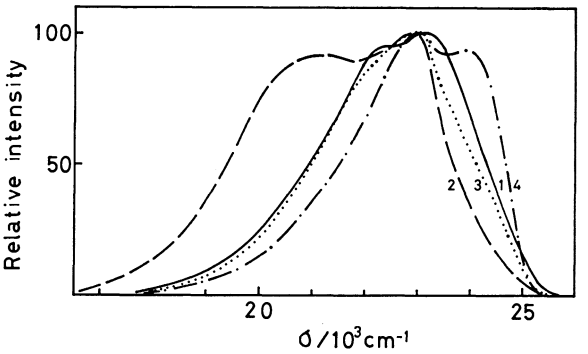

Fig. 12. The fluorescence spectra of 9-anthroic acid in diethyl ether at various temperatures. Solute concentration: 1.8×10^{-3} mol/l. Excitation wavelength: 362 nm. 1: 288 K, 2: 163 K, 3: 124 K, 4: 77 K.

lowering of temperature shifting the fluorescence to the blue, in line with the general behavior of the temperature dependence of fluorescence.[21]

The temperature dependence of fluorescence of 9-anthroic acid in diethyl ether at higher concentration is given in Fig. 12. At room temperature, 9-anthroic acid shows D fluorescence. On lowering the temperature, the component of E fluorescence appears in the spectrum. On further lowering of temperature, the emission shows blue shifts and E fluorescence disappears. Figure 13 gives the temperature dependence of 9-anthroic acid in diethyl ether at lower concentration. No component of E fluorescence appears in the whole temperature range at lower concentration. This indicates that excimer fluorescences can be observed in solvents other than alcohol, if appropriate conditions on concentration and temperature are fulfilled.

Figure 14 gives plots of $\log R$ *vs.* $1/T$ for 7.02×10^{-4} mol/l solution of 9-anthroic acid in propylene glycol. R is I_E/I_M, where I_E and I_M refer to the fluorescence intensity of E and M fluorescences, respectivley. The curve in Fig. 14 shows typical excimer behavior.[22,23] We can evaluate the binding energy of excimer, B, and the activation energy of excimer formation, W. On the assumption that the temperature dependence of the equilibrium constant is negligible within the limit-

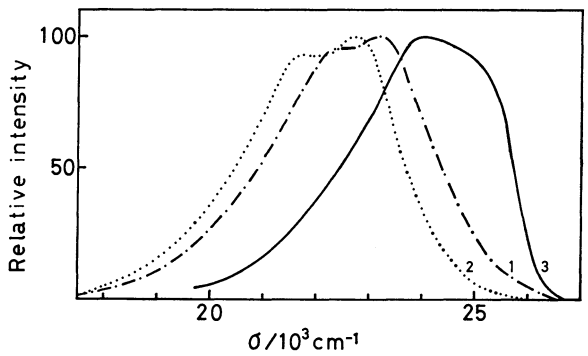

Fig. 13. The fluorescence spectra of 9-anthroic acid in diethyl ether at various temperatures. Solute concentration: 4.7×10^{-6} mol/l. Excitation wavelength: 362 nm. 1: 290 K, 2: 157 K, 3: 77 K.

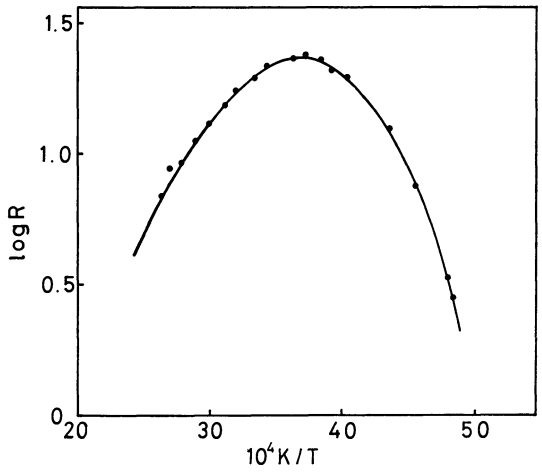

Fig. 14. The log R plot *vs.* $1/T$ for 7.02×10^{-4} mol/l solution of 9-anthroic acid in propylene glycol.

ed temperature range, $B=0.20$ eV was obtained from the slope at higher temperatures. The value of $W=0.36$ eV was also derived from the low-temperature slope of the curve. The values are in line with those obtained for other excimer-forming compounds. This indicates a "universal" type of excimer interaction on the dimer of 9-anthroic acid. Such behavior is unfavorable in the system involving proton dissociation. These findings support the excimer formation from the hydrogen-bonded dimers.

Kinetic Consideration. The ratio of the excimer fluorescence quantum yield to the monomer one is observed to be proportional to the monomer concentration in the case of usual excimer formation.[24] For 9-anthroic acid we propose the following scheme: A hydrogen-bonded dimer of 9-anthroic acid is excited and then associates with an unexcited dimer yielding an excited tetramer from which E emission occurs (Table 1). For steady excitation with light of intensity I_0, the rate equations for this scheme are

$$d[M^*]/dt = aI_0[M] - k_M[M^*],$$

$$d[D^*]/dt = bI_0[D] - (k_D + k_{ED}[D])[D^*] + k_{DE}[E^*],$$

$$d[E^*]/dt = k_{ED}[D][D^*] - (k_E + k_{DE})[E^*].$$

In the equations, the following supplementary parameters are defined:

Table 1. Reaction scheme

Process	Description	Rate parameter
$M^*\rightarrow M+h\nu_M$	fluorescence of M*	k_{FM}
$M^*\rightarrow M$	internal quenching of M*	k_{QM}
$D^*\rightarrow D+h\nu_D$	fluorescence of D*	k_{FD}
$D^*\rightarrow D$	internal quenching of D*	k_{QD}
$D^*+D\rightarrow E^*$	excimer formation	$k_{DE}[D]$
$E^*\rightarrow D^*+D$	regeneration of D* from dissociation of E*	k_{DE}
$E^*\rightarrow D+D+h\nu_E$	fluorescence of E*	k_{FE}
$E^*\rightarrow D+D$	internal quenching of E	k_{QE}

$$k_M = k_{FM} + k_{QM},$$

$$k_D = k_{FD} + k_{QD},$$

$$k_E = k_{FE} + k_{QE}.$$

M, D, and E refer to the monomer, hydrogen-bonded dimer, and excited tetramer, respectively. Under photostationary conditions $d[M^*]/dt=d[D^*]/dt=d[E^*]/dt=0$, and the following relations are obtained:

$$[D]/[M]^2 = K_D,$$

$$[E^*]/([D][D^*]) = K_E,$$

$$R = \frac{I_E}{I_M} = \frac{k_{FE}[E^*]}{k_{FM}[M^*]} \propto \frac{k_{FE}k_M K_E K_D^{1/2}}{k_{FM}} \frac{[D]^{3/2}}{k_D+(k_{ED}-k_{DE}K_E)[D]}.$$

The equation for R indicates that the ratio I_E/I_M is proportional to $[D]^{3/2}$ at low dimer concentrations.

The plot of log R *vs.* log [D] is given in Fig. 15. The I_M and I_E values are evaluated from the areas under the sharp and broad components, which are obtained by subtraction of the corrected M fluorescence spectrum, observed at the lowest concentration, from the corrected spectra observed at various concentrations. The broad component thus obtained closely resembles E fluorescence, indicating that the dimer fluorescence is not actually emitted in this system. It is seen from Fig. 15 that the slope of the plot for 9-anthroic acid

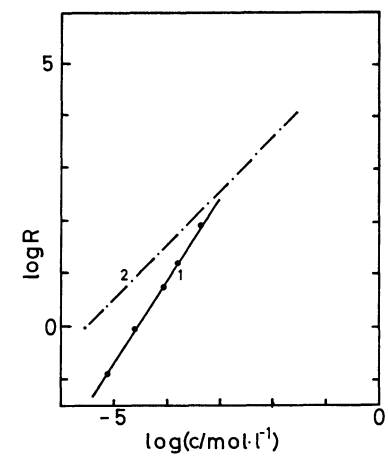

Fig. 15. The log R plot *vs.* log c. 1: The log R plot *vs.* log [D] for 9-anthroic acid in ethanol. 2: The log R plot *vs.* log [M] for 3-methylpyrene in cyclohexane.[23]

is 3/2. Figure 15 includes the plot of log R *vs.* log [M] for 3-methylpyrene, which forms a usual excimer. The slope of the plot is 1 as was expected. If we assume the reaction scheme according to Bazilevskaya and Cherkasov, the slope of the plot for log R *vs.* log [D] should be 1/2. On the other hand, the reaction scheme according to Werner and Hercules gives the slope of 1/2 *vs.* log [M]. We can therefore rule out the reaction scheme proposed by Bazilevskaya and Cherkasov and that by Werner and Hercules. If we assume that a hydrogen-bonded dimer molecule in the excited state associates with an unexcited monomer molecule, we can show that the slope of the plot for log R is 1 *vs.* log [D]. Kinetic consideration indicates the validity of the excited tetramer formed by the association of a hydrogen-bonded dimer in the excited state with a hydrogen-bonded dimer in the ground state.

Other Remarks and Conclusion. Cohen *et al.* gave a theoretical treatment on the general problem of the excimer emission from crystal, and applied it to the anthracene derivatives.[25] They suggested that 9-anthroic acid forms excimers in the head-to-head configurations in the crystal. Polarization study shows that the transition moment of the broad fluorescence has a component perpendicular to the dimer plane.[26] This observation also supports the conclusion stated above. The broad emission of 9-anthroic acid in alcoholic solvents originates from the excited tetramer formed by the association of an excited hydrogen-bonded dimer with an unexcited hydrogen-bonded dimer.

Far-infrared Reflection Spectra, Raman Spectra and Lattice Vibrations of $CsMgCl_3$ and $CsCaCl_3$

Yoshiyuki MORIOKA* and Ichiro NAKAGAWA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received December 13, 1977)

Far-infrared reflection spectra of single crystals of $CsMgCl_3$ and $CsCaCl_3$ have been measured, and the frequencies of transverse and longitudinal modes of infrared active vibrations have been determined using Kramers-Kronig relation. For $CsMgCl_3$ a measurement of polarized Raman spectra has been made. A normal coordinate analysis of the optically active lattice vibrations has been performed, in which the rigid ion model for long range Coulomb interactions and the central force field including the 1st differential coefficients of the pair-wise potential functions have been used. The obtained short range force constants K(Mg–Cl) and K(Ca–Cl) are 0.715 and 0.63 mdyn/Å, respectively, which indicate that some amount of covalent character exists in the Mg–Cl and Ca–Cl bonds.

During the course of our studies on the lattice vibrations and interionic interations in the metal halide crystals of the type MX_2 and AMX_3 (M: divalent metal, A: alkali metal, and X: halogen), the rigid ion model for the Coulomb interaction and the central force field for the short range interaction have been used successfully for the normal coordinate analysis of the optically active vibration of crystals.[1,2] In order to establish the interionic potential in the metal halide crystals, further investigations for various types of crystals are needed.

In this paper we present the far-infrared reflection spectra and Raman spectra of $CsMgCl_3$ and $CsCaCl_3$ crystals and the results of the calculation for the interionic potential constants and effective ionic charges. There have been no data of the crystal spectra for these salts, although McPherson and Chang reported the infrared transmission spectra of the powder sample of $CsMgCl_3$.[3]

The crystal structure of $CsMgCl_3$ belongs to the space group D_{6h}^4-$P6_3/mmc$, and a primitive unit cell consists of 2 formula units (Fig. 1).[4] The crystal structure of $CsCaCl_3$ is the cubic perovskite structure with the space group O_h^1-Pm3m and a primitive unit cell consists of 1 formula unit (Fig. 2).[5] The numbers of optically active lattice vibrations in different species are determined by factor group analysis. The results are shown in Table 1.

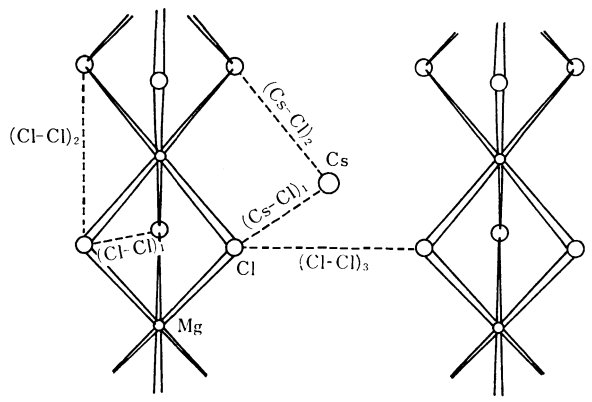

Fig. 1. Crystal structure of $CsMgCl_3$.

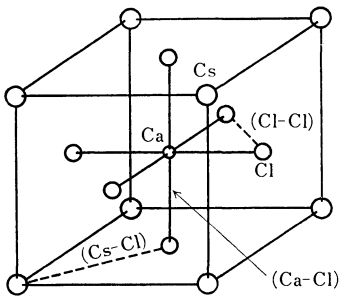

Fig. 2. Crystal structure of $CsCaCl_3$.

TABLE 1. RESULTS OF FACTOR GROUP ANALYSIS FOR OPTICALLY ACTIVE LATTICE VIBRATIONS OF $CsMgCl_3$ AND $CsCaCl_3$

Compound	Space group	Number of modes in each species
$CsMgCl_3$	D_{6h}^4-$P6_3/mmc$	$1a_{1g}+1a_{2g}+2b_{1g}+1e_{1g}+3e_{2g}+2a_{2u}+1b_{1u}+2b_{2u}+3e_{1u}+2e_{2u}$ (IR active: a_{2u}, e_{1u}; Raman active; a_{1g}, e_{1g}, e_{2g}[a])
$CsCaCl_3$	O_h^1-Pm3m	$3f_{1u}+f_{2u}$ (IR active: f_{1u})

a) Raman tensor; $\alpha_{xx}=\alpha_{yy}$, α_{zz}: a_{1g}, $\alpha_{xz}=\alpha_{yz}$: e_{1g}, α_{xy}, $\alpha_{xx}=-\alpha_{yy}$: e_{2g}.

Experimental

$CsMgCl_3$ was prepared from CsCl and $MgCl_2$. Equimolar amounts of CsCl and $MgCl_2$ were heated in the atmosphere of dry HCl gas for several hours, and then fused in vacuum. Polycrystalline samples of $CsMgCl_3$ were sealed into quartz ampoules, and single crystals were grown from the melt by Bridgman method. Obtained crystals cleave readily along the (110) plane. This cleavage plane includes the c axis of the hexagonal lattice, and was used for polarized infrared reflection measurements. Size of the reflecting plane was about 7×10 mm.

For polarized Raman measurements, a specimen of approximately $2\times2\times5$ mm, which was sealed into a glass tube to protect from hydration, was used.

$CsCaCl_3$ was prepared from CsCl and $CaCl_2$. A method of

preparation and a single crystal growth were the same as in the case of $CsMgCl_3$. Obtained crystals cleave along the (100) plane of the cubic lattice. This cleavage plane was used for infrared reflection measurements.

Spectrometers used for infrared reflection measurements were a Hitachi 285 infrared spectrometer for the range 4000—250 cm^{-1} and a Hitachi 070 far-infrared interferometer for the range 400—10 cm^{-1}, with wire-grid polarizers. A chromium mirror was used for the reference.

Polarized Raman spectra were recorded using a Narumi model 750Z-1200 double monochromator with a 514.5 nm line of an Ar^+ ion laser as a source.

Observed Spectra and Vibrational Frequencies

Observed reflection spectra of $CsMgCl_3$ by two types of linearly polarized light are shown in Figs. 3(a) and 3(b). When the polarization of the incident light is parallel to the c axis, the spectrum is related to the a_{2u} modes of lattice vibrations (Fig. 3(a)). When the polarization is perpendicular to the c axis, the spectrum is related to the e_{1u} modes (Fig. 3(b)).

The TO and LO frequencies were obtained by the procedure described in the previous paper,[2] among which one of the LO frequencies for the e_{1u} mode was determined from the maximum of $-\mathrm{Im}(1/\hat{\varepsilon}(\nu))$ as shown in Fig. 3(b).[6]

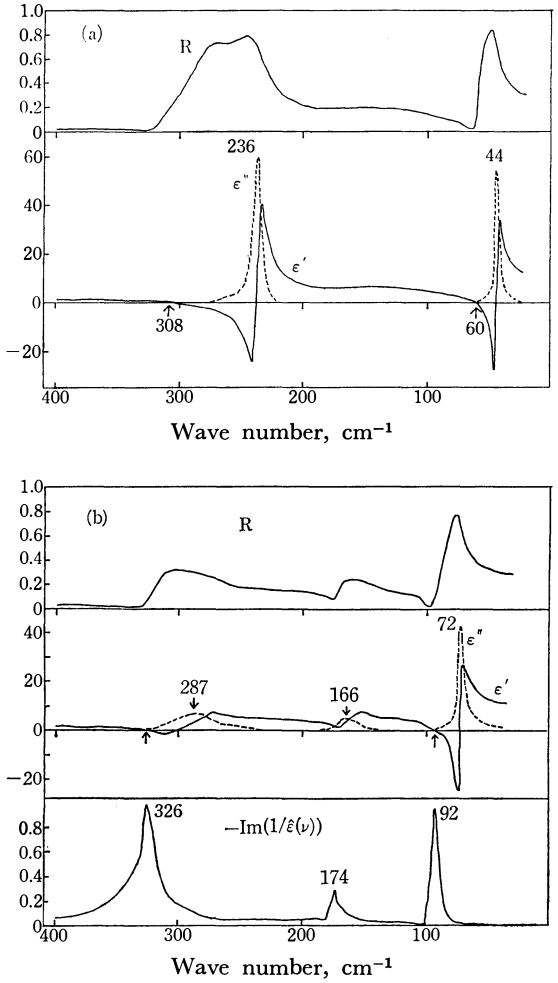

Fig. 3. Reflectivity and dielectric constants of $CsMgCl_3$. (a) The polarization of the light is parallel to the c axis, and (b) the polarization of the light is perpendicular to the c axis.

Figure 4 shows Raman spectra of $CsMgCl_3$, where the notations by Damen, Porto, and Tell are given.[7] A z-axis was taken to be parallel to the c axis of the crystal, and x,y-axes were taken to be perpendicular to the c axis.

The observed reflection spectrum and dielectric constants of $CsCaCl_3$ are shown in Fig. 5.

The observed frequencies of $CsMgCl_3$ and $CsCaCl_3$ are listed in Tables 3 and 5, respectively.

Normal Coordiante Analysis for the Optically Active Lattice Vibrations

The procedure of the normal coordinate analysis has been described in the previous paper.[2]

The relation between the effective ionic charges and the TO-LO splittings is expressed as:[8]

$$\frac{4\pi}{v_a}\left(2\frac{Z_{Cs}{}^2e^2}{m_{Cs}}+2\frac{Z_{Mg}{}^2e^2}{m_{Mg}}+6\frac{Z_{Cl}{}^2e^2}{m_{Cl}}\right) = \sum_i (\lambda_i(\mathrm{LO})-\lambda_i(\mathrm{TO})) \quad (1)$$

for $CsMgCl_3$,** and

$$\frac{4\pi}{v_a}\left(\frac{Z_{Cs}{}^2e^2}{m_{Cs}}+\frac{Z_{Ca}{}^2e^2}{m_{Ca}}+3\frac{Z_{Cl}{}^2e^2}{m_{Cl}}\right)=\sum_i(\lambda_i(LO)-\lambda_i(TO)), \quad (2)$$

for $CsCaCl_3$,** where v_a is the volume of the unit cell, Z_A and m_A are the effective ionic charge and mass of the A ion, and λ_i is the frequency parameter $4\pi^2\nu_i{}^2$ of the i-th mode of vibration. On considering a further condition on the electrical neutrality of a crystal as a whole ($\sum Z_i=0$), only one Z_i becomes independent in each crystal.

The short range interactions for the ion pairs within a distance of 4.0 Å were taken into account, which are shown in Figs. 1 and 2. The force constants are listed in the first column of Table 2 ($CsMgCl_3$) and Table 4 ($CsCaCl_3$). K(A–B) denotes $[\varphi''_{A-B}(r)]_{r=r_0(A-B)}$, and k(A–B) denote $[(1/r)\varphi'_{A-B}(r)]_{r=r_0(A-B)}$, where $\varphi_{A-B}(r)$ is the centrosymmetric potential function between A and B.

The equilibrium condition for the 1st differential coefficients of the pair-wise potential functions

$$\sum_{k,l'k'}\left[\frac{dr}{d\rho}\varphi'_{kk'}(r)\right]_{r=r_0(lk;\ l'k')}+\left[\alpha_M\frac{e^2}{\rho^2}\right]_{\rho=\rho_0}=0 \quad (3)$$

was taken into consideration, where α_M is the Madelung constant referred to ρ, and $r_0(lk;l'k')$ is an interionic distance between the k-th ion in the l-th unit cell and the k'-th ion in the l'-th unit cell. The Madelung constant of $CsMgCl_3$ referred to a_0, 34.03, was used. This value was calculated by Ewald's method. As for $CsCaCl_3$, the Madelung constant referred to a_0, 12.377, was used, which was calculated by Sherman for the cubic perovskite structure.[9]

Table 2. Short-range repulsive force constants and effective ionic charges of $CsMgCl_3$[a]

e_{1u}(LO)	92	80.0

The short range repulsive force constants between chlorine ions, $K(Cl–Cl)_i$ and $k(Cl–Cl)_i$, were estimated from the nonbonded chlorine-chlorine interaction potential of Lennard-Jones 6-12 type.[10] Other short range force constants were determined by the least squares method for several sets of effective ionic charges which satisfy Eqs. 1 and 2 and the condition of electrical neutrality for each crystal.

In the case of $CsMgCl_3$, the set of effective ionic charges corresponding to $Z_{Cl}=-0.66$ gives a most satisfactory result. (The sum of the squared deviations of the calculated frequencies from the observed ones becomes minimum for this set of Z_i's when Z_{Cl} is varied from −0.58 to −0.82). Obtained force constants and calculated frequencies are given in Tables 2 and 3.

In the case of $CsCaCl_3$, the sum of the squared deviations is more or less alike for the sets of Z_i's when Z_{Cl} is varied in the range $-0.78\leq Z_{Cl}\leq -0.58$. The converged sets of the short-range force constants and the calculated frequencies for three sets of effective ionic charges in the above range of Z_{Cl} are listed in Tables 4 and 5. Among these three sets of short range force constants and effective ionic charges, the set III may be most appropriate, on comparing the values of Z_{Cs} and Z_{Ca} in $CsCaCl_3$ with those of Z_{Cs} and Z_{Mg} in $CsMgCl_3$.

Discussion

The assumptions used in the calculation are the following:

(1) Ions are rigid and not deformable.

(2) Ions interact with neighbouring ions through central forces. Unlike valence force potential, angle bending forces are not taken into consideration.

(3) The interaction potential between the chlorine ions is the 6-12 Lennard-Jones type potential which

is applicable in the case of molecular force field. This model is simple but it explains quantitatively the TO-LO splittings, which are characteristic to ionic crystals.

The agreement between the observed and calculated frequencies is satisfactory as a whole . The metal-chlorine repulsive force constant K(Mg–Cl) 0.715 mdyn/Å in $CsMgCl_3$ is comparable with K(Ni–Cl) 0.764 mdyn/Å in $CsNiCl_3$.[2] This is quite reasonable, on comparing the interionic distance r_0(Mg–Cl)= 2.50 Å with r_0(Ni–Cl)=2.44 Å. K(Ca–Cl)=0.63 mdyn/Å in $CsCaCl_3$ is smaller than K(Mg–Cl), reflecting that r_0(Ca–Cl)=2.70 Å is longer than r_0-(Mg–Cl)=2.50 Å. It is to be noted that K(Ca–Cl) is larger than K(Cd–Cl)=0.540 mdyn/Å in $CdCl_2$, although r_0(Ca–Cl) is almost equal to r_0(Cd–Cl)= 2.69 Å in $CdCl_2$.[1] This is explained by the fact that the ionic radius of Cd^{2+} 0.95 Å is smaller than that of Ca^{2+} 1.00 Å and accordingly the contact of the metal ion with the chlorine ion is more tight in $CsCaCl_3$ than in $CdCl_2$.[11]

Since the metal-chlorine force constants K(Mg–Cl) and K(Ca–Cl) in $CsMgCl_3$ and $CsCaCl_3$ are rather larger than K(Na–Cl) or K(K–Cl) ≈0.2 mdyn/Å in NaCl or KCl crystals which are considered to be purely ionic crystals,[12] there may exist some amount of covalency in Mg–Cl and Ca–Cl bonds.

As for the potential constants corresponding to the $Cs^+\cdots Cl^-$ interaction, reasonable values of K(Cs–Cl) and k(Cs–Cl) were obtained with small standard deviations for $CsCaCl_3$. However, for $CsMgCl_3$ which has two kinds of $Cs^+\cdots Cl^-$ (3.64 and 3.82 Å), the converged force constants have rather large standard deviations as seen in Table 2. The values of $K(Cs–Cl)_1$ and $k(Cs–Cl)_1$ are too large while those of $K(Cs–Cl)_2$ and $k(Cs–Cl)_2$ are too small, on considering the corresponding interionic distances.***

Finally, the displacement of each ion for each vibration will be discussed for the AMX_3 crystal of cubic perovskite structure. This may be described on the basis of the eigenvectors $\boldsymbol{L}_x$ for $\boldsymbol{M}^{-1}(\boldsymbol{F}_x^R+\boldsymbol{F}_x^C)$, $\boldsymbol{X}=\boldsymbol{L}_x\boldsymbol{Q}$, where $\boldsymbol{F}_x^R$ and $\boldsymbol{F}_x^C$ are $\boldsymbol{F}$ matrices, in terms of Cartesian displacement coordinates, corre-

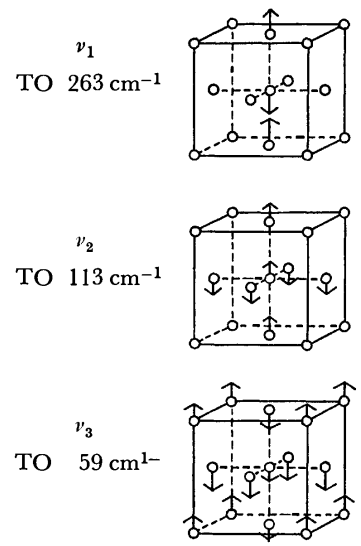

Fig. 6. Displacement of ions for three infrared active vibrations of $CsCaCl_3$.

*** The interionic distance $(Cs\cdots Cl)_2$ in $CsMgCl_3$ equals to that for (Cs···Cl) in $CsCaCl_3$. If we assume the values of $K(Cs–Cl)_2$ and $k(Cs–Cl)_2$ take the same values as those for $CsCaCl_3$ and perform the least squares calculation, the values of $K(Cs–Cl)_1$ and $k(Cs–Cl)_1$ would be converged to smaller values with less standard deviations.

sponding to the short-range repulsive and long-range Coulomb potentials. The result for $CsCaCl_3$ is given schematically in Fig. 6, which shows that the highest vibration ν_1 is a Ca–Cl stretching mode, ν_2 is a Ca–Cl bending mode and the lowest one ν_3 is a Cs– *vs.* $-CaCl_3$ type lattice mode. This result is in correspondence with that for BMO_3 studied by Last,[13] but in contrast with that for AMF_3 where the ν_1 mode is a M–F bending mode and the ν_2 mode is a M–F stretching mode.[14]

The authors wish to express their sincere thanks to Professor Ito Mitsuoof Tohoku University for permitting us to use a laser Raman spectrometer in his laboratory.

The Application of Mathematical Programming in Theoretical Chemistry. I. Saddle-point-search Method Applied to a H_3 Molecule*

Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 23, 1977)

A new method to find the activated state of a reaction *without* preparing its potential energy surface was proposed and proved useful with the example of a H_3 molecule. The first and the second derivatives of the total energy, with respect to every cartesian coordinate of a H_3 molecule, were calculated by means of a perturbation method employing a modified EHMO. First, the bottom of the valley in the potential energy surface leading to the saddle point is sought with the aid of the quadratic approximation on the superplane on which the maximum curvature at the representative point lies. Second, the ascending path is determined to be the reverse of the steepest decending path according to the principle of microscopic reversibility. By repeating these procedures, the activated state was found without preparing the potential energy surface. The classical activation energy thus found was 8.8 kcal/mol, which is in good agreement with the experimental values.

The theoretical determination of activated state of a given reaction generally requires knowledge of the potential energy surface (PES) of the system. Quantum chemical calculations, non-empirical[1] and semi-empirical,[2] have been published on the gas-phase exchange reaction $H+H_2=H_2+H$ and its isotopic variants, which belong to the simplest class of chemical reactions. In these calculations, the activated state, or the saddle point, was pinpointed on a two-dimensional contour map, because the linear complex of a H_3 molecule is, fortunately, more stable than the non-linear one. The dimerization of two carbene molecules to produce an ethylene molecule[3] is a yet simpler reaction; the preparation of a complete PES of the system is, however, practically impossible because of its already large degree of freedom beyond two, *i.e.*, $6\times3-6=12$; hence, a fairly large number of calculations are necessary to obtain the total energies at the eighteen dimensional grid points. Thus, in the practical calculation, the bond distance, r_{CH}, was kept constant throughout the reaction and only a schematic diagram could be shown instead of a contour map.

Therefore, the development of a method which requires only a feasible number of calculations to obtain the reaction path is strongly desirable. By virtue of the method of optimization adopted, the method described in this paper does not require the preparation of the complete PES, and it is, therefore, particularly suitable when we need only information on the activated state and the reaction path.

Several methods of optimization, techniques in mathematical programming, have been widely employed, especially in engineering, to determine extreme value(s) without preparing a contour map of a given function; only the first derivatives (the first and second derivatives in some techniques) of the function at the successively proceeding representative point are required to arrive at the peak of the mountain.

A doctrinal formulation of reaction paths and activated states has been proposed by Fukui.[4] The purpose of the present work is to develop a new practical method for climbing up from the foot (the reactant) to the saddle point (the activated state) along the bottom of the valley connecting them, and then going down to another foot (the product). The simplest example, the H_3 system, will be presented to demonstrate the usefulness of this method.

The energy may be calculated by means of any method, including even the molecular force field, provided that the derivatives are calculable. In this paper, the energy was calculated quantum-chemically by means of a modified extended Hückel molecular orbital (EHMO) method.

This method can also be employed in larger systems with semi-empirical MO calculations; some results with MINDO/2 and 3 will be published later.

Theoretical

Saddle-point Search. The geometry of a reacting system such as H_3 is described by a representative point in a $3N_{at}$ dimensional space, where N_{at} is the number of atoms in the system. When $q_u(u=1$ to $3N_{at})$ represents every 3-dimensional cartesian coordinate of all the atoms, and E_b is the total bond energy of the system, the saddle point is defined by

$$\frac{\partial E_b}{\partial q_1}=\frac{\partial E_b}{\partial q_2}=\cdots\cdots=\frac{\partial E_b}{\partial q_{3N_{at}}}=0, \tag{1a}$$

$$\frac{\partial^2 E_b}{\partial b_r^2}<0 \text{ and } \frac{\partial^2 E_b}{\partial b_f^2}<0, \tag{1b}$$

$$\frac{\partial^2 E_b}{\partial b_1^2}>0,\ \frac{\partial^2 E_b}{\partial b_2^2}>0,\ \cdots, \tag{1c}$$

where $\partial^2 E_b/\partial b^2$ implies the second derivative of the total bond energy with respect to the bond length of a bond, b, while Eq. 1b represents the criteria of the curvatures of the PES along the rupturing bond, b_r, and the forming one, b_f, whereas Eq. 1c represents the criteria along the bonds which are not directly related to the activated state. On the other hand, the criteria of the most stable structure of a molecule, or the minimum energy geometry, are described by Eqs. 1a and 2:

$$\frac{\partial^2 E_b}{\partial q_1^2}>0,\ \frac{\partial^2 E_b}{\partial q_2^2}>0,\ \cdots,\ \frac{\partial^2 E_b}{\partial q_{3N_{at}}^2}>0 \tag{2}$$

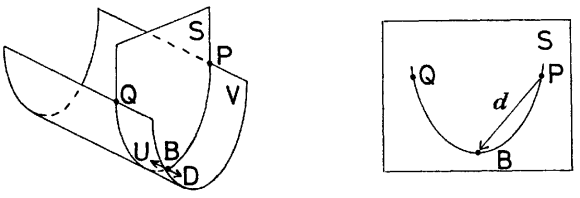
* CHEMOGRAM, a Computer Program Package for Chemical Logic, Part I. A preliminary report of this work was presented at the 31st National Meeting of the Chemical Society of Japan, Sendai, October, 1974.

Thus, the criteria of the saddle point in cartesian coordinates becomes as follows where Eq. 1a holds, Eq. 1d is satisfied for a few coordinates which are directly related to the rupturing or forming bonds, and Eq. 1e holds for the remaining coordinates, a majority:

$$\frac{\partial^2 E_b}{\partial q^2} < 0 \text{ (for a few coordinates)}, \quad (1d)$$

$$\frac{\partial^2 E_b}{\partial q^2} > 0 \text{ (for the majority of coordinates)}. \quad (1e)$$

The mathematical definition of the bottom of the valley on the PES will be discussed below. Figure 1a shows a schematic diagram of a superplane or a PES around a valley, V. P is a representative point of the system which is not at the bottom, but fairly near it. S is a superplane *orthogonal* to V, on which the point P and a curve, PQ, which is a section of S and V and which has the maximum curvature at P, are laid. The minimum point, B, on the PQ curve is the bottom of the valley near P, as is shown in Fig. 1b. The PQ curve may have its maximum curvature even at B, because P is near B. In practical calculations, the PQ curve is determined by the second derivatives of the total bond energy at P, while the location of B is estimated by the quadratic approximation with the aid of the first and the second derivatives at P. If the B thus estimated is far from P, the same procedure may be repeated to assure that the true bottom of the valley is attained.



(a) (b)

Fig. 1. Schematic diagram for saddle point search method.
(a) Potential energy surface near a bottom of a valley.
(b) Bottom of a valley on a superplane S.

The reaction path along the bottom of the valley, V, is determined as follows. First, the direction of the steepest descent, BD, is decided with the aid of the first derivatives at the point B. This direction leads the system to the initial geometry; hence, the path to the saddle point, BU, will be the reverse direction to BD, by the principle of microscopic reversibility. The BU distance should be small enough, say 0.05 Å, so that the above principle can be applied . Even if the BU step is short, it can not be guaranteed that the U point is still at the bottom; hence, the same procedure employed with P is applied at U before ascending further toward the saddle point.

Modified EHMO and Its Perturbational Calculation of First and Second Derivatives. Generally, empirical or semi-empirical MO's, such as EHMO, CNDO, INDO, or MINDO, do not give correct values of the equilibrium distance or the energy profile of a hydrogen molecule. The total electronic energy calculated by EHMO implicitly involves the nuclear repulsion energy;[5] hence, the total electronic energy minus the sum of the Coulomb integrals, which are geometry-independent, gives the total bond energy. Salomon[6] calculated a semi-empirical PES by means of the Heitler-London method, employing modified overlap integrals to obtain a better fit of the calculated bond energy of H_2 to that of the Morse function.

By the same principle, we introduced a modified EHMO. We do not insist that this modification is a novel improvement of EHMO; we just used it as a less expensive MO, applicable only for hydrogen atoms with s orbitals alone, to demonstrate the validity of the present saddle-point-search method.

The resonance integrals were formulated, as is shown in Eq. 3b, to make the total bond energy as close as possible to the experimental value of a hydrogen molecule at various interatomic distances of interest:

$$\text{Coulomb integral: } H_{rr} = -13.60 \text{ eV}, \quad (3a)$$

$$\text{resonance integral: } H_{rs} = \frac{1}{2}\sum_k^w a_k |S_{rs}|^{k-1} \times S_{rs}(H_{rr}+H_{ss}), \quad (3b)$$

where r and s denote atomic orbitals. Thus, the resonance integral is expressed as a power series of an overlap integral, S_{rs}, which is calculated with the Slater orbitals by means of the Mulliken method. Then the coefficients, a_k, can be determined by the least-squares method so as to fit the Morse function.

The derivatives could be calculated by the method of finite differences from the eigenvalues of a slightly distorted system. The calculation, however, requires two extra geometries for each coordinate of an atom; thus, the number of calculations amounts to $2\times 3N_{at}$, which is 18 even for the smallest system, H_3. As the computation time of the diagonalization of a secular equation usually increases nearly propotionally to $N^{2.5-3}$, where N is the number of atomic orbitals, the method of finite differences may be inappropriate for a larger system.

In the case of EHMO, the total (electronic) energy of a system is calculated from the sum of the eigenvalues of a secular equation,

$$|H^{(0)}{}_{rs} - \varepsilon S^{(0)}{}_{rs}| = 0. \quad (4)$$

When a small change in one coordinate of an atom (Δq) is regarded as a perturbation, the perturbed matrices, H and S, may be described by

$$H = H^{(0)} + \lambda H^{(1)} + \lambda^2 H^{(2)}, \quad (5a)$$

$$= H^{(0)} + \left(\frac{\partial H^{(0)}{}_{rs}}{\partial q}\right)(\Delta q) + \frac{1}{2}\left(\frac{\partial^2 H^{(0)}{}_{rs}}{\partial q^2}\right)(\Delta q)^2, \quad (5b)$$

$$S = S^{(0)} + \lambda S^{(1)}, \quad (5c)$$

where $S^{(2)}$ was omitted for the sake of simplification and where parentheses denote a matrix. The total energy after perturbation, E, is given by

$$E = E^{(0)} + \lambda E^{(1)} + \lambda^2 E^{(2)} \quad (5d)$$

$$= E^{(0)} + (\partial E^{(0)}/\partial q)(\Delta q) + (1/2)(\partial^2 E^{(0)}/\partial q^2)(\Delta q)^2. \quad (5e)$$

Therefore, the first and the second derivatives of the total energy of the system with respect to the designated coordinate are given by

$$\frac{\partial E^{(0)}}{\partial q} = E^{(1)}, \tag{5f}$$

$$\frac{\partial^2 E^{(0)}}{\partial q^2} = 2E^{(2)}. \tag{5g}$$

Since the difference between the total bond energy, E_b, and the total energy, E, are constant, the derivatives of the former with respect to the coordinates are equal to those of the latter.

The non-zero elements of the first- and second-order perturbation matrices are given by the following equations:

First-order:

$$\frac{\partial H_{rs}}{\partial q_u} = \frac{\partial H_{rs}}{\partial S_{rs}} \cdot \frac{\partial S_{rs}}{\partial q_u} \quad \text{for off-diagonal,} \tag{6a}$$

$$\frac{\partial S_{rs}}{\partial q_u} \quad \text{for off-diagonal.} \tag{6b}$$

Second-order:

$$\frac{1}{2}\frac{\partial^2 H_{rs}}{\partial q_u^2} = \frac{1}{2}\left\{\frac{\partial^2 H_{rs}}{\partial S_{rs}^2}\left(\frac{\partial S_{rs}}{\partial q_u}\right)^2 + \frac{\partial H_{rs}}{\partial S_{rs}}\frac{\partial^2 S_{rs}}{\partial q_u^2}\right\} \quad \text{for off-diagonal.} \tag{7}$$

The first and the second derivatives of overlap integral can easily be calculated with the method of finite differences by shifting the coordinate in two directions for a small distance (usually 0.05 Å). Elements of Hamiltonian perturbation matrices can be analytically calculated with ease by the use of Eqs. 3, 6, and 7. Then the perturbation energies can be calculated by the method reported by Carbo.[7]

Calculation

Coefficients of the Modified Resonance Integral. The parameters for the Morse function, Eq. 8, are selected as follows:

$$V = D_e[1-\exp\{-a(r-r_e)\}^2]^2, \tag{8}$$

where $D_e = -4.76$eV, $a = 1.957$Å^{-1}, and $r = 0.7413$Å.

A seven-term polynomial for Eq. 3b was chosen ($w=7$), and the seven coeffieients were estimated as shown below at 15 interatomic distances from $r = 0.9r_e$ to $2.3r_e$:

$a_1 = 1.0405$, $a_2 = 0.4695$, $a_3 = 0.6302$, $a_4 = -1.3501$,

$a_5 = -0.6601$, $a_6 = 5.8697$, and $a_7 = -5.3563$.

The coincidence between these two sets of values at distances of interest is satisfactory, the standard deviation of differences between them being 0.009 eV, or 0.2 kcal/mol, for this range.

Flow Chart of Computer Program. The computation was carried out on a HITAC 8800/8700 system at the Computer Centre of the University of Tokyo. The block-flow chart of the main program, EHMP1, is shown in Fig. 2. The input data, essentially composed of coordinates of initial system, quantum chemical parameters, constraint parameters, and control variables, are analyzed. The eigenvalues and the eigenvectors are calculated in a subroutine, EHCAL. Second, the derivatives are calculated in another subroutine, MPEHPT, following the procedure described above. Thirdly, either the bottom of the valley or the ascending path, decided by a control variable,

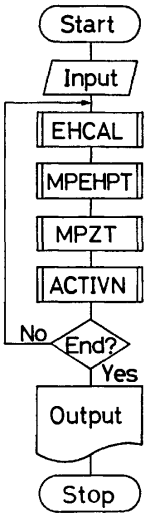


Fig. 2. Block flow chart of computer program EHMP1.

is searched with the above-mentioned algorithm stored in a third subroutine, MPZT. Finally, a fourth subroutine, ACTIVN, judges whether or not the saddle point is attained. If the system is still ascending, the procedures are repeated from EHCAL using renewed coordinates. During these iterations, the search of the bottom and that of the ascending path are repeated alternatively. If the representative point arrives at the saddle point, the coordinate is slightly changed so that the representative point is forced to move to the opposite side beyond the saddle point. Then repeated calculation from EHCAL searches the path down to the foot on the opposite side, that is, the product, by using the conventional optimization algorithm. The main program and subroutines are all written in FORTRAN IV. Some details of the procedures will now be explained.

Algorithm in Subroutines: The subtroutine EHCAL makes use of conventional quantum chemical calculations by using the EHMO, except that the modified resonance integrals shown in Eq. 3b are used.

The details of the processing in the subroutine MPEHPT are shown in Fig. 3. The input[1] consists of the eigenvalues and eigenvectors of the unperturbed system. The following processing is iterated[2] for x-, y-, and z- coordinates down to the decision box[9]. The overlap integral matrices of unperturbed($S^{(0)}$), and the first ($S^{(1)}$)- and the second ($S^{(2)}$)-order perturbation are calculated in the subroutine MPOVLP[3], Because the following relations hold throughout the system;

$$\partial S_{rs}/\partial q_v = -\partial S_{rs}/\partial q_w, \tag{9a}$$

$$\partial^2 S_{rs}/\partial q_v^2 = \partial^2 S_{rs}/\partial q_w^2, \tag{9b}$$

where the orbitals, r and s, belong to atoms whose coordinates along the same axis are q_v and q_w respectively, only one calculation in each iteration can give the derivatives for all atoms.

The perturbational calculation is iterated[4] for all the atoms from $u=1$ to $3N_{at}$ down to [8]. The perturbation matrices of the Hamiltonian of the first- and the second-order are prepared analytically. The

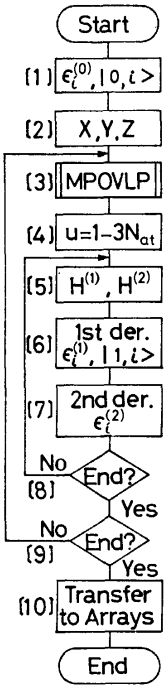

Fig. 3. Flow chart in a subroutine MPEHPT.

first-order perturbation eigenvalues and eigenvectors are calculated in [6] by following the algorithm of Carbo.[7] The second-order perturbation eigenvalues are calculated from them and $H^{(2)}$ by means of the above algorithm[7]. The derivatives of the total bond energy thus obtained are stored in arrays[10].

The algorithms in the subroutine MPZT are as follows. The vector, $\boldsymbol{d}$ in Fig. 1b that moves the representative point from P to B is given by the following equations (see Appendix):

$$d_i = -f_i'' \operatorname{sign}(f_i') \sum_i' \frac{|f_i'|f_i''}{\sum_i'(f_i'')^3} \quad \text{for } f_i'' \geqq 0, \tag{10a}$$

$$d_i = 0 \quad \text{for } f_i'' < 0, \tag{10b}$$

where

$$f_i' = \frac{\partial E^{(0)}}{\partial q_i}, \tag{10c}$$

$$f_i'' = \frac{\partial^2 E^{(0)}}{\partial q_i^2}, \tag{10d}$$

and

$$d = (d_1, d_2, \cdots\cdots d_i, \cdots\cdots d_{3N_{at}}) \tag{10e}$$

In this processing, the summation regarding a few coordinates which give negative second derivatives is excluded. If the bottom thus found is outside the designated restriction in distance from P, the same procedure is iterated using renewed coordinates.

The direction of the steepest decent, and hence that of the path to the saddle point, is then easily determined by using f_i' values.

The subroutine ACTIVN judges the arrival at the saddle point, and then moves the system beyond that point. The arrival at the saddle point is recognized when none of the absolute values of the first derivatives exceed the optioned threshold value, *EDRV1*. In spite of the criteria of the saddle point given in Eqs. 1d and 1e, judgement by Eq. 1a alone is sufficient because the system is ascending and no minimum can appear before any saddle point, even if a basin exists. Then the system is moved for twice the distance restricted by constraint parameters along the vector from the initial point to the saddle point. Thus, the system goes to the opposite side of the PES, sufficiently far from the saddle point for the system not to return to the original side, but close enough to it not to fall down beyond the ridges on the PES in another valley, which would guide the system to an unexpected product.

The path down to the product is determined by either linear or quadratic approximation methods in the subroutine MPZT.

Results and Discussion

The initial system is a linear molecule with interatomic distances of $r_{12}=1.600$ Å and $r_{23}=0.740$ Å, as

$$H^1 \cdots H^2 - H^3 \quad \text{(on X-axis)}. \tag{11}$$

The total bond energy of the molecule was −4.6437eV, with the parameters for the resonance integral given above. The first and the second derivatives with respect to the x-coordinate are compared in Table 1 with those obtained by the method of finite differences with a shift of the x-coordinates, δ, of ±0.025 Å. The agreement was proved excellent.

Table 1. Comparison of derivatives with respect to x values calculated by two methods

Method		Perturbation	Finite differences
First der. eV Å^{-1}	1[a]	0.404	0.402
	2	0.113	0.132
	3	−0.517	−0.538
Second der. eV Å^{-2}	1	0.90	0.84[b]
	2	37.0	36.8
	3	38.1	37.9

a) Atom ordinal. b) $\delta=\pm 0.05$ Å.

The parameters for processing were optioned as follows: the constraint parameters for atoms, which restrict their transfer distances in one step, were ±0.05 Å, and the threshold value, *EDRV1*, for the saddle point was 0.1 eV/Å.

At first, the bottom of a valley was searched for with derivatives of the initial system; it was found at the geometry of $r_{12}=1.592$ and $r_{23}=0.759$ Å with a total bond energy, *TBE*, of −4.6439 eV, which is 0.0002 eV lower than the initial one. Although we used no control to inhibit the change in coordinates along either the Y- or the Z-axis, the bond angle (123) was actually 180.0°, and this angle remained unchanged throughout the reaction.

Secondly, a control variable was changed in order to search for the ascending path, and the system was transferred to new coordinates, $r_{12}=1.540$ and $r_{23}=0.759$ Å, with $TBE=-4.6223$ eV. The above interim results and succeeding iterations are shown on a contour map, Fig. 4, which had been separately prepared by a conventional grid method for demonstration. Up to

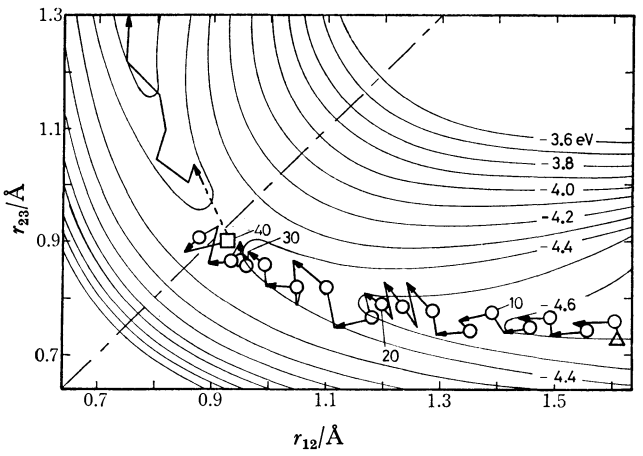

Fig. 4. Reaction path of H_3 system beyond activated state.
△: Initial system, ○: bottom of a valley.
←: Ascent during activation or decent during stabilization.
Numerals along the path indicate the iteration numbers, and those along the contour the *TBE*/eV.

TABLE 2. ATTRIBUTES OF ACTIVATED STATE SEARCHED FOR BY MATHEMATICAL PROGRAMMING

a. Activated state with restricted distance = 0.05 Å and *EDRV1* = 0.1 eV Å^{-1}.
1) Geometry: $r_{12}=0.9225$, $r_{23}=0.900$ Å, and angle(123) = 180.00°.
2) *TBE*: −4.3771 eV.
3) Derivatives along the X-axis:

Atom ordinal	1	2	3
First der./eV Å^{-1}	0.0459	−0.0207	−0.0252
Second der./eV Å^{-2}	7.75	−1.78	9.84

b. Symmetrical geometry.
1) Geometry: $r_{12}=r_{23}=0.91$ Å and angle(123) = 180.00°.
2) *TBE*: −4.3768 eV.
3) Derivatives along the X-axis:

Atom ordinal	1	2	3
First der./eV Å^{-1}	0.0530	0.0000	0.0530
Second der./eV Å^{-2}	8.88	−1.60	8.88

thirty iterations, the system, or the representative point, ascended nearly along the bottom of the valley leading to the saddle point. Meanwhile, two attempts to search for the bottom were carried out at the three iteration number of 16, 19, and 26. Beyond the iteration number of 30, the point began to wander on a fairly flat PES near the saddle point, designated by a square. At the iteration number of 40, all of the absolute values of the first derivatives became less than *EDRV1*, or 0.1 eV/Å in this case, and the system was judged to be at the saddle point. The system had the geometry, *TBE*, and derivatives shown in Table 2a. The first derivatives well satisfy one of the criteria, Eq. 1a, the second derivatives satisfy Eqs. 1d and 1e, and the H^2 atom is found to be related to the rupturing or forming bonds. The *TBE* of the reactant, that is, a hydrogen molecule with an equilibrium interatomic distance and a hydrogen atom which is sufficiently far from the former, is found to be −4.759eV by the present MO; thus, the classical activation energy, E_A(classical), is 0.382 eV = 8.8 kcal/mol, in good agreement with the experimental values.

No shallow basin seems to exist around the saddle point, judging from the wandering paths. Therefore, the true activated state is estimated to have a symmetric geometry of $r_{12}=r_{23}=0.91$Å. The attributes of the symmetric system are shown in Table 2b, where the first derivative of H^2 is naturally zero and where the second derivatives for H^1 and H^3 were identical, the value being negative for H^2. The *TBE* is −4.3768eV, only 0.0003 eV (7 cal/mol) higher than that in Table 2a. Hence, this symmetrical system can be regarded as the true activated state.

The coordinates of the system were changed by 0.1Å by means of the algorithm mentioned above along the arrow with a broken line. Then the system began to go down along the bottom of a new valley to the product, as the control variable changed the algorithm to stabilization.

The total CPU time on a HITAC 8800/8700 for 40 iterations up to the saddle point amounted to 10 s.

This simplest example may be judged to verify the validity and usefulness of the new method for searching for the reaction path beyond the saddle point. The path shown in Fig. 4 is not a trajectory of the reaction, but only records the intermediate walks following the algorithm, because this method employs a static model instead of a dynamic treatment. The smoothed locus of open circles in Fig. 4, however, may give a fairly good reaction trajectroy.

The author's thanks are due to Dr. Makoto Misono for his valuable discussion.

Appendix

Algorithm for Estimation of a Bottom of a Valley. The energy $E(\boldsymbol{d})$ at B in Fig. 1b, which was moved from P by a vector, $\boldsymbol{d}$, is expressed by the Taylor expansion by neglecting cross terms:

$$E(\boldsymbol{d}) \approx E(\boldsymbol{0}) + \sum_{i}^{3N_{at}} \left(f_i' d_i + \frac{1}{2} f_i'' d_i^2 \right), \tag{A1}$$

where $E(\boldsymbol{0})$ denotes the energy at P.

The $\boldsymbol{d}$ vector should be parallel to the $\boldsymbol{f}''$ vector, where its elements are f_i'', negative values being replaced with zero. The sign of d_i should be decided so as to decrease the energy from P to B; hence, the d_i component is given by Eq. A2, taking into account the fact that the effective f_i'' is non-negative:

$$d_i = \frac{k f_i'' \mathrm{sign}(-f_i')}{\{\sum_i{}' (f_i'')^2\}^{1/2}}, \tag{A2}$$

where Σ' denotes that the negative f_i'' is excluded from summation and where k is an undetermined multiplier.

Equation Al is converted to Eq. A3 by means of Eq. A2:

$$E(\boldsymbol{d}) = E(\boldsymbol{0}) + C\sum_i{}' \{ f_i' f_i'' \,\mathrm{sign}(-f_i') k + \frac{1}{2} C (f_i'')^3 k^2 \}, \tag{A3}$$

where $C=\{\sum_i{}'(f_i'')^2\}^{-1/2}$.

The energy at B should be at its minimum along the PQ curves; hence,

$$\frac{dE(\boldsymbol{d})}{dk} = C\sum_i{}'\{f_i'f_i'' \operatorname{sign}(-f_i') + C(f_i'')^3 k\} = 0. \quad \text{(A4)}$$

Thus,

$$k = -\frac{\sum_i{}' f_i'f_i'' \operatorname{sign}(-f_i')}{C\sum_i{}'(f_i'')^3}. \quad \text{(A5)}$$

Finally, the elements of $\boldsymbol{d}$—that is, the shifts in the coordinates—are derived as Eq. 10a from Eqs. A2 and A5, considering that $f_i' \operatorname{sign}(-f_i') = -|f_i'|$ and $\operatorname{sign}(-f_i') = -\operatorname{sign}(f_i')$.

Absolute Intensity Measurement of Infrared Absorption by the Use of CO_2 Laser Source

Tetsuo SUZUKI and Tsunetake FUJIYAMA*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received January 9, 1978)

The absolute infrared absorption intensities have been measured for the $^{Q}R_0(0)$ line (ν_3 fundamental) of methyl fluoride and the $^{R}R_8(9)$ line (ν_6 fundamental) of methyl iodide by the use of CO_2 laser lines of P(16) and P(8), respectively. The observed intensities, Γ, were: 12500 ± 4300 cm$^2\cdot$mol^{-1} for the ν_3 band of methyl fluoride and 1040 ± 40 cm$^2\cdot$mol^{-1} for the ν_6 band of methyl iodide.

The absorption intensity of vibration spectrum has been discussed as an intensity integrated over the whole absorption band.[1] This has been largely due to the limited resolution that the dispersion type spectrometers have which is insufficient to observe individual vibration-rotation lines. As the absorption intensities of vibration-rotation lines in the gas phase are often influenced by intramolecular interactions like Coriolis interaction, it is very important to observe intensities of individual vibration-rotation lines separately. Moreover, there are many problems to be examined in conventional intensity measurement of infrared absorptions, the most fundamental arising from the lack of resolution.[1]

From these respects, attention has been focussed on the highly monochromatic property of the laser radiation and an attempt has been made to measure the absorption intensity of a single vibration-rotation line by the use of a laser source. The CO_2 laser was used in this work, because of its ease of construction and handling. Although the output frequencies are not tunable, it is possible to measure absorption intensities by the use of pressure broadening of an absorption line at a relatively high sample gas pressure. The principles of the present work are based upon the ideas proposed by Shimizu *et al.*[2]

The ν_3 band of methyl fluoride and the ν_6 band of methyl iodide have been chosen because their vibration-rotation spectra have been fully analyzed[3–5] and their vibrational intensities have been reported by the use of conventional methods.[6,7]

Experimental

The experimental arrangement is shown in Fig. 1. The instrument was composed of an infrared laser source, a sample cell with Stark plates, and a detecting system. The CO_2 laser used in this experiment as an infrared radiation source was composed of a 2 m water-cooled discharge tube sealed with NaCl Brewster windows, a concave mirror (radius of 5 m), and a plane grating blazed at 10.6 μm (Photo Technical Research, Inc.). The concave mirror and the plane grating made up a laser cavity which was about 2.5 m in length. First order light of the grating was used for the resonant cavity and zero order light was obtained as the output power. The concave mirror was attached on a voice coil in order to finely adjust the cavity length by changing the direct electric current of the voice coil. The laser components were mounted on a steel H-beam.

The absorption cell was made of Pyrex galss 52.5 cm in length. Parallel aluminum electrodes were installed in the cell for observation of the Stark effect. The electrode glass spacers were 1.31 mm in thickness. In the case of a strong absorption intensity, an absorption cell 10 cm in length was used.

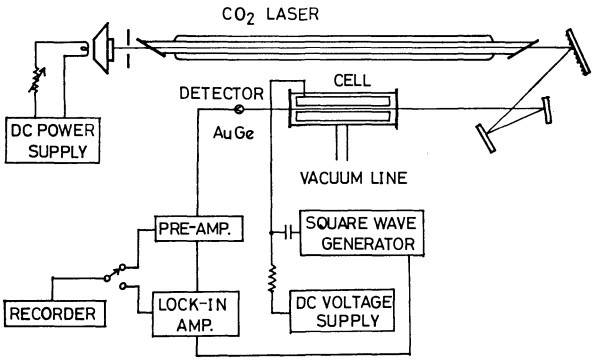

Fig. 1. Block diagram of the experimental arrangement.

The detecting system consisted of a gold doped germanium detector (Barnes Engineering, A-200), a hand-made preamplifier, a lock-in amplifier (NF Circuit Design Block, LI-573), and a pen recorder (Yokogawa Electric Works, Ltd., 3051). After passing through the absorption cell, the laser beam was detected by the gold doped germanium detector cooled by liquid nitrogen. The output signal from the detector was amplified and recorded by the pen recorder. In the case of the observation of Stark effect of an absorption line, the signal was detected by the standard phase sensitive detection method with square wave modulation of the Stark field. Potential across the electrodes was measured by a voltage divider and a potentiometer. The accuracy and the precision of the voltage measurement were 0.25 and 0.1%, respectively.

An absorption coefficient was determined by the intenstiy ratio of the light passing through an empty cell to that passing through a cell filled with sample gas. Pressure of the sample gas was measured by the use of an oil or mercury manometer, the precision of which was ascertained to be about 5%.

Results and Discussion

Generally, frequency of a laser line does not coincide with that of a molecular absorption line, so the absorption of laser radiation by molecules cannot usually be observed. In the case where the frequency difference between an absorption line and a laser line is small, however, we may observe the absorption of light by increasing the sample pressure and, therefore, by broadening the width of the absorption line. In the case where a line-width is mainly determined by collision broadening, the shape of a molecular absorption

line may be approximated by a Lorentzian function. Then, the absorption coefficient, $\alpha(\nu_l)$, of the molecular line at the frequency, ν_l, of laser light is given by the formula

$$\alpha(\nu_l) = \frac{\alpha_0(\gamma_p \cdot P)^2}{(\gamma_p \cdot P)^2 + (\nu_l - \nu_m)^2}, \quad (1)$$

where ν_m is the center frequency of the molecular absorption line, P the sample pressure, γ_p the pressure broadening parameter, and α_0 the constant independent of pressure. α_0 should be equal to the absorption coefficient at the center frequency of the absorption line. Equation 1 is reduced to a more convenient relation as[2]

$$\frac{1}{\alpha(\nu_l)} = \frac{1}{\alpha_0}\left(1 + \gamma^2 \frac{1}{P^2}\right), \quad (2)$$

where

$$\gamma = \frac{|\nu_l - \nu_m|}{\gamma_p}.$$

Equation 2 shows that the inverse of $\alpha(\nu_l)$ linearly depends on the inverse of P^2. If we measure the absorption coefficients at various pressures and plot $1/\alpha(\nu_l)$ against $1/P^2$, a straight line with a slope of γ^2/α_0 should be generated. The extrapolated $1/\alpha(\nu_l)$ value at $1/P^2 \to 0$ corresponds to the $1/\alpha_0$ value. If a $|\nu_l - \nu_m|$ value is known, the γ_p value may be determined and the value of the transition moment calcualted with α_0 and γ_p values. In the present work, the $|\nu_l - \nu_m|$ value was determined by observing the Stark effect.

ν_3 Band of CH_3F. It has been known that the vibration-rotation spectrum of methyl fluoride ν_3 band appears in the 9.4 μm region of the CO_2 laser.[3] This band has been previously studied by Stark spectroscopy using a CO_2 laser.[4] By the aid of these results, the absorption lines of $^qQ_1(1)$ and $^qR_0(0)$ were easily found near the CO_2 laser lines of P(18) and P(16), respectively. The absorption coefficients were measured

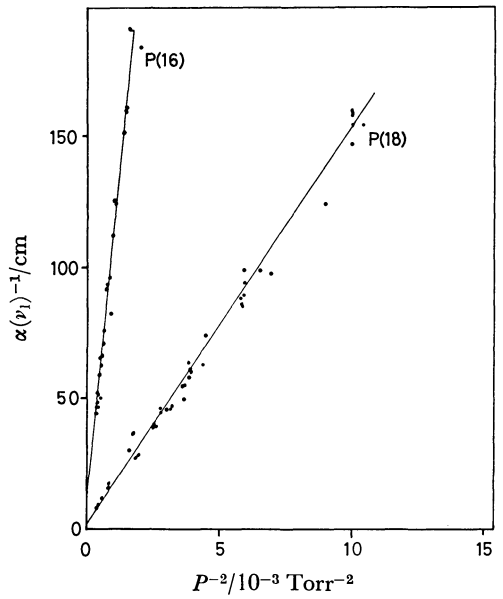

Fig. 2. Plots of measured $\alpha(\nu_l)^{-1}$ against P^{-2} for ν_3 band of CH_3F.

Table 1. Observed values of α_0, γ^2, $|\nu_l - \nu_m|$, γ_p, and $|\langle\partial\mu/\partial Q\rangle\langle 0|Q|1\rangle|$ for ν_3 band of CH_3F

	CH_3F ν_3

at these two laser lines for various pressures. The measured $\alpha(\nu_l)^{-1}$ values were plotted againts P^{-2} values, the results of which are shown in Fig. 2. The values of α_0 and γ were determined by means of the least-squares method. The $|\nu_l - \nu_m|$ values obtained by Stark spectroscopy were used for the determination of the γ_p values. The resultant values of α_0, γ^2, $|\nu_l - \nu_m|$ and γ_p are shown in Table 1.

The transition dipole moment of ν_3 fundamental, $\langle\partial\mu/\partial Q\rangle\langle 0|Q|1\rangle$, was calculated from the observed α_0 and γ_p values for the convenience of comparing the present result with the integrated intensity previously observed by conventional infrared techniques. For a symmetric top molecule an absorption coefficient, α_0, is related to a transition dipole moment as[8]

$$\alpha_0 = \frac{8\pi^2 N_0 \nu_m d g_K g_I}{3ch\gamma_p Z_{R,V}} \exp\left(-\frac{E''}{kT}\right) \times \left\{1 - \exp\left(-\frac{h\nu_m}{kT}\right)\right\} |\Phi_{JK}^{J'K'}|^2 \left|\left\langle\frac{\partial\mu}{\partial Q}\right\rangle\langle 0|Q|1\rangle\right|^2, \quad (3)$$

where N_0 is the number density of molecules at unit pressure, d the degree of vibrational degeneracy, g_I the nuclear statistical weight, $Z_{R,V}$ the vibrational and rotational partition function, E'' the energy of the initial state, $\Phi_{JK}^{J'K'}$ a matrix element of a direction cosine, and $g_K = 1$ for $K = 0$ and $g_K = 2$ for $K > 0$. The value of the transition moment calculated from Eq. 3 is given in the last row of Table 1.

As seen from Table 1, the two values of the transition moments obtained at the laser lines, P(16) and P(18), do not agree with each other . The detailed spectral features of the ν_3 band in the neighborhood of two

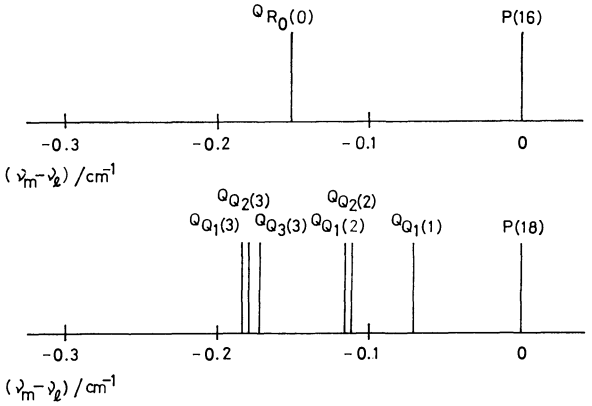

Fig. 3. Detailed spectral features of ν_3 band of CH_3F in the neighborhood of P(16) and P(18) laser lines.

laser lines are illustrated in Fig. 3. It is seen from the figure that there is only one absorption line, $^{Q}R_0(0)$, in the neighborhood of the P(16) line. In the neighborhood of the P(18) laser line, on the other hand, there are several Q-branch lines $^{Q}Q_2(2)$, $^{Q}Q_1(2)$, *etc.* in addition to the $^{Q}Q_1(1)$ line. Therefore the apparent value of the transition moment obtained from P(18) is expected to be larger than that from P(16), because of the contribution of the neighboring lines to the absorption of the P(18) laser radiation. In order to see the reliability of the observed transition moment value, the magnitude of the absorption of P(18) laser line due to these three absorption lines, $^{Q}Q_1(1)$, $^{Q}Q_2(2)$, and $^{Q}Q_1(2)$, was estimated by the use of the trasition dipole moment value of 0.224 Debye which was observed at the P(16) laser line. The $|\nu_1-\nu_m|$ values of these absorption lines were observed by Stark spectroscopy or calculated from the observed molecular constants.[4] The γ_p values of 25 MHz·Torr^{-1} were assumed for these absorption lines. The estimated pressure dependence of the absorption coefficient is shown in Fig. 4. The pressure dependence of the absorption estimated by taking into account only the $^{Q}Q_1(1)$ line is illustrated by the dash-dot line. This accounts for only half of the observed absorption. The absorption coefficient estimated by considering these three lines, $^{Q}Q_1(1)$, $^{Q}Q_2(2)$, and $^{Q}Q_1(2)$, is illustrated by the dashed line in Fig. 4. This explains the observed absorption coefficients very well. The solid line of Fig. 4 expresses the pressure dependence of the absorption coefficient calculated from the parameters given in Table 1. Thus it may be concluded that the transition moment value obtained at P(18) laser line is larger than that obtained at P(16) line because the absorption at P(18) laser line is not originating from a single absorption line, $^{Q}Q_1(1)$, but from a number of absorption lines. Consequently, the transition moment value obtained at the P(16) laser line has been adopted as the transition moment of the ν_3 fundamental of methyl fluoride.

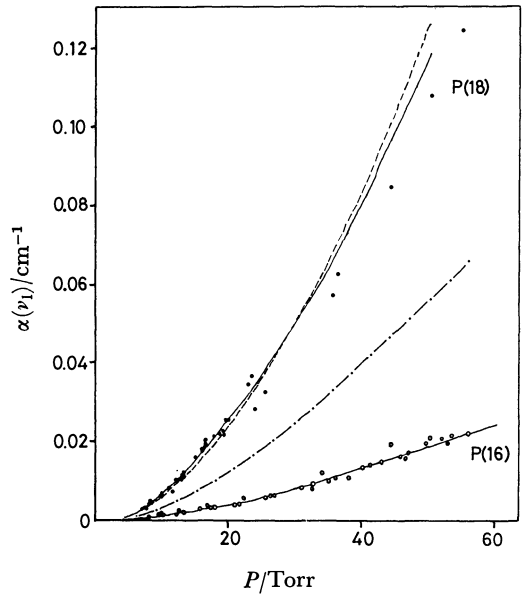

Fig. 4. Observed and estimated pressure dependence of absorption coeficients for CH_3F.

ν_6 Band of CH_3I. The band origin of the ν_6 band of methyl iodide is 882.7 cm^{-1} and a little far apart from the CO_2 laser region. However, the rotational structure spreads over a wide frequency range and, therefore, some of the absorption lines of this band may coincide with the 10.6 μm CO_2 laser lines. From the analysis of the conventional high resolution infrared spectrum[5] and the laser Stark spectroscopy, the $^{R}R_8(9)$ lines occurs near the P(8) line of the CO_2 laser. The observed values of $1/\alpha(\nu_1)$ at various pressures are shown in Fig. 5. The values of α_0, γ^2, $|\nu_1-\nu_m|$, and γ_p are calculated by the same way applied for the ν_3 band of methyl fluoride. The $1/\alpha(\nu_1)$ values observed at the pressure higher than 33 Torr were excluded from the least-squares fitting, because the $1/\alpha(\nu_1)$ values observed in this high pressure range were considered to be affected by the absorption of the neighboring lines. As the rotational energy levels of methyl iodide are expected to have hyperfine structures due to the nuclear quadrupole moment of the iodine atom, the ν_m value has been regarded as the center of the

unresolved hyperfine structures. In Fig. 6 the pressure dependence of the absorption coefficient reproduced from the parameters of Table 2 is expressed by the solid line and the observed values by the closed circles.

The uncertainty expected for the observed $1/\alpha(\nu_1)$ value is samll relative to that for methyl fluoride. In the plot of $1/\alpha(\nu_1)$ against $1/P^2$, the slope of the straight line decreases in magnitude as the $|\nu_1-\nu_m|$ values decreases. On the other hand, the dispersion of the resultant $1/\alpha(\nu_1)$ value due to the uncertainty of the pressure measurement is smaller, if the slope of the straight line is small. Therefore, the standard deviation of the resultant $1/\alpha(\nu_1)$ for methyl iodide is much smaller than that for methyl fluoride, because the $|\nu_1-\nu_m|$ value for methyl fluoride is much larger than that for methyl iodide.

Comparison with the Result from Conventioanl Methods. The obtained transition moment value was converted into the absolute absorption intensity value in order to compare the present results with the absorption intensities obtained by conventional methods. The absolute absorption intensity, Γ, which is integrated over the whole absorption band, is defined as

$$\Gamma = \frac{1}{c_B l}\int_{\text{band}} \ln\left(\frac{I_0}{I}\right) d(\ln \nu), \qquad (\text{cm}^2\cdot\text{mol}^{-1}), \qquad (4)$$

where c_B is the molecular density in mol·cm^{-3}, l the path length in cm, and the integration covers the whole absorption band. The relation between the absolute absorption intensity, Γ, and the trnasition moment, $(\partial\mu/\partial Q)\langle 0|Q|1\rangle$, is expressed as[1)]

$$\Gamma = \frac{4\pi^2 N_A d}{3c\hbar}\left|\left(\frac{\partial\mu}{\partial Q}\right)\langle 0|Q|1\rangle\right|^2, \qquad (5)$$

where N_A is the Avogadro constant, and d the degree of vibrational degeneracy. In Table 3 the Γ values calculated from Eqs. 3 and 5, and the observed α_0 are compared with the Γ values obtained by conventional methods.

For the ν_3 band of methyl fluoride, the Γ value obtained in this work is somewhat larger than those obtained by conventional methods. This might be due to the weak Coriolis interaction between the ν_3 and ν_6 bands.[3)] However, since the standard error is considerably large this will not be explored further.

For the methyl iodide ν_6 band, the present result agrees well with that obtained by conventional methods. This indicates that there is no intramolecular perturbaion which influences the absorption intensity in the $|v_6=1>$ state.

Conclusive Discussion. This work has shown that the absorption intensity of a single vibration-rotation line of a molecule may be meaured by this method if the frequency of the laser line nearly coincides with that of the molecular absorption line, although the frequency of the laser radiation is not tunable. An accurate intensity value cannot be obtained, in the case that the absorption of the laser line due to plural number of lines occures simultaneously. The accuracy of the observed intenstiy value is governed mainly by the magnitude of the γ-value. For an absorption line with small γ, the intensity may be obtained with high accuracy. On the other hand, the γ-value is determined by the magnitudes of $|\nu_1-\nu_m|$ and γ_p. The γ_p-values are almost 10—50 MHz·Torr^{-1} for usual simple molecules, we can safely conclude that the experimental criterion for the accurate intensity measurement is $|\nu_1-\nu_m|\leq 4$ GHz. It is often difficult to observe the absorption intensities of a series of vibration-rotation lines in a certain vibration band by means of a frequency fixed laser. This method does not appear to be appropriate form obtaining detailed knowledge about the intensity distribution in a vibration band.

Incidentally, a rigorous assignment of rotation-vibration lines is required to apply the present technique to the observation of their intensities.

Infrared Study of Surface Hydroxyl Groups on Zirconium Oxide

Tsutomu YAMAGUCHI,* Yasuko NAKANO, and Kozo TANABE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received January 17, 1978)

Zirconium oxide has two absorption bands, at 3780 and 3680 cm^{-1}, after several hours' evacuation at 500 °C. The exchange of deuterium with the surface hydroxyl groups was studied by using D_2O, acetone-d_6, 2-propanol-d_8, and chloroform-d. D_2O, acetone-d_6, and 2-propanol-d_8 could completely exchange the hydrogens of the surface hydroxyl groups at room temperature, while chloroform-d could not exchange them even under saturated vapor pressure at room temperature. Hydroxyls showing 3780 cm^{-1} band were selectively and irreversibly chlorinated by chloroform-d. After deuteration, two deuteroxyl bands were observed, at 2780 and 2705 cm^{-1}; these were exchanged rapidly with ammonia and slowly with propylene. At room temperature propylene exchanged the hydrogen with the hydroxyls with a 2780 cm^{-1} band more rapidly than with the hydroxyls with a 2705 cm^{-1} band. In the adsorption and desorption of 2-propanol, the behavior of the 2780 cm^{-1} band was also found to be different from that of the 2705 cm^{-1} band. It was concluded that the 3780 and 3680 cm^{-1} bands could be assigned to surface hydroxyl groups, the nearest neighbors of which have different configurations, and the hydroxyl group of 3780 cm^{-1} is more reactive than the hydroxyl group of 3680 cm^{-1}.

Infrared spectroscopy is one of the most useful methods for the investigation of solid surfaces, and much work has been done on the nature of the hydroxyl groups on various oxides.[1] The presence of five types of hydroxyl groups on Al_2O_3 was reported by Peri.[2] The different natures of the five hydroxyl groups were suggested to arise from the difference in their nearest-neighbor configuration.[2] The two types of hydroxyl groups on SiO_2 were assigned to the surface and the bulk hydroxyls.[3] The MgO evacuated at 310 °C gave two types of hydroxyls, which were attributed to the surface and the second-layer hydroxyls.[4] Three types of hydroxyls were observed on CaO and attributed to groups with different circumstances.[5] Many reports have been reported on the hydroxyl groups on TiO_2, in which the presence of more than two groups has been reported.[6] The results were explained by Peri's model or a surface model on the (110) plane of rutile.[6c,d]

We have reported an interesting catalytic action of ZrO_2 toward the preferential production of 1-butene in the dehydration reaction of 2-butanol and the selective formation of *cis*-2-butene in the isomerization of 1-butene.[7] The results were explained in terms of the basic and acidic nature of this catalyst. The hydrogenation of olefins was also observed[8] on this oxide at a relatively low reaction temperature (0—50 °C), where hardly no deuterium-exchange reactions took place until the reaction temperature was raised above 200 °C.

In view of the interesting aspects of ZrO_2, we have investigated the nature of hydroxyl groups on the oxide. Tretyakov *et al.*[9] reported that two kinds of hydroxyls exist on ZrO_2. However, the relative reactivity of the two hydroxyls is not known. The purpose of the present paper is to report the relative reactivity of D_2O, acetone-d_6, 2-propanol-d_8, chloroform-d, ammonia, and propylene.

Experimental

The preparation of ZrO_2 has been described elsewhere.[7] The D_2O, acetone-d_6, 2-propanol-d_8, and chloroform-d, all supplied by Merck & Co., Inc., were degassed prior to use. The cylinder NH_3 was purified through molecular sieve 3A and sodium metal which was dispersed over quartz wool. Propylene obtained from Takachiho Chem. Ind., Ltd., was used without further purification.

ZrO_2 was ground and pressed into self-supported discs 20 mm in diam under 250 kg/cm^2. The disc was placed in an IR cell and evacuated at the desired temperatures for several hours. Oxygen treatment was applied to burn out organic contamination if necessary. Though it has been reported that oxygen treatment affects the behavior of the surface hydroxyl groups on TiO_2,[6b] no effect was observed in the case of ZrO_2.

All the spectroscopic measurements were carried out at room temperature by using a JASCO (Japan Spectroscopic Co., Ltd.) DS 701-G double-beam spectrometer. About 50 mg of typical sample discs transmitted about 10% of incident radiation at 4000 cm^{-1} after standard pre-treatment. Ordinate or abscissa scale expansion was applied if it was needed; the reference beam was attenuated for obtaining an appropriate transmittance.

Results

Exchange with D_2O. After several hours' evacuation at 500 °C, ZrO_2 showed two absorption bands, at 3780 and 3680 cm^{-1} (Fig. 1), in agreement with the spectra observed by Tretyakov *et al.*[9] These bands are characteristic in their narrow and symmetrical contours and have been assigned to hydroxyl groups which hereafter, for the sake of convenience, will be referred to as $(OH)_I$ and $(OH)_{II}$ respectively. It is not surprising that the half-width of the $(OH)_I$ band is narrow, but it is noteworthy that the other band of a low frequency also has a relatively narrow half-width.

Two or three treatments with 8 mmHg of D_2O at room temperature, followed by evacuation at 500 °C, lead to an almost complete replacement of the original hydroxyl bands with new deuteroxyl bands at 2780 and 2705 cm^{-1}. The former will be referred to as $(OD)_I$ and the latter, as $(OD)_{II}$, which correspond to $(OH)_I$ and $(OH)_{II}$ respectively. The process of the appearance of these bands is shown in Figs. 1c—1e. The $(OD)_I$ begins to appear on evacuation above 200 °C with a decrease in the lower-frequency band at 2705 cm^{-1}. After evacuation above 300 °C, the band at 2705 cm^{-1} decreases markedly in intensity, and two well-resolved bands are obtained at 2780 and 2705 cm^{-1}.

Exchange with Deuterated Organic Compounds. The exchange between deuterated compounds and hydroxyl groups was also examined using acetone-d_6, 2-propanol-d_8, and chloroform-d.

a) Acetone-d_6. The results of the adsorption of acetone-d_6 are shown in Figs. 2 and 3. The adsorption of 1.35 mmHg of acetone-d_6 leads to the complete disappearance of the original OH bands and gives a broad band at 2655 cm^{-1}. The C–D stretching bands are also observed around 2225 cm^{-1}, and C–H bands which could originate from the partial exchange between C–D and hydroxyl groups, appear around 2935 cm^{-1}.

As is shown in Fig. 2, the two bands of $(OH)_I$ and $(OH)_{II}$ were reduced in intensity with an increase in the adsorption pressure of acetone-d_6, keeping their original shapes, while only a broad band appeared around 2700 cm^{-1}, no band of $(OD)_I$ being observed. This indicates that the deuteroxyl groups produced were hydrogen-bonded with each other or with acetone, and that no hydrogen bond was formed in the original hydroxyl groups in the course of adsorption.

During the course of desorption (Fig. 3), the behavior of the two deuteroxyl groups was nearly the same as in the case of D_2O. Evacuation at 200 °C resulted in the production of the $(OD)_I$ band at 2780 cm^{-1}, and above 300 °C two well-resolved bands were obtained, at 2780 and 2710 cm^{-1}.

The spectrum below 2000 cm^{-1} observed at temperatures lower than 200 °C indicates the presence of the formate and the acetate species, the former being assigned by means of the 1589 and 1350 cm^{-1} bands, and the latter, by means of the 1535 and 1440 cm^{-1} bands.[10] Formate species were removed by evacuation above 200 °C, while acetates could not be removed by evacuation up to 500 °C. The acetate species could only be removed by the admission of oxygen and by evacuation at 500 °C.

b) 2-Propanol-d_8. The adsorption of 2-propanol-d_8 at room temperature resulted in the disappearance of two hydroxyl groups and the appearance of a broad band at 2705 cm^{-1}. No marked difference was observed in the behavior of the two hydroxyl bands at 3780 and 3680 cm^{-1} in the course of the adsorption. The observed bands at 2225, 1165, 1095, and 1050 cm^{-1} were assigned to ν_{C-D}, ν_{C-O}, δ_{as}, and δ_s respectively (Fig. 4). Adsorbed alcohol was stable up to 300 °C, and most of these species decomposed between 300 and 400 °C. The composition of the desorbed gas, which was collected and analyzed by means of gas chromatography, was as follows:

Propylene:Alcohol:Acetone=100:10:1.

No indication of the formation of carboxylate species on the surface was obtained.

A difficulty in restoring $(OD)_I$ was observed in the course of the desorption of alcohol. Below 300 °C, there is only one absorption maximum, at 2705 cm^{-1}. The restoration of $(OH)_I$ or $(OD)_I$ was observed above 200 °C in the case of acetone-d_6 or ammonia (which will be discussed later), even if these compounds remained on the surface. This discrepancy can be understood if one assumes that different sites are used for the adsorption of alcohol. 2-Propanol is supposed to adsorb on the sites which produce $(OH)_I$ or $(OD)_I$, when H_2O or D_2O is admitted.

*c) Chloroform-*d. Since chloroform has been used for characterizing strong and weak basic sites on CaO by comparing the results of benzaldehyde and 2-propanol in terms of the relative ease of the proton abstraction from these molecules,[11] we tried to examine the adsorption of chloroform-*d* on ZrO_2.

The results are shown in Fig. 5. Unlike the cases of D_2O and acetone-d_6 adsorption, the introduction of a small amount of chloroform-*d* leads preferentially to a marked decrease in the $(OH)_I$ band and has little effect on $(OH)_{II}$ except for causing a slight shift to lower frequencies. The $(OH)_I$ almost disappeared after the introduction of 0.56 mmHg of chloroform-*d*, while the 3680 cm^{-1} band kept its intensity. The band broadening at lower frequencies of 3680 cm^{-1} indicates the presence of a hydrogen bond. The formation of new OD bands was quite small compared with the cases of D_2O and acetone-d_6, and no $(OD)_I$ band was observed. Evacuation at elevated temperatures or even the introduction of water vapor do not cause any restoration of the $(OH)_I$ band. On the other hand, though the $(OH)_{II}$ band was extinguished by the adsorption of chloroform at 200 °C, complete restoration was attained by H_2O treatment and evacuation at elevated temperatures.

The production of only a small amount of OD band suggests that hydrogen-deuterium exchange or the abstraction of deuterium by the surface is difficult. Thus, the ZrO_2 surface seems to have only weak basic sites, and the irreversibility of $(OH)_I$ suggests the possible chlorination of $(OH)_I$ by chloroform, though the adsorbed species of chloroform have not been identified.

Exchange with Ammonia and Propylene. The exchange between deuterated surface and ammonia or propylene was also eaxmined. After the deuteration of ZrO_2, ammonia was admitted at room temperature and the changes in the OH and OD bands were recorded. As is shown in Fig. 6, the reduction of the peak intensities in the two OD bands and the formation of an OH band were observed. Again, as in the case of acetone-d_6, the OD bands keep their original shapes, while being reduced in intensity, while the OH band produced shows hydrogen bonding. This indicates a rapid exchange between deuteroxyl groups and ammonia.

Adsorbed ammonia gives absorption bands at 3400, 3350, 1600, and near 1160 cm^{-1}, as is shown in Fig. 7, those bands are assigned to asymmetric and symmetric stretching modes, and to asymmetric and symmetric bending modes, of ammonia respectively. Metal–ammine complexes, such as $[Ni(NH_3)_6]Cl_2$, $[Co(NH_3)_6]Cl_2$, or $[Fe(NH_3)_6]Cl_2$, show deformation bands at about 1600 and near 1160 cm^{-1}, the latter, δ_s, being sensitive to the metal and the environment.[12] The 3400 and 3355 cm^{-1} bands obtained on alumina were assigned to the symmetric and asymmetric stretching vibrations of coordinated ammonia,[12] and the deformation band

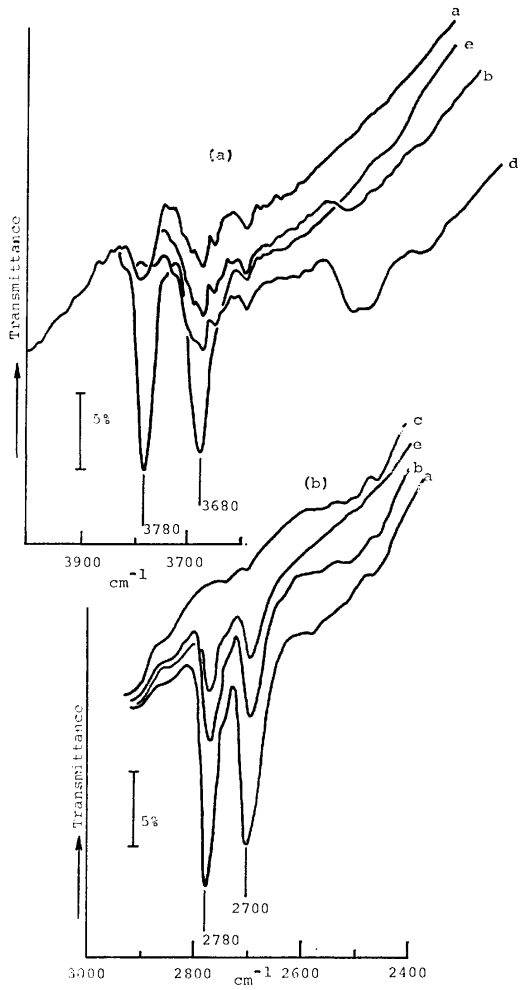

Fig. 6. Adsorption of ammonia on deuterated ZrO_2. (a) After exchange with D_2O. (b) 0.23 mmHg. (c) 0.56 mmHg. (d) 1.35 mmHg. Each spectrum was obtained after evacuation at room temperature for 1 h. (e) Evacuation at 500 °C.

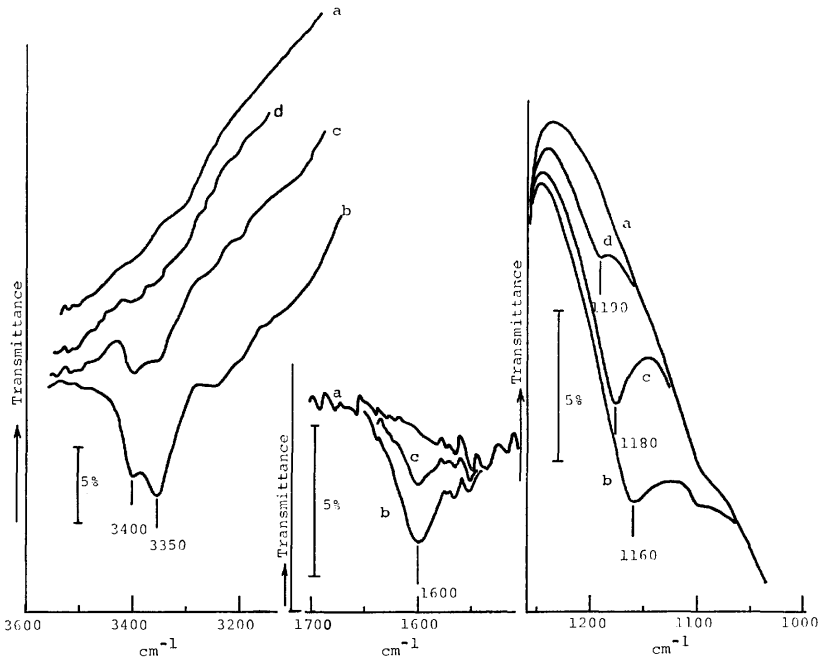

Fig. 7. Adsorption and desorption of ammonia.
(a) Background. (b) Adsorption of 1.35 mmHg of ammonia at room temperature followed by evacuation at room temperature for 1 h. (c) Evacuation at 200 °C. (d) Evacuation at 300 °C.

of coordinated ammonia appeared at 1620 cm^{-1}. Thus, on ZrO_2, the sets of the absorption bands obtained could be assigned to the ammonia coordinated to Lewis acid sites. The peak intensity of a 3350 cm^{-1} band was stronger than that of a 3400 cm^{-1} band when the adsorption pressure was high or the evacuation temperature was low. Thus, hydrogen-bonded species might be involved in the 3350 cm^{-1} band.

The isomerization of butenes took place at 80 °C, and *cis*-2-butene was the major product in the reaction from 1-butene.[7] In this connection, it is interesting to investigate the hydrogen exchanges between olefin molecules and surface hydroxyl groups. An exchange reaction was carried out, using propylene and deuterated ZrO_2, by following spectrometrically the intensity changes in deuteroxyl bands up to 300 °C. About half of the deuteroxyl groups were replaced by exchange in such a period as follows;

Temperature (°C)	r. t.	100	300
Time (h)	20	3	0.5

At higher temperatures, two deuteroxyl bands were reduced in intensity at the same rate, while the 2780 cm^{-1} band was reduced in intensity more rapidly than the 2705 cm^{-1} band at lower temperatures.

Discussion

More than two types of hydroxyl groups have been observed on various metal oxides, such as Al_2O_3,[2] SiO_2,[3] MgO,[4] CaO,[5] and TiO_2.[6] Typical hydroxyl groups on SiO_2[3] were assigned to the surface and the bulk hydroxyls, or to the isolated and the combined ones, on the basis of observations of the deuterium-exchange and particle-size dependencies. Peri has reported that the five types of hydroxyls which are present on the Al_2O_3 surface have different configurations in the nearest neighbors.[2] Because of the very high frequencies observed for the hydrogen–oxygen stretching vibrations of hydroxyl groups on Al_2O_3, Peri regarded them as ions rather than as groups covalently bonded to surface aluminum atoms. More than two kinds of hydroxyls have been observed on TiO_2 by many authors.[6] Parkyns[6d] found two main peaks, at 3728 and 3672 cm^{-1}, with reflections at 3707 and 3636 cm^{-1} on anatase evacuated at 400 °C; he also discussed the models, *i.e.*, the statistical, substitutional, and total hydration models, though he did not assign them individually. The presence of two kinds of hydroxyls (3780 and 3680 cm^{-1}) on rutile was reported by Parfitt,[6c] and these groups were attributed to bridged and terminal hydroxyls, assuming a model for the surface based on the (110) plane on rutile. From the different thermal stabilities of the two bands, the bridged type, $\overset{M}{M}\!>\!OH$, was thought to be more stable because of the bidentate configuration, while the terminal one, M–OH, was considered less stable.

The hydroxyl groups observed on ZrO_2 could be assigned to the surface hydroxyls by taking into consideration the peak shapes and exchange abilities observed in the present work. The assignment of $(OH)_{II}$ to the hydrogen-bonded ones seems to be unlikely because of its relatively narrow and symmetrical shape. We propose to assign two types of bands to the isolated surface hydroxyls which have different neighboring circumstances, *e.g.*, to the bridged and terminal groups, as has been postulated by Parfitt.[6c]

The characteristic behavior of the OH bands which were observed in the adsorption of the materials tested

here may be summarized as follows:

1. As is shown in Fig. 2 (acetone-d_6) and Fig. 6 (NH_3), the bands being reduced keep their original shapes, while the produced bands show a strongly hydrogen-bonded nature.
2. The $(OH)_I$ and $(OH)_{II}$ bands show different characters in the cases of alcohol and chloroform adsorption, in which the difficult restoration of $(OH)_I$ was observed during the desorption process.

The first phenomenon can be explained on the basis of a rapid hydrogen exchange between hydroxyls (or deuteroxyls) and adsorbates. When acetone-d_6 interacts with surface hydroxyls, rapid hydrogen-deuterium exchange may take place to form surface deuteroxyl groups, which are observed as a broad band at about 2655 cm^{-1} as a result of hydrogen bonding, while the OH groups which have not interacted with the adsorbate remain unchanged. The adsorption of 2-propanol may be supposed to cause an increase in the concentration of surface hydroxyl groups rather than an exclusive exchange of surface hydroxyl groups with 2-propanol. An increase in the surface hydroxyl groups causes an increase in hydrogen bonding in both the original and produced OH groups. The situation is the same in the case of NH_3, where the hydrogen bond was observed only in the produced hydroxyls, and not in the original deuteroxyls, as a result of the rapid exchange between the NH_3 and the surface OD groups.

The second phenomenon, in which the difficult restoration of the $(OH)_I$ group was observed, can be explained if we assume that alcohol and chloroform are adsorbed exclusively on $(OH)_I$ or $(OD)_I$ sites. As far as alcohol is concerned, the admission of alcohol to ZrO_2 may lead to an interaction only with the surface $(OH)_I$ and to the formation of alkoxyl groups on $(OH)_I$ sites. Such alkoxyl groups are stable up to 300 °C; they decompose to olefin above this temperature.

All the results obtained from the adsorption of chloroform or alcohol and the hydrogen-exchange reaction with propylene at lower temperatures reveal that $(OH)_I$ or $(OD)_I$ is more labile and reactive than $(OH)_{II}$ or $(OD)_{II}$.

The Absolute Rate Constants of Reaction of Hydrogen Atoms with Several Olefins

Yo-ichi ISHIKAWA, Masaki YAMABE, Akihiko NODA, and Shin SATO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 3, 1978)

Using the techniques of pulse-radiolysis and of the absorption of Lyman-α radiation by hydrogen atoms, the absolute rate constants of reaction of hydrogen atoms with several olefins have been measured at room temperature.

Olefin	$k/10^{-12}$ cm^3 molecule^{-1} s^{-1}
Ethylene	1.1±0.1
Propylene	1.7±0.1
1-Butene	2.0±0.5
trans-2-Butene	1.1±0.2
cis-2-Butene	1.0±0.1
2-Methyl-1-propene	5.2±0.6
2-Methyl-2-butene	2.4±0.3

These rate constants were invariant over hydrogen pressures ranging from 200 to 1200 Torr.

When hydrogen gas at one atmosphere is irradiated with high energy electrons, many different active species are produced and react with each other as well as with hydrogen molecules; however, in a very short time (≈ 10 μs) after the irradiation, active species other than hydrogen atoms disappear in the reaction system. Since the recombination of hydrogen atoms and the diffusion to the wall of the reaction vessel are slow processes, the concentration of hydrogen atoms actually remains constant for a while. If a small amount of an olefin is present in this system, the decrease in the concentration of hydrogen atoms results from the reaction of hydrogen atoms with the olefin. The change of the concentration of hydrogen atoms can be pursued by the absorption of Lyman-α radiation. Hikida *et al.* used this technique for the measurement of the rate constants of reaction of hydrogen atoms with oxygen, carbon monoxide, nitric oxide, and ethylene.[1] Mihelcic *et al.* extended this technique to the reactions of H and D atoms with C_2H_4, C_2D_4, and C_3H_6.[2]

On the other hand, the relative rates of reaction of hydrogen atoms with various olefins have been measured by many investigators. Among them, Cvetanović and coworkers used three different photochemical techniques: the mercury-photosensitized decompositions of butane[3] and of hydrogen[4] and the photolysis of hydrogen sulfide,[5] as sources of hydrogen atoms, and measured the relative rates. These relative rate constants are one of the important sets for the reactions of hydrogen atoms.

Recently, we have constructed an apparatus similar to that used by Mihelcic *et al.* and measured the absolute rate constants of reaction of hydrogen atoms with several olefins.

Experimental

A schematic diagram of the set-up of instruments is shown in Fig. 1. As the source of Lyman-α, a water-cooled capillary discharge lamp with a flow of a gas mixture of 5% hydrogen and 95% helium was used. The highest ratio of signal/noise, about 10, was obtained at 600 V and 0.6 A. We could not find any strong lines other than Lyman-α between 104 and 200 nm.

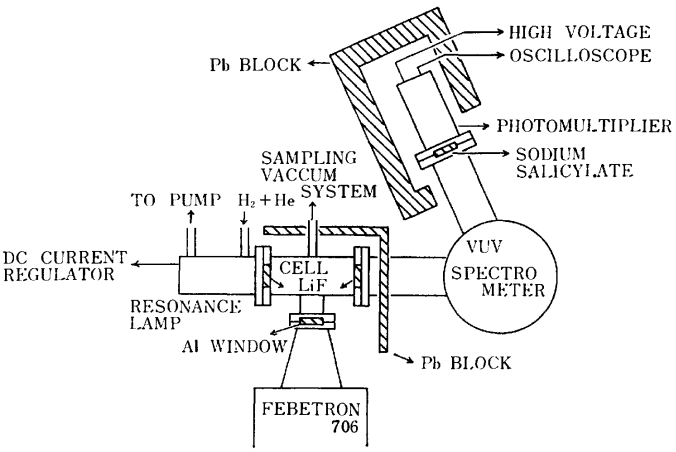

Fig. 1. The schematic diagram of the pulse radiolysis-resonance absorption apparatus.

The reaction vessel was made of stainless steel, 11 cm long and 5 cm in diameter. A pair of LiF windows was attached to the vessel perpendicularly to the path of the electron beam. At the entrance of the electron beam was framed another window covered with an aluminium foil, 80 μm in thickness. The LiF plates used were supplied by the Harshow Chem. Co., 2 mm thick, and can transmit over 70% of Lyman-α radiation.

The Lyman-α was isolated with the VUV monochromator (Shimadzu, Model SGV-50). The light signal was detected with a photomultiplier (Hamamatsu TV Co., R268) through the wave-shifter of sodium salicylate. The output of the photomultiplier was amplified and monitored with an oscilloscope (Tektronix 475). The risetime of the detection system was about 3 μs. The negative high voltage power sypply (Hamamatsu TV Co., Model HTV-C448) for the photomultiplier was operated at 700 V and the bleeder current was about 1 mA, which was about 10^3 times the signal current.

The pulsed electron beam— a few ns of the pulse-width and 600 keV of the upper-limit energy—was generated by a Febetron 706 (Hewlett Packard Co.). The total output energy was nominally 12 J pulse^{-1}. Only a small fraction of it was absorbed by the hydrogen gas because of the low electron density. The dose absorbed by hydrogen at 760 Torr

in the reaction vessel was estimated to be 10^{16} eV pulse^{-1} by using the dinitrogen oxide dosimeter. The *G*-value of nitrogen was assumed to be 12.4.[6]

The pressure of the gases introduced into the reaction vessel was measured with a Wallace and Tiernan type aneroid manometer (Nagano Keiki Co., Model GP 15-201). The high-purity dried hydrogen (Showa Denko Co.) was passed through a trap filled with molecular sieve 4A at the temperature of liquid nitrogen. The research grade olefins: ethylene, propylene, 1-butene, *cis*- and *trans*-2-butene, 2-methyl-1-propene, and 2-methyl-2-butene, were supplied by the Takachiho Shoji Co., and were used after thorough degassing.

Results

Pure Hydrogen. Figures 2a and 2b show the oscillograms for the time-dependence of hydrogen atom-concentration obtained with pure hydrogen at 1200 Torr. As Fig. 2a shows, the formation of hydrogen atoms is completed within 20 μs after the pulse irradiation. The signal shown before 20 μs does not correspond to the true change of the concentration of hydrogen atoms, because the recovery of the detection system from the large noise induced by the electron pulse is slow.

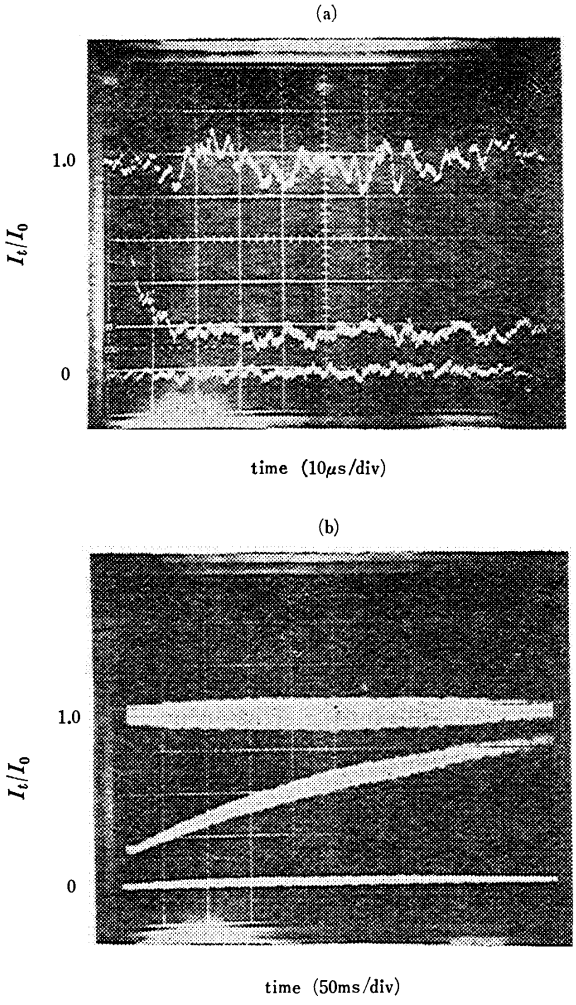

Fig. 2. Transmission of Lyman-α in the pulse irradiated pure hydrogen at 1200 Torr.

Figure 2b shows the gradual decrease of the concentration of hydrogen atoms. Most of the curves obtained with pure hydrogen at various pressures obeyed the first-order decay; for example, the lifetime obtained at 760 Torr was 0.18 s. As is shown later, this decay rate is two orders of magnitude slower than the slowest decay rate obtained in the presence of an olefin. The decrease in the concentration of hydrogen atoms observed with pure hydrogen is probably due to the diffusion of hydrogen atoms to the wall of the reaction vessel; however, the reaction with impurities eventually introduced cannot be ignored. Consequently, no further analysis has been attempted in the present experiment.

For the measurement of the concentration of hydrogen atoms, the present experiment uses the optical density for the Lyman-α radiation from the discharge lamp. However, since the profile of the Lyman-α cannot be the same as that of the absorption line of hydrogen atoms produced in the reaction vessel, the linearity between the concentration of hydrogen atoms and the optical density may not always hold.

Figure 3 shows the maximum optical density obtained with pure hydrogen after the pulse irradiation as a function of the hydrogen pressure. At low pressures, the energy transferred from high energy electrons to hydrogen gas may be regarded as proportional to the pressure; that is, the concentration of hydrogen atoms produced may be proportional to the pressure of hydrogen. As Fig. 3 shows, if the absorbance is lower than 60%, the linearity between the hydrogen atom-concentration and the optical density for Lyman-α may be used in the present experiment.

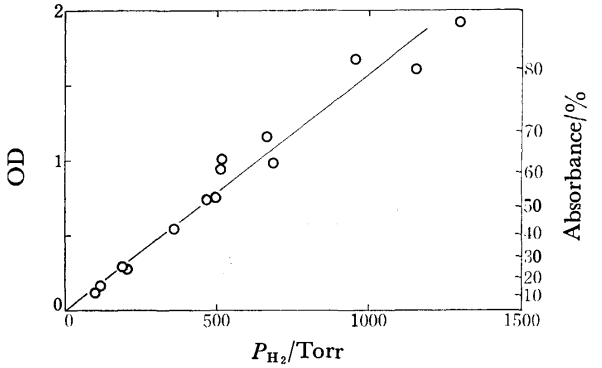

Fig. 3. The highest optical density after pulse irradiation as a function of the hydrogen pressure.

In the Presence of Olefin. Because of the high absorption coefficient of olefins at 121.6 nm, the pressure of olefins could not be raised above 0.15 Torr, which corresponds to 8.4×10^{-9} mol cm^{-3}.

One of the oscillograms for the decay of hydrogen atoms obtained in the presence of ethylene is shown in Fig. 4. From this oscillogram, we plotted the logarithm of the optical density as a function of time, as is shown in Fig. 5. The slope of this plot corresponds to the decay rate of hydrogen atoms. The rate constant of the reaction between hydrogen atoms and ethylene can be calculated by dividing this decay rate by the concentration of ethylene.

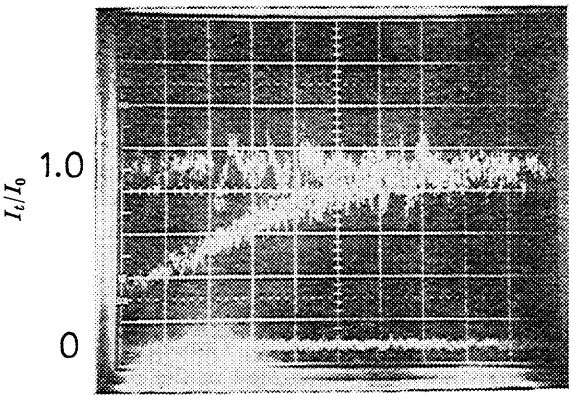

Fig. 4. Transmission of Lyman-α in the pulse irradiated hydrogen at 750 Torr containing 50 mTorr ethylene.

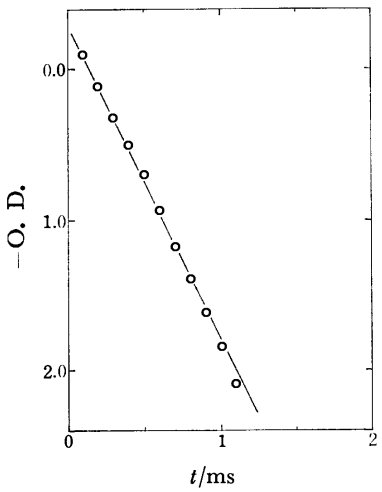

Fig. 5. The first order decay plot for the reaction of hydrogen atoms with ethylene.

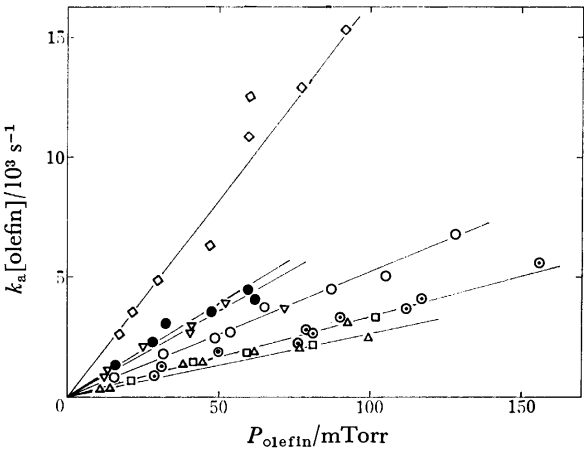

Fig. 6. Plots of the decay rates against the olefin pressures. The hydrogen pressure is around 750 Torr. ⊙: Ethylene, ○: propylene, ▽: 1-butene, □: *trans*-2-butene, △: *cis*-2-butene, ◇: 2-methyl-1-propene, ●: 2-methyl-2-butene.

All of the rate constants thus calculated are summarized in the last column of Table 1. The hydrogen pressure ranges from 200 to 1200 Torr and the olefin pressure from 0.02 to 0.15 Torr. The rate constant obtained with an olefin is independent of both the hydrogen and olefin pressures within the experimental errors. Figure 6 shows the decay rates obtained at around 750 Torr of hydrogen as functions of the pressures of olefins examined.

Discussion

The Initial Concentration of Hydrogen Atoms. Since no stable products can be obtained, the radiolysis of hydrogen has not been investigated except for that of the mixture of hydrogen and deuterium. For this mixture system, the famous chain reaction:

$$H_2^+ + H_2 \rightarrow H_3^+ + H,$$
$$H_3^+ + H_2 \rightarrow H_2 + H_3^+,$$

has been studied.[7] However, the G-value of hydrogen atoms has not been measured.

According to the theoretical calculation,[8] the G-values of initial active species in the radiolysis of hydrogen are as follows: $G(H_2^*, \text{excited state}) = 1.92$, $G(H^*, \text{hot atoms}) = 0.94$, $G(H) = 2.49$, $G(H^+) = 0.40$, and $G(H_2^+) = 2.43$. With these values, we can estimate the upper limit of the G-value of hydrogen atoms.

$$G(H) = 1.92 \times 2 + 0.94 + 2.49 + 0.40 + 2.43 \times 2$$
$$= 12.53$$

Using the absorbed dose of 10^{16} eV pulse^{-1}, the initial concentration of hydrogen atoms in the reaction system can be estimated to be 10^{-11} mol cm^{-3}.

An independent estimation can be made as follows. In the study of the reaction of hydrogen atoms, Michael and Weston measured the relationship between the optical density for Lyman-α and the concentration of hydrogen atoms.[9] The optical density of 0.5 was obtained at the hydrogen atom-concentration of 13.3×10^{12} atoms cm^{-3} with the optical path of 3.5 cm. Since their procedure is similar to the method in the present experiment, let us assume that the relation obtained by Michael and Weston holds for the present measurement, in which the optical path is 11 cm. Then, the concentration of hydrogen atoms at the optical density of 0.5 can be calculated to be 0.7×10^{-11} mol cm^{-3}.

The lowest olefin pressure used in the present experiment was 0.02 Torr, which corresponds to 1.0×10^{-9} mol cm^{-3}. The concentration ratio [H]/[olefin], therefore, is always smaller than 10^{-2}.

Active Species other than Hydrogen Atoms. The thermalization times of high energy electrons in various gases have been measured by Warman and Sauer.[10] In hydrogen gas, the product of the thermalization time and pressure, $\tau_{th} \times p$, was estimated to be 1.5×10^{-6} s Torr; *i.e.*, the thermalization time in hydrogen at 760 Torr is about 2 ns. Since the species heavier than electrons are thermalized more rapidly than electrons, all of the active species produced in hydrogen must be thermalized in a few ns after the electron pulse.

The neutralization time is one of the problems in radiation chemistry. In the study of the emission from the helium–mercury system irradiated by high energy electrons, we have recently measured the time-dependence of the emission and found that the slowest emission resulted from the neutralization reaction between mercury ions and thermalized electrons in helium at 760 Torr, which was completed within 10 μs.[11] Consequently, we can conclude that, at 20 μs after the pulse irradiation, no active species other than hydrogen atoms are present in the reaction system and that all hydrogen atoms are thermalized.

The Contribution of the Reaction of Alkyl Radicals. It is now well known that the reaction between hydrogen atoms and olefins is mainly the addition reaction forming alkyl radicals, and that the abstraction reactions of a hydrogen atom from an olefin make up less than 10% of the total reaction.[4]

$$\begin{aligned} H + \text{Olefin} &\rightarrow R && (1) \\ &\rightarrow H_2 + R' && (1') \end{aligned} \quad k_a$$

If the pressure in the reaction system is low, the radical produced in Reaction 1 may decompose before the thermalization. In the case of ethylene, this decomposition leads to the reformation of hydrogen atoms, so that the apparent decay rate of hydrogen atoms may be decreased with the decrease in the total pressure. However, as stated in the Results section, no such pressure dependence could be observed under the present experimental condition. Probably such a decomposition would occur at pressures lower than 200 Torr. In the present experiment, we could not make any measurements at pressures lower than 200 Torr, because the concentration of hydrogen atoms produced was too low for the measurement of decay rate.

The successive reactions of the radicals produced in Reaction 1 may be written as follows:

$$\begin{aligned} R + R &\rightarrow R_2 && (2) \\ &\rightarrow RH + \text{Olefin} && (2') \end{aligned} \quad k_b$$
$$\begin{aligned} R + H &\rightarrow RH && (3) \\ &\rightarrow H_2 + \text{Olefin} && (3') \end{aligned} \quad k_c$$

If Reactions 3 and 3′ are the only process for the disappearance of alkyl radicals, the decay rate of hydrogen atoms would become twice the value of k_a, the sum of the rate constants of Reactions 1 and 1′. However, Reactions 2 and 2′ are also fast processes and contribute to the disappearance of alkyl radicals. If the concentration ratio [H]/[olefin] is infinitely small, the apparent decay rate of hydrogen atoms is exactly equal to the sum of the rate of Reactions 1 and 1′.

In order to estimate the contribution of Reactions 3 and 3′, we defined the following correction factor:

$$\gamma = \frac{-\mathrm{d} \ln[H]/\mathrm{d}t}{k_a[\text{Olefin}]_0}.$$

Here $[\text{olefin}]_0$ stands for the initial concentration of olefins. On the basis of the reaction mechanism from (1) to (3′), we can construct simultaneous differential equations for [H], [olefin], and [R]. Using the Runge-Kutta numerical integration procedure, we calculated the value of γ as functions of the ratio of $[\text{olefin}]_0$ to $[H]_0$ and of the ratio of k_a/k_c. In this calculation, the following values were assumed: $k_b = 9.0 \times 10^{-12}$ cm^3 mol-

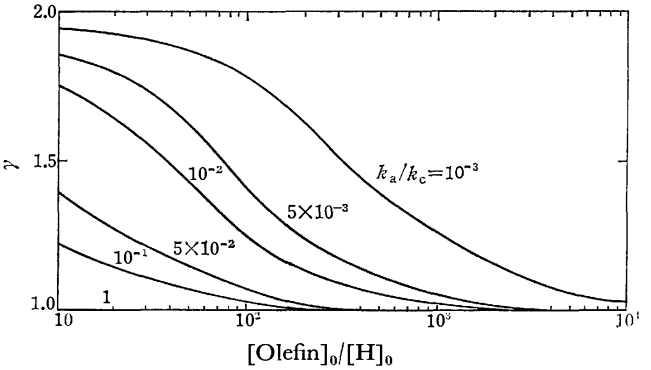

Fig. 7. The correction factor, γ, as functions of the ratios, $[\text{olefin}]_0/[H]_0$ and k_a/k_c.

Table 2. Relative rate constants of reaction of hydrogen atoms with olefins at room temperature

ecule^{-1} s^{-1},[12] $k_c=6.0\times10^{-11}$ cm^3 molecule^{-1} s^{-1},[13] and $[H]_0=6.0\times10^{12}$ molecule cm^{-3}. The result is shown in Fig. 7.

In the present experiment, $[olefin]_0/[H]_0>10^2$ and k_a/k_c is of the order of 10^{-2}. Therefore, the value of γ must be lower than 1.1. This means that no correction is needed for the present measurement of k_a.

Comparison with Other Measurements. Table 1 compares some of the measurements made for obtaining the absolute rate constants of reaction of hydrogen atoms with simple olefins.

As Mihelcic and coworkers summarized, numerous measurements have been reported for the reaction with ethylene.[2] The rate constants reported range from 0.15 to 1.5×10^{-12} cm^3 molecule^{-1} s^{-1}. The value obtained by Hikida *et al.* is $0.91\pm0.09\times10^{-12}$ cm^3 molecule^{-1} s^{-1}. The present result lies between the values obtained by two measurements in which the pulse radiolysis technique was used.

On the other hand, Table 2 compares our result with the relative rate constants obtained by Cvetanović and coworkers[3-5] and Cowfer *et al.*[14] Except for the values obtained with 2-methyl-1-propene and 2-methyl-2-butene, the present result is in good agreement with those reported by Cvetanović.

Far-infrared Absorption Intensities and the Dipole Moments of Some Molecules in Solutions

Kimihiro SATO, Yusei OHKUBO, Tadaharu MORITSU, Shun-ichi IKAWA, and Masao KIMURA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 17, 1978)

The integrated intensities of the far-infrared absorptions of CH_3I, $CHCl_3$, CH_2Cl_2, CH_3CN, and their deuterated compounds in dilute solutions have been measured. They can be well explained by the rotational motion of the molecules with the dipole moments enlarged by Onsager's reaction field.

It is well known that the broad far-infrared absorption of a dipolar molecule in the liquid phase contains valuable information about the molecular rotational motion in the liquid. If the absorption is attributed solely to the rotational motion of the molecule, its band shape is reducible to the reorientational correlation function by the Fourier transformation[1] and its integrated intensity after correcting for the internal field effect[2-4] is related through Gordon's sum rule[5] to the dipole moment and the moments of inertia of the molecule. But all the integrated intensities so far observed,[6-15] except for the previous result for HCl dissolved in CCl_4,[16] are appreciably larger than the values estimated on the basis of the permanent dipole moments in the gas phase. Hitherto the excess absorptions have simply been ascribed to the temporary dipole moments induced by collision with neighboring molecules. However, even in the simple form of Gordon's sum rule, which was widely used,[6-16] the dipole moment involved is considered to be a gross dipole moment consisting of the permanent dipole moment in the free state and the statistical average of the induced dipole moment. In this case, the dipole moment may conveniently be interpreted in the macroscopic point of view. In the theory of dielectrics,[17,18] the actual dipole moment of a molecule in the liquid phase differs from the gas-phase value owing to the reaction field. Since the actual dipole moment which was referred to as the *internal moment* by Fröhlich,[17] simply follows the rotation of the molecular framework, it takes part in the far-infrared absorption. Then, the actual dipole moments estimated by the theory of dielectrics are worth comparing with the dipole moments obtained by Gordon's sum rule from the far-infrared absorption intensities.

In the present study, we have measured the far-infrared absorption intensities of CH_3I, $CHCl_3$, CH_2Cl_2, CH_3CN, and their deuterated compounds dissolved in non-polar solvents and adopted Onsager's reaction field for estimating the internal moments of the molecules.

Experimental

The far-infrared spectra were measured at room temperature on a HITACHI FIS-21 single beam spectrophotometer equipped with a germanium-bolometer detector which was operated at pumped liquid-helium temperature, 1.8 K. The resolution was higher than 2 cm^{-1} over the observed region, 10—360 cm^{-1}. Two cells of equal thickness with low-density polyethylene windows were set in a closed compartment placed between the monochromator and the detector. Atmospheric water vapor in the compartment was purged by a steady flow of dried nitrogen gas, while the monochromator was evacuated by a rotary pump. The two cells filled with the solution and the solvent were alternately introduced into the light path by manipulating from outside. The transmitted intensities were determined by observing for 5 min at every fixed wave number with intervals of 5—10 cm^{-1}. In this way, the S/N ratio was improved and the influences of the long-time fluctuations of the light source (high-pressure mercury lamp) and the bolometer sensitivity were effectively eliminated from the results. Spectroscopic grade reagents were used for C_6H_6, CCl_4, CS_2, n-C_6H_{14}, CH_2Cl_2, and CH_3CN. For CH_3I and $CHCl_3$, the commercially available samples were used after purification[19] to eliminate a slight amount of polar impurities, such as H_2O and C_2H_5OH. The deuterated compounds were purchased from CEA and used without further purification. The concentration ranges employed were 0.20—1.1 M, 0.25—1.1 M, 0.13—0.48 M, and 0.03—0.16 M for the solutions of CH_3I, $CHCl_3$, CH_2Cl_2, and CH_3CN respectively.

Results and Discussion

The observed absorption coefficients, $\sigma(\nu)$, of CH_3I dissolved in the non-polar solvents are shown in Fig. 1 as examples. The band shapes for all the solutions studied do not depend on concentration, but they depend appreciably on the solvents. By extrapolating the observed spectra to the origin, as shown by the fine broken lines in Fig. 1, the integrated intensities

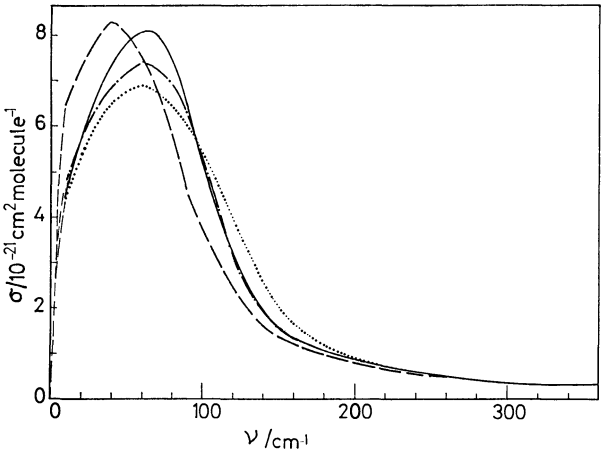

Fig. 1. Far-infrared absorption bands of CH_3I dissolved in C_6H_6(·····), CCl_4(——), CS_2(—·—), and n-C_6H_{14} (— — —).

were obtained by

$$A = \int_0^{360} \sigma(\nu)\mathrm{d}\nu, \tag{1}$$

where

$$\sigma(\nu) = \frac{1}{\rho l}\ln(T_0/T)_\nu ,$$

and ρ denotes the concentration of the dipolar molecule (molecules·cm^{-3}), l the sample thickness (cm), and T_0 and T the transmittance of the solvent and the solution, respectively. The most probable values of A were evaluated from the slopes of the Beer's law plots shown in Fig. 2, and are listed in Table 1. The internal-field correction was applied to A. The corrected intensities, A_c, were obtained by the equation[3,4]

$$A_c = n_s\left[\frac{(n/n_s)^2+2}{n^2+2}\right]^2 A, \tag{2}$$

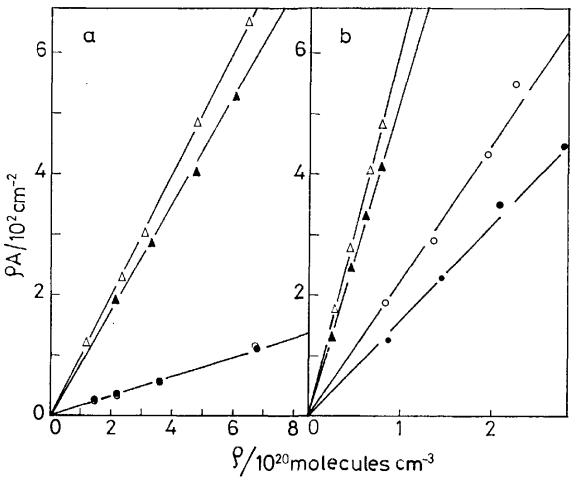

Fig. 2. Beer's law plots for CH_3I(a- △), CD_3I(a- ▲), $CHCl_3$(a- ○), $CDCl_3$(a- ●), CH_3CN(b- △), CD_3CN(b- ▲), CH_2Cl_2(b- ○), and CD_2Cl_2(b- ●) dissolved in CCl_4.

where n and n_s denote the refractive indices of the solute and the solvent respectively. In the present study, they were replaced by the values for the Na_D-line. This replacement introduces only a few percent uncertainty in the A_c values.

Since the dipole moment of the C_{2v} or C_{3v} symmetric molecule lies along one of the principal axes of the moment of inertia, say the z axis, Gordon's sum rule is reduced to[5]

$$A_c = \frac{\pi\mu^2}{3c^2}\left(\frac{1}{I_x}+\frac{1}{I_y}\right), \tag{3}$$

where c is the velocity of light, μ the dipole moment, and I_x and I_y the principal moments of inertia about the x and y axes. The μ values calculated from A_c by Eq. 3 are shown in Table 1, together with the values of the moments of inertia and the permanent dipole moments in the gas phase, μ_0, taken from the literature. The μ values are about 10—20% larger than the μ_0 values for all the compounds studied. Moreover, almost the same μ values were obtained for the H- and D- compounds, which have different moments of inertia. These facts can be explained by regarding μ as the internal moments in the solutions. According to the concept of the reaction field in the theory of the dielectrics,[17,18] the internal moment, μ^*, is larger than the dipole moment in vacuum or in the gas phase, μ_0.

In Onsager's model, the internal moment μ^* is expressed as[17,18]

$$\mu^* = \frac{1}{1-f\alpha}\mu_0, \tag{4}$$

where

$$f = \frac{1}{a^3}\cdot\frac{2\varepsilon-2}{2\varepsilon+1}, \tag{5}$$

and α is the average polarizability of the molecule, ε the dielectric constant of a continuous medium, and $a^3=3/4\pi N$ (N: the number of the molecules per cm^3). Introducing Eq. 5 into Eq. 4 and rewriting by the use

a) Calculated from the rotational constants taken from Ref. 20. b) Ref. 20. c) Ref. 21.

of the Lorenz-Lorentz relation, $\alpha/a^3=(n^2-1)/(n^2+2)$, we have[17,18]

$$\boldsymbol{\mu}^* = \frac{(n^2+2)(2\varepsilon+1)}{3(2\varepsilon+n^2)}\boldsymbol{\mu}_0. \quad (6)$$

Since ε can be replaced by n_s^2 to a good approximation, Eq. 6 is also written as

$$\boldsymbol{\mu}^* = \frac{(n^2+2)(2n_s^2+1)}{3(2n_s^2+n^2)}\boldsymbol{\mu}_0. \quad (7)$$

Since $\boldsymbol{\mu}^*$ will always be in the same direction as $\boldsymbol{\mu}_0$, it follows the rotation of the molecular framework as $\boldsymbol{\mu}_0$ does. Then the molecule in the solution absorbs the far-infrared radiation through the dipole moment of μ^*.

The μ^* values calculated from μ_0 using Eq. 7 are listed in Table 1. They are in good agreement with the observed μ values. Thus, the far-infrared absorptions observed in the present study can be explained almost wholly by the rotational motion of the $\boldsymbol{\mu}^*$ vector. It follows that the observed band shape corresponds directly to the Fourier transform of the reorientational correlation function of the molecule.

The observed μ value of HCl dissolved in CCl_4 was nearly equal to the μ_0 value,[16] in contrast with the cases in the present study. Since the molar volume of CCl_4 is considerably larger than that of HCl, the cavity radius in Onsager's model must be larger than that estimated from the actual molar volume of HCl. In this case the $f\cdot\alpha$ value becomes small, or n^2 approaches to unity, so that the μ^* value may be nearly equal to the μ_0 value.

The authors wish to thank Prof. Tsunetake Fujiyama and Mr. Tetsuo Suzuki of Tokyo Metropolitan University for valuable discussions.

Reaction Mechanism of the Photooxidation of the Toluene–NO_2–O_2–N_2 System in the Gas Phase

Hajime Akimoto,* Mikio Hoshino, Gen Inoue, Michio Okuda, and Nobuaki Washida

The National Institute for Environmental Studies, P.O. Yatabe, Ibaraki 300-21

(Received February 15, 1978)

Photooxidation of the toluene (34 ppm)–NO_2(8—207 ppm)–N_2 and/or O_2(1 atm) system has been studied in a 67 dm^3 reaction chamber. The reaction was initiated by $O(^3P)$ atoms formed in the photolysis of NO_2. The main products were benzaldehyde, cresols, benzyl nitrate, *m*-nitrotoluene, 6-nitro-*o*-cresol, and 2-nitro-*p*-cresol. Their relative yields were studied as functions of reactant concentrations. The formation mechanisms of the products were proposed on the basis of the reactions of $O(^3P)$ and OH radicals with toluene in the presence of NO_2 and O_2.

Studies have been made on the photochemical oxidation of alkylbenzenes in the presence of nitrogen oxides (NO_x) and air in relation to photochemical air pollution. However, they deal mostly[1] with ozone formation and the so-called "photochemical reactivity."[2] A few reports[3-6] have been given on the reaction products and mechanisms of the gas phase photooxidation of alkylbenzenes–NO_x–air system.

Kopczynski[3] studied the photooxidation of alkylbenzenes–NO_2–air systems using a long-path infrared spectrometer and identified aldehydes, CO, CO_2, formic acid, and peroxyacetyl nitrate as reaction products. Nojima *et al.*[4a] studied the photooxidation of the benzene–NO_2–air system and identified nitrobenzene, nitrophenols, and dinitrophenols. They also reported[4b] the formation of glyoxal, methylglyoxal, and biacetyl which would have been produced by the cleaving of benzene rings in the photooxidation of benzene, toluene, and xylene. Ando *et al.*[5] studied the formation yield of nitrobenzenes in the benzene–NO_2–O_2–N_2 system as functions of O_2 and NO_2 concentrations.

Photooxidation of alkylbenzenes in the atmosphere is thought to be initiated by OH or O atoms. The photooxidation of alkylbenzene–HNO_2–air systems, in which OH radicals initiated the oxidation of benzene, toluene, and ethylbenzene, was studied and the reaction mechanisms were discussed in our previous study.[6] In this work,[7] photooxidation of the reaction systems of toluene (34 ppm), NO_2(8—207 ppm) in N_2 and/or O_2 at 1 atm was studied for the case in which O atoms from NO_2 initiate the oxidation, giving most of the oxidized products. The final reaction products and their relative yields as functions of reactant concentrations are reported and a discussion of the reaction mechanisms is presented.

Experimental

Figure 1 shows a schematic diagram of the apparatus. The reaction chamber is a Pyrex cylinder, 225 mm i.d., 1660 mm in length, 67 dm^3 in volume: evacuated to less than 1×10^{-6} Torr. Metal parts containing gas inlets and outlets are attached to both ends of the Pyrex cylinder with Viton O-rings, the inside walls of the metal parts being lined with Teflon in order to avoid any catalytic reactions on the metal surfaces. Each end of the reaction chamber is sealed with a Pyrex window 20 mm thick, through which a photolyzing light beam can be transmitted into the gas sample.

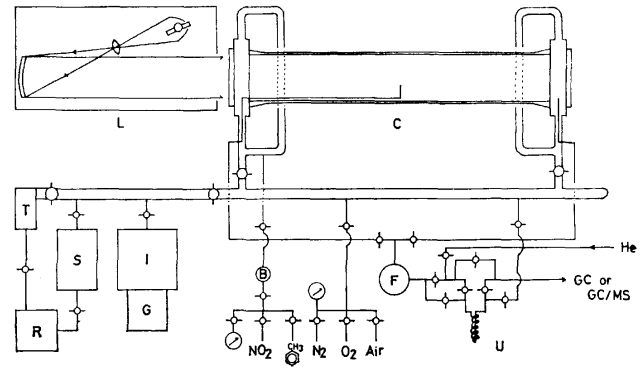

Fig. 1. Schematic diagram of the experimental apparatus. C: Reaction chamber; L: xenon arc lamp house; I: sputter ion pump; G: titanium getter pump; S: sorption pump; T: foreline trap; R: rotary pump; B: gas burette; F: sampling flask; U: low temperature spiral trap.

The light source was a 500 W xenon short arc lamp. A parallel light beam of *ca.* 200 mmϕ was obtained by using an elliptical mirror, lens, and an off-axis parabolic mirror. The effective light intensity as measured by the primary photodecomposition rate of NO_2 was 0.08 min^{-1}. The wavelengths of the irradiated light were greater than 320 nm. An oil free pumping system consisting of a sputter ion pump, titanium getter pump, cryo-sorption pump, and a rotary pump with a liquid nitrogen cooled foreline trap was used.

Toluene and NO_2 were first put into a 105-ml glass flask and then expanded into the reaction chamber. Air, O_2, or N_2 was then introduced through four gas inlets shown in Fig. 1. The pressure was measured with Capsulon gauges (Edward High Vacuum Co.), 50 and 760 Torr full scale which were calibrated by a mercury manometer. In order to confirm that the sample gases were mixed homogeneously, four sampling ports were attached to the chamber (only two of them are shown in Fig. 1), at the center, at one-fourth of the chamber length distance from one end, and at both ends. One hour after the gases had been introduced the concentration of the toluene taken from the four different ports was found to be the same, and irradiation was thus started. Sampling was repeatedly carried out through the center port at suitable time intervals. "Pure Air" (dew point lower than −70 °C), O_2 (>99.9%, graded as "Pure gas B") and N_2 (>99.995%, graded as "Pure gas B") were supplied from Nippon Sanso Co. NO_2 was obtained by mixing NO (research grade, Matheson) with excess O_2. Toluene (research grade, Wako Pure Chemical Ind.) was used without further pruification except

degassing. It contains *ca.* 0.01% xylenes, as impurity, which is negligible in the present study.

The reaction mixture was first introduced into a 700-ml constant volume glass flask and then concentrated in a GC sampling tube. The sampling tube, a Pyrex spiral of 2 mm i. d., about 4 m in extended length, was cooled to −60 °C. After the concentration, the sampling tube was heated with hot water and the sample was fed directly into a gas chromatograph. This procedure was found to minimize the yields of the products of thermal reactions of NO_2 with toluene and cresols in the smapling tube. Sampling for the GC analysis was made periodically every 45—60 min. GC analysis was carried out using a 3-m column of 5% SE-30 on Shimalite W. The GC oven temperature was raised from 80 to 200 °C at a rate of 4 °C/min. The concentration of NO_2 was monitored for several runs by the method of single beam photometry at a wavelength of 450 nm using the irradiation light as a light source. Identification of product was carried out by comparing the reference mass pattern and GC retention time using a GC-MS (JEOL, JMS-100) and a GC. In order to obtain the reference mass patterns and GC retention times, standard samples of benzaldehyde, *o*-, *m*-, *p*-cresols, benzyl nitrate, *o*-, *m*-, *p*-nitrotoluenes, *o*-nitrophenol, and 2- nitro-*p*-cresol were used. All chemicals except for benzyl nitrate were commercial products (Wako Pure Chemical Co.). Benzyl nitrate was prepared by fractional distillation of the reaction mixture of benzyl chloride and $AgNO_3$ in a dried acetonitrile solution. Identification of 6-nitro-*o*-cresol was performed by comparing the GC retention time with the reference sample obtained by the thermal reaction between *o*-cresol and NO_2. The mass pattern of 6-nitro-*o*-cresol was found to be nearly identical with that of 2-nitro-*p*-cresol.

For several experimental runs on the photooxidation of the HNO_2–NO_x–toluene–air system, known amounts of toluene and NO_2 were first introduced into the reaction chamber and then HNO_2–air mixture was introduced under a total pressure of 1 atm. The HNO_2–air mixture was produced by using 10 ml of 0.05 M $NaNO_2$ and 10 ml of 5% H_2SO_4.[6] The concentrations of HNO_2 and nitrogen oxides in the HNO_2–air mixture were determined[6] by the method of Cox[8] using a commercial chemiluminescence NO_x analyzer (Monitor Labs, Model 8440). The HNO_2–air mixture produced by the above method was found to contain *ca.* 12 ppm of HNO_2 and 2 ppm each of NO_2 and NO.

Results

The reaction products observed in the photooxidation of the toluene (34 ppm)–NO_2(8—207 ppm)–air(1 atm) system were benzaldehyde, cresols, benzyl nitrate, *m*-nitrotoluene, 6-nitro-*o*-cresol, and 2-nitro-*p*-cresol. Smaller amounts of *o*-nitrophenol and *o*- and *p*-nitrotoluene were also detected. The relative yield of *o*-cresol was about 80% of the total amout of cresols, the sum of *m*- and *p*-cresol being about 20% of the total. By means of the gas chromatograph column used in this work, *m*- and *p*-cresols could not be seperated. Figure 2 shows the relative product yields as functions of irradiation time for a typical run of toluene (34 ppm), NO_2 (7.7 ppm) and 1 atm air. In the present study product analysis was carried out at a low reactant conversion (<1%). Under these conditions amounts of all the products increased linearly with irradiation time and ratios of products could be calculated from

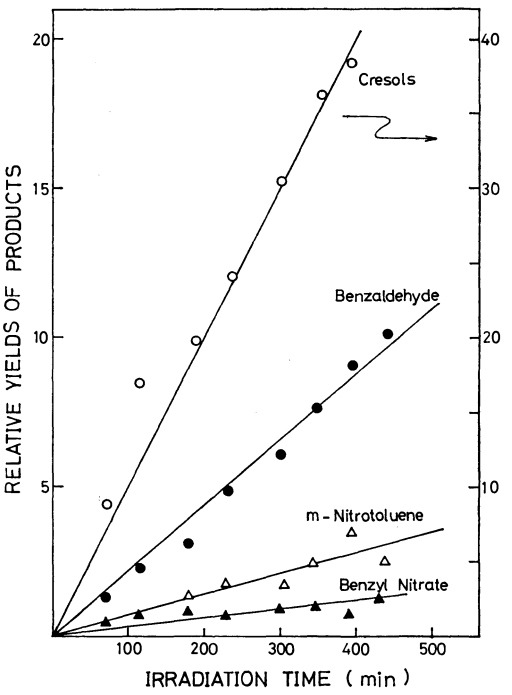

Fig. 2. Relative yields of the products *vs.* irradiation time in the photooxidation of NO_2 (7.7 ppm)–toluene (34 ppm)–air (1 atm) system. ○ Cresols; ● benzaldehyde; △ *m*-nitrotoluene and ▲ benzyl nitrate.

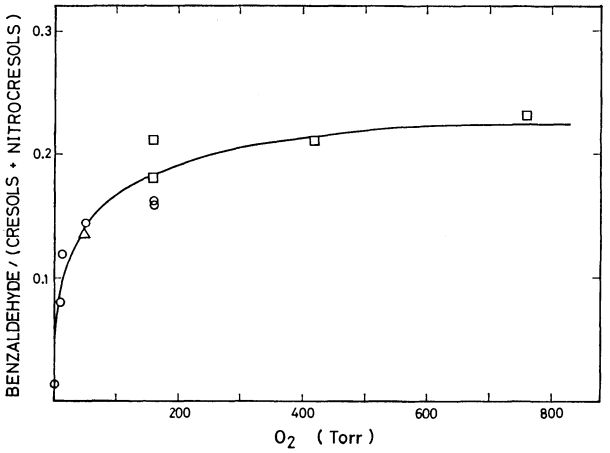

Fig. 3. The formation ratio of benzaldehyde to the sum of cresols and nitrocresols *vs.* partial pressure of O_2 in the photooxidation of NO_2–toluene (34 ppm)–O_2–N_2 (1 atm) system. Initial concentration of NO_2 are △ 6.4, ○ 24, and □ 30 ppm.

the slope ratio of the linear plots.

In order to clarify the formation mechanism of the products, experiments were carried out by varying the initial concentrations of O_2 and NO_2. Figure 3 shows the ratio of benzaldehyde to cresol as a function of O_2 partial pressure for several initial concentrations of NO_2. In these experiments, total pressure was kept at 760 Torr using N_2 as a buffer gas. It shoud be noted that in the absence of O_2 (NO_2–toluene–N_2 system) no benzaldehyde was formed, cresol being the major condensable product with trace amounts of

nitrocresols. The yields of nitrocresols were found to be much smaller than those in the NO_2–toluene–air system for the same initial concentration of NO_2. As shown in Fig. 3, the ratio of benzaldehyde to cresols increases with increase in the concentration of O_2, reaching a saturated value at an O_2 partial pressure higher than a few hundred Torr.

The ratio of nitrocresols (the sum of 6-nitro-*o*-cresol and 2-nitro-*p*-cresol) to cresols increases linearly with the concentration of NO_2 (Fig. 4), NO_2 being measured by UV absorption at 450 nm. Figure 5 shows the ratio of benzaldehyde to the sum of cresols and nitrocresols as a function of the photo-equilibrium concentration of NO_2. In the reaction system of air at 1 atm, the concentration of NO_2 reached the photoequilibrium level within 20 min after irradiation was started, remaining nearly constant during the course of irradiation time. The photo-equilibrium concentration of NO_2 was about 50% of the initial concentration of NO_2.

As shown in Fig. 5 the yield ratio of benzaldehyde to the sum of cresols and nitrocresols is independent of the concentration of NO_2. Thus, the yield of other products could be normalized by the sum of cresols and nitrocresols. Typical data for the product yields are given in Table 1.

The ratio of benzyl nitrate to benzaldehyde increased with an increase in the concentration ratio of NO_2 to O_2 (Fig. 6). Figure 7 shows the relative yield of *m*-nitrotoluene as a function of the initial concentration

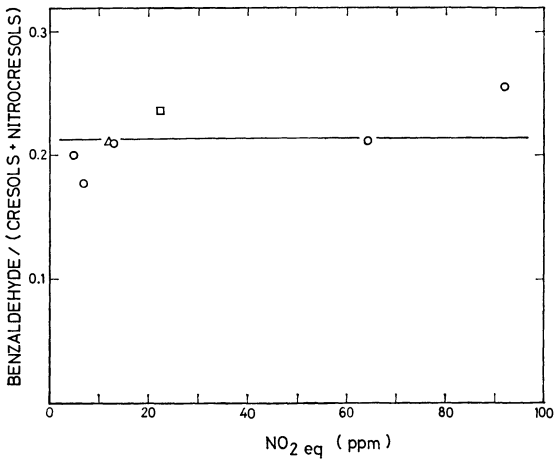

Fig. 5. The formation ratio of benzaldehyde to the sum of cresols and nitrocresols *vs.* equilibrium concentration of NO_2 for the NO_2–toluene (34 ppm)–O_2–N_2 (1 atm) system. Partial pressure of O_2 are ○ 160, △ 418, and □ 760 Torr.

of NO_2. It is remarkable that the relative yield of *m*-nitrotoluene, one of the nitrated products decreases with increase in NO_2 concentration. In order to compare the yield of *m*-nitrotoluene in the NO_2–toluene–air system with that in the HNO_2–NO_x–toluene–air system at a comparable initial concentrations of NO_2, two runs for the HNO_2 (12 ppm)–NO_2 (15 ppm and 25 ppm)–toluene(34 ppm)–air(1 atm) system were carried out. The result is shown in Fig. 9, where four data points for HNO_2 runs of lower NO_2 concentrations (less than 2 ppm) are taken from the work of Hoshino *et al.*[6]

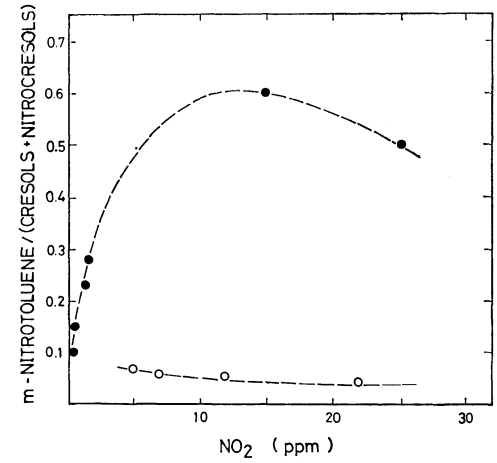

Fig. 9. The formation ratio of *m*-nitrotoluene to the sum of cresols and nitrocresols *vs.* initial concentration of NO_2 for the HNO_2–NO_2–toluene (34 ppm)–air (1 atm) system (●) and the NO_2–toluene (34 ppm)–air (1 atm) system (○).

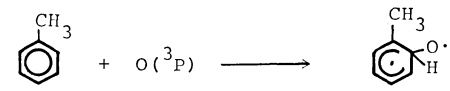
Discussion

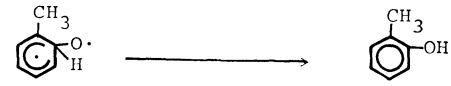
Formation Mechanisms of Cresol and Nitrocresol. Since in the present study the wavelength of the irradiated light is greater than 320 nm and toluene absorbs no light in this spectral region, the photooxidation is initiated by $O(^3P)$ atoms formed in the photolysis of NO_2:

$$NO_2 + h\nu(320\text{—}400\ \text{nm}) \longrightarrow NO + O(^3P). \quad (1)$$

The reaction of $O(^3P)$ atoms with toluene has been studied[9–11] in some detail by mercury photosensitization of the N_2O–toluene system. The main volatile products were cresols and CO. Small amounts of phenol, methane, and ethane, and predominant polymer formation were observed. There are differences in the relative yields of cresol isomers in these studies. The ratios of *o*-cresol to total cresols were reported to be 64% (Jones and Cvetanović[9]), 78% (Grovenstein and Mosher[10]), and 94% (Gaffney *et al.*[11]). Formation of *p*-cresol was noted only by Jones and Cvetanović.[9] In the present reaction system of NO_2–toluene–O_2–N_2, the cresols are the major condensable products in the absence of O_2, and also main products in the presence of O_2 (see Table 1). In both cases, more than 80% of total cresols was *o*-cresol. This is closer to the results of Gaffney *et al.*[11] From these data, the formation of *o*-cresols in the present reaction system is considered to be mainly due to the reaction of the $O(^3P)$ atom with toluene. This reaction would proceed *via* oxygen atom addition to the benzene ring followed by the intramolecular hydrogen atom transfer reaction.[9]



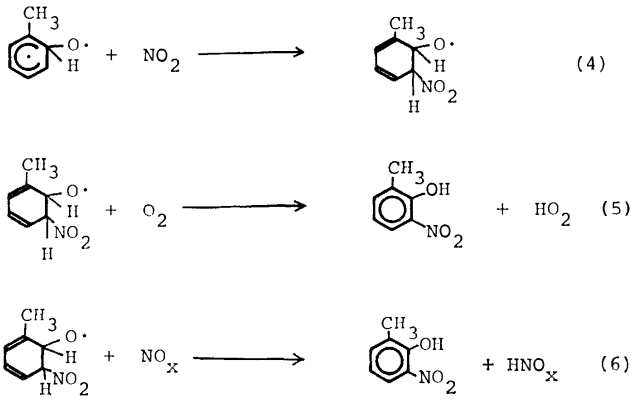
(2)



(3)

The existence of the long-lived biradical formed in Reaction 2 has been suggested in the work of Mani and Sauer.[12] However, it should be noted that the reaction of OH radicals with toluene also gives *o*-cresol.[6]

The ratio of nitrocresols to cresols increases linearly with the photo-equilibrium concentration of NO_2, while the ratio of the sum of cresols and nitrocresols to benzaldehyde remains constant (Figs. 4 and 5). The results suggest that nitrocresols should be formed in the competitive reaction of NO_2 with the same precursor as that giving cresols. The following reaction mechanism is proposed:



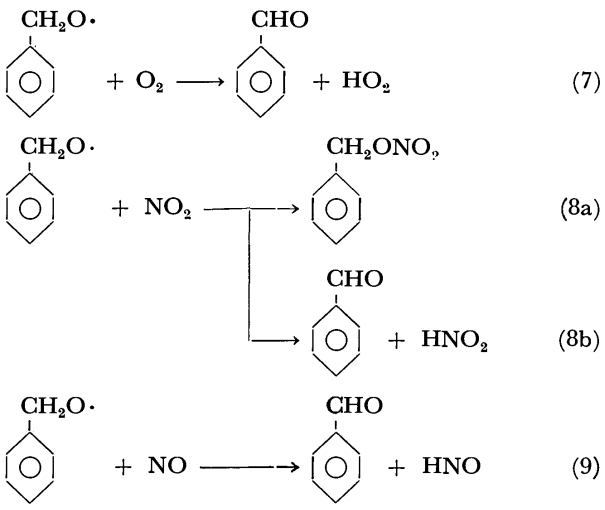
(4)

(5)

(6)

where NO_x denotes NO or NO_2. The result showing that the formation of nitrocresol is suppressed in the absence of O_2 can be explained by the absence of Reaction 5. According to Reactions 2—6, 6-nitro-*o*-cresol should be the major product among nitrocresol isomers if we assume that NO_2 combines with the biradical almost entirely at the carbon atom adjacent to the one to which the oxygen atom is attached (Reaction 4).

Formation Mechanisms of Benzaldehyde and Benzyl Nitrate. Benzaldehyde and benzyl nitrate were formed only in the presence of O_2. Formation of these products strongly suggests the presence of the benzyloxyl radical as their precursor in the reaction system. Competitive reactions



(7)

(8a)

(8b)

(9)

yield the relation

$$\frac{[\text{B.A.}]}{[\text{B.N.}]} = \frac{k_7}{k_{8a}}\frac{[O_2]}{[NO_2]_{eq}} + \frac{1}{k_{8a}}\left(k_{8b} + k_9\frac{[NO]_{eq}}{[NO_2]_{eq}}\right) \quad (10)$$

where B.A. and B.N. stand for benzaldehyde and benzyl nitrate, respectively, and $[NO]_{eq}$ and $[NO_2]_{eq}$ are the concentrations of NO and NO_2 under photoequilibrium. Under the conditions of 1 atm air, $[NO]_{eq}/[NO_2]_{eq}$ was nearly constant (≈ 1.0) irrespective of the initial NO_2 concentration. Thus, the plot of [B.A.]/[B.N.] *vs.* $[O_2]/[NO_2]_{eq}$ should give a straight line according to Eq. 10. The points (circular) in Fig. 6 are plotted again in Fig. 8 on the scale of [B.A.]/[B.N.] *vs.* $1/[NO_2]_{eq}$. From the slope of Fig. 8, the value of k_7/k_{8a} was deduced to be 1.4×10^{-4}. For similar reactions of methoxyl radicals

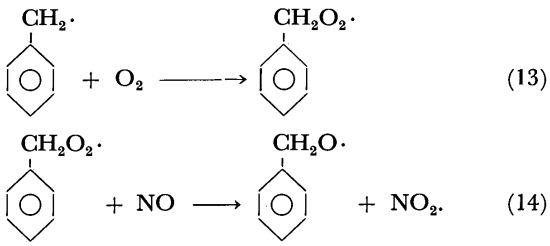
$$CH_3O + O_2 \longrightarrow CH_2O + HO_2 \quad (11)$$

$$CH_3O + NO_2 \longrightarrow CH_2ONO_2 \quad (12a)$$

$$\longrightarrow CH_2O + HNO_2 \quad (12b)$$

the value of $k_{11}/k_{12}=5.6\times10^{-5}$ was given by Wiebe *et al.*[13] Glasson[14] reported the value of $k_{11}/k_{12a}<(7.4\pm0.7)\times10^{-5}$. Our value for the benzyloxyl radical is nearly of the same order of magnitude, but slightly higher than the above values for the methoxyl radical.

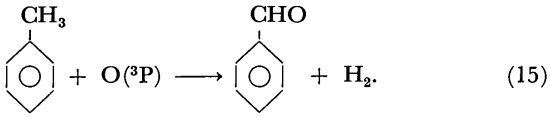
Benzyloxyl radicals are thought to be formed *via* reactions



(13)

(14)

Analogous reactions for alkyl radicals have been proposed by Heicklen *et al.*[15] According to the above reaction scheme, no benzaldehyde and benzyl nitrate would be formed in the absence of O_2. Their yields would increase with the increase of the concentration of O_2 to the extent where all benzyl radicals are trapped by O_2. Our experimental result (Fig. 3) confirmed that this is the case for benzaldehyde. Our results that no benzaldehyde and benzyl nitrate could be detected in the O_2 free system also suggests the above reaction mechanism. Recently, Sloane[16] observed the product with an *m/e* of 106 in the reaction of $O(^3P)$ and toluene under molecular beam conditions and proposed a reaction

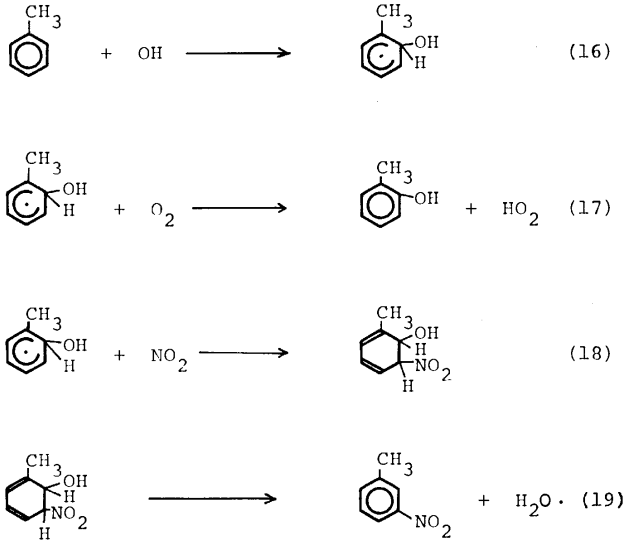


(15)

If this reaction had occurred in the present reaction system, benzaldehyde would have been formed even in the O_2 free system. Thus, Reaction 15 is not important under our experimental conditions.

Formation Mechanism of m-*Nitrotoluene.* The yield of *m*-nitrotoluene decreases with increase of NO_2. This unexpected behavior of *m*-nitrotoluene can be explained if we assume that it is formed by the reaction which is initiated by OH radicals rather than by $O(^3P)$ atoms. In our study of the photooxidation of toluene in the HNO_2–NO_x–toluene–air system, where the OH radical reaction predominates, the relative yield of *m*-nitro-

toluene to cresols is much higher than that in the present system. The yield of *m*-nitrotoluene in the HNO_2–NO_x–toluene–air system is compared with that in the NO_2–toluene–air system in Fig. 9. In the HNO_2 system, the relative yield of *m*-nitrotoluene to cresols+nitrocresols increases when the concentration of NO_2 increases in the region less than 10 ppm of NO_2. An opposite tendency is observed in the NO_2 system. The formation mechanism of *m*-nitrotoluene and cresols in the HNO_2–NO_x–toluene–air system, was proposed[6] to be as follows.



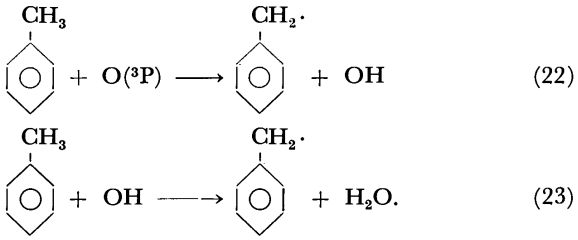
The increase in the ratio of *m*-nitrotoluene to cresols with increase in the concentration of NO_2 can be explained by the competition between Reactions 17 and 18. On the other hand, in the present reaction system of NO_2–toluene–air, most of the cresols are formed in the reaction of $O(^3P)$ with toluene, *m*-nitrotoluene being assumed to be formed in Reactions 16, 18, and 19. In this case, the competition between Reaction 16 and the following Reactions 20 and 21 would result in a decrease in the relative yield of *m*-nitrotoluene at higher NO_2 concentrations because of the quenching of OH radicals by NO_2 and NO.

$$OH + NO_2 \xrightarrow{M} HNO_3 \quad (20)$$

$$OH + NO \xrightarrow{M} HNO_2 \quad (21)$$

Although second order rate constants at 760 Torr for Reactions 20 and 21 are comparable,[17,18] Reaction 20 would be more effective sink of OH radicals since the photolysis of HNO_2 regenerates them.

Formation of Benzyl Radicals. According to the proposed reaction mechanism, side chain oxidation products, benzaldehyde and benzyl nitrate are formed *via* benzyloxyl radicals, which should be formed from benzyl radicals *via* Reactions 13 and 14. Benzyl radicals could be formed in the present reaction by the reaction of toluene with either $O(^3P)$ or OH radicals, *i.e.*,



OH radicals are produced mainly by the reaction

$$HO_2 + NO \longrightarrow OH + NO_2 \quad (24)$$

where HO_2 radicals are formed in Reactions 5, 7, and 17. Reaction 22 and the photolysis of HNO_2 formed in Reactions 6, 8b, and 21 would also contribute to the production of OH radicals.

OH radicals abstract hydrogen atoms from the methyl group of toluene(Reaction 23) and also add to benzene ring (Reaction 16) at room temperature. From the pressure dependence of the rate constant of the reaction of OH radicals with toluene, Davis *et al.*[19] deduced that over half of the total reaction proceeds *via* addition reaction. Perry *et al.*[20] estimated the room temperature rate constant of the hydrogen abstraction reaction by extrapolation of the data above 380 K, where the reaction is assumed to proceed solely *via* abstraction, and obtained the fraction of the abstraction reaction of $16\pm^{0.07}_{0.05}\%$ at room temperature. In our product analysis study of OH radicals with toluene,[6] the fraction of abstraction reaction was estimated to be 25—35%.

The reaction of toluene with $O(^3P)$ has been thought to proceed only *via* ring addition since no dibenzyl formation takes place in the mercury photosensitization of the N_2O and toluene system. However, the NO_2 dependency on the formation of *m*-nitrotoluene (Fig. 9) shows that the contribution of OH radicals in the NO_2 system is not remarkable. Thus, the formation of benzaldehyde in the present study would be explained by Reaction 22. About 20% of the reaction of $O(^3P)$ with toluene should proceed *via* hydrogen abstraction from the methyl group of toluene.

The discrepancy might be caused by either of the following: (1) the contribution of OH radicals cannot be neglected in the present NO_2 system; the NO_2 dependency on the formation of *m*-nitrotoluene is a result of other unknown reactions or, (2) although benzyl radicals are formed in the mercury photosensitization of the N_2O and toluene system, they are quenched by the excess of oxygen atoms, turning polymers.

The authors wish to thank Dr. Matsui, the Hokuriku University, for his suggestion to synthesize benzyl nitrate.

(Received February 18, 1978)

The sensitized photoisomerization of stilbene was studied with nanosecond time-resolved absorption spectroscopy at room temperature. In non-viscous solvents (heptane, benzene, and ethanol), the transient spectrum does not depend upon a starting material being either *cis*- or *trans*-stilbene. The kinetic analysis of the transient spectrum due to stilbene shows that the observed spectrum consists of the T_n-T_1 absorption spectrum of *trans*-stilbene and that of twisted triplet (phantom triplet) stilbene. The lifetime of the twisted triplet stilbene is determined to be approximately 120 ns. In a viscous solvent (*t*-butyl alcohol), the transient behavior of triplet stilbene is dependent upon the starting materials being either *cis*- or *trans*-stilbene. The contribution of the twisted triplet stilbene to the transient spectrum is larger for the case starting from *cis*-stilbene than for the case starting from *trans*-stilbene.

In the reaction of *cis-trans* photoisomerization of stilbene, two possible mechanisms have been proposed mainly with the aid of the steady state method; (i) reaction occurs through the lowest triplet state (triplet mechanism), or (ii) through the lowest excited singlet state, S_1 (singlet mechanism). In both cases, the phantom singlet and triplet states with the twisted central double bond are possible intermediates in the course of the isomerization.[1-3] In searching these interesting species many attempts have been made without success by flash photolysis or laser photolysis.[4,5]

In the sensitized photoisomerization of stilbene, the reaction was found to occur through the triplet state of stilbene.[1] From the temperature dependence of quenching experiments, it was suggested that a small potential barrier existed between the triplet state of *trans*-stilbene and the phantom triplet state.[6,7] Very recently Benson and Williams[8] proposed a potential barrier from an experiment of the direct excitation to the triplet state by an argon-ion laser. The energy barriers obtained by direct and sensitized photoisomerization agree well with each other. From quenching experiments Saltiel *et al.*[9] estimated the effective lifetime of the triplet state of *trans*-stilbene to be of the order of 10^{-8} s in fluid solution.[10]

On the other hand, in the direct photoisomerization of stilbene, Saltiel and his coworkers[1,12] proposed the singlet mechanism on the basis of their quenching experiments. They further assumed that a phantom singlet state (^{1}p) is a possible intermediate of the reaction. Recently a decay of fluorescence consisting of two exponential decay components with the time constants of $\leq$0.2 and 1.4 ns at room temperature was reported by a photon-counting method.[13] The result was explained by a rapid equilibration of the population between S_1 and ^{1}p. Very recently, we investigated with a picosecond Nd^{3+}:YAG laser the temperature dependence of the fluorescence lifetime of *trans*-stilbene.[14] A smooth sigmoidal relation was obtained, quite similar to the temperature dependence of fluorescence quantum yields. Contrary to the photon-counting experiment the fluorescence had only one exponential decay component (0.11 ns) at room temperature and agreed with the S_1 lifetime estimated by a quenching experiment.[15] The results indicate that the back reaction to S_1 from the ^{1}p state does not contribute to the fluorescence decay, the ^{1}p state has a very short lifetime or the rate of back reaction is very slow.

In order to understand more clearly the *cis-trans* photoisomerization mechanism, it is necessary to elucidate the dynamical behavior of the reaction intermediate—^{1}p or ^{3}p. In the present work we examined the sensitized excitation of *cis*- and *trans*-stilbene to their triplet state and observed an absorption spectrum of a reaction intermediate by laser-flash time-resolved spectroscopy. The sensitized *cis-trans* isomerization mechanism and a role of the phantom triplet state were discussed on the basis of the observation of the transient absorption.

Experimental

The details of a N_2-laser photolysis system[6] and a dye laser photolysis system[7] were reported elsewhere. We used a coaxial type N_2-laser (peak power at 337 nm, 100 kW; pulse duration, 7 ns FWHM) as an actinic light for the photolysis with 2-acetonaphthone as a sensitizer. Stilbene is not excited efficiently by a N_2-laser. For the photolysis with biacetyl, we used a dye-laser with POPOP which was excited by a travelling-wave type N_2-laser (peak power, 1 MW; pulse duration, 6 ns FWHM).

An analyzing light was monitored by means of a Hamamatsu R666 photomultiplier and the signal was fed either to a Tektronix 465 oscilloscope or to a Tektronix 561B sampling oscilloscope combined with a 3S1 dual-trace sampling unit and a 3T77A sampling sweep unit.

The signal from the photomultiplier was monitored and amplified with a 465 oscilloscope. The amplified output signal from the oscilloscope was divided into two halves with a Tektronix 874-TPD divider. One of the signals was connected to the channel A of the 3S1 unit, and the other was passed through a delay cable and put into the channel B of the 3S1 unit. The sampling time of the channel A was fixed manually at a suitable delay position of the absorption with an intensity of $I(t)$, while the channel B was set before the pulse irradiation with an intensity of $I(0)$ (Fig. 1). The recorder output signals of the A and B channels were divided with an operational amplifier. A time-resolved absorption spectrum was obtained by scanning the wavelength and recording $I(t)/I(0)$. By sampling $I(t)$ and $I(0)$ form the same laser shot, we measured $I(t)/I(0)$ quite accurately ir-

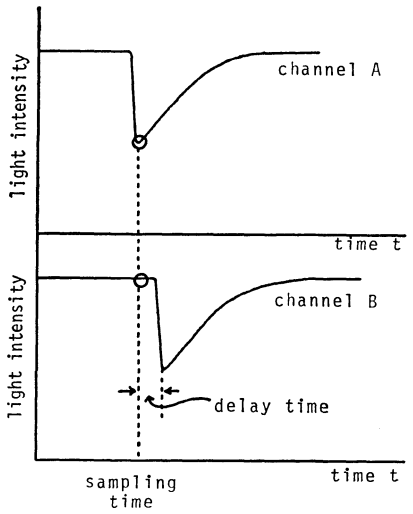

Fig. 1. The timing correlation of the absorption intensity at $t(I(t))$ and that at $t=0$ $(I(0))$. The former is fed into the channel A of the sampling oscilloscope and the latter into the channel B (see the text).

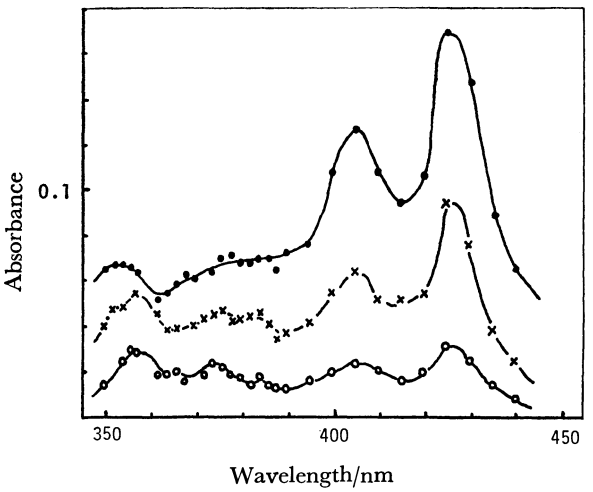

Fig. 2. Time-resolved absorption spectra of the 2-acetonaphthone-stilbene system in heptane: —●—, immediately after; —×—, 30 ns after; —○—, 70 ns after a laser pulse reached its maximum intensity.

respective of considerable amplitude variation of the laser pulse. The $I(t)/I(0)$ values were later converted to the absorbance scale.

trans-Stilbene and 2-acetonaphthone were purified with alumina column chromatography. *cis*-Stilbene and biacetyl were purified by distillation. The purity of all the samples was checked with gas chromatography to be more than 99%. The sample was deaerated with nitrogen flow and a fresh sample was supplied for each run.

Gas chromatographic analysis showed that the *cis-trans* isomerization reaction was straightforward and no other reaction took place during the laser irradiation.

Results

Transient Spectra. We chose 2-acetonaphthone as a sensitizer of the photoisomerization since the energy of the triplet state (E_T) is 59.3 kcal/mol (the lowest triplet state in $\pi\pi^*$,[18] just above the triplet state of *cis*-(E_T=56.7 kcal/mol) and *trans*-(E_T=49 kcal/mol) stilbenes. Figure 2 shows the time-resolved absorption spectra of *cis*-stilbene with 2-acetonaphthone in heptane at room temperature. We used heptane (η=0.418 cP; 20 °C) and benzene (η=0.649 cP; 20 °C) as nonpolar solvents and ethanol (η=1.08 cP; 25 °C) as a polar solvent. The absorption maxima, the shape of the absorption profile, and the time course of the absorption were found to be unaffected by the solvents so far as the viscosity is low. The "0 ns" spectrum (a spectrum observed just after the laser irradiation) has intense absorption bands at 424, 404, and 384 nm. These bands were assigned to the T_n-T_1 absorption of the sensitizer, 2-acetonaphthone, since the "0 ns" spectrum of 2-acetonaphthone in heptane gave the same spectrum. These bands decayed quickly and different absorption bands appeared about 70 ns after the laser pulse, irrespective of the starting materials being either *cis*- or *trans*-stilbene. The lifetime of this species was 110± 10 ns. This transient absorption spectrum was also observed in an additional experiment using biacetyl (the lowest triplet state is $n\pi^*$, E_T=56.3 kcal/mol[19]) as triplet sensitizer. We excited biacetyl with a dye-laser at 428 nm. Again the main spectral features in the region of 345—390 nm and the lifetimes were identical irrespective of the starting isomers. As described later, this transient absorption is due to a mixture of the triplet state of *trans*-stilbene and the phantom triplet.

The Rate of Triplet Energy Transfer from 2-Acetonaphthone to cis- *or* trans-*Stilbene.* In order to elucidate the mechanism of sensitization processes of the triplet state of *trans*-stilbene and twisted stilbene, we examined the first order decay rate of the 2-acetonaphthone triplet state as a function of the concentration of *cis*- or *trans*-stilbene. Figure 3 shows the Stern-Volmer relationship observed by the T_n-T_1 absorption at 430 nm in heptane. The plots give a straight line with a slope of 8.9×10^9 M^{-1} s^{-1} for *trans*-stilbene and 5.2×10^9 M^{-1} s^{-1} for *cis*-stilbene at room temperature.

*Transient Absorption in a Viscous Solvent (*t*-Butyl Alcohol).* The transient absorption of *cis*- or *trans*-stilbene in *t*-butyl alcohol with 2-acetonaphthone as a sensitizer has two components; the T_n-T_1 absorption of the sensitizer,

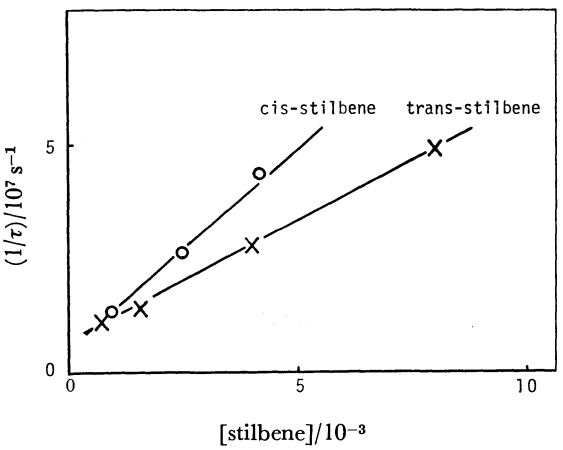

Fig. 3. The first-order decay rate of the 2-acetonaphthone triplet quenched by *cis*- and *trans*-stilbenes in heptane at room temperature.

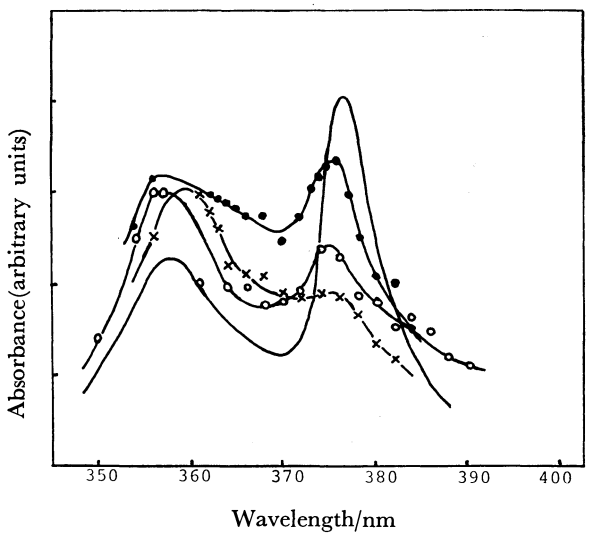

Fig. 4. Transient absorption of stilbene: —○—, *trans*-stilbene in non-viscous solvent; —●—, *trans*-stilbene in viscous solvent; —×—, *cis*-stilbene in viscous solvent; ——, the T_n-T_1 absorption spectrum of *trans*-stilbene at 77 K from Ref. 26.

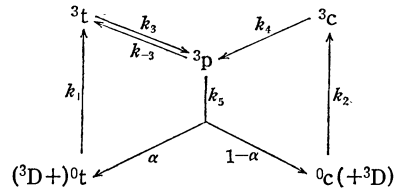
2-acetonaphthone, which promptly decays, and the absorption due to the mixture of the triplet *trans*-stilbene and the phantom triplet. The time-resolved absorption spectrum of the long-lived species measured 60 ns after the laser irradiation is shown in Fig. 4. In a viscous solvent, contrary to the behavior in non-viscous solvents, the profiles of the transient absorption spectra were different for *cis*- and *trans*-stilbenes. The decay time of the long lived species was 120±10 ns and 80±10 ns for *cis*- and *trans*-stilbenes, respectively.

Discussion

Reaction Paths. The simplest mechanism which accounts for various observations of the sensitized photoisomerization of stilbene with a triplet donor (^{3}D) is shown as follows:[1,20]



In the above diagram, t, c, and p stand for the *trans*-, *cis*-, and twisted stilbene, respectively. The superscripts 0 and 3 indicate the ground state and the lowest triplet state. The fraction of ^{3}p decaying to the transoid ground state is given by α. k's are the corresponding rate constants.

Recent theoretical studies show that the σ-π excited configuration mixing plays an important role in photochemical rearrengements involving rotation around double bonds. The results of an *ab initio* calculation for ethylene[21] show that the potential energy curve of the triplet state changes smoothly with an absolute minimum at $\theta=90°$, and stays always above the ground state potential. Thus there is no crossing. 1,3,5-Hexatriene, with the simplest π bond system in both sides of the central double bond, behaves in the same manner as ethylene for twisting the central double bond.[21] For styrene, Bruni *et al.*[22] discussed the predominant nature of the lowest triplet state was ethylenic, and showed a similar behavior as ethylene for twisting. In all cases, the main configuration of the lowest triplet state is the ethylenic π system, and becomes more and more localized in the ethylenic π bond during the internal rotation. We consider the same discussion is applicable to the potential surface of stilbene,[23–25] and a potential crossing between the ground and triplet state at $\theta=90°$ is not accounted.

Using 2-acetonaphthone as a sensitizer, the excitation rate constants k_1 and k_2 in heptane were obtained from the slope of the Stern-Volmer plots to be 8.9×10^9 and 5.2×10^9 M^{-1} s^{-1}, respectively. Considering the effect of the viscosity (η(benzene)/η(heptane) =1.5—1.6) on the bimolecular rate constants in benzene, these values become 5.6×10^9 and 3.2×10^9 M^{-1} s^{-1}, respectively. These are in good agreement with the values (5.0×10^9 M^{-1} s^{-1} for k_1, and 3.4×10^9 M^{-1} s^{-1} for k_2) obtained by Herkstroeter and Hammond[4] with conventional flash photolysis.

Kinetic Analysis of Observed Absorption. Let us analyze the observed absorption from the kinetic point of view based upon the reaction scheme in the previous section.

For the excitation of *trans*-stilbene,

$$d[^3t]/dt = k_1[^0t][^3D] + k_{-3}[^3p] - k_3[^3t], \quad (1)$$

$$d[^3p]/dt = k_3[^3t] - (k_{-3}+k_5)[^3p]. \quad (2)$$

For the excitation of *cis*-stilbene,

$$d[^3t]/dt = k_{-3}[^3p] - k_3[^3t], \quad (3)$$

$$d[^3p]/dt = k_4[^3c] + k_3[^3t] - (k_{-3}+k_5)[^3p]. \quad (4)$$

The differential equations are solved approximately as follows (see Appendix):

For the excitation of *trans*-stilbene,

$$[^3p]_t = k_3[^3D_0](e^{-\lambda_1 t}-e^{-\lambda_2 t})/a, \quad (5)$$

$$[^3t]_t = [^3D_0]\{(d-\lambda_1)e^{-\lambda_1 t}+(\lambda_2-d)e^{-\lambda_2 t}\}/a. \quad (6)$$

For the excitation of *cis*-stilbene,

$$[^3p]_c = [^3D_0]\{(k_3-\lambda_1)e^{-\lambda_1 t}+(\lambda_2-k_3)e^{-\lambda_2 t}\}/a, \quad (7)$$

$$[^3t]_c = k_{-3}[^3D_0](e^{-\lambda_1 t}-e^{-\lambda_2 t})/a. \quad (8)$$

Here

$$\lambda_{1,2} = \frac{1}{2}[(k_3+k_{-3}+k_5) \mp \{(k_3+k_{-3}+k_5)^2-4k_3k_5\}^{1/2}], \quad (9)$$

$$a = \lambda_2 - \lambda_1. \quad (9')$$

The ratio of $[^3t]$ to $[^3p]$ at time t is given as follows:

$$\left(\frac{[^3t]}{[^3p]}\right)_t = \frac{(d-\lambda_1)e^{-\lambda_1 t}+(\lambda_2-d)e^{-\lambda_2 t}}{k_3(e^{-\lambda_1 t}-e^{-\lambda_2 t})}, \quad (10)$$

$$\left(\frac{[^3t]}{[^3p]}\right)_c = \frac{k_{-3}(e^{-\lambda_1 t}-e^{-\lambda_2 t})}{(k_3-\lambda_1)e^{-\lambda_1 t}+(\lambda_2-k_3)e^{-\lambda_2 t}}. \quad (11)$$

Here $d=k_{-3}+k_5$.

In such non-viscous solvents as heptane, the observed

new transient species has a nearly single exponential decay. The decay rate of ^{3}p and ^{3}t are both approximated by the same λ_1. Therefore λ_1 should correspond to the observed long decay time ($\approx$110 ns). Since $\lambda_2 \gg \lambda_1$, the terms including $e^{-\lambda_2 t}$ can safely be disregarded in Eqs. 10 and 11.

$$\frac{([^3t]/[^3p])_t}{([^3t]/[^3p])_c} = \frac{(d-\lambda_1)(k_3-\lambda_1)}{k_3k_{-3}} = 1 \qquad (12)$$

This means that the transient absorption spectrum observed with the non-viscous solution is independent of the starting material being either *cis*- or *trans*-stilbene. The spectrum in the wavelength region, 345—390 nm, is quite similar to the T_n-T_1 absorption spectrum of *trans*-stilbene reported by Herkstroeter and McClure in solid solution at 77 K[26] (see Fig. 4). The spectrum is the absorption of ^{3}t, since the isomerization does not take place at 77 K. However, at shorter wavelengths, our spectrum has distinctly higher intensity. Subtracting the ^{3}t absorption from the transient absorption observed with the non-viscous solution, we have a new absorption band at $\approx$360 nm. The band is assigned to the intermediate between ^{3}t and the isomerization product, namely ^{3}p. The band at $\approx$360 nm becomes more predominant in the viscous solution.

The behavior of the transient species in a viscous solvent is dependent upon the starting materials as is shown in Fig. 4. The rotation is hindered in a viscous solvent. Since the forward rate constant k_3 is about nine times smaller in *t*-butyl alcohol than in benzene at room temperature[15], it is difficult to ignore the contribution of $e^{-\lambda_2 t}$ in the viscous solution. Thus we obtain much more complicated relation than Eq. 12,

$$\frac{([^3t]/[^3p])_t}{([^3t]/[^3p])_c} \approx \frac{e^{-2\lambda_1 t}+e^{-2\lambda_2 t}+e^{-(\lambda_1+\lambda_2)t}\{(k_3-\lambda_1)^2+(\lambda_2-k_3)^2\}/k_3k_{-3}}{e^{-2\lambda_1 t}+e^{-2\lambda_2 t}-2e^{-(\lambda_1+\lambda_2)t}} > 1. \qquad (13)$$

This relation shows that the concentration of ^{3}p relative to that of ^{3}t increases for the reaction from the *cis* isomer compared with the reaction from the *trans* isomer: in other words, the spectrum of the phantom triplet is more predominant in the transient spectrum from *cis*-stilbene than in that from *trans*-stilbene. This is consistent with the observation shown in Fig. 4 supporting the assignment of the 360 nm band to ^{3}p. We can see from Fig. 4 that the intensity ratio of the 360 nm band to the 376 nm band in the viscous solution is much larger in the transient spectrum from *cis*-stilbene than in that from the *trans*-stilbene.

In a viscous solvent the transient absorption decays differently depending upon the starting material. Exciting *trans*-stilbene, the lifetime is 80 ns at room temperature and this decay process (represented by λ_2) is considered to be from ^{3}t since the transient absorption spectrum mainly consists of the T_n-T_1 absorption spectrum. Exciting *cis*-stilbene, the transient absorption spectrum decays with the lifetime of 120 ns and is mainly due to ^{3}p, the decay process being controlled by λ_1.

The ratios of $[^3t]/[^3p]$ in heptane and *t*-butyl alcohol are estimated by taking the most reliable rate constants.[1,3] With the aid of Eqs. 10 and 11, these values *ca.* 50 ns after the laser irradiation are calculated and given in Table 1. We can see that in a viscous solvent $[^3t]/[^3p]$ is greatly different for *cis*- and *trans*-stilbenes.

Table 1. Viscosity dependence of $[^3t]/[^3p]$

Solvent		Heptane (non-viscous solv.)	*t*-Butyl alcohol (viscous solv.)
Viscosity(cP)	η	0.40	3.88
Rate constants (s^{-1})	k_3	10^8	1.3×10^7
	k_{-3}	10^7	1.3×10^6
	k_5	10^7	10^7
	λ_1	0.9×10^7	7.95×10^6
	λ_2	1.11×10^7	1.64×10^7
$([^3t]/[^3p])_t$		0.12	1.4
$([^3t]/[^3p])_c$		0.12	0.06

The initial concentrations of ^{0}t and ^{0}c are 0.1 M.

Appendix

The exact solution of linear differential equations 1, 2, 3, and 4 is as follows:
for the excitation of *trans*-stilbene,

$$[^3p]_t = k_3k_1[^0t][^3D_0]\left\{\frac{e^{-\lambda_1 t}}{ab}+\frac{e^{-\lambda_2 t}}{ac}+\frac{e^{-k_1[^0t]t}}{bc}\right\}, \qquad (A1)$$

$$[^3t]_t = k_1[^0t][^3D_0] \times \left\{\frac{d-\lambda_1}{ab}e^{-\lambda_1 t}-\frac{\lambda_2-d}{ac}e^{-\lambda_2 t}-\frac{k_1[^0t]-d}{bc}e^{-k_1[^0t]t}\right\}, \qquad (A2)$$

for the excitation of *cis*-stilbene,

$$[^3p]_c = k_2[^0c][^3D_0] \times \left\{\frac{k_3-\lambda_1}{ab'}e^{-\lambda_1 t}-\frac{\lambda_2-k_3}{ac'}e^{-\lambda_2 t}-\frac{k_3-k_2[^0c]}{b'c'}e^{-k_2[^0c]t}\right\}, \qquad (A3)$$

$$[^3t]_c = k_{-3}k_2[^0c][^3D_0]\left\{\frac{e^{-\lambda_1 t}}{ab'}+\frac{e^{-\lambda_2 t}}{ac'}+\frac{e^{-k_2[^0c]t}}{b'c'}\right\}, \qquad (A4)$$

where

$$\lambda_{1,2} = \frac{1}{2}[(k_3+k_{-3}+k_5) \mp \{(k_3+k_{-3}+k_5)^2-4k_3k_5\}^{1/2}],$$

$a = \lambda_2 - \lambda_1$,
$b = k_1[^0t] - \lambda_1$, $\quad b' = k_2[^0c] - \lambda_1$,
$c = \lambda_2 - k_1[^0t]$, $\quad c' = \lambda_2 - k_2[^0c]$,
$d = k_{-3} + k_5$.

$[^0c]$, $[^0t]$, and $[^3D_0]$ are the initial concentration of *cis*-stilbene, *trans*-stilbene, and sensitizer, respectively. Under our experimental conditions, we can make the concentrations of ^{0}t and ^{0}c high enough to have $k_1[^0t]$ and $k_2[^0c] \gg \lambda_1$, λ_2. The equations A1 to A4 are able to be approximated as Eqs. 5 to 8.

Studies on the Aqueous Solutions of Guanidinium Salts. VII. Activity Coefficients and Partial Molar Volumes for Guanidinium Salts with Hydrophobic Counter Anions in Aqueous Solutions

Koichiro MIYAJIMA,* Hiromitsu YOSHIDA, and Masayuki NAKAGAKI

Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida-shimoadachi-cho, Sakyo-ku, Kyoto 606

(Received February 23, 1978)

Mean activity coefficients ($\gamma_\pm$) and partial molar volumes of guanidinium salts with hydrophobic counter anions were measured by isopiestic comparison method and densitometry, respectively. The values of $\gamma_\pm$ were low and the order of $\gamma_\pm$ values found to be acetate>propionate>benzoate. The b_v values from the Redlich-Rosenfeld's equation were slightly positive at 15 and 25 °C, and decreased with increased temperature. These results were interpreted in terms of the unique structure breaking action of guanidinium ions and the interionic interactions.

In a previous paper,[1] activity coefficients and partial molar volumes for guanidinium salts with hydrophilic counter anions in aqueous solutions were reported. The low mean activity coefficients ($\gamma_\pm$) of these salts were attributed to the structure breaking actions of these salts. The order of $\gamma_\pm$ values among these salts with different anions was interpreted as the interactions between the hydrated anions and cations. Among these salts, guanidinium acetate had the largest value of $\gamma_\pm$. The acetate ion has a methyl group which is different from other counter anions used in the previous studies.

To further investigate the properties of aqueous guanidinium ions and their interactions, mean activity coefficients and partial molar volumes of some guanidinium salts with hydrophobic counter anions were obtained by the isopiestic comparison method and densitometry, respectively. The results were interpreted in terms of the structure breaking action of the guanidinium ion and the interionic interactions.

Experimental

Materials. Guanidinium acetate, propionate, and benzoate were prepared by titrating aqueous guanidine solution with the corresponding carboxylic acid below 25 °C. These salts were recrystallized twice or more from an ethanol–ether mixture, and the elementary analyses are shown in Table 1. Reagent grade potassium chloride was used without further purification for the reference solute in the isopiestic measurements. These salts were dissolved in redistilled and deionized water.

Method. Osmotic coefficients were measured at 25±0.02 °C by the isopiestic method described elsewhere.[1] From the osmotic coefficient (ϕ), $\gamma_\pm$ was calculated from

$$\ln\gamma_\pm = (\phi-1)+2\int_0^{\sqrt{m}}\frac{\phi-1}{\sqrt{m}}\mathrm{d}\sqrt{m}, \quad (1)$$

where m is the molality. Density measurements were made at 15, 25, and 35±0.01 °C using a Seiko SDM-410 densimeter. Buoyancy corrections were made for guanidinium salts on the assumption that the densities of the solid states were all unity. From the densities of aqueous solutions, the apparent molar volume (ϕ_v) and the partial molar volume ($\overline{V}_2$) were calculated by

$$\phi_v = \frac{1000(d_0-d)}{Cd_0}+\frac{M}{d_0}, \quad (2)$$

$$\overline{V}_2 = \phi_v + \frac{1000-C\phi_v}{2000+C^{3/2}(\partial\phi_v/\partial\sqrt{C})}C^{1/2}\left(\frac{\partial\phi_v}{\partial\sqrt{C}}\right), \quad (3)$$

where d and d_0 are the densities of solution and solvent, respectively, and M and C are the molecular weight and molarity of the salt, respectively. The densities and the isopiestic molalities of aqueous solutions are shown in Tables 2 and 3. The reproducibility of the density measurements was found to be 5×10^{-5} g/cm^3 and the experimental determination of isopiestic concentrations was precise to 0.2%. Viscosities of aqueous BSA solutions were measured by using a Ubbelohde type viscometer at 25±0.01 °C. The reproducibility of flow time was found to be 5×10^{-2} s.

	(Calcd)	6.12	53.03	23.09	17.56

Results and Discussion

Mean Activity Coefficients. The values of the mean activity coefficients and the osmotic coefficients are shown in Table 4. The plots of log $\gamma_\pm$ *vs.* concentration for guanidinium salts are shown in Fig. 1 together with those of the sodium salts of fatty acids.[3] Generally these curves reflect the ion-ion and ion-solvent interactions. All curves approach the Debye-Hückel limiting line (DH-L) from above at low concentrations, indicating the absense of ion pairs, as with cadmium sulfate. The relatively low values of log $\gamma_\pm$ for guanidinium salts compared with those of the sodium salts are attributed to the structure breaking action of the guanidinium ion. As seen in Fig. 1, the log $\gamma_\pm$ values of sodium acetate are lower than those of sodium propionate, while the log $\gamma_\pm$ values of guanidinium acetate are larger than those of guanidinium propionate. This may be explained as follows: The sodium ion is a hydrophilic structure maker in contrast with the guanidinium

ion which is a structure breaker.[1,4-6] It is well known that a hydrophobic ion forms water structures around itself, which is so called "iceberg"[7] or "hydrophobic hydration."[8] The structure of the hydrated cosphere around the sodium ion and that of the hydrophobic ion are incompatible with each other and result in "structure salting out."[9] This explains why the $\gamma_{\pm}$ values of sodium propionate are larger than those of sodium acetate. The guanidinium ion is a large monovalent organic ion whose shape and size are quite similar to that of urea and its electric field to orient water molecules radially around itself is weaker than

that of the alkali-metal ion. The guanidinium ion, however, has the ability to form hydrogen bonds with water molecules like urea, and the orientation of the hydrogen bonds with water does not fit the three dimensional network of ice-like structure. This leads to the conclusion that the structure breaking action of the guanidinium ion is different from that of the alkali-metal ions, such as Rb^+ and Cs^+. In fact, alkali halides and guanidinium halides behave in a different way when they are mixed with hydrocarbon gases[10] or symmetrical tetraalkylammonium halides[11] in aqueous solutions. Large alkali-metal halides produce salting out effects towards hydrophobic solutes,[11] while guanidinium halides produce salting in effects.[10,12]

The order of the $\gamma_\pm$ values among guanidinium salts with hydrophobic anions may be explained in two ways. As discussed above, the guanidinium ion breaks the structure of the bulk water which is in equilibrium with the structured water around the hydrophobic solute. This structure breaking action of the guanidinium ion is more pronounced in the highly structured solution containing the hydrophobic solute and results in the decrease of the $\gamma_\pm$ values of the salts. A second explanation is based on the more direct interaction between the guanidinium ion and the hydrophobic anion. Assuming that the hydrogen bond participates in the interaction between the guanidinium ion and the hydrated water molecules around it, may be possible to share the hydration cosphere with that of the hydrophobic anion. This interaction works as an attractive rather than a repulsive force and decreases the $\gamma_\pm$ values of the hydrophobic salts of guanidine. Although there is no evidence to support such an interaction, it cannot be neglected since the hydrophobic tetraalkylammonium halides form crystalline complexes with guanidinium halides and water,[13] and the $\gamma_\pm$ values of either salts in aqueous ternary solutions decrease each other as compared with those in each binary solution.[12] We cannot decide which of these mechanisms is really working at the present stage. Judging from the hydrophobicities of the counter anions, the $\gamma_\pm$ values of these salts should decrease in the order benzoate, propionate, and acetate in either mechanism.

Partial Molar Volumes of Guanidinium Salts. In general, the apparent molar volume (ϕ_v) of the salt may be expressed by Masson's equation (Eq. 4) or Redlich-Rosenfeld's equation (Eq. 5).[14]

$$\phi_v = \phi_v^0 + S_v^* \sqrt{C} \tag{4}$$

$$\phi_v = \phi_v^0 + S_v \sqrt{C} + b_v C \tag{5}$$

In these equations, ϕ_v is the apparent molar volume at infinite dilution and equal to $\overline{V}_2^0$, the partial molar volume at infinite dilution, C is the molarity and S_v^* is the experimental slope, and S_v is the constant obtained from the free energy change on pressure assuming that the $\gamma_\pm$ obeys the Debye-Hückel limiting law.[15] Therefore, b_v is the constant concerning the deviation of

TABLE 5. $\bar{V}_2^0$, S_v^*, AND b_v VALUES FOR GUANIDINIUM SALTS IN AQUEOUS SOLUTIONS AT VARIOUS TEMPERATURES

	Guanidinium acetate	Guanidinium propionate	Guanidinium benzoate	Temp (°C)
$\bar{V}_2^0$ (cm³/mol)	88.3	102.1	113.6	
S_v^* (cm³·l$^{1/2}$·mol^{-2})	2.0	2.2	2.4	15
b_v (cm³·l$^{1/2}$·mol$^{-3/2}$)	0.3	0.5	0.7	
$\bar{V}_2^0$ (cm³/mol)	90.0	103.6	136.4	
S_v^* (cm³·l$^{1/2}$·mol^{-2})	2.0	2.0	2.1	25
b_v (cm³·l$^{1/2}$·mol$^{-3/2}$)	0.1	0.2	0.2	
$\bar{V}_2^0$ (cm³/mol)	90.7	105.0	137.8	
S_v^* (cm³·l$^{1/2}$·mol^{-2})	1.7	2.0	2.1	35
b_v (cm³·l$^{1/2}$·mol$^{-3/2}$)	−0.4	−0.3	0.1	

volume from the predicted value by the Debye-Hückel theory and is regarded as a measure of the ion-solvent interactions. Negative b_v values have been reported on the aqueous solutions of various ammonium salts, such as tetraalkylammonium salts,[16] *n*-alkylamine hydrobromides,[17] and cyclic amine hydrochlorides.[18] These negative b_v values were attributed to the decrease in ice-likeness with increase of concentration by overlapping of the structural region around the hydrophobic solute,[17,18] or the increase of cage-like structure with increase of concentration.[19]

Concerning the sodium salts of fatty acids,[20] the values of b_v were slightly negative at 25 °C and these negative values increased with the carbon numbers of the chain as in the case of alkylamine hydrobromides. However, the temperature dependence of b_v values was negative in contrast with the case of the higher homolog of alkylamine salts. From the viscosity[21] and the NMR study,[5] the acetate ion was concluded to be a structure maker. Judging from the size of the ion and the delocalization of the charge,[22] the carboxylate ion may not have so much influence on the structure of water. If this is the case correct, then the structure making ability of the acetate ion originates from the methyl group of the acetate ion, that is, the acetate ion is a hydrophobic structure maker.

The formation of a cage-like structure around the hydrophobic solute makes a negative contribution to the partial molar volume of the solute.[23] If the guanidinium ion breaks the water structure around the hydrophobic ion in the unique way as discussed in the previous section, the guanidinium ion will increase the partial molar volume of the salt. Therefore the b_v values of the guanidinium salts will be positive if the structure breaking effect of the guanidinium ion dominates the structure making effect of the hydrophobic anions.

As seen in Table 5, the b_v values of three guanidinium salts were all positive at 25 °C and increased with the hydrophobicities of the counter anions. The negative b_v values of acetate and propionate at 35 °C and the negative temperature dependence of the b_v values for the each salt mean that the structure breaking ability of the guanidinium ion decreased with temperature increase, since the water structure was already broken to a considerable extent at high temperature.

Reduced Viscosity of BSA. The relation between the reduced viscosities of BSA (η_{sp}/C_2) and the concentration of guanidinium salts are shown in Fig. 2. The initial concentrations necessary to produce the denaturation are around 3 mol/l for these salts with hydrophobic anions and about 1 mol/l for chloride. The difference of the denaturation abilities of these two kinds of salts together cannot be compared, since the chloride ion is hydrophilic and the other two ions are hydrophobic. As discussed in the previous paper[1] and preceding sections of this paper, the modes of the interaction between the guanidinium ion and these two kinds of anions are different from each other. This suggests that the interactions of these two kinds of salts with proteins are also different. It does appear that the hydrophobic anions weaken the denaturating ability of the guanidinium ions. Assuming that the structure breaking actions of these salts play the most important role in the various interactions involved in the denaturation of BSA, the effective concentration of the

propionate for the denaturation of BSA might be expected to be larger than that of acetate. In fact, the concentration of propionate was slightly smaller than that of acetate. This result is consistent with the denaturation of ribonuclease by tetraalkylammonium salts.[24] In the tetraalkylammonium salts, the homolog with larger alkyl chains promoted the denaturation more strongly than those with shorter alkyl chains.

In conclusion, it was difficult to explain the order of the denaturation abilities of the hydrophobic salts of guanidine only in terms of the $\gamma_{\pm}$ values and volume data of the aqueous binary solutions.

Studies of Zone Melting. IV. The Equilibrium Distribution Coefficient of the Bibenzyl–Stilbene System†

Hidemoto NOJIMA

Department of Industrial Chemistry, Faculty of Engineering, Meiji University, Ikuta, Tama-ku, Kawasaki 214

(Received March 7, 1978)

Determinations of the equilibrium distribution coefficients of stilbene in bibenzyl by the zone-melting method were performed by using the theory proposed by Burton and his co-workers from the effective distribution coefficients, which were measured at various zone travel rates (0.73, 0.98, 1.16, and 1.47 cm/h) on five samples of bibenzyl containing 0.3, 0.5, 1.0, 2.0, and 4.0 wt % of stilbene. Also, the equilibrium distribution coefficient independent of the concentration was obtained as 5.08 by the extrapolation of the equilibrium distribution coefficient *vs.* the concentration plots to zero concentration. The validity of the obtained results is discussed by a comparison of the values estimated individually by two other methods: the equilibrium distribution coefficient (5.23) determined from the phase diagram of the bibenzyl–stilbene system, and that (5.08) calculated thermodynamically.

It is well known that the distribution of either a solute or an impurity between the solid and liquid phases in the fractional solidification process, in which the zone-melting method is included, is generally not in equilibrium because of the advance of the solid-liquid interface at a considerably rapid rate and the incomplete diffusion of the solute in the molten phase under ordinary experimental conditions.

If the argument is restricted to the binary systems, the distribution of the solute in both phases is represented by the effective distribution coefficient under the non-equilibrium conditions. On the other hand, if an equilibrium is established between the two phases, the distribution of the solute is indicated by the equilibrium distribution coefficient.

For the reasons described above, it is usually difficult for the equilibrium distribution coefficient to be determined directly from a zone-melting experiment. However, it can be estimated with the theory proposed by Burton and his co-workers[1] from the effective distribution coefficients obtained at various zone travel rates.

Determinations of the equilibrium distribution coefficients in this way have been achieved for a variety of binary systems, but the validity of the obtained results has been little discussed in terms of other methods, such as the phase diagram and thermodynamic theory.

In the previous paper,[2] the author attempted to estimate the equilibrium distribution coefficient of azobenzene in stilbene, which is less than unity, through the theory given by Burton and his co-workers[1] from zone-melting experiments, and also to compare it with the results obtained from the phase diagram of the system and from the thermodynamic theory of ideal solutions.

It will also be worth-while to study a system in which the distribution coefficient is greater than unity according to the above methods. Therefore, in this paper, similar discussions will be undertaken of the equilibrium distribution coefficient of *trans*-stilbene in bibenzyl, which is greater than unity. The obtained result was somewhat different from that found in the stilbene–azobenzene system.

No zone-melting experiments have previously been reported for the bibenzyl–stilbene system.

Experimental

Materials. The bibenzyl was purified once by recrystallization from ethanol, and the stilbene was zone-refined. The bibenzyl was mixed with stilbene in Pyrex beakers in the concentrations of 0.3, 0.5, 1.0, 2.0, and 4.0 wt %. After a small amount of acetone had been added to these mixtures, they were warmed and stirred gently until all of them were dissoved in acetone, and then the acetone was removed by evaporation in a vacuum desiccator. The samples were powdered in an agate mortar.

The bibenzyl was placed in a length of 27 cm in a Pyrex tube with an internal diameter of 0.7 cm and an outer diameter of 0.9 cm. In addition, the bibenzyl–stilbene mixture prepared by the procedures described above was placed on bibenzyl to a length of 3 cm. Then the tube was sealed off under a dry nitrogen atmosphere of about 0.9 atm.

Apparatus and Procedures. The zone-melting experiments were carried out with the apparatus described in a previous paper.[3]

The experiments of a single zone pass were carried out under the following conditions: the sample tube was moved upward at the different travel rates of 0.73, 0.98, 1.16, and 1.47 cm/h; the zone length was kept at 3 cm, and the zone temperature was set at 60 °C.

After a single passage of the molten zone, the sample was cut into 3-cm-long divisions. The concentration of stilbene in each portion was determined spectrophotometrically in an ethanol solution by means of a Hitachi 101 spectrophotometer at a wavelength of 295 nm.

Phase Diagram of the Bibenzyl–stilbene System. On the phase diagram of this system, several works have been reported.[4–6] Kolosov's work,[6] which is shown in Fig. 1, seems the most accurate among these works. Unfortunately, however, the accuracy in the range of low concentrations of stilbene, which is required for the determination of the equilibrium distribution coefficient from the phase diagram, is as poor in his diagram as in the others. For the purpose of correcting inaccuracies in Kolosov's data, the solidus and liquidus curves at low concentrations of stilbene were determined in detail with a Shimadzu differential scanning calorimeter, SC-20. The obtained results are presented in Fig. 2.

† A preliminary report of this work was presented at the 34th National Meeting of the Chemical Society of Japan, Hiratsuka, April 1976.

Results and Discussion

Zone-melting Experiments. With the distributions of stilbene along the length of the samples after a single zone pass, the effective distribution coefficients were evaluated by the method of Sue and his co-workers.[7] In this method, the charge of the initial zone length consists of two components, that is, the solute whose distribution coefficient is to be measured and a solvent, while the remainder of the charge consists of a solvent only. The solute concentration, C, after a single zone passage is given at a distance, x, from the top of the sample by

$$\log\frac{C}{C_0} = -0.4343K_e\frac{x}{l} + \log K_e, \qquad (1)$$

where K_e is the effective distribution coefficient; C_0 is the initial concentration of the solute, and l is the zone length. Therefore, a plot of $\log(C/C_0)$ *vs.* x/l yields a straight line, and the slope and intercept of the line give the value of K_e. These relationships are shown in Fig. 3, in which, however, no whole data are represented in order to avoid complication; the values of K_e are shown in Table 1. The slope of Eq. 1 in the systems with distribution coefficients greater than unity is steeper than that in the systems with distribution coefficients less than unity, and the greater the coefficient, the steeper the slope. For this reason, the effective distribution coefficients were unavoidably estimated from only the three plots shown in Fig. 3.

Though the values of K_e estimated from both the slope and intercept in Eq. 1 should coincide with each other, the agreement is poor in the experimental results.[8,9] As one reason for this discrepancy, it may be considered that the assumptions used to derive Eq. 1 are not necessarily rigorously valid; the assumptions used are as follows: a constant distribution coefficient, no diffusion in the solid, a uniform concentration in

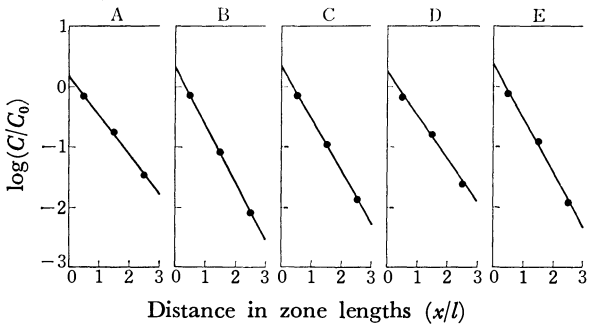

Fig. 3. $\log(C/C_0)$ *vs.* x/l.

4.0	0.73	2.36	2.06
	0.98	2.50	2.16
	1.16	2.18	1.99
	1.47	2.06	1.86

a) The effective distribution coefficient obtained from the slope was adopted to calculate the equilibrium distribution coefficient.

the liquid, and no change in density on freezing.

The equilibrium distribution coefficient can be obtained from the effective distribution coefficients determined at various zone travel rates and expressed by the following equation by Burton *et al.*:[1]

$$\log\left(1-\frac{1}{K_e}\right)=\log\left(1-\frac{1}{K_0}\right)-0.4343\frac{\delta V}{D}, \qquad (2)$$

where K_e and K_0 are the effective and equilibrium distribution coefficients respectively; D, the diffusion coefficient of the solute in the melt; δ, the boundary layer thickness, and V, the freezing rate, which may be assumed to be identical with the zone travel rate in the zone-melting experiments. The value of K_0 can be estimated from the plot of $\log(1-1/K_e)$ *vs.* V by Eq. 2. In the estimation of K_0 from Eq. 2, for K_e we employed the values obtained from the intercepts in Fig. 3 except when the value of K_e was taken from the slope: the zone travel rate of 0.73 cm/h for 1.0% of stilbene.

The experimental results are represented in Fig. 4, while Table 2 and Fig. 5 show the relationship between the values of K_0 obtained from the intercepts of the lines in Fig. 4 and the concentrations of stilbene, C. This relationship can be expressed approximately by the following empirical equation:

$$K_0 = 2.50\exp(-3.11C) + 2.58. \qquad (3)$$

Then, the equilibrium distribution coefficient independent of the concentration is evaluated by substituting zero into the C in Eq. 3. Thus the value of 5.08 is obtained.

Here we found that, in contrast to finding for the stilbene–azobenzene system, the concentration dependence of the equilibrium distribution coefficient is fairly great.

Stilbene and azobenzene have the same crystal structure and almost the same molecular size, and form a complete series of solid solutions. On the other hand,

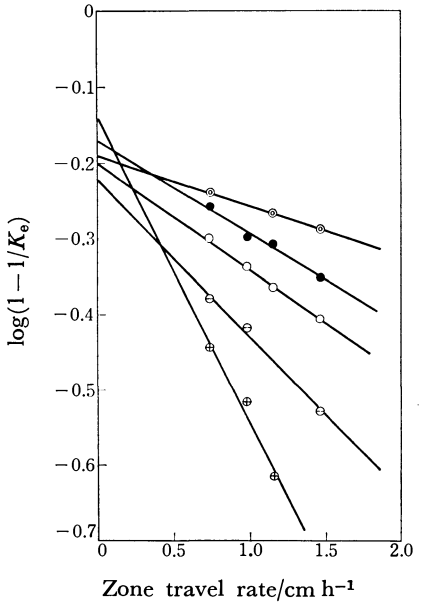

Fig. 4. $\log(1-1/K_e)$ *vs.* zone travel rate.

●: Observed values, ——: calculated curve by Eq. 3.

TABLE 2. THE RELATION BETWEEN THE CONCENTRAION OF STILBENE AND THE EQUILIBRIUM DISTRIBUTION COEFFICIENT

Concentration of stilbene (wt %)	Equilibrium distribution coefficient	
	Obsd	Calcd from Eq. 3
0.3	3.64	3.56
0.5	3.06	3.11
1.0	2.71	2.69
2.0	2.50	2.58
4.0	2.82	2.58

the similarities of the crystal structure and molecular size of bibenzyl and stilbene are less than those of stilbene and azobenzene;[10] hence, bibenzyl and stilbene form a peritectic system.

As one reason for such a difference between the concentration dependence of the equilibrium distribution coefficients found in the two systems, the fact described above may be considered.

In Fig. 4 straight lines for 0.5, 1.0, and 2.0% of stilbene are arranged in order of concentration. On the deviations from these arrangements of straight lines found in 0.3 and 4.0% of stilbene, it is considered that the effective distribution coefficient of 0.3% of stilbene might be smaller than the others because of the variation in the value of either D or δ for some reason. However the regularity, as shown in Table 2 and Fig. 5, might be restored in the equilibrium distribution coefficient, for it is independent of the above two factors. In the case of 4.0% of stilbene, the effective distribution coefficient becomes greater than those of 0.5—2.0% of stilbene. This result may be due to the transition at the peritectic point, at which a discontinuous change occurs in the distribution coefficient; this phenomenon is the so-called peritectic jump reported by Schildknecht.[11]

Determination by Phase Diagram. The solidus and liquidus curves shown in Fig. 2 are approximately

straight lines; their empirical equations are as follows:

$$t_s = 0.199C_s + 51.8, \quad (4)$$

$$t_l = 1.04C_l + 51.8, \quad (5)$$

where t_s and t_l are the solidus and liquidus temperatures in degrees of centigrade, and where C_s and C_l are the concentrations of stilbene in the solid and liquid phases respectively.

The equilibrium distribution coefficient independent of the concentration is given by Eq. 6 from the definition of distribution coefficient and Eqs. 4 and 5:

$$K_0 = \frac{C_s}{C_l} = \frac{1.04}{0.199} = 5.23. \quad (6)$$

Despite the fact that both solidus and liquidus curves are approximately straight, as shown in Fig. 2, the concentration dependence of the equilibrium distribution coefficient is fairly great in the results of the zone-melting experiments. This suggests that the equilibrium distribution coefficient estimated by the theory of Burton and his co-workers is the so-called interfacial distribution coefficient,[12] which seems to be not necessarily the same as the equilibrium distribution coefficient obtained by the phase diagram.

Determination by Thermodynamic Theory. In the binary systems, the relationship for the solid-liquid phase equilibrium is thermodynamically expressed by Eq. 7 at a constant pressure:

$$\ln\frac{a_s}{a_l} = \frac{\Delta H_0}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right) + \frac{\Delta C_p}{R}\left(1 - \frac{T_0}{T} + \ln\frac{T_0}{T}\right), \quad (7)$$

where a_s and a_l are the activities of the solute in the solid and liquid phases respectively. ΔH_0 and T_0 are the heat of fusion and the melting point of the solute; T is the temperature at which the solid and liquid phases are in equilibrium with each other; ΔC_p is the difference between the heat capacities of the liquid and the solid solute at the melting point; R is the gas constant. The definition of the activity prescribes that, as the concentration of the solute tends to zero, the activity tends to be equal to the concentration. Therefore, for a dilute solution, the equilibrium distribution coefficient may be written as follows:

$$K_0 = \frac{a_s}{a_l} = \frac{C_s}{C_l}. \quad (8)$$

That is, the left-hand side of Eq. 7 can be rewritten as $\ln K_0$.

Since the tendency of the solute concentration to tend to zero is, in other words, for the composition to tend to that of a pure solvent, substituting the melting point of the solvent for T in Eq. 7 may yield an equilibrium distribution coefficient independent of the concentration.

In Fig. 2, the smaller the concentration of stilbene, the closer the gap between the observed lines, represented by the full lines, and those calculated by the thermodynamic theory of the ideal solution, represented by the dotted lines. Therefore, the equilibrium distribution coefficient independent of the concentration can be calculated by means of Eqs. 7 and 8. To calculate the value of K_0, the numerical values substituted in Eq. 7 are as fusion:

ΔH_0 is the heat of fusion of stilbene: 25800 J/mol,*

T_0 is the melting point of stilbene: 397.6 K,*

T is the melting point of bibenzyl: 325.0 K,*

ΔC_p is the difference between the heat capacities of liquid and solid stilbene at the melting point: 45.3 J/mol.**

Thus, the value of 5.08 was obtained.

Though the similarities in the crystal structure and in molecular size between stilbene and bibenzyl are less than those of stilbene and azobenzene, as has already been described, the assumption of an ideal solution also, in this system, holds in low concentrations of stilbene. Moreover, the equilibrium distribution coefficient calculated thermodynamically agrees with those obtained from the zone-melting experiments and phase diagram, as shown in Table 3.

Table 3. The equilibrium distribution coefficients determined by the three methods

Method employed for the determination of the equilibrium distribution coefficient	Equilibrium distribution coefficient
Zone melting	5.08
Phase diagram	5.23
Thermodynamic theory	5.08

Conclusion

In the zone-melting experiments, the equilibrium distribution coefficient extrapolated to zero concentration of stilbene agreed ultimately with the values determined from the phase diagram and thermodynamic theory. This fact differs considerably from that found in the stilbene–azobenzene system with regard to the concentration dependence of the equilibrium distribution coefficient. However, the determination of the equilibrium distribution coefficient through the theory of Burton and his co-workers, which is based on a dynamic process consisting of a heterogeneous reaction, was related to the methods taking account of the equilibrium conditions, that is, the phase diagram and the thermodynamic theory.

The author wishes to thank Professor Masaru Inagaki, of Meiji University, and Professor Sohachiro Hayakawa, of Tokyo Institute of Technology, for their valuable advice.

Hydrates of Organic Compounds. III. The Formation of Clathrate-like Hydrates of Tetrabutylammonium Dicarboxylates

Haruo NAKAYAMA* and Kazuichi WATANABE

Department of Chemistry, Faculty of Engineering, Yokohama National University, Ooka-machi, Minami-ku, Yokohama 232

(Received March 22, 1978)

The solid-liquid phase diagrams for the binary mixtures of water with 20 tetrabutylammonium dicarboxylates, $[(n\text{-}C_4H_9)_4N]_2OOC\text{–}R\text{–}COO$ (R = methylene chain ranging from 0 to 10 carbon atoms; methylene chain containing substituted groups such as $-CH_3$, $-C_2H_5$, $-NH_2$, and $-OH$; and $-C_6H_4-$ (three phthalate isomers)), have been investigated to see the effect of dicarboxylate anions on the formation of clathrate-like hydrates. It has been found that, with only the one exception of the dodecanedioate, all the other salts form hydrates which have large hydration numbers. Judging from these large hydration numbers, they are believed to be clathrate-like hydrates. From the relationship between the hydration numbers and the melting points, these hydrates can be classified into three groups at least. All the hydrates other than those of oxalate and of terephthalate are newly found in this study.

In 1959 McMullan and Jeffrey[1] pointed out that a series of hydrates formed by tetrabutyl(and tetraisopentyl)ammonium salts, which were originally found by Kraus and his co-workers,[2] were clathrate-like hydrates similar to the gas hydrates.[3] Later this reasoning was verified by detailed structural studies.[4–6]

In general, in these hydrates, each alkyl chain of the ammonium cation (and also each hydrophobic group of an anion, if such exists) is accommodated within a polyhedron (such as 14- or 15-hedron) which is constructed by hydrogen-bonded water molecules. Since most of these hydrates can easily be formed at moderate conditions, they provide us with a suitable model system for studying the nature of the interaction between water and hydrophobic molecules, especially in connection with the structural modification of water molecules in the vicinity of hydrophobic solutes in an aqueous solution.

The previous study[7] clearly showed that the most suitable alkyl chain of a tetraalkylammonium cation for the formation of stable clathrate-like hydrates was either butyl or isopentyl, and further that a shorter or longer chain than these groups drastically affected the stability of the hydrates. On the other hand, in the case of anions it is well known that many tetrabutyl(or isopentyl)ammonium salts with various anions (such as F^-, Cl^-, Br^-, CH_3COO^-, HCO_3^-, CrO_4^{2-}, WO_4^{2-}, $C_2O_4^{2-}$, and HPO_4^{2-}) can form clathrate hydrates,[1] and that the effect of an anion on the stability (*i.e.*, the melting points) of these hydrates is not so marked as that of the alkyl-chain length of the cation.

Of the anions which form clathrate-like hydrates, a carboxylate anion seems to be of special importance, since it may have an additional hydrophobic group. The formation of clathrate hydrates of tetrabutylammonium monocarboxylates have been reported for formate,[2] acetate,[1,2] propionate,[2] butyrate,[8] pentanoate,[8] benzoate,[2,5] and *m*-chlorobenzoate.[8] Such properties as hydration numbers and melting points for these hydrates have been either measured or estimated. The detailed crystal structure is known only for benzoate hydrate.[5] In this hydrate ($(n\text{-}C_4H_9)_4N\cdot OOCC_6H_5\cdot 39.5H_2O$), not only four butyl groups of the cation but also the benzyl group is enclathrated by the hydrogen-bonded water framework, and the oxygen atoms of the benzoate anion are hydrogen-bonded to the water framework and form part of the polyhedral structure. Essentially similar structures will be expected for the propionate, butyrate, and *m*-chlorobenzoate hydrates. The cases of the formate and the acetate are less simple to predict.[5]

On the other hand, for tetrabutylammonium dicarboxylates the formation of clathrate hydrate is known only for oxalate[1,2,8] and terephthalate,[8] for which hydration numbers have either been measured directly or estimated from the X-ray results (the Laue symmetry, unit-cell dimensions, and so forth). So far no other study has been reported about the formation of clathrate hydrates of a tetrabutylammonium dicarboxylate. In this paper, through the determination of the solid-liquid phase diagrams for the tetrabutylammonium dicarboxylate–water binary systems, an extensive study has been made in order to examine a variety of effects of dicarboxylate anions on the formation of clathrate hydrates: (1) the effect of the length of the methylene chain introduced between two carboxyl groups; (2) the effect of the type and the position of the substituted groups (such as $-CH_3$, $-C_2H_5$, $-NH_2$, and $-OH$); and (3) the effect of the geometrical relationship between the two carboxyl groups.

Experimental

Materials. The following tetrabutylammonium dicarboxylates $[(n\text{-}C_4H_9)_4N]_2OOC\text{–}R\text{–}COO$, were used, where R were: (1) $-(CH_2)_n-$ (n=0—8, and 10); (2) $-CH(C_2H_5)-$; (3) $-CH_2-CH(CH_3)-(CH_2)_m-$ (m=0—2); (4) $-CH(NH_2)-(CH_2)_l-$ (l=1,2); (5) $-CH_2-CH(OH)-$; and (6) $-C_6H_4-$ (*o*-, *m*-, and *p*-). All the salts were prepared by neutralizing tetrabutylammonium hydroxide solutions with the corresponding acids. The hydroxide was prepared from tetrabutylammonium iodide by means of silver oxide,[1,2] and purified by recrystallization from its dilute aqueous solution in the form of clathrate hydrate crystal.[2] The tetrabutylammonium iodide was prepared by the reaction between tributylamine and butyl iodide and was purified by repeated recrystallization from ethyl acetate.[7] All acids were reagent grade commercial materials and used without further purification except phthalic and isophthalic acids and four acids $HOOC(CH_2)_nCOOH$, whose n=3—8: phthalic and isophthalic acids were recrystallized from ethyl alcohol and

the latter acids from water. The salts which could form stable hydrates (whose melting points were higher than about 10 °C) were purified by recrystallization from water in the hydrate forms.

Procedures. For each salt, a sample (about 1—2 ml) of known composition was prepared by weighing its concentrated solution and water, and then was sealed in a small glass ampoule. No special care was taken to remove the air dissolved in the solution. The concentrated salt solution was prepared by dehydrating a relatively dilute solution over P_2O_5 in an desiccator; its concentration (water content) was determined by the Karl Fisher titration method on a MK-AII apparatus (Kyoto Electronics Manufacturing Co.). Each ampoule was gradually cooled until the solid phase appeared and was annealed for at least 24 h. After that, the ampoule was slowly warmed (at the rate about 0.3 °C per hour) with vigorous shaking in a constant temperature bath. The solid-liquid phase diagrams were determined by measuring the temperature at which the solid phase completely disappeared. When the temperature determination was somewhat ambiguous, especially at high mole fractions and at low temperatures, the differential scanning calorimeter (DSC) (Shimadzu Seisakusho, SC-20) was also employed.

Results

The solid-liquid phase diagrams for the salts of $[(n\text{-}C_4H_9)_4N]_2OOC\text{-}(CH_2)_n\text{-}COO$ with n=0—4 are shown in Fig. 1, and with n=5—8, and 10 in Fig. 2. With only one exception, the salt with n=10, all the other salts form hydrates with a large number of water molecules. All these hydrates melt congruently.

The oxalate (n=0) hydrate is quite stable. Its melting point is 16.6 °C and its hydration number is 58±1. This melting point is in good agreement with 16.8±0.1 reported by Jeffrey and co-workers[1] for the tetragonal structure. The hydration number, however, is greatly different from their values, 67 (by chemical analysis) and 64 (estimated from crystallographic data).[1] On the other hand, their other hydration number,

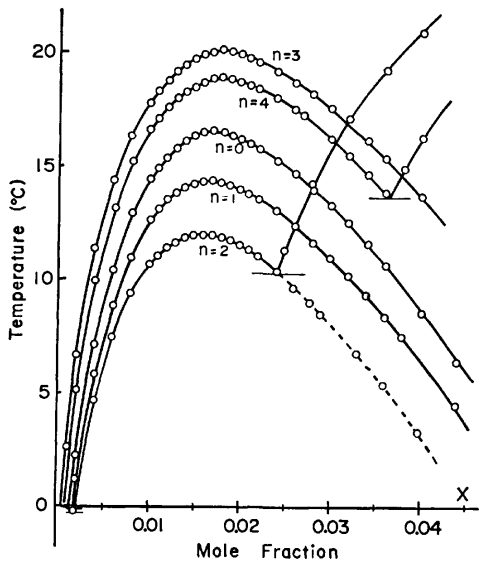

Fig. 1. The solid-liquid phase diagrams for the water-$[(n\text{-}C_4H_9)_4N]_2OOC(CH_2)_nCOO$ systems; n=0—4.

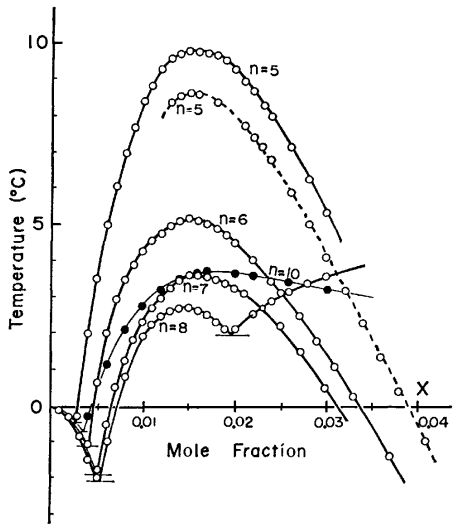

Fig. 2. The solid-liquid phase diagrams for the water-$[(n\text{-}C_4H_9)_4N]_2OOC(CH_2)_nCOO$ systems; n=5—8, and 10.

57.3±2,[8] which has been estimated for the cubic structure (a=24.58 Å) is in agreement with ours, though the melting point of this structure has not been reported.

As is seen from Figs. 1 and 2, the stabilities (*i.e.*, melting points) of these hydrates decrease, as a general trend, upon increasing the length of the methylene chain located between the two carboxyl groups. However, the hydrates of glutarate (n=3) and adipate (n=4) are exceptionally stable, indicating that $OOC\text{-}(CH_2)_3\text{-}COO$ and $OOC\text{-}(CH_2)_4\text{-}COO$ anions are most suitable for being accommodated within the hydrogen-bonded water framework. For the pimelic salt (n=5), another metastable phase appears when its aqueous solution is cooled rapidly. The stable phase appears only when the solution is maintained at temperatures around 0 °C for several days. The salt concentration of the hydrates (*i.e.*, the concentration of maximum temperature in each phase diagram) slightly decreases with increasing n from 0 to 2, shifts to a high (and almost the same) value for the salts with n=3 and 4, and again decreases and holds an approximately constant value for the salts with n=5—8 (Fig. 2).

In the case of the salts with n=2, 4, and 8, another solid phase appears at high mole fractions, around 0.02 for n=2 and 8 and 0.04 for n=4. It is not certain whether these phases are lower hydrates or anhydrous solids. For the salt with n=10, the phase diagram (Fig. 2) shows a very broad peak in the vicinity of X= 0.016—0.018. This solid phase, however, does not seem to be a hydrate similar to those of the other salts, judging from the fact that the shape of the phase diagram differs from the others and that it takes a long time to attain the dissolution equilibrium, as compared with other salts.

All the melting points and hydration numbers obtained in this paper are summarized in Table 1. The phase diagrams of such salts as ethylmalonate, methylsuccinate, aminosuccinate (L-asparate), hydroxysuccinate (L-malate), 3-methylglutarate, 2-aminoglutarate (L-glutamate), and 3-methyladipate have essentially

similar shapes to those of each parent salt, as shown in Fig. 1. Therefore, for the hydrates of these salts, only the melting points and hydration numbers which are read off each phase diagram are listed in Table 1.

Figure 3 gives the phase diagrams of three isomeric (*o*-, *m*-, and *p*-) phthalates. The phthalate gives the most stable hydrate among the salts studied in this paper. Although the water content of these hydrates is approximately identical, their melting points decrease in intervals of 4.0 degrees in the order of phthalate, isophthalate, and terephthalate. In the case of terephthalate, another solid phase appears at high mole fractions around 0.04; its composition is not known. The observed melting point and hydration number for the terephthalate hydrate, 12.3 °C and 62±2 (Table 1), are in disagreement with those reported by Jeffrey *et al.*,[8] 9.5 °C and 84±4. The latter hydration number has been deduced by inference from the structures already known.

$-C_6H_4-$ phthalate	20.3	62±1
isophthalate	16.3	62±1
terephthalate	12.3	62±2

Discussion

These results show that all the salts, except dodecanedioate, form hydrates which have large hydration numbers ranging from 55 to 65 and melt congruently. Although there is no evidence about the structure of these hydrates, they are believed to be clathrate-like hydrates for the following reasons. In general, arguing from the structure of several tetraalkylammonium salt hydrates,[1,4-7] 7—8 water molecules per one alkyl group, such as butyl and isopentyl, are needed in order to accommodate it by making a hydrogen-bonded water framework. Since the salts used in this study have 8 or 9 hydrophobic groups, the hydration numbers for these salt hydrates are expected to have values around 60 if they form similar types of hydrates, in good agreement with the values actually found.

As mentioned earlier, the detailed crystal structure of tetrabutylammonium carboxylate hydrates is known only for benzoate hydrate,[5] in which two oxygen atoms of the benzoate anion occupy two adjacent polyhedral sites. Thus it may be reasonably anticipated that, in the dicarboxylate hydrates found in this paper, four oxygen atoms of two terminal carboxyl groups will likewise occupy the appropriate hydrogen-bonded sites of the polyhedral vertices. This restriction will be one of the factors which will affect the stabilities of these hydrates. In addition, we may list other stability-controlling factors, such as (1) how well a hydrophobic group existing between two carboxyl groups is

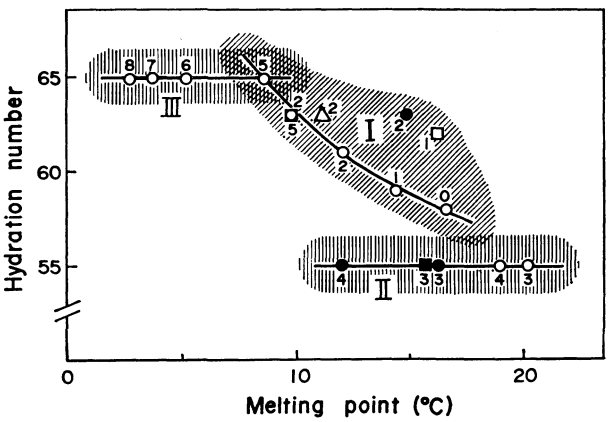

Fig. 4. The correlations between the hydration numbers and the melting points of the hydrates of tetrabutylammonium dicarboxylates. ○: Anions with no substituted group; ●: anions with methyl group; □: anions with ethyl group; ■: anions with $-NH_2$ group; △: anion with $-OH$ group. A numeral attached to each point indicates the number of carbon atoms in the methylene chain of the dicarboxylate anion.

accommodated within a hydrogen-bonded framework of waters and (2) the change in electrostatic potential due to the positional change of carboxyl anions with respect to a central $(n\text{-}C_4H_9)_4N^+$ cation.

Figure 4 gives the relationship between the hydration numbers and the melting points observed for our series of hydrates. The number attached to each point stands for the number of carbon atoms of the methylene chain in a dicarboxylate anion. From this figure we may tentatively classify these hydrates into three groups: I, II, and III.

Group I consists of the hydrates of the salts with $n=$ 0, 1, 2, and 5 and all their derivatives. In this group of hydrates the hydration number varies within the range of 58 and 63 depending upon the size and/or shape of the hydrophobic group of the anion and increases, in general, with decreasing the melting points. Of these hydrates, oxalate hydrate is the most stable and the stability gradually decreases upon increasing the length of the methylene chain. This fact will suggest that neither a small methylene chain as in the malonate ($n=1$) and the succinate ($n=2$) nor a large one as in the pimelic salt ($n=5$) is suitable in size to be encaged stably by a hydrogen-bonded water framework. The stabilities of these hydrates seem to be strongly influenced by the relative difficulty of fixing four oxygen atoms of two carboxyl groups into appropriate polyhedral sites. From the fact that oxalate (and also phthalate hydrate, Fig. 3 and Table 1) is fairly stable, it may be said that the existence of two carboxyl groups in the vicinity of one tetrabutylammonium cation is favorable for forming a stable hydrate. Thus in the oxalate hydrate, for example, the hydrate is made up by $[(n\text{-}C_4H_9)_4N\cdot OOC\text{–}COO]^-$ anions and $(n\text{-}C_4H_9)_4N^+$ cations, each surrounded by a hydrogen-bonded water framework.

It is interesting to note that the ethylmalonate hydrate is more stable than that of the malonate itself; the same relation is found between methylsuccinate and succinate hydrates. This indicates that the introduction of an ethyl or methyl group onto such small hydrophobic anions makes them more suitable in size to be surrounded by the hydrogen-bonded framework of water. The substitution of polar groups like $-NH_2$ and $-OH$ onto the succinic acid anion causes a slight decrease in the melting points of their hydrates. This presumably occurs as a result of the overlapping of two conflicting factors: a favorable factor of increasing the molecular volume of such a small anion; and a inconvenient factor of the disturbance in the stable formation of water polyhedra due to the occurrence of directional interaction (hydrogen-bonding) between these polar groups and water molecules which construct polyhedral cages. This effect of the introduction of a polar group into a guest molecule on the stability of its hydrate is, however, much less than expected; salts such as $(n\text{-}C_4H_9)_3(C_3H_6OH)NF$ and $(n\text{-}C_4H_9)_3(CH_3COOCH_2)NF$ cannot form stable hydrates at all,[9] in striking contrast to a very stable $(n\text{-}C_4H_9)_4NF$ hydrate.[7]

Group II consists of the hydrates of the salts having $n=3$ (glutarate) and $n=4$ (adipate) which are fairly stable and have the smallest hydration number of 55; these salts are favorable for water molecules to form the hydrogen-bonded framework most efficiently by sharing common faces of adjacent polyhedra as much as possible. The fact that the hydrates of these salts, including their methyl and amino derivatives, have almost the same hydration number will suggest that these hydrates have essentially the same structures, although their melting points are considerably changed by the type of anions. In contrast to the case of the malonate and succinate hydrates mentioned above, the introduction of a methyl group onto the methylene chain of a glutaric or adipic acid anion causes a decrease in the melting point of its hydrate. As pointed out above, since the dicarboxylate anion having three or four methylene groups with no substituted groups seems to be the optimum anion for the formation of a stable hydrate, the presence of the substituted group will either make the hydrophobic group unfavorably large or disturb the best fit of the methylene chain by reducing the degree of positional freedom of occupation. The effect of the substituted amino group on the stability of hydrate is relatively slight, just as in the case of the succinate.

The series of salts having $n=5$ (metastable phase), 6, 7, and 8 form fairly unstable hydrates whose hydration numbers lie about 65. These are classified as group III hydrates. From the fact that their hydration number is large and almost constant, and that the anions of these salts have rather long methylene chains which must be too large to be accommodated within a typical water polyhedron, and further that the salt with $n=5$ forms two kinds of hydrates (stable and metastable phases), this group of hydrates will presumably have a different crystal structure from the other two groups. Although there is no evidence about the crystal structure, we may imagine the following structure.

The principal constituents of these hydrates may be the tetrabutylammonium cations, each butyl group of which is encaged by a hydrogen-bonded water framework; an anion which has a long methylene chain is accommodated within a fairly distorted void made between the two adjacent cation sheaths. These hydrates will owe a considerable part of their stability to the closeness of fit in the cages of butyl groups of the cation. The long methylene chain of the anion will considerably distort the water framework in which it is accommodated, and therefore it will make the hydrates unstable rather than stabilize them, owing to its hydrophobic nature. These concepts are consistent with the experimental results that the melting points of these hydrates decrease with increasing the length of the methylene chain and that the salt with $n=10$ is no longer able to form a stable hydrate. It is uncertain whether this estimated structure has some correlation with the structure of fairly stable clathrate-like hydrates[10,11] made by a series of salts having the general formula $[(n\text{-}C_4H_9)_3N\text{–}(CH_2)_m\text{–}N(n\text{-}C_4H_9)_3]F_2$ ($m=5$, 6, and 8).

Three isomers of the phthalate also form hydrates which have almost the same hydration number of 62, indicating that they are isostructural. Although the benzene ring of the anion is large enough to be accom-

modated within a hydrogen-bonded framework, the distortion caused by the restriction that the four oxygen atoms of the two carboxyl groups, which are fixed at the specific position of the benzene ring, must be placed at one of the hydrogen-bonded sites of the polyhedral vertices seems to be the dominant factor which determines the stability of the hydrates. Because of this distortion effect, the water framework around the benzene ring could not be constructed as efficiently as in the group II hydrates, giving a fairly large hydration number as compared with 55 of the group II hydrates. It is not certain whether these hydrates should be included in group I or be classified as another group.

Optical and Magnetic Properties of Solid Anion Radical Salts Derived from Halogen-Substituted *p*-Benzoquinones

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 22, 1978)

Crystalline anion radical salts derived from halogen-substituted *p*-benzoquinones are known to show charge-transfer transition between anion radicals in the low-energy region and to possess antiferromagnetic spin exchange interaction between the anion radicals. Using Hubbard Hamiltonian, the optical and magnetic properties of Na^+ *p*-Chloranil$^-$ were explained in terms of a dimer model, while those of K^+ *p*-Chloranil$^-$ and K^+ *p*-Bromanil$^-$, in terms of an infinite non-alternant linear chain model.

The prominent magnetic, electrical and optical properties of a number of solid ion radical salts have been the subject of many theoretical and experimental investigations over the past fifteen years.[1-5] In such ion radical salts, the planar ion radical molecules are known to form, in themselves, a segregated stacking into columns so as to make a large overlap between their half-occupied molecular orbitals.[5-8] In one case, ion radical molecules stack predominantly in a pair-by-pair manner, so that the crystal system can be practically confined to a dimer of ion radicals. Another case is that ion radical molecules stack into infinite non-alternant one-dimensional column. In both cases, since any individual radical molecule interacts through charge-transfer most strongly with other neighboring radicals, the electronic spectrum of the solid salt differs distinctly from the monomer spectrum of the radical ion in solution but shows a charge-transfer transition between ion radicals in the low-energy region.[3-5] In the present paper, we apply half-filled Hubbard Hamiltonian to the dimer and the non-alternant one-dimensional system of ion radical molecules and investigate the optical and magnetic properties of certain crystalline anion radical salts derived from *p*-chloranil, *p*-bromanil and 2,5-dibromo-3,6-dichloro-*p*-benzoquinone (*p*-QBr_2Cl_2).

Fig. 1. The anion radical salts derived from (a) *p*-chloranil, (b) *p*-bromanil, and (c) 2,5-dibromo-3,6-dichloro-*p*-benzoquinone (*p*-QBr_2Cl_2). M^+ represents an alkali metal cation such as sodium or potassium cation.

Na^+ *p*-Chloranil$^-$

Several years ago,[4] we measured the diffuse reflection spectrum of this solid salt, together with the absorption spectrum of the *p*-chloranil anion radical in acetone solution. The monomer spectrum of the *p*-chloranil anion radical consists of absorption bands at 22200 cm^{-1}, 26700, and 30300. These absorptions were assigned to the $^2B_{3g} \rightarrow {}^2B_{1u}$, $^2B_{3g} \rightarrow {}^2A_u$, and $^2B_{3g} \rightarrow {}^2B_{1u}$ transitions, respectively.[4] On the other hand, the solid-state spectrum of Na^+ *p*-Chloranil$^-$ salt shows a strong low-energy absorption at 11600 cm^{-1}, a high-energy band at 26500 and a shoulder beyond 30000. The high-energy band at 26500 cm^{-1} was assigned to the shifted band of the $^2B_{3g} \rightarrow {}^2B_{1u}$ transition at 22200 for the anion radical monomer, while the strong low-energy band at 11600 cm^{-1} characteristic of the solid salt, to the charge-transfer transition between *p*-chloranil anion radicals in the solid state.[4]

The magnetic property of solid Na^+ *p*-Chloranil$^-$ salt was examined by Sugano and Kuroda.[9] The temperature dependence of the observed static magnetic susceptibility could be well explained in terms of a dimer model of the *p*-chloranil anion radicals. The paramagnetism comes from triplet excited state lying $\delta = 1130$ cm^{-1} above the ground singlet state.

In order to understand the above experimental results in more detail, we consider the optical and magnetic properties of the dimer model of ion radicals in terms of Hubbard Hamiltonian, which is written by[10,11]

$$\mathscr{H} = \sum_{\sigma} T(C_{1\sigma}{}^{+}C_{2\sigma} + C_{2\sigma}{}^{+}C_{1\sigma}) + I(n_{1\uparrow}n_{1\downarrow} + n_{2\uparrow}n_{2\downarrow}), \qquad (1)$$

where $n_{i\sigma} = C_{i\sigma}{}^{+}C_{i\sigma}$, and $C_{i\sigma}{}^{+}$ and $C_{i\sigma}$, ($i=1$ or 2), are the creation and annihilation operators of an electron with σ-spin at the i-th site, respectively, and where T (<0) is the transfer matrix element between ion radicals in a dimer, and the repulsive potential, I, appears only when two electrons are at the same site. If we only take the half-occupied molecular orbital of ion radical for each site, there are six bases of the wave functions for the dimer. After solving the eigenvalue problem, we obtain, for the triplet state, $c = C_{1\uparrow}{}^{+}C_{2\uparrow}{}^{+}|0>$, $d = C_{1\downarrow}{}^{+}C_{2\downarrow}{}^{+}|0>$, and $a^+ = 2^{-1/2} \times \{C_{1\uparrow}{}^{+}C_{2\downarrow}{}^{+} + C_{1\downarrow}{}^{+}C_{2\uparrow}{}^{+}\}|0>$ with energy zero, while we obtain, for the singlet states, $(1+(E_{\pm}/2T)^2)^{-1/2} \times (a^- + (E_{\pm}/2T)b^+)$ with energy $E_{\pm} = I/2 \pm \{(I/2)^2 + (2T)^2\}^{1/2}$, and b^- with energy I. Here, $a^- = 2^{-1/2} \times \{C_{1\uparrow}{}^{+}C_{2\downarrow}{}^{+} - C_{1\downarrow}{}^{+}C_{2\uparrow}{}^{+}\}|0>$, $b^{\pm} = 2^{-1/2}\{C_{1\uparrow}{}^{+}C_{1\downarrow}{}^{+} \pm C_{2\uparrow}{}^{+}C_{2\downarrow}{}^{+}\}|0>$, and $|0>$ indicates the state of the dimer without any unpaired electron. The charge-transfer absorption of the dimer corresponds to the optical transition from the ground singlet state of $(1+(E_-/2T)^2)^{-1/2}(a^- + (E_-/2T)b^+)$ to the excited charge-transfer singlet state, b^-. Therefore, in the dimer model of ion radicals, the energy of the charge-

transfer absorption, $h\nu_{CT}$, and the singlet-triplet energy separation, δ, are given by[12]

$$h\nu_{CT} = \left\{\left(\frac{1}{2}I\right)^2 + (2T)^2\right\}^{1/2} + \frac{1}{2}I, \quad (2)$$

$$\delta = \left\{\left(\frac{1}{2}I\right)^2 + (2T)^2\right\}^{1/2} - \frac{1}{2}I. \quad (3)$$

This model was then applied to the above experimental results of the solid Na^+ p-Chloranil$^-$ anion radical salt. By putting the observed values of $h\nu_{CT}=11600\ cm^{-1}$ and $\delta=1130\ cm^{-1}$ into Eqs. 2 and 3, we obtain $I=h\nu_{CT}-\delta=10470\ cm^{-1}$ and $T=-1800\ cm^{-1}$, respectively. The $I=10470\ cm^{-1}$ value thus estimated for the Na^+ p-Chloranil$^-$ salt corresponds to the effective Coulomb repulsion energy in the solid salt. The repulsion energy is screened in the presence of neighboring sodium cations roughly by a factor of $(1-\alpha/r^3)$, where α is the polarizability of the cation and r is the effective distance between p-chloranil anion radical and neighboring cation.[13,14] In fact, in addition to the dimer formation in crystal, the p-chloranil anion radicals are known to dimerize even in ethanol solution,[15] where the screening appears to be less effective than in the solid state. The charge-transfer absorption of the dimer in ethanol solution is found at 14900 cm^{-1}, suggesting the I value much larger than the $I=10470$ cm^{-1} value of the dimer in the solid Na^+ p-Chloranil$^-$ salt.

Another interesting fact is that the charge-transfer band of solid Na^+ p-Chloranil$^-$ salt at 11600 cm^{-1} is much influenced by applying a pressure; the peak position exhibits a red-shift with 58 cm^{-1} per kbar.[15] As is shown in Eq. 2, if the applied pressure only causes an increase in the transfer matrix element, $|T|$, the charge-transfer band peak will show a blue-shift under high pressure. The main reason for the observed red-shift is then attributable to the decrease of the I value, because the factor $(1-\alpha/r^3)$ will be decreased with the decrease of the distance between p-chloranil anion radical and neighboring sodium cation by applying pressure.

K^+ p-Chloranil$^-$ and K^+ p-Bromanil$^-$

The crystal structure analysis of K^+ p-Chloranil$^-$ salt was made by Konno *et al.*[8] Although there are several polymorphs, in the structure of the orthorhombic α-form the p-chloranil anion radicals are stacked with equal intervals, forming non-alternant one-dimensional columns parallel to the c-axis, the interplanar spacing being 3.47 Å. The K^+ ion lies at the center of a rectangle formed by four oxygen atoms of the p-chloranil anion radicals related by c translation.

Earlier, we measured the solid-state spectrum of K^+ p-Chloranil$^-$ salt,[4] which shows a weak low-energy band at 11800 cm^{-1}, a strong high-energy band at 23300 and a shoulder around 30000. The latter two high-energy absorptions were assigned to the $^2B_{3g}\rightarrow{}^2B_{1u}$ transitions at 22200 cm^{-1} and at 30300, respectively, of the monomer spectrum, while the low-energy band at 11800 cm^{-1}, to the charge-transfer transition between the anion radicals along the one-dimensional column in the solid state. It was further noted that the spectroscopic features of the solid K^+ p-Chloranil$^-$ salt was rather similar to the monomer spectrum of the p-chloranil anion radical. On the other hand, although there is a phase transition around 210—260 K,[16] the temperature dependence of the observed magnetic susceptibility of the K^+ p-Chloranil$^-$ salt in the region above the transition temperature was well explained in terms of an antiferromagnetic linear Ising model with exchange interaction of 113 cm^{-1}.[9]

In previous papers,[17-20] we examined the optical and magnetic properties for a system of non-alternant one-dimensional stacks of ion radicals in terms of Hubbard Hamiltonian, which can be written by

$$\mathscr{H} = \sum_{i,j,\sigma} T_{ij}C_{i\sigma}^{+}C_{j\sigma} + I\sum_{i} n_{i\uparrow}n_{i\downarrow}, \quad (4)$$

where $T_{ij}(<0)$ is the transfer matrix element between the i-th and j-th sites. For non-alternant one-dimensional column of ion radicals, we consider the half-occupied molecular orbital of the unpaired electron as one site of ion radical molecule, and only take into account the transfer matrix element between the nearest neighbor sites. Hereafter, it is simply denoted by $T(<0)$. We consider a paramagnetic state for our system, and further assume a δ-function for each elementary transition in which the spin and the wave vector of an electron are conserved. The intermolecular charge-transfer absorption, $\sigma(\omega)$, is given by[17]

$$\sigma(\omega) \propto \frac{e^2}{4}\frac{I^2}{\omega^2\sqrt{\omega^2-I^2}}\sqrt{4T^2-\omega^2+I^2}. \quad (5)$$

A schematic representation of the absorption line shape has been given in Fig. 1 of Ref. 17. The theoretical charge-transfer absorption has a sharp divergent peak at $\omega=I$, and has a band width of $\sqrt{I^2+4T^2}-I$ in the region $\omega>I$. On the other hand, we examine the magnetic properties of the same system. In a region of small $|T|$ limit, the Hubbard model leads to a non-alternant one-dimensional antiferromagnet with an exchange interaction $J\approx 2T^2/I$ for our case.[14] Therefore, if we combine the experimental data on the peak energy of the observed charge-transfer absorption and the exchange interaction parameter derived from the magnetic susceptibility measurement, we can uniquely determine the magnitudes of I and T for our system.

We apply this approach to the system of non-alternant one-dimensional column of the K^+ p-Chloranil$^-$ salt. The observed peak energy of the charge-transfer absorption, 11800 cm^{-1}, thus corresponds to $I=11800\ cm^{-1}$. As for the antiferromagnetic exchange interaction, rigorously speaking, the J value of Heisenberg model should correspond to $2T^2/I$, but only the J value estimated with Ising model is available at the present time. Therefore, we approximately use the estimated $J=113\ cm^{-1}$ value as $J\approx 2T^2/I$. By putting the $I=11800\ cm^{-1}$ value into this relation, we obtain $T=-820\ cm^{-1}$ for the one-dimensional system of the potassium salt. The $|T|$ value thus estimated is found to be much smaller than the $|T|=1800\ cm^{-1}$ value of the Na^+ p-Chloranil$^-$ salt, indicating weak intermolecular interaction between the p-chloranil anion radicals in the potassium salt. This is sup-

ported by the fact that the intermolecular distance between the anion radicals in the potassium salt is as large as 3.47 Å and also by the spectroscopic features that the high-energy bands at 23300 cm^{-1} and 30000 of the potassium salt show no appreciable shifts in comparison with those of the monomer spectrum of the *p*-chloranil anion radical.

Next, we examine the case of solid K^+ *p*-Bromanil$^-$ salt, whose situation is found to be very similar to that of K^+ *p*-Chloranil$^-$. The solid-state spectrum of the K^+ *p*-Bromanil$^-$ salt shows a very weak charge-transfer band at 10900 cm^{-1}, a weak shoulder at 17500 and a strong high-energy band at 23000.[4] For this salt, the observed magnetic susceptibility data were analyzed with linear Ising model, and the antiferromagnetic spin exchange parameter, J, was estimated to be 97 cm^{-1}.[9] Therefore, in a way similar to that of K^+ *p*-Chloranil$^-$, the values of $I=10900$ cm^{-1} and $T=-730$ cm^{-1} were estimated for the one-dimensional system of the K^+ *p*-Bromanil$^-$ salt. Again, the $|T|$ value is found to be as small as that of the K^+ *p*-Chloranil$^-$ salt. Although there is no crystal structure data for purposes of reference, the intermolecular interaction between the *p*-bromanil anion radicals is certainly weak in the K^+ *p*-Bromanil$^-$ salt.

Na^+ *p*-$QBr_2Cl_2^-$ and K^+ *p*-$QBr_2Cl_2^-$

The solid-state spectrum of Na^+ *p*-$QBr_2Cl_2^-$ salt is quite different from the monomer spectrum of the *p*-QBr_2Cl_2 anion radical but shows a strong low-energy charge-transfer absorption at 12200 cm^{-1} and a high-energy band at 26300.[4] The latter band was assigned to the shifted band of the monomer absorption at 22100 cm^{-1}. Earlier, we measured the temperature dependence of the magnetic susceptibility of the Na^+ *p*-$QBr_2Cl_2^-$ salt.[21] Although no rigorous agreement between the observed and theoretical temperature dependences was obtained either by the singlet-triplet model or by the linear Ising model, the singlet-triplet energy separation, $\delta=970$ cm^{-1}, was estimated by the dimer model, while the antiferromagnetic exchange parameter, $J=810$ cm^{-1}, was estimated by the linear Ising model.[21] Although no crystal structure data are available at the present time, we may explain the electronic state of this solid salt in terms of either the dimer model or the non-alternant one-dimensional system of the anion radicals. In the case of the dimer model, we again took an approach similar to that of Na^+ *p*-Chloranil$^-$, and the values of $I=11200$ cm^{-1} and $T=-1730$ cm^{-1} were thus estimated for the Na^+ *p*-$QBr_2Cl_2^-$ salt. If the non-alternant one-dimensional model was applied, the values of I and T were found to be 12200 cm^{-1} and -2200 cm^{-1}, respectively.

On the other hand, the solid-state spectrum of K^+ *p*-$QBr_2Cl_2^-$ salt is rather similar to the monomer spectrum of the *p*-QBr_2Cl_2 anion radical and has a very weak charge-transfer absorption at 11500 cm^{-1}.[4] As for the magnetic properties, although no rigorous agreement between the observed and theoretical magnetic susceptibilities was again obtained, the singlet-triplet energy separation, $\delta=153$ cm^{-1}, was estimated by the dimer model, while $J=97$ cm^{-1} was estimated by the linear Ising model.[21] These optical and magnetic data lead to $I=11300$ cm^{-1} and $T=-710$ cm^{-1} for the dimer model or to $I=11500$ cm^{-1} and $T=-750$ cm^{-1} for the non-alternant one-dimensional model.

In either of the models, the magnitude of the transfer matrix element of the K^+ *p*-$QBr_2Cl_2^-$ salt was found to be much smaller than that of the Na^+ *p*-$QBr_2Cl_2^-$ salt. This means that the *p*-QBr_2Cl_2 anion radicals in the sodium salt stack, in themselves, very closely, while the intermolecular interaction between the anion radicals is very weak in the potassium salt. Detailed crystal structure analyses of the Na^+ *p*-$QBr_2Cl_2^-$ and K^+ *p*-$QBr_2Cl_2^-$ salts are now required to confirm the above situation and also to determine by which model (dimer model or non-alternant one-dimensional model) the *p*-QBr_2Cl_2 anion radicals are stacked in those solid salts.

12) As for the intensity of the charge-transfer absorption of the dimer, the transition dipole moment, μ_{EN}, is expressed by $(1+(E_-/2T)^2)^{-1/2}(\mu_0+(E_-/2T)\mu_1)$, where $\mu_0=-e\times\int b^-\sum_i \boldsymbol{r}_i a^- d\tau$ and $\mu_1=-e\int b^-\sum_i \boldsymbol{r}_i b^+ d\tau$. The μ_0 term will be proportional to the overlap integral between the half-occupied molecular orbitals of the dimer. In the weak interaction limit of $2|T|\ll I$, we have $E_-/2T\approx 2|T|/I$. In this case, the quantity involving the overlap integral will usually be rather small, and μ_{EN} may be approximated by $2|T|\mu_1/I$. The theoretical oscillator strength of the charge-transfer absorption, f, is proportional to $h\nu_{CT}\mu_{EN}^2\approx 4T^2\mu_1^2/I$, where we used the approximation $h\nu_{CT}\approx I$ in the limit of $2|T|\ll I$. Under the same condition, the singlet-triplet energy separation, δ, can be approximated by $\{(I/2)^2+(2T)^2\}^{1/2}-I/2\approx 4T^2/I$, so that we see that f is also proportional to δ.

^{1}H and ^{19}F NMR Study of *p*-Chlorobenzylidyne Trifluoride Partially Oriented in a Nematic Phase

Yuuji SUGINO and Kensuke TAKAHASHI*

Department of Industrial Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received March 23, 1978)

The ^{1}H and ^{19}F NMR spectra of *p*-chlorobenzylidyne trifluoride dissolved in a nematic phase of EBBA have been analyzed, and the structure of the proton and fluorine skeleton has been determined. No presice information about the anisotropy of the indirect F-F coupling can be given.

Since Saupe and Englert first observed the NMR spectra in liquid crystals, many studies have been reported in this area.[1-4] The method has also been applied to the molecules with internal rotation.[5-10] There are few studies, however, about the molecules containing ^{19}F nuclei with internal rotation.[11] We have analyzed the ^{1}H and ^{19}F NMR spectra of *p*-chlorobenzylidyne trifluoride in a nematic phase of EBBA (*N*-(*p*-ethoxybenzylidene)-*p*-butylaniline), and obtained the relative internuclear distances and the orientation parameters of this molecule in EBBA.

Experimental

The sample studied consisted of a 14 mol% solution of commercially available *p*-chlorobenzylidyne trifluoride in EBBA. It was contained in a 5-mm NMR sample tube and degassed by repeated freeze-pump-thaw cycles and then sealed *in vacuo*. The ^{1}H NMR spectra were observed with a Hitachi R-20B spectrometer operated at 60 MHz in the field sweep mode without locking. The ^{19}F NMR spectra were observed with the same spectrometer equipped with a R-203F-B attachment at 56.45 MHz in the frequency sweep mode with an external lock. The ^{1}H and ^{19}F spectra extended over about 9.7 and 11.5 kHz, respectively, and contained 40 and 25 resolved lines; all resolvable lines were used for the determination of the spectral parameters. In both cases the spectra were obtained at 31.0±0.5 °C and accumulated on a Hitachi Al600-A signal averaging analyzer; the line width of each signal was about 20 Hz. The resonance position of the signal was determined on each recording chart by interpolation: the sweep width was calibrated by either the frequency counter or the side-band method; the error was about 5 Hz. The calculation of spectral and structural analyses was made by a HITAC-8450 computer system located in this Institute or a FACOM-230-75 system located in the Computer Center of Nagoya University.

Results and Discussion

Analyses of the Spectra. The ^{1}H and ^{19}F spectra of the sample are center-symmetric and divided into two and three parts, respectively. The observed upfield ^{1}H and ^{19}F spectra consisted of 20 and 10 resolved lines, and are shown in Figs. 1-a and 1-b. The central part of the observed ^{19}F spectrum consisted of 5 strong lines. Analyses of the spectra were followed by a program LAOCN3+D, which includes the direct coupling constants as the spectral parameters. This was slightly modified from the original LAOCN3,[12] described by Diehl *et al.*[13] The indirect coupling constants were kept constant in the iteration calculation and the values were estimated by means of an additivity.[14,15] The spectral parameters thus obtained are shown in Table 1. The numberings of the nuclei are shown in Fig. 2.

TABLE 1. SPECTRAL PARAMETERS FOR *p*-CHLOROBENZYLIDYNE TRIFLUORIDE IN Hz[a]

Direct coupling[b]		Indirect coupling[c]	
D_{23}	−2282.74±0.16	J_{23}	8.40
D_{25}	28.29±0.17	J_{25}	0.38
D_{26}	204.60±0.70	J_{26}	2.31
D_{35}	203.97±0.69	J_{35}	2.19
D_{27}	−494.63±0.34	J_{27}	−0.74
D_{37}	−169.00±0.34	J_{37}	0.82
D_{78}	1480.46±0.14		

a) The numberings of the nuclei are given in Fig. 2. b) The errors shown in the Table are the probable program output errors. The differences between the D_{26} and D_{35} and between W(2) and W(3) are small and within the experimental error; they are not important. c) The parameters are taken from Refs. 14 and 15.

Analyses of the Molecular Structure. The parameters obtained in Table 1 were used to obtain the geometrical information about the sample. The following assumptions were made: 1. The trifluoromethyl group rotates freely around the C_1–C_7 bond; 2. The benzene ring forms a hexagonal plane and the C–C and C–H bond lengths can be taken as 1.397 and 1.084 Å;[16] 3. The molecular vibrations need not be taken into consideration; 4. Anisotropies of the proton-fluorine and proton-proton indirect couplings are negligible. Relations between the ratios of the inter-proton distances and the direct couplings are given by the following equations:

$$r_{35}/r_{26} = (D_{26}/D_{35})^{1/3}, \tag{1}$$

$$D_{23}(r_{23}/r_{26}) - D_{25}\{(D_{26}/D_{35})^{1/3} + (r_{23}/r_{26})^2\}^{5/2} = -D_{26}(D_{26}/D_{35})^{1/3}, \tag{2}$$

$$(r_{25}/r_{26})^2 = (D_{26}/D_{35})^{1/3} + (r_{23}/r_{26})^2. \tag{3}$$

The orientation parameters S_{xx} and S_{zz} are related to the D's and r's by[3]

$$S_{xx} = -(4\pi^2/h\gamma_H^2)D_{26}r_{26}^3, \tag{4}$$

$$S_{zz} = -(4\pi^2/h\gamma_H^2)r_{23}^3[D_{23} - (D_{26}/4)(r_{23}/r_{26})^{-5} \times \{(D_{26}/D_{35})^{1/3} - 1\}^2]/[1 - (1/4)(r_{23}/r_{26})^{-2} \times \{(D_{26}/D_{35})^{1/3} - 1\}^2]. \tag{5}$$

By means of these equations, the inter-proton distances

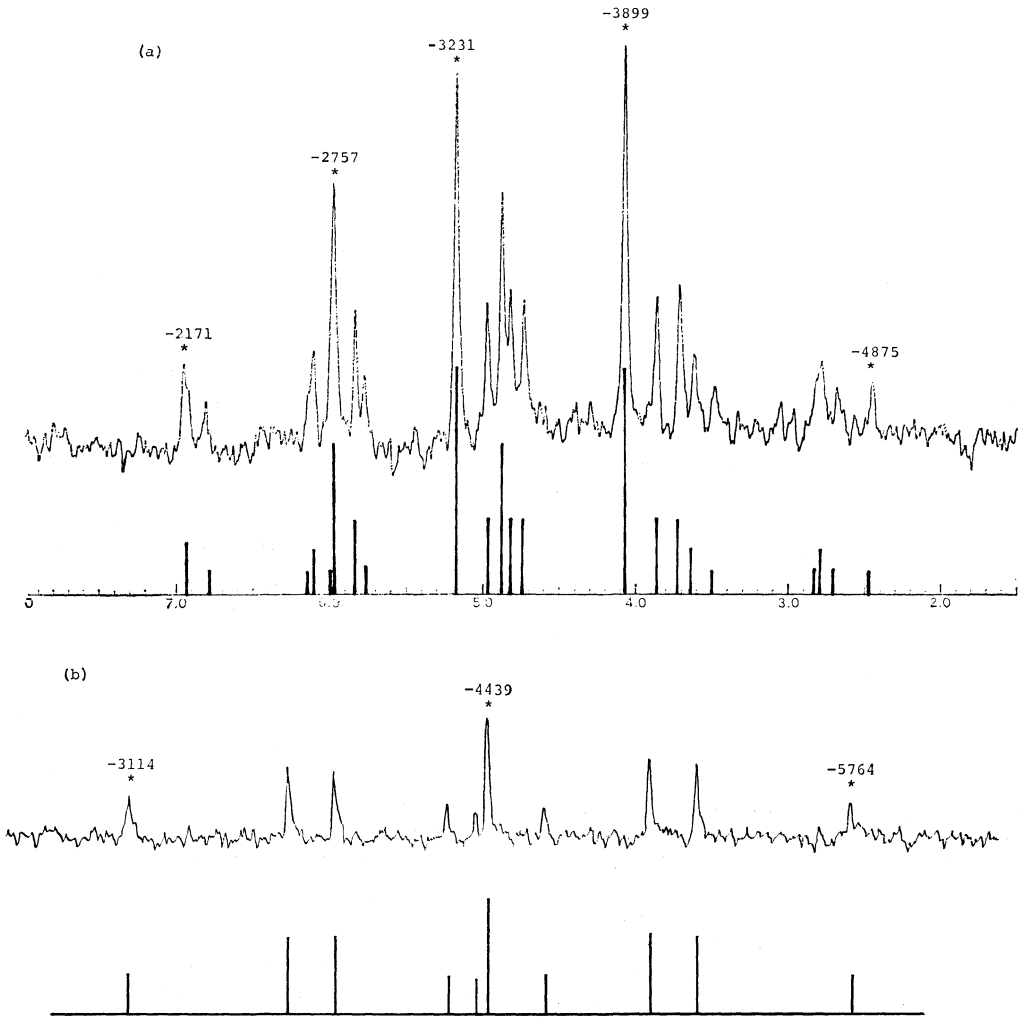

Fig. 1. Observed ^1H and ^{19}F NMR spectra of *p*-chlorobenzylidyne trifluoride dissolved in EBBA. Several peak positions are given in Hz with asterisk. Calculated stick spectra are also given under the observed one; (a) An upfield ^1H spectrum, accumulated 36 scans, (b) an upfield ^{19}F spectrum, accumulated 25 scans.

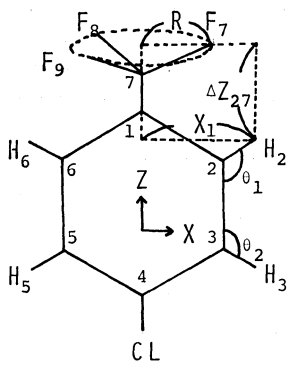

Fig. 2. Numbering system for *p*-chlorobenzylidyne trifluoride.

and the orientation parameters are determined as given in Table 2. The distances between the rotating trifluoromethyl fluorines and the protons are determined by the method used in Ref. 7. These values are also given in Table 2. The inter-proton distances obtained for the sample are similar to those obtained for benzene[16] (r_{23}=2.481, and r_{26}=4.297 Å)and a little different from those obtained for chlorobenzen[17] (r_{23}=2.509—2.465, r_{26}=4.297, and r_{35}=4.350—4.230) and benzylidyne trifluoride[11] (r_{23}=2.482, r_{26}=4.324, and r_{35}=4.298). The interfluorine distance obtained is smaller than that of benzylidyne trifluoride (r_{78}=2.165 Å).[11] Thus the radius of the circle formed by three fluorine nuclei is 1.228 Å, which is smaller than that of benzylidyne trifluoride (1.250 Å).[11]

TABLE 2. STRUCTURAL AND ORIENTATION PARAMETERS DERIVED FROM THE ^1H AND ^{19}F SPECTRA

r_{23}	2.481 ±0.003 Å
r_{26}	4.295 ±0.005 Å

S_{zz}	0.2902 ±0.0009

The Anisotropy of the Indirect Coupling. The D_{78} (or D_{FF}) coupling constant may contain a contribution from the anisotropy of the indirect coupling between the geminal fluorine nuclei. In the case of a trifluoromethyl group having a C_3 symmetry axis, the following relation has been reported:[3]

$$D_{78}^{exp} = D_{78}^{dir} + D_{78}^{ind}, \quad (6)$$

$$D_{78}^{ind} = S_{zz}\Delta J_{78}/3, \quad (7)$$

where

$$\Delta J_{78} = |J_{zz} - (J_{xx} + J_{yy})/2|_{78}.$$

J_{zz}, J_{xx}, and J_{yy} are the diagonal elements of the J-tensor. Due to the low accuracy of the determined r_{FF} distance in Table 2, the ΔJ_{FF} value can not be obtained uniquely. The anisotropy of J_{FF} is given as a function of r_{FF} in Table 3. The ΔJ_{FF} value shown in Table 3 is negative and this agrees with other reported values for CF_2 and CF_3 groups.[11,18,19]

The Crystal and Molecular Structures of (*SR*/*RS*)- and (*SS*/*RR*)-Dimethyl 2-(*p*-Tolylsulfinyl)-1,1-cyclopropanedicarboxylate

Fujiko Iwasaki,* Shuichi Mitamura,† and Gen-ichi Tsuchihashi†

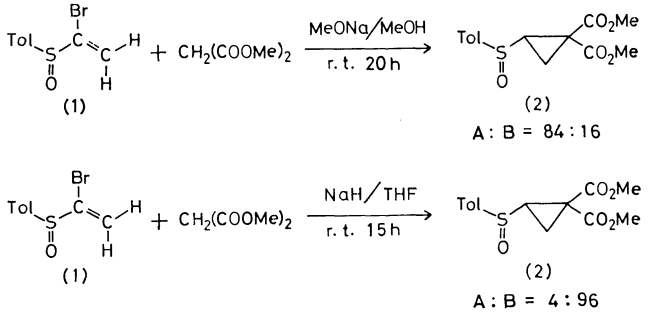
Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo 182

† *Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229*

(Received March 23, 1978)

The crystal structures of two diastereomers of dimethyl 2-(*p*-tolylsulfinyl)-1,1-cyclopropanedicarboxylate have been determined by the X-ray diffraction method. The configurations of these isomers have been elucidated to be (*SR*/*RS*) (**A**) and (*SS*/*RR*) (**B**). Crystals of **A** are monoclinic; the space group $P2_1/c$; $a=9.557$ (2), $b=18.400$ (5), $c=8.277$ (2) Å, $\beta=98.52$ (2)°, and $Z=4$. Those of **B** are triclinic; the space group $P\bar{1}$; $a=6.442$ (3), $b=18.243$ (8), $c=6.554$ (2) Å, $\alpha=90.59$ (4), $\beta=99.03$ (5), $\gamma=103.12$ (4)°, and $Z=2$. The structures were solved by the heavy-atom method and refined by the full-matrix least-squares method. The final R values were 0.063 for **A** and 0.050 for **B** respectively. Based on the established configurations and conformations of these isomers, a mechanism which involves the preferential formation of one of two diastereomers by the Michael addition of dimethyl malonate to 1-bromovinyl *p*-tolyl sulfoxide under specified reaction conditions is proposed.

The Michael addition of dimethyl malonate to 1-bromovinyl *p*-tolyl sulfoxide (**1**), with the concominant dehydrobromination, resulted in the formation of two diastereomers (isomer **A** and isomer **B**) of dimethyl 2-(*p*-tolylsulfinyl)-1,1-cyclopropanedicarboxylate (**2**). When the reaction was carried out in methanol in the presence of sodium methoxide, isomer **A** (mp 107—109 °C) was preferentially formed. On the other hand, the reaction in tetrahydrofuran (THF) in the presence of sodium hydride resulted in the exclusive formation of isomer **B** (mp 69—71 °C). Since the oxidation of these isomers gave the same sulfone, they should be diastereomers related to the chiral center of the sulfur atom.[1] An X-ray diffraction study was undertaken to establish the molecular conformations and configurations of these isomers in order to elucidate such a specific reaction mechanism.



Scheme 1.

Experimental

Each of the isomers, **A** and **B**, was recrystallized from a hexane-ethanol solution. The crystals of **A** are colorless needles elongated along the b axis. The crystals of **B** are colorless flat plates with developed form {010}. They are both stable in air. The crystal data of both isomers are listed in Table 1.

Intensity data for both isomers were collected on a Rigaku automatic diffractometer, with Cu $K\alpha$ radiation monochromatized by a graphite monochromator. Reflections in the range $2\theta \leq 120°$ were measured by scanning in the ω-2θ mode with a scanning width of $\Delta\omega = 1.0° + 0.5° \tan\theta$ and a scanning speed of $4° \text{ min}^{-1}$ in 2θ. Background was counted for 10 s at both ends of the scan range for each reflection. For **A**, 1458 reflections had $|F_o| > 3\sigma(F_o)$ and were considered as observed. For **B**, 1893 reflections were obtained with $|F_o| > 3\sigma(F_o)$. No absorption corrections were applied.

Structure Determination

For each isomer, a sharpened three-dimensional Patterson synthesis was calculated from which the coordinates of the sulfur atom could be determined. A sulfur-phased Fourier synthesis then made it possible to locate all the carbon and oxygen atoms. The structure was refined using the block-diagonal least-squares method. When the R values were 0.085 and 0.080 for isomer **A** and isomer **B** respectively, difference syntheses were calculated which revealed the positions of all the hydrogen atoms. All the atoms were refined with three cycles of the block-diagonal least-squares method and one cycle of the full-matrix least-squares method, using anisotropic temperature factors for non-hydrogen atoms and isotropic ones for hydrogen atoms. The anomalous dispersion effect on the sulfur atoms was taken into consideration. The quantity minimized was $\Sigma w(|F_o| - k^{-1}|F_c|)^2$, where $w = 1/\sigma^2(F_o)$, as derived from the counting statistics. The final R values are 0.063 for **A** and 0.050 for **B**. The

Table 2. Atomic parameters with their estimated standard deviations of **A**

(a) Atomic coordinates and thermal parameters of non-hydrogen atoms. ($u_{ij} = 10^3 U_{ij}/\text{Å}^2$)
The anisotropic temperature factors are of the form:
$\exp\{-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*)\}$.
The B_{eq} values are the equivalent isotropic temperature factors.

atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[2] The final atomic parameters and their estimated standard deviations are given in Tables 2 and 3. The observed and calculated structure factors are listed in Tables 4 and 5.[3]

Results and Discussion

Crystal Structures. The crystal structures of **A** and **B** are shown in Figs. 1 and 2 respectively. The distances of the molecular contacts are listed in Table 6.

The analyses established the configurations of the two diastereomers as (S_SR_C/R_SS_C) for **A** and (S_SS_C/R_SR_C) for **B**.

The packing arrangements of these two isomers are entirely different because of their different molecular geometries. These contacts are of the van der Waals type, but in each isomer relatively short contacts are observed between different groups. For **A**, the short contacts are found between the oxygen atom O(4) and the sulfur and C(2) atoms (C(2)···O(4^{v}), 3.162 Å; S···O(4^{v}), 3.631 Å). The short contacts of **B** are those between sulfinyl oxygen and carbon atoms of the tolyl group (O(1)···C(5^{ii}), 3.056 Å; O(1)···C(6^{ii}), 3.212 Å) and between methoxycarbonyl groups (O(2)···O(2^{vi}), 3.271 Å; O(2)···C(11^{vi}), 3.199 Å).

Molecular Structures. Figure 3 shows stereoscopic views of the **A** and **B** molecules. The bond lengths and angles, with their estimated standard deviations, are listed in Table 7. Deviations from the least-squares planes are listed in Table 8. The projections of the molecules onto the cyclopropane ring, with the numbering of atoms and some intramolecular nonbonding distances, are shown in Fig. 4.

The molecular dimensions of the two isomers almost agree with each other within the limits of experimental error, although the conformations and configurations of these molecules are quite different. The S–O distance of **B** (1.485 Å) is slightly shorter than that of **A** (1.497 Å), although these distances are close to those in other sulfoxides.[4–6] The S–C(2) distance

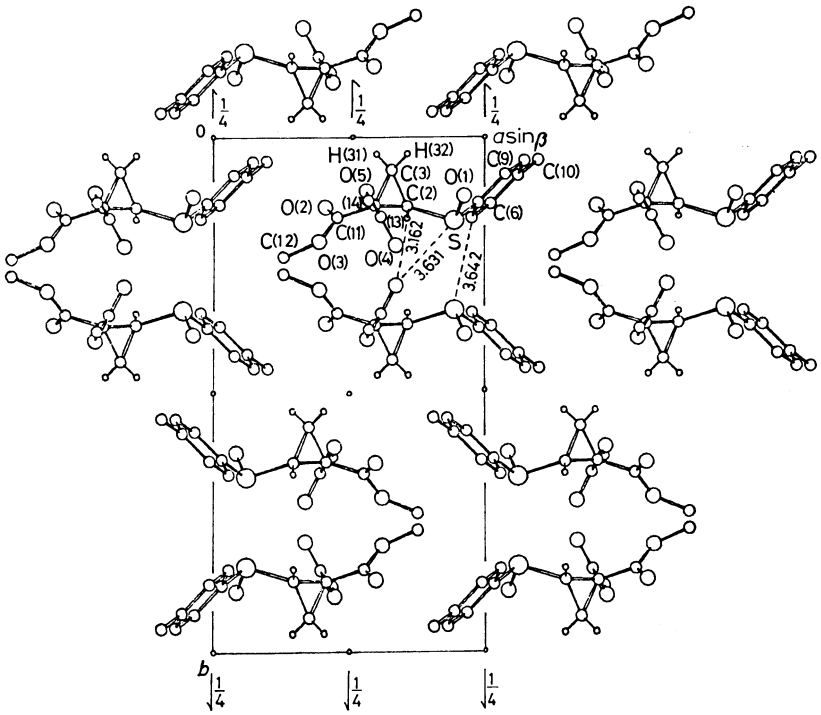

Fig. 1. Projection of the structure of **A** along the c axis.

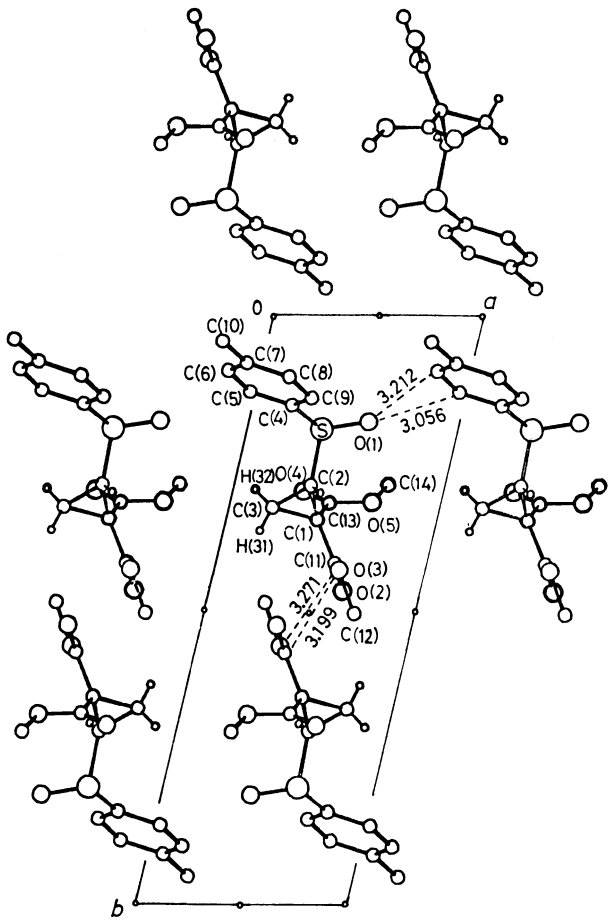

Fig. 2. Projection of the structure of **B** along the c* axis.

(1.806 Å) of **A** is significantly longer than that of **B** (1.767 Å). The former length agrees with the S–C length of (+)methyl *p*-tolyl sulfoxide.[5] The difference in S–C(2) between **A** and **B** is attributable to the conformational difference between **A** and **B**, the difference in non-bonding intramolecular contacts between sulfoxide and cyclopropane rings. The non-bonding distances, O(1)···C(3) are 2.979 and 3.960 Å for **A** and **B** respectively. The S–C(4) lengths (1.774 Å for **A**, 1.786 Å for **B**) are very close to those of other *p*-tolyl sulfoxides. The O(1)SC(2), O(1)SC(4), and C(2)SC(4) angles of both isomers have normal values of sulfoxides.

The average C–C distances in the cyclopropane rings are 1.486 and 1.500 Å for **A** and **B** respectively, virtually the same as those in cyclopropanecarbohydrazide (1.497 Å)[7] and cyclopropanecarboxamide (1.498 Å)[8] and slightly less than those in 1,1-cyclopropanedicarboxylic acid (1.510 Å).[9] The individual C–C lengths within the ring are remarkably different, however, the C–C lengths involving the carbon atom C(1), which connects the methoxycarbonyl groups, are longer than that of the 'back ring' bonds, C(2)–C(3) (1.462 Å for **A**, 1.475 Å for **B**). Such shortenings of the back-ring bonds with respect to the average ring-bond lengths have been found in 1,1-cyclopropanedicarboxylic acid (1.462 Å) and also cyclopropanecarboxamide (1.481 Å). The C(2)C(1)C(3) angles are slightly smaller than the other two intra-ring bond angles.

The SC(2)C(1) and SC(2)C(3) angles of both isomers are almost the same, but the angles related with the C(1) atoms and methoxycarbonyl groups, especially C(2)C(1)C(11), C(2)C(1)C(13), and C(3)C(1)C(13), are significantly different between **A** and **B**. Each

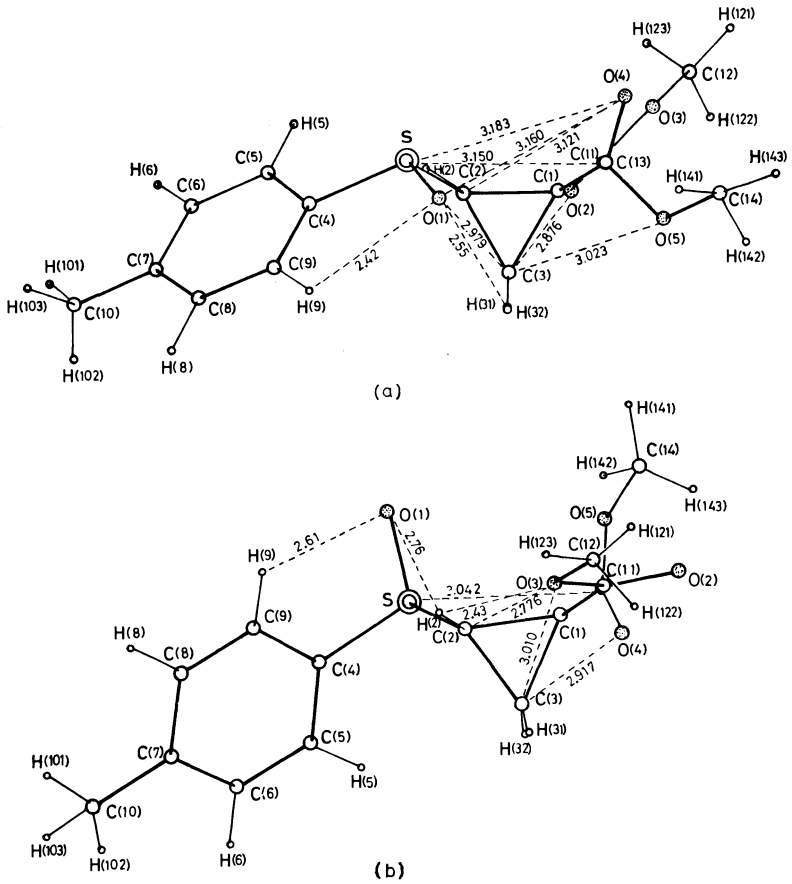

Fig. 4. Projections of the molecules onto the cyclopropane ring with the numbering of atoms and some intramolecular non-bonding distances. (a) The isomer **A**, (b) the isomer **B**.

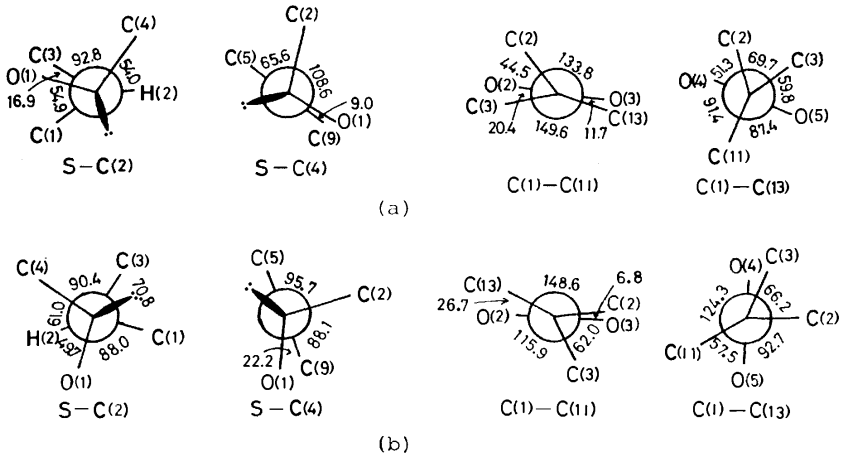

Fig. 5. Torsion angles in the molecules. (a) **A**, (b) **B**.

methoxycarbonyl group except the methyl group is planar. The angles between two planar C–C$\langle^{O}_{O}$ groups are 86.7° for **A** and 70.0° for **B**. For both isomers two methoxycarbonyl groups are non-equivalent to the cyclopropane ring. The dihedral angle between planes of the cyclopropane ring and the methoxycarbonyl group, being *trans* to the sulfinyl group about C(1)–C(2), is 93.4° for **A**. On the other hand, the angle between the cyclopropane ring and the *cis* methoxycarbonyl group is 53.3° for **A**. The corresponding values for **B** are 77.1 and 65.6° respectively. In the molecules of cyclopropanecarboxamide and 1,1-cyclopropane-dicarboxylic acid and other related compounds, the planes of the substituents are nearly perpendicular to the ring plane, and the oxygen atom lies over the three-membered ring. In the present case, the conformation of the *trans* methoxycarbonyl group for each isomer is similar to that in those compounds. The intramolecular O(2)···C(2) and O(2)···C(3) distances are 2.923 and 2.876 Å for **A** and O(3)···C(2) and O(3)···C(3) are 2.776 and 3.010 Å for **B**. The conformations of *cis* methoxycarbonyl groups are different from those of trans groups; the oxygen atoms are not pointed towards the cyclopropane ring, especially in the case of **A**. This may be due to the steric interaction between sulfinyl and methoxycarbonyl groups. The dimensions of the methoxycarbonyl groups are comparable with those of dimethyl α,α'-dimethyl-β,β'-dibromoadipate and the related compounds.[10]

Molecular Conformations. The torsion angles of the groups around the S–C(2), S–C(4), C(1)–C(11), and C(1)–C(13) bonds are shown in Fig. 5. The sulfinyl oxygen is *cis* to one of the carbon atoms, C(9), in the tolyl ring across the S–C(4) bond in each isomer. This conformation is similar to that of other *p*-tolyl sulfoxides.

For **A**, the hydrogen atom, H(2), is *trans* to the sulfinyl oxygen, O(1), and also *gauche* to the lone-pair orbital of the sulfur atom across the S–C(2) bond. On the other hand, H(2) is *gauche* to O(1) and *trans* to the lone-pair orbital of the sulfur in the case of **B**. The configuration of **A** is determined to be *S* at the sulfur atom and *R* at C(2), or *R* at sulfur and *S* at C(2). The configuration of **B** is S_SS_C or R_SR_C.

Since the configuration at the sulfur atom is considered to be retained during the course of the reaction,[1,4] an inspection of the molecular structures of these two isomers reveals the stereochemical pathway of the present reaction. The following reaction scheme will account for the formation of cyclopropane, **2**: the Michael addition of dimethyl malonate to **1** initially gives α-sulfinyl carbanion, **3**, which then turns into the more stable carbanion **4**. Then, the intramolecular S_N2 reaction of **4** proceeds, with the inversion of the configuration at C(2), to yield cyclopropane, **2**, as the final product. According to this reaction scheme, the crucial step in determining the stereochemistry of the whole reaction is the proton transfer, namely, the reaction from **3** to **4**. Thus, the dominant formation of isomer **A** in the sodium methoxide–methanol system is ascribed to the preferential formation of carbanion **4a**. The preference of **4a** is due to the conformational stability of the corresponding α-sulfinyl carbanion, **3a**, the electron lobe of which is located at the position *trans* to the sulfinyl oxygen. On the other hand, the exclusive formation of isomer **B** in the sodium hydride–THF system is attributed to the formation of **4b**, and

therefore the stability of the α-sulfinyl carbanion, **3b**, the electron lobe of which is *gauche* to the sulfinyl oxygen. The conformational stability of the carbanion, **3b**, in the sodium hydride–THF system may be caused by the chelation between the counter cation, *i.e.*, Na^+, and the sulfinyl oxygen in a nonpolar solvent such as THF. The difference in these conformational stabilities of the carbanion adjacent to the chiral sulfinyl group under various reaction conditions accords with the Michael addition of diethyl malonate to (+)-(*R*)-*trans*-styryl *p*-tolyl sulfoxide[1] and the studies of the conformational stability of the carbanion adjacent to the chiral sulfinyl group.[11]

All the crystallographic computations were performed on a HITAC 8700/8800 computer of the Computer Center of the University of Tokyo, using the local version of the program system UNICS.[12] Figures 1, 2, and 3 were drawn by using the program ORTEP.[13]

The authors wish to express their thanks to Dr. Ei-ichi Asada and Mrs. Midori Goto, of the National Chemical Laboratory for Industry, for the use of the X-ray diffractometer.

The Phosphate on the Iron Core of Horse Spleen Ferritin as Studied by a ^1H NMR Probe Method

Noboru IMAI,* Haruo TERADA, Yoji ARATA, and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received April 20, 1978)

Glycylglycylglycylglycine and tetramethylammonium chloride have been used as ^1H NMR probes to study the state and role of the phosphate on the surface of the iron core of ferritin. ^1H NMR signals of the probe molecules in a ferritin solution do not show any observable paramagnetic shift, and the linewidths are very small compared to an aqueous iron(III) solution which contains the same amount of iron. Iron of ferritin is markedly different from that of aqueous iron(III), but quite resembles that of synthetic iron polymer. It has been shown that the parameter k, which is the linewidth for the NMR probe divided by the concentration of iron, is dependent on the content of the phosphorus in ferritin. The k value for glycylglycylglycylglycine has a maximum in the physiological pH range 6—7, whereas that for tertramethylammonium chloride in which the charge does not change in the whole pH range gives a sigmoidal curve. From the pH dependence of the k values for tetramethylammonium chloride, the pK_a value of the phosphate group on the surface of the iron core has been estimated at 7.0 ± 0.2.

Ferritin, an iron storage protein distributed widely in both plant and animal kingdoms, consists of a shell of protein subunits surrounding the iron core which contains up to approximately 4000 iron atoms.[1,2] Several methods such as X-ray diffraction,[3] electron microscopy,[4,5] and neutron scattering[6] have so far been applied for the investigation of the structure of the iron core. The magnetic properties of the iron core have also been studied by the measurements of magnetic susceptibility[7,8] and Mössbauer effect.[9] It is well established that about 1 to 1.5% phosphate is contained in the iron core, and it has been suggested that the concentration of the phosphate group is higher on the surface than in the inner part of the iron core.[3,10] It has also been suggested that the negatively charged phosphate group is acting as a *go-between* for the binding of the iron core to the protein shell.[1]

Silk and Breslow[11] have carried out the potentiometric titration of apoferritin and ferritin, and observed that ferritin is more stable than apoferritin in the pH range 2.3—3.0, and above pH 8, there exists a large difference in the titration behavior between the two proteins. They have also shown that, compared to apoferritin, ferritin has two more groups per protein subunit which dissociate reversibly in the pH range 5.5—7.5, and concluded that these additional groups are the phosphate group on the iron core. In the present work, high resolution nuclear magnetic resonance (NMR) is used to investigate the structure and magnetic properties of the iron core of ferritin with emphasis on the phosphate group. Because of the large size of the molecule (molecular weight, 445000) and the existence of a large amount of paramagnetic iron, any NMR signal from the protein shell of the native ferritin cannot be detected; only ^1H signal observed is of the solvent water. ^{31}P NMR signal of the phosphate group was also not observable.

In a method presented in this paper, tetramethylammonium ion, glycylglycylglycylglycine, and water are used as the NMR probe to obtain information about the surface of ferritin. When the probe molecules are in close contact with the iron core of ferritin, the NMR signals of the probes are broadened as a result of the magnetic dipolar interactions. The dipolar interactions are strongly influenced by the electrostatic interactions between the probe molecules and the surface of ferritin. In view of this, we use tetramethylammonium ion with a positive charge throughout the pH range examined, and glycylglycylglycylglycine which has at the physiological pH a negative and positive charge at the N and C terminals of the peptide chain, respectively. The water molecule is also used as a neutral probe. On the basis of these experiments, the dissociation constant of the phosphate group on the surface of the iron core will be estimated.

Experimental

Materials. Horse spleen ferritin (crystallized twice, Cd free) was purchased from Nutritional Biochemicals Corporation (lot No. 4871 and 4493), and dialyzed against distilled water before use. Tetramethylammonium chloride, glycylglycylglycylglycine and other reagents used are of reagent grade. Polymeric iron hydrolysate (hereafter designated as iron polymer) was prepared by adding 0.5 M $NaHCO_3$ and 0.05 M NaOH to a 0.03 M ferric citrate solution; the iron polymer thus produced was isolated on a column of Bio-Gel P-30.[12] Iron polymer was also prepared by heating a 0.02 M solution of ferric nitrate at 80—85 °C for 10—20 h, followed by dialysis of the resultant solution.[13]

Analysis. The concentration of iron in ferritin preparations were determined by atomic absorption. No attempt was made to decompose the iron core before the samples were subject to atomic absorption. The iron content determined in this way is in excellent agreement with that obtained by atomic absorption with the iron core decomposed by reducing it with sodium sulfite. The result is also consistent with the value determined colorimetrically by using 2,2′-bipyridyl.[14] Protein concentrations were determined by the Lowry method,[15] and the concentration of the phosphate by a colorimetric method using ammonium molybdate and ascorbic acid.[16]

Instruments. ^1H NMR spectra were recorded using a JEOL PS-100 spectrometer operating at 100 MHz.

Methods. NMR spectra of glycylglycylglycylglycine (Gly_4) were measured in D_2O; in H_2O, due to the NH protons of the amino groups, the signals from the methylene protons of Gly_4 become complicated. The spectrum of tetramethylammonium chloride (TMA) was observed in H_2O. The concentrations of Gly_4 and TMA were constant throughout the experiments (10 mM). The concentration of ferritin in sample solutions was adjusted in either of the following two ways:

1) A small amount of a stock solution of ferritin at high concentrations (approximately 0.2—0.4 M as iron) was added to a Gly_4 or TMA solution. 2) Ferritin solutions were dialyzed against a glycine–HCl buffer solution which contains 10 mM TMA, and iron concentration of the solution was determined after dialysis. In all experiments described in the present work, the pH was changed by dialyzing a solution for 24 h against a 10 mM glycine–HCl buffer, and the dialyzed ferritin solution was added to a 10 mM Gly_4 or TMA solution where the pH was pre-adjusted to that of the ferritin solution added; before and after this treatment, very little change in pH is observed.

Results

^1H NMR Signals of the Solvent H_2O Containing Ferritin and Synthetic Iron Polymer. The H_2O proton signals of aqueous iron(III) solution, ferritin, and synthetic iron polymer solution are reproduced in Fig. 1. ^1H NMR signals of H_2O containing varying amounts of ferritin have the following common features. First, the signal is shifted to high field from that of pure H_2O. Presumably, this is because the bulk susceptibility of ferritin solutions is increased by the presence of a large quantity of paramagnetic iron. The observed difference in chemical shift between the ferritin solution and water would give the bulk magnetic susceptibility of the ferritin iron in water.[17] The result obtained was 3.8 μ_B. This value can be compared to that of Michaelis, 3.7—3.9 μ_B, which was obtained by using powder samples.[7] Second, the H_2O signal in ferritin solutions does not show any paramagnetic shift in the concentration range 0—0.4 M (as iron). This observation is in a marked contrast with a large paramagnetic shift which is observed in an aqueous iron(III) ion solution. Third, the linewidth of the H_2O signal of ferritin solutions is only about 2.5% of that for an aqueous iron(III) solution ($Fe(ClO_4)_3$/2 M $HClO_4$; solution 2, Fig. 1) which has the same iron concentration. Table 1 shows the paramagnetic shifts and linewidths of the H_2O signals of 0.05 M iron(III) and iron(II) solutions. The water signal of aqueous iron(III) solutions (d^5, high spin) always has very large linewidths (200—400 Hz); even a iron(III)–EDTA complex gives a linewidth of the water signal of larger than 100 Hz. It should also be noted that paramagnetic shifts are very small, if any, in the case of ferritin and synthetic iron polymers, whereas they are in the range of 100—200 Hz in the case of aqueous iron(III) and iron(II) solutions.

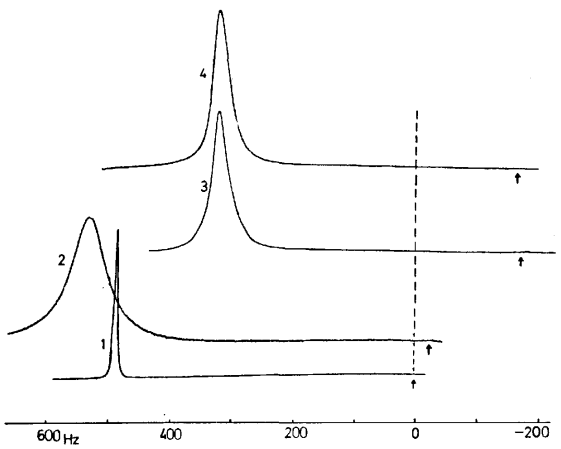

Fig. 1. ^1H NMR spectra of H_2O of 1: pure water, and aqueous solutions containing, 2: ferric ion (0.010 M $Fe(ClO_4)_3$/2 M $HClO_4$), 3: ferritin (0.11 M as iron, pH 7.4), and 4: iron polymer (0.13 M as iron pH 5.5). Arrows indicate the position of the peak of DSS used as internal reference. Locking on external H_2O was used in order to observe a relative shift of the DSS peak in spectra 2, 3, and 4 with respect to that for pure water. The observed shift presumably reflects a change in bulk magnetic susceptibility of the aqueous solutions.

Table 1. The paramagnetic shifts and the linewidths of H_2O solutions containing aqueous iron(III) and iron(II) ions, synthetic iron polymers and ferritin[a]

	Paramagetic shift (Hz)[b]	Linewidth (Hz)[b]
$Fe(ClO_4)_3$/2 M $HClO_4$	224	405
$FeCl_3$/2 M HCl	172	192
$Fe(NO_3)_3$/2 M HNO_3	194	385
$FeSO_4(NH_4)_2SO_4$/2M H_2SO_4	143	12
Fe(III)–EDTA	52	114
Ferritin	≈0	13
Iron polymer	≈0	11

a) The concentration of iron is 0.05 M in all cases.
b) Accurate to ±2 Hz.

As shown in Table 1, the iron polymer markedly resembles the iron core of ferritin; the H_2O signal of solutions of the iron polymer exhibits no paramagnetic shift and the linewidth is quite small. From the chemical shift of the H_2O signal, the magnetic susceptibility of the iron polymer of iron(III) citrate was estimated at 3.5 μ_B.

^1H NMR Spectra of Gly_4 and TMA in the Presence of Ferritin, Synthetic Iron Polymer, and Aqueous Iron(III) Ion. In order to compare more closely the different types of iron mentioned above, a small peptide Gly_4 was used as an NMR probe. Four peaks which correspond to the four kinds of the methylene protons (which from the N terminal will be designated as N, N2, N3, and C) can be observed separately in D_2O. The spectra of Gly_4 in the presence of either one of the three kinds of iron, *i.e.*, aqueous iron(III) ion ($Fe(ClO_4)_3$), ferritin, and synthetic iron polymer, are shown in Fig. 2. Upon adding an aqueous iron(III) solution, differential broadening of the four methylene peaks are clearly observed; the peak from the C terminal first becomes broad. Each of the four methylene peaks shows paramagnetic shift as shown in Fig. 2, A. In contrast to this, when ferritin is added, all four peaks become broader almost uniformly, without any paramagnetic shift. The dependence of the chemical shifts of the Gly_4 signals is plotted in Fig. 3 as a function of the iron concentration.

In the case of the ferritin solutions, although all lines are almost uniformly broadened, the peak from the N terminal broadens a little faster than the others

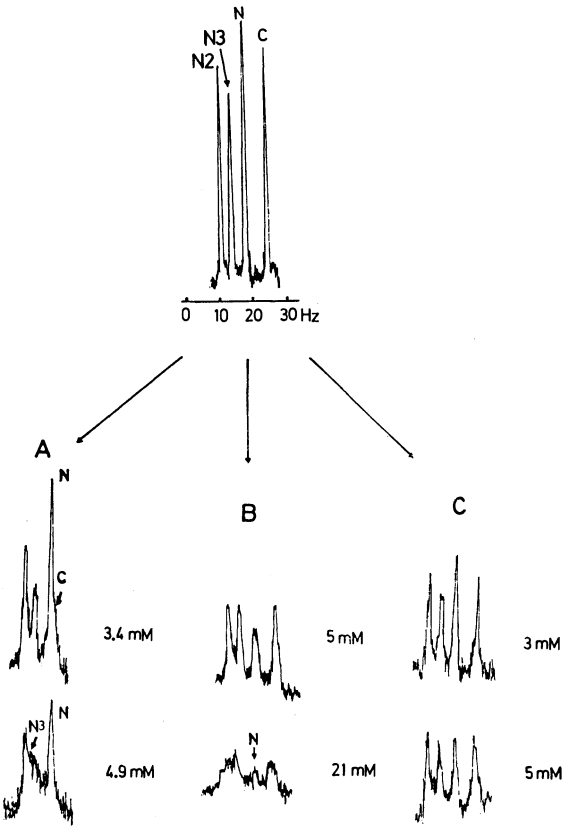

Fig. 2. ^1H NMR spectra of Gly_4 in D_2O in the presence of either one of the three kinds of iron. A, aqueous iron(III) ion ($Fe(ClO_4)_3$), pH 6.8; B, ferritin, pH 6.8; C, synthetic iron polymer, pH 6.8. The concentrations of iron added, and the assignment of the peaks are shown in the figure.

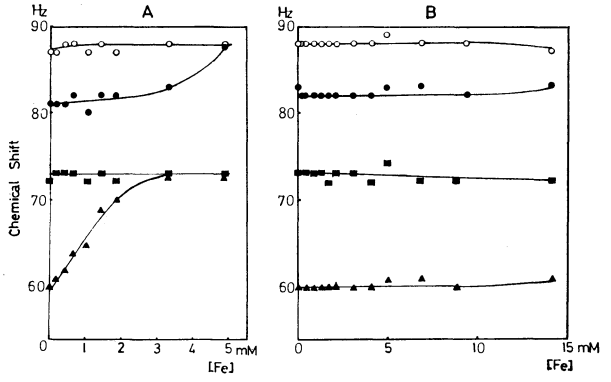

Fig. 3. The dependence of the chemical shifts of the Gly_4 signals as a function of the concentration of iron. (A) aqueous iron(III) ion, (B) ferritin. ▲, C terminal peak; ■, N terminal peak; ●, N3 peak; ○, N2 peak.

(Fig. 4, B). It has been confirmed that the linewidth of the NMR probes examined is not influenced by the presence of apoferritin. This means that the line broadening of the NMR probes is independent of the protein part, and therefore a contribution from the iron core can be observed separately by NMR. In view of this result, the paramagnetic contribution for each peak may be represented quantitatively by using the slope which is obtained from the relation between the

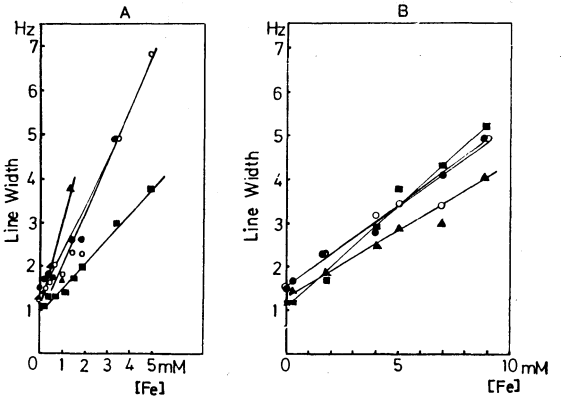

Fig. 4. The linewidths of the Gly_4 signals as a function of the concentration of iron. (A) aqueous iron(III) ion, (B) ferritin. ▲, C terminal peak; ■, N terminal peak; ●, N3 peak; ○, N2 peak.

iron added and the linewidths of the peaks. The observed linewidth ΔH_{obsd} may be written as follows:

$$\Delta H_{obsd} = \Delta H_0 + \Delta H_p, \quad (1)$$

where ΔH_0 is the intrinsic linewidth of each peak and ΔH_p represents the paramagnetic contribution. In the case of fast exchange where exchange between molecules which are under the influence of the iron core, and those which are free in solution is fast enough, the paramagnetic term (ΔH_p) should increase linearly with the iron concentration added. In this case, $k=\Delta H_p/C$ which represents a normalized paramagnetic contribution should be constant, and therefore Eq. 1 may be written as

$$\Delta H_{obsd} = \Delta H_0 + kC. \quad (2)$$

In Fig. 4 the observed linewidths are plotted as a function of the concentrations of iron added. The slopes k obtained from Fig. 4 may be considered as representing the binding ability of Gly_4 to ferritin, and therefore may be used to estimate the binding constant of Gly_4 with iron. The k values obtained are summarized in Table 2. In view of the fact that the k value for the C terminal protons is largest in an aqueous iron(III) solution and that the peak from the C terminal exhibits a largest paramagnetic shift, it is obvious that an aqueous iron(III) ion forms a complex with the carboxyl group of Gly_4. In the case of ferritin solutions, the slopes for the four peaks of Gly_4 are all small, and almost equal to each other. The slope for the N terminal protons are slightly larger than that of the C terminal

TABLE 2. THE OBSERVED k VALUES FOR Gly_4 IN H_2O SOLUTIONS OF AQUEOUS IRON(III) ION AND TWO DIFFERENT FERRITIN PREPARATIONS WHICH CONTAIN A DIFFERENT AMOUNT OF THE PHOSPHATE

	N2	N3	N	C

Ferritin[a)]	0.39	0.53	0.45	0.30
Ferritin[b)]	0.06	0.06	0.11	0.08

a) P/Fe=0.10. b) P/Fe=0.08.

protons. This result may be interpreted in terms of the existence of the negative charge of the phosphate group on the surface of the iron core.

For the sake of comparison, a synthetic iron polymer which does not contain any phosphate group, and also a different batch of ferritin which contains a less amount of the phosphate were examined. It has been confirmed that in the case of the iron polymer, the N-terminal peak is less broad than others as shown in Fig. 2, C. It is shown in Table 2 that the k values for the Gly_4 peaks in the presence of ferritin containing a less amount of phosphate are much smaller, and that the difference in k between the N and C terminal peaks becomes small. Furthermore, it was confirmed that the linewidth of the solvent H_2O signal is independent of the concentration of phosphate in the iron core. Therefore, it may be concluded that the broadening of the Gly_4 peaks is due to the existence of the negative charge of the phosphate on the surface of the iron core. The titration curve of k for Gly_4 shown in Fig. 5 indicates that the curve has a maximum and decrease above pH 7. Most probably, this is because the amino group of Gly_4 loses its charge at high pH and as a result of this, the interaction between Gly_4 and ferritin becomes weaker in this pH range. TMA in which the charge does not change in the whole pH range was used at the same time as a reference, and the results are given in Fig. 6.

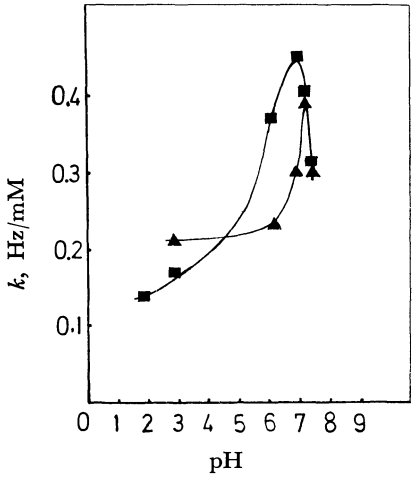

Fig. 5. The titration curve of the k values for Gly_4. ▲, C terminal peak; ■, N terminal peak.

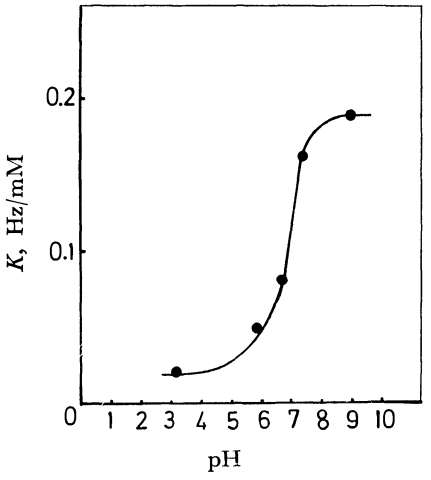

Fig. 6. The titration curve of the k values for tetramethylammonium ion.

The lienwidths of the peaks for Gly_4 are designated as ΔH_{mono} and ΔH_{di} when the phosphate group exists as mono- and di-anion, respectively. The fraction of the dianion is denoted by x. Then, the observed linewidth in the presence of ferritin may be given by

$$\Delta H_{obsd} = \Delta H_{mono} \cdot (1-x) + \Delta H_{di} \cdot x. \quad (3)$$

This equation is normalized by dividing it by C.

$$k_{obsd} = k_{mono} \cdot (1-x) + k_{di} \cdot x$$
$$= k_{mono} + (k_{di} - k_{mono}) \cdot x, \quad (4)$$

where C is the concentration of ferritin (as iron), $k_{obsd} = \Delta H_{obsd}/C$, $k_{mono} = \Delta H_{mono}/C$, $k_{di} = \Delta H_{di}/C$. A plot of k_{obsd} as a function of pH should represent the dissociation of the phosphate, and therefore give the pK_a of the phosphate group. From the plot in Fig. 6 obtained for TMA, a pK_a of 7.0 ± 0.2 for the phosphate is obtained. It is quite interesting that the value obtained is close to $pK_a = 7.2$ which has been reported for the second dissociation of an inorganic phosphate ion. In the case of Gly_4, the pH dependence of k is shown in Fig. 5. The curve for Gly_4 has a maximum in the pH range 6—7, suggesting that the interaction between Gly_4 and the phosphate becomes strongest in this pH range. In this narrow pH range, the slope for the C terminal methylene peak is much smaller than that for the N terminal. This suggests that in this pH range the positive charge of the amino group of Gly_4 is attracted to the negative charge of the phosphate group on the iron core.

Discussion

As mentioned previously, the linewidth of the H_2O signal in ferritin solution is quite small, and only about 2.5% of that for an aqueous iron(III) solution which contains the same amount of iron. The H_2O signal of ferritin solutions markedly resembles that for a solution containing synthetic iron polymer. This result suggests that the number of iron(III) ions which are in contact with water becomes very small when the ions polymerize, forming a large iron core. Therefore, a change in the surface area should greatly influence the linewidth. In the case of the ferritin preparation (lot No. 4871) used in most of the present experiment, the ratio of iron to protein is 0.20. The iron core is assumed to be spherical in shape; then in a close packing model[3], the radius of the sphere would be 24 Å and the core could contain 1600 iron atoms. This means that the average surface area per iorn atom of the iron core is about 1/16 of that for a free iron(III) ion. In addition to this, there is a difference in magnetic susceptibility between an aqueous iron(III) ion (5.9 μ_B) and ferritin iron (3.8 μ_B). Therefore, if the linewidth solely due to dipolar interactions between H_2O and the electron spin of iron, a factor of $(3.8/5.9)^2 = 0.41$ should also be considered for the linewidth of the NMR probes.[18] In the above simple model, a total reduction in linewidth becomes 2.4% ($1/16 \times 0.41 \times 100$) which

agrees well with the observed value. A quite similar result has been obtained in the case of a different batch of ferritin preparation (lot No. 4493). Although the quantitative agreement may be fortuitous, it appears that the observed linewidths may be accounted for by the above simple model.

It has been confirmed that the linewidth of the NMR probes examined is not influenced by the presence of apoferritin. This means that the line broadening of the NMR probes is independent of the protein part, and therefore a contribution from the iron core can be observed separately by NMR. In this respect, the present experiment using the NMR probes is essentially different from that by Silk and Breslow who using potentiometry attempted to acquire information concerning the phosphate on the iron core.[11] Since all dissociable groups are observed together in potentiometry, it is generally difficult to distinguish the dissociation in protein from that in the iron core. In fact, they assigned a group which dissociates in the pH range 5.5—7.5 to either histidine in the protein part, or the phosphate group on the iron core. Since the results obtained in potentiometry are based on the difference of the titration curves between ferritin and apoferritin, it is necessary to assume that in the whole pH range examined a difference in conformation between the two proteins, if any, does not influence the titration behavior. However, there is evidence on the basis of circular dichroism spectra that there is actually a difference in conformation in the two proteins.[19] These ambiguities do not occur in using the NMR probe method where information concerning the iron core can be obtained separately.

Evidences which support the role of the phosphate on the broadening of the NMR probes may be summarized as follows: 1) Broadening of the N terminal peak of Gly_4 occurs faster than that of the C terminal peak, indicating broadening of the Gly_4 signals is influenced by the negative charge. It should also be noted that the difference in broadening between the C and N terminal peaks becomes particularly larger in the pH range where the phosphate group dissociates. 2) In the case of the iron polymer which does not contain any phosphate group, the N terminal peak becomes equally broad as the C terminal peak. 3) In a ferritin preparation which contains less phosphate, the broadening of the Gly_4 peaks is less extensive. 4) The linewidth of the H_2O peaks remains constant in the pH range 2—10. From these results it is clear that the broadening of the Gly_4 peaks is primarily due to the phosphate group on the iron core. The protein part of ferritin also has the negative charge. However, the positive and negative charges are distributed over the surface of the protein, and effective negative net charge is -2——-6 in the pH range 5.5—7.5.[11] In contrast to this, the number of phosphate groups in one ferritin molecule is about 290 for the ferritin preparation (lot No. 4493) where the ratio iron/protein is 0.20 and phosphorus/iron is 0.10. If four fifth of these phosphate groups is assumed to exist on the surface of the core,[3] the number of charge on the core is more than two hundred, and becomes twice when the phosphate groups dissociate above pH 7. This result along with more extensive study using a variety of NMR probes now in progress in this laboratory further confirms that the NMR probe method presented here is quite useful in investigating in detail the surface of the iron core.

It should also be pointed out that when the pH of ferritin solutions is adjusted by adding acid or base directly to the solutions as performed in Silk and Breslow's experiments, it is quite likely that the quaternary structure of ferritin is perturbed, particularly in the high and low pH range.

It should be noted that Gly_4 interacts with ferritin most strongly at pH 6—7, and the interaction becomes weak with an increase or decrease in pH (see Fig. 5). In view of this result, it appears that the phosphate on the surface of the iron core interacts with the amino groups on the inner surface of the protein shell, playing a role to bind the iron core to the protein. It is quite interesting that the interaction between Gly_4 and ferritin becomes maximum at pH 6—7, the physiological pH which would be favorable for the binding of the iron core to the inner surface of the protein.

Application of Gel Chromatography to the Determination of the Stability Constants of a Magnesium Complex with Diphosphate

Tohru MIYAJIMA* and Shigeru OHASHI

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashiku, Fukuoka 812

(Received July 29, 1977)

Hummel-Dreyer's method was examined for its applicability to inorganic complexes, and a modified method was proposed. A sample solution containing magnesium and diphosphate was eluted with magnesium chloride solution on a gel column. The change of magnesium concentration in an effluent was measured with an atomic absorption detector. From the peak area of the eluted complex the stability constants ($\lg \beta_1$) at $I=0.1$ and 25 °C were evaluated to be 5.57 in tetramethylammonium chloride solution and 5.06 in sodium perchlorate solution. In the modified method the total magnesium concentration in a sample solution is made to be much higher than that in an eluent. This enables one to shorten the elution time.

Hummel and Dreyer first applied gel chromatography to the investigation of complex formation between biological macromolecules and low-molecular-weight substances.[1] Since then several workers have studied the complex formation of metal ions with biological macromolecules by this method.[2-6] However, no application has been reported to the complex formation of metal ions with relatively small ligands. In the present investigation, the fundamental problems of the gel chromatographic method for the determination of stability constants of such a metal complex were examined in detail, and the original Hummel-Dreyer's method was modified to overcome some difficulties encountered therein. As ligand, diphosphate ion was chosen, because it is fairly stable against hydrolytic degradation. As metal magnesium ion was chosen, because it was shown by our previous studies[7] that the elution behavior of magnesium on a gel column could be automatically recorded with an atomic absorption spectrophotometer. The stability constants of magnesium complexes with diphosphate were determined by this method, and the values obtained were compared with those obtained by other methods.

Theoretical

A reversible complex formation between a metal ion, M, and a ligand, L, is considered. L forms successively a series of complexes, ML, M_2L, ..., and M_nL. Charges are omitted for simplicity. The stability constant for the n-th complex is defined as follows:

$$\beta_n = \frac{[M_nL]}{[M]^n[L]}. \quad (1)$$

When the sample solution containing M, L, and the complexes is applied to a gel column conditioned with an eluent containing the same metal of a known concentration, $[M]_0$, and eluted with the same eluent, the elution pattern shown schematically in Fig. 1 is obtained. The initial free metal ion concentration in the sample solution, $[M]_s$, in general, differs from $[M]_0$. However, as the sample ligand zone (zone α) migrates through the column, the free metal ion concentration at zone α, $[M]_\alpha$, approaches $[M]_0$, and eventually becomes equal to $[M]_0$. After this time, the steady state at zone α is characterized by the specific condition that $[M]_\alpha=[M]_0$. A straightforward proof of the attainment of the above condition is the appearance of a horizontal line equal to $[M]_0$ at the right hand side of zone α, as shown in Fig. 1. Equation 1 can be rewritten as

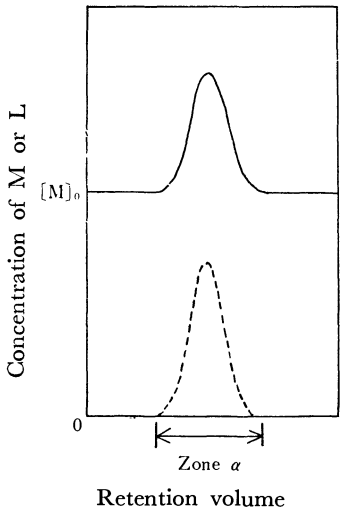

Fig. 1. Schematic elution pattern of zone α. The solid line refers to total metal ion concentration, and the broken line to total ligand concentration.

$$\beta_n = \frac{[M_nL]}{[M]_0^n[L]}. \quad (2)$$

The peak area of zone α represents the amount of bound metal which is present as complexes. The average number of bound metal ions per one ligand, $\bar{n}$, in zone α is obtained by dividing the amount of bound metal by the total amount of a ligand in zone α, which is equal to the total amount of the ligand applied to the column. $\bar{n}$ can be written as

$$\bar{n} = \frac{\sum_1^n i\beta_i[M]_0^i}{1+\sum_1^n \beta_i[M]_0^i}. \quad (3)$$

The following four prerequisites have to be fulfilled to use this method.

1. The size of the ligand should be much larger than that of the metal ion.
2. The peaks due to the ligand and the complexes should not be separated from one another. This can be achieved when the complex equilibria are established

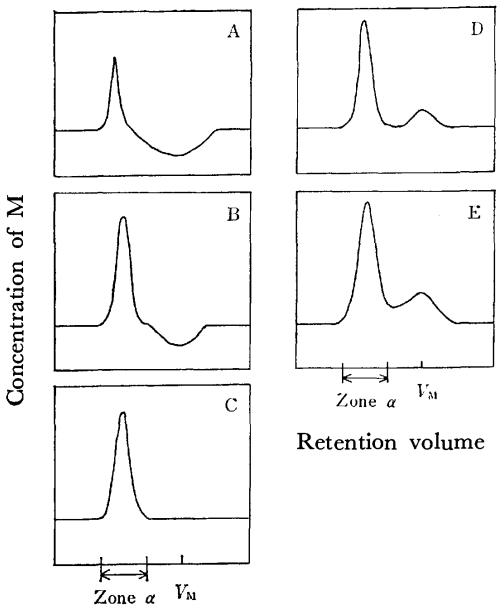

Fig. 2. Typical elution patterns of equilibrium systems of metal and ligand.

A ; $[M]_s \ll [M]_0$ $[M]_\alpha \fallingdotseq [M]_0$
B ; $[M]_s < [M]_0$
C ; $[M]_s = [M]_0$ $[M]_\alpha = [M]_0$
D ; $[M]_s > [M]_0$
E ; $[M]_s \gg [M]_0$ $[M]_\alpha \fallingdotseq [M]_0$

so fast that this separation is prevented.

3. The condition of the steady state, *i.e.*, $[M]_\alpha = [M]_0$, should be establsihed before zone α leaves the column.

4. The ionic strength of the eluent should be kept sufficiently high to prevent the Donnan redistribution. In other words $[M]_\alpha$ should be equal to $[M]_0$.

Figure 2 shows the schematic elution patterns of the metal ion on the assumption that the total ligand concentration in a sample solution, $[L]_t$, and $[M]_0$ are kept constant and that the total metal ion concentration in a sample, $[M]_t$, is varied. If, incidentally, $[M]_s$ is equal to $[M]_0$, an elution pattern such as that shown in Fig. 2C is obtained. Here, only the broadening of zone α occurs. When the difference between $[M]_s$ and $[M]_0$ is relatively small, a pattern like Figs. 2B or 2D is obtained. At the retention volume of the free metal ion, V_M, a negative or positive peak appears. In the three cases mentioned above, the peak areas of zone α are equal to one another. This indicates that the steady state mentioned above is established . However, when $[M]_s$ is much lower or higher than $[M]_0$, the steady state cannot be established until zone α leaves the column (Fig. 2A or 2E). The peak area of zone α in Fig. 2A is smaller than those in Figs. 2B, 2C, and 2D, and that in Fig. 2E is larger.

According to Hummel-Dreyer's method, a sample solution is prepared by dissolving the ligand in an eluent containing metal ions of $[M]_0$. The procedure is particular in that $[M]_t$ is equal to $[M]_0$. The expected elution pattern will be like that in Figs. 2A or 2B. Hummel-Dreyer's method has the disadvantage that, if the free metal ion is significantly depleted by the complex formation, there is no appearance of a horizontal line between a positive and a negative peak, as shown in Fig. 2A. In this case a longer column should be used to separate the two peaks completely. This requires a longer time for elution. In order to overcome this difficulty, a sample solution should be prepared so as to contain metal ions of $[M]_t$ much higher than $[M]_0$.

Experimental

Chemicals. A stock solution of magnesium chloride was standardized volumetrically with EDTA, using Eriochrome Black T as an indicator. A stock solution of sodium diphosphate prepared from analytical grade tetrasodium diphosphate decahydrate was standardized colorimetrically with a molybdenum(V)–molybdenum(VI) reagent.[8] Tetramethylammonium chloride obtained from Tokyo Kasei Kogyo Co. was used without further purification as a background electrolyte.

High Speed Gel Chromatographic Device with an Atomic Absorption Detector. A column of 8×700 mm Pyrex tubing was packed with Sephadex G-15 (Pharmacia). The temperature of the column was kept at 25.0 ± 0.1 °C. A JLC-P2 pumping system (JEOL) was used. A Model 403 atomic absorption spectrophotometer (Perkin Elmer) was used as a detector. The details of the present device were described elsewhere.[9-11]

Elution Experiments. The column was first conditioned with an eluent containing magnesium chloride of a desired concentration, 0.1 mol dm^{-3} tetramethylammonium chloride, and 5×10^{-3} mol dm^{-3} ammonia–10^{-3} mol dm^{-3} ammonium chloride as a buffer of pH 10. At this pH, the diphosphate ion is considered to be almost deprotonated. Sample solutions contained magnesium chloride and sodium diphosphate in varying concentrations, in addition to tetramethylammonium chloride, ammonia, and ammonium chloride of the same concentrations as those in the eluent. A 1.00 cm^3 portion of a sample solution was fed onto the column with an injection valve. The elution flow rate was kept at 1.71 cm^3 min^{-1}. The effluent was introduced into the detector for the automatic recording of the absorbance of magnesium at 285.2 nm. An effluent fraction of 2—6 min and that of 6—10 min were collected manually. The magnesium concentrations in these two fractions were determined by means of atomic absorption spectrophotometry.

Results and Discussion

The Effects of M and L Concentrations in a Sample Solution. The effects of $[M]_t$ and $[L]_t$ on the peak area of zone α were investigated for the complex formation of magnesium with diphosphate. The notations $[Mg]_0$, $[Mg]_t$, $[Mg]_s$, $[Mg]_\alpha$, and $[P]_t$ will be used hereafter. These correspond to $[M]_0$, $[M]_t$, $[M]_s$, $[M]_\alpha$, and $[L]_t$ which are defined in the "Theoretical" section. The elution patterns shown in Figs. 2A, 2B, *etc.*, will be called type A, type B, *etc.*

Figure 3 shows the peak areas of zone α for various $[Mg]_t$ and $[P]_t$. $[Mg]_0$ was fixed at 3.06×10^{-6} mol dm^{-3}. In the region on the left hand side of line X, the elution patterns of type A were obtained. This means that $[Mg]_s \ll [Mg]_0$. In the region on the right hand side of line Y, the elution patterns of type E were obtained. This means that $[Mg]_s \gg [Mg]_0$. In the

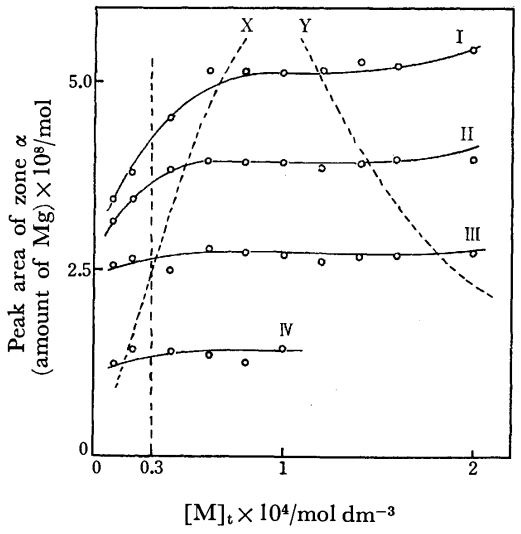

Fig. 3. Effects of $[Mg]_t$ and $[P]_t$ on the peak area of zone α.
$[Mg]_0=3.06\times10^{-6}$ mol dm^{-3}.
$[P]_t\times10^5$ /mol dm^{-3}; I: 9.90, II: 7.43, III: 4.95, IV: 2.48.

region between lines X and Y, the elution patterns of type B, C, or D were obtained. In these cases the steady state was established, *i.e.*, $[Mg]_\alpha=[Mg]_0$.

As shown in Fig. 3, for example, when $[Mg]_t=0.3\times10^{-4}$ mol dm^{-3}, the elution pattern of type B, C, or D will be obtained in case IV, but that of type A in cases I, II, and III. This indicates that, because $[P]_t$ is lower, the time for attainment of the condition that $[Mg]_\alpha=[Mg]_0$ is shorter. However, too low a value of $[P]_t$ leads to a small peak area of zone α, giving rise to a large error in the determination of $\bar{n}$. According to the original Hummel-Dreyer's method, $[Mg]_t$ is equal to $[Mg]_0$, *i.e.*, 3.06×10^{-6} mol dm^{-3}. In this case a much longer column should be used for the present purpose. Since in the modified method $[Mg]_t$ is made to be much higher than $[Mg]_0$, it is possible to use a shorter column.

The amount of bound magnesium thus obtained was plotted against the amount of total diphosphate. The resulting straight line is good evidence for the absence of an ML_2 type complex. The slope, $\bar{n}$, at $[Mg]_0=3.06\times10^{-6}$ mol dm^{-3} was 0.52.

The Effect of a Background Electrolyte. As mentioned above, it is important to confirm prerequisite 4. It should be noted that the anions of a background electrolyte in an eluent are excluded by the Donnan effect from zone α.[12] This in turn may result in the variation of magnesium ion concentration in zone α.

The magnitude of this effect was calculated according to the equation presented by Jordan *et al.*[13] in the case of the highest concentration of the fully deprotonated ligand used in this study, *i.e.*, 10^{-4} mol dm^{-3} of $P_2O_7^{4-}$. Even in this limiting case, the concentrations of free magnesium ions in the mobile and the stationary phases differ from each other by less than 0.5%.

A Source Material of Ligand. As a source material of diphosphate we used its sodium salt, but not its tetramethylammonium salt. The sodium ions in a sample solution are expected to be removed from zone α while this zone migrates through the column. In order to check this point, the sodium emission spectra of an effluent were examined. The peak of the sodium ions was found at 16 min and was completely separate from zone α (6—10 min, see Fig. 4). Therefore, it is concluded that we need not take into account the ion-pair formation of sodium ions with diphosphate ions. Consequently, we need not necessarily use a tetramethylammonium salt of diphosphate, which is usually employed for the determination of stability constants. This is the most remarkable characteristic of the gel chromatographic method.

Calculation of the Stability Constant. In Fig.4, the representative elution patterns for the magnesium–diphosphate system are shown. The positive peak at 7.7 min corresponds to the complexes formed (zone α), and the positive or the negative peak in the range of 12—17 min corresponds to free magnesium ions. When the negative peak appears, it is not clear whether zone α has reached the steady state or not, because of the overlapping of the positive peak at 7.7 min and the negative peak. On the contrary, zone α reaches the steady state when there appears a horizontal line between the rear edge of zone α and the front edge of a positive peak of free magnesium ions.

The amounts of bound magnesium can be calculated directly from the peak area of complexes.[11] In

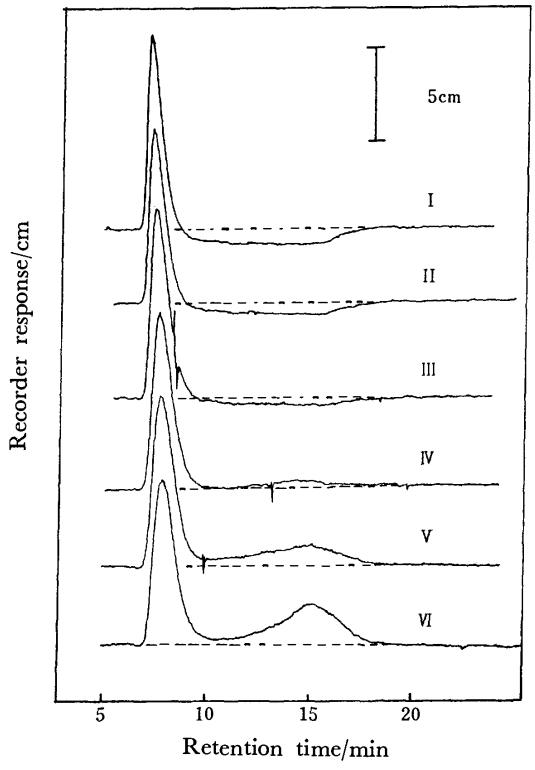

Fig. 4. Representative elution patterns of the Mg–P_2O_7 system.

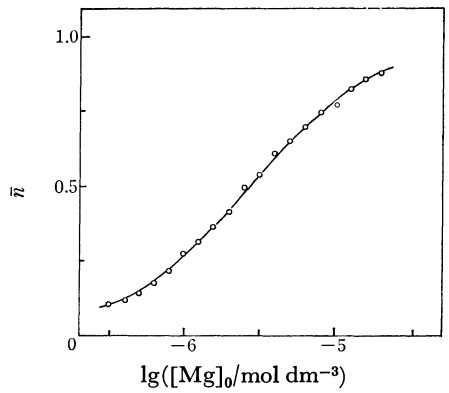

Fig. 5. Plots of $\bar{n}$ *vs.* lg $[Mg]_0$.
$[P]_t=0.828\times10^{-4}$ mol dm^{-3}.
The solid line is calculated from Eq. 3, when only the formation of an ML type complex is considered, and lg $\beta_1=5.57$.

this work, however, an effluent was fractionated as follows in order to determine $\bar{n}$ more precisely. The amount of bound magnesium was calculated from the difference between the total amount of magnesium in zone α (fraction of 6—10 min) and the amount of free magnesium ions in the preceding zone (fraction of 2—6 min). $\bar{n}$ obtained is tabulated in Table 1. The elution patterns obtained in these experiments were types B, C, and D. In Fig. 5 the plots of $\bar{n}$ *versus* lg $[Mg]_0$ are shown.

Since $\bar{n}$ is between 0.1 and 0.9, only the complexes of ML and M_2L type are taken into consideration. Equation 3 can be written as

$$\bar{n}=\frac{\beta_1[Mg]_0+2\beta_2[Mg]_0^2}{1+\beta_1[Mg]_0+\beta_2[Mg]_0^2}. \quad (4)$$

Equation 4 can be rearranged into

$$\frac{\bar{n}}{2-\bar{n}}\cdot\frac{1}{[Mg]_0^2}=\beta_2+\beta_1\frac{1-\bar{n}}{2-\bar{n}}\cdot\frac{1}{[Mg]_0}. \quad (5)$$

By plotting $\bar{n}/(2-\bar{n})[Mg]_0^2$ *versus* $(1-\bar{n})/(2-\bar{n})[Mg]_0$, we can obtain β_1 from the slope and β_2 from the intercept. By using the least squares method, β_1 was found to be 3.7×10^5 (lg $\beta_1=5.57$). Since the intercept was found to be nearly zero, it was concluded that the formation of the complex ML was predominant under these experimental conditions. The experimental plots in Fig. 5 lie close to the theoretical curve calculated from the value of lg β_1, 5.57.

The side reaction coefficient of ammonium ions for diphosphate ions is estimated to be nearly unity, because the stability constants of ion-pairs of ammonium ions are in general lower than those of potassium ions (lg β_1 for diphosphate, 0.80 at $I=1$ and at 25 °C),[14] and $[NH_4^+]=10^{-3}$ mol dm^{-3}.

The Stability Constants Obtained by Various Methods. For the purposes of comparison, the stability constant of an ML type complex of magnesium and diphosphate in sodium perchlorate solution was determined by both the gel chromatographic method and the ion-exchange method. For the latter, Schubert's method was employed.[15]

Table 2. Stability constants of MgP_2O_7 complex

lg (β_1/ mol^{-1} dm^3)	Method[a]	Ionic strength / mol dm^{-3}	Supporting electrolyte	Temp °C	Ref.
5.42	A	1	Me_4NBr	25	16
5.41	A	1	Me_4NCl	25	17
5.57	B	0.1	Me_4NCl	25	This work
4.7	A	0.1	$NaNO_3$	25	18
5.18	C	0.1	$NaClO_4$	21	This work
5.06	B	0.1	$NaClO_4$	25	This work

a) A: pH titration method; B: gel chromatographic method; C: cation-exchange method.

The stability constants of a magnesium–diphosphate complex thus obtained as well as those reported by other workers are listed in Table 2. The stability constants obtained by both the pH titration method and the gel chromatographic method agree fairly well with each other, even though the two methods are based on quite different principles. The stability constant obtained by the gel chromatographic method is somewhat larger than those obtained by the pH titration method. One of the possible reasons for this discrepancy may be due to the difference in the ionic strengths. The stability constants of the complex in sodium perchlorate solution obtained by both the ion-exchange method and the gel chromatographic method accord fairly well with each other. However, the stability constants of the complex in sodium nitrate solution obtained by the pH titration method is considered to be a little too low.

It has been shown by the present investigation that the gel chromatographic method is applicable even in the field of inorganic complex chemistry.

The authors wish to express their appreciation to Dr. Norimasa Yoza for his interest in this work and for many helpful suggestions.

New Palladium(II) Carbene Complexes Containing a Cyclometallated Aryl Group†

Katsuma HIRAKI,* Masayoshi ONISHI,* Kiyoshi SEWAKI, and Keiichi SUGINO

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received October 11, 1977)

New carbene complexes of (acetophenone oxime, 2-*C,N*)chloro(1,3-diphenylimidazolidin-2-ylidene)palladium(II) (**1**), (benzophenone oxime,2-*C,N*)chloro(1,3-diphenylimidazolidin-2-ylidene)palladium(II) (**2**), and chloro(*N,N*-dimethylbenzylamine,2-*C,N*)(1,3-diphenylimidazolidin-2-ylidene)palladium(II) (**3**) have been prepared by reactions between dimeric cyclopalladated complexes and 1,1′,3,3′-tetraphenyl-2,2′-biimidazolidinylidene. Chlorine atoms were shown to be situated at the *trans* position to the aryl-palladium σ bond on the basis of IR spectra. These carbene complexes underwent halogen metathesis with LiBr to yield the corresponding bromo derivatives. Triphenylphosphine displaced the chlorine atom in **1**, **2**, and **3**, converting each to a cationic carbene complex, in which the nitrogen donor of cyclopalladation moiety remained coordinated to palladium.

The electron rich olefin, 1,1′,3,3′-tetraphenyl-2,2′-biimidazolidinylidene,[1] has been used as an organic precursor for the syntheses of transition metal carbene complexes by Lappert *et al.*[2] Some palladium(II) carbene complexes have been prepared in reactions between di-μ-chloro-dichlorobis(trialkylphosphine)dipalladium(II) and the electron rich olefin.[2]

We have been interested in the halogen-bridge splitting reaction of cyclopalladated dimeric complexes and presented earlier a brief report on some palladium(II) complexes prepared with this method.[3] This paper will deal with several new palladium(II) complexes, which have been prepared by the halogen-bridge splitting reactions between the cyclopalladated dimeric complexes and the electron rich olefin. The product has been shown to contain both the carbene ligand and an aryl-palladium σ bond.

† A preliminary report of this work was presented at the 36th National Meeting of the Chemical Society of Japan, Higashi-Osaka, April 1977.

Experimental

General Procedures. Melting points were determined in capillary tubes on a Yanagimoto MP-S3 microstage apparatus and are uncorrected. IR spectra were recorded on a Hitachi model 285 spectrometer and a Shimadzu IR 450 spectrometer. ^{1}H-NMR spectra were run on a Japan Electron Optics Laboratory model JNM-MH-100 spectrometer (100 MHz), using tetramethylsilane as an internal standard. ^{13}C-NMR spectra were measured on a Bruker WH-90 spectrometer, operating the Fourier transform model at 22.63 MHz.[4] Molecular weights were determined using a JEOL model JMS-01SG double-focussing mass spectrometer referring to parent ion peaks. Molar conductivities were measured with a Toa Denpa CM-6A instrument.

Starting materials, [{PdCl(C_6H_4–C(=N–OH)R, 2-*C,N*)}$_2$],[5] [{PdCl($C_6H_4CH_2NMe_2$,2-*C,N*)}$_2$],[6] and 1,1′,3,3′-tetraphenyl-2,2′-biimidazolidinylidene (L_2)[7] were prepared and purified according to the methods described in the literature. Reactions were performed under dry nitrogen.

Reactions of the Electron Rich Olefin with the Dimeric Cyclopalladated Complexes. The olefin L_2 (0.45 g) and [{PdCl(C_6H_4–C(=N–OH)CH_3,2-*C,N*)}$_2$] (0.56 g) were heated under reflux in *m*-xylene for 10 min. The reaction mixture was allowed to cool and then filtered. The separated solid was recrystallized from dichloromethane and hexane to give a pale yellow crystalline powder, [PdCl(C_6H_4–C(=N–OH)CH_3, 2-*C,N*)L] (L = 1,3-diphenylimidazolidin-2-ylidene) (**1**), 0.58 g.

[PdCl(C_6H_4–C(=N–OH)C_6H_5,2-*C,N*)L]·$(CH_3)_2CO$ (**2**) and [PdCl($C_6H_4CH_2NMe_2$,2-*C,N*)L]·1/2$(CH_3)_2CO$ (**3a**) were prepared in a similar method as used for **1**, but acetone was used for the recrystallization. Complex **3a** was converted into a non-solvated complex (**3b**) by recrystallization from acetone and diethyl ether. The removal of acetone was confirmed by elemental analysis, IR, and ^{1}H-NMR spectrum of **3b**.

*Halogen Metathesis Reactions of **1**, **2**, and **3a**.* The chloro complex **1** (0.20 g) was treated with an excess of LiBr (0.1 g) in methanol under reflux for 4 h. The suspension was cooled and filtered. The separated solid was washed with methanol and diethyl ether to yield a pale yellow powder, [PdBr(C_6H_4–C(=N–OH)CH_3,2-*C,N*)L] (**4**), 0.14 g.

The complex **2** (0.15 g) and LiBr (0.05 g) were heated under reflux in acetone for 5 h. The solvent was evaporated, and the residue was washed with methanol and diethyl ether to give [PdBr(C_6H_4–C(=N–OH)C_6H_5,2-*C,N*)L] (**5**), 0.12 g.

[PdBr($C_6H_4CH_2NMe_2$,2-*C,N*)L] (**6**) was obtained similarly.

*Reactions of **1**, **2**, and **3a** with Triphenylphosphine.* The complex **1** (0.20 g) and PPh_3 (0.15 g) in acetone were heated

for 5 h with stirring. The reaction mixture was allowed to cool and filtered. Sodium perchlorate–water(1/1) (0.06 g) was added to the filtrate. After the suspension was stirred overnight, the solvent was removed *in vacuo*. The residue was recrystallized from dichloromethane and diethyl ether to afford a white crystalline product, [Pd(C_6H_4–C(=N–OH)CH_3, 2-*C*,*N*)L(PPh_3)]ClO_4 (**7**), 0.05 g.

[Pd(C_6H_4–C(=N–OH)C_6H_5,2-*C*,*N*)L(PPh_3)]ClO_4 (**8**) and [Pd($C_6H_4CH_2NMe_2$,2-*C*,*N*)L(PPh_3)]ClO_4 (**9**) were obtained similarly.

Results and Discussion

When the electron rich olefin and the cyclopalladated halogen-bridged dimeric complex were mixed in *m*-xylene under reflux, the reaction mixture immediately changed from pale yellow to pale orange or reddish violet and then to a black suspension owing to partial decomposition. A similarly highly colored state has also been observed in the reaction between the olefin and di-μ-chloro-dichlorobis(trialkylphosphine)dipalladium(II) or -diplatinum(II) by Lappert *et al.*[2] They assumed the formation of an intermediate π-complex, followed by cleavage of the double bond to yield a carbene complex.

The complexes, **1**, **2**, and **3a** underwent halogen metathesis with lithium bromide to yield the corresponding bromo-derivatives, and reacted with triphenylphosphine affording **7**, **8**, and **9**, respectively. Tables 1, 2, and 3 give the yields, analytical data, and physical and spectroscopic properties of the complexes obtained in this study.

Complexes **1**, **2**, and **3a** exhibited low conductivities, indicating non-ionic character[8] (Table 1). However, **7**, **8**, and **9** have been ascribed to the cationic complexes on the basis of high conductivities.[8] In the conversion of **1**, **2**, and **3a** to **7**, **8**, and **9**, respectively, triphenylphosphine displaced the chlorine atom of the initial complex and the nitrogen donor remained coordinated to the central metal.

TABLE 3. ^{1}H-NMR DATA OF THE CARBENE COMPLEXES

6[c]		8.28—6.66(c)	4.34(s)	3.66(s)	2.64(s)

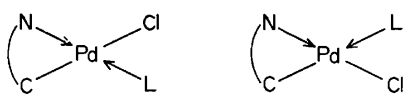
a) δ value relative to TMS; in CD_2Cl_2, unless noted elsewhere. b) s=singlet, c=complex. c) In $CDCl_3$.

^{13}C-NMR spectrum of **3b** in $CDCl_3$ showed a resonance at δ 201.6 from TMS, assignable to a carbene carbon atom. As for the 1,3-diphenylimidazolidin-2-ylidene ligand, two methylene carbons showed a single resonance, indicating that the N–$C_{carbene}$–N plane was perpendicular to the coordination plane of the palladium atom and the *N*-substituted two phenyl carbons were spectroscopically equivalent. In the range of δ 137 to 160, the spectrum also gave resonances at δ 149.1, 147.8, and 141.8, which are assignable to three kinds of quarternary carbon atoms, methylene- and palladium-substituted phenylene carbons (1-C and 2-C) in the cyclopalladated moiety and *N*-substituted two phenyl carbons in the carbene ligand.[9]

On the basis of these facts, complex **3b** was ascribed to a new carbene complex which retained the cyclopalladated chelate structure of the starting compound. The complexes, **1** and **2** also exhibited chemical and spectroscopic properties similar to **3b**, and were assumed to have a structure similar to **3b**. These carbene complexes containing the cyclometallated aryl group are stable in air at room temperature.

Four methylene protons of the imidazolidin-2-ylidene group were represented by an A_2B_2 spin system in the ^{1}H-NMR spectra and showed a complex signal in chloro-type complexes, **1**, **2**, and **3b**, as shown in Table 3. Each of the bromo-type complexes, **4**, **5**, and **6**, gave virtually a singlet in the A_4 limit for the methylene protons.

The IR spectra of these nine carbene complexes showed a strong band near 1275 cm^{-1} for $\nu(C_{aromatic}–N)$ of the 1,3-diphenylimidazolidin-2-ylidene ligand. Two bands were observed in the range 3200—3500 cm^{-1} in **7** and **8**. The lower frequency band was tentatively assigned as a hydrogen-bonding ν(O–H) of an oxime group and the sharp higher frequency band as that of a non-hydrogen-bonding ν(O–H).[10]



A B

Two structures are stereochemically possible for the carbene complexes, **1**, **2**, and **3b**. Crociani *et al.*[11] studied the ν(Pd–Cl) frequencies of mononuclear complexes derived from di-μ-chloro-bis(*N*,*N*-dimethylbenzylamine, 2-*C*,*N*)dipalladium(II) or related complexes and donor ligands. They reported that the ν(Pd–Cl) frequency *trans* to a tertiary amine-nitrogen donor fell in the range of 353—321 cm^{-1} and the ν(Pd–Cl) frequency *trans* to an aryl group in the range of 299—280 cm^{-1}, and correlated the differences of these frequencies to that of the *trans* influence of the respective ligands. In consideration of the data reported here and related ones,[12,13] structure A has been assigned for complexes **1** and **3b**. No evidence supporting the presence of the other geometrical isomer B for **1** and **3b** were found in the NMR and IR (450—200 cm^{-1}) spectra.

The ν(Pd–Cl) band for **2** could not be clearly assigned. However, **2** also appears to have structure A, since no band was observed in the range of 353—321 cm^{-1}. Obscurity of the ν(Pd–Cl) assignment of **2** may be accounted for either by overlapping of the weak ν(Pd–Cl) band with strong bands at 303—315 cm^{-1}, or by the large shift of the ν(Pd–Cl) frequency towards the lower wavenumber probably due to the intramolecular hydrogen-bonding of chlorine.

We are grateful to Professor Keinosuke Hamada and Mr. Hirofumi Morishita, Nagasaki University, for their help in the far IR measurements.

ESR Study of ^{63}Cu(II) Doped in Single Crystals of Bis(methyl 3-alkylidenedithiocarbazato)nickel(II)

Takayuki ONIKI

Pre-dental Course of Kyushu Dental College, Manazuru, Kokurakita-ku, Kitakyushu 803

(Received December 16, 1977)

ESR spectra of ^{63}Cu(II) diluted by various single crystals of the title Ni(II) complexes are reported. The alkylidene groups denote 1-(2-naphthyl)ethylidene, 1-(*p*-tolyl)ethylidene, 1-phenylethylidene, benzylidene, 1-(*m*-nitrophenyl)ethylidene, and 1-(*p*-nitrophenyl)ethylidene, and the corresponding Ni(II) complexes are abbreviated as Ni(nedc)$_2$, Ni(tedc)$_2$, Ni(pedc)$_2$, Ni(bdc)$_2$, Ni(mndc)$_2$, and Ni(pndc)$_2$ respectively. Before the analyses of the ESR data, the crystal structures of Ni(nedc)$_2$ and Ni(tedc)$_2$ were determined. In both Ni(II) complexes, the molecules have been found to be of a C_2 symmetry, with a tetrahedrally distorted *cis*-NiN_2S_2 arrangement. The unpaired electrons of the Cu(II) complexes were thus described in terms of C_2 symmetry except for the case of Cu(bdc)$_2$. The d-orbital coefficients of the ground-state Kramers doublet were determined from the observed *g* values in such a way that the hyperfine parameters calculated from the coefficients closely reproduce the observed values. In ^{63}Cu(II)/Ni(bdc)$_2$, the *g* values are rhombic, and an additional hyperfine structure due to atoms which do not directly coordinate to Cu(II) ion was observed. The coordination of the Cu(II) ion in Ni(bdc)$_2$ was concluded from the ESR data to be a *trans* arrangement.

The complexes containing Cu–S bonds are interesting for their covalent character. The copper-ligand bindings have been studied by ESR, mainly in complexes with oxygen and nitrogen ligands, and there have been many studies of the square planar, CuS_4-type complexes, that is dithiocarbamates,[1,2] dithiophosphate,[3] bis(maleonitriledithiolato)copper(II),[4] and 1,4,8,11-tetrathiacyclotetradecane copper(II) tetrafluoroborate.[5] However relatively few studies have been reported of the CuN_2S_2-type complexes, that is *trans*-bis(thiosemicarbazide)copper(II) nitrate,[6] α-thiopicolinanilide copper(II),[7] and *N*,*N*′-ethylene bis(monothioacethylacetoniminato)copper(II).[8]

The evaluation of the bonding parameters from the ESR data requires a knowledge of the assignment of the d-d transition bands in the electronic spectra of Cu(II) complexes. In the electronic spectra of bis(methyl 3-alkylidenedithiocarbazato) copper(II), however, the intense charge-transfer bands mask the d-d transitions. The general method of calculating covalent parameters by the use of d-d energy could not be employed for these complexes.

In this study, the ESR spectra of ^{63}Cu(II) diluted by single crystals of six Ni(II) complexes and the crystal structures of Ni(nedc)$_2$ and Ni(tedc)$_2$ are reported (Fig. 1). The d-orbital coefficients of the ground state are determined from the *g* values with C_2 symmetry except for the case of Cu(bdc)$_2$, in which D_{2h} symmetry was used. The method of treating the ESR data follows the general scheme of Swalen *et al.*,[10] extended to C_2 symmetry.

Fig. 1. Assumed basic structure of bis(methyl 3-alkylidenedithiocarbazato)metal(II), and abbreviations of copper(II) complexes. The coordination around Cu(II) in Ni(bdc)$_2$ was concluded to be *trans* arrangement from ESR.

Experimental

The complexes were prepared according to a modification of the methods of Ref. 11. The single crystals were obtained by the slow evaporation of chloroform–ethanol solutions.

X-Ray Analyses. Three-dimensional intensity data were collected by the 2θ-θ scan technique on a Syntex $P\bar{1}$ four-circle diffractometer using Mo K_α radiation monochromated by a graphite plate. All the reflections with $2\theta \leqq 48°$ were collected. In this way, 3265 independent reflections were measured for Ni(tedc)$_2$, and 2100 for Ni(nedc)$_2$, of which 2642 and 1946 having $I \geqq 2\sigma$ (I) were used in the subsequent analyses. They were corrected for Lorentz and polarization effects, but corrections for absorption were not applied, as the samples were sufficiently small. The calculations were performed on the FACOM 230-75 computer of the Computer Center of Kyushu University, using the UNICS program system.[12] The scattering factors for all the atoms were taken from Ref. 13. The F_o-F_c table is kept at the office of This Bulletin as Document No. 7827.

ESR Measurements. The ESR spectra were recorded every 15° around three mutually perpendicular rotational axes. The most elongated axis was defined as the 2-axis, which is parallel to the crystal b-axis in the case of Ni(nedc)$_2$ or Ni(tedc)$_2$. The 1- and 3-axes were taken at will in the plane perpendicular to the 2-axis. The spectra were taken on a JEOL ME 3X spectrometer at the X band. Mn(II) diluted with MgO and DPPH were used as the *g* marker.

Results

Crystal Structures. The structures were solved by the heavy-atom technique. After block-diagonal least-squares refinement with anisotropic thermal

parameters for non-hydrogen atoms, the final R values became 0.058 in both crystals. The parameters obtained are given in Tables 1—4.

Ni(nedc)$_2$: $NiS_4N_4C_{28}H_{26}$, formula weight 605.48, monoclinic, space group C2/c, a=26.518(8), b=8.399(1), c=14.546(3) Å, β=121.05(2)°, V=2775.6 Å^3, Z=4, D_m=1.423 g·cm^{-3} (by floatation), D_x=1.449 g·cm^{-3}.

The Ni atoms lie on the crystallographic two-fold axes. Each of the ligands is bonded to the Ni atom through the thiol S atom and one of the hydrazine N atoms, yielding a 5-membered chelate ring, and the Ni atom has a *cis*-planar coordination by two S and two N atoms. The molecule has a crystallographically imposed two-fold axis which bisects the S–Ni–S bond angle and which is parallel to the b-axis. The four ligator atoms are somewhat tetrahedrally disposed around the Ni atom. The interplanar angle between N–Ni–S planes is 22°. The packing of the complexes is illustrated in Fig. 2.

Ni(tedc)$_2$: $NiS_4N_4C_{22}H_{26}$, formula weight 533.41, monoclinic, space group $P2_1/c$, a=14.793(5), b=8.835(3), c=20.309(5) Å, β=110.77(2)°, V=2481.8 Å^3, Z=4, D_m=1.419 g·cm^{-3}, D_x=1.427 g·cm^{-3}.

The Ni atom has a coordination similar to that of $Ni(nedc)_2$. The molecule has a fictitious two-fold axis which is inclined from the b-axis. The interplanar angle between N–Ni–S planes is 24°. The packing is illustrated in Fig. 3.

ESR Spectra. *$^{63}Cu(II)/Ni(nedc)_2$*: There are four molecules in the unit cell. It was found, however, that there is only one copper quartet in all the crystal orientations. All the sites for copper ions were, therefore, magnetically indistinguishable. Figure 4 shows some representative spectra. The crystal b-axis is along the 2-axis. When the magnetic field($\boldsymbol{H}_0$) is in the 31-plane, the two Cu–N bondings are magnetically equivalent and the equally spaced nitrogen hyperfine structure(hfs) with an intensity ratio of 1:2:3:2:1 was well defined. The crystal c-axis is parallel to the 1-axis and nearly bisects the N–Cu–N angle, and the two Cu–N bondings are equivalent. The 23-plane is nearly parallel to the molecular plane. When the $\boldsymbol{H}_0$ is within 15° of one Cu–N bond direction, a nonequivalent nitrogen hfs is obtained (see b in Fig. 4). The g_z direction is parallel to the crystal b-axis, which is the molecular two-fold axis. The forbidden spectra corresponding to $\Delta m=\pm1$ and ±2 were not clearly

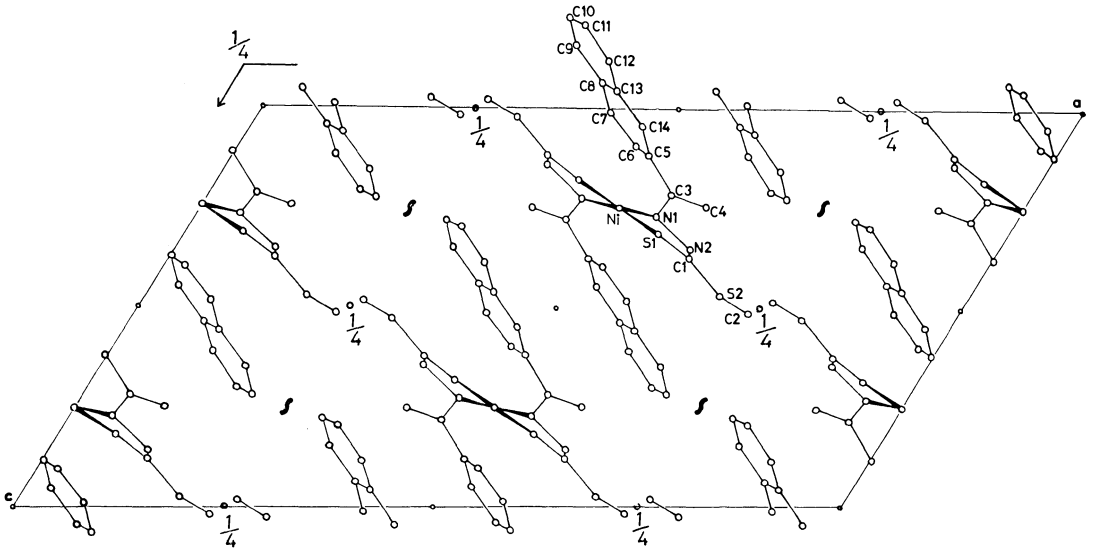

Fig. 2. Projection of the crystal structure along the b-axis of $Ni(nedc)_2$.

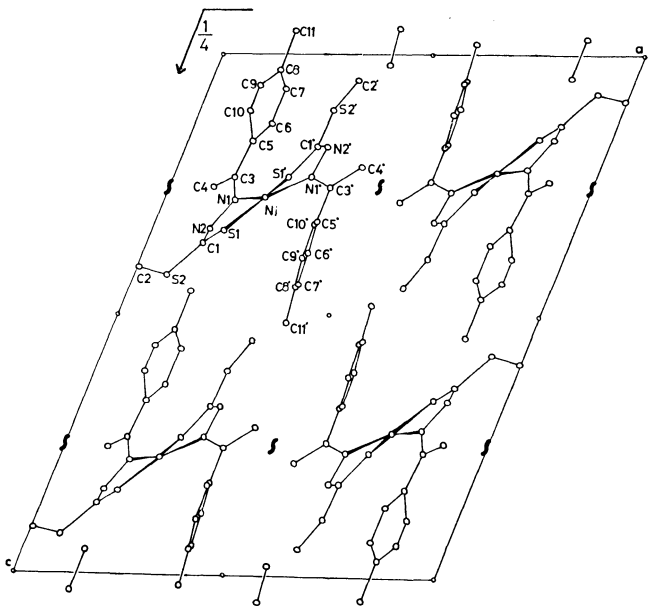

Fig. 3. Projection of the crystal structure along the b-axis of $Ni(tedc)_2$.

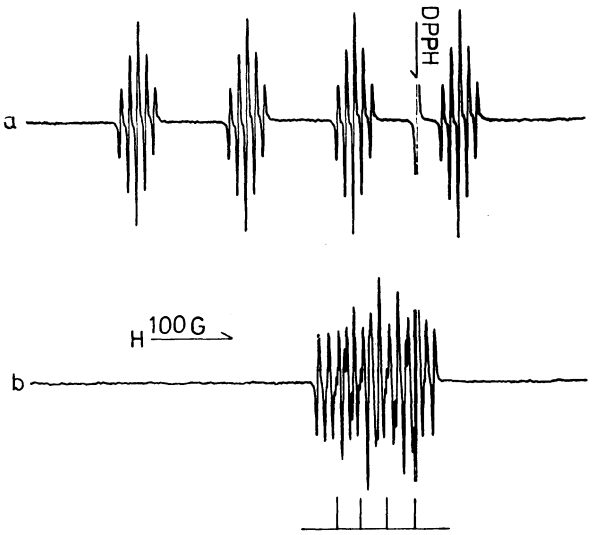

Fig. 4. Single crystal ESR spectra of $^{63}Cu(II)/Ni(nedc)_2$. a: $(\theta,\varphi)=(120°,0°)$, b: $(60°,90°)$.

identified, hence, no attempt was made to determine quadrupole coupling parameters. The g values and hf coupling constants were determined by a method similar to that of Fujimoto *et al.*[14]

$^{63}Cu(II)/Ni(mndc)_2$ and $Ni(pedc)_2$: The spectra in both complexes were very similar to those of $^{63}Cu(II)/Ni(nedc)_2$ except for the difference in the laboratory coordinate systems.

$^{63}Cu(II)/Ni(tedc)_2$: The crystal b- and a-axes are parallel to the 2- and 1-axes respectively. One set of absorption is obtained when $\boldsymbol{H}_0$ is in the 31-plane or along the 2-axis, while two sets are observed when $\boldsymbol{H}_0$ is in the 12- or 23-plane. The deviation of the g_z direction from the crystal b-axis is 24°.

$^{63}Cu(II)/Ni(pndc)_2$: Four sets of absorptions are observed when $\boldsymbol{H}_0$ is in the 31-plane. The four resonances merge into two more intense lines when $\boldsymbol{H}_0$

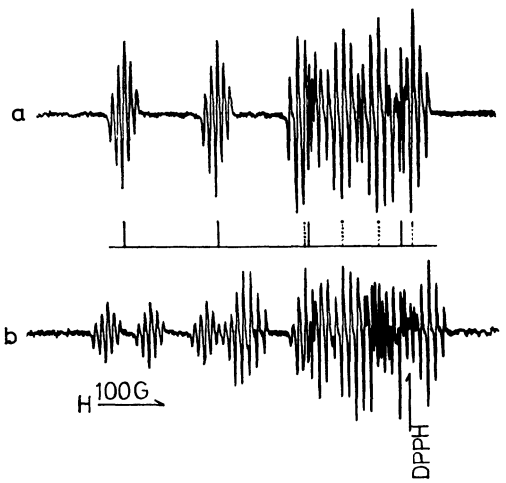

Fig. 5. Single crystal ESR spectra of $^{63}Cu(II)/Ni(pndc)_2$. a: (90°,15°), b: (165°,0°).

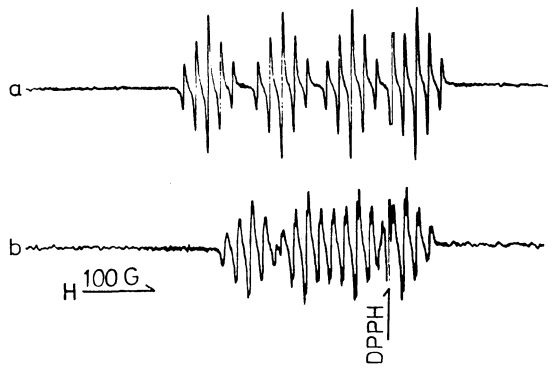

Fig. 6. Single crystal ESR spectra of ^{63}Cu(II)/Ni(bdc)$_2$.
a: (90°,0°), b: (15°,0°).

is along the 3- or 1-axis and when $\theta=45$ or 135°. When $\boldsymbol{H}_0$ is in the 12- or 23-plane, two sets are obtained, and these spectra are exactly identical in both planes.

^{63}Cu(II)/Ni(bdc)$_2$: When $\boldsymbol{H}_0$ is in the 31-plane or along the 2-axis, a single spectrum is observed, while two spectra are observed when $\boldsymbol{H}_0$ is in the 12- or 23-plane. The g and A^{Cu} values are rhombic. The nitrogen hfs is very large compared with those of the other samples, and the maximum direction of the nitrogen hfs agrees roughly with the g_x direction. The intensity ratio is 1:2:3:2:1 in all the crystal orientations. These results indicate that the Cu(II) ion in Ni(bdc)$_2$ is in a *trans* arrangement. The ESR parameters and the principal directions are very similar to those of *trans*-bis(thiosemicarbazide)copper(II) nitrate.[6]

When $\boldsymbol{H}_0$ is within 30° from the 3-axis, the additional hfs was observed (see b in Fig. 6). In the other orientations, the line width was very sharp but no additional hfs could be detected at room temperature. As far as the details of measurements around the 3-axis, it was found that the spectra consist of 3 lines with an intensity ratio of about 1:4:1. It is uncertain whether this hfs should be assigned to azomethine hydrogen or to two nitrogens in which one of the hfs is very small. The details are now under investigation.

Discussion

The molecule in Ni(nedc)$_2$ or Ni(tedc)$_2$ has the C_2 or the fictitious C_2 symmetry. The ESR results shall, therefore, be analyzed in terms of the C_2 symmetry except in the case of Cu(bdc)$_2$.

The ESR data of Cu(II) ions generally have been analyzed by the method of Abragam and Pryce,[15,16] which was adapted by Maki and McGarvey[17] to the ligand-field concept.[9,18] There is, however, difficulty caused by the increased number of parameters to be determined in the C_2 symmetry, since some coefficients in the linear combination of the Kramers doublet are complex.

The iteration method introduced by Swalen *et al.*[10] can determine the coefficients of the atomic d-orbitals from only the experimental g values and the normalization condition. The copper hfs is used only for a consistency check. The same procedure is followed in this work, and the hole description is adopted throughout in the formulation.

In the C_2 symmetry, $3d_{zx}$- and $3d_{yz}$-type orbitals belong to the same irreducible representation and form a linear combination:

$$\psi = a|zx> + ib|yz>. \tag{1}$$

In this case, the symmetry axis is parallel to the z-axis, and the $3d_{xy}$, $3d_{z^2}$, and $3d_{x^2-y^2}$ orbitals are then admixed *via* spinorbit coupling, $\xi \boldsymbol{l}\cdot\boldsymbol{s}$, to give the general expression for the Kramers doublet:

$$\psi^\alpha = a|zx>^\alpha + ib|yz>^\alpha + c|z^2>^\beta - d|x^2-y^2>^\beta - ie|xy>^\beta, \tag{2-1}$$

$$\psi^\beta = i\{a|zx>^\beta - ib|yz>^\beta - c|z^2>^\alpha + d|x^2-y^2>^\alpha - ie|xy>^\alpha\}, \tag{2-2}$$

where the superscripts α and β designate the spin functions.

The expressions for the g values are obtained as the matrix elements of the Zeeman term, $\boldsymbol{H}=\beta(\boldsymbol{l}+g_e\boldsymbol{s})\cdot\boldsymbol{H}_0$:[19]

$$g_x = (1-2b^2-2c^2-2d^2)g_e + 4ae - 4bd + 4\sqrt{3}\,bc, \tag{3-1}$$

$$g_y = (1-2b^2-2e^2)g_e - 4be + 4ad + 4\sqrt{3}\,ac, \tag{3-2}$$

$$g_z = (1-2c^2-2d^2-2e^2)g_e + 8de + 4ab, \tag{3-3}$$

where g_e represents the g value of the free electron.

The expressions for the hyperfine coupling constants are derived as follows:[20]

$$A_x = P[4ae-4bd+4\sqrt{3}\,bc-k(1-2b^2-2c^2-2d^2) + (2/7)(1+b^2-2d^2-3ab-\sqrt{3}\,ac+3ad-3be - 2\sqrt{3}\,cd-2\sqrt{3}\,ce)], \tag{4-1}$$

$$A_y = P[-4be+4ad+4\sqrt{3}\,ac-k(1-2b^2-2e^2) + (2/7)(-1-a^2+2d^2+3ab-\sqrt{3}\,bc-3bd + 3ae-2\sqrt{3}\,cd-2\sqrt{3}\,ce)], \tag{4-2}$$

$$A_z = P[8de+4ab-k(1-2c^2-2d^2-2e^2) + (2/7)(1-3c^2+d^2+e^2+\sqrt{3}\,ac-3ad - 3ae-\sqrt{3}\,bc-3bd-3be)], \tag{4-3}$$

where $P=g_e g_N \beta_e \beta_N \langle r^{-3}\rangle_{3d}$, and where k is the contact term.

The 3 equations and the normalization condition form a set of nonlinear simultaneous equations for a, b, c, d, and e, an iteration procedure similar to that of Swalen *et al.*[8] being used. The solutions were made with a value of $r(=c/d)$ between 0.5 and 2.0 by the use of an Olivetti P652 computer. The calculated values are given in Table 6.

Nitrogen hfs. From Table 6, the contributions of the upper states may be found to be very small. We shall thus ignore these admixtures in our calculation of the nitrogen hfs. We obtain the following antibonding molecular orbital of the unpaired electron:

$$|zx> = N^{1/2}[d_{zx} - (\alpha_1/\sqrt{2})(s^1-s^2) - (\alpha_2/2) \times (-p_x^1-p_z^2-p_x^1+p_z^2) - (\alpha_3/\sqrt{2}) \times (-s^3+s^4) - (\alpha_4/2)(p_x^3+p_x^4-p_z^3+p_z^4)], \tag{5}$$

where the z axis is along the two-fold axis, and 1,2 and 3,4 represent, respectively, the ligand nitrogen and sulfur atoms. The normalization of this orbital gives

$$N(1+\alpha_1^2+\alpha_2^2+\alpha_3^2+\alpha_4^2-2\sqrt{2}\,\alpha_1 S_1-4\alpha_2 S_2 - 2\sqrt{2}\,\alpha_3 S_3-4\alpha_4 S_4) = 1, \tag{6}$$

where $S_1=\langle d_{zx}|s^1\rangle$, $S_2=\langle d_{zx}|-p_x^1\rangle$, $S_3=\langle d_{zx}|-s^3\rangle$, and $S_4=\langle d_{zx}|p_x^3\rangle$.

The components of the nitrogen hfs are

$$A_\parallel^N = A_s + 2A_p, \tag{7-1}$$

$$A_\perp^N = A_s - A_p, \tag{7-2}$$

where the isotropic part, A_s, and anisotropic part, A_p, are

$$A_s = (8\pi/3)g_e g_N \beta_e \beta_N \times (1/2)N\alpha_1^2 \times |\psi_{2s}(0)|^2, \tag{8-1}$$

$$A_p = (4/5)g_e g_N \beta_e \beta_N \times (1/4)N\alpha_2^2 \times \langle r^{-3}\rangle_{2p}. \tag{8-2}$$

The values of $32.4\times10^{24}\,cm^{-3}$ for $|\psi_{2s}(0)|^2$ and $20.9\times10^{24}\,cm^{-3}$ for $\langle r^{-3}\rangle_{2p}$ of a nitrogen atom are obtained from the analytical SCF wave functions.[21] Table 7 gives the values of $N\alpha_1^2$, $N\alpha_2^2$, and $N\alpha_4^2$, the $N\alpha_4^2$ values have been calculated on the following bases: (1) the overlap integrals, $S_1=0.085$, $S_2=0.097$,

and S_4=0.065, are assumed for the Cu–N and Cu–S distances of 1.92Å and 2.15Å; (2) α_3=0, and (3) the value of N is assumed to be 0.7 or 0.75, either of which is a reasonable value for CuN_2S_2 complexes.[6]

^{63}Cu(II)/Ni(bdc)$_2$. In a *trans* arrangement, $d_{x^2-y^2}$ and d_{z^2} belong to the same irreducible representation and the spin-orbitals of the ground state are

$$\psi^\alpha = a|x^2-y^2>^\alpha + b|z^2>^\alpha + ic|xy>^\alpha - id|yz>^\beta + e|zx>^\beta, \quad (9\text{-}1)$$

$$\psi^\beta = i\{a|x^2-y^2>^\beta + b|z^2>^\beta - ic|xy>^\beta - id|yz>^\alpha - e|zx>^\alpha\}, \quad (9\text{-}2)$$

x and y being the Cu–N and Cu–S bond directions respectively. By analogy with the case of C_2, the g and A^{Cu} values are calculated as follows:

$$g_x = (1-2c^2-2e^2)g_e + 4\sqrt{3}bd + 4ce + 4ad, \quad (10\text{-}1)$$

$$g_y = (1-2c^2-2d^2)g_e - 4\sqrt{3}be + 4ae + 4cd, \quad (10\text{-}2)$$

$$g_z = (1-2d^2-2e^2)g_e + 8ac - 4de, \quad (10\text{-}3)$$

$$A_x = P[4\sqrt{3}bd+4ce+4ad-k(1-2c^2-2e^2) + (2/7)\{-1+2a^2-d^2-2\sqrt{3}ab - \sqrt{3}b(e-2c)-3cd-3ae+3de\}], \quad (11\text{-}1)$$

$$A_y = P[-4\sqrt{3}be+4ae+4cd-k(1-2c^2-2d^2) + (2/7)\{-1+2a^2-e^2+2\sqrt{3}ab + \sqrt{3}b(d-2c)-3ce-3ad+3de\}], \quad (11\text{-}2)$$

$$A_z = P[8ac-4de-k(1-2d^2-2e^2) + (2/7)\{-1-a^2+3b^2-c^2-\sqrt{3}b(d-e) - 3(d+e)(c-a)\}]. \quad (11\text{-}3)$$

The molecular orbitals which contribute to the A^N values are

$$|A_{1g}> = N_1^{1/2}[d_{x^2-y^2} + (b/a)d_{z^2} - (\alpha_1/\sqrt{2})(s^1+s^2) - (\alpha_2/\sqrt{2})(-p_x^1+p_x^2) - (\alpha_3/\sqrt{2})(p_y^3-p_y^4)], \quad (12\text{-}1)$$

$$|zx> = N_2^{1/2}[d_{zx} - (\beta/\sqrt{2})(p_z^1-p_z^2)]. \quad (12\text{-}2)$$

The components of the A^N are

$$A_x^N = A_s + 2A_\sigma + A_\pi, \quad (13\text{-}1)$$

$$A_y^N = A_s - A_\sigma, \quad (13\text{-}2)$$

$$A_z^N = A_s - A_\sigma - A_\pi, \quad (13\text{-}3)$$

where A_s, A_σ, and A_π are

$$A_s = (8\pi/3)g_e g_N \beta_e \beta_N \times (1/2)a^2 N_1 \alpha_1^2 |\psi_{2s}(0)|^2, \quad (14\text{-}1)$$

$$A_\sigma = (4/5)g_e g_N \beta_e \beta_N \times (1/4)a^2 N_1 \alpha_2^2 \langle r^{-3}\rangle_{2p}, \quad (14\text{-}2)$$

$$A_\pi = (4/5)g_e g_N \beta_e \beta_N \times (3/4)ae(N_1N_2)^{1/2}\alpha_2\beta\langle r^{-3}\rangle_{2p}. \quad (14\text{-}3)$$

The calculation was performed with $r(=d/e)$ value from 0.5 to 1.0. The calculated values are given in Tables 6 and 7. The β value could not be determined because of the experimental error between A_z^N and A_y^N values.

In *cis*-planar copper(II) complexes, the g values have an axial symmetry. When tetrahedral distortion occurs, this is not true. The g_z and g_x values are no longer equal, as may be seen in Eq. 3. Even if the distortion occurs, the g values sometimes chance to have an axial symmetry. In *cis* bis(methyl 3-alkylidenedithiocarbazato)copper(II), however, the tetrahedral distortion of about 20° does not break the axial symmetry of the g values.

The values of g are rhombic in a *trans* arrangement.[6,14,22] It was concluded from this fact that Cu(II) in $Ni(bdc)_2$ is in a *trans* arrangement.

The ESR spectra in chloroform solutions of copper(II) complexes at room temperature have A^{Cu} values between 66 and 72×10^{-4} cm^{-1} for the *cis* complexes and of 82×10^{-4} cm^{-1} for $Cu(bdc)_2$. These values are in reasonable agreement with the attributions of negative signs to all the A^{Cu} components.

The A^N values are smaller in the *cis* complexes than in $Cu(bdc)_2$. It is expected that in the *cis* complexes, the Cu–N bond length is longer than in the *trans* arrangement because of steric repulsion by the large phenyl groups.

The author is grateful to Professor Tetsuya Komori of Kyushu University for his kind advice and for allowing him to use the Syntex P$\bar{1}$ automatic diffractometer, and to Professor Ikuhiko Ueda of Kyushu University for allowing him to take the Weissenberg photographs. Thanks are also due to Professor Sigeo Kida and Dr. Toshiyuki Isobe for allowing him to take ESR measurements. A part of this work has been carried out at the Coordination Chemistry Laboratory of Kyushu University.

Glass Formation in the Li_2O-TiO_2-P_2O_5, MgO-TiO_2-P_2O_5, and CaO-TiO_2-P_2O_5 Systems

Akira KISHIOKA

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho, Chiyoda-ku, Tokyo 102

(Received December 20, 1977)

The glass-forming regions in the Li_2O–TiO_2–P_2O_5, MgO–TiO_2–P_2O_5, and CaO–TiO_2–P_2O_5 systems have been determined. Homogeneous glasses were formed with compositions of less than 50 mol% P_2O_5 in all three systems. The largest quantities of TiO_2 could be introduced into glass for compositions of 30 mol% P_2O_5. In compositions with more than 50 mol% P_2O_5 only a mixture of the glass and crystal was formed. With an increase in the TiO_2 content, the density of the glass increased and the volume per mole of oxygen decreased. These results indicate that the TiO_2 had been easily incorporated into the glass with compositions of lower P_2O_5 contents, contributing to the stabilization of the glass structure.

The role of intermediate ions such as Ti^{4+} and Al^{3+} in glass formation in ternary phosphate systems is interesting, since it reflects the glass structure. Reports concerning the glass-forming regions in ternary phosphate systems, however, are relatively few compared with those in ternary systems containing other glass-forming oxides. Recently, glass formation in the BeO–TiO_2–P_2O_5, CaO–TiO_2–P_2O_5, and K_2O–TiO_2–P_2O_5 systems and the electrical resistivity have been reported by Hayashi *et al.*[1] The present authors have reported glass formation in the Na_2O–BaO–TiO_2–P_2O_5 four-component system,[2] the ternary phosphate systems containing Al_2O_3,[3] and the role of the Al^{3+} ion in alkali aluminophosphate glasses.[4]

In this paper, glass-forming regions for the Li_2O–TiO_2–P_2O_5, MgO–TiO_2–P_2O_5, and CaO–TiO_2–P_2O_5 systems have been determined. The density of the glass has been determined and the volume per mole of oxygen calculated. On the basis of these results, the role of the titanium ion in the glass has been discussed.

Experimental

Determination of Glass-Forming Region. The materials used were reagent grade chemicals of titanium dioxide, orthophosphoric acid (85%), lithium hydroxide monohydrate, magnesium oxide, calcium hydrogenphosphate dihydrate, and calcium carbonate. A batch (15-g) obtained by mixing appropriate amounts of the above chemicals was placed in platinum dishes and heated in an electric furnace. After dehydration, the batch was kept at 1350 °C for 1 h. The melt was poured out and quenched by pressing with a copper plate cooled with water. The homogeneity of the glass was checked with a polarizing microscope and the naked eye.

Density of Glass. The density of the glass was determined pycnometrically using 1-butanol at 25.0 °C. For samples containing a small amount of crystal, only the glassy part was used for measurement.

Volume of Glass. The volume of the glass per mole of oxygen was calculated by the following equation:[5]

$$V_0 = (G.F.W./D) \times 1/N_0,$$

where V_0 is the volume of the glass per mole of oxygen, $G.F.W.$ is the gramme formula weight of the glass based on the batch composition, D is the density of the glass, and N_0 is the number of gramme molecular weights of oxygen (32 g units) in the glass.

Results and Discussion

Glass-Forming Tendency. The results are given in Figs. 1—3. The compositions whose batches melted completely at 1350 °C have been surrounded by dotted lines in the Figs. Homogeneous glasses were formed in compositions with less than 50 mol% P_2O_5. As shown by the arrows in Figs. 1—3, the content of TiO_2 in the glass was largest for compositions with 30 mol% P_2O_5 of each system; it was the largest for the MgO–TiO_2–P_2O_5 system. Considering that the phosphate species in the $47.5Na_2O \cdot 20Al_2O_3 \cdot 32.5P_2O_5$ glass were exclusively PO_4^{3-}-type ions,[4] those in the glasses with 30 mol% P_2O_5 containing more than 20 mol% TiO_2 are presumably also only PO_4^{3-} ions. Therefore, the above results indicate that the TiO_2 is incorporated easily into the glass with compositions of lower P_2O_5 content and the formation of the glass with higher TiO_2 contents is most favorable when there are no P–O–P chains.

All glasses were colored by the titanium ion of lower valency and the MgO–TiO_2–P_2O_5 glasses with higher TiO_2 content were brownish black. The Li_2O–TiO_2–

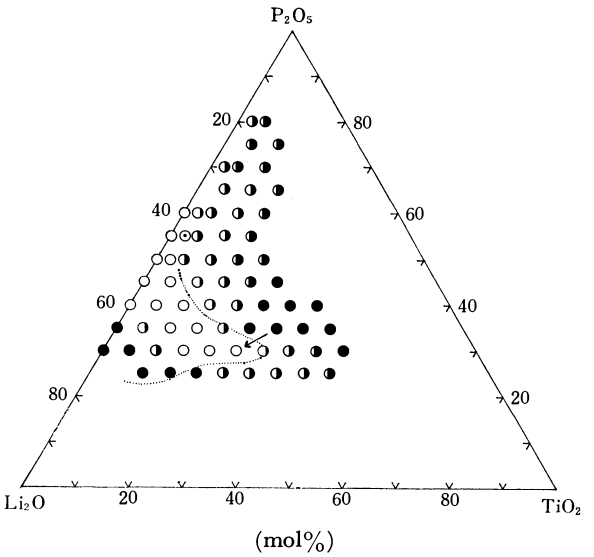

Fig. 1. Glass-forming region in Li_2O–TiO_2–P_2O_5 system. ○: Homogeneous glass, ⊙: trace amounts of crystal in glass, ◑: glass and crystal, ●: crystal.

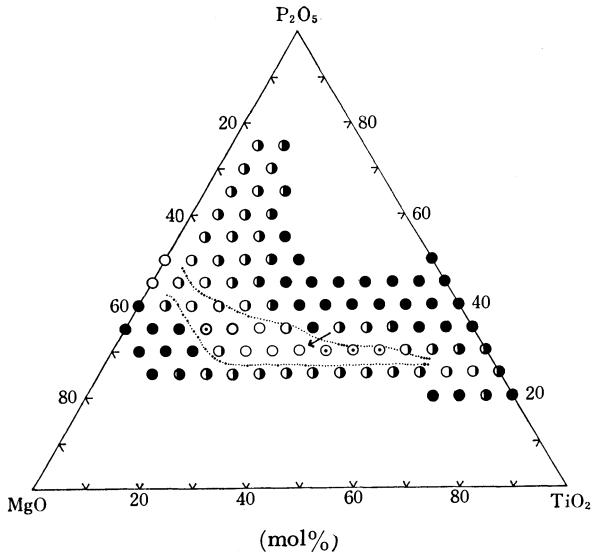

Fig. 2. Glass-forming region in MgO–TiO_2–P_2O_5 system.

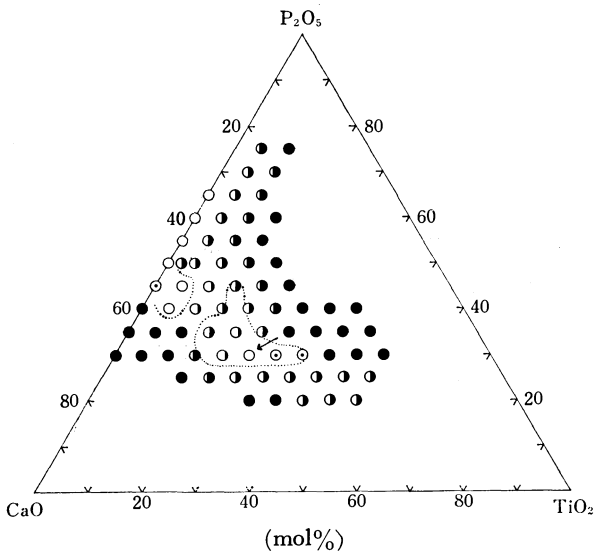

Fig. 3. Glass-forming region in CaO–TiO_2–P_2O_5 system.

P_2O_5 glasses were less colored than those containing MgO or CaO of the same molar composition.

In addition to the homogeneous glass, the following two types of products were formed; (a) a mixture of glass and crystal (produced by partial devitrification of the melt during quenching or separation of crystalline substance in the melt) and (b) a crystalline product formed as a result of devitrification during quenching or non-melting of the batch.

The glass-forming region in each system in the present work was smaller than those reported by Hayashi *et al.*[1] However, the observed tendency of glass formation in compositions with less than 50 mol% P_2O_5 agrees well with the results reported.[1]

In compositions with more than 50 mol% P_2O_5, only the mixture of the glass and the crystal was formed as the result of the separation of the crystalline substance in the melt. This makes a marked difference from the alkali (or alkaline earth) aluminophosphate system[3] where the homogeneous glasses were formed in the region with more than 50 mol% P_2O_5 in a three-component diagram. It can be considered that the action of the titanium ion in the glass formation is fairly different from that of the Al^{3+} ion in the same P_2O_5 content.

Density and Volume of Glass. The density and the volume per mole of oxygen of the glasses are given in Figs. 4—7. In Figs. 4 (a) and (b), the density and the volume in the Li_2O–TiO_2–P_2O_5 glasses with the same Li_2O contents are plotted *vs.* the TiO_2 content respectively. The plots of the density and the volume *vs.* the TiO_2 content in the glasses with the same P_2O_5 contents are given in Figs. 5—7. Except for Fig. 4 (b), these plots showed linear relationships. The density of the glass increased and the volume of the glass per mole of oxygen decreased with an increase in the TiO_2 content in all the systems. This indicates the

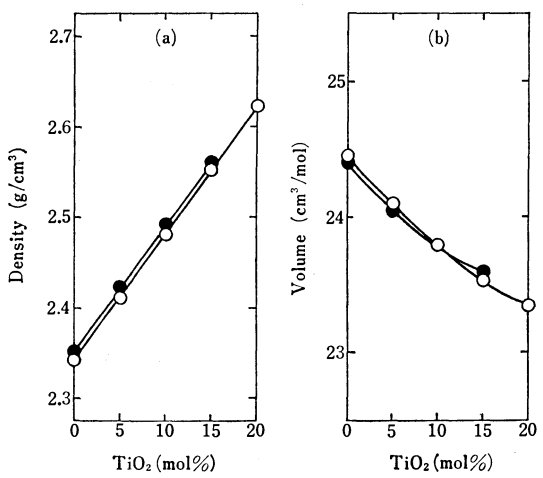

Fig. 4. Plots of (a) density *vs.* TiO_2 content, and (b) volume per mole of oxygen *vs.* TiO_2 content in the Li_2O–TiO_2–P_2O_5 glass with the same Li_2O contents. ○: 50 mol% Li_2O, ●: 55 mol% Li_2O.

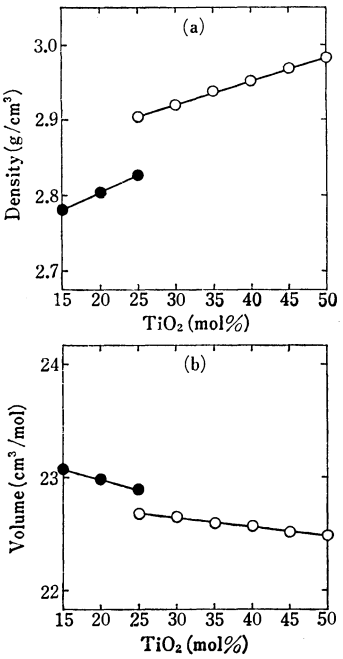

Fig. 6. Plots of (a) density *vs.* TiO_2 content, and (b) volume per mole of oxygen *vs.* TiO_2 content in the MgO–TiO_2–P_2O_5 glass with the same P_2O_5 contents. ○: 30 mol% P_2O_5, ●: 35 mol% P_2O_5.

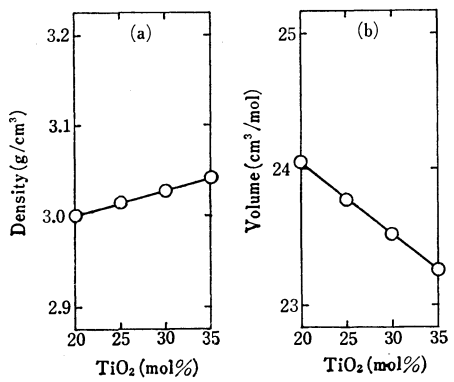

Fig. 7. Plot of (a) density *vs.* TiO_2 content, and (b) volume per mole of oxygen *vs.* TiO_2 content in the CaO–TiO_2–P_2O_5 glass with 30 mol% P_2O_5.

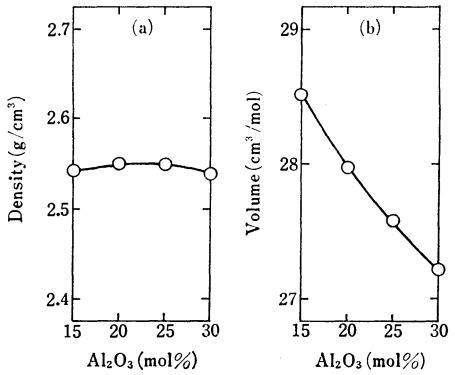

Fig. 8. Plot of (a) density *vs.* Al_2O_3 content, and (b) volume per mole of oxygen *vs.* Al_2O_3 content in the Na_2O–Al_2O_3–P_2O_5 glass with 32.5 mol% P_2O_5.

strength of the titanium ion contribution to the strengthening of the glass structure.

The contractions in the volume of the MgO–TiO_2–P_2O_5 glasses with an increase in the TiO_2 content (Fig. 6 (b)) are less than those of the glasses in the Li_2O- and CaO-systems (Figs. 5 (b) and 7 (b)). It can be said that the role of the titanium ion in the glass structure is similar to that of the Mg^{2+} ion and also that the titanium ion replaces the Mg^{2+} ion.

As shown in Fig. 8 (a), no increase was found in the density on an increase in the Al_2O_3 content for the Na_2O–Al_2O_3–P_2O_5 glass with 32.5 mol% P_2O_5. This suggests that the role of the titanium ion in the glass structure is different from that of the Al^{3+} ion in compositions with less than 50 mol% P_2O_5.

The author wishes to thank Associate Professor Makio Kinoshita of Sophia University for his interest and encouragement, and also Mr. Yuichi Yokoyama for his assistance in the experimental work.

Kinetics of the Oxidative Addition of Hydrogen to Chloro(acrylonitrile)-bis(triphenylphosphine)rhodium(I) in Benzene

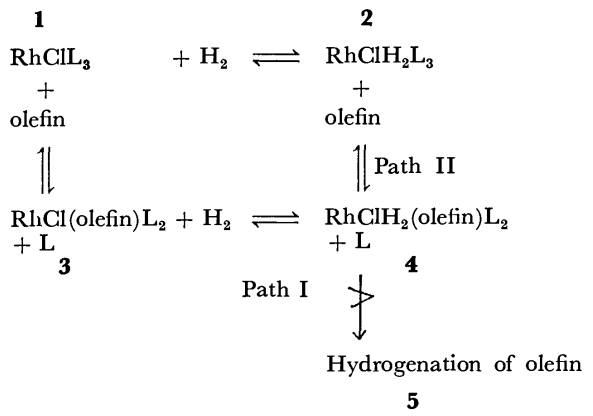
Yoshimi OHTANI, Akihiko YAMAGISHI, and Masatoshi FUJIMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received January 6, 1978)

The reaction between chloro(acrylonitrile)bis(triphenylphosphine)rhodium(I) and hydrogen was studied by the stopped-flow method under an anaerobic condition. A solution of $RhCl(CH_2{=}CHCN)(PPh_3)_2$ was mixed with a benzene solution containing hydrogen under the condition of $[Rh]<[H_2]_0<[CH_2{=}CHCN]$. A fast decrease in the absorbance was followed by a slow increase in the absorbance, until finally the absorbance returned to the initial value. It was proved that the faster reaction was the oxidative addition of hydrogen to $RhCl(CH_2{=}CHCN)(PPh_3)_2$; $RhCl(CH_2{=}CHCN)(PPh_3)_2+H_2 \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} RhClH_2(CH_2{=}CHCN)(PPh_3)_2$. The slower reaction was the process in which hydrogen was consumed in the course of the hydrogenation of acrylonitrile and $RhCl(CH_2{=}CHCN)(PPh_3)_2$ was reproduced. The values of the rate constants were evaluated to be $k_{34} \geq 7.8\times10^3$ mol^{-1} dm^3 s^{-1} and $k_{43} \leq 53$ s^{-1}.

Wilkinson's complex, $RhClL_3$ ($L=PPh_3$), is a useful catalyst for the hydrogenation of olefins.[1] Although many studies have been made to elucidate the reaction mechanism of the hydrogenation of olefins by means of Wilkinson's complex,[2-7] the mechanism has not yet been fully made clear. We previously proposed the following reaction mechanism, in which complex formation processes are assumed as a pre-equilibrium step,[7] though an intermediate species ($RhClH_2$(olefin)L_2) could not be detected spectrophotometrically:



The predominant species of the Rh complex is considered to be $RhClH_2L_3$ (**2**) or $RhCl$(olefin)L_2 (**3**). Whether the $RhCl$(olefin)L_2 species becomes a predominant species or not depends on the coordinating ability of the olefin. Thus, the hydrogenation of olefins with a weakly coordinating power may proceed mainly through a so-called "hydride route" (Path II) as proposed by Halpern *et al.*[6] However, the hydrogenation of olefins with a strongly coordinating power is expected to proceed predominantly through an "unsaturate route" (Path I). However, the latter has not so far been observed with the use of Wilkinson's complex.

We intend in the present study to detect the intermediate species, $RhClH_2$(olefin)L_2 (**4**), and also to obtain the kinetic data of the reaction 3⇌4. Acrylonitrile was chosen as an olefin since it strongly coordinates to Wilkinson's complex and is rapidly hydrogenated.[3] The concentration of $RhClH_2(CH_2{=}CHCN)L_2$ increases as the concentration of free PPh_3 decreases. Thus, a solution of $RhCl(CH_2{=}CHCN)L_2$ containing no free PPh_3 was prepared by dissolving $RhCl(C_2H_4)L_2$ in a benzene solution containing acrylonitrile. The coordinated ethylene was then replaced by an acrylonitrile molecule[7] and $RhCl(CH_2{=}CHCN)L_2$ was produced in the solution. As there was no free PPh_3 in the solution, only olefin complexes **3** and **4** can exist. The oxidative addition of hydrogen to $RhCl(CH_2{=}CHCN)L_2$ was observed by the addition of a solution containing hydrogen to a solution of $RhCl(CH_2{=}CHCN)L_2$.

Experimental

A solution of $RhCl(CH_2{=}CHCN)(PPh_3)_2$ was prepared by dissolving $RhCl(C_2H_4)(PPh_3)_2$ in oxygen-free benzene containing acrylonitrile and by removing the dissociated ethylene. The coordinated ethylene was easily replaced by acrylonitrile,[7] and $RhCl(CH_2{=}CHCN)(PPh_3)_2$ was produced in benzene. The value of the equilibrium constant $K=[RhCl(CH_2{=}CHCN)(PPh_3)_2][C_2H_4]/[RhCl(C_2H_4)(PPh_3)_2][CH_2{=}CHCN]$ was calculated to be 0.5 from the values of $K'=[RhCl(C_2H_4)(PPh_3)_2][PPh_3]/[RhCl(PPh_3)_3][C_2H_4]=0.4$[5] and $K''=[RhCl(CH_2{=}CHCN)(PPh_3)_2][PPh_3]/[RhCl(PPh_3)_3]\cdot[CH_2{=}CHCN]=0.2$.

Chloro(ethylene)bis(triphenynylphosphine)rhodium(I), $RhCl(C_2H_4)(PPh_3)_2$ was prepared from $RhCl(PPh_3)_3$.[2] Benzene was distilled. Acrylonitrile was distilled under reduced pressure. Commercial hydrogen was used without purification; the concentration was determined by gas-chromatography using a Molecular sieve 5A.

Kinetic measurements were made at 20 °C using a Union Giken RA-1300 stopped-flow apparatus. A solution of $RhCl(CH_2{=}CHCN)(PPh_3)_2$ containing an appropriate concentration of acrylonitrile (0.004—0.228 mol dm^{-3}) was mixed with a solution of hydrogen containing the same concentration of acrylonitrile as in the solution of $RhCl(CH_2{=}CHCN)(PPh_3)_2$ ($[H_2]=(0.8—2.8)\times10^{-3}$ and $[CH_2{=}CHCN]=0.004—0.228$ mol dm^{-3}). The reaction was then carried out under a nitrogen or a hydrogen atmosphere. The change in the absorbance was observed at 458 nm (λ_{max} of $RhCl(CH_2{=}CHCN)(PPh_3)_2$).

The rate of hydrogen-gas uptake was measured as follows. A catalytic hydrogenation apparatus was evacuated and filled with 1 atm hydrogen. A benzene solution (10 ml) containing an appropriate concentration of acrylonitrile was introduced into the apparatus. The solution was vigorously stirred in order to saturate the apparatus with benzene vapor. The total pressure in the apparatus was 1 atm, and no attempt was made to compensate for the partial pressure of benzene. A

benzene solution of the Rh complex (10 ml; the Rh complex existed in the form of $H_2[RhCl(PPh_3)_2]_2$), saturated with 1 atm of hydrogen beforehand, was dropped into the vessel while the solution was being vigorously stirred. The dimeric form of the Rh complex was rapidly decomposed to a monomeric olefin complex by the reaction with acrylonitrile.[8] The absorption rate of hydrogen was measured by means of a 10 ml gas buret. The limitation of the uptake rate due to the ability of the apparatus was not less than 0.25 ml s^{-1}. In the kinetic runs, the fastest uptake rate was 0.02 ml s^{-1}, so there was no hydrogen starvation in the solution.

Results and Discussion

When a solution containing $RhCl(CH_2{=}CHCN)L_2$ was mixed with a solution containing hydrogen, stepwise reactions took place. Figure 1 shows a typical example of the absorbance changes.

The first decrease in the absorbance shows an exponential curve. It terminates within 0.1 s. The rate does not depend on $[CH_2{=}CHCN]$, but depends somewhat on $[H_2]$ (Fig. 2). The change in the absorbance

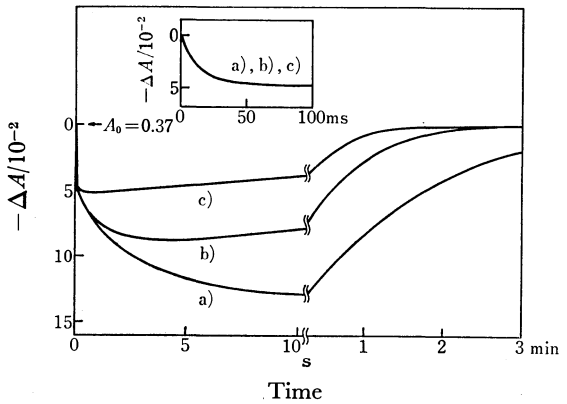


Fig. 1. Typical absorbance changes in the reaction between $RhCl(CH_2{=}CHCN)L_2$ and hydrogen in benzene. Inset shows an expanded signals for the first step of the reaction. $[RhCl(CH_2{=}CHCN)L_2]_0=3.2\times10^{-4}$ mol dm^{-3}, $[H_2]_0=1.4\times10^{-3}$ mol dm^{-3}, at 458 nm, and 20 °C. a) $[CH_2{=}CHCN]=0.004$, b) 0.076, and c) 0.228 mol dm^{-3}.

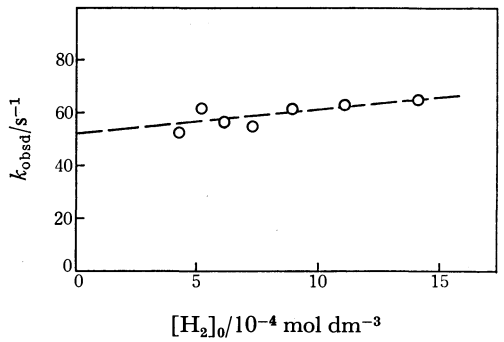

Fig. 2. Plot of k_{obsd} in the first step *vs.* $[H_2]_0$. $[Rh]=3.6\times10^{-4}$, $[CH_2{=}CHCN]=0.076$ mol dm^{-3}. Broken line is drawn assuming $K_{34}=k_{34}/k_{43}=1.5\times10^2$ $mol^{-1}\cdot dm^3$. As the concentration of $RhClH_2(CH_2{=}CHCN)L_2$ is small, the concentration of H_2, $[H_2]=[H_2]_0-[RhClH_2(CH_2{=}CHCN)L_2]$, is held nearly constant during the reaction.

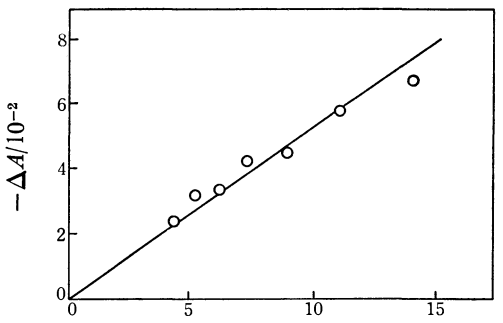

Fig. 3. Plot of the absorbance change, ΔA, in the first step *vs.* $[H_2]_0$. $[Rh]=3.6\times10^{-4}$, $[CH_2{=}CHCN]=0.076$ mol dm^{-3}.

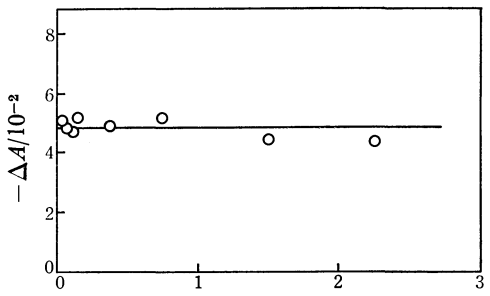

Fig. 4. Plot of the absorbance change, ΔA, in the first step *vs.* $[CH_2{=}CHCN]$. $[Rh]=3.2\times10^{-4}$ and $[H_2]_0=1.4\times10^{-3}$ mol dm^{-3}.

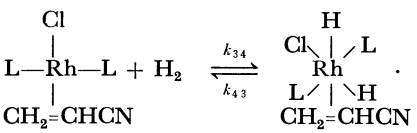
is nearly proportional to $[H_2]$ (Fig. 3), but does not depend on $[CH_2{=}CHCN]$ (Fig. 4). From these results it may be concluded that the coordination of hydrogen does not cause the dissociation of the previously coordinated acrylonitrile. The reaction in the first step is:



(1)

Figure 3 suggests that the equilibrium lies far to the reactant side even when $[H_2]=1.4\times10^{-3}$ mol dm^{-3}. If the molar absorption coefficient of the octahedral $RhClH_2(CH_2{=}CHCN)L_2$ at 458 nm is very small (as in the case of $RhClH_2L_3$) compared with that of the square-planar $RhCl(CH_2{=}CHCN)L_2$, the lower limit of the equilibrium constant of reaction (1) can be calculated by an equation: $K_{34}\geq(A_0-A)/A[H_2]$, where A_0 is the initial absorbance and A is the absorbance at the end of the first absorbance change. From Fig. 3, the value of K_{34} was evaluated to be $K_{34}\geq1.5\times10^2$ $mol^{-1}\cdot dm^3$. The broken line in Fig. 2 is drawn assuming that $K_{34}=k_{34}/k_{43}=1.5\times10^2$ mol^{-1} dm^3. The observed rate constant, $k_{obsd}=k_{34}[H_2]+k_{43}$, was mainly attributed to the rate constant of the reverse reaction. The rate constants were $k_{43}\leq53$ s^{-1} and $k_{34}\geq7.8\times10^3$ $mol^{-1}\cdot dm^3$ s^{-1}.

The addition and the dissociation rate constants, k_{34} and k_{43}, for several Rh(I) complexes are listed in

TABLE 1. ADDITION AND DISSOCIATION RATE CONSTANTS FOR THE HYDROGENATION OF SEVERAL Rh(I) COMPLEXES

Rh complex	k_1/mol^{-1} dm^3 s^{-1}	k_{-1}/s^{-1}	K_1/mol^{-1} dm^3
$RhCl(PPh_3)_3$ [a]	4.8	2.3×10^{-4} [d]	2.1×10^4
$RhCl(NCCH_3)(PPh_3)_2$ [b]	1.4×10^2	5.6×10^{-3} [d]	2.5×10^4
$RhCl(CH_2=CHCN)(PPh_3)_2$ [c]	$\geq7.8\times10^3$	≤53	$\geq1.5\times10^2$
$RhCl(PPh_3)_2$ [a]	$>7\times10^4$	—	

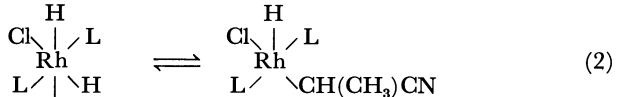
a) At 25 °C, from Ref. 4. b) At 20 °C, from Ref. 9. c) At 20 °C, the present study. d) Calculated from $k_{-1}=k_1/K_1$.

Table 1. The values of k_{34} increased in the sequence: $RhClL_3 < RhCl(NCCH_3)L_2 < RhCl(CH_2=CHCN)L_2 < RhClL_2$. The larger rate constant for $RhClL_2$ indicates that $RhClL_2$ has a labile site to which the benzene molecule coordinates. That the rate constant for $RhCl(CH_2=CHCN)L_2$ is larger than that for $RhClL_3$ suggests that $CH_2=CHCN$ is sterically less hindered than the PPh_3 attached to $RhClL_3$. A larger rate constant for $RhCl(CH_2=CHCN)L_2$ than that for $RhCl(NCCH_3)L_2$ may be predicted from the fact that the coordination of olefin stabilizes the lower valency state of the central metal more than the coordination of acetonitrile does.

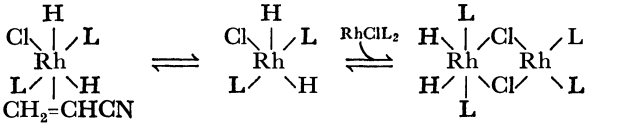
The values of k_{43} increased in the sequence: $RhClL_3 < RhCl(NCCH_3)L_2 \ll RhCl(CH_2=CHCN)L_2$. $RhCl(CH_2=CHCN)L_2$ had an especially large rate constant. $CH_2=CHCN$ has the largest *trans*-effect among $CH_2=CHCN$, CH_3CN, and PPh_3. The Rh–H bond may be most weakened through the coordination of $CH_2=CHCN$. Thus, the dissociation of hydrogen from $RhClH_2(CH_2=CHCN)L_2$ is accelerated.

When $[CH_2=CHCN]$ is small, a second, slower decrease in the absorbance is observed (Fig. 1). The absorbance change gradually decreased with the increase in $[CH_2=CHCN]$ and finally disappeared. The accurate value of the rate constant cannot be obtained since the signal overlaps with that of the third step. The observed rate constant was about 0.35 ± 0.15 s^{-1} when $[H_2]_0=(1.41—0.56)\times10^{-3}$ and $[CH_2=CHCN]=7.6\times10^{-3}$ mol dm^{-3}.

Alternative explanations of the results will be presented below. One is an interpretation by the formation of a reaction intermediate alkyl complex (2), and another is an interpretation by the formation of a dimeric dihydrido species (3) which is inactive for the hydrogenation of olefin.



(2)



(3)

The less characteristic spectrum prevented us from distinguishing between $RhClH(-CH(CH_3)CN)L_2$ and $H_2(RhClL_2)_2$.

In the third step, the absorbance returned to that of the initial stage (Fig. 1). This step involves the consumption of hydrogen for the hydrogenation of acrylonitrile. The rate is dependent on $[CH_2=CHCN]$ when it is small, but gradually approaches the constant value as $[CH_2=CHCN]$ increases. The measurements of the hydrogen-gas uptake also showed that the hydrogenation rate depended on $[CH_2=CHCN]$ when it was small (Fig. 5). From Fig. 5, the value of k_{45}, the rate constant of the hydrogenation of $CH_2=CHCN$ in $RhClH_2(CH_2=CHCN)L_2$, can be estimated by means of the following equation

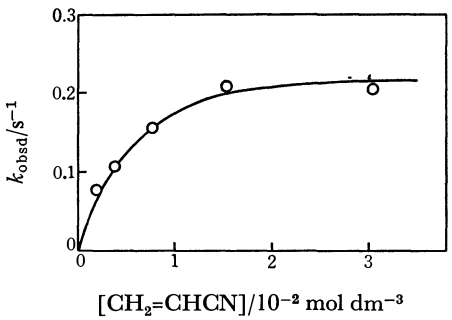


Fig. 5. Plot of the number of H_2 molecules taken up per Rh per s *vs.* $[CH_2=CHCN]$. $[Rh]=1.4\times10^{-4}$ mol dm^{-3} (2.8×10^{-6} mol), and $[H_2]=2.8\times10^{-3}$ mol dm^{-3} ($P(H_2)=1$ atm).

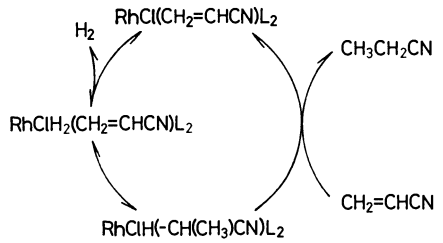
$$k_{45}=\frac{[RhCl(CH_2=CHCN)L_2]+[RhClH_2(CH_2=CHCN)L_2]}{[RhClH_2(CH_2=CHCN)L_2]}\times k_{obsd} \quad (4)$$
$$=\left(1+\frac{1}{K_{34}[H_2]}\right)\times0.22\ s^{-1}$$
$$\leq 0.74\ s^{-1}.$$

If an alkyl complex is formed in the second step, this result can be interpreted as follows: the addition of acrylonitrile to the vacant site of the alkyl complex weakens the *trans* Rh–H bond, and the insertion of the alkyl group to the second hydride is accelerated. At a high $[CH_2=CHCN]$ value, the formation of the alkyl complex becomes rate-determining for the hydrogenation of acrylonitrile.

If a dimeric dihydrido species is formed in the second step, the rate of hydrogenation depends on $[CH_2=CHCN]$ as the concentration of the active species decreases.

The total mechanism proposed is shown in Scheme 1. Because of the absence of the free PPh_3 molecule and the strong coordinating power of acrylonitrile, the hydrogenation of acrylonitrile proceeds through a so-called "unsaturate route." The existence of an intermediate species, $RhClH_2(CH_2=CHCN)L_2$, is indicated by the absorbance change, but no certain evidence of another reaction intermediate, $RhClH(-CH(CH_3)CN)L_2$, is



Scheme 1.

obtained in the present study.

Since the coordinating power of CH_3CH_2CN would be much smaller than that of $CH_2=CHCN$,[10] and since its concentration is small ($[CH_3CH_2CN] \leq [H_2]_0$), the formation of a propionitrile complex is very unlikely during the course of the hydrogenation.

(Received January 10, 1978)

The lifetime of *ortho*-positronium(*o*-Ps) was measured in benzene solutions of several lanthanoid dipivaloylmethanates. None of the paramagnetic lanthanoid dipivaloylmethanates, $Ln(dpm)_3$ (Ln=Eu, Gd, Tb, Dy, Ho, Er, and Yb), accelerated the *o*-Ps decay (τ_2=3.2 ns). On the other hand, diamagnetic tetrakis(dipivaloylmethanato)cerium(IV), $Ce(dpm)_4$, shortened the lifetime of *o*-Ps (τ_2=1.9 ns for a 0.02 mol dm^{-3} solution in benzene). These results clearly indicate that the acceleration of the *o*-Ps decay by lanthanoid complexes occurs through the oxidation mechanism, not through the spin-conversion mechanism. This confirms the previous conclusion from experiments with 3d transition-metal β-diketonates that the oxidation of *o*-Ps is mainly responsible for the rapid *o*-Ps decay caused by the Fe(III) and Mn(III) complexes. Factors which influence the intensity and decay rate of *o*-Ps are discussed in connection with the experimental results.

The reaction of *ortho*-positronium(*o*-Ps) with inorganic ions in aqueous solutions has been studied by many investigators. Jackson and McGervey[1] measured the lifetime of *o*-Ps in solutions of $KMnO_4$, $HgCl_2$, *etc.* and attributed the observed acceleration of *o*-Ps decay to the oxidation of *o*-Ps by the oxidizing ions. Ache and his coworkers[2-4] observed no significant changes in the lifetime of *o*-Ps in aqueous solutions containing Sn(II), Pb(II), Cd(II), *etc.* up to a concentration of about 2 M. On the other hand, the intensity (I_2) of *o*-Ps decreased with an increase in the solute concentration and approached a saturation value characteristic of each solute. The results were explained in terms of hot Ps reactions with solute species.

Previously,[5-6] we measured the lifetime of *o*-Ps in benzene solutions of 3d transition-metal acetylacetonates and dipivaloylmethanates, and showed that the decay rate of *o*-Ps was accelerated to a great extent by the Fe(III) and Mn(III) complexes and to a lesser extent by the Cu(II), Co(II), Co(III), and Cr(III) complexes, but that no acceleration was observed with the Al(III), Ni(II), and Zn(II) complexes. The complexes of the first group are oxidizing, those of the second group (except for the Co(III) complexes) are paramagnetic and poorly oxidizing, and the third-group complexes are non-oxidizing and diamagnetic. The conclusion was that, while the oxidation of *o*-Ps by oxidizing complexes proceeds very rapidly to result in a great acceleration of the *o*-Ps decay, the spin conversion of *o*-Ps through interaction with paramagnetic complexes proceeds slowly to result in a slight acceleration of the *o*-Ps decay.

The present study has been made with the intention of substantiating the previous conclusion and of determining the factors governing the rate of spin conversion. Lanthanoid dipivaloylmethanates were chosen for this purpose, since they show a series of different spin and total angular momenta (different quantum numbers, S and J) and since they include cerium(IV) dipivaloylmethanate, a unique compound which is diamagnetic and highly oxidizing.

Experimental

Lanthanoid tris(dipivaloylmethanato) complexes, $Ln(dpm)_3$, were prepared according to the procedure reported by Eisentraut and Sievers.[7] The compounds were purified by repeated sublimations and by recrystallization from mixed benzene-hexane. Tetrakis(dipivalolylmethanato)cerium(IV) was synthesized by a method analogous to that presented for tetrakis(acetylacetonato)cerium(IV), $Ce(acac)_4$.[8] The preparation of the dipivaloylmethanates of aluminium and 3d transition metals were described in a previous paper.[6] The compounds were identified by elemental analyses. A definite amount of each compound was dissolved in distilled benzene. The solution was then placed in a Pyrex tube and degassed repeatedly by a vacuum freeze-thaw technique. About 6 μCi of $^{22}Na(NaCl)$ of a high specific activity was used as the positron source. The lifetimes of the positron and positronium were measured with a fast-slow coincidence system, the details of which have been described elsewhere,[9] while the lifetime sepctrum was accumulated by means of a Hitachi 512-channel pulse-height analyzer. The time calibration was made by using coaxial cables of various lengths. The system as a whole gave a resolution (FWHM) of 750 ps for ^{60}Co prompt gamma rays and a 25 ns range of linear conversion.

Cyclic-voltammetric measurements were made of $Ce(dpm)_4$, $Eu(dpm)_3$, $Fe(dpm)_3$, $Co(dpm)_3$, $Co(acac)_2$, and $Cu(dpm)_2$ in dichloromethane(CH_2Cl_2) and partly in *N,N*-dimethylformamide(DMF), using 0.1 M tetrabutylammonium perchlorate(TBAP) as the supporting electrolyte. The measurement was carried out in a three-necked cell at room temperature. A platinum-inlay electrode (Beckman 32273) was used as the working electrode; the counter electrode was a piece of platinum wire. A saturated calomel electrode, used as a reference, was connected to the cell by two salt bridges: a saturated KCl solution in water and a 0.1 M TBAP solution in CH_2Cl_2 (or DMF). A Hokuto Denko Model HA-101 potentiostat and a Hokuto Denko Model HB-107 function generator were used. The scan rate was 0.50 and 1.00 V/s, and voltammograms were recorded by means of a Rikadenki X-Y recorder, Model BW 133.

Results and Discussion

The lifetimes of *o*-Ps, obtained from the measured lifetime spectra, are listed in Table 1, together with the I_2 values. The obtained decay constant, λ_2, of

o-Ps is plotted against the solute concentration in Fig. 1. None of the $Ln(dpm)_3$-type complexes (Ln=La, Gd, Tb, Ho, Dy, Er, and Yb) changed the lifetime of *o*-Ps in benzene, while $Ce(dpm)_4$ greatly accelerated the *o*-Ps decay. Since cerium(IV) has no unpaired electrons, the acceleration of the *o*-Ps decay by $Ce(dpm)_4$ can undoubtedly be attributed to its highly oxidizing nature, which was confirmed by cyclic voltammetry. The voltammograms of $Ce(dpm)_4$ and $Fe(dpm)_3$ in dichloromethane are compared in Fig. 2, while the E_{pc} values are listed in Table 2. It can be inferred from these results that $Ce(dpm)_4$ would be more oxidizing than $Fe(dpm)_3$ in benzene, too. Therefore,

a) E_{pc}=Potential corresponding to the cathodic peak current (scan rate 0.5 and 1.0 V/s). b) The potential where the reduction of CH_2Cl_2 took place. c) k=rate constant for the reaction with *o*-Ps.

one might expect that *o*-Ps decay would be accelerated to a greater extent by the more oxidizing $Ce(dpm)_4$ than by the less oxidizing $Fe(dpm)_3$. However, experiments showed that the two complexes differed only slightly from each other in the rate constants for their reactions with *o*-Ps. This can be taken as demonstrating that the reaction is almost encounter-controlled in both cases.

Tripositive europium ions are known to be easily reduced to a dipositive state. However, the normal λ_2 value observed for a $Eu(dpm)_3$ solution shows that the complex is not oxidizing enough. Consistently, the E_{pc} value for $Eu(dpm)_3$ was found to be more negative than the potential where the reduction of the CH_2Cl_2 solvent took place.

Unlike 3d-transition-metal complexes, the paramagnetic lanthanoid complexes did not accelerate the *o*-Ps decay. In order to find the reason for this dissimilarity, the spin-conversion mechanism of *o*-Ps decay will now be examined. Whenever spin exchange occurs between

o-Ps and a metal complex with unpaired electrons, spin pairing will occur in the complex except when the partly filled shell has only one electron or hole. Thus, in order for spin exchange to occur, the kinetic energy of the *o*-Ps must at least counterbalance the spin-pairing energy. The latter is estimated to be about 2.5 eV for most lanthanoid complexes other than $Gd(dpm)_3$ ($\approx$3.9 eV), $Ho(dpm)_3$ ($\approx$3.5 eV), and $Yb(dpm)_3$ ($\approx$0).[10]

The Oré theory[11] shows that the most efficient formation of Ps occurs when the kinetic energy of a positron goes below the energy of the first excited level of the solvent (4.90 eV for benzene). Then, the kinetic energy of the positronium formed will be distributed mainly in the range below 2.46 eV; *i.e.*, (kinetic energy of positron) + (binding energy of positronium) − (ionization energy of benzene) = 4.90 + 6.80 − 9.24 = 2.46 (see Fig. 3).

Oré diagram for positronium formation in benzene (eV)			Kinetic energy of positronium (eV)

Fig. 3. Oré diagram of positronium formation in benzene and the kinetic energy of positronium.

The foregoing argument raises an expectation that the *o*-Ps decay would be accelerated by $Yb(dpm)_3$, which requires no spin-pairing energy. The experimental results, however, failed to show this. This leads to the conclusion that the lanthanoid complexes (at least $Yb(dpm)_3$, but not $Ce(dpm)_4$) fail to accelerate the *o*-Ps decay, not because of a matter of energy balance, but because of the inertness of the 4f unpaired electrons. Abundant evidence shows that the 4f orbitals of the lanthanoid ions are well shielded from the surrounding ions by the 5s—5p closed shell. Thus, the overlap of the 4f orbital with the *o*-Ps orbital can be expected to be negligibly small. The present experimental findings not only conform with the negligible overlap, but also indicate that there exist no appreciable long-range interactions that would result in spin exchange between the 4f and *o*-Ps orbitals.

The effect of $Ce(dpm)_4$ on the I_2 value was not so great as that of $Fe(dpm)_3$, and it was similar to that of other lanthanoid complexes. With the Oré model of Ps formation, this can be attributed to the fact that, because of its closed-shell electron configuration, $Ce(dpm)_4$ has a relatively small number of excited states compared with the number for $Fe(dpm)_3$. When a molecule has thinly distributed excited states, it will have small chance of being excited on collision with a positron. Therefore, in a $Ce(dpm)_4$ solution, the *o*-Ps formation can be expected to compete favorably with the excitation of the complex, thus resulting in an unaffected I_2 value.

According to the spur model,[12,13] however, positrons combine with the electrons produced in the radiation spurs to form Ps. If an electron scavenger is present, the electron concentration in the spur will be reduced, and, therefore, a smaller amount of Ps will be formed. In the system investigated here, $Ce(dpm)_4$ is as strong an oxidizing agent or electron scavenger as $Fe(dpm)_3$, and should result in a reduced I_2. This is not consistent with the experimental results. If, however, the spur model is applicable to the present system, the observed inertness of $Ce(dpm)_4$ can be considered to show its slow rate of electron scavenging as compared with the rate of Ps formation.

(Received January 12, 1978)

New five-coordinate complexes $[MCl_3L(H^+L)]$, where M=Mn(II), Fe(II), Co(II), and Ni(II) and L=1,4-diazabicyclo[2.2.2]octane, were prepared in anhydrous ethanol. On being heated in the solid state, they begin to lose the non-charged ligand (L) in the order Co(147 °C)≪Fe(184 °C)<Ni(190 °C)<Mn(196 °C) and are transformed into the tetrahedral complexes $[MCl_3(H^+L)]$. The thermal stability of the five-coordinate complexes depends markedly on the nature of M(II). The octahedral complex $[NiCl_4(H_2O)_2]H_2L\cdot H_2O$ obtained from an aqueous solution shows a series of complicated color and structural changes on heating according to stepwise decomposition: $[NiCl_4(H_2O)_2]H_2L\cdot H_2O$ (greenish yellow, octahedral)→$[NiCl_4]H_2L$(light blue, tetrahedral)→$[NiCl_3(H^+L)]$(cobalt blue, tetrahedral)→$[NiCl_2L_{1/2}]$(reddish brown, probably square-pyramidal)→$NiCl_2$(yellow, octahedral).

Ouagliano and co-workers reported that the protonated and methylated cations of the cagelike ditertiary amine 1,4-diazabicyclo[2.2.2]octane(dabco; denoted in this paper by L) react with some bivalent transition metal halides to form four- and/or five-coordinate complexes.[1-3] The trigonal-bipyramidal complexes $[MX_3(H^+L)_2]X$ formed with Mn(II), Fe(II), Ni(II), and Cu(II) (X=halide anions) are generally insoluble and stable only in the crystalline state in the absence of moisture. Thus to study their relative stability, we considered that thermogravimetry would be a favorable technique.

We prepared the five-coordinate complexes according to the reported method,[2] but somewhat different results were obtained, *i.e.*, the formula of the complexes was $[MCl_3L(H^+L)]$ and not $[MCl_3(H^+L)_2]Cl$, except in the case of Cu(II), a five-coordinate complex of the same type being obtained with Co(II). The complexes $[MCl_3L(H^+L)]$ were found to be transformed into the tetrahedral complexes $[MCl_3(H^+L)]$ by heating with evolution of L. We could thus compare the thermal stability of the five-coordinate complexes of Mn(II), Fe(II), Co(II), and Ni(II) from their initial weight-loss temperatures determined by thermogravimetric analyses.

The cobalt(II) and nickel(II) complexes with the cagelike ditertiary amine 1,3,5,7-tetraazatricyclo[3.3.1.-$1^{3,7}$]decane (hmta), prepared from aqueous solutions, show striking color changes in the course of dehydration. With a proper combination of thermal analyses with visible and infrared spectroscopy, we have confirmed that these complexes can be formulated as $[M(H_2O)_6]X_2\cdot hmta\cdot nH_2O$ (X=Cl^-, Br^-, I^-), and the decrease in the number of coordinated water molecules brings about the coordination of halide ions first, and that of hmta only in the last stage of dehydration, with the decrease in coordination number from 6 to 4. This apparent reluctance of an amine, which usually shows a stronger coordination tendency than halide ions and water, is probably due to the bulkiness of hmta and its weak basicity(pK_b=8.87). In continuation of this study on the color and structural changes of the complexes containing water, anions and a cagelike amine by heating,[4] we undertook preparation of such a complex with L from an aqueous solution. Owing to the strong basicity of L(pK_b=5.40), hydroxide precipitates formed when cobalt and nickel salts were mixed with L in aqueous solutions. We therefore used the diprotonated species H_2LCl_2 and succeeded in the preparation of $[NiCl_4(H_2O)_2]H_2L\cdot H_2O$. As expected, the complex showed complicated color and structural changes involving dehydration and the elimination of HCl and L, which we could elucidate in some detail.

Experimental

Preparation of H_2LCl_2. A solution of 10 g of L in warm acetone was added with stirring to a warm solution prepared from 10 ml of concd HCl and 15 ml of 1,1-dimethoxypropane (dehydrating agent). The white crystals separated were recrystallized from anhydrous ethanol, and dried *in vacuo*. The analytical data are given in Table 1. Although the monoprotonated species HLCl has been reported,[1] only a diprotonated one was obtained in the present work, regardless of the L:HCl ratio.

General Preparation of $[MCl_3L(H^+L)]$(M=Mn(II), Fe(II), Co(II), and Ni(II)). A hot solution of anhydrous metal chloride (0.001 mol) in anhydrous ethanol was added with stirring to a hot solution of L(0.005 mol) and H_2LCl_2(0.005 mol) in the same solvent. In the case of Co(II), slight excess of L was necessary in order to avoid formation of the tetrahedral complex. The resulting solutions were allowed to stand at 60—70 °C for several hours under anhydrous conditions. The crystals formed were filtered in a stream of dry nitrogen, and dried *in vacuo* (Table 1). The iron complex is partially decomposed by air oxidation, turning yellowish, so that its data differ somethat from theoretical values. We tried to prepare the same complexes of Zn(II) and Cu(II), but the reactions of $CuCl_2$ and $ZnCl_2$ with a large excess of the ligands yielded only $[ZnCl_3(H^+L)]$ and $[CuCl_3(H^+L)_2]Cl$, respectively, which have already been prepared by Quagliano *et al.*[1,2]

Preparation of $[NiCl_4(H_2O)_2]H_2L\cdot H_2O$. An aqueous solution of H_2LCl_2(0.003 mol) with a few drops of concd, HCl was added to an aqueous solution of $NiCl_2\cdot 6H_2O$(0.001 mol). The resulting solution was allowed to stand in the open air at roon temperature until greenish yellow crystals appeared, which were filtered and dried in the open air (Table 1).

fore and after heating were obtained by the diffuse reflection method with a Hitachi EPS-3T spectrophotometer equipped with a standard integrating sphere attachment. All the measurements were carried out at room temperature using MgO as a reference material. Thermogravimetry(TG) and differential thermal analysis(DTA) were performed simultaneously with a Shinku Riko TGD-3000 differential thermal micro balance in a nitrogen atmosphere with a heating rate of 5 °C/min, 15—20 mg of sample being used for each measurement. The infrared absorption spectra(4000—250 cm^{-1}) were measured with a Hitachi 215 spectrophotometer by the Nujol mull method. X-Ray diffraction charts were obtained with a Toshiba ADG-101 diffractometer using manganese-filtered Fe $K\alpha$ radiation.

Results and Discussion

Spectral and Thermal Properties of the Five-Coordinate Complexes. The reflectance spectra of the colored five-coordinate complexes are shown in Fig. 1. The blue $[CoCl_3L(H^+L)]$ showed three absoptions at 15300, 16700, and 18300 cm^{-1} in the region 10000—30000 cm^{-1}. High spin trigonal-bipyramidal cobalt(II) complexes show at least four well-separated absorption bands in the region 5000—25000 cm^{-1}. Bertini *et al.*[5] showed that $[CoBr(Me_6tren)]Br$ gives well-separated absorptions at 5700, 12300, 16100, and 19600 cm^{-1} in its diffuse reflectance spectrum. They also presented the spectra of the tetrahedrally distorted trigonal-bipyramidal cobalt(II) complexes with similar ligands, and discussed spectral changes in going from an octahedral to a tetrahedral structure. A comparison with their results indicates that the outlook of the spectrum of $[CoCl_3L(H^+L)]$ is understandable if we assume that Co(II) is in a nearly undistorted trigonal-bipyramidal environment.

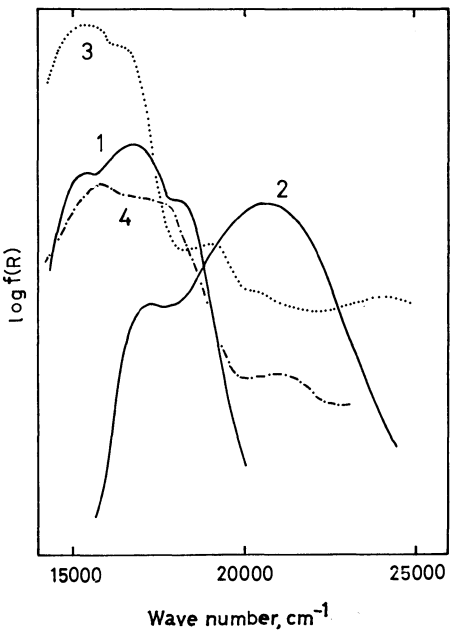

Fig. 1. Reflectance spectra of (1) $[CoCl_3L(H^+L)]$, (2) $[NiCl_3L(H^+L)]$, (3) $[CoCl_3(H^+L)]$, and (4) $[NiCl_3(H^+L)]$.

The deep pink $[NiCl_3L(H^+L)]$ shows two absorption bands at 17000 and 20600 cm^{-1}. This spectrum was quite similar to that of red $[NiCl_3(H_2O)(CH_3{}^+L)]$ which was found by X-ray analysis[6] to be in an almost undistorted trigonal-bipyramidal environment with three Cl atoms in the equatorial plane. Recently, similar structures were found for $[MCl_3(CH_3{}^+L)_2]ClO_4$ (M=Ni(II) and Cu(II)) by X-ray analyses.[7]

$[CoCl_3L(H^+L)]$ gives a very strong diffraction line at d=5.47 Å and some weak lines at 7.67, 4.22, 3.41, and 2.42 Å in its X-ray powder pattern. The corresponding Mn, Fe, and Ni complexes were found to be isomorphous with the cobalt complex. The infrared spectra of $[MCl_3L(H^+L)]$ were similar among the complexes of Mn, Fe, Co, and Ni. Thus, we conclude that the complexes of Mn and Fe have essentially the same trigonal-bipyramidal structure as that of Co and Ni. As an example, IR frequencies of the Co complex are given in Table 2, together with those of $[CuCl_3(H^+L)_2]Cl$ which shows a somewhat different spectrum.

The non-charged ligand L in $[MCl_3L(H^+L)]$ is expected to be released more easily than the protonated ligand H^+L on heating, a complex with a coordination number four being obtained. The TG-DTA curves of the complexes are shown in Fig. 2. A distinct break point is observed on each TG curve, the weight-loss values up to this point being 29.4(29.0), 21.3(28.9), 26.9(28.3), and 26.0(28.3)% for the Mn, Fe, Co, and Ni complexes respectively. The values in parentheses are the calculated ones for the evolution of L. The difference between the observed and calculated values for the Fe complex might be due to its partial decomposition owing to air oxidation before the TG measurement. The formation of the complex $[MCl_3(H^+L)]$ at this stage was also confirmed by IR and/or reflectance spectra of the products, together with their tetrahedral structure(*cf.* curves 3 and 4, Fig. 1).

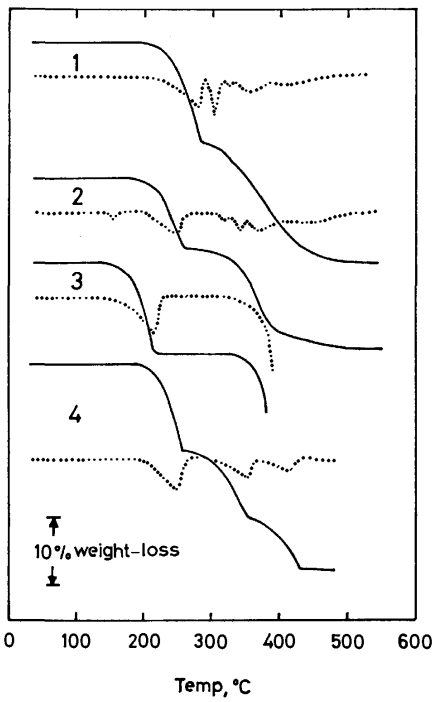

Fig. 2. TG(solid line) and DTA(dotted line) curves of $[MCl_3L(H^+L)]$. (1) Mn(II), (2) Fe(II), (3) Co(II), and (4) Ni(II).

From the spectral and thermal measurements, we can imagine the most probable structure of $[MCl_3L(H^+L)]$ to be as shown in Fig. 3. The unusual trigonal-bipyramidal coordination seems to be brought about chiefly by the steric requirements of the bulky and rigid cagelike ligands. The orientation of the ligands which favor the formation of the –N–H--N– hydrogen bonding might greatly contribute to the stabilization of the complex including both L and H^+L.[8]

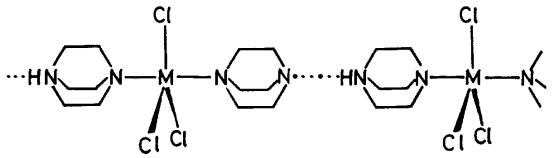

Fig. 3. Postulated structure of $[MCl_3L(H^+L)]$.

It seems to be of interest to examine the effect of the nature of metal ion on the trigonal-bipyramidal coordination. The initial weight-loss temperatures(t_i) on the TG curves can be considered as a measure of the relative stability of the complexes if the elimination reactions of L from them proceed with the same mechanism for all the complexes. The TG and DTA curves in the first step are similar among the four complexes of Mn to Ni (Fig. 2), supporting the assumption. The t_i values are summarized in Table 3, together with those of the tetrahedral complexes formed, which were observed on further heating. The order of corresponding DTA peak temperatures(t_m) was the same as that of t_i. We can conclude that the thermal stability of the trigonal-bipyramidal coordination depends strongly on the nature of the metal, increasing in the order Co≪Fe<Ni<Mn. In general, the trigonal-bipyramidal coordination seems to be favored with increase in the ionic radius of metal, except for the Ni complex which has the largest crystal field stabilization energy in the high-spin trigonal-bipyramidal environment.[9]

It is also of interest to compare the order of t_i of the trigonal-bipyramidal complexes with that of the tetrahedral complexes. As seen in Table 3, the stability of the latter complexes also depends on the nature of the metal. The TG and DTA curves in the second step are not similar in the complexes studied, no plateau being observed in the case of Mn between the two steps on its TG curve. In spite of this, however, we can safely say that the Co complex shows the largest thermal stability. This may also be the driving force for the thermal decomposition of $[CoCl_3L(H^+L)]$, which leads to its especially low thermal stability.

Thermal Decompositions of the Complex $[NiCl_4(H_2O)_2]$-$H_2L\cdot H_2O$. The reflectance spectrum of the greenish yellow $[NiCl_4(H_2O)_2]H_2L\cdot H_2O$ shows a pattern

Table 3. Comparison of initial weight-loss temperatures (t_i)

M	t_i/°C	M	t_i/°C
Mn	196	Mn	<281
Fe	184	Fe	266
Co	147	Co	300
Ni	190	Ni	263

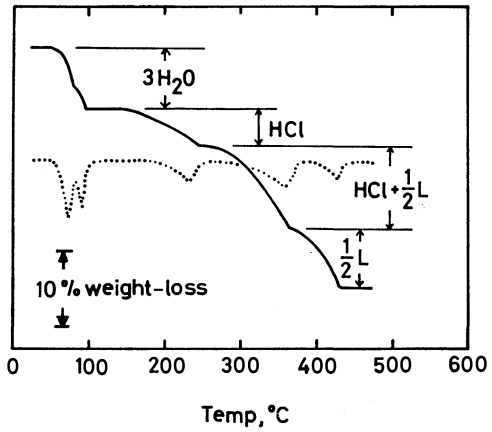

Fig. 4. TG(solid line) and DTA(dotted line) curves of $[NiCl_4(H_2O)]H_2L \cdot H_2O$.

characteristic of an octahedral coordination, and its ν_{max} (23000 cm^{-1}) lies between that of $NiCl_2 \cdot 2H_2O$ (22800 cm^{-1}) and $NiCl_2 \cdot 4H_2O$(23400 cm^{-1}), but is closer to the former, which is in fact a $NiCl_4O_2$-type complex with bridging Cl atoms. The IR spectrum indicates that L in this complex is not coordinated to the metal but is held in the crystal lattice as a counter cation(H_2L^{2+}). The formulation of this complex is based on these spectral data. Similar Ni(II) complexes with protonated *N*-methyl-dabco[1] and protonated piperazine[10] have been described.

The TG and DTA curves of $[NiCl_4(H_2O)_2]H_2L \cdot H_2O$ show that this complex decomposes in five steps up to 500 °C as shown in Fig. 4. In the first step, it loses $2H_2O$ and becomes yellow; in the second step, it loses the rest of water turning light blue. In the third step, HCl is evolved, and a cobalt blue substance of the composition $NiCl_3(H^+L)$ remains. In the fourth step, a reddish brown substance is obtained. Both TG and elemental analyses indicate that its composition is close to $NiCl_2L_{1/2}$. In the last step, yellow anhydrous $NiCl_2$ is obtained.

There were some difficulties in isolating these intermediate substances in pure form and/or in large quantities, except for the light blue one, since (i) there were no well-developed plateaus on the TG curve except for the second stage, (ii) the sample formed in the fourth step melted when it was kept in a crucible forming a thick layer, and (iii) the products formed in the last two stages contained a small amount of free carbon when the sample was heated in an inert gas atmosphere. We found that the melting can be avoided when the sample is heated very slowly in the form of a thin layer. No free carbon is formed when the sample is heated in the air, probably owing to the reaction $C+O_2 \rightarrow CO_2$, although $NiCl_2$ formed at the last stage is transformed gradually into NiO in the air. We could thus obtain only a mixture of $NiCl_2$ and NiO at the last stage.

We obtained each of the intermediates in an almost pure form by heating the complex at the desired temperatures in the air, and measured their reflectance and infrared spectra. The reflectance spectra of the light blue and reddish brown substances are shown in Fig. 5, together with that of the original complex.

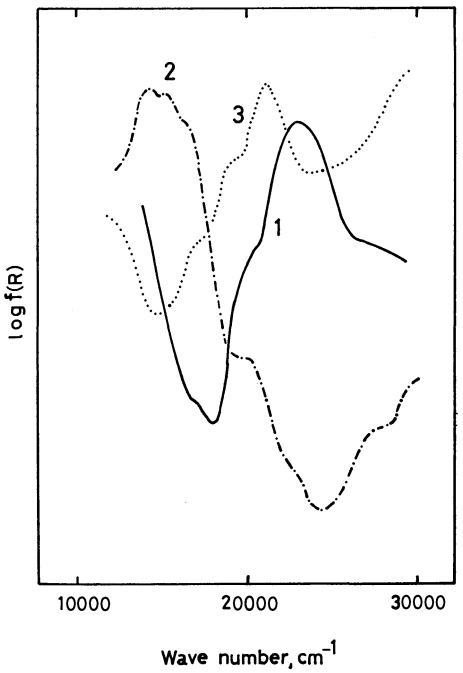

Fig. 5. Reflectance spectra of (1) $[NiCl_4(H_2O)_2]H_2L \cdot H_2O$, (2) $[NiCl_4]H_2L$, and (3) $[NiCl_2L_{1/2}]$.

The yellow substance of the composition $NiCl_4 \cdot H_2L \cdot H_2O$ shows the peak maximum at 22300 cm^{-1}, the frequency of which is still lower than that of the original complex. Thus the nickel atom in it seems to be surrounded by five or more chlorine atoms. The spectrum of the light blue substance of composition $NiCl_4 \cdot H_2L$ is very similar to that of $[NiCl_4]^{2-}$ in the literature[11] and therefore it should be formulated as $[NiCl_4]H_2L$. The spectrum of the cobalt blue substance of composition $NiCl_3(H^+L)$ is just the same as that of tetrahedral $[NiCl_3(H^+L)]$.

The reddish brown substance of composition $NiCl_2L_{1/2}$ shows three absorption bands at 17000, 19200, and 21000 cm^{-1}. The spectrum is somewhat similar to that of trigonal-bipyramidal $[NiCl_3L(H^+L)]$ except for a shoulder at 19200 cm^{-1} (*cf.* curve 2, Fig. 1). However, since the difference between the electronic spectrum of a trigonal-bipyramidal complex and that of a square-pyramidal one is not very large[12] in the region 15000—30000 cm^{-1}, this can not be taken as proof for its geometry. On the other hand, the infrared spectral pattern of $NiCl_2L_{1/2}$ in the region 650—1400 cm^{-1} was essentially similar to that of free L

Table 4. Comparison of IR frequencies (cm^{-1}) in the region 700—1400 cm^{-1} for $[NiCl_2L_{1/2}]$ and L

$[NiCl_2L_{1/2}]$	L[a]	Assignment
1321 m	1350 w	ωCH_2
1055 s	1057 vs	ν_{as}N-C-C
1013 m	986 m	ν_sN-C-C

844 m	830 m	$\nu_{as} NC_3$
812 s	755 m	ρCH_2

a) Values taken from Ref. 13.

molecule although there are considerable differences in the frequency values(Table 4). This indicates that the bands of L in the complex can be best assigned in terms of its D_{3h} symmetry.[13] This suggests that the complex consists of polymeric chains in which the nickels are surrounded by four bridging chlorines in a plane, and one bridging L perpendicular to the plane, forming a square-pyramidal coordination structure as shown in Fig. 6.

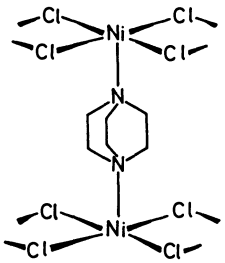

Fig. 6. Postulated structure of $[NiCl_2L_{1/2}]$.

The decomposition processes of $[NiCl_4(H_2O)_2]H_2L\cdot H_2O$ can be summarized as follows: $[NiCl_4(H_2O)_2]H_2L\cdot H_2O$(greensih yellow, octahedral) $\xrightarrow{-2H_2O}$ $NiCl_4H_2L\cdot H_2O$(yellow, octahedral) $\xrightarrow{-H_2O}$ $[NiCl_4]H_2L$(light blue, tetrahedral) $\xrightarrow{-HCl}$ $[NiCl_3(H^+L)]$ (cobalt blue, tetrahedral) $\xrightarrow{-(HCl+1/2L)}$ $[NiCl_2L_{1/2}]$(reddish brown, probably square-pyramidal) $\xrightarrow{-1/2L}$ $NiCl_2$(yellow, octahedral).

Comparing the results of the present study on the dabco complexes with those of our previous study on hmta complexes,[4] we find some differences between the two amines. (i) When hmta reacts with a heavy metal halide(MX_2) in aqueous solution, a complex containing $[M(H_2O)_6]^{2+}$ and uncoordinated hmta precipitates easily, whereas dabco precipitates only $M(OH)_2$ from aqueous solution (only when H_2L^{2+} is used instead of L, the complex $[NiCl_4(H_2O)_2]H_2L\cdot H_2O$ could be obtained). (ii) The complexes containing coordinated hmta, which are formed only at the last stage of dehydration of the complexes with $[M(H_2O)_6]^{2+}$, are mostly tetrahedral, but those of coordinated dabco obtained from ethanolic solutions are trigonal-bipyramidal. (iii) Heating of the anhydrous hmta complexes leads to decomposition, but heating of the anhydrous dabco complexes leads to the elimination of L and formation of new complexes with different geometries. These remarkable differences between the two amines are probably related to their difference in size, basicity, and the number and disposition of N atoms.

Analytical Application of Oleophilic Quaternary Ammonium Salts. XV. Extraction of the Uranium(VI)–4-(2-Pyridylazo)resorcinol Complex with Tridodecylethylammonium Bromide

Yoshio SHIJO* and Kaoru SAKAI

Department of Environmental Chemistry, Faculty of Engineering, University of Utsunomiya, Ishii-machi, Utsunomiya 321-31

(Received January 14, 1978)

The uranium(VI)-4-(2-pyridylazo)resorcinol(PAR) chelate anion was extracted with tridodecylethylammonium bromide(TDEABr) into chloroform to form an ion associate. The ternary complex has an absorption maximum at 550 nm in the organic layer. The optimum pH range for the extraction is 6.8—10.7. The distribution ratio and the molar absorptivity are 1.34×10^{2} and 4.25×10^{4} cm^{-1} mol^{-1} l, respectively. The composition of the ternary complex is estimated to be $UO_2(X)(PAR)(R_3R'N)$. The equation representing the extraction equilibrium would be

$$UO_2(X)(PAR)^- + R_3R'NBr_{(o)} = UO_2(X)(PAR)(R_3R'N)_{(o)} + Br^-.$$

The extraction constant K_{ex} is given by $\log K_{ex}=3.07$.

4-(2-pyridylazo)resorcinol(PAR)[1] is a well-known chelating agent which is useful for the sensitive colorimetric determination of various metal ions. Recently, the ion-pairs of the metal–PAR chelate anions with bulky organic cations have been studied by several workers; the spectrophotometric determination of many metals was made by the extraction method. The PAR chelate anions of cobalt(III),[2,3] chromium,[4] copper,[5] iron(II),[2] iron(III),[6] gallium,[7] niobium,[8] nickel,[2,9] palladium,[10] vanadium(III),[11] vanadium(V),[2,12,13] and zinc[14] were extracted into an organic layer in the presence of zephiramine, tetraphenylarsonium, diphenylguanidine, or Crystal Violet. Uranium(VI) reacts with PAR to form a water-soluble red chelate. The chelate is slightly extractable into butanol, but not extractable into chloroform, carbon tetrachloride, and benzene. From the extraction experiments, it was found that the uranium(VI)–PAR chelate anion was extracted with tridodecylethylammonium bromide(TDEABr) in chloroform to form an ionic associate. The oleophilic quaternary ammonium salts such as TDEABr have been already used for the extraction of metal-Xylenol Oranges,[15]- Eriochrome Cyanine R,[16] and -Pyrocatechol Violet[17] chelate anions. In the present study, the fundamental conditions for the extraction of uranium(VI) as the uranium(VI)–PAR–TDEA ternary complex in chloroform and the composition of the ternary complex will be discussed.

Experimental

Reagent. About 2.5×10^{-3} M uranium(VI) solution was prepared by dissolving a definite amount of uranyl acetate in 0.05 M sulfuric acid. The resulting solution was standardized by the gravimetric method. The solution was diluted as required. A 5×10^{-4} M PAR solution was prepared by dissolving the Dotite PAR in a small amount of 0.2 M NaOH and diluted with deionized water. The TDEABr was prepared by refluxing an ethanolic solution of tridodecylamine and ethyl bromide for 4 h. After the evaporation of the solvent, the salt was recrystallized two times from butyl acetate. A 10^{-3} M TDEABr solution was prepared by dissolving the above TDEABr in the purified chloroform. A 0.05 M sodium borate solution was used as a buffer solution. All the other chemicals used were of guaranteed reagent quality.

Apparatus. A Hitachi 101 spectrophotometer, a Hitachi UV-vis. recording spectrophotometer, and a Hitachi-Horiba F-7 pH meter were employed.

Standard Procedure. Up to 30 μg of uranium(VI), a definite amount of 0.1 M sulfuric acid, and 2 ml of 5×10^{-4} M PAR solution were mixed in a 100 ml polypropylene beaker. The pH of the solution was adjusted to 9 by the addition of 5 ml of 0.05 M sodium borate solution and then the solution was diluted to 25 ml with deionized water. The solution was transferred into a 35 ml test tube and 5 ml of 5×10^{-3} M TDEABr in chloroform was added. The extraction was carried out for 5 min by turning the test tube upside down twice every 5 s. After the phase separation, the organic layer was taken out and centrifuged for 2 min at 3000 rpm.

The extract was transferred into an absorption cell and the absorbance at 550 nm was measured aginst the reagent blank obtained in the same way.

Results and Discussion

Absorption Spectra. The absorption spectra of the ternary complex extracted into chloroform and of

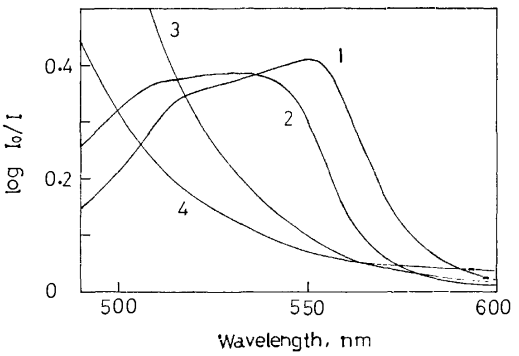

Fig. 1. Absorption spectra of the U–PAR–TDEA complex in chlorohorm and the U–PAR chelate in aqueous solution.
pH=9, V_{aq}=25 ml, V_o=5 ml, $[TDEABr]_o=5\times10^{-3}$ M.
(1): U-PAR-TDEA in chloroform, $[U]_{aq}=2\times10^{-6}$ M,
(2): U-PAR in aq soln, $[U]_{aq}=1\times10^{-5}$ M,
(3): PAR-TDEA in chloroform, $[PAR]_{aq}=4\times10^{-5}$ M,
(4): PAR in aq soln, $[PAR]_{aq}=2\times10^{-4}$M.

the uranium(VI)–PAR chelate anion in an aqueous solution, and also the absorption spectra of the respective blank solutions, are shown in Fig. 1. The ternary complex and the uranium(VI)–PAR chelate anion have an absorption maximum at 550 nm and 530 nm respectively. As compared with the corresponding absorption maximum of the chelate anion, that of the ternary complex is shifted toward the longer wavelengths by 20 nm.

Effect of pH. The aqueous solution containing uranium(VI) and PAR was adjusted to various pH values with the sodium acetate or sodiun borate buffer solution and the extraction was carried out by the above procedure. The results are shown in Fig. 2. The extraction of the ternary complex starts at pH>3, reaches a maximum at pH 6.8, and thereafter remains constant over a wide range (pH 7—10.7). The chloroform extract was stable for at least 1 h. PAR itself is readily extracted from aqueous solution.

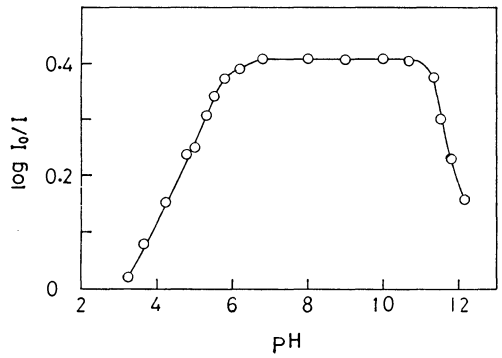

Fig. 2. Effect of pH on the extraction of the U-PAR-TDEA complex.
$[U]_{aq}=2\times10^{-6}$ M, $[PAR]_{aq}=4\times10^{-5}$ M, $[TDEABr]_o=5\times10^{-3}$ M, 550 nm.

Organic Solvents. Several kind of organic solvents which dissolved TDEABr were tested in order to achieve a quantitative extraction of the uranium(VI)–PAR chelate anion. The ternary complex is extracted in such solvents as chloroform, carbon tetrachloride, 1-butanol, butyl acetate, isobutyl methyl ketone, nitrobenzene, and benzene. Molar absorptivities of the ternary complex are much the same in these solvents. Chloroform was used throughout these experiments as the common solvent.

The Effect of the PAR Concentration. The extraction of uranium(VI) from an aqueous solution containing PAR of various concentrations was examined. The absorbance of the extract was found to be constant in the concentration range from 1×10^{-5} M to 1×10^{-4} M. The extraction of the ternary complex is depressed by use of a large excess of the PAR over the TDEABr.

The Effect of the TDEABr Concentration. The concentration of TDEABr in chloroform was varied. The absorbance of the extract was found to be constant in the concentration range from 1×10^{-3} to 5×10^{-3} M.

Effect of the Mixing Time. The mixing time was varied from 30 s to 10 min. The absorbance of the extract was constant for the mixing times from 3 to 10 min.

Extractability and Molar Absorptivity. An aqueous solution of 25 ml containing 29.8 μg of uranium(VI) and PAR was shaken with 5 ml of 5×10^{-3} M TDEABr in chloroform under the optimum conditions. Extraction was repeated for the remaining aqueous phase after the separation of the extract. The extractability of uranium was calculated from the absorbances of the extracts. It was found that 96.4% of uranium(VI) was extracted by one extraction. The distribution ratio and the molar absorptivity are 1.34×10^2 and 4.25×10^4 cm^{-1} mol^{-1} l respectively.

Calibration Curve. A calibration curve for the determination of uranium(VI) was made under the optimum conditions. A good linear relationship was obtained over the concentration range from 1 μg to 30 μg of uranium per 5 ml of chloroform.

The Composition of the Ternary Complex. Using the continuous variation method and the equilibrium-shift method, the mole ratio of uranium: PAR was found to be 1:1, as are shown in Figs. 3 and 4. The mole ratio of uranium: TDEA was found to be 1:1, as are shown in Figs. 5 and 6. The same resutls were obtained by applying the mole ratio method. Thus, the composition of the ternary complex was estimated to be $UO_2(X)(PAR)(R_3R'N)$.

Equilibrium Constant. When the uranium–PAR chelate anion is extracted with TDEABr into chloroform, the equation representing the extraction equilibrium would be

$$UO_2(X)(PAR)^- + R_3R'NBr_{(o)} = UO_2(X)(PAR)(R_3R'N)_{(o)} + Br^- \quad (1)$$

The extraction constant K_{ex} is given by

$$K_{ex} = \frac{[UO_2(X)(PAR)(R_3R'N)]_o[Br^-]}{[UO_2(X)(PAR)][R_3R'NBr]_o}, \quad (2)$$

where subscript o denotes the organic layer and X represents an unidentified univalent anion.

Determination of each of the component concentrations in Eq. 1 is a difficult problem, because the complete formation of the uranium–PAR chelate anion occurs in the presence of excess PAR. Under such conditions the equilibrium in Eq. 1 can be represented by the following two steps.

$$PAR^- + R_3R'NBr_{(o)} = R_3R'NPAR_{(o)} + Br^- \quad (3)$$

$$K_{ex1} = \frac{[R_3R'NPAR]_o[Br^-]}{[PAR^-][R_3R'NBr]_o} \quad (4)$$

$$UO_2(X)(PAR)^- + R_3R'NPAR_{(o)} = UO_2(X)(PAR)(R_3R'N)_{(o)} + PAR^- \quad (5)$$

$$K_{ex2} = \frac{[UO_2(X)(PAR)(R_3R'N)]_o[PAR^-]}{[UO_2(X)(PAR)^-][R_3R'NPAR]_o} \quad (6)$$

Thus K_{ex} is given by $K_{ex}=K_{ex1}K_{ex2}$. The concentrations of the $R_3R'NPAR_{(o)}$ species in Eq. 3 and the $UO_2(X)(PAR)(R_3R'N)_{(o)}$ species in Eq. 5 were determined spectrophotometrically as a function of $[Br^-]$ or $[PAR^-]$ respectively. The values of K_{ex1} and K_{ex2} were found to be 52.9 and 22.3 under the conditions shown in Table 1. The value of K_{ex} calculated from K_{ex1} and K_{ex2} is 1180, therefore log K_{ex}=3.07. The distribution ratio of the uranium complex between chloroform and water is described by

$$D = \frac{[UO_2(X)(PAR)(R_3R'N)]_o}{[UO_2(X)(PAR)]}. \quad (7)$$

Combining Eqs. 2 and 7, we have

$$D = K_{ex}\frac{[R_3R'NBr]_o}{[Br^-]}. \quad (8)$$

From Eq. 8, one can see that the value of D is a function of $[R_3R'NBr]_o$ and $[Br^-]$. That is, the value of D increases with the TDEABr concentration in chloroform. The larger solubility (about 0.1 M) of TDEABr in chloroform than in other solvents is favorable for the quantitative extraction of the uranium complex. The anions such as perchlorate, thiocyanate and io-

Derivatographic Studies on Transition Metal Complexes. XX.[1] Thermal Electron Transfer Reactions of Cobalt(III) Complexes Containing Phenylbiguanide in the Solid Phase[2]

Yoshinori IHARA, Akira UEHARA, Ryokichi TSUCHIYA,* and Eishin KYUNO**

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

***Department of Pharmaceutical Science, School of Pharmacy, Hokuriku University, Kanazawa 920*

(Received February 7, 1978)

The following six cobalt(III) complexes containing phenylbiguanide were prepared and the thermal reactions were followed both isothermally and non-isothermally (derivatographically) in the solid phase: *trans*-$[Co(A)_2(phbgH)_2]X_3 \cdot nH_2O$, where A denotes volatile ligands such as NH_3, CH_3NH_2 or C_5H_5N; phbgH denotes 1-phenylbiguanide, X chloride or bromide ion; and *n* is 2 or 3. From the electronic, IR and far-IR spectra and magnetic susceptibilities of these complexes before and after heating, the products obtained by evolving volatile ligands were found to be uniform bivalent cobalt complexes without rupture of the bonds of phbgH to cobalt in spite of the reduction of central cobalt(III) ion, except for the complexes containing ammonia. The reaction seems to be caused by the electron transfer from the coordinated phbgH to cobalt, not from the outer-sphere anions.

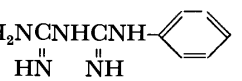
Werner found that the hydroxoaqua-cobalt(III) complexes *cis*-$[Co(OH)(NH_3)_4(H_2O)]X_2$ (X=Cl or Br) evolve water at *ca.* 100 °C to form the corresponding diol complexes in the solid phase.[3] Since then, thermal reactions of several cobalt(III) complexes have occasionally been investigated in the solid phase; *e.g.*, anation of $[Co(H_2O)(NH_3)_5]X_3$ (X=NO_3,[4a] Br,[4b] or ReO_4[4c]), *cis*↔*trans* isomerization of $[CoCl_2(NH_3)_4]IO_3$,[5] $[CoCl_2pn_2](H_5O_2)Cl_2$,[6] and $[CoCl_2(NH_3)_2en]SCN$,[7] and kinetics of the thermal decomposition of $[Co(NH_3)_6]X_3$ (X=Cl, Br, or I).[8]

Few systematic investigations have been carried out for cobalt(III) complexes to clarify their reactions in the solid phase. This is mainly due to the instability of cobalt(III) complexes upon heating. Most cobalt(III) complexes are apt to undergo a reduction of Co(III) to Co(II) ions followed by rapid and complicated decomposition. In fact, Tanaka and Nagase pointed out that the decomposition of the ammine complexes is initiated by the electron transfer from outer-sphere anions to central Co(III) ions.[8]

It was found that *trans*-$[Co(CH_3NH_2$ or $C_5H_5N)_2(bgH)_2]X_3$ (bgH=biguanide and X=Cl or Br) lose two moles of methylamine or pyridine to yield uniform bivalent cobalt(II) complexes without destruction of the bond of the bgH with cobalt ion upon heating.[9] The stiffness of the complexes was thought to be due to the inherent characteristics of biguanide; namely biguanide can form extremely stable planar complexes[10] containing pseudoaromaticity.[11]

The present study was undertaken (1) to prepare such instructive model complexes in which the skeletons are indestructible even at the end of the reduction of Co(III) to Co(II) ions, (2) to investigate isothermally and non-isothermally overall reaction processes of the complexes obtained, and (3) to confirm the origin of the electron transfer; *i.e.*, whether it is promoted from counter anion or ligand to Co(III) ion.

As compounds suitable for our purposes, *trans*-$[Co(A)_2(phbgH)_2]X_3 \cdot nH_2O$ were selected. PhbgH has the following characteristics: two molecules of each bidentate ligand can occupy the opposite four coordination sites of octahedral cobalt(III) ion with planar geometry; pseudoaromaticity can be induced by coordination to Co(III) ion. PhbgH has the following constitutional formula:



phbgH .

It is π-electron-rich as compared with bgH by virtue of the electron-donating effect of an introduced $-C_6H_5$ group.

Experimental

Preparation of Ligand. 1-Phenylbiguanide ($C_6H_5NHC(=NH)NHC(=NH)NH_2 \cdot HCl$) was prepared by the method reported.[12]

Preparation of Complexes. trans-$[Co(A)_2(phbgH)_2]X_3 \cdot nH_2O$ *(A=NH_3, CH_3NH_2 or C_5H_5N; X=Cl or Br).* These complexes were prepated by the method of Rây[13] modified as follows: 6.5 g of phbgH·HCl was dissolved in 150 ml of 10% sodium hydroxide solution. To this was added drop by drop with stirring a solution of $CoCl_2 \cdot 6H_2O$ (3.5 g) in 10 ml of water. When the solution turned yellow from brown, yellow precipitates (probably $[Co(phbg)_2]$) were obtained. After filtration, the precipitates were suspended in appropriate bases and oxidized by addition of a few deops of 35% hydrogen peroxide solution. As the bases, 120 ml of 28% aqueous ammonia, 120 ml of 40% methylamine solution and 120 ml of 60% pyridine solution were used to prepare *trans*-diammine, *trans*-bis(methylamine) and *trans*-bis(pyridine) complexes, respectively. After a small portion of cobalt(II) hydroxide deposited had been filtered off, the filtrate was neutralized by using concentrated hydrochloric acid. The use of concentrated hydrobromic acid instead of concd HCl gave the corresponding bromide complexes. As soon as neutralization was complete, pink crystals were obtained. They were recrystallized from water, and then washed with cold ethanol and ether. Yield about 2 g for each complex.

The analytical data of the six complexes are summarized in Table 1, together with deamination temperatures and isothermal conditions which were determined from the respective derivatograms (Figs. 1 to 3).

Derivatographic Measurements. The derivatograms for the above complexes were recorded with a MOM Derivatograph Typ-OD-102. All the measurements were carried out

Table 1. Analytical data, deamination temperatures, and isothermal conditions of the starting complexes

under a constant flow of nitrogen at a heating rate 1.0—1.5 °C $min.^{-1}$.

Isothermal Measurements. The products from which methylamine or pyridine was eliminated were obtained by an isothermal method using Cho 100-L thermobalance in static air. The isothermal conditions for obtaining uniform products are given in Table 1.

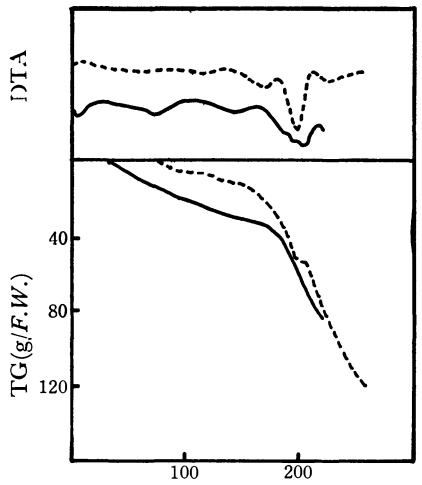

Fig. 1. Derivatograms of complexes I (——) and II (----).

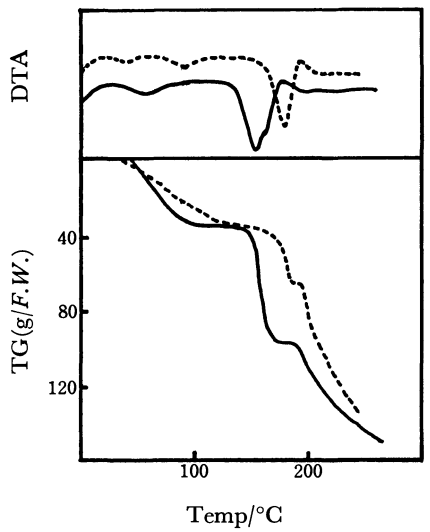

Fig. 2. Derivatograms of complexes III (——) and IV (---).

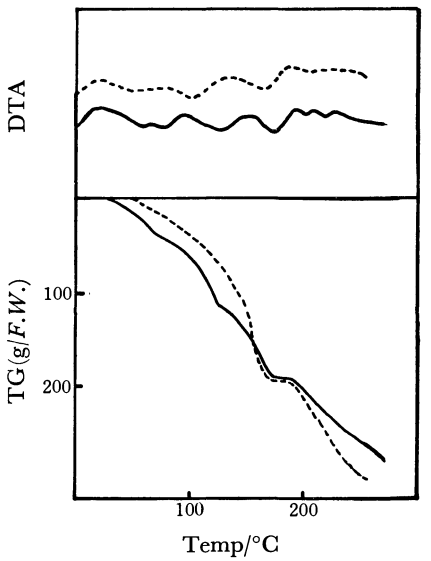

Fig. 3. Derivatograms of complexes V (——) and VI (----).

Spectral Measurements. The electronic spectra in the solid state were measured by a diffuse reflectance method with a Hitachi EPU-2A spectrophotometer equipped with a standard Hitachi reflection attachment (Type R-3). The IR and far-IR specta were measured by the KBr disk method with a JASCO-A-3 infrated spectrophotometer and by the Nujol method with a JASCO IR-F far-infrared spectrophotometer.

Measurements of Magnetic Susceptibilities. The effective magnetic moments were evaluated from the magnetic susceptibilities measured by the Gouy method at room temperature. $Hg[Co(NCS)_4]$ was employed as a reference material. The susceptibitities of the complexes were corrected by using Pascal's constants for each element or atomic group contained.

Results and Discussion

Derivatography. The derivatograms of a series of *trans*-$[Co(A)_2(phbgH)_2]X_3 \cdot nH_2O$ are shown in Figs. 1—3, the complexes being numbered according to Table 1. The TG and DTA curves in complex IV exhibit two distinct thermal steps, the first corresponding to the evolution of water and the second to the liberation of one mole of methylamine coordinated. Two thermal steps are also observed in complexes III, V, and VI, the second step corresponding to the liberation of

two moles of amines. On the other hand, no such distinct steps accompanied by the liberation of ammonia could be observed in complexes I and II owing to rapid decomposition. The liberation of amines in each complex was confirmed.

Thermal Two-mol-deamination Reaction ($[Co(A)_2(phbgH)_2]X_3 \cdot nH_2O \rightarrow Co(II)\text{-}product + 2A + nH_2O$). Complexes III, V, and VI fall in this category; complex III is discussed in detail. The gas evolved from complex III by isothermal heating at 160 °C in a silicon bath was dissolved in water. The resulting solution turned violet by addition of an ethanol containing chloranil ($C_6Cl_4O_2$). The solution was neutralized with dilute hydrochloric acid and concentrated to obtain white precipitates. The IR spectrum of the precipitates resembles that of methylamine hydrochloride prepared as a reference material. The results support the view that the evolved gas is not ammonia formed by the decomposition of phbgH, but methylamine itself.

Figure 4 shows the IR spectra of complex III before and after heating together with the spectrum of complex IV. By comparing their IR spectra with that of methylamine hydrochloride, the peaks at 1419, 1293, and 817 cm^{-1} before heating are considered to be characteristic bands with respect to methylamine. They disappeared completely after heating. Thus, the liberated molecule was found to be two moles of the coordinated methylamine in *trans* position.

Figure 5 shows the far-IR spectra of complex III before and after heating. The peak at 498 cm^{-1}, which is due to the Co–N(CH_3NH_2) stretching vibration, disappears upon heating. On the other hand, the peak at 510 cm^{-1} assignable to the Co–N(phbgH) stretching vibration remains even after heating. The assignments of these peaks were made by a comparison of the two peaks appearing in the other *trans*-diamine-bis(phbgH) complexes.

The analytical data, absorption maxima and magnetic moments for all the complexes obtained upon heating are summarized in Table 2. The electronic spectrum of complex III in the solid state changes remarkably upon heating (Fig. 6). The distinct feature of the spectra commonly found in these complexes before heating lies in the strong charge trnasfer band, which covers the second absorption band, suggesting the presence of the strong π-bond character

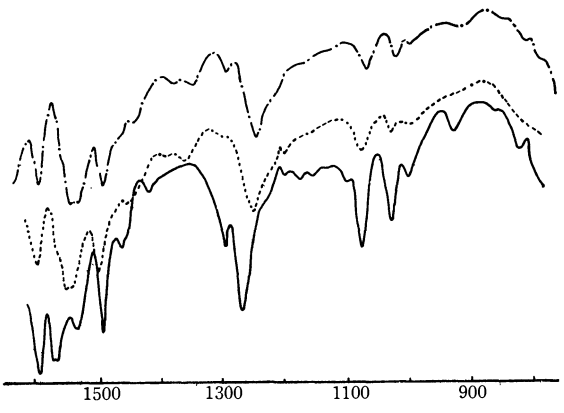

Fig. 4. IR spectra of complex III before heating (——) and after heating (----), and complex IV after heating (—·—).

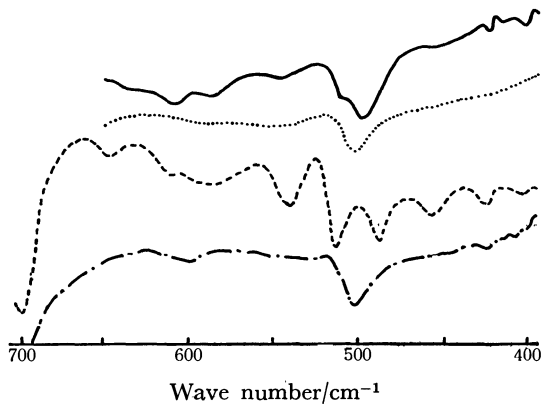

Fig. 5. Far-IR spectra of complex III before heating (——) and after heating (·····), and complex VI before heating (----) and after heating (—·—).

VI	$[CoBr(phbgHBr)_2]\cdot 2H_2O$	29.25	29.42	3.95	3.40	21.09	21.45	14.7	20.5	2.96

of the phbgH to the metal. On the other hand, three bands including charge transfer band are observed after heating at 160 °C. The obvious difference in the spectra before and after heating is the appearance of the peak at 14.8×10^3 cm^{-1} after heating. The peak has a narrow half-width characteristic of bivalent cobalt complexes.[14] In studies on the low spin five-coordinated cobalt(II) complexes, three peaks are often detected at 6—9, 14—17, and 19—25×10^3 cm^{-1}.[15] The spectral pattern of the product resembles them, especially those of the five-coordinated complexes, $[CoCl(dpe)_2]ClO_4$[15d] and β-$Co(paphy)Cl_2$,[15e] where dpe and paphy are 1,2-bis-(diphenylphosphino)ethane and 1,3-bis(2′-pyridyl)-2,3-diaza-1-propene, respectively.

The value of 2.4 B. M. for the heated product of complex III suggests it to be the low spin cobalt(II) complexes.[16] Since the coordination structure of the C_{4v} symmetry mode is considered to require low spin state from the ligand field splitting pattern[17] and two molecules of biguanides coordinated have a tendency to occupy the plane containing a metal ion in the bis-type complexes,[10,11] the product is presumed to be the low spin, square pyramidal five-coordinated cobalt-(II) complex.

The evolved gas analyses for chlorine were carried out to confirm whether or not the reduction by halide ions takes place. However, neither the color reaction by *o*-tolidine (3,3′-dimethylbenzidine) nor KI-starch method denied the evolution of gaseous chlorine. In order to detect chlorine, the solution containing the evolved gas was acidified with sodium hydrogensulfite which can convert chlorine into chloride ion. However, addition of silver nitrate to the solution produced no precipitates of silver chloride. Futhermore, no mass losses corresponding to the evolution of gaseous chlorine were observed in the TG curve. Thus, it is conceivable that the reduction is not due to the chloride ions in outer-sphere. The coordinated methylamines are also not responsible for the reaction since they were liberated without any change in structure.

The cause might be attributed to the ligand (phbgH), which forms a six-membered chelate ring with π-electron delocalization with a metal ion. The reduction of Co(III) to Co(II) ion can be understood to be due to the electron transfer from the two π-electron-rich phbgH's to the central cobalt ion. This is supported by the IR and far-IR data. As is shown in Fig. 4, both bands at 1572 and 1267 cm^{-1} in complex III which are assigned to the stretching vibrations of C=N and C–N bonds, respectively, shift to lower wavenumber regions by about 20 cm^{-1}. The shifts may arise from the decrease of π-electron delocalization in the phbgH due to the electron transfer from the phbgH to the cobalt(III) ion.

The decrease in the stretching vibration of Co–N (phbgH) is also observed in far-IR region upon heating (510 sh→502 cm^{-1}, Fig. 5). The decrease may result from the difference in the force constants of Co(III)–N and Co(II)–N bonds. Actually, the values of the force constants in the hexaammine complexes are reported to be 1.05 and 0.33 mdyn/A(UBF) for Co(III)–N and Co(II)–N, respectively,[18] the energy difference in the stretching vibrations being beyond 100 cm^{-1}. Taking the above value into account, the energy difference observed in the stretching vibrations of Co(III)–N (phbgH) and Co(II)–N(phbgH) is considerably smaller. Such difference between the known and the observed values may be ascribed to the increasing character of the covalent bond between cobalt and phbgH in the bivalent cobalt complex, which supports the occurrence of the inner-sphere electron transfer reaction.

The final problem is to determine the outcome of the chloride ions upon heating, which are generally known to enter into the coordination sphere through anation. A key to this lies in the appearance of a peak at 1355 cm^{-1} in the IR region which is newly observed after heating (Fig. 4), PhbgH is thought to have the coordination mode with a positive charge at N(4) site due to the six membered ring aromaticity.[11] The positive charge will increase owing to the electron transfer. It is reasonable to consider that the band is attributable to the vibration of the NH^+–Cl^- which seems to be formed after heating. Thus, of the three chloride ions, two are added to the phbgH, and the remaining one enters into the coordination sphere.

The following reaction scheme can be represented for the thermal electron trnasfer reaction of complex III.

$$\textit{trans}\text{-}[Co(CH_3NH_2)_2(phbgH)_2]Cl_3\cdot2H_2O \xrightarrow[\Delta]{-(2H_2O+2CH_3NH_2)} [Co^{II}Cl(phbgHCl)_2]$$

The product is stable in the solid state, but unstable in various solvents; it decomposes even by the addition of ethanol separating white crystals. The IR spectrum of the crystals shows the structure of the phbgH to remain even after the electron transfer reaction.

The patterns of the thermal reactions of complexes V and VI can be understood in a similar way. As an example, the far-IR spectra of complex VI are shown in Fig. 5. The three peaks at 645, 487, and 455 cm^{-1} which are specified to be in-plane ring deformation of pyridine molecule, Co–N(py) stretching vibration and out of plane ring deformation of pyridine molecule, respectively, are entirely quenched by the thermal treatment. This indicates the liberation of two moles of the coordinated pyridine.

The band shifts and the appearance of the peak near 1350 cm^{-1} upon heating of complexes V and VI are summarized in Table 3. The bands of the Co–N (phbgH) stretching vibration are also shifted to lower

Table 3. IR data of complexes V and VI before and after heating

	Complex V		Complex VI	
	Before heating	After heating	Before heating	After heating
	(cm^{-1})		(cm^{-1})	
$\nu_{C=N}$	1550	1540	1550	1538
ν_{C-N}	1270	1247	1273	1248
δ_{NH_2}	1674	1685	1668	1679
$\delta_{NH^+-X^-}$	—	1354	—	1356

wavenumber regions in the far-IR spectra (510→504 cm^{-1}, and 513→502 cm^{-1} for complexes V and VI, respectively).

The electronic spectral pattern of both products obtained upon heating are identical with the pattern of complex III. The absorption maxima and the values of magnetic mometns are given in Table 2 for the products of complexes V and VI.

The following thermal electron transfer reactions are considered to proceed during the course of thermal treatment in complexes V and VI:

$$trans\text{-}[Co(py)_2(phbgH)_2]X_3\cdot 2H_2O \xrightarrow[\Delta]{-(2H_2O+2py)} [Co^{II}X(phbgHX)_2] \quad (X=Cl \text{ or } Br).$$

Thermal One-mol-deamination Reaction ($[Co(A)_2(phbgH)_2]X_3\cdot nH_2O \rightarrow Co(II)\text{-}product + A + nH_2O$). The IR spectrum of complex IV after heating is shown in Fig. 4. The peaks at 1292, 1000, and 820 cm^{-1}, characteristic of methylamine, remain even in the heated product. Shifts similar to those of complexes III, V, and VI are observed in the IR region upon heating ($\nu_{C=N}$, 1561→1545 cm^{-1}; ν_{C-N}, 1258→1243 cm^{-1}), suggesting the occurrence of electron transfer from the phbgH to the cobalt(III) ion. A new peak assignable to the vibration of the NH^+–Br^- bond appears at 1350 cm^{-1}.

The electronic spectral pattern of the product was analogous to those of complexes III, V, and VI. However, the absorption maximum of the product from complex IV (14.3×10^3 cm^{-1}) appears in a lower wavenumber region to some extent as compared with those ($14.7—14.9\times10^3$ cm^{-1}) of complexes III, V, and VI (Table 2). The shift is attributable to the coordination of the remaining one mole of methylamine.

The following equation might hold for the thermal reaction of complex IV:

$$trans\text{-}[Co(CH_3NH_2)_2(phbgH)_2]Br_3\cdot 2H_2O \xrightarrow[\Delta]{-(2H_2O+CH_3NH_2)} [Co^{II}(CH_3NH_2)(phbgHBr)_2]Br.$$

Difference in the Ease of Electron Transfer. A comparison of the liberation temperatures of amines is suitable for estimating the reactivity in the thermal reaction. The temperatures observed in the derivatograms are summarized as deamination temperatures in Table 1. We see the following order of reactivity depending upon the kind of the coordinated amine and counter ion.

i) $NH_3 < CH_3NH_2 <$ py

ii) $Br^- < Cl^-$

Order i), the reverse of that in the strength of the ligand field, is the order of the ease of the liberation of the coordinated amine. This is understandable if the liberation of the coordianted amines is considered to be a trigger of the reactions. The fact that ammine complexes I and II decomposed without a distict liberation step of ammonia upon heating can be explained by the fact that the temperatures of complexes I and II reached the decomposition points prior to the liberation of the coordinated ammonia. The liberation temperatures of ammonia in these complexes might be higher than those of the methylamine or pyridine complexes.

Order ii) is related to the order of the ease of anation and addition of the halide ions to phbgH.

Studies of the Yields of ^{57}Fe(II)-species Produced after the EC-decay and of ^{60}Co(II)-species Produced in the (n, γ) Reaction in Cobalt(III) Coordination Compounds

Hirotoshi SANO,* Masayuki HARADA, and Kazutoyo ENDO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya, Tokyo 158

(Received February 13, 1978)

The yields of ^{57}Fe(II)-species produced after EC-decay were compared with those of ^{60}Co(II)-species produced in the ^{59}Co(n,γ)^{60}Co reaction for twelve cobalt(III) coordination compounds. The results indicate that the radiochemical yield of ^{60}Co(II)-species correlates with the yield of ^{57}Fe(II)-species except in the case of $[Co(NH_3)_6]_2(CrO_4)_3$. The anomalously low yield of ^{57}Fe(II)-species in $[Co(NH_3)_6]_2(CrO_4)_3$ is ascribed to the reaction of chromate anions with ammine ligands initiated by the nuclear transformation in a solid.

A number of studies of the chemical effects of ^{59}Co(n,γ)^{60}Co nuclear reactions in cobalt(III) coordination compounds have thus far been reported. Although several working hypotheses have been proposed in hot-atom chemistry concerning the initial distribution of the transformed nuclides into different chemical states,[1] these hypotheses have all been made on the assumption that radiochemical separation processes have little influence on the analytical results of the transformed nuclides. It is well-known, however, that the results depend on the experimental conditions, such as the time and the temperature both of irradiation and storage, and the chemical and physical state of the sample used for irradiation.[1,2]

Mössbauer emission spectroscopy provides a unique way of studying *in situ* the chemical state of atoms produced as a result of nuclear decay in a solid. The technique has been extensively used in investigations of ^{57}Fe-species produced after the EC-decay of ^{57}Co, but few studies of the Mössbauer emission spectroscopy of cobalt(III) compounds have been concerned with the results of ^{59}Co(n,γ)^{60}Co hot-atom chemistry. We have reported previously that the chemical states of ^{57}Fe produced after the EC-decay of ^{57}Co depend upon the radiolytic character of the ligands or anions surrounding the decaying atoms.[3,4] In the present work, the radiochemical yield of ^{60}Co(II)-species found in the (n,γ) reaction was compared with the yield of ^{57}Fe(II)-species produced after the EC-decay for twelve cobalt(III) coordination compounds, including three compounds reported previously.[4]

Experimental

Target and ^{57}Co-labelled Compounds. $[Co(NH_3)_6]CO_3Cl$,[5] $[Co(NH_3)_6]SO_3Cl$,[6] $[Co(NH_3)_6]_2(CO_3)_3\cdot 3H_2O$,[7] $[Co(NH_3)_6]_2(SO_4)_3\cdot 5H_2O$,[8] $[Co(NH_3)_6]_2(CrO_4)_3$,[9] $[Co(NH_3)_6](NO_3)_3$,[8] $[Co(NH_3)_6]Cl_3$,[8] $[Co(NH_3)_5(OH_2)](NO_3)_3$,[10] and $[Co(NH_3)_5(OH_2)]_2(C_2O_4)_3\cdot 4H_2O$[10] were prepared from soltuions, each containing 50 mg of cobalt(II), by following the methods described in Refs. 5 to 10. The ^{57}Co-labelled compounds were prepared from solutions containing about 1 mCi ^{57}Co, but otherwise in the same way as described above. The purity was checked by elemental analysis and X-ray diffraction and found to be at least 97%.

Neutron Irradiation and Chemical Separation. The samples were irradiated for 10 min at the reactor temperature in a thermal column in a TRIGA Mark II reactor at the Institute for Atomic Energy of Rikkyo University. After being allowed to stand for half an hour, the irradiated sample was dissolved into an aqueous solution containing 10 mg cobalt(II) chloride as a carrier, after which a small amount of diluted hydrochloric acid was added to keep the acidity at pH 3—4. The cobalt(II) species were separated by solvent extraction after adding 1-nitroso-2-naphthol, hydrogen peroxide, and chloroform to the solution. The radiochemical yield of ^{60}Co(II) was determined by counting 1.17 and 1.33 MeV γ-rays with a Ge(Li) semiconductor detector and a multichannel analyser, CANBERRA Model 8100.

Mössbauer Emission Spectroscopic Measurements. The ^{57}Co-labelled compounds were kept in a crysotat, and the Mössbauer spectra were measured against an ^{57}Fe-enriched stainless-steel absorber moving in a constant-acceleration mode at room temperature. The velocity calibrartions were carried out by using an ^{57}Fe-enriched iron foil absorber moving against a stationary ^{57}Co(Pt) source at room temperature.

Results and Discussion

Some typical Mössbauer emission spectra of the source compounds measured at 78 K are shown in Figs. 1 and 2. The peak component ascribed to ^{57}Fe(II)-species was estimated from the isomer-shift and quadrupole-splitting values. The yield of ^{57}Fe(II)-species was evaluated from the area under the component and the total area of the spectrum by assuming that the recoil-free fraction of each ^{57}Fe-species was nearly the same at 78 K, as has previously been described in Ref. 4.

Table 1 summarizes the results concerning the radiochemical yield of ^{60}Co(II), together with the yield of ^{57}Fe(II) evaluated from the Mössbauer emission spectroscopy. It has already been reported that practically the same yield of ^{60}Co(II) is obtained by using either solvent extraction or paper electrophoresis for neutron-irradiated tris(dimethylglyoximato)cobalt(III).[11] Our previous result concerning the radiochemical yield of ^{60}Co(II) obtained for the neutron-irradiated $[Co(NH_3)_6](NO_3)_3$ by means of paper electrophoresis is shown in Table 1 for the sake of comparison.

We have demonstrated repeatedly that the distribution of the decayed atom into the different chemical states depends on the radiolytical property of the species surrounding the decayed atom.[17-19] It was also reported that not only the nearest neighbors of the decayed atom, but also the next nearest neighbors,

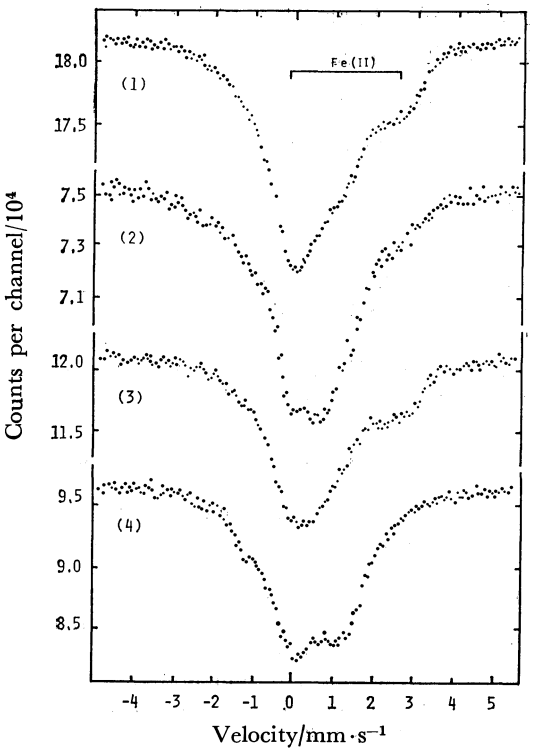

Fig. 1. Mössbauer spectra at 78 K of ^{57}Co-labelled (1) $[Co(NH_3)_6]Cl_3$, (2) $[Co(NH_3)_6]_2(CO_3)_3\cdot 3H_2O$, (3) $[Co(NH_3)_6]_2(SO_4)_3\cdot 5H_2O$, and (4) $[Co(NH_3)_6]_2(CrO_4)_3$ sources.
All the velocity scales were normalized with respect to metallic iron.

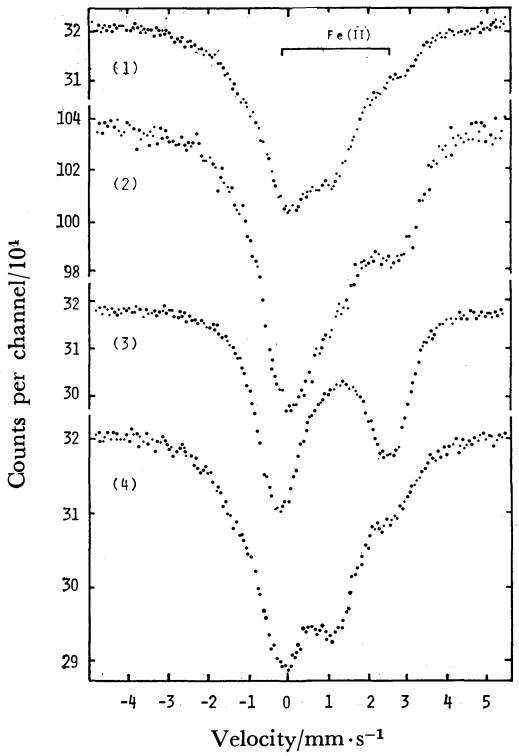

Fig. 2. Mössbauer spectra at 78 K of ^{57}Co-labelled (1) $[Co(NH_3)_6]CO_3Cl$, (2) $[Co(NH_3)_6]SO_3Cl$, (3) $[Co(NH_3)_5OH_2]_2(C_2O_4)\cdot 4H_2O$, and (4) $[Co(NH_3)_5OH_2](NO_3)_3$ sources.
All the velocity scales were normalized with respect to metallic iron.

TABLE 1. SUMMARY OF THE YIELDS OF ^{57}Fe(II)-SPECIES PRODUCED AFTER EC-DECAY AND THE RADIOCHEMICAL YIELDS OF THE ^{60}Co(II)-SPECIES IN THE HOT-ATOM CHEMISTRY OF THE ^{59}Co(n, γ)^{60}Co REACTION

Compound	Yield of ^{57}Fe(II) in EC-decay, %	Yield of ^{60}Co(II) in ^{59}Co(n γ)^{60}Co, %
$[Co(NH_3)_6]Cl_3$	42±1	57.5
$[Co(NH_3)_6]_2(CO_3)_3\cdot 3H_2O$	34±1	45.1
$[Co(NH_3)_6]_2(SO_4)_3\cdot 5H_2O$	54±1	96.0[12]
$[Co(NH_3)_6]_2(CrO_4)_3$	1±1	63.2[12]
$[Co(NH_3)_6]CO_3Cl$	41±1	61.0
$[Co(NH_3)_6]SO_3Cl$	52±1	67.8
$[Co(NH_3)_6](NO_3)_3$	38±1; 40±1[14]	66.9; 66.7[12]
$[Co(NH_3)_6]_2(C_2O_4)_3\cdot 4H_2O$	72±1[14]	91.0[14]
$[Co(NH_3)_5OH_2](NO_3)_3$	34±1	51.3[13]
$[Co(NH_3)_5OH_2]_2(C_2O_4)\cdot 4H_2O$	68±1	82.9[13]
$[Co(NH_2CH_2CH_2NH_2)_3](NO_3)_3$	53±1[14]	69.4[15]
$K_3[Co(C_2O_4)_3]\cdot 3H_2O$	85[16]	98.6[14]

are involved in determining the oxidation state of the decayed atom in the local radiolytic processes initiated by the EC-decay.[3,4] A large amount of ^{57}Fe(II)-species found in the spectrum of $[Co(NH_3)_5(OH_2)]_2(C_2O_4)_3\cdot 4H_2O$ can be ascribed to the effect of oxalate anions in the second coordination sphere, as was mentioned in the case of $[Co(NH_3)_6]_2(C_2O_4)_3\cdot 4H_2O$.[4] Electrons produced in the process:

$$C_2O_4^{2-} \longrightarrow 2CO_2 + 2e^-$$

may be involved in enhancing the yield of ^{57}Fe(II)-species.

Including our previous data on $[Co(NH_3)_6](NO_3)_3$, $[Co(NH_3)_6]_2(C_2O_4)_3\cdot 4H_2O$, and $K_3[Co(C_2O_4)_3]\cdot 3H_2O$, Fig. 3 compares the yield of ^{60}Co(II) after the (n,γ) reaction with the yield of ^{57}Fe(II) after the EC-decay. A fairly good correlation may be found between them except for $[Co(NH_3)_6]_2(CrO_4)_3$ which shows a very low yield in the ^{57}Fe(II) state, whereas there is quite large yield in the ^{60}Co(II) state. The correlation between the yield of ^{57}Fe(II) and that of ^{60}Co(II) for the other compounds can be understood by assuming that there should be little irregular influence on the trend of distribution of ^{60}Co atoms produced in the (n,γ) hot-atom reaction through traditional chemical separation.

The results suggest that the fate of the ^{60}Co atoms produced in the (n,γ) reaction is similar, after their slow-down, to that of the ^{57}Fe atoms produced in the EC-decay except for the difference between the chemical behavior of cobalt and iron. The similarlity may be partly explained by the fact that ^{60}Co-species are also produced through the ^{59}Co(n,γ)^{60m}Co reaction and the I. T. (I. C.) process. The large cross-section of the ^{59}Co(n,γ)^{60m}Co reaction (σ : 18 barn), the short ir-

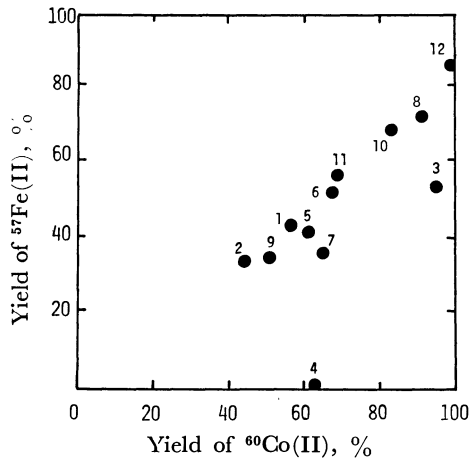

Fig. 3. Comparison of the radiochmiecal yield of $^{60}Co(II)$-species in the $^{59}Co(n,\gamma)^{60}Co$ hot-atom chemistry with the yield of $^{57}Fe(II)$-species produced after EC-decay.
1: $[Co(NH_3)_6]Cl_3$, 2: $[Co(NH_3)_6]_2(CO_3)_3 \cdot 3H_2O$, 3: $[Co(NH_3)_6]_2(SO_4)_3 \cdot 5H_2O$, 4: $[Co(NH_3)_6]_2(CrO_4)_3$, 5: $[Co(NH_3)_6]CO_3Cl$, 6: $[Co(NH_3)_6]SO_3Cl$, 7: $[Co(NH_3)_6](NO_3)_3$, 8: $[Co(NH_3)_6]_2(C_2O_4) \cdot 4H_2O$, 9: $[Co(NH_3)_5OH_2](NO_3)_3$, 10: $[Co(NH_3)_5OH_2]_2(C_2O_4)_3 \cdot 4H_2O$, 11: $[Co(NH_2CH_2CH_2NH_2)_3](NO_3)_3$, and 12: $K_3[Co(C_2O_4)_3] \cdot 3H_2O$.

radiation time, and the large internal conversion coefficient (α_k : 41) provide the conditions necessary to produce multi-charge decayed atoms just like those provided by the EC-decay process.[21] The fate of the so-called hot-atoms may be determined through the chemical interaction with the host material—local radiolytic process—either after the (n,γ) reaction or after the EC-decay. The distribution of ^{60}Co atoms in the reduced state, Co(II), may depend upon the local radiolytic property of the host cobalt(III) coordination compound, which determines the yield of the ^{57}Fe atoms produced in the EC-decay into the reduced ferrous state as well.

The anomalous results found in the case of $[Co(NH_3)_6]_2(CrO_4)_3$ indicate that the decayed ^{57}Fe atoms remain in the ligand-deficient Fe(III) state after the EC-decay process. It seems reasonable to assume that the following process:

$$CrO_4^{2-} + 2e^- \longrightarrow CrO_4^{4-}$$

consumes electrons and keeps the decaying atoms in a higher oxidation state, since chromate(IV) anions are known to be stable in Ba_2CrO_4 and Ca_2CrO_4.[20] Chromate(VI) anions may also be supposed to react with ammine lignads in the following processes:

$$CrO_4^{2-} + NH_3 \rightarrow \frac{1}{2}Cr_2O_3 + \frac{1}{2}N_2 + \frac{1}{2}H_2O + OH^-$$

$$Cr_4O^{2-} + \frac{2}{3}NH_3 \rightarrow CrO_2 + \frac{1}{3}N_2 + 2OH^-$$

through the local radiolytic process triggered by the nuclear transformation, giving reduced Cr(IV) or Cr(III) species, nitrogen, and hydroxide ions. The ligand-deficient species produced through the nuclear transformation may decompose into a reduced species, giving a large radiochemical yield of the reduced species—the $^{60}Co(II)$-species in the present case—after the sample has been dissolved for the traditional radiochemical analysis, whereas the ligand-deficient ^{57}Fe-species remaining in the original oxidation state can be observed as $^{57}Fe(III)$-species by the Mössbauer emission spectroscopy. A similar trend is also found slightly in the case of $[Co(NH_3)_6]_2(SO_4)_3$, although here the effect of sulfate anions seems not so remarkable as that of chromate(VI) anions.

The present results indicate that the trends observed in the traditional hot-atom chemistry correlate with those observed in the Mössbauer emission experiments, if there are no or few addtional effects through the chemical analyses, and that the comparison of the results obtained for the hot-atom chemistry of the (n,γ) process in cobalt compounds with those of the Mössbauer emission spectroscopic studies of the same compounds can provide clues for use in clarifying the reaction mechanism which may occur around the "hot-atoms" in a solid.

Absorption and Circular Dichroism Spectra of Cobalt(III) Complexes Containing *N,N*-Dimethylethylenediamine

Keiji AKAMATSU* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received March 3, 1978)

Nine new cobalt(III) complexes containing *N,N*-dimethylethylenediamine are prepared. The geometrical configurations of isomers are assigned on the basis of their visible and ultraviolet absorption spectra, proton magnetic resonance spectra, and the optical resolution of the chiral isomers. The absorption and circular dichroism spectra are discussed in comparison with those of the corresponding complexes containing ethylenediamine, *N*-methylethylenediamine, *N,N'*-dimethylethylenediamine, or tris-2-(aminoethyl)amine.

There have been several investigations concerning the Co(III) complexes of *N*-methylethylnediamine (*N*-Me-en)[1-3] and *N,N'*-dimethylethylenediamine (*N,N'*-Me_2-en).[3,4] No Co(III) complexes have ever been reported for *N,N*-dimethylethylenediamine (*N,N*-Me_2-en), though some Cu(II),[5] Ni(II),[6] and Rh(III)[7] complexes have been prepared for this tertiary amine ligand. In this paper the preparation and the properties of the Co(III) complexes containing *N,N*-dimethylethylenediamine are reported.

Experimental

Preparations. *(1)* trans(*NO_2*)-[*Co(*NO_2*)*$_2$(N,N-*Me_2*-en)*$_2$]-*ClO_4*: This complex was prepared by the same method as that of Buckingham *et al.*[2] for *trans*, *trans*-[$Co(NO_2)_2$-(*N*-Me-en)$_2$]ClO_4. To an ice-cold solution of $CoCl_2 \cdot 6H_2O$(4.76 g, 2.0×10^{-2} mol) in 10 cm^3 of water was added a cold solusion of *N,N*-dimethylethylenediamine(3.52 g, 4.0×10^{-2} mol) in 1.7 cm^3 of 12 M HCl, and then $NaNO_2$(2.8 g, 4.2×10^{-2} mol) was added. A vigorous stream of air was introduced to this red bown solution for 5 h at room temperature. The resulting solution was evaporated to dryness by a rotary evaporator below 40 °C. To the residue was added 50 cm^3 of methanol and the resulting NaCl precipitated was filtered off. Ten grams of $NaClO_4$ was added to precipitate a crystalline powder by scratching the flask. This was filtered and recrystallized from warm water. Found: C, 22.28; H, 5.75; N, 19.66%. Calcd for [$Co(NO_2)_2$(*N,N*-Me_2-en)$_2$]-ClO_4: C, 22.51; H, 5.68; N, 19.69%.

(2) cis*(Cl)*-[*CoCl*$_2$*(*N,N-*Me*$_2$*-en)*$_2$]*Cl*O_4: Three grams of *trans*(NO_2)-[$Co(NO_2)_2$(*N,N*-Me_2-en)$_2$]ClO_4 was suspended in 50 cm^3 of alcoholic hydrogen chloride(saturated at ice-bath temperature) and stirred overnight at room temperature. The blue green powder deposited was filtered, washed with ethanol and ether, and dried in air. Found: C, 23.87; H, 6.15; N, 14.10%. Calcd for [$CoCl_2$(*N,N*-Me_2-en)$_2$]-ClO_4: C, 23.68; H, 5.97; N, 13.81%.

(3) trans*(*N_3*)-* *and* cis*(*N_3*)*-[*Co(*N_3*)*$_2$*(*N,N-*Me*$_2$*-en)*$_2$]X; *X*=*ClO*$_4$*(*trans*)* *and* *Cl*·H_2O*(*cis*)*: One gram of *cis*(Cl)-[$CoCl_2$(*N,N*-Me_2-en)$_2$]ClO_4 was dissolved in 5 cm^3 of water, and to this blue solution was added 0.6 g of NaN_3 and stirred at 40 °C for 1 h. On cooling to room temperature, dark brown-violet crystals were deposited. The crystals were separated by filtration from the dark green solution and recrystallized from water at 50 °C. From the measurement of absorption spectrum it was found that this brown-violet isomer has a *trans*(N_3) structure. Found: C, 22.69; H, 5.81; N, 33.67%. Calcd for *trans*(N_3)-[$Co(N_3)_2$(*N,N*-Me_2-en)$_2$]-ClO_4: C, 22.94; H, 5.78; N, 33.45%.

The corresponding *cis* isomer was isolated from the same reaction mixture by column chromatographic method. The reaction mixture was completely dissolved with water and poured into a cation exchanger column(SP-Sephadex C-25, Na^+ form) and eluted with a 0.05 M NaCl aqueous solution. Two bands appeared; dark brown-violet one(*trans* isomer) and dark green one(*cis* isomer), in this order. The dark green band was eluted and evaporated to dryness below 30 °C by a rotary evaporator. From the residue the complex was extracted into methanol and NaCl precipitated was filtered off. The dark green filtrate was evaporated to dryness and the resulting powder was recrystallized from the minimum amount of water and dried in air. This was proved to be a *cis*(N_3) isomer through the optical resolution. Found: C, 25.34; H, 6.94; N, 36.88%. Calcd for *cis*(N_3)-[$Co(N_3)_2$(*N,N*-Me_2-en)$_2$]Cl·H_2O: C, 25.77; H, 7.04; N, 37.58%.

(4) *Optical Resolution of* cis*(*N_3*)*-[*Co(*N_3*)*$_2$*(*N,N-*Me*$_2$*-en)*$_2$]-*Cl*·H_2O: The racemic chloride monohydrate, *cis*(N_3)-[$Co(N_3)_2$(*N,N*-Me_2-en)$_2$]Cl·H_2O (0.2 g, 5.6×10^{-4} mol) was dissolved in 2 cm^3 of water and to this dark green solution was added ammonium $(+)_{589}$-(1*R*, 3*S*, 4*S*, 7*R*)-3-bromocamphor-9-sulfonate(0.17 g, 5.0×10^{-4} mol). On stirring, a crystalline powder was deposited, filtered, and washed with a small amount of water. This diastereoisomer was sparingly soluble in water at room temperature but soluble in methanol, ethanol, or acetone. The less soluble diastereoisomer was recrystallized from water at 30 °C, washed with water and dried in air. Found: C, 32.40; H, 6.33; N, 20.83%. Calcd for [$Co(N_3)_2$(*N,N*-Me_2-en)$_2$]$C_{10}H_{14}O_4SBr\cdot2H_2O$: C, 32.48; H, 6.37; N, 21.10%.

The less soluble diastereoisomer was converted into $(+)_{589}$-perchlorate by use of a column chromatographic method. Found: C, 22.61; H, 5.85; N, 33.45%. Calcd for $(+)_{589}$-[$Co(N_3)_2$(*N,N*-Me_2-en)$_2$]ClO_4: C, 22.94; H, 5.79; N, 33.45%.

(5) trans*(NCS)-* *and* cis*(NCS)*-[*Co(NCS)*$_2$*(*N,N-*Me*$_2$*-en)*$_2$]-*Cl*·H_2O: One and three tenths grams of *cis*(Cl)-[$CoCl_2$(*N,N*-Me_2-en)$_2$]ClO_4 and four tenths grams of KSCN were dissolved in 50 cm^3 of water and stirred at 40 °C for thirty min to obtain a red violet solution. The resulting solution was poured into a cation exchanger column(SP-Sephadex C-25, Na^+ form) and the adsorbed complex was eluted with a 0.05 M NaCl aqueous solution. Four bands appeared; dark reddish purple, deep purple, light purple, and dark purple ones in this order. The fractions of each the first and the second band were collected and evaporated to dryness below 30 °C by a rotary evaporator. From the residue the complex was extracted into methanol and the solution was evaporated to dryness. The crystalline powder was recrystallized from water and dried in air. The first dark purple band was proved to be a *trans*(NCS) isomer from the measurement of absorption spectrum. Found: C, 29.14; H, 6.34; N, 21.00%. Calcd for *trans*(NCS)-[$Co(NCS)_2$(*N,N*-Me_2-en)$_2$]Cl·H_2O: C, 29.66; H, 6.48; N, 20.76%. The second deep purple band was proved to be a *cis*(NCS) isomer from the successful optical resolution. Found: C, 29.17; H, 6.46; N, 20.62%. Calcd

for *cis*(NCS)-[$Co(NCS)_2$(*N,N*-Me_2-en)$_2$]Cl·H_2O: C, 29.66; H, 6.48; N, 20.76%. The third and fourth bands turned out to be monoisothiocyanato complexes from their elemental analyses.

(6) Optical Resolution of cis*(NCS)*-[*Co(NCS)*$_2$(N,N-*Me*$_2$-*en*)$_2$]*Cl·H*$_2$*O*: The racemic chloride monohydrate, *cis*(NCS)-[$Co(NCS)_2$(*N,N*-Me_2-en)$_2$]Cl·H_2O (0.23 g, 5.7×10^{-4} mol) and ammonium $(+)_{589}$-(1*R*, 3*S*, 4*S*, 7*R*)-3-bromocamphor-9-sulfonate(0.19 g, 5.8×10^{-4} mol) were dissolved in 30 cm^3 of water at 40 °C. The reddish purple solution was evaporated to half the initial volume and cooled in a refrigerator overnight. Reddish purple crystals deposited were filtered and washed with a small amount of water and dried in air. This diastereoisomer was rather soluble in methanol, ethanol, or acetone than in water. Found: C, 35.55; H, 5.75; N, 12.54%. Calcd for [$Co(NCS)_2$(*N,N*-Me_2-en)$_2$]$C_{10}H_{14}O_4$-SBr·0.5H_2O: C, 35.82; H, 5.87; N, 12.53%.

The less soluble diastereoisomer was converted into $(+)_{589}$-perchlorate by a column chromatographic method: C, 25.78; H, 5.47; N, 18.13%. Calcd for $(+)_{589}$-[$Co(NCS)_2$(*N,N*-Me_2-en)$_2$]ClO_4·0.5H_2O: C, 26.11; H, 5.49; N, 18.28%.

(7) [*Co(CO*$_3$*)*(N,N-*Me*$_2$-*en*)$_2$]*ClO*$_4$: The dichloro complex, *cis*(Cl)-[$CoCl_2$(*N,N*-Me_2-en)$_2$]ClO_4(0.4 g, 1.0×10^{-3} mol) was ground with Ag_2CO_3(0.3 g, 1.1×10^{-3} mol). Five cm^3 of water was added and the grinding was continued for half an hour. The color of the solution changed from blue green to violet. The solid AgCl deposited was filtered off and washed with a small amount of water. The filtrate and washing were evaporated almost to dryness and 10 cm^3 of ethanol was added. The blue-violet crystalline solid precipitated was filtered, washed with ethanol and ether and dried in a desiccator. Found: C, 26.29; H, 6.58; N, 13.99%. Calcd for [$Co(CO_3)$(*N,N*-Me_2-en)$_2$]ClO_4·0.5H_2O: C, 26.77: H, 6.25; N, 13.88%.

(8) [*Co(ox)*(N,N-*Me*$_2$-*en*)$_2$]*ClO*$_4$: To a solution of *cis*(Cl)-[$CoCl_2$(*N,N*-Me_2-en)$_2$]ClO_4(1.0 g, 2.5×10^{-3} mol) in 10 cm^3 of water was added five tenths grams of oxalic acid dihydrate, and this mixture was heated to 90 °C in a water bath, concentrated to half the initial volume, and cooled to room temperature. The red-purple crystalline powder precipitated was filtered, washed with ethanol and ether, and dried in air. Found: C, 27.11; H, 6.87; N, 12.75%. Calcd for [Co(ox)(*N,N*-Me_2-en)$_2$]ClO_4·H_2O: C, 27.27; H, 5.96; N, 12.71%.

(9) [*Co(NH*$_3$*)*$_4$(N,N-*Me*$_2$-*en*)]*Cl*$_3$: Two grams of *cis*(Cl)-[$CoCl_2$(*N,N*-Me_2-en)$_2$]ClO_4 was treated with 30 cm^3 of liquid ammonia in a pressure bottle. The blue green complex dissolved in liquid ammonia to give a pale orange solution. After removal of ammonia by introducing dry air, the pink-orange powder was suspended in methanol, and filtered, washed with ethanol and ether, and recrystallized from the minimum amount of water by adding ethanol. Found: C, 13.38; H, 7.72; N, 24.18%. Calcd for [$Co(NH_3)_4$(*N,N*-Me_2-en)]Cl_3·1.5H_2O: C, 13.78; H, 7.82; N, 24.11%.

(10) Other Complexes: Other complexes were prepared by the same methods as seen in the literature: en,[8-12] *N*-Me-en,[2] *N,N'*-Me_2-en,[4] and tris(aminoethyl)amine (tren)[13] complexes. The diazido- and diisothiocyanato-complexes containing *N*-Me-en or tren were prepared by the ligand substitution of *trans*(Cl)-[$CoCl_2$(*N*-Me-en)$_2$]$^{+}$[2] or [$CoCl_2$-(tren)]$^{+}$[14] with KSCN or NaN_3.

Measurements. The visible and ultraviolet absorption measurements were made by a Shimadzu UV-200 spectrophotometer in aqueous solutions, except for the dichloro complex, which was measured in methanol to prevent the aquation. The CD spectra were recorded on a JASCO MOE-1 spectropolarimeter and the PMR spectra were obtained in dimethyl-d_6 sulfoxide on a Varian XL-100-15 spectrometer using tetramethylsilane(TMS) as an internal standard.

Results and Discussion

Preparation and Isomerization. Three methods were tried for the preparation of the dinitro complex, [$Co(NO_2)_2$(*N,N*-Me_2-en)$_2$]$^{+}$; by use of atmospheric oxidation of a mixture of Co^{2+}, *N,N*-Me_2-en, $NaNO_2$, and HCl, and by use of ligand-substitution of either [$Co(CO_3)_3$]$^{3-}$ or [$Co(NO_2)_6$]$^{3-}$. The air-oxidation method only was successful. The product of this reaction was proved to be a *trans*(NO_2) isomer from the parallel relationship between the absorption spectra of this and the corresponding *trans*(NO_2)-[$Co(NO_2)_2$-(en)$_2$]$^{+}$ complex. The *cis*-dinitro complex was not obtaned, although the *cis* isomers of diazido-, diisothiocyanato-, and dichloro-complexes were prepared. The diammine complex, [$Co(NH_3)_2$(*N,N*-Me_2-en)$_2$]$^{3+}$ was not yielded on the tretment of the dichloro complex, *cis*(Cl)-[$CoCl_2$(*N,N*-Me_2-en)$_2$]$^{+}$ with liquid ammonia; the reaction gave only tetraammine complex, [$Co(NH_3)_4$(*N,N*-Me_2-en)]$^{3+}$. When the *trans*-dinitro complex was treated with either alcoholic hydrogen chloride at room temperature of concentrated aqueous hydrogen chloride at 70 °C, only a *cis* isomer of the dichloro complex was obtained, and the reaction of the dichloro complex with $NaNO_2$ yielded only one dinitro complex which was identical with the starting material, *trans*(NO_2)-[$Co(NO_2)_2$(*N,N*-Me_2-en)$_2$]$^{+}$. The dichloro complex was decomposed in the presence of moisture to give a brown insoluble mud. The substitution reaction of *cis*(Cl)-[$CoCl_2$(*N,N*-Me_2-en)$_2$]$^{+}$ with NaN_3 or KSCN resulted in the production of both *trans* and *cis* isomers of diazido or diisothiocyanato complex. The correseponding substitution reaction of *trans*(Cl)-[$CoCl_2$(*N*-Me-en)$_2$]$^{+}$ with either NaN_3 or KSCN gave only the *trans* isomer, and *trans*(Cl)-[$CoCl_2$(*N,N'*-Me_2-en)$_2$]$^{+}$ did not react with these reagents.

Structural Assignments. Figure 1 shows five possible geometrical isomers of a [CoX_2(A-B)$_2$] type complex and their symmetries. In this paper X stands for anions (Cl^-, NO_2^-, N_3^-, or NCS^-) and A-B for *N,N*-dimethylethylenediamine; where A and B signify a

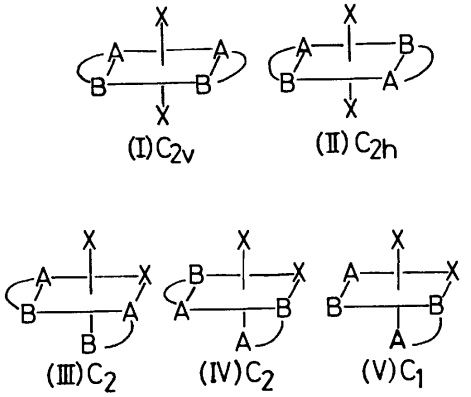

Fig. 1. Possible configurations of [CoX_2(A-B)$_2$]$^{+}$ type complex.

Table 1. Assignment of chemical shifts for PMR of $[CoX_2(N,N\text{-}Me_2\text{-}en)_2]^+$ ($X=N_3^-$, NCS^-, and NO_2^-)
(All frequencies in ppm on low-field side of TMS)

Complex	N-CH_3	-CH_2-CH_2-	N-H	Structure
trans(NO_2)-	2.07	≈2.40, 3.11	5.68	II
trans(N_3)-	2.09	2.29, 2.82	5.60	II
trans(NCS)-	2.21	≈2.46, 2.91	6.43	II
cis(N_3)-	2.10, 2.14	≈2.40, ≈3.2[a]	4.72, 5.56	III
cis(NCS)-	2.25, 2.37	≈2.5,[b] ≈2.95	5.70, 6.00	III

a) Overlapped with -OH signal. b) Overlapped with dimethyl sulfoxide signal.

tertiary and a primary amine, respectively. The upper two complexes I and II in Fig. 1 are *trans*(X) isomers and the lower three III-V *cis*(X) ones. All the three *cis*(X) isomers are chiral and therefore the isomer which can be resolved turns out to be one of the *cis*(X) isomers. PMR spectra can also distinguish among the isomers (I, II), (III, IV), and (V).

Table 1 shows the chemical shifts(in ppm) for PMR spectra of $[CoX_2(N,N\text{-}Me_2\text{-}en)_2]^+$($X=NO_2^-$, NCS^-, and N_3^-). From the PMR data it is confirmed that the *trans* isomers of dinitro-, diisothiocyanato-, and diazido-complexes have I or II structure and that the *cis* isomers of diazido- and diisothiocyanato-complexes III or IV structure. No well-defined PMR spectrum was obtained for the dichloro complex, because of the unstable nature of this complex. It is impossible to distinguish between isomers I and II or between isomers III and IV solely on the basis of the PMR splitting patterns. However a consideration of molecular models provides the following answers for this problem.

The structure I has bulky *N,N*-dimethyl-substituted amines(A) in *cis* positions, which produce rather large repulsion between them and make the structure unstable. A similar consideration is true for the *cis*(X) isomers, that is, the structure IV and V are less stable than the structure III. Accordingly, it is concluded that the *trans*(X) isomers have the structure II and the *cis*(X) isomers the structure III. This conclusion is well supported by the consideration of the absorption spectra mentioned below.

Absorption and Circular Dichroism Spectra. Figure 2 shows the electronic absorption spectra of *trans*-(NO_2)-complexes of en, *N*-Me-en, *N,N'*-Me_2-en, and *N,N*-Me_2-en. It is found that the increase in the number of the *N*-methyl-groups induces the shift of the spectra to lower side, and that the *N,N*-Me_2-en complex has its absorption at lower energy than the *N,N'*-Me_2-en complex. The trough at *ca.* 25000 cm^{-1} disappears in the *N,N*-Me_2-en complex owing to the overlap of the first charge transfer band at *ca.* 27000 cm^{-1}.

Figures 3 and 4 show the absorption spectra of *trans*-(NCS)- and *trans*(N_3)-complexes, respectively. Besides the shift of each band to longer wavelength region with an increase in the degree of *N*-methyl-substitution, two more features are found. The first is the splitting of the first d-d absorption band; there is a broad peak at 19300 cm^{-1} with a shoulder at about 16500 cm^{-1} for the diisothiocyanato *N,N*-Me_2-en complex, and two distinct peaks at 14300 and 18200 cm^{-1} for the diazido

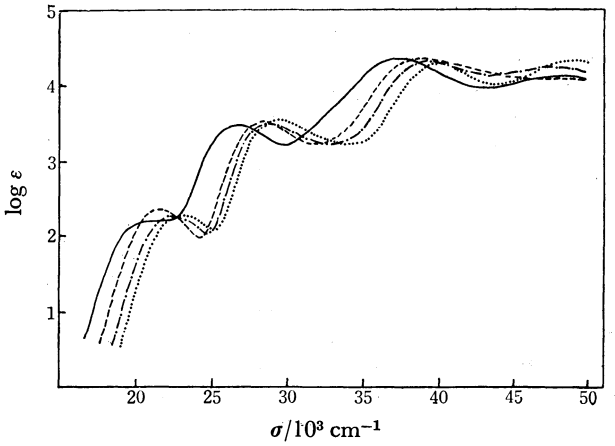

Fig. 2. Absorption spectra of *trans*(NO_2)-[$Co(NO_2)_2$-(diamine)$_2$]$^+$: *N,N*-Me_2-en (——); *N,N'*-Me_2-en (----); *N*-Me-en (—·—); and en (·····).

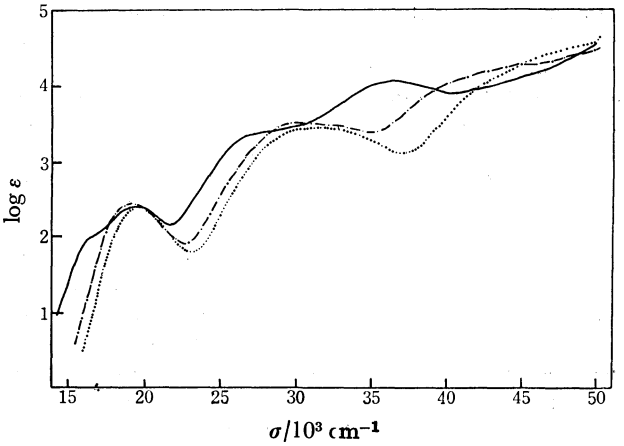

Fig. 3. Absorption spectra of *trans*(NCS)-[$Co(NCS)_2$-(diamine)$_2$]$^+$: *N,N*-Me_2-en (——); *N*-Me-en (—·—); and en (·····).

N,N-Me_2-en complex. The second is a new peak (log $\varepsilon \approx 4$) in the ultraviolet region 35000—40000 cm^{-1} for both NCS- and N_3-complexes; the band is not found for the corresponding ethylenediamine and *N*-methylethylenediamine complexes. The new ultraviolet absorption band also appears for *cis* isomers of the *N,N*-Me_2-en complex at about the same position with the same intensity as those for the *trans* isomers (see Figs. 5 and 6, and Table 2).

Figures 5 and 6 show the absorption and the CD spectra of *cis*(NCS)- and *cis*(N_3)-complexes of en,

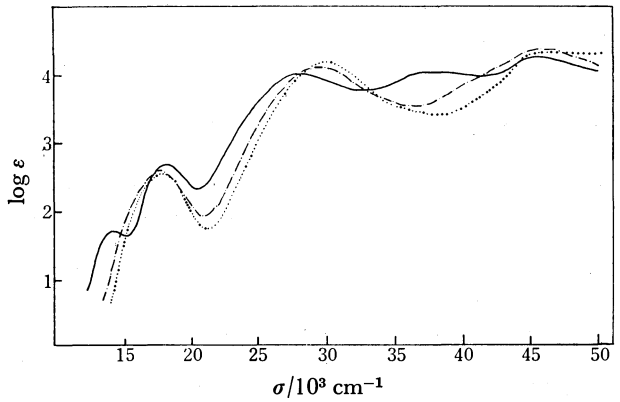

Fig. 4. Absorption spectra of *trans*(N_3)-[$Co(N_3)_2$-(diamine)$_2$]$^+$: *N,N*-Me_2-en (——); *N*-Me-en (—·—); and en (·····).

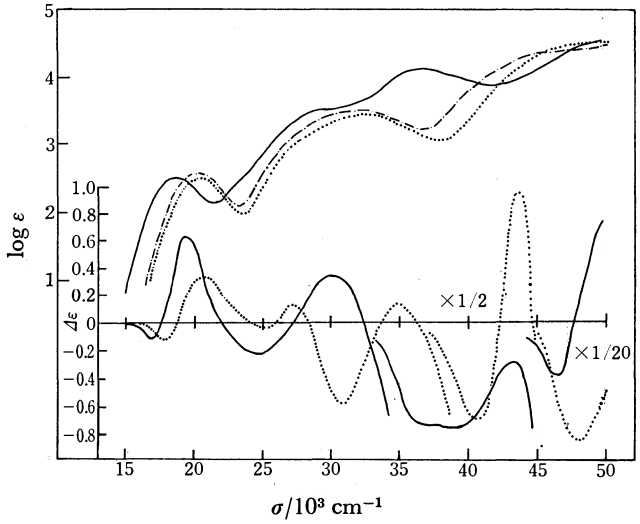

Fig. 5. Absorption and CD spectra of *cis*(NCS)-[Co-(NCS)$_2$(amine)]$^+$: $(+)_{589}$-(*N,N*-Me_2-en)$_2$ (——); tren (—·—); and $(-)_{589}$-$(en)_2$ (·····).

tren, and *N,N*-Me_2-en. Tren is a tripod tetradentate amine and the *cis*-[CoX_2(tren)]$^+$ complexes (X=NCS$^-$ and N_3^-) have a plane of symmetry and are achiral. Both absorption and CD spectra of *N,N*-Me_2-en complexes shift to longer wavelength region than those of the en complexes. The CD spectrum of $(+)_{589}$-[$Co(N_3)_2$(*N,N*-Me_2-en)$_2$]$^+$ correlates to that of $(-)_{589}$-[$Co(N_3)_2(en)_2$]$^+$ on the whole, except a small negative band at 38000 cm^{-1} related to the new absorption peak (Fig. 6). On the other hand, the CD spectrum of $(+)_{589}$-[$Co(NCS)_2$(*N,N*-Me_2-en)$_2$]$^+$ may not correlate at a glance, to that of $(-)_{589}$[$Co(NCS)_2(en)_2$]$^+$ in the ultraviolet region (Fig. 5). This is because the intensity ratio of the CD peaks at 25000—35000 cm^{-1} is reversed between *N,N*-Me_2-en and en complexes; the intensity is weak at 24600 cm^{-1} and strong at 30000 cm^{-1} in the *N,N*-Me_2-en complex(solid line), but strong at 31000 cm^{-1} and weak at 35000 cm^{-1} in the en complex(broken line). At the new absorption peak of 36600 cm^{-1} one or two negative CD bands appear.

Table 2. The absorption data of Co(III) complexes containing *N,N*-Me_2-en and related amines
(Wave numbers and log ε values (in parentheses) are given in 10^3 cm^{-1} and mol^{-1} dm^3 cm^{-1}, respectively.)

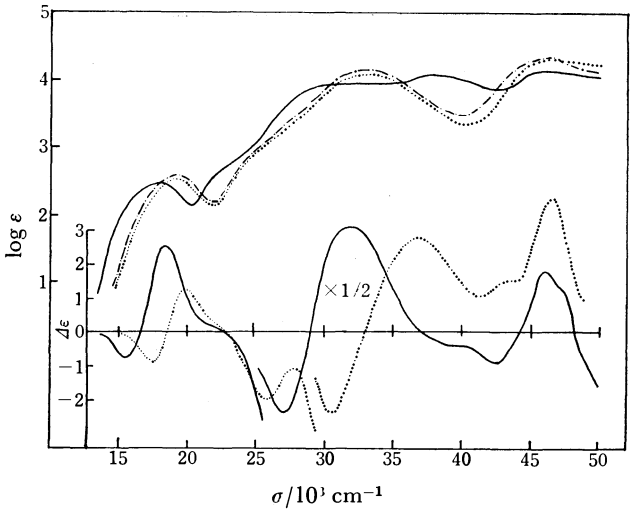

Fig. 6. Absorption and CD spectra of *cis*(N_3)-[Co(N_3)$_2$(amine)]$^+$: $(+)_{589}$-(*N*,*N*-Me_2-en)$_2$ (——); tren (—·—); and $(-)_{589}$-(en)$_2$ (·····).

The feature of the absorption spectra of the Co(III) complexes containing *N*,*N*-Me_2-en is well explained with an assumption that the diamine(A-B) has different ligand-field strengths at each end; the tertiary amine end(A) has very weak ligand-field and the primary amine end(B) the same as ethylenediamine. Yamatera's parameter[15] of the tertiary amine end, δ(A), can be calculated from the absorption data of the *trans*(N_3) isomer which shows a large splitting in the first absorption band region. Such a large splitting can be explained well by the structure II and not by I. Thus the peak situated at lower energy is thought to be shifted by $1/2\delta(N_3)+1/2\delta(A)$ from the peak of the parent complex, $[Co(en)_3]^{3+}$(21400 cm^{-1}). That is, $1/2\delta(N_3)+1/2\delta(A)=14300-21400=-7100\ cm^{-1}$, and with an assumption that $\delta(N_3)=-7900\ cm^{-1}$ (from the first absorption band position 17250 cm^{-1} of *mer*-$[Co(N_3)_3(NH_3)_3]$,[16] we obtain $\delta(A)=-6300\ cm^{-1}$, which is weaker than those of the oxalato and carbonato ligands, $\delta(ox)=-4800$ cm^{-1} and $\delta(CO_3)=-5900\ cm^{-1}$ obtained from the reported absorption spectral data.[17,18] Therefore, on the whole, *N*,*N*-dimethylethylenediamine has somewhat weak strength in the ligand-field as compared with amino acids. From this and the other values, $\delta(NO_2)=+4000\ cm^{-1}$ and $\delta(NCS)=-4300\ cm^{-1}$ (from the first absorption band position 23210 cm^{-1} and 19050 cm^{-1} of *mer*-$[Co(NO_2)_3(NH_3)_3]$[19] and *mer*-$[Co(NCS)_3(NH_3)_3]$[20], respectively), the first absorption bands of all the *trans* isomers of *N*,*N*-Me_2-en complexes can be well explained. Yamatera's rule predicts that the *cis*(N_3) complex of structure III has the split components of the first absorption band at 16300 and 17500 cm^{-1}, while that of the structure IV at 14300 and 17900 cm^{-1}. The observed first absorption band of the *cis*(N_3) complex is located at 17610 cm^{-1}. The absence of the band of 14300 cm^{-1} supports strongly the structure III for this complex. Similarly the *cis*(NCS) complex is assigned to have the strucutre III, which is parallel to the conclusion from pmr and molecular model considerations. The dichloro complex cannot be assigned on the basis of PMR spectra. However, if it is the *trans*(Cl) isomer II, it should have a split component at *ca.* 12900 cm^{-1} (from $\delta(Cl)=-10700$ cm^{-1} [21]). Because the complex shows no component there, it is assigned to the *cis*(Cl) isomer.

In a previous paper we reported that the near ultraviolet charge-transfer band (so-called specific band) of a *trans* isomer of bis(aniono) Co(III) complexes is more bathochromic than that of the corresponding *cis* isomer.[22] This is also the case of the present *N*,*N*-Me_2-en complexes; for example, the band of the *trans*-(N_3) complex is at 28010 cm^{-1}, while that of *cis*(N_3) at 32260 cm^{-1}. All the present dianiono complexes of *N*,*N*-Me_2-en show a broad absorption band in the region of 35000—39000 cm^{-1} (Table 2). The tetraamine complex, $[Co(NH_3)_4(N,N\text{-}Me_2\text{-}en)]^{3+}$ also shows this kind of band at *ca.* 42000 cm^{-1}. This new band of charge-transfer character is attributed to the coordinated tertiary amine; the observed peak or so-called end absorption at *ca.* 50000 cm^{-1} may be attributed to the coordinated primary amine. In this connection it is worthwhile to point out that none of the tren complexes show the peak attributed to the tertiary amine, which may reflects that the tertiary amine of the tren ligand has a nature different from that of *N*,*N*-Me_2-en.

Absolute Configuration. From the parallel relationship between the CD spectra of $(+)_{589}$-$[CoX_2(N,N\text{-}Me_2\text{-}en)_2]^+$ and $(-)_{589}$-$[CoX_2(en)_2]^+$ (X=N_3^- and NCS^-), it is concluded that the $(+)_{589}$ -isomers of *cis* dianiono complexes of *N*,*N*-Me_2-en have the absolute configuration same as that of the $(-)_{589}$-isomers of the corresponding en complexes (see Table 3). Because the latter complexes have been assigned to *Λ* configuration,[12] the present $(+)_{589}$-*N*,*N*-Me_2-en complexes

are also assigned to *Λ*.

In a previous paper[12] it was reported that the *Λ* isomers of diazido- and diisothiocyanatobis(ethylenediamine)cobalt(III) complexes show a CD pattern of negative and then positive signs in the order of increasing energy in the longest wavelength charge-transfer band region, so-called specific band region. As is seen in Figs. 5 and 6, and in Table 3, this is also valid for the *N,N*-Me_2-en complexes. The CD sign in the region of tertiary amine band is negative for the *Λ* isomers.

Preparation and Properties of Cu(II) Complexes of *N*-Picolinoyl-*S,S*-tetramethylenesulfilimine, *N*-(Trimethylammonio)-picolinamidate, and Related Ylides

Hideo KISE* and Manabu SENŌ

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received April 8, 1978)

The reactions of *N*-picolinoyl-*S,S*-tetramethylenesulfilimine (PS) and *N*-(trimethylammonio)picolinamidate (PA) with copper(II) chloride dihydrate in ethanol afforded complexes of the formula $CuCl_2(Y)$ and $CuCl_2(Y)_2$ (Y=PA or PS). The structures of these complexes were examined by spectroscopic and magnetic methods, and it was found that all of them have mononuclear chelate structures. It was concluded that in $CuCl_2(PS)$, the ligand is coordinated through two nitrogen atoms, whereas in $CuCl_2(PS)_2$, the ligands are coordinated through carbonyl oxygens and nitrogens in pyridine rings. The structures of $CuCl_2(PA)$, $CuCl_2(PA)_2$, and CuCl(PA) are closely similar to each other and the possibility of coordination through ylidic nitrogens with large ionic contributions to the structures was strongly suggested. Several Cu(II) complexes with monodentate sulfilimines and aminimides were also prepared, and the structural analyses revealed that the nature of the coordination depends largely on the structure of the ylides.

It has been reported that *N*-picolinoyl-*S,S*-tetramethylenesulfilimine (PS) and *N*-(trimethylammonio)-picolinamidate (PA) are bidentate and ambident ligands and form 1:1 chelate complexes with $PdCl_2$ and $PtCl_2$ in which the ligands are coordinated through two nitrogen atoms.[1] In this paper the formation of Cu(II) and Cu(I) complexes of these ylides and the determination of their structure by magnetic and spectroscopic methods are reported. An interesting feature of the chemistry is the nature of the metal-ligand coordination bonds which has not been investigated in detail.

Although numerous reports have been published on the transition metal–ylide complexes, only a limited number of them describe copper complexes. Chia *et al.*[2] claim that *N*-(1-pyridinio)benzenesulfonamidate forms complexes with Cu(II) perchlorate and halides *via* ylidic nitrogen atoms. Measurements of magnetic moments suggested a dimeric structure for the $CuCl_2$ complex, whereas *N*-(1-pyridinio)benzamidate gave a monomeric complex with $CuCl_2$ by coordination *via* ylidic nitrogen. Another Cu(II)–ylide complex reported is the reaction product of triphenylphosphonium phenacylide with $CuCl_2$,[3] which is diamagnetic and likely to have a dimeric or polymeric structure.

Results and Discussion

Complexes of N-*Picolinoyl*-S,S-*tetramethylenesulfilimine (PS) with* $CuCl_2$. By addition of an ethanol solution of PS to an ethanol solution of $CuCl_2 \cdot 2H_2O$ in an equimolar ratio, a 1:1 complex was obtained as a precipitate. The magnetic moment of the complex (Table 1) is normal for an isolated Cu(II) metal and rules out dimeric or polymeric structures. The ylide PS has resonance structures shown below, and the anionic charge is considered to be delocalized over the N–C–O atoms. The large contribution of the enolate ion structure is confirmed by the low C=O stretching band (1547 cm^{-1}), which is comparable to that of carboxylate ions. The IR spectrum of the 1:1 complex exhibits a C=O stretching band at 1655 cm^{-1}, which is 108 cm^{-1} higher than that of the free ligand (Table 2) and close to the bands of carboxamides, clearly indicating coordination through ylidic nitrogen. The proposed square plannar structure in Fig. 1 (**1**) requires coordination through another nitrogen in the pyridine ring, and this is supported by the observed higher frequency shift of the pyridine deformation band from 615 cm^{-1} in the free ligand to 647 cm^{-1} in the complex.[4] These results are quite similar to those of the complexes of PS with $PdCl_2$ and $PtCl_2$, and it may be concluded that the complex has a structure shown in Fig. 1 (**1**) in which the Cu(II)–ylidic nitrogen coordination is essentially covalent (σ) bonding. Although an alternative dimeric square plannar structure like that of dihalo(2-methylpyridine)copper(II) may be possible, in which the two planes interact through Cu–Cl–Cu bond,[5] the inter-

action would be very weak considering the large magnetic moment of $CuCl_2$(PS).

The electronic spectral data are summarized in Table 3. The ligand PS and PA have structural similarity to picolinamides which liberate a hydrogen atom in alkaline media to form neutral complexes with Cu(II). An example is shown in Fig. 1 (**7**) which was reported to be reddish violet and to have λ_{max} at 530 and 585 nm in chloroform and water, respectively.[6] It is interesting to note that in the case of $CuCl_2$(PS), only a small difference in the absorption maximum was observed in chloroform and water, in contrast to complex **7** which shows a red shift in water due to the coordination of water to form an octahedral structure. The electric conductivity of $CuCl_2$(PS) in chloroform is low and indicates no dissociation, but in water the complex is a strong electrolyte (Table 3). Therefore, the chloride ions are considered to be fully replaced by water, and this might compensate for the red shift which is expected in the change to the octahedral structure in water.

From the reaction of $CuCl_2\cdot 2H_2O$ with two equivalents of PS, a complex was obtained which was formulated as $CuCl_2(PS)_2$ and has the normal paramagnetic character of a monomeric structure. However, the C=O stretching absorption band appears at 1530 cm^{-1}, 17 cm^{-1} lower than that of the free ligand, in contrast to the higher frequency shift of $CuCl_2$(PS) described above. In addition, the C–N stretching band shifts from 1330 to 1375 cm^{-1} indicating an increase in double bond character in the complex, and it is very likely that the ligands are coordinated through carbonyl oxygens.

Table 3. Electronic spectral data and molar conductivity of complexes

Complex	$\lambda_{max}(\varepsilon)$		Λ[a]	
	in H_2O	in $CHCl_3$	in H_2O	in $CHCl_3$
$CuCl_2$(PS)	715(27)	720(70)	267	1.03
$CuCl_2(PS)_2$	670(39)	820(106)	221	1.89
$CuCl_2(FS)_2$	815(15)	—[b]	274	—[b]
$CuCl_2$(AS)	800(13)	—[b]	202	—[b]
$CuCl_2$(PA)	710(24)	730(99)	250	1.04
$CuCl_2(PA)_2$	660(44)	850(155)	227	2.99
CuCl(PA)	660(41)	840(82)	117	1.72
$CuCl_2$(AA)	830(3.4)	—[b]	184	—[b]
$CuCl_2$(BA)	820(9.7)	—[b]	265	—[b]

a) Measured at 10^{-3} M, $\mho\,cm^2\,mol^{-1}$. b) Insoluble in $CHCl_3$.

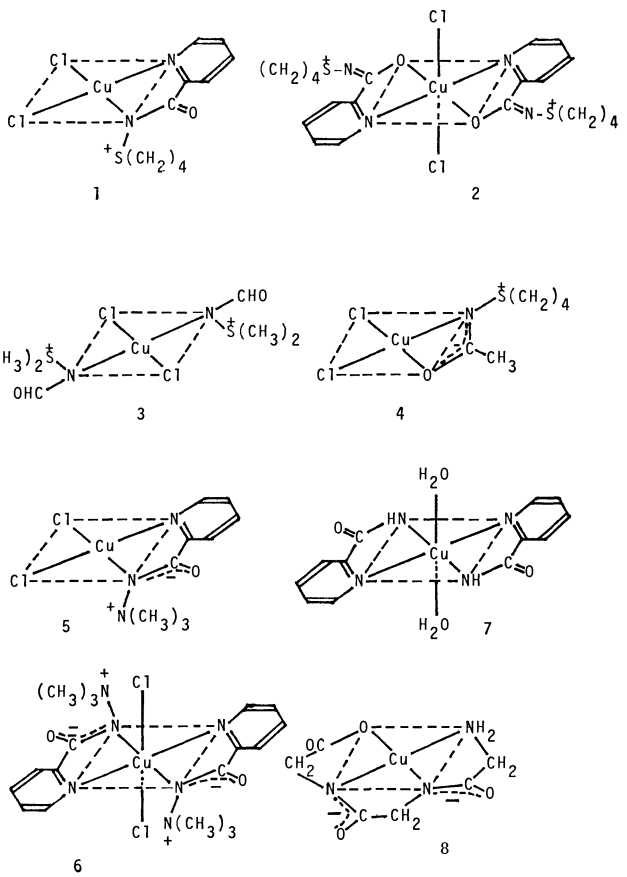

Fig. 1. Structure of Cu(II) complexes.

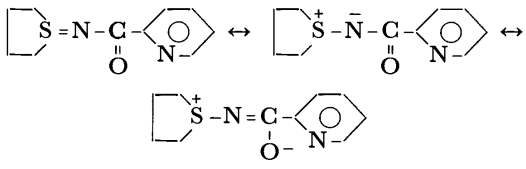
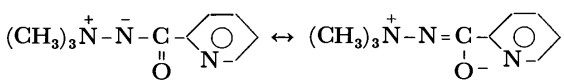
Although a large number of metal complexes of carbonyl-stabilized ylides have been reported, very few have coordination *via* carbonyl oxygens.[7] The change of the coordination site from the ylidic nitrogen to the carbonyl oxygen in going from 1:1 to 1:2 complexes may be the consequence of the steric hindrance around Cu(II). A close interaction observed in a structural model between a pyridine ring of a ligand and a tetramethylenesulfonium group in another one supports this consideration. The 1:2 complex is also a nonelectrolyte and has absorption maximum at 820 nm in chloroform, and an octahedral structure was proposed as shown in Fig. 1 (**2**). In water this complex is a strong electrolyte and the absorption band falls to 670 nm, probably because of the lowering of the microsymmetry to a more distorted octahedral or square plannar structure due to the weaker metal–chloride bonding by strong hydration of the chloride ions.



PS



PA

Complexes of N-*Formyl*-S,S-*dimethylsulfilimine (FS) and* N-*Acetyl*-S,S-*tetramethylenesulfilimine (AS) with* $CuCl_2$. These ligands behave quite differently in the complex formation. Elemental analyses reveal that the ylide FS forms a 1:2 complex, while AS forms a 1:1 complex. Furthermore, the former exhibits a C=O stretching band at 1600 cm^{-1}, 26 cm^{-1} higher than in the free ligand, whereas the latter exhibits the C=O band at 1502 cm^{-1}, 38 cm^{-1} lower than in the free ligand. Thus, metal–ylidic nitrogen and metal–carbonyl oxygen coordinations are implied for $CuCl_2(FS)_2$ and $CuCl_2(AS)$, respectively, and supported also by each observed shift of the C–N stretching band in going from the free ligands to the complexes. The complexes show normal paramagnetism (Table 1), and the most probable structures are indicated in Fig. 1 (**3**) and (**4**). Taking into consideration the small shift of the carbonyl band in $CuCl_2(FS)_2$, the Cu(II)–ylide bond is likely to have ionic character; that is, the ligand has appreciable ylidic nature retained in the complex. The structure in Fig. 1 (**4**) is similar to those of π-allyl complexes, but only few ylides have been reported to form complexes of this η^3 structure.[7] Electronic spectra were not obtained in nonpolar solvents because of the low solubility of the complexes, and the data available do not allow more positive conclusions on the structure of these complexes.

Complexes of N-*(Trimethylammonio)picolinamidate (PA) with* $CuCl_2$ *and* $CuCl$. Both 1:1 and 1:2 complexes of PA with $CuCl_2$ were prepared in similar ways to those of the PS complexes. In addition, the reaction of PA with two equivalents of CuCl afforded a 1:1 complex, CuCl(PA). A characteristic feature for these PA complexes is that they give almost identical IR spectra (Table 2), implying an identical coordination mode of the ligand in these complexes. The C=O bands appear near 1580 cm^{-1}, about 20 cm^{-1} higher than that of the free PA suggesting coordination *via* ylidic nitrogen. However, the shifts are relatively small compared to that observed in $CuCl_2(PS)$ and the complexes of PA with Pd(II) and Pt(II),[1] and the frequencies are much lower than that of picolinamide. The C=O band frequency of Pd(II) and Pt(II) complexes is sensitive to the structure of the ylide and has been discussed in terms of the covalent and ionic character of the metal–ylide bond.[1] Since the basicity of aminimides is higher than that of the sulfilimines,[8] the small frequency shifts of PA complexes are more likely to be a consequence of the large ionic character of the coordination than that of the weak covalent bond between Cu(II) and the ylides. The situation may be analogous to the Cu(II) complexes of oligopeptides, one of which is shown in Fig. 1 (**8**).[9]

The d-d transition spectra of $CuCl_2(PA)$ and $CuCl_2(PA)_2$ and their solvent effects are quite similar to those of $CuCl_2(PS)$ and $CuCl_2(PS)_2$ (Table 3), and analogous discussion may be made for the PA complexes and the proposed structures are shown in Fig. 1 (**5**) and (**6**).

The electronic spectrum and electric conductivity of CuCl(PA) as well as IR spectrum are close to those of $CuCl_2(PA)_2$. Therefore, the nature of the ligand coordination is considered to be similar to the Cu(II) complex, though it is difficult to draw any definite structure.

Complexes of N-*(Trimethylammonio)acetamidate (AA) and* N-*(Trimethylammonio)benzamidate (BA) with* $CuCl_2$. Both AA and BA afforded 1:1 complexes with $CuCl_2$, but the magnetic moment of the latter is lower than the supposed value for a monomeric structure, whereas the former gave a normal value for paramagnetism. In the case of $CuCl_2(AA)$, spectroscopic data are in accord with the structure analogous to **4** in Fig. 1, in which the ligand is coordinated through N and O atoms. On the other hand, the IR spectrum of BA complex exhibits two carbonyl absorption bands at 1545 and 1690 cm^{-1}. Considering also a low magnetic moment, the complex is considered to be a mixture of N- and O- bonded monomeric or polymeric structures.

Experimental

Melting points, uncorrected, were determined on a Yamato model MP-21 apparatus using open capillaries. Infrared spectra were taken on a JASCO IRA-2 spectrometer using KBr disks, and electronic spectra were recorded on a Union 401 spectrometer. Elemental analyses were performed on a Perkin Elmer 240 analyzer, and magnetic susceptibility was measured by the Faraday method at room temperature with a Shimadzu magnetic balance. Electric conductivity was determined with a Toa CM-2A conductometer at 25±0.2 °C.

The syntheses of the sulfilimines and aminimides which were used as ligands have been described in previous papers.[1,8]

Preparation of Complexes. The preparation of dichloro(*N*-picolinoyl-*S*,*S*-tetramethylenesulfilimine)copper(II), $CuCl_2(PS)$, is described as a standard method for the preparation of the complexes. A solution of *N*-picolinoyl-*S*,*S*-tetramethylenesulfilimine (PS) (0.456 g, 2.19 mmol) in

ethanol (5 ml) was added with stirring to a solution of copper dichloride dihydtate (0.364 g, 2.14 mmol) in ethanol (5 ml) at room temperature. The mixture was stirred overnight, and the blue-green precipitate was separated by filtration, washed with small portions of ethanol and dried *in vacuo*. The product is soluble in water and methanol, slightly soluble in ethanol and chloroform, and insoluble in hydrocarbons. It gradually decomposes above 198 °C changing to a brown color. Reprecipitation from methanol–ether afforded the compound with almost the same spectroscopic properties and thermal stability as the crude product.

From the reaction of $CuCl_2 \cdot 2H_2O$ with two equivalents of the sulfilimine, a clear blue solution with a small amount of precipitate was obtained under the same conditions as described above. After the removal of the precipitates by filtration, ether was added to the filtrate and the precipitates formed were separated, washed with ether, and dried *in vacuo*. The product has the formula of $CuCl_2(PS)_2$ and is soluble in water and ethanol, partly soluble in chloroform, and insoluble in hydrocarbons.

Other complexes were prepared under essentially the same conditions as shown above, and the complexes $CuCl_2(FS)_2$, $CuCl_2$(AS), $CuCl_2$(PA), and $CuCl_2$(AA) were obtained simply from the reaction mixture as precipitates, while $CuCl_2(PA)_2$, CuCl(PA), and $CuCl_2$(BA) were obtained by the addition of ether to the reaction mixtures. The reactions of PS and AA with CuCl gave crude products which were not analytically pure and the purification was unsuccessful. The reaction of *N*-benzoyl-*S*,*S*-tetramethylenesulfilimine with $CuCl_2 \cdot 2H_2O$, and those of FS, AS, and BA with CuCl were also attempted, but no solid products were isolated by the above described methods.

Ultrasonic Absorption Studies of the Nickel(II) Amino Acid Complexes in Aqueous Solutions

Shoji HARADA, Kazumi HIGASHI, Kiyoshi TAMURA, Michinori HIRAISHI, and Tatsuya YASUNAGA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received April 17, 1978)

The ultrasonic absorption has been measured in aqueous solutions of Ni(II) complexes of glycine, β-alanine, 4-aminobutyric acid, and 6-aminohexanoic acid. The relaxation absorption could not be ascribed to one of the steps of the ordinary step-by-step complex formation mechanism. Kinetic data were obtained as functions of the initial concentrations of Ni(II) and amino acids, the pH, and the temperature. The relaxation absorption was attributed to the formation-breaking equilibrium of an intramolecular hydrogen bond due to the carboxylato group of amino acid coordinated to the Ni(II) ion. The rate constant of the hydrogen bond-breaking process has been obtained. The relationship between the relaxation parameters and the acid dissociation constant of the carboxyl group of the amino acid ligands is discussed with reference to the analogous result for the carboxylato ligands reported previously. Supplementary work is also carried out for Ni(II)–aspartato and glutamato complexes.

With the help of the relaxation techniques, the kinetics of the metal complex formation has been widely studied, and a step-by-step complex formation mechanism involving the rate-determining release of the solvent molecule from the inner-sphere of the metal ion has been proposed.[1] Most of the ultrasonic relaxation absorptions in the metal complex solutions have been interpreted in terms of the above mechanism.[2–4] In a previous paper,[5] the present authors have reported that the ultrasonic relaxation absorption in the Ni(II)–carboxylato solutions can be ascribed to a reaction different from one of the steps of the above mechanism. Recently, the same kind of relaxation absorption has also been found in the Ni(II)–amino acid complex solutions.

The metal–amino acid complexation is not only interesting in itself, but is also important as the model system for the metal–protein interaction, and so it has been extensively studied from the static[6] and the kinetic[7–11] points of view. The purposes of the present investigation are to assign the relaxation absorption in the MHz frequency range, to obtain the kinetic parameters of the very fast reaction related to this absorption, and, moreover, to obtain information concerning the details of the Ni(II)–amino acid complex formation reaction. Studies were carried out for the Ni(II) complexes of glycine(gly), β-alanine(β-ala), 4-aminobutyric acid(ABA), and 6-aminohexanoic acid(AHA). Supplementary work was also performed for the complexes of aspartic acid(asp) and glutamic acid(glu).

Experimental

All the chemicals used were of a reagent grade and were used without further purification. Deionized and distilled water was used for the preparation of all solutions. Sample solutions were freshly prepared by dissolving $Ni(NO_3)_2$ and amino acid in water and by adjusting the pH by the drop-by-drop of dilute NaOH and/or HNO_3. The pH was adjusted to an appropriate value by taking into account the dissociation constant, K_a, of carboxyl group of amino acid and the hydrolysis of the Ni(II) ion. The ionic strength was kept constant at 2, with some exceptions, by addition of $NaNO_3$.

The ultrasonic absorption was measured by the pulse method[12] in the frequency range from 3.5 to 95 MHz. The sound velocity was measured at 1.92 MHz by the sing-around method. All the measurements were carried out at 25.0± 0.05 °C. All of the absorptions were expressed by the following single-relaxation equation for the excess absorption per wavelength $(\alpha'\lambda)$:[13]

$$(\alpha'\lambda) = 2(\alpha'\lambda)_{max} \cdot \frac{(f/f_r)}{1+(f/f_r)^2} \quad (1)$$

were α' is the excess absorption coefficient;[14] λ, the wavelength; f, the frequency, and f_r, the relaxation frequency; the subscript, max, indicates the maximum value.

A blank solution of either $Ni(NO_3)_2$ or amino acid showed no discernible relaxation absorption. These results suggest that the present relaxation absorption is ascribed to the Ni(II)–amino acid complex formation reaction, but to neither the hydrolysis of the Ni(II) ion nor to the protonation of amino acid.[15,16]

Results and Discussion

The relaxation absorption was studied as functions of Ni(II) and amino acid concentrations by keeping one constant and varying the other. The results are summarized in Table 1, where three features may be noted. The first is the independence of the relaxation frequency of both the Ni(II) and amino acid concent-

rations. The second is the increase in the absorption with the increases in both the Ni(II) and amino acid concentrations. The third is the specificity of the ligand effect on the relaxation frequency and the excess absorption. Some representative absorptions of the Ni(II)–amino acid solutions are shown in Fig. 1.

The effect of the pH on the relaxation absorption was studied for the Ni(II)–glu system. As may be seen in Table 2, a decrease in pH causes an increase in f_r and a decrease in the excess absorption. The temperature dependence of the relaxation absorption was studied for the Ni(II)–ABA system; the results are shown in Table 3. In order to obtain the value of pK_a of amino acids, an experiment of pH titration was carried out at 25 °C. The results are listed in Table 4.

The complex formation reactions of Ni(II) with amino acids (*e.g.*, gly[7] or β-ala[8]) have been expressed as follows:

$$\underset{①}{NiL_{n-1} + L} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} \underset{②}{NiL_{n-1}O\overset{H}{\underset{H}{<}} L} \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} \underset{③}{NiL_n} \quad (n=1,\ 2,\ \text{or}\ 3) \qquad (2)$$

Here ① is the free ions, ② the outer-sphere complex, and ③ the inner-sphere complex; L is the ligand complexing with the metal (the charges have been neglected in this paper). To begin with, the present relaxation absorption was investigated by assigning it to one of these steps.

The outer-sphere complex formation process, ①⇌②, is considered to be very rapid, and the relaxation frequency of this process would lie, if observed, in a frequency range not lower than 200 MHz. Moreover, the ligand specificity should not be reflected in this process.[1,13] These characteristics were not, however, observed.

Table 2. pH dependence of the ultrasonic parameters for the Ni(II)–glutamic acid complex solutions at 25 °C

Table 3. Temperature dependence of the ultrasonic parameters for the Ni(II)–4-aminobutyric acid complex solutions

ΣNi (M)	ΣABA (M)	pH	t (°C)	f_r (MHz)	$(\alpha'\lambda)_{max} \times 10^5$
1.0	2.0	5.9	10	8.0	139
1.0	2.0	5.9	20	10.8	162
1.0	2.0	5.9	25	11.5	173
1.0	2.0	5.9	30	13.5	196

The inner-sphere complex formation, ②⇌③, is the rate-determining process, and the relaxation time $\tau(=(2\pi f_r)^{-1})$ is expressed by the following equation:

$$\tau^{-1} = 2\pi f_r = k_{23} \cdot \frac{K_{12}\{[NiL_{n-1}]+[L]\}}{1+K_{12}\{[NiL_{n-1}]+[L]\}} + k_{32}, \qquad (3)$$

where $K_{12}=k_{12}/k_{21}$.

When the following relations are introduced,

$$0 < \frac{K_{12}\{[NiL_{n-1}]+[L]\}}{1+K_{12}\{[NiL_{n-1}]+[L]\}} < 1, \qquad (4)$$

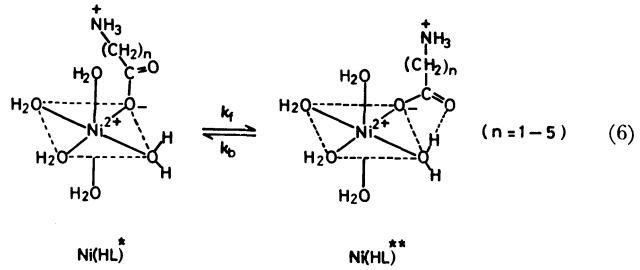
Eq. 3 gives

$$\tau^{-1} < k_{23} + k_{32}. \qquad (5)$$

The k_{23} values for the water release from NiL_{n-1} are: $3\times10^4\ s^{-1}$ for $n=1$ (*i.e.*, Ni^{2+} ion), $1.2\times10^5\ s^{-1}$ for $n=2$, and $4.0\times10^5\ s^{-1}$ for $n=3$ when L=gly.[7] In the Ni(II)–amino acid system, $k_{32} \ll k_{23}$ is generally established. Then, the τ^{-1} value due to the ②⇌③ process cannot exceed $10^6\ s^{-1}$ (or $f_r<0.2$ MHz), no matter how increased the ionic concentration is. When L=β-ala,[8] the chelate-ring closure step is known to be rate-determining. The rate constant of this process is smaller than that for the first coordination to the metal. The above discussion shows that the present relaxation absorption of $\tau^{-1}>3\times10^7\ s^{-1}$ can not be ascribed to one of the steps of the inner-sphere complex-formation reaction where the release of the coordinated water molecule from Ni(II) is connected and rate-determining.

It is generally believed that the zwitterionic form of amino acid is unreactive and that only the anionic form is reactive for the complex formation.[7-11,17,18] Cassatt and Wilkins[10] discussed the unreactivity of the zwitterionic form of the amino acid and argued that even if the coordination is initiated by the carboxylato

group, the bond breaks much faster than the deprotonation of the $-NH_3^+$ group, followed by a chelate formation. On the other hand, the results of the present relaxation absorption studies definitely show that relatively stable complexes are formed even in the case of the ABA and AHA systems, where the chelate complex is not conceivable. This implies that the zwitterionic form of amino acid can form a complex by the coordination of its carboxylato group to Ni(II), by analogy with the corresponding carboxylato ion. Some of the experimental evidence of the complex formation of the zwitterionic form has also been given by pH titration,[19] solubility,[20] and Raman spectral[21] investigations.



$(n=1-5)$ (6)

Fig. 2. Appropriate model of the intramolecular hydrogen bond equilibrium of the Ni(II)–amino acid complex.

The reaction associated with the relaxation absorption has the following features: (1) it involves the Ni(II) complex of the zwitterionic form of amino acid unidentated by its carboxylato group; (2) it is not concerned with the water release from Ni(II), and (3) it occurs very rapidly and has a time constant of the order of 10^{-7}—10^{-8} s. An appropriate mechanism is Reaction 6 in Fig. 2. This is similar to that earlier proposed by the present authors for the interpretation of the relaxation absorption of the Ni(II)–carboxylato solutions.[5] Further support for the assignment is as follows: (1) For Reaction 6, the relaxation frequency is related to the rate constants by this equation:[22]

$$2\pi f_r = k_f + k_b. \tag{7}$$

As the concentration term is not involved in this equation, the independence of f_r of the ionic concentrations can be approved.

(2) The maximum excess absorption per wavelength, $(\alpha'\lambda)_{max}$, for Reaction 6 is given by[13]

$$(\alpha'\lambda)_{max} = \frac{\pi(\Delta V)^2}{2\beta_0 RT}\cdot\left\{\frac{1}{[Ni(HL)^*]}+\frac{1}{[Ni(HL)^{**}]}\right\}^{-1} = \frac{\pi(\Delta V)^2}{2\beta_0 RT}\cdot[Ni(HL)]\cdot\frac{K}{(1+K)^2}, \tag{8}$$

where $[Ni(HL)]=[Ni(HL)^*]+[Ni(HL)^{**}]$, $K=k_f/k_b$, ΔV is the reaction volume change, and β_0 is the adiabatic compressibility. This equation shows that $(\alpha'\lambda)_{max}$ is proportional to the Ni(HL) complex concentration. Since the stability constant for the complex of the zwitterionic form of amino acid, K_{HL},

$$K_{HL} = \frac{[Ni(HL)]}{[Ni]\cdot[HL]} \tag{9}$$

has not been reported for Ni(II), the absolute value

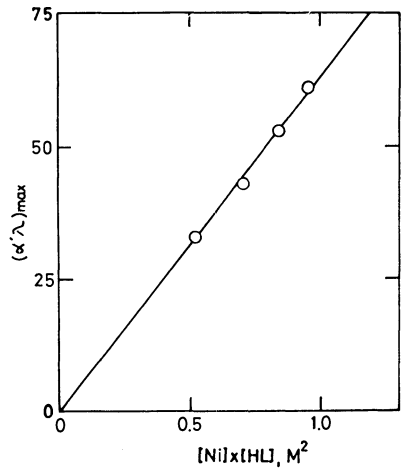


Fig. 3. $(\alpha'\lambda)_{max}$ *vs.* [Ni]·[HL] plot for the Ni(II)–β-ala system.

of the Ni(HL) complex concentration cannot be known. However, the relative change can be assumed by replacing with $K_{HL}\cdot[Ni]\cdot[HL]$ (see Eq. 9). Figure 3 shows the $(\alpha'\lambda)_{max}$ *vs.* [Ni]·[HL] plot for the Ni(II)–β-ala system, for which the literature values of the stability constants[23] enabled us to calculate the ionic concentrations. The plot gives a straight line which cuts through the origin of the coordinates. This result conforms to Eq. 8.

(3) As may be seen in the data of the Ni(II)–glu system in Table 2, the relaxation absorption decreases with the decrease in the pH. This result can be easily understood from the fact that the complex concentration decreases with the decrease in the concentration of the unprotonated ligand. On the other hand, however, the increase in f_r with the decrease in the pH cannot be easily understood because the decrease in the concentration of the unprotonated ligand generally induces a decrease in f_r. The conflict has now been resolved by considering the catalyzing effect of the hydrogen ion on the hydrogen-bond formation and breaking.[24] According to this idea, the increase in f_r can be considered to be due to that of the rate constant, k_b and/or k_f, induced by the increase in the proton concentration.

(4) The apparent activation energy can be obtained from the temperature dependence of f_r. For the Ni(II)–ABA system, $\Delta H^*=4$ kcal mol^{-1} was obtained. This value is relatively small compared to those of the ordinary complex formations, but it is appropriate for the formation of a hydrogen bond.[25] The same value was also obtained in the case of the Ni(II)–carboxylato system.[5]

(5) One of the features of the relaxation absorption of the amino acid complexes is the intimate correlation between the pK_a value of the carboxyl group and the relaxation parameters, f_r and $(\alpha'\lambda)_{max}$. As is shown in Table 1 and Fig. 1, f_r increases and $(\alpha'\lambda)_{max}$ decreases with the decrease in the pK_a of the amino acid ligand. The same tendency was observed in the case of the Ni(II)–carboxylato complexes.[5] Moreover, as is shown in Fig. 4, the overlapping of the f_r *vs.* pK_a plots for the two groups suggests that the present absorption is caused

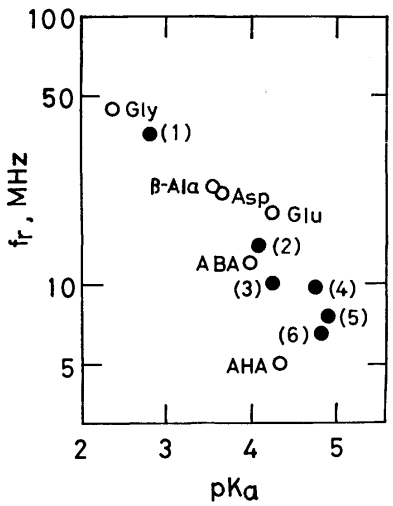

Fig. 4. f_r *vs.* pK_a plot for a series of Ni(II)–amino acid complexes(○) and Ni(II)–carboxylato complexes(●) at 25 °C: (1) chloroacetate, (2) 3-chloropropionate, (3) acrylate, (4) acetate, (5) propionate, (6) butyrate.

by the interactions between Ni(II) and the carboxylato group. If one assumes the $k_f \ll k_b$ relation, Eq. 7 can be reduced to

$$2\pi f_r = k_b. \tag{10}$$

The lower the value of pK_a of the carboxyl group is, the more labile the complex becomes. Analogously, the decrease of the pK_a value labilizes the hydrogen bond[26] in Ni(HL)**, which will induce the increase of the k_b value. Therefore the values of pK_a may be inversely proportional to f_r, as is shown in Fig. 4. The k_b values for the series of Ni(II)–amino acid complexes were obtained by means of Eq. 10: they are listed in Table 4. The magnitude of $(\alpha'\lambda)_{max}$ was in the order of the AHA>ABA>β-ala>gly systems under the same metal-ligand concentration, as is shown in Fig. 1. For a series of complexes, the ΔV value can be assumed to be the same. Therefore, from Eq. 8, the factors which contribute mainly to the value of $(\alpha'\lambda)_{max}$ seem to be the concentration and the K terms. Since the stability constant K_{HL} of Eq. 9 depends on the pK_a of the carboxyl group[26] and the electrostatic repulsion between the metal and the $-NH_3^+$ group,[27] the magnitude of the concentrations of Ni(HL) would seem to be in the order of: AHA>ABA>β-ala>gly. On the other hand, the larger the pK_a of a ligand is, the stronger will the intramolecular interaction between the carboxylato ion and the water molecule become. Therefore, the values of K in Eq. 8 would be in the order of: AHA>ABA>β-ala>gly. Whether the contribution of the concentration of Ni(HL) is predominant or that of the value of K, the ligand specificity observed in $(\alpha'\lambda)_{max}$ may, then, be well interpreted by the present mechanism.

Table 4. Rate constants of the intramolecular hydrogen bond-breaking process for the Ni(II)–amino acid complexes and the pK_a values of the carboxyl group of the amino acids

Ligand	pK_a	$k_b \times 10^{-7}$ (s^{-1})
Glycine	2.45[a]	28
β-Alanine	3.70[a]	15
4-Aminobutyric acid	3.94[b]	7.5
6-Aminohexanoic acid	4.34[b]	3.1
Aspartic acid	3.78[a]	14
Glutamic acid	4.25[a]	11

a) R. C. Weast, "Handbook of Chemistry and Physics," ed by J. Lewis and R. G. Wilkins, Interscience, New York, N. Y. (1960). b) This work.

The kinetic information obtained in this study of the Ni(II)–amino acid complexes, together with that reported previously on the Ni(II)–carboxylato complexes, provides a new type of equilibrium involving the coordination of the carboxylato group to the metal, as is shown in Reaction 6. As the relaxation effect is due to the motion of the carboxylato groups, the same kind of absorption can be expected to be observed in other divalent metal complexes of carboxylic acids and amino acids. Unfortunately, however, in other divalent metal systems, the relaxation effect based on the inner-sphere complex formation reaction falls into nearly the same time range as that of the present relaxation effect, and so it becomes rather difficult to study the latter effect separately. Studies of some of these systems are now in progess, however, and will be reported on it due course.

Aromatic Nucleophilic Substitution. X.[1] Confirmation of the Anionic σ Complex in the Base-catalyzed Smiles Rearrangement of 2-(Acetylamino)ethyl 2,4-Dinitrophenyl Ether in Dimethyl Sulfoxide

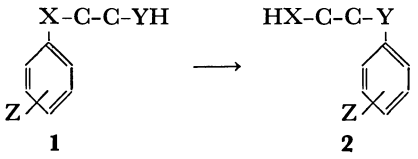
Keiji OKADA, Kohji MATSUI, and Shizen SEKIGUCHI*

Department of Synthetic Chemistry, Gunma University, Tenjincho, Kiryu, Gunma 376

(Received July 27, 1977)

2,4-Dinitrofluorobenzene reacts with 2-(acetylamino)ethanol in dioxane in the presence of sodium to give 2-(acetylamino)ethanol 2,4-dinitrophenyl ether (**7**), *N*-(2-acetoxyethyl)-2,4-dinitroaniline (**8**), which is considered to be a Smiles rearranged product of **7**, and *N*-(2-hydroxyethyl)-2,4-dinitroaniline (**9**), a hydrolysis product of **8**. Furthermore, **7** undergoes a Smiles rearrangement in DMSO in the presence of $NaOCH_3$ or $KOC(CH_3)_3$, giving **8** and **9**. Spiro Janovsky complex was spectrometrically confirmed to exist during the course of rearrangement.

The Smiles rearrangement is known as a typical intramolecular aromatic nucleophilic substitution reaction:

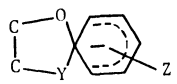


1 **2**

Z: activating group

It is well established that aromatic nucleophilic substitution reactions proceed *via* Bunnett's intermediate mechanism.[2] The Smiles rearrangement is considered to be a good model for studying the mechanism of aromatic nucleophilic substitution reactions.

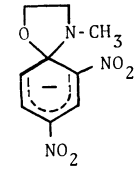
Although several pathways are possible for the conversion of **1** into **2**, the intermediate (**3**) (spiro Meisenheimer or Janovsky complex, hereinafter referred to as σ complex) might be confirmed spectrometrically or



3

isolated in certain systems in which an aromatic ring is much activated by nitro, cyano, or other electron-attracting group. This has been recently reviewed in detail.[3] Kleb[4] reported the rearrangement of 2-(methylamino)ethyl 4-nitrophenyl ether to *N*-(2-hydroxyethyl)-*N*-methyl-4-nitroaniline, in which the reaction proceeds very rapidly, no cyclic intermediate being detected.

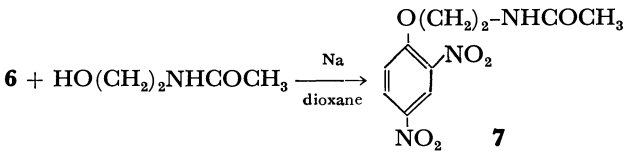
Bernasconi *et al.*[5] reported the base-catalyzed reverse Smiles rearrangement of *N*-methyl-*N*-(2-hydroxyethyl)-2,4-dinitroaniline (**4**), in which the formation of the spiro σ complex (**5**) was confirmed by absorption and NMR spectra. Skarzewski and Skrowaczeska[6] recently carried out the Smiles rearrangement of 2,4-dinitrofluorobenzene (**6**) with 2-(acetylamino)ethoxides and



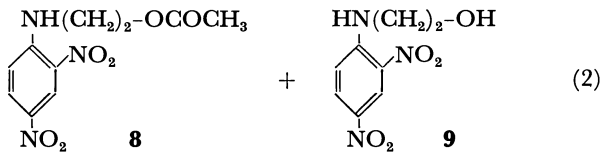
5

2-aminoethoxides, but they did not confirm the intervention of σ complexes such as **5**.

In order to study the reaction of 2-(acetylamino)ethyl 2,4-dinitrophenyl ether (**7**) with bases, we attempted to synthesize **7**



7



8 **9** (2)

by the following reaction. However, a mixture of **8** and **9** was obtained in a larger amount than **7**. **8** and **9** were formed from the base-catalyzed Smiles rearrangement of **7**.

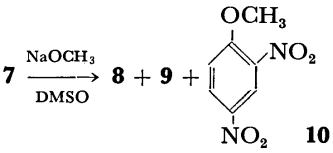
We wish to report the reaction path of the base-catalyzed Smiles rearrangement of **7** and the spectrometrical confirmation of an anionic σ complex during the course of rearrangement.

Results and Discussion

Reaction of 2,4-Dinitrofluorobenzene (6) with 2-(Acetylamino)ethanol (AAE). Treatment of **6** with AAE in the presence of metallic sodium (equivalent to **6**) in dioxane gave **7**, *N*-(2-acetoxyethyl)-2,4-dinitroaniline (**8**), and *N*-(2-hydroxyethyl)-2,4-dinitroaniline (**9**) in 14, 9, and 37% yields, respectively (see Experimental). **6** has a tendency to react with an oxide ion rather than an acetamido group.[7] The hydroxyl hydrogen of AAE is more acidic than the amide hydrogen.[8]

Thus AAE is expected to react with metallic sodium to give 2-(acetylamino)ethoxide ion, **7** being the main product. Compounds **8** and **9** can be considered to be formed *via* the Smiles rearrangement of **7**. The results prompted us to carry out the Smiles rearrangement of **7** under alkaline conditions.

Reaction of 2-(Acetylamino)ethyl 2,4-Dinitrophenyl Ether (7) with $NaOCH_3$ or $KOC(CH_3)_3$. Treatment of a solution of **7** in DMSO with an equimolar amount of $NaOCH_3$ at room temperature for 1 h gave **8** and **9** in 54 and 23% yields, respectively, and a small amount of **10** as shown in the following. No reaction took



(3)

place in the absence of $NaOCH_3$. This indicates that **8** in Eq. 2 is formed from **7** *via* the Smiles rearrangement and **8** partly decomposes into **9** with $NaOCH_3$.[9]

In order to obtain closer insight into the decomposition of **8** to **9**, **8** was treated under similar alkaline conditions. Treatment of **8** in DMSO with an equimolar amount of $NaOCH_3$ followed by neutralization with an aqueous HCl solution gave **9** in 89% yield. On the other hand, treatment of **7** in DMSO with an equimolar amount of $KOC(CH_3)_3$ followed by neutralization with an aqueous HCl solution gave **8** in 78% yield and a trace amount of **9**. Thus the formation of a larger amount of **9** in the case of $NaOCH_3$ than in the case of $KOC(CH_3)_3$ indicates that methoxide ion attacks **8** at the acetyl group more easily than *t*-butoxide ion due to the former being less bulky.

Visible and NMR Spectra Relevant to the Reactions of 2-(Acetoxylamino)ethyl 2,4-Dinitrophenyl Ether (7) and N-(2-Acetoxyethyl)-2,4-dinitroaniline (8) with $NaOCH_3$ or $KOC(CH_3)_3$. In order to study the detailed reaction path of the Smiles rearrangement of **7**, the absorption and NMR spectra relevant to the reactions of **7** and **8** with $NaOCH_3$ or $KOC(CH_3)_3$ in DMSO were measured.

Immediately after the addition of 50 equivalents of $NaOCH_3$, a solution of **7** (9.15×10^{-8} mol) in 3 ml of DMSO turned red [λ_{max} 346 (ε 14300), 359 (ε 13800), and 506 nm (ε 28000), Fig. 1b], indicating the formation of a complex. Curve b (Fig. 1) is similar in shape to that of **5** [λ_{max} 347 (ε 12400), 358 (sh), and 501 nm (ε 22800), aqueous 80% DMSO].[10] It turned into curve d [λ_{max} 432 and 490 nm (sh)] after 8 h. Similar

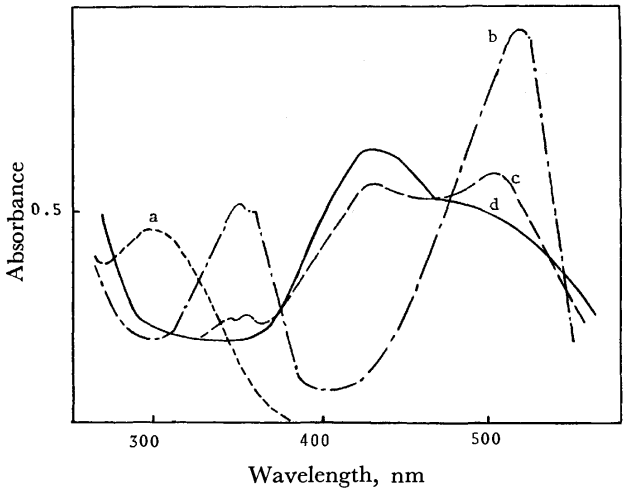


Fig. 1. Visible spectra relevent to the reaction of **7** (9.15×10^{-8} mol) with $NaOCH_3$ (molar ratio 1 : 50) in DMSO at 25 °C; curve a (----), **7** before the addition of $NaOCH_3$; curves b (——), c (——), and d (——) *ca.* 0, 4, 8 h after the addition of $NaOCH_3$, respectively.

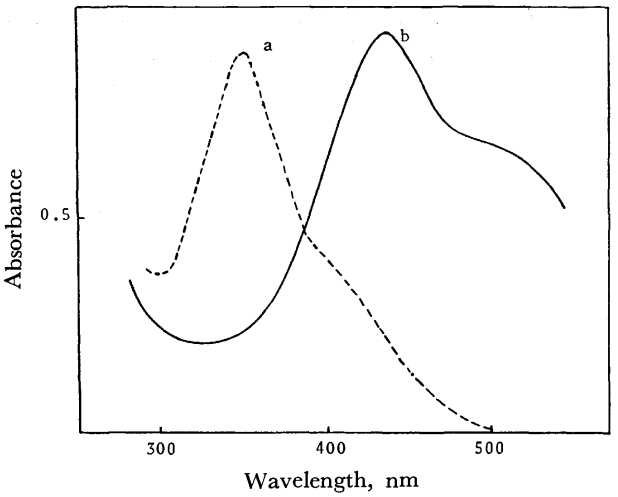

Fig. 2. Visible spectra relevant to the reaction of **8** (1.26×10^{-7} mol) with $NaOCH_3$ (molar ratio 1 : 50) in DMSO at 25 °C; curve a (----) **8** before addition of $NaOCH_3$; curve b (——) immediately after the addition of $NaOCH_3$.

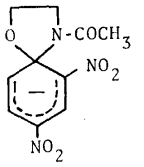
spectral changes were obtained for the molar ratios 100 and 1000.



11

A solution of **8** (1.26×10^{-7} mol, Fig. 2a) in 3 ml of DMSO immediately turned red [λ_{max} 432 (ε 21000) and 490 nm (sh, ε 15700), Fig. 2b] after the addition of 50 equivalents of $NaOCH_3$. Curve b (Fig. 2) is similar in shape to curve d (Fig. 1). Thus, curve d can be attributed to the anilide ion of **8**. Hosoya *et al.*[11] concluded by MO calculation that curve b is attributable to the σ complex (**11**).

In order to examine the reversible conversion between **7** and **11**, the visible spectral changes were measured when $NaOCH_3$ and HCl (aqueous solution) were successively added. On addition of 50 equivalents of $NaOCH_3$ (0.165 M, 27.8 μl), a solution of **7** (9.15×10^{-8} mol) in 3 ml of DMSO immediately turned red to give the same spectrum as that of curve b in Fig. 1. On subsequent addition of 100 equivalents of HCl (1.00 M, 9.2 μl), the solution immediately turned yellow to give the same spectrum as that of curve a (Fig. 1). When 150 equivalents of $NaOCH_3$ (1.65 M, 8.2 μl) were added thereto, **11** was immediately formed again. The results indicate that a reversible conversion between **7** and **11** exists and the life of **11** is relatively long.

The NMR spectra of the reaction system of **7** or **8** with $KOC(CH_3)_3$ were measured, since NMR measurements are known to be useful for the confirmation of anionic σ complexes.[12] Immediately after the addition of an equimolar amount of $KOC(CH_3)_3$, the red solution gave the spectrum (b) (sweep time 500 Hz/50 s), H^A resonance peak disappearing and H_3, H_5, and H_6

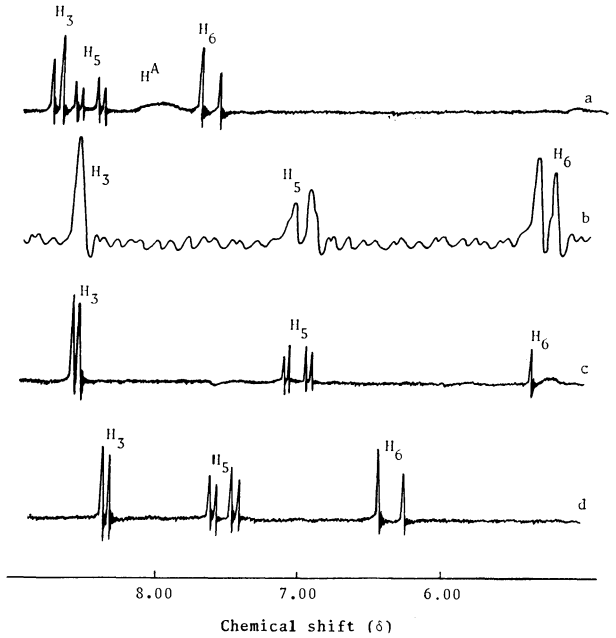


Fig. 3. NMR spectra of the reaction of **7** with $KOC(CH_3)_3$ in DMSO-d_6: a **7** before addition of $KOC(CH_3)_3$; b and c immediately after the addition of $KOC(CH_3)_3$, measured at the faster and normal sweep velocity; d several min after additon of $KOC(CH_3)_3$.

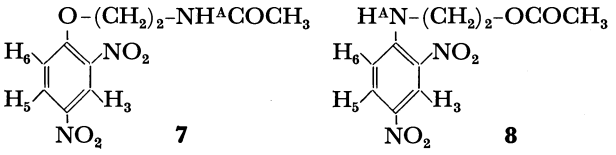
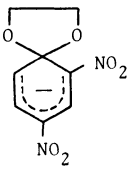


resonance peaks shifting upfield. The upfield shifts are typical of a negatively charged 2,4-dinitrobenzene or 1,1-disubstituted 2,4-dinitrophenyl anionic σ complex such as **5**, **11**, **12**, **16**, or **17**.[13] The chemical shifts of aromatic protons of other similar stable σ complexes are given in Table 1 for comparison. The results show that spectrum (b), where poor resolution is due to the fast sweep time (Fig. 3b), is attributable to **11**. Spectrum (c) measured at the normal sweep time immediately after the addition of $KOC(CH_3)_3$, is similar to spectrum (b), although the H_6 resonance peak collapsed a little in shape owing to the proceeding reaction. A few minutes after addition of $KOC(CH_3)_3$, spectrum (c) turned into spectrum (d) attributable to

Table 1. Chemical shifts of anionic σ complexes

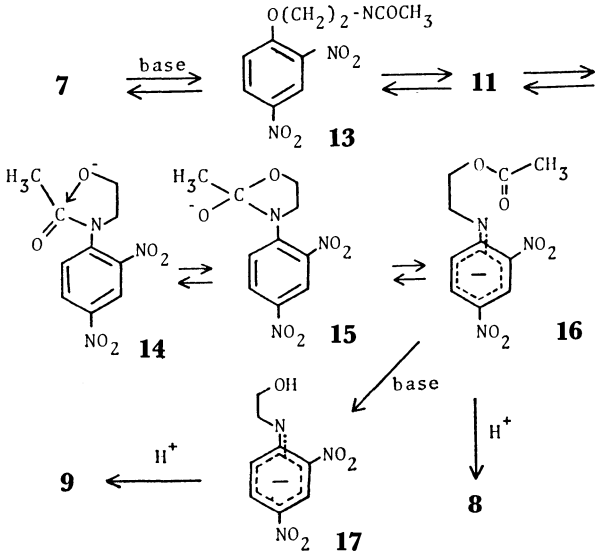
	5	12[a)]	11
H_3	8.50(d)	8.52(d)	8.57(d)
H_5	6.88(dd)	6.90(dd)	7.00(dd)
H_6	5.13(d)	5.36(d)	5.33(dd)

a) **12**: [13]



the anilide ion of **8** formed by the abstraction of H^A, since the same spectrum was obtained when **8** was treated with an equimolar amount of $KOC(CH_3)_3$ in DMSO.

All the results are in line with the following scheme:[12] **7** functions as an acid in strongly basic media[14] to produce the amide ion (**13**) and then **11**. In **11** the C_1–O bond is more easily cleaved than the C_1–N bond as seen in ordinary aromatic nucleophilic substitution.[15] The intramolecular attack of the oxide ion (**14**) on the carbonyl carbon gives **15** and then **16**. A less bulkier alkoxide ion such as CH_3O^- reacts with **16** at the carbonyl carbon to give **17**.



Scheme.

In the normal Smiles rearrangement our case is the first example in which the anionic σ complex was detected.

Experimental

Melting points were uncorrected. NMR spectra were recorded with a Varian A-60D spectrometer. Elemental analyses were performed at the Microanalytical Center of Gunma University. Visible spectra were measured with a Hitachi-124 UV-VIS spectrophotometer. All the reagents were purified by recrystallization or by ditillation.

2-(Acetylamino)ethyl 2,4-Dinitrophenyl Ether (7). After 0.60 g (0.030 mol) of metallic sodium had been added to a stirred solution of 4.64 g (0.045 mol) of 2-(acetylamino)-ethanol (AAE) in 50 ml of dioxane, the mixture was refluxed for 5 h so that sodium was completely dissolved. After a solution of 5.6 g (0.030 mol) of 2,4-dinitrofluorobenzene (**6**) in 30 ml of dioxane had been added dropwise under stirring, the mixture was stirred at 30 °C for 4 h. The mixture was then poured into 200 ml of ice–water and extracted with chloroform. After the organic layer had been dried over anhydrous Na_2SO_4, the solvent was evaporated to give crude products, which were separated by column chromatography (silica gel, benzene–acetone) and recrystallized from benzene or benzene–ligroin, mp 105—105.5 °C, λ_{max} 298 nm (ε 11300) (**7**), 131—132 °C, λ_{max} 358 (ε 17400) and 410 nm (sh) (**8**), and 91—92 °C, λ_{max} 362 (ε 17700) and 390 nm (sh) (**9**). Yield 14% (**7**), 9% (**8**), and 37% (**9**). Found: C, 44.33; H, 4.04%

for **7**; C, 44.42; H, 4.02% for **8**. Calcd for $C_{10}H_{11}N_3O_6$ (**7** and **8**): C, 44.61; H, 4.12%. Found: C, 44.01; H, 3.89%. Calcd for $C_8H_9N_3O_5$ (**9**): C, 44.29; H, 3.99%.

Reaction of **7** *with Sodium Methoxide.* (a) To a solution of 0.692 g (2.57×10^{-3} mol) of **7** in 10 ml of DMSO was added 0.68 ml (2.57×10^{-3} mol) of methanolic $NaOCH_3$ (3.78 M) at room temperature under stirring, and the mixture was stirred for 1 h. After 2.57 ml of 2.00 M HCl solution had been added under stirring, the mixture was poured into 100 ml of water, extracted with chloroform, and dried over anhydrous Na_2SO_4. The solvent was evaporated to give crude products, which were separated by column chromatography (silica gel, benzene) and recrystallized from benzene or benzene-ligroin. **8** and **9** were obtained in 82% yield and in a small amount, respectively. (b) To a stirred solution of 0.708 g (2.63×10^{-3} mol) of **7** in 3 ml of DMSO was added at room temperature 2.44 ml (2.64×10^{-3} mol) of methanolic $NaOCH_3$ (1.08 M). After the mixture had been stirred for 1 h, 5.26 ml of 1.00 M HCl aqueous solution was added. The mixture was treated according to procedure (a). **8**, **9**, and **10** were obtained in 54 and 23% yields and in a small amount, respectively.
